than 10%, and this makes the problems much more significant. This means that the properties of a plastic article may change with time, as a result of annealing or creep, even without any chemical reaction. If the part is reheated above the glass transition, molecular relaxation leads to shrinkage. However, even below the glass transition, polymers can show physical aging (1), the initial non equilibrium state slowly becoming more dense as a result of continuing crystallization or molecular rearrangement in the glassy state, so that the polymer can slowly distort during use (see AGING, PHYSICAL; GLASS TRANSITION).

Stresses can also arise from differential expansion where polymer is attached to metal or wood. A typical thermal expansion coefficient for a plastic is about $1 \times 10^{-4}/^{\circ}$C; for a metal it is $2 \times 10^{-5}/^{\circ}$C; and for glasses it is lower still. This means that a 150°C temperature change on cooling from the solidification temperature can result in a strain large enough to cause eventual fracture (qv) if the plastic does not creep to relieve it (see VISCOELASTICITY).

Commercial polymer production is dominated by the cheap and simple carbon-chain polymers, especially polyolefins, their substituted derivatives, and hydrocarbon elastomers. Their value is that they can be fabricated very easily and cheaply, by high temperature processing of the molten polymer. The price is that chemical degradation during processing may be significant and much effort is put into developing methods of preventing processing degradation. One problem is that the chemical changes induced by processing may have a determining effect on the lifetime of the polymer in subsequent use.

In use, plastics usually fail because of localized stresses in combination with some weakening of the material. Embrittlement is the most important practical consequence of any reaction of the polymer that reduces its molecular weight and/or cross-links the chains. A second common consequence of degradation is yellowing. Polyolefins are especially vulnerable to oxidation. If they are not stabilized in some way, they may have a lifetime of only a few days in bright sunlight before they become weakened and useless.

Very little chemistry may be needed to destroy the mechanical properties of a polymer. If 1% of the C—C bonds in a hydrocarbon fluid are broken, the effect is to form a small fraction of impurities, usually of little significance. The same fraction of breaks in a polyolefin will reduce it from a high molecular weight polymer to an oligomeric wax. Thus in polymers a very low level of chain breaks will cause failure, and polymers may lose their mechanical properties rather easily with negligible changes in mass. Some other properties, for example the dielectric constant, may be even more sensitive to formation of polar groups by oxidation.

Although academic studies of polymer degradation usually involve a single, pure polymer, the physical properties of commercial polymers are almost invariably modified by additives (qv). These may be low molecular weight substances, such as plasticizers (qv), pigments, stabilizers, fire retardants, antistatic agents (qv), and antiblocking agents, among many others (see RELEASE AGENTS). They also include particulate materials such as pigments and fillers. Physical loss, or chemical degradation, of these agents can lead to changes in properties over time. Contact with other materials can also cause changes in properties, owing to migration of additives from one material to another. Thus, the properties of an object may change with time, even without any chemical reactions of the polymer from which it is made.

Thus, polymers are not simple materials and articles fabricated from them are often complex formulations. The base polymer may vary in microstructure, molecular weight, molecular weight distribution, and structural defects and impurities. It usually forms one part of a complex product, containing many different types of additive, which may be there to improve the product, to provide color, to aid in its manufacture, to prolong its life, or to protect it from extremes, such as fire. In use or storage, the formulation will be exposed to oxygen and may be exposed to elevated temperatures, to contacting liquids, to sunlight, and to atmospheric pollutants, including very reactive compounds, such as ozone. All of this means that polymers are subject to a wide range of degradative influences, both physical and chemical. Physical degradation effects, especially aging, physical (qv) and environmental stress cracking are discussed elsewhere; in the following sections chemical degradation mechanisms are discussed in more detail.

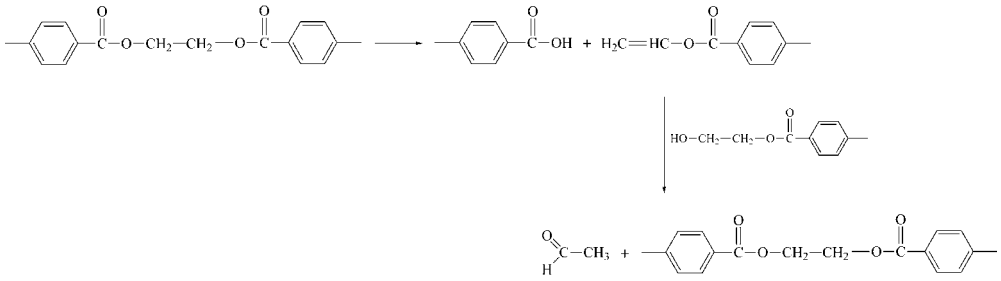
Thermal Degradation, Mechanistic Studies

Thermal degradation of polymers is the collection of chemical reactions that result in deterioration of properties in the absence of air or radiation. Purely thermal degradation, in inert atmosphere or vacuum (pyrolysis), defines the ultimate stability of a polymer in the absence of other degradative influences. It represents the point where the chemical bonds of the polymer acquire enough thermal energy to break or rearrange spontaneously at significant rates.

Pure thermal degradation is rarely significant in long-term use of polymers, because applications usually involve air contact and oxidative reactions dominate. However, it plays an important part in determining processibility. It can also introduce functional groups into the polymer, which produce color or influence long-term oxidative stability. Although pure thermal degradation is largely irrelevant to service use of polymers, there is continuing interest in its study, partly because of its role in the important areas of flammability and fire retardance, partly because of increased interest in the incineration of polymeric wastes, and partly because of increased interest in the possibility of recovering useful materials from waste plastics by inert-atmosphere pyrolysis.

Thermal degradation involves reactions at high temperatures in a solid or a very viscous liquid and loss of volatile products tends to be diffusion controlled, except in extremely thin films. Because the primary reaction products are trapped in the polymer at high temperatures, secondary reactions are common. None of this is of concern in pragmatic studies of industrial pyrolysis, except in the sense that laboratory studies need to be carried out under conditions matching the practical ones as closely as possible. In the academic sense however, thermal degradation is very difficult to study well and the literature contains much indifferent research and "paper chemistry." Model compound studies, although widely used, are often unreliable, either because the polymer decomposes through pathways different from those of the model compound or because polymers contain weak links arising from impurities or structural defects. For example, polyethylene (PE) decomposes rapidly enough to be measured easily at 300°C, whereas pure linear hydrocarbons are stable to over 400°C.

Thermal degradation reactions of polymers can be divided into two broad groups: molecular rearrangement reactions and reactions which involve homolytic scission of bonds to produce free radicals. In both cases the chemistry is typically complicated by the fact that primary products may be very reactive at the high temperatures involved in thermolysis, leading to rapid secondary chemistry. For example, the primary thermal degradation reaction in poly(ethylene terephthalate) (PET) is ester elimination at between 250 and 300°C to give carboxylic acid and vinyl ester groups:



(**1**)

At degradation temperatures the vinyl ester groups are not stable and rapidly form the first major volatile degradation product, acetaldehyde (**1**) (the keto tautomer of vinyl alcohol), possibly by transesterification with hydroxy ester end groups (2). Acetaldehyde formation is of some concern in the use of PET for manufacture of beverage bottles.

Most studies of thermal degradation of polymers are carried out under conditions where the rate is fast enough to give measurable reaction in times from seconds to hours. Whatever the mechanism, the rate constant for any elementary reaction can be expressed as a function of temperature in terms of the Arrhenius relation:

$$k = A \exp\left(- \frac{E_a}{RT} \right) \tag{1}$$

where k is the rate constant at temperature T, and E_a and A are the activation energy and preexponential factor. Equation 1 is soundly based in statistical mechanics only for elementary reactions in the gas phase. For reactions in liquid or solid phases, E_a is rarely a constant over a wide temperature range. This may be because the reaction is a complex process, but even elementary reactions in liquids and solids often have variable activation energies (3).

It is also important to remember that if parallel reactions have comparable rates at a given temperature, the one with the highest activation energy will increase in rate more rapidly with increasing temperature and slow down more rapidly with decreasing temperature. Thus, degradation at high temperatures may be dominated by high activation energy reactions which are relatively unimportant at lower temperatures.

It is now fairly clear that there can be substantial distinctions between addition and step-reaction (condensation) polymers. Addition polymers typically have C—C bonds along the chain and large numbers of aliphatic hydrogen atoms. The

dominant mechanisms of degradation typically involve the breaking of C—C bonds to form free radicals. At the temperatures of rapid decomposition of carbon-chain polymers (typically in the range 300–500°C), the resulting radicals are highly reactive and can readily undergo a range of reactions, including recombination and chain transfer, leading to complex mixtures of products, often with a great deal of uncertainty as to the exact mechanism of formation of any particular product.

In contrast, typical step-reaction polymers have polar functional groups at regular intervals along the chain. Although, like carbon-chain polymers, they can decompose by homolytic scission at high enough temperatures, they can also decompose by molecular rearrangement reactions, which are often highly selective for the particular functional groups in the chain and can occur at lower temperatures than do radical processes.

After many years of study, three distinct mechanisms of thermal degradation can be identified, although they are not mutually exclusive, and most polymers degrade by more than one mechanism, depending on the temperature. Detailed mechanisms of degradation of a wide range of carbon-chain polymers have been reviewed (4); degradation of step-reaction polymers has also been reviewed (5).

Chain Scission with Depropagation. Many carbon-chain polymers and other simple chains, such as acetal resins (polyethers), are produced by chain reaction polymerization, either via double bonds or by ring opening. Such polymerizations involve repeated addition of a monomer molecule to an active center, which may be a radical, an ion, or a coordination complex.

In principle, any such reaction is an equilibrium and can be written in the form

$$P_n^* + M \rightleftharpoons P_{n+1}^* \tag{2}$$

where P^*_n and P^*_{n+1} represent propagating chains with n and $n+1$ monomer units respectively. For large values of n (typically $n > 3$–4), it is well established that the rates of propagation and depropagation are independent of n, so that the two species P^*_n and P^*_{n+1} are not distinguishable. Thus, the equilibrium constant K_e is simply 1/[M], where [M] is the monomer concentration, and K_e can be written in the form

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ = -RT \ \ln K_e = RT \ln[M] \tag{3}$$

where ΔG°, ΔH° and ΔS° are the standard free energy, enthalpy, and entropy of polymerization respectively (6,7).

Thus, any concentration of monomer is in equilibrium with the corresponding propagating, or depropagating, chains at a temperature given by

$$T_c = \Delta H^\circ / (\Delta S^\circ + R \ \ln[M]) \tag{4}$$

Note that ΔH° and ΔS° depend upon the state of the polymer and the monomer. If [M] is set equal to the bulk concentration, T_c is the so-called *ceiling temperature* and is the upper limit at which propagating chains and monomer can coexist in equilibrium. Another approach is to recognize that polymerization requires

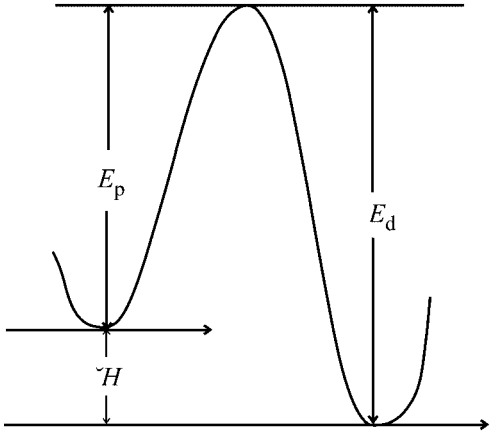


Fig. 1. Change in energy of a polymerization/depolymerization equilibrium along the reaction coordinate, showing the relation of the activation energies of propagation and depropagation and the heat of polymerization.

ordering of monomer units into regular chains and must have negative entropy change. The requirement for a negative free-energy change for spontaneous polymerization implies exothermic polymerization. This in turn means that the activation energy for depropagation must be higher than that for propagation by an amount equal to the heat of polymerization (Fig. 1). Thus as the temperature is raised, depropagation increases in rate faster than does propagation; for a given monomer concentration, the ceiling temperature is then the point at which the two rates become equal.

If a polymer is heated to the point where chemical bonds begin to break, radicals will normally be formed, rather than ions. Thus if chain scission takes place to produce free radicals at temperatures above T_c, rapid radical depolymerization, with production of monomer, is expected. This rapid depropagation is often termed *unzipping*. Table 1 shows some typical values for T_c for common polymers. They range widely from quite close to room temperature for polyacetal to close to 600°C for polytetrafluoroethylene. In reality, side reactions, which are discussed

Table 1. Ceiling Temperatures of Common Monomers

Monomer	State[a]	T_c, °C

later, mean that rather few polymers actually decompose smoothly to monomer by depropagation, the most well-studied example being poly(methyl methacrylate) (PMMA).

Most polymers are actually stable at temperatures above T_c because the activation energy for chain scission is high enough that radicals can only be formed by thermal scission at higher temperatures. This, however, has its own dangers. If radicals are induced in a polymer at temperatures above T_c then depolymerization may be very rapid. For example, it is common to mold PMMA at temperatures above T_c. Under these conditions chain scission induced by mechanochemical damage to the polymer in the high shear fields of the extrusion or molding operation results in the near instantaneous conversion of that chain into gaseous monomer, which can lead to bubbles or surface imperfections in the molding. Similarly, exposure of PMMA to uv, electron beam, or γ-irradiation above T_c will lead to very rapid degradation; degradation reactions of this type are the basis of some photoresist technologies.

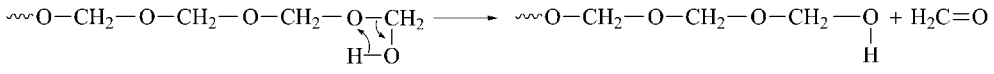
In principle, depropagation is initiated by the thermal scission of a main-chain backbone bond to produce a pair of depropagating radicals. If the depropagation is a simple chain reaction, the effective activation energy E_{ef} should be given by

$$E_{ef} = E_d + \frac{1}{2} E_i - \frac{1}{2} E_t \tag{5}$$

where E_d, E_i, and E_t are the activation energies for depropagation, initiation, and termination respectively. If E_i corresponds to the dissociation energy for the weakest bonds in the backbone, then E_{ef} should be an inherent property of the polymer. In practice it is sometimes found that the activation energy rises with temperature or degree of degradation, to reach a limiting value only at high temperatures or high conversions. It is also found that the rate of thermal degradation of, eg, PMMA is dependent on the initial degree of polymerization of the polymer. This behavior is associated with the presence of bonds that are weaker than average and can initiate production of depropagating radicals at lower temperatures. An important feature of the design of polymers is control of these thermally sensitive groups.

The presence and nature of "weak links" in polymer chains has been hotly debated over many years. The most important, and the most firmly established, example of such links is the end groups, associated with the initiator, with chain transfer, or with termination. Others include copolymerized oxygen, oxidation of the polymer in storage, and wrongly inserted monomer units. Control of polymerization conditions or post-polymerization modification of polymer structures can reduce the significance of such reactions and give polymers of greater thermal stability, and end-group control can be important in industrial processes. It has been shown (8) that the degradation of PMMA prepared by conventional radical polymerization occurs in at least three steps, which are associate with scissions of head-to-head linkages, with decomposition of vinylidene end groups, and with random main-chain scissions in order of increasing thermal stability. No difference between polymers produced with azo or peroxy initiators was detected (8).

An example of the importance of end-group control is in acetal resin or polyoxymethylene (POM). As normally prepared from cationic polymerization of sym-trioxane, this polymer has —OH end groups, which readily initiate depropagation to formaldehyde (**2**) by a molecular mechanism (9):



2

This reaction can be blocked by acetylation of the chain ends, leading to a polymer which can survive above T_c because there is no mechanism of chain scission with a low enough activation energy to initiate depropagation. Another approach is to copolymerize a small amount of a second monomer, such as styrene. The polymer is heated to initiate depropagation, which occurs until it encounters the first comonomer unit, at which point further depropagation is blocked. The evolved monomer is recycled.

Even where a polymer decomposes by simple depropagation reactions the kinetics of degradation are complex. The complexity is shown by the dependence of degradation rate on subtle changes in polymer structure, as discussed earlier (8), and by variations of the activation energy with conversion as chains of different stability are destroyed (10).

The kinetics of degradation of polymers which depropagate have been discussed in detail, especially for PMMA (see eg, Refs. 11–13). The analysis is complicated because the reaction volume changes with conversion as volatiles are evolved and because the *kinetic chain length* (the average number of depropagation events for each initial chain scission) may be controlled by the molecular weight of the chain. Termination may be by the bimolecular interaction of pairs of radicals or by radicals evaporating from the polymer.

Exactly what happens depends on the details of the reaction, but two extremes can be considered. If the reaction is initiated at the chain ends and the depropagation has a long kinetic chain length, all molecules have an equal probability of being initiated and each initiation results in the corresponding chain being completely removed as monomer. In this case the mass of the polymer decreases with degradation but there is no change in average molecular weight or in the distribution. In contrast, if the reaction is initiated by random scission and the kinetic chain length is long, long chains have a greater probability of scission and are removed completely as monomer. In this case, the mass of polymer falls, and the average molecular weight decreases with degradation.

In the ideal case, where only depropagation occurs, the mechanism can be deduced from the dependence of the observed first-order rate constant for weight loss on the initial degree of polymerization of the polymer. If depolymerization is both chain-end and chain-scission initiated and termination is first-order then application of the steady-state assumption to the concentration of depolymerizing radicals leads to the following relation (14,15):

$$k_{\mathrm{obs}} = \left(\frac{k_{\mathrm{i}}}{P_n} + 2k_{\mathrm{i}}'\right)\frac{k_{\mathrm{d}}}{k_{\mathrm{t}}'} \tag{6}$$

where P_n is the initial degree of polymerization, k_{obs} is the observed first-order rate constant for mass loss, and k_d is the rate constant for depropagation, k_i and k'_i are the rate constants for chain end and random scission initiation respectively, and k'_t is the rate constant for first-order termination. Thus the relative contributions of end initiation and main-chain scission can be deduced from the linear plot of k_{obs} against $1/P_n$.

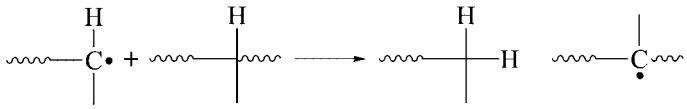
Conversely, if termination is bimolecular, then it can be shown (14,15) that

$$k_{obs}^2 = \left(\frac{k_i}{P_n} + 2k_i'\right)\frac{k_d^2 u}{2k_t \rho} \tag{7}$$

where k_t is the rate constant for bimolecular termination, u is the molecular weight of the polymer repeat unit, and ρ is the density of the polymer. Here the relative contributions of end initiation and main-chain scission can be deduced from the linear plot of $k^2{}_{obs}$ against $1/P_n$.

In a study of degradation of PMMA with end groups derived from chain transfer to lauryl mercaptan (11), it was shown that degradation at low (<340°C) temperatures was by end initiation with unimolecular termination. As the temperature was increased there was an increasing contribution from chain-scission initiation and at temperatures above 450°C it became the dominant initiation mechanism. At the highest temperatures low molecular weight polymers showed complete depropagation but the higher molecular weight ($D > 1500$) chains showed termination during unzip.

Random Scission without Depropagation. In radical polymerization, the simple chain-growth mechanism is complicated by side reactions of the propagating free radicals, which may undergo chain-transfer reactions in which the radical activity is transferred from one center to another, typically by hydrogen atom abstraction.



The hydrogen atom may come from any species in the mixture. Chain-transfer agents, often thiols, are often used to control molecular weight and end-group structure in polymerization chemistry.

Because the activation energy for chain propagation is much lower than that for chain transfer, transfer is usually a minor process in polymerization, although it can have important effects on both polymerization rate and polymer structure. The same is not true of depropagation. Although the activation energy for depropagation is higher than that for propagation, the high temperatures involved mean that rates of depropagation and chain transfer are comparable for most polymers at the temperatures involved in thermal degradation. Because of this, rather few polymers depropagate cleanly to high yields of monomer, because, as soon as a radical is produced, it undergoes chain transfer.

The relative frequency of chain transfer compared to depropagation is determined by the stability of the chain-end radical and by the availability of

Table 2. Some Typical Monomer Yields in Polymer Pyrolysis

Polymer	Monomer, %
Poly(methyl methacrylate)	100
Polystyrene	42
Poly(α-deuterostyrene)	70
Poly(α-methylstyrene)	100
Polyacrylonitrile	<5
Polymethacrylonitrile	100
Polytetrafluoroethylene	100
Poly(methyl acrylate)	0
Polyethylene	<1
Polypropylene	2
Polyisobutene	32
Polybutadiene	1.5
Polyisoprene	12

readily abstracted hydrogen atoms; only the very few polymers where a relatively stable radical is formed and chain transfer is restricted by the absence of easily abstractable hydrogen atoms depropagate cleanly. For example, while PMMA depolymerizes virtually completely, poly(methyl acrylate) with its readily abstractable α-hydrogen atom gives less than 1% monomer on pyrolysis, degrading instead to a complex mixture of low molecular weight fragments and char. Chain depropagation may also be inhibited by the presence of even very small fractions of comonomer units in the polymer chain acting as blocking groups for the unzip process. The resulting chain-end radicals often undergo transfer reactions.

Table 2 shows the typical monomer yields for thermolysis of common polymers. Essentially PMMA is the only polymer in common use which depropagates totally to monomer, although poly(α-methyl styrene) and poly(tetrafluoroethylene) also give close to 100% yields of monomer. For other polymers, the monomer yield ranges from zero to a significant fraction of the total volatile products.

The effect of chain transfer depends upon its frequency and the location of the abstractable hydrogens, but is typically the production of a complex mixture of low molecular weight volatile products.

Transfer may be intramolecular ("backbiting"), in which case it yields oligomeric fragments such as dimer and trimer by a process which is sometimes referred to as "unbuttoning." It has been suggested that products arising from six-membered backbite rings are at least an order of magnitude more probable than those from any other intramolecular process (16).

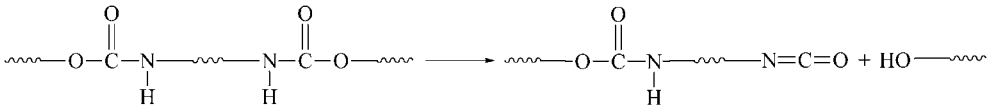
In contrast, if transfer occurs intermolecularly, then the new radical center is not at the chain end. Its scission results in rapid drop in molecular weight, initially without significant production of volatiles and the polymer undergoes random scission. As an example, pyrolysis–gas chromatography was used (17) to show that high molecular weight polyisobutene can degrade thermally to give more than 60 volatile products. A statistical analysis of the distribution of pyrolysis products,

grouped into general oligomeric types up to nonamer, suggested that random scission is the predominant mechanism leading to the wide range of oligomeric products. The observed monomer, dimer, and trimer yields were found to exceed the predictions of a statistical model, and these products were deduced to be due to depropagation plus backbiting transfer.

A problem arises when oligomers are observed as the principal products of thermal decomposition. They may arise from a high degree of random scission, intramolecular transfer during unzip, and/or secondary reactions of the primary products. These mechanisms can be differentiated by appropriate statistical plots of the yields of the products, quantitative measurements of rate constants for the evolution of the volatiles, and measurements of product yields and ratios as a function of sample size (18).

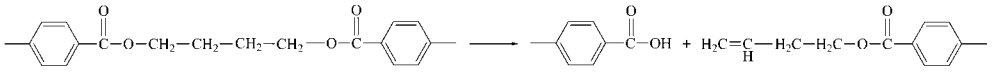
Where a polymer has functional groups in the main chain, typical of polymerization by step-reaction chemistry or chain polymerization of heterocyclic monomers, the functional groups in the chain are often the weakest and may undergo reactions which do not produce radicals. Thermal degradation by random scission, without significant yield of volatiles is typical of polymers such as polyesters, polyamides, and polyurethanes, all of which undergo thermolysis by reaction at the functional groups (5).

Examples of random scission reactions in step-reaction polymers include the decomposition of polyurethanes, which produces cleavage of the urethane groups via the facile transfer of the N—H hydrogen atom to the neighboring oxygen:



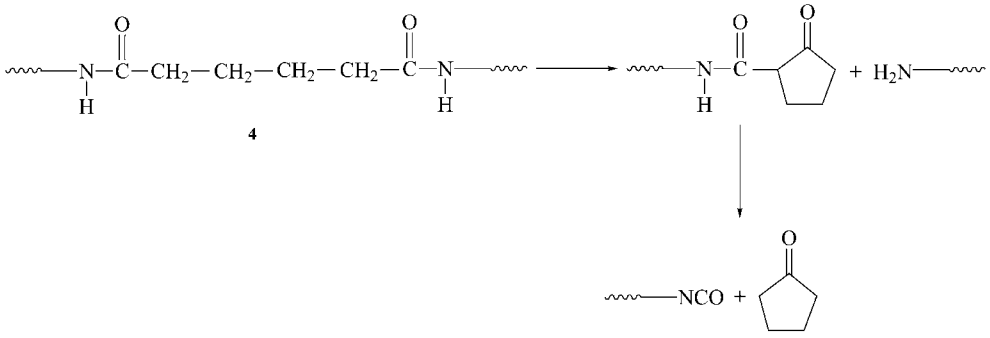
This reaction may give random scission or stepwise depolymerization, depending upon whether it occurs preferentially at the chain ends. Nylon-6 also degrades by formation of ε-caprolactam by random scission or stepwise depolymerization.

Aliphatic polyesters and polyesters formed from aromatic diacids and aliphatic diols eg, poly(ethylene terephthalate) and poly(butylene terephthalate) (**3**) cannot decompose by reversion of the polymerization, because the water, or alcohol, eliminated in the synthesis is no longer available. They initially decompose by β-C—H transfer reactions via a six-membered transition state:



(**3**)

Nylon 6,6 (**4**) initially decomposes by an α-C—H shift to yield amine and cyclopentanone end groups. At the temperature of thermolysis, the cyclopentanone end groups decompose further to produce cyclopentanone and isocyanate end groups.



4

At typical pyrolysis temperatures the isocyanate groups produced in pyrolysis of polyamides and polyurethanes are not stable and readily decompose to yield nitrile groups.

Random scission is also typical of the degradation of many polymers by reaction of chain bonds with other reagents. Hydrolytic and other chemical reactions and biological attack frequently show purely random scission, provided that the accessibility of the chain to the degrading agent is not limited by, eg, crystallinity or water permeability.

If the average chain lengths at time zero and time t are P_0 and P_t respectively and the average number of scissions per initial chain at time t is s then, if scission is purely statistical,

$$P_t = \frac{P_0}{s+1} \tag{8}$$

For random scission, the fraction of bonds broken at time t, α, is then given by

$$\alpha = \frac{1}{P_n} - \frac{1}{P_n^0} = kt \tag{9}$$

where k is the rate constant for the scission reaction. Thus a plot of α against time will be linear. For example, the natural bacterial polyester poly(hydroxybutyrate) (PHB) degrades thermally at temperatures just above its crystal melting point by the ester rearrangement to yield carboxylic acid and olefin end groups. A study of the degradation of this polymer under melt extrusion conditions (19) showed that equation 9 is followed well, although the gradient depended on the origin and degree of purity of the polymer, suggesting some catalysis of the scission by impurities.

A more severe test for random scission is the recognition that, whatever the initial distribution of molecular weights, random scission should lead to the "(Flory) most probable" distribution with a polydispersity index ($\bar{M}_w/\bar{M}_n$) equal to 2.0.

If α is the fraction of bonds which have undergone scission then the weight distribution function for the molecular weight in the case of random scission becomes (20):

$$w_x = x\alpha^2(1-\alpha)^{x-1} \tag{10}$$

where w_x is the weight fraction of chains with degree of polymerization x. Taking logarithms of both sides of equation 11

$$\ln(w_x/x) = 2\ \ln\alpha + (x+1)\ln(1-\alpha) \tag{11}$$

is obtained.

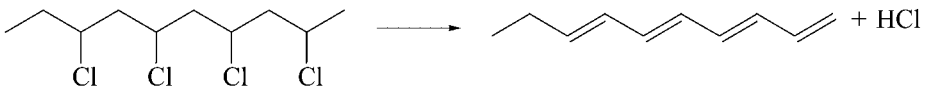
Equation 11 is the equation to a straight line whose slope and intercept are both determined by α. The assessment of random scission can thus be based on the extent to which molecular weight data fit a plot of equation 11, and (more particularly) the correspondence of values of α calculated from both the intercept and the slope of the plot (20,21).

This method can be more sensitive to small deviations from random scission. For example, the number and weight distributions of the oligomeric products observed on degradation of PHB have been compared with those predicted statistically (21). The results show that total thermolysis can be interpreted exclusively in terms of a random scission mechanism. However, the partial pyrolysis results are not consistent with random scission statistics; these results imply that there are some kinetically favored scissions occurring near the ends of the molecules. The product distributions from methanolysis were also slightly inconsistent with those expected on the basis of random scission and it was suggested that dimers hydrolyze more readily than do higher molecular weight species.

Although equation 9 implies a linear plot of α against time, such plots frequently show intercepts on the α-axis, which can be explained by the presence of small fractions of weak links which degrade preferentially at the beginning of the reaction. Such links are common in polymers synthesized by radical mechanisms, and are most likely due to small contents of copolymerized oxygen.

Thermal Reaction without Chain Scission. In any polymer, the chemical changes that occur at the highest rate at any given temperature will be the most significant causes of changes in properties. Often these are reactions that involve chain scission, either via radical intermediates or in molecular rearrangements which lead to scission. However, there are many other examples where reactions of substituent groups take place before scission, or may compete with it. In these cases the degree of polymerization remains the same but new structures are formed along the polymer chain.

Perhaps the most common such reaction in carbon-chain polymers is elimination of the substituent, with the formation of a double bond. The classic, and most important, example is the dehydrochlorination of poly(vinyl chloride)(PVC), which can be written formally as



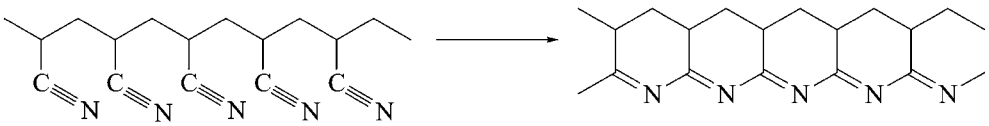
The important feature is the formation of polyene sequences by successive eliminations. These absorb visible light, causing the polymer initially to become yellow and eventually black. Similar reactions can occur with many polymers,

eg, poly(vinyl alcohol), poly(vinyl acetate), and cellulose and its esters. If the elimination reactions are allowed to go to high conversions, the polymer is typically transformed into a carbonaceous char, which may be quite thermally stable. Much of fire-retardant chemistry is aimed at increasing char yields in polymer thermolysis.

The reaction of PVC is important because it is the major pathway for degradation of this high tonnage polymer at relatively low temperatures. At high temperatures elimination and chain scission are competitive. PVC degradation has been extensively reviewed (see eg, Refs. 22–25). Despite a huge literature, even the most basic features remain contentious, and it is clear that the process has a much more complex mechanism than is implied by the equation above. It is initiated at reactive defect sites in the chain and catalyzed by the eliminated hydrochloric acid. Reactive sites include those which are part of the virgin polymer, such as allylic or tertiary chlorine atoms, produced in chain-transfer or termination reactions during polymerization; and hydroperoxy groups, introduced by thermal oxidation during processing. Although a wide variety of such sites has been identified in laboratory samples of PVC, it is probable that the hydroperoxides are dominant in processed commercial PVC materials.

Since many PVC formulations also contain pigments, plasticizers, and impact modifiers, this can be one of the most complex of plastics. Simple elimination is not the only reaction possible. Indeed, in pyrolysis conditions PVC containing plasticizer or impact modifier produces a very wide range of products, some from each component and others from cross-reactions (26,27). There has been considerable concern about the possibility of forming polychlorinated dibenzodioxins (PCDD) and dibenzofurans (PCDF) in PVC pyrolysis, related to the increased presence of PVC in input streams to commercial waste incinerators and the toxicity of PCDDs and PCDFs. Tars produced by PVC pyrolysis under different conditions of temperature and oxygen concentration have been analyzed (28). The tar collected after low temperature pyrolysis (500°C) in reduced oxygen atmosphere (12% O_2) had the highest toxicity, mainly owing to a high PCDF concentration. Pyrolysis at higher temperatures and higher oxygen pressures essentially eliminated the toxic products.

Another important example of a polymer which gives coloration due to side-group elimination is polyacrylonitrile (**5**), which colors slowly when heated and very rapidly on exposure to alkalis. This is usually attributed to the formation of conjugated, cyclic structures by reactions of the form

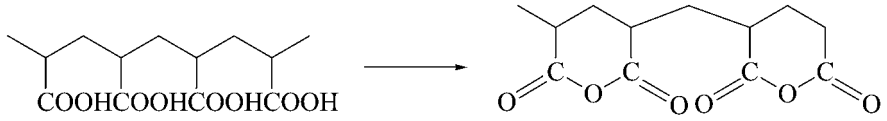


5

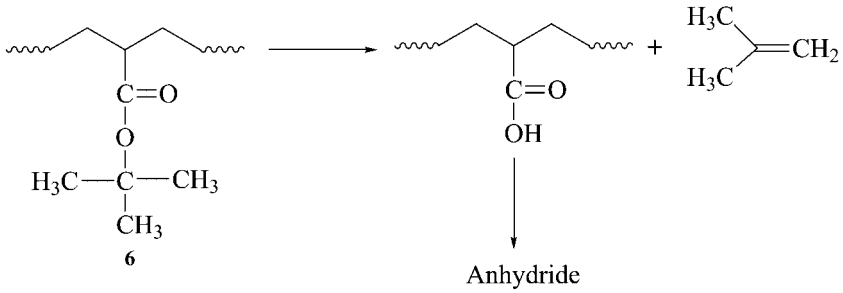
Although elimination reactions are clearly degradation, leading to color and char formation, they can have advantages. Conjugated sequences and ladder structures confer thermal stability on the polymers, forming stable chars. This is the basis of the preparation of carbon fibers by pyrolysis of polyacrylonitrile. It is also one reason for the use of plasticized PVC in electrical insulation; in a

fire, the char acts as a protective coating and maintains the electrical insulation properties of the cable.

Although elimination is a common and important nonscission reaction in degradation, it is not the only such reaction. For example, polymers which contain carboxylic acid groups undergo coupling reactions to form anhydride groups at relatively low temperatures. Anhydride formation may be intramolecular or intermolecular; in the latter case it produces cross-links.



The carboxyl groups may be present in the original polymer, but can also be formed by elimination reactions. Again, the product balance depends upon the relative rates of the possible reactions. For example, ester elimination in PMMA is impossible because of the absence of β-hydrogen atoms. In poly(*t*-butyl methacrylate) (**6**) there are nine β-hydrogens and thermolysis leads to virtually no monomer; elimination followed by cyclization is the dominant mechanism.



Other poly(*n*-alkyl methacrylate)s give a mixture of depolymerization and side-group rearrangement, depending on the number of β-hydrogens and the temperature.

Thermal Degradation, Analytical Methods

As outlined above, thermal degradation of polymers is complex and can be broadly divided between studies aimed at elucidating the fundamental mechanisms of reactions of the polymer, typically using tiny amounts of very pure polymer, and more pragmatic studies under conditions more representative of degradation of bulk material in fire or in industrial processing conditions.

Depending on the mechanism of degradation, a polymer may undergo chemical changes with virtually no loss of mass, or it may be converted almost entirely into volatile products. The latter may have a wide range of molecular weights, from easily condensable oils to very low boiling gases. The condensable oils are often referred to as the "cold-ring" fraction, because they are found as a condensate at the exit of the pyrolysis chamber. Both the solid residue and the gaseous products may

be quite simple, or they may be highly complex mixtures. Many normal chemical analytical techniques are routinely applied to study thermal degradation. They include ir and nmr spectroscopies of residues and cold-ring fractions, gas chromatography to separate gaseous products, and mass spectroscopy for their analysis and identification. However, the field has also developed a number of more specialized techniques.

Thermogravimetric Analysis. Thermogravimetric analysis (tga) is a deceptively simple technique, which has been very widely used in degradation studies because of the ready availability of commercial instruments at reasonable prices. Its use has been widely reviewed (29).

In its simplest form, a tga instrument consists of a small crucible holding a few milligrams of sample and attached to a recording microbalance. The crucible is positioned in a small furnace in which the atmosphere can be controlled, both inert and oxidizing conditions being possible. In a typical experiment the sample is heated at a programmed rate (typically 1–20°C/min) from ambient temperature to 800°C and the changes in mass with temperature are recorded. There are a number of critical features in the design of a good tga instrument to ensure that the sample temperature is known and controlled and that exothermic and endothermic reactions in the polymer do not lead to errors in measuring the sample temperature. These were problematic in early tga instruments, which used large samples. Modern instruments are usually exemplary in furnace and microbalance design. In most modern tga instruments, software provided by the manufacturer also allows differentiation of the weight-loss curve to produce a differential thermogravimetric (dtg) curve which has peaks corresponding to maxima or rate of weight loss. Figure 2 shows typical tga and dtg curves.

A recent development in tga is the so-called "high resolution" tga. In a conventional tga the heating rate is constant. In a high resolution instrument the heating rate is automatically varied with the rate of weight loss. If the sample is stable and not losing weight, the heating rate is kept high; if the sample begins to lose weight then the heating rate is automatically reduced. It is claimed that high resolution tga can help to separate thermal processes in similar temperature ranges.

The major information provided by a tga is the number of distinguishable stages of breakdown, the temperatures of onset and maximum rate of weight loss, and the amount of material lost at each temperature. In addition to giving information on degradation, tga can also be used in favorable cases to determine the content of inorganic fillers or carbon black by degrading away all of the polymer to leave the filler.

The major weakness of classical tga is that it gives information on weight loss but no chemical information. To overcome this problem, some modern tga instruments have been designed to be interfaced to chemical analysis instruments, the most popular being mass spectroscopy and Fourier transform infrared (ftir) spectroscopy. Both can give extremely useful information but care is needed to avoid problems from secondary reactions of volatile products and from loss of volatile products by condensation in transfer lines. The use of these so-called hyphenated techniques has been reviewed (30).

Although the thermal degradation of a polymer is complex and may involve successive and/or parallel steps, kinetic analysis of thermogravimetric data is

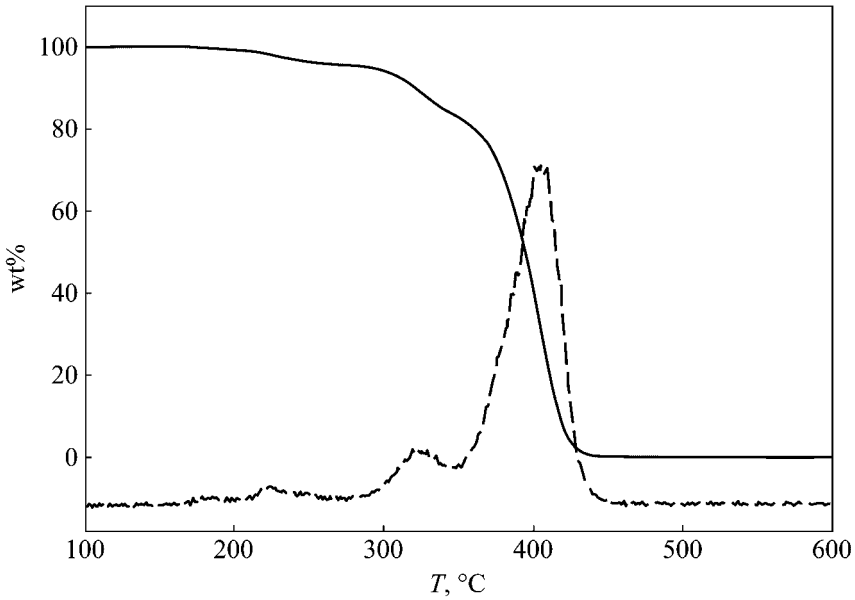


Fig. 2. Typical TG (solid line) and DTG (dotted line) curves. The example is for poly(methyl methacrylate) produced by free-radical polymerization. The major weight loss is due to depolymerization of chains with saturated ends. The peaks at lower temperatures are due to depolymerization of chains with weak links (copolymerized oxygen or unsaturated ends, produced by disproportionation termination).

often performed by using a single-step kinetic equation:

$$\beta \frac{\mathrm{d}\alpha}{\mathrm{d}T} = Af(\alpha) \exp\left(-\frac{E}{RT}\right) \tag{12}$$

where α is the fractional conversion at temperature T, β is the heating rate, $f(\alpha)$ is the differential form of the reaction model, relating the rate of reaction to α, and E_a and A are an activation energy and preexponential factor respectively. The three parameters E_a, A, and $f(\alpha)$ are often called the kinetic triplet. It might be easy to believe that appropriate mathematical manipulation of equation 12 should allow the kinetic parameters $f(\alpha)$, E_a and A to be determined from one or more tga experiments. Unfortunately, equation 12 is deceptively simple and a very wide range of approximate solutions has been proposed, leading to different methods for evaluation of the kinetic parameters by using a single tga curve recorded at a certain heating rate. The application of these methods typically consists in plotting a characteristic straight line. It is assumed that the true activation parameters correspond to the kinetic model for which the best linearization of the characteristic straight line is obtained. However, because of statistical variations it is often possible to fit the same tga curve equally well with more than one kinetic model and activation energies may vary by more than an order of magnitude, with equally good correlation coefficients, by simply choosing different reaction models (31). The fact that different models often fit the same data equally well suggests that these methods should be used more cautiously than is common.

There are two groups of approaches to the use of equation 12. In the first, the degradation is treated as a chemical process subject to the simple laws of homogeneous kinetics. The function $f(\alpha)$ is taken as

$$f(\alpha) = (1 - \alpha)^n \tag{13}$$

where n is the reaction order, and attempts are made to determine the appropriate kinetic parameters and relate them to a reaction mechanism. Other authors have suggested that the use of equation 13 is inappropriate to describe complex reactions and choose instead to use arbitrary versions of $f(\alpha)$ and fit the data with "apparent" kinetic parameters. Although this approach can give good fits to the data, the assumption that the parameters so derived will have value for different degradation conditions or for temperatures outside the measurement range is to say the least questionable. It is important to recognize that the use of a single tga curve for evaluation of the kinetic parameters of thermal and thermo-oxidative degradation is one of the main causes of much controversial kinetic data reported in the literature and that kinetic parameters evaluated using a single tgs curve cannot be used for prediction of the polymer degradation in conditions other than those corresponding to the tga curve used (32,33). Overinterpretation of tga data is facilitated by modern high performance computing and interpretation of tgs curves in terms of kinetic models should be undertaken only with extreme caution.

A much more reliable approach to tga data, which has developed rapidly in recent years, again because of advances in computation, is the use of model-free isoconversional methods. Such methods have been reviewed and compared with model-fitting approaches for thermal degradation of nitrate explosives (31). The basic assumption in these studies is that $f(\alpha)$ is independent of both temperature and heating rate and can be eliminated by using data measured at a series of heating rates, or a series of isothermal data, to calculate E_a as a function of α. Such models give internally consistent results from isothermal and nonisothermal data. In addition, since they do not force fit the data to a single activation energy, they can reveal kinetic complexity by showing variations of E_a as a function of α.

Analysis of tga data for thermal decomposition reactions has been the subject of a major comparative review (the ITACT project) of the application of various methods to both experimental and simulated data (34–37). The final conclusion is that isoconversional analyses tend to work fairly well and that "kinetic analysis using single heating rate methods should no longer be considered acceptable" (37).

Thermal Volatilization Analysis. While tga has been one of the most popular techniques for studying kinetics of polymer thermolysis, thermal volatilization analysis (tva) has been a popular method of studying product distribution (see eg, Ref. 38). Despite its utility no commercial tva instrument has been produced.

The basic approach of tva is to record (as a function of temperature or time) the pressure of volatile material produced when a small sample of polymer is heated in a continuously pumped vacuum chamber. Since the pressure developed is proportional to the rate of degradation, the tva curve is analogous to a dtg curve. A more advanced version of the tva instrument interposes a series of cold traps between the reaction chamber and the pumping system at temperatures in the range −196 to 0°C, with pressure sensing (Pirani) gauges between the traps.

Thus the output of the instrument consists of a series of tva curves for products fractionated according to their volatility and a considerable amount of data can be obtained from a single experiment. In the hands of its protagonists tva has been a powerful method of study, especially of complex polymers and formulations.

An advantage of tva over many other methods is that the volatile products are not destroyed by the pressure analysis but are trapped in their respective cold traps from which they can be recovered for analysis by conventional spectroscopic methods. At the same time, both residue and cold-ring fractions can be collected for analysis.

Coupled Pyrolysis Techniques. Perhaps the most powerful techniques currently available are those in which the polymer is pyrolyzed for a short time in a pyrolysis system directly coupled to a modern analytical instrument capable of analysis of the volatile products. Although direct pyrolysis coupled with ftir is available, the most common techniques have been gas chromatography, mass spectroscopy, and combinations of the two. In contrast to tga, these techniques provide no real information on the onset temperature of degradation or on the number of distinct stages, but they can give very detailed information about the products of reaction.

Pyrolysis–gas chromatography (Py-gc) takes advantage of the ability of gas chromatography to separate volatile species rapidly and efficiently. Since gc analysis of a mixture requires the near-instantaneous injection of a small sample of mixture into the flowing carrier gas, the technique requires very rapid degradation of the sample. This is achieved by mounting the sample directly in the inlet of the gc instrument and subjecting it to a brief pulse of heating to a temperature high enough to pyrolyze enough of the sample to give a measurable signal. Py-gc has been reviewed (12).

A close relative of Py-gc is direct pyrolysis mass spectroscopy (Py-ms or DPy-ms). In this technique a polymer sample is pyrolyzed directly in the inlet of the mass spectrometer and the products of degradation analyzed. The most sophisticated version is the use of tandem mass spectroscopy. The initial pyrolysis fragments are subjected to soft ionization in the first ms stage so as to determine their masses and to separate the individual fragments. The ions are then transferred to a second ms stage where they are fragmented by electron impact and the fragmentation pattern used to give structural information. This is an extremely expensive method of study but capable of enormous amounts of information. A more recent development is the use of laser radiation to pyrolyze a polymer at the inlet of the mass spectrometer. DPy-ms methods have been reviewed (39).

A third approach is pyrolysis gas chromatography–mass spectroscopy (Py-gcms). This is a hybrid of the two previous methods, in which the pyrolysis products are separated by gc and then injected directly into an on-line MS, often a small quadrupole instrument. The gc serves to give rapid separation of the products where the MS acts both as a gc detector (in total ion current mode) and as an analytical tool.

Pyrolyzer designs for Py-gc have been reviewed (40). Although many different designs have been published, most modern instruments use either filament or Curie point methods. In a filament pyrolyzer the sample is heated by passing a current through a resistive filament in the gc inlet. In many designs the electronics are arranged to give an initial high pulse of current to heat the filament very

rapidly to the pyrolysis temperature. The most sophisticated version (41) of this approach uses a thermocouple welded to the filament to provide feedback control of the temperature.

In an alternative approach (42) the sample is coated on a ferromagnetic wire in the inlet of the gc machine, surrounded by a coil connected to a radio frequency generator. A short pulse of radio frequency power causes the temperature of the wire to rise rapidly to its Curie point, where it remains until the power is switched off. In theory the great advantages of this approach are its self-thermostat action and the absence of direct contact between the power unit and the pyrolysis wire and this has made Curie point pyrolysis popular, with commercial units available. However, it has been pointed out (12) that neither the speed of temperature rise nor the self-thermostat action is as reliable as is often claimed.

Coupled pyrolysis techniques find three distinct areas of application. Polymers which degrade cleanly to relatively few volatile products, such as PMMA, polyisobutene, and many step-reaction polymers, are often amenable to detailed product analysis and to kinetic analysis of the formation of individual products (12,43).

In more complex cases it may not be possible to analyze the mechanisms in detail but identification of the fragments can be used as a method for analyzing microstructure of the original polymer or copolymer. This application is analogous to the classical methods of organic chemistry, in which an unknown compound is degraded by chemical reactions of predictable mechanism to give recognizable fragments, and the structure of the original molecule is deduced. In the hands of experts this approach to pyrolysis of polymers has given a great deal of information about sequence distribution in copolymers and similar problems (see eg, Refs. 44–50). It has also been used to characterize highly intractable cross-linked polymers, including lignins (51–53) (see LIGNIN).

Finally, in many cases the pyrolysis product distribution is so complex that it is not possible to separate and identify all of the components. In such cases a chemometric method, simply treating the pyrogram as a pattern, can be used to compare one sample with another. This approach has found many applications in forensic analysis, for example, of paints and in analysis of authenticity of art works (54). It has even been used to type bacteria (55–57). These applications often take advantage of the fact that the high sensitivity of the analytical method allows minute samples to be analyzed; they depend upon a database of pyrograms obtained under well-controlled conditions and analysis involves a statistical pattern-matching approach.

Direct Mass Spectroscopy. Although mass spectrometry (qv) has been used in studies of natural and synthetic polymers for many years, the applications have been mainly limited to polymers which have been chemically or thermally degraded to fragments small enough for conventional mass spectrometry. In recent years, the introduction of matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization (ESI) combined with the use of time-of-flight (TOF) and Fourier transform ion cyclotron resonance (FTICR) spectrometers has revolutionized the applicability of MS to polymers, by extending the accessible mass range to 500,000 and beyond and providing means of getting polymers into the mass spectrometer and ionized without fragmentation (58). Applications of MS to polymers have recently been reviewed (59). These applications are beginning to

influence degradation studies, because they allow structural analysis of polymers at low levels of degradation.

In ESI, a solution of the polymer is injected into the MS through a very fine needle so as to produce an aerosol. If the solution is very dilute, no droplet contains more than one polymer molecule, and evaporation of the solvent leaves the isolated polymer molecules in the gas phase. Ionization occurs as a result of a potential applied to the needle tip. Although ESI has had a major impact on studies of biopolymers, its use for synthetic polymers has been more limited, mainly because of the formation of multiply charged species (58).

The MALDI approach involves homogeneous dispersion of the polymer in a large excess of the "matrix," which is a small organic molecule. With high laser power and at the wavelength absorbed by the polymer it is possible to degrade the polymer but in MALDI the matrix and the laser wavelength are chosen so that the energy is absorbed by the supporting matrix. The high energy density causes evaporation of a small volume of the substrate and a mixture of ionized matrix and polymer molecules is released without damage to the polymer. MALDI of polymers has been reviewed (39,60).

In principle, MALDI is capable of measuring the molecular weight distribution (MWD) of a polymer, and hence all of the average molecular weights. However, even its most ardent early advocates have now recognized that the results are only reliable for polymers of relatively low polydispersity. Many of the problems have been reviewed (39). Most are a function of instrument design. For a mass spectrum to reflect the MWD over a wide range of molecular weights, both the ionization yield of the spectrometer and the detector response must be independent of chain length and neither of these conditions is fully met in current spectrometers. Additionally there can be mass discrimination in the laser desorption process and some care is needed to avoid degradation in MALDI experiments (61). Even if these problems can be overcome, it is important to recognize that MS is a number technique—the ideal detector response is proportional to the mole fraction of species of a given chain length, so that MWD data are biased toward low molecular weights.

Many of the problems of MALDI of polydisperse polymers can be overcome by using a combination of an initial fractionation by size exclusion chromatography (sec) followed by MALDI, taking advantage of the enormous sensitivity of MALDI to analyze the minute amounts of polymer eluted from the sec. This is probably now the best available method for getting MWD information but is complex.

Despite the problems of analyzing MWD information from MALDI, it remains an extremely powerful technique for getting information about structure in degraded polymers because the precise resolution allows chains of the same length with different end-groups to be separated. The method is being increasingly applied to polymer degradation. MALDI has been used to examine pyrolysis residues from many step-reaction polymers (39,62–64). Other examples include MALDI-TOF characterization of highly cross-linked, degradable polymer networks (65) and studies of poly(ethylene glycol) (66,67) and of poly(tetrahydrofuran) (68). The method is also finding applications to oxidation reactions. For example it has recently been applied to oxidation of nylon-6 (69) and of ethylene oxide–propylene oxide–ethylene oxide triblock copolymers (70).

Oxidative Degradation, Chemistry

Although pure thermal degradation is an important limiting factor in the processing of polymers and in their use at high temperatures, it has little relevance to applications at room temperature, especially when the polymer is in contact with air. For almost all polymers, the long-term stability is determined by resistance to oxidation.

Oxidation can be defined as the reaction of a polymer with oxygen at temperatures where thermal degradation is negligible. Thus it can be distinguished from *combustion*, which is the reaction between oxygen and the volatile products of thermal decomposition of the polymer. In fire situations the *degradation* is typically a complex mixture of oxidation and combustion, depending on the polymer and the conditions of degradation.

Studies of simple hydrocarbon models suggest that polymers should not oxidize significantly at service temperatures and this led to a widespread belief that polymers do not degrade in normal use. In fact, oxidation is a major technological problem and rather few polymers can be processed or used without stabilization. The reason is the presence of impurities and structural defects in polymers, especially after processing.

Oxidation is typically a very slow reaction between a solid, possibly semicrystalline, polymer and a gas. It is kinetically very complex, in the sense that the apparently simple overall behavior can be fitted by a very wide range of models, and the literature is characterized by a good deal of "paper chemistry". The main differences from thermal degradation are that the reactions are slow, over weeks or years, the production of volatiles may be almost negligible, and diffusion of oxygen into the polymer is required.

The conditions under which oxidation takes place vary widely, but there are two main cases. The first is during processing, where the temperature is high and there may be local "hot-spots" due to shear. The polymer is molten, the oxygen concentration is very low, and the high level of shear leads to the possibility of radical formation by mechanochemical scission of polymer chains. The second is normal use, where the polymer is solid, reactions are very slow, there is oxygen saturation, and there may be exposure to uv light, atmospheric pollutants, etc.

Oxidation of solid polymers in service use may lead to loss of mechanical properties—toughness, impact strength, elongation to break, flexural strength, etc, and the polymer typically embrittles at quite low levels of oxidation. It may also lead to marked changes in appearance—chalking, cracking, loss of gloss, and yellowing are all common.

Our understanding of the basic chemistry of oxidation is based on the classic work of Bolland and Gee (71–73) on natural rubber, and on earlier work on hydrocarbon oxidation. These studies showed that oxidation involves the chain reaction cycle of initiation, propagation, and termination. In the following, X is a primary radical, the origin of which is discussed later (Fig. 3).

(1) *Initiation*

$$RH + X \longrightarrow R\bullet + XH$$

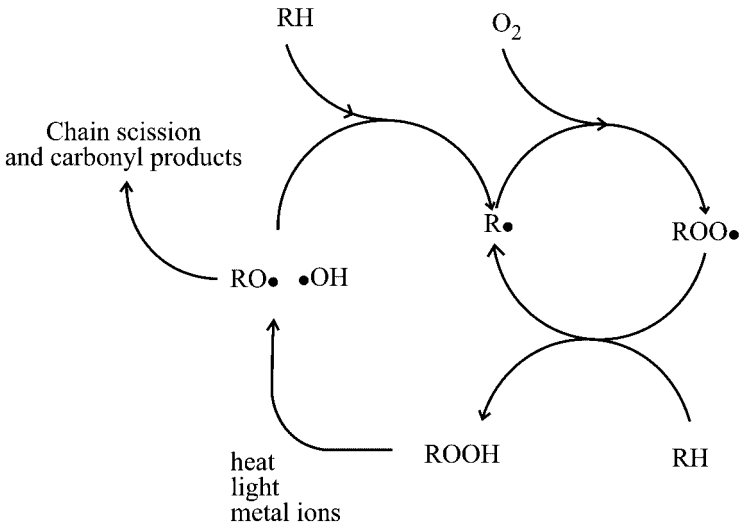

Fig. 3. The important reactions in polymer oxidation expressed as the interlocking cycles which eventually destroy the polymer through the scission reactions of alkoxy radicals.

(2) *Propagation*

$$R\bullet + O_2 \longrightarrow RO_2\bullet$$
$$RO_2\bullet + RH \longrightarrow ROOH + R\bullet$$

(3) *Termination*

$$RO_2\bullet(R\bullet) + RO_2\bullet(R\bullet) \longrightarrow \text{Inert products}$$

The product of this primary cycle is the polymer hydroperoxide ROOH. Under use conditions, these are unstable and decompose to yield new radicals, which initiate new chains. Thus, a chain reaction that regenerates its own initiator is started and the result is autoacceleration. Typically, there is an induction period of slow reaction, followed by rapid oxidation, as illustrated in Figure 4, which shows some data for accelerated aging of polypropylene (PP). In some cases, eg, PP, the formation of peroxides may be faster than their decomposition (depending on the temperature), so that they accumulate in the polymer. In other cases the peroxides are so unstable that they decompose as soon as they are formed.

Many initiation reactions have been proposed in the literature, eg,

$$RH \longrightarrow R\bullet + H\bullet$$
$$RH + O_2 \longrightarrow R\bullet + HO_2\bullet$$

All such direct reactions of the polymer by itself or with oxygen are thermodynamically unlikely at normal use and processing temperatures (which is why pure model compounds do not oxidize readily). The exact origin of initiation is still

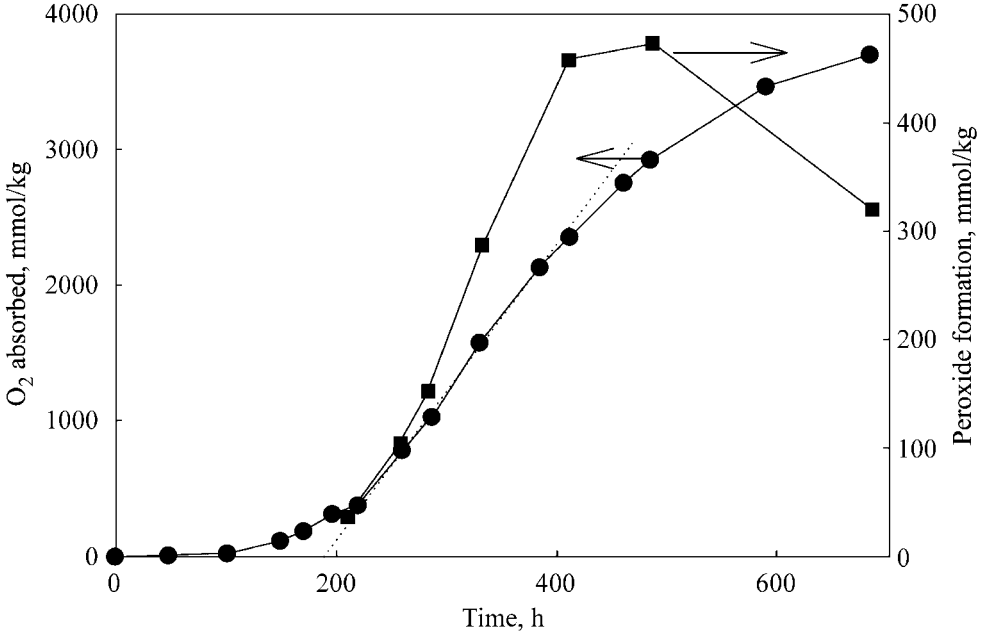

Fig. 4. Typical curves for oxygen uptake and formation of titratable peroxides in an unstabilized sample of PP at 70°C. The reaction is autoaccelerating. Extrapolation of the approximately linear part of the oxygen uptake curve, as indicated by the dotted line, gives the *induction period* where the polymer loses its useful mechanical properties. The amount of oxygen absorbed is low, corresponding to less than one molecule for every 100–150 polymer repeat units. Adapted from Ref. 74.

somewhat uncertain. The production of polymers totally free of impurities is not possible and small amounts of catalyst residues and other contaminants are always present and may react with the polymer, especially at the high temperatures of processing. Peroxides may also be formed in processing simply due to the effects of heat and mechanical shear in the presence of trace oxygen. It is now generally believed that most initiation is by the decomposition of traces of hydroperoxide, created by mechanochemically induced oxidation during processing.

Hydroperoxides are thermally unstable because of the weak O—O bond. The simplest decomposition is the unimolecular scission of the O—O bond to yield two radicals

$$\mathrm{ROOH} \longrightarrow \mathrm{RO\bullet} + \bullet\mathrm{OH}$$

Both alkoxy and hydroxy radicals are very reactive and HO• rapidly abstracts H from the polymer to form water:

$$\mathrm{HO\bullet} + \mathrm{RH} \longrightarrow \mathrm{R\bullet} + \mathrm{H_2O}$$

The RO• radical may react the same way to give ROH. In polymers it also leads to chain scission as discussed below.

In fact the situation is much more complex. In hydrocarbon media, hydrogen bonding of the polar hydroperoxides causes them to dimerize, leading to bimolecular decomposition:

$$2\ ROOH \longrightarrow RO\bullet + RO_2\bullet + H_2O$$

Again, RO• and RO_2• radicals produce R• by abstraction or scission reactions.

Hydroperoxides are also very sensitive to traces of metal ions with multiple oxidation states (eg Fe, Ti, Co, Mn, Cu, Cr). These are always present from catalysts or processing equipment and can catalyze rapid decomposition of peroxides:

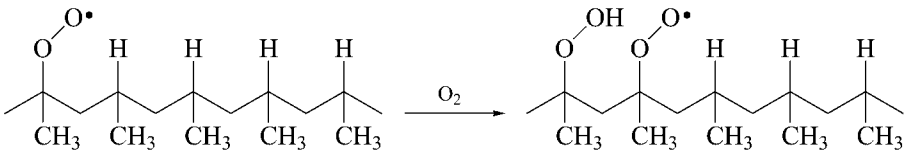
$$ROOH + M^+ \longrightarrow RO\bullet + {}^-OH + M^{2+}$$

$$ROOH + M^{2+} \longrightarrow RO_2\bullet + H^+ + M^+$$

This catalysis is normally a disadvantage but can be used to accelerate degradation. Further, hydroperoxides are very sensitive to photolysis at solar wavelengths. The extinction coefficients are very low, but the quantum efficiency for scission is close to 1. Hydroperoxide photolysis can be sensitized by pigments.

Of the two reactions that form the propagation cycle, the first, reaction of the alkyl radical with oxygen, is very much the faster. For almost all radicals involved in common polymers, it is encounter-controlled, with zero activation energy (75), so that alkyl radicals have very short lifetimes if there is oxygen in the polymer. The second stage, abstraction of a hydrogen atom from the polymer to form a new alkyl radical and a hydroperoxide, is much slower. Its activation energy depends upon the dissociation energy of the C—H bond being broken. Thus, in polymers like PP, which have several different RH bonds, the location of oxidation will depend on the reactivity of the RH bonds. In PP, most oxidation takes place at the tertiary C—H bonds. Similarly, in natural rubber, most oxidation is at the α-methylene groups and in nylons it is at the methylene groups α to nitrogen.

In oxidation of liquids, propagation is expected to be statistically random. In the solid phase the mobility of radicals can be limited, so that propagation takes place in a "zone" of local oxidation; eg, in PP there is evidence of intramolecular propagation:



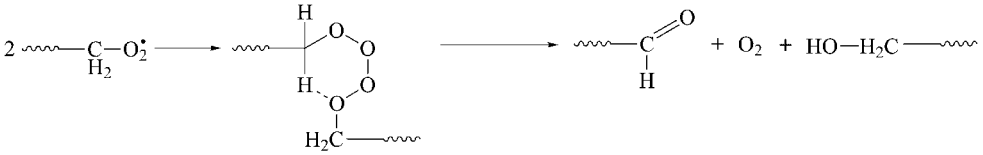
This gives short sequences of hydroperoxides. In polyethylene and rubbers, where mobility is higher, sequences are less common but hydroperoxidation may still be nonuniform.

Note also that the relative concentration of R• and RO_2• radicals depends upon the relative rates of the two propagation steps and therefore on the

concentration of oxygen. Under oxygen saturation conditions, the radical population is expected to be dominated by $RO_2\bullet$ radicals, but R• radicals may be much more important in processing, where the oxygen concentration is much lower; this has important implications for the choice of stabilizers (see eg, Ref. 76).

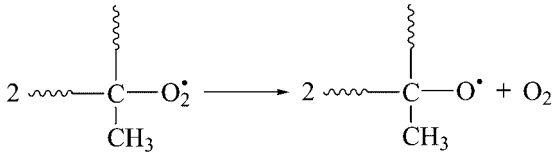
The chain termination reaction by bimolecular interaction of radicals may be more important in polymers than in liquids, because the kinetic chain length of solid-phase oxidation may be short. In oxygen-deficient conditions, coupling reactions of carbon-centered radicals can lead to cross-linking, and formation of gel particles can be a problem in film blowing of polyethylene. Under more normal conditions, the reactivity of carbon-centered radicals with oxygen means that only coupling of alkyl-peroxy radicals is significant.

Bimolecular interaction of alkyl-peroxy radicals must initially produce a highly unstable linear tetroxide. Where one of the radicals is secondary, this species rapidly reacts via the so-called Russell mechanism (77) to give a carbonyl and a hydroxy group:



This reaction is of some interest because it is implicated in the ultraweak chemiluminescence emitted by oxidizing polymers (78–82).

In the case of PP, where the terminating radicals are both expected to be tertiary, the Russell reaction is not possible and bimolecular interaction of radicals is believed to follow the path

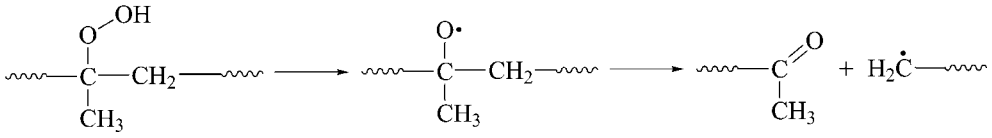


The existence of this reaction has been elegantly confirmed (83) by the unambiguous demonstration that the photochemical oxidation of PP in an atmosphere containing both $^{32}O_2$ and $^{36}O_2$ generates $^{34}O_2$.

The reaction cycle discussed so far consumes oxygen and converts it to hydroperoxides on the polymer chain. If this were the only set of reactions, it would not cause much trouble, except in applications involving high frequency electrical fields, where the introduction of polar groups has deleterious effects on dielectric losses. The real problem is that side reactions of radicals can cause chain scission and cross-linking.

In general, alkyl-peroxy radicals are rather stable and do not undergo side reactions. In an oxygen-saturated polymer, alkyl radicals are rapidly converted to alkyl-peroxy radicals by reaction with oxygen, so that their other reactions are not important. The most important side reaction is that of the alkoxy radical. In liquid hydrocarbons, the main reaction of alkoxy radicals is hydrogen abstraction to give

an alcohol. In contrast, in polymers β-scission can compete, to give a carbonyl group and an alkyl radical:



This is a key reaction because it leads to chain scission. The aldehyde or ketone formed is more reactive to oxidation than is the polymer. In the early stages of oxidation, the side products are mainly aldehydes and ketones but carboxylic acids, esters, and cyclic lactones become increasingly important with conversion.

Note that carbonyl groups are good photoinitiators for oxidation, so that increasing oxidation leads to increasing photosensitivity. Production of acids may also be important if the polymer has acid-sensitive groups, eg, polyacetals. Scission can be measured by following changes in molecular weight. It typically follows oxygen uptake, as is illustrated in Figure 5. Scission is inefficient, about 10 molecules of O_2 being absorbed for each scission.

In principle, termination of two alkoxy radicals would give a peroxide cross-link, where as termination of an alkoxy radical with an alkyl radical would give an ether cross-link. It is very difficult to get direct experimental evidence for either of these reactions, since both dialkyl peroxides and ethers are difficult to detect; however, there is no doubt that chain scission is dominant in saturated hydrocarbon polymers.

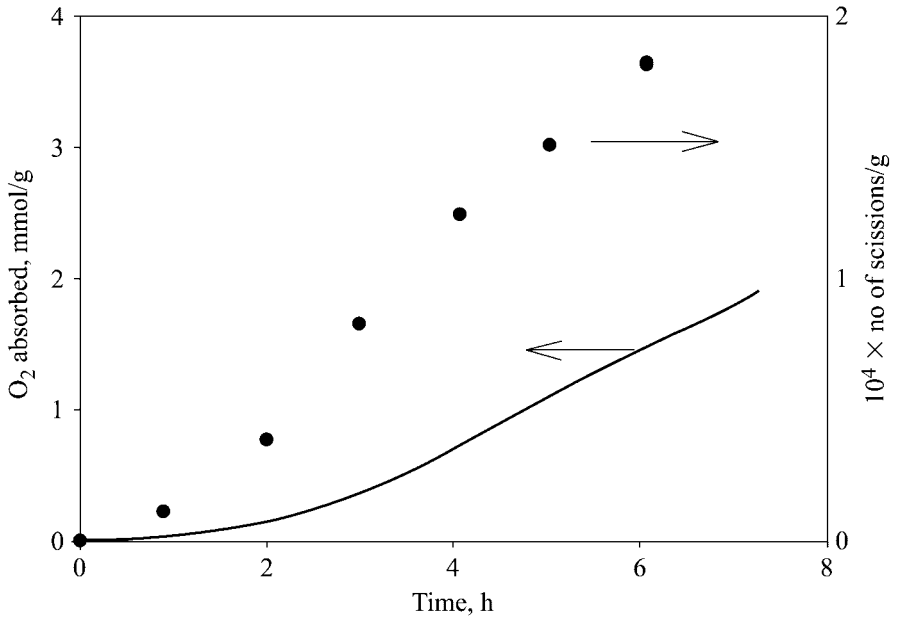


Fig. 5. Chain scission and oxygen absorption during oxidation of unstabilized PP at 120°C. The amount of scission is proportional to the amount of oxygen absorbed, although typically around 20 molecules of oxygen are taken up for each scission.

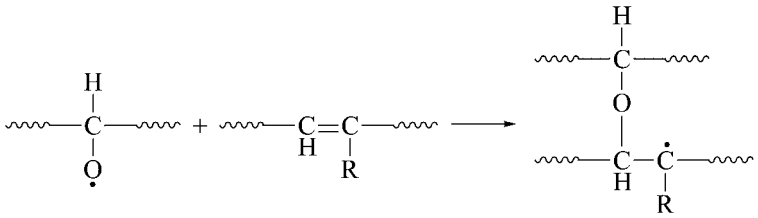
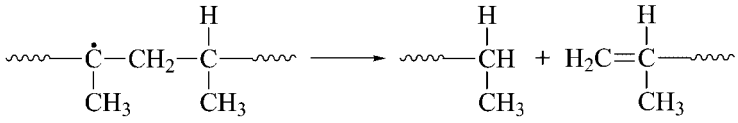
The alkoxy radical is most important because its high reactivity and ability to survive in the presence of oxygen mean that its reactions are responsible for chain scission and for most of the stable products of oxidation. Thus, the oxidation of saturated polymers under conditions of oxygen saturation leads to scission. In contrast, in unsaturated rubbers, the high concentration of C=C bonds means that attack on the C=C bond can compete with propagation and scission.

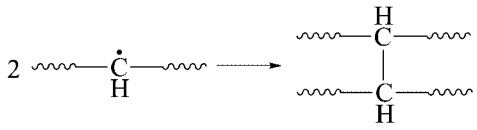


The result is that cross-linking, epoxidation, and formation of cyclic peroxides all occur in unsaturated rubbers. The increasing cross-link density leads to hardening of rubbers on oxidation.

If the oxygen concentration is low, as in processing, R• radicals are stable enough to react independently. There is a competition between recombination cross-linking and β-scission. The relative importance depends on the polymer: eg, polypropylene (**7**) undergoes scission in processing, but polyethylene (**8**) cross-links.



7



8

An extreme case of polymer oxidation is the involvement of polymers in fires, where the reactions may be a mixture of oxidation of the molten polymer, pyrolysis of the polymer, and oxidative combustion of volatile products. These reactions are discussed in more detail elsewhere, in the context of fire retardants. They have attracted the attention of the thermal analysis community and a number of quite elegant tga studies of polymer degradation in air have appeared. In general, the effect of changing the atmosphere in a tga experiment from nitrogen to air is to destabilize the polymer, causing a large downward shift in the temperature of rapid weight loss, and isoconversional methods of data analysis often show activation energies which vary with conversion (84). A notable exception is PMMA, whose initial pyrolysis temperature is increased by as much as 70°C in the presence of air or nitric oxide (85). This effect has been interpreted as due

to the trapping of radicals by oxygen or nitric oxide, leading to blocking of the depropagation reaction (10).

Although tga studies of oxidation are relevant to combustion, it must be emphasized that studying degradation under conditions of rapid weight loss from liquid samples at over 200°C has no relevance for degradation of solid polymers in service use. Furthermore, unless exceedingly thin sample are used, such studies are almost certainly influenced by oxygen diffusion effects discussed below.

Heterogeneous Oxidation. Oxidation of a polymer in service is a reaction between the solid polymer and a reactive gas, oxygen. In polyolefins the situation is complicated by the semicrystalline morphology. It is important to ask whether oxidation can be treated as effectively homogeneous and subject to the normal rules of liquid-phase kinetics, or whether the oxidation is more heterogeneous.

Although there is a massive literature on the kinetics of polymer oxidation, based on homogeneous models, the possibility that the reactions are actually locally heterogeneous has been considered seriously. It has been suggested (86,87) that the uneven distribution of catalyst residues and other impurities in PP can lead to oxidation in localized zones of a few micrometers in size, which spread through the matrix. More recently, chemiluminescence imaging studies (88,89) have supported this view.

Raman microscopy has been used to probe photo-oxidation of unstabilized PP (90). It was concluded that the catalyst residues, for the type of PP studied, tend to stabilize the polymer in the immediate vicinity, but also form reactive species that diffuse away from the catalyst to initiate oxidation. Localized oxidation was also confirmed by examining the distribution of polystyrene grafted onto the hydroperoxide sites in photo-oxidized PP (91).

It has been suggested (92–94) that oxidation of PP can be modeled as a process of "infectious spreading," analogous to the spread of infectious disease. However, these kinetic arguments must be interpreted with caution. It has been shown (95–99) that kinetic models of PP oxidation based on both homogeneous and heterogeneous models can give equally good fits to data for functional group formation in oxidation of PP. It seems that in most cases sufficient data of enough precision are not available to distinguish complex models.

Whatever the situation at the micrometer level, there is no doubt that oxidation of bulk polymer samples may be heterogeneous in the sense that oxygen may be consumed at the surface of the sample, leading to a profile of oxidation across the sample thickness. Such surface limited degradation has been demonstrated in many ways (100), including density profiling (101), modulus profiling (102), and ftir, using both microscopy and photoacoustic techniques (103). The thickness of the oxidized layer depends on the relative rates of oxygen diffusion and consumption, and theoretical models have been reviewed (104–106).

A rigorous test of theoretical treatments for diffusion-limited oxidation has been reported (107); an extensive series of radiation-initiated oxidation experiments was conducted on a commercial rubber. Oxidation profiles were monitored from density changes; the resulting profile shapes and magnitudes could be quantitatively fitted, and the theoretical parameters derived from fitting allowed quantitative confirmation of a governing theoretical expression relating them to independently measured values for the oxygen consumption and permeation rates.

Mechanical Effects of Oxidation

Whatever the chemical reactions, the ultimate problem of oxidation is that it leads to failure of the polymer. Whether the initial material is a rubber or a tough plastic, failure will usually take one of two forms. Either the product loses its surface appearance by discoloration, loss of gloss, or appearance of white deposits (chalking) or it cracks and breaks. The relation between chemical change and mechanical failure is quite complex.

Fracture (qv) is the result of the stress on the object, locally exceeding the breaking strength. If the polymer is an intrinsically tough material, such as PE, it normally yields and deforms under excess load, rather than fracturing. One common consequence of degradation is a progressive loss of toughness, until the polymer becomes brittle and fails by cracking. The stress that causes the failure may be externally imposed in use, or internal stress resulting from differential shrinkage or expansion of different sections of the piece. In some cases the loss of tensile elongation is gradual; in other cases, especially where effective stabilizers are used, failure can be very rapid at the end of a long induction period in which the properties are stable.

In unsaturated rubbers, the dominant chemical process in oxidation is cross-linking, owing to radical formation in the presence of high concentrations of double bonds. Increased cross-link density reduces the average molecular weight between cross-links and causes an increase in modulus until the glass-transition temperature rises sufficiently above the use temperature that the polymer becomes brittle. If the sample is thin enough, crack propagation under load then causes mechanical failure. Embrittlement failure of this type is typical of rubbers in film or sheet form. In extreme cases, the rubber may deteriorate to a friable powder.

In contrast, in thick samples oxygen diffusion restrictions may limit the initial oxidation to the surface of the polymer. The effect of surface cross-linking may be to further restrict diffusion of oxygen into the bulk, giving a hardened surface layer which protects the bulk polymer from further oxidation. The effect is analogous to passivation of aluminum by formation of an oxide layer. It is this which allows the successful use of a highly oxygen-sensitive material like natural rubber in large slabs for a variety of engineering and building applications, where very long lifetimes are expected. Many of the newer rubbers formed by ring-opening metathesis chemistry also fall into the category of self-protecting polymers.

In semicrystalline polyolefins, failure is also often by embrittlement, but for different reasons. The main mechanism is chain scission, with lowering of molecular weight and of T_g. Failure occurs at very low levels of oxidation; the molecular weight typically falls by less than a factor of 2 and there is less than one O_2 molecule per 100 carbon atoms. The reason for this sensitivity lies in the complex morphology of many polymers.

Many of the most oxidation-sensitive polymers, especially polyolefins, are semicrystalline, their morphology depending on the conditions of crystallization. Slow crystallization at low undercooling gives spherulites. Rapid crystallization at high undercooling gives much less organization, although often similar overall crystallinity is measured by, eg, x ray or dsc. In PE, where T_g is -100°C, crystallization is easy. In PP, T_g is much closer to room temperature and very rapid

cooling during molding may lead to a highly disordered smectic crystal structure. Diffusion of oxygen is restricted to the amorphous component of semicrystalline polymers and oxidation is restricted to the amorphous phase. This is fortunate because stabilizers also cannot get into the crystalline regions.

The useful mechanical properties of polyolefins arise from this semicrystalline morphology. For normal use temperatures ($T_g < T < T_m$) these polymers are effectively "composites" of rigid crystalline units in a soft, rubbery matrix. In slow loading, the ability of the chains to slip through crystals gives great toughness. At lower temperatures or higher strain rates (impact), failure becomes brittle, although the frequencies required for embrittlement of undegraded materials may be close to ballistic.

Chain scission changes the balance between plastic flow and brittle fracture, toward brittle fracture. Scission is confined to the amorphous regions between crystallites, so that it removes the ability to transfer load to the crystallite, decreasing plastic flow. Also, scission increases the freedom of the chains, especially at the surface. It allows recrystallization at the surface to relieve stress. The result is increased surface density and crystallinity, together with formation of surface cracks.

The final result depends on the point where crack propagation becomes favored over plastic flow. In a thick molding this may only happen at the surface, so that changes in surface appearance occur with little loss in bulk strength. In marginally tough materials, a crack started by surface embrittlement can propagate across the remaining tough plastic. In films, where great toughness is needed, small amounts of degradation can cause rapid embrittlement.

In contrast to semicrystalline polymers (qv), amorphous polymers (qv), such as PVC, typically discolor and chalk with less loss of strength. Amorphous, glassy polymers such as polystyrene are typically quite resistant to loss of mechanical properties by oxidation, but are prone to discoloration. Oxidation of polymers which have aromatic rings can lead to hydroxylation of the ring, followed by oxidative coupling of the phenolic products. The coupling products may show intense absorption of visible light, so that polymers such as polystyrene, poly(ethylene terephthalate), and aromatic polyurethanes often show major yellowing without much loss of tensile strength.

The extensive use of polymers in engineering applications has led to the development of many biphasic polymer blends, in which a small fraction of rubber particles is dispersed in a matrix of the host polymer. Such particles act to improve impact strength by dissipating energy at the tip of a propagating crack. Examples where the matrix is amorphous include high impact polystyrene (HIPS) and acrylonitrile–butadiene–styrene (ABS) copolymers. These are typically made by polymerizing styrene or styrene–acrylonitrile mixtures in the presence of a polybutadiene latex. Another very important group is the rubber-toughened polyolefins. These may be produced by mechanical blending of, eg, ethylene–propylene (EP) rubber or natural rubber into PP. Alternatively they can be made by feeding ethylene into a PP synthesis at the end of the reaction so as to form the so-called reactor "block copolymers." PP toughened with EP rubber is a major engineering plastic, with many applications in motor vehicles, eg, as bumpers.

In such materials the effects of degradation are complex and depend upon the chemistry and relative extent of degradation of the two phases. For materials

toughened with diene polymers, oxidative cross-linking and hardening of the rubber causes rapid loss of impact strength, while oxidation of the styrenic component in HIPS or ABS causes simultaneous yellowing. In contrast, in toughened PP the rubber is usually the more stable phase and degradation of thick sections such as bumper moldings most often involves surface deterioration through microcracking, with loss of color and gloss.

Photodegradation and Photo-oxidation

Many polymers are sensitive to light and photodegradation has been extensively studied. For any chemical reaction to be photoinitiated, several conditions have to be satisfied. First, the light must be absorbed by the reacting molecule or an impurity; second, the absorbed photon must have sufficient energy to break the appropriate bonds; and third, the excited molecule must photoreact rather than losing its energy in other ways.

For polymers in normal use, the usual source of light is solar radiation. Although the sun emits light from the infrared to the high energy ultraviolet, the combined effects of atmospheric oxygen and ozone cut off all radiation below around 300 nm. The exact range depends on latitude and atmospheric conditions (108,109).

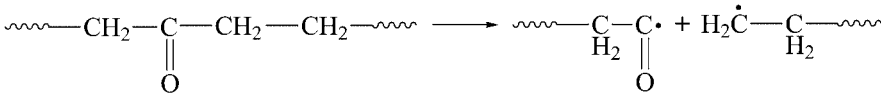
There is a very large literature on the effects of ultraviolet radiation, typically at 254 nm, on polymers in inert atmospheres or vacuum (see eg Refs. 110 and 111). Most of this is irrelevant to polymers in normal use, although there are a few exceptions, for example the use of polycarbonate as impact-resistant lenses for mercury-vapor lamps in street lighting.

Because polymers in normal use are likely to be exposed to light only above 290–300 nm, they can be divided into two groups: those which have structural features (chromophores) that are able to absorb wavelengths in this range, and those which do not. In the former group, photochemistry is an inherent property of the polymer while in the second it is associated with impurities. A second important factor is the presence of oxygen. Since photodegradation involves chain scission, radicals are formed and their reactions in the presence and absence of oxygen may be quite different. Photodegradation of polymers has been very extensively reviewed (112).

Polymers with Intrinsic Chromophores. The most important intrinsic chromophore for solar radiation in many commercial polymers is the carbonyl group, in the form of ester, amide, and carbonate groups. These typically have weak absorbance above 290 nm, offset partially by the high concentration of chromophore groups. Fortunately, the quantum efficiencies for chain scission in rigid polymers are usually very low and materials such as polycarbonate, aromatic polyesters, and PMMA are regarded as reasonably stable. However, they will suffer loss of mechanical properties over long periods of solar exposure. Polycarbonate and polyesters also slowly yellow. PMMA degrades by unzipping and does not discolor.

Studies of the photolysis of carbonyl-containing polymers (see eg Ref. 113) have revealed two main mechanisms of degradation. The first, the Norrish

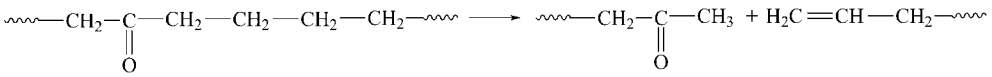
Type I cleavage, involves direct scission of the bond α to the excited carbonyl, with the production of two radicals.



Although this reaction dominates gas- and liquid-phase photolysis of ketones, the quantum efficiency in polymers is usually low (0.001), because the formation of two radicals in close proximity in a rigid matrix often leads to recombination. The overall effect of Norrish I cleavage depends upon temperature and the presence of oxygen. At high enough temperatures, in inert atmospheres, it can initiate depolymerization. At temperatures well below the ceiling temperature the effects may be scission or cross-linking, depending upon the structure and reactions of the radicals. In the presence of oxygen, the quantum efficiency for scission can be high because reaction of the radicals with oxygen competes with their recombination and may initiate photo-oxidation. However, the most important point is that the polymer can undergo continuing radical photochemistry even in the absence of oxygen. For example PET and aromatic polyurethanes undergo photoinduced cross-linking and darken in color even if they are irradiated in inert atmosphere. Indeed the darkened polymer may photobleach if irradiated in air, because the products of inert atmosphere photolysis are themselves sensitive to photo-oxidation. This is a familiar problem with many modern white paints.

Competition between photolysis and photo-oxidation can also occur when thick sections of materials such as PET are irradiated. Here, the low permeability of the polymer to oxygen can mean that the surface layers undergo photo-oxidation, while the deeper layers photolyze. It is fortunate for many applications that the quantum efficiencies of all of these processes are low.

An alternative to photochemical radical generation is the Norrish Type II reaction, which is effectively a hydrogen abstraction by the excited carbonyl.



This leads to a chain scission without producing radicals. The quantum efficiency is much higher than for the Type I reaction (typically around 0.02) but is still low in polymers because of the constraints on formation of the six-membered transition state. It has been shown that ketone groups in polymers are photolyzed almost exclusively by the Norrish II mechanism, whereas aldehydes photolyze almost completely by the Norrish I mechanism (114). Since aldehydes do not normally survive in oxidative conditions, being rapidly oxidized to acid, the Norrish II mechanism is more important.

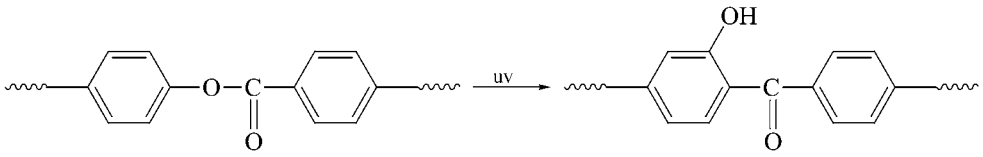
The deliberate introduction of carbonyl groups into polymers, either in the main chain by copolymerization with carbon monoxide or in the side chains by copolymerization with vinyl ketones, is the basis of at least one type of plastic designed to photodegrade rapidly in outdoor exposure (115). These copolymers are widely used in the United States for the six-pack ring packaging of soft drinks, whose damaging effect on marine life has been of great concern.

Aliphatic esters absorb light at rather shorter wavelengths than the ketone copolymers and, like PMMA, are regarded as having good photostability. Aliphatic polyamides are much less photostable and nylons degrade in outdoor exposure by a combination of photocleavage and photo-oxidation (116–118).

The introduction of aromatic groups increases extinction coefficients and shifts the maximum absorption to longer wavelengths. The ability of aromatic groups to dissipate excitation energy reduces the quantum efficiency for photo-reactions relative to other deactivation processes. It also allows the formation of conjugated aromatic structures, which can lead to yellowing. Although the wide range of aromatic polymers are regarded as stable, high performance materials, most suffer from yellowing, cross-linking, scission, and deterioration of properties on solar exposure over long periods.

Polystyrene absorbs solar uv, because of the aromatic group. It degrades slowly via a mixture of scission and oxidation reactions (119–121). The polymer yellows even on irradiation in vacuum, due to formation of conjugated sequences of double bonds.

It has been shown (122) that aromatic polyesters degrade by a combination of Norrish I and Norrish II photolyses, with photo-oxidation playing an important part. Aromatic esters may also undergo an important photochemical reaction, known as the photo-Fries rearrangement (123).



This reaction is important in polymer photochemistry, because it can occur with significant efficiency even in glassy, solid polymers. It has been suggested to contribute significantly to photoinduced yellowing in aromatic polymers, particularly polycarbonates (124). The photo-Fries rearrangement has also been identified as a source of photo-yellowing in aromatic polyamides (125). However, more recently, it has been suggested (126–128) that the photo-Fries reaction is more important for wavelengths below 300 nm, and that photo-oxidation reactions may be more important in yellowing of aromatic polymers at solar wavelengths. In a review (129) of degradation of polycarbonate by sunlight in Florida exposure it was shown that the observed products originate in a combination of Fries reactions and photo-oxidation of both the ring and the aliphatic components.

The combination of photoscission, photo-oxidation, and photorearrangement means that even very high performance polymers, such as epoxy resins, aromatic polyethers polyketones, and polysulfones, and the aromatic polyamides poly(1,3-phenylene isophthalamide) and poly(1,4-phenylene terephthalamide) (Nomex and Kevlar respectively) will degrade significantly on solar exposure. For example, it has been shown (108) that poly(phenylene oxide) and polysulfone both lose about 50% of their initial tensile strength after 2 years of outdoor exposure in Queensland.

Polymers with Impurity Chromophores. Although all the polymers with intrinsic chromophores are inherently sensitive to degradation, at least some are regarded as relatively stable materials, able to resist solar exposure for long

periods. In contrast, polymers such as the polyolefins and the hydrocarbon rubbers have remarkably poor lifetimes when exposed to solar light. Unstabilized PP film, for example, has a lifetime of only a few weeks in outdoor exposure.

At first sight, this observation is strange, because simple hydrocarbon analogues of these polymers have absorption spectra which have no overlap with the solar radiation spectrum at the earth's surface. The implication is that the effective chromophore for uv light is an impurity.

There have been many candidates for the chromophoric impurity in polymers. They include oxygen–polymer charge-transfer complexes; carbonyl and hydroperoxide groups, introduced by mechanochemical oxidation in processing; catalyst residues; pigments; and polynuclear aromatic hydrocarbons deriving from atmospheric pollution. The potential significance of these species has been discussed at length in the literature (see eg, Refs. 112,130, and 131).

Although there is little doubt that all can be important in particular circumstances, it is generally agreed that hydroperoxides are normally the key to the initial photoinstability in hydrocarbon polymers. Hydroperoxides are present in commercial PP at levels of around 10^{-3} – 10^{-4} mol/kg and have molar extinction coefficients at 310 nm of around 0.4 l/(mol·cm). Carbonyl groups are typically present at around 10^{-3} mol/kg and have molar extinction coefficients at 310 nm of around 10 l/(mol·cm) (112). However, the quantum efficiency for radical generation in hydroperoxide photolysis is 1, whereas it is of the order of 0.05 for carbonyl groups, partly because radicals formed by Norrish I reaction recombine rather easily and partly because of the preference for Norrish II chemistry, which does not give radicals.

There have been major improvements in recent years in reducing the initial concentration of oxidation products in processed polymers. Better process stabilization, lower catalyst residues, and better extruder materials have all contributed to cleaner polymers. However, even these materials photo-oxidize readily if unstabilized. There is some evidence that oxygen charge-transfer complexes may play a role in polymers which have very low hydroperoxide content (132), although this is still controversial (133,134). It has been demonstrated (135) that lifetimes of PP in accelerated photoaging are influenced by atmospheric ozone levels and suggested that radical generation by photolysis of ozone may contribute to initiation; nitrogen and sulfur oxides from atmospheric pollution may have a similar role. However, others were unable to reproduce the ozone effect in laboratory conditions (136).

Apart from the photochemical initiation, the photo-oxidation of polymers follows the same mechanism as thermal oxidation, although there may be kinetic differences arising from the different temperatures. This is true at least up to the point where the buildup of carbonyl groups is large enough to allow their photolysis to become significant. The key reaction is the chain scission, by decomposition of the polymeric alkoxy radical, produced in photoscission of the hydroperoxides. This reaction occurs solely in the oxygen-permeable amorphous phase of polyolefins. It leads to restructuring and recrystallization of amorphous material, producing microcracks in the polymer surface and a consequent dramatic loss in tensile properties.

An important point in photo-oxidation is that it is a chain reaction. The accumulation of reaction products and hence of chain scissions is a function of

both the total amount of light absorbed and the rate of its absorption. Low light intensities are expected to give longer kinetic chains than do high intensities. Thus for the same total dose, more mechanical damage is expected from low intensities of light over long periods than from the same dose absorbed rapidly. This is an important concept for comparison of natural and accelerated aging data.

Methods of Study of Oxidation and Lifetime Prediction

Studies of oxidation of polymers are divided into two main groups. In academic laboratories the concern is usually to establish oxidation conditions which do not lead to diffusion control and then to measure the kinetics of oxygen absorption and the formation of intermediate and final products, with the aim of elucidating detailed mechanisms of oxidation. In industrial laboratories, where the need is to try to predict service life of formulated products, the approach is typically more pragmatic and involves exposure of the polymer to high temperatures and/or artificial sunlight and measurement of loss of significant properties, typically embrittlement or loss of surface appearance.

It might be thought that measurement of oxygen absorption would be the most straightforward method of following oxidation, and methods of measurement have been reviewed (137). They typically involve monitoring the pressure change in a closed system resulting from oxygen uptake. In principle modern pressure transducers allow virtually limitless sensitivity. However, the sensitivity is limited by the problem of temperature control, even where a reference volume is used in the same thermostat. There are also problems associated with the emission of volatile materials from the polymer, particularly at higher degrees of oxidation. For these reasons, oxygen uptake has never enjoyed real popularity.

The primary product of oxidation is the hydroperoxide group and analysis of peroxide formation is an important feature of many studies. The most commonly used methods take advantage of the ability of hydroperoxides to oxidize either iron (II) or iodide ions in acidic solutions (138,139). They can be extremely sensitive but are time consuming and require very careful control to avoid problems from adventitious oxidation of solvents. In principle, hydroperoxides are detectable by ir spectroscopy, but their characterization is complicated by the broad absorption due to hydrogen bonding interaction with other hydroperoxides and with —OH groups, and the overlap with —OH vibrations. Studies of hydroperoxides in PP using CPMAS nmr spectroscopy on ^{13}C-enriched polymer have been reported (140).

Undoubtedly the most powerful method of study in academic laboratories has been ir spectroscopy, advanced rapidly in recent years by the development of FTIR and microspectroscopy and by rapid improvement in sampling methods. Infrared spectroscopy can easily detect the formation of hydroxyl and carbonyl species, and a common technique is to monitor the time dependence of the so-called *carbonyl index*, the ratio of the intensity of the carbonyl absorption envelope to that of a chosen reference band.

A problem with FTIR studies is that —OH, —C=O, and —OOH groups are all formed simultaneously, often in many different forms and with overlapping and interacting bands. The major advance in the last few years, which has transformed the understanding of polymer oxidation mechanisms, has been the development

of gas-phase reagents which react with specific functional groups in the polymer to give products with high extinction coefficients and absorptions in otherwise clear regions of the ir spectrum. This approach has been reviewed (141). It has proved to be an extremely powerful tool for study of degradation mechanisms (see eg, Refs. 142 and 143).

One example is the reaction of nitric oxide with oxidized polymers, which converts —OH to alkyl nitrite groups and —OOH to alkyl nitrate groups. Since these groups are not H bonded, they have sharp, intense bands and it is possible not only to distinguish —OH and —OOH groups but to identify primary, secondary, and tertiary groups (144). Another example is the reaction of SF_4 with oxidized polymers, which converts all C—OH species to C—F. This has proved to be a particularly valuable reagent, since it converts —COOH groups to —COF, allowing quantitative discrimination of —COOH groups from other carbonyls; since —COOH groups are produced by chain scission, they are one of the best groups to monitor in predicting loss of mechanical properties.

A recent approach to analysis of the multicomponent mixtures produced by polymer oxidation has been reported (145) in a study of the oxidation of polyisoprene in ^{17}O-labeled oxygen. It was shown that it is easily possible to identify nonvolatile degradation products by ^{17}O nmr spectroscopy, even at relatively low concentrations; the very high cost of ^{17}O-labeled oxygen means that this approach is unlikely to become very popular.

Prediction of service lifetimes is a continuing major challenge for the polymer industry, especially for materials expected to perform reliably for many decades. It is also critical in guiding the comparative evaluation of new materials in the development stages. In view of the importance of degradation to commercial users, there are many pragmatic methods that attempt to predict the lifetime of a sample of polymer under ambient conditions from accelerated measurements, without specific chemical analysis. Manufacturers wish to be able to guarantee a lifetime for a particular formulation of polymer and stabilizers without having to test samples for five or more years. The usual method is to adopt some regime of accelerated aging at high levels of illumination or high temperatures. These results are extrapolated to give expected lifetimes under normal conditions.

If thermal degradation is considered, it is reasonable to measure a time to failure at a series of temperatures and extrapolate to room temperature. Failure may be defined in terms of an extent of discoloration, a degree of oxygen absorption, fracture under a fixed load or other convenient test. Since oxidation processes show an induction time followed by accelerating reaction, most measurements will yield reasonably consistent data if they detect the end of the induction time.

The obvious method of extrapolation is to assume that the rate-determining step is characterized by a single activation energy and the Arrhenius equation can be applied (146). The applicability of this method has been analyzed critically and it has also been suggested that it is normally invalid except for extrapolation over a short range of temperature (147). Failure models have also been described based on the concept that material damage is cumulative (148). For the case where degradation data can be rigorously time–temperature superposed over a given temperature range, the researchers (148) show that the remaining lifetime at a second, higher temperature should be linearly related to the aging time prior to the step. This implies that it should be possible to estimate the remaining and

therefore the service lifetime of polymers by completing the aging at an accelerated temperature. They refer to this method as the "wear-out" approach.

As outlined above, degradation can occur through various pathways and the relative importance of these is likely to change with temperature. Thus, as was pointed out earlier, degradation at high temperatures may be dominated by high activation energy reactions which are relatively unimportant at lower temperatures. It is this feature that makes predicting polymer lifetimes by extrapolation to lower temperatures of data obtained at the high temperatures of typical experiments extremely hazardous. This is particularly true of oxidation reactions where both the chemistry and the physical properties of stabilizing additives contribute to lifetime. For example, it has been shown (149) that the Arrhenius plot for times to embrittlement of PP samples stabilized with a phenolic antioxidant is downwardly and upwardly curved at higher and lower temperatures, respectively, thus having a sigmoidal shape. The reasons for these complexities are not always clear and there may be more than one contributory factor. For instance, an antioxidant which is effective at scavenging radicals at high temperatures where it is mobile, may be less effective at low temperatures where rates could be dominated by diffusion of oxygen molecules to radicals. Similarly antioxidant loss may be diffusion limited at high temperatures but limited by evaporation rate at low temperatures. It has been suggested (150) that curvature in the Arrhenius plot for lifetimes of PP is due to the catalytic effect of catalyst residues on hydroperoxide decomposition at low temperatures being swamped by the much higher activation energy noncatalyzed decomposition at high temperatures. Multicomponent materials are even more likely to show complex, non-Arrhenius responses to aging temperature.

Similar points can be made in relation to photo-oxidative degradation where it is normal to test lifetimes using artificial irradiation with a solar distribution of wavelengths but very high intensity (for example the Xenotest). If care is taken to keep the sample at 20°C, it is natural to extrapolate the expected lifetime by multiplying by a factor which is the ratio of test intensity to normal averaged solar intensity. However, the higher rate of radical generation can be expected to change the relative importance of radical recombination processes and so change the overall kinetics. One compromise is to expose samples under natural sunlight in regions where most days are sunny. The two conditions usually considered are hot and dry (Arizona or Israel) and hot and humid (Florida or Queensland). Atmospheric acid pollution might also be added as a further factor by choosing a city environment.

Although all extrapolations are unsatisfactory, there is little choice since actual lifetime testing is impracticable. Accelerated tests are widely used to compare different stabilizer formulations. Interpretation must be coupled with some understanding of underlying mechanisms based on a range of complementary methods for monitoring degradation. A wide range of methods has been critically reviewed (151).

Degradation by High Energy Radiation

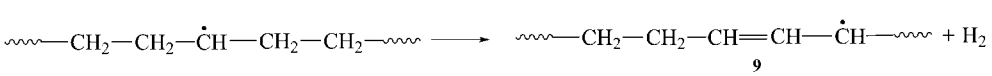
The degradation of polymers resulting from exposure to high energy radiation is an important subject for many reasons. In a negative sense, polymers are increasingly

exposed to radiation in their applications in eg, insulation of cables used in nuclear installations, where any degradation is critical (152). Radiation is also increasingly used for sterilization of medical plastics and degradation during storage or use can be important (153–155). In a more positive sense, the degradation of polymers by radiation forms the basis of most of the modern lithographic techniques used in forming electronic devices. Radiation-induced degradation has been well reviewed (156–159).

High energy radiation is defined as all forms of radiation with energies much higher than those of chemical bonds. It includes both electromagnetic radiation (x-rays, γ-rays, etc) and particulate beams (α- and β-particles, electrons, neutrons, etc). The range of energies is very wide but much higher than chemical bond energies. Unlike the absorption of visible and near-uv light, discussed earlier, high energy radiation is absorbed nonspecifically; ie, it does not require a chromophore. Radiation is absorbed by interaction with either the atomic nuclei or the electron clouds; for the light atoms typical of polymers, absorption by the electron clouds is usually more important. The efficiency of absorption varies widely. α-particles are stopped by condensed matter in very short (mm) distances, whereas γ-radiation can penetrate large (>cm) distances.

Whatever the nature of the radiation, interaction with the electron clouds of molecules initially results in the transfer of energy to the molecules to form ions, with the ejection of a secondary electron (160,161). These secondary electrons usually have enough kinetic energy to cause further ionization and excitation of nearby molecules. In the case of highly penetrating radiation, interaction between the primary photon and the substrate electrons may be relatively rare, whereas secondary electrons lose their energy in the region of their formation. Thus energy absorption occurs in a heterogeneous manner along "tracks," each consisting of a series of "spurs."

The immediate consequence of absorption of high energy radiation is thus the formation of a range of energetic species, including trapped electrons, ions, and radical ions. These are usually highly transient species at room temperature, although they can have long lifetimes in glassy materials at low temperatures. The decay of the excited species usually results in fragmentation to give free radicals. In many polymers, scission of main-chain C-C bonds gives radical pairs which recombine rather rapidly because of the close proximity of two macroradicals. In contrast, scission of C—H bonds leads to relatively stable radicals and formation of molecular hydrogen. Thus, the overall effect of radiation at room temperature is typically to produce polymer-derived free radicals. Radicals formed by radiation are easily detected by esr spectroscopy and there is a very large literature on the subject. The primary radical formed by irradiation may not be stable. For example, irradiation of PE with γ-radiation at 77 K produces the secondary radical, which is stable more or less indefinitely at this temperature. However, if the sample is allowed to warm up, the first process is the elimination of hydrogen and formation of the allyl radical (**9**):



9

Color change is an important problem in commercial applications involving the radiation-processing of polymers, or their use in optical devices in radiation

environments. Discoloration arises due to formation of two different types of color centers: "permanent" and "annealable" (162,163). Annealable color centers are associated with radical or ionic species trapped in the polymer matrix. They disappear with time through recombination reactions and reaction with oxygen diffusing from the surrounding atmosphere. The ratio of permanent and annealable color centers and the rate of post-irradiation annealing vary greatly in different polymer types. The ability of a polymer to form conjugated structures, under the influence of the free-radical chemistry induced by irradiation, is an important factor in the extent to which the material discolors.

It is important to bear in mind that a free radical, once formed, has no "memory" of its origins and its reactions will be exactly the same as a radical produced by any other means. In the absence of oxygen, carbon-centered radicals may undergo cross-linking, by recombination, or chain scission, by β-elimination, or both, depending on the radical structure. This is the same chemistry as described earlier for alkyl radicals in the absence of oxygen, although the balance of the two reactions may be different in irradiation conditions at room temperature and in high temperature processing conditions.

Polymers can thus be divided into two main groups, those which respond to radiation in inert conditions by cross-linking, with a concomitant increase in molecular weight, and those which lose molecular weight by chain scission, although both can occur in many polymers. The ability of radiation to induce cross-linking or scission is usually expressed as the corresponding G value, G_X or G_S, where G is the number of bonds formed or broken for each 100 eV of absorbed energy.

Table 3 shows some typical values of G_X and G_S for common polymers. In general, an increase in the degree of substitution of the carbon backbone increases the contribution of chain scission.

Table 3. Radiation Chemical Yields of Chain Scission and Cross-linking in Polymers Irradiated in Inert Atmosphere[a]

Polymer	G_S[b]	G_X[b]	Dominant process
Polyethylene		2.0	Cross-linking
Polypropylene	0.6	0.9	Cross-linking
Polyisobutene	4.0	<0.05	Scission
Polystyrene	0.02	0.03	Cross-linking
Poly(α-methylstyrene)	0.25		Scission
Poly(methyl methacrylate)	1.8		Scission
Poly(vinyl chloride)	2.2		Scission
Poly(tetrafluoroethylene)	0.1–0.2		Scission
Poly(ethylene oxide)	2.0	1.8	Cross-linking
Poly(dimethylsiloxane)	0.07	2.3	Cross-linking
Poly(butene-1-sulfone)	10.7		Scission
Nylon-6,6	2.4	0.7	Scission
Poly(ethylene terephthalate)	0.07	2.3	Cross-linking
Cellulose	3.3–6.8		Scission
DNA	0.8		Scission

[a] Adapted from Ref. 157 with additions.
[b] G = number of bonds formed (G_X) or broken (G_S) for each 100 eV of absorbed energy.

The sensitivity of PE to cross-linking by radiation is the basis of commercial processes for producing cross-linked polymers by, eg, electron-beam irradiation. Conversely the easy scission of polysulfones, with elimination of SO_2, is the basis of some photoresists.

Because of the involvement of free radicals, and their reactivity with oxygen, radiation-induced degradation is highly sensitive to oxygen. Indeed, high energy irradiation is an excellent means of initiating oxidation. Once carbon radicals are formed, their reactions with oxygen are identical to those of any other radical and the chemistry is the same as that of thermal or photo-oxidation. However, the accelerating effect of radiation means that the combination of radiation and oxygen can be extremely destructive. Since oxidation can lead to both cross-linking and chain scission, depending on the polymer, the effects are quite complex. They are further complicated by the fact that the high rate of initiation induced by radiation can result in oxygen being depleted in the polymer faster than it can be replaced by diffusion. This leads to dose-rate-dependent behavior. Thus a polymer which cross-links on irradiation but scissions on oxidation may show softening of the surface layers and hardening of the bulk, to a degree dependent on dose rate, and the converse may also occur (164). Oxidation under the influence of irradiation is a key problem in many applications of polymers, especially the increasingly popular use of γ-radiation or electron beams to sterilize medical prosthetic devices and instruments (154,165).

Hydrolytic and Biological Degradation

Hydrolytic Degradation. Many applications of polymers involve contact with water, either in weathering by rain or in their use as containers and pipes. Contact with liquids can have deleterious effects due to stress cracking or due to leaching of antioxidants (qv) or plasticizers (qv). However, direct chemical reaction between the polymer and water is also a possible route to degradation.

Hydrolysis can occur only if the polymer has functional groups capable of reaction with water and if the water can gain access. Hydrocarbon polymers are very resistant to hydrolysis because they are not wetted by water and contain no hydrolyzable groups. In the polyolefins, water access is also restricted by the semicrystalline nature of the polymers. In complete contrast, many natural polymers, especially the polysaccharides (cellulose, starch, etc), are quite readily hydrolyzed at appropriate pH, because they are water absorbing and contain readily hydrolyzable links.

Most synthetic polymers lie between these two extremes. Typical step-reaction polymers, such as polyesters, polyamides, polycarbonates, polyurethanes, and cellulose esters, all contain hydrolyzable groups in the main chain. On the other hand, many chain reaction polymers, such as polyacrylonitrile, PMMA, and PVC, contain substituent groups which may hydrolyze at appropriate pH.

Most of these polymers are regarded as highly stable in water because they are insoluble, often semicrystalline, and absorb only very low levels of water. However, most of them will undergo surface attack in acids or alkalis and are generally unsatisfactory for long-term use in these media. The same is true of

most cross-linked materials; epoxy resins, formaldehyde resins, and unsaturated polyesters all suffer hydrolytic scission over long periods, especially at extremes of pH.

Another problem can arise when some of these thermosetting resins are used as the matrix in fiber-reinforced composites. In such materials there is a high area of fiber-matrix interface and hydrolysis in the interfacial zones is a common source of failure. Interfacial degradation is a common problem in the use of glass-reinforced polyester in marine applications.

Water-soluble or -swellable synthetic polymers, such as poly(vinyl alcohol), polyacetals, poly(acrylic acid), and polyacrylamide, are all relatively stable at neutral pH, but undergo quite rapid chain scission under acidic or basic conditions. Typical commercial polymers can be classified according to their resistance to hydrolysis (158) as follows.

Polymers resistant to hydrolysis in all media include polyolefins, hydrocarbon rubbers, polystyrene, polytetrafluoroethylene, and unplasticized poly(vinyl chloride). Polymers sensitive to hydrolysis in both alkaline and acidic media are, eg, cellulose esters, plasticized poly(vinyl chloride), poly(methyl methacrylate), polyacrylonitrile, polyoxymethylene, polyamides, polyesters, polycarbonates, and polysulfones. Polymers sensitive to alkalis but not acids are unsaturated polyester resins and phenol-formaldehyde resins.

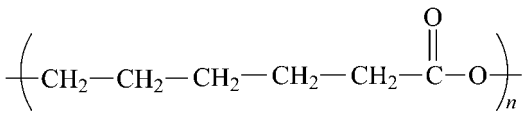
Hydro-biodegradation. Most organic polymers are much more hydrophobic than those found in nature, and living organisms have not evolved enzymes which can effectively penetrate and cleave them. Polymers which resist hydrolysis are also resistant to biodegradation, since enzymes operate in aqueous media. Thus synthetic polymers are typically much more resistant to biological attack than are the natural polymers, such as proteins and polysaccharides. Biodegradability of polymers has been well reviewed (see eg, Refs. 166–169) (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

Water-swellable or -soluble polymers may be biodegraded by microorganisms if they contain functional groups that are susceptible to enzymatic cleavage. There is considerable evidence that biodegradation is synergistic with hydrolysis, which may be chemical or enzymatic and is required to reduce the molecular weight to the point where bioassimilation is possible.

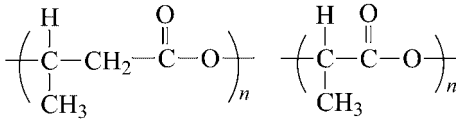
Much of the discussion of biodegradability is bedeviled by problems of definition. Under appropriate conditions pure cellulose can be biodegraded completely to carbon dioxide and water in a few weeks. In contrast, lignin, although undoubtedly biodegradable, may survive for centuries, as is shown by the very long lifetimes of some tree species after falling. Many synthetic polymers can support growth of microorganisms to a degree wholly unacceptable in biomedical applications, yet are highly resistant to complete bioassimilation.

Nature has evolved enzymes that can cleave the links in natural polymers, so that proteins, nucleic acids, and polysaccharides are highly biodegradable. Synthetic polymers are much more resistant since they usually contain functional groupings resistant to enzymatic cleavage, often have surface energies that resist wetting, and are resistant to water permeation. Further, even when an enzymatic cleavage is available, it frequently results in attack from the chain ends, with only a very slow reduction in molecular weight, and little effect on mechanical properties.

Intrinsically biodegradable polymers have clear advantages in some applications, notably in medicine and agriculture. Unfortunately, most of the readily degradable natural polymers are not amenable to fabrication by the usual methods of the polymer engineer, because they undergo thermal degradation at temperatures well below those at which they become thermoplastic. The major group of processible synthetic polymers susceptible to biodegradation is the aliphatic polyesters, which are found as components of several commercial polymer systems, notably some block copolymer elastomers. Some examples are poly(ε-caprolactone), poly(lactic acid), and poly(2-hydroxybutyrate).



10



11 **12**

Poly(ε-caprolactone) (**10**) has been used as a biodegradable polymer in agricultural applications and other aliphatic polyesters find applications in medicine, as biodegradable sutures.

The natural polyester, poly(2-hydroxybutyrate) (**11**), is prepared commercially by bacterial fermentation (170) and finds limited markets where its biodegradation is an asset. Poly(lactic acid) (**12**) is another thermoplastic polyester with good biodegradability (171). It finds applications in sutures and is being developed as a "green" packaging material. Other biodegradable polymers include poly(vinyl alcohol) and its copolymers, and some aliphatic polyurethanes and poly(ester-amides), again often as segments of copolymer elastomers.

Although native starch is not thermoplastic, it can be gelatinized by cooking in an extruder to produce a processable material which is biodegradable (172). However, the high moisture sensitivity makes it of limited application. Thermoplastic biodegradable polymers can also be formed by blending of starch with synthetic polymers. Novamont (Italy) has pioneered starch-based biodegradable materials, and now has several classes of materials, sold under the trademark Mater-Bi, all containing starch and different synthetic components (172–175). Some grades contain ethylene-vinyl alcohol copolymers and are classified as biodegradable but not compostable. Other grades contain aliphatic polyesters and are classified as both biodegradable and compostable.

Another approach to biodegradability is to blend a biodegradable natural polymer with a thermoplastic synthetic polymer. Blends of starch with PE or with poly(vinyl alcohol) have been commercialized as packaging materials (176), although they have mainly been used in niche markets. Early materials were rather poor because the encapsulating effect of the PE on the starch protected it from water access, and, even if the starch was biodegraded, the PE was left

behind as a mechanically weak but nonbiodegradable residue. In an only partially successful effort to overcome these problems a wide range of pro-oxidant additives, typically mixtures of fatty acids and transition metal salts, has been added to the PE used in these formulations.

Oxo-biodegradation. Synthetic polymers are very resistant to biodegradation. However, there is very strong synergism between thermal or photochemical oxidation and subsequent biodegradation (see eg, Refs. 177–180). Although it is widely believed that synthetic polymers are biologically inert, there is now ample evidence that they will become completely biodegradable if they are initially heavily enough oxidized to reduce the molecular weight and introduce enough polarity to allow the polymer to be wetted (166,168,181–184).

This is an important feature of the so-called oxo-biodegradable polymers, which have applications in agriculture as mulch films, and are increasingly of interest for applications in packaging and landfill cover. A typical example is the Scott–Gilead process (185). PE film is doped with a mixture of iron and nickel salts which provide stability during processing but initiate photochemical formation of radicals in sunlight, causing the polymer to photodegrade at a rate controlled by the iron/nickel ratio. More recently, similar materials based on thermal activation rather than photoactivation have been commercialized (186–189).

DIELECTRIC RELAXATION

Introduction

The control of dielectric permittivity and loss of solid polymers, through an understanding of the origins of their dipole relaxation and ionic conduction processes, is essential for their use in electrical insulation, in electrical/electronic circuits, and devices operated over wide power ranges. This article discusses dielectric properties and behavior of polymers and briefly describes measurement techniques and applications.

Dielectric Properties

The dielectric properties of polymer materials are usually expressed in terms of the complex dielectric permittivity $\varepsilon(\omega)$ relative to vacuum, defined as $\varepsilon(\omega) = \varepsilon'(\omega) - i\varepsilon''(\omega)$, where $i = \sqrt{-1}$, $\omega = 2\pi f$, and f is the measurement frequency. The real permittivity ε' and loss factor ε'' for polymers depend on frequency due to (*1*) electric polarization arising from the tumbling motions of electric dipoles in the polymer chains and (*2*) conduction due to the translational motions of electric charges (intrinsic or extrinsic ions and electrons) (1–4). For essentially nonpolar polymers such as polyethylene, polypropylene, polystyrene, and polytetrafluoroethylene in their pure state, the absence of dipoles and ions results in (*1*) low values of ε' (in the range 2–3 since here $\varepsilon' \sim n^2$, where n is the optical refractive index), and (*2*) very small values of loss ($\varepsilon'' < 10^{-3}$) across the entire frequency range from 10^{-6} to 10^{12} Hz. These low permittivity, low loss materials are dielectric insulators and so find wide applications in electrical cables and capacitors and in electrical and electronic circuits. Polar polymers contain dipolar groups, such as

ether, ester, halide, and amide groups, repeated regularly along the chains. Those polar polymers that are glasses (eg, poly(vinyl chloride), poly(methyl methacrylate), aliphatic and aromatic polyesters, and polycarbonates at room temperature) or are highly crystalline (eg, polyoxymethylene and polyoxyethylene at room temperature) also exhibit low values of ε' and ε'' since the dipoles and the extraneous ions present are immobilized. Polar polymers that are liquid or elastomeric (eg, polar polymers above their glass-transition temperature T_g) exhibit frequency-dependent ε' values (typically in the range 3–20) together with complementary losses because above T_g the dipolar groups are mobile, allowing the dipole polarization to contribute to $\varepsilon(\omega)$. If such polymers also contain ions, as in polymer electrolytes, then ionic conduction and electrode polarization effects contribute to ε' and ε'' at low frequencies ($<10^5$ Hz), leading to large values ($>10^2$) of both ε' and ε''. The dielectric properties of polymers, as observed in plots of ε' and ε'' against log f/Hz, reflect contributions due to the reorientational motions of dipoles and the translational motions of ions and from the effects of interfacial and electrode polarizations (1–4).

When an electric field E is applied as a step at $t = 0$ to a slab of dielectric material the electric charge passing through the material has two components $q_P(t)$ and $q_i(t)$ due to electric polarization and ion conduction, respectively. For $q_P(t)$ the initial response q_∞ is rapid ($<10^{-12}$ s) and is due to both electronic polarization (arising from the displacement of electron charge clouds in the molecules) and atomic polarization (arising from the relative displacement of atomic positions in the molecules). There is a delayed response that takes q_P up to a steady value q_0 because the field perturbs the spatial distribution of dipole directions, giving a macroscopic dipole polarization P in line with the field. The timescale for this response is determined by the rate of the reorientational motions of the chain dipoles in the absence of the field, which will depend on the chemical structure of the polymer and its temperature. Below T_g the response time becomes very large and so there is little or no dipole polarization. The material appears to be nonpolar [except from a minor contribution to $q_P(t)$ from small-amplitude motions of dipoles in the glassy state (see below)]. On removal of the field the process is reversed; the fast decay of $q_P(t)$ is followed by the delayed response. The normalized rise and decay functions for dipole relaxation $\Phi(t) = [q_P(t) - q_\infty]/(q_0 - q_\infty)$ are equivalent; this is one condition for a linear dielectric material, the other being that $\varepsilon(\omega)$ is independent of the field strength. An *average relaxation time* $\langle\tau\rangle$ is defined as the time taken for the decay function to fall to $1/e$ of its original value at $t = 0$. For liquid water, $\langle\tau\rangle \sim 10^{-11}$ s. For polymers temperature has a large effect on the rate of molecular motions, eg, $\langle\tau\rangle$ for poly(vinyl acetate) increases from about 10^{-11} to 10^2s as the temperature is reduced toward T_g.

In addition, ionic conduction causes a charge $q_i(t)$ to pass through the material, which rises from zero and then becomes linearly dependent on time to give a constant current $I(t) = dq_i/dt$. In contrast to $q_P(t)$, which becomes constant at long times (since the dipolar system reaches thermodynamic equilibrium in the presence of the steady field), $q_i(t)$ increases without limit in the absence of interfacial and electrode polarization effects, giving a continual dissipation of energy via the conduction process. The fact that the steady conduction current takes time to get established means that the ac real conductivity $\sigma'(\omega)$ is constant at low frequencies and becomes f-dependent at high frequencies.

Although the nature of dipole polarization and ionic conduction are readily understood in the time domain, dielectric measurements for polymers are normally made in the frequency domain. The range 10^{-6}–10^{12} Hz can be covered using a combination of techniques, but the working range for most studies in the older literature was from about 1 to 10^7 Hz (1–5). Below 1 MHz the dielectric may be regarded as an electrical equivalent circuit comprising a capacitor C_p in parallel with a resistor R_p measured at a frequency $f = \omega/2\pi$ (1). Measurements made using an impedance analyzer allow the complex electrical admittance $Y(\omega)$ or its reciprocal—the impedance $Z(\omega)$—to be determined where

$$Y(\omega) = G_P(\omega) + i\omega C_P(\omega) \tag{1}$$

Here $G_p(\omega) = [R_p(\omega)]^{-1}$ is the electrical conductance. The complex permittivity ε, complex conductivity $\sigma = \sigma' + i\sigma''$, and complex electrical modulus $M = M' + M''$ are determined from Y, using the relations

$$\varepsilon(\omega) = \frac{Y(\omega)}{i\omega C_0} = \frac{\sigma(\omega)}{i\omega\varepsilon_v} = \frac{1}{M(\omega)} \tag{2}$$

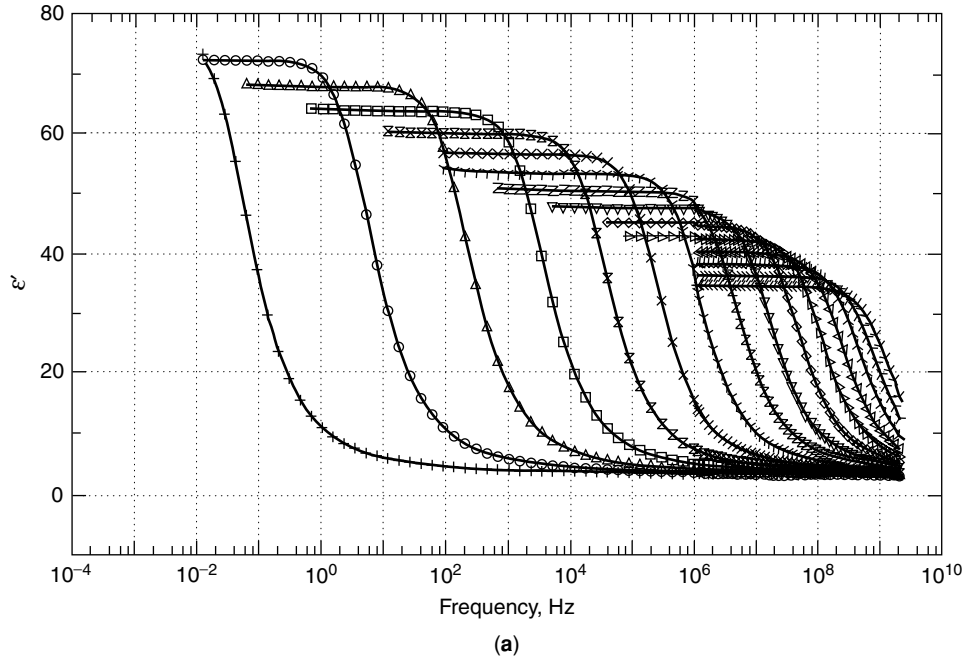
Here ε_v is the permittivity of vacuum ($= 8.854 \times 10^{-12}$ F·m^{-1}) and C_0 is the geometrical capacitance of the sample. The dielectric properties of polymers are variously reported in terms of Z, Y, ε, M, σ and its reciprocal, the resistivity ρ. This is a source of confusion and makes it difficult to compare literature data for different polymer materials. The preferred representations of data when dipole polarization and ion conductivity are present will be indicated below.

At microwave frequencies ($f > 10^8$ Hz) a polymer material is regarded as a distributed circuit having a complex propagation coefficient $\gamma = \alpha + i\beta$, where α and β are the electrical attenuation and phase factors of the material. These are measured using microwave techniques and ε' and ε'' follow as

$$\varepsilon'(\omega) = [n(\omega)]^2\{1 - [\alpha(\omega)/\beta(\omega)]^2\}; \qquad \varepsilon''(\omega) = 2[n(\omega)]^2\alpha(\omega)/\beta(\omega) \tag{3}$$

where $n(\omega) = c\beta(\omega)/\omega$ is the refractive index at ω and c is the velocity of light.

As an example of dielectric relaxation behavior, Figure 1 shows plots of ε' and ε'' against log f/Hz for glycerol, a polyhydroxyl liquid, studied over a wide temperature range. At each temperature, ε' at low frequencies is constant (at ε_0) and then falls with increasing frequency to values typical of a nonpolar material. Dispersion of ε' is accompanied by a loss peak whose frequency of maximum loss (f_{max}) determines the average relaxation time $\langle\tau\rangle = [2\pi f_{max}]^{-1}$. For glycerol $\langle\tau\rangle$ increases by 10 orders of magnitude as the temperature is reduced toward T_g. In addition, ionic conduction gives the increasing loss at low frequencies. The dielectric behavior of glycerol is representative of all amorphous polymers and glass-forming liquids that contain dipolar molecules (1–5).



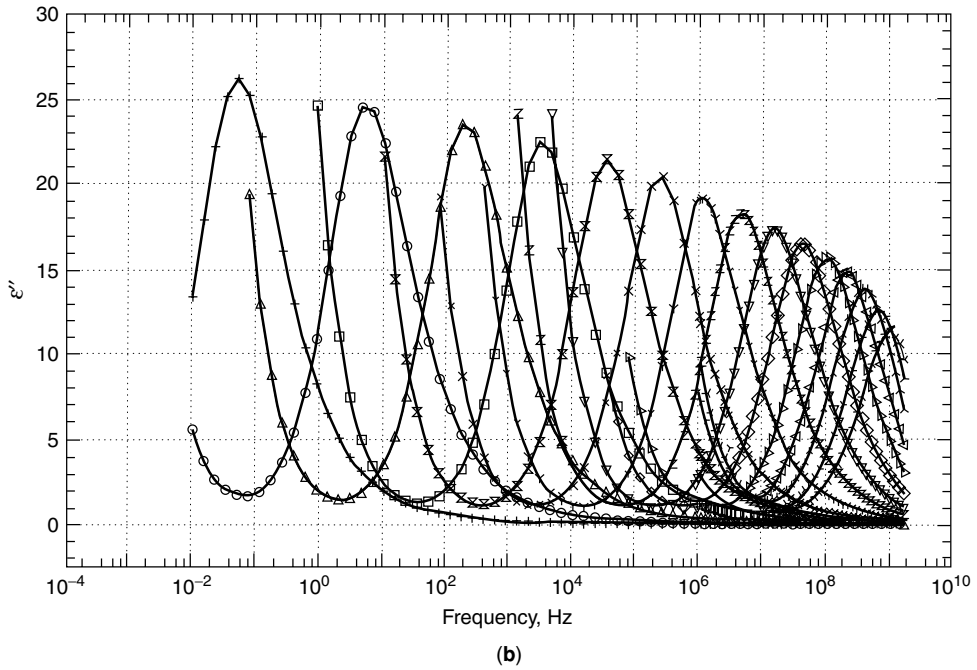


Fig. 1. Plots of (**a**) ε' and (**b**) ε'' against frequency (Hz) for glycerol at 10 K intervals from 193.15 K (+) to 333.15 K (◊). Data provided by Dr G. Schaumburg, Novocontrol GmbH.

Theory

The normalized decay function $\Phi(t)$ of the dipole polarization is related to $\varepsilon(\omega)$ according to (1,5)

$$\frac{\varepsilon(\omega)-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty}=1-i\omega\Im[\Phi(t)] \tag{4}$$

Where ε_0 and ε_∞ are the limiting low and high frequency real permittivities, and $\Im$ indicates a one-sided Fourier transformation. A simple form for $\Phi(t)$ is the single exponential decay function

$$\Phi(t)=\exp(-t/\tau) \tag{5}$$

Insertion into equation 4 gives the paired relations

$$\frac{\varepsilon'(\omega)-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty}=\frac{1}{1+\omega^2\tau^2} \tag{6}$$

$$\frac{\varepsilon''(\omega)}{\varepsilon_0-\varepsilon_\infty}=\frac{\omega\tau}{1+\omega^2\tau^2} \tag{7}$$

Here $\varepsilon_0-\varepsilon_\infty$ ($=\Delta\varepsilon$, say) is the relaxation strength. Figure 2 shows plots of ε' and ε'' against log $\omega\tau$ for $\varepsilon_0=13$, $\varepsilon_\infty=3$ for equations 6,7 [the single relaxation time (SRT) function]. $\omega_{\max}\tau=1$ at the loss peak. Thus dielectric relaxation is characterized by $\Delta\varepsilon$ and τ for this function. The steady ionic conductivity σ_0 contributes an additional, rising loss at low frequencies given by $\varepsilon_i''=\sigma_0/\omega\varepsilon_v$, but this process makes no contribution to $\varepsilon'(\omega)$ in this case.

In practice dielectric relaxation curves for polymers (1–5) and glass-forming liquids (eg, Fig. 1) are far broader than that for an SRT process. Numerous empirical relaxation functions have been proposed for this behavior (1,2,5). One function is the stretched exponential function of Kohlrausch, Williams, and Watts (KWW) (4–6), that is widely applied to dielectric and other relaxation data for amorphous polymers:

$$\Phi(t)=\exp[-(t/\tau)^{\bar\beta}] \tag{8}$$

$0<\bar\beta\leq 1$. Figure 2 includes curves for ε' and ε'' calculated using equation 4 and the KWW function for $\bar\beta=0.50$. The loss curve is broad and nonsymmetrical, with a total half-width $\Delta_{1/2}\sim 2.2$ (cf 1.14 for the SRT process). The dielectric data for glycerol conform approximately to the KWW function ($\bar\beta$ increases from about 0.6 to 0.95 as temperature is increased). Thus dielectric relaxation in polymers and other materials is characterized by the *shapes* of the ε' and ε'' curves in addition to $\Delta\varepsilon$ and $\langle\tau\rangle$.

Molecular theories for the static permittivity ε_0 of dipolar liquids developed originally by Onsager, Kirkwood, and Fröhlich were adapted for linear bulk

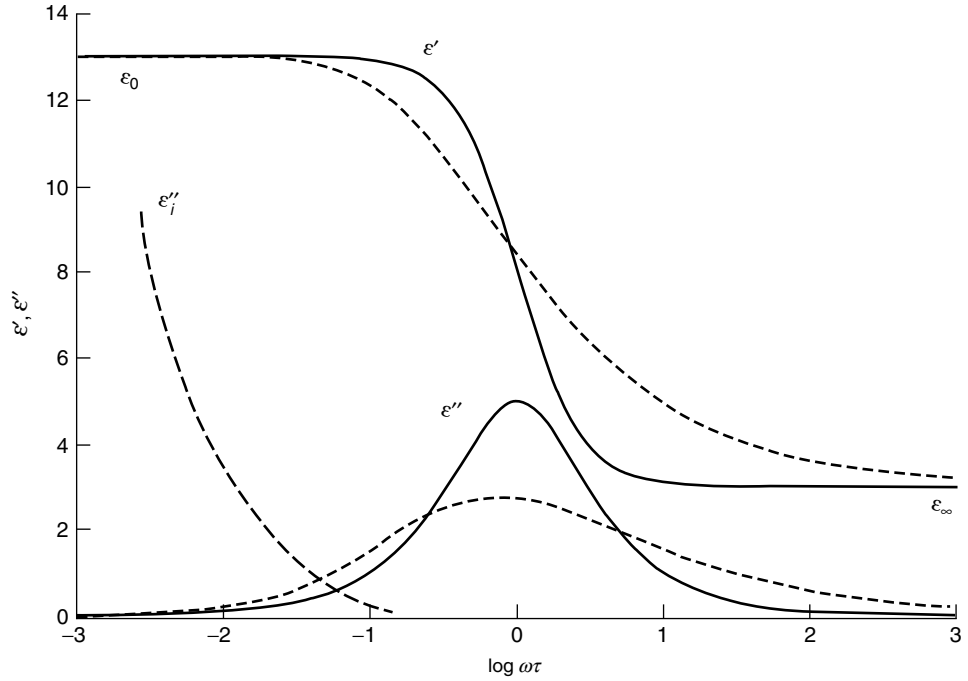

Fig. 2. Plots of ε' and ε'' against $\log_{10}\omega\tau$ for the SRT function (——) $\beta = 1.0$ and the KWW function (- - - -) for $\bar{\beta} = 0.50$. The increasing loss ε_i'' at low frequencies (– – –) is due to the steady conductivity σ_0.

polymers by Williams and co-workers (1,7) giving

$$\varepsilon_0 - \varepsilon_\infty = \frac{4\pi}{3kT}\left(\frac{3\varepsilon_0}{2\varepsilon_0 + \varepsilon_\infty}\right)\left(\frac{\varepsilon_\infty + 2}{3}\right)^2 c_r g \mu^2 \tag{9}$$

Where c_r is the concentration of the dipolar repeat units, each of dipole moment μ, and g is the Kirkwood–Fröhlich factor for orientational correlations of dipoles along and between chains.

$$g = 1 + \sum_{ij} \langle \cos \theta_{ij} \rangle \tag{10}$$

where $\langle \cos \theta_{ij} \rangle$ is the equilibrium average projection of dipole j on a reference dipole i, which can be calculated using statistical mechanics (4,5,8). Parallel or antiparallel alignment of dipoles leads to $g > 1$ and $g < 1$, respectively. The large values of ε_0 for glycerol (Fig. 1) arise since intermolecular H-bonding leads to $g > 1$. In liquid water, H-bonding gives $g \sim 2.5$, which raises ε_0 to ~80 at room temperature.

Dipole relaxation in polymers is conveniently considered in terms of the normalized dipole correlation function $\Phi_\mu(t)$ for the reorientational motions of dipolar groups.

$$\Phi_\mu(\mathrm{t}) = \frac{\langle \mu_i(0)\mu_i(\mathrm{t})\rangle + \sum_j \langle \mu_i(0)\mu_j(\mathrm{t})\rangle}{\langle \mu_i^2\rangle + \sum_j \langle \mu_i(0)\mu_j(0)\rangle} \tag{11}$$

where $\langle \mu_i(0)\mu_i(\mathrm{t})\rangle$ and $\langle \mu_i(0)\mu_j(\mathrm{t})\rangle$ are the autocorrelation function (ACF) and cross-correlation function (CCF) for dipole motions of a reference dipole i and further dipoles j along and between chains. The ACF is readily understood. At time $t = 0$ the dipole i has a particular value $\mu_i(0)$. The normalized ACF $\langle \mu_i(0)\mu_i(t)\rangle / \langle \mu_i^2\rangle = \langle \cos\theta_{ii}(t)\rangle$ is the average projection of $\mu_i(t)$ at time t on $\mu_i(0)$ at $t = 0$. This decays to zero with time. The CCFs in equation 11 account for the dynamic cross-correlations between dipole i and the neighboring dipoles j. It is found (5) that $\Phi_\mu(t) \approx \Phi(t)$, the macroscopic relaxation function, and so $\varepsilon(\omega)$ can be determined using equation 4. $\Phi_\mu(t)$ may decay as a SRT function, a broadened function (eg, the KWW function), a weighted sum of SRT functions (known as a "distribution of relaxation processes"), or decay in several discrete stages—which leads to discrete multiple loss peaks in the f-domain (1,3,5). The overall loss curve gives information on the mechanism(s) of the dipole relaxation process(es) in the polymer material (1–5).

For ionic conduction the complex conductivity is given by (9,10)

$$\sigma(\omega) = \sum_i a_i \Im\langle v_i(0)v_i(t)\rangle = \omega^2 \sum_i a_i \Im\left[\left\langle \Delta R_i^2(t)\right\rangle\right] \tag{12}$$

Here $a_i = [c_i q_i^2 / kT]$, c_i and q_i are, respectively, the concentration and charge of species i (anions and cations). $\langle v_i(0)v_i(t)\rangle$ and $\langle \Delta R_i^2(t)\rangle$ are, respectively, the velocity correlation function (VCF) and mean-squared displacement in time of species i. The steady current behavior at long times in the step-on experiment (see above) means that $\langle \Delta R_i^2(t)\rangle$ becomes linearly dependent on time, giving the Nernst–Einstein equation that connects the low-f conductivity $\sigma'(0)$ $(=\sigma_0)$ to the diffusion coefficients D_i for the translational motions of the ions (9,10):

$$\sigma_0 = \sum_i a_i D_i \tag{13}$$

$$D_i = \frac{1}{3}\int_0^\infty \langle v_i(0)v_i(t)\rangle \mathrm{d}t \tag{14}$$

$$D_i = \frac{1}{6}\frac{\left\langle \Delta R_i^2(t)\right\rangle}{t} \tag{15}$$

Hopping motions of ions at short times are influenced by the surrounding molecules, leading to a "bounce-back mechanism" that causes $\langle \Delta R_i^2(t)\rangle$ to be lower at short times than it would be if the long time behavior was extrapolated to zero (9,10). As a result the real conductivity $\sigma'(\omega)$ for polymers and most amorphous disordered solids is a constant (σ_0) at low frequencies but obeys a power law $(\omega^m, 0 < m \leq 1.0)$ at high frequencies (9,10).

In view of the above we note that plots of $\varepsilon''(\omega)$ against log f/Hz give information on the *reorientational motions* of chain dipoles through $\Phi_\mu(t)$ (eqs. 4, 6,7 and 11) while plots of $\sigma'(\omega)$ against log f/Hz give information on the *translational motions* of ions through $\langle v_i(0)v_i(t)\rangle$ and $\langle \Delta R_i^2(t)\rangle$ (eqs. 12 and 14,15).

The other representations Z, Y, M, and ρ refer indirectly to these molecular dynamic properties (see eq. 2).

Dielectric Behavior of Polymers

Dielectric spectroscopy (DS) provides a means of studying chain dynamics of amorphous, crystalline, and liquid crystalline (LC) polymers (1,3–5,11). As one example Figure 3 shows plots of ε'' against $\log f$/Hz for the amorphous polymer poly(vinyl acetate) at different temperatures. The α loss peak (Fig. 3a) is due to the large-scale motions of chain dipoles and moves to ultralow frequencies as T_g is approached. $\langle\tau_\alpha(T)\rangle$ obeys the Vogel–Fulcher–Tammann equation

$$\langle\tau_\alpha(T)\rangle = A\exp[B/(T - T_\infty)] \tag{16}$$

where A, B, and T_∞ are material constants. T_g is often defined operationally as the temperature at which $\langle\tau_\alpha\rangle = 10^2$ s. The loss curves for poly(vinyl acetate) may be fitted approximately using the KWW function ($\bar{\beta}$ increases from 0.6 to 0.8 in this T-range). Below T_g a small secondary loss process (β process) is observed (Fig. 3b) because of limited motions of chain backbones and side chains. $\langle\tau_\beta(T)\rangle$ obeys the Arrhenius equation with activation energy $Q_\beta \sim 40$ kJ·mol^{-1}. All dipolar amorphous polymers (and small-molecule glass-forming liquids) give dielectric behavior similar to poly(vinyl acetate) (1–5) [ie, they exhibit an α process (lower-f process with large $\Delta\varepsilon_\alpha$) and a β process (higher-f process with small $\Delta\varepsilon_\beta$)]. Syndiotactic poly(methyl methacrylate) is an exception, having $\Delta\varepsilon_\beta > \Delta\varepsilon_\alpha$ (1,3). Static permittivities $\varepsilon_0(T)$ have been reported for numerous amorphous polymers and (using eq. 9) have enabled $g\mu^2$ to be determined in several cases (1,5,8).

Dielectric relaxation data for individual polymers are frequently compared with complementary data obtained from NMR, dynamic mechanical, quasi-elastic light/neutron scattering, and time-resolved fluorescence depolarization experiments (12). Many studies show (1–5,12) that the β process is due to spatially limited motions of chain segments or side chains occurring in a range of local environments, leading to a dielectric relaxation strength $\Delta\varepsilon_\beta \propto\langle\mu^2\rangle - \langle\mu\rangle^2]$, where $\langle\mu\rangle$ is the mean dipole moment that remains after the local motions (β process) have taken place. The α-process is due to the large-scale motions (micro-Brownian motions) of chains and has a relaxation strength $\Delta\varepsilon_\alpha \propto\langle\mu\rangle^2$. If pressure is applied in order to reduce $\Delta\varepsilon_\beta$, there is a complementary increase in $\Delta\varepsilon_\alpha$ [as demonstrated for poly(alkyl methacrylates) (3–5)]. For polymers with rotatable side groups [eg, poly(alkyl methacrylates)] the dielectric α and β processes merge in the MHz region to form the $\alpha\beta$ process (1–5,13). For polymers without rotatable side groups, eg, poly(ethylene terephthalate), polyesters and polycarbonates, the α and β processes merge only at very high frequencies ($>10^9$ Hz) (1–5,13). The origins of α,β and $\alpha\beta$ relaxations, their relaxation functions, and their T-dependencies for amorphous polymers and glass-forming liquids have received much attention (1–5,11–13). Models for chain dynamics based on mode-coupling theories, transient energy landscapes, and local "dynamic heterogeneities", together with large-scale molecular dynamics/Monte Carlo simulations of assemblies of polymer chains, have been developed and applied to relaxation, spectroscopic, and scattering data

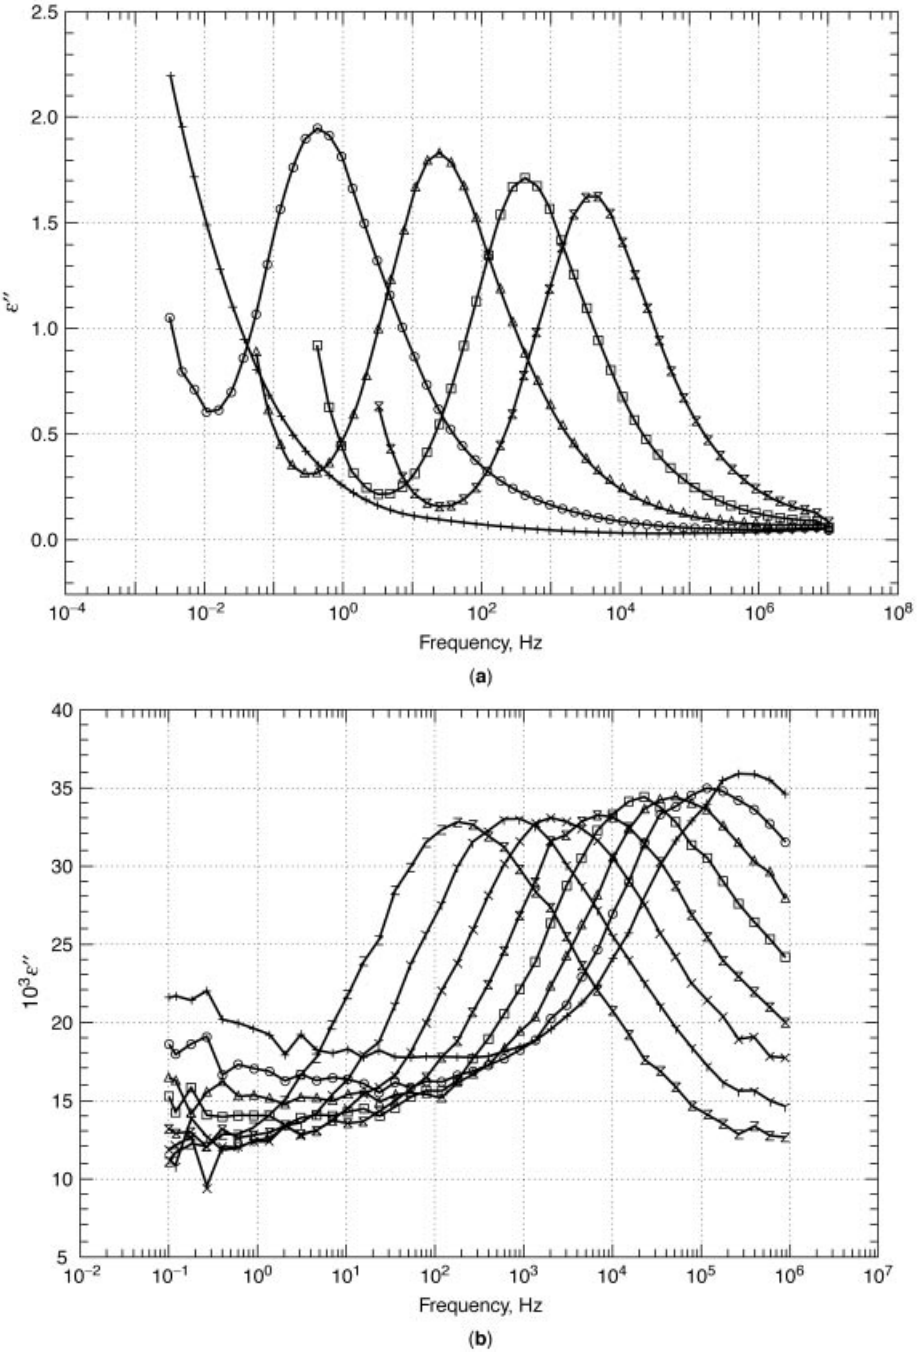

Fig. 3. Plots of ε'' against frequency (Hz) for poly(vinyl acetate): (**a**) the α-relaxation region from 293.15 K (+) to 333.15 K (Δ) in intervals of 10 K and (**b**) the β-relaxation region from 183 K (z) to 253 K (+) in intervals of 10 K. Data provided by Dr G. Schaumburg, Novocontrol GmbH.

(see, eg, Ref. 12). At a more practical level, DS is used to study the structure and dynamics of complex amorphous polymer systems. For example local inhomogeneity in polymer blends and random copolymers that exhibit a single T_g was revealed for blends of poly(*o*-chlorostyrene)/polystyrene and their random copolymers using broadband DS (see Ref. 14 and references therein). The width $\Delta_{1/2}$ of the α-peak was far broader than those for the pure homopolymers and broadened further as temperature was reduced, showing the presence of microphase separation and allowing the distribution of local concentrations to be determined (14). In certain polymers (eg, polypropylene oxide and polyisoprene) there is a small cumulative dipole moment along the chain contour and so for these materials DS can monitor the long-range motions (Rouse modes) of linear chains and multi-armed stars (11,15,16). The dependence of dielectric relaxation time $\langle\tau\rangle$ on molecular weight M is of interest; eg, for linear *cis*-polyisoprenes, $\langle\tau\rangle \sim M^2$ for $M < M_c$ and $\langle\tau\rangle \sim M^{3.7}$ for $M > M_c$, where M_c is the critical value for chain entanglements (15). The dielectric and dynamic mechanical relaxation data for the normal-mode relaxations in such polymers may be compared.

The dielectric behavior of crystalline polymers is more complex (1,2,4,17). For most materials (eg, the nylons, polyesters) motions of dipoles in the crystalline regions are totally suppressed. Polyethylene is an exception since chain rotation accompanied by translation of whole chains occurs within the lamellar crystals (17). Chain motions are possible in disordered regions on the surfaces of the lamellae (as occur in linear polyethylenes) or in the abnormal amorphous regions between the lamellar (as in the nylons). For polyethylene, which is nonpolar, motions occurring within the lamellae (α_c and γ_c processes) and the amorphous regions (β_a and γ_a processes) are activated for dielectric studies by incorporating carbonyl or C—Cl dipoles into the chains (1,3,17). Melt-crystallized polyamides (nylons) and polyesters are 100% spherulitic (by optical microscopy) but may be only ~50% crystalline. The motions of the amorphous phase within spherulites are severely influenced by the crystals, giving an α' process that is far broader and slower than the normal α process for the amorphous form of the polymer. Real-time dielectric studies of such polymers [eg, poly(ethylene terephthalate)] made during crystallization monitor the disappearance of the α process and the appearance of the α' process (18), thus providing a novel means of studying both the kinetics of crystallization and the dynamics of chains in the abnormal amorphous regions within spherulites.

Dielectric studies have been made for thermotropic LC polymers having mesogenic (LC-forming) dipolar groups in the side chains. These are a rare example of *dielectrically variable materials*, ie materials whose dielectric properties can be changed *in situ* using applied electric or magnetic fields. Motions of the mesogenic groups give four active dielectric relaxation modes (00, 01, 10, and 11) while motions of the chain backbone contribute to an α process (3,4,19,20). Aligned LC polymer films are made using strong ac electric fields of high and low frequencies ("two-frequency addressing principle"), yielding samples having homeotropic (H), planar (P), or intermediate (I) alignment of the LC director (n) with respect to the measuring field direction (the z-axis normal to the the plane of the film) (19,20). H samples ($n \| E$) and P samples ($n \perp E$) exhibit [00, 01] and [10,11] modes, respectively, and so have very different dielectric properties. The δ process (00 mode) is dominant for the H material but is absent for the P material. In general

$$\varepsilon(\omega) = (1 + 2S_d)\varepsilon_{\parallel}(\omega)/3 + 2(1 - S_d)\varepsilon_{\perp}(\omega)/3 \quad (17)$$

S_d is the "director order parameter" and is 1, 0, −1/2 for H-unaligned and P-aligned materials, respectively. $\varepsilon_{\parallel}(\omega)$ and $\varepsilon_{\perp}(\omega)$ are the principal permittivities of the LC phase and are related to dipole moment components $\mu_{\parallel}$ and $\mu_{\perp}$ of the side groups and the local order parameter S_l of the phase. Ferroelectric polymers, made by introducing chiral polar groups as mesogenic groups in side-chain LC polymers (21), exhibit two low frequency dielectric processes, (*1*) the Goldstone mode and (*2*) the soft mode, both having large relaxation strengths. The soft mode occurs only in the chiral S^*_c phase and is suppressed by application of a biasing electric field (21).

Solid polymer electrolytes are of interest for battery applications, and are either homogeneous polymers having electrically charged chains with labile counterions or blends of neutral polymers with inorganic salts. A practical aim is to prepare stable films having dc conductivities $\sigma_0 > 10^{-5}$ S·cm^{-1} at room temperature. Many materials have been investigated (22). In all cases σ_0 decreases by up to 8 orders of magnitude as temperature is reduced toward T_g(polymer) as a result of two effects: (*1*) reduced ion mobility, due to the slowing down of molecular motions, and (*2*) increasing ion-association, which removes ions and creates dipolar aggregates that exhibit dielectric relaxation. Plots of $\sigma'(\omega)$ against log f/Hz feature (*1*) a plateau over a wide intermediate f-range that provides $\sigma_0(T)$ values, (*2*) a decrease in σ' at low frequencies as a result of electrode polarization, and (*3*) a power-law increase of σ' at high frequencies (see, eg, Refs. 22 and 23) as a result of the short-time "backlash effect" mentioned above. Such data for a polymer electrolyte at different temperatures or applied pressures (23) are used to construct a master curve of log $\sigma'(\gamma\omega)/\sigma_0$ against log $\gamma\omega$, where log γ is a horizontal shift factor (9,10). Near-universal behavior for these master plots is obtained for polymer electrolytes and many other disordered amorphous materials (9,10). Models proposed to account for this behavior include those for the hopping of charge carriers over local barriers between temporary sites in the solid (9,10). In general, polymer electrolytes contain dipolar species in addition to the ions, and so give dipole relaxation processes in addition to ionic conduction. Insufficient attention has been given in the literature to the separation of dipole relaxation and conduction processes in the plots of $\sigma'(\omega)$ and $\varepsilon''(\omega)$ against log f/Hz for polymer electrolytes.

Real-time dielectric studies of polymerizing systems give information on the changes in molecular dynamics that occur during reaction. Condensation (step) and radical-chain (addition) reactions yielding glassy or elastomeric products, initiated thermally or photochemically, have been studied in this way (see Refs. 24–26 and references therein). Figure 4 shows 3D plots of ε' and ε'' against {log f/Hz, time/s} for the reaction of an equimolar mixture of a diepoxide DGEBA (diglycidyl ether of bisphenol A) with an alicyclic diamine at 60°C (27). ε' values (Fig. 4a) decrease from those of a liquid at $t = 0$ to a glass at long times. The ε'' curves (Fig. 4b) exhibit (*1*) losses at low frequencies/short times due to ionic conduction, that decrease rapidly as the viscosity of the reaction mixture increases, and (*2*) the α-relaxation process, which moves to ultralow frequencies with time as the glass is formed. These data, taken together with those for the extent of reaction with time, show that decreasing molecular mobility (as monitored by the location of the α-process) causes the reaction to become diffusion-controlled, leading to a

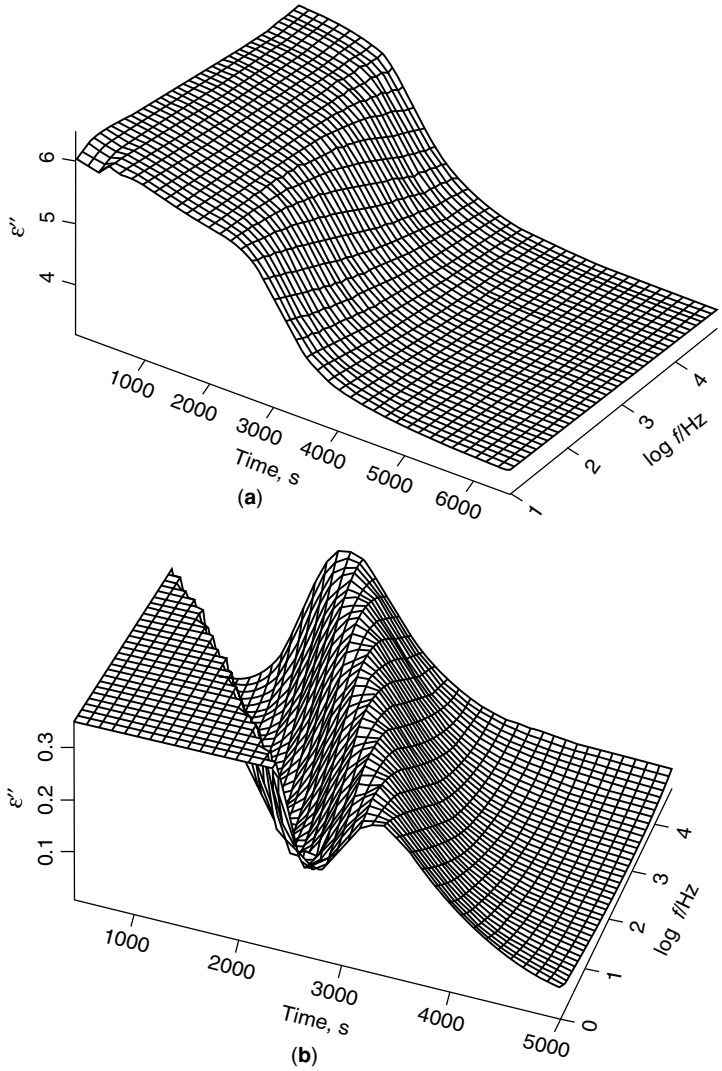

Fig. 4. Plots of (**a**) ε' and (**b**) ε'' against $\{\log_{10} f/\text{Hz}, \text{time/s}\}$ for an epoxide/amine thermosetting reaction at 60°C. Data provided by Dr I.K. Smith (27).

chemically unstable glass at long times. In other cases reaction is completed before diffusion-control sets in, and so a chemically stable elastomer is formed (25,26). The "floor temperature" T_f, below which the product is a glass and above which the product is an elastomer, can be determined using DS for thermopolymerization reactions (25,26).

Measurement Techniques and Applications

Measurements of $\varepsilon(\omega)$ and $\sigma(\omega)$ are made using commercial frequency-reponse analyzers (10^{-5} – 10^6 Hz), impedance analyzers (10^2 – 10^6 Hz), time-domain

reflectometers ($10^6 - 10^9$ Hz), and network analyzers ($10^7 - 10^{12}$ Hz) (28). At very high frequencies (GHz to THz) special quasi-optical and far-infrared spectrometers have been developed (28,29). At ultralow frequencies ($10^{-5} - 1$ Hz) transient charge/current methods provide an alternative (and faster) method to ac methods (1,28). Thermally stimulated current methods (30) provide a very useful way of observing multiple relaxation peaks for polymers at low effective frequencies ($<10^{-2}$ Hz).

The control of dielectric permittivity and loss of solid polymers, through an understanding of the origins of their dipole relaxation and ionic conduction processes, is essential for their use in electrical insulation, in electrical/electronic circuits, and devices operated over wide power ranges. DS provides information on chain dynamics and charge transport in amorphous, crystalline, LC polymers, and polymer electrolytes. It is ideally suited to the study of polymers in confined environments (eg, in sol–gel–glass) and thin films [since capacitance $\propto$ 1/(film thickness)]. Real-time DS can be applied inter alia to polymer systems undergoing crystallization and polymerization; the switching behavior of LC polymers and polymer-dispersed liquid crystals; phase separation in polymer mixtures/blends induced by chemical reaction or heating [that gives an additional loss process in the product due to interfacial (Maxwell–Wagner) polarization (1,25,31)].

ELASTOMERS, THERMOPLASTIC

Introduction

Thermoplastic elastomers were introduced in the 1960s. They have shown rapid growth since then and have been the subject of many conferences, symposia, etc. In particular, the developments in this field have been covered fairly recently in two books: one being a comprehensive survey of the subject (1) and the other being a general introduction (2). Thermoplastic elastomers have many of the physical properties of rubbers, ie, softness, flexibility, and resilience; but in contrast to conventional rubbers, they are processed as thermoplastics. Rubbers must be cross-linked to give useful properties. In the terminology of the plastics industry, vulcanization is a thermosetting process. Like other thermosetting processes, it is slow and irreversible and takes place upon heating. With thermoplastic elastomers, on the other hand, the transition from a processible melt to a solid, rubber-like object is rapid and reversible and takes place upon cooling. Thermoplastic elastomers can be processed using conventional plastics techniques, such as injection molding and extrusion; scrap is usually recycled.

Because of increased production and the lower cost of raw material, thermoplastic elastomeric materials are a significant and growing part of the total polymers market. World consumption in 2000 was estimated to be about 1,300,000 t (3). However, because the melt to solid transition is reversible, some properties of thermoplastic elastomers, eg, compression set, solvent resistance, and resistance to deformation at high temperatures, are usually not as good as those of the conventional vulcanized rubbers. Applications of thermoplastic elastomers are, therefore, in areas where these properties are less important, eg, footwear, wire insulation, adhesives, polymer blending, and not in areas such as automobile tires.

Table 1. Comparison of Thermoplastic Elastomers with Conventional Plastics and Rubbers

	Processing method	
Property	Thermosetting	Thermoplastic
Rigid	Epoxies, phenol–formaldehyde, urea–formaldehyde	Polystyrene, polypropylene, PVC, high density polyethylene
Flexible	Highly filled and/or highly vulcanized rubbers	Low density polyethylene, EVA, plasticized PVC
Rubbery	Vulcanized rubbers (NR, SBR, IR, etc)	Thermoplastic elastomers

The classification given in Table 1 is based on the process, ie, thermosetting or thermoplastic, by which polymers in general are formed into useful articles and on the mechanical properties, ie, rigid, flexible, or rubbery, of the final product. All commercial polymers used for molding, extrusion, etc, fit into one of these six classifications; the thermoplastic elastomers are the newest.

Structure

Most thermoplastic elastomers are multiphase compositions in which the phases are intimately dispersed. In many cases, the phases are chemically bonded by block or graft copolymerization. In others, a fine dispersion is apparently sufficient. In these multiphase systems, at least one phase consists of a material that is hard at room temperature but becomes fluid upon heating. Another phase consists of a softer material that is rubber-like at room temperature. A simple structure is an A–B–A block copolymer, where A is a hard phase and B an elastomer, eg, poly(styrene-*b*-elastomer-*b*-styrene) (see BLOCK COPOLYMERS).

Most polymer pairs are thermodynamically incompatible and mixtures separate into two phases. This is true even when the polymeric species are part of the same molecule, as in these block copolymers. Poly(styrene-*b*-elastomer-*b*-styrene) copolymers, in which the elastomer is the main constituent, should have a structure similar to that shown in Figure 1. Here, the polystyrene end segments form separate spherical regions, ie, domains, dispersed in a continuous elastomer phase. Most of the polymer molecules have end polystyrene segments in different domains. At room temperature, these polystyrene domains are hard and act as physical cross-links, tying the elastomer chains together in a three-dimensional network. In some ways, this is similar to the network formed by vulcanizing conventional rubbers using sulfur cross-links. The main difference is that in thermoplastic elastomers the domains lose their strength when the material is heated or dissolved in solvents. This allows the polymer or its solution to flow. When the material is cooled down or the solvent is evaporated, the domains harden and the network regains its original integrity. This explanation of the properties of thermoplastic elastomers has been given in terms of a poly(styrene-*b*-elastomer-*b*-styrene) block copolymer, but it would apply to any block copolymer with the multiblock structure A–B–A–B····, as well as to branched block copolymers $(A–B)_n x$ (where x represents an n functional junction point). In principle, A can be any polymer normally regarded as a hard

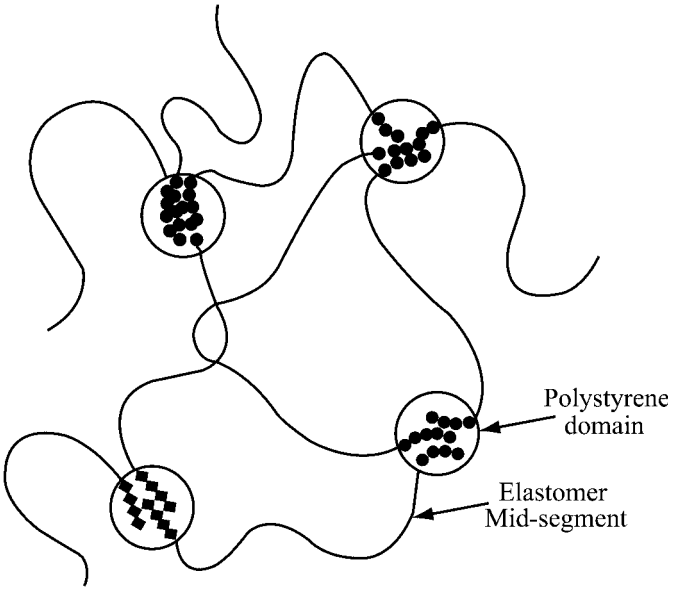

Fig. 1. Phase arrangement in styrenic block copolymers.

thermoplastic, eg, polystyrene, polyethylene, or polypropylene, and B can be any polymer normally regarded as elastomeric, eg, polyisoprene, polybutadiene, poly(ethylene-propylene), or polydimethylsiloxane (Table 2).

Block copolymers with structures such as A–B or B–A–B are not thermoplastic elastomers, because for a continuous network to exist, both ends of the elastomer segment must be immobilized in the hard domains. Instead, they are much weaker materials resembling conventional unvulcanized synthetic rubbers (4).

Besides the thermoplastic elastomers based on poly(styrene-*b*-elastomer-*b*-styrene) block copolymers, five others are of commercial importance: polyurethane/elastomer block copolymers, polyester/elastomer block copolymers, polyamide/elastomer block copolymers, polyolefin block copolymers, and polyetherimide/polysiloxane block copolymers. All five have the multiblock A–B–A–B····· structure. The morphology of the polyurethane, polyester, polyamide, and polyolefin block copolymers is shown diagrammatically in Figure 2. It has some similarities to that of poly(styrene-*b*-elastomer-*b*-styrene) equivalents (Fig. 1) and also some important differences: (*1*) the hard domains are more interconnected; (*2*) they are crystalline; and (*3*) these long A–B–A–B····· molecules may run through several hard and soft phases. The polyetherimide–polysiloxane block copolymers share some features of both types. As in the poly(styrene-*b*-elastomer-*b*-styrene) analogues, their hard domains are amorphous. However, these polymers have multiblock A–B–A–B····· structure rather than A–B–A, and so again, each molecule may run through several hard and soft phases.

Not all thermoplastic elastomers are block copolymers. Those that are not are usually combinations of a hard thermoplastic with a softer, more rubber-like polymer (Table 3) (see POLYMER BLENDS).

Table 2. Thermoplastic Elastomers Based on Block Copolymers

Hard segment, A	Soft or elastomeric segment, B	Structure[a]	References

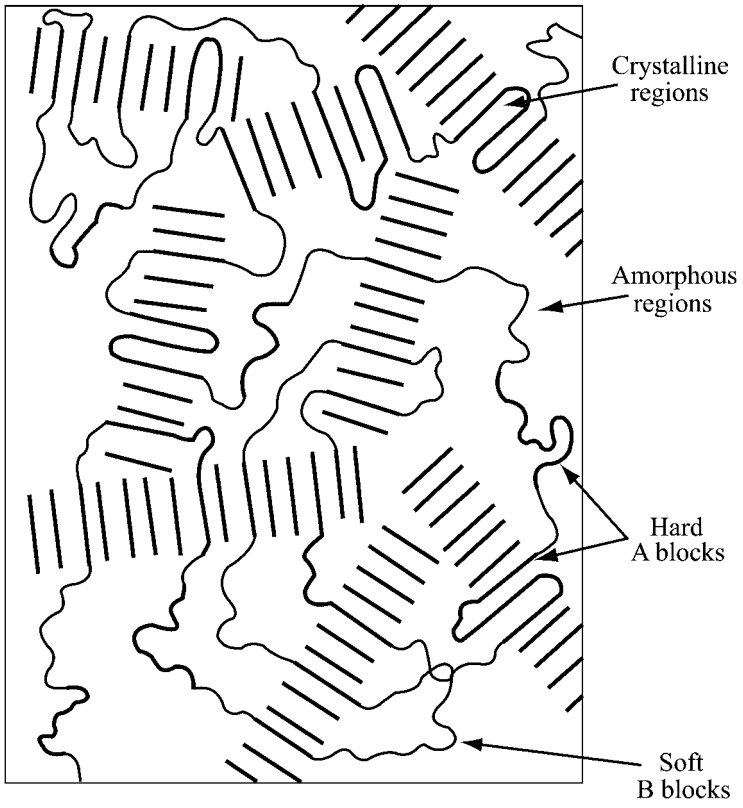

Fig. 2. Phase arrangement in crystalline block copolymers.

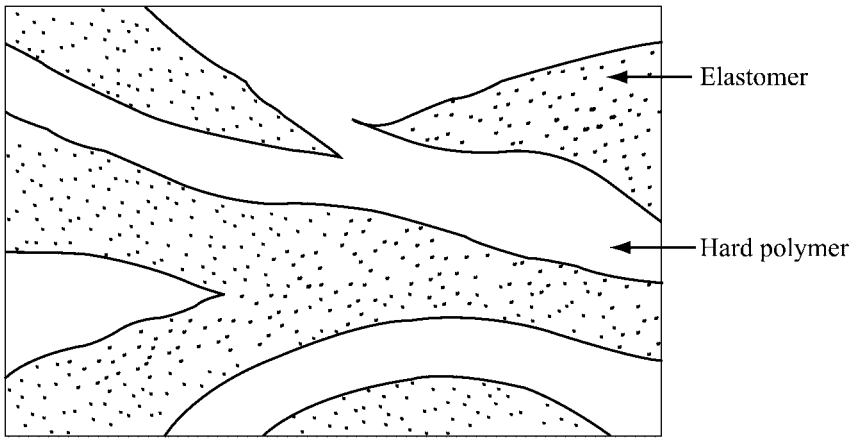

Fig. 3. Phase arrangement in hard polymer/elastomer blends.

Usually, the components are mechanically mixed together (24,25), although it is sometimes possible to produce the rubber component *in situ* during polymerization. Typically, the two components form interdispersed multiphase systems and a diagrammatic structure for blends of this type is shown in Figure 3. Blends

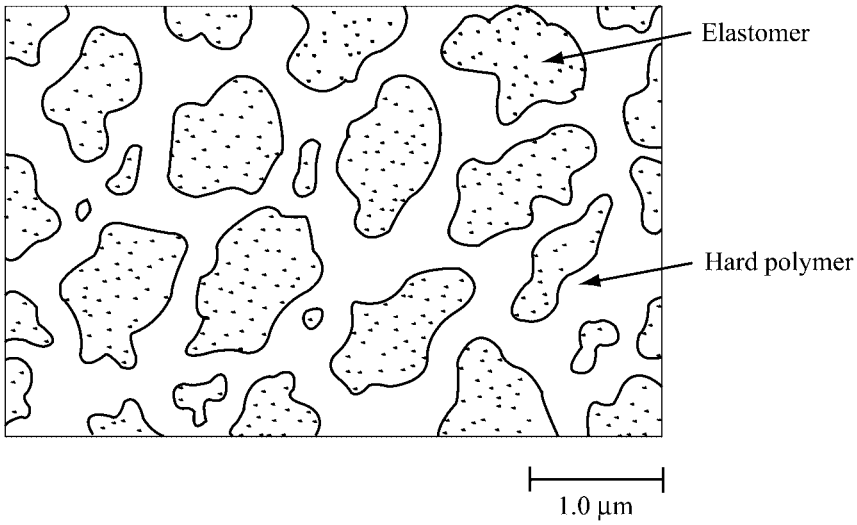

Fig. 4. Phase arrangement in hard polymer/elastomer combinations in which the elastomer phase has been dynamically vulcanized.

of polypropylene with ethylene–propylene–diene monomer (EPDM) were the first materials of this type (24,25). Blends with ethylene–propylene copolymer (EPR) are now more important commercially, and propylene copolymers often replace polypropylene homopolymer as the hard phase. However, some combinations of a hard thermoplastic with a rubber-like polymer are claimed to be single-phase systems (30). In some cases, the elastomer phase is cross-linked while the mixture is being highly sheared (24–26). This process is often referred to as "dynamic vulcanization" (27) and gives a finely dispersed and cross-linked elastomer phase (Fig. 4.).

Other thermoplastic elastomer combinations, in which the elastomer phase may or may not be cross-linked, include blends of polypropylene with nitrile (26), butyl (28), and natural (29) rubbers, blends of PVC with nitrile rubber and plasticizers (30–32), and blends of halogenated polyolefins with ethylene interpolymers (30). Commercially important products (33,34) based on blends of polystyrene with S–B–S and oil and also on blends of polypropylene with S–EB–S and oil are described later in this article. They are also considered as thermoplastic elastomer combinations. The oils used in these products are usually hydrocarbons but blends with silicone oils have also been described (35). Collectively, all thermoplastic elastomers of this type (both bends and dynamic vulcanizates) are referred to herein as hard polymer/elastomer combinations.

Thermoplastic elastomers based on blends of a silicone rubber (cross-linked during processing) with block copolymer thermoplastic elastomers have also been produced (36,37). Other types that have been studied (38) include graft copolymers and elastomeric ionomers, but these have not become commercially important.

Property–Structure Relationships

With such a variety of materials, it is to be expected that the properties of thermoplastic elastomers cover an exceptionally wide range. Some are very soft and

rubbery where others are hard and tough, and in fact approach the ill-defined interface between elastomers and flexible thermoplastics.

Since most thermoplastic elastomers are phase-separated systems, they show many of the characteristics of the individual polymers that constitute the phases. For example, each phase has its own glass-transition temperature (T_g) (or crystal melting point T_m if it is crystalline). These, in turn, determine the temperatures at which a particular thermoplastic elastomer goes through transitions in its physical properties. Thus, when the modulus of a thermoplastic elastomer is measured over a range of temperatures, there are three distinct regions (see Fig. 5).

At very low temperatures, both phases are hard and so the material is stiff and brittle. At a somewhat higher temperature the elastomer phase becomes soft and the thermoplastic elastomer now resembles a conventional vulcanizate. As the temperature is further increased, the modulus stays relatively constant (a region

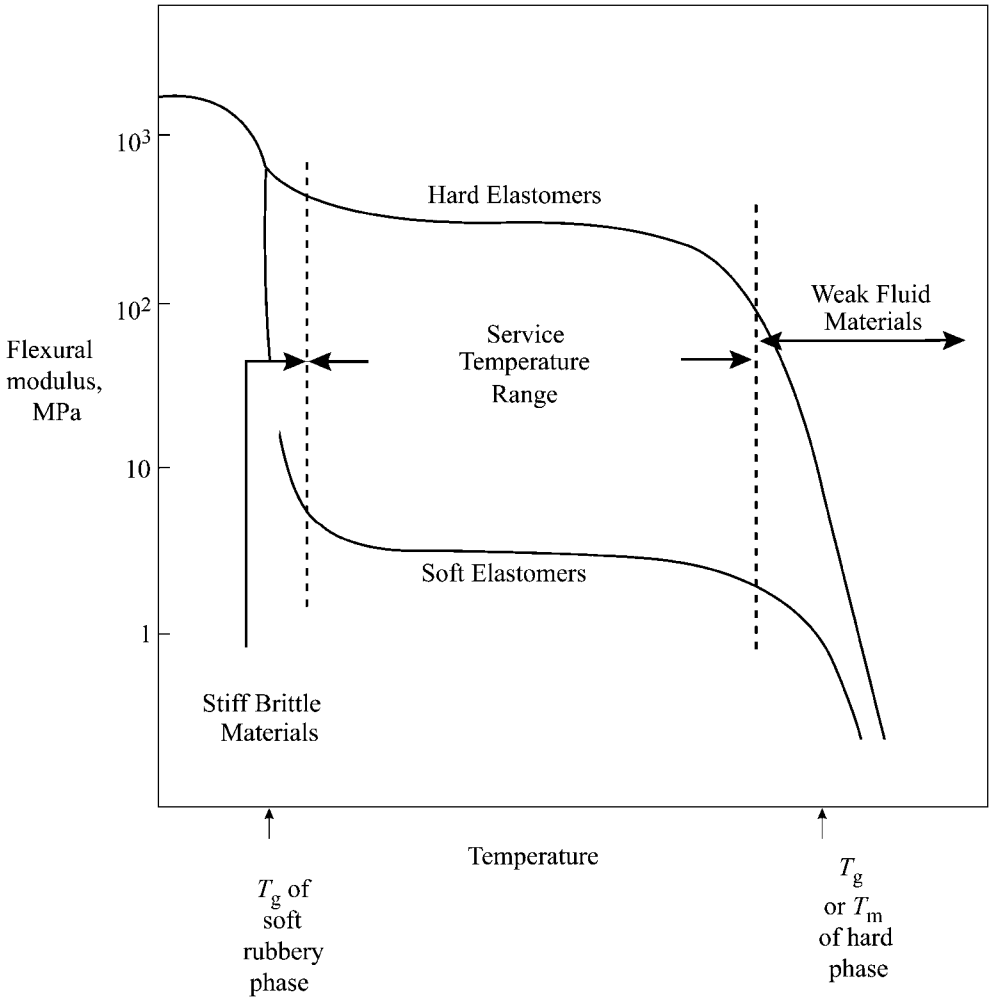

Fig. 5. Stiffnes of typical thermoplastic elastomers at various temperatures.

Table 4. Glass Transition and Crystal Melting Temperatures

Thermoplastic elastomer type	Soft, rubbery phase T_g, °C	Hard phase T_g or T_m, °C
Polystyrene/elastomer block copolymers		
S–B–S	−90	95 (T_g)
S–I–S	−60	95 (T_g)
S–EB–S and S–EP–S	−60	95 (T_g) and 165 (T_m)[a]
Multiblock copolymers		
Polyurethane/elastomer block copolymers	−40 to −60[b]	190 (T_m)
Polyester/elastomer block copolymers	−40	185 to 220 (T_m)
Polyamide/elastomer block copolymers	−40 to −60[b]	220 to 275 (T_m)
Polyethylene/poly(α-olefin) block copolymers	−50	70 (T_m)[c]
Polyetherimide/polysiloxane block colymers	−60	225 (T_g)
Hard Polymer/elastomer combinations		
Polypropylene/EPDM or EPR combinations	−50	165 (T_m)
Polypropylene/butyl rubber combinations	−60	165 (T_m)
Polypropylene/natural rubber combinations	−60	165 (T_m)
Polypropylene/nitrile rubber combinations	−40	165 (T_m)
PVC/nitrile rubber/DOP combinations	−30	80 (T_m)

[a] In compounds containing polypropylene.
[b] The values are for polyethers and polyesters respectively.
[c] This low value for T_m is presumably the result of the short length of the polyethylene segments.

often described as the "rubbery plateau") until finally the hard phase softens. At this point, the thermoplastic elastomer becomes fluid.

Thus, thermoplastic elastomers have two service temperatures. The lower service temperature depends on the T_g of the elastomer phase while the upper service temperature depends on the T_g or T_m of the hard phase. Values of T_g and T_m for the various phases in some commercially important thermoplastic elastomers are given in Table 4.

Some of the parameters that can be varied in order to change the properies of thermoplastic elastomers include the following:

Molecular Weight. Compared with homopolymers of similar molecular weight, styrenic block copolymers have very high melt viscosities which increase with increasing molecular weight. These effects are attributed to the persistence of the two-phase domain structure in the melt and the extra energy required to disrupt this structure during flow (4,5). If the styrene content is held constant, the total molecular weight has little or no effect on the modulus of the material at

ambient temperatures. This is attributed to the modulus of the elastomer phase being inversely proportional to the molecular weight between entanglements in the elastomer chains and the fact that this quantity is not affected by the total molecular weight.

Proportion of Hard Phase. The tensile behavior of otherwise similar block copolymers with differing hard segment contents shows a family of stress–strain curves (4,6,7,24). As the hard segment content is increased, the products change from very weak, soft, rubber-like materials to strong elastomers, then to leathery materials, and finally to hard flexible thermoplastics. The latter have been commercialized as clear, high impact polystyrenes under the trade name K-Resin (39) (Phillips Petroleum Co.). Thermoplastic elastomers in general show similar behavior; that is, as the ratio of the hard to soft phase is increased, the product in turn becomes harder.

Elastomer Phase. The choice of elastomer segment has a profound effect on the properties of block copolymers. In the styrenic block copolymers, four elastomers are commercially important: polybutadiene [9003-17-2], polyisoprene [9003-31-0], poly(ethylene-*co*-butylene) [9019-29-8], and poly(ethylene-*co*-propylene) [9010-79-1]. Polyisobutylene has also been extensively investigated (7,40) but the products have not been produced commercially. The corresponding styrenic triblock copolymers are referred to as S–B–S, S–I–S, S–EB–S,S–EP–S, and S–iB–S, respectively. Polybutadiene and polyisoprene both have one double bond per monomer unit. These double bonds are an obvious source of instability and limit the thermal and oxidative stability of the S–I–S and S–B–S block copolymers. In contrast, poly(ethylene-*co*-butylene) and poly(ethylene-*co*-propylene) are completely saturated, and so S–EB–S and S–EP–S block copolymers are much more stable. Another important aspect is the modulus of the materials. It is postulated that the modulus of styrenic block copolymers is inversely proportional to the molecular weight between chain entanglements (M_e), as well as to the effects of the polystyrene domains acting as reinforcing filler particles (4,40). Values of M_e are as follows (3,40): polyisobutylene, 8900; polyisoprene (natural rubber), 6100; polybutadiene, 1700; and poly(ethylene-*co*-propylene), 1660. The M_e for poly(ethylene-*co*-butylene) is similar to that of poly(ethylene-*co*-propylene). Because of these differences in M_e, S–iB–S block copolymers are the softest of all, S–I–S block copolymers are softer than the S–B–S analogues, and the S–EB–S and S–EP–S analogues are the hardest (40).

All these elastomers, especially poly(ethylene-*co*-butylene) and poly (ethylene-*co*-propylene), are nonpolar. The corresponding block copolymers can thus be compounded with hydrocarbon-based extending oils, but do not have much oil resistance. Conversely, block copolymers with polar polyester or polyether elastomer segments have little affinity for such hydrocarbon oils and so have better oil resistance.

Among the polyurethane, polyester, and polyamide thermoplastic elastomers, those with polyether-based elastomer segments have better hydrolytic stability and low temperature flexibility, whereas polyester-based analogues are tougher and have the best oil resistance (12). Polycaprolactones and aliphatic polycarbonates, two special types of polyesters, are used to produce premium-grade polyurethanes (12).

In the polyolefin-based block copolymers, the elastomeric segment is typically a copolymer of ethylene and 1-octene. It is nonpolar and very stable, as is the polysiloxane elastomer segment in the polyetherimide/polysiloxane block copolymers.

In the hard polymer/elastomer combinations, the elastomer is most often a stable nonpolar rubber such as EPR or EPDM. As noted above, substitution of a polar rubber (such as nitrile rubber) and/or cross-linking improves the resistance to oils and solvents.

Hard Phase. The choice of the hard phase determines the upper service temperature and also influences the solvent resistance. In styrenic block copolymers, those based on poly(α-methylstyrene) [25014-31-7] have higher upper service temperature and tensile strength than analogues based on polystyrene [9003-53-6] (6); both are soluble in common solvents. Replacing the polystyrene end segments in S–EB–S by polyethylene (giving E–EB–E block copolymer) improves solvent resistance; the phases are not separated in the melt (6).

In polyurethane/elastomer, polyester/elastomer, and polyamide block copolymers, the crystalline end segments, together with the polar center segments, impart good oil resistance and high upper service temperatures. In the polyolefin block copolymers, polyethylene is the hard phase. The polyethylene in this phase has a relativly low T_m (about 70°C) (24) and so these thermoplastic elastomers should have a low upper service temperature. The hard segment in the polyetherimide/polysiloxane block copolymers has a very high T_g (about 225°C) and so these thermoplastic elastomers have a very high upper service temperature.

Polypropylene is used as the hard phase in many hard polymer/elastomer combinations. It is low in cost and density and its T_m is quite high (about 165°C). This crystalline polypropylene phase imparts resistance to solvents and oils, as well as providing the products based on it with relatively high upper service temperatures.

Synthesis. Block copolymers are synthesized by a variety of methods; most important are sequential (41–46) and step-growth polymerization (47). In sequential polymerization, a polymer $(A)_n$ is first synthesized in such a way that it contains at least one group per molecule that can initiate polymerization of another monomer B.

$$A + A + A + \cdots \rightarrow A_n$$
$$A_n + B + B + B + \cdots \rightarrow A_n\text{–}B_m$$

The product can be converted to a triblock copolymer by further addition of A:

$$A_n\text{–}B_m + A + A + A + \cdots \rightarrow A_n\text{–}B_m\text{–}A_n$$

In a variation of this process, polymerization can start in the center (B_m) segment, and A_n segments can then be polymerized onto each end. Alternatively, A_n–B_m can be joined together by a coupling agent:

$$2A_n\text{–}B_m + X \rightarrow A_n\text{–}B_m\text{–}X\text{–}B_m\text{–}A_n$$

In this example, X is difunctional and the product is linear. If the functionality of X is higher, the product is a branched $(A–B)_nX$ polymer.

In step-growth polymerization, one or both segments can be produced separately as difunctional prepolymers. The products can then be linked together:

$$A_n + B_m + A_n + B_m + \cdots \rightarrow A_n–B_m–A_n–B_m\cdots$$

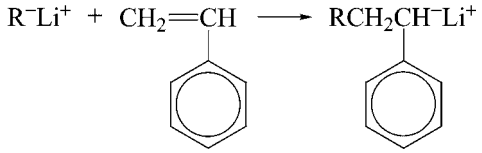
or react with more difunctional monomer:

$$A_n + mB + mC \rightarrow A_n–(BC)_m–A_n–(BC)_m\cdots$$

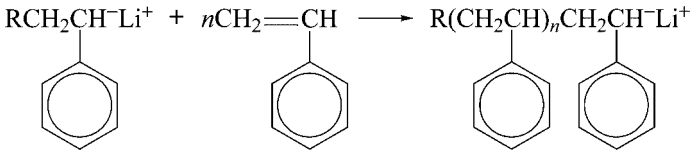
Thermoplastic elastomers that are hard polymer/elastomer combinations are usually not synthesized directly. Instead, the two polymers that form the hard and soft phases are intimately mixed on high shear equipment.

Commercial Production

The commercially available poly(styrene-*b*-elastomer-*b*-styrene) materials are made by anionic polymerization (5,6,40–42). An alkyllithium initiator (R^+Li^-) first reacts with styrene [100-42-5] monomer:



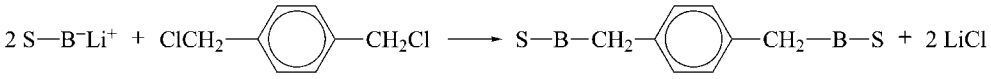
This product acts as an initiator for further polymerization:



The product, referred to here as S^-Li^+, is able to initiate further polymerization. Similar products have been termed living polymers (45). Addition of a second monomer, such as butadiene [106-99-0], gives

$$S^-Li^+ + nCH_2{=}CH{-}CH{=}CH_2 \rightarrow S{-}(CH_2CH{=}CHCH_2)_{(n-1)}CH_2CH{=}CH{-}CH_2^-Li^+$$

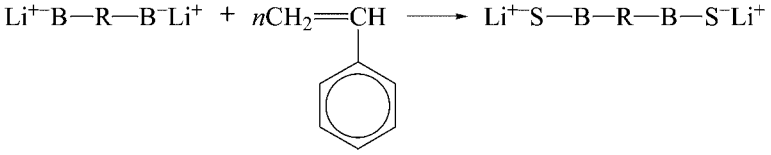
The product of this reaction ($S–B^-Li^+$) may initiate a further reaction with styrene monomer to give $S–B–S^-Li^+$. This, in turn, can react with an alcohol, ROH, to give S–B–SH + LiOR. Alternatively, $S–B^-Li^+$ may react with a coupling agent such as an organohalogen (46):



Other coupling agents include esters (46), chlorosilanes (41,46), and divinylbenzene (41). The last gives highly branched materials, whereas the others can give branched or linear products, depending on the functionality of the coupling agent. Another variation of anionic polymerization uses multifunctional initiators (5,6,40,41,45,46), in which the polymer chains grow outward from the center of the molecule. In the case considered here, a difunctional initiator ($Li^{+-}R^{-}Li^{+}$) first reacts with butadiene monomer:

$$Li^{+-}R^{-}Li^{+} + CH_2{=}CH{-}CH{=}CH_2 \rightarrow Li^{+-}B{-}R{-}B^{-}Li^{+}$$

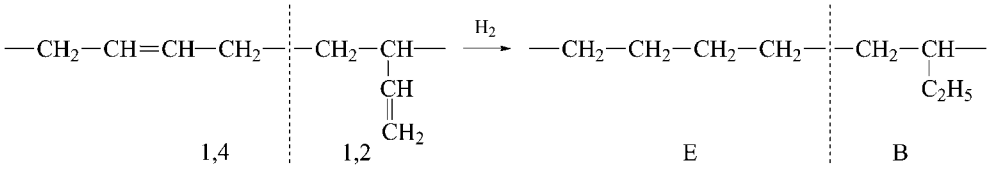
This product is a difunctional initiator and can polymerize styrene monomer:



and the final product can again react with an alcohol to give S–B–S, ignoring the minor amount of the R radical that is left at the center of the polymer.

All these polymerizations proceed only in the absence of oxygen or water, which react with the highly reactive propagating species. Polymerization is usually carried out in an inert, hydrocarbon solvent and under a nitrogen blanket. Under these conditions, polymers with narrow molecular-weight distributions and precise molecular weights can be produced in stoichiometric amounts.

Only three common monomers, styrene, butadiene, and isoprene [78-79-5] are easy to polymerize anionically; therefore only two useful A–B–A block copolymers, S–B–S and S–I–S, can be produced directly. In both cases, the elastomer segments contain double bonds which are reactive and limit the stability of the product. To improve stability, the polybutadiene mid-segment can be polymerized as a random mixture of two structural forms, the 1,4 and 1,2 isomers, by addition of an inert polar material to the polymerization solvent; ethers and amines have been suggested for this purpose (41). Upon hydrogenation, these isomers give a copolymer of ethylene and butylene.



The S–EB–S block copolymers produced in this way have excellent resistance to degradation. Similarly, S–I–S block copolymers can be hydrogenated to give the more stable S–EP–S equivalents.

S–iB–S block copolymers are made by cationic polymerization (7,40,43). So far, they have not been produced commercially.

Polyurethane block copolymers are produced from prepolymers by polycondensation (12,48). A relatively *high* molecular weight polyester or polyether with terminal hydroxy groups (a polyglycol) first reacts with an excess of a diisocyanate.

$$HOR_1OH + 2OC\ NR_2NCO \rightarrow OCNR_2NHCOOR_1OOCNHR_2NCO$$

This reaction continues to give a prepolymer in which the segments originally derived from the polyglycol and the diisocyanate alternate, and which is terminated by isocyanate groups. This prepolymer, designated $OCNR_3NCO$, cannot crystallize because it has an irregular structure (polyglycols are not a single species but have a broad range of molecular weights). It becomes the elastomeric or soft segment in the final polymer. It, in turn, reacts with a *low* molecular weight glycol such as 1,4-butanediol and with more diisocyanate.

$$OCNR_3NCO + HO(CH_2)_4OH + OCNR_2NCO \longrightarrow$$

prepolymer

$$+OOCNHR_3NHCOO(CH_2)_4OOCNHR_2NHCOO(CH_2)_4+_n$$

soft rubbery segment — hard crystalline segment

The segments derived from the condensation reaction of the *low* molecular weight glycol with the diisocyanate have a regular structure and so can crystallize. They agglomerate into separate hard domains. The elastomeric chains are thus cross-linked to form a network similar in many ways to that given by the simple poly(styrene-*b*-elastomer-*b*-styrene) polymer described previously (4,5,11). However, the polymer is a multiblock A–B–A–B····· rather than a simple A–B–A triblock, and the molecular weights and molecular weight distributions of the segments are not as well controlled. 4,4′-Diphenylmethane diisocyanate is the most common diisocyanate used in this application (12,48) but toluene and hexamethylene diisocyanates are alternatives.

Commercial polyester block copolymers are synthesized in a similar way (13,48) by the reaction of a relatively high molecular weight polyether glycol with terephthalic acid (or its dimethyl ester) to give a prepolymer. This then reacts with a low molecular weight glycol (usually 1,4-butanediol) and more terephthalic acid. The segments derived from the polyether-based prepolymer become the soft segments in the final product, whereas the terephthalic acid–1,4-butanediol copolymer forms the hard crystalline domains. Because the soft segments are derived from polyethers, these polymers are often known as polyether ester elastomers.

There are several types of polyamide block copolymers (15,48). Their synthesis is similar to that of the polyurethane and polyester equivalents. In some cases, only the soft segments are prepolymers; whereas in others, prepolymers are used to give both segmental types. Both polyesters and polyethers are used for the soft segments, and this choice affects the final properties of the product. Various

polyamides, including those based on aromatic groups, may be used for the hard segments. These all have different melting points and degrees of crystallinity and so give products with a wide range of properties.

The polyolefin thermoplastic elastomers are produced using metallocene catalysts (44). These are typically based on cyclopentadienyl groups linked to a halide of a transition metal (eg, Ti, Zr, Hf). Under the right conditions, these polymerize mixtures of ethylene and α-olefin monomers (usually 1-octene) into polymers with long repeating polyethylene segments, rather than into random copolymers. These polyethylene segments form the hard phase in the polymer. There are also copolymer segments with pendant groups, usually arranged atactically. Because of their random atactic structures, these segments cannot crystallize. Instead, they are amorphous materials with low glass-transition temperatures and so are soft and rubber-like at room temperature. They form the soft phase in the polymer.

The polyetherimide/polysiloxane block copolymers are synthesized by step-growth polymerization (47). Many other synthetic methods for preparing block copolymers have been described (14,16–20,22–25) but are currently not believed to be commercially important.

The production of the hard polymer/elastomer combinations is more simple. The two components are mixed together under conditions of intensive shear. To achieve a satisfactory dispersion, both the viscosities (at the mixing conditions) and the solubility parameters of the polymers must be carefully matched (49). In some cases, grafting may occur. In a variation of this technique, the elastomer can be cross-linked while the mixing is taking place and the products are described as dynamic vulcanizates (26,27,49).

Many dynamically vulcanized compositions have been investigated (26). In some cases, the components are technologically compatibilized by use of a grafting reaction, but usually a fine dispersion of the two phases is formed that is sufficient to give the product the properties of a thermoplastic elastomer.

Economic Aspects

Global consumption of thermoplastic rubbers of all types is estimated at about 1,300,000 tons/year (3). Of this, the market is estimated to be divided as follows: styrenic block copolymers, 50%; blends and thermoplastic vulcanizates based on polyolefins, 29%; polyurethane block copolymers and polyester block copolymers, 16%; and others, 6%. Annual growth rate during the period 1990–2000 was estimated to be 7%. The ranges of the hardness values, prices, and specific gravities of commercially available materials are given in Table 5.

Applications

The applications of these thermoplastic elastomers are described in detail in References 33 and 34. Trade names and suppliers of commercial thermoplastic elastomers of all types are given in Tables 6–8.

Table 5. Price and Property Ranges for Thermoplastic Elastomers[a]

Elastomer	Price range, $/kg	Specific gravity	Hardness (Shore A or D)
Polystyrene/elastomer block copolymers			
S–B–S (pure)	1.9–2.9	0.94	65A–75A
S–I–S (pure)	2.2–2.9	0.92	32A–37A
S–EB–S (pure)	4.1–6.2	0.91	65A–75A
S–B–S (compounds)	2.0–3.3	0.9–1.1	40A–45D
S–EB–S (compounds)	2.8–5.0	0.9–1.2	5A–60D
Multiblock Copolymers			
Polyurethane/elastomer block copolymers	5.0–8.3	1.05–1.25	70A–75D[b]
Polyester/elastomer block copolymers	6.1–8.3	1.15–1.40	35D–80D
Polyamide/elastomer block copolymers	9.9–12	1.0–1.15	60A–65D
Polyethylene/poly(α-olefin) block copolymers	1.8–2.4	0.85–0.90	65A–85A
Polyethimide/polysiloxane block copolymers	44	1.2	70D
Hard polymer/elastomer combinations			
Polypropylene/EPDM or EPR blends	1.8–2.7	0.9–1.0	60A–65D
Polypropylene/EPDM dynamic vulcanizates	3.6–6.6	0.95–1.0	35A–50D
Polypropylene/butyl rubber dynamic vulcanizates	4.6–7.9	0.95–1.0	50A–80D
Polypropylene/natural rubber dynamic vulcanizates	3.1–3.5	1.0–1.05	60A–45D
Polypropylene/nitrile rubber dynamic vulcanizates	4.4–5.5	1.0–1.1	70A–50D
PVC/nitrile rubber/DOP blends	2.9–3.3	1.20–1.33	50A–90A
Halogenated polyolefin/ethylene interpolymer blends	4.9–6.1	1.10–1.25	50A–80A

[a]These price and property ranges do not include fire-retardant grades or highly filled materials for sound deadening.
[b]As low as 60A when plasticized.

Styrenic Block Copolymers. In all their commercial application, the styrenic block copolymers are never used as pure materials. Instead, they are compounded with other polymers, oils, fillers, resins, etc, to give materials designed for the specific end use.

Substitute for Conventional Vulcanized Rubbers. For this application, the products are processed by techniques and equipment developed for conventional thermoplastics, ie, injection molding, extrusion, etc. The S–B–S and S–EB–S polymers are preferred (small amounts of S–EP–S are also used). To obtain a satisfactory balance of properties, they must be compounded with oils, fillers, or other polymers; compounding reduces costs. Compounding ingredients and their effects on properties are given in Table 9. Oils with high aromatic content should be avoided because they plasticize the polystyrene domains. Polystyrene is often used as an ingredient in S–B–S-based compounds; it makes the products harder and improves their processibility. In S–EB–S-based compounds, crystalline polyolefins such as polypropylene are preferred. Some work has been reported on blends of

Table 6. Some Trade Names of Thermoplastic Elastomers Based on Styrenic Block Copolymers

Trade name (Manufacturer)	Type	Elastomer segment	Notes
KRATON D (Kraton Polymers)[a]	Linear and branched	B or I	General purpose, soluble. Also compounded products
VECTOR (Dexco)[b]	Linear and branched	B or I	
SOLPRENE[c] (Phillips)	Branched	B or I	
TAIPOL (Taiwan Synthetic Rubber Company)	Linear and branched	B or I	
QUINTAC (Nippon Zeon)	Linear and branched	I	
FINAPRENE (Fina)	Linear	B	General purpose, soluble.
COPERBO (Petroflex)	Linear	B	Not available as compounded
TUFPRENE & ASAPRENE (Asahi)	Linear	B	products
CALPRENE (Dynasol)	Linear and branched	B	
KIBITON (Chi Mei)	Branched	B	
EUROPRENE SOL T (Enichem)	Linear and branched	B or I	
STEREON (Firestone)	Linear	B	High polystyrene content
K-RESIN (Phillips)	Branched	B	Very high polystyrene content. Hard and rigid
KRATON G (Kraton Polymers)[a]	Linear	EB or EP	
SEPTON (Kuraray)	Linear	EB or EP	Improved stability. Soluble
TUFTEC (Asahi)	Linear	EB	when uncompounded
CALPRENE H (Dynasol)	Linear	EB	
DYNAFLEX (GLS)	Linear	B or EB	
MULTI-FLEX (Multibase)	Linear	EB	
HERCUPRENE[d] (J-VON)	Linear	B or EB	Only compounded products
FLEXPRENE (Teknor Apex)	Linear	B	
TEKRON (Teknor Apex)	Linear	EB	
ELEXAR (Teknor Apex)[a]	Linear	EB	Wire and cable compounds
C-FLEX (Concept)[e]	Linear	EB	Medical applications. Contains silicon oil

[a] Formerly produced by Shell.
[b] Joint venture of Dow and Exxon.
[c] No longer made in the United States. Similar products are produced by Taiwan Synthetic Rubber and Enichem.
[d] Formerly produced by J-PLAST.
[e] Now Consolidated Polymer Technologies Inc.

liquid polysiloxanes (silicone oils) with S–EB–S block copolymers (35). The products are primarily intended for medical and pharmaceutical-type applications. Compounds based on S–EB–S with hardnesses as low as 5 on the Shore A scale have been reported (50).

Table 7. Some Trade Names of Thermoplastic Elastomers Based on Multiblock Copolymers

Trade name (Manufacturer)	Hard segment	Elastomer segment	Notes
ESTANE (B.F. Goodrich) MORTHANE[a] (Morton International) PELLETHANE[a] (Dow) ELASTOLLAN (BASF) DESMOPAN and TEXIN (Bayer)[b]	Polyurethane	Polyether or amorphous polyester	Hard and Tough. Abrasion and oil resistant. Good tear strength
HYTREL (DuPont) LOMOD (DSM)[c] URAFIL (Akzo) RITEFLEX (Hoechst) ECDEL (Eastman) ARNITEL (DSM)	Polyester	Polyether	Similar to polyurethanes but more expensive. Better low temperature flexibility. Low hysteresis. Fairly high cost
PEBAX (Elf Atochem) VESTAMIDE (Huls) GRILAMID and GRILON (EMS America)	Polyamide	Polyether or amorphous Polyester	Similar to polyurethanes but can be softer. Good low temperature flexibility Expensive
ENGAGE & AFFINITY(Dow) EXACT (Exxon) FLEXOMER (Union Carbide)	Polyethylene	Poly(α-olefins)	Flexible and low cost. Good low temperature flexibility. Limited at higher temperatures
SILTEM (GE)	Poly(etherimide)	Polysilicone	Fire resistant. Very high cost

[a]Including some with polycarprolactone segments.
[b]Formerly marketed by Mobay and Miles.
[c]Formerly GE.

Large amounts of inert fillers, such as whiting, talc, and clays, can be added. Very dense fillers, such as barium or strontium sulfates, are used to make compounds intended for sound-deadening applications. In contrast, high levels of reinforcing fillers, such as carbon black, produce undesirable properties in the final product.

A large volume usage of S–B–S-based compounds is in footwear. Canvas footwear, such as sneakers and unit soles, can be made by injection molding. Frictional properties resemble those of conventionally vulcanized rubbers and are superior to those of the flexible thermoplastics, such as plasticized poly(vinyl chloride). The products remain flexible under cold conditions because of the good low temperature properties of the polybutadiene segment.

Table 8. Some Trade Names of Thermoplastic Elastomers Based on Hard Polymer/Elastomer Combinations

Trade name (Manufacturer)	Type	Hard polymer	Elastomer	Notes
REN-FLEX (D&S)[a] HIFAX (Himont) POLYTROPE (Schulmam) TELCAR (Teknor Apex) FERROFLEX (Ferro) FLEXOTHENE (Equistar)[b]	Blend	Polypropylene	EPDM or EPR	Relatively hard, low density, not highly filled
SANTOPRENE (AES)[c] SARLINK 3000 & 4000 (Novacor)[d] NIPRENE (Teknor Apex) HIFAX MXL (Himont)	DV[e]	Polypropylene	EPDM	Better oil resistace, low compression set, softer
TREFSIN (AES) and SARLINK 2000 (Novacor)[d]	DV	Polypropylene	Butyl Rubber	Low permeability, high damping
VYRAM (AES)	DV	Polypropylene	Natural Rubber	Low cost
GEOLAST (AES)	DV	Polypropylene	Nitrile Rubber	Oil resistant
ALCRYN (Advanced Polymer Alloys)[f]	Blend	Halogenated Polyolefin	Ethylene Interpolymer	Single phase, oil resistant
SARLINK 1000 (Novacor)[d]	DV	PVC	Nitrile Rubber	Oil Resistant

[a] A joint venture between Dexter and Solvay.
[b] Formerly Quantum. Product is a blend of PP and EPR produced in the polymerization reactor.
[c] Advanced Elastomer Sytems—a joint venture between Solutia (formerly Monsanto) and Exxon Chemical.
[d] Now a part of DSM.
[e] Dynamic Vulcanizate—a composition in which the soft phase has been dynamically vulcanized, i.e., cross-linked during mixing.
[f] Formerly DuPont.

Compounds based on S–EB–S usually contain polypropylene, which improves solvent resistance and processibility and raises upper service temperatures. Compounds intended for use in the automotive industry are able to survive 1000 h of air exposure at temperatures of 125°C with only minor changes in properties (51). Very soft compounds have been developed to replace foam rubber for interior trim parts. In this and similar applications, these soft compounds are usually insert-molded over polypropylene or metal and then coated with flexible polyurethane paint (52). Other automotive applications include products intended

Table 9. Compounding Styrenic Block Copolymers

	Component				
Properties	Oils	Polystyrene	Polyethylene	Polypropylene	Fillers
Hardness	Decreases	Increases	Increases	Increases	Small increase
Processibility	Improves	Improves	Improves	Improves, especially with S–EB–S	Improves
Effect on oil resistance	None	None	Improves	Improves	None
Cost	Decreases	Decreases	Decreases	Decreases	Decreases
Other	Decreases uv resistance		Often gives satin finish	Improves high temperature properties	Often improves surface appearance

Table 10. Resins Used to Formulate Adhesives, Sealants, etc from Styrenic Block Copolymers

Resin type	Segment compatibility[a]
Polymerized C_5 resins (synthetic polyterpenes)	I
Hydrogenated rosin esters	B
Saturated hydrocarbon resins	EB
Naphthenic oils	I, B
Paraffinic oils	EB
Low molecular weight polybutenes	EB
Aromatic resins	S

[a] I indicates compatible with polyisoprene segments; B, compatible with polybutadiene segments; EB, compatible with poly(ethylene–butylene) segments; and S, compatible with polystyrene segments.

for sound deadening, flexible air ducts, and gear shifter boots, as well as improving the properties of sheet molding compounds.

Other uses for which special compounds have been developed include materials intended for food contact, wire insulation, and pharmaceutical applications.

Commercial products have hardnesses from 5 on the Shore A scale (which is extremely soft) to 45 on the Shore D scale (almost leathery). Specific gravities usually range from 0.9 to 1.20; some products intended for soundproofing have specific gravities as high as 1.95. Processing is relatively easy. In general, products based on S–B–S are processed under conditions appropriate for polystyrene, whereas products based on S–EB–S are processed under conditions appropriate for polypropylene. Predrying is usually not needed and scrap is recycled.

Adhesives, Coatings, and Sealants. For these applications, styrenic block copolymers must be compounded with resins and oils (Table 10) to obtain the desired properties (53–56). Materials compatible with the elastomer segments

soften the final product and give tack, whereas materials compatible with the polystyrene segments impart hardness. The latter are usually styrenic resins with relatively high softening points. Materials with low softening points are to be avoided, as are aromatic oils, since they plasticize the polystyrene domains and reduce the upper service temperature of the final products.

These resins and oils have low molecular weights, ie, typically below 1000. This, combined with the relatively low molecular weights of the styrenic block copolymers, typically 40,000–150,000, allows solutions in common solvents to be formulated at high solids levels. Alternatively, the products can be applied as hot melts, with considerable advantages in terms of safety, production rates, energy consumption, and air pollution.

Blends with Other Polymeric Materials. Styrenic block copolymers are technologically compatible with a surprisingly wide range of materials and can be blended to give useful products (57,58). Blending can often be carried out on the equipment producing the final article. Blends of S–B–S with polystyrene, polyethylene, or polypropylene show improved impact and tear resistance. Both S–B–S and S–EB–S can be blended with poly(phenylene oxide) to improve impact resistance (59). S–EB–S can also be blended with the less polar engineering thermoplastics such as polycarbonates. An unusual feature of these block copolymers is their ability to enable useful blends to be made from incompatible polymers, eg, polystyrene or poly(butylene terephthalate) with polyethylene (60). Another development is the use of functionalized S–EB–S block copolymers as impact modifiers for more polar engineering thermoplastics such as polyesters and polyamides (58). The functionality is given by maleic acid/anhydride groups grafted to the S–EB–S polymer chain. These functionalized S–EB–S block copolymers have also been found useful in the compatibilization of polyolefins with polyamides (61) and with poly(phenylene oxide) (62).

Special grades of styrenic block copolymers are useful modifiers for sheet molding compounds based on thermoset polyesters. They improve surface appearance, impact resistance, and hot strength.

Blends with Asphalts. Blends with styrenic block copolymers improve the flexibility of bitumens and asphalts. The block copolymer content of these blends is usually less than 20%; even as little as 3% can make significant differences to the properties of asphalt. The block copolymers make the products more flexible, especially at low temperatures, and increase their softening point. They generally decrease the penetration and reduce the tendency to flow at high service temperatures; and they also increase the stiffness, tensile strength, ductility, and elastic recovery of the final products. Melt viscosities at processing temperatures remain relatively low so the materials are still easy to apply. As the polymer concentration is increased to about 5%, an interconnected polymer network is formed. At this point the nature of the mixture changes from an asphalt modified by a polymer to a polymer extended with an asphalt.

It is important to choose the correct grade of asphalt; those with a low asphaltene content and/or high aromaticity in the maltene fraction usually give the best results (63,64). Applications include road surface dressings such as chip seals (applied to hold the aggregate in place when a road is resurfaced); slurry seals; hot-mix asphalt concrete (a mixture of asphalt and aggregate used in road surfaces); road crack sealants; roofing; and other waterproofing and adhesive

applications (64–66). Because of their lower cost, S–B–S block copolymers are usually chosen for this application; but in roofing and paving applications, the S–EB–S block copolymers are also used because of better long-term aging resistance.

Oil Gels. As noted previously, the styrenic block copolymers are very compatible with mineral oils. Blends with as little as 5% of an S–EB–S block copolymer (the remainder being 90% mineral oil and 5% wax) have been described for use as cable filling compounds (67,68). These fill the voids in "bundled" telephone cables and prevent water seepage. Another potential application is toys, hand exercising grips, etc (69).

Multiblock Copolymers. Replacement of conventional vulcanized rubber is the main application for the polar polyurethane, polyester, and polyamide block copolymers. Like styrenic block copolymers, they can be molded or extruded using equipment designed for processing thermoplastics. Melt temperatures during processing are between 175 and 225°C, and predrying is essential; scrap is reusable. These polymers are mostly used as essentially pure materials, although some work on blends with various thermoplastics (12,13,15,33,34,70–72) such as plasticized and unplasticized PVC and also ABS and polycarbonate has been reported. Plasticizers intended for use with PVC have also been blended with polyester block copolymers (70).

All three types of these block copolymers are relatively hard (from 70 on the Shore A scale to 70 on the Shore D scale) with specific gravities of 1.00–1.25. Applications (12,13,15,33,34) taking advantage of toughness, abrasion resistance, flexibility, and resistance to oils and solvents include belting, hydraulic hose, tires, shoe soles, wire coatings, and automobile parts. The surface of these molded parts can be easily painted or metallized. Medical uses, such as implants, are a significant application for the polyurethane block copolymers with polyether elastomer segments (73). Blends with silicone rubbers have been described for these applications (36,37). Another application is the use of a clear polyester thermoplastic elastomer as a replacement for glass bottles in medical applications.

Some grades of polyurethane and polyester copolymers are used as hot-melt adhesives. Applications include shoe manufacture and as an adhesive interlayer in coextrusion.

The polyolefin block copolymers are lower in cost. Their suggested applications (74) include wire and cable insulation, replacements for PVC and styrenic block copolymers, and blends with polypropylene, either to improve impact resistance or as the soft phase in a hard polymer/elastomer combination. Processing conditions are similar to those for polyethylene, and thermal stability is excellent.

The polyetherimide–polysiloxane multiblock copolymers are relatively hard (about 70 on the Shore D scale). Their main application is flame-resistant wire and cable covering (21,47), where they combine very low flammability with a low level of toxic products in the smoke. This unusual and vital combination of properties justifies their relatively high price, about $44/kg, at a specific gravity of about 1.2.

Hard Polymer/Elastomer Combinations. Substitution of conventional vulcanized rubbers is the main application for these materials (24–26,33,34).

The first ones to be developed were simple blends of polypropylene and EPDM, made by conventional mixing of the two components (24,25,49). EPR has largly replaced EPDM in this application because of its lower cost. These simple blends had some limitation, because unvulcanized EPDM or EPR has almost no tensile strength or oil resistance. Thus only fairly hard products, ie, those containing small amounts of these elastomers, had satisfactory properties and so the first products of this type had hardness values in the Shore D range (although somewhat softer versions are now available). In later work, products based on dynamic vulcanization (26) were produced. In this process, the elastomer, typically EPDM, is simultaneously cross-linked and mixed into the hard polymer, typically polypropylene. The result is a very fine dispersion of vulcanized elastomer particles in a hard polymer matrix. The improved properties of the elastomer phase allow much higher levels to be used, giving quite soft products (as low as about 35 on the Shore A scale). Compared to the mixtures of EPDM or EPR with polypropylene, the corresponding dynamic vulcanizates have lower compression set and better oil resistance. Natural (29) and butyl rubbers (28) have been used to replace EPDM in similar dynamically vulcanized products. Those based on natural rubber are low in cost and have properties intermediate between the EPDM-based dynamic vulcanizates and the simple EPDM-based mixtures. Those based on butyl rubber have low gas permeability and high damping, thus they can be used as vapor barriers or vibration isolators. An unexpected property advantage with those based on butyl rubber is that some grades show excellent adhesion when insert-molded against such polar engineering thermoplastics as poly(butylene terephthalate) and polyamides (75). Specific gravities of these various combinations of polypropylene with EPDM, EPR, butyl, and natural rubbers are between about 0.9 and 1.05. Molding and extrusion conditions are similar to those used for polypropylene, and the scrap is reusable. Important applications are wire insulation, appliance parts, and automobile exterior and interior parts (both painted and unpainted).

Even though vulcanized EPDM has some oil resistance, in contrast to unvulcanized EPDM which has virtually none, a rubber with inherent oil resistance should be even better. For this reason, more polar rubbers have replaced EPDM in applications where oil resistance is critical. Dynamic vulcanizates of nitrile rubber with polypropylene are the most important example. Commercial grades are somewhat harder than EPDM equivalents (between 70 on the Shore A scale to 40 on the Shore D scale) and are also more dense (about 1.0–1.1 specific gravity) (26,49).

PVC/nitrile rubber blends usually contain plasticizers such as dioctyl phthalate (30). Similar dynamic vulcanizates appear to be less important commercially. These blends have excellent oil resistance as well as resistance to flex cracking and abrasion (31–34). Hardness ranges from about 50 to 90 on the Shore A scale and specific gravity from about 1.2 to 1.3. Processing is basically similar to that of plasticized PVC. Blends of halogenated polyolefins with ethylene interpolymers are claimed to give single-phase systems (30). They have a very rubber-like feel and are similar to the PVC/nitrile rubber combinations as far as processing, hardness, and specific gravity are concerned. Like them, they have good oil resistance. All these products based on the more polar rubbers are often used in

molded appliance, automotive, and similar rubber-like parts where oil resistance is needed at a reasonable cost.

Health and Safety

Most thermoplastic elastomers are stable materials and decompose only slowly under normal processing conditions. If decomposition does occur, the products are usually not particularly hazardous and should not present a problem if good ventilation is provided. Products based on PVC and halogenated polyolefins are exceptions, and care should be taken to avoid overheating these materials. Extra caution should also be exercised when processing polyurethanes, especially those containing polycaprolactone segments. In these cases the decomposition products may include isocyanates and caprolactam, both of which are potential carcinogens.

Of course, all materials that are processed in the molten state can cause burns if the hot material comes in contact with the skin. Care must be taken to avoid this, and it should be noted that molten material left in the barrel of an extruder or injection-molding machine can "spit" unexpectedly. In all cases, it is recommended that the manufacturer's Material Safety Data Sheet be consulted before working with any of these materials.

Reprocessing

Easy reprocessing is one of the great advantages that thermoplastic elastomers have over conventional vulcanized rubbers. The scrap can be reground and is usually blended with virgin material before being reworked. Regrinding is not difficult if it is remembered that rubber must be cut rather than shattered. This means that the cutter blades must be sharp and clearances minimized. Immediately after regrinding, softer products should be dusted with an antiblocking agent. It is usually best to dry the ground scrap before reworking it, and for the polyurethanes, polyesters, and polyamides, drying is a necessity. Thermoplastic elastomers can also be used to "sweeten" regrind; that is, they can be blended with reground scrap from conventional thermoplastics to restore impact strength and reduce brittleness. Many applications, eg, coextrusion, generate mixed scrap, which usually has very poor properties. Thermoplastic elastomers can often convert this into useful material (60–62).

ELECTRICALLY ACTIVE POLYMERS

Introduction

The discovery that polyacetylene doped with iodine exhibited electrical conductivity many orders of magnitude higher than neutral polyacetylene was made in 1976 by Hideki Shirakawa, Alan MacDiarmid, and Alan Heeger; they received the 2000 Nobel Prize in Chemistry (1,2) for their work in this area. This discovery triggered the development of a new multidisciplinary field known as "synthetic metals" (3). The field of synthetic metals is at the crossroads of chemistry, physics, materials science and engineering, and biomedical engineering. This discovery marked what has been described as the "fourth generation of polymeric materials" (4). Since the early pioneering work of Shirakawa, MacDiarmid, and Heeger, numerous additional developments and discoveries in conductive polymers have occurred. As a result, the field of plastic electronics and photonics has matured to offer the promise of a wide range of novel applications exploiting the unique chemical, physical, and electrical properties of conductive polymers.

In order to begin describing electrically conductive polymers, several definitions of conductive polymers must be presented. There are four major classes of conducting polymers: filled polymers, ionically conducting polymers, charge-transfer polymers, and electrically conducting polymers (ECPs).

Filled polymers are intrinsically nonconductive polymers loaded with conductive fillers such as carbon black, graphite fiber, metal particles, or metal oxide particles (5–9). Filled polymers have the longest history and broadest application in electronic devices. These materials have been used since the 1930s in the prevention of corona discharge and later in advanced printed circuitries. The extensive use of these materials lies in their ease of processing, wide range of electrical properties, and relatively low cost. However, these materials are inhomogeneous,

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

containing three distinct phases: polymer, filler, and interface. This inhomogeneity results in a lack of reproducibility, a heavy process dependency, and a steep percolation threshold in conductivity (see CONDUCTIVE POLYMER COMPOSITES).

Ionically conducting polymers, also called ionomers (qv) or polyelectrolytes (qv), have been known for more than 30 years; several excellent reviews are available (10–13). These materials have found a wide range of potential commercial applications including rechargeable batteries (14,15), fuel cells (16,17), and polymer light-emitting devices (18). Ionic polymers are highly processable and can be synthesized using a wide variety of approaches. The major drawback to these materials is their sensitivity to moisture and humidity.

Charge-transfer materials were first investigated during the 1950s with the discovery of electrical conductivity on the order of 10^3 S/cm (19) in molecular charge-transfer complexes. In the 1960s a similar observation was made with iodine-doped poly(vinyl carbazole) (PVK) (20,21). The addition of an oxidant such as $SbCl_5$ and/or tri-(*p*-bromophenyl)ammonium hexachloroantimonate) to a charge-transport polymer (PVK) has produced materials that are known as semiconducting charge-transfer polymers (22). By varying the oxidant and charge-transport polymer combinations, various semiconducting polymers have been produced (23,24). The conductivity of these materials can be readily tuned by adjusting the concentrations of the charge transport group and oxidant. These materials offer many advantages as a result of their wide range of conductivities, high stability, excellent wear resistance, and high dielectric strength. However, the major drawback to these materials has been their low conductivities. The highest conductivities of polymeric charge-transfer materials have been only on the order of 10^{-5} S/cm (25).

The final materials to be discussed are intrinsically conducting/electrically conducting polymers (ICPs/ECPs) and/or electrically active polymers, which will be the focus of this review. While these terms have been used interchangeably, ICPs/ECPs are by definition conductive; electrically active polymers include ICPs/ECPs as well as conjugated but poorly conductive polymers. Throughout this article, the term electrically active polymers (EAPs) will be used to describe conjugated polymers, regardless of conductivity. EAPs are composed of conjugated polymer chains with delocalized π-electrons along the polymer backbone.

EAPs are either insulating or semiconducting in the undoped or neutral form. These neutral polymers are converted to the electrically conductive or doped forms by oxidation or reduction reactions, which form delocalized charge carriers. To maintain charge balance in such systems, an oppositely charged counterion is required. The conductivity of these materials is electronic in nature; there is no concurrent ion migration occurring in the polymer solid state, and the doping processes are reversible. These redox doping processes can be achieved by chemical and/or electrochemical methods. Thus, the conductivities of EAPs range from those of insulators ($<10^{-10}$ S/cm), to semiconductors like silicon ($\sim 10^{-5}$ S/cm), and as high as metals such as copper ($>10^4$ S/cm) (Table 1) (26,27).

There are many excellent reviews of EAPs that the reader is encouraged to examine that chronicle the historical achievements in this field of chemistry since 1976 (17,28–42). This article will review the synthesis, properties, and applications of redox-dopable electrically conducting polymers. Several specific examples will be used to illustrate general concepts and principles.

Table 1. Comparison of Electrical Conductivities of Insulators, Semiconductors, Metals, and EAPs[a]

Materials	Conductivity ($\log\sigma$), S/cm	EAPs	Classification
Ag, Cu, Pt	6		Metal
Fe	5	*d*-Polypyrrole,[b] *d*-polythiophene,[b] m*d*-poly(*para*-phenylene),[b] and *d*-polyacetylene	Metal
Bismuth	4	*d*-Polyaniline	Metal
InSb	1	*d*-Poly(phenylene sulfide)[b]	Semiconductor
Germanium	−2	trans-Polyacetylene	Semiconductor
Silicon	−5	trans-Polyacetylene	Semiconductor
Silicon bromide	−8	cis-Polyacetylene	Insulator
Glass	−10	Polyaniline	Insulator
DNA	−12		Insulator
Diamond	−14	Polythiophene, polypyrrole	Insulator
Nylon	−14		Insulator
Sulfur	−16		Insulator
Teflon/quartz	−18	Polystyrene	Insulator

Synthesis of Electrically Active Polymers

The number of new conducting polymer structures that are reported in the open literature continues to grow at nearly 500 articles per month. This incredible amount of research devoted to the study of EAPs attests to their unique scientific properties and their potential widespread use in commercial applications. In order to fully exploit their potential applications one must begin with their synthesis and properties.

The synthetic routes that have been developed for the preparation of conjugated polymers are diverse. This diversity is driven in part by the desire to develop substitutes for metallic conductors and semiconductors, but other properties unique to EAPs have also attracted intense interest. The effort to synthesize materials with tailor-made properties has been and continues to be pursued by hundreds of research groups. These researchers are seeking to develop EAP materials and improve their electrical, mechanical, optical, processing, and thermal properties. New EAP device concepts are being used to incorporate the most promising EAP material solutions.

Currently, there are several classes of EAPs that have been shown to exhibit conductivities of metals and semiconductors in the doped state. They are the polyacetylenes, poly(para-phenylene)s, polyheterocycles, poly(phenylene vinylene)s, polyanilines, and conjugated ladder polymers. Conducting polymers are made by both chemical and electrochemical polymerization. In the neutral (uncharged) state, EAPs are insulators or semiconductors. Oxidized (p-doped) EAPs have had electrons removed from the backbone, resulting in delocalized polymer cation formation. Reduced (n-doped) EAPs have had electrons added to the backbone, resulting in polymer anion formation.

The most stable (and therefore the most intensely studied) EAPs are the oxidized, cationic salts of highly conjugated polymers, although stability varies widely with chemical composition. Some cationic salts are quite stable in air (40), while others are highly reactive. The cationic salts (or p-doped polymers) are obtained by oxidation (chemical or electrochemical) of neutral polymers or of monomers. Chemical oxidation in this context refers to the removal of electrons using a chemical oxidant such as ferric chloride (43), whereas electrochemical oxidation occurs under an applied potential in the presence of an electrolyte (44). Anionic salts (n-doped polymers) can also be prepared from highly conjugated polymers by electrochemical reduction or treatment with reagents such as sodium naphthalide. However, the anionic salts, while conducting, are typically less stable than their cationic counterparts because they can react with air and water (45). Stability of both cationic and anionic salts of EAPs varies significantly with chemical composition.

Electropolymerization offers several advantageous features. Simple monomer oxidation (or more rarely, reduction) results in rapid synthesis of the doped, conducting form of the polymer adhered to the electrode surface, thus simplifying isolation and purification. Film thickness is easy to control, and patterned electrodes can be used for precise placement of the polymer. No catalyst is necessary, and aqueous polymerization is possible with a wide variety of monomers, so electropolymerization can be an environmentally friendly process. Disadvantages of electropolymerization include the relatively small scale of the reactions and the need for expensive equipment; additionally, some monomers do not polymerize electrochemically.

Polyacetylenes. Polyacetylene, one of the most studied of the EAPs, possesses the simplest EAP structure, consisting of alternating single and double carbon–carbon bonds, in either a cisoid or transoid configuration. (Fig. 1). The transoid configuration is thermodynamically favored, but cis–trans isomerization is a reversible process.

The first reported synthesis of polyacetylene was by Natta and co-workers in 1958 (46). For many years this polymer remained a material of limited interest to organic/polymer chemists and theoreticians because of its poor processability (47,48). However, Ito and co-workers discovered a synthetic route for making high quality flexible films of polyacetylene in 1974 (49). This discovery and the subsequent discovery that the electrical conductivity of doped polyacetylene could

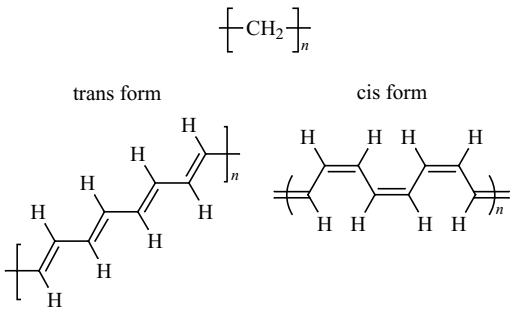

Fig. 1. Structure of polyacetylene.

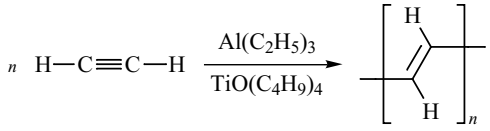
be increased from the semiconductor form to the metallic form ushered in the current field of EAPs (1,50,51). This synthetic process is known as the Shirakawa technique. The technique involves the polymerization of acetylene on a thin-film coating of a heterogeneous Ziegler–Natta initiator system (eq. 1), which consists of a combination of $Ti(O\text{-}n\text{-}C_4H_9)_4$ and $(C_2H_5)_3Al$. The initiator is soluble in organic solvents and is highly active for acetylene. The process produces mechanically strong, free-standing films of polyacetylene. The reagents are commercially available, allowing for low cost production.



(1)

The films obtained from these early studies were insoluble in all solvents and infusible, so structural characterization was not possible. The films had conductivities about 0.5 and 38 S/cm when doped with bromine and iodine, respectively (1,2,51), and 560 S/cm when doped with AsF_5 (52). Both the conducting and the insulating forms of these films are unstable in air. There have been numerous attempts to improve the conductivities of doped polyacetylene films and the synthetic methods leading to higher quality films. There are now several routes by which high quality polyacetylene can be prepared. Shirakawa has recently published an excellent review of synthetic approaches to polyacetylene (53).

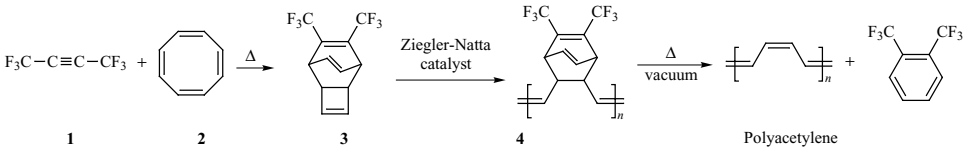
There are a wide variety of Ziegler–Natta, Luttenger, and metathesis catalysts that are very effective in the polymerization of acetylene; however, some of these catalysts produce undesireable by-products during the polymerization. Careful selection of the catalyst is important to produce good yields of high quality polyacetylene. Heterogenous catalysts are almost always employed to allow easy removal of the residual catalyst from the polymer.

The polymerization of acetylene with Luttinger catalysts was first carried out in the 1960s (47,54). The Luttinger catalyst consists of a hydridic reducing agent such as sodium borohydride and a salt or complex of a group VIII metal such as nickel chloride. This synthetic technique produces high molecular weight polyacetylene with no byproduct formation. It is easier to handle experimentally than the Ziegler–Natta or metathesis processes; hydrophilic solvents can be employed. In contrast, the Ziegler–Natta and metathesis processes require vigorously dehydrated hydrocarbon reagents and the rigorous exclusion of air and moisture. The catalytic activity of the Luttinger catalysts is much lower than that of the Ziegler–Natta catalysts, and high quality films of polyacetylene are typically difficult to obtain. However, Lieser and co-workers prepared high quality thin films of cis-rich polyacetylenes that showed no difference in morphology from those obtained using a Ziegler–Natta catalyst (55).

The polymerization of acetylene using metathesis catalysts was carried out by Aldissi and co-workers (56). Uniform films were prepared using a concentrated solution of a soluble catalyst in toluene. Polyacetylene has also been produced using Rh and Re catalysts (57,58). The chlorine-bridged Rh(I) complexes such as $[Rh(COD)Cl]_2$ and $Rh(NBD)Cl]_2$ where COD is cycloocta-1,5-diene and NBD

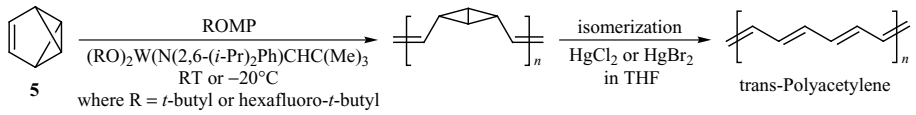
is bicyclo[2.2.1]hepta-2,5-diene with sodium ethoxide as cocatalyst produce polyacetylene as solid flakes. These catalysts are similar to the Luttinger catalyst in that they are stable in air and their catalytic ability is not inhibited by the presence of oxygen or moisture. Acetylene has also been polymerized by electrochemical methods (59), on the surface of metal oxides such as rutile (TiO_2) (60) and γ-alumina (γ-Al_2O_3) (61), and in the presence of a catalytic amount of AsF_5 at -75 to -198°C (62). Several miscellanous techniques have also been employed to polymerize acetylene, such as irradiation with γ-rays from a ^{60}Co source (63) and high pressure (64).

Each of the above techniques has resulted in high quality polyacetylene films. The major drawback for these techniques has been the intractable nature of polyacetylene, resulting in difficulties in purification, characterization, and processing. To eliminate these processability problems, it is necessary to employ a precursor route such as the widely studied Durham method to polyacetylene (65,66). In this process, an acetone-soluble precursor polymer is formed; processing occurs in this phase of the synthesis before conversion to the intractable polyacetylene. This approach is shown in equation 2.



(2)

Monomer synthesis is first accomplished by the thermal reaction of hexafluorobut-2-yne (**1**) with 1,3,5,7-cyclooctatetraene (COT) (**2**) to yield 7,8-bis(trifluoromethyl)tricyclo-[4.2.2.$0^{2,5}$]deca-3,7,9-triene (**3**). Ring-opening metathesis polymerization of **3** using a catalyst such as WCl_6–$(C_2H_5)_4Sn$ (W/Sn = 1:2) gives a cis/trans mixture of polyacetylene after thermal treatment of (**4**). The classical Ziegler–Natta catalyst such as $TiCl_4$-$(C_2H_5)_3Al$(Ti/Al = 1:2) gives the precursor polymer (**1**). Low temperature (ca 60°C) thermal elimination gives predominantly *cis*-polyacetylene, while higher temperatures yield the predominantly trans polymer. The major problem with the Durham method and other precursor routes is the neccessity of eliminating a large molecule during the thermal process. An alternative precursor method developed to eliminate this problem is the ring-opening metathesis polymerization (ROMP) of the highly reactive and commercially available monomer benzvalene (**5**) (67). The reaction is shown in equation 3.



(3)

A method has been developed recently to eliminate the thermal process for producing polyacetylene films. This technique is a liquid-crystal polymerization

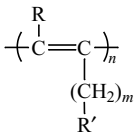


Fig. 2. Functional modifications of polyacetylene. Where R = H, alkyl, aryl; R′ = alkyl, aryl, ester, ether, amine, thienyl, cyano, vinyl, ethynyl, alkyl ammonium; $m = 0, 2$.

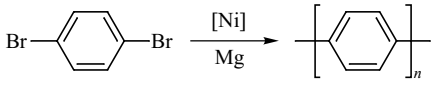
method, which allows oriented films to be prepared directly through an anisotropic reaction field (68–70). The field is produced by macroscopically orientated nematic liquid crystals, which are used as the polymerization solvent for a Ziegler–Natta catalyst. This technique yields highly oriented films in the trans configuration. This process produces polyacetylene with good conductivity (10^4 s/cm) without the need for thermal treatment and stretching, which causes defects and breaks fibrils in films.

Although most of the previous approaches have been directed at the synthesis of polyacetylene, much additional work has gone into the synthesis of derivatized polyacetylene (see ACETYLENIC POLYMERS, SUBSTITUTED). Incorporation of side groups, either before or after polymerization, is commonly used to improve solubility (71) and impart functionality. Functional groups such as ester, ether, amine, thienyl, cyano, vinyl, ethynyl (72,73), aryl (74), and ionic substituents such as pyridinium (75), alkyl sulfonates (76), and alkyl ammoniums (76) also yield soluble polymers (Fig. 2). In most cases, solubility increases are accompanied by decreases in conductivity due to loss of conjugation resulting from unfavorable steric interactions (75). Liquid crystalline groups are incorporated to increase order in the polymer, with alignment resulting in improved conductivity, reduced band gaps, and interesting photoresponsive properties (77,78).

Poly(*para*-phenylene). Poly(*para*-phenylene) (PPP) can be synthesized by both direct (79) and indirect methods (80). A comprehensive review of these synthetic routes has been presented by Schluter (81).

The direct approach consists of using monomers that contain a phenylene group that becomes the repeat unit of the final polymer. In the indirect approach, a precursor polymer is synthesized first, and the PPP is obtained after thermal treatment. Both approaches have serious drawbacks. In the direct approach, regioirregularities often result from the coupling reactions, as do low molecular weights, cross-linking, and other side reactions. In the indirect approach, structural irregularities contained in the precursor polymer are transplanted into the final product, and there are very few suitable precursor polymers available for PPP synthesis.

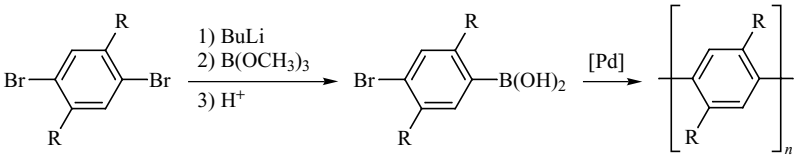
The direct approach has been demonstrated by Yamamoto (82,83); *p*-dibromobenzene was combined in a Grignard-type coupling reaction with one equivalent of magnesium in the presence of a transition-metal catalyst in THF to give a para-linked low molecular weight PPP (eq. 4). Linear poly(*p*-phenylene) and poly(*m*-phenylene) have also been obtained through a reductive coupling of *p*-dihalobenzene by electrolysis or with chemical reductants, although these materials remained insoluble and could not be completely characterized (84,85).



(4)

Several alternative direct methods have been employed to increase the molecular weight and processability of PPP. The key is the incorporation of solublizing substituents, such as long alkyl or alkoxy chains. Mullen reported the synthesis of relatively high molecular weight PPP derivatives by preparing alkylated polytetrahydropyrenes from the corresponding dibromo monomers using Ni/Mg catalysts (86). Highly soluble PPP derivatives have been obtained by oxidative copolymerization of alkoxy-substituted benzenes (87) and by polymerization of a charge-transfer (CT) complex between the monomer *N*,*N*-dimethylaniline and tetrachloro-*p*-quinone (88).

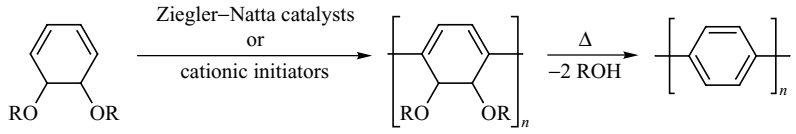
Perhaps the most successful direct approach to soluble PPPs is that pioneered by Rehahn and co-workers, first published in 1988 (89). In this method, aryl bromides are coupled with aryl boronic acids (or boronic esters) with palladium catalysts under Suzuki cross-coupling conditions (eq. 5). When the bromo and boronic acid groups are both on the same phenylene ring (**6**), the result is a homopolymer as shown in equation 5; copolymers can be prepared through reactions of dibromophenylenes with bisboronic acid substituted phenylenes. Boronic acids are typically much more stable than the corresponding Grignard compounds, allowing for purification of the intermediates and resulting in higher molecular weight polymers. This approach is now commonly used for the synthesis of soluble PPPs; an excellent review of the Suzuki polycondensation has recently been published (90).



6

(5)

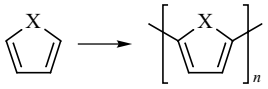
The indirect or precursor method for the preparation of PPPs was poineered by Marvel in the 1950s (91,92). Although Marvel's pioneering work produced low molecular weight precursor polymer, ICI researcher Ballard was successful in developing a monomer based on cyclohexadiene (93). The reaction sequence is shown in equation 6. The reaction starts with monomer **7**, which is a derivative of 5,6-dihydroxycyclohexa-1,3-diene and is polymerized using radical initiators to high molecular weight polymer precursors (**8**). The precursors are soluble in common organic solvents, and films and spun fibers can be produced. Thermal treatment results in elimination of the side groups to yield fully aromatic PPP, which is insoluble and intractible. An industrial process based on this chemistry was found to be impratical because the synthesis was unscaleable.



7 8 (6)

However, Ballard used a biomediated synthesis to circumvent these obstacles. The microorganism *Pseudomonous putida* 11767 oxidizes benzene within the bacterial cell (79). The dioxygenase E1 with the assistance of the protonated cocatalyst nicotinamide adenine dinucleotide (NADH) reacts with oxygen to give 5,6-dihydroxycyclohexa-1,3-diene. The organism was genetically modified in order to eliminate the aromatization step of 5,6-dihydroxycyclohexa-1,3-diene. The mild conditions of this process were found to be scaleable and are used in an industrial process. The resultant PPP has limited regio and stereospecific control during polymerization and is therefore not entirely composed of 1,4-linkages; approximately 15% 1,2-linkages result from this process.

Polyheterocycles. Heterocyclic monomers constitute a third class of monomers that can be polymerized to form fully conjugated polymers; the most common of these monomers, shown in equation 7, are pyrrole (X = NH), thiophene (X = S), and furan (X = O). They can be doped to give electrical conductivity when polymerization occurs in the 2,5-positions. These monomers can be polymerized both by electrochemical and chemical methods. The polyheterocycles have received considerable attention for their electron-rich nature, which leads to materials that are easily oxidized and therefore more stable in the oxidized state. Additionally, the increased structural complexity of polyheterocycles relative to polyacetylenes makes structural modifications possible for improved processability.



where X = O, NH, S (7)

By far the most commonly exploited polymerization of heterocycles is the oxidative polymerization, which can be carried out using chemical or electrochemical oxidation conditions. Chemical oxidative polymerization is advantageous in that the reactions are fast and simple, using relatively mild conditions (94), and polymers could presumably be mass-produced at a reasonable cost (95). Oxidation potentials depend upon the electron density of the monomers; the more electron-rich a monomer is, the easier it is to oxidize. The oxidative polymerization of thiophene is shown in Figure 3; this mechanism is equally applicable to other heterocycles. The mechanism is thought to involve a one-electron oxidation of the monomer to form a resonance-stabilized radical cation. This can couple with a molecule of starting material to form a radical cation dimer, which loses another electron to form the dicationic dimer, or the radical cation can couple with another radical cation to form a dicationic dimer. The dicationic dimer then loses two protons to form the neutral dimer, and the entire process is repeated to form polymer. The fundamental polymerization mechanism is the same for both chemical and

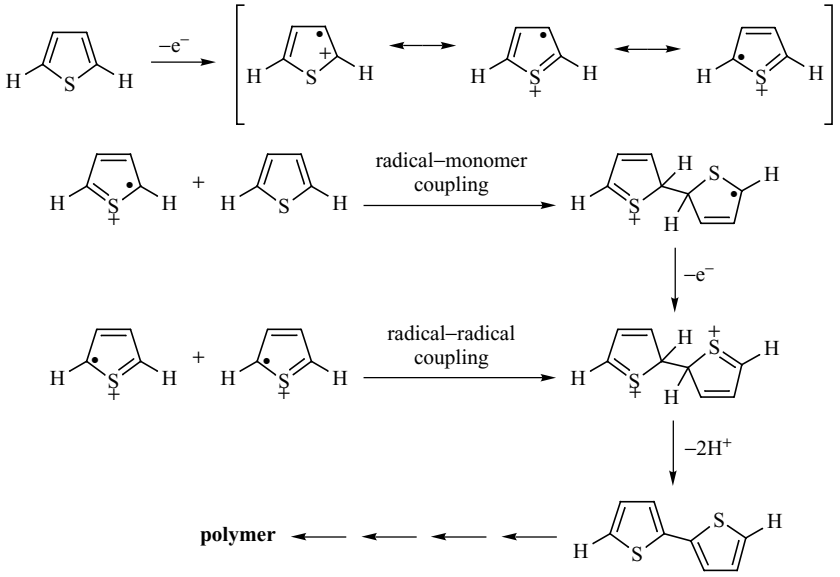


Fig. 3. Mechanism of oxidative polymerization of thiophene.

electrochemical polymerization, although there are additional factors (diffusion, scan rate, electrode characteristics, etc) that must be considered for electrochemical polymerization.

Among the problems associated with oxidative polymerization is the abundance of possible side reactions. Oxidation of the simple, unsubstituted heterocycles results in poorly soluble, poorly processable materials, so structural modifications are typically used to improve polymer properties. Often, the strong oxidation conditions required to effect polymerization cause overoxidation and decomposition. While coupling at a carbon adjacent to the heteroatom is favored, as it is the most electron-rich site, coupling is also possible at other unsubstituted carbons, and irregular polymer backbones can be formed as shown in Figure 4 for oxidative polymerization of thiophene. Coupling of heterocycles occurs predominantly through the 2- and 5-positions (α,α-coupling), but some coupling also occurs at the 3- and 4-positions to give a small amount of α,β and β,β-couplings. The mixture of couplings induces larger twist angles, reducing conjugation and yielding poor electronic properties (96). Multiple couplings on the same heterocyclic molecule can also occur, resulting in cross-linked polymers.

Coupling at β-positions during polymerization can be avoided by blocking the 3- and 4-positions of the heterocycle. If symmetrical substitution is used, problems associated with regioirregularity (see below) can be avoided. For instance, in the polymerization of 3,4-ethylenedioxythiophene (EDOT) shown below (Fig. 5), the ethylenedioxy bridge effectively prevents β-coupling, thereby yielding a linear polymer.

Polypyrroles. The first reported polymerization of pyrrole was in 1916 (97). Polypyrrole was prepared by the chemical oxidation of pyrrole using hydrogen peroxide. An amorphous black powder known as “pyrrole black” was obtained, which

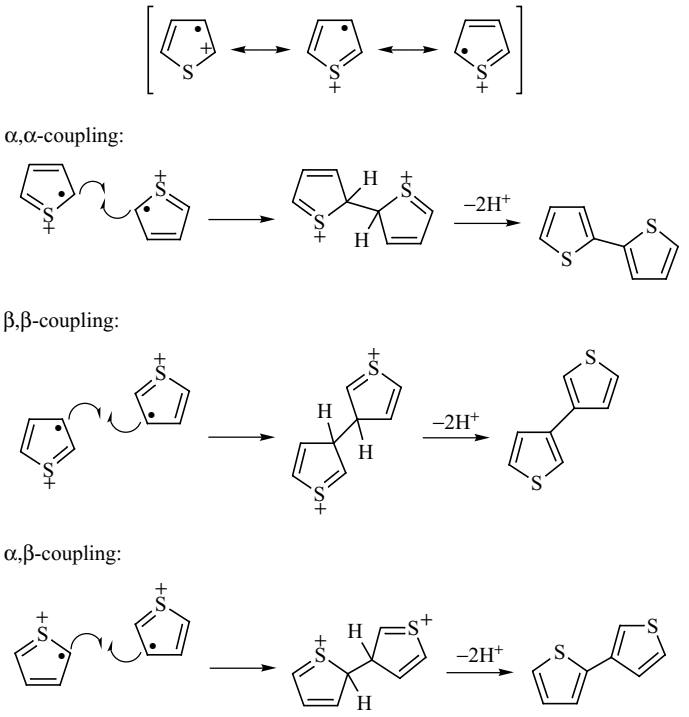

Fig. 4. Coupling pathways during oxidative polymerization of thiophene.

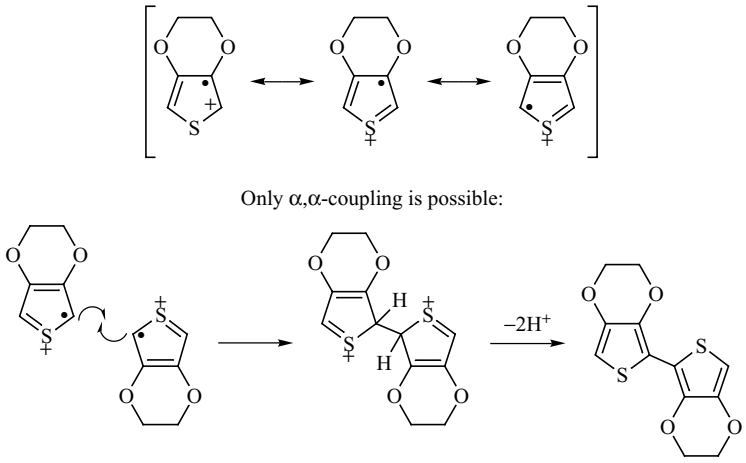

Fig. 5. Coupling pathways during oxidative polymerization of EDOT.

was insoluble in common organic solvents. One of the advantages of polypyrrole (PPy) is the low oxidation potential of pyrrole relative to other EAP precursors, facilitating oxidative polymerization; the half-wave oxidation potentials (in acetonitrile/0.5 M $NaClO_4$) of benzene, thiophene, and pyrrole are 2.08, 1.60, and

0.76 V vs Ag/Ag^+, respectively (44,98). Numerous oxidizing reagents have been used to polymerize pyrrole, including hydrogen peroxide in acetic acid, lead dioxide, ferric chloride, nitrous acid, and ozone (99,100).

The chemical oxidative polymerization of pyrrole results in low conductivities in the range of 10^{-10} to 10^{-11} S/cm, although conductivities of 10^{-5} S/cm have been reported with iodine doping (101). The low conductivities obtained from acid and peroxide initiators have been attributed (102) to the high degree of saturation of the pyrrole ring due to either oxygen incorporation and/or hydrogen saturation. The use of oxidative transition-metal ions such as ferric salts (eg $FeCl_3$, $Fe(NO_3)_3$, $Fe(ClO_4)_3$, $FeBr_3$) at low temperatures in both aqueous and organic solvents has improved the conductivities of PPy from 10^{-5} to 200 S/cm (103–106). The polymers that were obtained are infusible and insoluble powders. Approaches to produce processable PPy materials include the synthesis and polymerization of pyrrole compounds containing solubilizing groups in the 3-position (107) or attached to the nitrogen (108) as well as the use of soluble precursor molecules (109,110). Although these efforts result in improved processability of the polypyrroles, there is a concurrent loss of conductivity.

The chemical polymerization of pyrrole remains the simplest route to PPy, but electrochemical polymerization is the most important and versatile method for producing PPy films of high conductivity (111). There are numerous examples of PPy doped with a wide variety of anions that can be electrochemically polymerized on a variety of electrode materials in both aqueous and organic solvents (112–114).

Polythiophenes. Preparations of polythiophene (PT) include chemical oxidative couplings of thiophene (95), the cross-coupling of Grignard reagents of dihalothiophenes (96,115), and electrochemical polymerization (95,116). The PT powders and films that are produced either chemically or electrochemically are insoluble and infusible. In order to better characterize and process PTs, synthetic methods were developed to incorporate functional groups (such as *n*-alkyl groups) on the 3-position to improve processibility without significantly sacrificing conductivity. The synthesis of poly(3-alkylthiophene)s (P3ATs) that are chemically stable, soluble, processable, and moderately to highly conductive has been achieved by several research groups. Early work on the synthesis of P3ATs utilized the Kumada cross-coupling reaction (115), oxidative polymerization using $FeCl_3$ (116) or Cu powder with a catalytic amount of $PdCl_2$ in pyridine (118). These methods produce irregular homopolymers and copolymers of P3ATs with reasonable molecular weights and low to moderate conductivities.

Unsymmetrical monomers such as 3-alkylthiophenes are said to have a "head" (ie the 2-position of the thiophene ring) and a "tail" (ie the 5-position of the thiophene ring). Standard homopolymerization of 3-alkylthiophenes yields P3ATs that have "head-to-head" (2,2′, or H-H), "head-to-tail" (2,5′, or H-T), and "tail-to-tail" (5,5′, or T-T) bonds. Polymers having this type of bonding are said to be regioirregular, while polymers possessing purely H-T bonds are regioregular (Fig. 6). Regioirregular P3ATs are poorly conjugated, because the mixture of linkages leads to unfavorable interaction of side chains, resulting in a sterically driven twist of the polymer backbone (118). Polymer morphology is also affected by regiochemistry; regioregular polymers are typically crystalline, while regioirregular polymers are amorphous (119,120). Regioregularity problems can also be

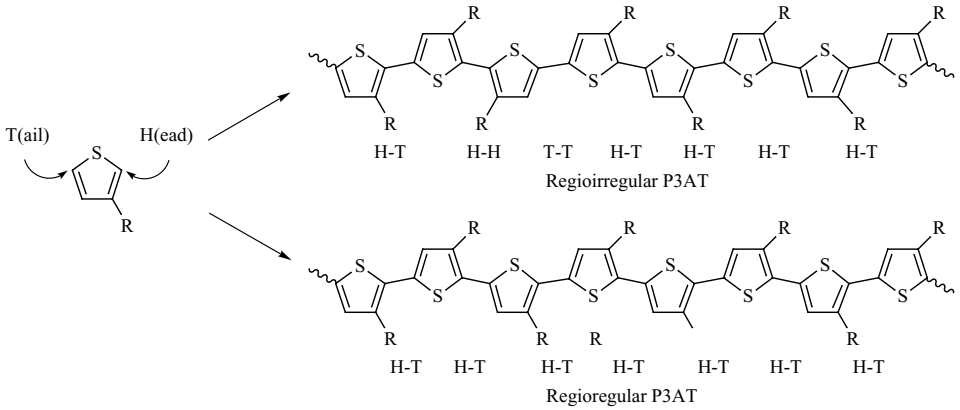

Fig. 6. Regiochemistry in poly(3-alkylthiophene).

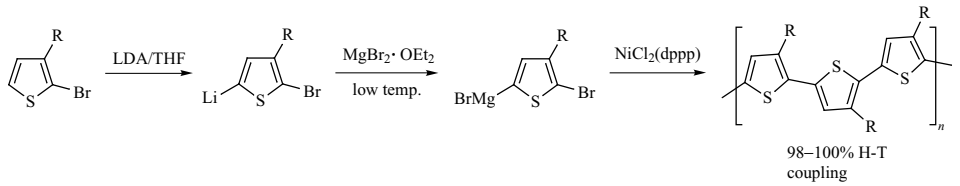
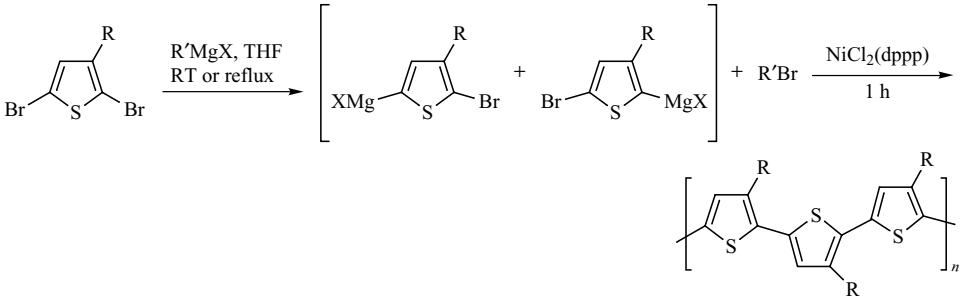
avoided by using symmetrical monomers; extended conjugation monomers such as alkyl-substituted terthiophenes (121) and mixed heterocycle extended conjugation monomers (122,123) have become commonplace (124). These extended conjugation monomers also exhibit lower oxidation potentials, and they can be designed to tailor properties for specific applications.

Several groups have demonstrated regiospecific synthetic processes for obtaining regioregular P3ATs. In the now-standard method pioneered by McCullough and Lowe (125), a monomer (2,5-dibromo-3-alkylthiophene) is reacted with lithium diisopropylamide at cryogenic temperatures, followed by transmetallation with $MgBr_2 \cdot Et_2O$. Polymerization is then accomplished using Kumada cross-coupling methods with catalytic amounts of $NiCl_2$(dppp) to give P3ATs with 98–100% H-T coupling in moderate to high yields (eq. 8) (126–128).



(8)

Since this early work by McCullough and others, improvements have been made in the synthesis of analytically pure highly regioregular H-T P3ATs without cryogenic temperatures. The Grignard metathasis (GRIM) polymerization (eq. 9) (129,130) is quick, easy, and cost-effective. The synthesis is as follows: a 2,5-dibromo-3-alkylthiophene is treated with one equivalent of an alkyl or vinyl Grignard reagent, followed by polymerization at room temperature with a catalytic amount of $NiCl_2$(dppp).



(9)

An alternative synthetic approach to the preparation of regioregular P3ATs was demonstrated by Chen and Rieke (131,132). Their method utilizes the highly reactive "Rieke zinc" (Zn∗), which is added to a solution of 2,5-dibromo-3-alkylthiophene at cryogenic temperatures. The metal reacts quantitatively to form a mixture of isomers: 2-bromo-3-alkyl-5-(bromozincio)thiophene and 2-(bromozincio)-3-alkyl-5-bromo-thiophene. The ratio between these two isomers depends on reaction temperature and the steric influence of the alkyl groups. The addition of a nickel cross-coupling catalyst leads to the formation of regioregular P3ATs (regardless of the isomer ratio), and regiorandom P3ATs are formed with the addition of a palladium cross-coupling catalyst (133).

Several additional homo-, co-, and terpolymers based on P3ATs have been synthesized recently. Monomers that incorporate two or three thiophenes such as the 4,4-dialkyl-2,2′-bithiophenes or 3,3-dialkyl-2,2′-bithiophenes with various substituent groups such as alkyl, oxyalkyl, β-aryl have been prepared by chemical and electrochemical methods (134–137).

The introduction of electron-donating substituents such as ether moieties lowers the *polymer band gap* (the energy difference between the valence and conduction bands of the polymer; for a more thorough discussion on band gap, please see under Transport Theory) by raising the energy of the valence electrons (HOMO destabilization) along the conjugated chain (138,139). These alkoxy substituents also decrease the oxidation potential of both the monomers and their polymers, allowing milder oxidative polymerization conditions, which results in fewer side reactions. Polymers based on 3,4-disubstituted thiophene derivatives such as EDOT (Fig. 5) have recently been synthesized by chemical and electrochemical methods. Poly(3,4-ethylenedioxythiophene) (PEDOT) (140–142) has a band gap of 1.5–1.6 eV as compared to thiophene (2.0–2.1 eV); poly(3,4-dimethoxythiophene) has an electrochemical band gap of 1.37 eV (143,144).

Polyfurans. Relative to polythiophenes and polypyrroles, little has been reported on polyfurans (PFu); this is likely a result of the high oxidation potential of furan ($\geq$1.7 V vs Ag/Ag$^+$), which results in side reactions during polymerization (145). While chemical polymerization of furan has been reported (146), the majority of PFu publications focus on electrochemically prepared PFu.

PFu was first reported by Tourillon and Garner (147), who used an electrochemical technique similar to that used by Diaz and co-workers to polymerize pyrrole (148). This PFu had reported conductivities from 10^{-5} to 10^{-3} S/cm. However, these early reports on the synthesis of PFu were incorrect because of inconsistent chemical and spectroscopic properties of the polymer obtained (149).

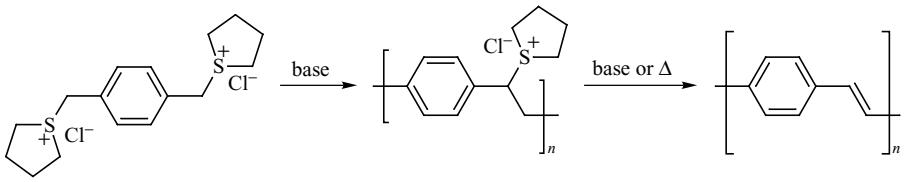
The high voltages required for electropolymerization (1.8–2.5 V vs SCE) of furan result in irreversible oxidation of the polymer, and the polymer contains significant hydrogenated units (150). A polyfuran structure was reported by Zotti and co-workers (151) by the cathodic reduction of 2,5-dibromofuran in acetonitrile using a Ni^{2+} catalyst. The PFu was obtained in trace amounts, with a significant content of the undoped, insulating form, which resulted in incomplete characterization of the material. Polyfuran films doped with ClO_4^- were obtained potentiostatically at several deposition potentials (152) and characterized by cyclic voltammetry, which showed highly complex voltammograms, indicative of a poorly defined polymer system. Free-standing films of PFu were obtained by the electrochemical polymerization of furan at 1.2 V vs Ag/AgCl in a binary solvent system (153); the resultant PFu showed well-defined cyclic voltammetry, moderate conductivity when doped with I_2 (10^{-2} S/cm), and good mechanical properties.

Regioregular and regiorandom poly-3-alkylfurans have also been reported (154). Conductivity was found to be highly dependent on degree of regioregularity, reaching 10^{-2} S/cm in the 95% head-to-tail (H-T) polymer but only 10^{-7} S/cm in the 75% H-T polymer.

To avoid the problems associated with furan's high oxidation potential, extended conjugation monomers incorporating furan have been prepared (145,155). A PFu prepared from terfuran showed a conductivity of 10^{-3} S/cm when doped with $CF_3SO_3^-$ (155). The PFu was highly susceptible to acid/base effects, which led to ring opening and a decrease in the conjugation length.

Poly(phenylene vinylene)s. The earliest reported synthesis of a Poly(p-phenylenevinylene) (qv) was accomplished by McDonald and Campbell in 1960 (156). They produced a PPV oligomer by a repetitive Wittig-type coupling of an aromatic bisphosphonium salt and a bisaldehyde. Several routes have been investigated for producing PPVs, such as coupling reactions of dichlorobenzene in liquid ammonia (157), reactions of tetrabromo-*p*-xylene with two equivalents of methylithium (158), and McMurray deoxygenative coupling of an aromatic dialdehyde (159). In all these cases PPVs were produced that were either insoluble or sparingly soluble and poorly processable.

Precursor routes to PPVs can be easy and efficient, and they produce soluble and processable high molecular weight PPVs The most widely used soluble precursor method is the Wessling and Zimmerman route eq. 10. This process involves the synthesis of the bis-sulfonium salt of 1,4-bis(chloromethyl)benzene, followed by sodium hydroxide elimination and polymerization at 0°C to give an aqueous solution of a precursor polymer. The soluble precursor is processed into films, foams, and/or fibers and converted to PPV by thermal elimination (160–163). The heating occurs under vacuum at temperatures ranging from 120°C for bromide salts to 200°C for chloride and fluoride salts to 300°C for acetate salts (164). Normally, a large variety of substituents can be tolerated on the aromatic ring, such as aromatic (165), alkoxy (166), silyl (167), halogen (168), sulfur (169), and amino groups (170), but electron-poor substitutents such as nitro or cyano groups polymerize with extreme difficulty (171). The major disadvantages of this method are the instability of the intermediate polymers and the stench of the sulfonium salts.



poly(phenylene vinylene)
(PPV)

(10)

There are several alternate routes for preparing PPV from soluble precursors. The Gilch route (172) uses a dichloro-*p*-xylene that is polymerized with potassium *tert*-butoxide in organic solvents. The alkoxy route (173) uses a methoxy-substituted polymer that is soluble in common organic solvents and is more stable than the sulfonium precursor. Polymerization is accomplished by removal of the alkoxy group by acid catalysis, followed by heating to produce PPV derivatives. A third route utilizes the Heck coupling reaction, which is compatible with a wide variety of functional groups (174,175), allows regiospecific synthesis (176), and yields polymers with molecular weights ca 10^4 g/mol (174,177). The Heck polymerization involves coupling of vinyl groups with bromides or iodides, either in an AA/BB copolymerization (as in the reaction of ethylene or a divinylbenzene with a dibromobenzene) or in an AB homopolymerization (typically the reaction of a 1-bromo-4-vinylbenzene), in the presence of a palladium catalyst (174).

All of these alternate routes allow a large range of substituted organic-soluble PPV derivatives to be synthesized, but none of the methods has a distinct advantage over Wessling and Zimmerman's sulfonium precursor method. The most studied solution-processable PPV is poly(1-methoxy-4-(2-ethylhexyloxy)-*p*-phenylene vinylene (MEH-PPV), commonly prepared via the Gilch method (178). Careful choice of PPV substitutents allows for tuning of the optical band gap, enabling the use of these polymers in electrooptical applications.

Several heteroaromatic ring structures have also been incorporated into poly(arylene vinylene) structures using the same soluble-precursor polymer methods used for PPV. Poly(thienylene vinylene) (179) and poly(furylene vinylene) (180) have been prepared. Metalloporphyrins have also been incorporated into poly(arylene vinylene)s (175) to investigate photorefractive properties. Aromatic poly(azomethines) have also been prepared from a solution condensation of an aromatic diamine with aromatic dialdehydes (181), but these materials are less conjugated than their PPV counterparts. Various copolymers of phenylene vinylenes with phenylene, thienylene, and furylene moieties have also been studied (182).

Polyanilines. Polyaniline was made nearly 140 years ago in 1862 by H. Letheby (183). At that time, polyaniline was known as "aniline black." This material was prepared by the oxidation of aniline under mild conditions. The material found use in dyes and printing. Initial preparations of polyaniline (PANI) led to insoluble materials that had poor thermal processability and solvent solubility. Only recently has the structure of PANI been fully determined. This was accomplished by using model compounds and polymers for definitive structural analysis. Poly(*p*-phenylene amineimine) (PPAI) was synthesized directly to demonstrate that PANI is purely para-linked (184–186).

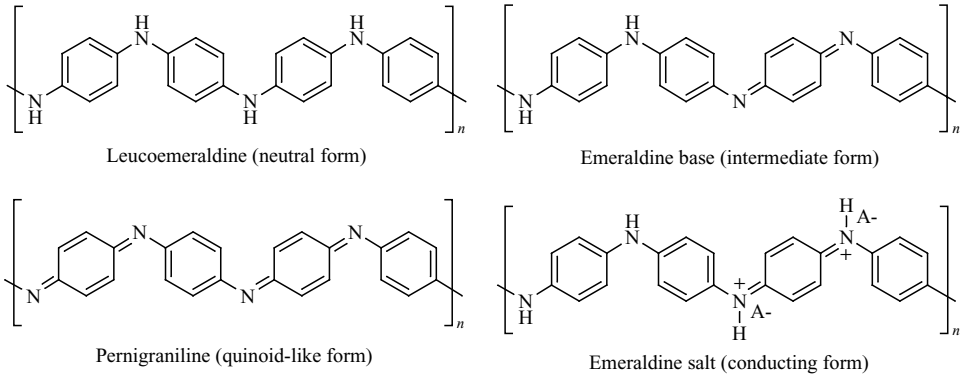


Fig. 7. Oxidation states of polyaniline.

PANI is commonly prepared by chemical polymerization of aniline using $(NH_4)_2S_2O_8$ in hydrogen chloride solution (187) and/or by electrochemical polymerization (188). PANI can exist in four different oxidation states: leucoemeraldine (neutral form), pernigraniline (quinoid-like form), emeraldine base (intermediate form), and emeraldine salt (conductive form), as shown in Figure 7. PANI is prepared as the emeraldine salt and then treated with base to yield the emeraldine base form, which is soluble in common organic solvents. After film casting or other processing, the emeraldine base can be treated with HCl to regenerate the conductive emeraldine salt form of PANI.

Methods have been developed to improve solubility and processability by introducing various alkyl, alkoxy, aryl, sulfonyl, and amino groups onto the PANI backbone (189). However, the presence of these substituents dramatically reduces yields of polymer, polymer molecular weight, and conductivity. Novel water-soluble PANI has been recently synthesized using horseradish peroxidase catalyzed by oxidative free-radical coupling of 2,5-diaminobenzenesulfonate (190). Unlike standard PANI preparations, the resultant polymer is fully sulfonated upon treatment with fuming sulfuric acid, and it shows strong pH dependance of absorption and other physical properties.

Conjugated Ladder Polymers. Since the 1930s double-stranded, ladder-type polymers have been prepared in a multistep process with limited success of cyclization (191,192). Other routes have also been explored such as those for poly(acrylonitrile) (193,194), poly(1,2-butadiene), poly(3,4-isoprene) (195), or poly(butadiyne)s (196). These materials were found to be poorly soluble and unworkable, with a considerable number of defects in the structure (incomplete cyclization, cross-linking, radical sites). The first successful synthesis of a ladder polymer with a completely defined structure was accomplished in 1991 by Sherf and Mullen (197). The first step was the AA/BB-type polycondensation of an aromatic diboronic acid with a substituted 2,5-dibromo-1,4-dibenzoylbenzene to give a single-stranded precursor PPP-type polymer, followed by cyclization to the ladder structure (Fig. 8). Several other examples exist that have resulted in ladder-type structures. These include angular polyacene (198,199), Diels–Alder polyaddition of AB-type diene–dienophiles (200), AA/BB-type Diels–Alder polyaddition of a bisdiene and a bisdienophile (201), thienylene units (202),

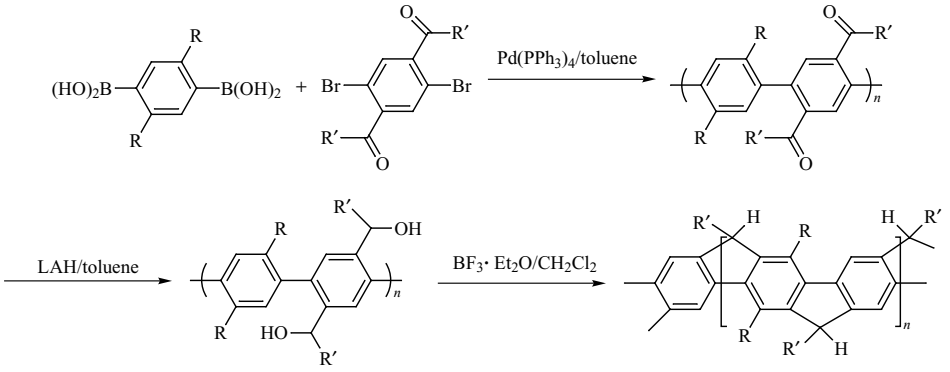

Fig. 8. Formation of ladder structures. Where R = n-C_6H_{13}; R′ = −1,4-C_6H_4-n-$C_{10}H_{21}$.

and polybenzimidazobenzophenanthroline (BBL) (203). All of these materials are structurally defined materials, but their drawbacks include poor solubility, poor thermal processability, and generally lack of workability.

Alternative Synthetic Approaches. Most EAPs are prepared via chemical or electrochemical oxidative polymerization, precursor routes, or coupling chemistry. However, several alternative approaches have recently been gaining attention.

Template-assisted polymerization is used to prepare specific conducting polymer architectures for use in a variety of applications (204). Polyacetylene has been prepared in the presence of liquid crystalline solvents for subsequent alignment (68–70). Polyaniline has been synthesized in the presence of DNA (205) to form helical PANI with interesting electrochemistry that is useful as a biosensor. Fibrillar morphologies can be produced by polymerization in channelized templates (such as microfiltration membranes); the resulting polymers show improved conductivity over analogous polymer films and were suggested for use in polymer light-emitting diodes (206,207). A variety of polymers have been grown around self-assembled colloidal templates (see Photonics section, below); the template can subsequently be dissolved away from the conducting polymers, producing opal-like EAP structures with the aim of improved charge transport for battery and capacitor applications. (208,209) While not strictly a template method, EAPs have also been prepared on the surface of a wide variety of particles and fibers (210,211), typically via chemical oxidative polymerization; the resulting composites/nanocomposites have found commercial application in static-dissipating paints, cloths, and carpets.

One synthetic approach gaining popularity for its ecologically friendly nature and its potential biological applications is that of biomediated polymerization. Enzymatic oxidants, such as horseradish peroxidase (212,213), are commonly used for chemical oxidative polymerization. Additionally, bacteria can be used to effect chemical reactions, as in the Ballard route to PPP described above (79).

Plasma polymerization is a solvent-free process that can be used to rapidly deposit thin polymer films onto a wide variety of substrates at room temperature (214,215). Monomer vapor is exposed to an electric field, and the resultant reactive fragments recombine to form polymer films. This technique is used for a wide

variety of polymer types including EAPs, and properties of the resultant polymers are often quite different from those prepared using more traditional techniques. Reaction conditions, including monomer flow rate, plasma power, reactor pressure, deposition time, and gas-phase composition, can be varied to tailor the properties of the resultant polymer. Other benefits of this technique include the environmentally friendly aspect of the solvent-free process, the ease of controlling film thickness, and the pinhole-free nature of the films. Plasma polymerization has been used to prepare polythiophene (216), polypyrrole (217), and polyaniline (218,219). While mechanical properties are typically better than those of traditionally prepared polymers (219), relatively poor conductivities are common in plasma-polymerized EAPs, possibly as a result of structural defects.

Conducting Polymer Blends, Composites, and Colloids. EAPs are in most cases prepared in the form of intractable films, gels, or powders that are insoluble in common organic solvents. Incorporation of solubilizing functional groups is but one technique available for chemists, materials scientists, and engineers to improve the processability of conductive polymers. Over the past decade research has focused on improving the processing characteristics of EAPs through the use of polymer blends, composites, and colloids (220).

Blends and composites of polymers offer certain combinations of desired properties that cannot be obtained from the individual components. EAP blends and composites offer a unique combination of good mechanical properties of an insulating host combined with the electrical conductivity of the guest. The conductive component's concentration threshold for the onset of electrical conductivity can be reduced to volume fractions well below that required for classical percolation (221). The critical factor in these formulations is the amount of EAP used; it must be enough to give a continuous conductive network (222). Blends and composites of EAPs are formed via simple, electrochemical, or diffusive mixing, by chemical treatment, by light-induced conversion and by counterion-induced processability. Numerous examples exist that describe the various methods used to form blends and composites using conductive polymers (221,223).

EAP colloids typically consist of a colloidal suspension of EAP particles or EAP-coated particles (latex, metal, silica, etc) in an aqueous medium; the dimensions of the dispersed particles are in the 1–1000-nm range. These materials are normally prepared via dispersion polymerization (224,225). While colloidal dispersions of EAPs are more processable than their noncolloidal EAP counterparts, the dispersions do not readily form films because of the high glass-transition temperatures (T_gs) of the EAPs, and applications are limited (226). A more promising approach involves coating particles (polystyrene, polyurethane, etc) with EAPs to form colloidal composites and nanocomposites. Much lower concentrations (ca 5–20%) of EAPs are used, so that the majority of the material is composed of low T_g, film-forming material. Conductivities of EAP-coated particles range from 10^{-5} to 10^{1} S/cm (227–229), and these materials are currently being marketed as water-borne anticorrosion and antistatic coatings.

Transport Theory

Conjugation and Conduction. As conjugation length increases, as with the progression from ethylene to 1,3-butadiene to 1,3,5,7,9,11-dodecahexane to

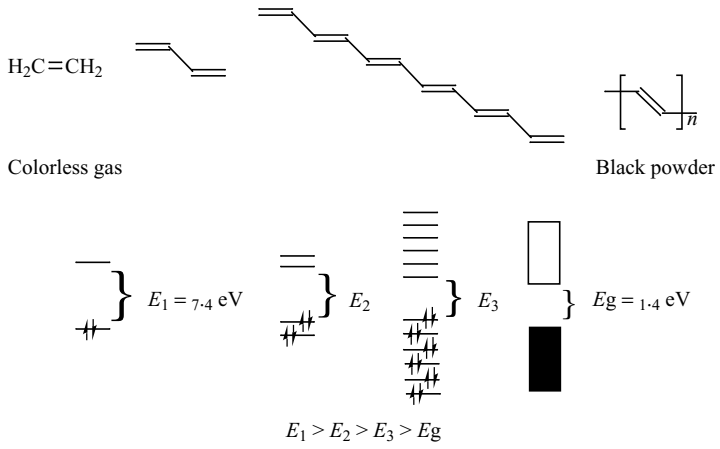

Fig. 9. Effect of conjugation on molecular energetics.

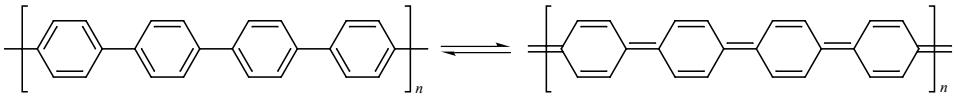
polyacetylene (Fig. 9), the degenerate orbitals spread to form nondegenerate energy bands, and the energy difference between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) decreases. This energy difference is a simple π to $\pi*$ transition in simple molecules and a band gap (E_g) in case of polymers (44). It can be determined for a neutral species from the onset of absorption in the UV–vis spectrum. Much research has focused on the development of low E_g materials for electrochromics applications (230). E_g can be lowered by functional group modification to raise the energy of the HOMO, but as a result the neutral polymers are very easily oxidized, and stability can be an issue.

Just as increasing conjugation length from ethylene to polyacetylene decreases the π to $\pi*$ transition, it also lowers oxidation potential. This is due to the high HOMO and increased resonance stabilization of the radical formed in the process. Similarly, other EAPs have lower oxidation potentials than their monomeric counterparts. Increasing conjugation in monomers also lowers oxidation potentials (124); the oxidation potential of thiophene (2.07 V vs SCE) is much higher than that of terthiophene (1.05 V vs SCE), which is higher than that of polythiophene (0.7 V vs SCE) (231). Extended conjugation monomers have therefore received considerable interest, because lower oxidation potentials lead to fewer side reactions and fewer defects (232,233). Among the defects minimized through the use of extended conjugation monomers are those caused by α,β-coupling, since several α,α-linkages are predetermined in these materials.

The conjugated nature of neutral EAPs allows them to have two electronically extreme states (eqs. 11 and 12). Unlike all other EAPs, the two resonance forms in *trans*-polyacetylene are degenerate, ie their ground states are thermodynamically equivalent (234). Other organic electroactive polymers possess nondegenerate ground states (235); for example, poly(*p*-phenylene) has both benzenoid and quinoid configurations (eqs. 11 and 12), of which the latter is the higher energy configuration (44), and so makes less of a contribution. Addition of either donors or acceptors in the process known as doping results in charge transfer and

the formation of charge carriers along the polymer chain, yielding the conductive form of EAPs (235). Several comprehensive treatments of charge carriers in EAPs can be found in the literature (38,236–238).

(11)



(12)

As a result of the degenerate ground states of *trans*-polyacetylene, charges formed during doping readily separate (because there is no increase in distortion energy.) The charge carrier, called a soliton, is relatively stable as a result of the degeneracy, and the energy required to create and move such a defect is relatively small (235). Calculations suggest that solitons are delocalized over 15 carbon atoms (239).

The most widely accepted mechanism of conduction in nondegenerate EAPs, illustrated in Figure 10 for polythiophene, was proposed simultaneously by Bredas and co-workers (240) and Bishop and co-workers (241) in 1981. This mechanism involves a one-electron oxidation to form a radical cation, which is called a polaron. This radical cation is resonance-stabilized over several rings. Removal of a second electron gives a dicationic species with no unpaired electrons, called a bipolaron. The two ions in a bipolaron need to be isolated from each other to minimize unfavorable interactions; recent work suggests that at least five rings are needed to stabilize a dicationic species (242,243). The conversion between neutral, polaronic, and bipolaronic species is reversible, using either chemical or electrochemical means to oxidize or reduce the polymer.

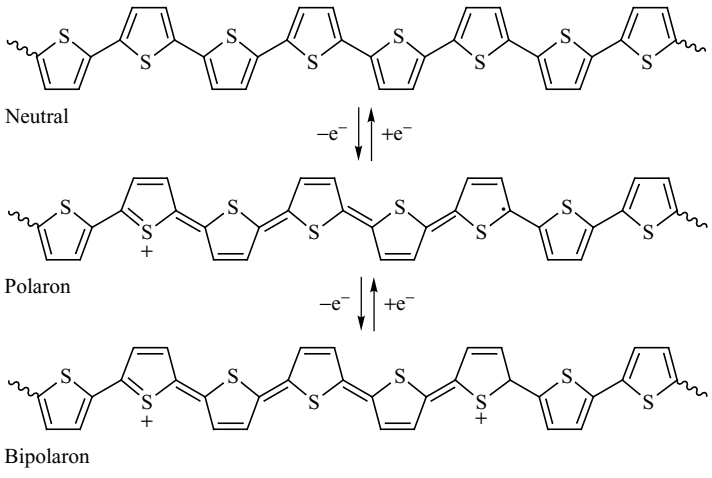


Fig. 10. Mechanism of conduction in nondegenerate EAPs.

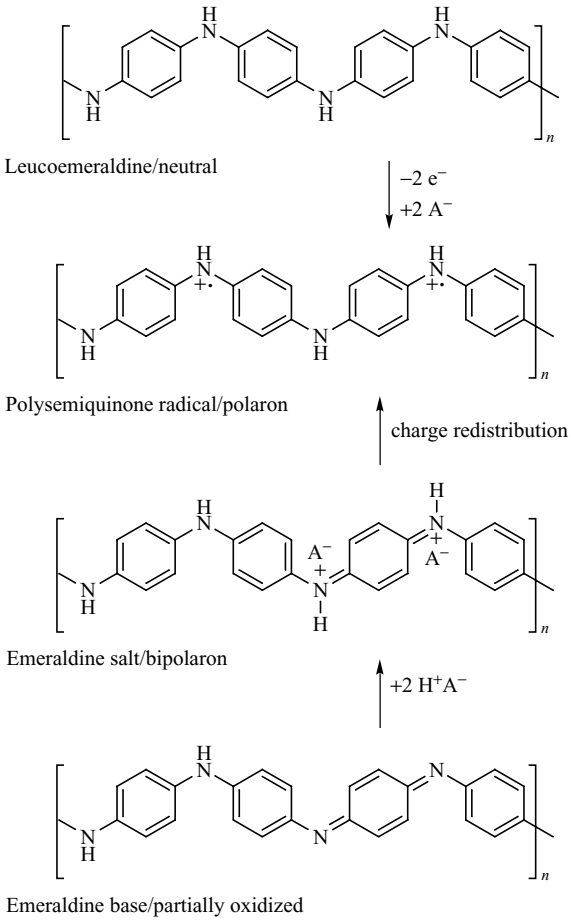

Fig. 11. Chemical doping of polyaniline.

PANI and other ECPs possessing strongly basic functionalities undergo a more complex chemical doping mechanism (187,188) (Fig. 11). While the leucoemeraldine form can undergo oxidative doping, leading to radical cation (polaron) formation, the emeraldine base form of PANI can also undergo protonation by acid–base chemistry to yield the emeraldine salt (bipolaron) form. Internal charge redistribution in the emeraldine salt also yields the polaron form.

Doping Processes. Reversible doping can be achieved by both chemical and electrochemical methods. The control of electrical conductivity of a conductive polymer from insulator to metal can be accomplished through the doping process; conductivity increases with an increase in the doping level (194–196). Several techniques exist for doping conjugated polymers (38). These techniques are as follows: (*1*) chemical doping by charge transfer, (*2*) electrochemical doping, (*3*) doping of PANI by acid–base chemistry (discussed above), (*4*) photodoping, and (*5*) charge injection at the metal–semiconducting polymer interface.

Chemical doping involves charge-transfer redox chemistry. Oxidative doping (p-type, electron accepting) with dopants such as I_2, AsF_5, O_2, and $FeCl_3$ is

commonly used, while reductive doping (n-type, electron donating) using dopants such as sodium naphthalide (244) or alkali metal vapors (245) is less common because of the reactivity of n-doped materials. This technique is simple and efficient, but control of the degree of doping is limited. High levels are easily achieved, whereas intermediate levels are not usually obtained.

Electrochemical doping refers to the supply by an electrode of the necessary redox potential to the conducting polymer (197). Ions diffuse in and out of the polymer structure from the nearby electrolyte, compensating for electronic charge formation along the polymer backbone. The doping level is controlled by the voltage between the conducting polymer and the counterelectrode. Thus, precise control of doping levels can be achieved.

Photodoping is a rapid process in which light is used to generate ions in solid polymer films (38). When an appropriate wavelength of light is absorbed to create an excited state, a close contact ion pair can be formed. No external counterions are present to stabilize these two mobile charge carriers. A transient change in the optical properties of the polymer occurs upon charge separation; resultant applications may include nonlinear optics and waveguides. In the absence of an electric field, the charges recombine in either a radiative (ie photoluminescence) or nonradiative process. In an electric field, these charges migrate to opposite electrodes, generating current; applications include solid-state photovoltaic cells.

Doping can also be accomplished by charge injection at a metal–semiconducting polymer interface. This type of doping, found in light-emitting diodes, occurs when electrons and holes are injected into the π and $\pi*$ bands of an EAP. In this method, the polymer is not doped in the chemical or electrochemical sense, because there are no counterions present.

Properties

While many properties of EAPs are also found in other materials, EAPs exhibit unique combinations of properties that have led to use in a variety of applications. Perhaps the most promising feature of EAPs is the switchable nature of many of the properties. The ability to reversibly switch EAPs between insulating and conducting, opaque and transparent, absorptive and emissive, or expanded and contracted drives much of the current EAP research.

Stability. In most cases, stability of EAPs is gauged in terms of changes in electrical conductivity. Thus, doped polyacetylene, while highly conductive in an inert environment, loses conductivity when exposed to air and is therefore considered unstable (51). Polypyrroles and polyanilines, on the other hand, are counted among the most stable EAPs, while polythiophenes exhibit intermediate stabilities. Environmental and thermal effects on polypyrrole and poly(3-alkylthiophene)s have been studied extensively (246,247); increased oxygen exposure and increased temperature frequently have detrimental effects on conductivity.

Mechanical Properties. Normally the mechanical properties of conductive polymers are very poor (211) because of the inherent nature of EAPs, which are normally intractable and poorly processable. Poor mechanical properties result from a lack of flexible linkages in the polymer backbone as well as from

low molecular weights. PANI is one exception that can be prepared as highly oriented crystalline fibers (248). The incorporation of EAPs into non-conductive polymer matrixes such as poly(vinyl chloride) (PVC) or poly(vinyl alcohol) (PVA) yields blend, composite, or laminate EAPs with unique combinations of electrical conductivity and processability (249). Such materials are discussed in detail elsewhere in this chapter. Processability is also improved by incorporating solublizing moieties pendant to the conjugated polymer chain as discussed previously; this often results in improved molecular weights, because polymer molecular weight is frequently solubility-limited.

Optical Properties. The optical properties of EAPs are a direct consequence of the electronic structure, which is determined by the chemical structure of the polymer. The optical properties of EAPs result from the energy difference between the valence and conduction bands in the conjugated polymer; this energy difference is called the band gap (E_g). EAP band gaps range from 0.5 to 3.0 eV (230,250), and typical absorption coefficients are on the order of 10^5 cm^{-1} (251).

The absorption characteristics of EAPs can be controlled by tailoring molecular structure; common methods include incorporation of electron-donating and electron-withdrawing groups (138,252–254) as well as alterations in conjugation length (usually by introduction of steric constraints). Because conjugation in neutral and doped EAPs is very different, changes in optical properties commonly occur during the redox process, leading to a variety of applications. These properties are exploited in the development of electrochromic and light-emitting devices, where materials have been produced spanning the entire spectrum.

Electrical Properties/Electrical Conductivities of EAPs. While conductivity in EAPs is typically at least one order of magnitude lower than that of the best metals, the ability to switch EAPs from conducting to insulating and the ease of processability of many EAPs have led to some unique applications.

The electrical conductivity, σ, of a conjugated polymer is equal to the inverse of its specific resistivity, ρ, which is a measure of the ability of the conjugated polymer to conduct an electrical charge. Electrical conductivity is determined by measuring the resistance, R, to charge transport through a known volume, where L is the length over which resistance is being measured and A is the cross-sectional area through which the current passes:

$$\sigma = 1/\rho = L/(R \cdot A)$$

Typically, electrical conductivity of EAPs is measured in units of S/cm. Both two- and four-point probe techniques are used to measure σ in films and pressed pellets (255). Conductivities as high as 10^5 S/cm have been reported for several EAPs. Values vary depending on synthetic procedures, fabrication techniques, and measurement methods. EAPs are typically only partially crystalline (256–258); amorphous EAPs have been reported (259–261). Therefore, disorder plays a significant role in their electrical conductivities, and the conductivity arises from the metal–insulator transition (262). As an example, PA with the highest conductivity reported so far shows temperature dependence of conductivity (263). Thus, electrical conductivity is limited by the disorder-induced localization of the electrons rather than by the intrinsic conductivity of the delocalized charges on the polymer backbone. Table 2 shows conductivities for several well-known EAPs (26–28).

Table 2. Electrical Conductivities of EAPs

EAP	Conductivity, S/cm
Poly(acetylene) (PA)	10^3–10^5
Poly(pyrrole) (PPy)	10^2–10^3
Poly(thiophene) (PT)	10^2
Poly(aniline) (PANI)	10–10^2
Poly(*p*-phenylene) (PPP)	10^2–10^3
Poly(phenylene vinylene) (PPV)	10^3–10^4

Applications

Light-Emitting Diodes (LEDs)/Light-Emitting Electrochemical Cells (LECs). *Electroluminescence* (EL) is the emission of light from a material when it is excited by an electric current. The discovery of EL in neutral (undoped, nonconductive) conjugated polymers, specifically PPVs, by Burroughs and co-workers in 1990 (264) led to extensive research into materials development and polymer light-emitting diode (PLED) research. EAPs compete with and may eventually replace current display technologies such as those based on inorganic materials and liquid crystalline displays (LCDs). Inorganic EL materials have been used in display applications for years; light-emitting diodes (qv) based on these materials have been commercially available since the 1960s (265).

PPV is a yellow fluorescent EAP with emission maxima at 551 nm (2.25 eV) and 520 nm (2.4 eV), in the yellow–green region of the visible spectrum (266). Soluble PPVs have been prepared by the precursor method, allowing for solution processing by spin coating onto a substrate (267).

PPVs and other EAPs offer unique advantages over their inorganic LED counterparts. Advantages include ease of processing on large-area substrates, good tensile properties of the chain-extended polymer (allowing the polymer to survive harsh conditions during device operation), and the ability to fine-tune the electronic and optical properties of EAPs through functionalization. The simplest PLED is a thin film of PPV sandwiched between two electrodes. The anode (hole-injecting electrode) is a semitransparent, high work-function material such as indium tin oxide (ITO), whereas the cathode (electron-injecting electrode) is a low work-function metal such as Al, Ca, or Mg (Fig. 12).

Under an applied voltage in an LED, oppositely charged carriers (electron and holes) are injected into the emissive layers from the opposing contacts and are swept through the device by the high electric field. The efficiency for EL devices is measured by the number of photons emitted per electron injected. This number is called the internal efficiency and is based on the assumption that all light generated is received by the viewer. The external efficiency is a factor of $2n^2$ smaller than the internal efficiency (where n is the refractive index). Typical external efficiencies for LED devices are between 0.1 and 5% (268); normal luminous efficiencies for LEDs range from 1 to 10 lm/W (269,270), and quantum efficiencies are now greater than 10% (269). Such a single-layer device is called an EL diode because it shows nonlinear I–V characteristics typical of diodes.

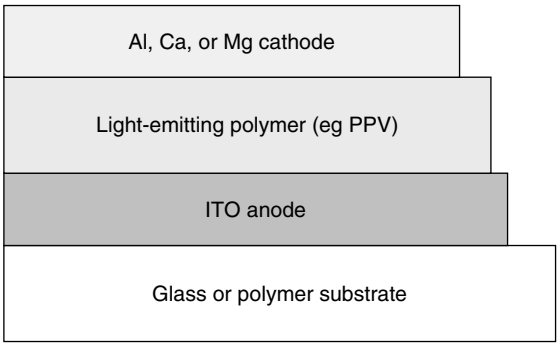

Fig. 12. Polymer LED.

The most studied of the PPV compounds are those containing at least one solubilizing alkoxy group (271–273); poly[(2-methoxy-5-(2-ethylhexyl)oxy-1,4-phenylene]vinylene (MEH-PPV) is most commonly used (274). The ability to fine-tune the color to produce red, green, and blue PLEDs has been demonstrated by appropriate functionalization of polymers (275–279), copolymerization (280–282), and blending (283–285). Several representative electroluminescent polymers covering the visible spectrum are shown in Table 3 (286–290).

In single-layer PLED devices the EL occurs mainly in the vicinity of the cathode because of the better mobility of the positive charges in conjugated polymers. The major drawback is the negative impact on luminance efficiency. To overcome this problem, two-layer devices have been investigated (291,292) in which the cathode and the EL polymer are separated by an electron-conducting/hole-blocking layer such as a polyoxadiazole (293). Multilayer devices made from several EL polymers have also been developed to emit white light (294,295). The enormous progress in developing materials with high purity, processibility (ink-jet techniques), and good thermal and oxidative stability has allowed commercialization of such devices by Epson, Philips, Toshiba, and UNIAX (296). Highly pure, undoped materials have been the primary focus for LEDs; doped polymers in such devices lead to a dramatic decrease in luminescence and device performance (297).

Light-emitting electrochemical cells (LECs) have received considerable interest because of the involvement of ionic species in the luminescent layer. LECs exhibit many unique features different from conventional LEDs (298). The principal idea behind the operation of an LEC is electrochemical doping to combine

Table 3. Light-Emitting Polymers Covering the Visible Spectrum

Polymer	Color (λ_{max}), nm
MEH-PPV	Red–orange (610)
CN-PPV	Red (710)
PT	Red (662)
PPV	Green (550)
PPP	Blue (459)

electrons and holes (forming a pn junction) *in situ*. An electrolyte provides the necessary ionic conductivity, allowing dopant ions to mix with the EAP. Under an applied electric field the electrons and holes interact to form excited species, which undergo radiative decay to emit light (299). Numerous examples of LECs are found in the literature (300,301), but slow response times (normally a second or longer) have limited the ability of LECs to compete with their LED counterparts (302–304).

Electrochromism. One of the most promising applications for EAPs is in electrochromic devices. Electrochromism, a reversible, reproducible spectral change that is produced electrochemically, results from changes in conjugation during the redox process. Until recently, the majority of research in this area has focused on inorganics, organometallics, and molecular organics (305–309), but developments in the area of EAPs have shifted the focus in recent years (310–313). EAPs are desirable substitutes for other types of electrochromic materials because EAPs typically switch much faster, they make good films, and their structures can be tailored to provide the desired color changes. Most work in electrochromics has focused on the ultraviolet and visible spectra; IR and RF electrochromics have also received attention.

Visible Electrochromics. Most EAPs exhibit UV–vis electrochromism, but not all exhibit significant optical contrast or switching stability for use in electrochromic devices. Polypyrrole switches reversibly between yellow in the neutral state and blue–black in the oxidized state, but contrast is poor in all but the thinnest films, and practical applications are limited (311). Polythiophene switches reversibly between red (neutral) and blue (oxidized), (313) while polyaniline switches very rapidly between four color states (yellow/green/blue/black). PANI switching stability is very good ($>10^6$ cycles) when switching is limited to the yellow–green transition, although this somewhat limits its potential applications (311).

With goals of additional color states, increased optical contrast, faster switching, and higher stability, recent research has looked at modifications of basic EAP structures. Incorporation of electron-donating substituents as in the PEDOT-based systems mentioned earlier lowers oxidation potentials and decreases band gaps while increasing the stability of oxidized polymers (314), and further incorporation of alkyl substituents tunes color and improves contrast without (in some cases) detracting from switching speeds (315). Carbazoles have been incorporated, providing multiple color transitions, fast switching, reasonable contrast, and high switching stability (316,317). Visible electrochromic applications for EAPs include smart windows, displays, automatically dimming rearview car mirrors (already commercially available), protective eyewear, and optical storage.

Infrared Electrochromics. While applications for visible electrochromics are widespread with many commercial possibilities, infrared (3–17 μm) electrochromics applications are limited. Disordered transition-metal oxides have been pursued because of their broad polaron absorption (318), but slow response times and processing difficulties have limited applications. As with most electrochromics applications, EAPs are attractive for IR electrochromics because of their rapid response times and ease of processing. Research to date in EAPs for IR electrochromics has focused on polyaniline-based (319–321) and poly(3,4-alkylenedioxythiophene)-based (322,323) systems. The

poly(3,4-alkylenedioxythiophene)-based devices exhibit improved contrast ratios over the PANI-based devices and good switching stability.

Microwave/Radio Frequency Electrochromics. In radio direction and ranging (radar) systems, electromagnetic waves are bounced off a target and collected by a receiver. The receiver analyzes the signal and determines the range, direction, and speed of the target. RF electrochromics function by absorbing the electromagnetic waves rather than reflecting them back to the receiver. RF electrochromics find use in commercial electromagnetic interference (EMI) shielding, and in law enforcement and military radar systems. EMI shielding materials (addressed below) are typically used in the conductive state only.

A number of studies on the microwave properties of EAPs have been published (324–328). EAP-coated textiles (329–331) and devices (332,333) have been explored for use in radio frequency applications.

Photovoltaics. The use of EAPs in the construction of plastic photovoltaic cells is another example of the versatility of these materials (334–336). Photovoltaic cells are constructed in a similar manner to single-layer PLEDs, but the photovoltaic cell transforms radiant energy into electricity (337,338). The most basic device construction consists of a conjugated polymer sandwiched between two working electrodes, usually Al and ITO. In devices this simple, the photoinduced charge generation is inefficient (339).

To improve these devices it is necessary to have an electron-accepting molecule in close proximity to the undoped conjugated polymer, which acts as an electron donor upon photoexcitation; a charge separation takes place because of photoinduced electron transfer. This process produces a stable charge storage configuration in which the polaron produced is highly delocalized and mobile. One of the best electron-accepting materials for this process is the fullerene molecule (C_{60}). The construction of photovoltaic cells using a combination of semiconducting polymer as the donor and molecular electron acceptor such as fullerene has been studied (340–344). Devices based on fullerenes and composite films of semiconducting polymer are known as "bulk-heterojunction" polymer photovoltaic cells. These devices have shown fast photoinduced charge transfer at the donor–acceptor interface. This results in a metastable charge-separated state. The interpenetrating network of both components consists of a large interfacial area and results in efficient charge generation. Photovoltaic power conversion efficiencies (η_e) of 2.5% under AM 1.5 illumination have been reported (345).

Organic Field Effect Transistors/Molecular Electronics. Organic field effect transistors (OFETS) and molecular electronics are two areas of intensive research for both academic and industrial institutions (346). The extensive research on these devices stems from their ability to be processed at low temperatures and from their compatibility with plastic substrates. Several applications of OFETs have been proposed, including smart cards (347), active matrix displays (348), and logic circuits (349). Both polymeric and oligomeric materials have been studied for use in OFETs because the properties can be tailored to vary the HOMO–LUMO gap; physical characteristics such as mechanical flexibility and processability are also advantageous (350).

Typical OFET construction is similar to that of inorganic FETs, which are a critical component of computer chips. The OFET device consists of electrodes (drain, gate, and source), a dielectric layer, and a semiconducting layer (Fig. 13).

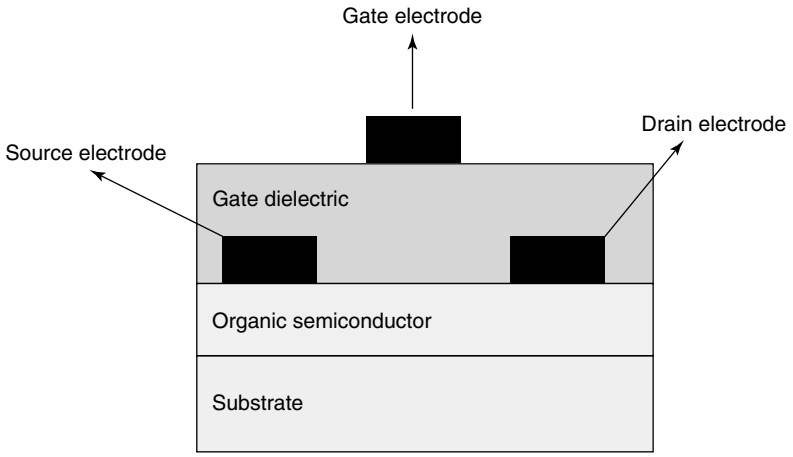

Fig. 13. OFET device.

The current flow between the drain and source electrodes is modulated by the applied gate voltage. When there is no voltage between the source and gate electrodes, the FET is in an insulating state. The device is activated by application of an electric field, resulting in charge carrier formation. These charge carriers can then move between source and drain; the charge carrier concentration can be controlled by small variations in the gate voltage. A crucial parameter in OFETs is the On/Off ratio, which is the ratio of conductivities with the gate voltage switched on and off (351). Highly purified and ordered layers of oligomers typically have charge carrier mobilities of between 0.1 and 0.2 $cm^2/(V \cdot s)$ (352), sufficient for most commercial applications.

Molecular electronics is an emerging field that proposes to replace wire, transistor, and other solid-state silicon components with conjugated, organic-based molecules of precise length and constitution (353). The main disadvantage of these systems is the difficulty of inducing three-dimensional order to allow for rapid charge transport (354,355). This fact currently limits their use as replacements in logic circuits and computing systems.

Nonlinear Optical Applications. Second-order nonlinear (NLO) materials based on EAPs have shown promise for use in the photonics industry; extensive research has been conducted in this area over the past several decades (356,357). Devices based on poly(diacetylene) have been used to demonstrate all-optical switching at 1.6 μm (358). The NLO process occurs when an electromagnetic field interacts with a medium. When the medium is subjected to an electric field $E(0)$ and an optical field $E(\omega)$, the nonlinear effect arises from field-induced modulation of the refractive index. This is known as the second-order NLO effect or the linear electrooptic (Pockels) effect. An NLO chromophore acts as the active molecular component that gives rise to the NLO property in π-conjugated polymers. These polymers typically consist of donor–acceptor (D-A) groups attached to a conjugated polymer backbone for increased charge transfer through π-electron

Fig. 14. Donor–acceptor groups attached to a conjugated polymer backbone.

delocalization (Fig. 14). The π-bridge system is very important in construction of the dye molecule; acetylenic and vinylic groups have been used extensively to construct such molecules (359,360).

Nonlinear optical materials are recognized as the key element for future photonic applications. Photonics, a technology that uses photons rather than electrons to carry information, offers several advantages over electronics. Advantages include larger bandwidths, faster response times, and less noise from extrinsic electromagnetic fields (361). Several approaches using EAPs for photonics applications have been reported (362).

Biomedical Applications. Electronic properties of EAPs are often very sensitive to small perturbations caused by exposure to chemical/biochemical analytes. This high degree of sensitivity and the variety of properties that are affected result in systems far superior to the conventional small molecule devices known as chemosensors (363). Surface charge characteristics are fundamental to cellular–biomaterial interactions (364); thus, the ability to control charge density in EAPs has led to promising biomedical applications in the areas of chemical/biological sensors, drug delivery, and for monitoring dynamic cell behavior. Applications of EAPs in tissue engineering and nerve regeneration are also promising, although little work has been published to date (365). Most of the biomedical applications of EAPs have focused on polypyrrole because of its proven stability in biological systems.

Chemical/Biological Sensors. EAPs are unique materials for coupling analyte–receptor interactions and nonspecific interactions into an observable response (366). Several EAP properties, including absorption and emission spectra as well as redox activity, are exploited for use in chemical and biological sensors. The band gap of EAPs yields efficient absorption or emission at the band edge, giving rise to a strong luminescence of the EAP. Fluorescence is widely used because of its high sensitivity (367), and because this method offers diverse transduction schemes based on changes in intensity, energy transfer, wavelength, and lifetime (368,369). Many sensors rely on the redox activity of EAPs; exposure to many analytes results in oxidation-state changes. These changes are manifested as changes in conductivity, which can easily be monitored. For a review of polymer-based chemical sensors, see reference 370.

Numerous examples are found in the literature of analyte detection using EAP systems. Arrays of EAPs are used in biomolecular recognition schemes, resulting in devices known as “electronic noses” and “electronic tongues” (371–373) that mimic the mammalian sensor receptors. EAPs functionalized to contain polyalkyl ether and crown ether moieties (374–378) or polymerized in the presence of polyelectrolyte dopants (379) have been used to detect a variety of ions (Li^+, Na^+, K^+, Ba^{2+}, Mg^{2+}, Cs^+, Zn^{2+}, Cu^+, $NR_4{}^+$) (see Fig. 15). EAPs have also been prepared with enantioselectivity toward chiral dopant ions (380,381) and functionalized for molecular recognition (382).

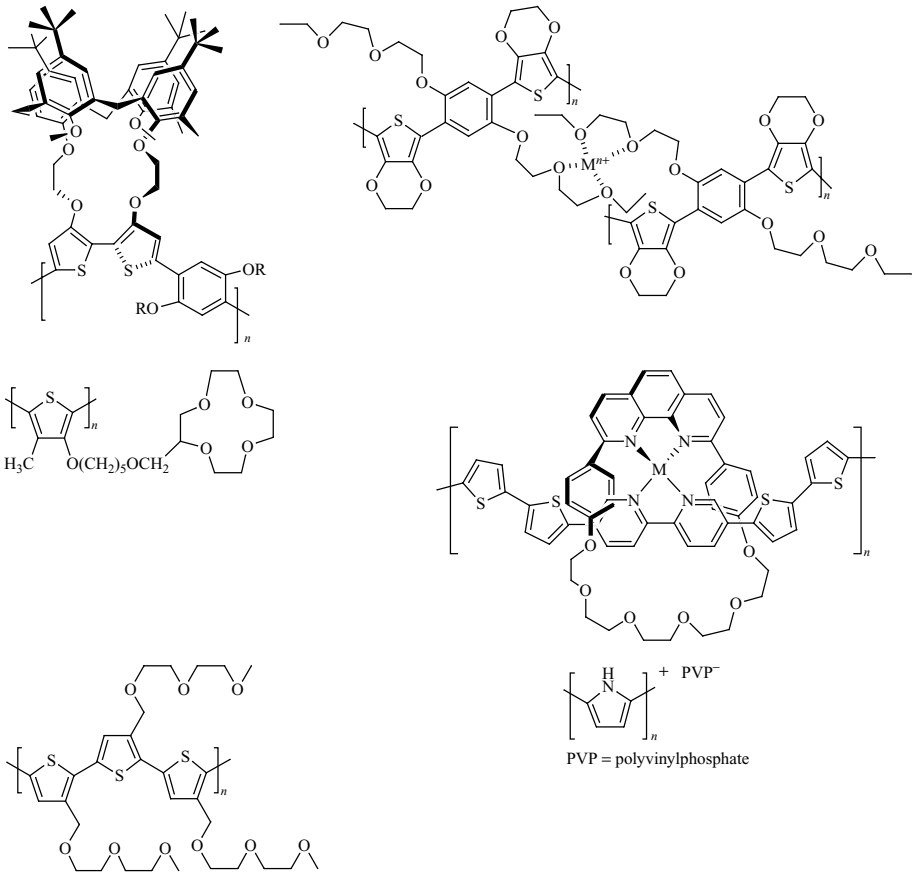

Fig. 15. EAPs functionalized with polyalkyl ether and crown ether moieties.

EAPs have proved to be effective at detection of small quantities of biomolecules, specifically in cancer detection and real-time monitoring of blood-borne analytes such as glucose and nucleic acids (383–389). These sensors employ EAPs containing natural biomolecular recognition units sometimes referred to as "biosensors." These biosensor moieties can be ligands, single strands of DNA, enzymes, antibodies, or synthetic proteins that can detect whole cells or individual proteins (390–392).

Drug Delivery. One very promising application for EAPs is in the area of drug delivery. This method takes advantage of the swelling and deswelling that occur in EAPs during the redox process. Bioactive molecules such as dopamine (393–395) and ATP (396–398) can be reversibly trapped in the polymer during polymerization or polymer oxidation and then released during reduction of the polymer. Such systems could conceivably be used in conjunction with biosensors as electroresponsive membranes, delivering small quantities of medicines as needed.

Dynamic Cell Behavior. While not as well-explored as sensors and drug delivery systems, dynamic cell behavior can also be investigated using EAPs.

Cell motility, motion, and proliferation can be monitored. For example, DNA-functionalized EAPs can be used to monitor genetic mutations (399). Direct detection of DNA hybridization has been accomplished with a functionalized polypyrrole (400).

Membranes for Gas Separation and Ion Exchange. As a result of the volume changes that occur as part of the redox process, EAPs undergo reversible changes in porosity. This interesting effect has led to studies of EAP membranes for separation of gases and liquids. Water permeability of PANI and PPy is much higher in the doped state than in the neutral state (401). Gas separation has been demonstrated with EAPs (402–404), and ion permselectivity has also been observed (405).

Batteries/Supercapacitors. Electrochemical charge storage systems (batteries and supercapacitors) are currently employed in a wide variety of applications (14); there is a constant demand for performance improvements and reduced environmental impact. Redox-active polymers are promising materials for use in batteries and supercapacitors because of their high gravimetric and volumetric charge capacities, fast charge/discharge rates, robustness, environmentally friendly nature, and lower costs relative to noble metal oxides (406–408).

Battery designs using electroactive polymers feature the EAP as the cathode, which is separated from an anode (such as Li, Na, Mg, and Zn) by an electrolyte. Normally, high specific energies of up to 3.5 V can be obtained (409). EAPs that have been used in rechargeable batteries include polyacetylene-, PANI-, PPy-, PT-, and PPP-based materials (410). The current drawback to full utilization of EAPs for rechargeable batteries is the rate limitations associated with low ionic mobilities of the polymers as well as the electrolytes (14).

Electroactive polymers have also been investigated for use in supercapacitors. These devices provide a higher power density than batteries at a lower operating voltage. Supercapacitors have a higher energy density than traditional capacitors because of the high capacitance of the electrode materials (411). Target applications are as computer memory backup, peak power for electric vehicles, and burst power for military platforms. Ruthenium oxide, the most promising inorganic supercapacitor material, exhibits capacitance values up to 720 F/g (412). EAP-based supercapacitors, which are expected to be less expensive than those based on metal oxides, exhibit capacitance values up to 350 F/g (413); further research is expected to increase this value considerably. Most EAP-based supercapacitors combine one or two p-dopable polymers (type I and type II supercapacitors, respectively); devices based on polypyrrole (414), polythiophenes (413,415), polyaniline (416), and poly(3,4-ethylenedioxythiophene) (417,418) have been investigated. Type III supercapacitors, those combining a p-dopable and an n-dopable polymer, could theoretically yield higher energy and power densities and operate at higher voltages than type I or type II supercapacitors (419). However, type III supercapacitors are currently plagued with long-term stability issues related to instability of the n-doped polymers.

Conductive Coatings for Electromagnetic Shielding and Static-Dissipating Applications. In addition to the RF electrochromics research discussed above, EAPs are also used as conductive coatings on textiles for radar-absorbing materials (RAMs) (420). Polypyrrole and PANI are both examples of EAPs used in composite formulations as RAMs (420,422).

Electromagnetic interference (EMI) shielding has become increasingly important because of the combination of increasing number of electrical systems (vehicles, computers, etc) and the increasing use of microwaves in advanced navigation and domestic appliances. Traditional EMI shielding has involved incorporation of conductive fillers (metal particles, conducting carbon black, or graphite fibers) into plastic housing materials (423,424); poor mechanical properties (328) and poor reproducibility of performance characteristics are the major drawbacks of these composite systems (324). EAPs do not necessarily suffer from these problems and have therefore been investigated as replacements for these filled materials (326), although mechanical instability of many EAPs of interest has led to the use of EAPs blended with non-conductive polymers (324,328,425).

The need for improved static control or electrostatic discharge materials poses a challenge for materials scientists and engineers (426). The protection of sensitive electronic devices requires an environment in which unwanted electrical charges, voltages, and electric fields are dissipated. The bulk of electronic packaging requires an insulating material that is clear, durable, and inexpensive. Insulating plastics are widely used as structural materials for the packaging industry, and static charge often builds up; the accumulated charge must be dissipated as rapidly as it is formed, and so conductive additives are required. Static-dissipating materials should have resistivities between 10^6 and 10^9 Ω/sq, and they should be transparent and durable even under extreme conditions (427).

The cheapest and most-often-employed materials have been polymer blends or composites containing carbon black as filler (428,429). However, high loading levels of conductive fillers are often required, leading to significant decreases in durability and transparency. In these cases, the use of EAPs, either as coatings or as fillers, is becoming more common (426).

EAPs are currently used as additives and melt processed with conventional resins such as polyethylene to form static-control articles such as films and trays (430). EAP coatings are also used in the production of static-dissipating carpets (431) and fabrics (432). Recently, EAP coatings have been shown to dissipate static in energetic materials more effectively than carbon black additives, providing a much-needed safety feature for the handling and storage of energetic materials (433).

Actuators. Inorganic piezoelectric and electrostrictive materials have shown a major technological role in converting electrical energy to mechanical energy in actuators. However, electroactive polymers offer several unique advantages over inorganic materials, including large dimensional changes, high stress generation, high work capacity per cycle, ease of fabrication, and low cost (434).

Numerous electroactive polymers, including polythiophenes, polypyrrole, poly(*p*-phenylene vinylene)s, poly(*p*-phenylene)s, and polyaniline, have shown significant dimensional changes upon doping and dedoping (435–440). These dimensional changes result from changes in the volume required to accommodate anions, cations, and/or cointercalating solvent species. Volume changes ranging from 0.1 to 10% are normally observed with doping (441).

This unique behavior has been exploited for applications including controlled release (discussed above) and electrochemically driven actuators.

EAP-based actuators have been explored for use in artificial muscle fibers (AMFs) (442–444) and microelectromechanical systems (MEMS) (437). Non-conductive polymeric gel systems have been used for several decades as actuator devices (445–447); but with low elastic modulus and low yield strength, applications of gel-based actuators are very limited. Gel-based actuators offer one significant advantage over EAPs in that their volume changes can exceed a factor of a thousand (448).

Corrosion Inhibition. EAPs have been investigated over the past decade as corrosion-inhibiting materials (449). The most extensively studied of the EAPs for corrosion prevention has been PANI (450–452). Researchers at Los Alamos National Laboratory (LANL) and the NASA Kennedy Space Center demonstrated that doped PANI coatings inhibited corrosion of carbon steel (451). Their tests were conducted in a 3.5 wt% NaCl/0.1 *M* HCl environment using ca 0.005-cm-thick films of PANI doped with *p*-toluenesulfonic acid on carbon steel; the PANI was covered with an epoxy topcoat. The PANI/epoxy coating performed significantly better than the epoxy topcoat alone. These initial results were used by researchers at LANL–NASA to develop EAP coatings to resist the corrosive effects of acid vapor generated during space shuttle launches. Their approach was based on earlier work suggesting that the interfacial contact between the metal and a doped EAP would generate an electric field that would restrict the flow of electrons from the metal to an outside oxidizing species, thus preventing and/or reducing corrosion (453).

There have been numerous reports in the literature regarding the use of EAPs in retarding corrosion on steel alloys (454,455). There is still debate on whether the doped or undoped form of PANI provides the best corrosion protection; several reports have shown that the undoped form of PANI can perform as well as or better than the doped form of PANI (456,457).

While there is general agreement that PANI performs well in retarding corrosion on carbon steel, the mechanism for this process is still under investigation. Several hypotheses are suggested for corrosion protection using EAPs: (*1*) PANI contributes to the formation of an electric field at the metal surface, restricting the flow of electrons from metal to oxidant; (*2*) PANI forms a dense, strongly adhering, low porosity film similar to a barrier coating; and (*3*) PANI causes the formation of protective layers of metal oxides on a metal surface.

While PANI has been extensively studied for corrosion control, its major drawback is its pH dependence. It works very well in acidic environments because of the formation of the conductive emeraldine salt, but at higher pH (>7) the non-conductive emeraldine base is formed, and the material no longer provides adequate protection against corrosion. Thus, use in a marine environment (pH $\sim$ 8) is not possible.

For marine applications, pH-stable EAPs have been investigated. Double-stranded PANI has been coated onto Al alloys (458); immersion tests in simulated seawater showed improved corrosion resistance as compared to control samples (epoxy coating) (459). Recently, poly(bis-dialkylamino)phenylene vinylene) (BAM-PPV) was shown to adhere to Al alloy in an immersion test using simulated seawater (pH $\sim$ 8) to retard corrosion (460,461). Quantitative evidence was obtained to show corrosion inhibition as compared to noncoated Al alloys.

Summary

The reversible addition or removal of electrons from the backbones of electrically active polymers is accompanied by significant changes in their physical and chemical properties. The ability to reversibly switch EAPs between insulating and conducting, opaque and transparent, absorptive and emissive, and expanded and contracted drives much of the current research. EAP properties are strongly dependent on polymer structure; the ability to tailor these properties through thoughtful synthetic methods facilitates the development of new devices to meet the increasing demands of today's society. Industry has already achieved success with commercial devices that utilize EAPs. Attempts to increase stability and to better understand structure–property relationships are crucial to the development of materials for new and improved applications.

ENVIRONMENTALLY DEGRADABLE PLASTICS

Introduction

Environmentally degradable plastics are sometimes referred to as "green plastics" where the word "green" is used in an ecological sense. The impact of plastics on the environment is hardly a new theme, but with increased interest in "green chemistry" and the broader "green revolution," the relationship between plastics and the environment is a topic of current interest.

Overviews on environmentally degradable plastics have recently appeared for the nonspecialist (1–4) as well as more technical symposia proceedings (5–13). Several extensive Web sites are maintained (14,15) and a commercial market report has been available (16) (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

Throughout the 1990s the two major issues relevant to a plastic's "greenness" were feedstock renewability and alternative late-stage disposal options based on degradability, biodegradability, and compostability. These issues are related to 2 of the 12 "principles of green chemistry" elucidated by Anastas and co-workers (17,18): (*1*) a feedstock should be renewable wherever technically and economically practicable and (*2*) products, at the end of their function, should break down into innocuous degradation products (17, p. 30).

Political considerations not particularly connected with the environment have also played a role in focusing attention on the production of plastics, including growing concern over dependence on foreign sources of crude oil, the desire to find additional markets for agricultural products, and the increasing costs and other difficulties of waste management (particularly strong in Europe and Japan) (3).

Since 1993, the International Standards Organization (ISO), through its Technical Committee 207, has been developing the 14000 series,

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

"Standardizations in the Field of Environmental Management." The long-term goal of this effort is to formulate life-cycle assessment (LCA) programs, environmental auditing procedures, product standards, and product-labeling programs that incorporate environmental aspects (14). In particular, LCA would provide the analytical tools and protocols for producing an inventory analysis of the material and energy inputs and outputs for a product system, and an environmental impact assessment that includes the inventory analysis and a product's complete environmental profile (19). One central concern in LCA is the origin and fate of the carbon contained in or released as carbon dioxide in the production, use, and disposal of the product. ISO 14040 describes the uses and limitations of LCA methodology.

LCA of plastic products is still in the early stages of development. While future reports on "green plastics" may have the benefit of well-documented LCAs containing quantitative results obtained with consensus analytical tools, the present report is limited to the two factors originally motivating attention to the environmental impact of plastics—the origin of the plastics feedstocks (renewable vs nonrenewable) and the ultimate environmental fate of discarded plastics (degradable/biodegradable/compostable vs recalcitrant).

Greenness and price are two separate issues. Even green plastics will have to have favorable price–performance ratios in order to compete in the marketplace, but complicating the issue of price is the reality that no accepted method for determining total cost exists that would account for such factors as the depletion of natural resources, the costs of guaranteeing the supply of raw materials, or the environmental burden of waste management.

Definitions. Standardization of definitions, test methods, and performance criteria are required for degradable, biodegradable, and compostable plastics (as for other plastics), to allow product stewardship, to enable regulatory programs, and to support consumer confidence. In the United States these responsibilities lie with the American Society for Testing and Materials (ASTM).

ASTM definitions of technical terms used in the plastics industry are the responsibility of ASTM Committee D20 on Plastics. Its Subcommittee D20.92 on Terminology originated, for example, ASTM document D883-00, "Standard Terminology Relating to Plastics." Several of the most important ASTM definitions from that standard related to the degradation of plastics are reproduced here:

Degradation: A deleterious change in the chemical structure, physical properties, or appearance of a plastic (see DEGRADATION).

Degradable plastic: A plastic designed to undergo a significant change in its chemical structure under specific environmental conditions, resulting in a loss of some properties that may vary as measured by standard test methods appropriate to the plastic and the application in a period of time that determines its classification.

Hydrolytically degradable plastic: A degradable plastic in which the degradation results from hydrolysis.

Oxidatively degradable plastic: A degradable plastic in which the degradation results from oxidation.

Photodegradable plastic: A degradable plastic in which the degradation results from the action of natural daylight.

Biodegradable plastic: A degradable plastic in which the degradation results from the action of naturally occurring microorganisms such as bacteria, fungi, and algae.

Compostable plastic: A plastic that undergoes degradation by biological processes during composting to yield carbon dioxide, water, inorganic compounds, and biomass at a rate consistent with other known compostable materials and leaves no visually distinguishable or toxic residues.

A plastic can be degradable but not necessarily biodegradable; it can be biodegradable without being compostable (ie, the rate of degradation is part of the definition of compostable); and it can be compostable without being biodegradable (ie, the degradation may be abiotic). Also notice that the definition of biodegradable plastic refers only to degradation by microorganisms, not macroorganisms.

Test Methods. Industry standard test methods for determining the environmental degradability, biodegradability, and compostability are the responsibility, in the United States, of ASTM's Subcommittee D20.96 on Environmentally Degradable Plastics. Standard ASTM test methods used to assess biodegradability include measurements of carbon dioxide production (eg, Sturm test and soil test), weight loss, extent of fragmentation, tensile properties, molecular weight and molecular weight distribution, enzyme assays, biochemical oxygen demand (BOD), and ecotoxicity (eg, cress seed test and earthworm test).

Multiple test procedures are necessary in evaluating a material because some tests are subject to false-positive interpretations. Examples are (*1*) an observed weight loss may result from the leaching of additives rather than polymer degradation; (*2*) carbon dioxide production might result from the degradation only of a low molecular weight polymer fraction; and (*3*) a large loss of material strength might come from a very small change in chemical makeup. To illustrate the application of such test procedures it can be said, for example, that poly(ε-caprolactone), by its disappearance in a soil burial test, is potentially biodegradable in soil, whereas unmodified polyolefins like polyethylene, polypropylene, and polystyrene are recalcitrant.

A distinction is necessary between evaluations of a polymer and a plastic made from that polymer because Additives (qv) (Plasticizers (qv), stabilizers, etc), processing, and fabrication may all have effects on environmental behavior. For example, a polymer or blend may be biodegradable and compostable as film, fibers, or foam, whereas injection-molded products may be inherently biodegradable but not environmentally compostable.

ASTM D6400. In 1999 ASTM announced its "Standard Specification for Compostable Plastics" (D6400-99). The standard establishes criteria to be met before a product can be labeled compostable. Briefly, a product must, at minimum, satisfy ASTM tests showing conversion to carbon dioxide at 60% for a homopolymer or a statistical random copolymer and 90% for other types of copolymers and blends in 180 days or less, and leave no more than 10% of the original weight on a 2-mm screen. If carbon-14 tests are used a test period of 365 days is allowable. Environmental toxicity issues are also addressed, including limits for heavy metals. The ASTM standard has counterparts in German (DIN 54900), European (EN 13432), and international (ISO 14855) documents.

The relatively short time scale of 6 months in ASTM D6400 identifies plastics that compost quickly, completely, and safely, and serves well the purpose

of diverting waste from landfills and incinerators to composting facilities. Some common and inherently compostable biomaterials, however, including wood and leaves, do not satisfy the D6400 specification. Discussion continues as to whether complete biodegradability is required for compostability. A longer time scale for compostability, with less rapid carbon dioxide evolution, may be suitable for purposes of providing long-term soil enhancers, and it may turn out that ASTM will develop a second standard of compostability aimed at plastics that degrade more slowly. But the potential impact of the accumulation of undegraded plastic residues on long-term agricultural productivity is an important issue that has not yet been resolved either by long-term scientific measurements or by consensus.

Products that comply with the ASTM specification, as confirmed by independent testing, can bear a logo developed jointly by the international Biodegradable Products Institute (BPI) and the United States Composting Council (USCC). Certified products are listed on the BPI Web site at www.bpiworld.org.

Markets. Green plastics typically can be produced in various forms (pellets, film, and fibers) and are compatible with a variety of processing methods (Extrusion (qv) and molding). Markets for green plastics are, therefore, potentially the same as those for conventional plastics. In order to be successful in those markets, green plastics will have to possess the physical properties required for the intended application and be cost-competitive; that is, regardless of the intended market, success will be determined by the cost–performance ratio in comparison to the conventional plastics targeting the same market.

Beyond that, however, markets for green plastics can be distinguished according to how biodegradability and compostability are related to the application. In some applications, biodegradability and compostability serve intrinsic functional purposes and give the product a performance capability that often cannot be matched by alternative products. For example, agricultural mulching films control soil temperature and moisture, reduce leaching of nutrients, and prevent weed growth, increasing productivity for vegetable and fruit crops (eg, tomatoes, peppers, melons, and sweet corn) by 50–350% (2). Compostable agricultural mulching film that can be plowed under after use eliminates the costs of collecting and disposing of nondegradable polyethylene covers. Similar advantages accrue with other compostable agricultural and horticultural products, such as planting pots, baling rope and twine, string, clips and hooks, labels, seed mats, time-released fertilizers (greensticks), and others.

Biodegradability and compostability are also central to the function of collection bags for compostable materials (like yard waste and food waste) and of trash bin liners. Approximately 10% of the 1.5 billion pounds of trash bags produced in the United States are used for lawn and leaf bags. Nondegradable bags and liners add to the costs of composting: (*1*) they have to be separated from the waste to avoid contamination of the compost, (*2*) imperfect separation degrades compost quality, and (*3*) nondegradable bags require disposal. Compostable waste bags and trash bin liners avoid these problems. Biodegradability is an intrinsic feature of some other applications, such as the institutional use of laundry bags that dissolve during the washing and then biodegrade after disposal into sewage.

In other applications the product's compostability, rather than serving a functional requirement of the application, provides an alternative waste-disposal method. Composting diverts waste from landfills and incinerators and contributes

to the sustainability of agriculture. Composting is especially important in Europe and Japan, where land is scarce and high landfill fees are common. In Japan, land is so scarce that over 90% of the solid-waste stream is incinerated, but concern has grown over the observed increasing levels of environmental dioxins. In the United States, many states are developing their composting infrastructures, especially for commercial and institutional sources, in order to increase their overall recycling rates.

Plastic packaging is an increasing component of municipal solid waste, and markets for compostable plastics are potentially large in the area of packaging—for industrial, commercial, and household use. Examples include single-use and limited-use disposable materials such as packaging film for food and nonfood items, bottles, jars, loose-fill packaging, and rigid foam packaging.

Food-service items constitute another significant end use, including cutlery, plates, cups, trays, and plastic coatings for paper products like plates and cups. Markets include institutions (hospitals, schools, prisons, and the military), the fast-food industry, and the general public. Another end use category is consumer products, including such products as diapers, personal care and hygiene articles, sports and recreation items, and others.

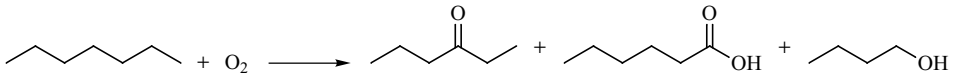
Some manufacturers emphasize the physical properties of their products, with little or no emphasis on biodegradability except as a corollary benefit.

Green plastics comprise only a very small part (less than 1%) of today's plastics. They do, however, make up a significant part of some specialty, niche markets: starch-based loose-fill packaging now constitutes 30% of the loose-fill packaging market. The plastics described here are those currently commercially available, and are limited mainly to those available in the United States. Manufacturers are named only for illustrative purposes; the list is not intended to be comprehensive. The plastics materials are described generically, with respect to the major polymer constituent(s); for each generic type there are likely to be many specific formulations. Brief mention is made, at the end, of some materials that have been studied in the laboratory. Biomedical applications are described separately (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

Many of the polymers mentioned below have separate entries in the encyclopedia. Here the focus is on their specialized use in the production of environmentally degradable plastics.

Petroleum-Based Polymers

Activated Polyolefins. Polyolefins degrade by oxidation (eq. 1) (2) but the rate in the environment is extremely slow; polyolefins are environmentally recalcitrant. In "activated polyolefins" the environmental degradation is enhanced. An early example was the photodegradable plastic produced when an olefin is copolymerized with carbon monoxide (CO) (2,20) (see POLYKETONES). A copolymer of ethylene and (∼1%) CO, on exposure to outdoor sunlight for approximately 3 weeks, becomes embrittled and fragments to a friable powder. A major application is the manufacture of plastic six-pack holders for beverage containers, which became important after 1990 when the United States Congress, in response to public concern over litter, passed Public Law 100-556 requiring that plastic ring carriers be made of degradable material. Manufacturers include Dow and DuPont.



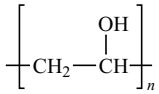
(1)

Various conventional ketone monomers can also be used in copolymerizations with olefins to introduce groups that promote oxidation. Transition-metal complexes (iron, nickel, cobalt) introduced after polymerization act as antioxidant stabilizers during processing but, following an induction period (the length of which depends on concentration), the complexes convert to products that are oxidation activators. Through formulation variations, the length of the induction period and the rate of degradation that follows can be controlled.

For applications where the expected disposal environment is earth burial, commercially available additive packages can be incorporated (~3% by weight) into polyethylene or polypropylene during processing to induce accelerated oxidative degradation initiated by natural daylight, heat, and/or mechanical stress. Applications include agricultural mulching film, compost bags, shopping and grocery bags, baling twine, and packaging film.

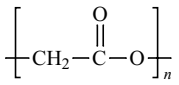
Activated polyolefins do not meet the requirements of compostability specified in ASTM D6400. They have market acceptance where cost is of paramount importance and adherence to the ASTM D6400 specification is not mandated.

Poly(vinyl alcohol), Poly(glycolic acid), and Poly(ε-caprolactone). Poly(vinyl alcohol) (**1**) (see VINYL ALCOHOL POLYMERS) is the most-produced water-soluble polymer in the world. It is prepared by free-radical polymerization of vinyl acetate followed by alcoholysis. It environmentally degrades (21,22) by oxidation to form carbonyl groups along the chain, and subsequent hydrolysis. Poly(vinyl alcohol) is an exception to the general rule that chains of carbon–carbon single bonds (as in polyolefins) are recalcitrant. Although considered to be a biodegradable synthetic polymer (the oxidation can be both enzymatic and nonenzymatic), the extent of degrading microorganisms appears to be limited. Poly(vinyl alcohol) has applications in hospital laundry bags, water-soluble packaging, agricultural products, and other film products. Poly(vinyl alcohol) is also used in blends (see below).



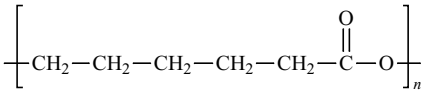
1

Poly(glycolic acid) (**2**) (23) is synthesized from condensation polymerization of glycolic acid or catalytic-ring-opening polymerization of the glycolide. (Although glycolic acid is found in nature it is commercially produced mainly through synthesis.) Poly(glycolic acid) is not only biodegradable, it is biocompatible—nontoxic and not rejected by the intended organism. It is therefore used in various biomedical applications (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS). In applications intended for large-scale use, glycolic acid is widely used in combination with either petroleum-based or renewable components (see below).



2

Poly(ε-caprolactone) (**3**) (23) is synthesized by ring-opening polymerization of ε-caprolactone using tin-octanoate as a catalyst (24). It is used, for example, as blown film for compost bags or in materials where it serves as a matrix for the controlled release of pesticides, herbicides, and fertilizers. The low melting point of poly(ε-caprolactone) (60°C) (Table 1) limits applications, but it has good mechanical properties and is more hydrophobic than—and compatible with—many biopolymers. It is therefore widely used to modify the properties of other degradable plastics in blends (see below).



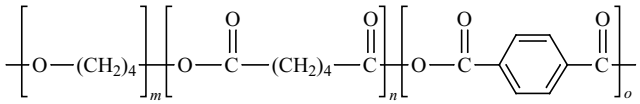
3

Aliphatic polyesters like poly(glycolic acid) and poly(ε-caprolactone) are biodegradable through the action of nonspecific enzymes including the esterases found abundantly in soil (23,33–36).

Copolyesters and Poly(ester amides). Many biodegradable thermoplastic copolyesters (aliphatic and aliphatic–aromatic) and poly(ester amides) are manufactured from conventional petroleum-based monomers (23). (see POLYESTERS, THERMOPLASTIC). The process often involves diols (eg, ethylene glycol, 1,4-butanediol, 1,6-hexanediol) and dicarboxylic acids (eg, adipic, succinic, sebacic). Terephthalic acid is sometimes a component; the aromatic diacid increases chain rigidity. These copolyesters biodegrade in a composting environment by surface growth of bacteria and fungi, and the action of hydrolytic enzymes. Degradation rates in compost depend on composition.

They are typically available as resins, films, or fibers; are usually extrusion-processed; and are characteristically strong, elastic, and waterproof. Applications variously include agricultural mulching film, compost bags, shopping bags that can later be used as compostable garbage bags, transparent film packaging, film coatings for paper and paperboard containers (eg, drinking cups), coatings for starch film, disposable diapers, nonwoven and fiber applications, and others.

EastarBio copolyester (**4**), (Table 1), manufactured by Eastman Chemical, is a random poly(butylene adipate-*co*-terephthalate) containing 50% terephthalate; film is prepared by solvent casting (Fig. 1). EastarBio copolyester biodegrades to the extent of 80% in 150 days in a compost environment.



4

Ecoflex, manufactured by BASF, is a random copolyester based on terephthalic acid (40–45%), adipic acid (55%), and 1,4-butanediol, plus chain-extending additives (Table 1). A modified poly(ethylene terephthalate) copolyester is manufactured by DuPont as Biomax (Table 1).

A fraction of the ester linkages can be substituted with amide linkages, which modifies interchain hydrogen bonding. Examples are the BAK poly(ester amides) previously manufactured by Bayer.

Table 1. Selected Properties: Typical Values for Film Products or Product Families

	Manufacturer	Trade name	Product	Density, g/cc	T_g,°C	Melting temperature, °C	Tensile strength, MPa	Elongation, %	Tensile modulus, MPa	Reference

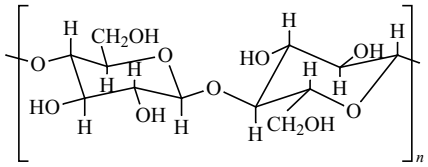
Polymers from Renewable Sources

Cellulose. Cellulose (qv), $\beta[1\rightarrow4]$-linked D-glucose (**5**) (37), is the most abundant biopolymer on earth and accounts for 40% of all organic matter. It is the main component of plant structural fiber that keeps the plant cell wall intact and gives it strength. Oven-dried cotton (qv) contains about 90% cellulose. An average wood (q.v.) has about 50% cellulose, the remaining components being lignin (qv) and hemicellulose. Well over 68 million metric tons of cellulose are produced commercially each year, mainly from wood.



5

Cellophane is an example of "regenerated cellulose." In the viscose process (38,39), shredded wood pulp is treated with caustic soda, producing alkali cellulose. After aging to produce the desired extent of cellulose degradation, the cellulose is treated with carbon disulfide to form a thick solution of xanthated cellulose, called viscose. The viscose is "ripened," and extruded into a bath of sulfuric

acid and sodium sulphite, generating a coagulated gel. The transluscent gel is washed, purified, and bleached. Softening agents—often either glycerol or ethylene glycol—and other chemicals are then added, and the resulting material is cast into a sheet consisting of an amorphous felt. The sheet has high water-vapor permeability, but good resistance to oils and greases. Coatings of nitrocellulose-wax or poly(vinylidene chloride) provide barriers to moisture and gases, solvent sealability, and heat sealability. Cellophane has a water-vapor permeability comparable to high density polyethylene.

Newer technology, based on the use of *N*-methylmorpholine-*N*-oxide as a cellulose solvent (40), has been developed with the aim of reducing hazardous by-products and producing a more environmentally friendly process. The viscose technology, however, still dominates (see CELLULOSE FIBERS, REGENERATED).

Production of cellophane peaked in the 1960s at about 340,000 t a year in the United States, but since then has largely been replaced by synthetic plastics such as polypropylene. Cellophane is still used in food packaging for such items as potato chips, candies, and baked goods; its stiffness allows bags to stand upright on shelves. Nonfood applications include cigarette packages, cigar wrappings, and others; it tears well when notched and has excellent printability.

Uncoated cellophane film readily biodegrades beginning with a hydrolysis reaction catalyzed by the extracellular enzyme cellulase. It disintegrates in 10–14 days and totally biodegrades in 1–2 months. Nitrocellulose–wax coatings also totally biodegrade, in 6 months or so. Coatings of poly(vinylidene chloride) do not biodegrade; they disintegrate to a friable powder.

Cellulose is not thermoplastic but can be chemically modified to produce a wide variety of cellulosic plastics—some of which are thermoplastic—and fibers. Before 1950 cellulosics were the most important group of thermoplastics; today, cellulosic fibers still make up about 8% of the fiber market. Some chemically modified celluloses do not have the biodegradability of cellulose.

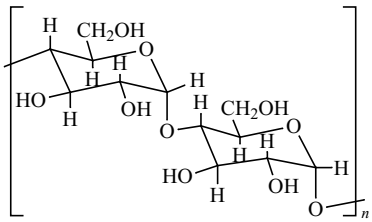
Cellulose acetate, one of the most important cellulosics, is produced by the reaction of cotton fiber with acetic acid and acetic anhydride using sulfuric acid as a catalyst. It is thermoplastic, and films can be obtained by extrusion as well as by casting from acetone solution. The film is clear and strong, and has high oxygen and water-vapor permeability. It "breathes" and does not fog, making it useful as packaging film for fresh produce and baked goods. It is also resistant to oils and greases. Cellulose acetate can also be molded (see CELLULOSE ESTERS).

The degradation of cellulose acetate begins with abiotic hydrolysis and oxidation, followed by complete biodegradation, but acetylation decreases the biodegradation rate relative to cellulose. For example, increasing the degree of substitution from an average of 1.7 of the three hydroxyl groups per monomer (**5**) to 2.5 significantly reduces the rate of biodegradation.

Starch. Starch, thermoplastic? (qv) (41,42) is a major agricultural commodity and, by far, the most inexpensive commercial biopolymer; it is the only biopolymer that is competitive with polyethylene in price. Annual world production, over 32 million metric tons, is from corn (maize), potatoes, rice, tapioca (cassava), barley, wheat, and other crops. Approximately 16 million metric tons are produced in the United States each year, mainly by extraction from corn but also from potatoes, wheat, and other sources.

Well over half the starch produced is partially hydrolyzed to manufacture corn syrup, dextrose (glucose), and other hydrolysis products that are used as sweeteners or as feedstocks for various manufacturing processes in the chemical, pharmaceutical, and brewing industries. Approximately 75% of the remaining starch, either in native form or modified, is used for nonfood industrial purposes in the manufacture of paper and cardboard, paper coatings and sizings, textile and carpet sizing, and adhesives. Food uses include baby foods, bread batter, cake mixes, confectioneries, puddings, pie fillings, glazes, and sauces.

Starch serves an energy storage function in plants; when starch is metabolized by plants, energy is released and used for plant growth. The major polymer components of starch are amylose and amylopectin. Amylose (**6**) is $\alpha[1 \rightarrow 4]$-linked D-glucose; its molecular weight ranges from 2×10^5 to 2×10^6. Amylopectin has a backbone of $\alpha[1 \rightarrow 4]$-linked D-glucose with $\alpha[1 \rightarrow 6]$-linked D-glucose at branch points; it has molecular weights up to 4×10^8. The relative amounts of amylose and amylopectin vary with the source plant. Cornstarch is typically 28% amylose and 72% amylopectin, but it can be genetically modified to have as much as 85% amylose or, for all practical purposes, 100% amylopectin (waxy maize starch). The physical properties of starch depend on the amylose/amylopectin ratio.



6

Natural starch occurs in the cell in the form of granules. The starch granules are gelatinized upon heating, whereupon the starch molecules become more disordered; the gelatinization temperature ranges from about 70°C in excess water to above 200°C at low moisture content. Depending upon treatment conditions, the starch granules and their crystalline structure may be completely destroyed. In time the starch may retrograde; that is, it reassociates into aggregates and precipitates at low concentrations or sets to a gel at higher concentrations, eventually becoming cloudy, releasing water, and shrinking into a rubbery consistency.

Under proper conditions of temperature, pressure, water content, and shear, the starch granular structure is totally disrupted (43). The starch exists as a continuous phase and in this state is called thermoplastic starch (TPS). TPS can be extruded, injection-molded, or formed into foams (44–48).

The major limitation in developing applications, representing an obstacle to be overcome, is the hydrophilicity of starch, which leads to water sensitivity in physical properties. Strategies for decreasing sensitivity to water include derivitization. For example, acetylation at a degree of substitution greater than 1.5 of the three hydroxyl groups per monomer (**6**) leads to water-resistant "hydrophobic" starch. Chemical modifications often increase water resistance without

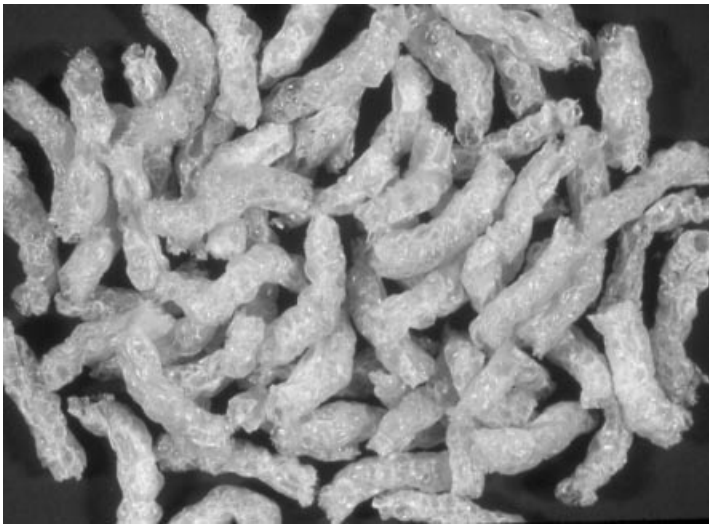


Fig. 2. Water-resistant foam packaging "peanuts" made by extruding starch acetate and water. Courtesy of R. Shogren, U. S. D. A.

significantly decreasing biodegradability. Plasticizers (qv) like glycerol acetate and diethyl succinate can be used to improve processability.

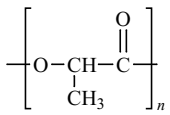
Extruded starch foam is produced by the flash generation of steam as the starch leaves the die (49,50). Foam packaging "peanuts," as a replacement for polystyrene, can be made by extruding starch acetate or hydroxypropylated starch and water (Fig. 2). A commercial example is EcoFoam, a water-soluble extruded hydroxypropylated starch foam manufactured by National Starch and Chemical Co.

Other strategies for overcoming the water sensitivity of starch include blending with other polymers and forming composites by the addition of polymeric or mineral fillers (see below).

Poly(lactic acid). Lactic acid, $CH_3CHOHCOOH$, occurs naturally in animals and in microorganisms. It can be produced commercially by chemical synthesis, but in the United States fermentation is the major route. In *bioreactors*, microorganisms are fed a carbon source substrate, such as dextrose, with yields of lactic acid greater than 90%. The lactic acid is recovered from the fermentation broth and purified in a multistep process that represents a major part of production costs. Eighty percent of the world's production of lactic acid is from corn sugar.

Poly(lactic acid) (PLA) (**7**) (Table 1) is the polyester synthesized from lactic acid (51–54). Condensation polymerization produces a low molecular weight prepolymer ($M_n \sim 5000$) that is treated with chain extenders to yield high molecular weight PLA. Condensation polymerization yields high molecular weight PLA directly when carried out in a high boiling point azeotropic solvent with removal of water by distillation at reduced pressure. Alternatively, the prepolymer is depolymerized in the melt under reduced pressure to produce lactide, the cyclic dimer of lactic acid (a dilactone). Metal-catalyzed ring-opening polymerization of lactide

produces a high molecular weight polymer ($M_n = 60{,}000–150{,}000$) PLAs are also called Polylactide (qv).



7

PLA from L- or D-monomers is semicrystalline, with a melting transition near 180°C and glass temperature around 67°C. In contrast, a racemic mixture of L- and D-lactic acid produces amorphous polymers with glass temperatures near room temperature. During the depolymerization of the prepolymer the stereoisomers are separated. The L-lactide is the primary component of the high molecular weight PLA; varying the amount of D-lactide allows a variation in physical properties (Table 1).

PLA is thermoplastic and can be processed by extrusion, injection molding, blow molding, and thermoforming. It is unstable in acid and alkaline solution, but is insoluble in water and has good moisture and grease resistance. Its mechanical properties depend on molecular weight and crystallinity. Properties can be varied so as to display, for example, the clarity of polystyrene, the stiffness and tensile strength of poly(ethylene terephthalate), and the twist-retention of cellophane. Other features include favorable flavor and aroma barrier properties, low temperature heat-sealing, and printability. Lactic acid can be copolymerized with glycolic acid or ε-caprolactone to extend the range of properties further.

Major current applications of PLA include clear packaging film and thermoformed articles for disposable food service items and other containers (Fig. 3). PLA can also be spun, and other current major applications are as fibers used in bedding products, clothing, carpets, sheets and towels, and wall coverings (Fig. 4). In addition, PLA can be used for agricultural mulching film and other compostable agricultural and horticultural products, compost bags, trash bin liners, sporting items such as golf tees, coatings for paper and cardboard, and other products. An example is NatureWorks manufactured by Cargill Dow (Figs. 3 and 4).

PLA degrades by hydrolysis, even in the absence of enzymes, and can be recycled back to the monomer. It is compostable, but the rate of biodegradability in a composting environment depends strongly on conditions of temperature, crystallinity, and size and shape of the article (23,34,55–58). The resistance of PLA to degradation by microorganisms plays a role in food packaging applications. PLA is also biocompatible (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

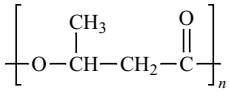
As new markets develop for the monomer, lactic acid, through, for example, its conversion to ethyl lactate for use as a biobased solvent, the cost of PLA may be reduced.

Microbial Polyhydroxyalkanoates. Some microorganisms produce polyesters as energy and carbon storage materials, metabolizing them when no external carbon source is available (59,60). Microbial polyesters are now produced commercially through large-scale fermentation processes carried out in bioreactors. Microorganisms (eg, *Ralstonia eutropha*) are fed carbon source substrates, promoting cell growth followed by polymer accumulation, which can result in as

Fig. 3. Sealed packaging tray made from NatureWorks™ PLA. Courtesy of Cargill Dow Co.

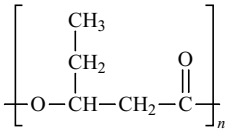
much as 80–95% of the cell's dry weight. The bacteria are collected and washed, and the cells ruptured. The polymer is extracted with a solvent, precipitated from water as a white powder, and converted to pellets (61).

The major commercial microial polyesters are polyhydroxyalkanoates (PHAs) (see POLY(3-HYDROXYALKANOATES)) Poly(3-hydroxybutyrate) (PHB) (**8**) is brittle, but as the number of carbon atoms in the side chains of PHAs increases, eg, poly(3-hydroxyvalerate) (PHV) (**9**), the properties tend from polypropylene-like to elastomeric. Copolymers, poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV), have a range of properties depending on composition (Table 1).



8

Fig. 4. Bedding products made from NatureWorks™ PLA. Courtesy of Cargill Dow Co.



9

The composition of the copolymer is controlled through the ratio of feedstocks used: glucose or sucrose (from sugar cane, sugar beets, or starch hydrolysates) can be used as substrates for butyrate; propionic acid (eg, from the fermentation of wood pulp waste) can be used for valerate.

PHBV is thermoplastic and can be processed by injection molding, extrusion, blow molding, film and fiber forming, and lamination techniques. Significantly, PHBV is stable in humid air and its barrier properties are not humidity-dependent.

Commercial PHBV can be processed into packaging materials such as bottles, jars, and films; food service products such as eating utensils, cups, and plates; toiletry articles such as combs and razor handles; and other products including credit cards, golf tees, and plant pots. An example is Biopol and other PHAs manufactured by Metabolix (Table 1).

Just as there is a wide range of microorganisms that can synthesize PHAs, there are a large number of microorganisms that can degrade PHAs. PHA biodegradation (23,62,63) begins with bacterial or fungal surface colonization. An extracellular PHA depolymerase degrades and solubilizes the polymer into

fragments that are then absorbed by the cell, resulting in complete biodegradation. PHAs biodegrade at a rate that depends on copolymer composition, molecular weight, degree of crystallinity, and the size and shape of the article. PHBV is also recyclable.

PHAs are biocompatible as well as biodegradable and PHBV is used in biomedical applications (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS). One of its degradation products, butyric acid, is a mammalian metabolite found in low concentrations in humans.

Blends and Composites

Starch-Based. Granular starch was used early on as a particulate filler of conventional polymers (eg, polyethylene and polypropylene) in films (64–66). The starch granules are surface-treated to increase compatibility with the hydrophobic matrix: poly(ethylene-*co*-acrylic acid) or poly(ethylene-*co*-vinyl alcohol) plasticizers may be used to reduce brittleness. At starch levels of less than 10%, intended applications were degradable agricultural mulching film and compost bags. The polyethylene encapsulates the starch granules and biodegradation of the starch granules leads to fragmentation of the film. Photocatalytic additives (transition-metal compounds, unsaturated polymers, oils, fats) aim to enhance degradation of the polyethylene. Compost bags, of 23–25% starch, have "curb sturdiness." Starch–polyethylene formulations of 20–80% starch have also been commercialized. Issues connected with the environmental fate and impact of the polyethylene residues remain, and are the subject of current research.

TPS (see above) interacts with hydrophilic and hydrophobic polymers, and can be blended with petroleum-based polymers that are biodegradable. By varying the composition and processing of the blends it is possible to manipulate blend properties to produce plastics that resist property changes at high relative humidity but are nevertheless compostable. Starch–poly(vinyl alcohol) blends, for example, are thermoplastic and can be processed by extrusion (qv), injection molding (qv), blow molding (qv), film blowing, and thermoforming (qv) (67). Their properties depend on composition and processing. In films there is some sensitivity to humidity, and in water they swell but do not dissolve. With one formulation, the mechanical properties at 55% relative humidity are similar to those of polyethylene. The degree of crystallinity of the poly(vinyl alcohol) component varies according to the level of residual acetate groups that remains following the preparation of the poly(vinyl alcohol) by alcoholysis of poly(vinyl acetate). A range of water-soluble blends can thereby be produced by varying the amount of poly(vinyl alcohol), its molecular weight, and its crystallinity. One application is water-soluble laundry bags (68). Starch–poly(vinyl alcohol) films degrade hydrolytically at a rate that depends on composition and crystallinity. In sludge, carbon dioxide measurements indicate greater than 90% degradation in 10 months.

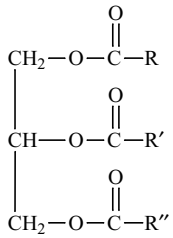
Starch–poly(vinyl alcohol) blends can also be extruded as foams. The poly(vinyl alcohol) increases water resistance relative to foam made from starch alone, allowing shaped applications such as foamed cups and plates.

Fig. 5. Agricultural products (mulch film, planting pots, clips) made from MaterBi™. Courtesy of Novamont S. P. A.

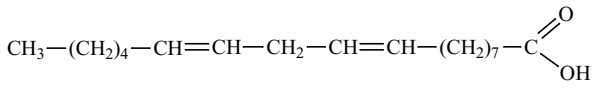
Starch–poly(ε-caprolactone) blends (69) are also water-resistant and totally biodegradable. Their strength and water resistance depend on composition, and film properties can be varied from those resembling low density to high density polyethylene. Applications include agricultural mulching film (12–15 μm) that biodegrades over a controlled period of time to allow cultivation periods from 1 to 5 months. Other applications are trash bin liners, compostable yard waste bags, plant pots, shopping bags, packaging film, cutlery and food service ware, diaper backings, and consumer items. An example of starch-based blends is MaterBi manufactured by Novamont S.P.A. (Italy) (Fig. 5) (Table 1).

Minerals—silicates (clay) or carbonates—increase the stiffness and toughness of starch. Earthshell Packaging manufactured by Earthshell Corp. is a starch–calcium carbonate fiber composite made for a variety of applications including the hinged-lid "clamshell" sandwich containers used in the fast-food industry (Fig. 6). Potato starch and limestone make up about 80% of the composite. They are mixed with water and fiber (eg, cellulose from recycled paper) to form a batter. Thickeners and release agents are added and the batter is placed between two heated mold plates. The water is converted to steam, expanding the batter. The product is finished with protective and water-proofing coatings.

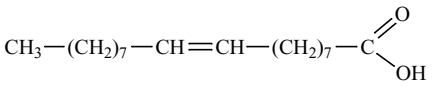
Others. Triacylglycerols (triglycerides) (**10**) (70–72) make up a large part of the storage lipids in animal and plant cells. They are now receiving renewed attention as a candidate feedstock for the production of polymer resins. When liquid at room temperature they are called oils. Commercially important oils are produced from the seeds of soybeans, corn (maize), cotton, sunflowers, flax (linseed), rape, castor beans, tung, palms, peanuts, olives, almonds, coconuts, and canola. Over 7.3 million metric tons of vegetable oils are produced in the United States each year, mainly from soybean, flax, and rapeseed. Soy oil alone accounts for 80% of the seed oils produced in the United States. Soy oil contains about 55% linoleic acid (**11**), 22% oleic acid (**12**) and 10% palmitic acid (**13**).



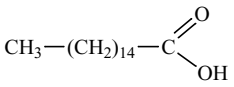
10



11



12



13

Vegetable and animal oils can be made more chemically reactive (eg, by epoxidation), and then cross-linked to form sturdy thermosets. Reinforced with glass fiber the composites have applications in the areas of agricultural equipment and the automotive industry. Plant fiber reinforcement, eg, from jute, hemp, flax, sisal, keraf, wood, straw, or hay, provides a biodegradable option (73).

A triglyceride-based thermoset has been developed from soybean and corn polymers as a sheet-metal alternative for side panels in agricultural equipment, replacing the conventional petroleum-based options (Fig. 7). Initial testing in 1997 involved the University of Delaware's ACRES (Affordable Composites from Renewable Resources) Program and the United Soybean Board. The vegetable-oil composite is strong and weighs 25% less than steel—and less than the petroleum-based products typically used to make panels. It also accepts paint. In 1999, a soy-based polymer was tested in the rear panel of John Deere combines, and beginning

Fig. 7. Prototype John Deere side panel for a hay baler (8′ × 3′, 25 lb.). A foam core is enclosed on both sides with a thermoset composite made from soybean oil resin reinforced with glass fiber. Courtesy of University of Delaware Center for Composite Materials.

with the 2002 model year, John Deere Harvester Works' line of combines has included panels made from the material HarvestForm.

Polyurethanes (qv) are now being made from polyols derived from soybean oil, eg, SoyOyl manufactured by Urethane Soy Systems Co. (USSC). Applications include carpet backing and padding, furniture and automobile seating foam, foam insulation, and others.

Laboratory Studies

Many other compositions and processes have been studied in the laboratory; some are in the development stage on their way to commercial production. A few illustrative examples are given here.

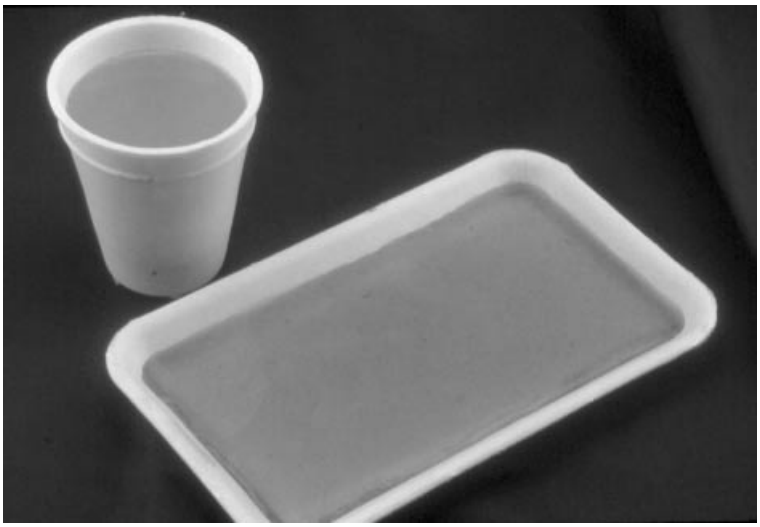

Fig. 8. Starch foam cup and tray coated with water-resistant PHBV. An adhesive layer of shellac, a natural resin, prevents delamination of PHBV from the starch. Courtesy of R. Shogren, U. S. D. A.

Nodax, under development by Proctor & Gamble, is made from renewable sources. It consists of a family of copolymers of 3-hydroxybutyrate and one or more 3-hydroxyalkanoates having a longer side chain, where the side chain has anywhere from 3 to 20 carbon atoms. The structures thereby resemble linear low density polyethylene, with the 3-hydroxybutyrate units providing a basis for crystallinity and the other units introducing structural irregularity and reduced crystallinity. Nodax can be converted into sheets, molded articles, foams, films, fibers, and nonwoven fabrics, and is both biodegradable and compostable.

Modifying the hydrophilicity of starch has been the goal of many strategies, so as to improve the resistance of starch to water. Starch has been chemically modified by reaction with caprolactone, producing a thermoplastic that needs no plasticizer (74). Coatings can also be used, as when starch films are coated with an waterproofing layer of a nitrocellulose–wax blend, as is done with cellophane. Or, starch sheeting can be laminated with a water-resistant layer of poly(ε-caprolactone) by coextrusion (75).

Starch-based foams can provide compostable packaging for the fast-food industry. The extruded starch foam can be coated with a outer layer of acetylated starch to provide water resistance, or a foamed starch-acetylated starch blend can be so coated (76,77). Starch has also been coated with the microbial polyester PHBV to provide resistance to hot and cold water; a natural resin, shellac, prevents delamination (78) (Fig. 8).

Starch can be blended with biodegradable polyesters from renewable sources, such as PLA or PHBV, or with biodegradable petroleum-based copolyesters or poly(ester amides). In these cases, the aim is to combine low cost starch with higher cost polymers having greater hydrophobicity and better physical properties. For example, biodegradable and compostable plastic eating utensils can be made using 55% cornstarch and 45% PLA (Fig. 9).

Fig. 9. Plastic eating utensils. The utensils on the left are made of 55% cornstarch and 45% poly(lactic acid). They are biodegradable and compostable. For comparison, nondegradable polystyrene utensils are shown on the right. Courtesy of R. Shogren, U. S. D. A.

Starch is also compatible with other biopolymers, including polysaccharides such as pectin (79) and agarose (80), and proteins such as casein (81) and gelatin (82).

Chitin (qv), a polysaccharide produced from shellfish waste, and chitosan (deacetylated chitin) are not thermoplastic, but films and fibers prepared by evaporation of solvent have good mechanical properties and low oxygen permeability (83). They mainly have pharmaceutical and biomedical applications, such as contact lenses and wound-healing treatments. Pullulan, a polysaccharide, is prepared commercially through yeast fermentation. It can be processed into a bioplastic that is hard, strong, tough, and elastic. Pullulan has good oxygen barrier properties and has been developed for food-packaging applications. Fibers have been drawn from concentrated solutions.

Commercial proteins (84) include zein—a water-insoluble protein from corn (maize). Zein is thermoplastic and can be processed with extrusion and injection-molding techniques. It forms strong, grease-resistant, and dyeable fibers. Starch has been blended with zein to increase water resistance; natural fibers were added for increased modulus (85). Other commercial proteins include wheat protein, soy protein, and casein.

Epoxidized soybean oil has been polymerized with citric acid and used to coat kraft paper for biodegradable agricultural mulching covers (86); the coating extends the lifetime of the paper mulch to a practical length (Figa. 10). Other plant oils that are being studied include castor seed oil, sunflower seed oil, corn (maize) oil, and rapeseed oil.

Lignin (qv) is an abundant renewable natural resource; it accounts for over 20% of all organic matter and is second in abundance only to cellulose. Approximately 46 million metric tons are isolated in the United States each year as a by-product of wood pulp processing. Its underutilization has often been described,

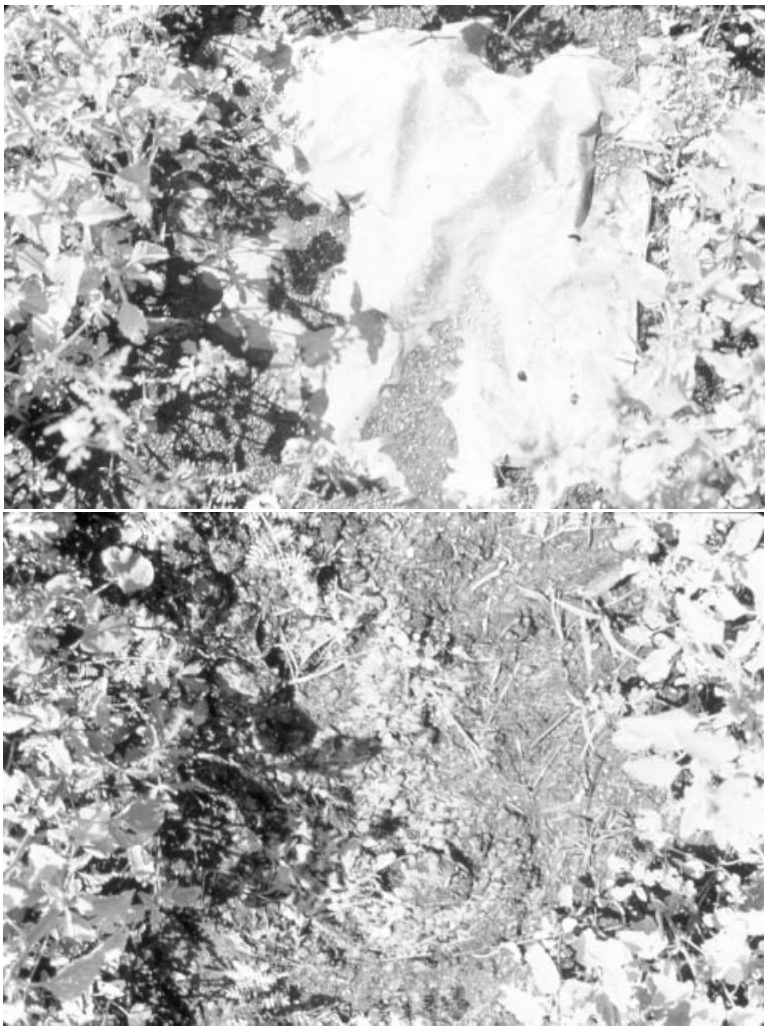

Fig. 10. Biodegradable mulch—kraft paper coated with a polyester made from a reaction product of epoxidized soybean oil and citric acid. The coating reduces the degradation rate and increases wet strength so the mulch can inhibit weed growth for more than 10 weeks. Courtesy of R. Shogren, U. S. D. A.

and the significance of its large-scale potential use in thermoplastics or thermosets has been noted (87). The development of lignin-containing plastics is a compelling objective because it would raise lignin to the status of a high value commodity material. Lignin bioproducts could also provide a stabilizing component to composts: lignin degrades at a slower rate than most other biopolymers, and in composts it would provide an important soil stabilizer, helping to maintain organic content and moisture level.

Lignin has been studied as a component in many nonbiodegradable thermoplastics materials: as a filler in lowdensity polyethylene and polypropylene

(88,89), in compression-molded unplasticized poly(vinyl chloride)–lignin blends (90), in blends of organosolv lignin and poly(vinyl chloride-*co*-vinyl acetate) (91), and in solvent-cast films of hydroxypropyl lignin–caprolactone copolymers blended with poly(vinyl chloride) (92).

Lignin and lignin esters have also been blended with various biodegradable thermoplastics: poly(ε-caprolactone)–lignin blends prepared by solvent casting (93), kraft lignin–poly(vinyl alcohol) blends (94), lignin–poly(ethylene oxide) blends (95), methylated lignin–poly(ethylene oxide) blends (95), and lignin and lignin esters blended with cellulose acetate butyrate, with poly(hydroxybutyrate), and with a starch-poly(ε-caprolactone) copolymer blend (96,97).

Derivatized kraft lignin has been incorporated at a level of 85% into poly(vinyl acetate) to produce a thermoplastic material that can be extrusion-molded (98). Alkylated 100% kraft lignin has been shown to give thermoplastic material that possesses tensile properties similar to polystyrene; pyrrolidinone was used as a solvent, diethyleneglycol dibenzoate and indene were used as plasticizers (99).

Lignin has also been used in thermosetting resins as additions to polyurethanes, epoxy resins, acrylic resins, and phenol resins. For example, IBM has explored the use of epoxidized lignin in producing thermosetting resins for circuit board applications (100).

How Green are Green Plastics?

There is a hope that LCA (8) of plastics will be developed to the point that meaningful product environmental profiles can be produced, whereby the environmental impacts of various plastics can be compared with one another. Initial LCA development has focused, in particular, on energy consumption and carbon dioxide release, but even then the dependence of carbon dioxide release on disposal method, for example, is not treated uniformly. In the coming years LCA methodologies are likely to be improved.

Certain trends, however, are beginning to emerge. A review of 20 LCA studies of biodegradable polymers (101,102) indicates that thermoplastic starch, the major component of approximately 75% of green plastics production, offers important environmental benefits compared to conventional polymers. Compared to starch, the environmental benefits of poly(lactic acid), currently accounting for 10–15% of production, and of biodegradable polymers made from nonrenewable resources, eg, poly(vinyl alcohol) and poly(ε-caprolactone), accounting for approximately 10% of production, seem to be smaller, but still greater than that of conventional polymers. For microbial polyhydroxyalkanoates, which currently make up a very small part of total green plastics production, the environmental advantage seems to be small (or perhaps nonexistent), but the fermentation technologies for producing microbial polyhydroxyalkanoates are among the most recently developed, and both the production method and the scale of production can influence evaluations of the overall environmental balance. One LCA that was published in the popular literature and received much attention (103) was limited to poly(lactic acid) and microbial polyhydroxyalkanoates; thermoplastic starch was not considered.

Future Prospects

The future of green plastics will be determined by the cost–performance ratio, where performance will include environmental attributes as well as physical properties. More than 90% of current conventional plastics are environmentally nondegradable, but at the present time they have a significant cost advantage. Within the group of degradable/biodegradable/compostable plastics, activated polyolefins, on account of the cost advantage they now enjoy and in spite of remaining questions related to their environmental fate and impact, will likely find continued market acceptance, especially in third-world countries where environmental considerations are perforce relegated to secondary status, and where interim solutions are being sought pending optimization of the bioplastics industry.

Hybrid materials, containing biodegradable, but nonrenewable, petroleum-based polymers combined with renewable biopolymers (mainly starch), constitute an environmental compromise, but hybrids provide improved physical properties relative to the biopolymers alone; they are biodegradable; and, in many cases, they are compostable. Hybrids satisfy many of the growing environmental concerns of the major industrialized regions of North America, Europe, and Asia.

Developing bioplastics, ie, biodegradable and compostable plastics that are derived entirely or almost entirely from renewable raw materials, faces the greatest technological challenge. Reducing cost will be a critical factor. Most surveys indicate that for green plastics consumers might be willing to pay a premium of 10–20% above the cost of conventional plastics. The cost of green plastics now exceeds that amount, partly because of unoptimized technologies and limited production.

One can envision two, not mutually exclusive, directions for the future. The usefulness of biomass polymers (starch, cellulose, and others) will continue to be extended through chemical modification, novel formulations, and processing innovations to produce an increasing number and variety of materials and applications. Concurrently, biomass polymers will be transformed into an increasing array of polymerizable monomers, using enzymatic and conventional means, followed by polymerization, also using both enzymatic and conventional means, to produce polymer materials having sequences and molecular weights required for the targeted applications.

As the "green chemistry" movement presses the polymer industry toward sustainability and low environmental impact, technologies that produce shifts in those directions will continue to emerge and develop. Significantly, the new technologies are being aided with help from governments that are impelled by environmental concern, need for reduced dependence on foreign crude oil, and desire for increased agricultural markets. The allure of a sustainable industry producing commodity plastics for an increasing world population will no doubt persist. It remains to be seen at what rate the required technologies will develop.

ENZYMATIC POLYMERIZATION. See Volume 2.

ETHYLENE COPOLYMERS

Introduction

Polyethylene and polystyrene are two high volume commodity polymers, widely studied in materials research, exemplifying the classes of semicrystalline polymers (qv) and amorphous polymers (qv) respectively (see ETHYLENE POLYMERS, HDPE; STYRENE POLYMERS). There has been considerable interest to produce copolymers from ethylene (E) and styrene (S). The incorporation of aromatic groups in polyethylene has been associated, for example, with enhanced radiation resistance (1) or electrical-breakdown resistance by enabling space charge dissipation (2). A variety of different copolymer molecular architectures can potentially be produced. In addition to the different comonomer distributions (random, alternating, or blocky nature), there are possibilities for chain branching and stereoregularity in the copolymer chain microstructure.

Various references describe efforts to copolymerize ethylene and styrene. The production of copolymers has been attempted by using conventional polymerization routes for either polyethylene or polystyrene with introduction of the alternate comonomer into the process. Many reported copolymerizations produce heterogeneous polymers consisting of mixtures of copolymers and homopolymers (3), for example U.S. patent number 3,117,945 describes the production of a "gross" copolymer, composed of various fractions that could be separated on the basis of their solubility parameter. Copolymers containing low levels ($<$4 mol%) of styrene incorporation have been prepared by both conventional Ziegler-Natta Catalysts (qv) (4–6) and free-radical processes (7). U.S. patent number 4,076,698 allegedly has examples of copolymers of ethylene with styrene and α-methylstyrene produced by coordination catalysts at low temperature (8), but does not give any significant characterization data for the polymers. These early synthetic routes

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

that were investigated do not provide commercially viable routes for the production of copolymers.

Developments published in the early 1990s demonstrated the ability of specific classes of metallocene catalysts (see METALLOCENES) to efficiently copolymerize ethylene and vinyl aromatic monomers, such as styrene. In particular, INSITE Technology (The Dow Chemical Co.), including developments of single-site, constrained-geometry, addition polymerization catalysts (9–11) has provided an efficient route to produce essentially random copolymers based on ethylene and styrene (see SINGLE-SITE CATALYSTS). The primary focus of subsequent sections is the preparation, characterization, and utility of poly(ethylene-*co*-styrene); "ethylene-*co*-styrene polymer" is also used as an alternate terminology throughout this chapter for coherence. It is pertinent to mention that INDEX Interpolymers (The Dow Chemical Co.) is the descriptive term for the family of products, including poly(ethylene-*co*-styrene), produced by INSITE technology, and many references have used the terminology "ethylene/styrene interpolymers," abbreviated to ESI, as a descriptor for the copolymers.

Metallocene-Catalyzed Polymerizations

Many studies have focused on catalysts that could potentially copolymerize ethylene and vinyl aromatic monomers, together with the associated polymerization chemistry and chemical analyses of the produced polymers. It is evident from a number of references (eg 12–14) that the catalyst structure and polymerization conditions, such as temperature and monomer feed ratios, have major influences on the reaction product in terms of production efficiency, product composition (copolymer, homopolymer contents), and copolymer microstructure, including stereoregularity.

Popular catalysts investigated for the preparation of copolymers have been single-site, constrained-geometry, addition polymerization catalysts based on titanocene complexes, exemplified by dimethylsilyl(tetramethylcyclopentadienyl)-(*t*-butylamido) titanium dichloride [$(CH_3)_2Si(CH_3)_4Cp$)(*N*-*t*-Butyl)$TiCl_2$]. Other catalysts of significant interest have been based on fluorenyl and indenyl ligand structures, such as those described by Mitsui Toatsu (15). A short overview of technology (16) has included identification of the most widely investigated catalysts cited in basic patents. Studies of catalyst systems that produce syndiotactic polystyrene provided the starting point for research at the University of Salerno (17). Some of their subsequent work on the production and characterization of copolymers, including aspects related to stereoregularity and crystallinity of copolymers, has been referred to in a review article by Pellecchia and Oliva (18).

Many copolymers that have been produced to date have contained less than 50 mol% styrene, in large part because the catalysts typically utilized for copolymerization have not allowed the incorporation of adjacent styrene units into the growing polymer chains. This structural feature is discussed further under Properties. Limited literature (19,20) has described the production of copolymers in which the catalyst selection and polymerization conditions employed have resulted in the incorporation of adjacent styrene units in the polymer chain. Hou and

co-workers (21) have recently reported on catalyst systems that can copolymerize the monomers into block styrene–ethylene copolymers, although the reaction products were mixtures of block copolymer with homopolymers.

A research program conducted in the group of Mulhaupt (University of Freiburg, Germany) included copolymerization of ethylene with styrene using methaluminoxane-activated half-sandwich complexes (22) and methaluminoxane-activated bis(phenolate) complexes (23). The influence of polymerization conditions on the copolymerization of styrene with ethylene using $(CH_3)_2Si((CH_3)_4Cp)(N\text{-}t\text{-butyl})TiCl_2$/methylaluminoxane (MAO) catalyst/cocatalyst system was studied (14). The fractionation and comprehensive characterization of a poly(ethylene-*co*-styrene) having 13.8 mol% styrene provided (24) strong evidence of a single-site mechanism for the copolymerization.

Alternating ethylene–styrene (ES) copolymers, or copolymers that contain alternating $(ES)_n$ sequences, have been synthesized. Suzuki and co-workers (25) described the preparation of alternating atactic $(ES)_n$ copolymers via hydrogenation of poly(phenylbutadienes), produced by anionic polymerization. Miyatake and co-workers (26) have disclosed the production of copolymers having a high degree of alternating isotactic polymer chain sequences. They further reported (27) that the alternating isotactic copolymer had a crystalline melting point of 116°C. Later references (eg 12,13,28) provide more details regarding catalysts, reaction mechanisms, and characterization of produced copolymers having stereoregular, alternating ES chain sequences. For example, Venditto and co-workers (28) described the composition, stereoregularity, and crystallinity of copolymers produced by ansa–zirconocene and half-titanocene based catalysts, with copolymers reported as having melting points in the range of 100–145°C, attributed to crystallization of alternating stereoregular $(ES)_n$ sequences. Izzo and co-workers (29) have produced low molecular weight model compounds of alternating ES copolymers with a range of catalysts, and characterization was considered to confirm the isotactic structure of copolymers.

Arai and co-workers (30) have shown that a copolymer having alternating polymer chain sequences that are isotactic and crystallizable can be produced when copolymerization is carried out at temperatures of 50°C or below, using, for example, *rac*-[isopropylidenebis(1-indenyl)]zirconium dichloride. Although the presence of crystallizable $(ES)_n$ polymer chain sequences could contribute to properties such as mechanical strength, it appears (31) that annealing or exposure to solvent is required to develop a significant level of crystallinity. This observation is analogous to the behavior of isotactic polystyrene; the latter polymer also has a slow rate of crystallization that has hindered its commercialization, because of the restricted ability to develop crystallinity under common melt-fabrication conditions (32).

Terpolymerizations. A number of references, mainly patents, teach the metallocene-catalyzed polymerization of ethylene and styrene with a range of additional monomers, providing potential manufacturing routes to materials with modified properties and functionality relative to ethylene-*co*-styrene polymers. Dienes such as ethylidene norbornene, 1,3-butadiene, and 1,5-hexadiene (33) introduce vinyl unsaturation into the copolymers, enabling more facile cross-linking of the copolymers. Other monomers of interest include propylene, higher α-olefins, and norbornene (34,35).

Propylene (P) is a termonomer that has received the most attention. Structure–property relationships of terpolymers based on ethylene, styrene, and propylene, have been published (36). The terpolymers are most differentiated from ethylene-*co*-styrene polymers when there is measurable crystallinity in the solid-state microstructure, because the introduction of methyl groups on the polymer chain modifies both the crystalline and amorphous phases of the solid-state microstructure. In another aspect of terpolymerization, ethylene has been investigated as a catalyst reactivator in propylene–styrene copolymerization by Caporaso and co-workers (37), with the research directed at introducing styrene units into isotactic polypropylene.

Chung and co-workers (38) have reported the synthesis of copolymers of ethylene and paramethylstyrene and has extended these studies to produce and characterize elastomeric terpolymers that further include propylene and 1-octene as the additional monomers (39,40).

Copolymer Manufacture: Solution Polymerization

The two monomers of major interest, styrene and ethylene, are well known and details can be found on all aspects of their technology elsewhere. Poly(ethylene-*co*-styrene) is primarily produced via solution polymerization techniques using metallocene catalyst/co-catalyst systems, analogous to the production of copolymers of ethylene with α-olefin monomers. Solvents that can be employed include ethyl-benzene, toluene, cyclohexane, and mixed alkanes (such as ISOPAR E, available from Exxon). The thermodynamic properties of poly(ethylene-*co*-styrene), including solvent interactions and solubility parameter assessments, are important factors in relation to polymer manufacture and processing, and have been reported by Hamedi and co-workers (41).

Key factors in the copolymer manufacture are

(1) Purity and cleanup of the solvent and monomers, especially styrene. Metallocene catalysts are noted for their susceptibility to polar molecules, and effective removal of species such as stabilizers, water, and oxygen is required to achieve high efficiencies.

(2) Polymer recovery via separation from unreacted monomers, especially styrene, and the process solvent. Typically carried out by devolatilization, as in the manufacture of polystyrene, the conditions (such as temperature and residence time) employed determine the amount, if any, of atactic polystyrene in the final product resulting from free-radical polymerization of styrene.

(3) Recovery and handling of the final product. A range of copolymers are either amorphous or have low levels of crystallinity and further have glass-transition temperatures (T_g's) close to or below 25°C, as discussed under Properties. These are soft tacky materials under typical ambient conditions. If produced in pellet form, these copolymers can require some form of antiblocking technology, such as the development of novel pellet coatings (42), to allow effective material handling.

Although classic analytical techniques can be employed, specific procedures such as Fourier transform infrared spectroscopy for analysis of polystyrene and copolymerized styrene (43) have contributed to the characterization and quality assurance of copolymer products.

Properties of Poly(ethylene-*co*-styrene)

Poly(ethylene-*co*-styrene) constitutes a broad family of materials. Although copolymers with stereoregular chain sequences could be produced, the catalyst and process conditions most often employed for production to date give copolymers that are atactic, and contain typically up to about 50 mol% (~ 80 wt%) styrene content. These copolymers have been described (10) as "pseudorandom," since successive head-to-tail styrene chain insertions have been shown to be absent, even at high levels of styrene incorporation. This structural feature, represented schematically in Figure 1, is important; each aromatic group is typically separated from its near neighbor by at least three methylene units, in contrast to polystyrene. Much of the research and technology developments are reported for copolymers with this chain microstructure. These copolymers have a continuum of solid-state microstructures ranging from highly crystalline to essentially amorphous, dependent primarily upon comonomer composition ratio.

A review (44) has provided more details on the structure, properties, and applications of the copolymers. Researchers at Case Western Reserve University, Cleveland, Ohio, have contributed significantly to the understanding of viscoelastic behavior and mechanical properties of these copolymers (45,46).

Thermal Properties, Crystallinity, and Density. Figure 2 correlates crystallization (T_c), melting (T_m), and glass-transition (T_g) temperatures measured by differential scanning calorimetry (DSC) with copolymer styrene content, and Figure 3 correlates the degree of crystallinity and density with copolymer styrene content.

Crystalline melting temperatures and crystallinity decrease with increasing copolymer styrene content. Copolymers with styrene contents of less than 40 wt% (~15 mol%) generally exhibit a well-defined melting process. Copolymers with styrene contents above 45 wt% (~18 mol%) are essentially amorphous. A critical sequence length of $(CH_2)_n$ units is required to enable crystallization of chain segments. Thus, introduction of pendent phenyl groups by copolymerization suppresses the crystallinity resulting from $(CH_2)_n$ polymer chain sequences because the phenyl groups are excluded from crystalline domains. It is pertinent to comment here that subtle differences may be found in the copolymer monomer sequence distributions as a consequence of catalyst selection and polymerization

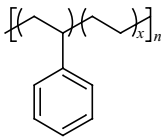

Fig. 1. Schematic representation of so-called pseudorandom copolymer structure.

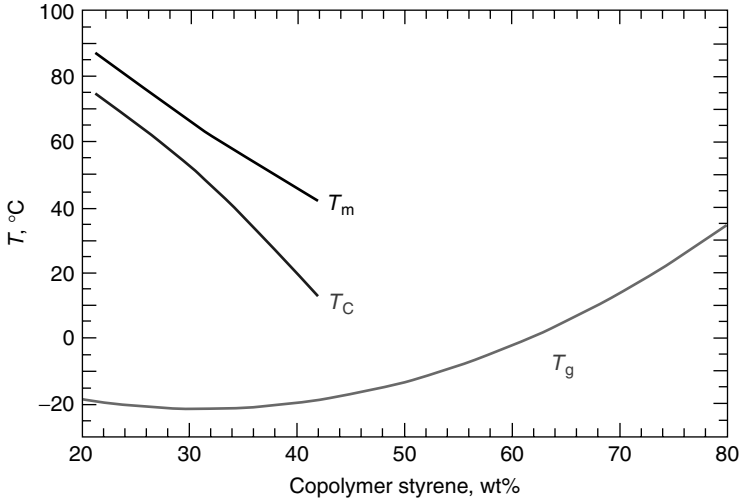

Fig. 2. Thermal transitions of poly(ethylene-*co*-styrene) (DSC data; 10°C/min heating, cooling rates).

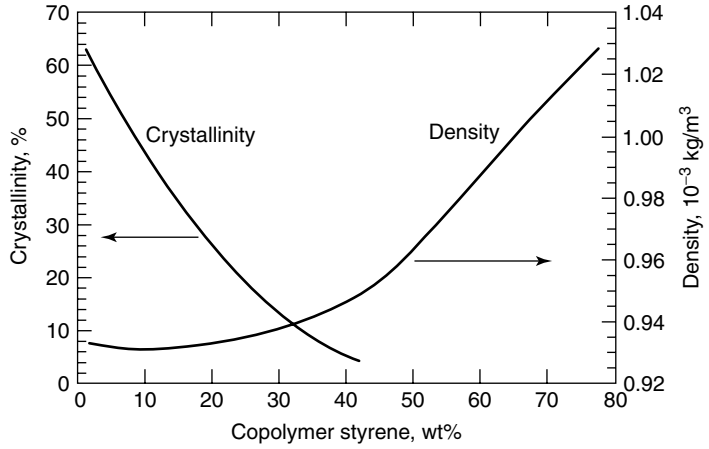

Fig. 3. Density and crystallinity of poly(ethylene-*co*-styrene).

conditions employed. As a result of this, copolymers with nominally the same comonomer content can exhibit some differences in structure-property relationships.

The copolymers have glass-transition temperatures in the range −20 to +30°C. Above about 45 wt% (18 mol%) styrene content, the copolymer T_g increases with increasing styrene content. Satisfactory correlation between copolymer composition and T_g has been found by considering them either as random copolymers of ethylene and styrene or as random copolymers of ethylene and ES dyads. Thus, T_g data were shown by Chen and co-workers (46) to satisfactorily fit

the Fox equation in the form

$$\frac{1}{T_g} = \frac{(1 - 1.27w_s)}{T_{g,e}} + \frac{1.27w_s}{T_{g,es}}$$

where $T_{g,e}$ is the glass-transition temperature of polyethylene, $T_{g,es}$ is the glass-transition temperature of the alternating ethylene–styrene copolymer, and w_s is the weight fraction of styrene incorporated into the copolymer. Extrapolation gave a glass-transition temperature of -66°C for amorphous polyethylene and 44°C for an alternating ES copolymer.

Thermogravimetric analyses (TGA) in both air and nitrogen show weight loss occurs at temperatures above 220°C for the copolymers, reflecting random chain scission as a predominant degradation mechanism.

Viscoelastic Properties: Dynamic Mechanical Spectroscopy (DMS). The viscoelastic properties and time–temperature–rate dependency of properties are key elements of the materials science of ethylene-*co*-styrene polymers. Dynamic mechanical loss spectra are presented in Figures 4a and 4b for selected semicrystalline copolymers, and low crystallinity and amorphous copolymers, respectively.

For the essentially amorphous copolymers, T_g increases with increasing styrene content. The mechanical loss processes associated with the amorphous-phase T_g have peak widths comparable to the T_g process for atactic polystyrene, and this provides strong evidence that the glass-transition process is characteristic of a homogeneous amorphous material. Of further note in Figure 4 is the so-called γ-transition. This low temperature mechanical loss process can be associated with local chain motions, analogous to polyethylenes (47).

For the semicrystalline copolymers, the loss peak in the temperature range -50 to $+50^\circ$C shows increasing breadth of the relaxation process as the copolymer styrene content decreases. The relaxation processes associated with this loss peak are complex in nature. The long-range chain segmental motions associated with the T_g process become hindered because of the restrictions imposed by the crystallites. The copolymers with less than about 25 wt% (8 mol%) comonomer styrene exhibit complex thermal transition behavior as a result of the increasing influence of the crystalline domains, restricting molecular mobility in the amorphous region, similar to the behavior of high density polyethylene (HDPE) (48).

Further detailed aspects of the viscoelastic behavior of amorphous copolymers that have been reported includes linear stress-relaxation behavior (49) and creep properties in the glass-transition region (50). Chen and co-workers (51) have also reported the large strain–stress relaxation and strain recovery of copolymers at temperatures above T_g, and found that the observed behavior could be rationalized in terms of various network models.

Mechanical Properties. The tensile stress–strain behavior of ethylene-*co*-styrene polymers, including the effects of crystallinity and molecular weight, has been extensively reported and analyzed. Figure 5 presents tensile stress–strain data for a series of copolymers differing primarily in styrene content. The copolymers generally exhibit large strain at rupture, and have been found to show uniform deformation behavior (46).

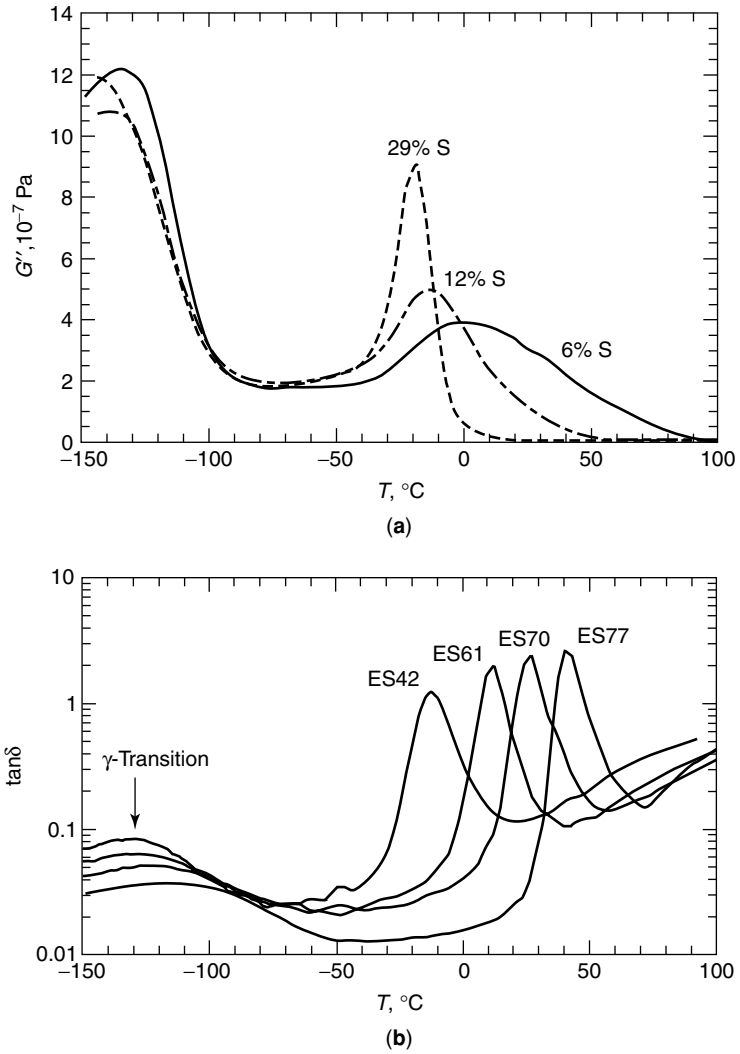

Fig. 4. Dynamic mechanical loss spectra of (**a**) Three semicrystalline ethylene-*co*-styrene polymers having different wt% comonomer compositions. (**b**) Amorphous or low crystallinity ethylene-*co*-styrene polymers. (The label ES## refers to a copolymer having ## wt% copolymerized styrene comonomer content.)

Chang and co-workers (52,53) studied the large-scale deformation behavior and recovery behavior of semicrystalline ethylene-*co*-styrene polymers as a function of temperature, comonomer content, and crystallinity and compared them to the behavior of metallocene-produced ethylene/1-octene copolymers. Chen and co-workers (54) have provided an in-depth comparison of the morphological structure and properties of copolymers and confirmed that aspects of deformation that depended on crystallinity, such as yielding and cold drawing, were determined primarily by comonomer content for both sets of copolymers.

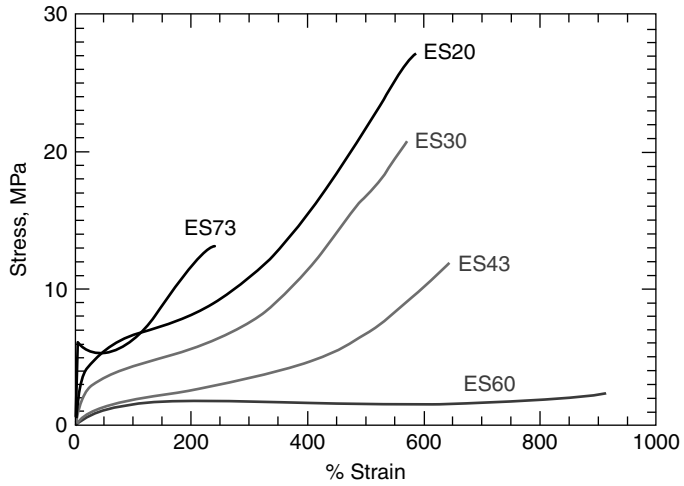

Fig. 5. Engineering stress–strain data (23°C, 5.7 min^{-1}) for ethylene-*co*-styrene polymers.

The copolymers with 40–60 wt% (about 15–30 mol%) styrene comonomer are characterized by low modulus and they show some elastomeric behavior. D'Aniello and co-workers (55) reported the physical properties for a poly(ethylene-*co*-styrene) having 20 mol% copolymer styrene, showing that the copolymer showed good elastic properties. Information on the deformation and recovery behavior of selected copolymers was reported by Mudrich and co-workers (56), with a copolymer having 45 wt% styrene of particular note in terms of strain recovery after deformation.

The effects of styrene become dominant in the high styrene region where the modulus and yield stress are seen to increase. Copolymers with T_g above ambient temperature are amorphous glasses, and these copolymers are reported (57) as exhibiting interesting shape/reshape functionality.

Good low temperature toughness of copolymers has been found in impact testing and low temperature tensile testing. Chen and co-workers (49) provided estimates of the copolymer entanglement molecular weights (M_e). The low M_e values found suggest high entanglement density in these copolymers, and was considered to contribute to the ability of the copolymers to shear yield at temperatures below T_g rather than undergo brittle fracture.

Melt Rheology and Processability. The melt rheological properties of a series of copolymers having up to 20.5 mol% styrene content were reported by Lobbrecht and co-workers (58). DMS data were generated for temperatures ranging from 120 to 200°C. Master curves were generated, and data analysis was considered to show that there was a difference in rheological behavior for those copolymers having greater than 16.5 mol% styrene.

The rheological properties and associated melt-processing characteristics of ethylene-*co*-styrene polymers, including solid-state DMS, melt strength, and pressure–volume–temperature (PVT) data, have been reported by Karjala and co-workers (59,60). Rheological master curves were generated via time–temperature

superposition, and viscosity–shear rate dependence were analyzed with a Cross model as a function of both styrene content and molecular weight.

The melt processability of copolymers is considered as favorable toward most fabrication techniques. Copolymers have been reported to show good thermal stability at melt-processing temperatures, viscosities that are a strong function of styrene content, in addition to molecular weight, shear thinning behavior at high shear rates, and good melt strength. These characteristics have allowed the fabrication of articles by a wide range of standard melt-processing techniques, including injection molding, film fabrication, blow-molding, and melt extrusion. The potential utility in calendering operations has been described by Karjala and coworkers (61). Selected copolymers were found to demonstrate the requisite rheological properties and thermal stability to be successfully calendered, and this was supported by commercial-scale validation. Where required, the standard thermal-stabilizer packages used in polyolefin formulations to improve processibility can also be employed in ethylene-*co*-styrene polymers.

Copolymer Utility: Materials Engineering Aspects

For many applications, the use of poly(ethylene-*co*-styrene) in preference to other ethylene homopolymers and copolymers will be determined by specific attributes that the aromatic functionality imparts. In one aspect, the aromatic ring can be chemically modified by sulfonation (62), and by a variety of electrophilic and nucleophilic reagents (63) to produce polymers with specific functionality.

In addition to showing good compatibility with a wide range of materials, other key characteristics, including the glass-transition temperature (T_g), viscoelastic properties, and excellent processability, further suggest that copolymers will find applications as components in formulated systems. The copolymers have shown inherent compatibility with low molecular weight materials, including bitumens (64), plasticizers (65), and tackifiers (66), in addition to a wide range of other polymers and fillers. The technology of blend systems, which includes copolymers as components and filler composites, is considered of particular relevance, and is discussed in more detail below.

Poly(ethylene-*co*-styrene) as a Polymer Blend Component. Diehl and co-workers (67) have reported that the copolymers are compatible with many other polymer families. The controllable combination of olefinic and aromatic functionality contributes to the compatibility of blends containing ethylene-*co*-styrene polymers. Significant toughening of atactic polystyrene (68) and syndiotactic polystyrene (69) can be achieved with selected copolymers. The olefinic functionality helps provide compatibility with olefin homopolymers and copolymers, including both polyethylenes and polypropylenes (70). Polymer families that have been blended with ethylene-*co*-styrene polymers include styrene block copolymers (71), poly(vinyl chloride) (PVC) based polymers (72), and polyphenylene ethers (73). Specific copolymers have also been demonstrated as effective blend compatibilizers, for example in polystyrene/polyethylene blends (74,75).

Blends of Poly(ethylene-*co*-styrene): Miscibility. Blends of two random copolymers are often immiscible when the difference in comonomer content between the copolymers is above a certain critical value. A study of

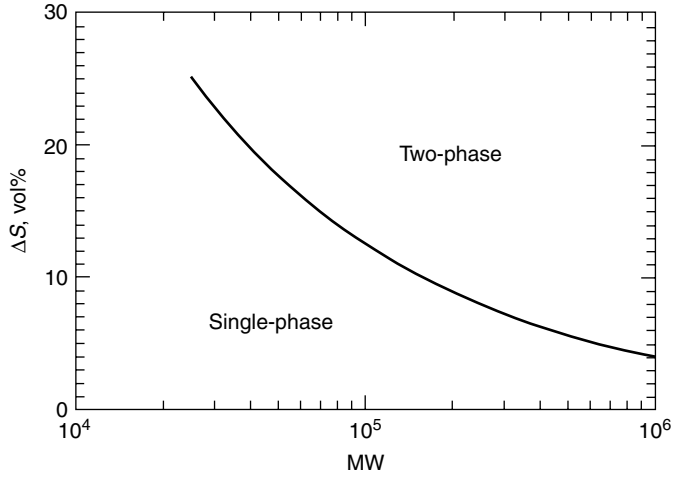

Fig. 6. Miscibility map for copolymer blends: the critical styrene content difference (ΔS in vol%) between two copolymers versus molecular weight (MW) of blend components for the onset of phase separation.

poly(ethylene-*co*-styrene) blends has combined predictions of miscibility with experimental observations (76). Critical composition differences for miscibility between ethylene-*co*-styrene polymers as a function of molecular weight are presented in Figure 6. Blends are predicted to be immiscible when the composition difference exceeds about 10 vol% (∼10 wt%) styrene between copolymers having molecular weights around 10^5 (note: vol%, the model parameter used, approximates to wt% in this case). This miscibility criteria was shown to be valid for copolymer blends from analysis of the thermal transitions of the blends and blend components.

The above rationale regarding miscibility extends to copolymer blends with polystyrene and polyethylene. Copolymers having less than about 90 wt% styrene comonomer content will be immiscible with polystyrene, unless the molecular weights of the respective polymers are very low. Similarly, copolymers with more than about 10 wt% styrene comonomer content will be immiscible with polyethylene.

Chen and co-workers (77) studied binary blends of copolymers over the full range of copolymer styrene contents for both amorphous and semicrystalline blend components. The transition from miscible to immiscible blend behavior, and the determination of upper critical solution temperature (UCST) for blends were uniquely evaluated by atomic force microscopy (AFM) techniques via the small, but significant, modulus differences between the respective copolymers used as blend components (78).

Blends of two or more copolymers differing in comonomer composition and/or molecular weight characteristics of the individual blend components find potential use in a range of applications. Thus, applications such as flooring systems, artificial leather and foams can utilize materials that have combinations of two or more interpolymers differing in styrene content to engineer, for example,

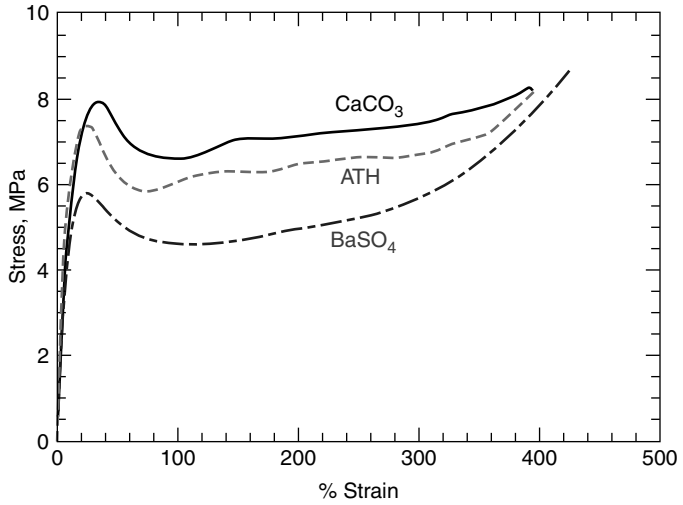

Fig. 7. Engineering stress–strain data (23°C, 5.7 min^{-1}) for an ethylene-*co*-styrene polymer (30 wt% styrene) containing 40 vol% filler.

the modulus–temperature relationship, glass-transition behavior, and damping characteristics.

Filler Composites. It is well known that the addition of fillers to polymers can enhance the stiffness, dimensional stability, upper service temperature, tensile strength, damping characteristics, and ignition resistance, as well as lower the cost of fabricated parts. The performance requirements for many applications that utilize poly(ethylene-*co*-styrene) can be met by modifying the balance of properties through the addition of fillers. The copolymers show good filler acceptance with a broad range of inorganic fillers, including calcium carbonate, barium sulfate, alumina trihydrate (ATH) and magnesium hydroxide ($Mg(OH)_2$) (79,80). Figure 7 presents tensile stress–strain data for a poly(ethylene-*co*-styrene) filled with 40 vol% of three different fillers. The resulting composite materials generally exhibit very good mechanical properties, even for relatively high loadings of fillers.

The filled copolymers have shown rheological characteristics which suggest that the compositions can be easily fabricated into final parts. Filled compositions are expected to find broad utility in applications, including, for example, wire and cable (81), flooring systems (82), injection-molded articles, film and sheet structures, and profile extrusions.

Applications

Potential markets/applications for poly(ethylene-*co*-styrene) can be discerned from various references and patent literature. In addition to the applications identified in the preceding sections, important applications discussed or identified include adhesives (66), paintable injection-molded toys (83), footwear,

Fig. 8. Examples of foam applications utilizing ethylene-*co*-styrene polymers.

automobile parts, bitumen modification, packaging, and blow-molded articles. Although intermaterial substitutions in existing applications based on thermoplastic elastomers such as styrene–butadiene block copolymers, flexible PVC, and polyethylene homopolymers and copolymers are potential application areas for copolymers, the novel combination of material attributes suggests that new application areas will emerge.

Developments using copolymer-based materials in foam applications are of particular note. Novel foam structures offer attractive properties and characteristics, including softness, aesthetics, and drape, for a wide range of thermoplastic and cross-linked foam applications. Other product technologies of interest are as injection-molded structural foams, as foamed layers in multilayer structures and as foamed blends of interpolymers with styrenic and olefinic polymers (Fig. 8) (84–86). Interpolymers also have potential for coextruded film and sheet applications.

Summary. Copolymers based on ethylene and styrene are a novel class of polymers exhibiting unique combinations of material attributes that are not found in polyethylenes, polystyrenes, or their blends. These copolymers offer unique opportunities for innovative developments in basic polymer chemistry, catalyst and process development, materials science and engineering, and application technology.

The effective production of these novel copolymers has been enabled by INSITE Technology. A product development plant to produce Interpolymers (Sarnia, Canada) had a successful start-up in September 1999. This plant, having a nameplate production capacity of around 22,500 metric tons per annum, has enabled further product and process developments, and application validation.

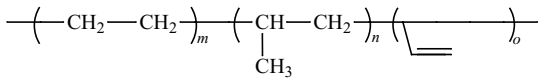
ETHYLENE–PROPYLENE ELASTOMERS

Introduction

Copolymers of ethylene and propylene (EPM) and terpolymers of ethylene, propylene, and a diene (EPDM) as manufactured today are rubbers based on the early work of Natta and co-workers (1). A generic formula for EPM and EPDM may be given as follows, where $m = \sim 1500$ ($\sim$60 mol%), $n = \sim 975$ ($\sim$39 mol%), o = $\sim$25 for EPDM ($\sim$1 mol%) and 0 for EPM in an average amorphous molecule, and the comonomers are preferably statistically distributed along the molecular chain.



1

EPM can be vulcanized radically by means of peroxides. A small amount of built-in third nonconjugated diene monomer in EPDM permits conventional vulcanization with sulfur at the allylic carbon atoms relative to the pendent sites of carbon–carbon unsaturation.

Among the variety of synthetic rubbers, EPM and EPDM are particularly known for their excellent ozone resistance in comparison with natural rubber (*cis*-1,4-polyisoprene) and its synthetic counterparts IR (isoprene rubber), SBR (styrene–butadiene rubber), and BR (butadiene rubber). Secondly, EPDM rubber can be extended with fillers and plasticizers to a very high level in comparison with the other elastomers mentioned, and still give good processability and properties in end articles. This leads to an attractive price/performance ratio for these polymers.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Even though EPM and EPDM rubbers have been commercially available for more than 40 years, the technology concerning these products, both their production and their applications, is still very much under development.

Polymer Properties

The properties of EPM copolymers are dependent on a number of structural parameters of the copolymer chains: the relative content of comonomer units in the copolymer chain, the way the comonomers are distributed in the chain (more or less randomly), the variation in the comonomer composition of different chains, average molecular weight, and molecular weight distribution. In the case of EPDM terpolymers there are additional structural features to be considered: amount and type of unsaturation introduced by the third monomer, the way the third monomer is distributed (more or less randomly) along the chain, and long-chain branching. These structural parameters can be regulated via the operating conditions during polymerization and the chemical composition of the catalyst.

Although the rubbery properties of ethylene–propylene copolymers are exhibited over a broad range of compositions, weight percentages of commercial products generally range from 45:55 to 80:20 wt% ethylene/propylene. On the high propylene side the polymer fails on thermal and ozone stability, because of the lower oxidative stability of the propylene units relative to ethylene units; on the high ethylene side the polymer is too highly crystalline and looses its rubbery character. Depending on the catalyst system and polymerization conditions used, the ethylene units may tend to group together to form blocky or sequential structures. The higher the ethylene/propylene ratio, the more pronounced is this tendency. These ethylene sequences impart a level of crystallinity to the EP(D)M rubbers of less than 1% at room temperature for 50:50 ethylene/propylene ratio—also designated as amorphous EP(D)M rubber—till above 10% for the high ethylene/propylene ratio—also called semicrystalline or sequential EP(D)M. Crystallinity renders the EP(D)M rubber a certain green strength: tensile strength in the unvulcanized state, making the polymer easier to handle and to store. Moreover, it adds to the strength of EP(D)M vulcanizates in those cases where carbon blacks cannot be used as reinforcing fillers and only less reinforcing light colored fillers can be applied. On the other side, these blocky structures or crystallinity have a detrimental effect on the rubbery properties of the polymer, particularly at subambient temperatures. They enhance the thermoplastic nature of the polymer.

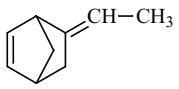
In addition to the ethylene/propylene ratio, the average molecular weight of the rubber is controlled by polymerization variables. While the polymer chemist generally measures the average molecular weight by gel permeation chromatography or intrinsic viscosity, the rubber compounder uses Mooney viscosity for practical purposes. The ethylene–propylene rubbers are controlled within a range of raw polymer Mooney viscosities that has been found to fit the various processing and applications requirements of the rubber industry and includes most other commercial synthetic rubbers. Mooney viscosity of EPM and EPDM is preferably measured 4 min after a 1-min warm-up at 125°C (2,3). The measurement is expressed as ML $(1+4)$ at 125°C and ranges between ca 10 and 90. Grades with higher molecular weight are also produced, but are generally extended with

either paraffinic or sometimes naphthenic oil to reduce the Mooney viscosity for processing purposes.

The structure of EPM shows it to be a saturated synthetic rubber. There are no double bonds in the polymer chain as there are in the case of natural rubber and most of the common commercial synthetic rubbers. The main-chain unsaturation in these latter materials introduces points of weakness. When exposed to the degrading influences of light, heat, oxygen, and ozone, the unsaturated rubbers tend to degrade through mechanisms of chain scission and cross-linking at the points of carbon–carbon unsaturation. Since EPM does not contain any carbon–carbon unsaturation, it demonstrates an inherently higher resistance to degradation by heat, light, oxygen, and, in particular, ozone.

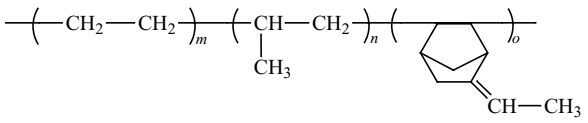
The double bonds in natural rubber and the common polydiene synthetic rubbers are essential to their curing, or also commonly called vulcanization into useful rubber products using conventional chemical accelerators and sulfur. As a saturated elastomer, EPM cannot be cured or cross-linked using these chemicals pertinent to the unsaturated rubbers. It can be vulcanized using peroxides. EPDM is a more commercially attractive product that retains the outstanding performance features, ie, heat, oxygen, and ozone resistance. It includes some carbon–carbon unsaturation—pendent to the main chain—from a small amount of an appropriate nonconjugated diene monomer to accommodate it to conventional sulfur vulcanization chemistry. A great variety of dienes were investigated in the past as third monomers (4), of which only two are used commercially at present in significant quantities. A characteristic of the structure of commercially used third monomers is that the two double bonds are nonconjugated. They are cyclic and bicyclic dienes with a bridged ring system.

The most commonly used third monomer is 5-ethylidene-2-norbornene [16219-75-3] (**2**), or ENB:



2

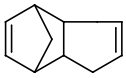
which is polymerized into the ethylene–propylene chain to give poly(ethylene-*co*-propylene-*co*-ENB) [25038-36-2] (**3**). The norbornene double bond in the bridged, or strained, ring is the more active with respect to polymerization and the five-membered ring with its double bond is left as a pendent substituent to the main polymer chain.



3

Less commonly used as third monomer is dicyclopentadiene [77-73-6] (**4**), or DCPD, for which, because of its symmetrical shape, the tendency of the second

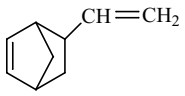
double bond to take part in the polymerization process is more pronounced than for ENB. This is one of the reasons for the formation of long-chain branches. The resulting product is poly(ethylene-*co*-propylene-*co*-DCPD) [25034-71-3].



4

Formerly, one manufacturer of EPDM used a noncyclic diene: 1,4-hexadiene [592-45-0], but this was displaced by ENB because of the latter's superior performance both in incorporation during polymerization and in vulcanization. EPDM containing hexadiene is not commercially available anymore.

Recently, the development of commercial EPDMs with 5-vinyl-2-norbornene [3048-64-4] (**5**), a precursor in the synthesis of ENB, as third monomers has been reported, aiming at a higher vulcanization yield with peroxide curatives, relative to ENB- or DCPD-containing EPDMs (5):



5

Also other third monomers are being proposed for better or faster vulcanization with sulfur or peroxide curatives, but have not reached commercial status yet (6).

Combinations of more than 1 third monomer are also applied. The amount of third monomer in general-purpose grades is about 1 mol% or ca 4 wt%. For faster curing grades this amount may be as high as 2 mol% or ca 8 wt% and there is a tendency to go to even higher amounts. At equal amounts of a third monomer (in mol%), DCPD as a third monomer leads to polymers which require about twice as long a curing time for sulfur vulcanization than ENB (7). Because of the consequent economic benefits in processing, ENB is mostly preferred as the third monomer.

Both EPDM and EPM show outstanding resistance to heat, light, oxygen, and ozone because one double bond is lost when the diene enters the polymer and the remaining double bond is not in the polymer backbone but external to it. Properties of typical EPDM rubbers are shown in Table 1.

Manufacture

The two principal raw materials for EPM and EPDM, ethylene [74-85-1] and propylene [115-07-1], both gases, are available in abundance at high purity. Propylene is commonly stored and transported as a liquid under pressure. Although ethylene can also be handled as a liquid, usually at cryogenic temperatures, it is generally transported in pipelines as a gas. Of the third monomers, DCPD is

Table 1. Properties of Raw Ethylene–Propylene–Diene Co- and Terpolymers

Property	Value
Specific gravity	0.86–0.87
Appearance	Glassy–white
Ethylene/propylene ratio by wt	
Amorphous types	50/50
Crystalline or sequential types	75/25
Onset of crystallinity, °C	
Amorphous types	Below −50
Crystalline types	Below ca 30
Glass-transition temperature,[a] °C	−45 to −60
Heat capacity, kJ/(kg·K)	2.18
Thermal conductivity, W/(m·K)	0.335
Thermal diffusivity, m/s	1.9×10^{-5}
Thermal coefficient of linear expansion per °C	1.8×10^{-4}
Mooney viscosity, ML (1 + 4) 125°C[b]	10–90

[a] Dependent on third monomer content.
[b] Oil extended grades, when viscosity > 100 for the raw polymer.

also available in large quantities. ENB is produced in a two-step process: a Diels–Alder reaction of cyclopentadiene (in equilibrium with DCPD) and butadiene; the resulting product vinyl-norbornene (VNB) is rearranged to ethylidene norbornene via proprietary processes.

EPM and EPDM rubbers are produced in continuous processes. All EPDM manufacturing processes are highly proprietary and differ greatly between various suppliers. A great series of patents covers the many details of various processes.

Solution Process. Most widely used are solution processes, in which the polymer produced is in the dissolved state in a hydrocarbon solvent (eg hexane). The choice of catalyst system is determined, among other things, by the nature of the third monomer and factors such as the width of the molecular weight distribution to be realized in the product. A number of articles review the influence of catalyst systems on the structural features of the products obtained (4,8–10). The catalyst comprises two main components: first, a transition metal halide, such as $TiCl_4$, VCl_4, $VOCl_3$, of which $VOCl_3$ is the most widely used; second, a metal alkyl component such as diethylaluminum chloride, $(C_2H_5)_2AlCl$, or monoethylaluminum dichloride, $(C_2H_5)AlCl_2$, or most commonly a mixture of the two, ie, ethylaluminum sesquichloride, $(C_2H_5)_3Al_2Cl_3$.

Under polymerization conditions, the active center of the transition-metal halide is progressively reduced to a lower valance state, ultimately to V^{2+}, which is unable to polymerize monomers other than ethylene. The ratio V^{3+}/V^{2+}, in particular, under reactor conditions is a measure for catalyst activity to produce EPM and EPDM species. This ratio V^{3+}/V^{2+} can be upgraded by adding to the reaction mixture a promoter, which causes oxidation of V^{2+} to V^{3+}. Examples of promoters in the earlier literature were carbon tetrachloride, hexachlorocyclopentadiene, trichloroacetic ester, and benzotrichloride (11). Later, butyl perchlorocrotonate and other proprietary compounds were introduced (12–14).

For EPDM, long-chain branching and gel can be introduced during the polymerization. This may happen by at least two mechanisms: by Ziegler polymerization through both double bonds of the diene third monomer or through cationic coupling of pendent double bonds (15,16). For Ziegler polymerization to occur through both double bonds, both must be accessible to the polymerization catalyst. The strained five-member ring in the norbornene structures is highly reactive and is rapidly incorporated in the polymer chain. Reaction of the second double bond results in a tetrafunctional branch point in the EPDM backbone. The ethylidene double bond in ENB is so sterically hindered that Ziegler polymerization of the second double bond is not possible under the production conditions for EPDM. Conversely, the use of a diene, such as VNB and to a lesser extent DCPD, can result in substantial amounts of branching because of the accessibility of the vinyl group in VNB to the polymerization catalyst and the second five-member ring in DCPD (see ZIEGLER–NATTA CATALYSTS).

During Ziegler polymerization it is also possible to couple the chains cationically through pendent olefinic groups (15). The extent of this reaction strongly depends on the Lewis acidity of the catalyst components. In general, the amount of cationic coupling decreases as the aluminum alkyl cocatalyst is varied from $(C_2H_5)AlCl_2$ through $(C_2H_5)_2AlCl$ to triethyl aluminum. Particularly ENB tends to cationically couple with another ENB molecule built into another polymer chain, thereby creating another form of long-chain branches. In the presence of Lewis bases this amount of branching is markedly reduced. By the same mechanism, the coordination Ziegler–Natta catalysts are extremely sensitive to water and other polar materials, as they decompose the catalyst to Lewis acids. Only a few parts per million of water are allowed in any of the feed streams. Extended forms of long-chain branching finally lead to gel formation, which damage the processability of the products in the final application.

In the solution process making use of Ziegler–Natta catalysis, dry solvent, ethylene, propylene, diene, and catalyst and cocatalyst solutions are continuously and proportionately fed to one or a series of polymerization vessels. Polymerization of individual molecules, or chains, is extremely fast, and a few seconds at most is the average life of a single growing polymer molecule from initiation to termination. The polymerization is highly exothermic. The heat must be removed, since the polymerization temperature (ca 35°C) has to be kept within narrow limits to ensure a product with the desired average molecular weight and molecular weight distribution. Therefore, these processes can be grouped into those in which the reactor is completely filled with the liquid phase, and those in which the reactor contents consist partly of gas and partly of a liquid phase. In the first case the heat of reaction (ca 2500 kJ/kg EPDM) is removed by means of cooling systems, either external cooling of the reactor wall or deep cooling of the reactor feed, or combinations. In the second case the evaporation heat from unreacted monomers also removes most of the heat of reaction. Most commonly hydrogen is used as chain transfer agent to regulate the average molecular weight.

As the polymer molecules form and dissociate from the catalyst, they remain in solution. The viscosity of the solution increases with increasing polymer concentration. As the EPDM polymerization is a continuous process run in stirred reactor(s) at high conversion and rubber solids concentration, the practical upper limit of solution viscosity is dictated by considerations of heat transfer, mass

transfer, and fluid flow. At a rubber solids concentration of 5–10%, depending on the molecular weight of the polymer produced a further increase in the solution viscosity becomes impractical, and the polymerization is stopped by killing the catalyst. This is usually done by vigorously stirring the solution with water. If this is not done quickly, the unkilled catalyst continues to react, leading to above described uncontrolled side reactions, resulting in an increase in Mooney viscosity called Mooney jumping.

The reactivity of ethylene is high, whereas that of propylene is low, and the various dienes have different polymerization reactivities. The viscous rubber solution contains some unpolymerized ethylene, propylene, unpolymerized diene, and about 5–10% EPDM, all in homogeneous solution. This solution is passed continuously into a flash tank, where reduced pressure causes most of the unpolymerized monomers to escape as gases, which are collected and recycled.

Catalyst residues, particularly vanadium and aluminum and chlorine, have to be removed as soluble salts in a water-washing and decanting operation. Vanadium residues, and to a lesser extent chlorine residues, in the finished products are kept to a few parts per million, because these may have a strong negative influence on the ageing characteristics of the EPDM. If oil-extended EPDM is the product, a metered flow of oil is added at this point. In addition, antioxidant, typically of the hindered phenol type, is added at this point.

The rubber is then separated from its solvent by steam stripping. The viscous cement is pumped into a violently agitated vessel partly full of boiling water. The hexane flashes off and, together with water vapor, passes overhead to a condenser and to a decanter for recovery and reuse after drying. Residual unpolymerized ethylene and propylene appear at the hexane condenser as noncondensibles, and are recovered for reuse after drying. Unreacted diene may be recovered with the solvent and further fractionated for purification and recycling. The polymer, freed from its carrier solvent, falls into the water in the form of crumb.

The rubber crumb, now a slurry in hot water, is pumped over a shaker screen to remove excess water. The dewatered crumb is fed to the first stage of a mechanical-screw dewatering and drying press. Here, in an action similar to a rubber extruder, all but 3–6% of the water is expressed as the rubber is pushed through a perforated plate by the action of the screw. The cohesive, essentially dry rubber then passes into the second-stage press. This is similar to the first-stage dewatering machine, except that the mechanical action of the screw causes the rubber in the barrel to heat up to temperatures as high as 150°C. This rubber is extruded through a perforated die plate at the end of the machine, the small amount of remaining water is flashed off as a vapor, and the nearly dry rubber crumb is finally subjected to air-drying in a fluid bed or tunnel drier at temperatures of ca 110°C to reduce the level of remaining volatile matter to <0.7, preferably <0.3 wt%. This EPDM crumb is then continuously weighed, pressed into bales, and packaged for storage and shipment. Highly crystalline or sequential types are sufficiently form-stable to be produced in the form of pellets by a direct extruder operation, if necessary with application of a small amount of a separating or partitioning agent.

Slurry Process. In this process a nonsolvent diluent and an operating temperature are used so that the monomers are soluble, but not the polymer. The diluent must also be inert with respect to the catalyst components.

As diluent the monomer propylene is used. It is of course not an inert substance, but its conversion level is low enough to allow for its use as a nonsolvent diluent.

The advantages of this process reside in the low viscosity of the dispersion of precipitated crumby EPDM particles in the low viscosity propylene medium. This bears on heat transfer, solvent recycle capacity, and slurry transport problems. For example, temperature control of the reactor can more readily be effected by controlled evaporation of the propylene and to a lesser extent ethylene. Another advantage lies in much higher production rates due to higher slurry concentrations (20–40%) compared to the solution process. The slurry process also allows for higher molecular weight EPDMs, because a viscosity rise of the solution does not apply in this case. Another advantage is the lower catalyst levels needed in comparison with the solution process, because the great abundance of propylene as monomer being diluent at the same time.

The disadvantage of the slurry process lies in the problems related to the removal of catalyst residues. Catalyst tends to become occluded in the precipitated EPDM. Although the slurry process has lower catalyst consumption, the problem with removing catalyst residues leads to higher catalyst residues in the final polymer. These catalyst residues then have the tendency to become involved in intermolecular branching reactions of the type described above, which increases the probability of premature cross-linking reactions (=gelation) during the killing step and during storage. Further, these catalyst residues contribute significantly to the degradation of rubber vulcanizates properties upon heat ageing.

The greatest benefit of this technology is achieved if the steam-stripping operation is replaced by a progressive series of degassing operations, vessels and extruders, for cost reasons and to do away with water in the whole operation (17).

Gas-Phase Process. Another noteworthy development in the field of EPDM manufacture is the so-called gas-phase process, as an extension of the well-known gas-phase processes for polyethylene and polypropylene (18). The process uses a fluid-bed reaction vessel to which gaseous ethylene, propylene, and third monomer ENB are fed. The reaction heat is removed through circulation of the gas, which serves to fluidize the polymer bed as well as to act as the raw material for the polymerization. In fact, this process can be pictured as a continuous percolating fountain of small EPDM granules, coated *in situ* with a steady stream of fluidization aid in order to prevent sticking together of the granules. As fluidization aid finely ground furnace carbon black is being used up till quantities of about 16 wt% or 20 phr (parts per hundred rubber) (19). This carbon black remains in the EPDM. The gas-phase technology is solvent- or diluent-free, and so no stripping is required. The nonconverted monomers are recovered by purging and are recycled. Drying and finishing is therefore not applicable to gas-phase produced EPDM as no water is involved in the process. The product is delivered in granular form, as directly recovered from the reactor.

Also this process offers the possibility of greatly reduced finishing operations and consequent cost savings. The gas-phase process does not permit catalyst removal. This is both an advantage in cost and a disadvantage in terms of catalyst residue. These polymers will have a high catalyst residue as long as conventional Ziegler–Natta catalysts are used. It may be possible to lower catalyst residue if

metallocene catalysts can be adapted for this process (see next section). It should also be noted that removal of unreacted ENB from the gas-phase product is not a trivial matter. An additional purging step is needed to remove the third monomer (20). The question applies, whether this technology will offer a comparable flexibility in due course to make the wide variety of EPDM molecular structures, which have been designed over the years to comply with market requirements for the various applications of EPDM rubber.

New Catalysis Technologies Using Metallocenes. Through the last years a very rapid development of single-site metallocene catalysts has taken place, primarily for polyethylene and polypropylene, but with spin-offs to EPDM manufacture (21–24). In combination with methylaluminoxane as the cocatalyst, these metallocene catalysts show an enormous increase in activity relative to the traditional Ziegler–Natta catalysts. They show a greatly increased catalyst activity for higher alpha-olefins, like the third monomers. In addition, they keep their activity at higher polymerization temperatures than commonly employed for Ziegler–Natta catalysts. Metallocene catalysts (qv) usually give a different comonomer distribution than traditional Ziegler–Natta catalysts (qv).

Various advantages are claimed for metallocene catalyst technology: such a low catalyst consumption that catalyst residues do not need to be removed from the polymer after deactivation. Further, the higher operating temperature of the catalyst allows for a higher temperature regime of the total process, resulting in a reduction of cooling operations. It also allows for higher solution concentrations with consequent lower stripping energies involved, particularly if this technology is combined with an older technology where the steam-stripping operation is replaced by the water-free finishing mentioned before (17).

In spite of the many advantages claimed for this technology, it has to be noted that many of these are offset by various countereffects: the need for higher pressure operations and consequent additional investments if the increased temperature regime of this technology is to be exploited; the need for highly purified raw materials, because these catalysts are much more sensitive to poisoning by adverse compounds than the traditional Ziegler–Natta catalysts; the question whether this technology will have a comparable flexibility in order to make the wide variety of EPDM molecular structures, which have been designed over the years as dictated by the market requirements.

Production Capacities. Production capacities of EPM/EPDM of the largest manufacturers are listed in Table 2 (25).

Compounding

EPM/EPDM grades have to be compounded with reinforcing fillers if high levels of mechanical properties are required. EPM/EPDM grades with a high Mooney viscosity and a high ethylene content are particularly capable of accepting high loadings of filler (eg, 200–400 phr) and plasticizer (eg, 100–200 phr) and still giving useful vulcanizates.

Carbon blacks are usually used as fillers. The semireinforcing types, such as FEF (fast extrusion furnace) and SRF (semireinforcing furnace), give the best performance. To lower the cost and improve the processability of light colored

Table 2. EPM/EPDM Rubber Production Capacities[a]

Manufacturer	Country	Capacity, t/year
Bayer/Polysar	United States and Germany	110,000
DSM Elastomers	United States, the Netherlands, and Brasil, Japan	216,000
DuPont Dow	United States	90,000

compounds, or to reduce the cost of black compounds, calcined clay or fine-particle-size calcium carbonates are used.

The most widely used plasticizers are paraffinic oils. For applications that specify high use temperatures, or for peroxide cures, paraffinic oils of low volatility are definitely recommended. Because paraffinic oils may tend to exudation at low temperatures from EPDM vulcanizates, or from high ethylene EPDMs, they are sometimes blended with naphthenic oils. On the other hand, naphthenic oils interfere with peroxide cures. Aromatic oils reduce the mechanical properties of vulcanizates, and they also interfere with peroxide cures. Therefore, they are generally not recommended for EPM/EPDM.

Although EPM can only be cross-linked with peroxides, peroxide or sulfur plus accelerators or even other vulcanization systems like resol resins can be used for EPDM. The choice of chemicals used in an EPDM vulcanizate depends on many factors, such as mixing equipment, mechanical properties, cost, safety, and compatibility. In sulfur vulcanization, ENB-containing EPDM is about twice as fast as DCPD-containing EPDM. If peroxide cures are required for better heat stability, DCPD-containing EPDM gives higher cure states than EPM. The reactivity of ENB–EPDM is a little lower in peroxide cures. For peroxide cures of EPM and to a lesser degree of DCPD–EPDM, activators such as small amounts of sulfur, acrylates, or maleimides are also needed. The chemistry involved in sulfur and resol resin curing of ENB-containing EPDM has been investigated in detail by several authors (26–29).

Because of the low level of C=C unsaturation in the polymer compared to, eg, natural rubber (NR) and SBR, EPDM needs significant amounts of highly active accelerators for sulfur vulcanization. Usually, combinations of benzothiazole derivatives or sulfenamides with so-called ultra-accelerators like thiuram compounds or dithiocarbamates are used. Because of the limited solubility of these various accelerators in EPDM versus the large quantities needed to obtain a sufficient level of vulcanization, an EPDM compound often contains four or more

accelerators next to elemental sulfur; every accelerator obeys its own maximum dosage related to its solubility limit.

Modern legislation puts much emphasis on the prevention of the formation of carcinogenic secondary *N*-nitrosamines as by-products of sulfur vulcanization (30). This limits the choice of possible accelerators to those which have no secondary amine groups embedded in their chemical structure or may contain residual secondary amines dating back to their synthesis: usually the ultra-accelerators mentioned above. In such cases it is extra difficult to develop a proper vulcanization system. New ultra-accelerator systems like dibenzyl dithiocarbamate or tetrabenzyl thiuramdisulfide may be used in such cases, where the dibenzylamine embedded in these compounds is an exception in that it does not generate *N*-nitrosamines carcinogenic to human beings (31).

In Table 3 a few examples are given of typical EPDM recipes with pertinent cured properties.

Processing

The larger part of EPM and EPDM rubber finds applications in continuous extruded profiles or calendered sheets for automotive and building sealing applications. A smaller part is being used for a diversity of applications, from molded goods till viscosity modifiers for lubricant oils. The processing of EPM and EPDM rubbers must be viewed in relationship to the sort of application envisaged.

Mixing. Compounds of low Mooney EPM or EPDM grades can be mixed on open mills. For most applications EPM and EPDM compounds are almost exclusively mixed in internal mixers. The mechanisms involved in the mixing of EPM/EPDM as a function of molecular structural parameters, in particular molecular weight, molecular weight distribution (32–34), and long-chain branching (35,36), have been studied in great detail. It turns out that the speed of carbon black dispersion is greatly dependent on these parameters for practical mixing cycles. The molecular weight distribution and level of long-chain branching of the EPM/EPDM rubber should be suitably chosen, depending on the desired degree of carbon black dispersion in the application concerned: a narrow distribution for average carbon black dispersions, and a broad distribution for applications requiring excellent carbon black dispersions. A pronounced high molecular weight fraction within the molecular weight distribution—often called *bimodality* or *tailored molecular weight*—has a beneficial effect on mixing behavior by raising the shear toughness of the EPDM: it allows for higher shear forces exerted by the mixer and consequently a better dispersion of the reinforcing filler: the better dispersed filler is somewhat less reinforcing, which generally results in a lower viscosity of the mixed compound (32–34). On the other hand, a more pronounced fraction of low molecular weight material acts like a plasticizer and also has a decreasing effect on the viscosity of the mixed compound. The concept of controlled long-chain branching, combining a narrow molecular weight distribution with a high level of long-chain branching, has proven to be particularly beneficial for ease of processing and good mechanical properties as a result of this (36).

For EPM/EPDM grades with high ethylene contents, the disintegration of the bales is a dominating factor. If the polymer is in the form of a compact

bale, it is difficult to disintegrate the rubber sufficiently to form a fine dispersion with the other compounding ingredients, so that the shearing action of the mixer can disperse the ingredients evenly. In such cases particulate forms of the rubber such as crumbs, pellets, and friable bales may shorten the mixing cycle considerably.

Extrusion. For automotive and building sealing profiles, extrusion is the common shaping technology. In general, EPM/EPDM compounds can be extruded on all commercial rubber extruders. The extrusion behavior of EPM and EPDM compounds must be seen in relation to the compound quality, as achieved during mixing and influenced by the same molecular structural parameters as quoted above (34,37–40).

Also for extrusion purposes long-chain branching has a particularly positive effect (40): it increases extrusion speed and the resistance against collapse: the tendency of extruded profiles of complicated shapes to deform under the influence of gravity between the extruder and the vulcanization line.

Curing. EPM/EPDM compounds are cured on all of the common rubber-factory equipment: press cure, transfer molding, steam cure, hot-air cure, and injection molding are all practical. Where profile extrusion is the shaping technique, hot-air tunnel curing and ultrahigh frequency (UHF) electromagnetic heating followed by a hot-air tunnel or molten-salt bath (LCM) cure are the most common vulcanization techniques (41).

Many hot-air lines are homemade and differ substantially in quality and efficiency. It is a cheap curing technique and therefore often favored. A wide variety of air temperatures and tunnel lengths are directly related to the production speed, which can be achieved with a particular line. Air speed is another important factor. The heat transfer from the hot air to the EPDM rubber profile is poor compared to the other techniques, dictating much longer hot-air lines than, eg, LCM or UHF lines to achieve the same states of cure.

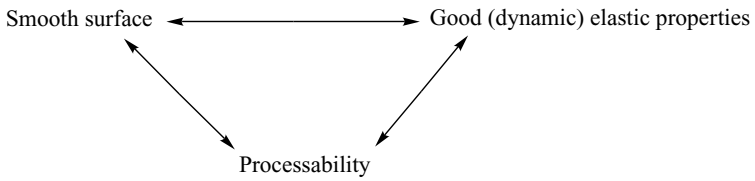
UHF heating is the continuous curing technique most commonly applied. The purpose of the UHF unit is a fast and homogeneous heating of even very complex shaped profiles, within a short distance. The following hot-air tunnel then serves to keep the profile at the curing temperature. Much milder hot-air conditions and shorter lines can be used than for hot air alone.

In spite of the somewhat old-fashioned nature and environmental problems of this curing technique, LCM curing is still the second most important continuous curing technique for EPDM sealing profiles. A major reason why this technique still survives or rather revives relative to the others is that this is the only continuous curing technique which allows for peroxide vulcanization. Peroxide vulcanization with free access of oxygen from the air—like in hot-air curing—leads to an intricate interaction between the oxygen molecules and peroxy radicals, which results in surface degradation instead of vulcanization and a consequent stickiness of the profile surface. This is an intrinsic problem of curing with peroxides, occurring with all other rubbers as well. The molten salt effectively shields the profile surface from this free oxygen. Another reason for the LCM revival is that this curing technique in general leads to the smoothest surface finish of extruded EPDM sponge profiles (see below).

Sponge Processing. Extrusion sponge represents a part of EPDM application technology, which requires the highest level of know-how, and consequently

includes all aspects of EPDM-compounding and EPDM-processing technology (42). In line with major automotive requirements calling for improved comfort and luxury, automotive body seals and profiles are becoming increasingly complex and numerous. Sponge plays a major role in this context. On a weight basis it represents a minor part of the profile technology, but because of the fact that sponge in most cases is coextruded with solid/dense profiles it represents about 50% of the sealing profiles on a volume basis. This combination with solid/dense extrusions calls for an integrated approach (43).

In summary the requirements on sponge converge on finding a good compromise between what could be called "the Magic Triangle" in EPDM-sponge technology:



Many, if not all, of these performance aspects can directly or indirectly be influenced by

(1) the seal cross-sectional design and dimensions;
(2) the sponge density, which must be adjusted by a proper balance between the amount of blowing agent and the curing accelerator package: to vary between 0.2 g/cm^3 till completely solid;
(3) closed vs open cell structure: a phenomenon difficult to quantify or adjust, but of major influence on the closed surface skin and the tendency of the sponge profile to absorb water.

With the great variety of curing techniques as described previously, it is not possible to come forward with "general" compounding rules for sponge. Every curing technique in combination with the vulcanization system requires its own set of compounding rules to obtain the best results. In summary a series of requirements can be formulated which generally apply:

(1) The Mooney viscosity of the sponge compound is generally adjusted to such a level, that the blowing agent can expand the compound to the required density, before being arrested by the curing: compound Mooney ML$(1+4)$ 100°C typically between 30 and 45 (but not limiting).
(2) Compound viscosity variations should be kept to a minimum to guarantee a reproducible and constant amount of blowing and curing from batch to batch: compound Mooney typically ± 2 Mooney units.
(3) A homogeneous and very fine dispersion of ingredients to guarantee a homogeneous blowing.

(4) Blowing agents are most often used in combinations and occasionally with activators. The selection and use of a proper blowing agent depends on many factors and is a difficult matter. They are activated by numerous compounding ingredients, generally reducing the decomposition temperature of the blowing agents. The reader is referred to the pertinent literature (44,45) for details.

(5) Carbon black loading alone tends to create a coarse cell structure and irregular sponge surface. Hence sponge compounds are often modified by the addition of mineral fillers such as whiting, calcined clay, and platy talcum: they serve as nucleating agents for the blowing agents, resulting in a fine and homogeneous cell structure and smooth surface finish.

(6) The choice of the vulcanization system in combination with the blowing agent(s) to produce smooth weatherstrip sponge is another difficult aspect. Commonly, highly active cure systems are applied with a variety of vulcanization accelerators added to their maximum solubility level in the compound, in order to raise the vulcanization speed and reduce scorch time. To achieve the right dimensions of the sponge profile at the right density, the expanding foam needs to be arrested by scorch just at the right moment. Many attempts were made to simulate this mutual interaction of blowing and curing in laboratory simulations (46–48), but it still is the experience and craftsmanship of the compounder which determines the chance of a quick success: the result of many iterative trials.

Properties of EPM and EPDM Vulcanizates

Mechanical properties depend considerably on the structural characteristics of the EPM/EPDM and the type and amount of fillers in the compound. A wide range of hardnesses can be obtained with EPM/EPDM vulcanizates. The elastic properties are superior to those of many other synthetic rubber vulcanizates, particularly of butyl rubber, but they do not reach the level obtained with NR of SBR vulcanizates. The resistance to compression set is surprisingly good, in particular for EPDM with a high ENB content or when cured with peroxide.

The resistance to heat and ageing of optimized EPM/EPDM vulcanizates is better than that of SBR and NR. Peroxide-cured EPM can, for instance, be exposed to 150°C for 1000 h without significant hardening. Particularly noteworthy is the ozone resistance of EPM/EPDM vulcanizates. Even after exposure for many months to ozone-rich air of 100 pphm, the vulcanizates will not be seriously harmed. EPM/EPDM vulcanizates have an excellent resistance to chemicals, such as dilute acids, alkalis, and alcohol. This is in contrast to the resistance to aliphatic, aromatic, or chlorinated hydrocarbons. EPM/EPDM vulcanizates swell considerably in these nonpolar media.

The electrical-insulating and dielectric properties of the pure EPM/EPDM are excellent, but in compounds they are also strongly dependent on the proper choice of fillers. The electrical properties of vulcanizates are also good at high temperatures and after heat-ageing. Because EPM/EPDM vulcanizates absorb little moisture, their good electrical properties suffer minimally when they are submerged in water.

Health and Safety Factors

EP(D)M is not classified as a hazardous material. It is not considered carcinogenic according to OSHA Hazard Communications Standard and IARC Monographs. Commonly used paraffinic extender oils contain less than 0.1 wt% polynuclear aromatic compounds PNAs.

In handling EPM/EPDM, normal industrial hygienic procedures should be followed. It is advisable to minimize skin contact. The use of EPM/EPDM is permitted for food contact under the conditions given in the respective FDA paragraphs: § 177.1520 for olefin polymers, and § 177.2600 for rubber articles intended for repeated contact with food.

Uses

Expressed as percentages of total annual synthetic rubber consumption worldwide, EPM and EPDM have increased from 0% in 1964 to 8.9% in 2000, as shown in Table 4. EPM and EPDM still show a steady growth over the years.

The main uses of EPM and EPDM are in automotive applications as weatherstrip profiles, automotive coolant hoses, air-conditioning and brake hoses, and seals. In building and construction EPDM is used in sealing profiles, roofing foil, and seals; in cable and wire as cable insulation and jacketing; and in appliances in a wide variety of mostly molded articles.

With respect to automotive coolant hoses, the ever-increasing temperatures under the hood, combined with a performance requirement of 10 years or 200,000 km, have led to significantly more stringent testing conditions. Temperatures commonly occurring under the hood in the area of the radiator hose are 110–125°C, with peak temperatures as high as 140°C locally. Sulfur-cured EPDM has established itself as the most preferred elastomer for radiator coolant hoses under these conditions. The newer automotive standards request for higher temperature resistance: typical operating temperatures between 125 and 150°C continuous use, with peaks as high as 175°C. Further, new metal alloys containing aluminum and magnesium are used for the car engines. These new metals as well as the higher temperatures dictate appropriate changes in the compositions of the cooling liquids, in particular the stabilization packages against metal corrosion. These lead to an increased tendency to form deposits with zinc and accelerator-remnants leached out of sulfur-cured EPDM. The deposits tend to block the cooling capillaries in the engine and the radiator, reducing heat transfer and eventually

Table 4. Worldwide EPM and EPDM Consumption as Percentage of Total Rubber Consumption[a]

Year	EPM/EPDM, t/year	EPM/EPDM consumption, %[b]
1964		0.0
1970	89,000	
1980	328,000	
1990	609,000	
2000	919,000	8.9

[b] Of total synthetic rubber consumption.

leading to engine break down. In these cases, where zinc is not acceptable in EPDM compounds, as well as for those cases where the temperature requirements surpass the ageing performance commonly achieved with sulfur cure, the alternative of peroxide curing of EPDM is the preferred method (49,50).

For the same reason of increased temperatures under the hood, the use of EPDM for dynamic applications is gaining importance as a replacement of NR, the natural choice for such applications because of its excellent fatigue resistance and low hysteresis. Applications envisaged are automotive engine mounts, vibration mountings, and muffler mounts. By a proper selection of EPDM characteristics—very high molecular weight, narrow molecular weight distribution, in combination with a relatively low amount of fillers added during compounding, EPDM practically matches the dynamic performance of NR in these applications. Its temperature resistance can even be improved by choosing peroxide rather than sulfur for the vulcanization, although the dynamic properties of peroxide cured compounds are generally somewhat reduced in comparison with sulfur cures (51).

The use of EPDM in low and medium voltage wire and cable applications has made steady progress, as a result of its superior electrical treeing retardancy. EPDM rubber insulated cables are more stable under wet conditions than crosslinked polyethylene insulation. The choice among various EPDM grades in designing insulation compounds is governed by the service requirements such as low electric loss, extrudates free of surface defects, high extrusion output, and good heat ageing properties (52). Also for this application long-chain branching has shown to be particularly beneficial for overall optimum performance (53).

Another application for EPDM is in blends with general-purpose rubbers. Ozone resistance is thus provided with the host rubber comprising the principal portion of the blend. This technique has been applied in enhancing the ozone and weathering resistance of tire sidewalls and cover strips. This use accounts for essentially all EPDM consumption in tires, as the dynamic and wear properties of EPDM do not favor its use for the carcass and tread parts of the tire. EPDM compounds are, moreover, nontacky, whereas tackiness is a prerequisite for building tires. Although this can be solved to some extent, there are no all-EPDM tires currently being produced. Economic factors favor the use of natural and general-purpose synthetic rubbers in tires.

Considerable amounts of EPM and EPDM are also used in blends with thermoplastics, eg, as impact modifier in quantities up to about 25 wt% for polyamides, polystyrenes, and particularly polypropylene. The latter products are used in many exterior automotive applications such as bumpers and body panels. In blends with polypropylene, wherein the EPDM component may be increased to become the larger portion, a thermoplastic elastomer is obtained. Provided the EPDM phase is vulcanized during the mixing with polypropylene (dynamic vulcanization) to suppress the flow of the EPDM phase, it gives the end product good set properties (54).

Substantial amounts of EPM are also used as viscosity modifiers in lubrication oils. Molecular weight, molecular weight distribution, ethylene propylene ratio and in particular sequence distribution are important parameters to meet the desired performance. They markedly influence the thickening efficiency, low temperature properties, temporary and permanent viscosity loss due to shear, and engine performance as a whole. Much work aims at modification of the EPM

backbone as a post-polymerization step with polar groupings: eg, by grafting maleic anhydride onto the EPM chain, followed by a reaction with a variety of polar groupings such as amines (55,56).

FATIGUE

Introduction

Polymers and polymer-based composites are increasingly displacing more traditional materials in a wide variety of engineering applications, and estimates by the National Institute of Standards and Technology place the total annual loss of engineering components due to fracture at more than $110 billion. Failure may occur for a variety of reasons. Most notably, failure can occur if the applied stress exceeds the strength limits of the material. Failure may also be attributed to material property deficiencies resulting from improper processing conditions that lead to defects (eg, gas or shrinkage pores, inclusions, and weld-and-flow-line defects). Surface defects can result from mechanical processing or handling. These include scratches, gouges, and other markings that introduce stress concentrations. Finally, defects can nucleate and grow in a material during service as a result of repeated loading at stress levels below the nominal yield strength, even when the material has satisfactory properties and contains no adventitious defects. When these failures occur as a consequence of a hygrothermal or mechanically induced cyclic loading condition, they are referred to as fatigue failures.

In general, a variety of mechanisms may contribute to the failure of actual components in service. These may include chemical degradation or oxidation: a chemical mechanism that may induce cross-linking and chain-scission. Alternately, other physical processes may alter the state of the polymer (eg, surface active agents in the presence of stress may induce crazes due to local diffusion of the agents near defects). These aspects are not discussed in this article.

Failure of a component due to fatigue generally occurs through a two-step process. The first step involves the initiation of microcracks or other damage at inhomogeneities or defects in the material. This damage can initiate and evolve

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

at nominal stress levels far below the yield or tensile strength of the material. This step is commonly referred to at the initiation stage. The second step involves the growth of damage through the coalescence of microcracks and the subcritical propagation of these small cracks to form large cracks and ultimately cause component failure. This step in the failure process is referred to as the propagation stage. For most polymeric materials, the initiation time can be orders of magnitude greater than the propagation time. The initiation of such microcracks and their subsequent propagation form the subject of this article. This article places emphasis on the fatigue behavior, and not necessarily on aspects of fatigue crack propagation (FCP), which is considered to be a topical subset of the fracture behavior of polymers and is out of the scope of this article (see FRACTURE). Nevertheless, some aspects of FCP and fracture are discussed as they relate to specific cumulative damage theories and lifetime prediction methods. Earlier reviews in polymer fatigue and FCP have appeared (1–7).

General Terminology

A common aspect to all fatigue failures is that they occur as a consequence of an imposed cyclic hygrothermal and/or mechanical loading process. In general, any cyclic loading condition can be imposed on any specimen geometry. However, the most common loading conditions for mechanically induced fatigue involve uniaxial (tension and/or compression) or flexural loading conditions. Although the stress state changes with specimen geometry and loading condition, the common approach is to describe the fatigue behavior in terms of the magnitude of some imposed cyclic stress. Two common specimen geometries used for fatigue studies include the *dogbone*-shaped tensile bars (ASTM D638) (8) for tension–tension fatigue experiments or flexure specimens (ASTM D671-71) (9) for tension–compression fatigue studies. These two specimen geometries are schematically shown in Figure 1. The flexural fatigue specimen in Figure 1 is tapered along its gage length to produce a nominal stress distribution that is constant along the gage length of the specimen. The flexure geometry is tested in a cantilever beam configuration. This configuration produces a bending moment across the specimen thickness that is linearly distributed along the beam length. By linearly altering the beam bending moment of inertia (via the tapered width), the stresses along the specimen gage length become constant. For polymer-based composites, flexural fatigue using the geometries illustrated in Figure 1, are quite common. Thus, both the tensile and flexure fatigue geometries produce stress distributions that are nominally constant along their gage lengths and are below those imposed at the grips. These attributes are critical for accurate measures of fatigue resistance of a material to ensure that specimen geometry does not alter the result by promoting premature failure at the grip locations.

It should be noted that there are subtle differences when comparing data generated in uniaxial tension and flexural fatigue tests. A uniaxially applied load nominally imposes a uniform normal stress throughout the cross section of the specimen, with a plane strain condition occurring at the specimen's center. In contrast, the normal stresses in a flexure test are linearly distributed across the specimen, with the maximum occurring at the outer surfaces of the specimen, and

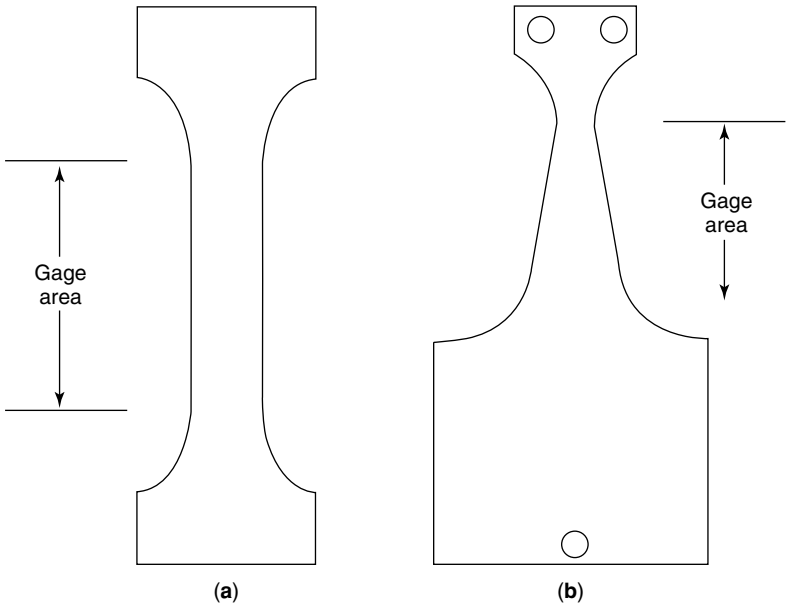

Fig. 1. Schematic of common specimen geometries used in fatigue testing of polymeric materials. (**a**) Tensile test specimen. (**b**) Flexural test specimen.

are zero at specimen's neutral axis (typically at the center for most specimens). Consequently, flexural fatigue tests are more affected by surface flaws while uniaxial tests are more affected by flaws within the specimen's interior. Also, because of the high internal damping and low thermal conductivity characteristic of most polymers, hysteretic heating and the associated effects are more prevalent in uniaxial tests than in flexure tests.

In mechanically induced fatigue tests, the stress or strain is oscillated about some mean stress (strain). If the peak or maximum stress is defined by σ_0 and the minimum stress by σ_u, then the stress ratio is often defined by R where

$$R = \frac{\sigma_0}{\sigma_u} \tag{1}$$

The type of cyclic is typically a sinusoidal, triangular, or square wave with the amplitude, mean stress, and frequency all adjustable parameters to consider. Some of these parameters are shown in Figure 2.

Numerous studies have shown that the cyclic lifetime of a test bar or component varies inversely with the magnitude of the applied cyclic stress, strain, or deflection. As a consequence, various test procedures have been developed to obtain mechanical property information useful in fatigue design analysis. Long ago, Wöhler (10) developed a procedure wherein a notched or unnotched specimen is subjected to a cyclic stress (σ) and the number of loading cycles (N) to cause failure is recorded. This procedure is repeated for a range of stress levels, and the data are presented in the form of a σ–N curve (11,12). Examples of σ–N fatigue curves are shown in Figure 3 (12).

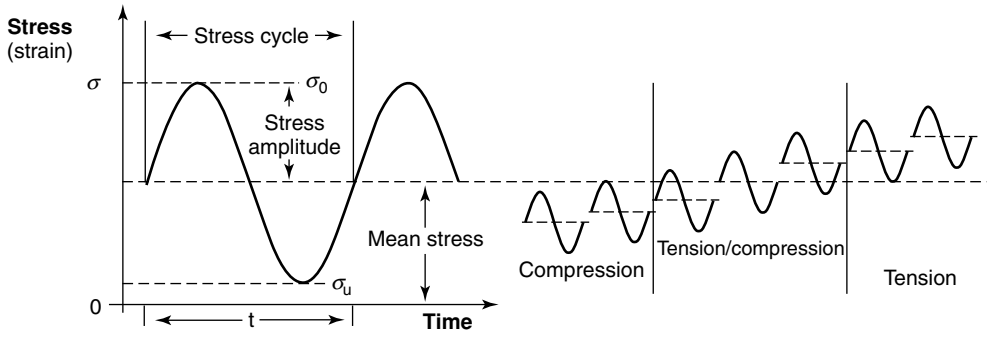

Fig. 2. Important parameters for fatigue experiments.

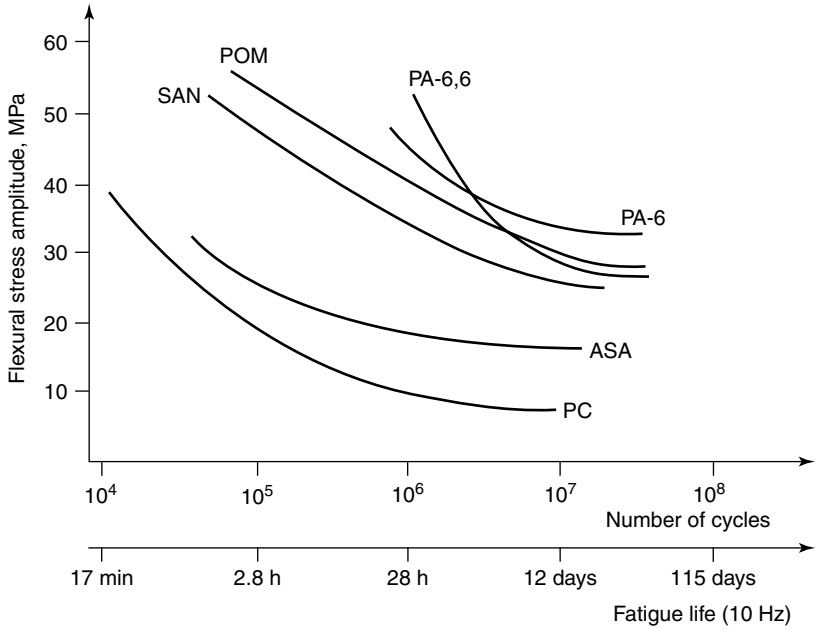

Fig. 3. Wöhler curves for different thermoplastics, generated via flexural fatigue loading at 10 Hz (12). To convert MPa to psi, multiply by 145.

The cyclic lifetime of a given polymer decreases with increasing applied stress consistent with greater damage accumulation per cycle at higher stress. Some of the plots in Figure 3 exhibit a relatively well-defined plateau, suggesting an endurance limit for a particular polymer below which fatigue damage does not significantly accumulate. By contrast, other engineering plastics reveal a steadily decreasing allowable cyclic stress with increasing number of loading cycles. Stress cyclic lifetime curves are used to define the permissible operating stress (or strain) in order to preclude fatigue failure for an anticipated number of cyclic excursions. For example, if it is desired that a component withstand at least N_1 loading cycles in a given lifetime, the part should be designed so that the applied cyclic stress is less than σ_1.

Fatigue tests are both costly and time consuming because of the number of samples that must be tested in an expensive test machine for days or weeks until fracture. Also, since fracture is a stochastic process by nature, repeated tests should be conducted at each stress level considered. Finally, the number of cycles to failure, N_I, gives no clear indication of the fatigue limits for a given application of a polymeric material because in many cases, the definition of failure is ambiguous. For example, failure may be defined as a decrease in specimen stiffness or other irreversible changes rather than actual specimen fracture.

Fatigue Behavior

In general, fatigue failure occurs by one of two possible modes: a mechanically dominated mechanism or a thermally dominated mechanism. A mechanically dominated process involves the nucleation of damage and its subsequent growth in the form of crazes, microcracks, and ultimately large cracks that are responsible for specimen failure. This process occurs at relatively lower stresses and frequencies and results in a higher fatigue life. This regime is commonly referred to as the high cycle regime and the failure mode of the polymeric material is quite often brittle in nature (13–16). This regime is also referred to as the *true* fatigue response of the material.

At relatively higher stresses and frequencies, hysteretic heating affects the physical and mechanical properties of the polymer. This effect is a combined consequence of the fact that most polymers demonstrate high internal damping and low thermal conductivity. In this process, heat generated from mechanical fatigue cannot be dissipated to the surroundings and the polymer temperature rises throughout the test. Failures usually occur rather quickly and the failure mode is usually ductile (13–16). This regime is referred to as the low cycle regime and is not considered to be an intrinsic response of the material to fatigue loading conditions. If one polymer exhibits a greater tendency than another for hysteretic heating under cyclic loading conditions, the relative ranking of the two polymers may differ greatly when the tests are conducted at both high and low cyclic frequencies.

Identifying whether a particular set of fatigue conditions is mechanically or thermally dominated can be observed in the evolution of the hysteresis loops. This is shown characteristically for the case of polyacetal in Figure 4 (13). In the low cycle region, hysteresis loops show a progressive increase in compliance and irreversible work as the material is fatigued. In contrast, the high cycle hysteresis loops show that the material initially becomes slightly stiffer and less viscoelastic (as evidenced by the decrease in irreversible work) as the cycles increase. This is fatigue-induced embrittlement and occurs prior to craze initiation and subsequent crack growth. A Wöhler plot of polyacetal showing the thermally and mechanically dominated regions is shown in Figure 5 (13). Note that a discontinuity occurs in the σ–N at the stress level where the transition occurs. This is critically important to recognize since data in the thermally dominated regime suggest that an endurance limit has been reached. However, as the stress level is reduced, a transition in the failure mode occurs from ductile to brittle, and failure is measured at a finite cycle number below the apparent endurance limit. Hence, extreme care should

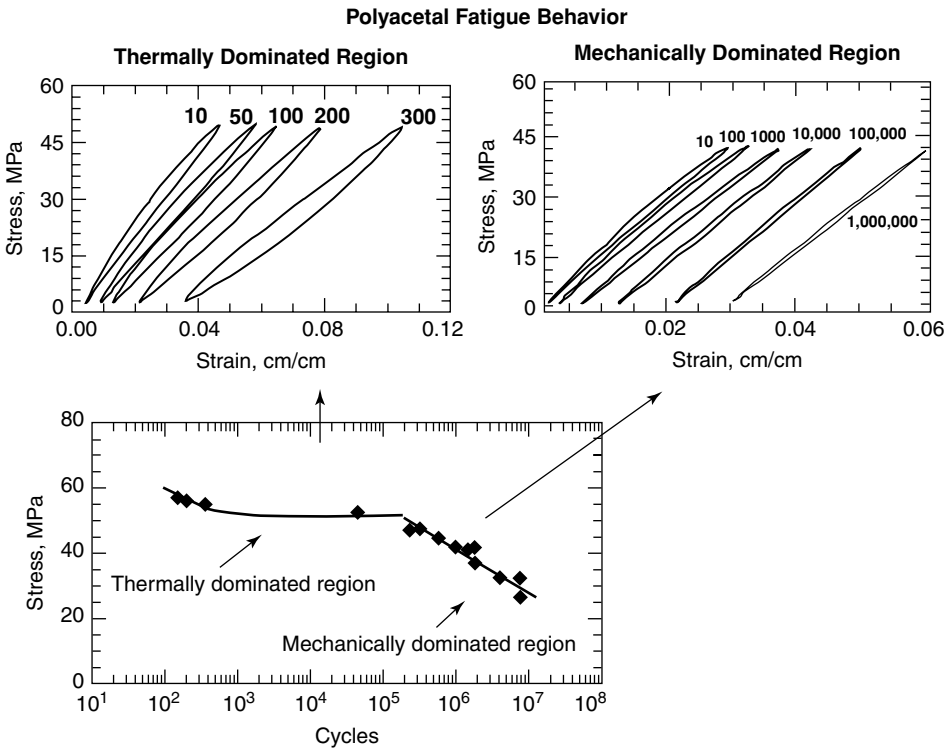

Fig. 4. Plots of hysteresis loops for polyacetal fatigued in the low cycle (thermally dominated) and high cycle (mechanically dominated) regions. The numbers located by each hysteresis loop indicate the cycle number (13). To convert MPa to psi, multiply by 145.

be exercised when using fatigue data for design considerations to ensure that the proper failure mode is observed from the accelerated tests.

Hysteretic Heating and the Low Cycle Regime. At relatively high frequencies and stress levels, many polymers may become overheated as a result of the accumulation of hysteretic energy generated during the loading cycles. Such energy dissipation produces a significant temperature rise within the specimen, which, in turn, causes the elastic modulus of the material to decrease. As a result, large specimen deflections contribute to even greater hysteretic energy losses with further cycling. In the limit, an autoaccelerating tendency for rapid specimen heating and increased compliance is experienced. Such thermal failure corresponds to the number of loading cycles at a given applied stress range that bring about an apparent modulus decay to 70% of the original modulus of the specimen (10–13). Extreme care should be taken in ranking the fatigue resistance of polymeric materials since the test conditions may effect the measurement of the true or the intrinsic fatigue resistance of the material. In general, results like those presented in Figure 3 should only be used to rank materials once it is assured that the tests are run properly to ensure the appropriate failure mechanisms. These test results can be applied in design only when all design factors including magnitude and state of the stress, part size and shape, temperature, heat transfer

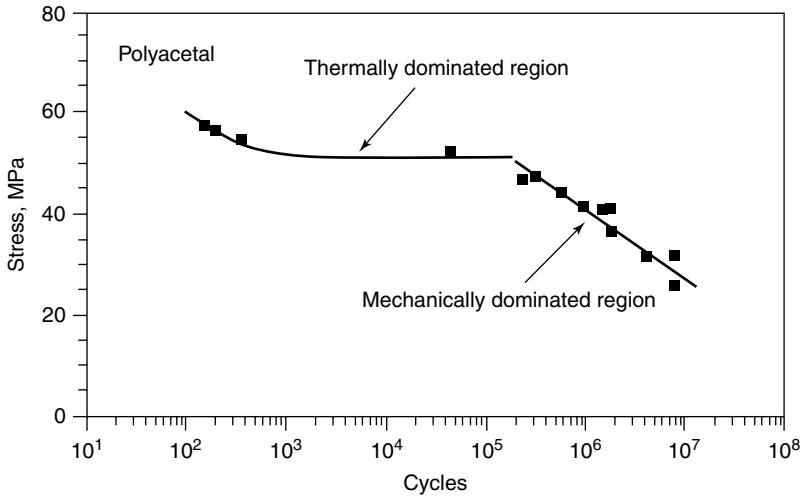

Fig. 5. Plot of fatigue σ–N curve for polyacetal resin, illustrating both thermally dominated and mechanically dominated regions. Note in the thermally dominated region an apparent endurance limit appears (13). To convert MPa to psi, multiply by 145.

conditions, cyclic frequency, and environmental conditions are comparable to the test conditions.

Studies (17–19) have shown that the energy dissipation rate under cyclic loading conditions varies directly with the test frequency, the loss compliance of the material, and the square of the applied stress. Neglecting heat losses to surrounding environment the temperature rise in the sample per unit time can be calculated as

$$\Delta\dot{T} = \frac{\pi f J''(f,T)\sigma^2}{\rho_{\mathrm{p}}^c} \tag{2}$$

where $\Delta\dot{T}$ is the temperature change/unit time, f the frequency, J'' the loss compliance, σ the peak stress, ρ the density, and c_{p} the specific heat. Previous studies (15,16,20) have shown that for all stress levels above the endurance limit, the polymer heats to the point of melting at failure. The temperature rise is stabilized at a maximum below the point of thermal failure. It should be noted that for conditions associated with thermal failure, cyclic lives can be enhanced by intermittent rest periods during the cyclic history of the sample (20–22). Temperature rise resulting from adiabatic heating can thus be dissipated periodically. Therefore, component life can be enhanced via cooling in thermally dominated fatigue applications (23).

The transition from thermal to mechanical failure has been described in terms of a changeover stress level, which depends on test frequency, mean stress, cyclic waveform, and specimen surface area-to-volume ratio (24). An empirical relationship between the uniaxial changeover stress and test frequency is shown in Figure 6 (24) and is given by

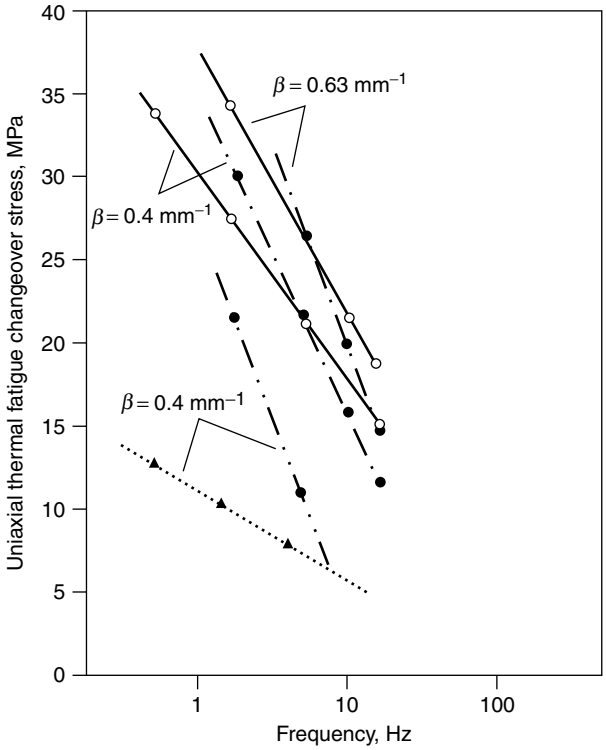

Fig. 6. Changeover stress from mechanical to thermal failure as a function of specimen surface area-to-volume ratio β and test frequency (24). To convert MPa to psi, multiply by 145.

$$\sigma_c = \sqrt{A/V}(C_1 - C_2 \log_{10} f) \tag{3}$$

where σ_c is the changeover stress, A the specimen surface area, V the specimen volume, and f the cyclic frequency. C_1 and C_2 are empirical constants and related to the heat capacity of the polymer and properties of the environment that the polymer is fatigued in. A similar methodology is also presented in Reference 16.

High Cycle Fatigue and Polymer Embrittlement. In the high cycle region (ie, at stress levels and frequencies low enough such that hysteretic heating is stabilized), failure of the material occurs through the nucleation of damage and subsequent propagation of cracks. In general, the total fatigue life of a specimen is a combination of an initiation (N_i) and a propagation (N_p) stage. The initiation stage is associated with the cycles required to initiate damage and develop a defect (crack) of a size such that the threshold stress intensity is reached. The propagation stage is associated with the number of cycles required to propagate the crack under subcritical conditions from the threshold size to the critical size (such that failure is imminent). Thus far, all discussions have associated with the total cycles (N) and

$$N = N_i + N_p \tag{4}$$

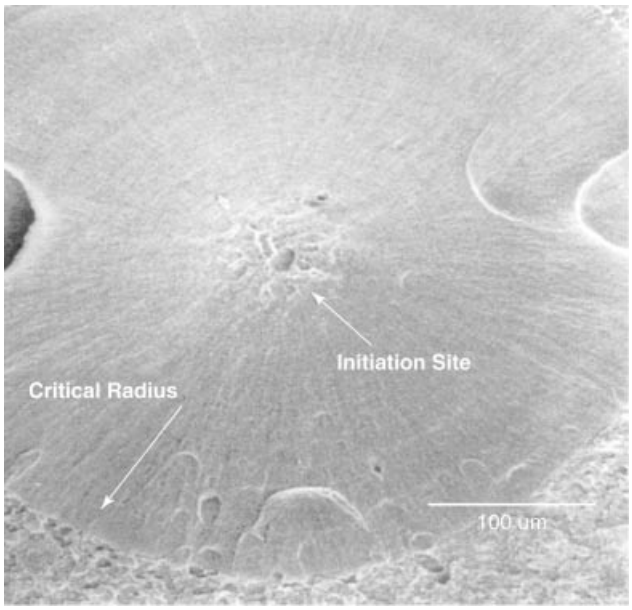

Fig. 7. Fracture surface in polyacetal resin specimen subjected to tensile fatigue. The penny-shaped crack initiated at a void or other inhomogeniety at its center (25).

If a defect is present in a component at the outset of its service life, N corresponds largely to the propagation stage of crack extension. Depending on the size and shape of the defect, N_i represents either a small or a large fraction of N. Depending on the polymer and processing conditions, damage may nucleate relatively early and the total life is dominated by the subcritical fracture resistance of the polymer. Figure 7 (12) illustrates such a case for poly(methyl methacrylate) (PMMA), where the time for craze initiation is relatively short compared to the total life of the specimen. In other cases (more typical of engineering thermoplastics with controlled processing conditions), the initiation stage governs the total fatigue life. Table 1 (13) shows a comparison between the initiation and propagation life for two engineering thermoplastics: polyacetal and nylon-6,6 exposed to a sinusoidally applied maximum cyclic stress of 30 MPa at 2 Hz. When comparing the cycles for initiation and propagation in Table 1, it is clear that the early stages of damage development involve mechanisms and kinetics not well described by processes that govern the subcritical fatigue crack growth (discussed in a later section).

Table 1. Comparison between Fatigue Initiation and Propagation Lifetimes for Polyacetal and Nylon-6,6[a]

Material	K_{th}, MPa·m$^{1/2}$	K_{Ic}, MPa·m$^{1/2}$	A	m	N_p	N_f	N_i
Nylon-6,6	2.0	6.0	5.4×10^{-9}	6.8	9000	2×10^7	$\sim 2 \times 10^7$
Polyacetal	2.5	3.1	1.3×10^{-17}	20.0	186000	5×10^6	$\sim 4.8 \times 10^6$

[a]Ref. 13.

It is generally well accepted that damage initiates at preexisting defects or other inhomogeneities within the material. This is typically illustrated in Figure 7 for a polyacetel resin specimen (25). Figure 7 shows the fracture surface from an injection molded ASTM D638 tensile bar subjected to a tensile cyclic fatigue. The initiation of the penny-shaped crack occurred at a void or other inhomogeniety and propagated subcritically under cyclic fatigue to a critical length prior to sudden failure. The specimen was subjected to approximately 5×10^6 cycles to cause failure and the number of cycles required to propagate the penny-shaped crack to the critical size is of the order of 2×10^5 cycles. Thus, the initiation of the penny-shaped crack at the defect site governed the total life of the polymer.

If the preexisting defects in the material are well below the threshold size of the polymer, the initiation process may involve a variety of morphological and microstructural changes. One phenomenon observed in some polymers involves the process of mechanically induced embrittlement. In this process, the polymer becomes slightly stiffer and less viscoelastic as evidenced by the hysteretic response of the material (13). This is illustrated for the case of polyacetal in Figure 4. Notice that the hysteresis loops in the high cycle region become slightly stiffer and the corresponding irreversible work decreases as the material is continually fatigues. This occurs while damage in the form of crazes, cavitation, and microcracks would all decrease the stiffness of the material. This suggests that additional morphological changes may occur during the fatigue of a polymer. Potential mechanisms of this process are discussed in a later section.

Classical Modeling Studies

Wöhler (10) curves are commonly used to rank polymers and identify endurance limits (see Fig. 3) for particular applications. However, they are of little use beyond this without the implementation of a theory that allows for the prediction of fatigue life under more arbitrary loading histories. Predictive methodologies that allow for lifetime estimates have been developed to address this issue. These theories are generally referred to as cumulative damage theories and may or may not incorporate aspects from fracture mechanics or physical characteristics of the materials. Some early theories developed originally for metals (26,27) recognize that total fatigue life is dominated by the initiation stage (see eq. 4) and therefore do not consider the propagation stage in lifetime estimates.

One of the earliest, and most popular, cumulative damage theory was introduced by Minor (26), and is now referred to as *Minor's Law*. Minor proposed that if a material would last a 100 cycles at a particular stress level, then 1/100 of its life is consumed in every cycle at that stress level. This basic postulate provides a framework whereby the σ–N curve (eg, Figs. 3 and 5) can be used to estimate the fatigue life of a material subjected to an arbitrary loading history. Consider that an arbitrary loading history can be fractionated into m blocks of cycles, each under constant fatigue conditions. Then, Minor's law can be written as

$$\sum_{j=1}^{m} \frac{n_j}{N_j} = 1 \tag{5}$$

In equation 5, n_j is the number of cycles within a block applied at stress level σ_j and N_j is the total number of cycles to failure at that stress level (obtained from the σ–N curve). If validated for a particular material, equation 5 can be used for any arbitrary loading condition. In this way, the fatigue data generated in the laboratory is referred to as an accelerated test and equation 5 is used much in the same way that time–temperature superposition is used to predict the viscoelastic deformation of a material. Note, however, that any predictive methodology like that presented in equation 5 must be validated before it is employed for lifetime estimates. In the case of Minor's law, the sequence of the loading history should have no effect on the total lifetime. That is, if one specimen is loaded for a selected portion of its life at stress level σ_1 and the remaining part of its life at σ_2, then the same total life would be achieved if the specimen is first loaded at stress level σ_2 followed by σ_1.

Another common theory was proposed by Manson (27) and is referred to as the *universal slopes equation*. In this model, the plastic strain or permanent deformation, is considered as a measure of the damage imposed in the material. On this basis, the true plastic strain amplitude can be used as a measure of the fatigue behavior. Moreover, the fatigue curve can be predicted in terms of the monotonic stress–strain curve. This empirical approach was initially statistically correlated with many metals and takes the following form:

$$\Delta\varepsilon = \left(\frac{N}{D}\right)^{-0.6} + 3.5\left(\frac{\sigma_u}{E}\right)N^{-0.12} \tag{6}$$

where $\Delta\varepsilon$ is the total strain, D is the ductility, E is the elastic modulus, and σ_u is the ultimate tensile strength. The ductility term D is calculated by

$$D = \ln\left(\frac{A_0}{A}\right) \tag{7}$$

In equation 7, A_0 is the original cross-sectional area and A is the final cross-sectional area at specimen failure. The coefficients 3.5, -0.6, and -0.12 in equation 6 are based on a statistical fit of over 29 metals. In that sense equation 6 universally predicts the fatigue behavior of a wide range of metals by using data obtained from a monotonic tensile test.

Opp and co-workers (14) attempted to extend the universal slopes equation to predict the behavior of polymer fatigue. However, in their attempts they showed that a form of equation 6 was not useful for predicting polymer behavior and instead developed a model to predict the low cycle fatigue behavior based on hysteretic heating. And in this sense is consistent with those presented in equation 3 and References 15–17.

Other classical methods to predict the fatigue behavior in complex or random load patterns involve the so-called rainflow and Markov methods (28). These methods utilize any form of a cumulative damage theory to predict the lifetime in random loading situations.

McKenna and Penn (29) developed a model for predicting the fatigue life of polymers and applied it to an amorphous glass, PMMA, and polyethylene. The model is characterized within the framework of a cumulative damage model. They

show that the mean failure times in constant rate of stress experiments can be successfully predicted from a model using a time to fail function obtained from constant stress experiments. In this manner they were able to bridge the gap between creep and fatigue loading conditions. In their model, the time to fail, t_b, is related to the stress history $\sigma(\xi)$ by the following equation:

$$\int_0^{t_b} \frac{d\xi}{\tau_b[(\xi)]} = 1 \tag{8}$$

where $\tau_b(\sigma)$ is the mean time to failure in constant stress experiments. Thus, each increment of time $d\xi$, during which the load is $\sigma(\xi)$, is weighted inversely as the lifetime $\tau_b(\sigma)$, which the specimen would have had under a constant stress σ.

Once $\tau_b(\sigma)$ is determined from creep (constant load experiments), equation 8 can be used to predict the failure under any stress history. The form of $\tau_b(\sigma)$ that was found to describe the data in Reference 29 is

$$\tau_b(\sigma) = Ae^{-B\sigma} \tag{9}$$

where A and B are constants. Equation 9 uses the form that is derived from molecular considerations by Tobolsky and Eyring (30), Coleman (31,32), and Zhurkov (33). Given the form for time to failure under constant stress in Equation 9, an explicit expression for a constant rate of stress can be explicitly obtained by integrating equation 8. The final expression takes the following form:

$$t_b = \frac{\ln(AB\,\dot{\sigma} + 1)}{B\,\dot{\sigma}} \tag{10}$$

In equation 10, t_b becomes the time to failure at a constant stress rate $\dot{\sigma}$. Similarly, for a sinusoidal stress history

$$\sigma(t) = p + q\sin(\omega t) \tag{11}$$

the time to failure becomes

$$t_b = \frac{\hat{t}_b(p)}{I_0(Bq)} \tag{12}$$

In equation 12, I_0 is the zero-order Bessel function, B is the constant from equation 9, and $\hat{t}_b(p)$ is the time to fail at a constant stress p.

Using equation 12, data from creep tests can be used to predict the failure in sample subjected to a sinusoidal load history. Figure 8 presents a comparison between experimental results and theoretical predictions (29) for PMMA by using equation 12. In this case the prediction underestimates the lifetime in some cases by nearly an order of magnitude but is generally very good. In the case of polyethylene (not shown) the model overestimates the experimentally observed fatigue life. Another practical limitation to the methodology presented in equations 8, 9, 10, 11, 12 is that creep failure data is needed to predict the fatigue

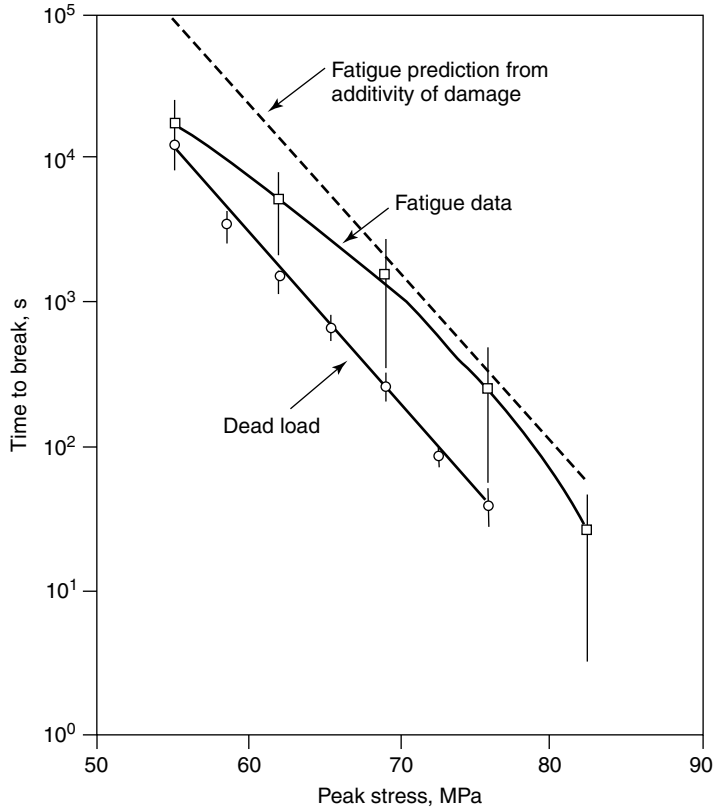

Fig. 8. Comparison of failure times obtained in zero-tension sinusoidal fatigue experiments with those predicted by equation 9 for PMMA at 0.164 Hz, $T = 297$ K (29). To convert MPa to psi, multiply by 145.

lifetime. Experimentally, creep experiments take considerably longer to conduct than fatigue experiments to failure.

Other approaches have been suggested to more formally define the form of damage that occurs during fatigue (34–37). These methods model damage as an array of microcracks (34,35) that inevitably require a tensoral definition of damage (36,37). These methodologies allow for multiaxial stress states to be considered. Thus far, these theories have had only limited applications in polymeric materials. One difficulty that arises from such a framework is the necessity to sum over an array of damage using Green's functions and hence linearity in the constitutive behavior of the material is required. Nonetheless, these approaches may be useful in applications where the nonlinearity imposed from the damage array dominates the material response.

Fatigue Damage Initiation

Physical and Morphological Changes. Some studies have discussed the microstructural and morphological changes that occur in polymers as a consequence of fatigue loads. These effects may occur before the formation of noticeable

damage in the form of voids or microcracks occur. These changes may be critical to understanding the nucleation of damage as well as its growth kinetics. Bouda (38) found that the effects of fatigue on glassy polymers can manifest either as a strain hardening or softening, depending, among other things, on the particular material being investigated. Changes in the dynamic viscoelastic behavior were also reported as well. Similarly, Takahara and co-workers in numerous investigations (39–41) measured changes in the viscoelastic response of a variety of different polymer systems. Both changes in the storage and loss moduli were observed during fatigue. More recently, Sakurai and co-workers (42) conducted a comprehensive investigation of changes induced in polyurethanes subjected to fatigue. They presented dramatic evidence of microstructural changes occurring after a fatigue load was applied. These changes were attributed to changes in crystallinity in addition to dissociation of the hard-segment microdomains.

A recent paper (13) presents results from *in situ* measurements of both the dynamic viscoelastic properties and energetics (ie, potential energy, strain energy, and irreversible work) of nylon-6,6 and polyacetal specimens subjected to fatigue. The measurements of dynamic viscoelastic behavior illustrate how the bulk material properties may be changing during fatigue. Measurements of the strain energy, potential energy, and irreversible work also indicate material changes but can also be more directly used in calculating energy release rates for crack growth. Thus, the evolution of energy release rates may also be an indicator of when crack (damage) growth occurs in the specimen. A plot of the dynamic viscoelastic behavior is shown in Figure 9 and the corresponding evolution of the energetics is given in Figure 10.

The transition from the low cycle to high cycle fatigue occurs between 48 and 50 MPa at a frequency of 2 Hz for polyacetal and this transition is clearly evident in both graphs. In the low cycle regime, the materials become softer and more viscoelastic as evidenced by the dramatic drop in storage modulus and corresponding increase in tan δ. Also, both the potential energy and irreversible work increase considerably in the low cycle regime. All of these results are consistent with the softening of the material due to hysteretic heating.

In the high cycle regime, the polyacetal becomes more compliant (see Figs. 9 and 10) as well, but the amount is more subtle than in the low cycle regime. More interesting, the material also becomes less viscoelastic as evidenced by the drop in tan δ and irreversible work. This is in contrast to low cycle regime and suggests that other morphological changes are occurring in addition to damage. Subsequent studies (13) also showed that the crystallinity increased slightly in both nylon-6,6 and polyacetal.

A similar study on polycarbonate showed that cyclic stress induced physical aging on polycarbonate (43). In this work it was noted that both the Young's moduli increases while the loss modulus decreases. This related phenomenon is referred to as fatigue aging. In contrast, thermophysical aging is the process of the spontaneous approach of the glassy state toward thermodynamic equilibrium. This phenomenon has been reviewed extensively by Struik (44) (see AGING PHYSICAL). This spontaneous change is accelerated perceptibly when the temperature of the glass is increased toward the glass transition. Physical aging causes an increase in density, relaxation modulus, and other properties. Physical aging alters the relative kinetics of crazing and shear banding processes, so that a normally tough

polymer becomes very brittle upon aging (45,46) apparently because the shear yielding process becomes retarded.

A common method employed to detect physical aging in glassy polymers involves the use of differential scanning calorimetry. Careful studies of the thermograms show an enthalpic overshoot as the polymer is heated through the glass-transition region. This overshoot occurs both with thermophysical aging and fatigue aging but the peak temperature of the endotherm is slightly increased for the fatigue aged samples (43). Figure 11 shows how the endothermic overshoots are affected by the stress amplitude for polycarbonate samples exposed to different

thermal histories before loading. In all cases, the fatigue tests were stopped after 8000 cycles. For samples exposed to low or moderate annealing prior to fatiguing, an increase in the enthalpic overshoot appeared and was relatively insensitive to the amplitude of stress. For the highly annealed material, the fatigue actually reduced the endothermic overshoot (ie, reversed the physical aging). Similarly Figure 12 shows how the enthalpic overshoot evolves during the early stages of fatigue.

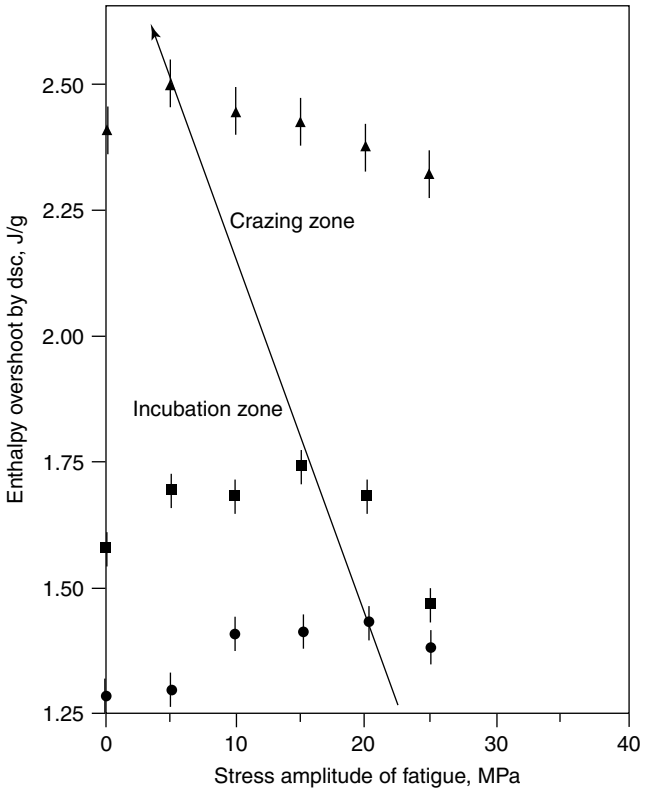

Fig. 11. Differential Scanning Calorimetry enthalpy overshoot of samples of different previous physical aging histories plotted as a function of cyclic stress amplitude for a fixed 8000 cycles (43). ▲ aged at 130°C for 24 h; ■ aged at 130°C for 12 h; ● aged at 130°C for 6 h. To convert MPa to psi, multiply by 145.

Early Stages of Damage Formation. A variety of studies have indicated that void formation, cavitation, or incipient nano-sized cracks occur in the polymer during the early stages of fatigue. The nucleated voids then continue to grow and coalesce while the fatigue process continues. The subcritical crack growth kinetics has been measured over a wide range of polymers (discussed in the next section). Once the flaws reach a threshold flaw size (of the order of 10^{-3} m for many polymers), the subcritical crack growth kinetics are generally well described for many polymers. However, the sizes of these flaws that nucleate and grow during a large portion of the fatigue life are quite often below the threshold flaw size for subcritical crack growth kinetics to govern. This section discusses research devoted to damage at this length scale.

Studies by Zhurkov (33,47) introduced the idea that breakage of primary chemical bonds plays a major role in the fracture of polymers. He found that the time to failure under a resistant uniaxial stress of PMMA and polystyrene below their glass-transition temperature could be expressed in terms of a thermally activated process involving three kinetic parameters:

$$t_b = t_0 e(U_0 - \gamma\sigma_0)/RT \tag{13}$$

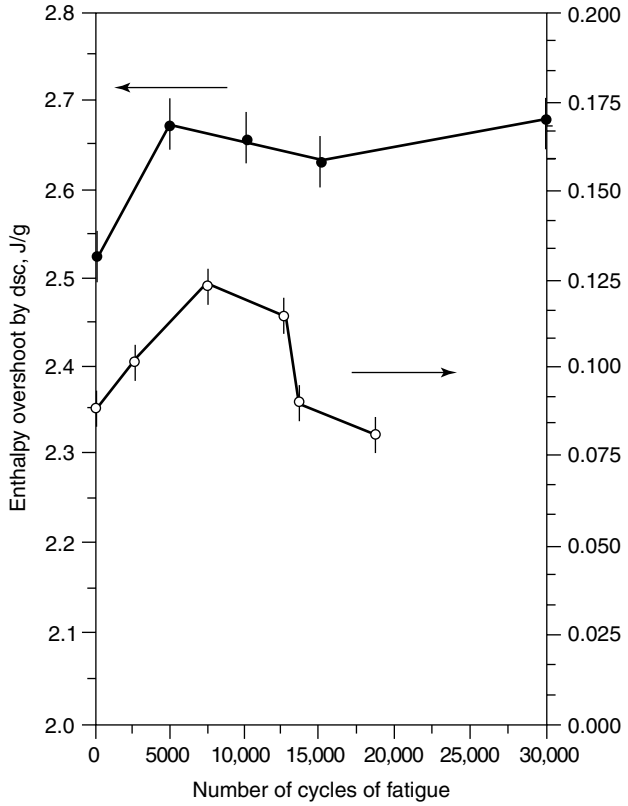

Fig. 12. Differential Scanning Calorimetry enthalpy overshoot as a function of cycle number at a given stress amplitude. Note the different scales in the data (43). ● aged at 130°C for 40 h and fatigued at 20 MPa; ○ quenched from 165°C and fatigued at 31 MPa. To convert MPa to psi, multiply by 145.

In equation 13, t_b is the time to failure, U_0 is interpreted as the activation energy for chain scission, t_0 is interpreted as the inverse of the molecular oscillation frequency, and γ is a structure-sensitive parameter. Experimentally he (47) observed the formation of platelet-shaped nanoscopic voids, which he referred to as incipient cracks, that form very early in the polymer once a tensile load is applied. Both the incipient cracks and their number density were measured from small-angle x-ray scattering studies on samples that had tensile loads applied to them. The characteristic sizes and number densities of the incipient cracks are included in Table 2. Zhurkov showed that the incipient cracks formed at the very early stages and the remaining life was associated with the coalescence of these incipient cracks to ultimately cause failure.

LeGrand and co-workers (48) conducted positional small-angle x-ray scattering studies on high impact polystyrene exposed to fatigue loading conditions. Their results clearly indicated that flaws of some type are nucleated and grow as a result of increasing fatigue. They also suggested that the nucleation and growth of flaws appears to follow a simple exponential law. However, the results regarding

how material properties or loading conditions affect the growth rates were clearly inconclusive in this study.

Positron annihilation lifetime spectroscopy studies (49) polycarbonate samples subjected to fatigue. Positron annihilation lifetime spectroscopy was used to probe structural changes in terms of the hole volume and number density of fatigued samples. The *ortho*-positronium (o-Ps) pickoff annihilation lifetime τ_3, as well as intensity I_3, were measured as a function of cyclic stress. It was found that τ_3, the longest of the three lifetime components, increases with fatigue cycles. The *holes* where the o-Ps can localize become larger upon fatigue aging. Commensurate with increasing hole size was an indication of hole coalescence from the o-Ps annihilation intensity. It was suggested that this process was the precursor to crazing. Complimentary transmission electron microscopy indicated that isolated voids of the order of 100 nm could be seen (50).

Tensile dilatometry (51–54), which is commonly used to monitor cavitation in rubber-modified glassy polymers, was extended to fatigue application to monitor the volume changes that occur during fatigue loading conditions (55). In this method, axial and transverse strain gages are attached to the sample during a uniaxial fatigue test. From the axial and transverse strain measurements the total volume change $(\frac{\Delta V}{V})_T$ can be calculated from

$$\left(\frac{\Delta V}{V}\right)_T = (1+\varepsilon_a)(1+\varepsilon_t)^2 - 1 \tag{14}$$

where ε_a is the axial strain and ε_t is the transverse strain. The volume change can then be further decomposed into an elastic part and an irreversible part denoted by the subscripts e and i respectively in equation 15 below:

$$\left(\frac{\Delta V}{V}\right)_T = \left(\frac{\Delta V}{V}\right)_e + \left(\frac{\Delta V}{V}\right)_i \tag{15}$$

The total volume change can be measured at the peak load during the fatigue test and the irreversible part can be measured at the unloaded portion of the cycle. In this way the evolution of both the elastic and inelastic volume change can be monitored during a fatigue test. Figure 13 shows how the irreversible

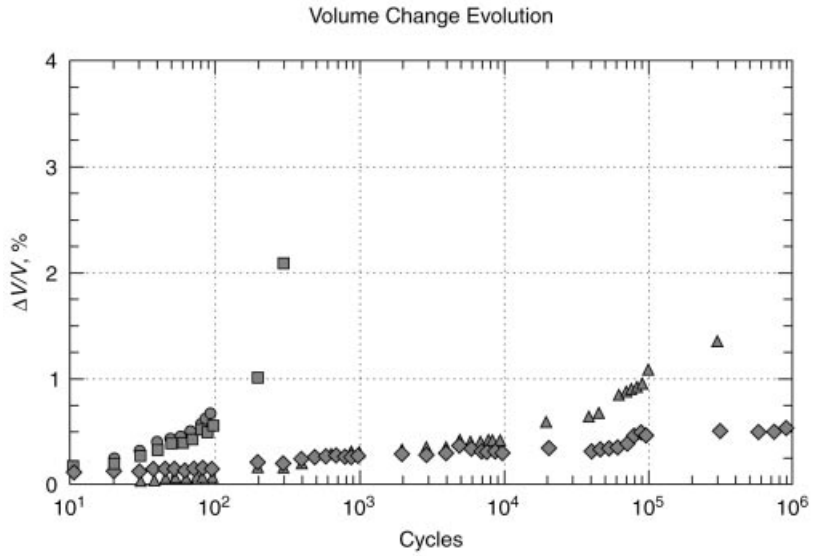

Fig. 13. Irreversible volume change evolution for polyacetal samples fatigued over a range of stress levels (55). ● $\sigma = 56$ MPa, $N_f = 10^2$ cycles; ■ $\sigma = 54$ MPa, $N_f = 3 \times 10^2$ cycles; ▲ $\sigma = 48$ MPa, $N_f = 3 \times 10^5$ cycles; ◆ $\sigma = 45$ MPa, $N_f = 10^6$ cycles. volume change evolves as a polyacetal specimen is fatigued over a range of stress levels. The results show that the irreversible volume increased as the sample was fatigued over a broad range of stress levels. Further, the Poisson's ratio (see Fig. 14) increases in the low cycle regime but decreases in the high cycle regime. The decrease in Poisson's ratio is characteristic of an increase in porosity in the material.

Recent studies on PMMA have shown that craze initiation appears at a relatively early stage in the fatigue life of the material (12). The total fatigue life is compared to the onset of craze initiation in Figure 15. In this particular case the lifetime is governed primarily by the growth of crazes until a defect (crack) approaches the threshold size.

More direct morphological studies were conducted on isotactic polypropylene (iPP) to isolate the mechanisms of fatigue damage and their kinetics (56). The damage imposed to samples fatigued in the high cycle regime occurs in the form of crazes. These are shown typically in Figure 16 for the case of iPP subjected to 6×10^6 cycles.

Figure 17 shows a sequence of optical micrographs illustrating the evolution of damage. During fatigue, small crazes initiate and grow homogenously through the material. However, as the fatigue test continues, small crazes coalesce and the arrangement of crazes becomes neither even nor randomly distributed. This becomes especially evident in the samples with a high level of fatigue damage. Clear patterns arise in the form of cascades of crazes (see high magnification in Fig. 17) that are clear evidence of craze–craze interactions where the stress intensity at one craze tip is shielded by the formation of another craze. Also, careful

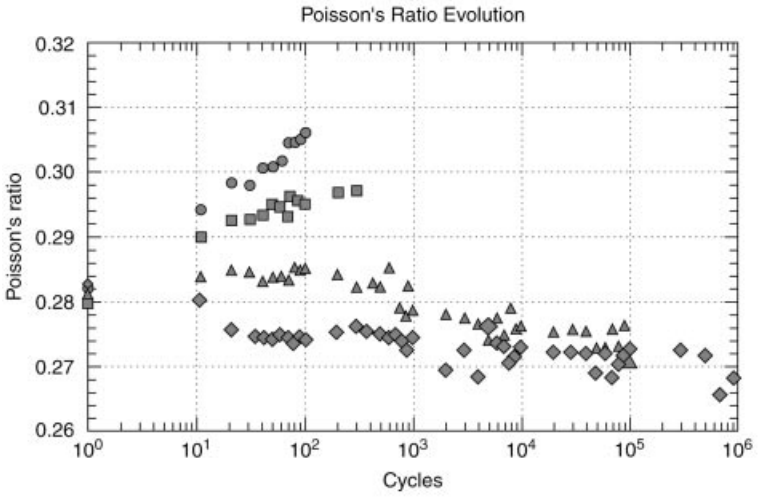

Fig. 14. Poisson's ratio evolution for polyacetal samples fatigued over a range of stress levels (55). ● $\sigma = 56$ MPa, $N_f = 10^2$ cycles; ■ $\sigma = 54$ MPa, $N_f = 3 \times 10^2$ cycles; ▲ $\sigma = 48$ MPa, $N_f = 3 \times 10^5$ cycles; ◆ $\sigma = 45$ MPa, $N_f = 10^6$ cycles. inspection of mature crazes indicates that as the crazes mature, much smaller crazes initiate and grow around each main craze in the form of a process zone, much like that which has been observed in crack propagation in polymers. Ultimately the sample becomes saturated with crazes that resemble a planar array of damage that is evidently completely dominated by the craze–craze interactions.

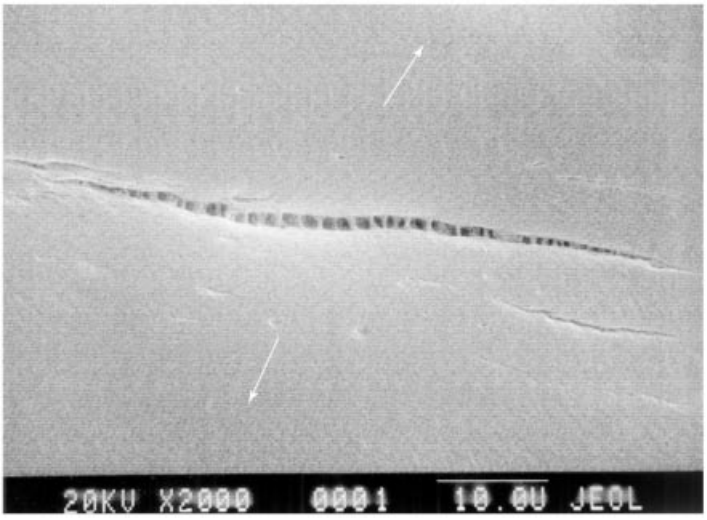

Fig. 16. Scanning electron micrograph of fatigue-damaged iPP. The arrows denote the direction of applied load (56).

Eventually, of the crazes approaches the threshold size and subcritical crack propagation ensues until failure.

The fatigue damage described in Figure 16 has also been quantitatively described and the energetics of craze growth has been evaluated (56). This analysis involved first approximating the stress intensity of a single craze by treating the craze as a microcrack of equivalent size with the craze fibrils replaced by a closure stress (traction) across the microcrack face. If a single craze is considered in an infinite plate, the stress intensity factor K_{tot} for the craze can be written as (56)

$$K_{\mathrm{tot}} = K_{\sigma_\infty} + K_{\sigma_c} = (\sigma_\infty - \sigma_c)\sqrt{\pi \ell} \tag{16}$$

where σ_∞ is the remotely applied stress, σ_c is the closure traction produced by the craze fibrils, and ℓ is the craze radius. By substituting an expression for the effective stress across the craze face as $\sigma = \sigma_\infty - \sigma_c$, the stress intensity due to a single craze takes the same form as that of a single crack. Hence, the potential energy change of a body containing a single craze would be given by

$$\frac{\Delta\Pi}{b} = 2\int_0^\ell G\,\mathrm{d}\ell = \frac{2}{E_0}\int_0^\ell K_{\mathrm{tot}}^2\,\mathrm{d}\ell = \frac{\pi\sigma^2\ell^2}{E_0} \tag{17}$$

In equation 17, $\Delta\Pi$ denotes the potential energy change in the specimen, b is the specimen thickness, G is the energy release rate, and E_0 is the storage modulus of the undamaged iPP.

In accordance with a Griffith-type criterion for the growth of a craze ($G - 2\gamma = 0$ for the necessary condition for craze growth), the following expression for the specific energy γ to form a craze is given by

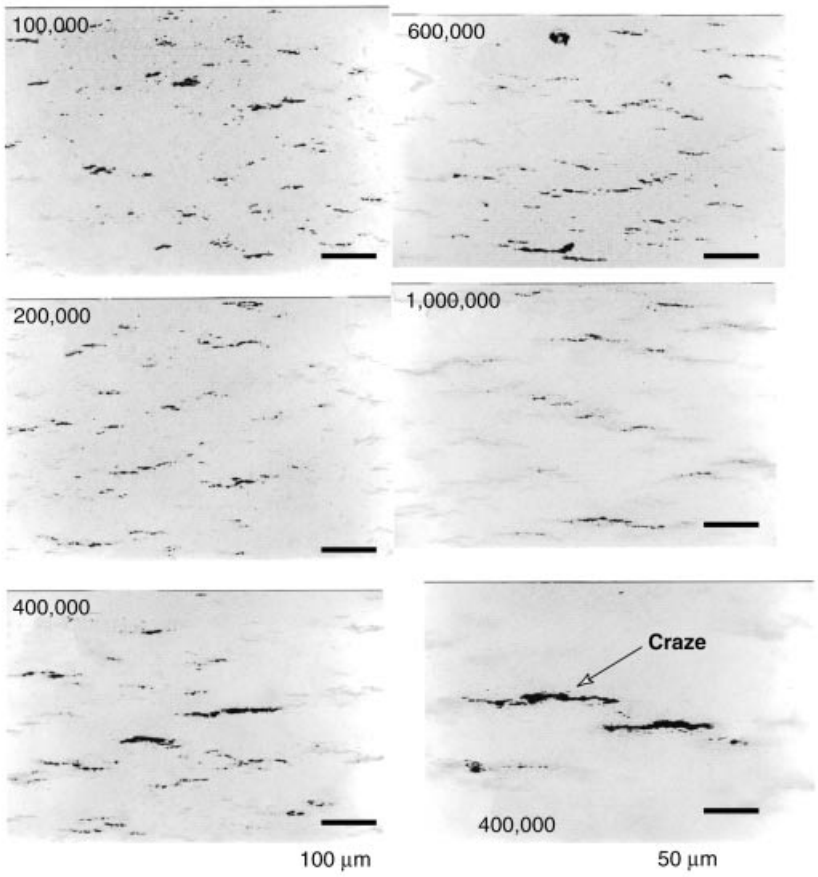

Fig. 17. Optical micrographs of fatigue damage in iPP tensile base, showing the progression of damage with increasing cycle number (56).

$$G = 2\gamma$$
$$\frac{K_{\text{tot}}^2}{E_0} = \frac{\sigma^2 \pi \ell}{E_0} = 2\gamma \tag{18}$$

Rearranging terms in equations 18 yields the following relationship:

$$\frac{\sigma^2}{E_0} = \frac{2\gamma}{\ell} \tag{19}$$

Thus far, the relationships apply to an isolated craze embedded in a specimen. To evaluate the energy release associated with an ensemble of crazes, the interaction of the crazes must be considered. In Reference 56, a damage parameter, similar in fashion to that introduced by Bristow (57), for a two-dimensional case was considered:

$$\rho = \frac{1}{A}\sum_{i=1}^{n} \ell_i^2 \approx n\ell^2 \tag{20}$$

In equation 20, A is some representative area and n becomes the number density of crazes of radius ℓ. The representative area A is related to the representative volume V by $V = bA$. Figure 18a describes how the number density of crazes and mean craze radii (from Fig. 17) change with fatigue life, while Figure 18b shows how the damage density ρ, as defined by equation 20, evolves. Note from the graphs in Figure 18 that the number density of crazes decreases with increasing

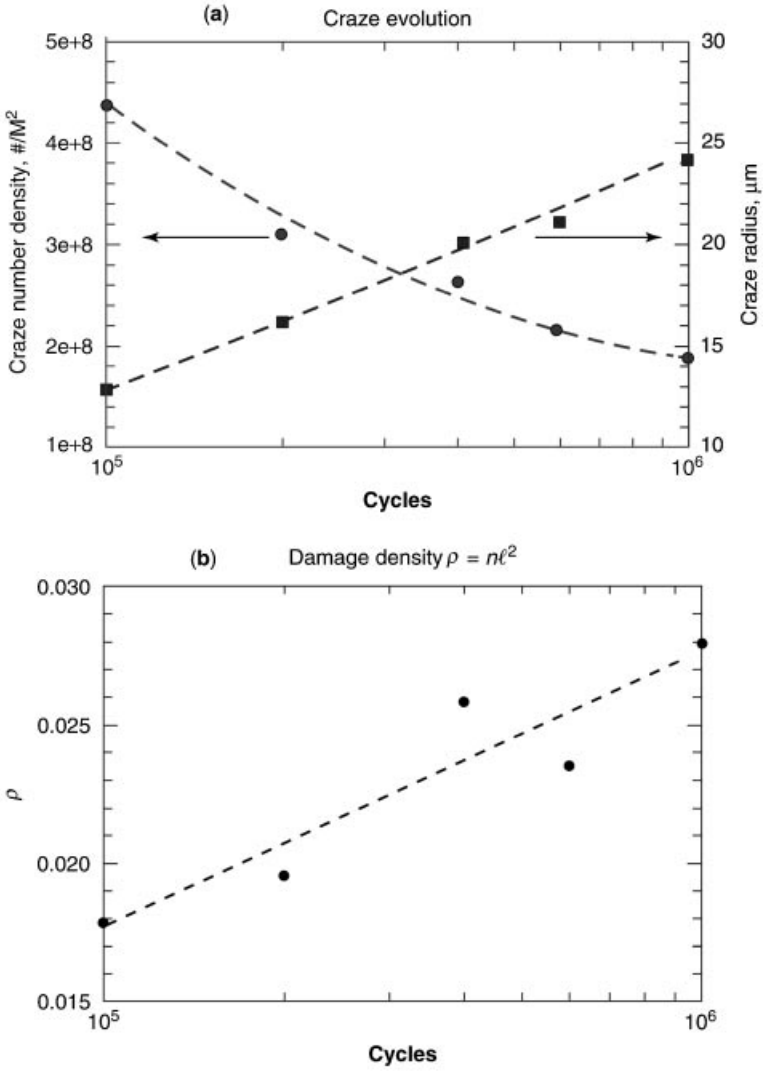

Fig. 18. Graphs describing the evolution of damage between 10^5 and 10^6 cycles. (**a**) Craze number density (circles and short dashes) and average craze radius (squares and long dashes) vs cycle number. (**b**) Damage density (eq. 20) vs number of cycles (56).

cycle number while the craze length continually increases. This indicates that coalescence is a dominating process during the stage of the fatigue process. Also, the damage density ρ continually increases as the fatigue process continues.

For a dilute suspension of cracks (crazes), Bristow (57) showed that the effective modulus E is linearly affected by the damage density in accordance with the following relationship:

$$\frac{E}{E_0} = 1 - \pi\rho = 1 - n\pi\ell^2 \tag{21}$$

In 1993, Kachanov (58) showed that the following nonlinear approximation (eq. 22) actually remains highly accurate at high crack (craze) densities, provided the crazes are homogeneously distributed.

$$\frac{E}{E_0} = \frac{1}{1+\pi\rho} = \frac{1}{1+n\pi\ell^2} \tag{22}$$

Kachanov showed that equation 22 holds at high crack (craze) densities since the competing interactions of shielding and amplification result in the following expression. In Reference 56, an expression for the change in the potential energy density (potential energy change per representative volume) associated with craze growth can be derived by combining equations 16, 17, 18, 19, 20, 21, 22:

$$\begin{aligned} \frac{\Delta\Pi}{V} &= n\left(2\int_0^{\ell} G\,\mathrm{d}\ell\right) = n\left(2\int_0^{\ell} \frac{K_{\mathrm{tot}}^2}{E}\,\mathrm{d}\ell\right) \\ \frac{\Delta\Pi}{V} &= \frac{\sigma^2\pi}{E_0}\left(n\ell^2 + \frac{1}{2}\pi n^2\ell^4\right) \\ \frac{\Delta\Pi}{V} &= \gamma(2n\ell + \pi n^2\ell^3) \end{aligned} \tag{23}$$

The latter expression in equations 23 describes the specific energy for craze growth in terms of changes in the potential energy density during the fatigue test. Using equations 23 along with measured information regarding the number density of crazes and craze radii (Fig. 17), the specific energy for craze growth, γ, was evaluated for iPP. The results indicated that the energy required to grow a craze is of the order of 13 J/m^2 and was generally constant over the decade of cycles measured.

Fatigue Crack Propagation

Background and Overall Considerations. Many aspects of FCP including both experimental approach and theory evolve from concepts well established in the area of fracture mechanics. Many treatments dealing with both the theory (59–63) as well as associated treatments to polymeric materials (2,5,64,65) have been published. The basic tenent of fracture mechanics is that the strength of most real solids is governed by the presence of flaws. Many theories have been

developed mathematically to describe the stresses in the presence of a crack as well as the energy released during crack propagation. Griffith (59) introduced a criterion based on an energy principle and argued that when the change in the elastic potential of a brittle glass equals or exceeds the energy required to create new crack surface area, the crack will propagate uncontrollably. It has been shown (60–63) that the Griffith criterion can be related to the elastic energy release rate and stress intensity factor for an elastic body. Thus, two parallel criteria arose to describe the critical conditions for the failure of a body containing a crack (defect). These criteria are written as follows:

$$\begin{aligned} G_{\mathrm{I}} &\geq G_{\mathrm{Ic}} \\ K_{\mathrm{I}} &\geq K_{\mathrm{Ic}} \end{aligned} \tag{24}$$

In equations 24, whenever the energy release rate G_{I} becomes greater than or equal to the critical energy release rate G_{Ic}, the fracture (failure) occurs. Similarly, when the stress intensity factor K_{I} exceeds the fracture toughness K_{Ic}, the fracture occurs. It should be noted that the subscript I in equations 24 refer to mode I failure (opening mode), and similar criteria can be written for modes II (shearing mode) and III (tearing mode). The criteria in equations 24 are conceptually different but are mathematically identical for a linear elastic body since the energy release rate and stress intensity factor are related by

$$G_{\mathrm{I}} = \frac{K_{\mathrm{I}}^2}{E'} \tag{25}$$

where $E' = E$ under plane stress conditions and $E' = E/(1 - \nu^2)$ under plane strain conditions. Both the energy release rate and stress intensity factor are a function of the specimen global geometry, applied stress level, and crack length. Consequently, the stress intensity (and/or energy release rate) will increase even if the stress level remains constant when the crack length increases. Thus, specimens with larger flaws have a lower nominal strength than specimens in which the flaw sizes are smaller. This type of approach is commonplace in many engineering applications today and has proven successful to describe the fracture behavior of a wide range of materials.

For a given stress level, if the flaw (crack) size is large enough such that the critical condition(s) expressed in equation(s) 24 is reached, then immediate failure is expected. If however, the stress level or flaw size is reduced, then immediate failure is postponed but subcritical crack growth may occur. Subcritical crack growth refers to the slow progressive growth of a crack prior to reaching a critical condition. One of the most common processes to accelerate this process is to apply a fatigue load to the body. Consequently, the associated study of subcritical crack growth under fatigue load is referred to as fatigue crack propagation (FCP). Many studies and texts have been devoted to measuring FCP kinetics of polymers and an excellent summary is provided in Reference 2.

One of the earliest attempts to describe the fatigue behavior of materials in general is referred to as the Paris Law (66–68). The Paris Law is an empirical relationship that exists between the crack growth rate $\mathrm{d}\ell/\mathrm{d}N$ and the change

in stress intensity factor by

$$\frac{d\ell}{dN} = A(\Delta K_I)^m \tag{26}$$

In equation 26, $\Delta K_I = K_{Imax} - K_{Imin}$, and K_{Imax} relates to the stress intensity factor associated with the maximum stress level in a given cycle and K_{Imin} is the corresponding stress intensity factor associated with the minimum stress in a given cycle. The coefficients A and m in equation 26 are considered material constants. Paris Law (eq. 26) and variations therein have been widely used to describe the crack growth kinetics of a broad range of materials (eg, Ref. 1). However, the application of equation 26 has shown to be applicable only over a certain range of stress intensities (which relates to a certain range of crack sizes).

Many studies have verified the log–log linear relationship between $d\ell/dN$ and ΔK, as predicted by equation 26, but others have shown sigmoidally shaped FCP plots. Crack growth rates almost always decrease to vanishingly low values as ΔK approaches a limiting threshold value ΔK_{th} and increase markedly at very high ΔK when K_{Imax} approaches K_{Ic}. The asymptote at low ΔK conditions describes FCP rates that diminish rapidly. As such, a limiting stress intensity factor range ΔK_{th} is defined and represents a service operating limit below which fatigue damage does not obey the Paris Law.

Figure 19 illustrates a typical sigmoidal-shaped crack growth behavior as illustrated by regions I, II, and III. In region I, a crack is below the threshold size and thus does not follow the growth kinetics as described by equation 26. Thus, region I is many times referred to as the nucleation stage. In region II, equation 26 applies. Region II is associated with subcritical crack growth and equation 26

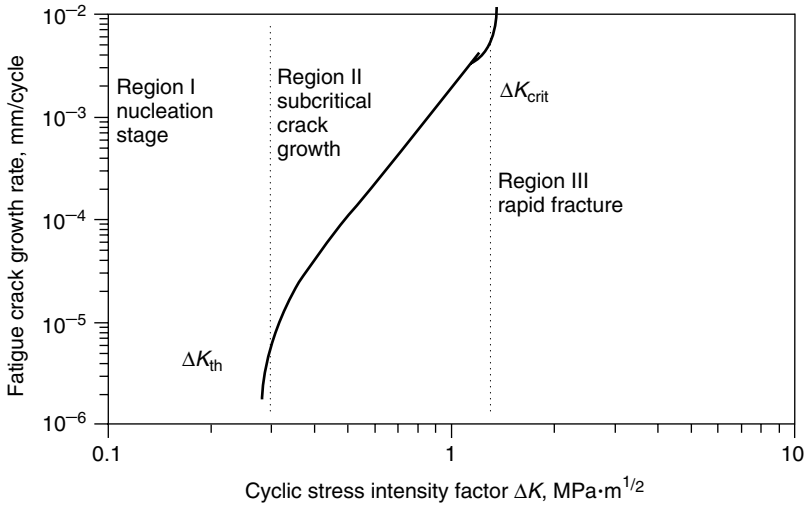

Fig. 19. Illustration of typical sigmoidal curve in $d\ell/dN$ vs ΔK plot of FCP data. Three regions are identified: region I associated with damage nucleation; region II associated with subcritical crack growth; and region III associated with unstable, rapid failure.

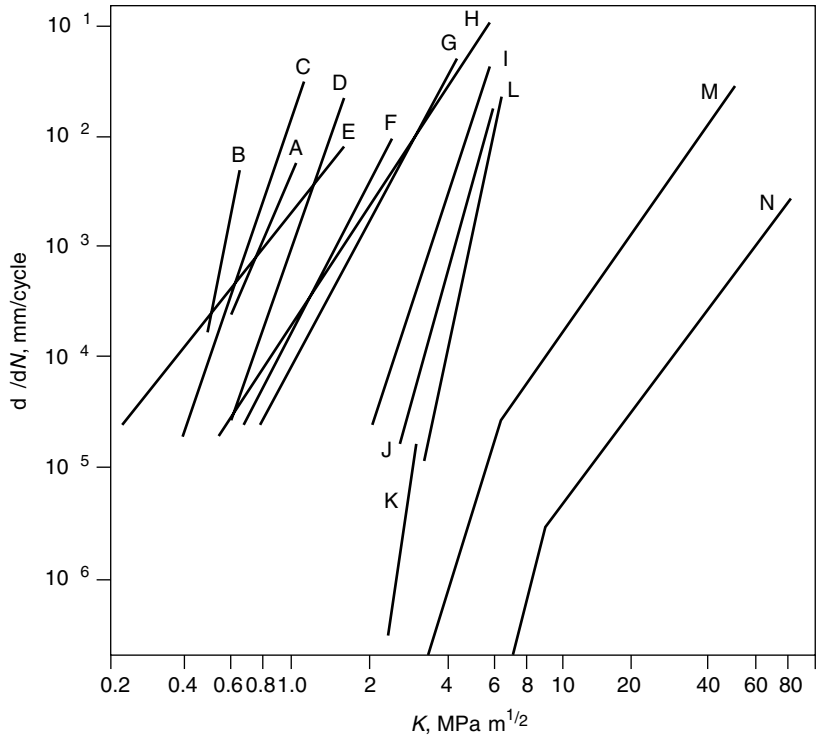

Fig. 20. FCP rates vs ΔK for several engineering plastics and metal alloys (39). A, LDPE; B, epoxy; C, PMMA; D, polysulfone; E, polystyrene; F, PVC; G, poly(phenylene oxide); H, polycarbonate; I, nylon-6,6; J, HI-nylon-6,6; K, poly(vinylidene fluoride); L, acetal resins; M, 2219-T851 aluminum alloy; N, 300M steel alloy.

can be integrated to predict remaining life of a body containing a crack in this region. Region III is associated with unstable, rapid fracture once the flaw has grown to a critical size.

Characteristic plots of the FCP data are shown in Figure 20 for several engineering plastics and metal alloys (69). The samples A–L are polymeric materials (both amorphous and semicrystalline) while M and N are metal alloys. Figure 20 demonstrates the universality of equation 26 to describe the subcritical crack growth kinetics of a wide range of materials. The data also generally suggest values for the threshold flaw size and critical stress intensity factor for each material. Notice that some semicrystalline materials show resistance to crack growth approaching that of metals.

Several studies have determined the threshold stress intensity for engineering plastics, eg, polycarbonate (5). The $d\ell/dN$ values are in excellent agreement for growth rates $> 10^{-5}$ mm/cycle but differ significantly for lower values. Additional threshold data have been reported for PMMA as a function of stress ratio R, where $R = K_{min}/K_{max}$ (70). Other studies have been conducted to characterize the near threshold crack propagation behavior (12,71). Figure 21 (12) shows a σ–N curve for polyethersulfone, including data at the near threshold level. Similarly

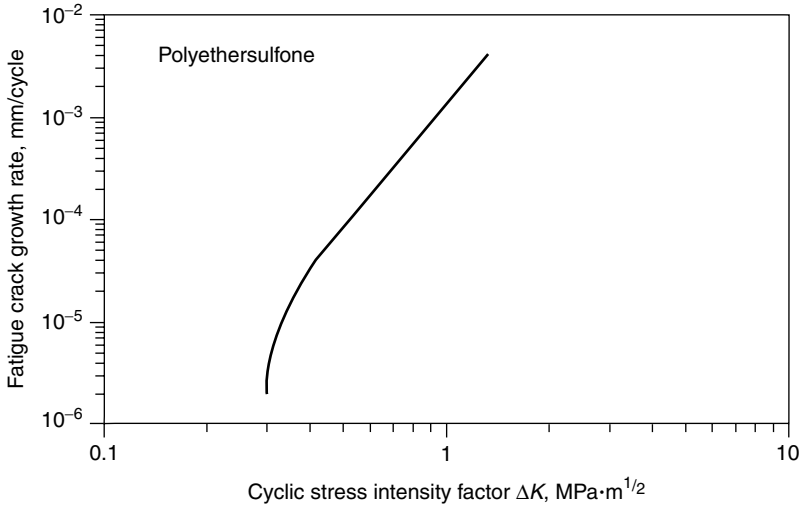

Fig. 21. Fatigue crack growth data for polyethersulfone, including data in the near threshold regime (12).

Table 3 (71) defines the threshold stress intensity and the range over which the Paris equation is valid for ultrahigh molecular weight polyethylene (UHMWPE) subjected to different processing conditions. From Table 3, it is clear that subtle processing conditions can alter the threshold level and the onset of FCP.

Unusual crack growth behavior has been reported in some semicrystalline polymers with FCP rates decreasing with increasing ΔK at intermediate levels (72–76). This transient response has been related in low density polyethylene (LDPE) to a change in the scale of the fracture micromechanism (72), whereas others attribute this kinetic transient to localized crack-tip heating, reasoning that such heating would reduce the yield strength and result in a large increase in the depth of the crack-tip damage layer (74). Chudnovsky and Moet (75,76) developed another theory to accommodate for this behavior changes. This theory, referred to as the *crack layer theory*, is formulated within the framework of thermodynamics of irreversible processes. The crack layer theory treats the crack and surrounding damage as a single entity. The rate of crack propagation becomes a thermodynamic

Table 3. Fatigue Threshold Stress Intensity Factor and Paris Regime or UHMWPE Subjected to Different Processing Conditions[a]

[a]Ref. 71.

flux within the theory, with complimentary thermodynamic forces being described through the energy release rate. This theory is capable of predicting the *stick-slip* character observed in some growth rates.

In the crack layer theory (75,76) the movement of the crack and surrounding damage is decomposed into elementary movements: translation, rotation, isotropic expansion, and distortion. In this way, the damage surrounding the tip can evolve in a general sense. These elementary movements become thermodynamic fluxes. The reciprocal forces contain an active part (energy release rates associated with each movement) A_i, and a resistive part (an energy barrier) R_i. Within the context of classical irreversible thermodynamics, the entropy of the system, S_i, can be expressed in terms of a bilinear form of forces and fluxes shown in equation 27.

$$T\dot{S} = \sum_{i=1}^{n} (A_i - \gamma R_i)\, \dot{\nu}_i \tag{27}$$

In equation 27, $(A_i - \gamma R_i)$ represent the thermodynamic forces for each elementary movement and ν_i are the corresponding reciprocal fluxes. The active parts correspond to the energy release associated with each movement. The resistive parts constitute the materials resistance to these movements and contain the *intrinsic material property*, γ, the specific enthalpy of damage (eg, crazing). The ability of this formalism to account for size and shape changes in the process zone during crack propagation produces changes in the translational crack propagation rate. Thus, non-Paris FCP can be modeled using this approach.

Effect of Test and Process Conditions. Many studies have evaluated the effects of test frequency on the FCP rates in polymers. Although hysteretic heating explains a decrease in fatigue resistance with increasing cyclic frequency in unnotched polymer test samples (eg, eq. 3, Fig. 6, Ref. 24), the fatigue resistance of notched polymers is exceedingly complex. FCP rates can decrease, remain unchanged, or increase with increasing test frequency (77–79). Figure 22 illustrates the effect that cyclic frequency has on the FCP rate of poly(vinyl chloride) (PVC). In the case of PVC, the crack speed decreases with increasing frequency, but the threshold stress intensity K_{th} and the fracture toughness K_{Ic} remain unchanged. Also notice from the similarity of slopes in the FCP data in Figure 22 that the material coefficient m as defined in the Paris equation (Eq. 26) is insensitive to test frequency. Similar studies (78,79) on polycarbonate showed that cyclic frequency had virtually no effect on its FCP kinetics. In contrast, the FCP kinetics in nylon-6,6 over a range of frequencies shows that higher crack speeds occur at higher frequencies. Consequently, no universal behavior is evident.

As expected, test temperature will have a dramatic effect on the FCP kinetics of polymers owing considerably to their temperature-dependent viscoelastic nature. Indeed, studies of polystyrene and acrylonitrile–butadiene–styrene (ABS) have shown that FCP rates for given ΔK level generally decrease with decreasing test temperature (80). By contrast, a minimum FCP resistance was noted in polycarbonate and polysulfone at intermediate test temperatures (81,82). A complex test-temperature response was also noted in studies on the influence

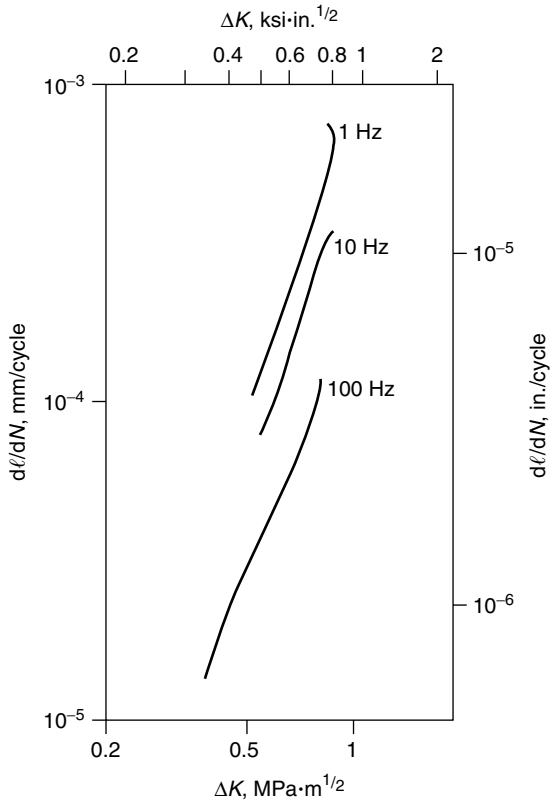

Fig. 22. Effect of cyclic frequency on the FCP rate in PVC (77–79).

of test temperature and absorbed water on FCP in nylon-6,6 (83). Of particular interest was the possibility to normalize the data (83) through empirical use of time–temperature superposition principles.

The effect of thermal history and process conditions can affect both the unnotched fatigue behavior (43) through physical aging (44) or through changes in the crystal morphology. Similarly the FCP behavior of semicrystalline polymers can also be affected through differences in thermal history (84–88). Some studies suggest that resistance to crack propagation increases with decreasing spherulite size (84,85), while others claim spherulite size has no effect (86,87). A recent report (88) showed that annealed specimens to have a lower resistance to crack initiation and subsequent propagation. Although the same fracture mechanism, in which the brittle crack gradually becomes more ductile, prevailed in both cases, the annealed material proved to be weaker. This was attributed to differences in the failure mechanisms at the root of the crack. The annealed sample showed a voided and fibrillated crack tip while the quenched sample showed a nonfibrillated structure.

Effect of Molecular Architecture, Morphology, and Microstructure. Striking effects of molecular weight on FCP rates in notched PMMA (89) and PVC (90) have been noted (91,92), and similar strong effects have been reported for

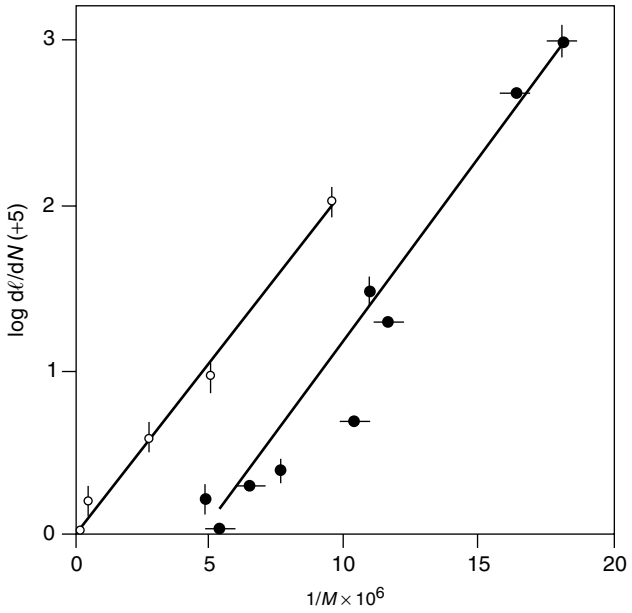

Fig. 23. Functional relationship between FCP rates in PMMA and PVC and reciprocal of molecular weight at 10 Hz for $\Delta K = 0.6$ MPa·m$^{1/2}$ (89). Data for PVC displaced to the right by a factor of 2.

polycarbonate (93) and polystyrene (94). In general, the Paris law is followed over a wide range of ΔK. It was found (94,95) that this data followed the following empirical relationship:

$$\frac{d\ell}{dN} = A' e^{B'/M_w} (\Delta K)^n \tag{28}$$

where A', B', and n are constants depending on the material and test conditions. Thus, even though values of static toughness may change relatively little over a given range of molecular weight, small increases in the molecular weight M_w may result in up to several orders of magnitude decrease in crack growth rate. Also, the effect is greater at lower molecular weights. This is shown for the case of PMMA and PVC in Figure 23 (89).

It has also been found (92) that the addition of small amounts of high or medium molecular weight to PMMA results in greater resistance to both fatigue and static loading, whereas the addition of low molecular weight has a deleterious effect. Since the FCP response can be correlated semiquantitatively with the proportion of high M_w species estimated by gel-permeation chromatography (96), it has been suggested that resistance to cyclic disentanglement is favored by high M_w species. While the short time scale of static fracture tests permits relatively little disentanglement, the longer time scale involved in fatigue allows the fracture process to reflect more strongly the energy dissipation concerned in breakdown of the entanglement network (2). In this sense, the fatigue process resembles the

longtime relaxation processes in time-to-failure tests (97,98) in which strong effects of molecular weight are also seen. Hence it is likely that during cycling, the entanglements in craze fibrils involving low M_w species are progressively broken down, but the longer molecules permit considerable strain hardening to occur in the fibrils (2,4,99). This conclusion is supported by fractographic evidence obtained for specimens of PMMA containing high and low molecular weights (100).

The FCP resistance in semicrystalline polymers is typically higher at higher molecular weight. Examples include high density and ultrahigh molecular weight polyethylene (101–103), acetal resin (104,105), nylon-6,6 (104), and polypropylene (103). The effect of molecular weight on the FCP rates for these polymers is shown in a comparative plot in Figure 24. In general, however, the sensitivity of the crack

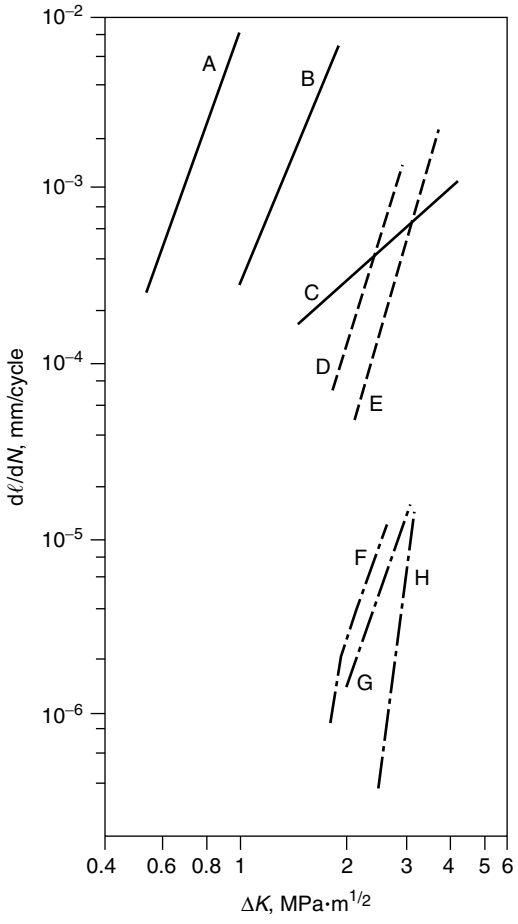

Fig. 24. Effect of molecular weight on fatigue crack growth rates in high density polyethylene (solid line): $M_w = 45{,}000$ (**A**), 70,000 (**B**), 200,000 (**C**) (101,102); nylon-6,6 (dashed line): $M_n = 17{,}000$ (**D**), 34,000 (**E**) (104); and acetal resins (dotted-dashed line): $M_n = 30{,}000$ (**F**), 40,000 (**G**), 70,000 (**H**) (105).

growth rate to molecular weight is less than that in amorphous polymers. This may be due to the effect of the crystal structure stabilizing the polymer through tie chains and the like.

Some attempts have been made to develop quantitative theories to rationalize the effects of molecular weight and have met with some success, at least with PMMA, PVC, and polystyrene (94,95,106). Thus it has been proposed that the FCP rate can be expressed as the product of two functions, one involving ΔK and the other characteristic of the relaxation process in the plastic zone (95):

$$\frac{\mathrm{d}\ell}{\mathrm{d}N} = f(\Delta K) \times \frac{1}{\tau_\mathrm{f}} \tag{29}$$

where $f(\Delta K)$ reflects the effect of applied stress and τ_f, the relaxation time, reflects the resistance to chain disentanglement. Increased FCP resistance has been correlated with increased characteristic stress-relaxation times in PVC (107) and a rubber–polystyrene interpenetrating polymer network (108). Considering that the relaxation time follows a Zhurkov-type rate process (33), the following may be expected:

$$\tau_\mathrm{f} = A' \exp\left(\frac{-V\sigma}{RT}\right) \tag{30}$$

where A' is a constant and V is the activation volume. Assuming that the stress involved is a localized average mean stress in the plastic zone, the following equation can be derived:

$$\frac{\mathrm{d}\ell}{\mathrm{d}N} = f(\Delta K) \exp\left(\frac{\sigma_{\mathrm{m,y}} V_\infty}{RT} \Psi(M)\right) \tag{31}$$

In equation 31, $\sigma_{\mathrm{m,y}} = \sigma_\mathrm{y}\ (1 + R)/2$, where σ_y is the yield stress and R is the load ratio. V_∞ is the activation volume for infinite molecular weight M, and $\psi(M)$ reflects the fraction of molecules that can form a mechanically effective entanglement network. In terms of molecular weight, $\psi(M)$ is defined as $\psi(M) = (V_\infty/V) = (W - W*)/(1 - W*)$, where W is the weight fraction of molecules when $M > M_0$; M_0 is the minimum value of M required for a stable network; and $W*$ is the minimum weight fraction of those molecules required to form a stable craze. The value of $(1 - W*)$ is consistent with the void volume of mature crazes in PMMA and PVC (95).

The model applies to PMMA and PVC and gives values of V that agree fairly well with values for static fracture. Thus a combination of rate process theory with fracture mechanics can usefully relate molecular and continuum ideas in rationalizing fatigue fracture. Vertical shifting of FCP curves gives master curves relative to a very high molecular weight specimen ($\psi \cong 1$) as long as ΔK_th is independent of M, ie, when M is greater than some limiting value. This is shown in Figure 25 for the case of polystyrene (94). The shift factor a_v is related to V and $\psi(M)$:

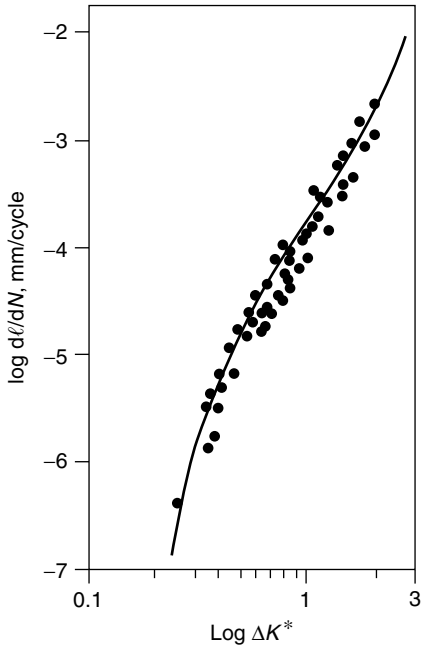

Fig. 25. Master curve for FCP in polystyrene (10 Hz, sine wave) as a function of stress intensity factor (94). Curve includes data for 12 specimens varying greatly in molecular weight and its distribution, and encompasses both the threshold of crack growth and the approach to catastrophic fracture.

$$a_v = \frac{\exp(V\sigma_{m,y})}{\exp(V_\infty \sigma_{m,y})} \tag{32}$$

An alternative, simpler approach has been proposed in which crack growth is essentially considered the reverse of crack healing (105). In effect, disentanglement is taken to be the reverse of interdiffusion of molecules at the surfaces of two planes in close contact. Thus, assuming scaling laws for characterizing molecular reptation hold, it has been suggested that $d\ell/dN$ is proportional to the quotient of the distance of interpenetration x to t_∞, the time required for complete molecular diffusion and interpenetration. Since $x \propto M^{1/2}$ and $t_\infty \propto M^3$, then

$$\frac{d\ell}{dN} \propto M^{-2.5} \tag{33}$$

Both equations 32 and 33 give a good agreement when applied to data in Reference 105.

A few controlled studies on the effects that cross-linking has on the FCP resistance have been done. When irradiation was used to increase M_w in polystyrene, keeping M_n constant, the fatigue life was affected very little by the total dose applied. In fact, the FCP behavior did not alter significantly even up to the gel point and beyond. The FCP resistance of cross-linked polystyrene is lower than

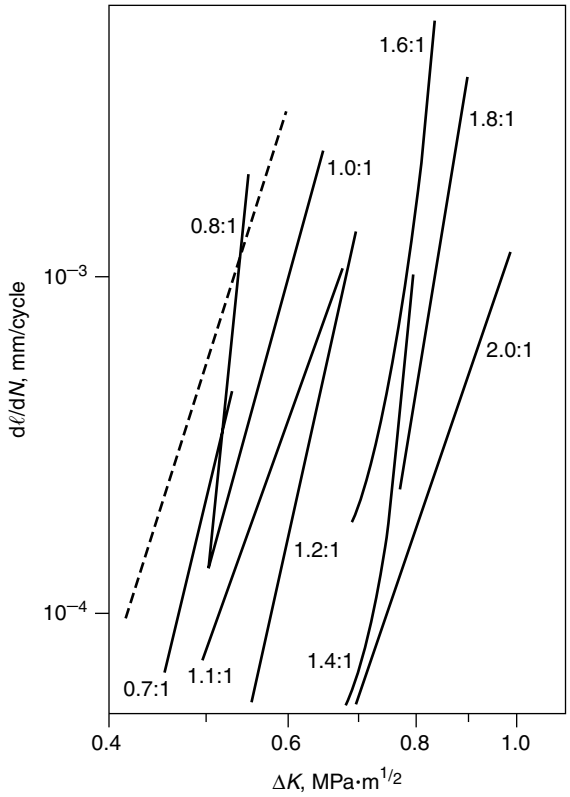

Fig. 26. FCP behavior in Epon 828/MDA epoxy as a function of amine/epoxy ratio (numbers labeling curves) at 10 Hz (113). Dotted line represents other data (110).

that of polystyrene or rubber-modified polystyrene (109). A typical epoxy resin is much less resistant to FCP than thermoplastic polymers (2,110). This observation is generally consistent with the ability of cross-linking to inhibit segmental mobility, crazing, and consequent energy dissipation.

Most systematic studies of cross-linked polymers confirm the above hypothesis, but one study reveals an interesting exception. As the percentage of a multifunctional acrylate cross-linking agent in PMMA increased from 0 to 11, the FCP rates increased by over 2 orders of magnitude (at $\Delta K = 0.5$ MPa·m$^{1/2}$); the slopes of the $d\ell/dN$ curves also increased (111). Similar deleterious effects of cross-linking are described in a study of static and fatigue performance in bisphenol A epoxies cured with methylenedianiline (112). These results are presented in Figure 26. Note that as the amine/epoxy ratio decreased from 2:1 to 1:1 (i.e., from a nearly linear to a densely cross-linked resin) K_{Ic} decreased and FCP rates increased by over an order of magnitude at a given ΔK. While an excess of amine increased FCP resistance, an excess of epoxy had the opposite effect. This difference can be explained by considering that the epoxy is difunctional and the curing agent is tetrafunctional. When an excess of di-epoxy exists, the resulting network has an effective increase in molecular weight between cross-links, approaching that of a rubbery network. However, when an excess of curing agent exists, the

molecular weight between cross-links is not necessarily increased and many terminal uncross-linked ends are produced. Thus, the results reflect this difference in network architecture. Note, however, that it would be interesting to compare fatigue results at similar temperatures relative to their glass transition rather than at one temperature since the glass transition is inversely related to the molecular weight between cross-links.

Fractography. The fatigue-fracture-surface micromorphology of engineering plastics is complex. In general, the surface may reveal a range of roughness, and this roughness is usually associated with either a change in stress intensity factor or stress states. In the interior of a specimen, the stress state is more confining than near the edges, and careful inspection of fracture surfaces usually reveals this effect. For example, the surface shown in Figure 7 (25) illustrates greater texture near the initiation site where the nucleation and growth process below the threshold level occurs. Once subcritical crack growth is established, the fracture surface produces a smoother and uniform texture. At the critical size, rapid fracture occurs and the crack speed approaches the stress wave speed in the material. A clear distinction appears at the critical radius in Figure 7, denoting this sudden change in crack speed. Note in this case, that the surface beyond the critical size is notably rougher than the other part of the surface (see also FRACTOGRAPHY).

Figure 27 illustrates a fracture surface on another semicrystalline polymer, an aliphatic polyketone terpolymer (114). When comparing Figure 7 with Figure 27, some generic features are noticed, but there are also some contrasting differences. Much like that observed in Figure 7, Figure 27 contains a clear penny-shaped crack whose center locates the nucleation site. However, in stark contrast to that observed in Figure 7, Figure 27 shows a distinctly more textured fracture surface up to the critical radius (see **A** in Fig. 27). Just at the regime where the crack reached a critical size, the fracture surface becomes remarkably smoother, followed by a more textured region, and ultimately a very textured region near the edge (**C** in Fig. 27). The region near the edge (Fig. 27C) illustrates how the boundary condition near the free edge affects the texture and indicated a *tearing* of the last ligaments during the last stage of failure.

In many polymers, fatigue striations can be observed at relatively high ΔK levels. These striations correspond to the successive location of the advancing crack front after each loading cycle or local crack jump. There is a clear distinction between macroscopically observed clamshell markings, which represent periods of

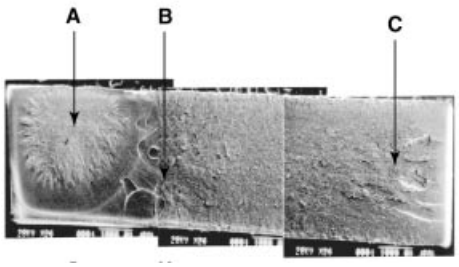

Fig. 27. Scanning electron composite micrograph of fatigue-induced fracture surface in aliphatic polyketone terpolymer: (**A**) initiation site and subcritical crack growth, (**B**) critical radius, and (**C**) texture associated with remaining ligaments (114).

growth during which hundreds or thousands of loading cycles may have occurred, and fatigue striations, which represent the extent of crack-front advance during one load excursion. Each fatigue clamshell marking may, therefore, represent the extent of crack advance corresponding to thousands or tens of thousands of individual load or strain excursions. The microscopic measurement of the FCP rate, ie, striation width, is in excellent agreement with macroscopically determined crack growth rates (115). This strong correlation between macroscopic and microscopic growth rates in polymeric solids reflects the fact that 100% of the fracture surface in this ΔK regime is striated—an observation not typically found in metal alloy systems. In the latter instance, other fracture mechanisms such as cleavage, microvoid coalescence, and intergranular failure are observed in various locations on the fracture surface.

It is common for significant damage to evolve under the crack surface as well. This occurs because the high stress in the vicinity of the crack tip promotes the formation of damage. This damage consumes significant energy and is largely responsible for the high apparent toughness that many polymers exhibit. The damage in the vicinity of the tip can take many different forms and is largely associated with the polymer. Common features include crazing in most semicrystalline polymers and some glassy polymers (eg, polystyrene). Glassy polymers with higher cohesive energy densities promote shear banding. Stress state will also play a role in this process. An excellent treatise describing these morphological features can be found in Reference 65. The damage that occurred below the surface shown in Figure 27 is illustrated in Figure 28 (114). The damage in this polymer occurs as an array of crazes, with the highest density near the surface of the main craze. As the distance from the fracture surface is increased, the size and density of crazes reduce. Earlier stages of this same process are illustrated for iPP in close-up micrograph in Figure 17 (56).

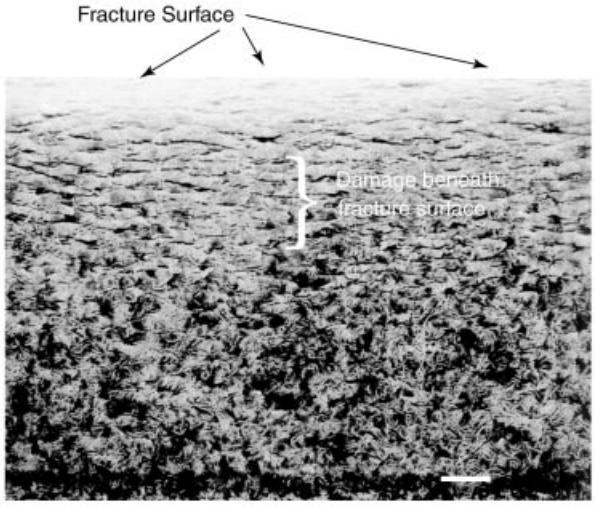

Fig. 28. Scanning electron micrograph of damage occurring below crack surface in an aliphatic polyketone polymer (Ref. 114). Note that the highest density of crazes occurs near the crack surface.

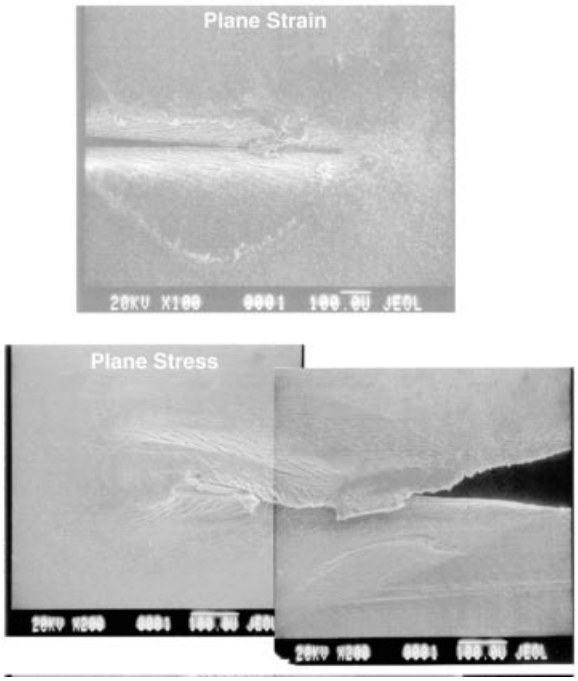

Fig. 29. Scanning electron micrographs of crack tip in plane strain (above) and plane stress (below) conditions for an aliphatic polyketone terpolymer (114).

The damage mechanisms produced in unnotched fatigue specimens can be compared to those where a controlled defect (razor sharp notch) is introduced into fatigue specimens. Figure 29 (13) illustrates the damage that surrounds the crack tip both in the interior of the specimen (plane strain condition) and at the outer surface (plane stress condition). In the plane strain condition, a high concentration of collinear crazes is apparent and is consistent with the damage produced at a natural defect (Fig. 28). Note that in both the plane strain and plane stress conditions, the damage surrounds the crack. This damage is referred to as a process zone since it is closely associated with the fracture process. In the case of plane stress (Fig. 29), the damage is inclined with respect to the fracture surface. These inclined features are shear bands and occur in the constraint-free regime near the surface.

Other factors can affect the type of fatigue damage, thereby changing the FCP and fracture toughness of the material. This is illustrated for the case of β-phase nucleated iPP (25) (see Fig. 30). When comparing the differences between beta phase (Fig. 30) and α-phase (Fig. 6), a clear difference in the fatigue damage is noticed. In the α-nucleated polymer (Fig. 6), highly fibrillated crazes evolve orthogonal to the loading condition and are not altered by the spherulitic morphology. In contrast, in the β-nucleated polymer (Fig. 30), the crazes show no fibrillation and appear to follow the lamellar direction of the spherulite.

The state of stress can dramatically affect the failure mode and strength of polymers. This effect alters the fracture surface characteristics when different modes of fracture are applied. Figure 31 shows comparative micrographs of

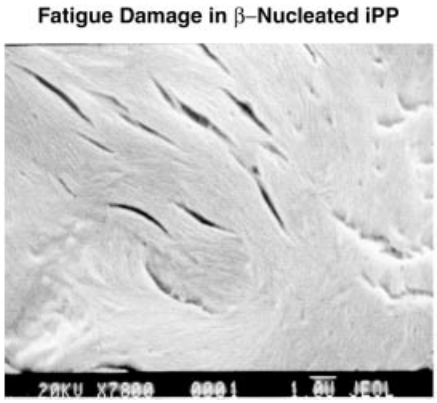

Fig. 30. Scanning electron micrograph of β-nucleated iPP subjected to 10^6 cycles (25).

fracture surfaces in carbon fiber epoxy resin composites tested in mode I (opening mode) and mode II (shear mode) loading conditions. Notice that the mode I fracture surface appears relatively smooth while the mode II surface has a characteristic hackled surface. Also, the fracture energy for the mode II sample is greater than that of the mode I sample.

Other Factors Affecting Total Fatigue Life

Effects of Chemistry in Homogeneous Polymers. Without knowing the relative importance of initiation and propagation stages of fatigue damage accumulation, it is many times difficult to identify the role of material characteristics such as molecular weight and impact modifier content on these two stages of fatigue damage process. Some preliminary experiments have been reported to identify the extent of the fatigue crack initiation process as influenced by molecular weight, impact modifier level (116), and stress level (6,117). Figure 32 shows a three-dimensional plot illustrating the interactive effects of M_w and rubber content (%) on fatigue crack initiation (FCI) lifetime (N_i) in impact-modified PVC. The rubber phase is methacrylate–butadiene–styrene (MBS) polymer. N_i is defined as the number of loading cycles necessary to nucleate a crack 0.25 in length from a semicircular surface notch with a radius of 1.59 mm. FCI lifetimes increase with increasing molecular weight for all rubbery phase contents. Conversely, in high M_w PVC blends, rubber modification lowers FCI resistance although the addition of MBS in low M_w PVC slightly improves FCI resistance. The addition of a rubbery phase to epoxy resin and nylon-6,6 also reduces FCI lifetimes and hastens thermal fatigue, respectively.

In addition to the FCP behavior, the molecular weight and distribution profoundly affect both thermal and mechanical properties of polymers (118–120). Thus tensile strength of many polymers is very low or negligible when the average M is low ($<10^4$ to 10^5), but increases rapidly above M_0, a characteristic value of molecular weight, and then levels off (119–124). When $M > M_0$, the relationship between strength and molecular weight may often be expressed by an empirical equation of the form

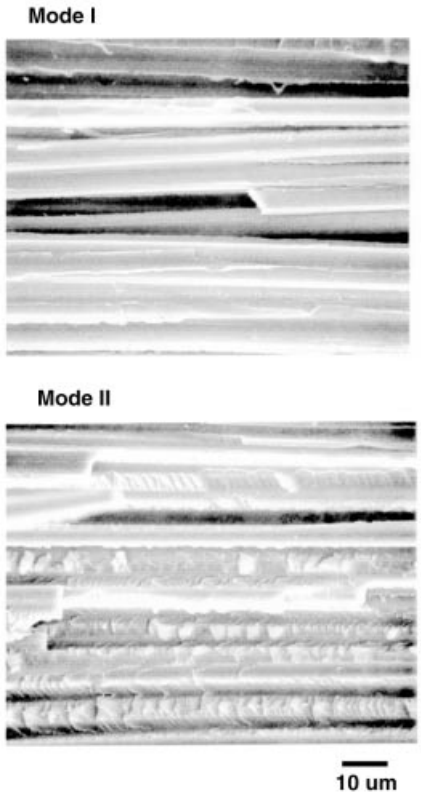

Fig. 31. Scanning electron micrographs of unidirectional carbon fiber epoxy resin composites tested in modes I and II test conditions (25).

$$\sigma_B = A - B/M_x \tag{34}$$

where σ_B is tensile strength, A and B are constants, and M_x is an average molecular weight. Often the number-average molecular weight M_n, which strongly reflects the presence of chain ends as defects, is appropriate (121,122). Other physical properties vary in a similar fashion (125–128); a sigmoidal shape over the whole range of M may sometimes be discerned on a log–log plot. The initiation and propagation of fatigue damage also depends strongly on molecular weight. Indeed both static and fatigue fracture are controlled by similar viscoelastic processes, although the balance of processes and intensity of expression in failure rates differ significantly (2). Energies and volumes of activation tend to be similar for molecular flow and fatigue processes (108,109), and the fatigue resistance of many polymers correlates well with fracture toughness (2). Thus an earlier proposal (124) that the nature of entanglement networks controls M_0 and fracture generally has been confirmed and amplified. Much evidence suggests that only molecules longer than the average length spanning a craze can form a ductile network that can effectively resist crack propagation (113,125,126,129–132). Equation 34 has been derived on this basis, with $A = \sigma_B$ for infinite M (132), and the role of l_c, the contour length between entanglements, has been shown to control

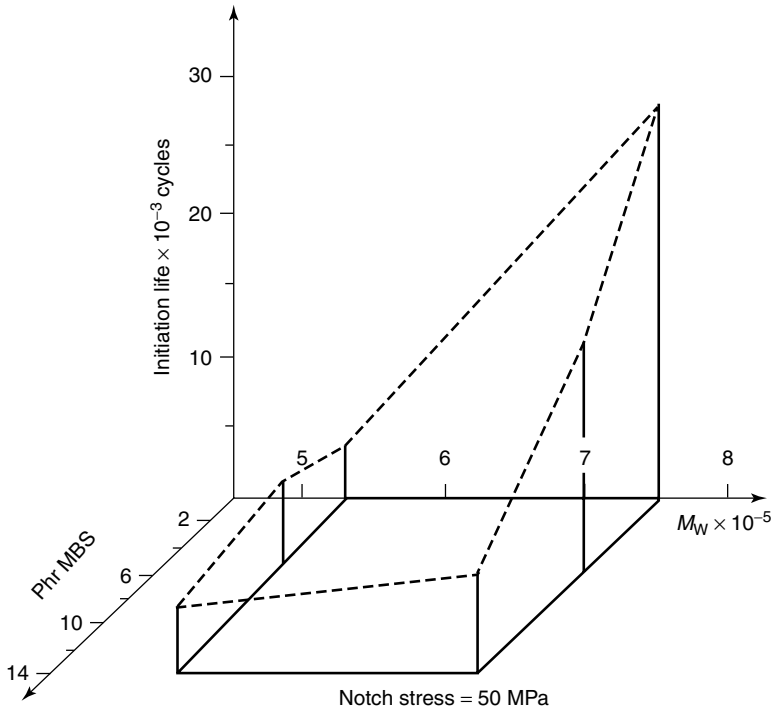

Fig. 32. Three-dimensional plot revealing interactive effects of M_w and rubber content (MBS) % on FCI lifetime in PVC (116).

the maximum elongation possible for a polymer (133,134). In addition, high and low values of the ratio of l_c to the rms end-to-end distance between entanglements tend to be associated with crazing and shear yielding, respectively. Experimental evidence clearly shows that dense, stable crazes can develop only when $M > M_0$ (113,135). Although molecular weight may or may not affect the crazing stress (135–137), a direct correlation exists between higher M values and greater ability to resist propagation of a crack through a craze.

The fatigue resistance depends strongly, and often dramatically, on molecular weight and its distribution (2,4). As M_w increases from 1.6×10^5 to 2×10^6 in three polystyrenes with narrow molecular weight distributions, the S–N (stress–fatigue life) curves (obtained under conditions yielding negligible hysteretic heating) shift upwards and to the right, and the fatigue endurance limit increases from ∼1/14 to 1/2 of the breaking stress (4,138) (see Fig. 33). Similar improvements in fatigue life with increasing molecular weight have also been noted in pulsed compression tests on polystyrene (104). Tensile strength increases by 25% over the range of molecular weight, whereas fatigue strength increases by 100% (4,138–140). Equation 34 holds for tensile strength, but a different dependence is seen for fatigue strength; the ratio of the former to the latter varies from 0.1 to 0.3. The σ–N curve for a polydisperse polystyrene ($M_w = 2.7 \times 10^5$) was not parallel to the others in Figure 33, and yielded an endurance limit higher than predicted on the basis of the other specimens (4,138,140). This finding is similar to that in which the addition of only 1% of high molecular weight species ($M_w = 7 \times 10^5$)

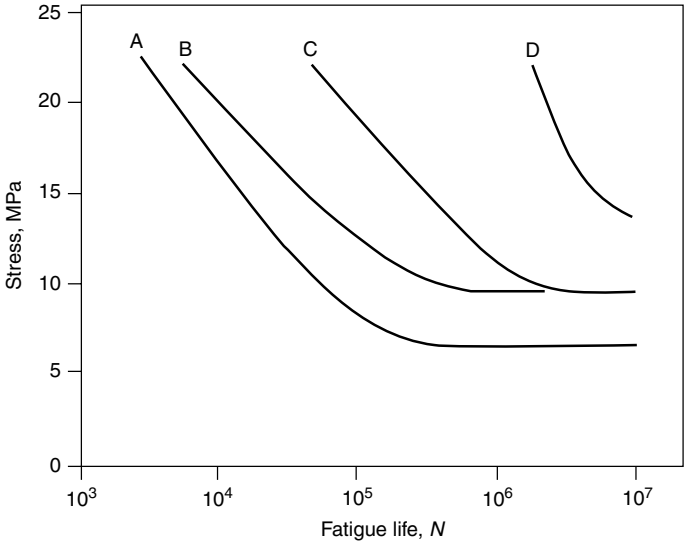

Fig. 33. Effect of molecular weight on fatigue life in polystyrene. $M_w = 1.6 \times 10^5$ (**A**), 3.3×10^5 (**B**), 8.6×10^5 (**C**), 2.0×10^6 (**D**). Specimen B has a broader distribution of molecular weight than the others (4). To convert MPa to psi, multiply by 145.

was able to induce craze stability in a brittle, low molecular weight polystyrene ($M_w = 10^4$) (113). These results have been attributed to increased entanglement density, and hence, orientation hardening of crazed fibrils, and decreased concentration of defects in the form of chain ends in long molecules (4,122). At the same time, increases in fatigue life are not noted when molecular weight is increased by irradiation, so that polydispersity is essentially constant (140). Under such conditions, even below the gel point, the benefits of increased molecular weight are clearly overwhelmed by the flaws introduced by chain ends.

Effect of Diluents and Plasticizers. Diluents, plasticizers (qv), residual solvents or monomers, or absorbed environmental agents greatly affect the viscoelastic response of a polymer and related properties such as damping, modulus, glass-transition temperature T_g, and yield strength. This resultant changes in properties can therefore affect fatigue behavior whether the diluents are dispersed uniformly in the bulk or only at the surface. The effects of lower stiffness differ depending on whether testing is conducted under constant stress or constant deflection conditions. In the first case, fatigue behavior may deteriorate because of the increase in strain experienced by more compliant specimen. In the latter case, the more compliant specimens (which experience lower stresses) may exhibit superior performance. The increase in compliance may also increase the fatigue life of a specimen by plasticizing the crack tip and blunting an otherwise brittle failure. Conversely, it may reduce the fatigue life by reducing the strength of the material in the presence of the crack or craze tip.

The σ–N behavior in tension–compression at 7 Hz of plasticized PVC containing 10 phr of dioctyl adipate exhibits several features characteristic of other polymers (141). Under conditions of high strain amplitude, high ambient temperature, and specimen cooling by natural convection, thermal failures are observed:

a steady increase in damping (tan δ) and a decrease in modulus was observed as failure was approached. In contrast, brittle failure along with crack temperatures, and an increase in storage modulus and a decrease in tan δ prior to failure. However, when thermal failure conditions are coupled with forced-air cooling, brittle fracture is also typical. Also, the criterion (142) for thermal failure is valid (141).

In PVC plasticized with dioctyl phthalate (DOP), FCP rates reportedly increased as the DOP concentration increased from 0 to 10–20% (143), suggesting that lower yield stress and modulus, and resultant tendency toward creep, may play an important role. Quite different results were obtained in a later study at a higher frequency, which may have hindered such creep (90). In this case, FCP rates were relatively unchanged by the presence of DOP, although K_{Ic} values were somewhat reduced, especially at the lowest concentration, 6%. Evidently the antiplasticizing embrittling effect of DOP at low concentrations was manifested more in the static than in the fatigue response. It is believed that PVC can form an effective entanglement network and stable crazes in the presence of much DOP, and the long time scale loading characteristic of fatigue may permit extensive cyclic disentanglement.

With internally plasticized PMMA, i.e., a copolymer with butyl acrylate, still other effects have been seen (89). As the concentration of butyl acrylate increases to mole fractions of 0.1 and then 0.2, FCP rates increase dramatically and K_{Ic} values decrease, presumably because increased ductility is associated with lower strength and modulus. However, with a mole fraction of 0.3 butyl acrylate, localized crack-tip heating and blunting develop from an increase in damping, and FCP rates decrease, so that the overall behavior, with respect to FCP only, resembles that of a commercial PMMA. Hence it appears that a plasticizing comonomer in a chain significantly facilitates the detailed local viscoelastic response and weakens craze fibrils, whereas a semimiscible external plasticizer may not necessarily inhibit the ability to form strong craze fibrils.

The plasticizing influence of absorbed water on the FCP response of polyamides has also been studied (144–150). Earlier data were difficult to interpret because various experiments employed different test frequencies, mean stress levels, amounts of imbibed water (0–8.5%), and different specimen configurations. According to the principles of linear elastic fracture mechanics, specimen configuration should have no bearing on material fatigue response, since the propagation of fatigue crack is assumed to be controlled entirely by the stress field near the crack tip and therefore to be a function of ΔK only. However, for the case of engineering plastics that exhibit significant viscoelastic heating at the prevailing test conditions, variations in specimen configuration have been shown to alter FCP resistance as a result of changes in overall stress range ($\Delta\sigma$) acting on the specimen (150,151). For example, crack growth rates determined with the center-cracked (CCT) specimens exceed those using wedge-opening load (WOL) samples (151). In addition, greater hysteretic heating occurs in the CCT samples when compared with those measured in WOL samples. These results are readily understood in terms of the expression for the stress intensity factor range, which takes into account the different geometries.

$$\Delta K = Y(\Delta\sigma)\sqrt{\ell} \tag{35}$$

In equation 35, the function Y accounts for the different specimen geometries (64). Since Y is much smaller for the CCT specimen than for the WOL specimen (64), it follows that $\Delta\sigma_{CCT}$ is much larger than $\Delta\sigma_{WOL}$; the latter difference in far-field stress distribution alters the hysteretic heat generation capability and the relative stiffness of these samples. Simply stated, the far-field stresses must be increased in the CCT specimen to achieve the same change in stress intensity as the WOL specimen. These higher far-field stresses, in turn, produce more hysteretic heating.

Nylon–water interactions and their associated influence on mechanical response are of considerable engineering importance since the absorption of moisture occurs readily when the nylon component is in service. Roughly 2.5 wt% water is imbibed after equilibration at 50% rh. Depending on the property and the amount of water absorbed, effects may be beneficial or deleterious. For example, RT modulus increases marginally with the addition of 2.2% water in nylon-6,6 but is significantly reduced with 8.5% water (152). Such differences in elastic modulus have been traced to the manner by which the water molecules are incorporated in the nylon. At low absorbed moisture, the polar H_2O molecules interrupt the hydrogen bonds between amide groups in neighboring chain segments and create water bridges between these groups. This tightly bound state is believed to persist until all of the hydrogen atoms bond in the amorphous fraction group ratio of 1/2 (153,154). At higher concentrations, weakly bound water is imbibed and essentially serves as a diluent.

Fatigue tests on unnotched samples have demonstrated that the fatigue strength (the stress corresponding to failure at a given number of cycles) is reduced by as much as 30% when nylon-6,6 is equilibrated at 50% rh (152) (see Fig. 34). In marked contrast, it has been found that fatigue growth rates in nylon-6,6 exhibit a pronounced minimum at an absorbed moisture content of 2.6 wt% water, and

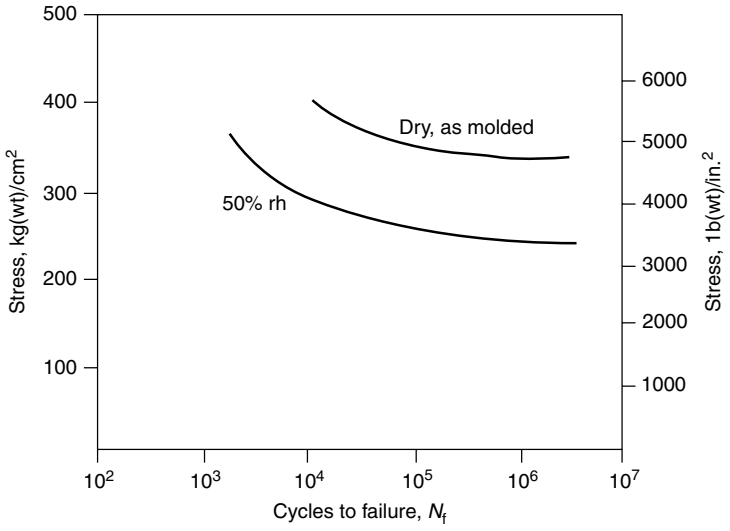

Fig. 34. Unnotched fatigue life in nylon-6,6 as a molded and equilibrated at 50% rh (155). The test specimen is 0.775 cm thick.

crack growth rates are higher in saturated material (8.5 wt% water) than in the dry polymer (149,156). The decrease in crack growth rates with increasing water content at low moisture can be attributed to enhanced chain mobility and an attendant increase in crack-tip blunting associated with localized crack-tip heating. In addition, fatigue resistance is believed to increase with the slight increase in elastic modulus that accompanies the addition of up to 2.5 wt% water. Conversely, the marked increase in crack growth rates at moisture >2.5 wt% is believed to result from the pronounced reduction of elastic modulus which accompanies high amounts of loosely bound absorbed water (152,154).

The complex influence of absorbed water on FCP resistance in nylon-6,6 and in nylon-6 (149) reflects a competition between the beneficial influence of crack-tip blunting and the deleterious effect of modulus degradation. This competitive interaction is reflected in the fatigue-mechanism transition discussed below. The blunting mechanism dominates the fatigue response at low moisture levels and the decrease in modulus overshadows crack blunting at higher water contents. The same deformation processes occur in fatigue tests on unnotched samples; however, overall global stress levels in these samples are much larger than for the case of precracked specimens. As a result, the greater amount of hysteretic heating in nylon-6,6 samples equilibrated at 50% rh reduces specimen stiffness resulting in more damage per cycle than that experienced inferior fatigue properties in the σ–N test.

The influence of absorbed water on FCP resistance is expected to be more significant for high impact nylon-6,6 (HI-N66) since this blend exhibits greater amounts of hysteretic heating than neat nylon-6,6 (157). In general, the effect of water content on relative ranking in FCP resistance for various nylon-6,6 blends is related to specimen temperature. At low water contents and low values of ΔK, heating is beneficial, and blends with more rubber show the best FCP resistance. For these conditions, heating is localized and contributes to crack-tip blunting, which lowers the effective ΔK. With increasing water content, and/or ΔK, greater specimen heating occurs which is detrimental to fatigue resistance. Since rubbery additions and extensive hysteretic heating bring about a substantial reduction in E', the principal cause for reduced FCP resistance in the rich blends containing water, it is interesting to note that when ΔK is normalized with respect to the elastic modulus, the richer blends exhibit greater resistance to cyclic strain (157). In general, variations in FCP behavior of HI-N66 depend strongly on changes in the dynamic storage and loss moduli resulting from hysteretic heating. Heat-induced changes in modulus are more important than the absolute temperature increase of the sample.

The absorption of water by PMMA also influences fatigue resistance in this amorphous polymer (158). There is significant reduction in fatigue lifetime with up to 1% water content for extruded PMMA ($M_w = 79{,}300$) tested at 27.6 MPa and 2 Hz (see Fig. 35). This is related to plasticization and reduction in resistance to craze initiation and subsequent breakdown. At higher water content, no further deterioration takes place even though the water molecules tend to cluster and aggregate.

Surface Finish and Modification. Previous examples involve essentially homogeneous polymer–diluent systems. Interesting effects with practical consequences also occur when unnotched samples are exposed to various environmental

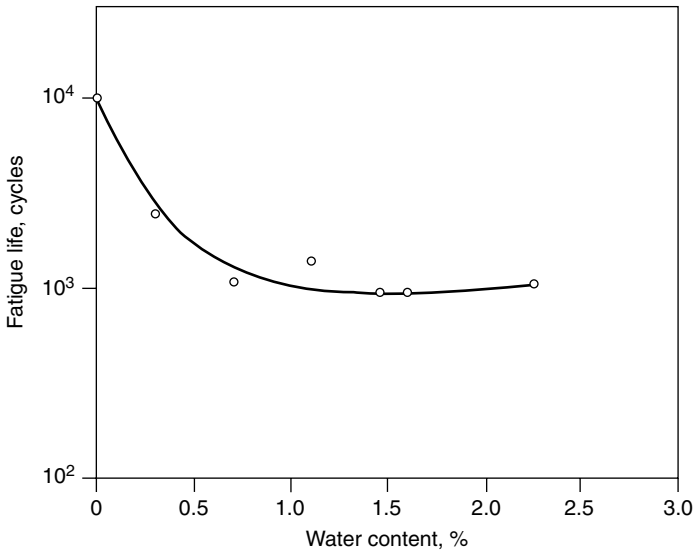

Fig. 35. Fatigue life vs water content in extruded PMMA (M_w = 79,300) tested at 27.6 MPa and 2 Hz (158).

media (4,159). Because fatigue failure in many cases usually involves initiation at the surface, such effects are to be expected.

Deleterious effects of atmospheric exposure on mechanical properties are well known. Surface oxidation in rubbers results in embrittlement, surface cracking, enhanced fatigue propagation, and reduced fatigue life. Even in a ductile plastic, the formation of brittle surface layers and cracks invariably facilitates the onset of crack propagation under static (51,160) or fatigue loading. For example, when exposed to natural weathering (qv), the fatigue strengths of polystyrene, ABS and acetal resin decrease both in an absolute sense and in a relative sense with respect to tensile and blending strength.

The role of surface oxidation in the fatigue of polystyrene has been clearly demonstrated (159). While control samples exhibit an average fatigue life of 25,000 cycles in air, lifetimes increase ~90% by coating with a ductile metal (aluminum or gold, 200 nm thick), and ~100% by testing in nitrogen. Coating with flexible, rubber polymers or with a low molecular weight oligomer of polystyrene also increases fatigue life in polystyrene (159,161). The relative effect is greater for unpolished specimens; interestingly, the coatings themselves are more effective than polishing. It seems likely that these coatings reduce stress concentrations at surface flaws. Even though the natural rubbers used are susceptible to oxidation, the polishing effect is dominant. On the other hand, coating high molecular weight brittle polystyrene layer results in a decrease in fatigue life (4); the propensity for facile initiation of craze cracks evidently overcomes any protective effect. Of course, oxidation is favored by stress.

Although liquid environments often induce environmental-stress crazing or crazing in glassy plastics, not all liquids are deleterious to fatigue performance, and some are beneficial. Typical liquids, eg, heptanes, esters, and alcohols,

decrease the fatigue life of polystyrene (162); the decrease is greater when solubility parameter is closer to that of polystyrene. The increased solubility and plasticization lowers the crazing stress and hence facilitates crack development. In contrast, with liquids known to increase crazing stresses in polystyrene, eg, water, ethylene glycol, or glycerol, fatigue lifetimes increase ~3×, 4×, and 9×, respectively. This effect is attributed to enhanced hydrogen bonding, to filling of surface voids and flaws, or to surface tension changes.

Increase in fatigue life for nylon-6,6 exposed to petroleum ether, water, and alcohols has been reported (163), and the effects of various liquids on fatigue of polycarbonate have been described (164). Various vapors can be beneficial to fatigue life in polystyrene (4,44).

Thermal History. This is an important parameter in determining viscoelastic and mechanical behavior (165). For example, in amorphous polymers, quenching from temperature above T_g increases the free volume and enthalpy, increases yield stress, and decreases fracture toughness (see also AGING). With crystalline polymers, the morphology (qv) depends very much on the balance between nucleation and growth corresponding to the rate and pattern of cooling from melt.

Although the fatigue behavior of semicrystalline polymers can be significantly altered by varying the thermal history, effects of such history on fatigue in amorphous polymers are not well documented. Even though sub-T_g annealing of polycarbonate reduces the static fracture toughness, relatively little effect on FCP response is noted (165). Similarly, only modest and difficult-to-reproduce FCP effects of quenching and annealing on FCP behavior have been reported for PVC (166,167). Although repetitive cycling can condition the state of a polymer, at least under some conditions (168), the fact that yielding occurs within the plastic zone implies the attainment of a state of mobility equivalent to a temperature high enough to erase some or all of the effects of the applied history.

Semicrystalline Polymers. As a class, semicrystalline polymers (qv) tend to exhibit superior fatigue resistance, relative to that of amorphous polymers (qv), both in terms of σ–N behavior and FCP rates (2,4,169), as long as tests are conducted at frequencies low enough to minimize excessive hysteretic heating. This is so, even allowing for variations, due to molecular weight. Indeed even though performance in a standard S–N test at 30 Hz may be relatively poor, many such polymers behave very well under service conditions involving lower frequencies and strains. Thus polypropylene is an excellent material for integral hinges.

Such inherently superior fatigue resistance is not fortuitous. Semicrystalline polymers having adequate intercrystalline linkages can not only dissipate considerable energy when the crystallites are deformed but also form a new and strong crystalline morphology (170,171). Crystallization developed during straining of amorphous polymers is responsible for the superior fatigue resistance of strain-crystallizing rubbers (172,173).

Confirmation of the general fatigue superiority of semicrystalline polymers is implicit in studies of σ–N behavior at frequencies low enough to minimize temperature rises (169). While the ratios of the endurance limit to tensile strength for typical amorphous polymers (polystyrene, PMMA, and cellulose acetate) are approximately 0.2, values for nylon-6,6, acetal resin, and polyterafluoroethylene are 0.3, 0.5, and 0.5, respectively. At a low frequency, polyethylene ($M_w > 50{,}000$) exhibits no failure after 5×10^6 cycles, even at the relatively high alternating stress

of 21 MPa (300 psi) (169). Curves for polymers such as nylon-6,6, poly(vinylidene fluoride), and acetal resin appear to the right of the curve and data for nylon-12 also fall in this region.

Polymer Alloys, Blends, and Composites. The fatigue behavior of multicomponent polymers can be complex. On one hand, the addition of inhomogeneities produces stress concentrations that can reduce the fatigue life of a structure dramatically. On the other hand, the heterogeneities may provide mechanisms of reinforcement, enhanced energy dissipation, or other features that may dramatically improve the overall fatigue life of a material (see POLYMER BLENDS).

With regard to particulate-filled or rubber-modified systems, the polymer matrix must provide the load bearing capability. The geometry and elastic properties of the discrete phase, together with quality of the interface, can all affect the stress concentration developed by the introduction of the particle. One can consider that at nominally low cyclic stresses the matrix material in the vicinity of the particles may be effectively cycling at much higher stresses. This, in turn, may shift the apparent high cycle/low cycle fatigue transition (eg, see Figs. 4 and 5) to lower stress levels or cycles. Also, the initiation time for damage may be effectively reduced by the introduction of the stress concentration. However, once the damage initiates, these same mechanisms may reduce the subcritical crack growth kinetics significantly by dramatically increasing the size of the process zone and increasing the energy dissipated within the process zone. For example, cavitation of a rubber particle can change the failure mode of the matrix polymer from a brittle mechanism (crazing or microcracking) to a ductile mechanism (shear banding), thereby increasing the fracture toughness of the material by as much as an order of magnitude (51).

The effect of a rubbery phase on the fatigue behavior is an example of such complex behavior. As with an unmodified polymer, high stresses or frequencies may generate enough hysteretic heating to induce failure by softening the matrix while at lower stresses and/or frequencies a nominally brittle failure can occur. This is shown for the case of ABS in Figure 36 (174). Although hysteretic heating is common without the introduction of a second phase, the rubbery phase can cause several specific effects. First, a significant decrease in the yield stress and modulus are typical along with an increase in the creep response. Moreover, the reduction in ultimate elongation associated with cyclic softening may be greater in rubber-modified polymers (175).

In another more recent study (176), FCP studies were conducted on rubber-toughened polycarbonate. The results indicated that over all ranges of ΔK, the crack growth rate was roughly a factor of 20 lower than that for unmodified polycarbonate. This was found over a range of mean stress levels. However, the threshold stress intensity factor ΔK_{th} dropped significantly in the modified system as compared to the unmodified system, indicating that the rubber-toughened system may have a shorter initiation time since smaller defects may start to propagate as cracks.

The behavior of polymer alloys and immiscible blends have generally the same complex behavior as rubber-modified systems. In the case of polystyrene/polyethylene blends (177), the crack growth rates of the blends were as much as 20 times lower than that of unmodified polystyrene. However, like the results in Reference 176, the results in Reference 177 show that

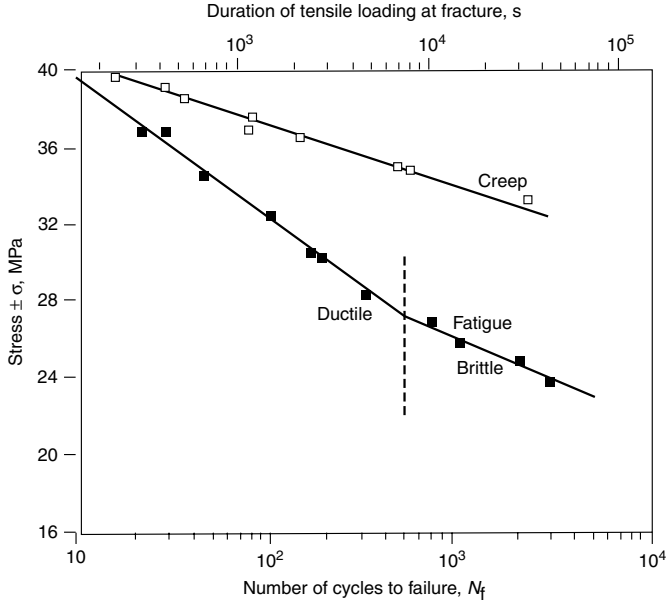

Fig. 36. Comparison of σ–N curve under a square-wave loading with creep-rupture data for a typical ABS polymer (175). Note that the creep-rupture time scale is equivalent to that of the fatigue cycle scale in terms of time under tensile load. To convert MPa to psi, multiply by 145.

the threshold stress intensity of the blend is lower than that of the modified system.

In some cases, the heterogeneity may provide an effective reinforcement for the matrix material (eg, chopped fiber composite). In this type of material, the load is transferred to the fiber from the matrix through shear and the mode II fracture strength of most polymers is much greater than the mode I strength (eg, Fig. 31). Thus, transmitting the load from the matrix to the reinforcement via shear is an efficient approach. Once the load is transferred, the fiber may provide the necessary strength and long-term durability. In order to realize this type of reinforcement, adequate fiber lengths and high interface strength are necessary.

FERROELECTRIC LIQUID CRYSTALLINE ELASTOMERS

Introduction

Ferroelectric materials are a subclass of pyro- and piezoelectric materials (Fig. 1) (see PIEZOELECTRIC POLYMERS). They are very rarely found in crystalline organic or polymeric materials because ferroelectric hysteresis requires enough molecular mobility to reorient molecular dipoles in space. So semicrystalline poly(vinylidene fluoride) (PVDF) is nearly the only known compound (1). On the contrary, ferroelectric behavior is very often observed in chiral liquid crystalline materials, both low molar mass and polymeric. For an overview of ferroelectric liquid crystals, see Reference 2. Tilted smectic liquid crystals that are made from chiral molecules lack the symmetry plane perpendicular to the smectic layer structure (Fig. 2). Therefore, they develop a spontaneous electric polarization, which is oriented perpendicular to the layer normal and perpendicular to the tilt direction. Because of the liquid-like structure inside the smectic layers, the direction of the tilt and thus the polar axis can be easily switched in external electric fields (see Figs. 2 and 3).

Here, we discuss materials (LC-elastomers) that combine a liquid crystalline phase and ferroelectric properties (preferably the chiral smectic C$*$ phase) in a polymer network structure (see Fig. 4). The coupling of the liquid crystalline director to the network or the softness of the network is chosen so that reorientation of the polar axis is still possible. Thus, densely cross-linked systems that possess a polar axis but cannot be switched (11) will be excluded. It is the role of the network (1) to form a rubbery matrix for the liquid crystalline phase and (2) to stabilize a director configuration. LC-materials that have these properties can be made either (see Fig. 4) by covalently linking the mesogenic groups to a slightly

cross-linked rubbery polymer network structure (see Fig. 4a) (4–6) or by dispersing a phase-separated polymer network structure within a low molar mass liquid crystal (see Fig. 4b) (9,12). Both systems possess locally a very different structure. They may show, however, macroscopically similar properties.

LC-elastomers (see Fig. 4a) have been investigated in detail (4–8). Although the liquid crystalline phase transitions are nearly unaffected by the network, the network retains the memory of the phase and director pattern during cross-linking

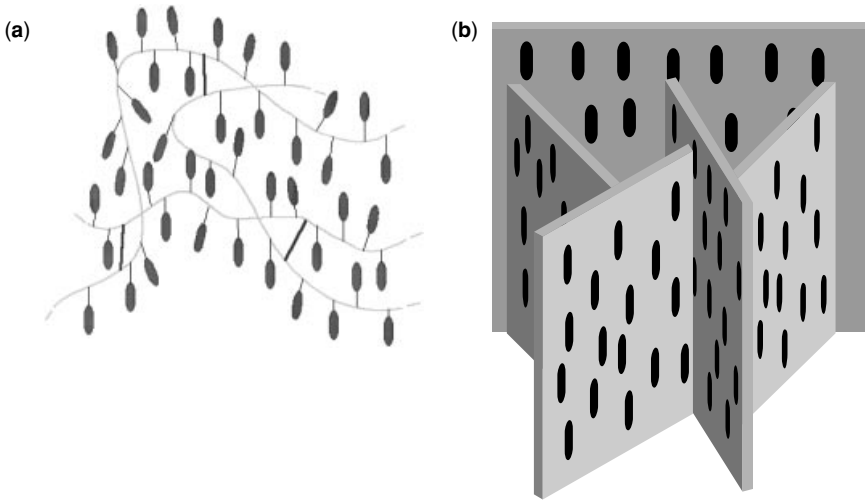

Fig. 3. Network: soft, can be transformed like rubber band, but retains its shape and couples to director orientation because (**a**) director is preferably parallel (or perpendicular) to polymer chains (LC-elastomer) (4–9); (**b**) director aligns (parallel) to chains in oriented phase-separated polymer network structure (low molar mass LC in LC-thermoset) (9,10).

(7,8). In addition, it freezes fluctuations of the smectic layers and leads to a real long range order in one dimension (13). An attempt to change the director pattern by electric or magnetic fields in LC-elastomers leads to a deformation of the network and to an elastic response (see Fig. 3). As a consequence of this, nematic LC-elastomers could never be switched in electric fields, if the shape of the elastomer was kept fixed. For freely suspended pieces of nematic LC-elastomers, shape variations in electric fields have been observed sometimes (14,15). In ferroelectric liquid crystals, the interaction with the electric field is, however, much larger. Thus, it has been possible to prepare real ferroelectric LC-elastomers (see Fig. 3) (3,16). In these systems, the polymer network stabilizes one switching state like a soft spring. It is, however, soft enough to allow ferroelectric switching. Therefore the ferroelectric hysteresis can therefore be measured in these systems. It is, however, shifted away from zero voltage (see Fig. 3).

Synthesis of Ferroelectric LC-Elastomers

The ferroelectric LC-elastomers described so far (3,16–21) are mostly prepared from cross-linkable ferroelectric polysiloxanes (see Fig. 5), which are prepared by hydrosilylation of precursor polysiloxanes (22) (see SILICONES). The cross-linking is finally initiated by irradiating a photoradical generator, which leads to oligomerization of acrylamide or acrylate groups (see Fig. 5). The functionality of the net points is thus high (equal to the degree of polymerization) and varies with the cross-linking conditions.

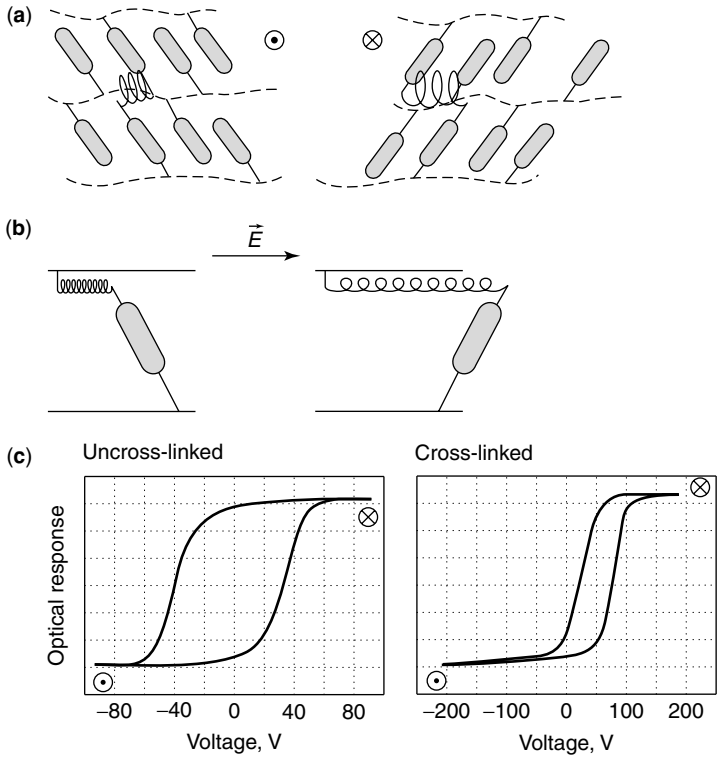

Fig. 4. Schematic drawing of the ferroelectric LC-elastomer and its two switching states (3): (**a**) A polymer chain acts as cross-linking point by connecting different mesogenic groups attached to the main polymer chains. A ferroelectric switching in this elastomer extends polymer chains. (**b**) The entropy elasticity arising from this acts like a spring that stabilizes one state. (**c**) For the uncross-linked system (left), the hysteresis is symmetrical to zero voltage and both states are equal. After cross-linking in one polar state (right), only that state is stable with no electric field, and the hysteresis is no longer symmetrical to zero voltage.

The advantage of this photochemical-initiated cross-linking is that the cross-linking can be started—at will after the liquid crystalline polymer is oriented and sufficiently characterized in the uncross-linked state (see Fig. 6). The advantage of using polymerizable groups (acrylates) for cross-linking is that small amounts of these groups are sufficient to transform a soluble polymer into a polymer gel and that the chemical reaction happens far away from the mesogen. Cinnamoyl moieties, on the other hand (23), require a high concentration of these groups for cross-linking. The dimers thus formed are, in addition, nonmesogenic. Figure 7 summarizes the ferroelectric LC-elastomers discussed in this article. Two different positions of cross-linkable groups are used. In polymer P1, the cross-linking group is close to the siloxane chains, which are known to microphase-separate from the mesogenic groups (22,23). Therefore, the cross-linking should proceed mostly within the siloxane sublayers. In polymers P2 and P3, the cross-linking group is located at the end of mesogens. Therefore, the cross-linking should proceed mostly

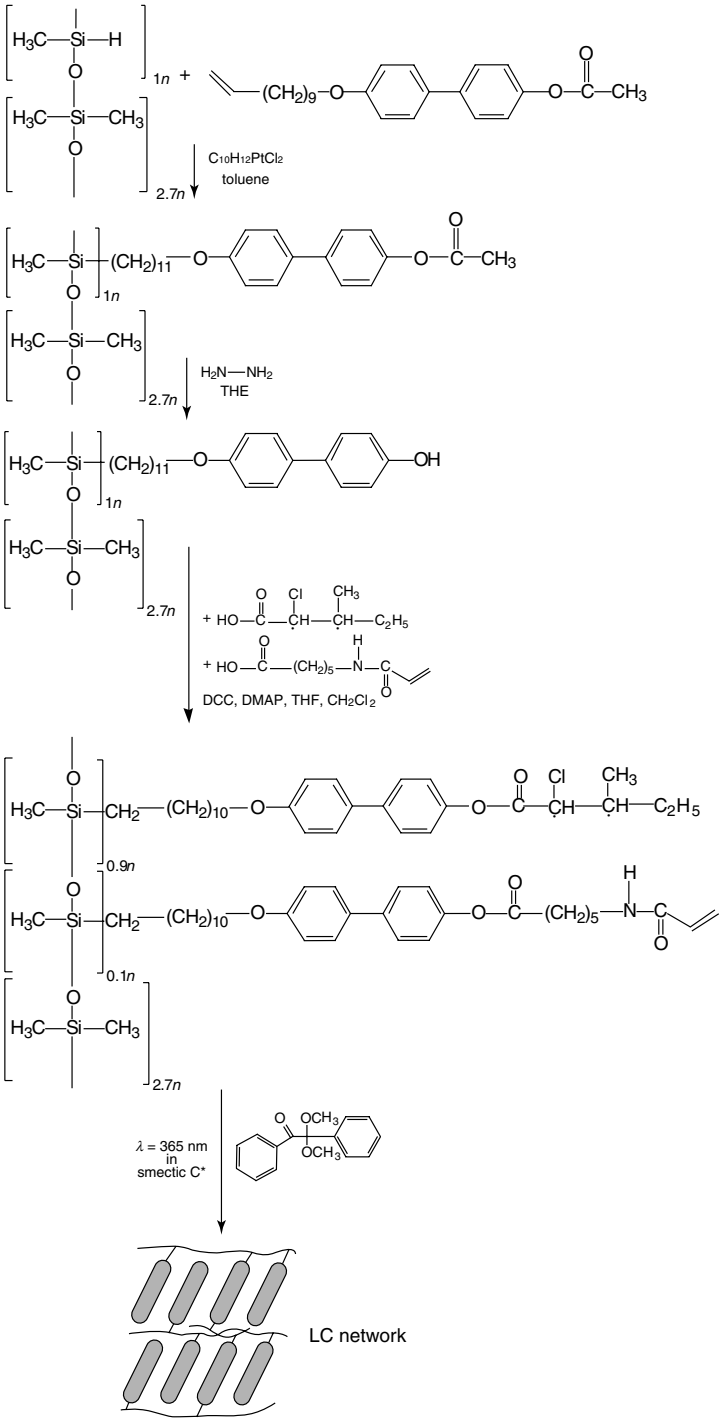

Fig. 5. Synthetic route to the cross-linkable polysiloxane P2 and the following preparation of the oriented smectic C∗ network using uv light in the presence of a photoinitiator (1,1-dimethoxy-1-phenyl-acetophenone) (3).

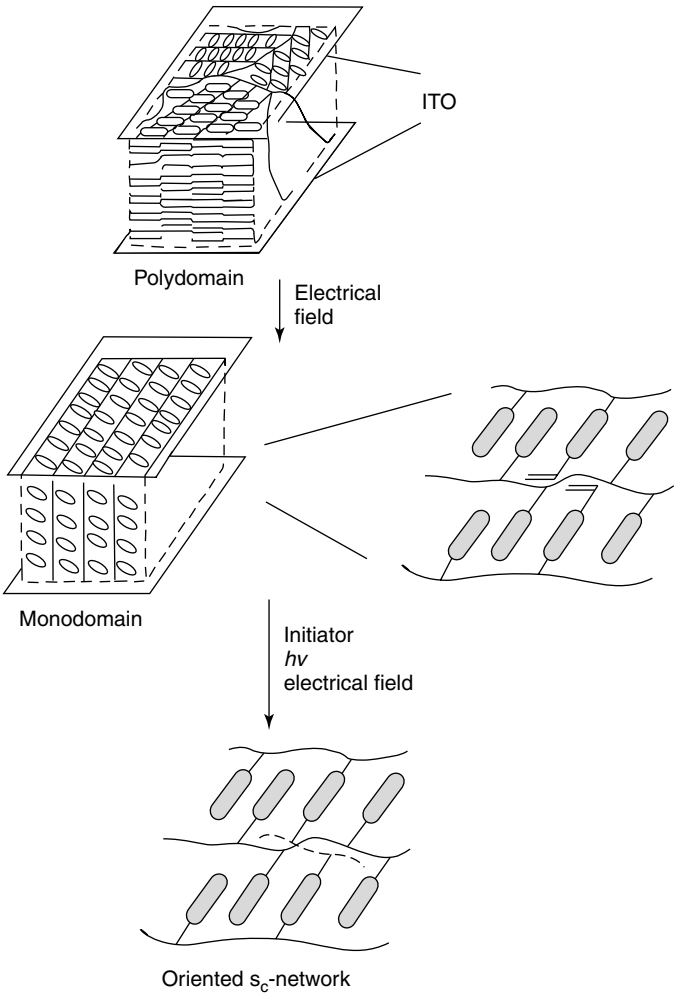

Fig. 6. Preparation of polar smectic C∗ monodomains (3,16) (ITO: indium tin oxide).

between different siloxane layers (see Fig. 7). A comparison of these elastomers allows evaluating structure–property relationships (18,24,25).

Properties and Characterization

Ferroelectric Characterization (Uncross-linked Systems). Before cross-linking, polarization, tilt angle, and switching times can be determined in the usual way (18,22,26). Figure 8 shows the temperature dependence of the spontaneous polarization for polymers P1–P3. For the homopolymer related to polymer P2, all relevant parameters were determined in a careful study (27). It seems that the electroclinic effect is especially strong in these polysiloxanes (16). This has implications for the freezing of a memory of the tilt angle present during

cross-linking. Therefore, ferroelectric elastomers, which have been crosslinked in the smectic A phase while applying an electric field, produce a stable macroscopic polarization (tilt) after cooling into the smectic C$*$ phase (18).

Mechanical Properties of Ferroelectric LC-Elastomers. The cross-linking reactions of a series of copolymers analogous to polymer P2, but differing in the amount of cross-linkable groups, were studied by ftir spectroscopy (17). These measurements show a decrease of the acrylamide double bond on irradiation. Conversions between 60 and 84% were observed. The uncertainty of the conversion, however, is high because only very few double bonds are present in polymer P2 and they are visible in the infrared spectrum at rather low intensity.

Mechanical measurements which show how this photo-chemical cross-linking (conversion of double bonds) leads to an elastic response of the network are, however, still at the beginning because photocross-linking can be performed only in thin layers of a few micrometers. It is best performed between two glass slides to exclude oxygen.

AFM measurements of photocross-linked free standing films show changes in topology during stretching (24). They, however, do not allow measuring elastic moduli.

The most promising approach to obtaining elastic data for these ferroelectric elastomers is investigation of LC-elastomer balloons (25,28). For this purpose, an experimental setup was developed on the basis of an apparatus designed to study smectic bubbles (28). Freely suspended films of the uncross-linked material behave like ordinary smectic films. They can be inflated to spherical bubbles several millimeters in diameter (the thickness of a smectic-layer skin is about 50 nm). These bubbles are stabilized by the smectic-layer structure and their inner pressure p is related to the surface tension and the bubble radius R by the Laplace–Young equation, $p \propto 1/R$. After exposure to uv light, the material is cross-linked, and an anisotropic elastomer is formed. When the cross-linked bubbles are inflated/deflated, the radius–pressure curve reverses its slope and gives direct access to the elastic moduli of the material (25). Because the deformation during inflation of the balloon is isotropic in the layer plane, the material should contract in the direction of the layer normal.

Mechanical measurements of chemically crosslinked LC-elastomers have been made extensively (4,5,29–34). For these systems, it can be shown that stretching allows orientation of the liquid crystalline phase. In ideal situations, it is thus possible to prepare a ferroelectric monodomain by stretching (30,31,35). This result can be rationalized as a two-stage deformation process (see Fig. 9) (31). This possibility of orienting or reorienting the polar axis mechanically is the basis for the piezoelectric properties to be discussed later. Ferroelectric switching could not be observed for any of the chemically crosslinked systems. This may occur because chemically cross-linked films are too thick (several 100 μm compared to about 10 μm for photochemically cross-linked systems) and the electric field applied is therefore too small. In addition, the cross-linking density in chemically cross-linked systems is presumably higher.

Ferroelectric Properties (Cross-linked Systems). The ferroelectric properties of the photochemically crosslinked elastomers E1–E3 differ significantly and depend on the topology of the network formed. For the systems that have interlayer cross-linking (see Fig. 7, E2 and E3), the switching time

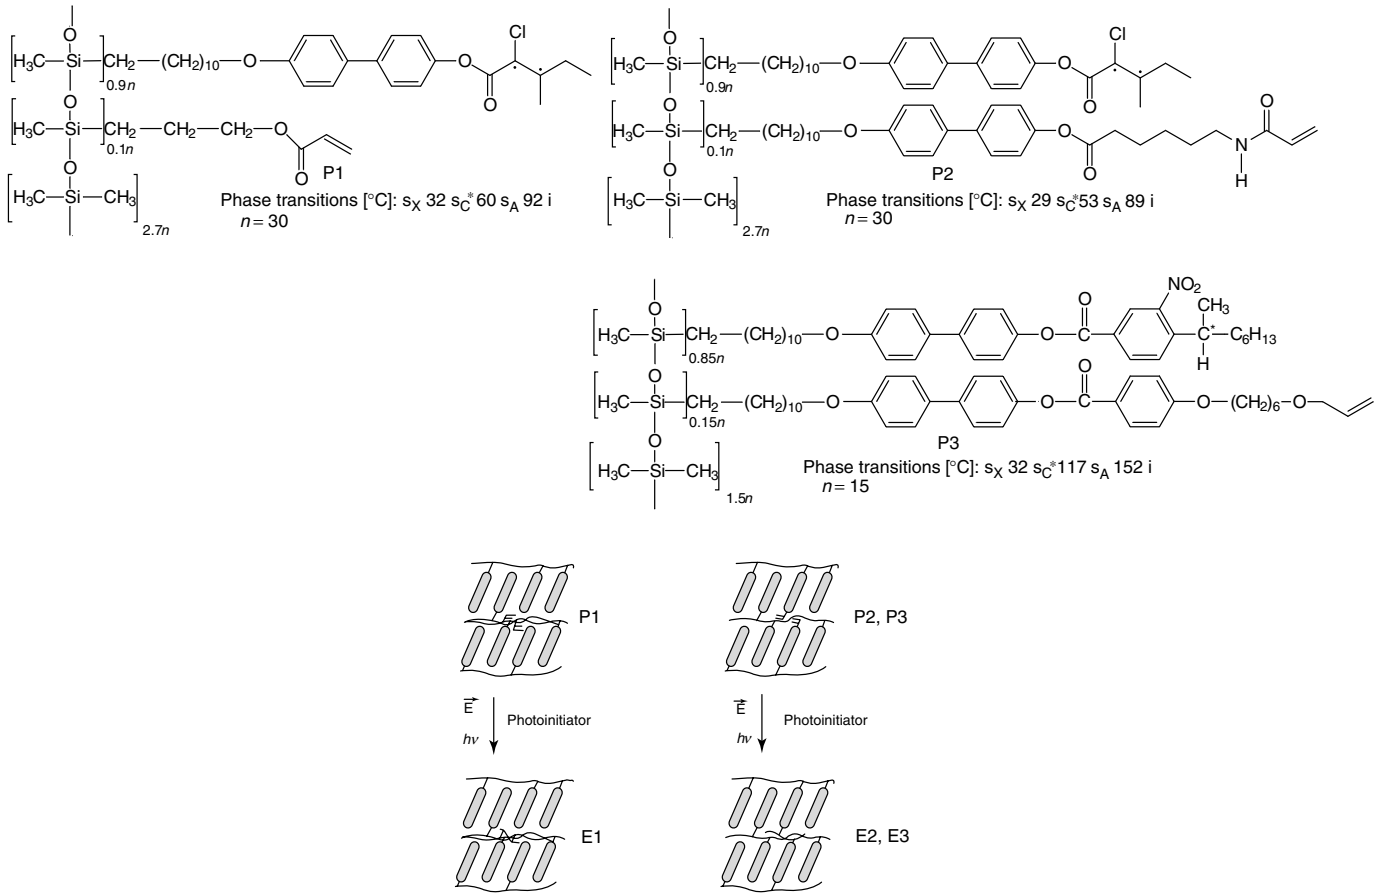

Fig. 7. Chemical structure and phase-transition temperatures of polymers P1–P3 (18). (**a**) P1 is designed to favor intralayer cross-linking; (**b**) P2 and P3 form an interlayer network.

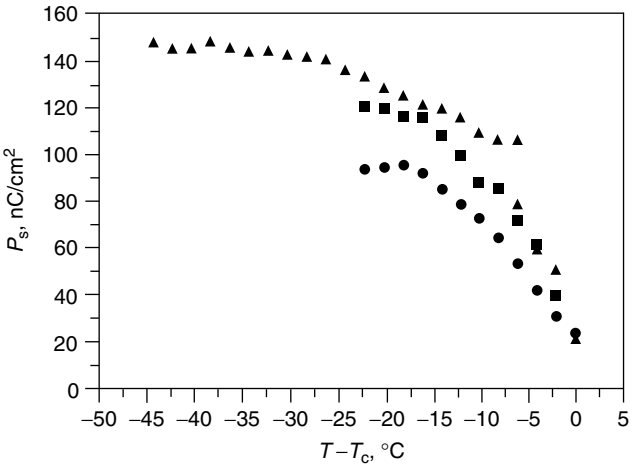

Fig. 8. Temperature dependence of the spontaneous polarization P_S for the polymers P1–P3 measured by the triangular wave method (18). p1 : ■, p2 : ●, p3 : ▲.

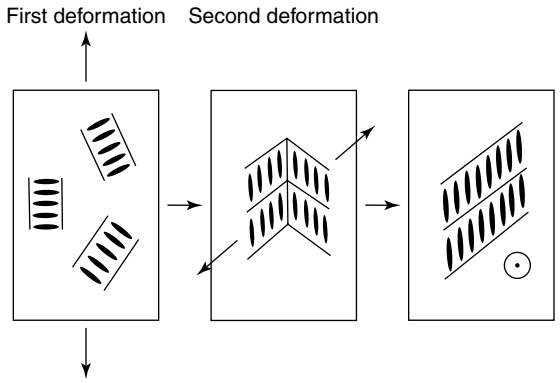

Fig. 9. Two-step deformation process of a chiral smectic C∗ elastomer that displays macroscopic polarization at the end (31).

is increased greatly. Therefore, spontaneous polarization can no longer be determined by the triangular wave method. Slow switching is, however, still possible and therefore ferroelectric hysteresis can be measured optically (see Figs. 3c and 10) (3,16). After photochemical cross-linking in a ferroelectric monodomain, the ferroelectric hysteresis shows stabilization of the orientation present during cross-linking. At zero external voltage, only this state is stable. The second switching state can, however, be reached. Therefore, the network acts like a spring that stabilized one state because switching to the other state leads to a deviation from the most probable conformation of the polymer chain (36) (see Fig. 10). Then, the shift of the center of the hysteretic loop away from zero voltage gives the magnitude of the electric field necessary to balance the mechanical field of the network. The asymmetry of the hysteresis increases with the cross-linking density (18). For

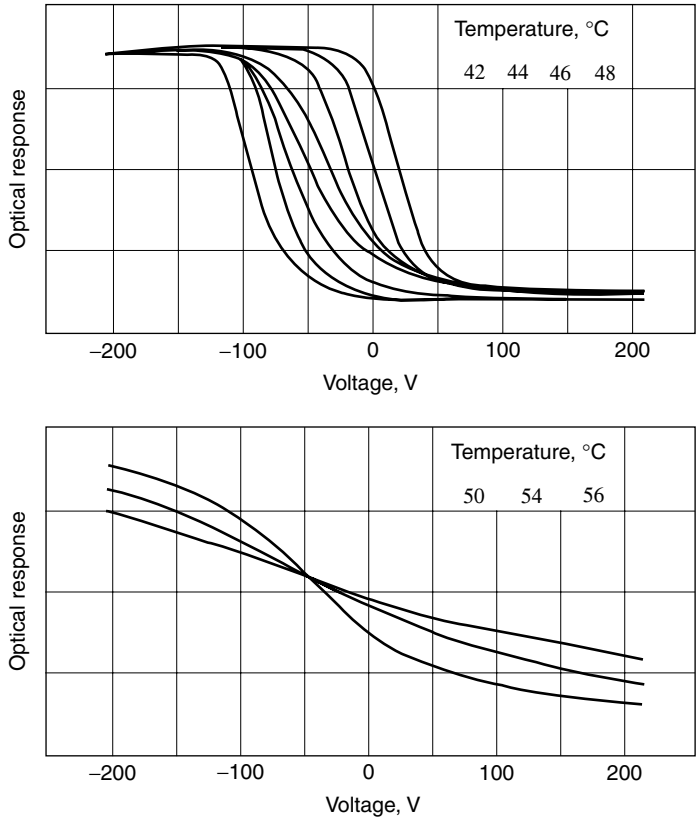

Fig. 10. Temperature dependence of the optical hysteresis of elastomer E2 (S_C* 49°C S_A) (15). (**a**) Ferroelectric behavior of the S_C* phase (42, 44, 46, and 48°C, respectively). (**b**) Electroclinic behavior of the S_A phase (50, 54, and 56°C, respectively).

high cross-linking densities, switching remains possible only if the spontaneous polarization is rather high (18). Otherwise, the network prohibits switching. The asymmetry of ferroelectric switching could also be proven by polarized ftir spectroscopy (37). Increasing the temperature of this ferroelectric elastomer leads to narrowing of the hysteretic loop, which is lost at the transition to the smectic A phase (see Fig. 10).

This behavior is best interpreted by plotting the liquid crystalline potential, the elastic potential of the network, and their superposition in one graph (16) (see Fig. 11). As the network is formed in the smectic C* phase, an internal elastic field is created, which has its minimum value for the tilt angle and tilt direction during cross-linking. Other tilt angles are destabilized.

The elastomer that has preferable intralayer cross-linking (E1, see Fig. 7) shows completely different behavior (see Fig. 12) (18,38). In this case, the switching time increases by less than a factor of 2, the polarization can still be determined, and measurement of the ferroelectric hysteresis shows no stabilization of the switching state present during cross-linking. Then, the coupling between the orientation of the mesogens and the network conformation is obviously very

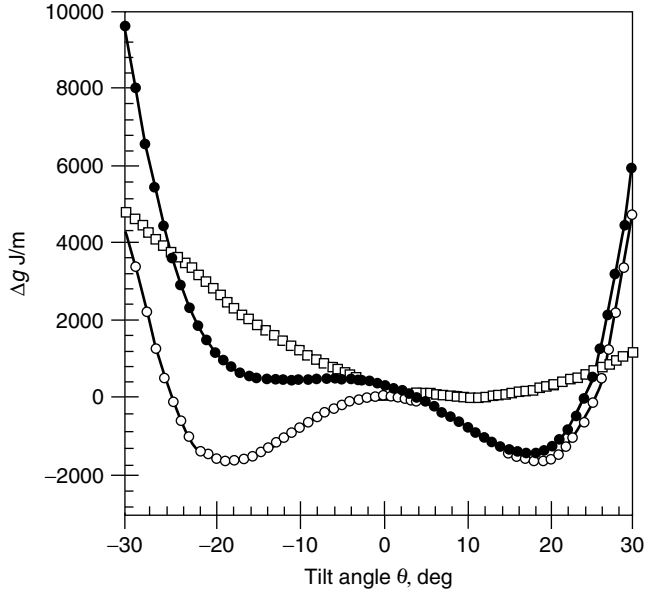

Fig. 11. Effect of network force on the free energy density (16) 2 K below the phase transition, S_C* phase: (○) calculated potential of the S_C*phase, (◇) force due to the network, and (●) superposition of both.

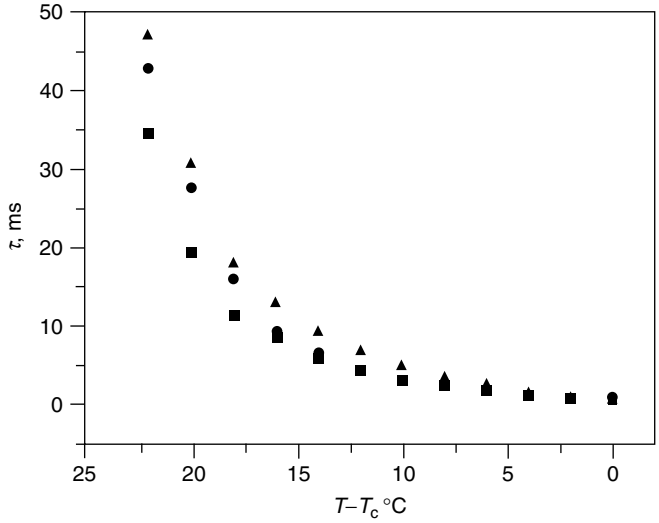

Fig. 12. Temperature dependence of the switching time τ (defined as 0–100% change in transmission) for P1 and E1 [see Ref. 18 for comparison].

weak. The network stabilizes the smectic layer structure, but it does not stabilize the tilt direction. Therefore, the polar axis can be switched easily. This is the result of the network topology (see Fig. 7) in which interlayer cross-linking is rare.

AFM Imaging of Thin Films. Freestanding films can be prepared from uncross-linked polymers (see also the smectic balloons in this context). They can be photocross-linked and transferred to a solid substrate. Thereafter, the topology of the films can be imaged by afm, which gives direct visualization of the smectic layer structure at low temperatures. The uncross-linked polymers can only be imaged at low temperatures, deep inside the smectic phase and in the tapping mode, which does not induce strong lateral forces. At higher temperatures, the sample is too soft and mobile to allow imaging. Cross-linked elastomers, on the other hand, are mechanically stable, and films sustain the tapping mode and also the contact mode of the atomic force microscope (39). This holds both for intra- and interlayer cross-linked systems. Because measurements can be done in all phases, it is also possible to determine the change of the smectic layer thickness at the phase transitions directly. For elastomer E1, for example, the smectic layer thickness is 4.2 nm in the smectic C$*$ phase (36°C, tilt angle about 30°). It increases to 4.4 nm at 50°C in the smectic A phase (39). This corresponds to x-ray measurements.

To analyze the impact of the molecular structure on network properties, elastomers are compared, which are identical except for the molecular position of the cross-linkable group: (*1*) elastomer E1 that has cross-linkable groups attached to the backbone via a short spacer (intralayer cross-linking) and (*2*) elastomer E2 where the cross-linkable group is in the terminal position of a mesogenic side group (interlayer cross-linking) (24,40). When mechanical stress (stretching) is imposed on thin films in homeotropic orientation, the two elastomers react differently to the deformation (24,40), as seen by afm imaging of the surface topology (see Fig. 13). For elastomer E1, "intralayer" cross-linking results in two-dimensional networks in the backbone layers, separated by liquid-like FLC side-group layers. Because there are practically no vertical connections in this intralayer network, no vertical distortions occur. Therefore, this elastomer can be stretched up to 100%, the surface remains smooth, and the layers deform affinely. In elastomer E2, a three-dimensional "interlayer" network is formed; the system reacts by distorting the smectic layering. Therefore, only smaller stretching ratios are accessible and the surface roughens and buckles during stretching. The distortion strength increases with a higher cross-linking density.

Piezoelectric Properties of Ferroelectric LC-Elastomers. Because a ferroelectric material has to be piezoelectric (see Fig. 1), observation of a piezoresponse is natural. It has been observed for ferroelectric LC-elastomers (3,16,19–21) and also for more densely cross-linked systems (10,31,41,42) for which no ferroelectric switching could be observed. For the elastomers described here it is, however, possible to change the piezoresponse (3) by reorienting the polar axis in an external field (see E2 in Fig. 14). For this experiment, the polar axis was kept in one orientation during cross-linking. This resulted in a positive piezoresponse (see Fig. 14). Thereafter, the direction of the polar axis was inverted by applying an external field of opposite direction. Then, the external field was removed and the piezocoefficient was measured. At first, a piezoresponse of opposite sign (negative) but identical value is determined (see Fig. 14). In the field-free state, this piezoresponse continuously decreases, it goes through zero, increases again, and finally reaches the original positive value. This experiment is comparable to the hysteresis measurements of Figs. 3 and 10 because it shows

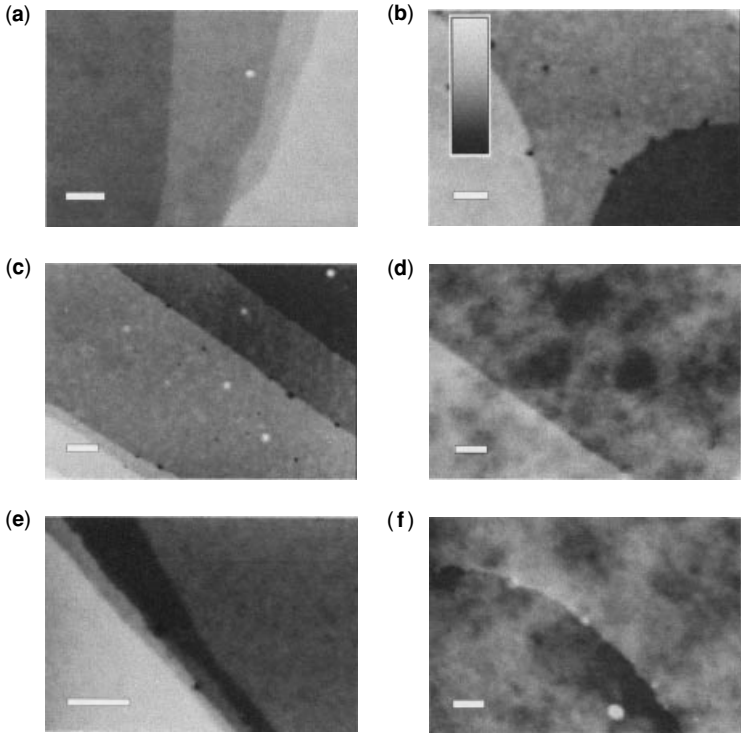

Fig. 13. Surface topography of prepared and stretched transferred films of elastomer $E1_{x=0.1}$ (**a**: $\lambda = 0$, **b**: $\lambda = 10\%$), $E2_{x=0.07}$ (**c**: $\lambda = 0$, **d**: $\lambda = 12\%$), and $E2_{x=0.25}$ (**e**: $\lambda = 0$, **f**: $\lambda = 2\%$,). Scale bars 1 μm, height scale 25 nm valid for all images. The surface of all polymers show plateau patterns. In the E2 samples, the lateral strain leads to surface deformation (40).

that two polar states are accessible, but the one present during cross-linking is stabilized.

The shape variation under application of an external electric field was most intensively studied for microtomized pieces of ferroelectric elastomers, which had been oriented by drawing (19–21). These experiments show only a small shape variation if the field is applied parallel to the polar axis of the monodomain. The effects become, on the other hand, rather large if the smectic layer structure (chevron texture) rearranges (19,21). To get a large electrostrictive response, which can be understood on a molecular level, the geometry presented in Fig. 15 was chosen (43). The application of an electric field parallel to a smectic layer leads to a tilt of the mesogens (electroclinic effect). Thereby, the thickness of the layer decreases. For a stack of layers, the effect sums up over all layers. As a result, the thickness perpendicular to the smectic layers decreases if a field is applied parallel to the layers (see Fig. 15). Because the electroclinic effect is relatively large in these polymers (16,37), a large variation in thickness is expected.

X-ray diffraction measurements prove the electrically induced shrinkage of single smectic layers. A freestanding ultrathin (75 nm) film of a ferroelectric liquid

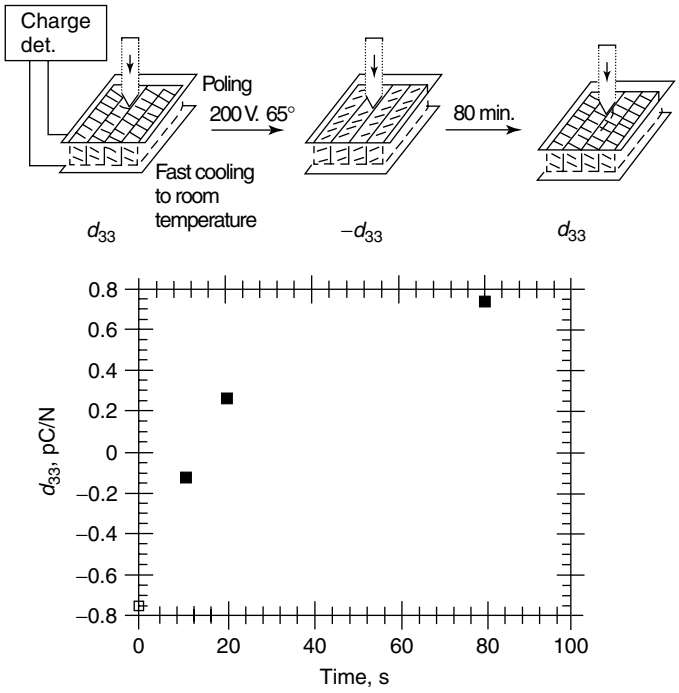

Fig. 14. Relaxation of the piezocoefficient d_{33} of elastomer E2 at room temperature after reversal poling at 65°C (S_A phase) (3).

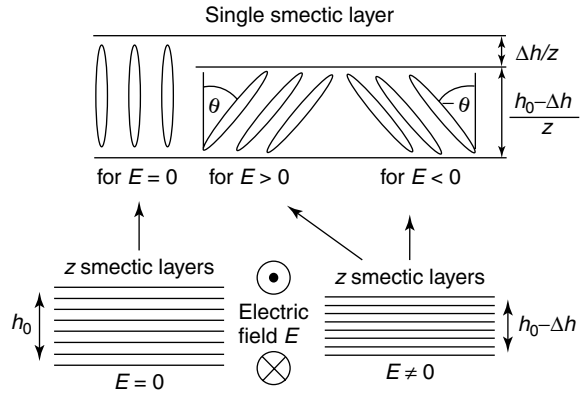

Fig. 15. In the S_A* phase, the mesogenic parts (depicted as ellipsoids) of the elastomeric macromolecule stand upright ($\theta = 0°$) inside the single smectic layers. By applying a lateral electric field (perpendicular to the plane of the paper), a tilt angle θ that is proportional to the electric field E can be induced (electroclinic effect). The sign of the tilt depends on the sign of the electric field E. Hence, each smectic layer shrinks by $\Delta h/z$ twice during one period of the electric field. The shrinkage Δh of the whole film is measured by the interferometer as an optical phase shift between the sample beam and the reference beam.

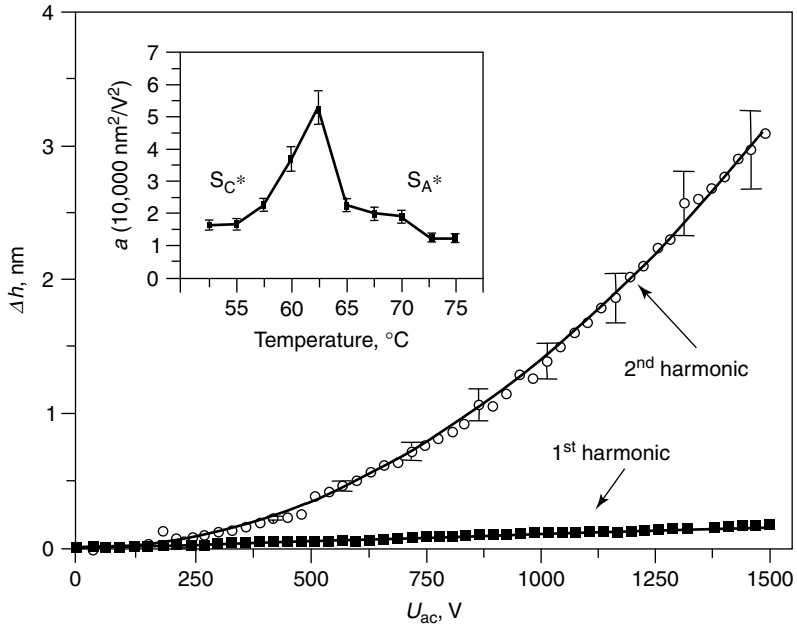

Fig. 16. Electrostriction of a ferroelectric LC-elastomer (43). Big diagram: Thickness variation Δh as a function of the applied ac voltage U_{ac}. Interferometric data were obtained at the fundamental frequency of the electric field (piezoelectricity, first harmonic: +) and at twice the frequency (electrostriction, second harmonic: ○). Sample temperature: 60°C. Inset: Electrostrictive coefficient a (+) versus temperature. At the temperature where the non-cross-linked polymer would have its phase transition S_C*–S_A* (about 62.5°C), the tilt angle of 0° is unstable. That is why the electroclinic effect is most effective at this temperature. An electric field of only 1.5 MV/m is sufficient to induce lateral strains of more than 4%.

crystalline elastomer (similiar to E2) was used to measure the shape variation (electrostrictive response) associated with this (43). It was measured by a high precision (±3 pm at 133 Hz) Michelson interferometer. The measurements (see Fig. 16) exhibit extremely high electrostrictive strains of 4% in an electric field of only 1.5 MV/m, which is, to our knowledge, a new world record for the corresponding electrostrictive coefficient a. The effect exhibits typical electroclinic behavior, which means that it is caused by an electrically induced tilt of the chiral LC molecules. As a consequence of chirality, the primary strain is perpendicular to the applied field. Hence, a new material that has a giant electrostriction effect is introduced, where the effect can be fully understood on a molecular level.

FIBERS, ELASTOMERIC

Introduction

Elastomeric fibers can be made from natural or synthetic polymeric materials that provide a product with high elongation, low modulus, and good recovery from stretching. Currently, these fibers are made primarily from polyisoprenes (natural rubber) or segmented polyurethanes, and to a lesser extent from segmented polyesters. In the United States the generic designation "spandex" has been given to a manufactured fiber in which the fiber-forming substance is a long-chain synthetic polymer consisting of at least 85% of a segmented polyurethane (1); in Europe the equivalent term "elastane" is commonly used.

The experimental production of elastomeric fibers based on segmented polyurethanes (qv) was first reported in the early 1950s by Farbenfabriken Bayer, a pioneer in urethane and diisocyanate chemistry (2,3). This was followed by semicommercial-scale production of polyurethane-based fibers by DuPont, in the late 1950s (4,5). Prior to development of the polyurethanes, most elastomeric fibers were made with natural rubber. Two processes were used: slitting rubber sheets to produce cut-rubber threads or extruding rubber latex into an acid coagulation bath, followed by washing, drying, and curing. Smaller amounts of cut-rubber threads have also been produced from synthetics such as neoprene and nitrile rubbers, especially where improved solvent resistance is required. Fiber cross sections are square or rectangular for cut rubbers and essentially round for extruded latex threads.

Thermoplastic, inelastic fibers, such as nylon and polyester, may be processed to provide spring-like, helical, or zigzag structures. These fibers can exhibit high elongations as the helical or zigzag structure is stretched, but the recovery force is very low. This apparent elasticity results from the geometric form of the filaments

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

as opposed to elastomeric fibers whose elastic properties depend primarily on entropy changes inherent within their polymer structure. Thus processed inelastic fibers must comprise a significant portion of a stretch fabric whereas an elastomeric fiber provides the necessary stretch properties at 5–20% of fabric weight.

Other elastomeric-type fibers include the biconstituents, which usually combine a polyamide or polyester with a segmented polyurethane-based fiber. These two constituents are melt-extruded simultaneously through the same spinnerette hole and may be arranged either side by side or in an eccentric sheath–core configuration. As these fibers are drawn, a differential shrinkage of the two components develops to produce a helical fiber configuration with elastic properties. An applied tensile force pulls out the helix and is resisted by the elastomeric component. Kanebo Ltd. has introduced a nylon–spandex sheath–core biconstituent fiber for hosiery, with the trade name Sideria (6).

Nonspandex elastomeric fibers are based on segmented polyesters; the fibers produced can be melt-spun into threads (7). The generic name for these fibers has been designated as "elastoesters" by the Federal Trade Commission because even though they are similar to polyester fibers chemically, they are physically different enough to warrant a new name. Teijin Ltd. produces an elastomeric fiber of this type with the trade name Rexe (see also POLYESTERS, FIBERS).

Chemical Composition

Rubber. Natural rubber, *cis*-1,4-polyisoprene [104389-31-3], itself is not elastomeric, but is converted into an elastomer for elastomeric fibers by blending the polymer with sulfur, and curing the material at an elevated temperature to promote vulcanization (see RUBBERS NATURAL). Prior to heat treatment the polymer mixture is either cast into a film and the final product is slit into rectangular threads, or the polymer mixture is extruded through a capillary to form a round rubber fiber. The molecular weight of the polymer between cross-links is of the order of 3000–10,000. The *cis*-1,4-polyisoprene chains are flexible and highly mobile because of the ease of rotation of the four-carbon unit in the polymer molecules. The chains are randomly oriented in the relaxed state at room temperature. The force required to stretch the fiber initally is very low, but at higher extensions the chains begin to crystallize, increasing the modulus and breaking strength of the fiber. Stretch-induced crystallization is an important property for elastomeric materials so that they may survive textile processing and wear without breaking. If the material is stretched to an extension below its breaking point, elastomeric fibers have the ability to return to their original unstretched dimension. After the stretching force is removed the covalent cross-links in the rubber thread and the mobility of the polymer chains are responsible for returning the stretched fiber to its original dimension.

Rubber threads are susceptible to oxidative degradation, and high concentrations of antioxidants are added to the mixture to make the high surface area fibers more resistant. Pigments, such as titanium dioxide, are used as fillers or to impart whiteness to the thread. Carbon black reinforcement is used in colored rubber materials. Other agents include accelerators and activators to promote the vulcanization process. With all the additives, a typical high grade rubber thread contains less than 85% elastomer.

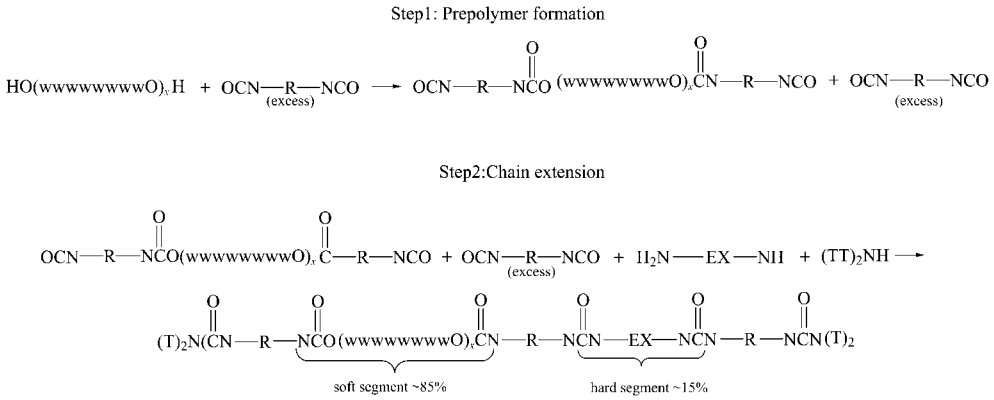

Fig. 1. Two-step synthesis of spandex polymer.

Synthetic rubber threads can also be produced, but do not have the same elastomeric properties as natural rubber because the polymer chains are less mobile and do not crystallize at high elongations. They are used in applications which require solvent resistance.

Spandex. Elastomers made for spandex fibers are segmented block copolymers that consist of a flexible "soft" segment made of long polyether or polyester sections that are liquid at the use temperature and therefore flow past each other and allow the fiber to stretch, and rigid "hard" segments that hydrogen bond between polymer chains to provide recovery after stretching back to the fiber's original dimension. The elastomer is made in a two-step reaction (Fig. 1), in which a prepolymer is made by reacting each end of the bifunctional macroglycol of 1000–4000 molecular weight with an excess of diisocyanate molecules to form an isocyanate-terminated prepolymer. The soft segment macroglycol can be either a polyether, a polyester, a polycarbonate, hydroxyl-terminated polycaprolactone, or a combination of these. Urethane groups are formed by the reaction of each end of the glycol polymers with one end of the diisocyante molecule. In the second step of polymerization, the rigid small diamine or diol molecules react both with the excess diisocyanate molecules and with the isocyanate ends of the prepolymer to extend the polymer chain into an elastomeric polymer. Urea groups are formed by the reaction of each isocyanate group and amine end. The molecular weight of the polymer is controlled by a monofunctional secondary amine molecule to give molecular weight of the order of 50,000–100,000. The general formula can be written as shown in Figure 1.

The long soft segment makes up between 80- and 85% of the polymer weight. For the fiber to be elastomeric the soft segment material must be a liquid at room temperature in order for these segments of the chain to be mobile and allow the yarn to be easily stretched. The other 15–20% of the polymer weight is made up of the rigid hard segment material. The urea groups in the hard segment can interact with one another by hydrogen bonding to form a psuedo crosslink. This is one of the most important characteristics of a spandex polymer for the balance of properties and processing advantages.

Because the polymer chains do not need to undergo a cross-linking step prior to spinning, the fibers can be made by economical solution or melt-spinning

methods. The cross-linking step required in conventional rubber processing is eliminated with a spandex polymer. The majority of the hydrogen bonding then occurs in the spinning cell. With fiber formation, hard segments from several chains associate into strongly bonded cluster domains which aggregate and convert the polymer to a phase-separated, three-dimensional network (8). Each phase has a different glass-transition temperature. The "tie points" allow the soft segments of the chains to slide past one another to a limit determined by the hard segment resistance. A liquid soft segment at the temperature the yarn will be used, and interacted/cross-linked chains are necessary characteristics of a synthetic spandex polymer.

Interchain bonding must be not only strong enough to prevent molecular slippage, but also concentrated so that the connecting soft segments can comprise a large fraction of the polymer chain. This result in high stretch along with low modulus. Urea hard segments that comprise less than 25% of polymer mass provide this needed concentrated bonding force. In contrast, the network structure in rubber depends on covalent bonds between chain molecules that result from vulcanization with sulfur. In both polyurethanes and rubber, modulus is directly related to tie-point density. Similarly, the relationship for maximum elongation is an inverse function of tie-point density. In rubber fibers, tie-point density is controlled by the amount of vulcanizing agent, accelerant, and reaction conditions. In polyurethanes, tie-point (hard segment) density is controlled by the soft segment molecular weight and the molar ratio used to prepare the glycol–diisocyanate prepolymer.

Mechanical Properties

In both rubber thread and spandex fibers, mechanical properties may be varied over a relatively broad range. In rubber, variations are made in the degree of cross-linking or vulcanization by changing the amount of vulcanizing agent, usually sulfur, and the accelerants used. In spandex fibers, many more possibilities for variation are available and there are a large number of polymers in the classification. Mechanical properties (qv) may be affected by changing the particular polyester or polyether glycol, diisocyanate, diamine(s), and monoamine used; they can be further modified by changing the molecular weight of the glycol and by changing the glycol–diisocyanate molar ratio (9,10).

The physical characteristics of current commercial rubber and spandex fibers are summarized in Table 1. Typical stress–strain curves for elastomeric fibers, hard fibers, and hard fibers with mechanical stretch properties are compared in Figure 2.

Manufacture

To produce cut-rubber thread, smoked rubber sheet or crepe rubber is milled with vulcanizing agents, stabilizers, and pigments. This milled stock is calendered into sheets of 0.3–1.3-mm thickness, depending on the final size of the rubber thread desired. Multiple sheets are layered, heat-treated to vulcanize, and then slit into

Table 1. Physical Properties of Elastomeric Fibers

Property	Spandex	Extruded rubber	Cut rubber
Sizes available[a]	1.1–250 tex[b]	16–610 tex[b]	2.5–21 μm dia[c]

Abrasion resistance	Very good	Poor	Poor

[a]Spandex size is usually expressed in denier which is weight in g/9000 m length. However, the SI unit is tex, the weight in g/1000 m. Rubber size is expressed as gauge, which is the reciprocal of diameter or size in inches.
[b]To convert tex to den, multiply by 9.09.
[c]1200–10,000 gauge.
[d]To convert N/tex to g·f/den, multiply by 11.33.
[e]First cycle stress at 300% elongation.
[f]Both spandex fibers and rubber threads normally contain antioxidants and other stabilizers.

threads for textile uses (Fig. 3). Individual threads have either square or rectangular cross sections.

In the manufacture of extruded latex thread, a concentrated (up to ca 50% solids) natural rubber latex is blended with aqueous dispersions of vulcanizing agents, stabilizers, and white pigments. This compounded latex is held under controlled temperature conditions until partial vulcanization occurs. This has the effect of increasing wet strength and thus the processibility of the extruded threads. The matured latex is extruded at constant pressure through precision-bore glass capillaries into a 15–55% acetic acid [64-19-7] bath where coagulation into thread form occurs. Threads are removed from the coagulation bath by transfer rollers, washed free of excess acid with water, and conducted through a dryer, after which a silicone oil-based finish is applied and the threads are formed into multiend ribbons. The ribbons are then vulcanized by multiple passes on a conveyer belt through an oven that can increase curing temperature in stages up to about 150°C. After vulcanization the multiend ribbons are packed without support in boxes for shipment to the customer. A typical extruded latex thread production line is shown in Figure 4. Latex thread production rates vary with thread size and equipment but, owing to hydrodynamic drag and the weak nature of the coagulating thread, maximum line take-up speeds are about 30 m/min.

Four different processes are currently used to produce spandex fibers commercially: melt extrusion, reaction spinning, solution dry spinning, and solution wet spinning. As shown in Figure 5, these processes involve different practical applications of basically similar chemistry. If the diol or diamine(s) reaction with the prepolymer is carried out in a solvent, the resulting block copolymer solution may

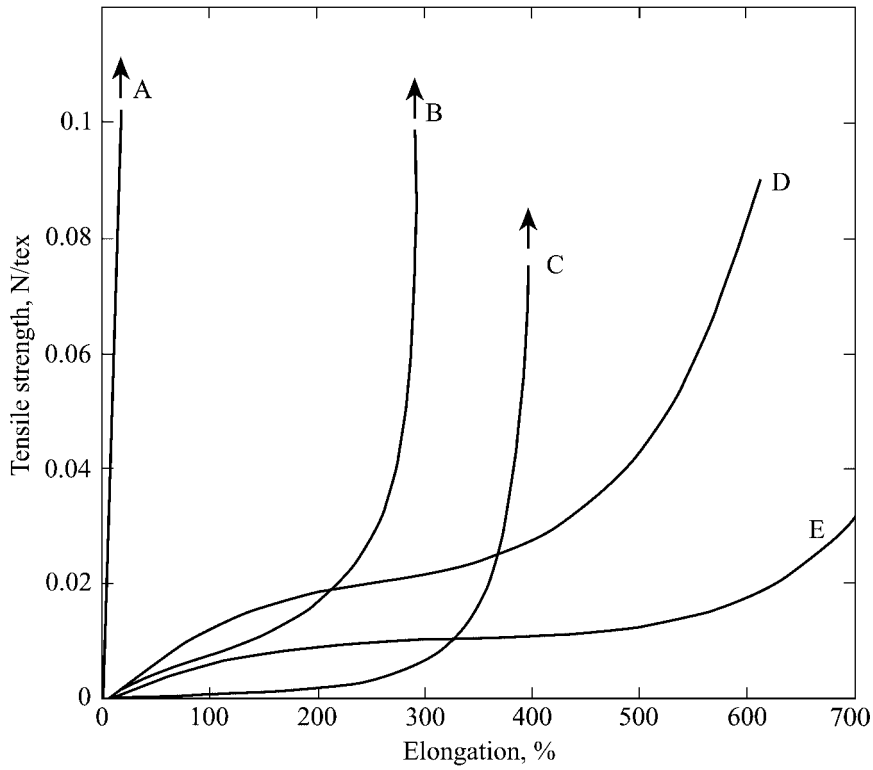

Fig. 2. Stress–strain curves: A, hard fiber, eg, nylon; B, biconstituent nylon–spandex fiber; C, mechanical stretch nylon; D, spandex fiber; E, extruded latex thread. To convert N/tex to g·f/den, multiply by 11.33.

be wet- or dry-spun into fiber. Alternatively, the prepolymer may be reaction-spun by extrusion into a bath containing diamine to form a fiber, or the prepolymer may be permitted to react in bulk with a diol and the resulting polymer melt-extruded in fiber form.

Currently, the principal producer of melt-spun spandex fibers is Far Eastern Textile, Ltd., in Taiwan. However, melt-spun spandex fibers are also produced by Nisshinbo Industries, Inc., and Kanebo Goshen, Ltd., both in Japan. Because of thermal stability constraints, only polymers that contain all urethane hard segments (glycol extended) can be melt-extruded. The intermolecular association between all urethane hard segments is inherently weaker compared with urea-based hard segments produced from diamine extenders; melt-spun fibers are normally made at higher diisocyanate–glycol ratios which in effect produce a relatively longer hard segment to compensate for the weaker intermolecular bonding forces.

More recently, melt-spun biconstituent sheath–core elastic fibers have been commercialized. They normally consist of a hard fiber sheath (polyamide or polyester) along with a segmented polyurethane core polymer (11,12). Kanebo Ltd. in Japan currently produces a biconstituent fiber for hosiery end uses, called Sideria.

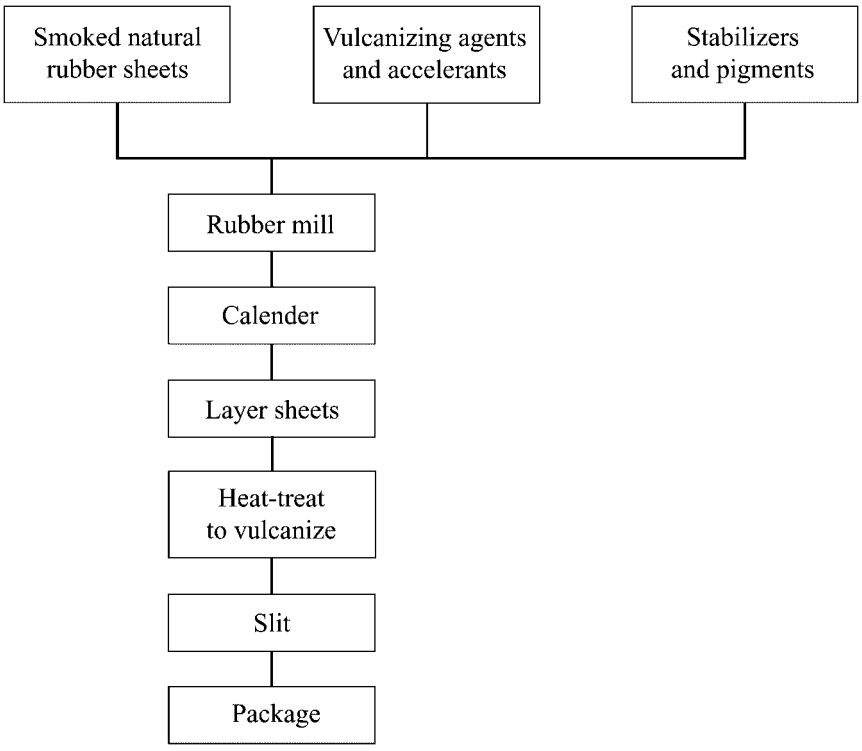

Fig. 3. Cut-rubber thread manufacture.

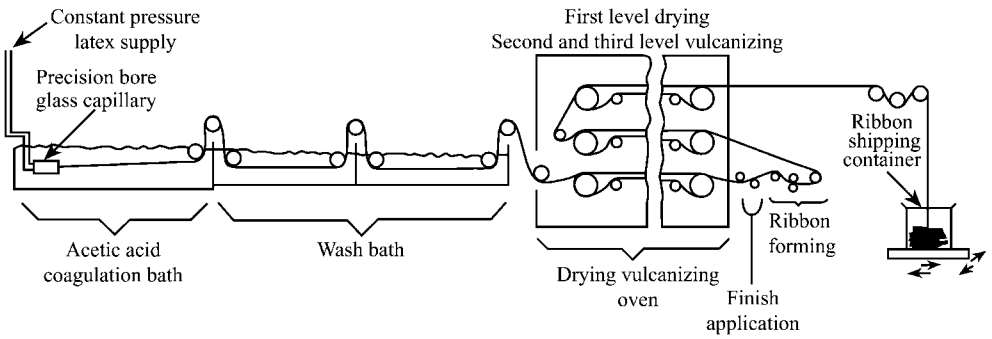

Fig. 4. Extruded latex thread production.

Several commercial spandex fibers were produced by reaction spinning in the 1950s by Globe Manufacturing Co. (13). This was the only producer of reaction-spun spandex fibers. Recently Radicci Spandex Corp. acquired Globe Manufacturing and its assests. Reaction-spun fibers include only products 7.7 tex (70 den) or higher; finer Radicci spandex fibers are dry-spun.

To produce a spandex fiber by reaction spinning, a 1000–3500 molecular weight polyester or polyether glycol reacts with a diisocyanate at a molar ratio of about 1:2. The viscosity of this isocyanate-terminated prepolymer may be adjusted

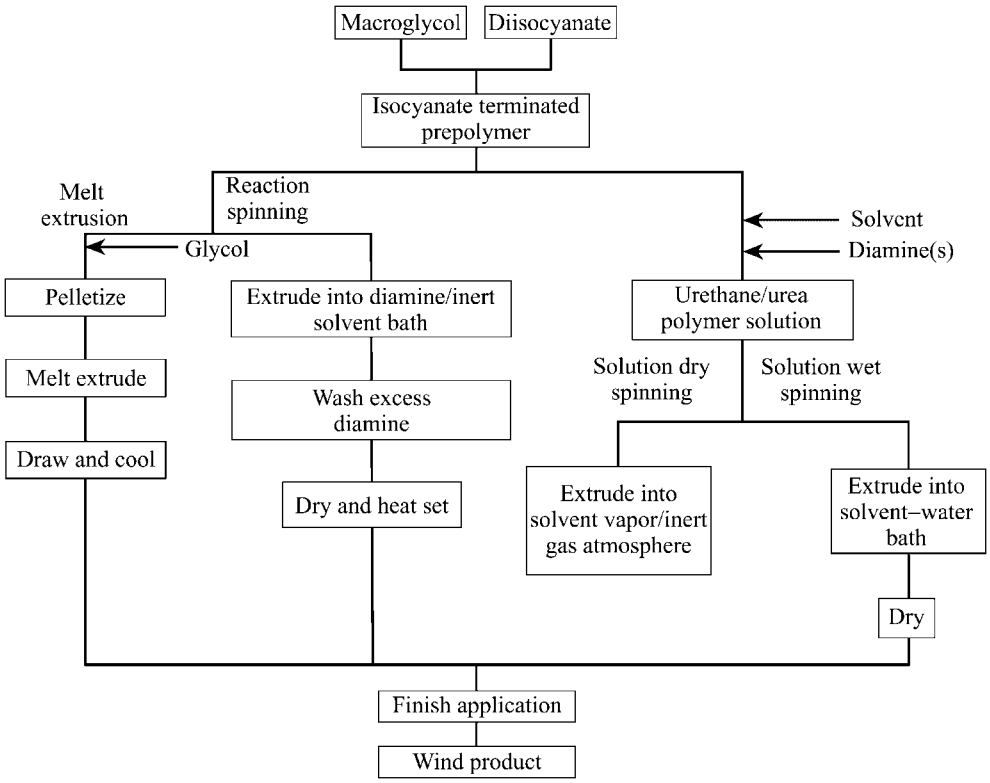

Fig. 5. Spandex fiber production methods.

by adding small amounts of an inert solvent, and then extruded into a coagulating bath that contains a diamine so that filament and polymer formation occurs simultaneously. Reactions are completed as the filaments are cured and solvent evaporated on a belt dryer. After application of a finish, the fibers are wound on tubes or bobbins and rewound if necessary to reduce interfiber cohesion.

Trifunctional hydroxy compounds, eg, glycerol [56-81-5] or 2-ethyl-2-(hydroxymethyl)-1,3-propanediol [787-99-6], may be added with the macroglycol to produce covalent cross-links in the reaction-spun spandex fiber. Also, covalent cross-links may result from allophanate and/or biuret formation during curing by reaction of free isocyanate end groups with urethane or urea —NH groups along the polymer chain. A multiplicity of filaments are normally extruded from each spinnerette of about 1.1–3.3 tex (10–30 den), and then collected in bundles of the desired tex at the exit of the reaction bath. This approach makes the surface area-to-mass ratio and diamine diffusion into the prepolymer cross section substantially constant irrespective of the final tex produced, thus minimizing condition changes required in changing tex. Because the individual filaments have reacted incompletely and are in a semiplastic state at the exit of the diamine bath, they interbond quite tightly into a fused multifilament. Production speeds in reaction spinning are limited by filament weakness in the bath along with hydrodynamic drag. Take-up speeds are limited to about 100 m/min.

Stabilizers and pigments are normally slurried with macroglycol and added to the polymeric glycol charge, prior to diisocyanate addition. Therefore, care must be taken to avoid additives that react significantly with diisocyanates or diamines under processing conditions. Also, stabilizers should be chosen that have no adverse catalytic effect on the prepolymer or chain-extension reactions.

Reaction-spinning equipment is quite similar to that of solution wet spinning. It differs principally in the use of fewer wash baths and in the use of belt-type dryers instead of heated cans.

The initial step to prepare polyurethane polymers for solution wet or dry spinning includes reaction of 1000–3500 molecular weight macroglycol with a diisocyanate at molar ratios of between about 1:1.4 and 1:2.0. Reaction conditions must be carefully selected and controlled to minimize side reactions, eg, allophanate and biuret formation, which can result in trifunctional branched chains and ultimately to insoluble cross-linked polymers. For the prepolymer reaction, poly(tetramethylene ether) glycol [25190-06-1] and bis(4-isocyanatophenyl) methane [101-68-8] are currently the most commonly used macroglycol and diisocyanate. Several types of polyester-based macroglycols are included in spandex producers product lines, but with the exception of Dorlastan, made by Bayer AG in Germany, the polyester-based products represent only a minor part of their spandex fiber production.

In the polymerization reaction, called chain extension, the prepolymer is dissolved in a solvent and reacts with diamine(s) to form a urethane–urea polymer in solution. In all commercial processes, the solvent used is either *N*,*N*-dimethylformamide [68-12-2] or *N*,*N*-dimethylacetamide [127-19-5]. Normally, one or two diamines are used as chain extenders. Because the reaction of diamine with diisocyanate is exceedingly rapid, prepolymer is normally diluted with solvent so that mixing in the polymer reactor is optimized. An improved mixing and chain-extension process has been described, whereby the solvent-diluted prepolymer is separated into two groups with chain extension being initiated by reaction of diamine solution with one of these groups, after which the prepolymer of the other group is mixed in and chain extension is completed (14). Molecular weights of polymers made in solution can be controlled by adding small amounts of a secondary monoamine to provide dialkylurea end groups. Branching reactions must be minimized in order to obtain a stable polymer solution for spinning. Stoichiometry of polymerization is normally adjusted to provide a urethane polymer solution of 20–40% solids and viscosity of 100–200 Pa·s (1000–2000 P). The viscosities and solids of solutions for dry spinning are generally higher than those used for wet spinning.

Stabilizers, pigments, and other additives (qv) are milled in spinning solvent, normally along with small amounts of the urethane polymer to improve dispersion stability; this dispersion is then blended to the desired concentration with polymer solution after chain extension. Most producers combine prepolymerization, chain extension, and additive addition and blending into a single integrated continuous production line.

On a worldwide basis, greater than 90% of all spandex fibers are produced by various adaptations of dry-spinning (15,16). The solution dry-spinning process is illustrated in Figure 6. The polymer spinning solution is metered at a constant

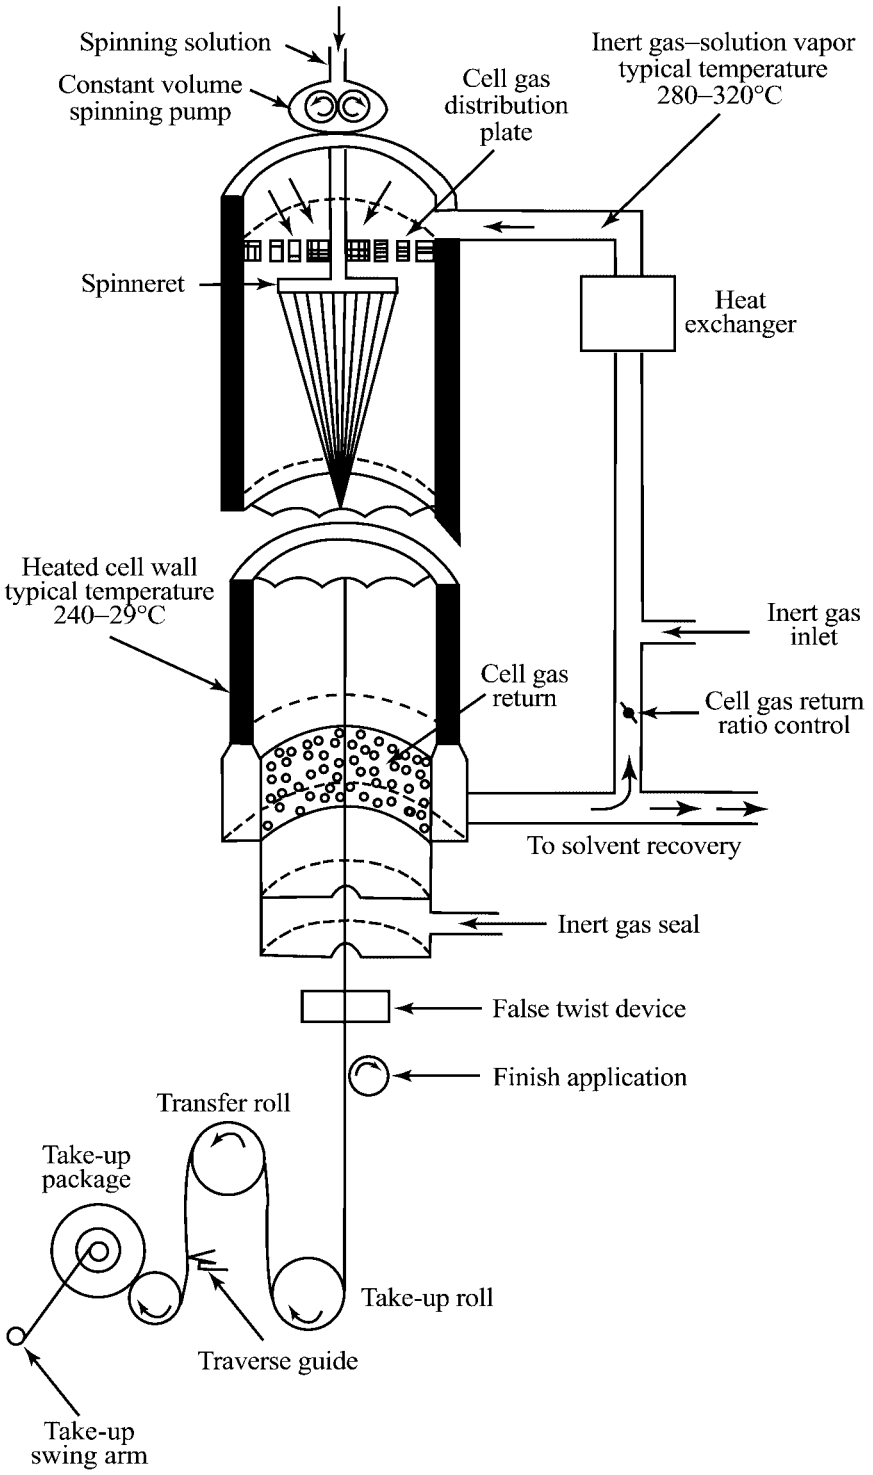

Fig. 6. Spandex production, solution dry-spinning process.

temperature by a precision gear pump through a spinnerette into a cylindrical spinning cell 3–8 m in length. Heated cell gas, made up of solvent vapor and an inert gas, normally nitrogen, is introduced at the top of the cell and passed through a distribution plate behind the spinnerette pack. Because both cell gas and cell walls are maintained at high temperatures, solvent evaporates rapidly from the filaments as they travel down the spinning cell. The spinning solvent is then condensed from the cell gases, purified by distillation, and returned for reuse. Individual filament size is normally maintained in the range of 0.6–1.7 tex (5–15 den) to maximize, within operable limits, surface area-to-mass ratio and solvent removal rate. Individual filaments are grouped into bundles of the desired final tex at the exit of the spinning cell by a coalescence guide. A commonly used guide employs compressed air to create a minivortex which imparts a false twist and rounded cross section to the filament bundle. Solution dry-spun spandex fibers are normally referred to as continuous multifilaments or coalesced multifilaments. However, the individual filaments do not coalesce into larger structures but remain discrete; they adhere to one another because of natural elastomer tack at their surface.

After coalescence, a finish is applied to the multifilament bundle before it is wound onto a tube. Commonly used finishing agents include polydimethylsiloxane [9016-00-6] (17) and magnesium stearate [557-04-0] (18) which provide lubrication for textile processing and prevent fibers from sticking together on the package. Windup speeds are in the range of 300–500 m/min, depending on tex and producer.

Any urethane–urea polymer that can be dry-spun may also be wet-spun; however, the productivity constraints of wet-spun processes have limited their utility. A typical wet-spinning process line is shown in Figure 7. Spinning solution is pumped by precision gear pumps through spinnerettes into a solvent–water coagulation bath. As with dry spinning, individual filament size is maintained at about 0.6–1.7 tex (5–15 den) in order to optimize solvent removal rates. At the exit of the coagulation bath, filaments are collected in bundles of the desired tex. A false twist may be imposed at the bath exit to give the multifilament bundles a more rounded cross section. After the coagulation bath, the multifilament bundles are countercurrently washed in successive extraction baths to remove residual solvent, then dried and heat-relaxed, generally on heated cans. Finally, as in dry

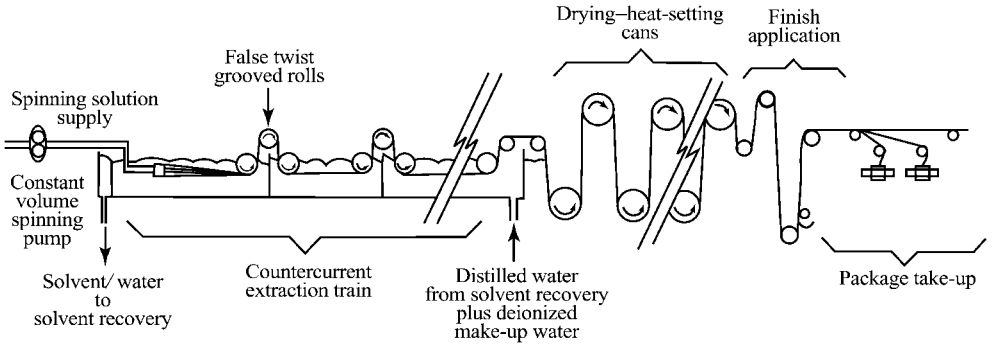

Fig. 7. Spandex production, solution wet-spinning process.

spinning, a finish is applied and the multifilaments wound on individual tubes. A typical spinning line may produce 100–300 multifilaments at side-by-side filament spacings of less than 5 mm.

Water is continuously added to the last extraction bath and flows countercurrently to filament from bath to bath. Maximum solvent concentration of 15–30% is reached in the coagulation bath and maintained constant by continuously removing the solvent–water mixture for solvent recovery. Spinning solvent is generally recovered by a two-stage process in which the excess water is initially removed by distillation followed by transfer of crude solvent to a second column where it is distilled and transferred for reuse in polymer manufacture.

In wet-spinning processes, spinning speeds are limited to about 100–150 m/min by hydrodynamic drag of the bath medium. It is this limitation that has apparently caused most spandex fiber producers to have chosen dry-spinning techniques. However, this limitation has been minimized by subjecting the spandex filament to drawing as much as three to four times after the spinning bath (19,20). Temperatures and residence times are selected so that the filaments are brought to temperatures above their second-order transition points, ie, the hard segment melting points. This allows the molecular chains to move freely to relieve stresses and results in filaments of fine tex but with similar mechanical properties as the heavier tex feed. Thus it is possible to windup fibers from a wet-spinning process at speeds in excess of 300 m/min by continuously drawing and heat-relaxing the filaments after drying.

Chemical Properties

Both rubber and spandex fibers are subject to oxidative attack by heat, light, atmospheric contaminants such as NO_x, and active chlorine. Rubber is especially subject to oxidative degradation from exposure to ozone whereas urethane polymers are relatively inert. Both rubber and spandex fibers are likely to contain antioxidants; the spandex fibers may also be stabilized to uv light and to atmospheric contaminants that cause discoloration. Spandex fibers use a variety of monomeric and polymeric hindered phenolic-type antioxidants (qv). Many spandex fibers also include uv screeners based on hydroxybenzotriazoles (see ANTIOXIDANTS; UV STABILIZERS). Several producers include the more recently developed hindered amine-type light stabilizers (21) that apparently act as radical scavengers and therefore also possess antioxidant activity. Compounds with tertiary amine functionality are commonly added to spandex fibers to inhibit discoloration from atmospheric pollutants such as oxides of nitrogen and chemicals that develop under smog-like conditions. Spandex producers have been designing stabilizers that are highly compatible with the segmented urethane polymer to enhance their effectiveness and durability (22–24). Spandex fibers based on polyester soft segments are susceptible to mildew attack in end uses such as swimwear; this type of degradation is minimized by either using antimildew additives or by soft segment structural modifications (25).

Elastomeric fibers tend to swell in certain organic solvents; rubber fibers swell in hydrocarbon solvents such as hexane. Spandex fibers become

highly swollen in chlorinated solvents such as tetrachloroethylene [127-18-4] (Perclene). Although the physical properties of spandex fibers return to normal after the solvent evaporates, considerable amounts of its stabilizers may have been extracted. Therefore, the development of stabilizers that are more resistant to solvent extraction has become important as solvent scouring during mill processing replaces aqueous scouring at many mills, especially in Europe (26).

Spandex fibers have an affinity for dispersed or acid dyes; rubber fibers normally cannot be dyed. Perfect dye matches between spandex and hard fibers are usually not necessary because the elastomer is well-hidden in the fabric. Clear spandex fibers can be left undyed when plied with dyed hard fiber yarns, thus avoiding loss of stretch properties from conditions of dyeing or bleaching. Nylon–spandex combinations are often dyed with disperse dyes, or, for better fastness, with acid dyes (27). Retarders may be needed to prevent the nylon from depleting the acid dye from the bath before the spandex fiber is dyed. With polyester–spandex fabrics, disperse dyes have been used with pressure dyeing or carriers to increase the dyeing rate for the hard fiber. However, spandex fibers exhibit relatively poor wetfastness to disperse dyes, and their retractive power can be reduced under pressure dyeing conditions needed for full shades on disperse dyed polyesters. For this reason, many polyester spandex fabrics now contain cationic dyeable polyester in combination with clear (transparent) spandex fiber. Since the spandex fibers have low affinity for cationic dyes, fastness is not a problem, and the fabrics can be dyed at lower temperatures to preserve spandex retractive power.

Economic Aspects

A worldwide list of spandex fiber and related elastomer producers is shown in Table 2. Most process developments have occurred in the United States, Germany, Japan, and Korea. A large proportion of worldwide capacity is controlled by DuPont, either directly or through subsidiaries and joint ventures. These include three plants in North America, two in South America, three in Europe, and three in Asia.

Commercially, elastomeric fibers are almost always used in combination with hard fibers such as nylon, polyester, or cotton. Use levels vary from a low of about 3% in some filling stretch cotton fabrics to a high of about 40% in some warp-knit tricot fabrics. Raschel fabrics used in foundation garments normally contain 10–20% spandex fiber.

Prices of spandex fibers are highly dependent on thread size; selling price generally increases as fiber tex decreases. Factors that contribute to the relatively high cost of spandex fibers include (*1*) the relatively high cost of raw materials, (*2*) the small size of the spandex market compared to that of hard fibers, which limits scale and thus efficiency of production units, and (*3*) the technical problems associated with stretch fibers, which limit productivity rates and conversion efficiencies. As an increasing number of companies have begun production of spandex fibers, the global market has become saturated in recent years. With a more competitive market, the price of spandex has drastically been reduced.

Table 2. Producers of Spandex and Related Fibers

Competitor	Country	Trade Name

Uses

The manufacturing technology for cut and extruded rubber thread is much older and more widely known than that for spandex fibers. Because production facilities can be installed with relatively modest capital investment, manufacture of rubber thread is fragmented and more widely distributed with a few major and many minor producers. On a worldwide basis, Fillattice of Italy is the largest rubber thread producer with modern extruded latex plants in Italy, Spain, Malaysia, and the United States. They also produce spandex fibers.

Table 3. Spandex Fiber Uses

Fiber form	Fabric types	Uses
Bare	Warp knits, circular knits, narrow fabrics (woven, knits, and braids), and hosiery (knit)	Foundation garments, swimwear, control tops for pantyhose, brassieres, elastic gloves, waist and leg bands, sportswear, and upholstery
Covered	Warp knits, circular knits, hosiery (knit), and narrow fabrics	Hosiery, elastic bandages, sportswear, upholstery, and sock tops
Core-spun	Wovens, circular knits, and men's hosiery (knit)	Shirting, slacks, and sportswear
Core-plied	Wovens	Blouses and trousers

Most extruded latex fibers are double covered with hard yarns in order to overcome deficiencies of the bare threads, such as abrasiveness, color, low power, and lack of dyeability. During covering, the elastic thread is wrapped under stretch, which prevents its return to original length when the stretch force is removed; thus the fiber operates farther on the stress–strain curve to take advantage of its higher elastic power. Covered rubber fibers are commonly found in narrow fabrics, braids, surgical hosiery, and strip lace.

Spandex fibers are supplied for processing into fabrics in four basic forms as outlined in Table 3. Bare yarns are supplied by the manufacturer on tubes or beams and can be processed on conventional textile equipment with the aid of special feed and tension devices. In covered yarns, the spandex fibers are covered with one or two layers of an inelastic filament or staple yarn; the hard yarn provides strength and rigidity at full extension, which facilitates knitting and weaving.

With core-spun yarns, the spandex fibers are stretched and combined with a roving of inelastic cotton or cotton–polyester staple fibers; twisting action of the hard sheath fibers around the elastomeric fiber core produces a spun yarn that contracts when tension is relieved. Woven fabrics with core-spun yarns generally contain small amounts of spandex fibers; stretch characteristics are the result of the intrinsic properties of the spandex fibers in their final form and interactions with hard fibers, which take place during weaving and heat setting (28). These interactions provide a permanent weave crimp in the hard fiber, which, together with the spandex component, imparts stretch and recovery to the fabric. Core-plied yarns are formed when stretched spandex fibers are plied with extended textured continuous filament yarns on a twisting machine; these yarns are used in high stretch woven fabrics.

Spandex fibers are available as fine as 1.1 tex (10 den), and the finest extruded latex thread available is about 16 tex (140 den). The availability of spandex fibers in such fine sizes and their unique properties compared to rubber, eg, dyeability, high modulus, abrasion resistance, and whiteness, has allowed extensive penetration into hosiery and sportswear markets.

FILMS, MANUFACTURE

Introduction

Virtually every polymer can be used in film form. Most thermoplastic polymer films are prepared by conventional extrusion techniques based on calendering, casting, and blown-film, or tenter-film systems. Other polymers, which cannot be easily melted, are formed into films by solvent casting. In the selection of a film for a particular application, the properties of the polymeric materials must be considered in view of the application. Thermal properties, molecular characteristics, and crystallinity of the polymer affect processing and film properties. Additives influence extrusion and orientation processes and improve film properties.

Polymer Properties

Molecular Weight and Molecular Weight Distribution. Molecular weight and molecular weight distribution affect extrusion and orientation processes and the physical properties of the film, eg, tensile strength, elongation, impact resistance, (qv) and optics (see MOLECULAR WEIGHT DETERMINATION).

Films prepared from high molecular weight materials exhibit excellent mechanical strength, impact strength, and orientability. As molecular weight increases, melt strength increases. Tubular orientation requires high molecular weight and a melt index (MI) of 0.1–3 (ASTM D1238E) to provide adequate melt strength during extrusion and orientation. However, high molecular weight impedes processing and results in a film with poor optical clarity, despite orientation. Films of lower molecular weight material are brittle, difficult to orient and have lower melt strength. Low molecular weight resins are characterized by good clarity and high extrusion or processing rates. Resins of low molecular weight

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

with a melt flow (MF) of 6–12 (ASTM D1238E) are used for sheet casting because melt strength is not required but good clarity is of prime importance. For tenter-process extrusion, polymers of a middle range are employed, eg, as polypropylene (PP) with MF 1.5–7 (ASTM D1238L), because melt strength is less critical. This is also true of tubular film processes that employ an initial melt quenching step. At the same molecular weight, optics, draw down, and impact strength increase as molecular weight distribution narrows, whereas melt strength, die swell, shrinkage, and processibility decrease.

Catalyst systems used for polymerization have a large impact on the molecular weight distribution and have undergone tremendous changes in the last decade (1). As older catalysts systems are replaced by new catalysts, film manufacturing processes and material selection have become more critical to ensure maintenance or improvement in film properties without adversely impacting the manufacturing process.

Crystallinity. The properties of a material are determined by its molecular structure and bulk properties are controlled by the spatial arrangement of the molecules. Polycrystalline materials are best understood in terms of a two-phase model consisting of amorphous and crystalline domains (2). The properties of each phase differ (see AMORPHOUS POLYMERS; SEMICRYSTALLINE POLYMERS). The observed properties of a material depend on the component-phase properties and the interaction of the two phases. Structural parameters are determined by the ratio of the two phases and the average orientation of the molecules in each phase (3). For polyolefin materials, such as polypropylene and polyethylene, new catalyst systems based upon metallocene materials are dramatically changing the molecular structure of the polymer chain relative to existing catalysts. The new molecular structure results in new material properties because of better control of the polymerization process. These new materials exhibit differences in melting point, crystallinity, and molecular weight distribution, and have a dramatic impact on film processing conditions and final film properties (4).

Increasing crystallinity of a semicrystalline polymer is accompanied by increases in modulus, stiffness, density, yield stress, chemical resistance, melting point, glass-transition temperature, abrasion resistance, creep resistance, and dimensional stability, and by reduction in impact resistance, elongation, thermal expansion, permeability, and swelling.

Final film crystallinity and crystalline- and amorphous-phase orientation for a given polymer depend strongly upon film processing conditions.

Thermal Properties. The chemical nature of the polymer determines its stability to temperature, light, water, and solvents. Polymer chains form ordered structures, and the thermodynamics of this ordered state determines melting point T_m, the glass-transition temperature T_g, and mechanical and electrical properties. Thermal properties (qv) of film polymers are given in Table 1 (5–11). The polymers best suited for films have a glass-transition temperature below 0°C, a melting point above 100°C, and a decomposition temperature at least 50°C above the melting point. Such polymers, eg, polyethylene (PE), polypropylene (PP), and polystyrene (PS), can be extruded in conventional extruders. Semicrystalline polymers with T_g above room temperature, such as poly(ethylene terephthalate) (PET), are most suitable for films if oriented to improve room temperature physical properties but are prone to pin hole cracking if flexed excessively.

Table 1. Thermal Properties of Film Polymers[a]

Class	Polymer	Common symbol	Glass-transition temperature T_g, °C	Melting temperature T_m, °C	Decomposition temperature T_{dec}, °C
Polyolefin	High density polyethylene	HDPE	−120 to −140	130–137	335–450
	Low density polyethylene	LDPE	−95 to −130	106–110	335–450
	Polypropylene	PP	−10	170	328–410
	Ethylene–propylene copolymer	EP	−30	128–145	328–410
	Poly(1-butene)	PB	−24	126	288–425
	Poly(4-methyl-1-pentene)	TPX	30	235	335
	Polytetrafluoroethylene	PTFE	27	330	508–538
Vinyl polymers	polystyrene	PS	85–105	240	285–440
	Poly(vinyl acetate)	PVAC	75–105	240	213–325
	Poly(vinyl chloride)	PVC	75–105	212–310	200–300
	Poly(vinylidene chloride)	PVDC	−18	210	225–275
	Poly(vinyl fluoride)	PVF	40	200–235	372–480
	Polyacrylonitrile	PAN	97	320	250–280
	Poly(methyl methacrylate)	PMMA	65	160	170–300
Polyethers	Polyoxymethylene	POM	−85 to −110	181	100
	Poly(phenylene sulfone)		220	300	310
	Cellulose triacetate	LA	105	306	250–310
Polyesters	poly(ethylene terephthalate)	PET	81	265	283–306
	Polycarbonate	PC	147	225	420–620
Polyamides	Polycaprolactam	NYLON-6	40–87	220	310–380
	Polyhexamethyleneadipimide	NYLON-6,6	50	265	310–380
	Polyundecanoamide	NYLON-11	46	194	310–380
	Polyimide			310–365	310–380

[a]Temperature quoted represents values for specific grades of commercial materials and may not be representative of all materials of this classification.

When the polymers' melting temperature is too close to the decomposition temperature a film can be produced by solvent casting. Alternatively, a reduction of the melting point of the polymer by copolymerization (12) is possible. This reduces the crystalline order of the polymer and lowers the melting point by decreasing the energy required for melting. In addition, the decomposition rate can be controlled by adding stabilizers. Extruder and die are designed with streamlined flow lines to avoid melt stagnation and push the polymer through extruder and die as quickly as possible. A lubricating additive may also be added to minimize melt adhering to the metal surface, reducing residence time and degradation. Unplasticized poly(vinyl chloride) (PVC), polyamides, and polyesters are extruded in this way (13). When the melting temperature is above the decomposition temperature, as with cellulose, poly(vinyl alcohol), or polyacrylonitrile, solvent casting and coagulation are used.

When no solvent is convenient and the use temperature of the film is below the T_g of the polymer, a nonvolatile liquid is required, which acts as solvent at high temperatures and as plasticizer at room temperature; both the T_g and the processing temperature are reduced. PVC plasticized with phthalates up to half its weight (13) can be extruded, as can be vinylidene chloride–vinyl chloride copolymer.

Additives. Organic and inorganic additives or coatings impart functionality to the finished product as demanded by the customer (9,14–16) (see Table 2). Additives (qv) must conform to government regulations for material handling and health hazards for both workers and consumers.

Stabilizers reduce degradation during film processing to prevent formation of lower molecular weight polymers, which would result in poor film properties, gels, and discoloration. Hindered phenol antioxidants combined with phosphites reduce thermal degradation of polyolefins. Other stabilizers improve long-term stability to heat and light (see STABILIZATION).

Slip agents such as saturated and unsaturated fatty acid amides can overcome film surface friction. These agents migrate to the film surface during processing and upon aging at elevated temperatures (see RELEASE AGENTS).

Antiblock agents (qv) are typically used to prevent adherence, ie blocking, of two film surfaces. They are small particle-size fillers affecting surface smoothness, controlling film-to-film surface separation distances without greatly affecting clarity.

Antistatic agents (qv), typically amine derivatives of glycerol monostearate, are primarily used to reduce static generation in packaging equipment. These additives are particularly effective for films designed for packaging powders by minimizing dust pick up on seal areas and package surfaces.

Rheology. *Rheology* is the study of deformation and flow. For polymers the viscous and elastic behavior of melts determines the design of extruder screws, melt pipes, filters, and die configuration. The elastic nature of the melt at any temperature affects surface smoothness, layer thickness, and stability. Solid phase rheology influences stretching, such as that occurs in the stepwise or simultaneous biaxial orientation. The rheology of the finished product also determines film behavior on packaging machines, printing presses, or laminators where the film is both heated and loaded by tension changes (14,15) (see also RHEOLOGY).

Table 2. Film Additives

Additive function	Supplier	Trade name	Chemical name or class
Antioxidants	Goodrich	Goodrite 3114	Phenolic
	Goodrich	Goodrite 3140	Amine

Extrusion-Based Manufacturing Processes

Extrusion. Extrusion (qv) is widely used for the manufacture of polymeric films because it permits the preparation of highly uniform polymer melts at high rates (17–20). An extruder (Fig. 1) consists of a hollow cylindrical barrel fitted with external heaters. The inner surface is coated with a hard metal liner such as Xaloy. A screw is fitted into this cylinder with a specific geometry determined by the polymer and the desired thermal condition of the melt. The screw is driven by an electric motor through a gear reducer sized for the speed and power requirements of the screw. The typical barrier screw shown in Figure 2 takes advantage of the melting mechanism in the extruder to increase efficiency. Most of the energy required to melt the polymer is supplied by the motor (21,22). Barrel temperature is maintained by electric heaters, which often contain channels for cooling water.

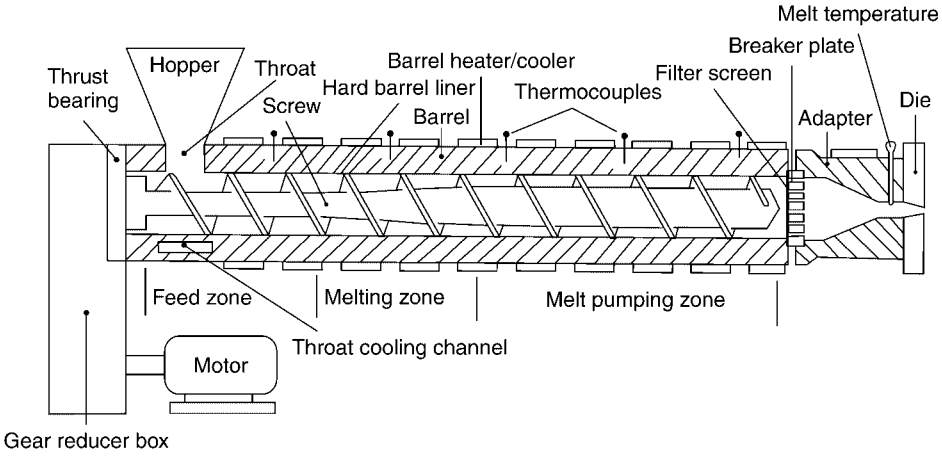

Fig. 1. Extruder.

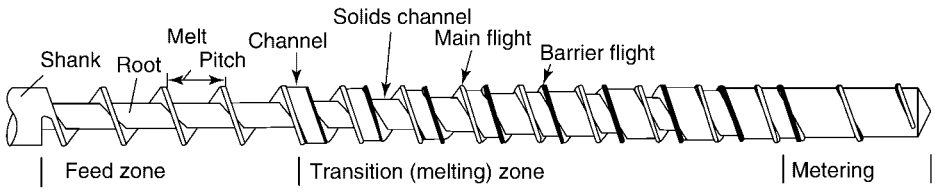

Fig. 2. Barrier flight screw.

The solid polymer is introduced into the feed throat of the extruder and conveyed into the screw by its turning motion (17). It is compacted into a solid plug, which is melted by contact with the hot barrel. Molten polymer is collected by the screw flights and pumped toward the end of the extruder. At the end of the screw, the polymer is completely melted. The melt is mixed by the screw rotation, which generates enough pressure to push the melt through a die and to the next step (23,24). The condition or quality of the melt is extremely important for film quality and process stability. The extrusion conditions affect crystallization behavior and molecular weight of the film.

The melt is produced by the viscous dissipation of mechanical energy into a very thin layer of molten polymer located between the compressed solid plug and the heated barrel surface (18) (Fig. 3). Owing to the high viscosity of the polymer melt, typically 50–1000 Pa·s (500–10,000 P), large amounts of energy are dissipated in the melt as the motor turns the screw. The energy is converted into heat, which is transferred to the solid polymer and the barrel, raising the temperature of the melt. Excessive temperatures or mechanical work can cause thermal, oxidative, or mechanical degradation of the polymer. A new generation of energy-efficient screw designs have been developed, which minimize the melt temperature by mixing the collected melt with the solid particles of the compacted bed (25,26). This is accomplished by purposely disrupting the melting mechanism of Figure 3 at some point, by changing the screw geometry to mix the solid with the melt.

The polymer melt flows through a die to the next process step; flat, circular, or slot dies are preferred. The flow through the die must be uniform across the exit plane. However, this is complicated by the nonlinear dependence of melt viscosity on both temperature and shear rate in the die (23,24). The suitability of a material is determined by measuring the flow properties with a capillary rheometer in the temperature and shear-rate range expected. Melt elasticity can cause flow instabilities, which affect haze and thickness (27,28) or the operation of downstream equipment. Exit melt velocity, flow characteristics, and quenching rate may impart significant orientation to the polymer. In some instances, melt orientation is reduced; in others, it is maintained by quenching.

In flat-die extruders, slot and coat hanger die geometries (Fig. 4) predominate, whereas in circular die extruders, spiral dies (Fig. 5) predominate. A die

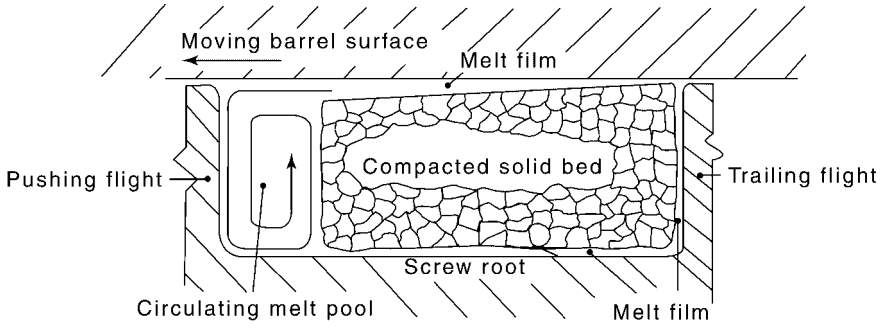

Fig. 3. Melting mechanism of single screw extruders.

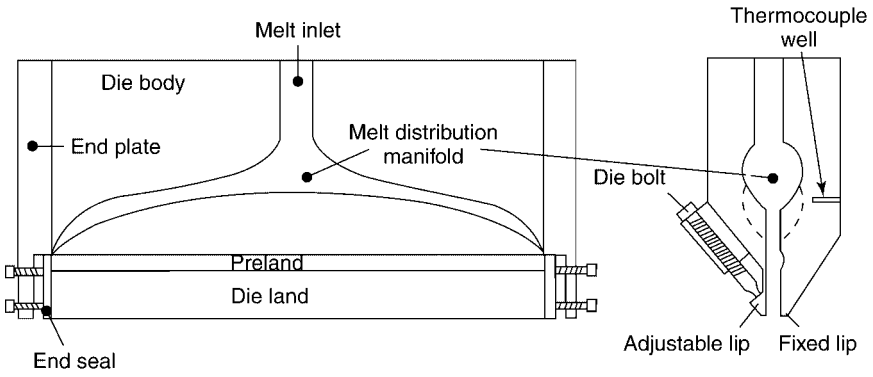

Fig. 4. Coat-hanger die.

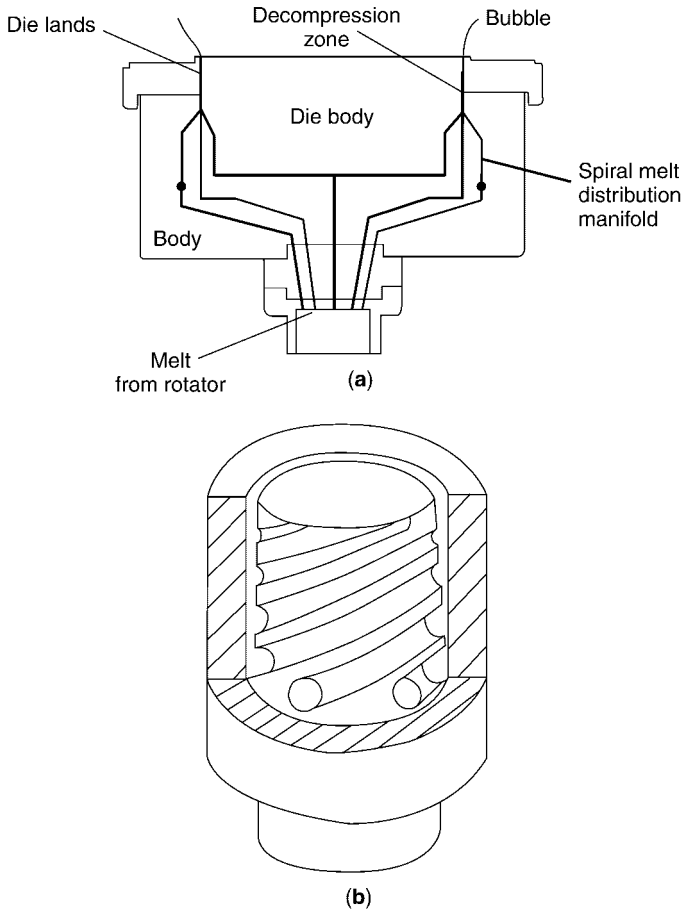

Fig. 5. (**a**) Tubular (three-layer) spiral die; (**b**) detail of spiral melt manifold.

is usually constructed of tool steel and heated to maintain the desired temperature for optimum flow. Temperature uniformity is very important. A uniform flow through the die is determined by the design of the internal distribution manifold. For good melt distribution, this section must be designed to maintain uniform flow rate, pressure drop, and shear (24). Independent flow adjustment is usually provided by an adjustable die lip or choker bar. These devices ensure a uniform flow by selectively changing the shear rate of the melt before it leaves the die. Multiple temperature zones, standard on most dies, permit the selective alteration of the temperature across the die face, ensuring production of a flat sheet. This is necessary to counteract gauge variations caused by possible nonhomogeneous melt from the extruder, inadequacies in the die design, and the physical limitations imposed in the machining of the internal configuration of the dies.

To ensure isothermal flow, die temperatures are maintained as close to the melt temperature as is practical. Die gaps vary, depending upon the speed with which material is removed from the die lips, as this determines the shear rate. This is important because of die swell and melt fracture. Die gap also determines the final film thickness. Die gaps are 0.25–2.5 mm (0.010–0.10 in.), which is small compared with the typical die width of 39–305 cm.

Coextrusion. Coextrusion technology has been developed in conjunction with new polymers, providing the film structures required for flexible packaging (see COEXTRUSION). Coextrusion is perhaps the most economical method of combining polymers into functional multilayer films.

Multiple melt streams from several extruders are combined either in a feed block (Fig. 6) or in a multiple cavity die (Fig. 7), resulting in a stratified flow from

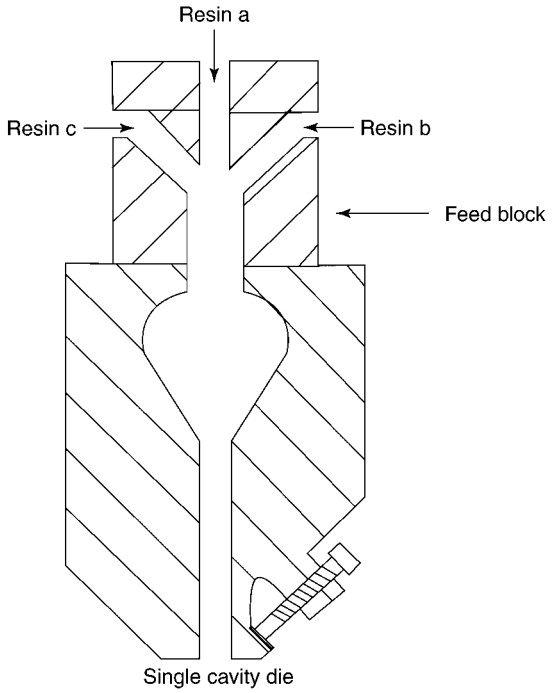

Fig. 6. Coextrusion system (single cavity die) using a feed block for three polymer streams.

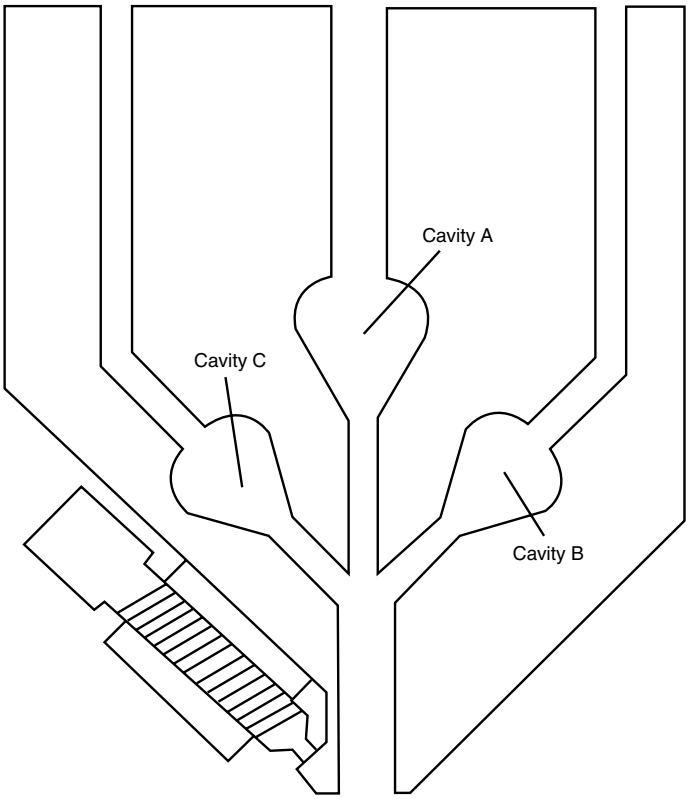

Fig. 7. Multiple cavity coextrusion die with multiple melt-distribution manifolds.

the die. A feed block may be used with a single cavity die or in conjunction with one cavity of a multiple cavity die to produce structures with many layers. Multiple cavity dies are used for films requiring several layers, which interact chemically to improve adhesion between the polymers but which may disturb the interface stability or noninteracting polymers, which must remain separate for as long as possible owing to poor rheological compatibility.

Coextrusion is promoted by the laminar flow of the melt in the feed block and die, which prevents the mixing of the various layers. The laminar flow is due to the low Reynolds numbers (low inertia between flow planes) that result from the high melt viscosities (23,24). However, the generation of interfaces between the flowing materials requires that melt viscosities and melt elasticity between the layers be sufficiently matched to prevent the formation of flow instabilities (29–32). Therefore, coextrusion requires superior equipment and process control throughout.

Multilayer spiral dies are becoming more common but are limited to rheological compatible polymers in the layers much as with the feed block method in flat dies. This is due to the long flow distances required for layer uniformity in the multilayer spiral dies, which makes them more prone to generate interfacial instabilities.

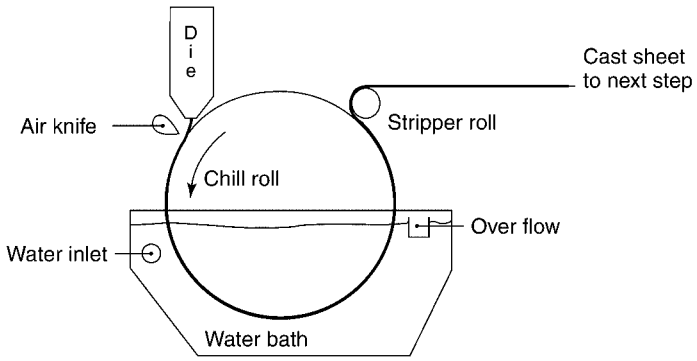

Fig. 8. Water bath–chill roll quenching system.

In another method, two or three melt streams from separate extruders can be combined and cast to form a multilayer structure. Alternatively, a melt stream and a quenched web or a quenched and uniaxially oriented web are combined on a chilled drum, providing the web with new surface functionality. This method is known as the extrusion coating process (14).

Casting. In casting, a self-supporting film or sheet is formed from a melt supplied by an extrusion system. Processing conditions have a profound effect on sheet properties and subsequent operations. Depending on the polymer, the rate of heat removal determines the extent and morphology of crystallinity of the sheet and the degree of residual orientation. Also important is the temperature at which the heat is removed from the sheet. Thus, heat-transfer analysis of casting processes is essential for the design of an efficient system.

Quenching is a continuous operation and must be regarded as an unsteady state. It can take place in water, on a continuous steel band, on a casting drum, or by a combination of these methods (see Fig. 8). The heat-transfer analyses for these systems are similar, differing primarily in the magnitude of heat-transfer coefficients. Heat-transfer rate, heat-transfer temperature, melt temperature, and crystallization kinetics determines the optimum quenching conditions. The cast sheet must be strong enough to be transported to the next stage of the manufacturing process.

If a high quality surface or a uniform heat-transfer rate is required, a pinning step may be needed. Pinning is defined as the forcible application of the molten film to the casting surface, it may be carried out by an air knife, a vacuum box, a nip roll, or a strong electrostatic field. Pinning is needed for high production rates while maintaining uniform properties across the quenched web. The pinning force prevents air from being trapped between the film and the casting surface. Choice of pinning method depends upon the speed of the operation and the quality of the sheet required for the particular product to ensure intimate contact with the surface against which the polymer is being solidified.

Examples of cast film are high clarity, low density polyethylene (LDPE) film for bread bags, pallet wraps, PVC sheets, and polycarbonate (PC) or acrylic sheets for glazing applications. Casting is the initial step in the production of biaxially oriented PP, PS, and PET films.

Uniaxial Orientation. Uniaxial orientation enhances the physical properties of sheets and films in one direction; properties in the perpendicular direction are usually far inferior (29). The orientation temperature, governed by the material, and the extent of orientation determines the final properties. Semicrystalline polymers (qv) are oriented between the glass-transition temperature T_g and the melting point T_m, whereas amorphous polymers (qv) are oriented above T_g. In general, rapid stretching in the temperature ranges described above, followed by rapid quenching, orients the polymer. Rapid quenching ensures that the orientation is not lost by molecular relaxation. The degree of orientation is determined by the extension rate and the degree of extension (3). A wide variety of commercial equipment is available for uniaxial orientation, as well as proprietary equipment developed for special processes or high production rates (see FILMS, ORIENTATION).

Orientation is a continuous operation and occurs in the direction of the film motion or the machine direction (MD). Usually, a cast sheet is transported on heated rollers (Fig. 9) to permit the sheet to reach a uniform temperature at which the polymer molecules are sufficiently mobile. Having reached this temperature, the sheet is abruptly accelerated between two rollers of different speeds. This point is defined as the draw point. In some instances, additional heat may be required to boost the temperature, or nip rolls are needed to regulate tension and to prevent film slippage (Fig. 9). Uniaxial film can be obtained by orienting perpendicular (transverse) to the MD using tenter frames or melt inflation, where the melt removal rate is equal to the melt velocity at the die. However, these two methods are seldom employed. The properties required by the user determine the orientation required to develop the desired physical properties.

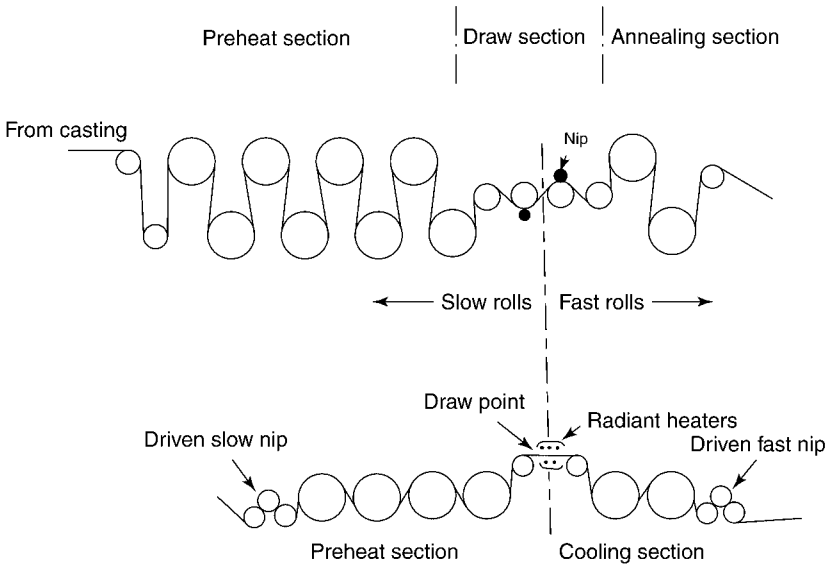

Fig. 9. Machine-direction (MD) orientation.

Amorphous and semicrystalline polymers behave very differently when subjected to uniaxial orientation. Amorphous polymers may be drawn to any extent or thickness if properly supported, whereas semicrystalline polymers show distinct and abrupt thickness changes, called necking, when drawn (3). Necking may limit the rate at which the polymer is drawn because of the heat generated in the neck region. The heat generated can be high enough to cause chain scission, resulting in breakage of the sheet at the draw point (33). Necking serves to define a minimum draw ratio for the material at the temperature and draw rate employed.

The relationships between physical properties and molecular orientation of uniaxial products are well understood for both amorphous and semicrystalline polymers (34). The principal change that occurs upon orientation is the preferential alignment of the *c*-axis of molecular chains in the direction of the orientation in the amorphous and crystalline phases of semicrystalline polymers (35,36). The preferred *c*-axis orientation allows the strong covalent bonds along the chain backbone to carry loads applied in the orientation direction. Perpendicular to the orientation direction, the weaker intermolecular van der Waals forces predominate between the molecular chains, giving a much lower load-carrying capability. For amorphous polymers, an average orientation function defines the only measure required to define the orientation state completely; it relates directly to the load-carrying amorphous phase. In semicrystalline polymers, the Hermans orientation function (3) describes the orientation contribution by the crystalline phase. This must be combined with the amorphous phase orientation to describe an average molecular orientation. Average orientation is more difficult to relate directly to physical properties because the crystalline phase does not contribute greatly to the load-bearing capabilities of the structure. Therefore, a more detailed analysis of the semicrystalline materials is required to determine the contributions from the amorphous and crystalline phases (34). Advanced analytical techniques are needed that are not readily available to many workers.

Biaxial Orientation. Biaxial orientation substantially improves the physical properties of the film and increases its commercial value. Biaxially oriented films are produced by stretching polymers in directions perpendicular to each other in the melt or rubbery state. The improvement over uniaxially oriented films is due to the redistribution of *c*-axis chain orientation (36). This results in a film with enhanced physical properties in both directions. The direction perpendicular to the MD is defined as the transverse direction (TD).

Commercial biaxially oriented films are produced by the tenter-frame (Fig. 10), double-bubble (Fig. 11), or blown-film process (Fig. 12). In the tenter-frame and double-bubble processes, the polymer is stretched in the solid state below the crystalline melting point. In the blown-film process, the polymer is oriented in the melt, followed by rapid quenching to immobilize the orientation.

The theoretical descriptions of biaxial orientation and the relationships to physical properties are not as well developed as those of uniaxial orientation. In amorphous polymers, birefringence can measure total molecular orientation and can be used to predict properties. For semicrystalline polymers, a more

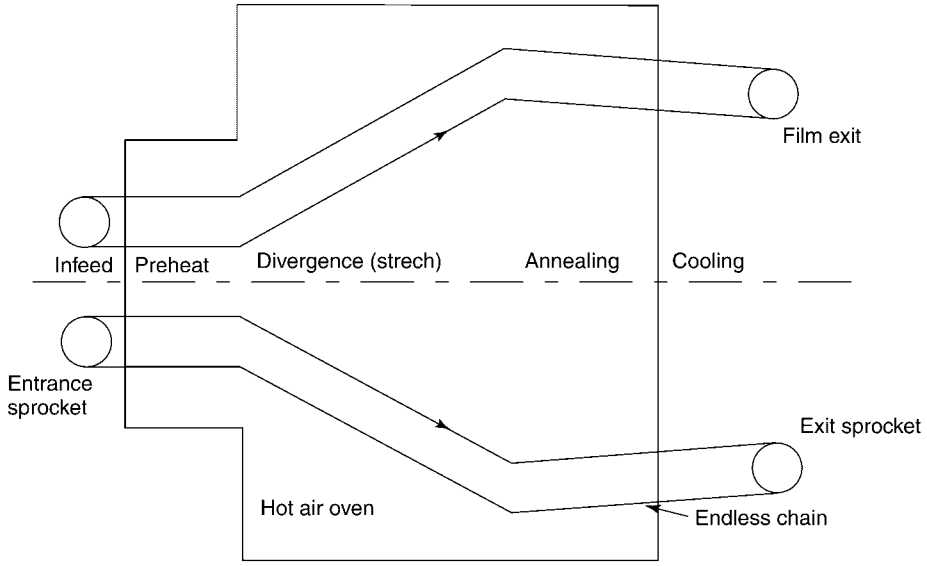

Fig. 10. Tenter orientation.

detailed description of the orientation is required before prediction of properties is possible.

Average-orientation, amorphous-orientation, and crystalline-orientation functions are required to describe the oriented state completely (3,36). This description permits the calculation of amorphous-phase orientation, which is required to relate and predict physical properties. The determination of crystalline orientation requires the more advanced analytical techniques of X-ray diffraction or dichroic ratios from polarized infrared spectroscopy. Average or total orientation functions are measured by birefringence. Amorphous and crystalline orientation functions are separated by measuring the sonic modulus and assuming a molecular model for the semicrystalline polymer (3).

Tenter-Frame Process. Tenter frames (Fig. 10) consist of two side-by-side endless chains that diverge at constant angle. The divergence of the chains forces the polymer to stretch as it is transported along the chain, and imparts the desired orientation. Stretch rate is determined by the chain speed, divergence angle, and extent of orientation. The extent of orientation is determined by the ratio of the width of the film entering to the width of the film leaving the system. Tenter systems have been developed primarily to impart TD orientation. Specialized systems allow simultaneous MD and TD stretching, but because of the mechanical complexity of these systems usually only TD orientation is carried out. The tenter frame, as part of a larger, sequential, biaxial-orientation system, can be located before or after MD orientation; it is usually located after MD orientation.

Depending upon polymer, the resin is extruded or coextruded as a flat sheet, approximately 0.75–2.5 mm thick, onto a large chill roll. For PP, the chill roll is in a water quench bath. The cast sheet is reheated and stretched in the longitudinal direction on a series of heated chrome rolls and fed into a tenter chain

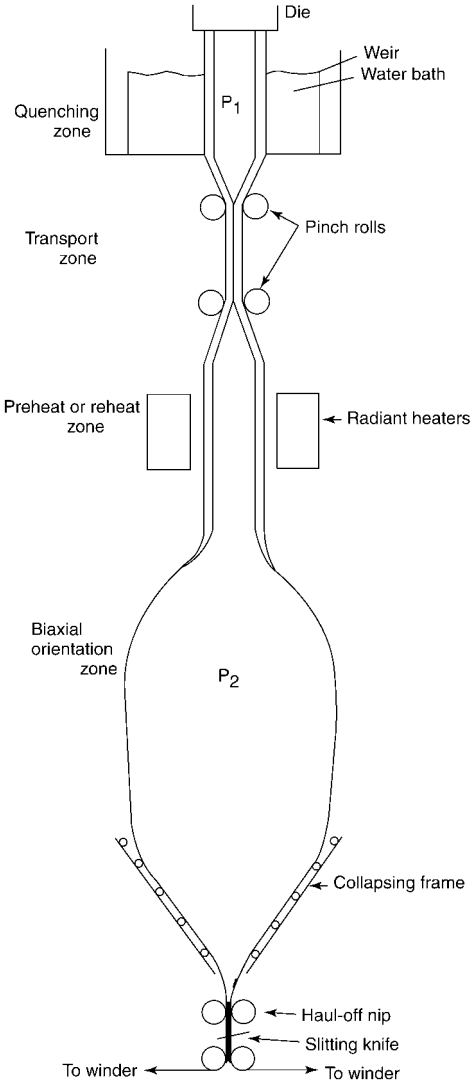

Fig. 11. Double-bubble orientation.

equipped with clips to grip the film. The chain system is located within a heat-transfer oven, where the sheet is heated to the temperature at which it is to be stretched. Heating is critical because the reliability of the stretching process and the film properties depend upon the temperature, stretch rate, and stretch ratio.

After preheating, the film is drawn in the transverse or cross direction by the divergence of the tenter chains, annealed, and released. The edges of the film are slit off, ground, and recycled, and the web may be wound full width or split into narrower webs, which are electric discharge or flame treated for enhancing printability and then wound onto rolls for further processing.

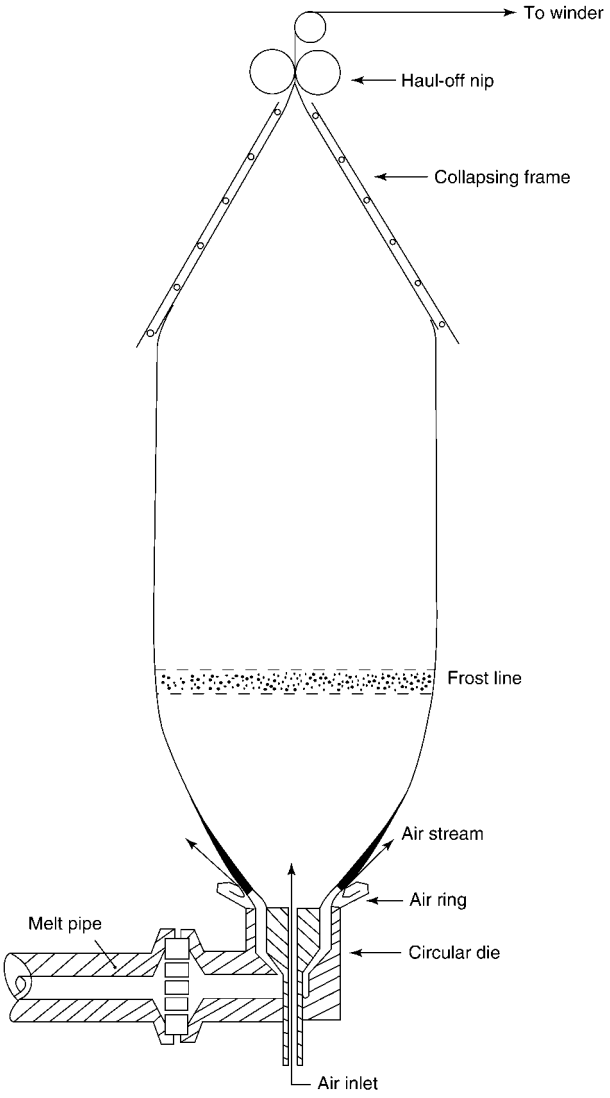

Fig. 12. Melt orientation.

In contrast to the double-bubble process, the tenter-frame process permits the direct manufacture of a film with improved dimensional stability because it is heat-set by adding a length of chain after the divergent section at the finished film width. This is very important for applications requiring good registration, as in printing or photographic applications. The film can be heated or cooled to a specific temperature while being restrained by the chain system. With line speeds in excess of 300 m/min possible and widths of 8–10 m common, oven heat transfer rates must also be high to control film annealing and crystallization.

Recently a new simultaneous biaxial orientation system has been developed using linear motors to drive the clips and impart MD stretch as the film travels

down the diverging tenter rails (37). This has replaced the mechanical complexity of the earlier simultaneous systems with electronic control complexity, which is readily handled by computer. This new tenter design has been implemented commercially and offers the potential to develop films with new orientation ratios and low melting surface polymers not possible with existing sequential stretching systems.

Blown-Film Processes. Bubble orientation technology permits simultaneous biaxial orientation directly from the melt (24) or by inflation of a quenched tube. With homogeneous films, the latter method may give films of slightly different properties than those of films produced on tenter frames. Melt orientation is less effective and properties are different because of lower orientation.

Double-Bubble Method. In the double-bubble method (Fig. 11), the resin is extruded as a tube that is quenched and gauged in cold water. The tube is then reheated and oriented by blowing it into a bubble. Simultaneously, the speed of the takeoff roll is increased for MD orientation; radiant electrical heaters control temperature. The bubble is collapsed, passed through nip rolls, reinflated, annealed in a controlled-temperature chamber, and collapsed again. After trimming the edges, it is separated into two webs, which are then treated by electric discharge for printability and wound onto rolls.

Melt Orientation. In melt orientation, the polymer melt is extruded from an annular die into a tube, which is simultaneously pulled away from the die as air is blown into the tube and around the outer surface (by an air ring attached to the die) to stabilize and quench the tube (24). This cools the melt as it accelerates in the machine and in the radial direction, thus conferring orientation. The action of the air solidifies the melt. The solidification point is called the frost line. The frost line height is important in determining the reliability of the process and the film properties. Above the frost line, the inflated tube is gradually collapsed and fed to the haul-off nip, which supplies the power to pull the melt from the die and prevents the bubble from collapsing by trapping air in the tube. The MD orientation is determined by the speed at which the melt is pulled away from the die (haul-off rate), the quenching rate (frost-line height), the die gap, and the melt properties. The TD orientation is determined by the final diameter of the inflated tube in relationship to the die diameter (*blow-up ratio*). The ratio of the die gap to the film thickness is called the *draw down ratio*. It affects the stability of the process and the orientation of the product. The tension pulling the melt away from the die (24) is called the *haul-off tension*. It cannot exceed the melt strength or the critical stress for melt fracture; the haul-off tension affects process stability and film properties.

Tensilizing. After biaxial orientation, film properties can be enhanced by additional MD orientation. This step is called tensilizing, and is performed by MD-drawing of the film after the initial biaxial MD and TD orientation, using sets of rollers, as previously discussed. Tensilized film can be produced with improved MD tensile strengths to permit use of thinner films as for magnetic recording tape or to increase the MD shrinkage of the film for use as a shrink label for complex packages such as cans and bottles.

A typical tensilized process consists of the casting step, the MD-orientation step, the TD-orientation step, and another MD-orientation or tensilizing step. This second MD orientation may be performed in-line as an additional step on the

orienter (38) or out-of-line as the film is slit for sale. It is also possible to add this second MD orientation to a tenter-frame or double-bubble process (39).

Solvent-Solution Casting

Films and sheets may be made from polymers that cannot be melt-extruded or that are extremely heat-sensitive by using polymer solutions. In this technology, a homogeneous polymer solution is filtered and degassed, followed by formation and drying of a gel film. The gel films are formed from the solutions by evaporation and coagulation. Drying of the gel films into self-supporting films is the rate-limiting step because it is diffusion-rate controlled. This also is of prime consideration in the formation of thick films, where drying times may be excessive. Consequently, these methods are generally limited to thin films. The characteristics of these films are low residual orientation, uniform properties in all directions, and excellent surface finishes (14,15).

Coagulation. Gel formation by coagulation depends upon the differential solubility of polymers in a blend of solvent, and nonsolvent, and solubility changes resulting from concentration changes of added chemicals. For example, solvents A and B are a good solvent and poor or nonsolvent, respectively, for polymer Y. A solution of Y is prepared in A and extruded into a bath of solvent mixture of A and B. The concentration difference causes diffusion of A out of the solution into the bath and the diffusion of B into the polymer solution. As the concentration of B increases and that of A decreases, the polymer becomes less soluble and eventually precipitates as insoluble gel; complete evaporation of A and B leaves the finished film. As an alternative, changes of pH by chemical additives may be sufficient to reverse the solubility or change the chemical nature of a polymer in solution, transforming it into an insoluble, stable gel. A good example of this technology is the casting of cellophane (15) (Fig. 13).

Evaporation. In this method (Fig. 14), the polymer solution is pumped through a die, cast upon a stainless-steel belt, and transferred to a drying chamber to evaporate. The solvent is recovered (15). As the solvent evaporates, a gel forms. Further drying gives a stable film. The film is stripped from the belt and rolled up.

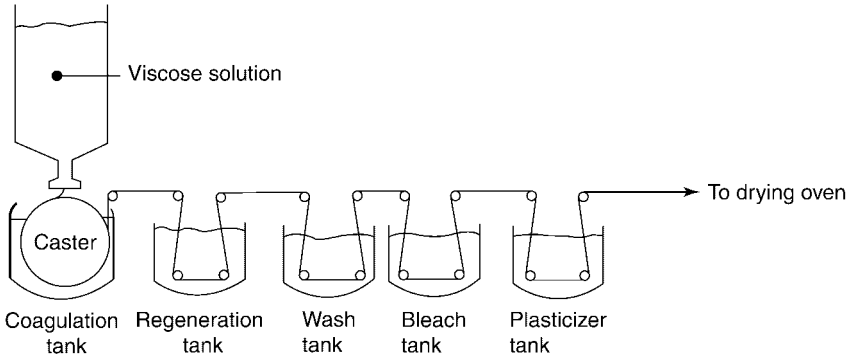

Fig. 13. Cellophane casting process.

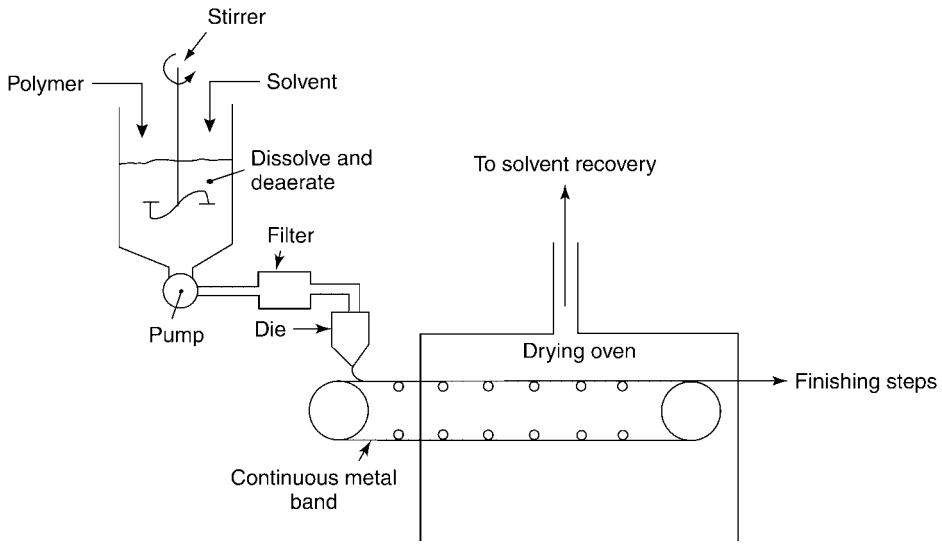

Fig. 14. Solvent casting process.

Rolling

Rolling produces a film with predominately MD orientation by accelerating the film from a nip point where the thickness is reduced. Large forces are found at the nip point, but overall orientation can be increased over other forms of MD orientation. Plastic strapping is oriented by this method (40).

Calendering

Calendering produces an unoriented cast sheet with uniform gauge at high throughput (41,42). The equipment (Fig. 15) is expensive and consists of a stack of especially hardened, driven rolls. The rolls are often supported in such a manner that they may be bent or skewed relative to one another during operation. This operation is required to maintain uniform thickness by overcoming the roll bending forces developed in the calender nip. The high separation forces, ie 180–1080 kg/cm of roll face, are generated by the melt (stock) viscosity and elasticity as the material passes through the nip point.

Calenders are usually composed of four rolls that form three nips: feed nip, metering nip, and finishing nip. The polymer is supplied to the feed nip from a compounding operation and further mixed and heated by the circulating melt bank formed at the feed nip. Alternatively, a melt of partially fluxed compound may be supplied to the calender from an extruder or Banbury. The sheet is reduced at the metering nip to the final desired thickness. The gauge uniformity is adjusted at the finishing nip by bending the last roll or skewing the middle or third roll.

Finishing Operations

Coating. Films are coated by metering a coating solution onto the surface and removing the excess solvent in an evaporation oven. Hundred percent solid

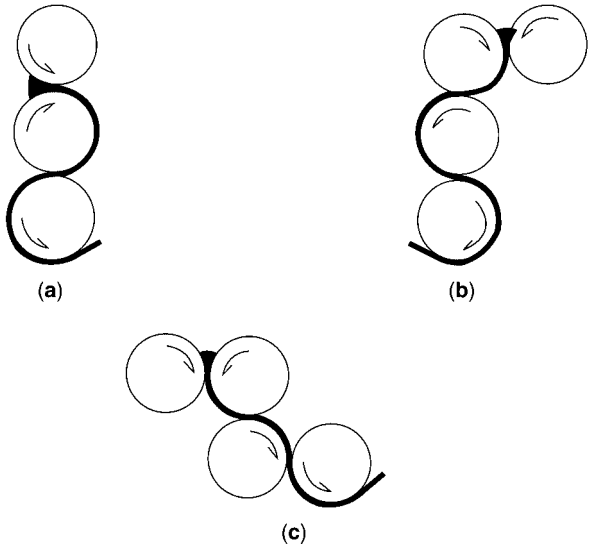

Fig. 15. Calendering-roll configurations: (**a**) three-roll superimposed type; (**b**) four-roll inverted-L type; (**c**) four-roll Z type.

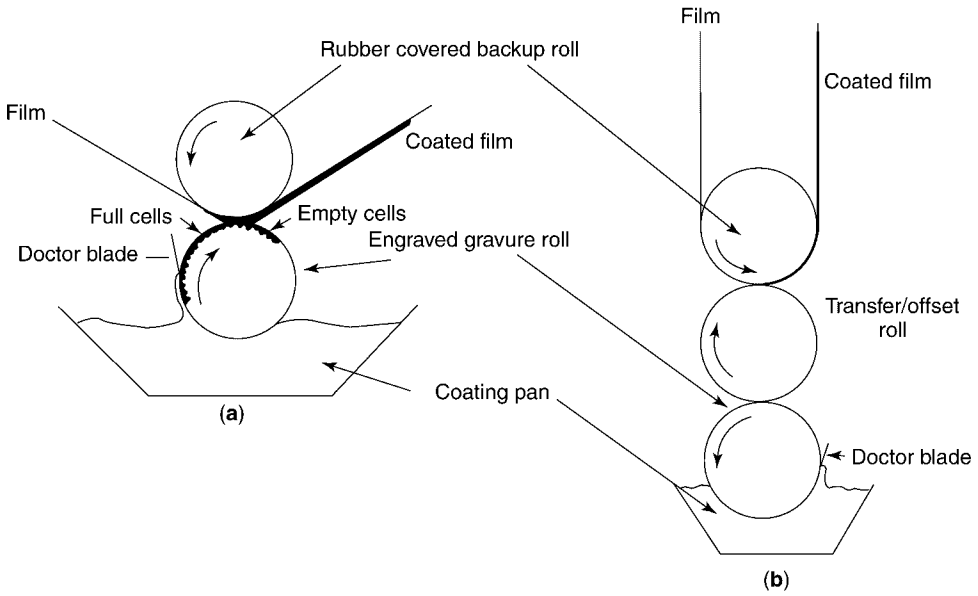

Fig. 16. (**a**) Direct and (**b**) indirect gravure systems.

(solvent-less) coatings are becoming more popular and may be heat or radiation cured. For metering, air knife-coaters, Meyer rod coaters, slot dies, and direct or indirect gravure coaters (Fig. 16) are used. The film is unwound onto the coater and may require surface treatment to ensure proper wet-out, especially with water-based coatings. The film is coated at the coating station and transferred to a drying oven. After drying, the film is rewound and ready for further processing (see also COATING METHODS).

Embossing. Embossing is used to modify the film texture or to decorate the film with a three-dimensional pattern (14). The film is heated to the softening point and distorted by passing it between a cooled roll with the three-dimensional pattern and a nip. This immobilizes the distorted pattern imposed by the embossing roll. The degree of distortion depends upon the film properties and the processing conditions. Microembossing may also be performed on coextruded or coated films to produce diffraction patterns and holographic images when metallized. In this process only the surface is embossed by first heating the film or just the film surface and then passing it through a nip between the etched embossing roll and a backing roll to force the polymer surface into the etched roll. This force is required to transfer the etched roll pattern to the film surface. The pattern is then enhanced by metallization of the film to cause light refraction from the patterned surface. This is a growing use for films in decorative and security applications.

Metallization. Film metallizing is a growing use for films for both decorative and the functional enhancement of light and gas barrier properties. A thin layer of aluminum metal coats film by a process of physical vapor deposition or sputtering. Rolls of film are mounted into a high vacuum chamber and evacuated to approximately 1×10^{-5} torr. Once this pressure level is reached aluminum metal is melted and flash evaporated on ceramic boats. The film is passed above the evaporation area at speeds approaching 500 m/min. This deposits a layer of aluminum approximately 100 nm thick. This layer thickness of aluminum reflects approximately 99% of the incident light and reduces the amount of moisture and oxygen permeation through the film to create an excellent packaging film for products subject to rancidity. Industrial uses for static dissipation, visible and IR radiation reflective window films, as well as clear IR radiation reflective films for glazing have also been widely used.

Surface Treatment. Most film surfaces require surface treatment for use in subsequent steps of coating, printing, lamination, or metallization. This treatment results in the chemical modification of the polymer at the surface. The most widely employed surface modification is oxidation of the polymer to create a polar surface (43). Processes that are widely employed are corona and flame treatment. Wet chemical oxidative treatments are seldom used and are restricted to low speed operations. A new surface oxidation technique has been recently developed which uses an atmospheric plasma generated in a hollow cathode with helium or helium gas blends (44).

FLASH DEVOLATILIZATION

Introduction

Flash devolatilization is a method for removing solvents and unreacted monomers from a polymer solution. The solution is heated and flashed into a chamber operated at reduced pressure. Boiling occurs by homogeneous nucleation and generates the surface area necessary for mass transfer of the volatile components from the liquid phase to the vapor phase. The overhead product is sent to a solvent recovery system. The bottom product, devolatilized polymer, is collected compressed, and pumped away. Figure 1 shows a typical process. Flash devolatilization is commonly used in vinyl polymerizations and in some condensation polymerizations. High volume, commercial examples include the removal of unreacted ethylene from low density, high pressure polyethylene (LDPE), the removal of hexane in the solution process for high density polyethylene (HDPE), and the removal of styrene and ethylbenzene in the bulk polymerization of polystyrene (see ETHYLENE POLYMERS, LDPE; ETHYLENE POLYMERS, HDPE; STYRENE POLYMERS; BULK AND SOLUTION POLYMERIZATIONS REACTORS.

Important process variables are the preflash temperature T_{in} and the post-flash pressure P_{out}. The flash illustrated in Figure 1 is rapid, adiabatic, and approaches thermodynamic equilibrium. The response variables are the outlet compositions of the vapor and polymer streams and their common outlet temperature T_{out}. The first step in analyzing this process is the estimation of thermodynamic equilibrium.

Equilibrium Calculations

A heat balance gives

$$T_{\text{out}} = T_{\text{in}} - \frac{\nu\lambda}{C_{\text{p}}} \tag{1}$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

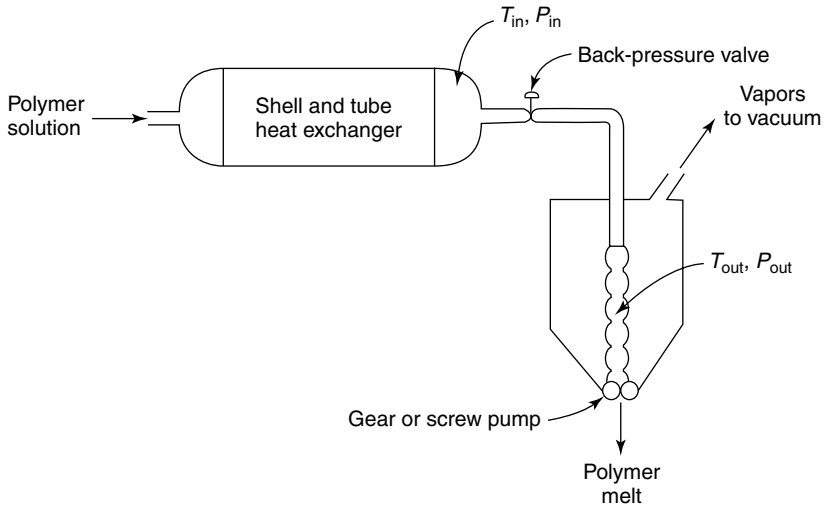

Fig. 1. Flash devolatilization process.

where ν is the weight fraction of the entering stream that is vaporized, λ is the heat of vaporization evaluated at T_{out}, and C_p is the specific heat of the polymer solution, prior to evaporation, evaluated as a mean value over the range from T_{in} to T_{out}. An overall material balance gives

$$w_{in} = \nu + (1 - \nu)_{out} \tag{2}$$

where w is the weight fraction of solvent. The volume fraction of solvent defined as

$$\phi = \rho_{mixture}/\rho_{solvent} \tag{3}$$

Assume that the partial pressure of the solvent equals the total pressure P_{out} in the flash chamber. Then

$$\frac{P_{out}}{P_{sat}} = \phi_{out} \exp\left[\left(1 - \frac{1}{m}\right)(1 - \phi_{out}) + \chi(1 - \phi_{out})^2\right] \tag{4}$$

where m is the degree of polymerization and χ is the FIory-Huggins interaction coefficient (typically 0.45 for a good solvent). The vapor pressure of the pure solvent P_{sat} is a function of T_{out} and is obtained from correlations such as the Antoine or Lee–Kesler equations. Equations 1–4 are solved simultaneously to determine the outlet temperature and solvent concentration.

The above treatment assumes there is only one volatile component, but the equations can be extended to multicomponent systems by writing a separate version of equation (4) for each component.

$$\frac{\text{Partial pressure of component } n}{\text{Vapor pressure of pure component } n} = (\phi_{out})_n \exp\left[\left(1 - \frac{1}{m}\right)(1 - \phi_{out}) + \chi(1 - \phi_{out})^2\right] \tag{5}$$

where $(\phi_{out})_n$ is the volume fraction of the nth component. The various partial pressures sum to P_{out}. The exponential term in equation 5 is the activity coefficient for that component. As indicated above, the same value is assumed for each solvent. It will have a value of about 4 for nearly complete devolatilization of a high molecular weight polymer. Special cases arise when the mixed solvents are highly nonideal or if the polymer crystallizes during the flash.

Many polymers degrade at the temperatures needed for devolatilization. Unzipping to monomer is typical of stryenics. The resulting volatiles are removed in the flash but will be regenerated if there is a substantial inventory of polymer in the process line after the flash. The degradation kinetics can be measured by isothermal weight loss in a thermal gravimetric analyzer. The degradation rates can be fit as a first-order reaction with Arrhenius temperature dependence. Unzipping to monomer imposes a practical limit of a few hundred ppm for polystyrene (see DEGRADATION).

Staged Flashes and Induced Foaming

A common application of flash devolatilization is the removal of 10–15% styrene-ethylbenzene from polystyrene. One commercial process uses $T_{in} = 240^{\circ}C$ and $P_{out} = 1.3$ kPa (10 torr). Equilibrium calculations for an adiabatic flash predict $T_{out} = 220^{\circ}C$ and $w_{out} = 500$ ppm; actual operation gives about 1200 ppm.

The secret to approaching equilibrium in a flash is the generation of surface area through foaming. Vapor bubbles nucleate, grow, and coalesce into an open-celled foam provided T_{out} exceeds the glass-transition temperature of the polymer. The small web thickness allows quick diffusion of the solvent from the polymer film, and the open-celled structure allows ready escape of the vapors. Thus equilibrium is approached; but as suggested by the polystyrene example, mass transfer limitations arise when w_{out} is low. Market demands for lower volatiles than achievable in a single flash prompted the use of a second flash. One process decreases the severity of the first flash so that 1–2% volatiles remain to cause natural foaming in the second flash. The partially devolatilized polymer is reheated and flashed a second time, again with $P_{out} = 1.3$ kPa (10 torr) but now with $T_{out} \cong 240^{\circ}C$ because the adiabatic temperature drop in the second flash is small. In practice, this process gives w_{out} 500–700 ppm. An alternative process retains the severe first flash but injects a foaming agent prior to the second flash. The foaming agent should be innocuous and highly volatile. It need not have significant solubility in the polymer, eg, water has been used for polystyrene. The primary purpose of the foaming agent is to generate an open-celled foam. A secondary benefit is the reduction in solvent partial pressure at a fixed total pressure in the flash chamber. The foaming agent can be mixed with the polymer using a short, melt-fed single-screw extruder. Pressure is applied so that the foaming agent remains a liquid. Static mixers have also been used.

A strictly adiabatic flash has disadvantages when polymerization or degradation reactions occur in the heat exchanger. Adiabatic operation forces high values of T_{in}, which can lead to by-products or undesired low molecular weight polymer. When the inlet viscosity is high, flashed polymer can be displaced from the heat exchanger by the incoming polymer solution. This allows boiling in the heat exchanger, giving higher heat transfer coefficients and a lower value for T_{in} because

some of the heat of vaporization is supplied directly rather than as sensible heat. In theory, the equilibrium flash calculations are easily modified to account for a partially vaporized feed. In practice, the extent of vaporization occurring within the tubes is difficult to calculate. A conservative approach to designing the heat exchanger is to assume that boiling does not occur. However, there is no need to apply back-pressure to the heat exchanger when the entering solution is highly viscous. For polystyrene, entering concentrations of 70% polymer are sufficient to allow boiling in the heat exchanger. Some designs install the heat exchanger directly above the flash chamber with no intermediate piping. Other designs use elaborate nozzles and foam distributors, but there is little evidence that these devices provide any practical advantage.

The generic process in Figure 1 can be applied to relatively dilute polymer solutions, although two- or three-staged flashes are needed for complete devolatilization. A process for recovering 10% polyethylene from a xylene solution employs a first flash with $w_{in} = 0.10$, $T_{in} = 280^{\circ}C$, and $P_{out} = 55$ kPa (8 psig). This gives a $T_{out} = 180^{\circ}C$ and $w_{out} = 0.85$. The P_{in} for this flash is set at 1896 kPa (275 psig) to avoid boiling and possible plugging of the heat exchanger. The second flash gives $w_{out} = 0.99$ and provides the fed to a rear-vented, single-screw extruder to complete the devolatilization.

Extruder and Wiped-Film Devolatilization

The surface area needed for mass transfer from the polymer phase to the vapor phase can be generated by mechanical devices such as single- and twin-screw extruders and wiped-film evaporators, but strictly mechanical generation of surface area scales up very poorly. The throughput of such devices scales as D^3, but the generation of surface area scales only as D^2 where D is the screw diameter. Surface area created by foaming scales as D^3 so that foaming is a highly desirable complement to the mechanical generation of surface area. Foaming occurs naturally in many extrusion processes so that some vendors suggest using $D^{2.5}$ as the scale-up factor where there is no explicit flash. Figure 2 shows a devolatilization scheme that has been employed in extruders to attain maximum removal of solvents.

The polymer solution is preheated and then flashed into the barrel of the extruder at a point downstream from the normal inlet. The polymer moves from left to right. Solvent vapors flow countercurrently and are removed at the rear end of the extruder. The partially devolatilized polymer is transported to the right. It is compressed, reheated, and pumped to a milling zone where additional devolatilization is caused by the mechanical generation of surface area. Figure 3 shows idealized results for devolatilization as a function of operating and scale-up variables. The y-axis indicates the extent of devolatilization, measured as $(w_{out} - w*)/(w_{in} - w*)$ where $w*$ is its equilibrium concentration of volatiles corresponding to the temperature and pressure in the extruder vent. The x-axis measures the collection of operating and scale-up variables that determine the extent of devolatilization according to a conventional model. These variables are the screw diameter D, the molecular diffusivity of the volatile component D the screw speed N, and the polymer flow rate Q (see EXTRUSION).

For the case of devolatilization extrusion with back-venting, Figure 2 shows a discontinuity at the origin that corresponds to a flash step at the inlet of the extruder. To a first approximation, the decrease in solvent concentration for this

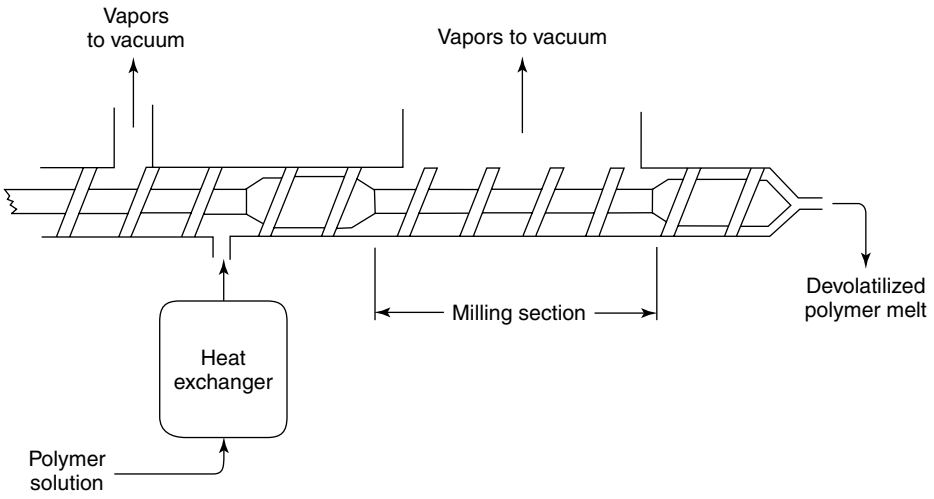

Fig. 2. Devolatilizing extruder with back-venting.

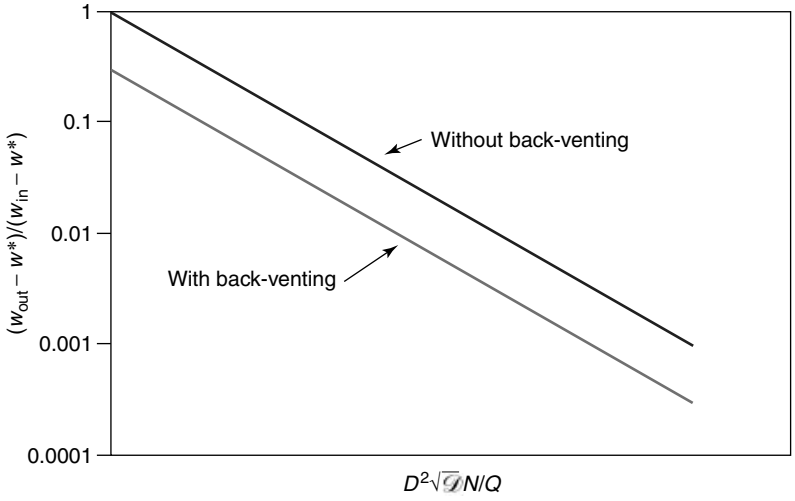

Fig. 3. Scale-up of devolatilizing extruders.

flash is independent of $D^2\sqrt{\mathcal{D}N}/Q$ and thus occurs to the same extent in any extruder, regardless of size. In the milling region, the solvent concentration decreases gradually, and the devolatilization capacity of this region scales rather uneconomically as $D^2\sqrt{\mathcal{D}N}/Q$. In practice, some foaming occurs in the milling section of extruders and in wiped-film evaporators. This foaming significantly improves devolatilization. Some extruder vendors suggest using a scale-up factor of $D^{2.5}\sqrt{\mathcal{D}N}/Q$ to account for foaming.

Equipment Considerations

Flash devolatilization is a relatively mature technology for the removal of volatile components from polymer melts and solutions. It was developed by major

companies during the 1960s and is now used in single-train units at rates exceeding 25 tons/h. The basic technology is applicable to a wide variety of systems. The capital cost is low compared to mechanical devolatilization, and the confidence in scaling up from pilot plant data is high. Despite these advantages, flash devolatilization is still confined to a relatively small number of companies that developed the technology originally or that acquired it from other companies. Dissemination of the technology has been inhibited by the lack of commercially available pilot-plant equipment. Individual units must be designed and fabricated from components. This is in sharp contrast to the situation with extruders and wiped-film devolatilizers, where many vendors supply pilot-scale units. The major equipment item for flash devolatilization is the pump used to extract the polymer from the flash chamber. Large capacity, jacketed gear pumps are available from several vendors. The inlet port to these pumps has been expanded to expose the gear teeth. These pumps work when the polymer foam falls on the gear teeth. There is no need for a suction head.

Conventional shell-and-tube heat exchangers are usually used to preheat the polymer solution prior to a flash, but flat-plate and spiral-wound heat-exchangers can be used for heat-sensitive materials.

GELATIN

Introduction

Gelatin [9000-70-80] is a protein obtained by partial hydrolysis of collagen, the chief protein component in skin, bones, hides, and white connective tissues of the animal body (see COLLAGEN). Type A gelatin is produced by acid processing of collagenous raw material; type B is produced by alkaline or lime processing. Because it is obtained from collagen by a controlled partial hydrolysis and does not exist in nature, gelatin is classified as a derived protein. Animal glue and gelatin hydrolysate, sometimes referred to as liquid protein, are products obtained by a more complete hydrolysis of collagen and can thus be considered as containing lower molecular-weight fractions of gelatin.

Use of animal glues was first recorded ca 4000 BC in ancient Egypt (1). Throughout subsequent centuries, glue and crude gelatin extracts with poor organoleptic properties were prepared by boiling bone and hide pieces and allowing the solution to cool and gel. Late in the seventeenth century, the first commercial gelatin manufacturing began. At the beginning of the nineteenth century, commercial production methods gradually were improved to achieve the manufacture of high molecular weight collagen extracts with good quality that form characteristic gelatin gels (1–3).

Uses of gelatin are based on its combination of properties: reversible gel-to-sol transition of aqueous solution; viscosity of warm aqueous solutions; ability to act as a protective colloid; water permeability; and insolubility in cold water, but complete solubility in hot water. It is also nutritious. These properties are utilized in the food, pharmaceutical, and photographic industries. In addition, gelatin forms strong, uniform, clear, moderately flexible coatings which readily swell and absorb water and are ideal for the manufacture of photographic films and pharmaceutical capsules.

Chemical Composition and Structure

Gelatin is not a single chemical substance. The main constituents of gelatin are large and complex polypeptide molecules of the same amino acid composition as the parent collagen, covering a broad molecular weight distribution range. In the parent collagen, the 18 different amino acids are arranged in ordered, long chains, each having ~95,000 mol wt. These chains are arranged in a rod-like, triple-helix structure consisting of two identical chains, called α_1, and one slightly different chain called α_2 (4–6). These chains are partially separated and broken, ie, hydrolyzed, in the gelatin manufacturing process. Different grades of gelatin have average molecular weight ranging from ~20,000 to 250,000 (7–18). Molecular weight distribution studies have been carried out by fractional precipitation with ethanol or 2-propanol and by complexing with anionic detergent molecules. The coacervates are isolated and recovered as gelatin fractions (19–22).

Analysis shows the presence of amino acids from 0.2% tyrosine to 30.5% glycine. The five most common amino acids are glycine [56-40-6], 26.4–30.5%; proline [147-85-3], 14.8(18%; hydroxyproline [51-35-4], 13.3–14.5%; glutamic acid [56-86-0], 11.1–11.7%; and alanine [56-41-7], 8.6–11.3%. The remaining amino acids in decreasing order are arginine [74-79-3], aspartic acid [56-84-8], lysine [56-87-1], serine [56-45-1], leucine [61-90-5], valine [72-18-4], phenylalanine [63-91-2], threonine [72-19-5], isoleucine [73-32-5], hydroxylysine [13204-98-3], histidine [71-00-1], methionine [63-68-3], and tyrosine [60-18-4] (18–25).

Warm gelatin solutions are more levorotatory than expected on the basis of the amino acid composition, indicating additional order in the molecule, which probably results from Gly-Pro-Pro and Gly-Pro-Hypro sequences (26). The α-chain form of gelatin behaves in solution like a random-coil polymer, whereas the gel form may contain as much as 70% helical conformation (27). The remaining molecules in nonhelical conformation link helical regions together to form the gel matrix. Helical regions are thought to contain both inter- and intramolecular associations of chain segments.

Gelatin structures have been studied with the aid of an electron microscope (28). The structure of the gel is a combination of fine and coarse interchain networks; the ratio depends on the temperature during the polymer–polymer and polymer–solvent interaction leading to bond formation. The rigidity of the gel is approximately proportional to the square of the gelatin concentration. Crystallites, indicated by X-ray diffraction pattern, are believed to be at the junctions of the polypeptide chains (29).

Homogeneous α-chain gelatin has been prepared by pretreating collagen with pronase in the presence of 0.4 M CaC_{l2} [10043-52-4], and extracting the gelatin with hot water at 80°C and pH 7.0 after inactivating the enzyme and removing the salts.

Stability. Dry gelatin stored in airtight containers at room temperature has a shelf life of many years. However, it decomposes above 100°C. For complete combustion, temperatures above 500°C are required. When dry gelatin is heated in air at relatively high humidity, < 60% rh, and at moderate temperatures, ie, above 45°C, it gradually loses its ability to swell and dissolve (25,26). Aqueous solutions or gels of gelatin are highly susceptible to microbial growth and breakdown by

proteolytic enzymes. Stability is a function of pH and electrolytes and decreases with increasing temperature because of hydrolysis.

Physical and Chemical Properties

Commercial gelatin is produced in mesh sizes ranging from coarse granules to fine powder. In Europe, gelatin is also produced in thin sheets for use in cooking. It is a vitreous, brittle solid, faintly yellow in color. Dry commercial gelatin contains about 9–13% moisture and is essentially tasteless and odorless with specific gravity between 1.3 and 1.4. Most physical and chemical properties of gelatin are measured on aqueous solutions and are functions of the source of collagen, method of manufacture, conditions during extraction and concentration, thermal history, pH, and chemical nature of impurities or additives.

Gelation. Perhaps the most useful property of gelatin solution is its capability to form heat reversible gel–sols. When an aqueous solution of gelatin with a concentration greater than about 0.5% is cooled to about 35–40°C, it first increases in viscosity, and then forms a gel. The gelation process is thought to proceed through three stages: (*1*) rearrangement of individual molecular chains into ordered, helical arrangement, or collagen fold (27–39); (*2*) association of two or three ordered segments to create crystallites (34,40,41); and (*3*) stabilization of the structure by lateral interchain hydrogen bonding within the helical regions. The rigidity or jelly strength of the gel depends on the concentration, the intrinsic strength of the gelatin sample, pH, temperature, and additives.

Because the economic value of gelatin is commonly determined by jelly strength, the test procedure for its determination is of great importance. Commercially, gelatin jelly strength is determined by standard tests which measure the force required to depress the surface of a carefully prepared gel by a distance of 4 mm using a flat-bottomed plunger 12.7 mm in diameter. The force applied may be measured in the form of the quantity of fine lead shot required to depress the plunger and is recorded in grams. The measurement is termed the Bloom strength after the inventor of the lead shot device (42,43). In the early 1990s, sophisticated testing equipment utilizing sensitive load cells for the measurement are commonly used.

The conversion temperature for gelatin is determined as setting point, ie, sol to gel, or melting point, ie, gel to sol. Commercial gelatins melt between 23 and 30°C, with the setting point being lower by 2–5°C. Melting point determination, described in Reference 44, utilizes test tubes filled with gelatin solution that are gently chilled to form a gel. The tubes are tilted and colored carbon tetrachloride solution is placed on the gelatin surface. The tube is gradually warmed and the end point is determined when the descent of the colored solution is observed. Several methods have been used to determine the setting point of gelatin (45).

Solubility. In most commercial applications, gelatin is used as a solution. Gelatin is soluble in water and in aqueous solutions of polyhydric alcohols such as glycerol [56-81-5] and propylene glycol [57-55-6]. Examples of highly polar, hydrogen-bonding organic solvents in which gelatin dissolves are acetic acid [64-19-7], trifluoroethanol [75-89-8], and formamide [75-12-7] (46). Gelatin is

practically insoluble in less polar organic solvents such as acetone, carbon tetrachloride, ethanol, ether, benzene, dimethylformamide, and most other nonpolar organic solvents. Many water-soluble organic solvents are compatible with gelatin, but interfere with gelling properties (47). Dry gelatin absorbs water exothermally. The rate and degree of swelling is a characteristic of the particular gelatin. Swelled gelatin granules dissolve rapidly in water above 35°C. The cross-linking of gelatin matrix by chemical means is used extensively in photographic products, and this so-called hardening permanently reduces the solubility of gelatin (33,48–54).

Amphoteric Character. The amphoteric character of gelatin is due to the functional groups of the amino acids and the terminal amino and carboxyl groups created during hydrolysis. In strongly acidic solution the gelatin is positively charged and migrates as a cation in an electric field. In strongly alkaline solution, it is negatively charged and migrates as an anion. The intermediate point, where net charge is zero and no migration occurs, is known as the isoelectric point and is designated in pH units (55,56). A related property, the isoionic point, can be determined by utilizing a mixed-bed ion-exchange resin to remove all nongelatin cations and anions. The resulting pH of the gelatin solution is the isoionic point and is expressed in pH units. The isoionic point is reproducible, whereas the isoelectric point depends on the salts present. Type A gelatin has a broad isoionic region between pH 7 and pH 10; type B is in a lower, more reproducible region, reaching an isoionic point of 5.2 after 4 weeks of liming, which drops to 4.8 after prolonged or more vigorous liming processes (57–60). The isoelectric point can also be estimated by determining a pH value at which a gelatin solution exhibits maximum turbidity (61). Many isoionic point references are recorded as isoelectric points even though the latter is defined as a pH at which gelatin has net charge of zero and thus shows no movement in the electric field (62).

Viscosity. The viscosity of gelatin solutions is affected by gelatin concentration, temperature, molecular weight of the gelatin sample, pH, additives, and impurities. In aqueous solution above 40°C, gelatin exhibits Newtonian behavior. Standard testing methods employ use of a capillary viscometer at 60°C and gelatin solutions at 6.67 or 12.5% solids (43,45). The viscosity of gelatin solutions increases with increasing gelatin concentration and with decreasing temperature. For a given gelatin, viscosity is at a minimum at the isoionic point and reaches maxima at pH values near 3 and 10.5 (63). At temperatures between 30 and 40°C, non-Newtonian behavior is observed, probably due to linking together of gelatin molecules to form aggregates (64,65). Addition of salts decreases the viscosity of gelatin solutions. This effect is most evident for concentrated gelatin solutions (66–68).

Colloid and Emulsifying Properties. Gelatin is an effective protective colloid that can prevent crystal, or particle, aggregation, thereby stabilizing a heterogeneous suspension. It acts as an emulsifying agent in cosmetics and pharmaceuticals involving oil-in-water dispersions. The anionic or cationic behavior of gelatin is important when used in conjunction with other ionic materials. The protective colloid property is important in photographic applications where it stabilizes and protects silver halide crystals while still allowing for their normal growth and sensitization during physical and chemical ripening processes.

Coacervation. A phenomenon associated with colloids wherein dispersed particles separate from solution to form a second liquid phase is termed

coacervation. Gelatin solutions form coacervates with the addition of salt such as sodium sulfate [7757-82-6], especially at pH below the isoionic point. In addition, gelatin solutions coacervate with solutions of oppositely charged polymers or macromolecules such as acacia. This property is useful for microencapsulation and photographic applications (69–74).

Swelling. The swelling property of gelatin is not only important in its solvation but also in photographic film processing and the dissolution of pharmaceutical capsules. That pH and electrolyte content affect swelling has been explained by the simple Donnan equilibrium theory, treating gelatin as a semipermeable membrane (75). This explains why gelatin exhibits the lowest swelling at its isoelectric pH. At pH below the isoelectric point, proper choice of anions can control swelling, whereas above the isoelectric point, cations primarily affect swelling. These effects probably involve breaking hydrogen bonds, resulting in increased swelling. The rate of swelling follows approximately a second-order equation (76,77). In photographic products, the swelling of the gelatin layer is controlled by coating conditions, drying conditions, chemical cross-linking, and the composition of the processing solutions (49–54). Conditioning at 90% rh and 20°C for 24 h greatly reduces swelling of hot dried film coatings (78–80). The ratio of lateral to vertical swelling is of great concern in the photographic industry since it can cause curling of photographic papers or films when changes in humidity or general moisture content take place.

Manufacture and Processing

Although new methods for processing gelatin, including ion exchange and cross-flow membrane filtration, have been introduced since 1960, the basic technology for modern gelatin manufacture was developed in the early 1920s. Acid and lime processes have separate facilities and are not interchangeable. In the past, bones and ossein, ie, decalcified bone, have been supplied by India and South America. In the 1990s, slaughterhouses and meat-packing houses are an important source of bones. The supply of bones has been greatly increased since the meat-packing industry introduced packaged and fabricated meats, assisted by the growth of fast-food restaurants. Dried and rendered bones yield about 14–18% gelatin, whereas pork skins yield about 18–22%.

Most type A gelatin is made from pork skins, yielding grease as a marketable by-product. The process includes macerating of skins, washing to remove extraneous matter, and swelling for 10–30 h in 1–5% hydrochloric acid [7647-01-0], phosphoric acid [7664-38-2], or sulfuric acid [7664-93-9]. Then four to five extractions are made at temperatures increasing from 55–65°C for the first extract to 95–100°C for the last extract. Each extraction lasts about 4–8 h. Grease is then removed, the gelatin solution filtered, and, for most applications, deionized. Concentration to 20–40% solids is carried out in several stages by continuous vacuum evaporation. The viscous solution is chilled, extruded into thin noodles, and dried at 30–60°C on a continuous wire-mesh belt. Drying is completed by passing the noodles through zones of successive temperature changes wherein conditioned air blows across the surface and through the noodle mass. The dry gelatin is then ground and blended to specification.

Type B gelatin is made mostly from bones, but also from bovine hides and pork skins. The bones for type B gelatin are crushed and degreased at the rendering facilities, which are usually located at a meat-packing plant. Rendered bone pieces, 0.5–4 cm, with less than 3% fat, are treated with cool, 4–7% hydrochloric acid from 4 to 14 days to remove the mineral content. An important by-product, dibasic calcium phosphate, is precipitated and recovered from the spent liquor. The demineralized bones, ie, ossein, are washed and transferred to large tanks where they are stored in a lime slurry with gentle daily agitation for 3–16 weeks. During the liming process, some deamination of the collagen occurs with evolution of ammonia. This is the primary process that results in low isoelectric ranges for type B gelatin. After washing for 15–30 h to remove the lime, the ossein is acidified to pH 5–7 with an appropriate acid. Then the extraction processing for type A gelatin is followed. Throughout the manufacturing process, cleanliness is important to avoid contamination by bacteria or proteolytic enzymes.

Bovine hides and skins are substantial sources of raw material for type B gelatin and are supplied in the form of splits, trimmings of dehaired hide, rawhide pieces, or salted hide pieces. Like pork skins, the hides are cut to smaller pieces before being processed. Sometimes the term calfskin gelatin is used to describe hide gelatin. The liming of hides usually takes a little longer than the liming of ossein from bone.

Most manufacturing equipment should be made of stainless steel. The liming tanks, however, can be either concrete or wood. Properly lined iron tanks are often used for the washing and acidification, ie, souring, operations. Most gelatin plants achieve efficient processes by operating around the clock. The product is tested in batches and again as blends to confirm conformance to customer specifications.

Economic Aspects

World gelatin production in 2000 was believed to be about 260,000 t. The United States produced about 45,000 t, followed by Germany, France, Brazil, Japan, and India. Of the gelatin produced in the United States, 59% is acid-processed, ie, type A. The U.S. food industry consumes about 25,000 t/year, with an annual growth rate of 0.5%; the pharmaceutical industry consumes about 20,000 t/year; and the photographic industry about 10,000 t/year. In the United States, the pharmaceutical gelatin market is expected to grow on the average of 2.5% per year. The photographic gelatin market has been stable or declining slightly.

Analytical Test Methods and Quality Standards. Gelatin is identified by a positive test for hydroxyproline [51-35-4], turbidity with tannic acid [1401-55-4], or a yellow precipitate with acidic potassium dichromate [7778-50-9] or trinitrophenol [88-89-1]. A 5% aqueous solution exhibits reversible gel-to-sol formation between 10 and 60°C. Gelatin gives a positive color test for aldehydes and sugars that are considered undesirable impurities in photographic gelatin; nucleic acids are considered restrainers in photographic gelatins and their concentration is monitored closely for this application (81). Elemental analysis of commercial gelatin is reported as carbon, 50.5%; hydrogen, 6.8%; nitrogen, 17%; and oxygen

25.2% (82); a purer sample analyzed for 18.2–18.4% nitrogen (23,25). Regulations for quality standards vary from country to country, but generally include specifications for ash content, SO_2, heavy metals, chromium, lead, fluoride, arsenic, odor, and for the color or clarity of solutions (83). In addition, certain bacteriological standards, including E. coli and Salmonella, are specified. Restrictions on certain additives and preservatives are also listed. In the United States, the *Food Chemicals Codex* published an updated specification for food-grade gelatin in 1996. Standard testing procedures for viscosity, pH, ash, moisture, heavy metals, arsenic, bacteria, and jelly strength are described (42,83–87). Additional test procedures have been published by the photographic and gelatin industries including the Japanese PAGI Method (88,89). Specific tests for photographic gelatin have been devised by the International Working Group for Photographic Gelatin (IAG) (90) in Fribourg, Switzerland, and by individual photographic companies and gelatin companies.

Uses

Food Products. Gelatin formulations in the food industry use almost exclusively water or aqueous polyhydric alcohols as solvents for candy, marshmallow, or dessert preparations. In dairy products and frozen foods, gelatin's protective colloid property prevents crystallization of ice and sugar. Gelatin products having a wide range of Bloom and viscosity values are utilized in the manufacture of food products, specific properties being selected depending on the needs of the application. For example, a 250-Bloom gelatin may be utilized at concentrations ranging from 0.25% in frozen pies to 0.5% in ice cream; the use of gelatin in ice cream has greatly diminished. In sour cream and cottage cheese, gelatin inhibits water separation, ie, syneresis. Marshmallows contain as much as 1.5% gelatin to restrain the crystallization of sugar, thereby keeping the marshmallows soft and plastic; gelatin also increases viscosity and stabilizes the foam in the manufacturing process. Many lozenges, wafers, and candy coatings contain up to 1% gelatin. In these instances, gelatin decreases the dissolution rate. In meat products, such as canned hams, various luncheon meats, corned beef, chicken rolls, jellied beef, and other similar products, gelatin in 1–5% concentration helps to retain the natural juices and enhance texture and flavor. Use of gelatin to form soft, chewy candies, so-called gummi candies, has increased worldwide gelatin demand significantly (ca 1992). Gelatin has also found new uses as an emulsifier and extender in the production of reduced-fat margarine products. The largest use of edible gelatin in the United States, however, is in the preparation of gelatin desserts in 1.5–2.5% concentrations. For this use, gelatin is sold either premixed with sugar and flavorings or as unflavored gelatin packets. Most edible gelatin is type A, but type B is also used.

Pharmaceutical Products. Gelatin is used in the pharmaceutical industry for the manufacture of soft and hard capsules. The formulations are made with water or aqueous polyhydric alcohols. Capsules are usually preferred over tablets in administering medicine (91). Elastic or soft capsules are made with a rotary die

from two plasticized gelatin sheets which form a sealed capsule around the material being encapsulated. Methods have been developed to encapsulate dry powders and water-soluble materials which may first be mixed with oil. The gelatin for soft capsules is low bloom type A, 170–180 g; type B, 150–175 g; or a mixture of type A and B. Hard capsules consisting of two parts are first formed and then filled. The manufacturing process is highly mechanized and sophisticated in order to produce capsules of uniform capacity and thickness. Medium-to-high bloom type A, 250–280 g; type B, 225–250 g; or the combination of type A and B gelatin are used for hard capsules. Usage of gelatin as a coating for tablets has increased dramatically. In a process similar to formation of gelatin capsules, tablets are coated by dipping in colored gelatin solutions, thereby giving the appearance and appeal of a capsule, but with some protection from adulteration of the medication. The use of glycerinated gelatin (83) as a base for suppositories offers advantages over carbowax or cocoa butter base (92). Coated or cross-linked gelatin is used for enteric capsules. Gelatin is used as a carrier or binder in tablets, pastilles, and troches.

For arresting hemorrhage during surgery, a special sterile gelatin sponge known as absorbable gelatin sponge (28) or Gelfoam is used. The gelatin is partially insolubilized by a cross-linking process. When moistened with a thrombin or sterile physiological salt solution, the gelatin sponge, left in place after bleeding stops, is slowly dissolved by tissue enzymes. Special fractionated and prepared type B gelatin can be used as a plasma expander.

Gelatin can be a source of essential amino acids when used as a diet supplement and therapeutic agent. As such, it has been widely used in muscular disorders, peptic ulcers, and infant feeding, and to spur nail growth. Gelatin is not a complete protein for mammalian nutrition, however, since it is lacking in the essential amino acid tryptophan [73-22-3] and is deficient in sulfur-containing amino acids.

Photographic Products. Gelatin has been used for over 100 years as a binder in light-sensitive products. The useful functions of gelatin in photographic film manufacture are a result of its protective colloidal properties during the precipitation and chemical ripening of silver halide crystals, setting and film-forming properties during coating, and swelling properties during processing of exposed film or paper. Quality requirements of photographic gelatin may be very elaborate and can include over 40 chemical and physical tests, in addition to photographic evaluation. Most chemical impurities are limited to less than 10 ppm. Aqueous solutions are employed for emulsions. Photographic gelatins are manufactured to standard specifications since the testing is time-consuming and costly. A new gelatin product may require 6–12 months of testing, including extensive field testing prior to commercialization. Photographic products may have up to 20 gelatin layers grouped into three categories: (*1*) light-sensitive silver halide-bearing layers of 2–10 μm thickness, referred to as emulsion layers; (*2*) surface, spacer, filter, or protective layers of 1–2 μm thickness; and (*3*) backing, antihalo, or noncurl layers coated on the opposite side of the film substrate from the emulsion layer. The quality and uniformity standards are highest for emulsion gelatin because it controls silver halide nucleation, crystal growth, chemical sensitization, latent image stability, and numerous other factors affecting the total photographic response. Since the early 1970s, the photographic industry has switched from so-called

active gelatins derived from hides to inert types derived from bones. The latter are very low or void of natural restrainers, reduction, and sulfur sensitizers. Other changes in techniques have been brought about by abandoning the lengthy noodle wash technique used to remove salts after silver halide precipitation in favor of precipitating, coagulating, or derivatizing gelatin and washing the precipitate by decanting or utilizing ultrafiltration techniques; by new coating techniques that allow simultaneous coating of several layers at one time at speeds 10 times as fast as before; and by short-time high temperature processing which may require new cross-linking agents unlike the aldehydes and metal salts previously used. Many new hardeners are extremely fast-acting and are metered into the solution during the coating operation. It is quite common to use a derivatized gelatin, such as phthalated gelatin, to precipitate silver halide (74). These materials with a low pH isoionic point form a coacervate at pH < 4.0. Precipitation in this case is accomplished by lowering the pH, washing at low pH, and then increasing pH to above 6.5 to dissolve and redisperse the emulsion before reconstituting it with gelatin. Gelatin used in the auxiliary layers must be able to withstand high temperature processing and allow high speed coating.

Gelatin is also used in so-called subbing formulations to prepare film bases such as polyester, cellulose acetate [9004-35-7], cellulose butyrate, and polyethylene-coated paper base for coating by aqueous formulations. Solvents such as methanol [67-56-1], acetone [67-64-1], or chlorinated solvents are used with small amounts of water. Gelatin containing low ash, low grease, and having good solubility in mixed solvents is required for these applications (see COATINGS). In certain lithographic printing, light-sensitive dichromated gelatin is used. Light causes permanent cross-linking of gelatin in the presence of the dichromate; this phenomenon is used to make relief images for printing. Dichromated gelatin coatings are commonly used in production of high quality holographic images. In this application, the light sensitivity of the image-receiving medium is less important than the image-resolving power (93,94). Gelatin coatings in photographic products are further tested for brittleness, scratch resistance, friction, swelling rate, drying rate, curling tendency, dry adhesion, wet adhesion, and pressure sensitivity. These properties are becoming more critical with the development of more sophisticated cameras and printing and processing equipment. Photographic technology offers a rapidly changing, highly sophisticated, very competitive market for photographic gelatin manufacturers.

Derivatized Gelatin. Chemically active groups in gelatin molecules are either the chain terminal groups or side-chain groups. In the process of modifying gelatin properties, some groups can be removed, eg, deamination of amino groups by nitrous acid [10024-97-2] (95), or removal of guanidine groups from arginine [74-79-3] by hypobromite oxidation (96); the latter destroys the protective colloid properties of gelatin. Commercially successful derivatized gelatins are made mostly for the photographic gelatin and microencapsulation markets. In both instances, the amino groups are acylated. Protein detergent is made by lauroylating gelatin. Phthalated gelatin is now widely used in the photographic industry (97). Arylsulfonylated gelatin has been patented for microencapsulation (qv) (98). Carbamoylated gelatin, made by treating gelatin with cyanate or nitrourea in neutral aqueous solution, is also used by the photographic industry (24,99–101). Active double bonds react with the amino groups in gelatin, and

acrylic polymers have been grafted to gelatin (102). Gelatin has been derivatized by epoxides (103), cyclic sulfones (104), and cyanamide [420-04-2] (105). Cross-linking or hardening of gelatin attacks the same active groups, but an agent with two active sites is needed, eg, divinylsulfone [77-77-0], bis(isomaleimide) [13676-54-5], aziridines, bisepoxides, epichlorohydrin [106-89-8], polyisocyanates, and dichlorotriazine. Aldehydes such as formaldehyde [50-00-0] and glyoxal [107-22-2] are still used and to a small extent even potassium chromium alum [7788-99-0], $Cr_2K_2(SO_4)_4 \cdot 24H_2O$, and potassium aluminum alum [7784-24-9], $Al_2K_2(SO_4)_4 \cdot 24H_2O$.

GENE-DELIVERY POLYMERS

Introduction to Human Gene Therapy

Gene therapy may be defined as the treatment of human disease by the transfer of genetic material into specific cells of the patient (1). The advances in molecular biology and biotechnology of the last 30 years have greatly enhanced our understanding of the genetics of pathogenesis and have led to the identification of numerous disease-causing genes. With the impending completion of the Human Genome Project, the list of genetic disease targets is likely to grow tremendously. It is not difficult to envision treatment of genetic diseases such as hemophilia (2), muscular dystrophy (3–5), or cystic fibrosis (6) through replacement of errant genes within the affected cells. However, gene therapy approaches are also being developed for treatments of virtually all forms of cardiovascular diseases (7), neurological diseases (8–10), infectious diseases (11), wound healing (12), and cancer (13–15). In these instances, the delivered genes may be intended to augment naturally occurring proteins (eg growth factors or cytokines), to alter the expression of existing genes facilitating a desired cellular or tissue response, or to produce cytotoxic proteins or prodrug-activating enzymes, for example, to kill tumor cells in cancer treatment (13,15) or proliferating endothelial cells to inhibit restenosis following balloon angioplasty (7,16). Finally, it has been shown that expression of viral genes within certain tissues can result in an efficient immune response, leading to the development of DNA vaccines (17).

Because of the potential to revolutionize treatment of a broad range of human diseases, including some of mankind's most-hated and currently intractable afflictions, gene therapy has been heavily investigated over the past decade. More than 17,000 papers containing the keywords "gene therapy" have appeared in the MEDLINE database since 1990. The first gene therapy clinical trial, for

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

severe combined immunodeficiency caused by a defect in the gene encoding the enzyme adenosine deaminase, was initiated in 1990 (18). However, it was not until April 2000 that Cavazzana-Calvo and co-workers (19) reported the first clinical success by treating two infants with γc-severe combined immunodeficiency. Also that year, Kay and co-workers (20) reported positive data in an early hemophilia clinical trial and Khuri and co-workers (21) reported the successful completion of a phase II clinical trial using a combination of a viral vector and traditional chemotherapy to treat recurrent squamous cell carcinoma of the head and neck. Considering that a total of 596 clinical trials have been completed, are ongoing, or are pending worldwide (22), the small number of successes has been disappointing.

A variety of factors is impacting the progress of human gene therapy. The first step is to identify the proper genes and target cells that will elicit the desired therapeutic effect. It is then necessary to transfer that gene, often specifically to the target cells only, with the highest possible efficiency. While short-term gene expression is sufficient for some applications, such as cancer therapies, long-term expression is needed for treatment of chronic conditions, including most genetic diseases. Unfortunately, however, maintenance of the expression has been difficult. Similarly, for many applications it will be critical to regulate the gene expression, keeping it at the required levels and also controlling when and how the gene expression is turned on and off. Finally, one must obviously accomplish each of these tasks in a way that is safe for the patient. Both toxicity/pathogenicity of the delivery vehicle and the patient's immune response to the treatment must be considered. The majority of these factors, with the exception of identifying a therapeutic gene, are primarily functions of gene delivery. Thus, the key limitation to development of human gene therapy remains the lack of a safe, efficient, and controllable methodology for gene delivery (23).

Methods of Gene Delivery

Gene delivery vehicles can be divided into essentially one of two categories: recombinant viruses and synthetic vectors. The majority of synthetic vectors, furthermore, can be divided into polymers (the subject of this review) and liposomes. Each type of material has important advantages and disadvantages. In order to best understand the problems facing polymer-based gene delivery vehicles and their current state of development, it is useful to briefly examine the alternate methodologies (Table 1).

Viral Vectors. The primary function of a virus is to efficiently carry its own genome from one host cell to another through (perhaps) "hostile" environments, enter the new target cell, navigate to the cell nucleus, and initiate expression of its genome—albeit for the purpose of self-replication. Viruses can be transformed into gene delivery vehicles by removing part of the virus' genome and replacing it with a therapeutic gene. If done carefully, the resulting recombinant virus will retain the functions essential for infection of specific target cells, but will be rendered incapable of replication and, hence, will be nonpathogenic. Because viruses evolved essentially as sophisticated gene delivery vehicles, such recombinant viral vectors are incredibly efficient. Viral vectors have been employed in the majority of gene

Table 1. Comparison of Three Classes of Gene Delivery Vectors

	Advantages	Disadvantages
Recombinant viruses 	Highly efficient Can infect dividing cells Prolonged expression possible Used in most clinical trials to date	Lack of cell specificity Pathogenicity Immunogenicity Difficult and expensive production and purification
Liposomes 	Relatively efficient Perform well *in vivo* Little immunogenicity Used in some clinical trials	Poorly stable Toxicity Lack of cell-specific targeting
Polyplexes 	Simple Inexpensive Potential for cell-specific targeting Flexible chemistry Potentially biocompatible	Low efficiency Work poorly *in vivo* Not used in clinical trials to date

delivery studies reported in the literature and in nearly three quarters of gene therapy clinical trials (429 of 596 protocols approved as of September 2001) (22).

Viral gene delivery vectors have been based upon retrovirus, lentivirus (eg, HIV), adenovirus (AdV), adeno-associated virus (AAV), herpes simplex virus (HSV), and pox virus. There are several important properties that determine the suitability of a viral vector for a specific indication. The duration and regulation of gene expression are often critical factors. For example, retrovirus, lentivirus, and AAV integrate their genetic payload with the host genome, leading to the potential for prolonged transgene expression. The range of host cells that may be infected is also very important. Retrovirus, AdV, and AAV can infect a wide variety of cell types while (wild-type) lentivirus and HSV are limited to specific white blood cells and neurons, respectively. Furthermore, most retroviruses can infect only actively dividing cells, which greatly limits the host cell range, especially for *in vivo* gene transfer. In contrast, the closely related lentivirus, as well as AdV and AAV, can infect nondividing cells. For more information on recombinant viral gene delivery vectors, several excellent reviews have been published recently (24–28).

While viruses are extremely efficient gene delivery vehicles, they are not ideal vectors for human gene therapy. Safety concerns have been the primary bottleneck to clinical application of viral gene delivery vectors. While recombinant viral vectors have been rendered nonreplicative, and therefore nonpathogenic, there still exists the possibility for reverting to a wild-type virion or copurifying replication competent virions. Furthermore, viruses are inherently immunogenic, not only leading to difficulty with repeat administrations, but also the possibility

of dangerous immune reactions. In fact, the death of 18-year-old Jesse Gelsinger in a gene therapy clinical trial in September 1999 was ultimately caused by a severe immune response to the adenoviral gene delivery vector employed in the study. Viral vectors are also limited by their natural target-cell specificity. Some viruses will infect only a limited number of cell types, and their specificity seldom overlaps with the needs of human gene therapy. Further, some viruses (including AdV, AAV, and the pseudotyped retro- and lentiviruses) are quite nonspecific, but for *in vivo* applications, it is often necessary to target only one type of cell. Finally, because the viral vectors are complex biological agents, production and purification are difficult and expensive.

Synthetic Vectors. Although viruses are incredibly efficient gene delivery agents, synthetic vectors provide opportunities for improved safety, greater flexibility, and more facile manufacturing. In general, synthetic vectors are materials that bind electrostatically to DNA or RNA, condensing the genetic material into nanometer-scale complexes (a few tens to several hundred nanometers in diameter) that protect the genes and allow them to enter cells. Such materials have included cationic peptides, proteins, polymers, and liposomes. Various synthetic vectors, including (diethylamino)ether (DEAE)-dextran (29) and calcium phosphate (30), have been used extensively for *in vitro* gene transfer studies since the 1960s. However, development of nonviral vectors for *in vivo* gene delivery, especially clinical applications, has suffered from problems including toxicity, low gene transfer efficiency, and *in vivo* instability.

Cationic Lipids. Use of cationic lipids for gene delivery was first reported in 1987 (31). Since that time, many different lipid structures have been used. Indeed, greater than 30 products are currently available commercially for *in vitro* gene transfer (eg, Transfectam®, LipofectAMINE®, Lipofectin®, and Lipofectace®). These various lipids differ in terms of the nature of their cationic headgroup, their hydrophobic tails, and the spacers linking the two. Cationic headgroups displaying different numbers of charged groups comprising primary, secondary, tertiary, and quaternary amines have been reported. The lipid tails can be saturated or unsaturated and of varying length. Also, cholesterol-based structures have been reported (eg, DC-Chol (32)). The linker can vary in length and hydrophilicity, and some have been designed to incorporate degradable linkages to enhance biocompatibility. These structural properties affect not only the interactions of the lipids with the polyanionic genetic material, but also influence the membrane properties of liposomes formed from them, both of which have been found to have a strong influence on gene delivery efficiency (33). Furthermore, the cationic lipids typically require a helper lipid, commonly di-oleoyl phosphatidylethanolamine (DOPE), that provides the membrane fluidity required to mediate efficient endocytosis and liposome-cell membrane fusion (34).

The variety of lipids and lipid mixtures used in gene delivery has resulted in steadily improving gene transfer efficiencies. This progress has been documented in several excellent reviews (35–38). As a result of their relatively high efficiency, cationic lipids have been the most widely studied of the synthetic vectors. “Lipofection” has been routinely employed in both *in vitro* and *in vivo* gene delivery studies, and in several human gene therapy clinical trials (22). However, lipid-based gene delivery has several critical limitations including lack of cell-specific targeting capacity, difficulty in reproducibly fabricating liposomes and

DNA–liposome complexes, and toxicity, especially upon systemic administration (39).

Cationic Polymers. Cationic polymers have been used as gene carriers since the late 1980s (40). Like the cationic lipids, these polymers, including off-the-shelf materials and polymers specifically designed for gene delivery, have included a wide variety of chemistries. DNA-binding moieties include primary, secondary, tertiary, and quaternary amines, as well as other positively charged groups such as amidines. The charges may reside in the polymer backbone, in pendant groups, or in grafted oligomers. The polymers themselves comprise linear, branched, and dendrimeric structures. Because of this flexibility in polymer chemistries that are available, it may be possible to provide the multiple functions required for efficient gene delivery while maintaining biocompatibility, facile manufacturing, and robust and stable formulation of DNA–polymer complexes (polyplexes). As a result, cationic polymers have great potential for human gene therapy. However, the poor gene transfer efficiency achieved thus far has limited clinical application of these vectors. The specific advantages and disadvantages of several important classes of cationic polymers is described in more detail below.

Barriers to Gene Delivery. All gene delivery vectors, whether viral or synthetic, must perform the same task of escorting genes from solution (eg, in a vial) to the cell nucleus. In order to complete this task, a vector must navigate a series of obstacles, both extracellular and intracellular (41). Viruses have evolved a set of functions to address each challenge. As a result, recombinant viral vectors are highly efficient gene delivery vehicles. In contrast, synthetic vectors are generally unsatisfactory because they typically lack one, or several, of the necessary functions. Therefore, consideration of the important barriers to gene delivery in the next two sections is important in order to understand the limitations of currently available cationic polymers and is necessary for the rational design of new polymers.

Extracellular Barriers

Gene delivery vectors face a first set of barriers in transporting genes from the test tube to the outer membrane of a target cell. These include *in vitro* barriers, such as binding and condensing plasmid DNA and maintaining the complex in solution, as well as *in vivo* barriers, including stability and survival in the blood stream, penetrating the blood vessel wall and surrounding tissue, and specific binding to the target cells of interest. Several of these barriers are discussed in this section.

Gene Packaging. Plasmid DNA is a fragile macromolecule and must be protected from ubiquitous nucleases found both *in vivo* and *in vitro*. Binding of plasmids by cationic polymers provides the needed protection by sterically blocking access of enzymes to the DNA backbone. Further, the physical size of plasmid DNA (∼3–5,000,000 Da; radius of gyration of several hundred nanometers) prevents it from easily crossing the membrane of most cells. The vector material must, therefore, condense the DNA into a smaller, more compact structure. Binding and condensation of genes by the vector material is a necessary first step to efficient gene delivery.

Gene delivery vectors bind to DNA through charge–charge interactions between the negative phosphates along the DNA backbone and positive charges displayed on the vector material. The process of condensation is entropically driven; the free energy decrease resulting from the increased translational entropy of counterions and water molecules dominates the binding energy and loss of entropy in the DNA and polymer (42). Thus, polyplexes form spontaneously upon mixing of cationic polymers with plasmid DNA. The resulting particles are typically toroidal or spherical structures (43,44) with diameters ranging from a few tens of to several hundred nanometers. Each polyplex particle typically comprises several DNA molecules along with many polymer chains. The structure and morphology of polyplexes appears to be kinetically controlled (45) and often depends on the order of mixing (polymer to DNA solution or DNA to polymer solution). Efforts have been made to better understand condensation (42,45,46), but further improvements in the theoretical understanding of the process and better physicochemical characterization of the resulting complexes are needed.

The structure of the polymer can affect DNA binding and condensation. Linear, branched, and dendrimeric polymers all bind plasmid DNA with similar strengths, but complexes containing linear poly-L-lysine (PLL) or polyamidoamine (PAMAM) dendrimers tend to aggregate while branched polyethylenimine (PEI) and "fractured" PAMAM dendrimers (Fig. 1) do not (47). The aggregation apparently leads to decreased gene transfer efficiency. Not surprisingly, the number of cationic moieties has a strong effect on the polymer–DNA interaction. Several groups have reported that a minimum of six to eight charges are required for efficient DNA condensation (48–52). The same groups disagree, however, on the effect of the oligopeptide sequence. Wadhwa and co-workers reported that addition of a single tryptophan (Trp) residue into PLL oligomers increased DNA binding (48). In contrast, Plank and co-workers found that Trp residues had no major effect on DNA binding and, in fact, decreased the "DNA-compacting potency" of the peptides (50). Additionally, placing the cationic moiety nearer the polymer backbone and keeping the charges to a minimum separation along the polymer backbone correlated with increased binding (53).

It is important to note that strong binding and efficient DNA condensation do not correlate directly with gene delivery efficiency. In fact, in some cases the opposite is true. This is likely because too tight binding prevents transcription from those plasmids that do reach the nucleus. Thus, a polymer must balance sufficient binding strength to protect the plasmid during transit to the nucleus with the ability to release the plasmid, perhaps due to competitive binding of genomic DNA or anionic lipids (54), once in the nucleus (52).

Solution Stability. The solution stability of polyplexes depends on the polymer structure and on the DNA/polymer charge ratio. Neutral polyplexes quickly form large aggregates, which are generally ineffective gene delivery agents. In contrast, positively charged polyplexes, as evidenced by zeta potential measurements, typically remain in solution. However, new studies have shown that the solubility and aggregate size of even positive complexes is time-dependent (45).

The concentration ranges over which polyplexes are soluble and stable are limited. For example, PLL/DNA complexes precipitate above about 20 μg DNA/mL

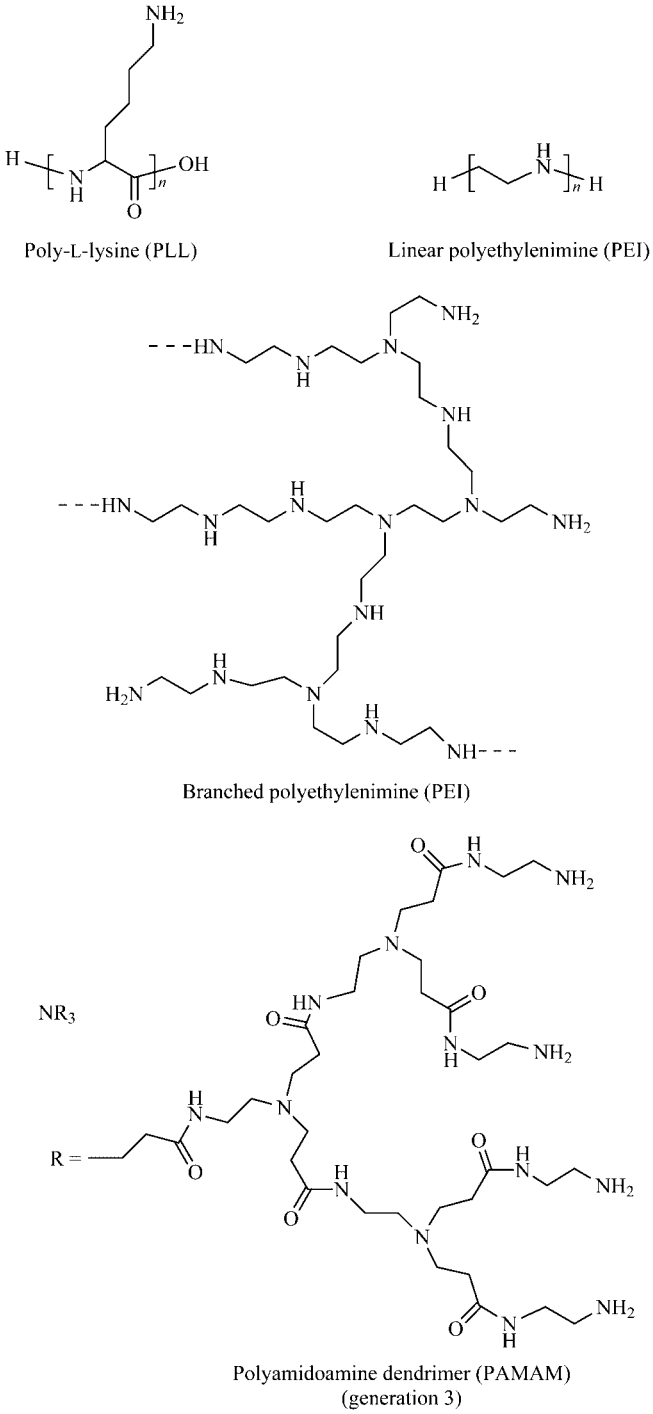

Fig. 1. Structures of several off-the-shelf gene delivery polymers.

(55). Other polymers show similar limits. The limited solubility imposes a maximum dose that can be administered in a reasonable injection volume.

Solution stability is further modified by the presence of salts and especially the protein milieu of the *in vivo* environment. In the presence of physiological salt concentrations, many polyplexes aggregate even at concentrations at which they are stable in water, which further limits the achievable dose and can even be toxic because of embolization of the particulates in the lung. Adsorption of serum albumin and other negatively charged proteins causes further aggregation and can lead to rapid clearance of the polyplexes by phagocytic cells and the reticuloendothelial system (56). Finally, polyplexes containing PLL, a fifth generation PAMAM dendrimer, and PEI, as well as some lipoplexes, have been shown to strongly activate the complement system upon intravenous administration (57).

Modification of polyplexes with poly(ethylene glycol) (PEG), typically grafted onto the polymer as a "brush," can stabilize polyplexes against salt-, protein-, and complement-induced inactivation (58,59). The increased stability due to PEGylation is presumed to result from steric effects leading to decreased particle–particle and particle–protein interactions. The effect depends on the PEG molecular weight, the grafting density, and the method of attachment of PEG to the polymer (58,60). Attachment of other hydrophilic polymers such as *N*-(2-hydroxypropyl)methacrylamide (HPMA) (59,61–64), oligosaccharides (59,65,66), sugars (67,68), and proteins (69) had similar effects.

Cell-Specific Targeting. The degree of target-cell specificity required for a given gene therapy varies widely. For some applications, such as hemophilia, the identity of the transduced cells is of little concern so long as sufficient levels of the therapeutic protein are produced. In other applications, such as cystic fibrosis, the transgene will act only in specific types of cells; expression in other cell types is largely benign. But in applications such as cancer therapies, wherein the goal is to kill the target cells, gene delivery to a very specific set of cells is required.

Polymers generally do not possess a capacity for cell-specific targeting. A typical polyplex, exhibiting an excess of positively charged groups over the negative phosphates, will bind to the negatively charged cell surface through nonspecific electrostatic interactions (70). However, polymers do provide flexible chemistry for modifying polyplexes with desired targeting moieties allowing both increased cell uptake and, often, cell specificity. Many membrane-bound receptor proteins can be used as targets. Derivatization of amino groups with glycosidic moieties, including galactose, glucose, mannose, and lactose (71–78), as well as other small molecules such as folate (79,80), provides selective targeting to cell types displaying the appropriate receptor protein. In two classic examples of protein-mediated targeting, asialoorosomucoid was attached to polylysine (40,81–83) in order to target the asialoglycoprotein receptor on hepatocytes, while Wagner and co-workers developed a method for targeting polyplexes to a variety of cell types, especially hematopoietic cells, through attachment of the iron-transport protein transferrin (43,84–87). Finally, certain other proteins may provide targeting to a more limited range of cells. Examples include epidermal growth factor (EGF) (88,89), antibodies or antibody fragments (90), and integrin-binding sequences (91).

The success of a targeting strategy, and the degree of specificity, will depend on the conjugation chemistry, the length of spacer between ligand and polyplex, the ligand–receptor binding strength, and the number of targeting ligands per polyplex. A variety of common cross-linking chemistries have been used to attach targeting ligands to the polymers including covalent bonds and biotin-streptavidin (88). However, care must be taken to ensure that the ligand-receptor interaction is not disrupted by the conjugation chemistry. Schaffer and co-workers found that for EGF-biotin/avidin-PLL conjugates, short cross-linkers between the EGF and biotin interfered with EGF/EGF-receptor binding, but a 30 Å spacer allowed nearly unhindered binding and resulted in significantly higher gene transfer efficiency. There also exists a balance between the specific targeting interactions and nonspecific electrostatic binding to the cell surface. Cell uptake and gene expression were found to be specific only within a narrow window of polymer/DNA ratios near electroneutrality (92). Finally, there is typically an optimum in ligand valency, because of saturation of both receptor binding and the cell's internalization machinery (92). Thus, efficient cell-specific targeting requires careful optimization of the various parameters that affect cell–surface binding.

Intracellular Barriers

Upon binding to the surface of a target cell and being internalized, gene delivery vehicles are challenged with a new set of intracellular obstacles. Several studies have shown that although >95% of cells in culture may internalize vectors rather efficiently (>100,000 copies per cell (93)), only a small fraction, typically <50%, express the transgene. Polyplexes are generally internalized by endocytosis, and once in the endocytic pathway, polyplexes may be trafficked to lysosomes, acidic vesicles filled with degradative enzymes (94). Gene delivery vectors must escape this pathway into the cytoplasm. Once in the cytoplasm, the vectors must be transported toward the nucleus and subsequently cross the nuclear membrane. Finally, at some point during this process, the polymer must release the genes so that the genes can be transcribed in the nucleus. The process is illustrated in Figure 2. Each step of this process represents a potential efficiency-limiting barrier, and a vector needs to provide functionality to overcome each one.

Endolysosomal Escape. Polyplexes bind to the surface of cells via nonspecific electrostatic interactions and are internalized via adsorptive pinocytosis. Alternatively, polyplexes derivatized with targeting ligands may bind to specific cell–surface receptors, in which case they are often internalized by receptor-mediated endocytosis. In either case, the polyplexes become localized within endocytic vesicles, which isolate the polyplex from the rest of the cell. The endocytic pathway represents a hostile environment for polyplexes. The first vesicle, termed the early endosome, fuses with sorting endosomes from which the internalized material may be transported back to the membrane and out of the cell by exocytosis. More generally, however, polyplexes are believed to be trafficked into late endosomes, vesicles that rapidly acidify to pH 5–6 because of the action of an ATPase proton-pump enzyme in the vesicle membrane. Polyplexes may subsequently be trafficked into lysosomes, which further acidify to

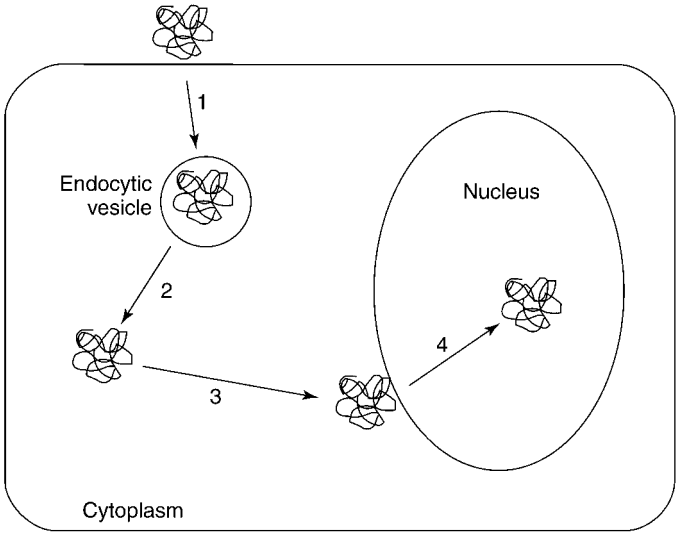

Fig. 2. Intracellular trafficking of polymer gene delivery vectors. 1, Internalization (often by adsorptive pinocytosis or receptor-mediated endocytosis); 2, escape from endocytic vesicles; 3, transport through the cytosol; 4, transport across the nuclear membrane. In addition, polyplexes must be unpackaged at some point in the process, although it is not known where in the process unpackaging occurs.

pH ~4.5 and contain various degradative nucleases, proteases, and lipases. It is believed that polyplexes will become trapped in these vesicles and be degraded. Only those vectors that escape into the cytoplasm can go on to reach the nucleus.

Several strategies have been employed to overcome this barrier. Concurrently, treating cells at the time of transfection with chloroquine, which is known to accumulate in the acidic vesicles and buffer their pH, results in improved gene delivery (95). While this approach has been commonly employed in *in vitro* studies with polymers such as PLL, it is impractical for *in vivo* gene delivery. Other researchers have tried to overcome this barrier by incorporating additional functional groups into polyplexes to provide for endosomal escape. For example, covalent attachment of whole, inactivated AdV particles to PLL was found to enhance gene transfer up to 2000-fold (96–99). It was proposed that this enhancement is due to more efficient endosomal escape, but the virion particle may also provide functionality for addressing subsequent barriers (see below). While successful, this approach is not practical because of the increased difficulty of preparing the vector and the safety concerns, especially immunogenicity, raised by the presence of the virus. Alternatively, fusogenic viral (100–103) or synthetic (104–108) peptides may also provide the endosomal escape function (109,110). These peptides are typically pH-sensitive amphiphiles that undergo a structural change, such as α-helix formation, at acidic pH and then insert into and disrupt the vesicle membrane. The peptides may be associated with polyplexes via electrostatic interactions or covalently attached to the polymer. Gene transfer is typically enhanced 1–3 orders of magnitude in this fashion.

Because of the versatile structures available in cationic polymer gene delivery vehicles, it is possible to build an endosomal escape function into the polymer itself. Polymers such as PEI and PAMAM dendrimers, which contain a large number of secondary and tertiary amines, can undergo large changes in protonation between physiological pH and lysosomal pH. It has been hypothesized that these polymers can, in fact, prevent acidification of endocytic vesicles. Furthermore, these polymers may act as "proton sponges" wherein their buffering capacity results in osmotic swelling and rupture of the endocytic vesicles (111–113). While it is not clear how these polymers function (whether simply by protecting the DNA from acidic pH and enzymatic degradation or by osmotic swelling of the vesicles), there is a clear relationship between polymer buffering capacity and gene delivery (47). Indeed, polymers designed specifically to provide such buffering capacity have proven to be highly successful (*vide infra*) (114–117).

Transport through the Cytoplasm. Once released from endosomal compartments, polyplexes must move through the cytoplasm to the nucleus. However, the cytoplasm is quite concentrated with protein, microtubules, and other organelles, all of which may hinder polyplex transport. In fact, previous studies have indicated that movement through the cytoplasm is size-dependent. Fluorescence recovery after photobleaching studies showed that dextran polymers with hydrodynamic radius more than 260 Å appear to be immobile (118). More recent studies of DNA mobility showed again that diffusion is size-dependent, with DNA larger than 3000 bp being essentially immobile (119). Given the large size of polyplexes, one might expect these vectors to be immobile as well. This fact, together with the known degradation of DNA in the cytosol as a result of the presence of cytosolic nucleases (120), presents an often-overlooked barrier to efficient gene delivery.

Viruses, in contrast, typically have evolved mechanisms for cytoplasmic transport. Subgroup C adenoviruses, including types 2 and 5 (Ad2 and Ad5) escape endosomes rapidly following endocytosis and, thus, are typically "far" from the nucleus. These virus particles have evolved mechanisms by which they then use cytoplasmic dynein motor proteins for active transport along microtubules (MT) toward the nucleus. In contrast, subgroup B Ad (eg, Ad7) lacks the ability to utilize dynein-mediated MT transport. Rather, Ad7 remains in endocytic vesicles and is transported toward the nucleus with their endocytic vesicles (as early endosomes mature into late endosomes and finally lysosomes, the vesicles are transported along MT toward the nuclear envelope). Ad7 then escapes from lysosomes (triggered by lower pH) near the nucleus, thereby mitigating the effects of low cytoplasmic motility (121). It may be possible that positively charged polyplexes use similar mechanisms by nonspecifically interacting with motor proteins, for example. Alternatively, polyplexes may be redistributed throughout the cell, with some ending up near the nucleus, becasue of the mixing that occurs during mitosis. The mechanisms of cytoplasmic polyplex transport need to be better characterized in order to facilitate design of improved polymeric vectors.

Nuclear Localization. Therapeutic genes must reach the cell nucleus to be expressed by the target cell. However, because the genome and nuclear machinery are vital to a cell's functions, nature has isolated the nucleus behind a

double-bilayer membrane with tightly regulated pores to allow import and export of a very specific set of biomolecules. The nuclear pore complex, a 10^7-kDa assembly of at least 30 distinct proteins, allows passage of small molecules, but proteins larger than 10–20 kDa require active transport via specific nuclear import proteins (eg, importins). Viruses have evolved mechanisms to utilize the cell's nuclear import machinery; polymers clearly do not have this capacity. Transfection immediately before cell division (and concomitant disruption of the nuclear membrane) is 30- to 500-fold more effective than transfection of cells at the beginning of their cell cycle (122). In contrast, nondividing cells are poorly transfected compared to dividing cells (122,124). Thus, transport across the nuclear membrane, especially for nondividing cells, appears to be a formidable obstacle to nonviral gene delivery vectors.

It may be possible to modify polyplex vectors to allow efficient nuclear import (125). For example, it is well known that many proteins are targeted to the nucleus by the presence of nuclear localization signals (NLS), short peptide sequences, typically highly cationic, that are recognized by importins. Because of their positive surface charge, it is possible that polyplexes could mimic NLS to a limited extent (126), but if so they are very inefficient as very few vectors typically reach the nucleus (127). However, there is some evidence that this is not a general phenomenon. Other polymers and cationic liposomes do not show an NLS effect (128,129). Several investigators have modified polyplexes by attachment of NLS with generally modest results (128–132). Further, nucleotide sequences on the genes themselves may provide some nuclear targeting (133–135), but this will not find general use as the nucleotide sequences are hidden by the polymer in most cases. In short, nuclear import of polyplex vectors is one of the most poorly characterized steps in the gene delivery process. A better understanding of nuclear transport mechanisms is needed.

Unpackaging. Just as incorporation into a polymer complex protects DNA from enzymatic degradation, so too will complexation prevent binding of the proteins required for initiation of gene expression. Thus, a gene delivery vector must release its DNA at some point in the delivery process. Indeed, efficient nuclear localization does not correlate with high gene expression. Several studies have found that reducing the polymer/DNA binding strength, by reducing the number of positive charges (136), conjugation of PEG chains (60), or decreasing the polymer molecular weight (52), leads to increased gene expression. Polymers must clearly be designed to incorporate a mechanism for nonspecific or environmentally responsive release of the genes, ideally in the nucleus.

"Off-the-Shelf" Polymers in Gene Delivery

Many of the early studies on polymer-mediated gene delivery employed commercially available polymers. As they were not designed for gene delivery, their efficacy as delivery vectors is somewhat serendipitous. Off-the-shelf polymers have nonetheless been very widely studied and form the basis for much of the gene delivery polymer literature. However, significant problems face these polymers, most

notably with cytotoxicity. Three of the major off-the-shelf polymers are described below.

Poly-L-lysine. Poly-L-lysine (PLL; Fig. 1) was one of the first cationic polymers used in the modern era of gene delivery research (40,55). It is commercially available in a range of sizes from oligomers to several hundred kilodaltons. For gene delivery, 20–50 kDa PLL is most commonly used. Polyplexes of DNA and PLL itself are poor gene delivery vectors, but addition of targeting ligands greatly enhances *in vitro* and *in vivo* gene delivery efficiency.

Some of the first reports of PLL-mediated gene delivery employed conjugation of the asialoorosomucoid glycoprotein to target the asialoglycoprotein receptor on mouse hepatocytes *in vitro* and *in vivo* (40,81,82). Shortly thereafter, a series of papers by Wagner and colleagues developed a process, termed transferrinfection, based on conjugation of the iron transport protein, transferrin, to PLL (reviewed in Refs. 87 and 137). These thorough studies provided a firm basis for much of the subsequent gene delivery literature, including some of the first studies of polyplex formation (43) and mechanisms of endolysosomal escape (86,99,100). PLL/DNA complexes have also been targeted to specific cells through conjugation of sugars (49,71–73,136,138), folate (79), RGD-displaying peptides (91,139), and antibodies (140).

Early studies on PLL were promising, but it now appears unlikely that PLL-based polyplexes will reach clinical application. Development has been limited by the relatively low efficiency. This is generally accepted to be the result of poor escape from the endocytic pathway. In recent years, PLL has been relegated to a role in basic mechanistic studies or as a point of comparison in studies of more promising polymers.

Polyethylenimine. PEI has been used as a gene delivery vector since 1995 (111). The polymer has been known for many years and has traditionally been used as a chelator, in water purification, and in shampoos. It is available in two main forms: linear and branched (Fig. 1). The branched polymer is synthesized via acid-catalyzed polymerization of aziridine, while the linear form is synthesized in a similar way but at reduced reaction temperatures (141). A range of molecular weights (eg, $<$1, 2, 22, 25, 50, 70, and 800 kDa) are commercially available from several manufacturers.

PEI is one of the most effective gene delivery polymers studied to date (142). Depending on the cell line, it is typically several orders of magnitude more efficient than PLL. Importantly, PEI mediates gene delivery efficiently in the absence of any exogenous endosomolytic agent such as chloroquine, inactivated viruses, or fusogenic peptides. PEI-containing polyplexes have been targeted to specific cell types by the conjugation of ligands including galactose (74,76), mannose (143), transferrin (90,144), and antibodies (145). Also, PEI has been highly successful for *in vivo* gene delivery to a variety of tissues including the central nervous system (146,147), kidney (148), lung (149,150), and tumor (151) (reviewed in Ref. 142).

The relatively high gene transfer efficiency mediated by PEI is believed to be due in large part to efficient escape from the endocytic pathway through a proposed mechanism known as the "proton-sponge" hypothesis (111,112) (Fig. 3). Endocytic vesicles are acidified by the action of an ATPase enzyme that actively transports protons from the cytosol into the vesicle. Because every third atom of the polymer

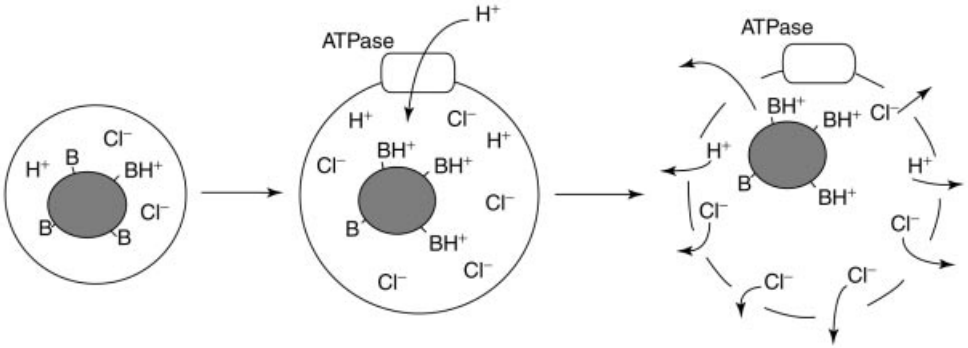

Fig. 3. Schematic of endocytic vesicle swelling and rupture as proposed by the "proton-sponge" hypothesis. The polymer, containing unprotonated basic moieties at neutral pH, buffers the pH within the vesicle and causes the ATPase to pump excess protons into the compartment. The concomitant influx of counterions increases the osmotic pressure across the membrane, causing the vesicle to swell and ultimately rupture.

is a nitrogen, PEI has a very high density of protonatable amines, only 15–20% of which are protonated at physiological pH (152). As a result, PEI will tend to buffer the endosomes causing the ATPase to transport many more protons to reach the desired pH. The accumulation of protons in the vesicle must be balanced by an influx of counterions, typically chloride. The increased ion concentration results in osmotic swelling of the vesicle and, eventually, in the rupture of the endosome membrane.

Despite its advantages, development of PEI gene delivery systems has been hindered by the polymer's relatively high cytotoxicity. Toxicity appears to be dependent on the polymer molecular weight. Recently, it has been shown that PEI as small as 10 kDa is a relatively successful vector with very low toxicity (153,154). Based on these findings, Gosselin and co-workers (155) generated a novel vector by cross-linking 800 Da PEI with disulfide linker groups. They hypothesized that the cross-links would be cleaved upon exposure to the reducing environment of the cytoplasm, presumably leading to lower toxicity. Gene expression mediated by these polymers was slightly reduced relative to 25 kDa PEI, but for some of the polymers cytotoxicity was virtually eliminated. Taking a different tack, Han and co-workers (156) synthesized a cholesterol-derivatized, low-molecular-weight PEI (termed water-soluble lipopolymer) that is less toxic than the standard 25-kDa PEI and mediates two- to threefold higher gene delivery efficiency, as well.

Polyamidoamine Dendrimers. Polyamidoamine ("Starburst") dendrimers are spheroidal, cascade polymers (Fig. 1) that can be synthesized from an ammonia or ethylenediamine core by successive addition of methyl acrylate and ethylenediamine (157). The size of the polymer, and importantly the surface charge, are controlled by varying the number of "generations" in the synthesis. Haensler and Szoka (113) originally reported the use of PAMAM dendrimers for gene delivery. They examined dendrimers of generations 1–10 and found that the sixth generation dendrimer was better than the others by ~10-fold. Because

of the large number of secondary and tertiary amines on the polymer, and its resulting buffering capacity, PAMAM dendrimers are thought to efficiently escape from the endocytic trafficking pathway by a mechanism similar to PEI. Indeed, gene delivery is unaffected by chloroquine, suggesting that endosomal escape is not limiting. Because of its relatively high gene delivery efficiency and good biocompatibility, PAMAM dendrimers have recently been employed in several *in vivo* gene delivery studies (158–161).

Interestingly, a partially degraded form of PAMAM dendrimer appears to be a more effective gene transfer agent than the intact polymer. Heat treatment of the polymer in various solvolytic solvents (eg, water or butanol) significantly degrades the polymer at the amide linkages, resulting in a heterodisperse population of compounds with molecular weight ranging from <1500 kDa to tens of kilodaltons. These "fractured" dendrimers show >50-fold enhanced transfection activity (162). The mechanism of the enhancement appears to be twofold. First, the fractured dendrimer exhibits greater flexibility, allowing a more beneficial interaction with the plasmid DNA (162). Second, polyplexes containing fractured PAMAM appear to have enhanced solution stability in comparison to polyplexes containing intact polymer, which tend to aggregate (47).

Polymers Designed for Gene Delivery

Many different types of polymers have been specifically designed for use as gene delivery vectors. In many cases, the polymers were designed to address one of the perceived gene delivery barriers; for example, DNA packaging and stability *in vivo*, biocompatibility, and endosomal escape have all been used as design criteria. The results of such studies have been mixed, with some polymers performing as well as, or even slightly better than, PEI and the PAMAM dendrimers. In the following, we cannot describe all of the polymers designed for gene delivery. Rather, we have chosen several new classes of polymers that appear to show promise.

Imidazole-Containing Polymers. "Proton-sponge" polymers are some of the best available off-the-shelf materials for gene delivery. However, they are limited by considerable cytotoxicity in some cell lines. It would be desirable to mimic the proton-sponge mechanism, which requires high buffering capacity between physiological and lysosomal pH, in a polymer that is more biocompatible. Several groups have recognized that imidazole exhibits the required protonation properties ($pK_a \sim 6$). Further, because imidazole is a component of several biological species (eg, the amino acid histidine), polymers incorporating imidazole may be expected to show increased biocompatibility.

One approach that has been reported was to use a homopolymer of histidine (pHis) (MW ~11,000) that was derivatized with gluconic acid to increase its solubility in aqueous solutions (G-pHis) (Fig. 4) (114). The polymer was shown to efficiently condense plasmid DNA into particles of ~100 nm diameter. Ternary complexes of DNA, G-pHis, and transferrin–polylysine conjugates (Tf-PLL) transfected COS-7 cells, in the absence of any exogenous endosomolytic agents, with efficiency similar to that of DNA/Tf-PLL complexes that required addition of

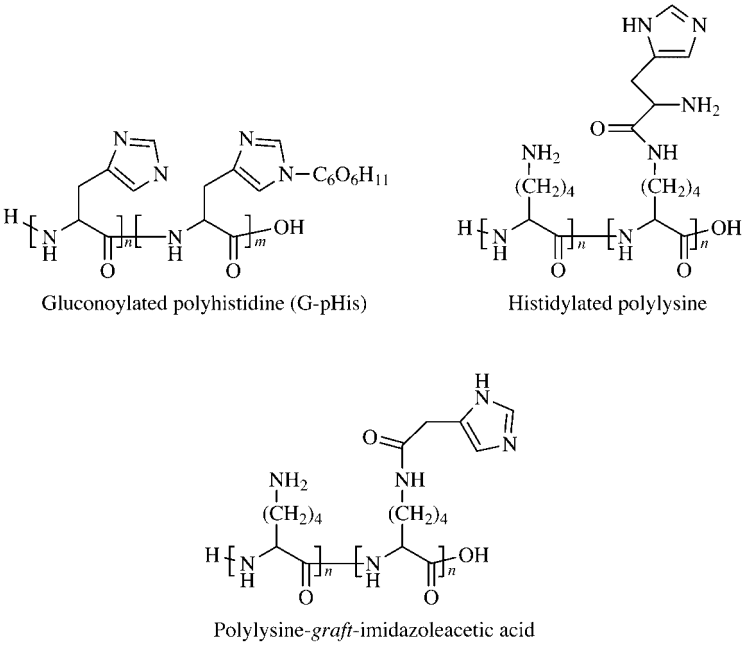

Fig. 4. Imidazole-containing, biocompatible "proton-sponge" polymers (114,115,117).

chloroquine. Further, the polymer showed negligible toxicity at concentrations employed in gene delivery studies.

A second approach is to derivatize PLL with imidazole-containing pendant groups (Fig. 4). Three chemistries have been reported. In the first, the $\bar{\varepsilon}$-amino groups of PLL or oligolysine were derivatized with (Boc-protected) histidine, resulting in an amide linkage with a primary amine (from the histidine) remaining (117,163). Thus, the imidazole group was introduced without reduction of the number of positive charges available for binding DNA. In the second, PLL was derivatized with imidazoleacetic acid yielding a similar amide linkage, but in the absence of the primary amine (115). Both polymers were found to efficiently transfect a variety of cell types in the absence of any exogenous endosomolytic agent, and gene expression levels increased with increasing imidazole content. Gene expression levels mediated by histidylated PLL were 3–4 orders of magnitude higher than with underivatized PLL (117). In fact, Putnam and co-workers reported gene expression levels comparable to those achieved with PEI polyplexes, yet in the absence of any cytotoxicity (under the same conditions, PEI reduced cell viability by ~80%). Finally, Benns and co-workers (164) reported a comb-type polymer of polyhistidine grafted onto the ε-amino groups of polylysine. This polymer was slight more efficient than PLL, but was still enhanced approximately two-fold by the addition of chloroquine.

Cyclodextrin-Containing Polymers. Cyclodextrins (CD) are cyclic oligomers of $\bar{\alpha}$-1,4-linked glucopyranose units that exhibit interesting guest–host properties. The cavity of the CD ring is relatively hydrophobic. Thus, CDs form inclusion complexes with many small hydrophobic molecules. This property has

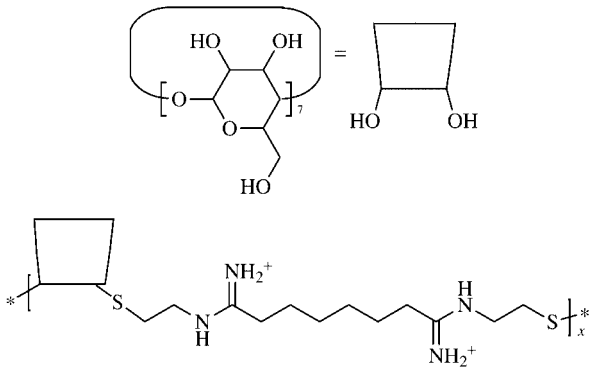

Fig. 5. Example of a cyclodextrin-containing polymer incorporating amidine linkages (166).

been exploited for drug delivery applications. An excellent review of CDs is available (165).

Linear CD-containing polymers for gene delivery have been synthesized by condensation of diamino-CD monomers with diimidate comonomers to yield a diamidine-containing polycation (Fig. 5) (166,167). The CDs were functionalized with amino groups of varying structure placed on opposite sides of the CD ring (166). Further, the length and chemistry of the spacer between the amidine moieties was systematically varied from 4 to 10 methylene units (167). Typically, the syntheses yielded highly water-soluble oligomers with degree of polymerization from 4 to 6 and molecular weights between 5800 and 8800. These polymers condensed plasmid DNA into particles of 100–150 nm in diameter at +/− charge ratios greater than 5, as measured by dynamic light scattering and transmission electron microscopy, and transfect cells at +/− ratios greater than 10. The best polymers of this class transfected cells in culture with efficiencies comparable to PEI and Lipofectamine. Transfection was enhanced 20-fold by the addition of chloroquine suggesting that, as for many other polymers, escape from the endocytic pathway is an efficiency-limiting barrier.

An important aspect of these polymers is their lack of cytotoxicity. The IC_{50} (polymer concentration at which cell viability is reduced by 50%) is in the millimolar range. Furthermore, the LD_{40} (dose of polymer in milligrams per kilogram that will cause death in 40% of the animals) in mice for the polymer shown in Figure 5 was found to be 200 mg/kg. These values are at least 10-fold higher than for other gene delivery polymers such as PEI. The low toxicity is clearly due to the presence of the CD (167).

Finally, it is interesting to note that the CD moieties provide an interesting opportunity for modification of the polyplexes with a variety of functionalities. For example, it may be possible to introduce receptor-targeting or nuclear-localization moieties with a bifunctional molecule containing the targeting moiety on one end and a CD-intercalating moiety (eg, adamantane) on the other end. Such a relatively simple route to introduce structural and functional diversity to the polyplexes may have many exciting applications.

Degradable Polycations. Two of the important barriers to polymeric gene delivery, unpackaging of the plasmid and cytotoxicity, have recently been addressed via synthesis of biodegradable polycations. For example, several cationic polyesters have been reported (168–171). One of these polymers, poly[$\bar{\alpha}$-(4-aminobutyl)-L-glycolic acid] (PAGA) was designed as a biodegradable mimic of PLL (170). PAGA (MW ~3300) degraded quickly in aqueous solution at pH 7.3 (37°C), but the degradation process was much slower for the polymer in polyplexes with plasmid DNA. PAGA showed no cytotoxicity under conditions where PLL reduced cell viability by 80%. In the presence of chloroquine, PAGA transfected cells threefold better than PLL at optimized conditions (170). Furthermore, PAGA has shown efficacy in delivering plasmid DNA *in vivo* by reducing the severity of autoimmune insulitis in nonobese diabetic mice (172,173) and in cytokine gene delivery for cancer treatment (174). Similarly, a hyperbranched poly(amino ester) was synthesized as a biodegradable mimic of PEI and/or PAMAM dendrimers (171). This polymer was minimally toxic in comparison to PEI and PAMAM dendrimers. Transfection efficiency was 1–2 orders of magnitude less efficient than PEI or PAMAM, but was 10-fold better than PAGA (without chloroquine).

Another class of polymers that has recently been developed for gene delivery are the poly($\bar{\beta}$-amino esters), synthesized by the addition of primary or secondary amines to diacrylates (175–177). Initially, a set of three poly(β-amino esters) (Fig. 6) was shown to be capable of binding and condensing plasmid DNA and exhibited negligible cytotoxicity to cells in culture (175). Subsequently, the authors employed a combinatorial approach to synthesis of a library of poly(β-amino esters) (177). Seven diacrylate monomers were reacted with 20 amine monomers to yield 140 structurally unique polymers (MW 2,000–50,000). The library was screened for solubility in aqueous buffer (pH 5) and DNA binding by gel electrophoresis. Fifty-six of the 70 water-soluble polymers interacted sufficiently with DNA to allow transfection studies. Six polymers were identified as "hits" worthy of further study, and two of the polymers mediated gene delivery similar to or exceeding that observed with PEI.

Another novel approach has been to employ disulfide-containing moieties that will be cleaved in a reducing medium such as the cytosol and nucleus. In one

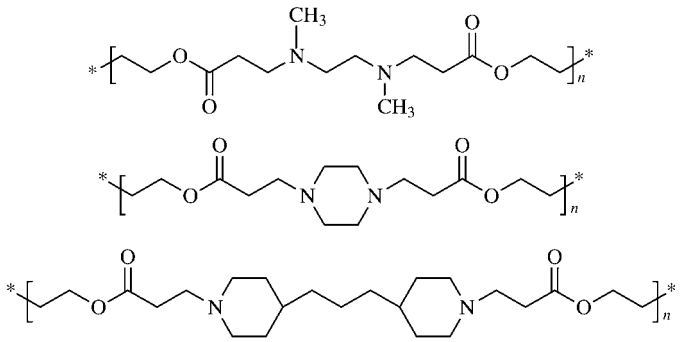

Fig. 6. Biodegradable poly(β-amino ester) polycations synthesized from the addition of diamine monomers to diacrylate comonomers (175).

such polymer, poly[Lys-(AEDTP)], the lysine ε-amino groups are substituted with 3-(2-aminoethyldithio)-propionyl residues such that the amino groups interacting with the DNA phosphates are linked to the polymer via a disulfide bond (178). Decondensation of polyplexes was observed in the presence of reducing agents including dithiothreitol and glutathione. Transfection of HepG2 cells was 50-fold more efficient with poly[Lys-(AEDTP)] compared to PLL polyplexes. PEI (800 Da) was reacted with two cross-linking reagents, dithiobis(succinimidylpropionate) and dimethyl-3,3′-dithiobispropionimidate, at two different amine cross-link ratios to generate a set of reducible conjugates (155). The gene transfer efficiency was found to be proportional to conjugate size. While none of the polymers was as effective as the commonly used 25-kDa PEI, they were all less toxic.

Conclusions

A variety of polymers has been employed in gene delivery studies to date, but their effectiveness as gene therapy vectors remains orders of magnitude poorer than viral vectors. As a result, polymers are generally considered unacceptable for clinical applications. The important extra- and intracellular barriers to efficient gene delivery are known. The lack of efficiency of polymer gene delivery vectors is due to a lack of functionality for overcoming one or several of these barriers. Based on the large number of studies of off-the-shelf gene delivery polymers, much has been learned about the structure–function relationships of polymer vectors. This knowledge has been applied to design and synthesis of new polymers, tailor-made for gene delivery, and a number of promising candidates have been reported in recent years. With our growing understanding of polymer gene delivery mechanisms and the continued efforts of creative and talented polymer chemists, it is likely that polymer-based gene delivery systems will become an important tool for human gene therapy.

GRAFT COPOLYMERS

Introduction

Graft copolymers are composed of a main polymer chain (the backbone) to which one or more side chains (the branches) are chemically connected through covalent bonds. A graft copolymer with one branch can be considered as a miktoarm star copolymer. The backbone and the branches may be homopolymers or copolymers but they differ in chemical nature or composition (1). The branches are usually equal in length and randomly distributed along the backbone because of the specific synthetic techniques used for their preparation. However, more elaborate recent methods have allowed the synthesis of regular graft copolymers with equally spaced and identical branches and of exact graft copolymers, where all the molecular and structural parameters can be accurately controlled (Fig. 1).

A simple graft copolymer can be represented as A_k-*graft*-B_m or polyA-*graft*-polyB or poly(A-*g*-B), where A_k or polyA is the backbone to which the B_m or polyB branches are grafted. The nomenclature of graft copolymers follows the rules recommended by the IUPAC Commission on Macromolecular Nomenclature (2).

Graft copolymers have been mainly used to modify polymer properties because of their unique mechanical, thermal, dilute solution, and melt properties (3–7). The availability of such materials has permitted the researchers to explore the correlation between the structure of the graft copolymers and their properties.

Synthesis of Graft Copolymers

Three general methods have been developed for the synthesis of randomly branched graft copolymers: (*1*) the "grafting onto", (*2*) the "grafting from", and (*3*) the macromonomer method (or "grafting through" method) (8) (Fig. 2).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

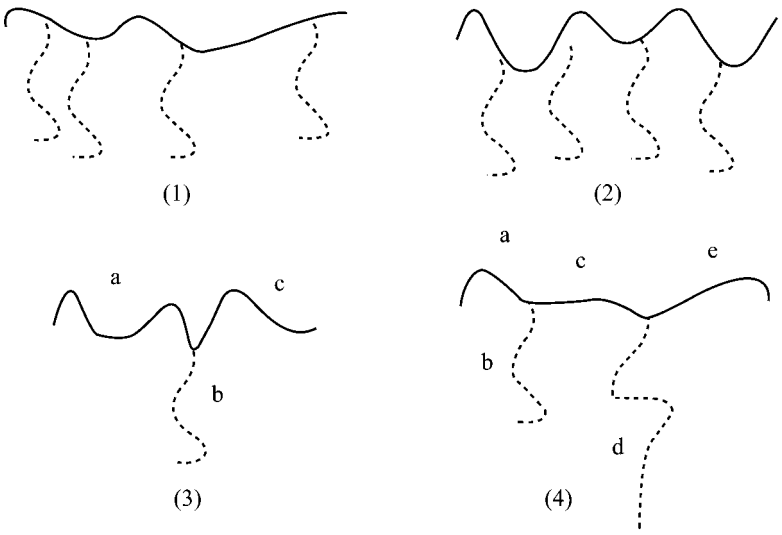

Fig. 1. Graft Copolymers (1) random graft copolymer (identical branches randomly distributed along the backbone); (2) regular graft copolymer (identical branches equally spaced along the backbone); (3) simple graft copolymer (3-miktoarm star copolymer); and (4) graft copolymer with two trifunctional branch points. Exact graft copolymers.

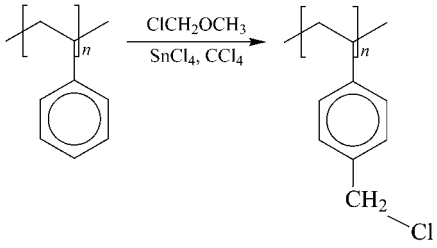
The "grafting onto" method involves the use of a backbone chain containing functional groups X randomly distributed along the chain and branches having reactive chain ends Y. The coupling reaction between the functional backbone and the end-reactive branches lead to the formation of graft copolymers.

In the "grafting from" method active sites are generated randomly along the backbone. These sites are capable of initiating the polymerization of a second monomer, leading to graft copolymers.

The most commonly used method for the synthesis of graft copolymers is the macromonomer method. Macromonomers are oligomeric or polymeric chains bearing a polymerizable end group. Macromonomers having two polymerizable end groups have also been reported (8). Copolymerization of preformed macromonomers with another monomer yields graft copolymers.

"Grafting onto" Methods. In the "grafting onto" method, reaction of preformed polymeric chains having functional groups, with other polymeric chains having active chain ends, takes place. In most cases the incorporation of functional groups is performed by chemical modification of the backbone (9–14). A common procedure is the chloro(bromo) methylation of polystyrene (eq. 1), and the subsequent reaction with living polymeric chains.



(1)

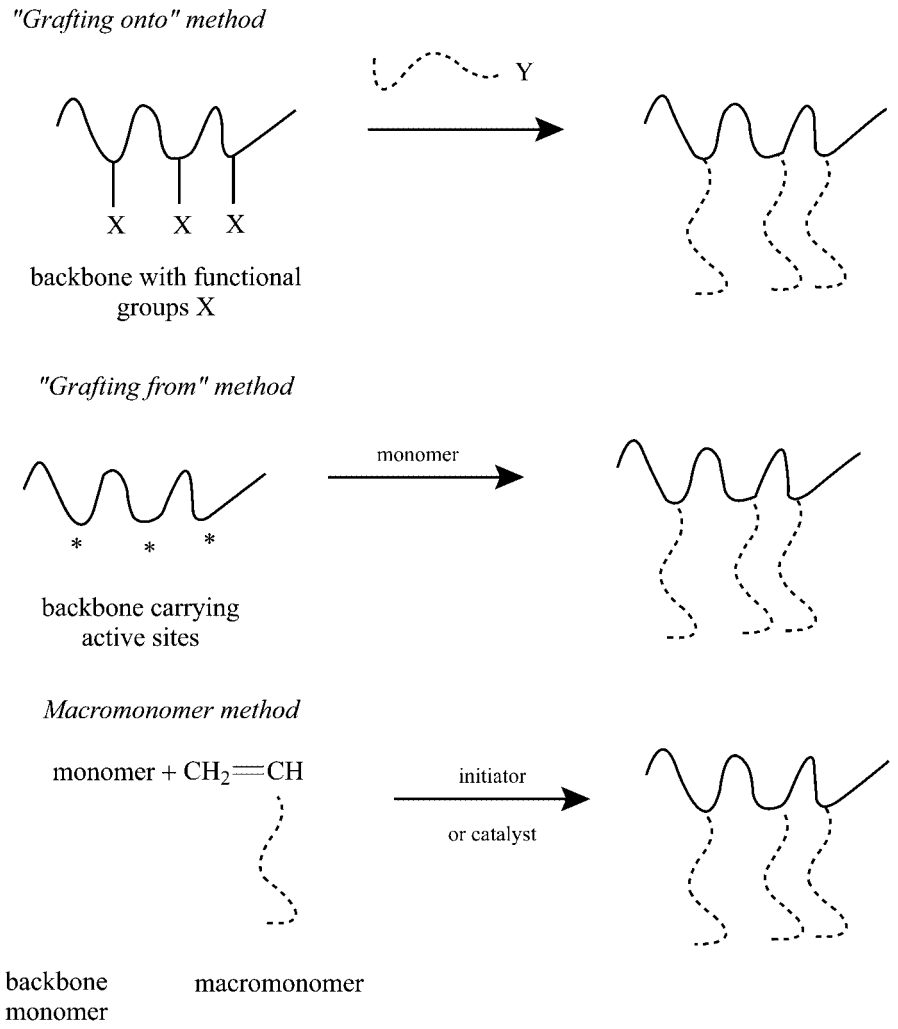


Fig. 2. Three general methods of synthesis of randomly branched graft copolymers.

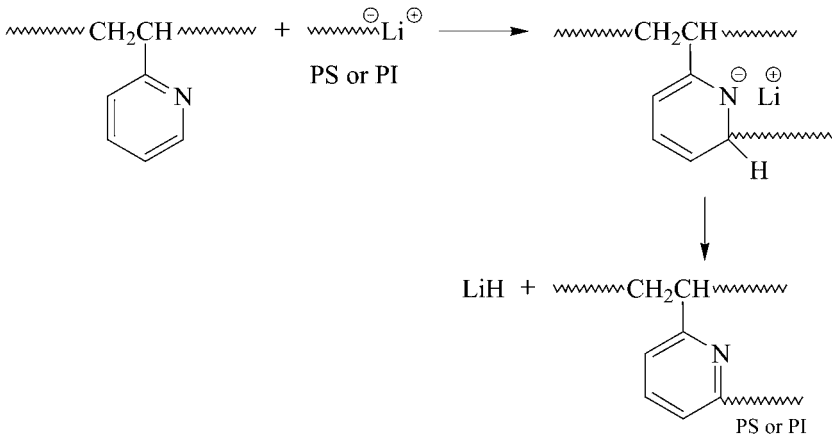
Using this method polystyrene-*g*-poly(ethylene oxide) (PS-*g*-PEO) graft copolymers were prepared (9–12). The chloromethylation of PS was performed using a CCl_4 solution of PS with chloromethyl methyl ether, with $SnCl_4$ as the catalyst. The reaction conditions were controlled in such a way so as to give low chloromethyl content (<10 wt%). A similar synthetic approach was adopted for the synthesis of PS-*g*-polyisoprene (PS-*g*-PI) graft copolymers (10,11). In order to avoid the side reactions involving lithium–chlorine exchange, the $-CH_2Cl$ groups were transformed to the $-Si(CH_3)_2Cl$ group before reaction with the living polymers. PS-*g*-poly(2-vinylpyridine) (PS-*g*-P2VP) and PS-*g*-P4VP graft copolymers were prepared by partial chloromethylation of PS polymeric chains (13,14). Grafting efficiency, ie, the ratio of the number of $-CH_2Cl$ groups used for the grafting reaction and the number of the incorporated groups on the backbone, was as low as 40% in this case. Chloromethylation of poly(*N*-vinyl carbazole) (PVCz) was also

used in order to synthesize poly(*N*-vinyl carbazole)-*g*-PI graft copolymers (15). The chloromethyl ether method was used in the presence of $ZnCl_2$. The grafting efficiency of PI chains was also found to be limited. Bromomethylation of anionically prepared PS backbone was used for the synthesis of PS-*g*-poly(methyl methacrylate) (PS-*g*-PMMA) copolymers (16). The polydispersity index of the resulted grafts was higher than the polymeric precursors, indicating the presence of undesirable reactions.

By taking advantage of living PS and PI anions with the phenyl rings of P2VP, P2VP-*g*-PS and P2VP-*g*-PI graft copolymers were synthesized (17) (eq. 2)



(2)

An excess of living chains compared to the 2VP groups were added. The polydispersity index of the final products was higher than the polydispersity of the backbone and the grafted chains, especially in the case of P2VP-*g*-PI samples. Graft copolymers having as backbone random terpolymers of styrene, maleic anhydride, and ethylhexyl methacrylate, or diethylfumarate, were synthesized by radical polymerization (18). In all cases, polyethylene oxides (PEO) were the grafted chains. Polyethylene glycol monomethyl ether was grafted to the backbones after reaction with the succinic anhydride groups. When the reaction was allowed to proceed to high conversions, gelation occurred. This was attributed to the presence of difunctional polyethylene glycol, which connects many backbones forming high molecular weight and cross-linked products.

The "grafting onto" methodology was followed also for the preparation of graft copolymers having poly(glycidyl methacrylate) as backbone and a mixture of PI and PS grafted chains (19). The epoxy groups were used as grafting sites for living PS and PI anionic chains. Graft terpolymers having poly[styrene-*co*-4-(vinylphenyl)-1-butene] as backbone and either PS, PI, or grafted chains were also prepared (20,21). The synthesis of the backbone involved the anionic copolymerization of styrene with 4-(vinylphenyl)-1-butene. The backbone was partly hydrosilylated, and the incorporated chlorodimethylbutylsilyl active groups were reacted with living PS or PI chains. The graft terpolymers exhibited low polydispersity

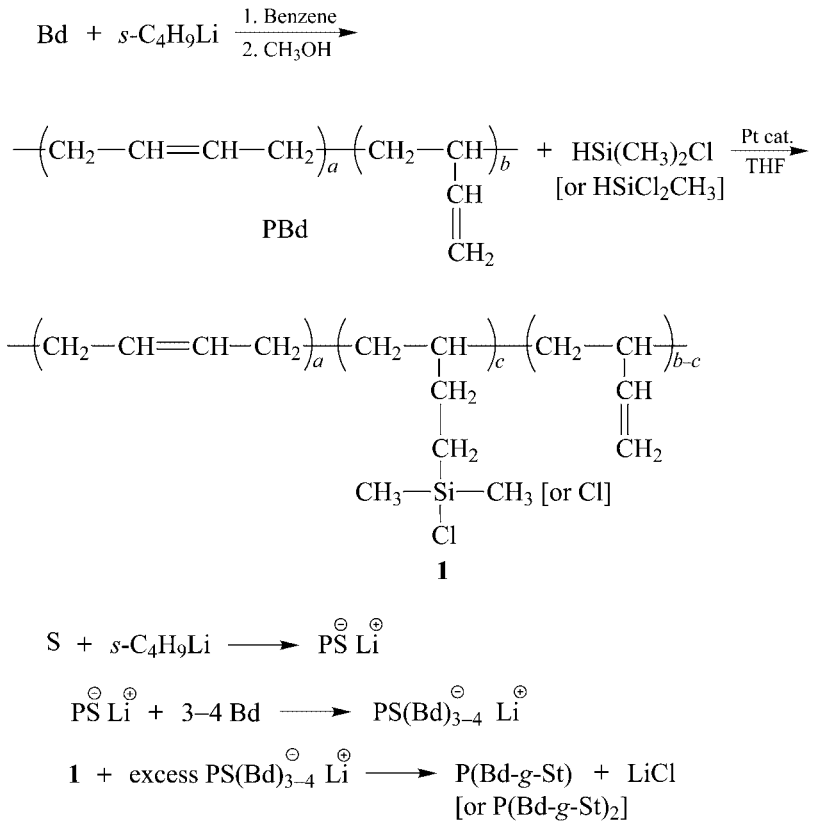


Fig. 3. Butadiene–styrene graft and double graft copolymers.

index comparable to the one of the precursors. Poly(carboxymethylcellulose)-*g*-poly(*N*-isopropylacrylamide) (CMC-*g*-PNIPAM) graft copolymers were synthesized (22) through formation of amide bonds. Amino-terminated NIPAM polymeric chains were obtained by radical polymerization in water. The coupling reaction between the carboxyl groups of the backbone and the terminal amine group of the grafts, performed in water, resulted in the formation of the desired products.

Well-defined butadiene–styrene graft copolymers (PBd-*g*-PS) were synthesized using hydrosilylation reactions (23). Catalytic hydrosilylation of the 1,2-Bd units (∼10%) of PBd introduced chlorosilane groups (Fig. 3). Linking reactions between living PS anions and the —Si—Cl groups of the backbone (**1**) gave PBd-*g*-PS graft copolymers with randomly placed single PS branches. When $HSiCl_2CH_3$ was used in the hydrosilylation step, difunctional branching sites were introduced in the backbone, resulting in the formation of P(Bd-*g*-S)$_2$ double grafts.

Block graft copolymers are copolymers having a backbone composed of a diblock copolymer. Grafted chains can be attached to one or both of the backbone blocks (Fig. 4). Block grafts with a triblock as the backbone are also possible (see BLOCK COPOLYMERS).

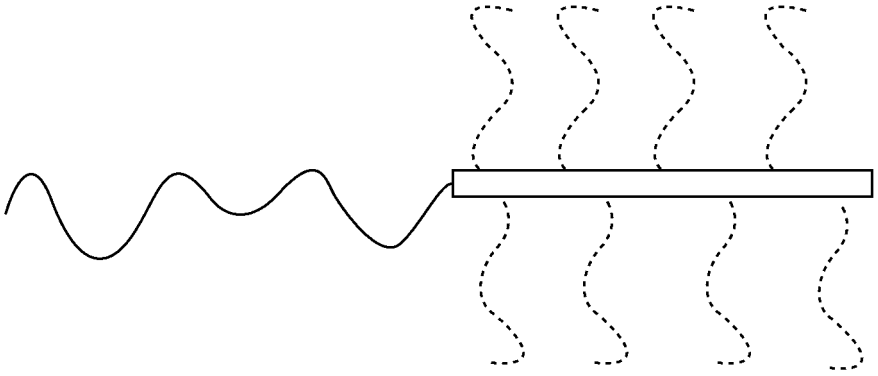

Fig. 4. Block-graft copolymer. In this case only one of the backbone blocks is grafted.

Using anionic polymerization techniques poly{styrene-*b*-[(4-vinylphenyl-dimethylsiloxane)-*g*-isoprene]}, P[S-*b*-(VS-*g*-I)], block graft copolymer was synthesized (24,25). The block copolymer P(S-*b*-VS) was prepared by the sequential addition of styrene and 4-vinyl phenyl dimethyl vinylsiloxane. Living PI chains were reacted with the vinylsilane groups of the block copolymer to form the block graft copolymers. In a similar fashion poly{4-methylstyrene-*b*-[(styrene-*co*-3- methylstyrene)-*g*-2-vinyl pyridine]} block graft terpolymers were synthesized (26). The backbone was prepared by coordination polymerization and sequential addition of 4-methylstyrene and a mixture of styrene and 3-methylstyrene. Chlorination of the methyl groups of the substituted styrenic monomeric units generated the grafting sites. The final coupling was accomplished by adding a THF solution of the chlorinated terpolymer to living P2VP chains at low temperature.

PS-*g*-PI, (PS-*g*-PI)-*b*-PS, and (PS-*g*-PS)-*b*-(PS-*g*-PI) copolymers have been synthesized by using a combination of TEMPO (2,2,6,6-tetramethylpiperidinyl-1-oxy) living free-radical and anionic polymerization (27) (Fig. 5).

The PS backbone of the PS-*g*-PI was synthesized by living free-radical batch copolymerization of styrene and *p*-chloromethylstyrene. PI living chains prepared by anionic polymerization, end capped with 1,1-diphenylethylene, reacted with the chloromethyl groups to give the grafts. In a similar way the synthesis of the (PS-*g*-PI)-*b*-PS block graft copolymers was performed. The synthetic approach of the (PS-*g*-PS)-*b*-(PS-*g*-PI) graft-block-graft copolymer involved first the preparation of the PS-*g*-PS grafts, followed by the copolymerization of styrene and *p*-chloromethyl styrene by living radical polymerization using the nitroxide end group of the PS backbone as the initiating site. Finally, living diphenylethylene-capped PI chains, prepared by anionic polymerization, were reacted with the chloromethyl groups of the extended PS backbone.

Model block-double graft copolymers and terpolymers of styrene, butadiene, and isoprene of the type poly[S-*b*-(PBd-1,2-*g*-X)] were recently synthesized (28), where X is either S, Bd, I, or S-*b*-I by a combination of anionic polymerization, hydrosilylation, and chlorosilane linking chemistry. The backbone P(S-*b*-1,2Bd) was synthesized by sequential addition of the monomers. The vinyl groups of the PBd-1,2 block were hydrosilylated with $HSiCH_3Cl_2$ and used for the attachment

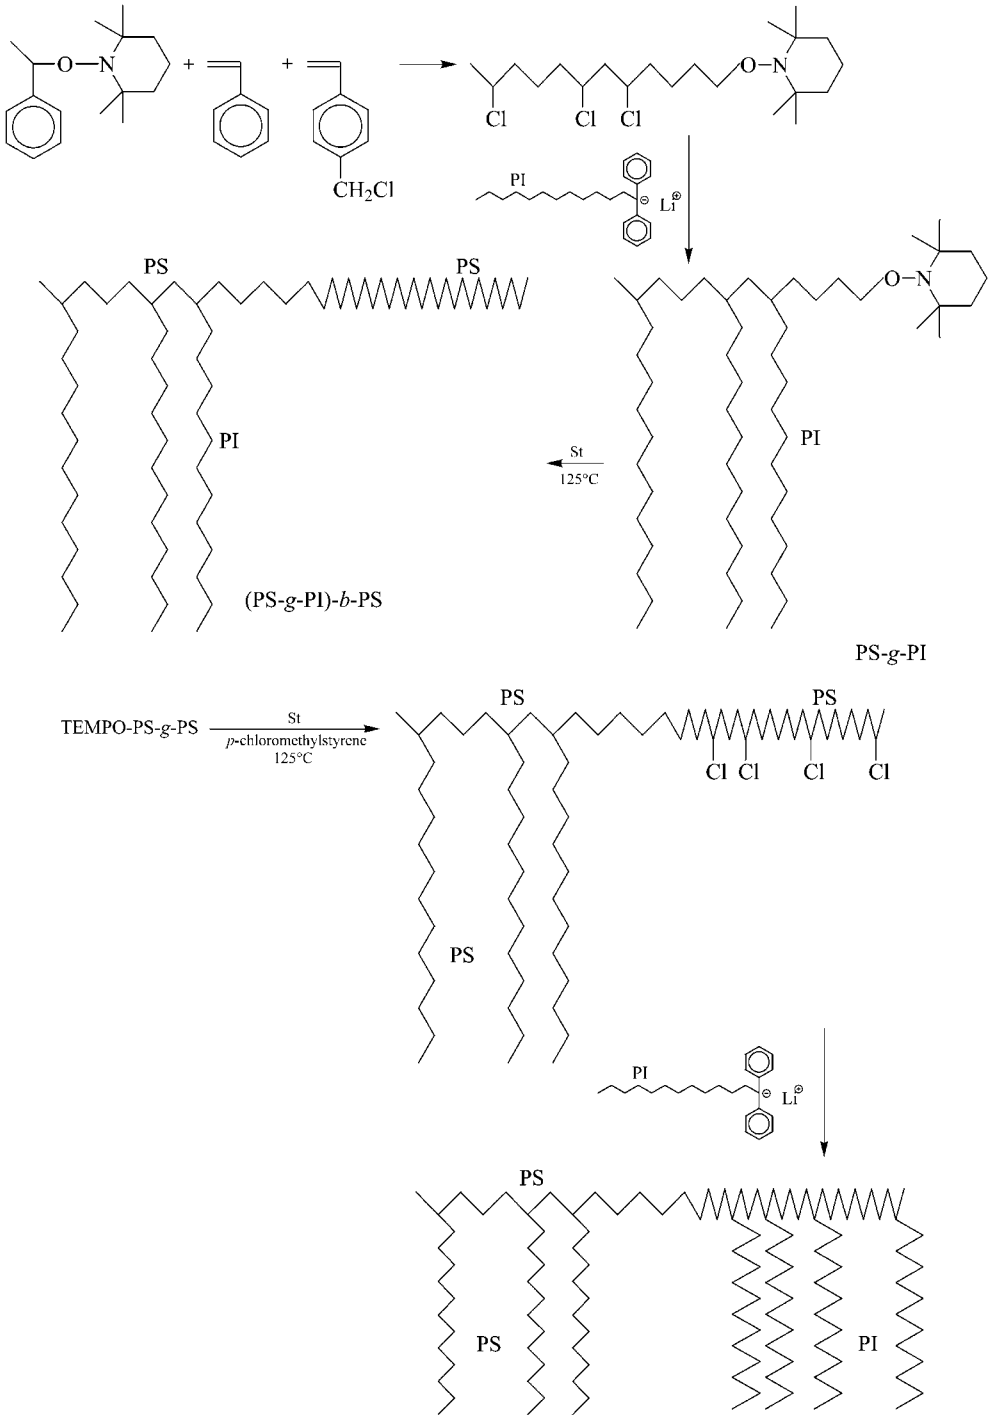

Fig. 5. Polystyrene–polyisoprene graft and block copolymers.

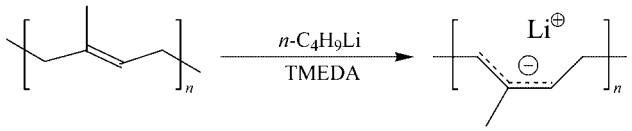
of living chains X, resulting in the formation of the corresponding block double graft copolymers.

"Grafting from" Methods. In the "grafting from" method, the backbone is chemically modified in order to introduce active sites capable of initiating the polymerization of a second monomer. The number of grafted chains can be controlled by the number of active sites generated along the backbone assuming that each one of them participate to the formation of one branch. However, mainly because of kinetic and steric hindrance effects there may be a difference in the lengths of the produced grafts.

Anionic grafting techniques were used for the synthesis of PI-*g*-PS and PBd-*g*-PS copolymers (29–33). The active sites were generated by metallation of the allylic double bonds of the polydiene backbone, by organometallic compounds such as n-C_4H_9Li, in the presence of strong chelating agents that facilitate the reaction (eq. 3). The most common metallation procedure involves the use of n-C_4H_9Li in the presence of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA). The activated polydiene then reacts in the styrene. The graft copolymers exhibited well-defined molecular characteristics.



(3)

By using the "grafting from" technique, PMMA-*g*-(β-butyrolactone) (34) copolymers were synthesized. Anionically polymerized PMMA was treated with 18-crown-6 complex of potassium hydroxide resulting in a macromolecular initiator (**2**) (Fig. 6).

The carboxylate active groups were used as initiating sites of β-butyrolactone. It was found that the grafting efficiency was high, and the density

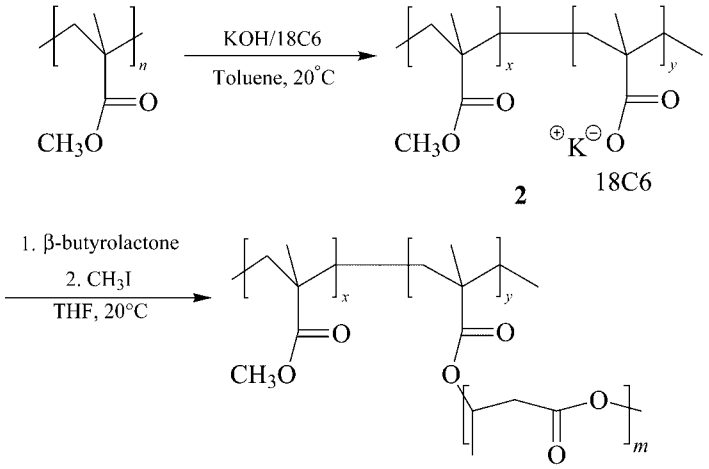


Fig. 6. PMMA backbone with β-butyrolactone grafts.

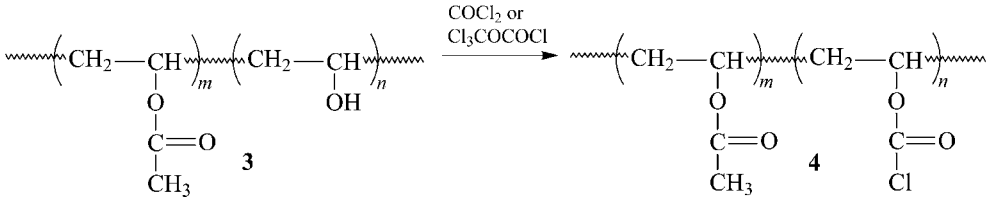
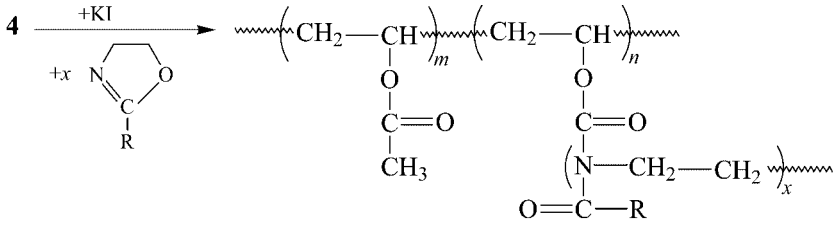
of grafting chains could be easily controlled. Poly(ethylene-*g*-styrene) copolymers were also prepared (35). The approach for the synthesis of the backbone involved the copolymerization of ethylene and *p*-methylstyrene by metallocene catalysts, such as $[C_5(CH_3)_4(Si(CH_3)_2N\text{-}t\text{-}C_4H_9)]TiCl_2/C_2H_5(Ind)_2ZrCl_2$. The methyl groups of the *p*-methylstyrene units were then metallated with $s\text{-}C_4H_9Li$/TMEDA complex. The active sites produced were used to initiate the anionic polymerization of styrene. The efficiency of the metallation was found to be 65%.

Cationic grafting techniques have been used for the synthesis on poly(ethyl vinyl ether-*g*-ethyloxazoline) graft copolymers (36). A random copolymer of ethyl vinyl ether with a small quantity of 2-chloroethyl vinyl ether was synthesized by cationic polymerization. The pendant alkyl groups were the initiating sites of the cationic polymerization of ethyloxazoline grafts. In a similar way, acid chloride groups were incorporated along the polymer chain by partial hydrolysis of poly(vinyl acetate) (**3**) and reaction of the produced hydroxyl groups with phosgene or diphosgene (37) (eq. 4). These groups were the initiating sites for the polymerization of 2-phenyl or 2-methyl oxazoline in the presence of potassium iodide (eq. 5).



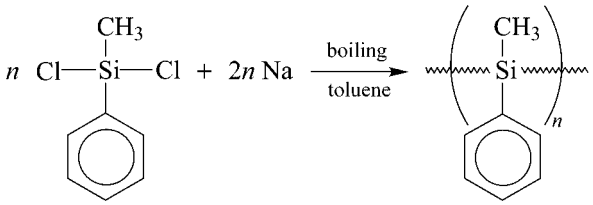
(4)



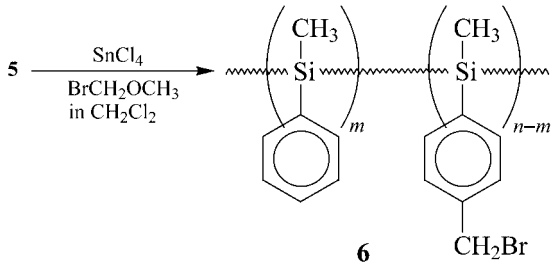
(5)

Poly(isobutylene-*g*-indene) and poly(isobutylene-*g*-styrene) copolymers were synthesized by cationic polymerization (38). The backbone was prepared by cationic copolymerization of isobutylene and *p*-chloromethylstyrene, using $TiCl_4/t\text{-}C_4H_9Cl$ as the initiator. The chloroalkyl groups were used, in the presence of $Al(C_2H_5)_2Cl$, as the initiation sites of the cationic polymerization of indene or styrene. The grafting efficiency was as low as 40–50 %. [MMA-*co*-(*p*-chloromethylstyrene)]-*g*-[2-methyl-2-oxazoline] amphiphilic copolymers were prepared by combining radical and cationic polymerization techniques (39). The synthesis of the backbone was performed by radical copolymerization of MMA and *p*-chloromethylstyrene in the bulk. The cationic macroinitiator was dissolved in benzonitrile along with 2-methyl-2-oxazoline (MeOXz) and the

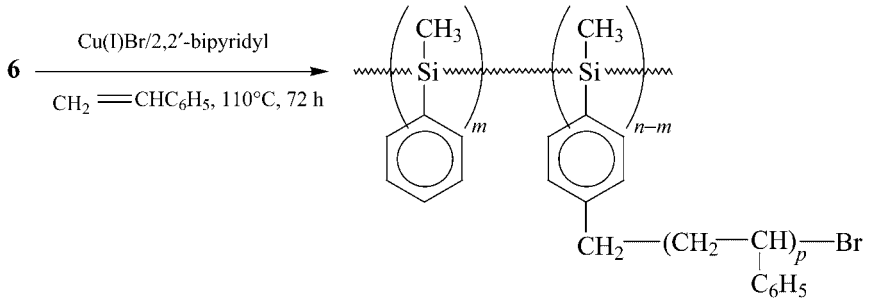
production of PmeOXz grafts took place at 110°C. A convenient route for the preparation of poly(methylphenylsilane)-*g*-PS was presented (40). The synthetic approach involved the alkali metal mediated reductive-coupling reaction of dichloro methylphenylsilane with sodium in toluene at 100°C (eq. 6). The phenyl groups were then bromomethylated (eq. 7), and the incorporated bromomethyl groups were used as the initiators of the polymerization of styrene by atom transfer radical polymerization (ATRP) (eq. 8).



5 (6)



6 (7)



(8)

Polypropylene-*g*-PS copolymers were synthesized by combination of metallocene and TEMPO living free-radical polymerization techniques (41). The backbone was synthesized by copolymerization of propylene and a TEMPO-functionalized derivative containing a α-double bond. The TEMPO groups were then used for the polymerization of styrene by living free-radical polymerization (Fig. 7).

By using ATRP, poly(2-hydroxyethyl methacrylate)-*g*-PS (PHEMA-*g*-PS) and PHEMA-*g*-poly(*n*-butyl acrylate) (42) were synthesized. The backbone, comprised

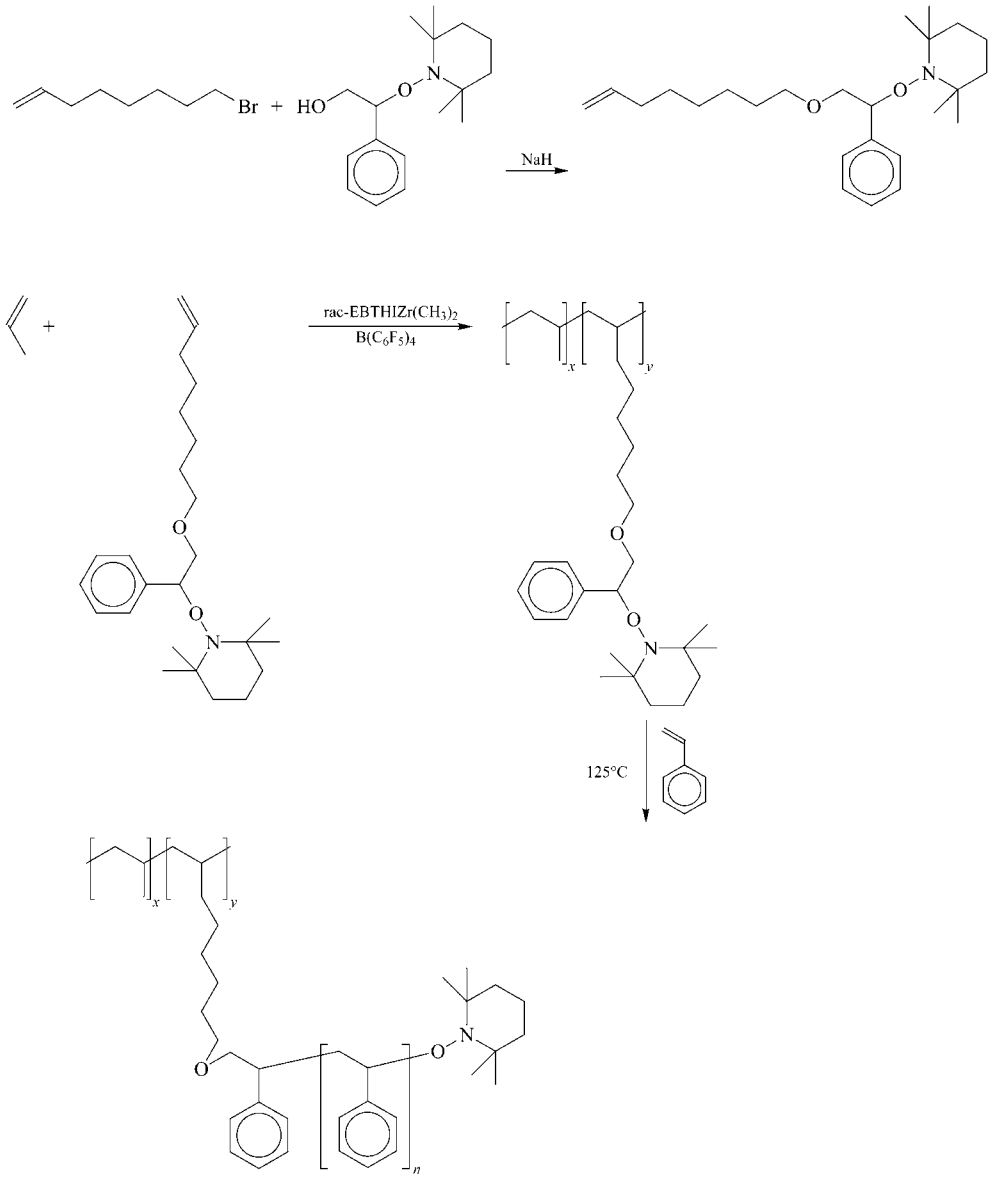


Fig. 7. Synthesis of Polypropylene-*g*-polystyrene.

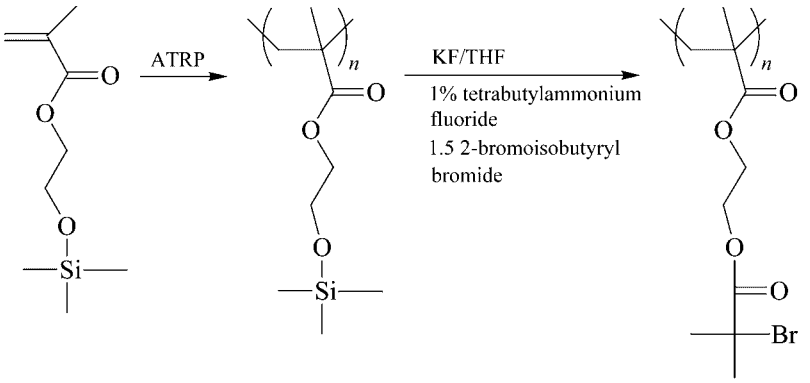
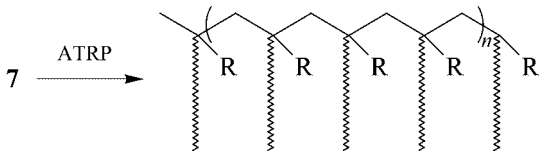
of trimethylsilyl-protected 2-hydroxyethyl methacrylate, was synthesized by using ATRP methodology, followed by deprotection of the hydroxyl group. Subsequent esterification (eq. 9) with 2-bromoisobutyryl bromide resulted in poly[2-(2-bromoisobutyryloxy)ethyl methacrylate]. (**7**).

PS or poly(*n*-butyl methacrylate) were then grafted from the macromolecular initiator (eq. 10). Subsequent analysis revealed that all the initiation sites participated in the polymerization of the second monomer.



7 (9)



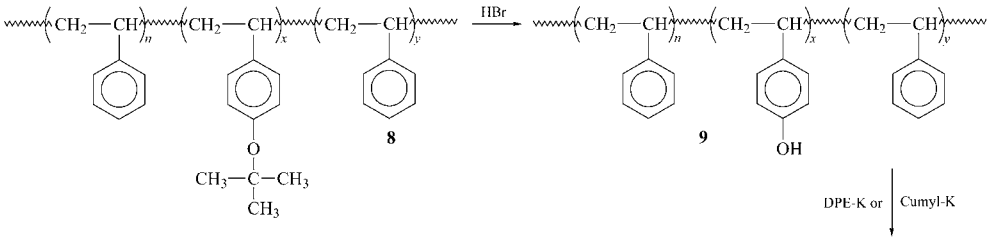
(10)

In a later work, copolymers of PVC with various grafted chains like poly(butyl acrylate), PMMA, PS, and poly(methyl acrylate) were synthesized (43). The backbone was a random copolymer of vinyl chloride and vinyl acetate. The carbonyl substituted alkyl halide groups were used as the initiator for the polymerization of these monomers by ATRP.

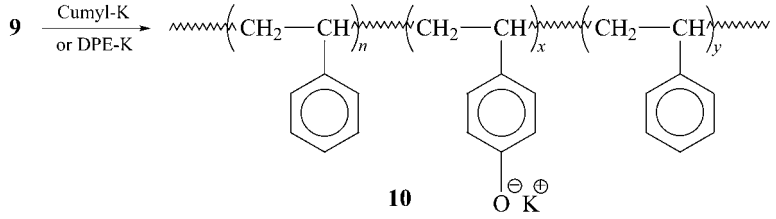
Metallocene and ATRP techniques were combined for the synthesis of graft ter- and quaterpolymers poly(ethylene-*co*-styrene) as backbone and one of PS, PMMA, PMMA-*b*-PS, PMMA-*b*-polymethylacrylate, and PMMA-*b*-PHEMA as grafted chain (44). The aromatic rings of styrene were partially brominated and the C–Br groups that were formed were subsequently used as initiating sites for ATRP polymerization.

Block-graft copolymers have also been prepared by the "grafting from" method. Reaction of the block copolymers P(S-*b*-V) (25) with n-C_4H_9Li in THF at -30°C for 1 h leads to metallation of the vinyl groups of the vinyl segments. Then D_3 was added for the formation of P[(S-*b*(VS-*g*-DMS)] block graft copolymers. The molecular characterization revealed that the number of the introduced PDMS branches was between 170 and 325.

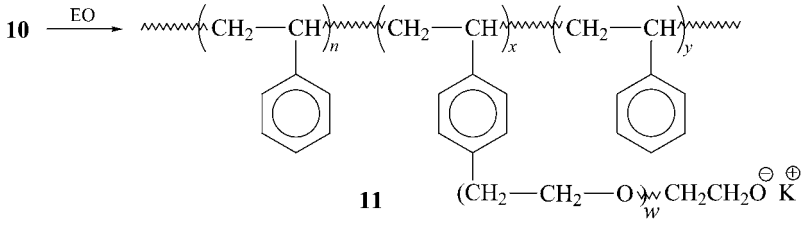
The synthesis of the poly[styrene-*b*-(hydroxystyrene-*g*-ethylene oxide)-*b*-styrene] (25), P[S-*b*-(HS-*g*-EO)-*b*-PS], has been reported. The backbone was a triblock copolymer, poly(styrene-*b*-*t*-butoxystyrene-*b*-styrene) (**8**), prepared by anionic polymerization by sequential addition of monomers. The protected *t*-butyl group was removed by treatment with HBr leading to the formation of P(S-*b*-HS-*b*-S) triblocks (**9**) (eq. 11). The metallation of the hydroxyl groups was performed in THF using either cumyl potassium or diphenylethylene potassium (eq. 12). The addition of EO generated the block graft copolymers (eq. 13).



(11)



(12)



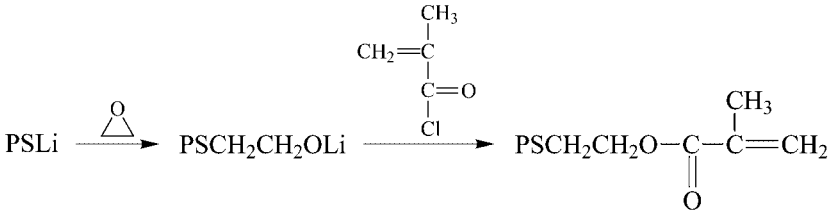
(13)

P(S-*g*-*t*-BMA) and PS-*b*-P(S-*g*-*t*-BMA) block graft copolymers were prepared using TEMPO living and atom transfer radical polymerization techniques (45). The backbone of the P(S-*g*-*t*-BMA) copolymer was synthesized by TEMPO living radical copolymerization of styrene and *p*-chloromethylstyrene. Subsequently, the chloromethyl groups in the presence of CuBr and bipyridine were used as initiation sites of ATRP of *t*-BMA. In the case of PS-*b*-P(S-*g*-*t*-BMA) copolymer, the synthesis was performed in a similar way.

Macromonomer Method. The synthesis of graft copolymers by the macromonomer method is characterized by its own specific features (46–49). The number of branches is determined by the ratio of the macromonomer and comonomer molar concentrations and their copolymerization behavior, described by the reactivity ratios r_1 and r_2. These parameters determine how random the placement of the branches along the backbone will be. It is evident that during the copolymerization the relative concentrations of the macromonomer and the comonomer change with time, leading to the formation of graft copolymers with subsequently different number of branches. In addition, the copolymerization is not homogeneous throughout the course of the reaction since phase separation may occur. For the above reasons it can be concluded that the graft copolymers prepared by this method are generally characterized by increased compositional and chemical heterogeneity.

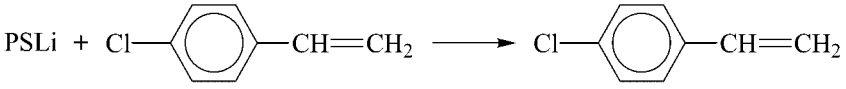
The synthesis of macromonomers can be accomplished by almost all the available polymerization techniques. Among them, living polymerization methods offer unique control over the molecular weight, the molecular weight distribution, and chain-end functionalization.

Anionic polymerization is one of the best methods for the synthesis of well-defined macromonomers. Functional initiation or termination by a suitable electrophilic reagents are the best ways for the incorporation of the reactive end groups (50). According to this methodology living polystyryllithium initially reacts with ethylene oxide to form the less reactive alkoxide, followed by the reaction with methacryloyl chloride for the synthesis of the macromonomer (eq. 14) (51).



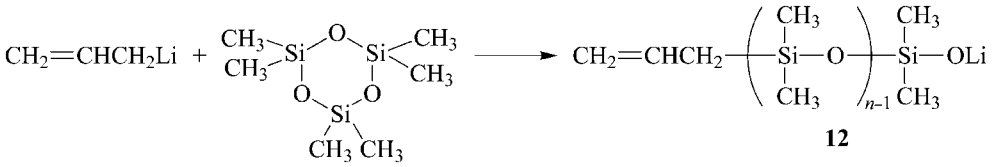
(14)

These macromonomers were then copolymerized with vinyl monomers mainly by free-radical techniques (52) and also other methods as by metallocene catalysts (53) to provide graft copolymers. The reaction of polystyryllithium with *p*-chlorovinylbenzene at low temperatures affords macromonomers with styryl end groups (eq. 15) (54).



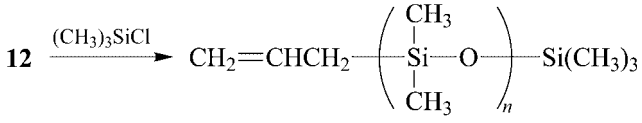
(15)

Allyllithium was used to polymerize hexamethylcyclotrisiloxane, D_3 (eq. 16). Subsequent termination (eq. 17) with chlorotrimethylsilane yielded polydimethylsiloxane (PDMS) macromonomers carrying allyl end groups (55).



12

(16)



(17)

Examples of graft copolymers synthesized using anionically prepared macromonomers are given in Table 1.

Table 1. Graft Copolymers Prepared by Macromonomers Synthesized Anionically

Macromonomer	End group	Comonomer	Copolymerization	Reference
PS	Methacrylate	MMA	Radical	56,57
PS	*p*-Vinylbenzene	MMA	Radical	54

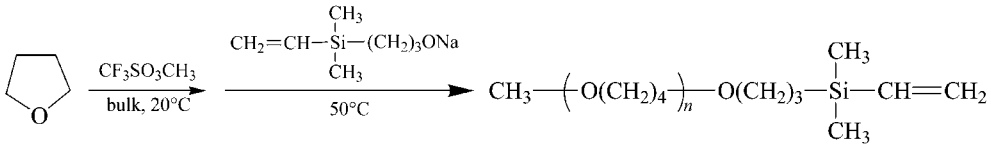
[a]Poly(*t*-butyl methacrylate).

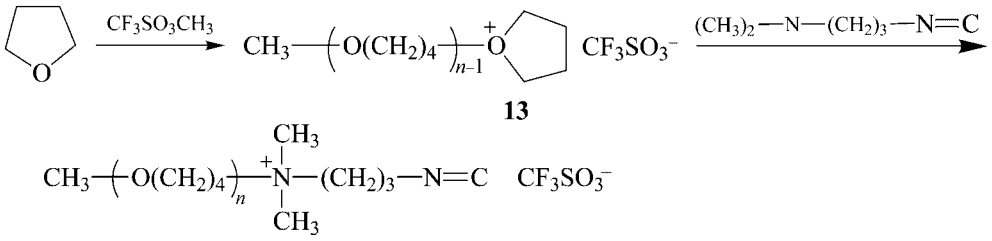
Cationic polymerization has also been used for the synthesis of macromonomers, especially after the development of living cationic polymerization techniques (73). Macromonomers were prepared by the cationic ring-opening polymerization of tetrahydrofuran (THF) using methyltrifluoromethane sulfonate, followed by termination with 3-sodio-propyloxydimethylvinylsilane to give a macromonomer with vinyl silane end groups (74) (eq. 18).



(18)

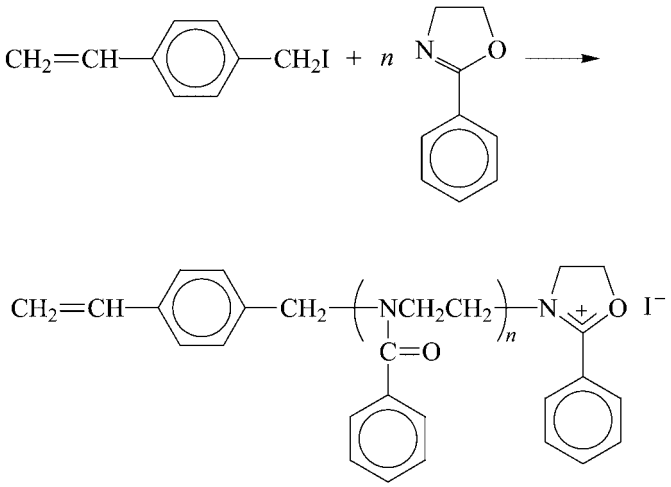
These macromonomers were copolymerized with vinyl acetate (Vac) using azobisisobutyronitrile (AIBN) as radical initiator to produce PVAc-*g*-PTHF graft copolymers. Subsequent saponification using NaOH provided poly(vinyl alcohol)-*g*-PTHF graft copolymers.

Termination of living PTHF (**13**) with 3-(dimethylamino propyl) isocyanide leads to the formation of macromonomers having end isocyanide groups (75) (eq. 19).



(19)

p-Iodomethylstyrene was used as a functional initiator to promote the polymerization of 2-phenyl-2-oxazoline leading to the formation of macromonomers having styryl end groups (76) (eq. 20).



(20)

Radical copolymerization with styrene produced PS-*g*-poly(2-phenyl-2-oxazoline) graft copolymers. Other examples of graft copolymers prepared using macromonomers, which were synthesized by cationic polymerization, are given in Table 2.

Free-radical polymerization has been the most common technique for the synthesis of macromonomers because of its less demanding experimental conditions, the absence of special purification procedures of reagents used, and its

Table 2. Graft Copolymers Prepared by Macromonomers Synthesized by Cationic Polymerization

Macromonomer	End group	Comonomer	Copolymerization	Reference

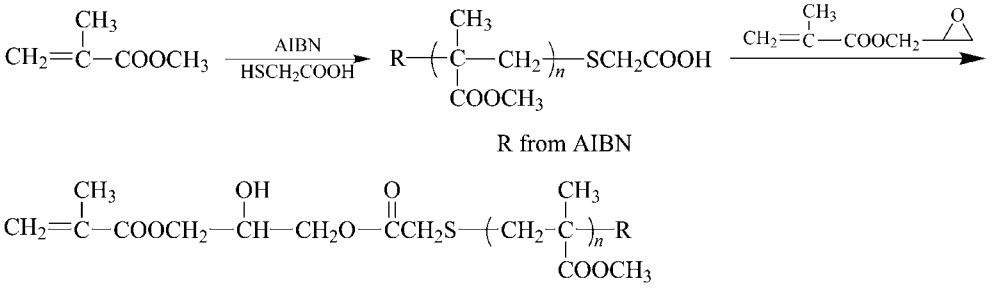
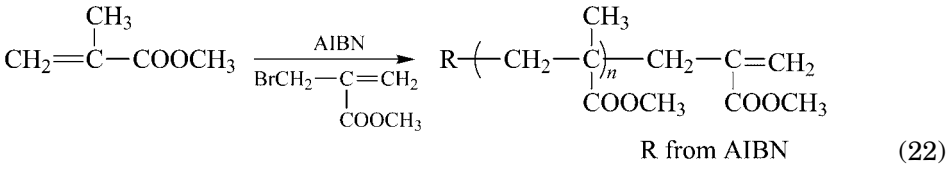
applicability to a wide variety of monomers. However, the method suffers many disadvantages such as the poor control over the molecular weight, the molecular weight distribution, and the degree of functionalization. The basic method for the incorporation of the functional end groups involves the use of chain-transfer agents (81).

Poly(methyl methacrylate) (PMMA) macromonomers have been prepared using thioglycolic acid as a chain-transfer agent, followed by reaction with glycidyl methacrylate (82) (eq. 21).



(21)

α-(Bromoethyl) acrylate has been also used as a chain-transfer agent for the synthesis of PMMA macromonomers carrying acrylic end groups (83) (eq. 22).



(22)

Table 3 summarizes examples of graft copolymers prepared by macromonomers that were synthesized by free-radical polymerization methods.

The evolution of the living free-radical polymerization techniques (mainly TEMPO (2,2,6,6-tetramethylpiperidinyl-1-oxy) and ATRP methods) very soon led to the synthesis of macromonomers. These methods combine the advantages of the free-radical polymerization with those of the living polymerization techniques, despite the fact that control over the functionalization reaction is not always comparable to the anionic polymerization methods (91,92).

A multifunctional reagent (**14**) containing reactive sites [TEMPO, oxazoline, and *t*-butyl dimethyl silyl protected hydroxyl (TBDMS) group] able to initiate anionic, cationic, and living free-radical polymerization was used to prepare a variety of macromonomers (93). Styrene was polymerized at high temperatures through the alkoxyamine functional group to produce macromonomers with oxazoline end groups (**15**) (eq. 23). Cationic copolymerization of these macromonomers with oxazoline using methyl triflate as initiator leads to the formation of polyoxazoline-*g*-PS graft copolymers.

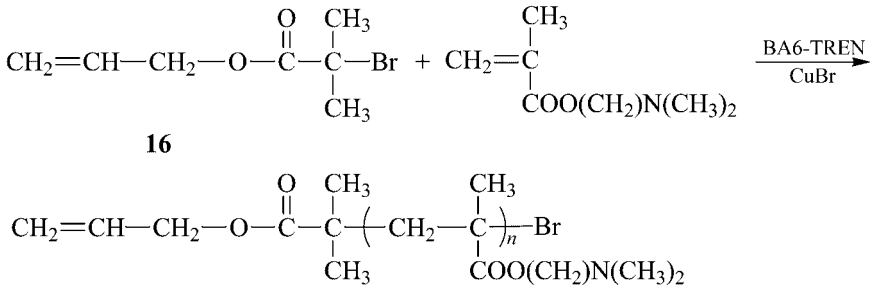
14 **15**

(23)

Poly(dimethylaminoethyl methacrylate) macromonomers were prepared by ATRP using allyl 2-bromoisobutyrate (ABIB, (**16**))/CuBr/tris[2-di(butyl acrylate) aminoethyl] amine, (BA6-TREN) or allyltrichloroacetamide/CuBr/BA6-TREN as the initiation systems (94) (eq. 24).

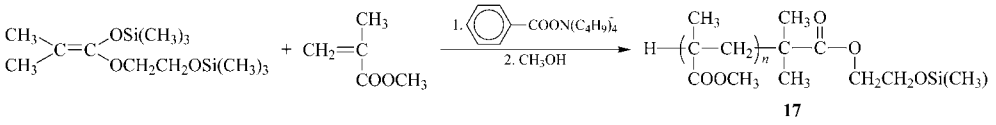


16

(24)

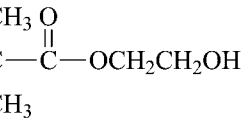
Group transfer polymerization has also been used for the synthesis of macromonomers. The functional end groups are incorporated mainly using the suitable initiation system (95). Trimethylsilyloxy ethyltrimethylsilyl dimethyl ketene was used as initiator for the synthesis of PMMA macromonomers (**17**)

in the presence of tetrabutylammonium benzoate as the catalyst (eq. 25). Treatment with dilute HCl (eq. 26) provided the —OH functional macromonomers (**18**), followed by the reaction with acryloyl chloride to give the final macromonomer structure (96) (eq. 27).

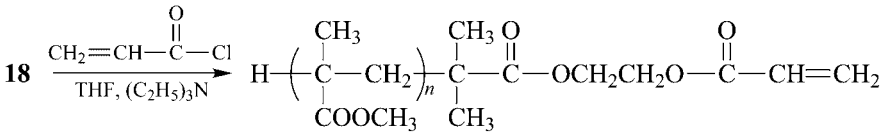


17

(25)

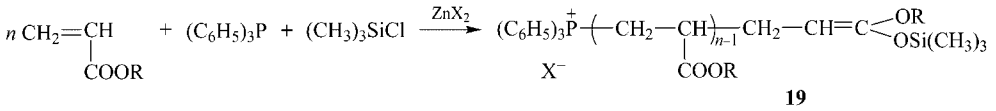


18 (26)



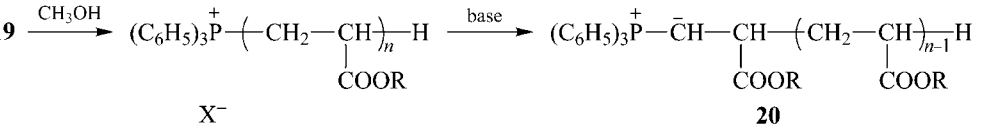
(27)

Polyacrylate macromonomers were prepared using triphenyl phosphine and trimethylchlorosilane in the presence of zinc halide as the catalyst (97) (eq. 28). The resulting polymers (**19**), having trimethylphosphinium end groups, were transformed to the corresponding macromolecular ylide (**20**) by reaction with sodium ethanolate (eq. 29). Subsequent Wittig reaction (eq. 30) of the ylide provides the macromonomer (**21**) where R = methyl, ethyl, or *n*-butyl.



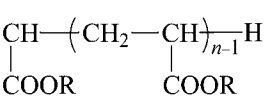
19

(28)



20

(29)



(30)

More examples concerning the synthesis of macromonomers by group transfer polymerization and the subsequent formation of graft copolymers are given in Table 4.

Table 4. Graft Copolymers Prepared by Macromonomers Synthesized by Group Transfer Polymerization

Macromonomer	End group	Comonomer	Copolymerization	Reference
Poly(vinyl alcohol)	*p*-Vinylbenzene	Styrene	Radical	98,99

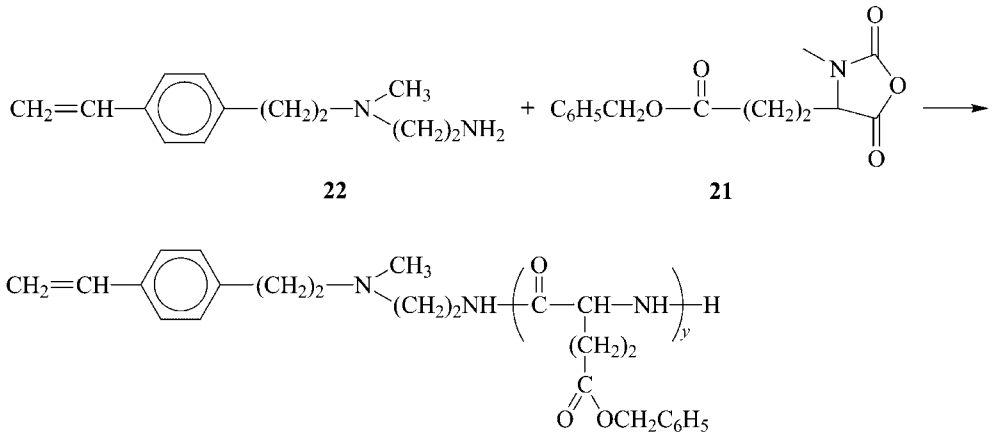
PMMA	Methacrylate	*n*-Butyl acrylate	ATRP, radical	102

Polycondensation techniques have been employed for the synthesis of macromonomers. Depending on the nature of the functional end group the copolymerization with comonomers can be performed with addition polymerization techniques, giving rise to very interesting graft copolymer structures.

Poly(γ-benzyl-L-glutamate) macromonomers were prepared by polymerization of benzyl(*S*)-3-(2,5-dioxo-1,3-oxazolidin-4-yl)propionate (**21**) (or γ-benzyl-L-glutamate-*N*-carboxyanhydride) using the primary amino group of the *N*-methyl-*N*-4-vinylphenethyl ethylene diamine (**22**)(103,104) (eq. 31).

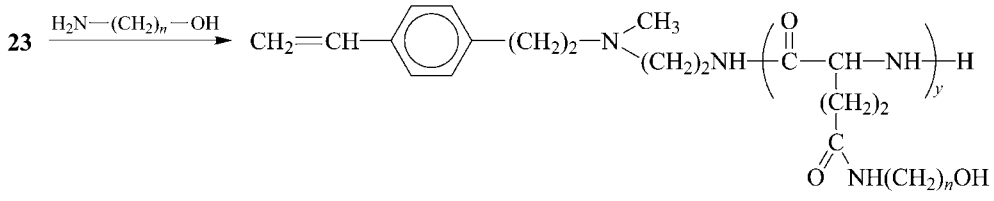


22 **21**

23

(31)

Subsequent reaction with aminoalcohols provides another type of macromonomer with side —OH groups (eq. 32).



(32)

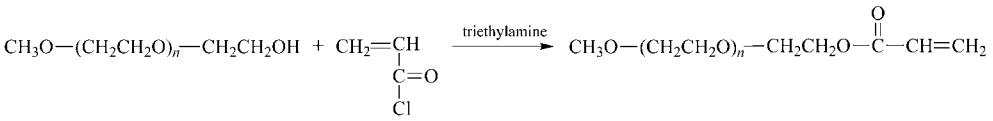
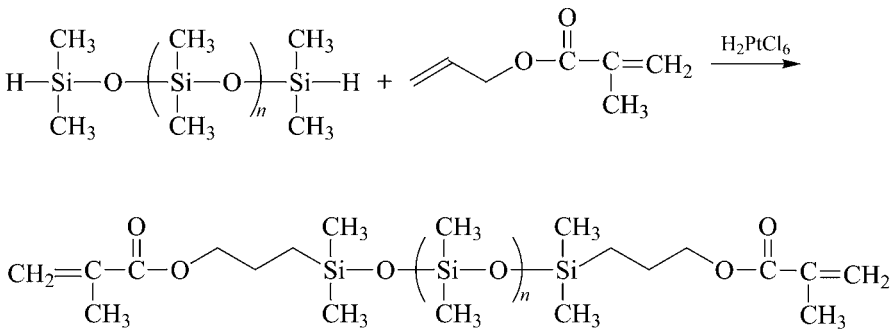
Characteristic examples concerning the synthesis of macromonomers prepared by polycondensation reactions and the subsequent formation of graft copolymers are given in Table 5.

Macromonomers have been also prepared by post-polymerization reactions. Poly(ethylene oxide) (PEO) or poly(propylene oxide) (PPO) has one or two —OH end groups depending on the method of their preparation. These —OH groups may react with (meth)acryloyl chloride, *p*-vinyl benzyl chloride, norbornenyl chloride, 4-vinyl benzoyl chloride, etc. for the synthesis of the corresponding macromonomers (109,110) (eq. 33).



(33)

Hydrosilyl-terminated PDMS chains may undergo hydrosilylation reactions with comonomers having double bonds to produce macromonomers (111,112) (eq. 34).



(34)

More examples of macromonomers prepared by post-polymerization reactions are provided in Table 6.

Other methods have also been employed for the synthesis of macromonomers. They do not have always general applicability but can be successfully used in specific cases. For example, polypropylene macromonomers with

Table 6. Graft Copolymers Prepared by Macromonomers Synthesized by Post-Polymerization Reactions

vinylidene end groups were prepared using metallocene-catalyzed polymerization. Bis(cyclopentadienyl)zirconium dichloride/methylaluminoxane (Cp_2ZrCl_2/MAO) and other catalytic systems were used. The olefinic end groups were obtained through the β-hydrogen elimination mechanism. These macromonomers were either used directly to produce graft copolymers after copolymerization with olefins using metallocene catalysts or were transformed to other structures by post-polymerization reactions. Addition of thioacetic acid introduced thiol functional groups, whereas hydroboration and subsequent reaction of the resulting hydroxyl group with methacrylic acid produced methacryloyl-terminated polypropylenes. Radical copolymerization with MMA provided PMMA-*g*-PP graft copolymers (117).

Styryl amylose amide (VAA) was prepared from maltopentose-substituted styrene (VM5A) by phosphorylase-catalyzed polymerization of glucose-1-phosphate (Glu-1P) (118) (Fig. 8). Subsequent radical copolymerization with acrylamide gave the corresponding graft copolymers..

Ring-opening metathesis polymerization was employed for the synthesis of polynorbornene macromonomers (**24**). A well-defined molybdenum initiator of the type $Mo(CHC(CH_3)_2C_6H_5)(N\text{-}2,6\text{-}(i\text{-}C_3H_7)_2C_6H_3)(OR)_2$ [R = $OC(CH_3)_3$, $OCCH_3(CF_3)_2$] was used. The polymers produced were cleaved from the initiator fragment in a Wittig-like reaction using *p*-$(CH_3)_3SiC_6H_4CHO$, according to a well-established method (eq. 35). Deprotection under basic conditions gave macromonomers having phenyl end groups (**25**) (eq. 36). Subsequent reaction with norbornene carboxylic acid chloride yields macromonomers with norbornene end groups (119) (eq. 37).

(37)

Regular Graft Copolymers. The term regular graft copolymers corresponds to graft copolymers with identical equally spaced branches along the backbone. Regular graft copolymers of PI-*g*-PS have been prepared. The synthetic approach involves the selective replacement of one chlorine atom of methyltrichlorosilane by PS followed by step-growth polymerization of the produced $(PS)Si(CH_3)Cl_2$ with α,ω-dilithium PI. The polydispersity of the reaction products

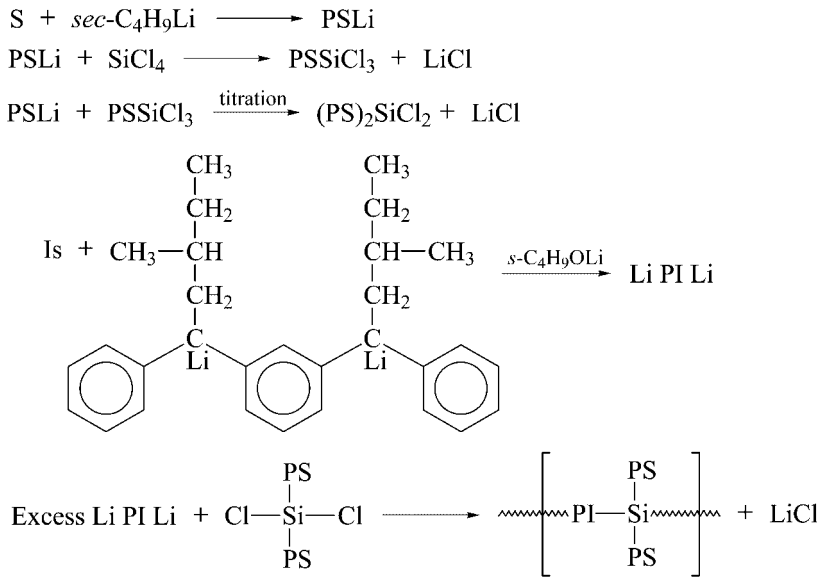

Fig. 9. Synthetic approach to regular PI–PS graft copolymers.

is high ($M_w/M_n = 2.0–3.0$) but it is reduced by fractionation ($M_w/M_n = 1.2–1.5$). By using $SiCl_4$ instead of $Si(CH_3)Cl_3$ and by the replacement of two chlorines by PS, graft copolymers with tetrafunctional branching points are synthesized (120) (Fig. 9).

Exact Graft Copolymers. The term exact graft copolymers refers to molecules where all the molecular and structural characteristics, such as the backbones' and branches' molecular weights and molecular weights distribution, the number of branches, and the specific grafting points on the backbone, can be controlled and varied at will. The parameters that are most difficult to control are the number and the spacing distribution of branches along the backbone chain.

Exact graft copolymers having rather simple structures, ie one or two branches, have been prepared so far. Among these are the A_2B and AA′B single graft copolymers (121–128) and the H- and π-shaped copolymers (129–131) (Fig. 10). Several techniques have been used for the synthesis of these structures and mainly anionic polymerization and controlled chlorosilane chemistry.

A new promising methodology was reported for the synthesis of exact graft copolymers with PI backbone and PS branches (132) (Fig. 11). The method is

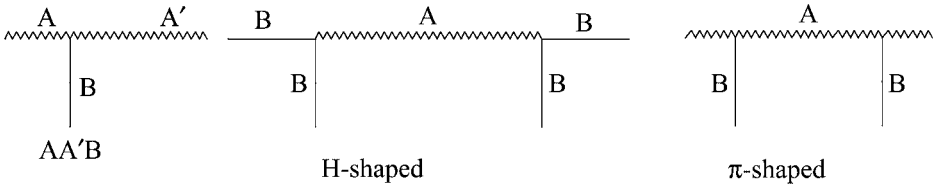

Fig. 10. Exact graft copolymers: AA′B, H-shaped, and π-shaped.

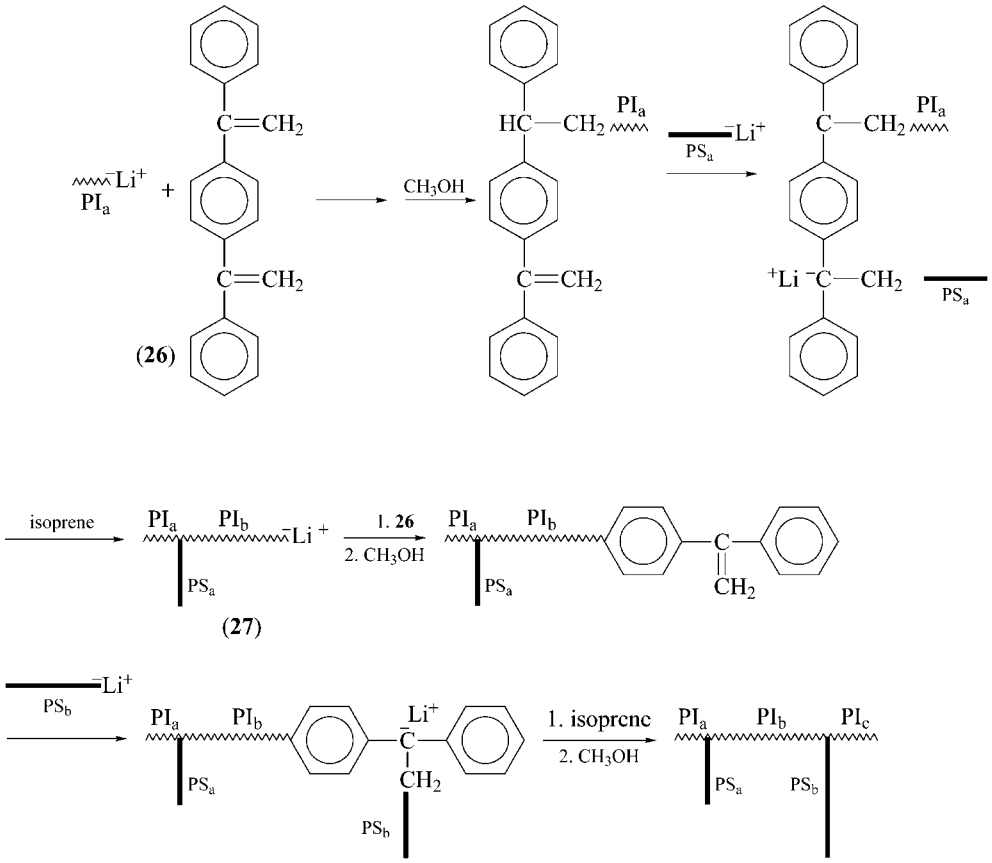

Fig. 11. Synthesis of exact graft copolymers of styrene and isoprene.

based on the use of 1,4-bis(1-phenylethenyl)benzene (**27**), which upon reaction with living polyisoprenyllithium leads to the formation of a PI macromonomer. This macromonomer is subsequently linked with polystyryllithium, followed by the anionic polymerization of isoprene. The living single graft copolymer (**27**) then reacts again with (**26**) and the same reaction sequence is repeated to produce the exact graft copolymer with two branches. In principle it is possible to continue the synthesis of graft copolymers with more branches, using the same reaction series.

Purification and Molecular Characterization of Graft Copolymers

Molecular characterization is an essential step in the study of graft copolymers since the knowledge that is gained is essential in deducing the structure–property relationships. Graft copolymers, like all copolymers, may present molecular weight, compositional, and architectural (distribution in the number of branches and the position of the branching points) heterogeneity (133–135). Following the synthesis of graft copolymers, the next step is to thoroughly characterize the

obtained samples in order to determine their average molecular weight, average composition, molecular and compositional homogeneity and obtain information on the architectural characteristics of the material. Additionally, information about the molecular size of the individual macromolecule may be desired. Because of the imperfections present in the synthetic methodology used for the preparation of nearly every synthetic macromolecule, the resulting material is a very complex system whose identity can only be revealed by the employment of a combination of analytical techniques (133,135).

Sometimes a number of purification procedures must be followed before the desired materials can be isolated and characterized. Graft copolymers may contain varying amounts of impurities, like homopolymers (ie, backbone or branches resulting from incomplete coupling) or copolymers of different architecture, as a result of the synthetic strategy followed for their preparation. These heterogeneities in all cases affect the final properties of the material. Fractionation is a powerful tool usually employed to separate heterogeneous mixtures of polymers before the final characterization of each fraction (134). Copolymers can be fractionated according to their molecular weight or chemical composition (135). The mostly used fractionation methods that result in the isolation of actual samples (fractions) are batch fractionation and column-elution fractionation. In some cases extraction with solvents selective for a specific impurity can be used, ie, in separating excess homopolymer branches.

Determination of Molecular Weight, Constitution, and Composition. Many analytical techniques are available for the determination of the primary molecular structure of a block copolymer and its average chemical composition. Among them spectroscopic techniques used for low molecular weight compounds are the most powerful and most widely employed. NMR can provide both qualitative and quantitative information with respect to comonomer composition and stereochemical configuration of polymeric molecules (136,137). The IR technique provides information on chemical, structural, and conformational aspects of polymeric chains (138). Because of the inherently high sensitivity of UV spectroscopy the technique is often utilized for the identification and quantitative determination of comonomers in block copolymers.

The average molecular weight of block copolymer is a very important parameter that characterizes a certain copolymer sample and it is strongly related with the properties of the polymeric material. Therefore, its determination and knowledge is imperative in the study of these materials. A variety of techniques are available for the determination of different average molecular weights of graft copolymers and polymers in general. These include membrane osmometry and light scattering for the determination of the absolute values of M_n and M_w respectively (133). In the case of light scattering it should be always kept in mind that the M_w obtained is apparent, unless the dn/dc is high for all parts of the graft copolymer (backbone and branches) and the material is characterized by high molecular weight and compositional homogeneity. Knowledge of the molecular weights of the individual components of the graft copolymer can be combined with the determination of the total molecular weight in order to determine the average number of branches per macromolecule. This determination can be aided by the selective sampling of individual parts of the graft copolymer during synthesis, when this is possible, or selective degradation of a part of the macromolecule

after isolation of the product. Size exclusion chromatography (sec) has emerged as a powerful analytical technique for the determination of molecular weight and molecular weight and composition distribution of block copolymers (139). A number of different types of mass/concentration and molecular mass detectors have been developed so far for simultaneous use in sec instruments, providing a large amount of information in a single run.

In cases where the molecular size of the graft copolymer must be known in solution, several methods can be applied. These include primarily static and dynamic light scattering, small-angle neutron and x-ray scattering, and viscometry. Static light, small-angle neutron (sans) and x-ray (saxs) scattering provide information for the radius of gyration of isolated chains (or parts of them using sans and contrast variation techniques) whereas dynamic light scattering and viscometry measure the hydrodynamic radius and properties of the molecules (133,140,141).

Properties and Uses

Solution Properties. Graft copolymer properties in solutions have been studied extensively for many decades. Because of the arrangement of branches along the backbone certain changes in its conformation and effective stiffness are observed. Studies on model graft copolymers have shown that the conformation of the whole molecule becomes more extended compared to linear chains (32,122,142). The phenomenon is more pronounced in the case of polymacromonomers (graft copolymers that are derived from the homopolymerization of macromonomers) where each repeating unit of the backbone carries a polymer chain (143–147). Crowding effects are maximal in this case, resulting in an increased induced stiffness on the backbone and a bottlebrush conformation. This specific conformation can impart interesting rheological properties in the corresponding solutions of polymacromonomers.

Detailed light scattering investigations were performed in the case of poly(isoprene-*g*-styrene) block copolymers in thermodynamically good solvents, isorefractive for different parts of the molecule (32). This technique enabled the determination of the size of the backbone and the branches independently, leading to the conclusion that segregation exists between the backbone and the grafts even in nonselective solvents and the molecule adopts a more or less core–shell structure.

In solvents selective for one of the parts of the molecule, graft copolymers show the ability for micelle formation (148–157). Micelles with cores comprised from the insoluble part and coronas comprised from the soluble one are formed. However, aggregation numbers and size of the micelles are lower than the corresponding ones for linear block copolymers. Critical micelle concentrations are also higher in the case of graft copolymers. This was attributed to the additional constraints imposed to micelle formation because of the presence of a large number of branching points along the backbone. Ideally these branching points should be situated at the micelle core–corona interface, a requirement that increases the free energy of the system as excluded volume effects between the branches and conformational entropy due to looping of backbone are increased. As a result of the molecular architecture, unimolecular micelles of graft copolymers are more easily

formed especially in the case where the solvent is selective for the branches (151–153). In this case the backbone can adopt a collapsed conformation protected from unfavorable interactions with the solvent molecules by the well-solvated branches forming the corona. The increased number of branches favors the stabilization of the structure in solution.

Morphology. The peculiar macromolecular architecture of graft copolymers also influences their bulk properties. The arrangement of a relatively large number of branching points along one of the constituent chains (the backbone) imparts some additional constraints in the formation of microphases and the geometry of the final microstructure. Macrophase separation cannot be excluded in graft copolymer systems where there is a large molecular, compositional, and architectural heterogeneity. Nevertheless, the bulk morphology of a graft copolymer substantially influences other properties of the material (mechanical, rheological, optical, etc). Therefore, elucidation of equilibrium morphology and factors affecting ordering are essential in the design of new materials for specific applications.

The effect of chain architecture on the phase separation, order–disorder transition, and final morphology of graft copolymer systems has been investigated both experimentally (123,127,129–131,158–161) and theoretically (162–164). Studies on model graft copolymers elucidated, using transmission electron microscopy (TEM) and saxs or sans, many aspects of microphase separation of these complex macromolecules. In general, microphase separation and long-range order decrease as the number of branches increases. The morphology of graft copolymers can be predicted from the four morphologies of the simple constituting units which is a miktoarm star copolymer. The same is valid in the case of π and H exact graft copolymers (Fig. 12).

This is attributed to the presence of the branching points. Each one of them can be considered as a point where interfacial curvature between the two phases changes, and this causes severe frustration during the organization of macromolecules within the microphases. Consequently, microdomain sizes and grain structure are altered.

Mechanical Properties. The viscoelastic and mechanical properties of bulk graft copolymers are directly connected to their morphology, which in turn depends on the molecular characteristics of the copolymer. Chemical nature of the backbone and grafts and their mutual solubility as well as the molecular weight and the degree of branching are the primary parameters affecting the mechanical properties of such systems (165–167). For example, Young's modulus, stress at break, toughness and yielding stress for poly(butyl acrylate-*g*-styrene) graft copolymers were found to increase, whereas yield elongation decreased as the number of branches increased (at the same branch molecular weight) (165) (Fig. 13).

This behavior was identified as a result of the increase in the hard phase (PS) content in the graft copolymer. Grafting of styrene and vinylacetate onto EPDM (ethylene–propylene–diene terpolymer) improved the tensile strength of the resulting material in comparison to ungrafted EPDM, whereas grafting of N-substituted acrylamides on EPDM gave copolymers with decreased tensile strength (166). Poly(isoprene-*g*-styrene) copolymers with tetrafunctional branch points were found to have increased strain at break (167) than the commercial thermoplastic elastomers (Fig. 14). The mechanical properties of polymeric blends

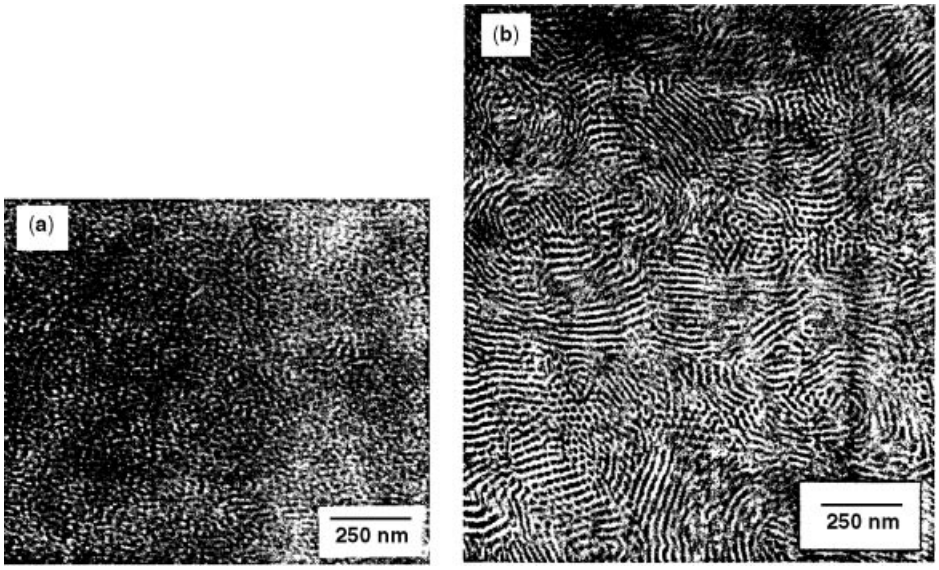

Fig. 12. (**a**) Transmission electron microscopy image of poly(butadiene-*g*-styrene) randomly branched graft copolymers with two PS branches on every grafting point. (**b**) Corresponding image for a poly(isoprene-*g*-styrene) regular graft copolymer with two PS branches on every grafting point. The copolymers contain approximately 61% and 67% by volume PS respectively. Notice the poor long-range order and the grain structure characteristics. From Refs. 158 and 159.

compatibilized with graft copolymers have received a relatively larger attention (168–171).

Compatibilization of Polymer Blends. Polymer blending is one of the most general, flexible, and efficient methods for generating new polymeric high performance materials (172). The resulting polymer mixture combines the properties of its components. These properties may in principle be varied by changing the blend composition according to the desired final performance of the material. However, because of entropic reasons, the majority of polymer pairs are incompatible. Graft copolymers are widely used as compatibilizing agents of immiscible blends (172–182). The different parts of a graft copolymer can be chosen and synthesized in such a way that interactions with the constituents of the blends are maximized. The constituents of the graft copolymer may have the same chemical structure with either the components of the blend or a chemical constitution (ie, complementary functional groups) that favors the interactions with the functional groups of the components. In this way graft copolymers are aiding in the adhesion of the different phases by forming a bicompatible interface. The interface reduces the interfacial energy between the phases in the blend and permits a more stable and finer dispersion of the components. The resulting mechanical properties of the formulation are improved since strong adhesion of phases helps in assimilating stresses and stains without disruption of the blend's morphology. The possibility of morphology changes during processing conditions is also minimized. A more recent compatibilization methodology, namely reactive blending, involves the formation of block or graft copolymers *in situ* (183–193). The method relies on the use

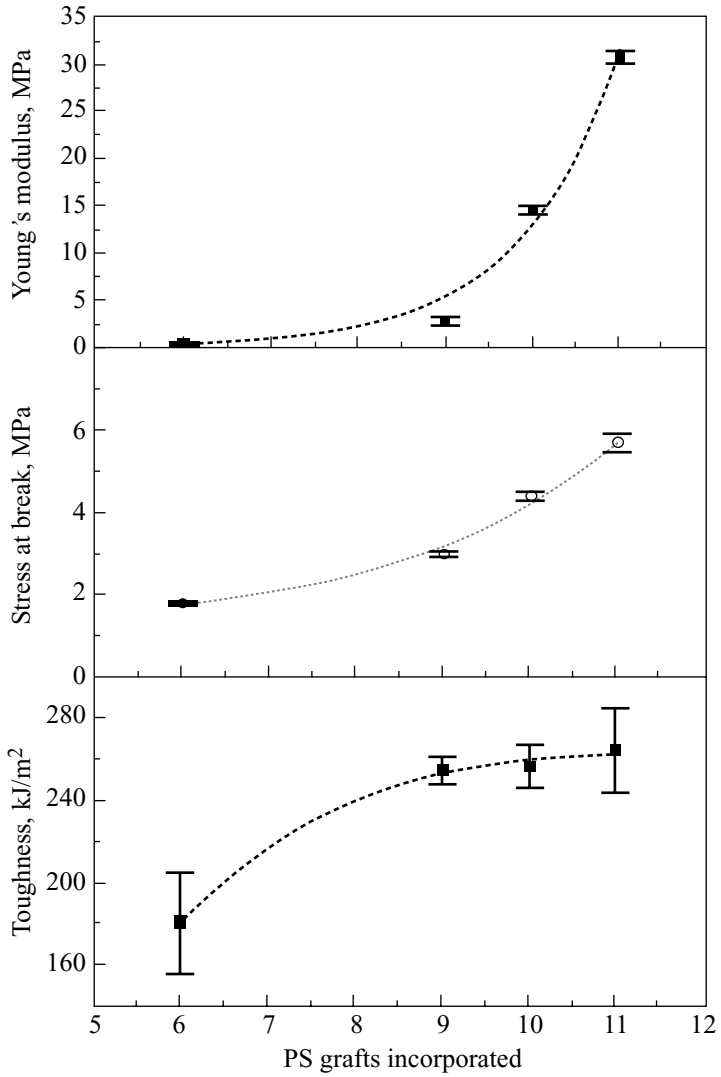

Fig. 13. Variation of the Young's modulus (E), tensile strength at break (σ_B), and toughness as a function of the number of PS grafts on the backbone for a poly(n-butyl methacrylate-g-styrene) graft copolymer prepared by the macromonomer technique. To convert MPa to psi, multiply by 145, to convert kJ/m^2 to ft·lbf/in.^{2}, divide by 2.10. From Ref. 165.

of reactive functionalities previously incorporated in one or more polymers of the blend for the production of block or graft copolymers after mixing the individual components and during melt-processing. This concept has been applied to a number of blend systems such as polyamide/polyolefins, polyamide/ABS, PS/olefins, polyester/polyamide using different types of reactions that can occur rapidly at elevated processing temperatures.

Other Present and Potential Applications. Graft copolymers are steadily assuming an increased importance because of their tremendous industrial

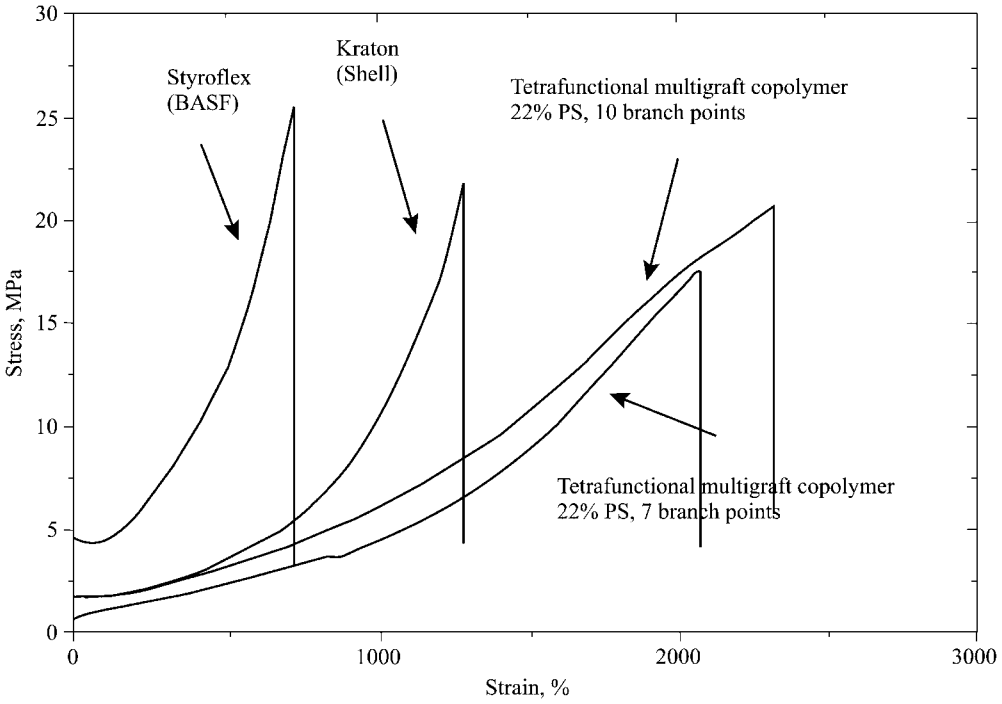

Fig. 14. Comparison of the mechanical properties of tetrafunctional multigraft poly(isoprene-*g*-styrene) copolymers with commercial Styroflex and Kraton copolymers. From Ref. 167.

application potential (194–205). Graft copolymers of commercial utility include ABS, obtained by grafting acrylonitrile and styrene monomers onto polybutadiene, high impact polystyrene, a family of poly(butadiene-*g*-styrene) materials, alkali-treated cellulose-*g*-acrylonitrile and starch-*g*-acrylonitrile which are used as "superabsorbent" components in diapers, sanitary napkins, and the like. Graft copolymers containing acrylic monomers are used as pressure-sensitive adhesives (197). Other graft copolymers are essential materials in oil recovery operations. A large number of commercial paint, printing, and coating formulations involve graft copolymers as dispersion stabilizers, rheology modifiers, and final coating properties improvers (eg, corrosion resistivity, environmental compatibility, etc.) (198–205).

The potential of using graft copolymer micelles and nanoparticles derived from graft copolymers as drug carriers for controlled drug delivery systems and for environmental purification methodologies is high (206–211). These applications rely on the ability of the micelles to solubilize low molecular weight compounds in their cores. By controlling the molecular characteristics of the copolymers and the chemical nature of the corona, drug containing vehicles of the desired size, loading capacity, release kinetics, targeting capabilities, biocompatibility and biodegradability can be produced. Formulations in the gel and bulk state are also candidates for this kind of application. Size and loading capabilities of the micellar microcontainers are also important in water treatment systems. The application of graft

copolymer membranes in separation processes, like removal of deleterious organic compounds from contaminated drinking water, is also of interest (212–214). With judicious choice of chemical components in conjunction with graft copolymer morphology design, perselectivity and permeability of the resulting membranes can be adjusted.

Graft Copolymer Production/Consumption

It is difficult to accurately measure the amount of graft copolymers produced commercially. Here we refer to those polymers made either by the reaction of two polymers with each or by the growth of a chain of one monomer from a polymer made of a different one. In each case one has a nonlinear structure where the various segments of the resultant polymer (ie, backbone, branches, etc.) are chemically different. The difficulty in determining how much of this kind of polymer is produced is that it is done in many ways, and it is not even clear whether the producers are always cognizant of what they have made. The grafting often occurs during a mixing process, and the graft polymer itself is not separated from the other components of the blend. However, it is clear that graft copolymer technology is crucial to the modern plastics industry and that graft copolymers are present in a large fraction of the plastic materials made today.

The largest portion of this can be found in the styrenic polymers. Impact polystyrene [often called high impact polystyrene (HIPS)] is produced by polymerizing styrene monomer in the presence of polybutadiene. This results in grafting of some of the growing PS chains to the PB ones, giving good impact strength to the final product. Of the 12.7 million tons (10^6 t) of PS made worldwide each year (215), perhaps a quarter to a third is HIPS (216–218). ABS is made in a similar fashion as HIPS, except that acrylonitrile is also added to the styrene as a polymerizing monomer (219–222). About 4.9×10^6 t of this polymer is made each year. The next most common use of grafting is probably in the "super-tough" polyamides, made by a grafting reaction between the polyamide and a functionalized ethylene–propylene rubber (223–227). Perhaps 10–20% of the 1.8×10^6 t of polyamide is made this way. There are many other uses of graft copolymers, mostly for compatibilizing various polymer blends (228). As stated above, it is difficult to capture the amount of these made. However, it is safe to say that between 5 and 10% of the 141×10^6 t of plastics made each year contain a significant fraction of graft copolymer.

HEAT STABILIZERS

Introduction

Heat stabilizers protect polymers from the chemical degrading effects of heat or uv irradiation. These additives include a wide variety of chemical substances, ranging from purely organic chemicals to metallic soaps to complex organometallic compounds. By far the most common polymer requiring the use of heat stabilizers is poly(vinyl chloride) (PVC). However, copolymers of PVC, chlorinated poly(vinyl chloride) (CPVC), poly(vinylidene chloride) (PVDC), and chlorinated polyethylene (CPE), also benefit from this technology. Without the use of heat stabilizers, PVC could not be the widely used polymer that it is, with worldwide production of over 20 million metric tons in 2000 (see VINYL CHLORIDE POLYMERS).

The discussion centers on heat stabilizers for PVC because this polymer is the most important class of halogenated polymers requiring these chemical additives. PVC of ideal chemical structure (**1**) should be a relatively stable compound as predicted from model studies using 2,4,6-trichloroheptane [13049-21-3] (**2**) (1).

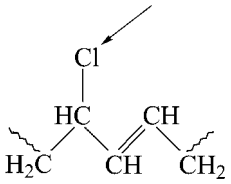
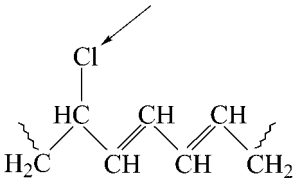
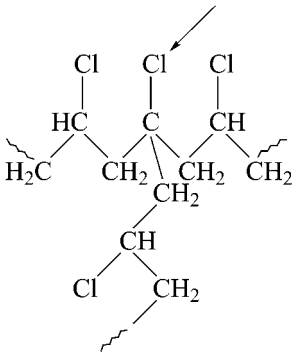
During the polymerization process the normal head-to-tail free-radical reaction of vinyl chloride deviates from the normal path and results in sites of lower chemical stability or defect sites along some of the polymer chains. These defect sites are small in number and are formed by autoxidation, chain termination, or chain-branching reactions. Heat stabilizer technology has grown from efforts to either chemically prevent or repair these defect sites. Partial structures (**3**), (**4**), (**5**), (**6**) are typical of the defect sites found in PVC homopolymers (2–5).



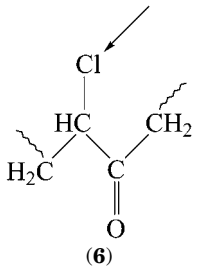
(**3**)



(**4**)



(**5**)



(**6**)

The dissociation energies for the highlighted (by pointing arrows) carbon–chloride bonds are significantly lower than that of a normal secondary C—Cl bond and can lead to thermal dehydrochlorination of the polymer backbone. In addition, the released HCl acts to catalyze further dehydrochlorination, indicating that both

homolytic and ionic processes are involved. As the conjugated polyene sequences grow in length, further weakening of the carbon–chlorine bond occurs, leading eventually to rapid, catastrophic dehydrochlorination, cross-linking, and chain scission resulting in loss of mechanical, electrical, and rheological properties in the final articles. A good indication of the onset of thermal degradation is the appearance of color in the polymer. When the conjugated polyenes reach a length of about seven double bonds, this chromophore begins to absorb visible light and appears yellow in color. Further degradation leads to brown and eventually black-colored products.

Some work has been conducted on the *in situ* or preventative stabilization of PVC, but these efforts have been largely unsuccessful, centering primarily on copolymerizing vinyl chloride with other vinyl monomers to block the conjugative ordering of the chlorine atoms in the polymer (6). The commercially important heat stabilizers are arrestive in nature. They chemically repair the defect sites or in some way reduce the deleterious nature of these sites during the processing and use of PVC articles. Just as important, most of the active heat stabilizers are also good HCl scavengers and reduce the catalytic effects of this deleterious by-product. PVC is so widely used because its properties are so easily manipulated by an inexhaustible variety of added components. Applications can range from rugged PVC pipes to crystal clear drinking water bottles to colorful toys to supple artificial leather, depending on the choice of additives in the formulation. The needs and choices of the heat stabilizer are dependent upon the final desired physical properties, compatibility with the other additives used, -and the processing methods used to form the articles. Figure 1 shows the complexity of PVC formulation alternatives. Only the heat stabilizers and, normally, lubricants are essential additives to process the polymer. All of the other classes of additives are

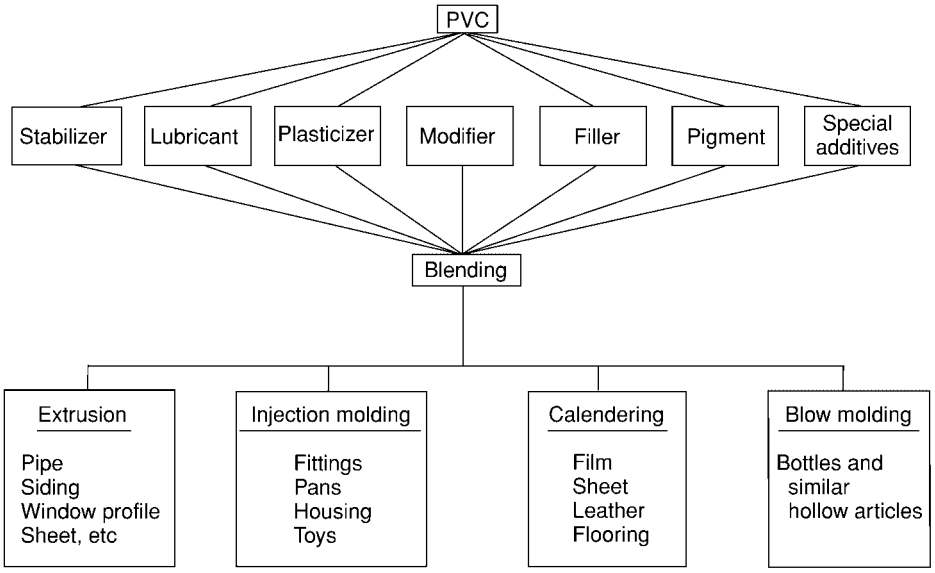


Fig. 1. PVC formulation alternatives.

discretionary, ie, they are present to change the physical properties of the final processed PVC articles.

In normal operations, PVC resin is intimately mixed with the desired ingredients under high intensity shear mixing conditions to produce a homogeneous dry powder compound. The heat stabilizers can be either liquids or powders and are added early in the blending cycle to afford stabilizing action during this operation. Preheating the resin to about the glass-transition temperature facilitates the adsorption of the liquid additives, giving the final compound better powder flow properties and decreasing the bulk density. Post-compounding operations, eg, extrusion pelletizing, can increase the overall heat history of the polymer, thus requiring slightly higher levels of heat stabilizers to compensate for this.

History of Stabilizer Development

Although PVC was discovered in the late nineteenth century in Germany, it was not until the discovery that certain lead soaps improved the thermal stability of the polymer in the early 1930s that commercialization of PVC began. Lead-based stabilizers have continually been used in certain applications, such as wire and cable coatings. Today, because of toxicity and ecotoxicity concerns, considerable efforts are being made to eliminate all uses of lead-based heat stabilizers, worldwide. In the mid-1930s, workers in the United States found that organotin carboxylates also provided good heat stability. The high activity, nonstaining, nondusting characteristics, and complete compatibility, allowing total transparency, made the organotin stabilizers good choices for rigid, flexible, and even plastisol end uses. During the 1940s, alkali and alkaline-earth metal soaps, especially those of cadmium, barium, zinc, and calcium, were discovered and commercialized as PVC heat stabilizers. By the 1950s combinations of these metal soaps with organic costabilizers, such as phosphites and epoxides, demonstrated great processing latitude and cost effectiveness, particularly in plasticized PVC. Some of these formulations remain state-of the-art technology for certain end uses. Just as in the case for lead, considerable pressure has been exerted on the plastics industry to discontinue uses of cadmium for both stabilizers and pigments because of its high toxicity. Organotin mercaptide chemistry was introduced as a new class of PVC heat stabilizers during the 1950s and played a significant role in the development of many rigid PVC applications. The efficiency per unit dose remains unsurpassed for the organotin mercaptide-stabilized formulations for food packaging (qv), water pipes, weatherable construction panels, and molded parts. Antimony mercaptides were also discovered in the 1950s and did complete with the organotin mercaptides in rigid PVC applications for several years, but again, toxicity concerns have nearly eliminated the use of this class of stabilizer.

Function of Stabilizers

Although great progress has been made since the 1960s to sort out the many reactions ongoing during the thermal degradation of PVC, much of the formulating and use of stabilizers remains an art in commercial practice. PVC degradation

proceeds by both free-radical and ionic reactions, although the latter appears to be the more important route. Lewis acid catalysts, such as zinc chloride or hydrogen chloride, can greatly accelerate the rate of dehydrochlorination of the polymer. Heat stabilizers serve several distinct functions during PVC processing: absorption of hydrogen chloride, replacement of labile chlorines, prevention of autoxidation, and disruption of polyunsaturated sequences. An ancillary function of many heat stabilizers is provision of uv stability, leading to good weathering properties for the final articles. Good uv stability depends on having adequate heat stability because partially degraded PVC is susceptible to uv degradation regardless of the choice of uv absorber additives used.

Absorption of Hydrogen Chloride. Effective heat stabilizers have the ability to bind hydrogen chloride. Most stabilizer systems contain one or more metallic soaps or salts which readily undergo a simple acid–base reaction with the by-product hydrogen chloride as the PVC degrades:

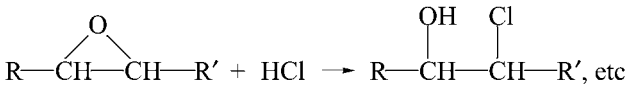
$$M(X)_n + HCl \rightarrow M(X)_{n-1}Cl + HX$$

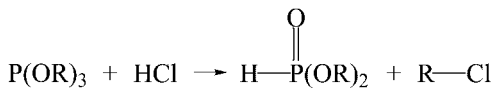
$$M(X)_{n-1}Cl + HCl \rightarrow M(X)_{n-2}Cl_2 + HX$$

where M is a metal, usually Pb, Zn, Ca, Ba, or Cd, and X is a carboxylic acid, usually a weakly acidic fatty acid ligand. Typical examples of effective metal soaps and salts used as PVC stabilizers include lead stearate, dibasic lead phthalate, tribasic lead sulfate, zinc octanoate [557-09-5], barium tallate, cadmium 2-ethylhexanoate, calcium stearate, calcium nonylphenate [30977-64-1].

A new type of inorganic metal complex, called hydrotalcite, has appeared (ca 1990). These synthetic minerals, functionally akin to zeolites, have layered structures of Al and Mg and function to trap hydrogen chloride between these layers (7). The hydrotalcite minerals are generally used with other stabilizers as part of a stabilizer system. A typical hydrotalcite may be represented by a formula such as $Mg_4Al_2(OH)_{12}CO_3 \cdot 3H_2O$. Many modifications can be made by changing the Al-to-Mg ratio and by including other metal salts, such as zinc oxide. Unlike most metallic salts, the hydrotalcites are compatible with PVC and can provide completely transparent PVC articles.

Many PVC stabilizer formulations also contain one or more organic costabilizers that can also absorb hydrogen chloride. Typical of these additives are epoxidized fatty acid esters and organophosphites:





Organotin mercaptides can also absorb hydrogen chloride.

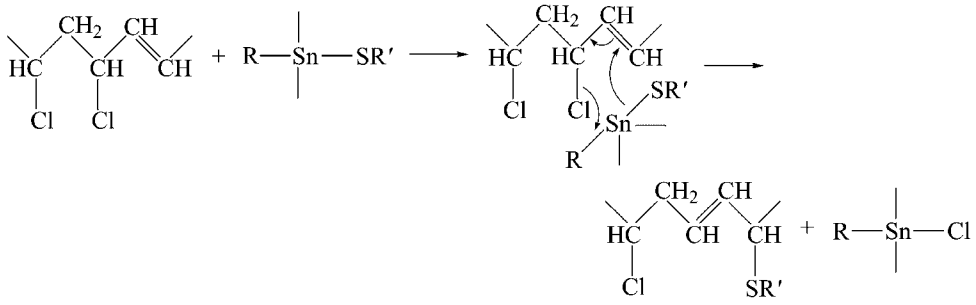
$$R{-}Sn(SR')_3 + HCl \rightarrow R{-}Sn(SR')_2Cl + HSR'$$

$$R{-}Sn(SR')_3Cl + HCl \rightarrow R{-}Sn(SR')\,Cl_2 + HSR', \text{ etc}$$

Some of these stabilizers are added specifically to react with evolved hydrogen chloride. When the primary function of the stabilizer is to repair defect sites or disrupt autoxidation reactions, the degree that these stabilizers react with hydrogen chloride can actually detract from their primary function, requiring the use of higher dosages of stabilizers in the PVC formulation.

Replacement of Labile Chlorines. When PVC is manufactured, reactions competing with the normal head-to-tail free-radical polymerization can sometimes take place. These side reactions are few in number yet their presence in the finished resin can be devastating. These abnormal structures have weakened carbon–chlorine bonds and are more susceptible to certain displacement reactions than are the normal PVC carbon–chlorine bonds. Carboxylate and mercaptide salts of certain metals, particularly organotin, zinc, cadmium, and antimony, attack these labile chlorine sites and replace them with a more thermally stable C—O or C—S bound ligand. These electrophilic metal centers can readily coordinate with the electronegative polarized chlorine atoms found at sites similar to structures (**3**), (**4**), (**5**), (**6**).

In the early 1960s, two different ^{14}C and one ^{113}Sn radio-labeled di-*n*-butyltin bis(isooctylthioglycolate) stabilizers were synthesized. Heat stability studies with these organotin compounds demonstrated the important replacement reactions, leading to the following proposed mechanism (8). It is believed that the salts of zinc, cadmium (9), and lead (10) also undergo these reactions resulting in their respective ligands substituting on the PVC chains.

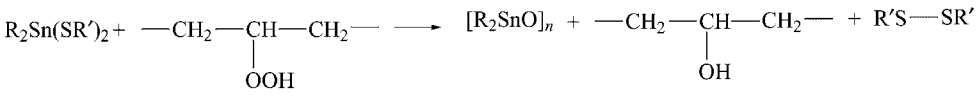


This mechanism not only accounts for the substitution of the more labile chlorine atom on the polymer chain, but also results in the elimination of a new potential initiation site by moving the double bond out of conjugation with any adjacent chlorine atoms. The newly formed C—O or C—S bonds, with $\Delta H > 484$ kJ/mol (100 kcal/mol), are significantly more thermally stable than even the normal C—Cl bonds in PVC at about 411 kJ/mol (85 kcal/mol) (11).

Ultimately, as the stabilization reactions continue, the metallic salts or soaps are depleted and the by-product metal chlorides result. These metal chlorides are potential Lewis acid catalysts and can greatly accelerate the undesired dehydrochlorination of PVC. Both zinc chloride and cadmium chloride are particularly strong Lewis acids compared to the weakly acidic organotin chlorides and lead chlorides. This significant complication is effectively dealt with in commercial practice by the coaddition of alkaline-earth soaps or salts, such as calcium stearate or barium stearate, ie, by the use of mixed metal stabilizers.

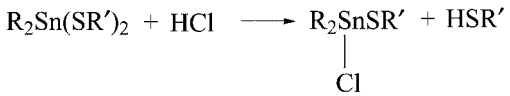
Displacement of activated chlorine atoms also proceeds with certain types of organic compounds, but only in the presence of Lewis acid catalysts. Particular examples include epoxides, polyhydric alcohols, trialkylphosphites (12), and β-aminocrotonates (13). These additives are commonly used in conjunction with metallic stabilizers to provide complete, high performance, commercial stabilizer packages.

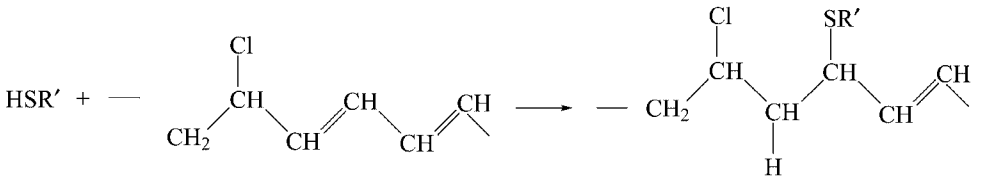
Prevention of Autoxidation. The observation that PVC thermally degrades more rapidly in air than in a nitrogen atmosphere leads to the conclusion that the prevention of oxidative reactions can improve the thermal stability of PVC (14). When phenolic antioxidants are included in the formulation, the rate of hydrogen chloride evolution, at 180°C in air, is noticeably retarded. Therefore, good stabilizers must also provide antioxidant protection. Many of the additives previously discussed, which provide HCl scavenging and labile chlorine displacements, are also fairly good antioxidants as evidenced by their activity in other nonhalogenated polymers, particularly trialkyl- and triarylphosphites, β-aminocrotonates, and organotin mercaptides. The organotin mercaptides are particularly efficient in their reduction of hydroperoxides (15):



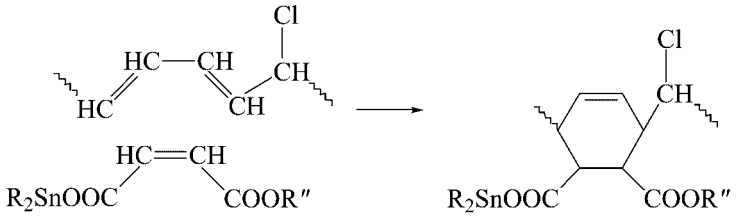
Disruption of Polyunsaturated Sequences. Sequential lengthening of the conjugated double bonds along a PVC molecule leads to the gradual development of color resulting from absorption of visible light (see COLOR). This lengthening conjugation further weakens the already weak allylic C—Cl bonds and leads to further loss of hydrogen chloride which, in turn, catalyzes further degradation. Left unchecked, the complete catastrophic degradation of the polymer is imminent.

Disruption of the conjugation of these long polyene groups can lead to color bleaching of the partially degraded PVC. Simple mercaptans effectively add to these highly reactive double bonds (16). Organotin mercaptides are also known to undergo this reaction, although it is likely that the actual reagent is the free mercaptan resulting from reaction with evolved HCl (17):





The organotin maleate and maleate half-ester derivatives also exhibit this bleaching effect reportedly by a Diels–Alder addition reaction (18). The reaction is specific to the organotin maleates; other organotin carboxylates containing normal dieneophiles fail to produce similar results (19).



Stabilizer Test Methods

Heat stabilizers are tested in a variety of ways to simulate their performance during PVC processing, ie, calendering, extrusion, pressing, heat curing, and molding. Because of the wide number of these applications, it is impossible to provide one or two definitive laboratory tests for all stabilizer products. In general, heat stabilizers are tested as a component in a complete formulation where each ingredient has a measured effect on the overall performance. Stabilizer performance is generally evaluated by visually inspecting the color of the test pieces as a function of heating and processing time. Static oven aging, dynamic two-roll milling, and torque rheometry are three of the most common tests used to evaluate heat stabilizers. A whole host of tests are conducted on the final products of the various processes to make judgments as to the effectiveness of any particular PVC formulation. Standard tests for stabilizer evaluation include ASTM D2115, Oven Stability of PVC Compounds; ASTM D2538, Fusion of PVC Compounds Using a Torque Rheometer; ASTM D1499, Stability of PVC to Light Exposure; and DIN 53-381F, Heat Stability of PVC Compounds by Metrastat Oven.

Classes of Heat Stabilizers

Organotin Compounds. Organotin-based heat stabilizers are the most efficient and universally used PVC stabilizers. Nearly 40% of the 75,000 t of stabilizers used in the United States during 2000 were organotin-based products. These are all derivatives of tetravalent tin, and all have either one or two alkyl groups covalently bonded directly to the tin atom. The commercially important

alkyltins are the methyltin, *n*-butyltin, and *n*-octyltin species. For about 10 years between 1980 and 1990, estertin or β-carboalkoxyethyltin derivatives were produced commercially. Aryltin and branched alkyltin derivatives are relatively poor heat stabilizers (20). The class of tri-*n*-alkyltin compounds are known to be toxic, and because they are very poor stabilizers, they are completely avoided in PVC heat stabilizer applications. The anionic ligands can be chosen from a wide variety of groupings but are normally chosen from maleate, alkylmaleate, esters of thioglycolic acid, or esters of mercaptoethanol, depending on the end-use application and the processing conditions for the PVC compound. Almost all organotin stabilizer products are formulated with mixtures of monoalkyltin and dialkyltin species in a ratio so as to maximize the stability of the PVC, together with all of the other microingredients in a given PVC formulation for a given processing method.

Alkyltin Intermediates. For the most part, organotin stabilizers are produced commercially from the respective alkyltin chloride intermediates. There are several processes used to manufacture these intermediates. The desired ratio of monoalkyltin trichloride to dialkyltin dichloride is generally achieved by a redistribution reaction involving a second-step reaction with stannic chloride [tin(IV) chloride]. By far, the most easily synthesized alkyltin chloride intermediates are the methyltin chlorides because methyl chloride reacts directly with tin metal in the presence of a catalyst to form dimethyltin dichloride cleanly in high yields (21). Coaddition of stannic chloride to the reactor leads directly to almost any desired mixture of mono- and dimethyltin chloride intermediates:

$$Sn^{\circ} + 2\,Cl_2 \longrightarrow SnCl_4$$

$$Sn^{\circ} + 2\,CH_3Cl \longrightarrow (CH_3)_2SnCl_2$$

$$(y + x)\,(CH_3)_2SnCl_2 + x\,SnCl_4 \longrightarrow y\,(CH_3)_2SnCl_2 + 2x\,CH_3SnCl_3$$

The direct reaction of other alkyl chlorides, such as butyl chloride, results in unacceptably low overall product yields along with the by-product butene resulting from dehydrochlorination. All alkyl halides having a hydrogen atom in a β position to the chlorine atom are subject to this complication.

The other important direct alkylation processes involve reaction of electron-rich olefinic compounds with either tin metal or stannous chloride [tin(II) chloride] in the presence of stoichiometric amounts of hydrogen chloride (22). Butyl acrylate (R = C_4H_9) was used commercially in this process to prepare the estertin or β-carboalkoxyethyltin chlorides as illustrated in the following.

$$Sn^{\circ} + 2\,HCl + 2H_2C{=}CHCOOR \longrightarrow (ROOCCH_2CH_2)_2SnCl_2$$

$$Sn^{\circ}Cl_2 + HCl + H_2C{=}CHCOOR \longrightarrow ROOCCH_2CH_2SnCl_3$$

A number of activated olefinic compounds react very well in this scheme, including methacrylates, crotonates, acrylonitrile, and vinyl ketones. These reactions are typically run in an etherial solvent and can be run without the complications of undesirable side reactions leading to trialkylated tin species.

The other commercially important routes to alkyltin chloride intermediates utilize an indirect method having a tetraalkyltin intermediate. Tetraalkyltins are made by transmetallation of stannic chloride with a metal alkyl where the metal is typically magnesium or aluminum. Subsequent redistribution reactions with additional stannic chloride yield the desired mixture of monoalkyltin trichloride and dialkyltin dichloride. Both *n*-butyltin and *n*-octyltin intermediates are manufactured by one of these schemes.

$$2\ R_2Mg + SnCl_4 \rightarrow R_4Sn + 2\ MgCl_2$$

$$4\ R_3Al + 3\ SnCl_4 \rightarrow 3\ R_4Sn + 4\ AlCl_3$$

$$R_4Sn + 2\ SnCl_4 \rightarrow 2\ RSnCl_3 + R_2SnCl_2$$

Stabilizer Synthesis. The selected alkyltin chloride intermediate reacts with either a carboxylic acid or a mercaptan in the presence of an appropriate base, such as sodium hydroxide, to yield the alkyltin carboxylate or alkyltin mercaptide heat stabilizer. Alternatively, the alkyltin chloride can react with the base to yield the alkyltin oxide, which may or may not be isolated for subsequent condensation with the selected carboxylic acid or mercaptan.

$$R_2SnCl_2 + 2\ R'SH + 2\ NaOH \rightarrow R_2Sn(SR')_2 + 2\ NaCl + H_2O$$

$$R_2SnCl_2 + 2\ NaOH \rightarrow (R_2SnO)_n + 2\ NaCl + H_2O$$

$$(R_2SnO)_n + 2\ R'COOH \rightarrow R_2Sn(OOCR')_2 + H_2O$$

Typically, alkyltin carboxylates are prepared from isolated alkyltin oxides because this route leads to higher efficiency and purity for these products. In many of the modern alkyltin mercaptide stabilizers, sulfide sulfur ligands are also used in combination with mercaptide ligands. Usually the sulfide groups are introduced as sodium sulfide and added along with the mercaptan and base to the alkyltin chloride intermediate. The resulting stabilizer is a mixture of products having both sulfide and mercaptide groups bound to each of the alkyltin compounds.

Costabilizers. In most cases the alkyltin stabilizers are particularly efficient heat stabilizers for PVC without the addition of costabilizers. Many of the traditional coadditives, such as antioxidants, epoxy compounds, and phosphites, used with the mixed metal stabilizer systems, afford only minimal benefits when used with the alkyltin mercaptides. Mercaptans are quite effective costabilizers

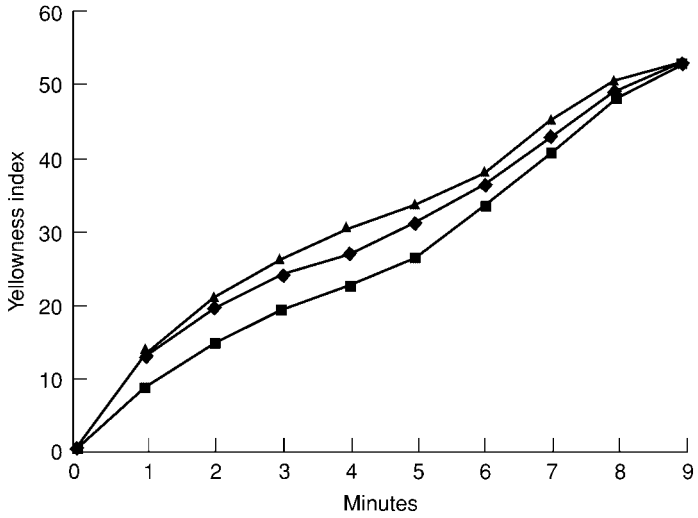


Fig. 2. Yellowness index vs two-roll mill heat stability, where the mercaptide ligands,—SCH_2COOR (▲), $–SCH_2CH_2\ COOR'$ (◆), and $–SCH_2CH_2\ COOR' + HSCH_2\ CH_2COOR'$ (■), are 17, 9, and 6% Sn, respectively. $R=C_8H_{17}$; $R' = C_{18}H_{33}$.

for some of the alkyltin mercaptides, particularly those based on mercaptoethyl ester technology (23). Combinations of mercaptan and alkyltin mercaptide are currently the most efficient stabilizers for PVC extrusion processes. The level of tin metal in the stabilizer composition can be reduced by up to 50% while maintaining equivalent performance. Figure 2 shows the two-roll mill performance of some methyltin stabilizers in a PVC pipe formulation as a function of the tin content and the mercaptide groups at 200°C. The test formulation contains 100 parts of PVC (Fikentscher K = 65), 1.2 parts of paraffin wax, 0.6 parts of calcium stearate, and 0.4 parts of methyltin-based stabilizers.

The various lubricants formulated into PVC to improve the processing can also enhance the performance of the stabilizer. In pigmented applications, calcium soaps, eg, calcium stearate, are commonly used as lubricants to promote PVC fusion and reduce melt viscosity. This additive is also a powerful costabilizer for the alkyltin mercaptide stabilizers at use levels of 0.2–0.7 phr. Calcium stearate can significantly improve the early color and increase the long-term stability at low levels; however, as the concentration increases, significant yellowing begins to occur particularly at low pigment dosages.

Commercial Stabilizers. A wide variety of alkyltin stabilizers have been used commercially since the 1960s, because no particular compound universally satisfies every requirement of PVC processing. In general, the alkyltin mercaptides exhibit the highest overall heat stability together with imparting excellent rheological properties to the polymer. The alkyltin carboxylates, on the other hand, are unsurpassed for imparting excellent weathering properties but generally give poor rheological characteristics. Table 1 lists the commercially important alkyltin stabilizer compounds. These compounds are typically formulated with several different adjuvants, both active and inert, to tailor their performance to given

Table 1. Commercially Important Alkyltin Compounds

Name	CAS registry number	Structure
Poly(dibutyltin maleate)	[32076-99-6]	$+(C_4H_9)_2SnOOCCH{=}CHCOO+_n$
Poly(dioctyltin maleate)	[32077-00-2]	$+(C_8H_{17})_2SnOOCCH{=}CHCOO+_n$
Dibutyltin bis(butyl maleate)	[17209-76-6]	$(C_4H_9)_2Sn(OOCCH{=}CHCOOC_4H_9)_2$
Dimethltin bis(2-ethylhexyl) thioglycolate)	[26636-01-1]	$(CH_3)_2Sn(SCH_2COOC_8H_{17})_2$
Dibutyltin bis(2-ethylhexyl) thioglycolate)	[25168-24-5]	$(C_4H_9)_2Sn(SCH_2COOC_8H_{17})_2$
Dioctyltin bis(2-ethylhexyl) thioglycolate)	[26401-97-8]	$(C_8H_{17})_2Sn(SCH_2COOC_8H_{17})_2$
Dibutyltin sulfide	[4253-22-9]	$[(C_4H_9)_2SnS]_3$
Methyltin tris(2-ethylhexyl) thioglycolate)	[54849-38-6]	$CH_3Sn(SCH_2COOC_8H_{17})_3$
Butyltin tris(2-ethylhexyl) thioglycolate)	[25852-70-4]	$C_4H_9Sn(SCH_2COOC_8H_{17})_3$
Octyltin tris(2-ethylhexyl) thioglycolate)	[26401-86-8]	$C_8H_{17}Sn(SCH_2COOC_8H_{17})_3$
Methyltin tris(2-mercaptoethyl) oleate)	[59118-9-5]	$CH_3Sn(SCH_2CH_2OCOC_{17}H_{33})_3$
Methyltin (2-mercaptoethyl oleate)sulfide	[68442-12-6]	$CH_3Sn(SCH_2CH_2OCOC_{17}H_{33})(S)$

Table 2. U.S. Producers and Trade Names of Alkyltin Stabilizers and Mixed Metal Stabilizers

	Trade name	
Producers	Alkyltin	Mixed metal
Akzo Chemicals, Inc., Dobbs Ferry, N.Y.	Stanclear	Interstab

Ferro Corp., Bedford, Ohio		Therm-Chek Synpro
M-R-S Chemicals, Inc., Maryland Hts, Mo.		MiRaStab

commercial applications. Table 2 lists the stabilizer manufacturers and the trade names associated with each.

Economics. The pricing of stabilizers is generally based on the PVC processing application, the type of PVC used, and the other microingredients present in the formulation. In facile extrusion operations, such as the manufacture of PVC pipes, stabilizer formulations usually contain relatively low levels of the alkyltin compounds; about 5–10% tin is usual. More difficult extrusion applications, such as window lineals, extruded sheets, and house siding, require significantly higher levels of more efficient stabilizers. Injection molding of pipe

Table 3. Typical Uses and Prices for Alkyltin Stabilizers

Application	Stabilizer type	Use level[a]	Tin (%)	Price,[b] $/kg
	Extrusion			
PVC pipe	Mercaptide/mercaptan	0.3–0.6	5–10	2.75–4.50
Window profile/siding	Mercaptide	1.3–1.7	14–19	7.00–10.00
Siding substrate	Mercaptide/mercaptan	0.7–1.2	9–14	4.00–8.50
Weatherable clear	Carboxylate	2.5–3.5	14–20	9.00–14.00
	Molding			
Pipe fittings	Mercaptide	1.3–2.0	16–19	8.00–10.00
	Mercaptide/mercaptan	1.3–2.0	11–16	4.5–8.50
Food bottles	Methyl/octyltin Mercaptides	0.8–1.4	16–19	8.00–11.00
	Calendered sheet			
Food packaging film	Methyl/octyl tin mercaptides	0.8–1.4	16–19	8.00–11.00
General-purpose film	Mercaptides	1.0–2.0	16–19	8.00–10.00

[a]Parts per hundred parts of PVC resin.
[b]2000.

fittings and accessories also requires more efficient stabilizers. Blow molding and calendered sheet applications, particularly where glass-like clarity is required, are the most demanding processing conditions. Stabilizers for these applications are typically the highest efficiency formulations in the marketplace. Table 3 summarizes the typical applications of the tin stabilizers and their current price range.

Health and Safety Aspects. Many of the alkyltin stabilizers are considered safe to use in almost every conceivable end use for PVC (24). Particularly, the U.S. FDA, German BGA, and Japanese JHPA have sanctioned the use of mixtures of dimethyltin and monomethyltin isooctyl thioglycolate (25), mixtures of di-*n*-octyltin and mono-*n*-octyltin isooctyl thioglycolate (26), and poly(di-*n*-octyltin maleate) as the primary heat stabilizers for PVC used for food-packaging purposes. This same group of products is also approved for use in pharmaceutical applications such as pill containers and PVC tubings (27). Since the migration into water of the alkyltin mercaptide-based products from PVC is found to be extremely low, most of these stabilizers are suitable for pipes carrying drinking water according to NSF International (28), a private industry supported regulatory agency complying with all current U.S. EPA guidelines. Tin-stabilized formulations for drinking water pipes have been in use since the late 1960s throughout North America. A risk analysis on the use of these stabilizers in PVC has been compiled (29), which emphasizes the low toxicity and ecotoxicity of this class of PVC stabilizers. The key to the safety and low toxicity for the alkyltin stabilizers lies in the fact that modern manufacturing practices eliminate the production of any significant amounts of the more toxic trialkyltin species from all stabilizers.

Several studies have chosen to focus on the volatility of the alkyltin stabilizers and their by-products of PVC stabilization, alkyltin chlorides, during the calendering operation because this process presents a worst case scenerio for PVC processing: relatively high stabilizer levels, very high exposed surface area of hot

PVC melt, and high processing temperatures. In two of these studies conducted by the NATEC Institute in Germany, extremely low levels of volatilized alkyltin compounds were observed (30). Similar studies conducted by Morton International (now Rohm and Haas Co.) confirmed these results (31). All of these studies demonstrate that the level of volatile tin compounds in the air during PVC processing operations are significantly below the TLV of 0.1 mg/m^3 for tin compounds established for the United States workplace.

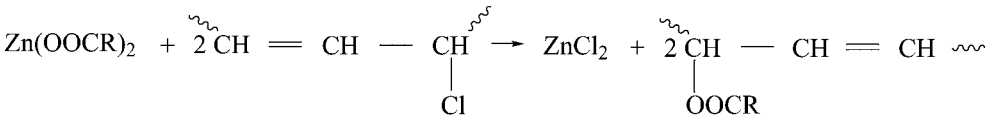
Mixed Metal Stabilizers. The second most widely used class of stabilizers, with nearly 29,000 t sold in the United States in 2000, are the mixed metal combinations. These products predominate in the flexible PVC applications in the United States; however, they find competition from the lead-based products in Europe Mixed metal products are growing rapidly for electrical wire and cable coatings where the lead products have been the preferred stabilizers for many years. Alternative mixed metal stabilizers are continually being commercialized to replace the leads in this application, as well. In Europe, mixed metal stabilizers are preferred for the extruded rigid building profiles because they provide good weathering and physical properties to the PVC in this use.

The commercially important alkali and alkaline-earth metals used in these stabilizer systems are based on the salts and soaps of calcium, zinc, magnesium, barium, and cadmium. These metal salts and soaps are combined to make a stabilizer system; there is synergy between these compounds during PVC processing. Because the chloride salts of both zinc and cadmium are easily formed during PVC processing and are strong Lewis acids, it is not surprising that short stability times and catastrophic degradation are observed when either zinc or cadmium soaps are used alone. In fact, zinc carboxylates, by themselves, are worthless as PVC stabilizers. When zinc and cadmium salts are combined with other compounds, which prevent or delay the formation of the respective Lewis acids, good PVC stability can be obtained. Particularly, the salts of calcium and barium serve this purpose. Other organic compounds, such as phosphites, epoxides, polyols, and β-diketones, can also be added to enhance the performance further.

The most popular commercial products are combinations including calcium–zinc, barium–calcium–zinc, barium–zinc, and barium–cadmium. Barium–cadmium combinations were, at one time, the most widely used mixtures, but as of the early 1990s their use has decreased considerably because of toxicity and ecotoxicity concerns surrounding cadmium compounds. In fact, many Eurpoean countries have imposed bans on the uses of cadmium in all applications for plastics. Modern calcium–zinc, barium–zinc, and barium–calcium–zinc mixtures are touted as effective replacements for many of these barium–cadmium formulations. The safety of these newer products are unquestioned and certain calcium–zinc mixtures are widely used to stabilize PVC food packaging, mineral water bottles, and pharmaceutical containers throughout the world. In many applications, particularly in plasticized PVC, the mixed metal products effectively offer the right combination of processibility, heat and light stability, low odor, and nonsulfur staining characteristics to be the best choice of stabilizer.

Stabilization Mechanism. Zinc and cadmium salts react with defect sites on PVC to displace the labile chloride atoms (32). This reaction ultimately leads to the formation of the respective chloride salts, which can be very damaging to the polymer. The role of the calcium and/or barium carboxylate is to react with the newly formed zinc–chlorine or cadmium–chlorine bonds by exchanging ligands (33). In effect, this regenerates the active zinc or cadmium stabilizer and delays the formation of significant concentrations of strong Lewis acids.

Reaction with defect site



Regeneration of stabilizer

The chloride salts of calcium and barium are weak Lewis acids and do not tend to promote PVC degradation. By carefully choosing the ratio of zinc or cadmium salt to calcium and/or barium soap, the overall stabilizing effects can be tuned to an optimum level for a given application or process. The typical mixed metal products usually contain between a 2:1 and 1:2 ratio of the metal salts. Ultimately, though, these delaying tactics are spent and the zinc or cadmium chlorides form, resulting in rapid hydrogen chloride evolution and cross-linking reactions leading to a brittle, black, crumbling product of no value. Although it is not completely understood, the maximum level of stability for these mixtures is reached at a concentration of stabilizer of about 4–5% of the polymer. Adding higher amounts of stabilizer has little effect on the overall stability of the PVC; this same phenomenon is also observed for the alkyltin stabilizers.

Mixed Metal Stabilizer Synthesis. The mixed metal salts and soaps are generally prepared by reaction of commercially available metal oxides or hydroxides with the desired C_8–C_{18} carboxylic acids. The liquid stabilizer products sometimes employ metal alkylphenates and overbased metal alkylphenates, particularly calcium or barium alkylphenates, in place of the metal carboxylates. The desired ratio of metal salts can be achieved by coprecipitation from the appropriate ratio of metal oxides or, more often, from isolated metal salts by blending to give the correct ratios. During the blending process, a variety of other coadditives or secondary stabilizers, such as phosphites, polyols, epoxides, β-diketones, or antioxidants, can be added to complete the stabilizer package. Modern stabilizers are provided as either liquids or nondusting powders, which are easily handled in totally automated compounding operations.

Commercial Stabilizers. There is a great variety of commercial formulations utilizing the mixture of the alkali and alkaline-earth metal salts and soaps.

In many cases, products are custom formulated to meet the needs of a particular application or customer. The acidic ligands used in these products vary widely and have dramatic effects on the physical properties of the PVC formulations. The choice of ligands can affect the heat stability, rheology, lubricity, plate-out tendency, clarity, heat sealability, and electrical and mechanical properties of the final products. No single representative formulation can cover the variety of PVC applications where these stabilizers are used.

Typically, solid stabilizers utilize natural saturated fatty acid ligands with chain lengths of C_8–C_{18}. Zinc stearate [557-05-1], zinc neodecanoate [27253-29-8], calcium stearate [1592-23-0], barium stearate [6865-35-6], and cadmium laurate [2605-44-9] are some examples. To complete the package, the solid products also contain other solid additives such as polyols, antioxidants, and lubricants. Liquid stabilizers can make use of metal soaps of oleic acid, tall oil acids, 2-ethyl-hexanoic acid, octylphenol, and nonylphenol. Barium bis(nonylphenate) [41157-58-8], zinc 2-ethylhexanoate [136-53-8], cadmium 2-ethylhexanoate [2420-98-6], and overbased barium tallate [68855-79-8] are normally used in the liquid formulations along with solubilizers such as plasticizers, phosphites, and/or epoxidized oils. The majority of the liquid barium–cadmium formulations relies on barium nonylphenate as the source of that metal. There are even some mixed metal stabilizers supplied as pastes. The U.S. FDA approved that calcium–zinc stabilizers are good examples because they contain a mixture of calcium stearate and zinc stearate suspended in epoxidized soya oil. Table 4 shows examples of typical mixed metal stabilizers.

Costabilizers. The variety of known costabilizers for the mixed metal stabilizers is a very long listing. There are, however, a relatively small number of commercially used costabilizers. Some of these additives can also be added by the PVC compounder or processor in addition to the stabilizer package to further enhance the desired performance characteristics. The epoxy compounds and phenolic antioxidants are among the most commonly used costabilizers with the mixed metal stabilizers.

Epoxy Compounds. Epoxidized soya oil (ESO) is the most widely used epoxy-type additive and is found in most mixed metal stabilized PVC formulations at 1.0–3.0 phr because of its versatility and cost effectiveness. Other useful epoxy compounds are epoxidized glycerol monooleate, epoxidized linseed oil, and alkyl esters of epoxidized tall oil fatty acid.

Antioxidants. Phenolic antioxidants, added at about 0.1–0.5 phr, are usually chosen from among butylated hydroxytoluene [128-37-0], and *p*-nonylphenol [104-40-5] for liquid stabilizer formulations and bisphenol A [80-05-7]

Table 4. Formulations of Mixed Metal Stabilizers, %

Liquid formula	Solid formula	Paste formula
Barium tallate overbase, 30	Barium stearate, 25	Zinc stearate, 15
Barium bis(nonylphenate), 20	Cadmium laurate, 50	Calcium stearate, 15
Zinc 2-ethylhexanoate, 15	Bisphenol A, 5	Tris(nonylphenyl) phosphite, 30
Diphenyl decylphosphite, 30	Pentaerythritol, 20	
Dibenzoylmethane, 5		Epoxidized soya oil, 40

[2,2-bis-(*p*-hydroxyphenyl)propane] for the solid systems. Low melting thioesters, dilauryl thiodipropionate [123-28-4] or distearyl thiodipropionate [693-36-7], are commonly added along with the phenolics to enhance their antioxidant performance. Usually a 3:1 ratio of thiodipropionate to phenolic antioxidant provides the desired protection. Most mixed metal stabilizer products contain the antioxidant ingredient (see ANTIOXIDANTS).

Polyols. Polyols, such as pentaerythritol [115-77-5], dipentaerythritol [126-58-9], and sorbitol [50-70-4], most likely chelate the active metal centers to reduce their activity toward the undesired dehydrochlorination reaction. These additives are generally included in the stabilizer formulation, used in the range of 0.2–0.7 phr.

Phosphites. Tertiary phosphites are also commonly used and are particularly effective in most mixed metal stabilizers at a use level of 0.25–1.0 phr. They can take part in a number of different reactions during PVC processing: they can react with HCl, displace activated chlorine atoms on the polymer, provide antioxidant functionality, and coordinate with the metals to alter the Lewis acidity of the chloride salts. Typical examples of phosphites are triphenyl phosphite [101-02-0], diphenyl decyl phosphite [3287-06-7], tridecyl phosphite [2929-86-4], and polyphosphites made by reaction of PCl_3 with polyols and capping alcohols. The phosphites are often included in commercial stabilizer packages.

β-Diketones. A new class of costabilizer has emerged that is effective with the mixed metal systems. The β-diketones can significantly enhance the performance of the calcium–zinc and barium–calcium–zinc systems when used at 0.1 to about 0.7 phr. Although relatively expensive, the β-diketones greatly improve early color stability and rheological performance while benefitting the weatherability of the final PVC articles. Typical of these additives are dibenzoylmethane [2929-86-4] and stearoyl benzoyl methane [58446-52-9]. These additives are generally formulated as part of the mixed metal stabilizer package.

Specialty Amines. Some substituted nitrogenous compounds can provide similar benefits. Esters of 2-aminocrotonate and bis-2-aminocrotonate, and appropriately substituted dihydropyridines, eg, 3,5-bis-lauryloxycarboxy-2,6-dimethyl-1,4-dihydropyridine [37044-66-7] and 3,5-bis-ethoxycarboxy-2,6-dimethyl-1,4-dihydropyridine [1149-23-1], are examples of these costabilizers. These relatively expensive costabilizers are used at 0.1–0.7 phr and are particularly effective when added to the calcium–zinc stabilizers.

Hydrotalcite. Synthetic hydrotalcite minerals are gaining commercial acceptance for their ability to costabilize PVC in the presence of other primary stabilizers (see Table 2). The performance of the mixed metal stabilizers are particularly boosted when an equal part level, about 2–3 phr, of hydrotalcite is added to the PVC formulation. These minerals function by trapping HCl within the layered lattice arrangement of atoms. The formula, $Mg_4Al_2(OH)_{12}CO_3{\cdot}3H_2O$, is commonly written; however, these minerals are generally nonstoichiometric by nature and can include some amounts of alternative elements in their compositions. They function similarly to the zeolites but exist in layered structures and have a different trapping mechanism. In addition to their performance enhancement, the hydrotalcite minerals are compatible with PVC and can be

used effectively in clear PVC applications as well as the pigmented formulations.

Economics. As with the alkyltin stabilizers, the market pricing of the mixed metal stabilizers tend to be directed by the particular application. The calcium–zinc and barium–cadmium packages are typically used at 2.0–3.0 parts per hundred of PVC resin (phr) in the formulation. These completely formulated products are sold for $2.40–5.50/kg for the liquid products and $2.00–4.00/kg for the solids and pastes. The higher efficiency products aimed at rigid applications tend toward the higher end of the cost range.

The basic metal salts and soaps tend to be less costly than the alkyltin stabilizers; for example, in the United States, the market price in 2000 for calcium stearate was about $1.30–1.60/kg, zinc stearate was $1.70–2.00/kg, and barium stearate was $2.40–2.80/kg. Not all of the coadditives are necessary in every PVC compound. Typically, commercial mixed metal stabilizers contain most of the necessary coadditives and usually an epoxy compound and a phosphite are the only additional products that may be added by the processor. The required costabilizers, however, significantly add to the stabilization costs. Typical phosphites, used in most flexible PVC formulations, are sold for $3.00–4.50/kg. Typical antioxidants are bisphenol A, selling at $2.00/kg; *p*-nonylphenol at $1.25/kg; and BHT at $3.50/kg, respectively. Pricing for ESO is about $1.50–2.00/kg. Polyols, such as pentaerythritol, used with the barium–cadmium systems, sells at $2.00/kg, whereas the derivative dipentaerythritol costs over three times as much. The β-diketones and specialized dihydropyridines, which are powerful costabilizers for calcium–zinc and barium–zinc systems, are very costly. These additives are $10.00 and $20.00/kg, respectively, contributing significantly to the overall stabilizer costs. Hydrotalcites are sold for about $3.00–5.00/kg.

Health and Safety Aspects. Overall, the mixed metal stabilizer industry is undergoing significant change during the early 1990s because of the increasing restrictions on cadmium compounds. Most of the research effort has focused on new products to replace the traditional barium–cadmium formulations with technical and cost-effective products. In some regions, cadmium is allowed only in applications where there are no effective replacement technologies. The replacement products generally contain salts of barium, zinc, calcium, and/or potassium; all these compositions are considered safe in the many flexible PVC end uses.

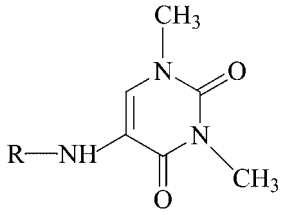
Calcium–zinc soaps are used in many PVC food container applications because these heat stabilizers are universally accepted as safe by the U.S. FDA, German BGA, Japanese JHPA, and other government regulatory groups.

Organic Stabilizers. Since the early 1990s there has been a significant effort to reduce or eliminate most metals from PVC heat stabilizers. This crusade was launched in the name of improving both human health and environmental effects from metals that leach from PVC products. As a result, a totally new class of heat stabilizers was developed which relies on nonmetallic organic chemicals as the primary heat stabilizing components. The idea of these nonmetallic stabilizers is to make PVC products, particularly drinking water piping systems that have no metals to leach either into the water or into the environment. Significant interest in these new stabilizer types is strong in the Nordic countries, particularly Sweden

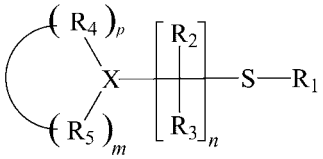
and Denmark, where both lead- and tin-based stabilizers have been targeted for elimination by environmental regulations.

The earlier entry into this new class of stabilizers was built upon a 6-aminouracil compound (**7**) formulated with some costabilizers, particularly the hydrotalcites (34,35) and lubricants. Shortly after this, another chemistry was introduced which relied on "protected" mercaptan compounds, called "latent mercaptans" of general structure (**8**). In this second type, a small amount of a metal "kicker" must be added to start the stabilizing activity of the latent mercaptan (36). The preferred metal kicker is reported to be zinc which could be used at as low as 0.04% in the PVC to be effective in the new stabilizer. Most of the stabilizer development has been for applications in soft PVC formulations; however, the more recent work has focused on efficient stabilizer one-packs for rigid extrusion compounds.

Both stabilizer systems reportedly provide sufficient heat stability for PVC pipe extrusion and provide excellent physical properties in the final pipes.



(**7**)



(**8**)

Significant efforts have been made to completely demonstrate the efficiencies of these emerging stabilizer chemistries, although they remain noncommercial because of their higher projected costs compared to the current lead-stabilizer systems and because the lead-based systems continue to be allowed until at least 2002.

Lead Stabilizers. In use since the 1940s, the lead-based stabilizers have played an extremely important role in the development of PVC as a high performance polymer. The myriad of toxicological and ecotoxicological problems surrounding the use of any lead chemicals has restricted lead stabilizers to uses in flexible PVC wire and cable coatings in the United States, with consumption in the mid-1990s estimated at 15,000 t, but it has leveled off during the past few years. In Europe and Asia, the lead stabilizers predominate for wire and cable uses and are also widely used to stabilize PVC pipe and weatherable building profiles. It is estimated that as much as 70% of all stabilizers sold in Europe and Asia are based on some type of lead compounds. These are solid products and are supplied as powders, flakes, or strands, usually in special packaging to control dusting.

The commonly used commercial lead-based PVC stabilizers rely on one or more lead(II) oxide groups bound to the primary bivalent lead salt. These overbased lead compounds have higher levels of lead and are more basic, thus reacting more readily with evolved hydrogen chloride during PVC processing. It is typical to find combinations of mono-, di-, and tribasic lead compounds as the primary heat stabilizers because these often work together to provide a good balance of both early and long-term stability. The choice of anion also effects the performance by reducing the reactivity of the lead oxide toward other ingredients in the formulation as well as the polymer. The stabilization by-product, lead dichloride, is nearly inert, ie, it is white in color, nonionic, insoluble in water, and has low Lewis acidity. It is these properties that give lead-stabilized PVC such a low conductivity in electrical applications. Commercially, most lead stabilizers are combinations containing lead stearates which also provide good lubrication to PVC compounds. Additional lubricants often are not necessary for thermally processing these PVC formulations.

Their high toxicity has greatly limited the applications for lead stabilizers in North America and is now spreading around the world. Environmental agencies such as WHO and U.S. EPA are continually lowering recommended human exposures to lead compounds. Another limitation is that lead products have a high refractive index and as a result can only be used in opaque applications. Overbased lead salts have a high degree of reactivity and tend to interact, many times disfavorably, with other ingredients in the formulation. Also, they have a very high specific gravity compared to other stabilizers, resulting in higher density PVC products. Lastly, the lead stabilizers can react with almost any source of sulfur to form black lead sulfide, the so-called *lead stain phenomenon*. Despite these drawbacks, they remain highly effective PVC heat stabilizers.

Stabilization Mechanism. Traditionally, lead salts were thought to perform only as acid scavengers during PVC stabilization; it is likely that this activity leads to good long-term stability. Bivalent lead compounds can readily form complexes, and recently workers have proposed that these products also displace labile chlorines on the polymer in a fashion similar to the mixed metal stabilizers. A free-radical mechanism is proposed for this displacement which improves the early color hold of the PVC (10). Because the lead chloride is such a weak Lewis acid, costabilizers used in the mixed metal systems are generally ineffective and unnecessary. Increasing stabilizer concentration in the polymer generally leads to increased stability times.

Lead Stabilizer Synthesis. Most commercial stabilizers are produced by reaction of a water slurry of lead oxide with the appropriate acid while heating, yielding a solid product with a particle size of about 1 μm. This condensation proceeds, leaving the desired level of overbasing in the final product. Most often, the lead product is treated with a coating agent to reduce dusting and improve dispersability in the PVC. The stabilizer is then filtered, dried, and packaged. During the drying and coating step, other coadditives such as pigments, lubricants, and fillers can be blended into the mixture to make a total package formulation.

Commercial Stabilizers. There are six lead salts and soaps that are typically used in the commercial PVC stabilizers. The lead stearate soaps are often combined with the lead salts to provide lubrication and added stabilizer activity.

Table 5. Principal Lead Stabilizers

Stabilizer	CAS registry number	Formula	PbO (%)	Specific gravity
Tribasic lead sulfate	[12202-17-4]	$PbSO_4 \cdot 3PbO \cdot H_2O$	89	6.9
Dibasic lead phosphite	[12141-20-7]	$PbHPO_3 \cdot 2PbO \cdot \frac{1}{2}H_2O$	90	6.1
Dibasic lead phthalate	[17976-43-1]	$C_4H_4(COO)_2Pb \cdot 2PbO$	80	4.2
Basic lead carbonate	[1319-46-6]	$2PbCO_3 \cdot Pb(OH)_2$	87	6.7
Dibasic lead stearate	[56189-09-4]	$Pb(OOCC_{17}H_{35})_2 \cdot 2PbO$	55	2.0
Lead stearate	[1092-35-7]	$Pb(OOCC_{17}H_{35})_2$	29	1.4

The key to the high activity of these stabilizers is the very high lead content. Table 5 describes six commonly used lead stabilizers.

By far the most common lead salt used for PVC stabilization is tribasic lead sulfate. It can be found either alone or combined with another lead salt in almost every lead-stabilized PVC formulation. Many of the combinations are actually coprecipitated hybrid products, ie, basic lead sulfophthalates. Dibasic lead stearate and lead stearate are generally used as costabilizers combined with other primary lead salts, particularly in rigid PVC formulations where they contribute lubrication properties; dibasic lead stearate provides internal lubrication and lead stearate is a good external lubricant.

Flexible Applications. The only remaining application of the lead stabilizers in the United States is in flexible wire and cable coating applications. The nonconductive nature of lead stabilizers is unsurpassed by other classes of stabilizers. Rather high levels of stabilizers are necessary for these uses because of the required high temperature aging specifications for most insulating materials. Typically 5–8 phr of lead stabilizer is needed in most insulation compounds. Careful consideration must be given to the choice of lead stabilizer because of the high reactivity of the basic lead oxide groups with other ingredients in the formulation. This is particularly true of the plasticizer choice. The more demanding, high temperature applications require stabilizers rich in dibasic lead phthalate to provide high levels of heat aging stability; the less demanding applications, jacketing and low temperature insulation, usually rely on tribasic lead sulfate as the primary stabilizer. Under high temperature aging conditions, tribasic lead sulfate tends to react with the ester-type plasticizers to increase volatility and reduce the resilience of the PVC insulation.

Rigid Applications. The use of the lead stabilizers is very limited in the United States; but, they are still used in several rigid PVC applications in Europe and Asia. The highest use of lead stabilizers in rigid PVC is for pipe and conduit applications. Tribasic lead sulfate is the primary heat stabilizer, with lead stearates included to provide lubrication. The lead products are typically fully formulated, usually including lubricants and pigments for pipe extrusion applications. These lead one-packs, when used at about 1.8–2.5 phr, provide all of the stabilizer and lubrication needed to process the polymer. A lead one-pack contains tribasic lead sulfate, dibasic lead stearate, calcium stearate, polyethylene wax, paraffin wax, ester wax, and pigments.

Dibasic lead phosphite is used in rigid building profile applications because the PVC weathering properties are found to be very good. Normally, the titanium dioxide pigment loading is increased to about 5 phr in these formulations. In less critical uses, ie, interior profiles, tribasic lead sulfate remains the standard. There remains only one U.S. producer of note for lead stabilizers: Hammond Lead Co., Halstab Div., (Hammond, Indiana) sells Halstab, Halbase, Halphal, Halphos, Tribase, Dythal Dyphos, and Leadstar.

Economics. The lead-based stabilizers tend to be priced relatively low, with 2000 prices ranging from $1.40 to $3.60/kg in the United States. The lead phthalates tend toward the higher end of this range, whereas the pipe one-pack products fall into the low end.

Health and Safety Aspects. Worldwide, there is continuing pressure by environmental and human toxicologists to reduce the use of heavy metals such as lead in every application. In the United States, the EPA and OSHA provide regulations over the producers and users of lead stabilizers. The permissible exposure level (PEL) of workers is regulated at 50 $\mu g/m^3$ of airborne lead per 8-h workday. Further, workers are not allowed to be exposed to greater than 30 $\mu g/m^3$ for more than 30 days/year (37). The state of California increased the safety factor further in 1990 by regulating exposure to less than 5 $\mu g/m^3$ for any exposure. Warning labels describing the toxic effects of lead compounds must be applied to all lead stabilizer packaging. In some states, ie, New Jersey and California, any product containing more than 0.1% lead must be labeled as containing lead.

Lead stabilizers have not been used to manufacture drinking water pipes in the United States since 1970 because of the migration levels of lead found in the water from the stabilizers. In 1991, U.S. EPA further reduced the allowable level of lead in drinking water to zero (action level of only 15 ppb lead). In 1993, WHO provided new guidelines targeting the level of lead in drinking water to less than 10 ppb. All uses of lead in PVC pipes are under scrutiny and the stabilizer industry is responding with nontoxic tin-based and calcium–zinc-based technologies. Significant efforts are underway to reduce the uses of lead stabilizers in flexible wire and cable applications as well. New mixed metal formulations are now being touted as providing the needed high levels of both heat stability and nonconducting electrical properties.

Antimony Mercaptide Stabilizers. In the mid-1950s antimony mercaptides were first proposed as PVC heat stabilizers (38). Antimony tris(laurylmercaptide) [6939-83-9] and antimony tris(isooctylthioglycolate) [27288-44-4] are typical of this class of heat stabilizers. These compounds were used mainly in rigid PVC applications, particularly pipes, competing with the alkyltin mercaptides. Their use has greatly diminished during the late 1980s and early 1990s for a variety of reasons. Particularly, questions raising doubts about the toxicological safety of antimony compounds have arisen. The performance of the antimony products has also reduced their uses in many processes. For example, they are less compatible with PVC, which leads to a cloudy appearance in clear applications; they react with sulfur sources to form Sb_2S_3, an orange-colored byproduct; and they detract from the weatherability of PVC formulations. Further, because the cost of tin metal decreased significantly during the 1980s, antimony pricing has continued to rise, making these products less economically attractive than they once had been.

The performance of the antimony stabilizers is significantly enhanced by adding polyhydroxybenzene compounds, eg, catechol, to the PVC (39). In commercial practice, about 5–10% catechol is formulated with the antimony mercaptide stabilizer products. The antimony mercaptides are normally prepared by heating antimony oxide with the appropriate mercaptan, normally isooctyl thioglycolate, under conditions to remove water.

$$Sb_2O_3 + 6\,HSCH_2COOR' \rightarrow 2\,Sb(SCH_2COOR')_3 + 3\,H_2O$$

Health and Safety Aspects. The U.S. EPA has significantly reduced the allowed levels of antimony compounds in drinking water, causing a toxicity cloud over the viability of this class of stabilizers. Presently, antimony products are no longer allowed for use as potable water pipe stabilizers under NSF International's current Standard 61(28). For these reasons, antimony stabilizer technology is no longer commercial in the United States.

HETEROPHASE POLYMERIZATION

Introduction

Heterophase polymerization is a generic term that describes polymerization reactions under nonhomogeneous conditions with respect to physical and chemical properties of the reaction mixture. This means the existence of gradients such as in density and chemical composition and consequently, the coexistence of different phases. Heterophase polymerizations are best defined in a very general way as processes resulting in polymer dispersions. *Polymer dispersion* is a state of matter where polymers are finely dispersed in a continuous phase. In this sense these polymerization processes are colloidal in nature and thus bridge two important scientific areas: polymer science and colloid science. Colloid science characterizes systems by two general features, heterogeneity and dispersity, which necessarily occur mutually. *Heterogeneity* means the coexistence of different phases and is a qualitative feature. It implies that phase boundaries, processes at phase boundaries, mixed interfaces, and in some cases phase formations also are of importance. *Dispersity* is a quantitative measure that characterizes the degree of division of the heterophase system. It is defined as the reciprocal average characteristic length scale. Besides dispersity the shape, the size, and the interface per mass of the dispersed phase are other characteristic features. In particular, dispersity is responsible for new properties of colloidal systems absent in homogeneous ones, because with increasing dispersity interfacial effects become more and more important. Furthermore, heterogeneity and dispersity together cause an energetic characterization of a dispersion, that is, the existence of an interfacial tension between coexisting phases and an interfacial free energy (interfacial tension times interfacial area). The interfacial free energy contributes substantially to the overall free energy of dispersions, and in many cases it governs the

Table 1. Colloidal Dispersions Made of Various Combinations of States of Matter

Dispersed phase	Continuous phase	Examples	Technical term
Liquid	Gas	Clouds/sprays	Aerosol
Solid	Gas	Smog/dust	Aerosol
Gas	Liquid	Lather/meringue	Foam
Liquid	Liquid	Milk/creams	Emulsion
Solid	Liquid	Paint/blood	Suspension
Gas	Solid	Pumice/cork	Solid foam
Liquid	Solid	Oil shale/opals	Porous material
Solid	Solid	Bones/teeth	Solid suspension

behavior completely. Also, the interface is responsible for all peculiarities, for all pros and cons of heterophase polymerization techniques.

The context of heterogeneity and dispersity requires that the material forming the dispersed phase is insoluble/immiscible in the continuous phase. From that follows directly that the interfaces in dispersed systems can be made of all possible combinations of states of matter except the gas–gas combination. Examples of dispersed colloidal systems are given in Table 1. It is interesting to note that indeed all of these combinations can be used to carry out polymerizations. The various kinds of heterophase polymerization techniques are put together in Table 2 in the order of ascending number of components; the components are listed, except the initiating system.

In most polymerizations the kind of dispersed system changes in the course of the process owing the fact that a gaseous or liquid monomer is transformed into a solid polymer. Examples are catalytic gas-phase polymerizations on solid catalyst beads (1) or polymerizations in liquid continuous phases of gaseous monomers. Heterophase polymerization can also be carried out in pores of inorganic solid materials such as Zeolites (2–5), or mesoporous MCM-41 and similar silicates (6,7), or inside interlayers of montmorillonite (8). Other special types of heterophase polymerizations in a solid continuous phase are used to modify the pores in solid polymer monoliths (9) or pores in polymeric membranes (10).

Table 2. Overview of Heterophase Polymerization Techniques

Technique (common name)	Components
Bulk or mass polymerization[a]	Monomer, polymer
Gas-phase polymerization	Monomer, polymer
Precipitation polymerization	Dispersion medium, monomer, polymer
Suspension polymerization	Stabilizer, dispersion medium, monomer, polymer
Microsuspension polymerization	Stabilizer, dispersion medium, monomer, polymer
Dispersion polymerization	Stabilizer, dispersion medium, monomer, polymer
Emulsion polymerization	Stabilizer, dispersion medium, monomer, polymer
Miniemulsion polymerization	Stabilizer, dispersion medium, monomer, polymer
Microemulsion polymerization	Stabilizer, dispersion medium, monomer, polymer

[a]Only if the polymer is insoluble in its own monomer such as vinyl chloride/poly (vinyl chloride) or acrylonitrile/polyacrylonitrile.

The dramatic changes in the physico-chemical properties on the way from monomers to polymers leads to changes in the overall reaction conditions during any kind of polymerization. In the case of heterophase polymerizations these changes have a considerable influence on the colloidal properties as well, raising questions with respect to the existence of equilibrium situations of important colloid chemical properties. In this sense the final, stable polymer dispersion is a colloidal system in equilibrium and very well suited as models for colloid chemical investigations.

In practice, the term *polymer dispersion* is used almost exclusively for systems with a liquid continuous phase. In this sense and from the colloid chemical point of view, heterophase polymerizations deal with emulsions and suspensions. A polymer dispersion is nowadays frequently also called a latex, which in Latin means "liquid or "fluid," and goes back to the Greek word *látax*, which means "droplet". The word latex has become a generic term that comprises all kinds of polymer dispersions (11). In this article the terms *polymer dispersion, polymer suspension*, and *latex* are used interchangeably. Synonyms for the continuous phase are *dispersion medium, homogenous phase*, and *serum*. Any liquid can be a dispersion medium provided it is a nonsolvent for the dispersed material. But in fact, by far the most important industrial dispersion agent is water, for cost, safety, and environmental reasons. In this article, heterophase polymerization and polymer dispersion means an aqueous continuous phase whereas the term *inverse*, put in front, denotes systems with organic continuous phases. Furthermore, a chain-growth polymerization by a free-radical initiation mechanism is considered, if not otherwise stated. The aim of this article is to provide a condensed view of heterophase polymerizations in liquid media, ie to point out common features rather than to give comprehensive or detailed views on peculiarities of the different kinds of heterophase polymerizations. The list of references is intended to be useful as a starting point for further literature searches rather than an attempt to provide all references, which would be daunting to author and reader alike. After a brief look at the history and the actual meaning of polymer dispersions, general features will be considered, which thereafter will be applied to the variants of heterophase polymerizations.

History. It is historically proven that the Mayas already in 1600 BC were able to use the sap of certain trees to make out of it useful things such as rubber balls, glue, waterproofed clothes, medicine, and much more (12–14). They called this sap *caa o-chu* "crying wood," from which the French word for rubber, *caoutchouc*, was derived. A broader scientific interest in *caoutchouc* was initiated by the report of Charles de la Condamine and Francois Fresneau on their tour through South America in 1736 and their experiences with the milky white resin and the products thereof (15). There is no doubt that the development of polymer science has been strongly connected with polymer dispersions, ie the investigation of natural rubber (see RUBBER, NATURAL). Michael Faraday determined the exact composition of natural rubber as hydrocarbon in 1826 (16), and precisely described the separation of the rubber and its cleaning—basically with the same techniques that are applied still today. After the discovery of vulcanization by Charles Goodyear in 1839, natural rubber became a raw material of increasing importance. Thirty years later, C. Greville Williams isolated by destructive distillation *caoutchouc* decomposition products and named the lightest isoprene (17)

and concluded that the *caoutchouc* hydrocarbon is composed of isoprene polymers. Less than two decades later it was claimed that the reverse process was possible, ie, rubber could be synthesized by polymerizing isoprene (18). Note, the term *polymeric* was introduced 1832 by J. Berzelius from the Greek $\pi o\lambda\nu\zeta$, which means "several," to describe substances possessing the same composition but different properties (19).

In the first decade of the 20th century a team headed by F. Hofmann in Germany was successful in developing polymerization of isoprene either in bulk or in benzene solution. The polymerizations were initiated thermally and carried out in autoclaves at temperatures below 250°C for 10–150 h. (20). The idea of using an aqueous emulsion of a monomer to carry out polymerization dates back to 1912, when the first patent was filed (21). This patent represents the birth of what we call today heterophase polymerization, and Kurt Gottlob was the pioneer researcher (22,23). In order to copy the conditions employed by Nature during the synthesis of *caoutchouc*, Gottlob used viscous fluids such as egg albumin, starch, or gelatin as stabilizers. The addition of alkali or organic bases leads to an improvement of the latex stability, and coagulation was possible by decreasing the pH. Polymerization was started thermally with 7 g of egg albumin in 500 g of water and 300 mL of isoprene in an autoclave. The mixture was stirred for several weeks at 60°C. Significant progress in the development of heterophase polymerizations was made during the following decades, when typical surfactants such as oleates and alkyl aryl sulfonates were used together with water as well as monomer-soluble peroxides (24–26). An almost comprehensive overview of the development of synthetic rubber and products thereof until the early thirties can be found in References 27 and 28. A description of developments that took place on polymerizations of olefins and diolefins during the following period of time until the end of World War II can be found in References 29 and 30. The pace of development in these early days of heterophase polymerization was mainly determined in industrial research labs, with the benefit that the time span between first laboratory results and commercially available products was short. After World War II more and more research activities were started at universities and independent research institutes all over the world. Summaries of today's knowledge of heterophase polymerization techniques can be found in References 31–36. Whereas there were only a handful of polymeric products based on heterophase polymerizations during the 1930s in Germany (37), by 1951 there were nearly 200 synthetic latexes made of various polymers commercially available in the USA (38), and today products based on heterophase polymerization techniques determine in almost all fields our living standard, including construction and automobile industry, medical diagnostics, and paper making (39).

Economic Importance of Heterophase Polymerizations. Polymer dispersions are an important part of the worldwide polymer business, not only because of their outstanding role in the historic development of polymer chemistry but mainly because of their versatility with respect to both properties and applications. Figure 1 illustrates both the position of polymer dispersions in the hierarchy of science and shows the variety of applications in which they are found. These examples illustrate on the one hand the different branches of industry, that take advantage of polymer dispersions and on the other hand how the daily life is influenced. Heterophase polymerizations are important technologies that can

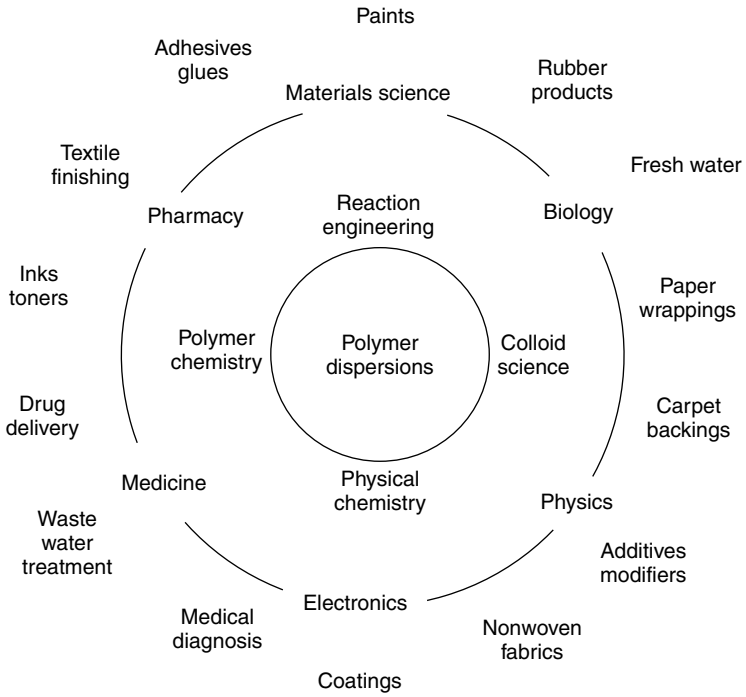

Fig. 1. Illustration of the importance and meaning of heterophase polymerizations/polymer dispersions. Polymer dispersions as the centerpiece belong to chemistry and have strong interrelations to disciplines of chemistry mentioned in the next level. Also, other scientific areas, which are listed in the third level, use polymer dispersions for research and development. Finally, the outer level contains important application fields of polymers, which were produced by heterophase polymerizations.

produce on a volume scale from only a few milliliters up to 200 m^3 high quality polymers with specifically tailored properties. Polymer dispersion is a description for a special state of matter and not connected to a special chemical composition of the polymeric material. Any kind of polymer can be transferred into the state of polymer dispersion. For instance, water-soluble polymers are prepared by inverse heterophase polymerization techniques in organic media. Poly(acrylic acid) or poly(methacrylic acid) polymers and copolymers, quaternary ammonium polymers and copolymers, and polyacrylamide polymers and copolymers belong to this class of important synthetic polymers. The main application areas of these polymers are water and wastewater treatment, detergents, papermaking, coatings, adhesives, textiles, and super-absorbent polymers. The generic term *polymer dispersion* can be illustrated by means of a "family tree," as depicted in Figure 2. Primary dispersions are the direct result of heterophase polymerizations and can be subdivided into naturally occurring latexes and synthetic latexes. Secondary dispersions comprise examples where polymers are transferred into polymer dispersions only after their preparation. Artificial latexes are obtained after dispersing solid polymer or emulsifying polymer solution in a proper dispersion medium. The emulsion can be transferred in a second step into a suspension by removing

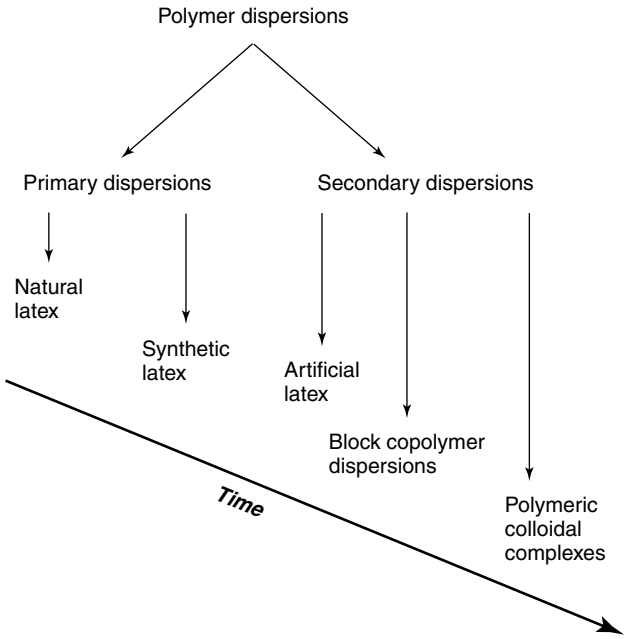

Fig. 2. Family tree of polymer dispersions. The time axis in this graph denotes the time when the different kinds of polymer dispersions came to awareness of mankind starting with natural latex and ending with recent developments in polymeric colloidal complexes. Some important historic milestones are the following: the biosynthesis of natural rubber in plants takes place on earth since millions of years, the first heterophase polymerization was mentioned in a patent filed in 1912 (21), the first process description to make an artificial latex was published in 1923 (40), and the first block copolymer dispersion made by heterophase polymerization was described in 1952 (41).

the solvent. Artificial latexes have until now never gained much industrial interest although several methods have been developed. There are basically three driving forces for the development of artificial latexes: The first is economic because it is more advantageous to transport polymers as dry solid material instead of as dispersions with about 50% by weight dispersion medium. The second reason has to do with the superior material properties of polymers that cannot be prepared by heterophase polymerization techniques—such as polyurethanes or chlorosulfonated polyolefins—but whose application as polymer dispersion is advantageous or desirable. Combinations of different materials such as mineral substances and polymers in the form of composite polymer dispersions for various potential applications are the third reason for an ongoing research on artificial latexes. Block copolymers in selective solvents for only one block form micelles, which are in fact sterically stabilized polymer particles and thus belong to the class of polymer dispersions (42–44). Moreover, heterophase polymerization techniques can be used to prepare bock copolymers in a very efficient way (45–48). One of the oldest attempts, if not the oldest, to prepare block copolymers by radical polymerization was undertaken via aqueous heterophase polymerization (41). Polymeric colloidal complexes are the result of manipulating polymer solutions

by inducing interactions that lead to dispersions. These interactions can be either hydrophobic or electrostatic in nature. Examples are the formation of hollow spheres via layer-by-layer assembly of oppositely charged polyelectrolytes onto various templates (49–52). But also a single kind of block copolymer can form polymeric colloidal complexes via self-assembly, such as poly(ethylene glycol)-b-poly(*N*-isopropyl acrylamide) copolymers, where the poly(*N*-isopropyl acrylamide) block becomes insoluble at temperatures above 32°C and particles are formed via hydrophobic interactions. These particles consist of a poly(*N*-isopropyl acrylamide) core and a stabilizing poly(ethylene glycol) shell. Such particles can easily be prepared by heterophase polymerization started with poly(ethylene glycol)–ceric ion redox system (53). Other examples of such dispersions are complexes between amphiphilic block copolymers with one polyelectrolyte block and either oppositely charged surfactants (48,54–56) or other amphiphilic block copolymers with oppositely charged polyelectrolyte block (48,57). Besides these recent developments in research on preparation of polymer dispersions, they also play an important role (*1*) as model systems for soft matter physics, especially in understanding interactions in colloids (58–60), (*2*) as materials to trigger new characterization methods (61), (*3*) as objects to observe directly nucleation and growth of crystals (62), (*4*) as components in advanced material science research (63), and (*5*) also as object of single particles' handling and modification (64). The economic importance of heterophase polymerization products is not easy to quantify. There is on the one hand the direct value of the polymer products and on the other hand the value added to products, which are made involving polymer dispersions or which are even made only on the base of very specialized polymer dispersions. Table 3 presents the breakdown of worldwide annually produced amounts of different kinds of polymers/polymer dispersions by aqueous heterophase polymerization techniques. According to these numbers about 25% of the total amount of synthetic polymers, that is at the moment some 2×10^8 t per annum worldwide (39), is prepared by heterophase polymerizations. Except some very minor amount of copolymers for paints, poly(vinyl chloride) is exclusively produced by heterophase polymerization techniques. About 80% is produced by suspension polymerization, followed with about 15% by emulsion and microsuspension polymerization, and the rest is by mass or bulk polymerization (65,66,70). Contrary to polystyrene, poly(vinyl chloride) is insoluble in its own monomer. But vinyl chloride still swells its polymer to about 35% at saturation [the Flory–Huggins interaction parameter is between 0.9 and 1.0 (71)] and hence, the vinyl chloride bulk polymerization is a precipitation polymerization where a swollen polymeric phase is formed after a

Table 3. Worldwide Aqueous Heterophase Polymerization Products (Solids)

Product	Amount, 10^6 t	Reference

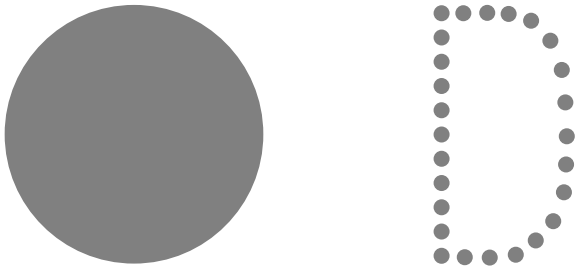
Other latexes	8	68
Natural rubber	7	66
Polystyrene	2	69

few percents of conversion. The 2×10^8 t of polymers produced worldwide represent a financial value of more than euro 200 billion (39) and consequently, as a rough estimate, heterophase polymerization techniques contribute at least with one quarter. This is very likely a lower limit because the about 8×10^6 t of emulsion polymers represent a value of more than euro 20 billion (72). Inverse heterophase polymerization techniques are employed on an industrial scale to produce about 1.5×10^6 t of various synthetic water-soluble polymers. The global consumption of such polymers in the year 2000 was about 2.2×10^6 t representing a value of about euro 3.5 billion, where roughly two-thirds is estimated to be realized by polymers produced via inverse heterophase polymerization techniques (73).

Peculiarities of Heterophase Polymerization

The peculiarities of heterophase polymerizations are directly connected with the dispersed state. Figure 3 shows schematically the main difference between 1 g of polystyrene as bulk material and as a dispersion. The bulk material is a single particle with a diameter (D) of 1.22 cm and a total surface area (A_P) of 4.676 cm^2, whereas the same amount of material in the dispersed state with an average particle size of 50 nm is subdivided or compartmentalized into 1.455×10^{16} particles (N), with a total surface of 1.143×10^6 cm^2. This increase in both N and A_P causes both the advantages and problems of heterophase polymerizations and polymer dispersions compared to homogeneous counterparts. The prices mentioned in Figure 3 for that 1 g of polystyrene in different states show interestingly that the increase in the total surface area almost corresponds to the increase in the



Macroscopic	Dispersed
$D = 1.22$ cm	$D = 50 \times 10^{-7}$ cm
$N = 1$	$N = 1.455 \times 10^{16}$
$A_P = 4.767$ cm^2	$A_P = 1.143 \times 10^6$ cm^2
Price: ~ € 1×10^{-3} g^{-1}	Price: ~ € 3.1×10^2 g^{-1}

Fig. 3. Illustration of the physical effect of dispersion (not to scale); 1 g of polystyrene with a volume V_p of 0.952 cm^3.

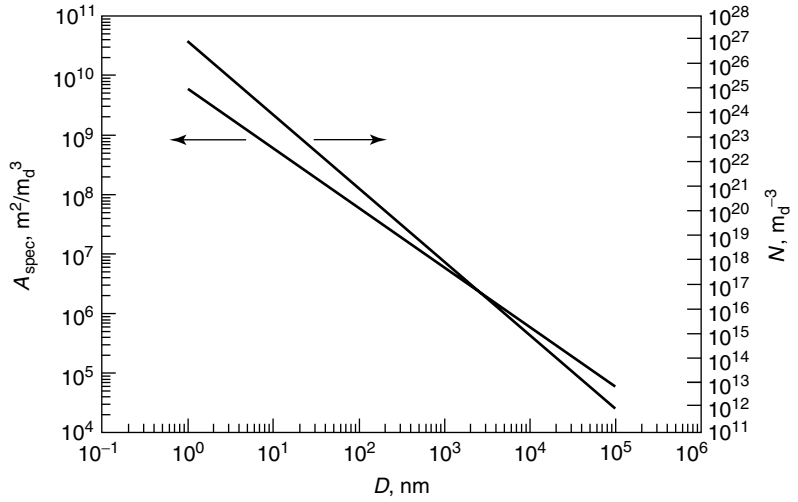


Fig. 4. Specific surface area and particle number for the model dispersion in dependence on the average particle size.

price. The price for the dispersion is that of carboxylated polystyrene spheres with a diameter of 50 nm, which are sold as size-calibration standards in 10-ml batches with a solids content of 2.5% (74). Some of the most important consequences of compartmentalization are illustrated by means of a model dispersion, which is composed of equal volumes of water and organic phase in dependence on average particle size (D in nm). These features are the specific surface area (A_{spec}) and the number of particles (N), both calculated per dispersion volume in $m_d{}^3$ (cf Fig. 4), the average distance between dispersed particles (d_{pp}) and the amount of surfactant relative to the mass of total organic phase ($W_{surf,t}$) (cf Fig. 5), the number

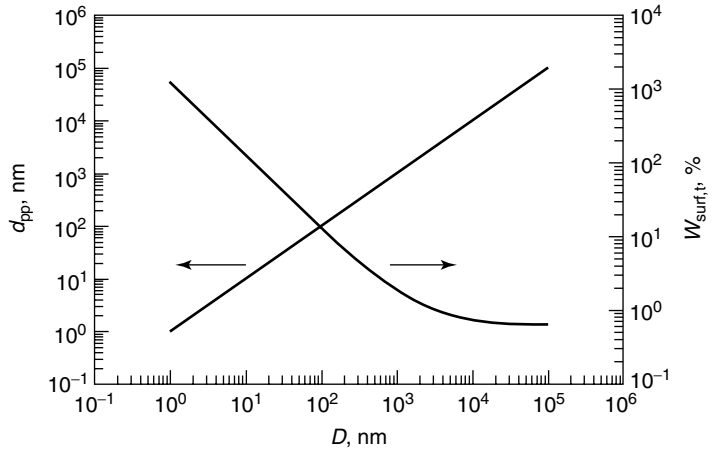

Fig. 5. Average distances between the particles and amount of surfactant to cover the whole interface with a saturated layer in dependence on average particle size for the model dispersion.

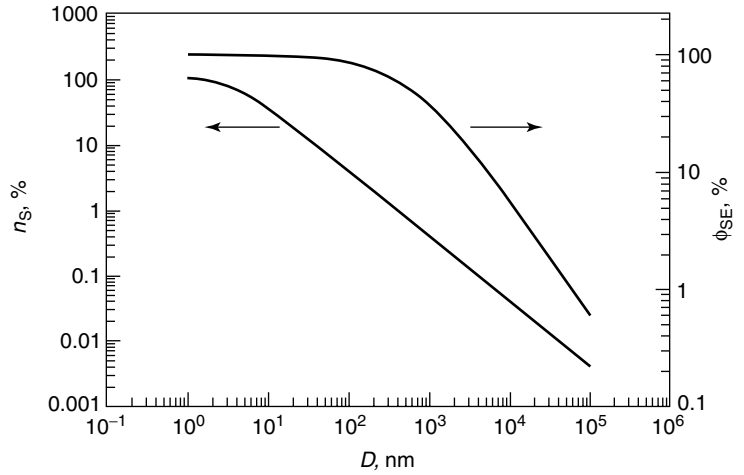

Fig. 6. Fraction of interface molecules per particle and fraction of interfacial free energy in dependence on average particle size for the model dispersion.

of molecules in the surface layer of the particle relative to the total number of molecules per particle (n_S) and the fraction of free surface energy relative to the total free energy of the droplet (ϕ_{SE}) (cf Fig. 6).

$$A_{spec} = \frac{6}{D} 10^9 \tag{1}$$

$$N = \frac{\varphi_{dp} 6}{\pi D^{-3}} 10^{27} \tag{2}$$

$$d_{pp} = \sqrt[-3]{N} \tag{3}$$

$$W_{surf,t} = \frac{10^2 M_S}{\varphi_{dp} \rho_{dp}} \left(cmc + \frac{A_{spec}}{N_A a_s} \right) \tag{4}$$

$$n_s = 10^2 \left(1 - \frac{(D - 2D_{dp})^3}{D^3} \right) \tag{5}$$

$$\phi_{SE} = \frac{\sigma A_{spec}}{\sigma A_{spec} + P_d v} \tag{6}$$

Figures 4–6 were generated by means of the following assumptions. The volume fraction φ_{dp} of the dispersed phase is 0.5, its density ρ_{dp} is 0.9 g/cm^3, the surfactant is sodium dodecylsulfate with a molecular weight $M_S = 288.4$ g/mol, a surface coberage $a_s = 0.50$ nm^2 per molecule, and a critical micelle concentration cmc $= 10^{-2}$ M, the volume of a single particle is v and the pressure inside is $P_d = 10^5$ N/m^2, the interfacial tension between dispersed phase and continuous

fluid phase is $\sigma = 10^{-2}$ N/m, and the size of a molecule of the dispersed phase is $D_{dp} = 0.7$ nm. Note that the terms *particle* and *droplet* are used interchangeably, to describe the dispersed phase without taking into account at the moment a particular state of matter of this phase. σA_{spec} corresponds to the amount of work required to expand the interfacial area or surface area. The data depicted in Figures 3–6 clearly reveal the colloidal nature of heterophase polymerization systems. In particular, model dispersions with an average particle size of 50 nm and 50 μm consist of 7.643×10^{21} m_d^{-3} and 7.643×10^{12} m_d^{-3} particles, have specific surfaces of 1.2×10^8 m^2/m_d^{-3} and 1.2×10^5 m^2/m_d^{-3}, an average distance between particle surfaces of 50.8 and 50,800 nm, an amount of 8.167% and 8.4×10^{-3}% of surface molecules, need 26.15% and 0.665% of sodium dodecylsulfate to cover the interface completely, and the surface free energy contributes with 92.3 and 1.18% to the overall free energy, respectively. Just for comparison, a soccer field is about 10^4 m^2 large and a ball for that game has a fraction of 8.75×10^{-7}% surface molecules, provided it consists of bulk rubber. The high surface free energy and hence the higher total free energy of a dispersion in comparison with a homogeneous system is the reason that permanently acting forces reduce the total free energy, ie they lower the interfacial area by coalescence or coagulation processes. Thus, working with heterophase polymerization techniques also means facing the problem of colloidal stability.

From a technical point of view there are three main advantages compared with homogeneous systems because of the compartmentalization. First, the viscosity of polymer dispersions is independent of the degree of polymerization and can be kept low up to high solids content. Second, the heat of polymerization caused by the enthalpy of the chain growth reaction, which for common monomers is between −50 and −100 kJ/mol is removed easily in tiny portions coming from the individual particles through the continuous phase. Third, the particle size in the micrometer and submicrometer range allows morphological variations on length scales, which are accessible with difficulty by means of other procedures.

Another important relation of these rather general considerations is with respect to the initiator concentration (C_I), which for radical polymerizations is typically in the order of 10^{-3} M. Interesting quantities are the (formal) number of initiator molecules per particle (n_I) and the number of radicals in the steady state ($n_{R,equ}$) per particle calculated according to equation 7 assuming a termination rate constant k_t of 10^8 L/(mol · s) and an initiator decomposition rate constant $2fk_d$ of 8.5×10^{-5} s^{-1}.

$$n_{R,equ} = \frac{1}{N}\left(\frac{2fk_dC_I}{k_t}\right)^{1/2} \tag{7}$$

Curves for n_I and $n_{R,equ}$ are plotted in Figure 7 for two initiator concentrations $C_I = 10^{-3}$ M (curves a_1, b_1) and $C_I = 1$ M (curves a_2, b_2). The horizontal gray line meets the curves at values for n_I and $n_{R,equ}$ equal to 1. The corresponding particle or droplet sizes represent limiting values above which enough initiator molecules are present and radicals are generated to have one initiator molecule per particle and to start polymerization in each compartment, respectively. Note that for both initiator concentrations, even for the unrealistically high value of

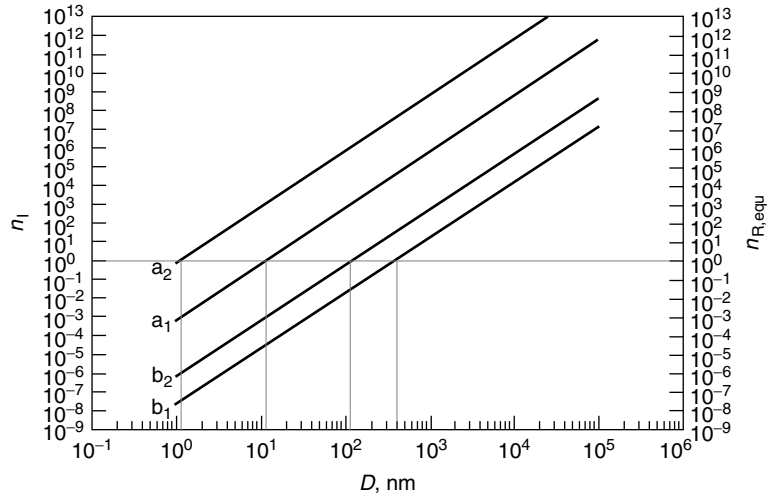

Fig. 7. Average number of initiator molecules per particle (a_1, a_2, left axis) and steady-state radical concentration per particle (b_1, b_2, right axis) in dependence on the average particle size for the model dispersion.

$C_I = 1\ M$, the necessary particle sizes to contain at least one growing radical per particle are above 100 nm. Even if this is a formal and crude appraisal, it leads to interesting consequences with respect to polymerizations in preformed monomer drops.

The various heterophase polymerization techniques mentioned in Table 2 can be distinguished with respect to the average particle sizes at the end of the polymerization. Figure 8 compares these values with characteristic length scales of other colloidal systems and the wavelength of electromagnetic radiations, which are frequently used to investigate polymer dispersions. This diagram clarifies that heterophase polymerization techniques cover the whole size range of colloidal systems. The larger the size of the final latex, the broader is the size range the particles pass through during their genesis and consequently, the larger is the changes in colloidal properties and effects influencing particle morphology. For instance, microemulsion polymerization, where the final particle size is clearly below 100 nm and in many cases even below 50 nm, the particles change their size only few tens of nanometers during the process. In contrast, during precipitation polymerization the average particle size changes over several orders of magnitude, say from less than 50 nm to more than 500 μm in some cases. Second, joint consideration of Figures 5 and 8 reveals that the amount of stabilizer necessary for a particular type of heterophase polymerization strongly depends on the average particle size. This is important with respect to end use properties of the polymeric product because stabilizers are auxiliary materials that may influence the desired polymer properties badly. Microemulsion polymerizations require amounts of stabilizers in the order of the monomer mass, whereas suspension polymerization at the other end of the size scale manage with stabilizer concentrations less than 0.1% relative to monomer mass.

The interrelation between polymer and colloid science in the case of heterophase polymerizations is nicely expressed by the following consideration.

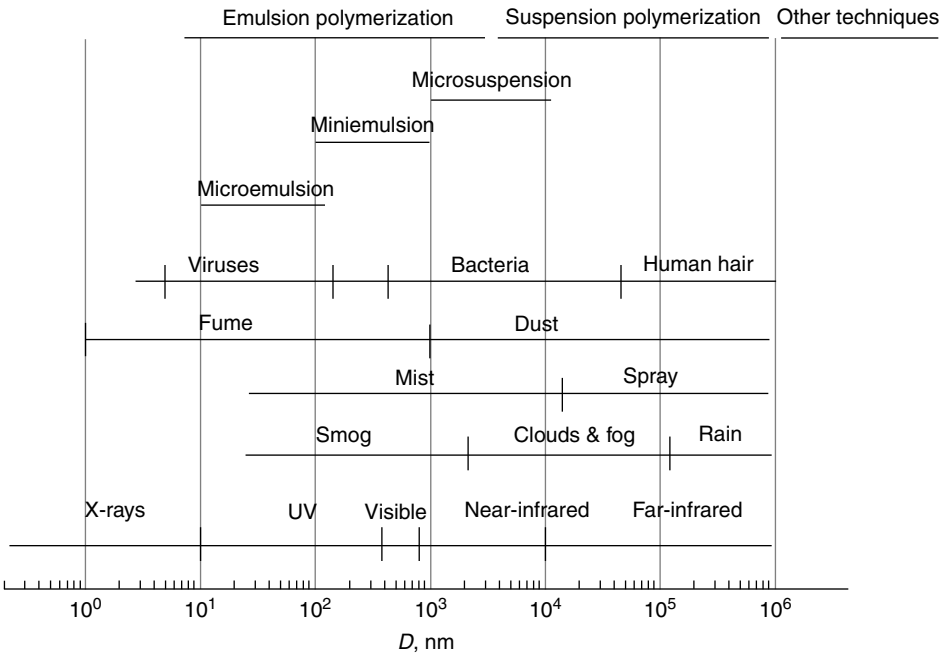

Fig. 8. Characterization of colloidal systems by characteristic length scales.

Heterophase polymerizations may be considered as compartmentalized homogeneous polymerizations, with a lot of interactions between the compartments (particles, drops) on the one hand and between compartments and the continuous phase on the other. In almost all cases, a polymer particle consists of more than one macromolecule. For instance, if the polystyrene of the example given in Figure 3 has a molecular weight of 6.022×10^5 g/mol (average degree of polymerization P_n of about 6000) the single bulk particle consists of 10^{18} macromolecules, whereas each of the colloidal particles is composed of 69 polymer molecules. Each polymer chain can be regarded as a permanent record of all the reactions by which it was produced. For a free-radical polymerization mechanism, which is by far the most important one for heterophase polymerizations, the duration of these reactions (τ_{pol}) can be estimated by means of equation 8 to be in the order of seconds or even less for the above polystyrene example, depending on the polymerization temperature (monomer concentration $C_{\mathrm{M}} \approx 6\,M$, propagation rate constant $k_{\mathrm{p}} =$ 237, 341, 480 L/(mol · s) for 50, 60, 70°C, respectively (75).

$$\tau_{\mathrm{pol}} = \frac{P_n}{k_{\mathrm{p}} C_{\mathrm{M}}} = \frac{2}{(2 f k_{\mathrm{d}} C_{\mathrm{I}} k_{\mathrm{t,d}})^{1/2}} \tag{8}$$

In contrast to single polymer molecules, the particles grow during the entire reaction and hence, they can be regarded as a permanent record of the overall polymerization reaction. The duration of heterophase polymerizations is typically in the order of hours. In this sense, recording molecular weight and particle size data should allow an almost perfect reaction control on different timescales.

Another peculiarity of heterophase polymerization is that almost all kinds of hydrophilic and hydrophobic monomers, stabilizers, initiators, chain-transfer agents, and other auxiliary materials can be applied together in one polymerization system. Of course, this can lead to a pretty muddled scenario where a variety of interactions and reactions between both phases have to be taken into account. Furthermore, a clear demarcation between the different kinds of heterophase polymerizations is often not possible. The particle size is not suited to classify heterophase polymerizations unambiguously, because between all techniques regions exist that more or less overlap, and the particle size at the end of the polymerization depends on particular conditions. Also the names of heterophase polymerizations appear somewhat illogical rather than rational. For example, according to the general definitions in Table 1, the names *emulsion* and *suspension* polymerization describe the situations at the beginning and at the end of the process, respectively, whereas the name dispersion polymerization is based on the generic term in colloid science. However, this situation points out the importance of whether a liquid (emulsion) or a solid (dispersion) forms the dispersed phase, which may change in the course of the polymerization. The main difference between a liquid and a solid interface with respect to the surface tension is given. In either case, the surface tension is a region where the stress differs from that in the bulk of the droplets. In case of a liquid, the surface tension is the same at all points and for all directions in the surface. It is a force that stretches the interface isotropically in all directions. But the surface tension of a solid surface need not be isotropic and hence, its value can be different for different directions in the surface. The impacts of this fundamental difference between an emulsion and a suspension on the mechanism of heterophase polymerizations are poorly understood.

Despite all the problems mentioned, an attempt at demarcation is made in Table 4 by means of the absolutely necessary prerequisites to carry out a particular type of heterophase polymerization. The minimum requirements for carrying out emulsion polymerization are a certain concentration of monomer dissolved in the continuous phase and an initiator. The concentration of the monomer must be high enough to ensure that both the chain length and the concentration of oligomers or polymers formed during the initial period in the continuous phase are high enough to form polymer particles. The same minimum requirements are

Table 4. Absolutely Necessary Prerequisites for Various Kinds of Heterophase Polymerizations in Liquid Dispersion Media

Polymerization	Stabilizer	Free or dispersed monomer phase	Solubility of initiator
Bulk	No	Yes	Monomer phase
Precipitation	No	No	Either phase
Dispersion	No	No	Either phase
Suspension	Yes	Yes	Monomer phase
Microsuspension	Yes	Yes	Monomer phase
Emulsion	No	No	Either phase
Miniemulsion	Yes	Yes	Either phase
Microemulsion	Yes	Yes	Either phase

necessary for bulk, precipitation, and dispersion polymerizations. Note that in a bulk polymerization the monomer also forms the continuous phase for its own insoluble polymer. With this it is possible to make a clear demarcation between suspension, microsuspension, miniemulsion, and microemulsion polymerizations, where the presence of a free, dispersed monomer phase (monomer droplets) is a prerequisite by definition. Another criterion to distinguish between bulk, suspension, and microsuspension polymerization and the different techniques is the initiator type: whereas the former techniques need an initiator that is soluble in the monomer phase, the initiator type plays practically no role for the other polymerization techniques listed in Table 4.

Kinetics of Heterophase Polymerizations

In general, all reactions according to the particular polymerization mechanism can take place in either phase of a two-phase system. For free-radical polymerization this means initiation, propagation, termination, and chain transfer can take place in both the continuous and the dispersed phase. The kinetics inside the dispersed phase is of special interest, as the goal of heterophase polymerization is to take advantage of the compartmentalized reaction system, which is only possible if the major part of the monomer conversion takes place inside the particles. If this condition is fulfilled, the overall polymerization rate (r_P) can be expressed by equation 9. The product $k_p C_M P$ is the expression for a homogeneous reaction system, where k_p, C_M, and P are the polymerization rate constant, the monomer concentration, and the radical concentration, respectively. The further equality on the right-hand side describes the overall rate of a compartmentalized polymerization, where $C_{M,p}$ is the monomer concentration inside the compartments and the radical concentration is expressed by means of the average number of radicals per particle ($\bar{n}$), the total number of particles (N), and Avogadro's number (N_A).

$$r_P = k_P C_M P = k_p C_{M,p} \frac{\bar{n}\, N}{N_A} \tag{9}$$

All of the four unknowns in equation 9 (k_p, $C_{M,p}$, $\bar{n}$, and N) can be determined experimentally. Values for k_p are nowadays also determined by pulse polymerization techniques in combination with size-exclusion chromatography under conditions of heterophase polymerizations. Briefly, high radiation pulses generate radicals, where a few of them terminate but most of them will start to propagate. After a distinct time interval a second pulse generates again a lot of small radicals, which terminate almost all of the growing radicals. If termination between two pulses is neglected, the propagation rate constant can now be estimated by $k_p = \mathrm{DP}/(C_M \Delta t)$. DP is the degree of polymerization determined by size-exclusion chromatography, Δt is the time between two pulses, and C_M is the monomer concentration, which in case of neat droplets is $C_M = 1/v_{mon}$ where v_{mon} is the molar volume of the monomer. N is calculated via the relation

$$N = \frac{6\mathrm{FG}}{\pi \left(100 - \mathrm{FG}\right) \rho_2 D^3}$$

where ρ_2 is the particle density. The calculation of N requires the determination of both solids content and average particle size. In contrast, the determination of $C_{M,p}$ is much more lavish because it requires the determination of the amount of unreacted monomer that can be present either in the form of neat monomer droplets or inside monomer-swollen polymer particles. For a monomer, which is liquid at room temperature, $C_{M,p}$ can be determined in the following way. A certain amount of latex with known solids content is centrifuged just with a speed that is high enough to separate the monomer, which is present in neat droplets. Then, to the latex, which still contains monomer-swollen particles, initiator is added and a polymerization is started. After determination of the solids content of the treated latex, the amount of monomer in the swollen particles can be calculated from the increase in solids content. Finally, $\bar{n}$ can be calculated from equation 9 and the heterophase polymerization is completely characterized by experimental means. From the viewpoint of the mechanism of heterophase polymerization both $\bar{n}$ and N have inspired researchers since the early days of heterophase polymerization research. N is strongly connected with the particle nucleation mechanism and $\bar{n}$ with the distribution of active centers among the phases and hence the overall kinetics.

The Formation of Polymer Particles

The common feature among heterophase polymerization techniques with respect to particle formation is the formation of a new phase, ie the polymeric phase. Besides phase formation the terms *generation* or *nucleation* of particles can be used synonymously to describe the process, which finally leads to the manifestation of the polymer as new phase. This phase formation may, in some cases where the reaction system is at the beginning a homogenous single phase, coincide with the development of the heterogeneous nature of the polymerizing system as it is, according to Table 4, the case for dispersion, precipitation, and heterogeneous bulk and emulsion polymerizations. In such cases the polymerization reaction starts in the homogeneous phase and the generation of the polymer phase exhibits all characteristics of a first-order phase transformation, ie thermodynamic functions and parameters such as molar volume and free energy show abrupt changes at the phase transition point. In contrast, if the reaction system is at the beginning heterogeneous, the polymerization reaction can start in either phase. If the polymerization happens predominantly inside the monomer droplets the kind of phase transformation depends on the Flory–Huggins interaction parameter ($\chi_{m,p}$).

The criteria for solubility or insolubility within the framework of the Flory–Huggins theory are for high molecular weight polymers over the whole composition range $\chi_{m,p} \leq 0.5$ and $\chi_{m,p} \geq 0.5$, respectively. The larger the $\chi_{m,p}$, above 0.5, the *more insoluble* is the polymer in its own monomer or the less favored is the interaction between monomer and polymer. For example, for the systems styrene/polystyrene, vinyl chloride/poly(vinyl chloride), and acrylonitrile/polyacrylonitrile, $\chi_{m,p}$ values are $\sim$0.5, > 0.9, and >1, respectively. These values suggest that polystyrene is completely soluble in styrene, and poly(vinyl chloride) is only swollen by its monomer, but polyacrylonitrile is insoluble in acrylonitrile. Hence, the consequences for formation of the polymer phase during polymerization

inside monomer droplets are as follows. For styrene/polystyrene, the transition from monomer droplets to polymer particles proceeds very smoothly via a polymer in monomer solution. The polymer concentration of this solution increases correspondingly to the overall conversion as long as at complete conversion solid polystyrene particles remain. Vinyl chloride is not a solvent for its polymer and hence, phase separation inside the monomer phase takes place at low conversion. But as the polymer is swollen by its monomer, the transition into the glassy (solid) state starts only at a conversion above 70%. The situation is still a little more different for acrylonitrile, which swells its polymer only to a negligible extent, as in that case $\chi_{m,p} \geq 1$ (76). Consequently, a sharp phase transition (first-order) takes place at very low conversion but in contrast to the other two systems the polymerization proceeds in an outer layer by precipitation of growing polymer chains onto existing polymer particles. Another consequence of the absence of an interaction between monomer and polymer is the formation of nonspherical particles, as the glass-transition temperature of polyacrylonitrile ($T_g \sim 100^\circ$C) is higher than polymerization temperature and hence the polymer inside the particles is almost immobile, and the spherical equilibrium shape, which is obtained if the particle is able to minimize its interfacial free energy, cannot be attained. Note that for a given interfacial tension the interfacial free energy is determined by the interfacial area, and the area per unit volume is the lowest for a sphere compared with any other body (eg the surface area per unit volume is 4.83 for sphere, 5.56 for a right cylinder, 6 for a cube or cuboid, and 6.83 for a cone). In summary, if formation of the polymer phase takes place inside the monomer droplets (a process that is sometimes referred to as droplet nucleation) the phase transformation itself is rather unspectacular. The transition from a solution to a solid is, if it ever will takes place during the polymerization under the particular conditions, finished only at high conversion, when the T_g of the polymer/monomer mixture in the particles is above the polymerization temperature. Thus, the more interesting case is the formation of polymer particles in the continuous phase, such as during dispersion and emulsion polymerization. Under these conditions, a clear first-order phase transition is observed because the system changes in a very short period of time from homogeneous to heterogeneous.

Nucleation in emulsion polymerization has been a matter of controversial discussion because for more than five decades no direct experimental data on the nucleation process were available. Discussions were mainly centered on the question of the role of emulsifying agents, in particular on the role of micelles as precursors of polymer particles. "Micellar nucleation theory," as it was expressed by Smith–Ewart (77) on the baseis of ideas developed by William Harkins (78–80), states:

> When a free radical from the surrounding water phase enters a micelle, it initiates polymerization of the monomer in the micelle. When this polymerization starts, monomer from the surrounding medium diffuses into the polymerizing region until shortly this region is no longer identified as a micelle, but is now considered a growing polymer particle. . . .

In other words, a polymer particle is formed ad hoc when a radical enters a micelle. That this is an oversimplification is revealed in Harkin's original papers.

He considered three possible loci for "the initiation of polymer particle nuclei" (79), based on his studies during 1942–1943 in connection with the Rubber Reserve Company (Synthetic Rubber Program of the United States Government) (*1*) the soap micelles, if present, (*2*) the aqueous phase, excluding soap micelles and polymer–monomer particles, and (*3*) the monomer droplets. He considered the monomer droplets as

> . . . relatively unimportant in initiating new polymer particles, since thus far no evidence has been obtained to show that a monomer droplet can do more than change into a polymer particle of smaller size.

With regard to the micelles as locus of polymer particle initiation, Harkins described very interesting results of X-ray scattering investigations (78,80,81). It was found that styrene at saturation concentration increases the diameter of fatty acid micelles by 1.2 nm (styrene is present only as dissolved in water and solubilized in micelles but not as droplets) but upon polymerization initiated with peroxodisulfate the size of the micelles decreased to its initial value. This process could be repeated several times by consecutive swelling and polymerization until the surface of the polymer particles was grown so large that the soap concentration decreased as a result of the adsorption on the particles below the cmc. These results led to the important conclusion that a growing polystyrene chain is incompatible with the alkyl chains in the interior of micelles and hence, polymer chains grow out of micelles. The incompatibility between polystyrene and alkyl chains was repeatedly proved more than 50 years later by attempts to polymerize the monomer inside double layers of dioctadecyldimethyl ammonium bromide vesicles. Transmission electron microscopy pictures reveal that phase separation takes place during the polymerization in a way that the polystyrene molecules gather at a particular place, whereas the monomer was uniformly distributed over the whole bilayer (82). A remaining question of importance is at which chain length of the growing polymer molecule the phase separation occurs. If the further fate of escaped radicals is considered, two other mechanisms of particle formation are possible. besides micellar nucleation. The first of these nonmicellar theories of particle formation is known as homogeneous nucleation and its development and quantification owes entirely to Robert Fitch (83–86). This theory, originally developed for more water-soluble monomers such as methyl methacrylate, considers initiation in the aqueous phase, capture of growing radicals by existing particles, and precipitation of a single chain if it becomes insoluble in water as individual steps. The second possibility is called aggregative nucleation, according to which nucleation occurs when a critical supersaturation of growing or dead oligomers in the continuous phase is reached and this solution becomes unstable and separates into a polymer phase and a less concentrated continuous phase (87,88). In contrast to so-called homogeneous nucleation the aggregative nucleation is a multichain process, which is governed by thermodynamic rules known from classical nucleation theory (89) or spinodal decomposition (90). It is interesting to note that Harkins came to a conclusion, which completely agrees with aggregative nucleation mechanism when he concluded (81), that in the absence of monomer droplets, "It is not improbable that several polymer molecules may meet each other and form a small aggregate as the source of a single particle." Experimental techniques have

been developed that allow a direct observation of the nucleation step in emulsion polymerization (88,91–93), The results obtained so far clearly support the aggregative nucleation mechanism. Moreover, the results confirm that nucleation in heterophase polymerization can be considered and treated within the framework of general nucleation theories as bubble formation, or condensation, or crystallization processes. According to these theories nucleation requires supersaturation of the nucleating species, which are oligomers born in the continuous phase. In this sense another nucleation criterion for heterophase polymerizations is to bring the system, which is in this situation a solution of oligomers in the continuous phase, into a thermodynamically unstable intermediate state.

Role of Emulsifiers. There is no doubt that all kinds of surface-active compounds have a strong influence on particle formation as they influence the interfacial tension of the nuclei, which is an essential parameter. On the other hand, emulsion polymerization can be carried out at emulsifier concentrations below the cmc or even in the absence of emulsifiers. In the latter case one has to take care that polymer end groups arising from primary radicals or water-soluble comonomers contribute to stability. However, as a general rule for all kinds of heterophase polymerizations, for a given recipe the particle number depends strongly on the stabilizer concentration as is shown in Figure 9. Similar curves were also obtained for styrene, with ammonium peroxodisulfate as initiator as well as for different acrylic and methacrylic acid ester monomers (94). The most striking feature of the curve in Figure 9 is the S shape, which suggests regions of different stabilizer efficiency with respect to particle concentration if it would be expressed as d log$N$/d logC_s (cf Fig. 10). Another measure for the efficiency of a surfactant is its surface tension–concentration plot. A comparison of both plots (as is also shown

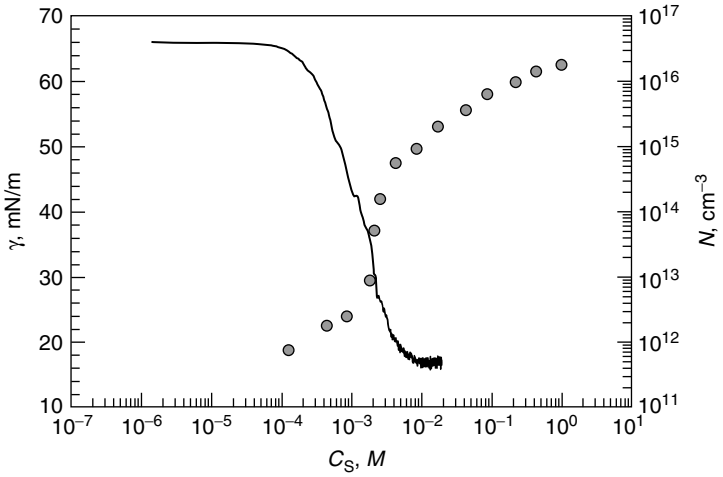

Fig. 9. Particle concentration in dependence on SDS concentration for batch emulsion polymerization of styrene (filled circles) and interfacial tension concentration plot for SDS (black line, further details see text). (Recipe: 40 g of water, 10 g of styrene, 0.32 g of potassium peroxodisulfate, variable amounts of SDS, temperature 80°C, particle concentration calculated from solids content and particle size at final conversion, particle size: intensity average from dynamic light scattering.)

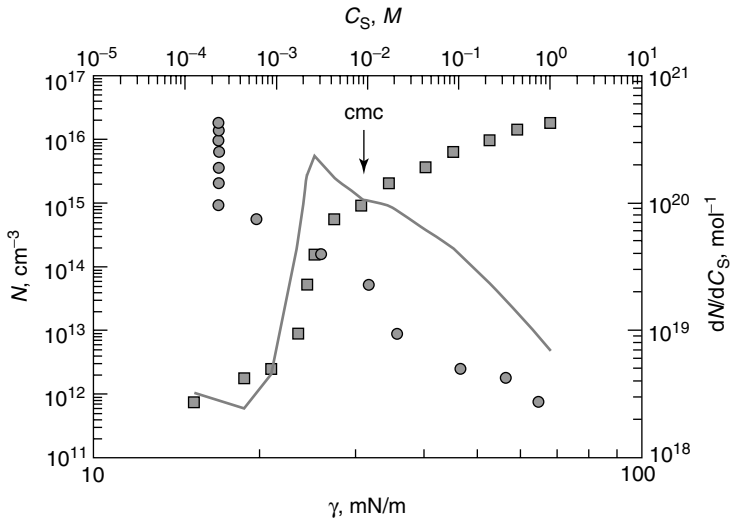

Fig. 10. Plots of the final particle number of styrene emulsion polymerization versus interfacial tension of a SDS solution with the same concentration (filled circles), final particle number versus SDS concentration (filled squares), and the efficiency of the surfactant with regard to the final particle number in a styrene emulsion polymerization (gray line) (recipe: cf. caption of Fig. 9).

in Figure 9) reveals that the regions with the steepest change in both curves coincide. The surface tension–concentration plot was measured with a bubble pressure tensiometer using the bubble pressure difference method as described in Reference 95. This method is especially designed not to measure exact surface tension values but rather changes under various conditions even inside stirred reactors at elevated temperatures. To draw conclusions regarding the role of emulsifiers in heterophase polymerizations the surface tension measurements should be conducted under conditions that correspond as closely as possible to those during the polymerizations. This is of special importance because it is known that the cmc of sodium dodecylsulfate increases with temperature but decreases with increasing ionic strength (96). The surface tension–concentration plot depicted in Figure 9 was obtained at polymerization temperature (80°C) in presence of potassium sulfate at a concentration corresponding to the potassium peroxodisulfate concentration employed for polymerization and the water was saturated with toluene to mimic the influence of styrene. Experimental conditions have been controlled so that the curves in Figure 9 can be directly compared. The steep decrease in γ and the steep increase in N originate from the effect of increasing surfactant adsorption at a given surface area. In the case of γ measurement this is the nitrogen bubble interface to water and during emulsion polymerization it is the particle water interface. The strong dependence between γ and N at surfactant concentrations below the cmc shows in the logN versus logγ plot in Figure 10. Furthermore, this plot proves that the S shape of the logN–logC_S curve is a consequence of surfactant adsorption. If this is true, then the good correlation between N and γ suggests that the interface area of the nuclei formed during the particle nucleation period does not depend on the surfactant concentration but is rather

constant for a given rate of initiation. Consequently, the surfactant concentration and the adsorption behavior of the surfactant determines the particle surface area, which can be stabilized and hence the number of final latex particles. This argument leads to the conclusion that it could happen that the number or the total surface area of nuclei formed at the end of the particle nucleation period is at low surfactant concentration larger than the amount that can be stabilized by the particular surfactant concentration. Consequently, the number of particles decreases by coagulation or coalescence processes until the particle area matches the area of surfactant necessary for stabilization, which is $a_s C_{S,C}$, where a_s is the area covered by 1 mol of surfactant and $C_{S,C}$ is the critical surfactant concentration necessary for stabilization of all nuclei formed during the nucleation period. Increasing the surfactant concentrations leads to a point where the surface area of the nuclei matches $a_s C_{S,C}$ and the number of particles remains constant after nucleation. The higher the surfactant concentration, the longer is the duration of the nucleation period. On the other hand, increasing surfactant concentration means that the period of time between the start of the polymerization and the appearance of the first particles (ie the duration of the prenucleation period) decreases, as it was concluded from model calculations (88). All these effects have also been observed experimentally (88,91,97). The data summarized in Figures 9 and 10 make clear that the cmc is no special point with regard to the final particle concentration as it falls in a region where the efficiency ($\mathrm{d}\log N/\mathrm{d}\log C_s$) decreases in dependence on the sodium dodecylsulfate concentration. The decreasing efficiency with increasing surfactant concentration can be explained with the increasing duration of the nucleation period. The longer the nucleation period, the larger the earlier-formed particles can grow and the more they compete with the newly formed ones for the surfactant. This interpretation of the role of emulsifier in emulsion polymerization agrees with experimental results, which were obtained in a series of very well designed experiments by Dunn and Al-Shahib (98–100). They used a series of sodium alkyl sulfate surfactants from C_8 to C_{18} at equal concentrations of 60 mM in styrene emulsion polymerization and were able to show that the number of micelles initially present does not govern the final particle number. A reexamination of these results as it was done in Reference 101 revealed that the number of particles correlates with the cmc (the lower the cmc, the higher is the number) and the adsorption energies of the surfactants (the higher the adsorption energy, the higher is the number). These results clearly support the idea that the stabilizing power or the adsorption strength of the surfactants, which are the stronger the larger the hydrophobic chains, determines the final particle number. This is the same effect as expressed in Figure 10 by the correlation between the surface tension and the particle number for a particular surfactant.

For heterophase polymerizations, which start in the continuous phase, such as emulsion polymerization (in the absence of monomer droplets) or dispersion polymerization (cf Table 4), a question of importance might be at which degree of conversion or, more general, at which solids content the first particles appear. This question can be answered by sensitive in-line or on-line characterization techniques such as conductivity and turbidity measurements or dynamic light scattering as described for emulsion polymerization in References 91 and 93 or dispersion polymerization in Reference 102. These results show that nucleation takes place after a distinct period of time where polymerization proceeds under

homogeneous conditions (the prenucleation period) at very low solids content. For instance, the duration of the prenucleation period for an emulsifier-free styrene emulsion polymerization started with potassium peroxodisulfate (2.5 mM) at 60°C was found to be 431 s. Within 1 s a huge number of particles is formed (1.76×10^{13} cm^{-3}), with an average diameter of 13 nm (92). From these numbers it can be concluded that each particle consists of about 7000 styrene units at maximum, and the minimum amount of polystyrene formed up to this moment is 2.13×10^{-5} g/cm^3. For dispersion polymerization of methyl methacrylate in methanol (5 wt%) at 55°C with poly(vinylpyrrolidone) as stabilizer and 2,2′-azobisisobutyronitrile as initiator, the first particles were detected with dynamic light scattering 3–4 min after starting the reaction (102). Both sets of experiments reveal another common feature, which is typical for phase transformation or nucleation processes (103). The experimental data are afflicted with large scatter and to get trustworthy results requires enormous experimental efforts and a large number of repeats. The reason for this is of general nature, ie, any first-order phase transition is characterized by the necessity to surmount an energy barrier via fluctuations. A free energy of activation for such processes exists, which strongly depends on all experimental conditions such as temperature, pressure, and composition. Even minor changes in the experimental conditions can cause huge effects, because the rate of the phase transition depends exponentially on the activation free energy. This strong influence on heterophase polymerizations means, for example, that the kind of reactor material or even the replacement of a stirrer can change reaction rate and product properties. In a comprehensive study it was shown that emulsion polymerization of methyl methacrylate is strongly influenced by the kind of reactor material (stainless steel, Teflon, glass) especially at low emulsifier concentrations (104).

In many technical emulsion polymerizations the problems connected with particle nucleation are avoided by using so-called seed latexes. In this case polymerization is started heterogeneously in presence of preformed polymer particles (seed particles). Polymerization recipe and procedure are adjusted (sometimes) carefully in such a way that a high radical absorption rate (cf eq. 12) is realized to capture all radicals from the continuous (aqueous) phase by seed particles in order to avoid both supersaturation of oligomers in the continuous phase and subsequently nucleation of new particles (105). Although the particular mechanism may differ, the common feature of particle nucleation in heterophase polymerizations is the formation of the polymeric phase. Furthermore, the final number of polymeric particles depends on the stabilization, which is employed in the particular heterophase polymerization process. Again, the larger the average particle size at a given solids content, the lower is the interfacial area, which has to be stabilized and hence, the lower the amount of stabilizing groups needed. In aqueous emulsion polymerization the micellar nucleation mechanism is very popular, although clear experimental evidence has not been found at any time. There might be mainly two reasons for this popularity. First, it is the simplicity of this approach together with the similarity to seed polymerization techniques where polymerization starts inside the seed particles by entry of radicals from the continuous phase. Although seed particles differ from micelles in many respects (dynamic behavior, size, and composition) a clear demarcation is complicated as several common features exist, such as swelling with monomer and ability of radical absorption

from the continuous phase. The situation is even more complicated in the case of micelles made of polymeric surfactant, where the gap to a seed particle is still narrower because dynamic behavior and composition can be almost identical to seed particles (106,107). Second, the lack of any direct experimental data on the nucleation step during aqueous heterophase polymerization may have hindered the acceptance of nucleation models based on general nucleation theories, although for dispersion polymerization in organic media the classical nucleation theory has been considered as a possible mechanism at least since the mid-1970s (108).

Compartmentalized Polymerization Kinetics

Average Number of Radicals per Particle. The centerpiece of equation 9 and of all heterophase polymerization kinetics is a formula to calculate the concentration of growing radicals inside each compartment. The situation sketched in Figure 11 can be used to derive a suitable general expression. If the number of radicals per particles is denoted with n the particles can be classified as N_n, which means the number of particles containing n radicals. The formation of radicals by initiator decomposition and subsequent initiation of the chain growth is allowed to take place in either phase ($r_{\mathrm{i,w}}$ and $r_{\mathrm{i,d}}$ is rate of initiation in continuous and dispersed phase, respectively). Furthermore, the number of radicals in the dispersed phase increases by absorption or entry (r_{abs} denotes the rate) and decreases by exit or desorption and termination. In these equations $k_{\mathrm{d,w}}$ and $k_{\mathrm{d,d}}$ are the rate constants of initiator decomposition in the continuous and in the dispersed phases, respectively, and f is the efficiency factor, $k_{\mathrm{abs,i}}$ is the rate constant of primary radical absorption by the droplets, $k_{\mathrm{abs}}^{\mathrm{j},e}$ is the absorption rate constant of propagating radicals ($P_{j,e,\mathrm{w}}$) in dependence on chain length (j) and kind of end group (e), $k_{\mathrm{t,d}}$ is the termination rate constant in the dispersed phase, and k_{des} is the desorption rate constant. If in steady-state the rate of formation of N_n particles

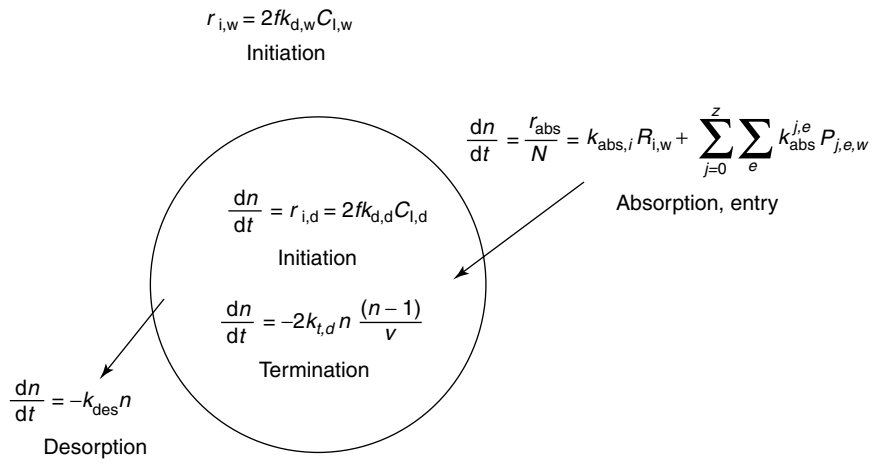

Fig. 11. Illustration of most important reactions in heterophase polymerization systems.

equals the rate of their disappearance the recursion formula given by equation 10 is obtained.

$$(n+2)(n+1)N_{n+2}+\delta(n+1)N_{n+1}+\alpha N_{n-1}+\beta_{\mathrm{d}}N_{n-2}=\ \mathrm{N}_n\left[n(n-1)+\delta n+\alpha\right]+\beta_{\mathrm{d}}N_n \tag{10}$$

A balance of the radicals in the continuous phase leads to equation 11, where $k_{\mathrm{t,w}}^{\mathrm{j},e}$ is the termination rate constant of propagating radicals ($P_{j,e,\mathrm{w}}$) in dependence on chain length (j) and kind of end group (e), termination rate constant of primary radicals and $R_{\mathrm{i,w}}$ is the concentration of primary radicals.

$$r_{\mathrm{abs}}=r_{\mathrm{i,w}}+k_{\mathrm{des}}\sum_{n=1}^{\infty}nN-2\sum_{j=0}^{z}\sum_{e}k_{\mathrm{t,w}}^{\mathrm{j},e}P_{\mathrm{j},e,\mathrm{w}}^{2}-2k_{\mathrm{t,w}}R_{\mathrm{i,w}}^{2} \tag{11}$$

Rearrangement, and defining, the coefficient by combination of rate constants into equations 12, lead to equation 13, which together with equation 10 can be used to calculate $\bar{n}$. The average number of radicals per particles is defined by equation 14.

$$\delta=\frac{k_{\mathrm{des}}\upsilon N_{\mathrm{A}}}{k_{\mathrm{t,d}}};\ \alpha=\frac{r_{\mathrm{abs}}\upsilon N_{\mathrm{A}}^{2}}{Nk_{\mathrm{t,d}}};\ \beta_{\mathrm{d}}=\frac{r_{\mathrm{i,d}}\upsilon N_{\mathrm{A}}^{2}}{k_{\mathrm{t,d}}N};\ \beta_{\mathrm{d}}=\frac{r_{\mathrm{i,d}}\upsilon N_{\mathrm{A}}^{2}}{k_{\mathrm{t,d}}N}$$

$$r_{\mathrm{abs}}=k_{\mathrm{abs,i}}R_{\mathrm{i,w}}+\sum_{j=0}^{z}\sum_{e}k_{\mathrm{abs}}^{\mathrm{j,e}}P_{\mathrm{j,e,w}}\cong k_{\mathrm{abs}}C_{\mathrm{rad,w}}\ Y=\frac{2Nk_{\mathrm{t,d}}k_{\mathrm{t,w}}}{k_{\mathrm{abs}}^{2}\upsilon N_{\mathrm{A}}^{2}} \tag{12}$$

$$\alpha=\beta_{\mathrm{w}}+\delta\ \bar{n}\ -Y\alpha^{2} \tag{13}$$

$$\bar{n}\ =\frac{\sum nN_{\mathrm{n}}}{N}\quad\text{with}\quad N=\sum N_{\mathrm{n}} \tag{14}$$

Various researches have contributed over decades to our present knowledge. Wendell Smith and Roswell Ewart started in 1948 (77) by writing down their famous recursion formula for emulsion polymerization, which takes into account absorption, desorption, and termination of radicals, where initiator decomposition is assumed to take place exclusively in the continuous phase. Two months after the Smith–Ewart paper appeared, anarticle—nowadays virtually forgotten—was submitted by Haward dealing with polymerization in a system of discrete particles (109). He took into account generation of either single radicals or two at once inside particles and termination. Either consideration (77,109) led to the identical recursion formula if the formation of single radicals inside the particles is considered to be equivalent to radical entry from the continuous phase. As an analytical solution of the recursion formula is impossible, approximations have to

be considered. Assuming that there is only radical entry or generation of single radicals inside particles, and termination equation 10 leads for $n = 0$, 1, and 2 to equations 15, 16, 18,

$$n = 0 \Rightarrow N_2 = \frac{\alpha}{2} N_0 \tag{15}$$

$$n = 1 \Rightarrow N_3 = \frac{\alpha}{6} (N_1 - N_0) \tag{16}$$

$$n = 2 \Rightarrow N_4 = \frac{\alpha}{12} \left[\frac{\alpha}{2} N_0 - (N_1 - N_0) \right] \tag{17}$$

Now Haward's argumentation was as follows. The higher the dispersity (ie smaller the v or larger the N), the smaller the α, and for $v \to 0$ or $N \to \infty$, this results in $N_2 = N_3 = N_4 = 0$. From equations 16 and 17, it follows that $N_1 = N_0$ and hence that $\bar{n} = \frac{1}{2}$, which is an important limiting case for small particles. This result is identical to the famous Smith–Ewart's case 2, where they argued that $\bar{n} = \frac{1}{2}$ when the particles are so small that entry of a radical into a particle N_1 results in immediate termination. Thus a particle contains either none or only one radical on average. The argumentation that $v \to 0$ or $N \to \infty$ is obviously more appropriate, as equations 10–14 suggest that $\bar{n}$ strongly depends on the degree of dispersity. However, the treatment of Smith–Ewart is more general than that of Haward as it allows radical exchange between both phases via radical absorption into the particles from the continuous phase and radical exit out of the particles into the continuous phase. This leads to an analogous form of equation 15 if radical exit, entry, and termination are considered:

$$n = 0 \Rightarrow N_1 = \frac{1}{\delta} \left(\alpha N_0 - 2N_2 \right) \text{ or } N_2 = \frac{1}{2} (\alpha N_0 - \delta N_1)$$

Following the arguments of Smith and Ewart (77), two more limiting cases with respect to $\bar{n}$ are possible. Case 1: if $\delta \gg \alpha$, it follows that $N_1 \to 0$ and $N \to N_0$, and hence $\bar{n} \ll 1$. Case 3: if radical absorption (or generation inside particles) is much larger than desorption ($\delta \ll \alpha$), it follows that $N_2 \Longrightarrow N_0$, which leads, only if the particle size is large enough, to $\bar{n} \gg \frac{1}{2}$ and hence to an approximation of bulk kinetics. In the next two decades, Stockmayer (110) and O'Toole (111) dealt with exact solutions of the recursion formula by means of modified Bessel functions. In particular, O'Toole presented explicit expressions for N_n and showed that the solution obtained by Stockmayer is physically questionable for small but finite rates of radical desorption. Although these contributions represent a crucial step in the direction of a better understanding of heterophase polymerization kinetics, they still leave important questions unanswered, especially regarding the interplay between kinetic events inside and outside the particles. John Ugelstad and his group in two benchmark papers in 1967 and 1976 have treated in particular the role of continuous phase kinetics (112,113). They introduced radical balances in the continuous phase as described by equations 11 and 13. They solved equation 13 taking the procedure described by O'Toole with Bessel functions. Employing continued fractions to describe the ratio of Bessel functions, they finally obtained

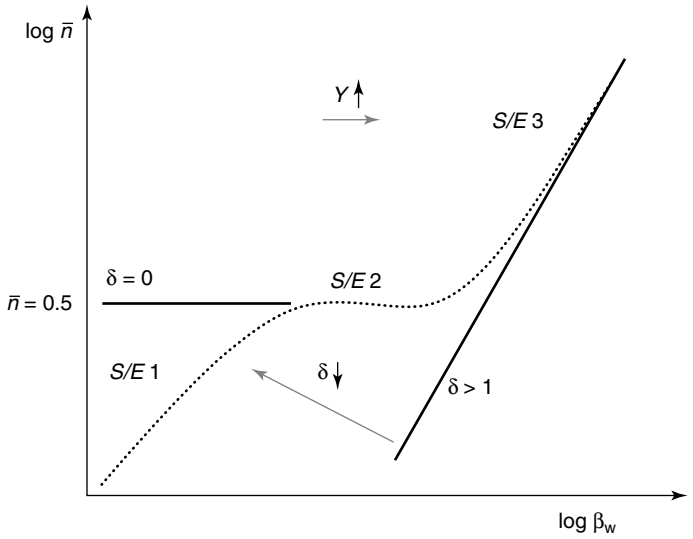

Fig. 12. Illustration of an Ugelstad plot.

a rather simple expression in form of a series:

$$\bar{n} = \frac{1}{2}\frac{2\alpha}{\delta} + \frac{2\alpha}{\delta+1} + \frac{2\alpha}{\delta+2} + \cdots$$

which converges fast for all $\alpha \geq 0$ and $\delta \geq 0$ (112). $\bar{n}$ is now computed in dependence on α for given values of δ, and finally equation 13 is solved with these values of $\bar{n}$ and appropriate values of Y to get corresponding values of β_w. The results of this procedure are the famous Ugelstad plots, where $\log \bar{n}$ is plotted versus $\log\beta_w$, with δ and Y as parameters. Such a plot is schematically shown in Figure 12. The three limiting cases of the Smith–Ewart theory can be clearly seen. The gray arrows indicate the shift of the solution behavior if one of the parameters δ or Y is changed. For instance, on the one hand decreasing δ values (which means decreasing desorption or increasing termination) lead to the appearance of a typical Smith–Ewart case 2 behavior characterized by $\bar{n} = 0.5$. On the other hand increasing Y from zero ($Y = 0$ means, according to equation 11, that no termination takes place in the continuous phase) leads to a spreading of the curves, with δ as the parameter along β_w-axis. This means that the linear relation $\log \bar{n}$ versus $\log\beta_w$, which is obtained for $\delta > 1$, is shifted to larger β_w values. Shinzu Omi has pointed out that a recursion formula, which considers only radical formation inside the particles and desorption (only β_d and δ are considered in eq. 10) could be used to describe polymerization in large monomer droplets (114). As α (ie the droplet size) increases, $\bar{n}$ converges to a straight line, which corresponds to the solution of bulk kinetics [$\bar{n} = (\beta_d)^{1/2}$].

The average number of radicals per compartment is indeed the centerpiece of heterophase polymerization kinetics. For theoretical descriptions of $\bar{n}$, detailed knowledge not only about kinetic events in either phase but also regarding exchange processes between particles and dispersion medium are required.

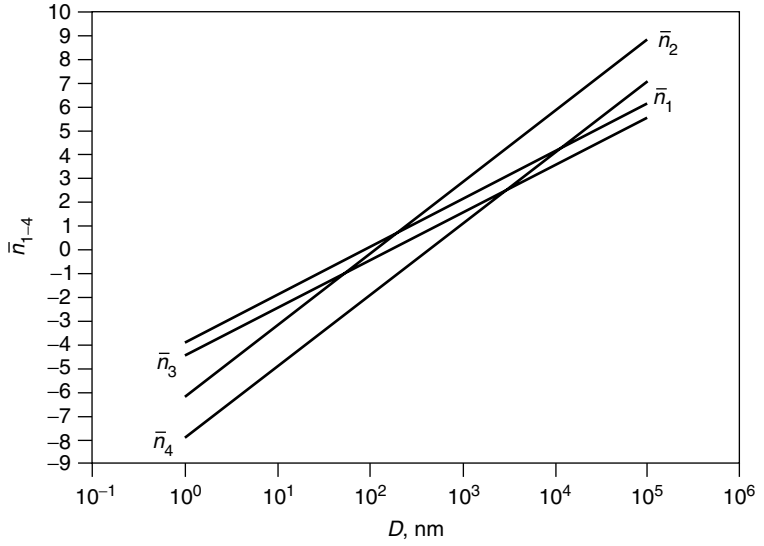

Fig. 13. Calculation of with various approximations of $\bar{n}$ the recursion formula equation 10 (cf text).

The Influence of Dispersity. For different types of heterophase polymerization and in context with dispersity as a characteristic feature, it is necessary to emphasize that $\bar{n}$ strongly depends on particle size. To describe this behavior, several approximations based on equation 10 can be found (113,114). In Figure 13, some $\bar{n}$ approximations are compared regarding their dependence on the particle size, which is given by the definitions in equations 12. The first approximation $\bar{n}_1 = (\alpha/2)^{1/2}$ is based on Stockmayer's solution for the Smith–Ewart case 3 ($\bar{n} \gg 1$). This can be directly compared with the approximation for bulk kinetics proposed by Omi (114), $\bar{n}_4 = (\beta_d)^{1/2}$, and also with the hypothetical number of radicals per particle in equilibrium ($n_{R,equ}$), as depicted in Figure 7. Another approximation derived by Ugelstad and Hansen for Smith–Ewart case 3 kinetics is $\bar{n}_3 = (\beta_w/4Y)^{1/2}$, with consideration of water phase termination ($Y \neq 0$). Finally an approximation for Smith–Ewart case 1 derived by Ugelstad and Hansen (113) is considered ($\bar{n}_2$), which however is valid for the whole range of $\bar{n}$ as long as the following relations are fulfilled: $\delta\,\bar{n} \gg \beta_w\, Y\alpha^2$ and $Y\alpha^2 \gg \alpha - \delta\bar{n}$. Equation 9 can be used to calculate $\bar{n}$ from experimental polymerization rate data provided $C_{M,p}$, k_p and N are known. To do so is really extensive and tedious work, as one has to determine solids content, particle size, and monomer concentration inside the particles in the course of the polymerization. Figure 14 shows an example of such investigations for a batch styrene emulsion polymerization in dependence on both conversion (X) and average particle size (115). The results of this procedure are influenced by some experimental problems such as the estimation of r_P by numerical differentiation of conversion–time curves, the experimental determination of $C_{M,p}$, and the proper choice of the particle size average value to calculate N. Despite all these problems the results depicted in Figure 14 lead to important conclusions. Batch emulsion polymerization of styrene, even if 2,2′-azobisisobutyronitrile is used as initiator,

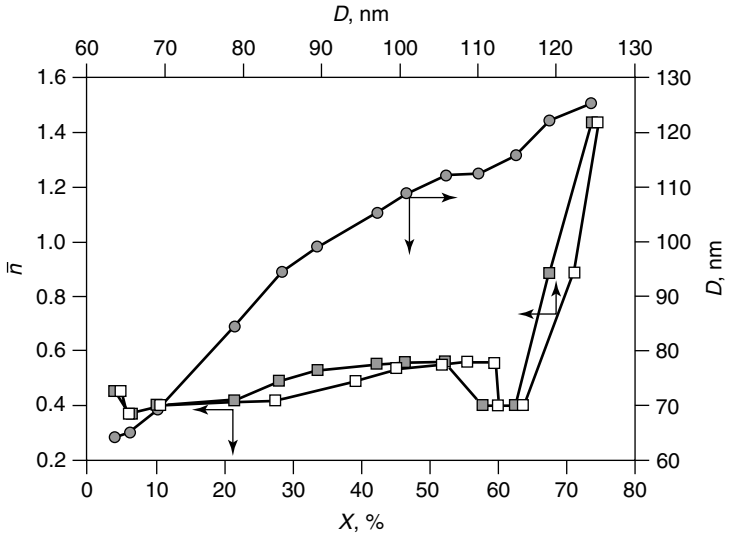

Fig. 14. Average number of radicals per particles in dependence on both conversion and particle size and particle size in dependence on conversion for a batch styrene emulsion polymerization; gray squares $\bar{n}$ versus conversion; open squares $\bar{n}$ versus particle size; gray circles' D versus conversion. (Recipe: 1000 g of water, 200 g of styrene, 4.268 g of SDS, and 1.74 g of 2,2′-azobisisobutyronitrile as initiator, temperature 60°C, for details see Ref. 115.

which is soluble in both phases [about 10% of AIBN is dissolved in water at 25°C (116)] obeys Smith–Ewart case 2 nicely as $\bar{n}$ is between 0.4 and 0.6, with a slight tendency to increase between 5 and 60% of conversion and to increase much steeply thereafter. This increase, even if only slight at conversions below 65%, indicates that there are still other conditions influencing $\bar{n}$. One of these possible influences is the change in the average particle size during polymerization, which may cause a change in $\bar{n}$ as discussed above. The particle size data depicted in Figure 14 (gray circles, bottom x-axis and right y-axis) show an almost linear increase with conversion over the whole range. Indeed, the change in D can explain the slight increase in $\bar{n}$ at low conversions. The steep increase in $\bar{n}$, however, cannot be explained with the increase in D, which is very smooth (cf data in Fig. 13). Another possible explanation of the increase in $\bar{n}$ is, according to equation 9, a change in $C_{\mathrm{M,p}}$. Figure 15 shows that $C_{\mathrm{M,p}}$ also changes over the whole conversion range (115,117,118). $C_{\mathrm{M,p}}$ is expressed as the volume fraction of monomer in the swollen particles ϕ_{M}, which relates to $C_{\mathrm{M,p}}$ with the following relation: $\phi_{\mathrm{M}} = C_{\mathrm{M,p}} \mathrm{v}\, V_{\mathrm{mon}}$. This experimental result contradicts an important assumption of emulsion polymerization theory, where constant $C_{\mathrm{M,p}}$ values are assumed as long as a free monomer phase is present. For styrene, this should be a conversion of up to about 50%. But the experimental results are trustworthy because they were obtained at different times, in different laboratories, and by different researchers. Consequently, the decrease in $C_{\mathrm{M,p}}$ may contribute over the whole conversion range to increasing $\bar{n}$ values. Waning monomer concentration inside the droplets V/particles leads to an increase in viscosity, which at the same time causes decreasing mobility and radical termination inside the droplets. This gel or Trommsdorff effect, although known

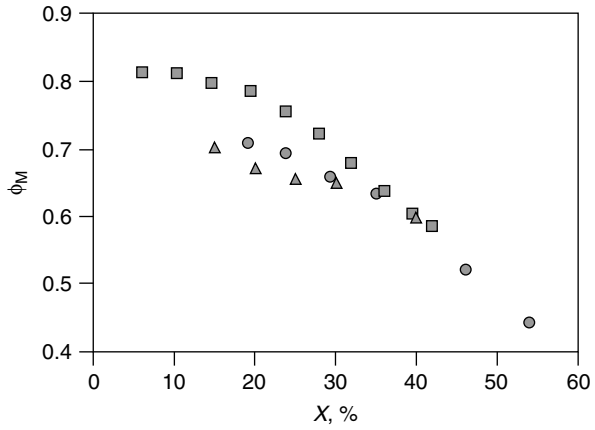

Fig. 15. Change of monomer volume fraction in latex particles during batch styrene emulsion polymerization with SDS as emulsifier. △ Initiator: potassium peroxodisulfate (117); □ Initiator: 2,2′-azobisisobutyronitrile (118); ○ Initiator: 2,2′-azobisisobutyronitrile (115).

to be not very pronounced in styrene emulsion polymerization (70), finds its expression under conditions of emulsion polymerization in a steep increase in $\bar{n}$. In contrast, a drastic increase in the number of radicals per particle by more than an order of magnitude was directly observed in emulsion polymerizations of methyl methacrylate (MMA) with electron spin resonance spectroscopy (119).

A Smith–Ewart case 1 behavior ($\bar{n} \ll 1$) can be observed during emulsion polymerization of monomers with a high chain-transfer rate constant such as vinyl chloride because the monomer radicals have a high tendency to escape from the particles. Especially for vinyl chloride emulsion polymerization, Ugelstad and Hansen (113) derived the following equation 18 to calculate $\bar{n}$, which predicts dependence, $\bar{n} \propto D^{3/2}$.

$$\bar{n} = N^{-1/2} \left(k_1 D^3 + k_2 D^2\right)^{1/2} \; k_1 = \left(6/\pi\right) \left(r_{\mathrm{i,w}}/2k_{\mathrm{t,w}}\right) \; k_2 = \left(6/\pi\right)^{2/3} \left(r_{\mathrm{i,w}}/2k_{\mathrm{des}}\right) \tag{18}$$

It was shown that $\bar{n}$ values calculated with this equation agree well with estimated ones by means of equation 9 up to a conversion of some 60% in batch emulsion polymerization of vinyl chloride, leading to particle sizes below 80 nm (120). Under these conditions the $\bar{n}$ values for vinyl chloride, are between 10^{-4} and 10^{-3}. However, for technically important continuous emulsion polymerizations of vinyl chloride, it was found that under steady-state conditions $\bar{n}$ depends on the square of D, as described by equation 19 (120).

$$\bar{n} = k'' D^2 \tag{19}$$

The data depicted in Figure 16 show that for a continuous emulsion polymerization of vinyl chloride leading to a very broad particle size distribution (10 nm $< D <$ 2000 nm) $\bar{n}$ changes over almost 5 orders of magnitude from 10^{-4} up to 10.

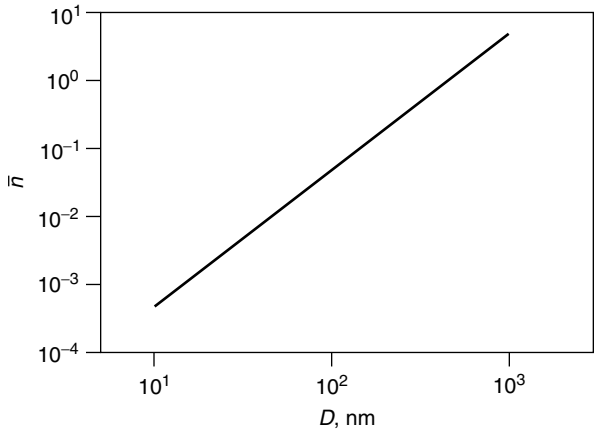

Fig. 16. Calculated average number of radicals per particle during a continuous emulsion polymerization of vinyl chloride (120).

This is a peculiar situation because at the same time particles do coexist, showing all features of compartmentalization effect ($\bar{n} < 1$) together with particles obeying bulk or solution kinetics ($\bar{n} > 1$).

In summary of this part, the average number of radicals per compartment is the centerpiece of heterophase polymerization kinetics. Its value depends mainly on the rate with which active, propagating centers appear inside the particles either by decomposition of monomer-soluble initiators or by entry from the continuous phase. Furthermore, particle size and overall concentration of compartments influence $\bar{n}$ in such a way that it increases with both increasing D and decreasing N. If the viscosity inside the particles is so high that termination by radical recombination is hindered, $\bar{n}$ increases as an expression of the gel effect in compartmentalized polymerization systems.

Competitive Growth of Particles with Different Size. Particle growth kinetics is an important aspect especially if at the end of polymerization a certain particle size or size distribution is required. In this context the relative growth of particles with different diameters is of importance (so-called competitive growth) and consequently, how a given particle size distribution changes during polymerization (if nucleation of new particles is excluded by taking appropriate action). The volume growth of a particle is given by equation 20, where K is assumed to be independent of particle size.

$$\frac{\mathrm{d}v}{\mathrm{d}t} = KD^{\mathrm{x}} \tag{20}$$

For the size growth follows equation 21, with volume $v = \frac{\pi}{6}D^3$, which leads under the assumption that both K and K' independent of time (ie K and K' only depend on polymerization conditions) after integration to equation 21. Note that the particle size is always the unswollen size; thus using equation 21 means the size dependence of the monomer concentration is neglected, which is reasonable for surfactant-stabilized particles with sizes larger than 50 nm (121). D and D_0

are the sizes at the beginning and the end of polymerization with duration Δt, respectively.

$$\frac{\mathrm{d}D}{\mathrm{d}t} = K' D^{x-2} \tag{21}$$

$$D^{3-x} - D_0^{3-x} = K'' \Delta t \tag{22}$$

A closer inspection of equations 21 and 22 reveals that if $x < 3$, smaller particles will grow faster and the particle size distribution is self-sharpening. On the contrary, if $x > 3$, the distribution becomes broader as larger particles grow faster than smaller ones. However, if $x = 3$, particle growth does not depend on particle size. There is experimental evidence that competitive growth during seeded emulsion polymerization slightly favors smaller particles (122). Other experimental and theoretical studies confirmed in the case of water-soluble peroxodisulfate initiator growth exponents of $x = 2.5$ for particle sizes larger than about 150 nm, which decreased toward zero when the particle size was decreased below 150 nm. However, for oil-soluble initiators, x was equal to 2.5 for a larger size range until the particles reached a critical size needed to sustain two growing radicals (123). This means that for larger particles, ie pseudo-bulk systems, particle growth does not depend on particle size and hence, the particle size distribution evolves uniformly in time. In a series of vinyl chloride emulsion polymerizations an exponent of x between 2 and 3 was determined, which slightly decreases with increasing initiator concentration (peroxodisulfate) as predicted by a theory considering desorption and reabsorption of radicals (124). Model calculations on the kinetics of competitive growth in aqueous polymerization of bidisperse seed systems with oil-soluble initiators showed that x is strongly dependent on rate of initiator decomposition, desorption rate, and the diameter ratio. If only 1% of the initiator is soluble in water, x approaches a value of 3 for low and high decomposition rates, independent of desorption rate. For intermediate values of initiator decomposition rate, $x < 3$ is obtained, indicating self-sharpening of the particle size distribution. In contrast, with a completely water-insoluble initiator the order is found to be constantly equal to 3, which indicates size-independent growth rate (125). Also, more sophisticated model considerations with regard to particle growth come to similar conclusions; for example, one author stated that as particle size distribution evolves it usually becomes narrower, and a more monodisperse distribution can be obtained provided formation of new particles can be avoided (126).

An essential advantage of heterophase polymerization, especially emulsion polymerization and related procedures, is that it allows simultaneously high polymerization rates and high molecular weights owing to its compartmentalized nature. In this context a question arises with regard to the relation between particle size and molecular weight. There are at least two contradictory effects necessary to consider: the dependence of the average number of radicals on the particle size (cf above) and the dependence of the monomer concentration inside the particles (cf below). As both values get larger with increasing particle size and on the one hand the molecular weight increases with increasing monomer concentration but decreases with higher $\bar{n}$, a theoretical prediction is very hard. Figure 17 shows for

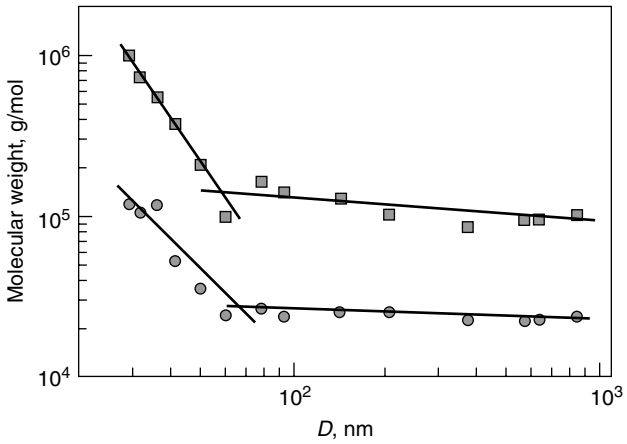

Fig. 17. Average molecular weights in dependence on average particle sizes for emulsion polymerizations of styrene, where changing emulsifier concentration varied the particle size (conditions cf. caption of Fig. 9); lines are for guiding the eye. □ M_w; ○ M_n.

the same polymerization as in Figures 9 and 10 the experimentally determined dependence of the weight- and number-average molecular weights on the average particle size for the final latexes. For this particular set of experiments the average molecular weight increases with decreasing average particle size. The slope in this log–log plot changes for particle sizes below 100 nm. For smaller particles the molecular weight increase is much steeper than for larger particles. The plots in Figure 18 reveal that in dependence on the emulsifier concentration

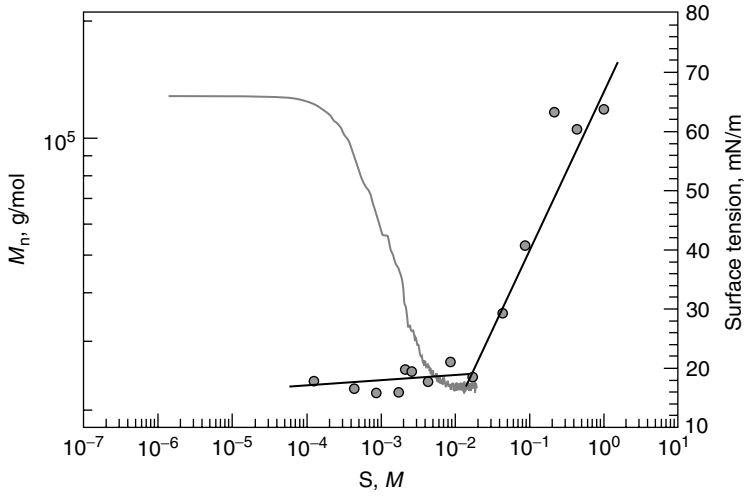

Fig. 18. Experimentally obtained relation between number-average molecular weight (M_n), left ordinate, and surface tension, right ordinate, and emulsifier concentration (for polymerization conditions, see caption of Fig. 9); lines are for guiding the eye. — surface tension; ○ M_n.

the increase in the molecular weight starts in the vicinity of the critical micelle concentration. At this point a large number of particles can be stabilized and the effect of compartmentalization really starts to act.

Technical Realizations

The easiest way to carry out heterophase polymerization is to mix water and a monomer, say styrene, which is able to undergo thermal polymerization, in a vessel at elevated temperatures. After a couple of hours. (the time depends on the temperature) the mixture becomes turbid because of the formation of polystyrene particles. Figure 19 shows a transmission electron microscopy picture of polystyrene particles obtained in this simple way. Although the amount of polystyrene formed was low and the reproducibility of this procedure very bad, a heterophase polymerization took place, and this offers a nice example of how easily heterophase polymerization can be carried out.

Recipes. The minimum number of chemically different components for heterophase polymerizations is two. This is the case if a monomer, which is a nonsolvent for its own polymer is polymerized in bulk. Light-induced bulk polymerization of acrylonitrile and vinyl chloride might be examples for this procedure. However, well-defined products especially with regard to colloidal properties, require more efforts. In order to carry out reproducible heterophase polymerization up to high conversions with highly controlled polymeric and colloidal properties, at

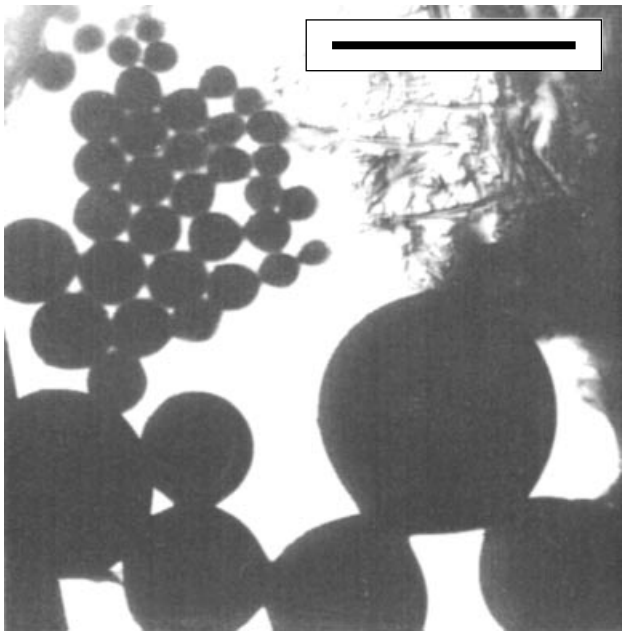

Fig. 19. Transmission electron microscopy pictures of polystyrene particles obtained by thermal polymerization at 90°C in an all-Teflon (DuPont) reactor after duration of 7 h; the bar indicates 3.5 μm.

least three more components may be necessary, that is, an initiator, a dispersion medium or continuous phase, and a stabilizer. The kind of chain-growth mechanism (condensation or addition) together with the desired polymeric product determines whether a catalyst or an initiator, and which kind, is employed. The thermal properties of the monomers and polymers determine the polymerization temperature and hence the properties of the initiating system.

The Continuous Phase. As a general rule any polymerization recipe that works well under homogeneous conditions can be transformed into a heterogeneous system by the choice of a corresponding continuous phase that should be liquid at least at polymerization temperature. The continuous phase has to fulfill three basic requirements: it should be chemically inert, a nonsolvent for the polymer, and possess good heat-transfer properties. If however, the continuous phase interferes with recipe components, the transfer from homogeneous to heterogeneous polymerization conditions requires additional efforts and if needed, changes of one or the other recipe component. Table 5 gives examples of the types of polymerization chemistry applied in heterogeneous polymerization with fluid continuous phases. A variety of different media have been used as continuous phases, for example, aqueous solutions with high ionic strength (130), polymeric melts (47), or supercritical CO_2 (132).

Other Components. The smaller the particle size, at a given phase ratio, the more difficult it is to ensure colloidal stability (cf Fig. 5). This means that for aqueous heterophase polymerizations in the order suspension < microsuspension < emulsion ≤ miniemulsion < microemulsion, the stabilizer concentration increases. Contrary to the simple polymerization of styrene in water, polymerization recipes for industrially important polymer dispersions comprise up to six monomers, frequently more than two emulsifiers, more than one initiating system, and a few other aids like biocides, defoaming agents, plasticizers for supporting film formation (39). The monomer-to-water ratio is adjusted in such a way that a solid content results typically between 40 and 60% or even higher. The amounts of surfactants and initiator (mainly peroxodisulfate) are typically between 0.5 and 2% (w/w) relative to the monomers and 0.5% (w/w) relative to water, respectively.

A peculiarity of suspension polymerization relates somewhat to recipes and more so to reactor operation. Industrial suspension polymerizations are carried out batchwise in reactors with a volume of up to 200 m^3. These reactors are designed with a maximum cooling capacity corresponding to the maximum heat release. However, the maximum heat release normally occurs only for a limited period of time (gel effect) and hence the average heat release during the entire polymerization is much lower. In order to increase the reactor output, so-called initiator cocktails are used that allow polymerization as long as possible at the maximum rate (148,149). Another possibility to avoid a substantial loss in reactor productivity at conversions where the maximum rate of polymerization is not attained is the use of temperature-programmed reaction. An example of such a procedure in order to increase the productivity of vinyl chloride suspension polymerization reactors is given in Reference 150.

Reactors and Operation Modes. A large variety of reactors and mixing systems can be used for heterophase polymerizations. The enzymatic biosynthesis of natural rubber in *Hevea brasiliensis* trees or of poly-3-(hyroxyalkylalkanoates) in bacteria cells takes place in living organisms. For instance, the enzymatic

Table 5. Types of Polymerization Chemistry Applied in Heterophase Polymerization

Polymerization chemistry	Example	Reference
Enzymatic biosynthesis	(*1*) Synthesis of *cis*-1,4-polyisoprene by enzymatic condensation of *iso*-pentenyl pyrophosphate in plants	127
	(*2*) Synthesis of poly-3-(hydroxyalkylalkanoates) in bacteria even an industrial scale	128
Condensation	(*1*) Preparation of polyurethanes via miniemulsion from isophorone diisocyanate and bisphenol A or dodecane diol in aqueous media	129
	(*2*) Tetraethyl silicate reaction in alcoholic solution in presence of water under alkaline conditions	130
Ring opening (pseudo-anionic)	(*1*) Polymerization of cyclic esters such as ε-caprolactone in 1,4-dioxane and heptane with diethyl aluminum ethoxide or sodium trimethyl silanoate as initiator	131
	(*2*) Copolymerization of D,L-lactide and glycolide in supercritical CO_2 with stannous octoate as catalyst	132
Ionic polymerization	(*1*) Cationic polymerization of permethyl cyclosiloxanes with tetraalkylammonium chloride surfactants in alkaline aqueous solutions	133
	(*2*) Anionic polymerization of permethyl cyclosiloxanes with dodecylbenzene sulfonic acid as both catalyst and surfactants in acid aqueous solutions	134
	(*3*) Styrene polymerization in hexane with *sec*-butyl lithium as initiator	135
Noble metal–olefin complexes	(*1*) Olefin complexes of rhodium(I) chloride for aqueous emulsion polymerization of 1,3-butadiene to get crystalline *trans*-1,4-polybutadiene	136
	(*2*) Binuclear nickel ylide catalysts to get high density polyethylene in aqueous emulsion or miniemulsion	137

condensation of dimethylallylpyrophosphate to *cis*-poly-1,4-isoprene takes place in tubular vessels in the tissues of the tree, which might be considered as a continuous tube reactor at least during the harvest. There are basically two different types of reactors for synthetic heterophase polymerization: the well-mixed stirred tank reactors or the tube flow reactors. The former may operate batchwise, semibatchwise, or continuously whereas the latter is restricted to continuous operations. Both types of reactors, that is a single continuous stirred-tank reactor and a tube flow reactor, differ significantly in their residence time distribution. This is of particular importance because the particle size distributions, provided particle growth processes mainly govern the size distribution, reflect the residence time distributions. Remember, particles grow during the entire reaction time in contrast to the case of polymer molecules in radical polymerizations.

Compared with homogeneous condensation or bulk polymerizations, the technical realization of emulsion polymerizations in both laboratory and on an industrial scale is easy. The minimum equipment needed is a container that can be closed and that is chemically resistant to water and the monomers. In the case of gaseous monomers, the container must additionally withstand the corresponding vapor pressure. This type of reactor, for instance beverage bottles of different styles with crown caps or caps with a septum to allow sampling, was employed for many investigations during the early days of emulsion polymerization (151). These so-called bottle reactors were fixed to a rotating shaft and immersed in a thermostated bath. Nowadays rotation thermostats with metal block heaters are available and frequently in use (152). With a large number of reaction vials it is possible to investigate many recipe variations simultaneously or to acquire conversion time data with sampling volumes large enough for the necessary latex and polymer characterizations. Moreover, for laboratory investigations, stirred vessels with heating and cooling jackets are widely used, although, especially if larger sampling volumes are desired, the bottle reactors still have some advantages.

In industrial processes stirred reactors with numerous technical variations are mainly employed. Besides jacket cooling, the heat of polymerization can be removed by various techniques as, for instance, hot cooling or internal fittings inside the reactor. Reactors for commercial processes have a size between 10 and 200 m^3 and are pressure-proof up to 200 MPa (2000 atm) if necessary (39). The vessels normally have a cylindrical shape with dished tops and bottoms. The mixing system depends on the particular heterophase polymerization technique, as it has to fulfill different requests. A detailed discussion is beyond the scope of this article and the reader is referred to chemical engineering text books or reviews dealing with special heterophase polymerization techniques such as for emulsion polymerization (153,154) and for bulk and suspension polymerization (155,156).

Currently, commercially pure batch processes play a major role for suspension and bulk polymerization but only a minor role for emulsion polymerizations. The most important procedure for effecting polymer dispersions by emulsion polymerization on a technical scale is semibatch or feed processes, which are very flexible regarding product properties. Depending on the required properties with respect to particle size distribution, molecular weight distribution, chemical composition in the case of copolymerization, and particle morphology, numerous feeding policies have been developed. Almost all kinds of consecutive

shell morphologies can be prepared nowadays by means of computer-controlled monomer feed streams. This is a tremendous improvement compared to the early attempts to prepare heterogeneous particle morphology by changing the monomer feed compositions with the aid of so–called near tanks and far tanks, as described in Reference 157. A variety of emulsion polymerizations [for example poly(vinyl chloride) and rubber production] are carried out continuously, mainly in continuous stirred-tank reactors (CSTRs) or in a series consisting of up to 8 CSTRs. In the latter case intermediate feed streams are frequently applied to control copolymer composition and particle morphology. A specific and very exciting feature of continuous processes in stirred tank reactors is the occurrence of damped or sustained oscillation of conversion and also of latex and polymer properties (particle size, molecular weight, and the corresponding distributions) even at the steady state for different monomers (158–163).

Although continuous emulsion polymerization technology is more than 60 years old it is still attracting researchers investigating the dynamic behavior in order to achieve control (164) and also developing procedures that allow transfer of products from batch or semibatch processes to continuous reactors in order to increase productivity (165).

In large-scale technical reactors, the hydrodynamic conditions are much more important than in laboratory-scale reactors. Sufficient emulsification is essential for a proper control of the polymerization process and product properties. If the stirring conditions are not optimized, problems can arise regarding the homogeneity of the reaction mixture as well as heat removal. In contrast, if the shear forces are too high the latex may become unstable to coagulation [cf below and (39)]. It is generally assumed that agitation has no effect on the kinetics and this topic is ignored in almost all textbooks. However, a few results have been published indicating an influence. For example, kinetics may be affected if the inert gas for purging contains traces of oxygen, if a chain-transfer agent has to diffuse out of the monomer droplets into the particles (166), if the monomer diffusion to the reaction loci is influenced (167), or if the emulsifier distribution between the interfaces is changed considerably (168). Nowadays, the influence of the stirrer speed receives more and more attention (169–172), and increasing the stirrer speed, starting from well-mixed conditions, has been carried out in all these investigations. A drastic change in both the kinetics and the polymer and particle properties has been reported if the stirrer speed is increased starting from values so low that a bulky free monomer phase on top of the reactor still exists (104). Increasing the stirrer speed leads to an increase in the polymerization rate, the particle size, and the molecular weight. Besides stirred tank reactors, in which the composition per volume unit is the same over the entire reactor volume, tubular reactors have aroused increasing interest over the last few years. The references in Table 6 seem to support this trend. Even for suspension polymerization, more and more continuous procedures based on tube reactors are being investigated. For instance, a 5-m^3 batch tank reactor can be replaced by a 0.05-m^3 continuous loop reactor (175).

In summary, many different technical realizations exist for preparing polymer dispersions, ranging from biosynthesis in many plants and bacteria over bottle reactors to high-tech and computer-controlled production systems. Emulsion polymerizations have even been carried out in space under the conditions

of zero gravity (182) under the supervision of the Lehigh Emulsion Polymers Institute.

Procedures. From a technological point of view heterophase polymerizations can be carried out either batchwise, semicontinuous (or semibatch), or continuous. In the batchwise case the reactor is filled with all ingredients before the polymerization is started and the reactor content is removed at the end of the polymerization. In a semibatch procedure, at the start of the polymerization the reactor is filled only partially and a stream of either neat monomers or monomer emulsion with constant or deliberately changed composition is fed continuously until the reactor is filled. After a final post-feeding batch reaction period, the reactor is emptied. A continuous procedure means that all necessary ingredients are fed and final latex is removed continuously. In all three cases the polymerization can be carried out in the absence or presence of preformed particles (so-called seed particles). Reactions in the absence of seed particles are frequently called ab initio polymerizations and require that particle nucleation takes place. Table 7 is an

attempt at a condensed view of the great variety of procedures for carrying out heterophase polymerization. A few typical characteristics of various techniques are put together there. The references given in Table 7, except those for dispersion polymerization, refer mainly to water as continuous phase. As already pointed out, the corresponding processes with nonaqueous continuous phases are denoted with the prefix inverse (223). In inverse heterophase polymerization systems the dispersed phase is hydrophilic and in cases where the monomer is a solid and insoluble in the continuous phase, aqueous solutions of the monomers are used in order to support emulsification. In this sense all procedures except dispersion polymerization have inverse mirror images. The interested reader can find detailed information with regard to inverse precipitation and suspension polymerization in Reference 224, inverse emulsion and suspension polymerization in Reference 225, all types of inverse polymerization in Reference 139, and inverse emulsion and microemulsion polymerization in References 226 and 227.

On closer examination of this information, together with that in Tables 2 and 4, one may come to the conclusion that a classification with regard to the final particle size is much more meaningful than with regard to separate recipe components as is frequently done. The final polymer dispersion is the result of a complicated interplay between all recipe components and the polymerization temperature that governs thermodynamics. This is especially true for technical polymerizations owing to the increased number of components.

Initiators and Stabilizers. The combinations of initiator and stabilizer play a crucial role. Studies of the influence of the kind of initiator on heterophase polymerization and latex properties have been published. Some efforts have been made to investigate the influence of water-soluble and oil-soluble initiators on emulsion polymerization (213,228–230) and microemulsion polymerization (116,231). In systematic kinetic studies it turned out that the general behavior of emulsion polymerization is the same for water-soluble and oil-soluble initiators (232). The reason for the similar behavior is the desorption of initiator radicals from the polymer particles, which governed the kinetics under the particular conditions, rather than the contribution of the fraction of oil-soluble initiators dissolved in the dispersed phase. Note that this can only be valid for recipes containing surfactants because the polymerization of lyophobic monomers with lyophobic initiators in the absence of stabilizers is a precipitation polymerization without any control of colloidal stability. There are not only similarities but also differences between lyophobic and lyophilic initiators. For instance in Reference 229, the authors found that use of dibenzoyl peroxide leads to lower average molecular weight (about a factor of 5) of the polystyrene than use of potassium peroxodisulfate (emulsifier: hexadecanoic acid) because of chain transfer to the initiator. But for both initiators the authors claimed a rapid exchange of low molecular weight radicals between latex particles and water phase. The type of oil-soluble peroxide, especially its polarity, influenced the results (233). The authors found that higher the polarity, higher was the initiation rate in emulsion polymerization (emulsifier: Nekal, which is of the short-chain alkyl naphthalene sulfonate type) compared to bulk polymerization of styrene. Thus *sec*-butylhydroperoxide had a 14000 times higher initiation rate in emulsion polymerization whereas that of dibenzoyl peroxide was the same in both cases. The application of a mixture of potassium peroxodisulfate and dibenzoyl peroxide in emulsion polymerization styrene (emulsifier:

alkyl sulfonate, E30) is described in Reference 234. The authors found that the rate of polymerization depends on potassium peroxodisulfate concentration but not on dibenzoyl peroxide concentration. In contrast, the molecular weight depends on dibenzoyl peroxide concentration and not on peroxodisulfate concentration under the particular polymerization conditions. However, these results are contradictory to those of Reference 229 and reveal the necessity to compare experimental data obtained under almost identical conditions. Also, for heterophase polymerizations there is the sensitivity of radical polymerization kinetics to changes in colloidal conditions that must be considered. A systematic study of emulsion polymerization of styrene with different initiator–emulsifier systems (IES) at temperatures between ambient and 100°C was carried out (235). This study included sodium dodecylsulfate and sodium C_{15}-alkylsulfonate (E30, average carbon chain length of 15) as emulsifiers and potassium peroxodisulfate, 2,2′-azobisisobutyronitrile, and various symmetrical poly(ethylene glycol)–azo compounds as initiators (PEGA initiators where the added number denotes the molecular weight of the poly(ethylene glycol) chain). Note, PEGA200 is soluble in both phases owing to the bizarre solubility pattern of poly(ethylene glycol) (45,47 and references therein) and PEGAS200 (the sulfate of PEGA200) is a surface-active initiator mainly located at the interface. With this selection all possible loci of initiator decomposition were covered: the water phase, the oil phase, and the interface. The experiments were evaluated in the form of Arrhenius plots for the average degree of polymerization and the particle number. Both data sets revealed a strong influence of the IES on the experimentally observed dependencies in the case of styrene emulsion polymerization. For instance, the activation energy of the mean degree of polymerization mainly depends on the initiator decomposition and on the locus of radical formation. The activation energy changes in the following order: potassium peroxodisulfate ($E_A \sim -35$ kJ/mol), 2,2′-azobisisobutyronitrile and PEGA200 ($E_A \sim -50$ kJ/mol), and PEGAS200 ($E_A \sim -80$ kJ/mol), independent of the kind of emulsifier and its concentration. The foregoing results for a variety of lyophilic and lyophobic initiators were obtained with low molecular surfactants/emulsifiers as is typical of emulsion or microemulsion recipes. For suspension polymerizations polymeric stabilizers such poly(vinyl alcohol) are typically employed. In a study of suspension polymerization of vinyl chloride [stabilizer: poly(vinyl alcohol) having a degree of hydrolysis of 72.5%] it was shown that the locus of initiator decomposition has an influence on the final particle size distribution. This study is special in the sense that the oil-soluble initiator [bis(4-*t*-butylcyclohexyl)peroxodicarbonate] was either dispersed in the continuous phase or predissolved in the monomer (236). When the initiator was predissolved in the monomer, the polymerization occurred uniformly in all drops (ideal suspension polymerization behavior), whereas in the other case, additionally to suspension polymerization an emulsion polymerization took place leading to a fraction of smaller-sized particles. The following recipe was used to investigate the influence of the kind of initiator (water- or oil-soluble or both) on the suspension polymerization of styrene at 80°C: 40 g of water, 10 g of styrene, 10 mg of poly(vinyl alcohol) (type W25/140 from Wacker Polymer Systems with a degree of hydrolysis of 84–89%), 1.184×10^{-3} *M* initiator (ie 0.32 g of potassium peroxodisulfate or 0.2867 g of dibenzoyl peroxide or 0.673 g PEGA200). The final dispersions at complete conversion have a different appearance, as illustrated by the photograph in Figure 20. From potassium peroxodisulfate to

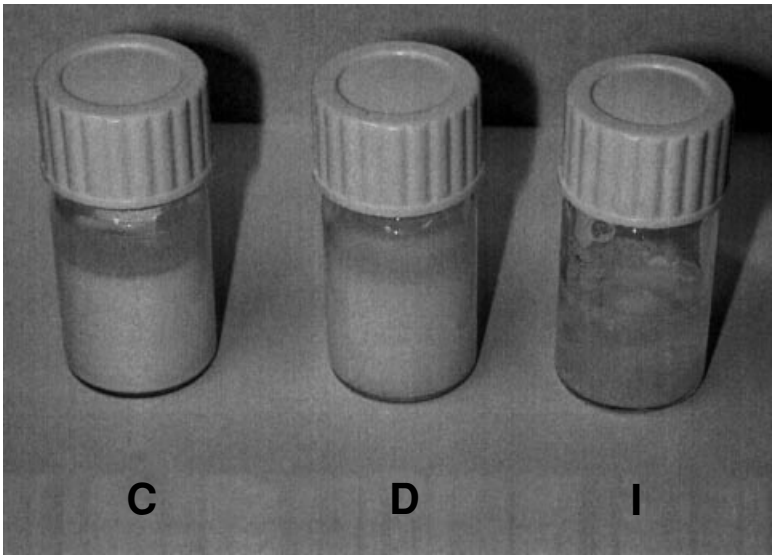

Fig. 20. Appearance of polystyrene dispersions stabilized with poly(vinyl alcohol) prepared with different initiators. *C*: initiator soluble in the continuous phase, potassium peroxodisulfate; *D*: initiator soluble in the disperse phase, dibenzoyl peroxide; *I*: initiator located mainly at the interface, PEGA200.

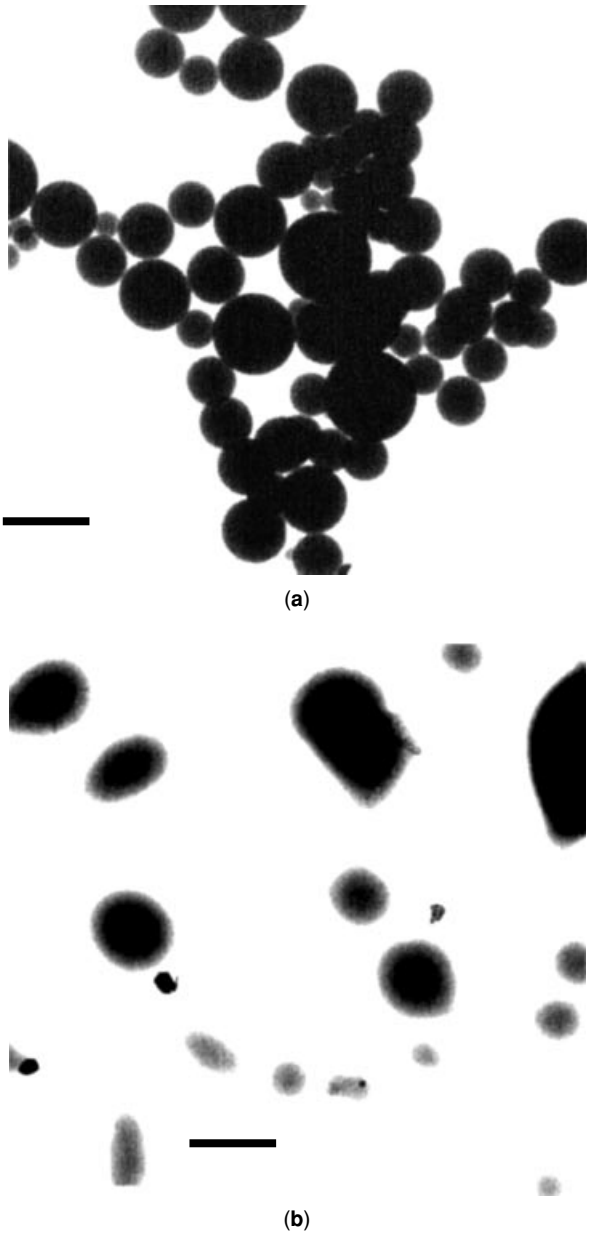
dibenzoyl peroxide to PEGA200, the main loci of initiator decomposition is shifted from the aqueous phase via the oil phase to the interface. The dispersion appears coarser and coarser. In case of PEGA complete phase separation occurred, with large aggregates floating around. The difference between dibenzoyl peroxide and potassium peroxodisulfate is less pronounced—but clearly revealed by the transmission electron microscopy pictures shown in Figure 21. The particles obtained in presence of potassium peroxodisulfate look like normal latex particles (spherical solid particles), whereas the particles prepared with the oil-soluble initiator resemble much softer or bleeded structures. However, the scanning electron microscopy pictures of the main fractions of both dispersions (cf Fig. 22) at a glance hardly show any difference. If there is a difference, then the particle size distribution of dispersion (*D* with dibenzoyl peroxide) appears to be a little broader. Furthermore, in case of initiation in the styrene phase with dibenzoyl peroxide, a few larger particles are also visible (cf Fig. 23), representing either polymerized single-monomer droplets or coalescence structures. These results on the one hand confirm the results of Brooks (236) and on the other reveal that the overall particle size distribution for poly(vinyl alcohol) as polymeric stabilizer depends strongly on the kind of initiator, in contradiction to the above results with low molecular weight emulsifiers. Besides the distinctions in morphology, differences with regard to the molecular properties also exist, as shown by means of molecular weight distributions (cf Fig. 24) and average molecular weights (cf Table 8). Looking at these data, one has to consider that, although the initiator concentration was the same on a molar basis, the decomposition rates, and hence the initiation rates, were different. The decomposition rate constants at 80°C for potassium peroxodisulfate,



(**a**)

dibenzoyl peroxide, and PEGA 200 are $3.5 \times 10^{-4}\,s^{-1}$ (237), $8.1 \times 10^{-4}\,s^{-1}$ (238), and $6.0 \times 10^{-4}\,s^{-1}$ (47), respectively. A comparison with the data in Table 8 shows, that obviously effects other than the initiator decomposition rate determine the molecular weight (potassium peroxodisulfate should lead to the lowest molecular

weight and dibenzoyl peroxide to the highest). One possibility to explain the low molecular weights in case of dibenzoyl peroxide is the chain-transfer reaction as mentioned in Reference 229. This effect might contribute but cannot explain the whole situation. Moreover, there are distinct differences not only in the average molecular weights but also in the shape of the molecular weight distribution. Polymerization I leads to the polymer with the highest molecular weight, followed by sample C and finally sample D. The molecular weight distribution in all three cases is characterized by shoulders or even separated peaks in a range between 2 and 3×10^4 g/mol and about 10^5 g/mol. Additionally the polymer obtained with PEGA200 has a shoulder at 10^6 g/mol, which is typical for this kind of initiator (152). The distributions of Figure 24 show that sample *D* covers the lower molecular weight range whereas sample I covers the higher molecular weight range and interestingly, sample C extends over the whole range. Note that all the molecular weight data are reproducible, as indicated by the average values given in Table 8. In the sense that the molecular weight distribution is a permanent record of the polymerization reaction, an explanation of these data (Fig. 24 and Table 8) might

be attributed to various reaction loci (continuous phase, dispersed phase, and interface), but a real proof needs further investigation. Consequently, an important point in heterophase polymerization is the control of the particle size or particle size distribution, especially in cases where the dispersed state, besides the polymer properties, is important for application.

Control of Particle Size. In principle, particle size control requires the control of the formation of the dispersed phase either by control of the nucleation process or by restricting the polymerization to a preformed dispersed state. Because the control of nucleation is complicated, the second possibility is the method of choice for most of the industrial applications of heterophase polymerization. A more or less well-defined dispersed state as a starting point for polymerization is realized either by the application of seed particles or by emulsification processes. The former method means that preformed particles are used, which serve as reaction loci. The seed particles can either be swollen with the monomer mixture (seeded batch process) or the monomer mixture can be continuously fed into the reactor (so-called seed and feed procedures, or semibatch or semicontinuous process). The polymerization can be restricted to the seed particles by the application of proper means (33) such as the application of radical scavengers (which are soluble in the continuous phase) in the case of radical polymerizations. The second method requires the preparation of monomer droplets of average size a little larger than the desired final particle size because of the shrinkage taking place during polymerization. The two principal techniques for the preparation of emulsions are comminution and condensation (cf (239) and references therein). Comminution techniques require the input of mechanical energy to crush the bulk monomer phase into smaller drops, whereas condensation techniques are thermodynamically driven phase transitions leading to droplet formation. Four main groups of comminution techniques can be distinguished: rotor/stator systems (including all type of stirrers), high pressure homogenizers, ultrasound devices, and membranes. Except for membrane techniques these methods are based on the input of mechanical energy, in the course of which eddies are formed, transferring the mechanical energy to the droplets. The emulsification proceeds in such a way that as soon as the shear exerted by the turbulent microeddies on the droplet interface exceeds the cohesive forces of the liquids in the drops, they split up to smaller units. The cleavage occurs as long as a balance between the external stress and the internal stress is reached. At this steady state the droplet size distribution becomes time-independent. The final droplet size is influenced by various parameters such as the volume–phase ratio, the viscosity of both phases, the mutual solubility of both phases, the kind and concentration of surfactants, the power input, the stirrer as well as the vessel geometry, the diminution energy, and thermodynamic changes during the emulsification process (reactions, temperature). Contrary to

comminution techniques, the preparation of emulsions by condensation does not require mechanical energy, except gentle stirring sometimes to avoid creaming or settling as a result of density differences between both phases. Condensation processes are mainly determined by thermodynamic principles. There are basically two different types of condensation methods: droplet nucleation and swelling of dispersed phases; but the combination of both also has some meaning, especially for heterophase polymerizations (cf Swelling and Nucleation). Microemulsions are the most prominent example of purely thermodynamically driven emulsion formation, which can be considered as swelling of surfactant solutions. Preparation of emulsions and their use in various heterophase polymerization processes has been reviewed (239). An emulsion made by comminution techniques is thermodynamically not stable and hence it is exposed to degradation processes.

Degradation of Emulsions. Emulsions can degrade via different mechanisms: phase separation, Ostwald ripening, aggregation (as generic term for flocculation or coagulation and coalescence), and phase inversion. Additionally, changes in the thermodynamic conditions (composition and temperature) compared to the preparation conditions may have a devastating influence on emulsion stability. *Phase separation* means that an emulsion may separate into two phases: one phase enriched with the droplets and the other enriched with the continuous phase. Depending on the density difference between the continuous and dispersed phase these kinds of separation are called creaming or sedimentation depending on whether the upper or the lower phase is formed by the droplets, respectively. *Aggregation* processes (flocculation, coagulation, coalescence) can take place when the average distance between emulsion droplets is so close that attractive forces become dominant. The stability of emulsions can be controlled very effectively by the addition of proper stabilizers in sufficient concentrations so that generally in practice the aggregation of emulsions is not a serious problem. *Phase inversion* is a process where for a given stabilizer the continuous phase becomes the dispersed one and vice versa. This is mainly observed in the case of polymeric surfactants with a stabilizing moiety possessing a critical solution temperature. Prominent examples are surfactants with poly(ethylene glycol) units. Increasing the temperature leads to an increase in the hydrophobicity of the surfactant and it may subsequently promote the stabilization of water in oil instead of oil in water emulsion (cf Bancrofts's rule). Furthermore, whether phase inversion occurs or not depends on the polarity of the oil phase; the kind of electrolyte and its concentration; other additives as for example organic, water-soluble solvents increasing the oil solubility in water; and on the oil volume fraction. Ostwald *ripening* as a degradation mechanism is a direct consequence of the polydispersity of the droplet size distribution after comminution. Thermal fluctuation in the size or in the curvature may produce polydispersity as well. It is easy to show (cf for instance (239)) that the chemical potential of a dispersed phase compared to that of the same bulk material is increased by $4\sigma V_{\mathrm{mon}}/D_{\mathrm{d}}$. Consequently, for the concentration of the dispersed phase just at the interface $C(D)$ (where σ holds) follows equation 23, with C_0 being the solubility of the dispersed phase in the continuous medium.

$$k_{\mathrm{B}}T\,\ln C\,(D) = \frac{4\sigma v_{\mathrm{mon}}}{D_{\mathrm{d}}} + k_{\mathrm{B}}T\,\ln C_0 \tag{23}$$

From equation 23 it can be seen that smaller the objects, higher is the $C(D)$. As D_d goes to infinity $C(D)$ equals C_0. This means that smaller objects have a tendency to dissolve whereas larger objects grow by the uptake of matter that is released from the small ones. Two points are important for heterophase polymerization: (*1*) For Ostwald ripening to occur, a certain water solubility is required (this is given for many monomers in Table 9) and (*2*) a direct contact between the droplets is not necessary as molecular diffusion through the continuous phase is sufficient. On the basis of these considerations it was supposed that it might be possible to stabilize emulsions against Ostwald ripening by addition of small amounts of a lyophobic substance. This was done by Higuchi and Misra (240) and experimentally verified by stabilization of carbon tetrachloride droplets in water with hexadecane. Kabalnov investigated Ostwald ripening theoretically under such conditions (241). Two cases are of special interest for polymerization. First, that the solubility of the lyophob in the continuous phase is zero ($C_{LC0} = 0$), which means that the total number of particles remains constant. However, the distribution of the dispersed phase from small to large particles changes the composition of the particles. The volume fraction of the lyophob (ϕ_L) in the smaller particles increases and in the larger ones decreases. Indeed, investigations on Ostwald ripening with sedimentation field-flow fractionation in fluorocarbon emulsions confirmed this theoretical prediction (242). This redistribution of the dispersed phase comes to an end when the capillary and the concentration forces (Raoult's law) are in equilibrium. The equilibrium condition requires that the chemical potential of the monomer is the same in all particles. Equation 24 illustrates the situation at equilibrium (subscript e) regarding the lyophob for two particles [superscripts (1) and (2)] of different diameters, where v_m is the molar volume of the monomer.

$$\phi_{L,e}^{1} - \frac{4\sigma v_{mon}}{k_B T} \frac{1}{D_{d,e}^{(1)}} = \phi_{L,e}^{2} - \frac{4\sigma v_{mon}}{k_B T} \frac{1}{D_{d,e}^{(2)}} \tag{24}$$

Compensating for the Ostwald ripening requires ϕ_L values depending on the droplet size, in the sense that smaller drops require a higher ϕ_L and *vice versa*. However, this is practically impossible to control during the initial emulsification process and consequently, Ostwlad ripening inevitably takes place during and after any emulsification process and leads to a change in droplet size distribution during a certain maturation time. An equilibrium size distribution can be reached and Ostwald ripening will stop if between the average drop size ($\bar{D}_{d,i}$) and ϕ_L at the end of the comminution process (subscript i) the inequality given by equation 25 holds. A detailed discussion and derivation of the equations can be found in References 239 and 241.

$$\phi_{L,i} > \frac{4\sigma v_{mon}}{3k_B T\, \bar{D}_{d,i}} \tag{25}$$

If this condition is not met, Ostwald ripening will further increase the differences in the chemical potential for particles with different sizes. This means that

the addition of a completely water-insoluble hydrophobic compound during the emulsification also does not per se prevent Ostwald ripening. Ostwald ripening takes place in any case, except for an exactly monodisperse droplet size distribution, which is hard to realize in actual practice. Hexadecane, which is frequently used as lyophob in miniemulsion polymerization, has a water solubility of about $4 \times 10^{-11}\,M$ at room temperature (243), which is low but not zero. In this case the analysis of Ostwald ripening (241) shows that there exists a critical drop size ($D_{d,c}$) in the droplet size distribution for which the flux of the lyophob out of the drops is zero. The critical drop size is given by equation 26, where C_{LC} is the concentration of the lyophob in the continuous phase.

$$D_{d,c} = \frac{4v_{mon}\sigma}{k_B T \ln\left[C_{LC}/C_{LC0}\phi_L(D_{d,c})\right]} \tag{26}$$

Note that for $D_d > D_{d,c}$ and $D_d < D_{d,c}$, the flux is positive and negative, respectively. The characteristic time of the exchange of monomer from droplets during Ostwald ripening (τ_{ex}) is given by relation 27, where ϕ_{MC} is the dimensionless solubility of the monomer in the continuous phase ($\phi_{MC0} = C_{MC0}V_{mon}$) and D_{MC} is the monomer diffusion coefficient in the continuous phase.

$$\tau_{ex} \propto \frac{D_d^2}{\phi_{MC0} D_{MC}} \tag{27}$$

To preserve the droplets as reaction loci, the polymerization has to compete with the bleeding of the emulsion droplets (239). A consequence of these considerations is that the best lyophob for the preparation of emulsion droplets for subsequent polymerization are polymers in form of seed particles. Swelling is a thermodynamically controlled process and consequently, swollen seed particles are not subjected to degradation processes to the same extent as emulsion droplets made by comminution processes. Furthermore, in most cases the chemistry of the seed particles does not interfere with the final properties of the dispersion. For example a seed particle with a diameter of 20 nm represents in final particles of about 100 nm diameter only less than 1% of the total volume. However, seed processes with suppressed nucleation of new particles are not always the method of choice.

High Solids Polymer Dispersions. Polymer dispersions with higher solids content, clearly above 50 wt%, gain increasing interest for at least two reasons: increasing reactor capacity or productivity (cost reduction) and improved product properties (244–246). From the practical point of view the problem of high solids polymer dispersions is directly connected with rheology, as the viscosity of dispersions goes to infinity at certain solids content. The central problem is very general, that is, consideration of filling space with spheres goes back to Johannes Kepler. The stacking of cannon balls or oranges is intuitively done in a way that uses the available space in the most effective way. In two dimensions, exactly six spheres fit around a single sphere in the center, and six fit around each of the outer spheres. The next layer of spheres fits into the hollows of the first layer and again there is a hexagonal pattern. Kepler suspected that this filling pattern (about 75%) is the tightest way to pack spheres, but he was unable to prove it. This is known as Kepler's conjecture and is still today a matter of research (247). For latex spheres close packing depends on the potential that imparts stability to them. Soft potentials interact over long distances and prevent closer contacts between the particles (cf stabilization). In this sense it is not the mass fraction (solids content) but the effective volume fraction (including a hydrodynamic layer thickness) that determines viscosity. To get latexes with solids content of about 70% or even higher requires polymodal particle size distributions with larger and smaller spheres (the smaller spheres have to fit in the interstitial space between the larger ones). This principle was successfully applied to get high solids polymer latexes, with up to 70% solids content and low viscosity (245). It was found that there is a critical ratio between the larger and smaller sphere diameters, which should be above 10 in order to get both low viscosities and high solids content. The preparation of polymodal latexes requires the occurrence of multiple nucleation events in the course of the polymerization, which can be realized either by emulsifier feeding policies (244,246) and/or by proper choice of recipe components (comonomers) (245). In summary, the application of seed particles in heterophase polymerizations is very promising and indeed, for many industrial polymerizations state-of-the-art (39). Furthermore, particles with special properties such as particle size, monodispersity, functionality, and porosity are prepared by the application of seed particles and activated swelling procedures [cf below and (248–250,252)].

Solubility and Solubilization in the Continuous Phase

Monomers. One of the most important properties of a particular monomer or monomer mixture that is subjected to heterophase polymerization is its solubility in the continuous phase. Table 9 summarizes the water solubility of monomers, which are frequently used in heterophase polymerizations. Monomers with different water solubility of course behave differently during the polymerization process in several ways. Although the data in Table 9 for a particular monomer show some scatter they confirm that there is indeed no limit for monomers with regard to their water solubility to be applied in heterophase polymerization. Even if the monomers are so hydrophilic that their polymers are water-soluble they can be applied as comonomers together with more hydrophobic monomers. Of course, the water solubility of monomers depends on temperature, and for gaseous monomers also on pressure, as indicated in Table 9. However, the water-solubility is not always a linear function of temperature, as is demonstrated in Figure 25 for styrene and methyl methacrylate. Besides the range of the solubility, the shape of the curves is also distinctly different for both monomers. Whereas the water solubility for styrene increases over the entire temperature range, the curve for methyl methacrylate goes through a shallow minimum at about 45°C. At temperatures

n-Octyl methacrylate	51.6[b]		

[a]Values from Ref. 255.
[b]Values calculated from the regression $\sigma_{m,w} = -11.667 \times \log C_{m,w} + 11.179$, which was determined from data given in Ref. 255.

below 25°C the values for styrene obtained with different methods do not agree closely, but at temperatures above 40°C the agreement is almost perfect. Furthermore, Figure 25 reveals that it is always necessary to consider mutual solubilities for a particular monomer/water combination as not only monomers are soluble in water but water also is soluble in monomers. In the case of some hydrophobic monomers like styrene, the solubility of water in the organic phase is even higher than that of the monomer in water. This is the case for many alkanes and alcohols as well (259). The consequence of this fact is of some importance as together with water, hydrophilic radicals may enter the monomer phase and start polymerization. Moreover, as the forces between the molecules of the liquids forming an emulsion (the cohesive and adhesive forces) determine not only the interfacial tension but also the mutual solubilities there is a relation between the interfacial tension and the miscibility (the higher the miscibility, the lower is the interfacial tension). Table 10 summarizes values for the interfacial tension between monomer droplets and the corresponding polymer particles and water, respectively, which clearly show this effect. The interfacial tensions of polymer–water interfaces are not directly accessible, but have been calculated mainly on the basis of polymer polarity data (255). Furthermore, Table 10 shows that the sodium dodecylsulfate adsorption on the polymer particles is also influenced by the polarity of the polymer surface. There is a general rule: the higher the polarity of the interface, the larger is the area covered by one sodium dodecylsulfate molecule in a saturated adsorption layer. Consequently, the lower the number of stabilizing groups per unit area, the higher is the polarity of the interface. Thus, the hydrophilicity of a monomer and the polarity of a polymer have direct influence on all colloid chemical properties during heterophase polymerization, as the interfacial tension influences nucleation, swelling of the particles with monomer, surfactant adsorption, and stability of the droplets/particles. Also, the polymerization kinetics in both phases is influenced because the rate of polymerization is directly proportional to the monomer concentration (cf above)..

Table 11. Solubility and Solubilization of Organic Molecules (Monomers and *n*-Heptyl Mercaptan) in Water and Surfactant Solutions, Respectively[a]

Monomer	Surfactant	Solubility/solubilization, *M*

[f]*n*-HM is *n*-heptyl mercaptan.

In the context of solubility it is necessary to briefly mention the phenomena of solubilization. This *terminus technicus* was introduced by J. W. McBain for a particular process of increasing the solution concentration of substances in a given medium (263). Solubilization can be understood as a sorption phenomenon as it leads to a decrease in the number of molecules of a substance in a reservoir outside the solution but in equilibrium with the solution, by adding an adsorbent to the solution (see ADSORPTION). For heterophase polymerizations the adsorbents are surfactant molecules, which decrease the number of molecules outside the continuous phase (eg in monomer droplets). The amount of the adsorbed or solubilized material increases steeply with increasing stabilizer concentration and levels in the vicinity of the cmc. Solubilization has nothing to do with a true solution but is an effect connected with colloidal systems, which can be formed either by micelles or other particles able to interact with the adsorbate. For aqueous heterophase polymerizations this means that the solubilizing power of micelles, or in other words the solubility of a monomer in a surfactant solution is much greater than in water (cf selected data in Table 11). As solubilization is mediated by micelles and hence colloidal in nature, it depends on the ionic strength in aqueous solution and on temperature.

Dissolved Gases. Oxygen is known to interfere with radical polymerization in different ways. On the one hand its presence leads to detrimental effects such as induction periods, retardation, and side products via peroxide formation. On the other hand in vinyl chloride emulsion polymerization, a certain level of oxygen leads in the presence of basic buffers to an acceleration of the polymerization as a result of decomposition of *in situ*–formed peroxides (265). Either at higher concentrations of oxygen or in the absence of buffer, retardation of the polymerization and long inhibition periods are observed. Studies of the influence of oxygen have been carried out since the beginning of heterophase polymerization

research, when oxygen was, even if unintentionally, the sole initiator (21,24). Under conditions of heterophase polymerization, it is important to consider oxygen partition between all phases. In principle, there are three places where oxygen can be found: in the headspace, the continuous phase, and the dispersed phase. In aqueous emulsion polymerization, most of the oxygen is concentrated in the headspace and smaller amounts only in organic phases and water. However, it is necessary to consider that the solubility of oxygen is higher in many organic solvents than in water (266).

In a calorimetric study of both seeded styrene and seeded styrene/butyl acrylate emulsion polymerization, the presence of oxygen leads to an inhibition period and in due course the redistribution of oxygen from the headspace causes a retardation of the reaction (267). The action of oxygen as both a water–soluble and a monomer–soluble gas was proven in a series of styrene emulsion polymerizations at 60°C with sodium dodecyl sulfate as emulsifier and potassium peroxodisulfate as initiator (268). The authors determined the saturation concentration of oxygen in watery solutions of various compositions at polymerization temperature. The saturation value for pure water, water plus emulsifier, and water plus emulsifier plus styrene was found to be 5.40, 5.58, and 6.53 ppm, respectively. A saturated continuous phase under polymerization conditions (water plus emulsifier plus styrene) sparged with nitrogen of high purity would decrease in dissolved oxygen to a level lower than 0.05 ppm in about 10 min. The authors observed a significant inhibition period only if oxygen is present in concentrations higher than 50% of the saturation concentration. Furthermore, at the end of the inhibition period the oxygen level in the aqueous phase was found to be about 3 ppm independent of the starting values. This experimental finding suggests that high enough initiation rates can outweigh the inhibition action of dissolved oxygen. Another action of dissolved gas, not only oxygen but also nitrogen or other inert gases, is its interference with the nucleation process, as was shown in Reference 91. The reproducibility during the nucleation stage of an ab initio emulsion polymerization was drastically improved if the water and the monomer were carefully degassed instead of purged with nitrogen prior to polymerization and if the water was added to the reactor at a temperature higher than polymerization temperature in order to avoid bubble generation.

Swelling of Polymer Particles

Swelling means that polymer particles in a dispersed state even in the presence of an excess amount of solvent for the polymer do not dissolve but imbibe only a limited amount of that solvent. The importance of this phenomenon for heterophase polymerizations becomes clear by the fact that most of the monomers (acrylates, methacrylates, styrene) are good solvents note only for their own but also other polymers. Thus, during heterophase polymerization monomer droplets and polymer particles can coexist side by side. Swelling is of special practical importance because the colloidal particles consisting of both polymer and monomer are the main reaction loci. The monomer concentration in swollen polymer particles is governed by equilibrating the free energy of mixing between polymer and monomer with the interfacial free energy of the particles and the swelling

pressure (cf equation 28) (121). The term on the right-hand side of equation 28 is the free energy of mixing between polymer and monomer, where the Flory–Huggins–Rehner expression for cross-linked polymers is used. In equation 28, σ is the interfacial tension between the swollen particles and the continuous phase, P_{SW} is the swelling pressure, χ_{mp} is the polymer monomer interaction parameter, ϕ_2 is the polymer volume fraction in the swollen particle, RT is the thermal energy, j is the average degree of polymerization of the polymer molecules, ρ_2 is the polymer density, and $\bar{M}_c$ is the average molecular weight between two cross-links in the network. If the latex particles are not cross-linked ($\bar{M}_c \Longrightarrow \infty$) and if P_{SW} 0, equation 28 becomes identical with the Morton–Kaizerman–Altier equation (269) also (270). Between ϕ_1, the monomer volume fraction, and ϕ_2, the relation $\phi_1 + \phi_2 = 1$ exists. The swollen (r) and unswollen particle radii (r_0) are connected with ϕ_2 via $(r/r_0)^3 = 1/\phi_2$, whereas ϕ_1 is related to $C_{M,p}$ via $\varphi_1 = C_{M,p} V_{mon} = \frac{V_{m,p}}{V_{m,p} + V_{p,p}}$, with $V_{m,p}$ and $V_{p,p}$ being the monomer volume and the polymer volume inside the swollen particles, respectively.

$$\left(\frac{2\sigma}{r} + P_{SW}\right)\frac{v_{mon}}{RT} = -\left[\ln(1-\phi_2) + \left(1 - \frac{1}{j}\right)\phi_2 + \chi_{m,p}\phi_2^2 + \frac{v_{mon}\rho_2}{\bar{M}_C}(\phi_2^{1/3} - \phi_2/2)\right] \tag{28}$$

The right-hand side of equation 28, except the last term, for which one needs to consider only for cross-linked particles, promotes swelling whereas the terms on the left-hand side counteract swelling. The first term on the left-hand side is the interfacial free energy, which counteracts swelling as a result of an increase in the particle interface. The second term on the left-hand side originates from a volume work due to attractive forces between polymer chains in concentrated solutions, as it has been concluded from osmotic modulus measurements (271). The pressure in equation 28 can be considered as swelling pressure of colloidal particles, comparable to that known from the swelling of macroscopic gels, contributing together with the partial molar free interfacial energy to the equilibrium with the chemical potential of the swelling agent ($\Delta\mu_1$). It can be in the order of up to 10 MPa, depending on the decoration of the particle interface (272). An illustration of the dependence of the equilibrium monomer volume fraction (ϕ_1) on the particle size is shown in Figure 26. The higher the ϕ_1, the larger are the particles, the lower is the interfacial tension, and the higher is the temperature, but it decreases with increasing degree of cross-linking and with increasing Flory–Huggins interaction parameter. The two limiting cases of equation 28 for $r \Longrightarrow \infty$ and $\phi_2 \Longrightarrow$ o is of special meaning. In the case of a bulk polymer ($r \Longrightarrow \infty$) the resulting equation is the osmotic or swelling pressure relation given by the equation $\Delta\mu_1 = -\Pi_s V_{mon}$, with $P_{SW} = -\pi_s$. If the polymer concentration is vanishing ($\phi_2 \Longrightarrow 0$), the result is the Young–Laplace equation ($\Delta P_d = 2\sigma/r$) for a colloidal droplet or bubble embedded in a fluid phase. This behavior can be regarded as expression of the situation that the swollen latex particles represent a polymer gel or solution but with colloidal dimensions. Equation 28 considers the influence of surfactants on swelling only via the interfacial tension. But this may be insufficient as entropy effects are completely neglected. The above results

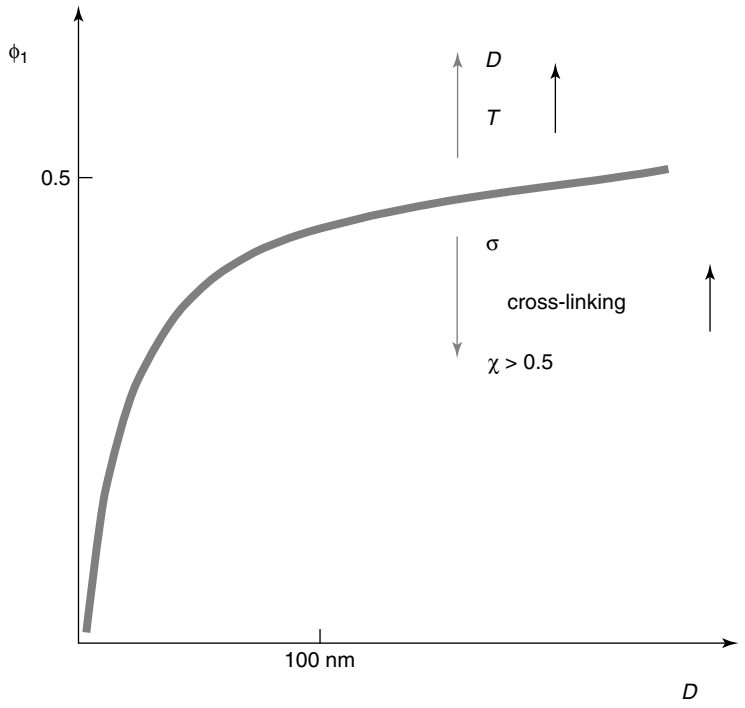

Fig. 26. Illustration of the dependence of ϕ_2 on polymer and particle parameters.

with regard to the behavior of swollen micelles, which are stable as long as the monomer is not polymerized and the surfactant tails can keep their mobility, demonstrate the influence of entropic effects on surfactant–monomer interaction. For monomer partition inside swollen latex particles, which are stabilized with adsorbed surfactants these effects favor the formation of a monomer rich shell rather than a uniform distribution throughout the whole particle volume. This effect is very similar to adsolubilization, which describes the solubilization of organic compounds inside adsorbed stabilizer layers on inorganic particles in order to modify them by admicellar polymerization (273). There is clear experimental evidence by small-angle X-ray scattering that in poly(methyl methacrylate) particles swollen with methyl methacrylate the monomer is concentrated inside an outer shell of approximately 2-nm thickness. The particles were stabilized with two kinds of surfactants: sodium dodecylsulfate, which was present already during the polymerization, and sodium dodecylbenzenesulfate, which was added during the swelling experiments to avoid coagulation (274). Swollen polymer particles are high concentration polymer solutions (about 50% by weight) and hence, the swelling pressure counteracts swelling due to attractive forces between entangled polymer chains and might contribute to formation of the monomer-rich shell. This gradient with regard to monomer concentration inside swollen particles should cause during polymerizations, especially in seeded polymerizations, a morphology gradient with regard to composition. In this sense, the morphology of polymer particles in heterophase polymerization, especially emulsion polymerization, has

been a matter of ongoing discussion for several decades (275–279). The monomer concentration inside the particles as main reaction loci (ie swelling of latex particles) determines rate of polymerization, particle morphology, molecular weight, and in copolymerizations the chemical composition also of the copolymers. Consequently, methods either to measure or to predict the monomer concentration inside particles are a key aspect in heterophase polymerization research and are of permanent importance (280–282).

John Ugelstad's theoretical and experimental work to development new methods of monomer emulsion preparation (283) makes good use of one of the pillars of colloid science, the Kelvin equation. The Kelvin equation says that larger objects, in coexistence with smaller ones, will grow in size at the expense of the smaller objects, which have a tendency to dissolve. This effect is known in colloid science as Ostwald ripening (discussed earlier). Equation 29 shows the Kelvin equation for liquid droplets surrounded by vapor where p' is the vapor pressure outside the drop, p_0 is the bulk vapor pressure, v″ is the molar volume of the liquid, and RT is the thermal energy (284). The smaller the radius of the drops (r), the larger is p' and hence, the higher the tendency to degrade.

$$\ln\frac{p'}{p_0} = \frac{2\sigma}{r}\frac{v''}{\mathrm{RT}} \tag{29}$$

However, as discussed above, the dissolution can be retarded or even prevented if the drops contain a substance that is insoluble in the continuous phase (compound 2 or lyophob). In this case the decrease in size increases the chemical potential of the lyophob inside the smaller drops and generates a force counteracting Ostwald ripening. A detailed discussion of emulsion stability with regard to subsequent polymerization can be found in Reference 239. In addition to the stabilizing effect of compound 2, Ugelstad was able to show that compound 2 has an additional effect on swelling, as the entropy term in the swelling equation (eq. 28), is $(1 - 1/j)\phi_2$, becomes more and more important as long as compound 2 has a low molecular weight (or suppose it is an oligomer where j is in the order of about 5). On the basis of these two effects, Ugelstad and co-workers developed an activated two-step swelling procedure, which enabled them to prepare and to commercialize large monodisperse particles for various applications as high value specialty polymer colloids (251,285). In brief, in the first step an emulsion of the low molecular and highly water-insoluble compound 2, which may contain a solvent that is water-soluble, is added to a suspension of polymer particles (seed). The solvent promotes the transport of compound 2 through the aqueous phase and allows swelling of the polymer particles, which is further facilitated if the emulsion droplets are smaller than the seed particles (action of the Kelvin equation). Then, in a second swelling step the monomer emulsion is added. Because of the high entropy gain caused by mixing of compound 2, with the monomer inside the particles the swelling ability of the seed is activated compared to particles without compound 2. For instance, using dioctyladipate as compound 2, it was possible to swell polystyrene particles with a diameter of 1.55 μm with chlorobenzene as model compound to a diameter of about 30 μm, ie the seed particles imbibed more than a 7000-fold amount of their own volume. During subsequent polymerization,

if instead of chlorobenzene a monomer is used in the second swelling step, precautions are necessary to avoid nucleation of new particles. The interaction between monomers and polymers during heterophase polymerizations is very complex and determines essential features of the particular heterophase polymerization technique such as polymerization rate and particle morphology. A control of swelling enables the preparation of polymer particles with specially tailored properties.

Shrinkage of Monomer-Swollen Polymer Particles

Any polymerization reaction causes a decrease in the average distance between the acting molecules, ie the average distance between individual monomer molecules is larger than that between the repeating units in the polymer. This causes an increase in density although the length of a carbon–carbon double bond is shorter than that of single bond. Table 12 summarizes densities of selected monomers and polymers, which play an important role in heterophase polymerization. The densities of the monomers depend much more on the temperature than those for the polymers, as shown in Figure 27. To illustrate the shrinkage, the volume per monomer molecule and per repeating unit $v_{\mathrm{mol}}^{\mathrm{mon}}$ and $v_{\mathrm{ru}}^{\mathrm{mol}}$, respectively, can be calculated by means of equation 30, where M_{mon} is the molecular weight of the monomer, N_{A} the Avogadro's number, and ρ_1 and ρ_2 are the monomer and polymer densities, respectively..

Table 12. Densities of Selected Monomers (ρ_{m}) and Corresponding Polymers (ρ_{p}) at Various Temperatures

	Monomer		Polymer	
	T°C	ρm[a] g/cm^3	$T^{\circ}C$	ρp,[b] g/cm^3
Methyl methacrylate	20	0.9428	0	1.195
	40	0.9203	20	1.190
	60	0.8971	25	1.180
	80	0.8730		
Styrene	20	0.9049		ρ_{p}- 1.04–1.065; Average $\rho_{\mathrm{p}} = 1.05$
	40	0.8869		
	60	0.8686		
	80	0.8498		
Vinyl chloride	20	0.9115		ρ_{p}- 1.391–1.431; depending on polymerization temperature, average ρ_{p}- 1.40
	40	0.8760		
	60	0.8375		
	80	0.7950		
Vinyl acetate	20	0.9323	20	1.191
	40	0.9075	25	1.190
	60	0.8816	50	1.17
	80	0.8544	1120	1.110

[a]Values taken from Ref. 286.
[b]Values taken from Ref. 287.

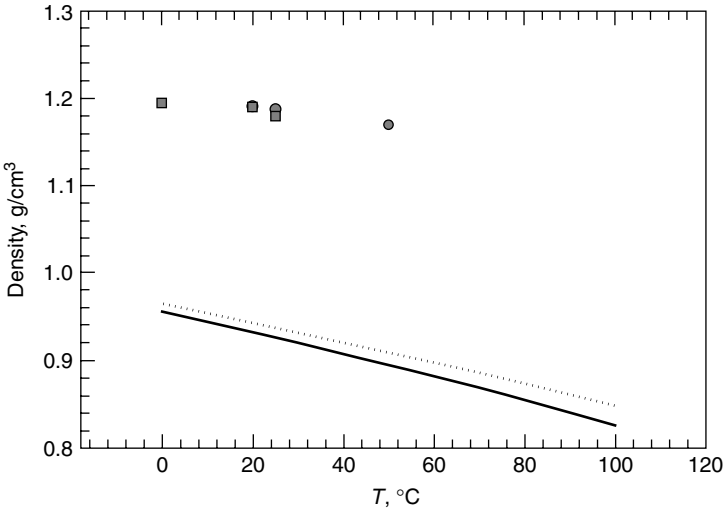

Fig. 27. The dependence of density of selected monomers and polymers on temperature (cf also Table 12). — Vinyl acetate; -●- poly(vinly acetate); ····· methyl methacrylate; -□- poly(metnyl methacrylate).

$$v_{\mathrm{mol}}^{\mathrm{mon}} = \frac{M_{\mathrm{mon}}}{N_{\mathrm{A}}\rho_1} \; v_{\mathrm{mol}}^{\mathrm{ru}} = \frac{M_{\mathrm{mon}}}{N_{\mathrm{A}}\rho_2} \tag{30}$$

With the data given in Table 12 the corresponding values for styrene are, at 80°C when the average polystyrene density of 1.05 g/cm^3 is used, $v_{\mathrm{mol}}^{\mathrm{mon}} = 2.04 \times 10^{-22}$ cm^3 and $v_{\mathrm{mol}}^{\mathrm{ru}} = 1.65 \times 10^{-22}$ cm^3. These values mean that styrene drops, under the assumption that there is no mass transfer, would shrink from the start until the end of the polymerization at 80°C by about 19.12%. This is an enormous number and has in the case of heterophase polymerizations much more important consequences than for homogeneous polymerizations, where the reaction volume shrinks evenly. The sketch in Figure 28 elucidates these consequences. Case A is the ideal behavior where a polymerization proceeds smoothly within a droplet beginning from the center and ending with an evenly shrunk particle with homogeneous density throughout the whole particle volume. Case B represents the other extreme where polymerization starts at the particle–water interface and thus, a shell is formed that might prevent shrinkage of the polymerizing drop (indicated by the stacking of the triangles). In that case, as polymerization proceeds, monomer moves from the center to the shell as a result of swelling and leaves just one big hole in the middle. Because the size of the final particle is that of the starting drop, this process is called constraint shrinkage. Case C is intended to illustrate the real situation where polymerization begins at many sites inside a drop. In that case shrinkage is in between both extremes, and a void structure on the nanometer-size scale characterizes the particle morphology. Equations 31 can be used to quantify the droplet shrinkage and to estimate the magnitude of the

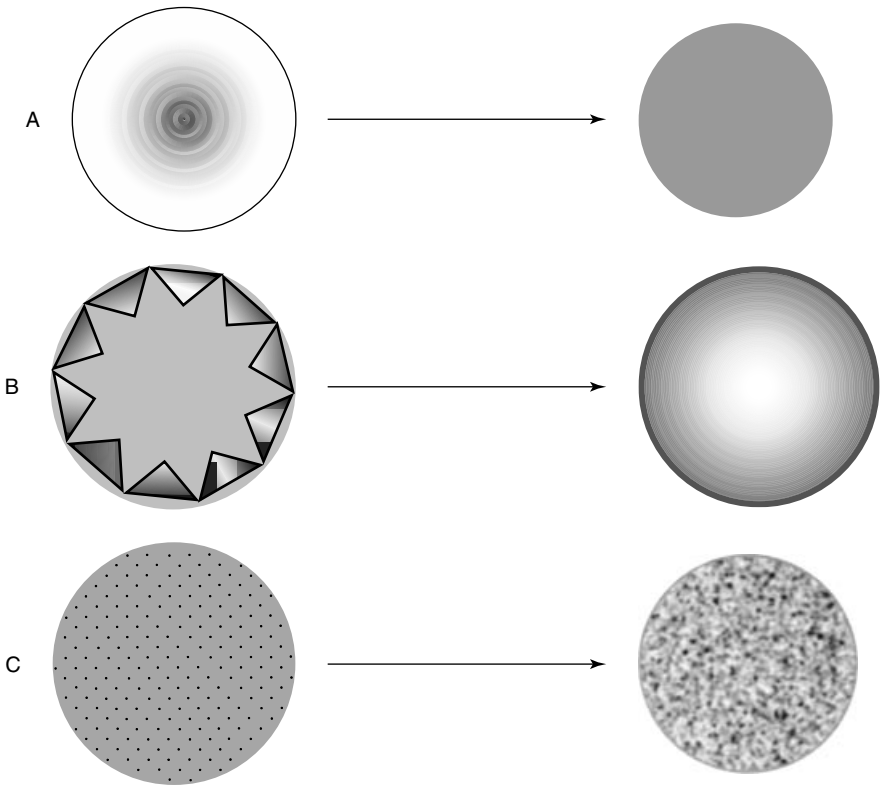

Fig. 28. Illustration of effects caused by volume shrinkage during polymerization in discrete particles.

effects. D_p and D_m denote the polymer particle and monomer droplet diameter, respectively, ΔD is the decrease in diameter due to shrinkage according to case A, and d_h is the size of the single hole formed as described in case B (cf Fig. 28).

$$D_p = D_m \left(\frac{\rho_m}{\rho_p}\right)^{1/3} \quad \Delta D = D_m \left[1 - \left(\frac{\rho_m}{\rho_p}\right)^{1/3}\right] \quad d_h = D_m \left(1 - \frac{\rho_m}{\rho_p}\right)^{1/3} \tag{31}$$

The data plotted in Figure 29 show the development of Δ_D and d_h for styrene and vinyl chloride polymerizations in dependence on temperature, where for the polymers the average density value as given in Table 8 were used. These model calculations show that shrinkage is an important factor during heterophase polymerization, which decisively influences particle morphology and should not be neglected, especially not in cases where the polymerization takes place mainly inside monomer-swollen droplets. Shrinkage may lead to porous particles and can also be utilized to prepare hollow particles.

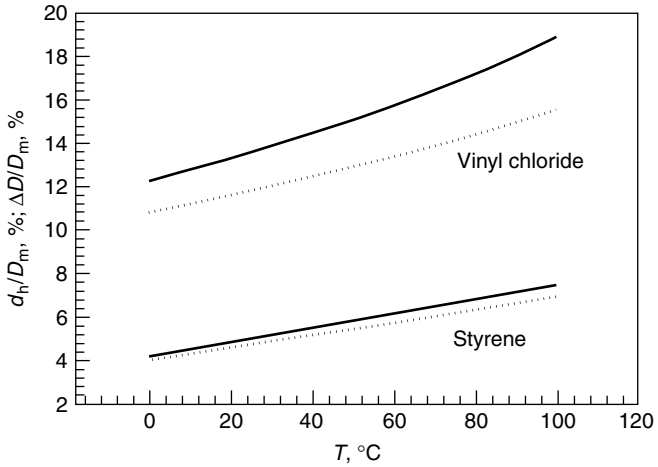

Fig. 29. Shrinkage and hole diameter with respect to the droplet size for polymerization of styrene and vinyl chloride in dependence on polymerization temperature (according to equations 31 and case A and B in Fig. 28). — ΔD; $\cdots\cdots$ d_h.

Stabilization and Stabilizers

The excess interfacial energy of polymer dispersions, compared with bulk or solution systems, is the driving force for an inherent tendency to decrease the interfacial area and hence, to instability. Stabilization of particles and droplets was recognized as a key issue in heterophase polymerization from the very beginning, when Kurt Gottlob described in the first patent (21) the utilization of natural polymers such as starch, egg albumin, or gelatin as stabilizers. Some excellent contributions placing special emphasis on colloidal stabilization in connection with heterophase polymerization can be found in References 288–291. The most important principle of stabilization is that the stabilizer or the stabilizing groups must be soluble in or strongly interacting with the continuous phase. This principle is known as Bancroft's rule and was formulated in 1912 by Wilder Bancroft in a paper on titled The Theory of Emulsification, when he generalized the results of emulsification experiments known at that time: "When water is the dispersing phase, the emulsifying agent should be a hydrophile colloid. . ., the emulsifying agent should be an oleophile colloid in case the emulsion is to contain water in drops" (292). The same principle is behind the empirical HLB (hydrophilic–lipophilic balance) concept, which was developed mid-20th century in order to make the choice of the most effective emulsifier for a desired emulsion easier (293). Hydrophilic emulsifiers, which favor the formation of oil-in-water emulsions have HLB numbers greater than 10, whereas emulsifiers that are more soluble in oil phases have lower HLB numbers and stabilize water–in–oil emulsions more easily. A scientific basis for the HLB concept can be found in the cohesive energy ratio of emulsions that was developed by Beerbower and Hill (294) and which was successfully applied to formulate for instance polymerizable microemulsions (295). Stability is achieved if the Gibbs free energy of mixing is negative. In this sense colloids can be of two basic types, lyophobic and lyophilic. Lyophilic colloids interact strongly

whereas lyophobic colloids have only a very restricted interaction with the continuous phase. Polymer dispersions can be of both types. Examples of lyophilic polymer dispersions, which can also be absolutely stable in a stricter thermodynamic sense are block copolymers in selected solvents or microgel particles such as cross-linked polystyrene in toluene or cross-linked poly(styrene sulfonate) particles in water. In contrast lyophobic polymer colloids in a bare state are thermodynamically unstable and need, in order to keep dispersed for a longer period of time, to be stabilized by third substances.

Attractive Forces. The origin of attractive forces, which are summarized as van der Waals forces, between adjacent particles is the interaction between the molecules and atoms of which the particles are made and is basically electromagnetic in nature. There are three sources of forces attracting uncharged molecules: First, forces produced by aligned permanent dipoles in separate molecules (Keesom forces). Second, forces between permanent dipoles and induced dipoles (Debye forces). Both forces account mainly for binary interactions, because two dipoles, which are in optimum alignment for attractive interaction, cannot be at the same time in the optimum position for attractive interaction with a third molecule. The third kind of forces are of quantum-mechanical nature (London forces) and caused by interaction due to the coupling of random fluctuations of the electrical fields of adjacent molecules, which reduces the free energy and hence are attractive. The London attractive forces are fundamentally different from Keesom or Debye forces, as a molecule can interact by means of London forces with all molecules in its neighborhood at the same time. The attractive potential energy (V_A) decreases with increasing separation distance (d_{pp}) according to equation 32, where k_L is the London interaction constant, Z is the number of electrons in the outer shell, ν_c is the frequency of the fluctuations, h is Planck's constant, and α_0 the static polarizability of the molecules.

$$V_A = -\frac{k_L}{d_{pp}^6}\; k_L = 0.75 Z^{0.5} h \nu_c \alpha_0^2 \tag{32}$$

The calculation of the attractive potential between condensed particles separated by vacuum goes back to Hamaker (296–298). He obtained, under the assumption that the pairwise interaction as used by London for gas molecules can be applied to condensed phases, from an integration over all possible interactions between attracting elements of two particles the following expression (eq. 33), where A is the Hamaker constant, which has the dimension of energy, q is the concentration of interacting centers per unit volume, and H a geometrical function of the particles. An approximate expression of H is given for two spheres of radius r at distance $d_{pp} \ll r$. Equation 33 shows that the energy of attraction varies with the reciprocal of the separation distance. Model calculations have shown that it might be of importance over a distance of tens of nanometers rather than within the close-contact region below 1 nm.

$$V_A = -AH\; A = \pi^2 q^2 k_L\; H = \frac{D}{2} \cdot \frac{1}{d_{pp \cdot 12}} \tag{33}$$

There are several possibilities to refine these calculations such as the consideration of correlation frequencies over the whole spectral range (London considered only ultraviolet frequencies) and the use of a continuum electrodynamic model rather than the assumption of pairwise interaction. Notwithstanding these problems, the Hamaker model can also be applied to the interaction of condensed particles in liquid media to gain knowledge of the basic principles. As the electromagnetic coupling of fluctuating dipoles needs a certain time the fluctuations can move out of phase in dependence on the distance of the interacting particles, which leads to decreasing attractive potential (retardation effect). The properties of the intervening medium between interacting bodies contribute in specific ways. The primary medium effect is due to the medium influence on the transmission of the electromagnetic field between interacting particles. The strength of the radiation of the electric field depends inversely on the dielectric constant, and the optical path length between interacting particles increases in proportional to the square root of the dielectric constant of the medium. The latter influences the retardation effect and reduces attraction. The secondary medium effect considers the finite attraction between particles and molecules of the continuous phase. Under such circumstances the attractive energy is smaller than that between the particles in vacuum, and for the energy balance one has to consider that particle–molecule contacts of the medium will be replaced by particle–particle contacts. This means that chemically identical or similar particles will attract each other, but that this must not necessarily be the case for chemically different particles, where under particular circumstances the dispersed state may be energetically favored. For attracting particles the secondary medium effect finds its expression in a so–called effective Hamaker constant, as defined by equation 34, where A_p is the Hamaker constant of the polymeric particles and A_m that of the medium in vacuum.

$$A_{eff} = \left(A_p^{1/2} - A_m^{1/2}\right)^2 \tag{34}$$

Some values of Hamaker constants for various polymers and liquids that can be applied as continuous phase in heterophase polymerizations are put together in Tables 13 and 14. These data reveal that effective Hamaker constants are clearly smaller than the values for the corresponding polymers and continuous phases. However, the data collected in Table 13 show that Hamaker constants of various polymers are not that much different but the values obtained with different methods for the same polymer differ much more. Consequently, before using values of Hamaker constants it is always necessary to check their origin in order to be sure to compare values obtained with same approximations. According to equation 34 it is possible that the effective Hamaker constant, and hence the London attraction forces also, can be zero. Such situations are virtually obtained in the case of lyophilic microgel particles, which are highly swollen with dispersion medium.

To counteract the attractive forces in lyophobic colloids repulsive forces must operate and consequently, the question regarding an overall interaction potential between colloidal particles arises. Equation 31 leads for separation distances close

Table 13. Hamaker Constants for Different Polymers (A in 10^{-20} J) Calculated with Different Approximate Procedures[a]

Polymer	1[b]	2[c]	3[d]	4[e]	5[f]	6[g]
Polystyrene	4.62	7.7	7.7	—	5.7	3.46

to zero to an infinite attraction. However, this result contradicts the practical experience that any material can be comminuted into colloidal objects.

Repulsive Forces. For an overall balance of interaction forces, one has to consider the repulsion that occurs if surfaces come as close as an atomic diameter together. This strong repulsion is known as Born repulsion ($V_{R,B}$) and changes in proportion to d_{pp}^{-x}, where x is a number of order larger than 10 (290). As the Born repulsive potential acts only at separation distances of atomic diameters, it does not contribute to the stability of colloidal polymer dispersions. There are

other forces counteracting already the inherent attraction at larger separation distances.

Charge Stabilization. The contact between materials with different dielectric constants leads according to Coehn's rule (303,304) to electric charges, as the material with the lower permittivity charges negatively. For water as continuous phase, with a permittivity of about 80, which is larger than that of polymers and many inorganic materials, this means that interfaces in contact will charge negatively. Coehn's rule means furthermore that charge stabilization is inherently present in colloidal systems.

For practical applications in polymer dispersions (ie also during heterophase polymerizations) the effect of charge stabilization due to permanent charges, either by ionic stabilizers, comonomers, or initiator fragments, is much more important. The repulsive potential between two equally charged particles ($V_{R,es}$) separated at a center-to-center distance of ($d_{pp} + D$) is given by equation 35, where Q is the charge on each particle and α is the permittivity of the continuous phase.

$$V_{R,es} = \frac{Q^2}{(d_{pp} + D)\varepsilon} \tag{35}$$

Equation 35 can be rewritten by using the capacitance of a conducting sphere ($CD\varepsilon/2$) and the surface potential ($\Psi = Q/C$) in the form of equation 36.

$$V_{R,es} = \frac{\Psi^2 \left(D/2\right)^2 \varepsilon}{\left(d_{pp} + D\right)} \tag{36}$$

A closer inspection of equation 36 reveals that (*1*) particles in water have both larger capacitance and repulsive potential than those in organic continuous media, (*2*) the repulsive potential falls with increasing separation between the particles, and (*3*) at separation distances much smaller than the particle size, larger particles are easier to stabilize than smaller ones because $V_{R,es} = (D/4)\varepsilon \times \zeta$ and the ratio $V_{R,es}\ V_A$ is independent of D. For electrostatically stabilized particles the interaction energy between two approaching particles can be calculated by means of a theory, which was developed independently during the 1940s by Derjagin and Landau in the former Soviet Union and by Verwey and Overbeek in the Netherlands. This so–called DLVO theory assumes that long-range interactions determine colloidal stability and hence, the interaction potential (V_{int}) is calculated as the sum of attractive van der Waals–London forces and repulsive electrostatic forces based on the Goy–Chapman theory of charge distribution near a surface (305). Equations 37a–c can be used to calculate V_{int} in dependence on the separation distance in order to get insight into the principles of the interaction between charge-stabilized colloids. In these equations A_{eff} is the effective Hamaker constant of particles interacting through the continuous phase, V_{salt} is the ionic strength, κ^{-1} is the Debye screening length, ε and ε_0 are the permittivities in the continuous phase and in vacuum, z is the stoichiometric valency of the electrolyte,

and Ψ is the surface potential of the particles.

$$V_{\text{int}}(d_{\text{PP}}) = \pi a\left[-\frac{A_{\text{eff}}}{12\pi}\frac{1}{d_{\text{PP}}} + \frac{64k_{\text{B}}TC_{\text{salt}}\Gamma_0^2}{\kappa^2}\exp(-\kappa d_{\text{PP}})\right] \tag{37a}$$

$$\kappa^{-1} = \left(\frac{\varepsilon\varepsilon_0 k_{\text{B}}T}{\sum_i (z_{\text{i}}e)^2 C_{\text{salt}}}\right)^{0.5} \tag{37b}$$

$$\Gamma_0 = \tanh\left(\frac{ze\Psi}{4k_{\text{B}}T}\right) \tag{37c}$$

Figures 30a and 30b illustrate the interaction between charged particles in dependence on particle size and ionic strength in the continuous phase. Both parameters (D and V_{salt}) have a strong influence on the interaction potential. The maximum at small separation distances (usually d_{pp} <10 nm) in the interaction potential, which is frequently called primary maximum, prevents the particles from coagulating irreversibly in the primary minimum, which is at still smaller separation distances and which has a depth of approximately twice the dispersive contribution to the surface energy of the particles. The primary maximum is larger, the larger the particles at a given ionic strength, and is smaller, the higher the ionic strength at a given particle size. Furthermore, the depth of the secondary minimum also depends on particle size and ionic strength and is responsible for much looser particle aggregation than in the primary minimum, where the colloidal system is completely unstable. At high ionic strength (Fig. 30b at $C_{\text{salt}} = 10^{-1}$ M) the primary maximum vanishes and the electrostatic system becomes unstable to coagulation. On the other hand at low ionic strength the repulsive forces are extended to pretty large distances. This is an effect that essentially contributes to the crystallization of monodisperse polymer colloids, which occurs at still lower ionic strength. The ionic strength has a strong influence on the Debye screening length (eq. 37b), which determines at which distance a particle recognizes a second particle in his neighborhood. For example, at ionic strengths of 1×10^{-3}, 1×10^{-2}, 1×10^{-1}, and 1 M, the Debye screening length κ^{-1} is 9.2, 2.9, 0.92, and 0.29 nm, respectively. For the sake of completeness, heterocoagulation is the *terminus technicus* for association of oppositely charged particles that are either of the same or different size and are composed either of the same or different materials. This technique can be utilized to prepare polymer particles with special architecture (290).

Perikinetic and Orthokinetic Flocculation. Particles in a dispersion are subjected under any circumstances to Brownian motion (the average velocity is distributed according to the Boltzmann exponential law) and hence, it is the absolute barrier height compared to the thermal energy ($k_{\text{B}}T$) that determines stability. This means that larger particles are more stable against thermal motion (perikinetic flocculation) than smaller particles. However, of practical importance during heterophase polymerization is the behavior of particles in dependence on the stirrer speed (orthokinetic flocculation), where their velocity depends on the

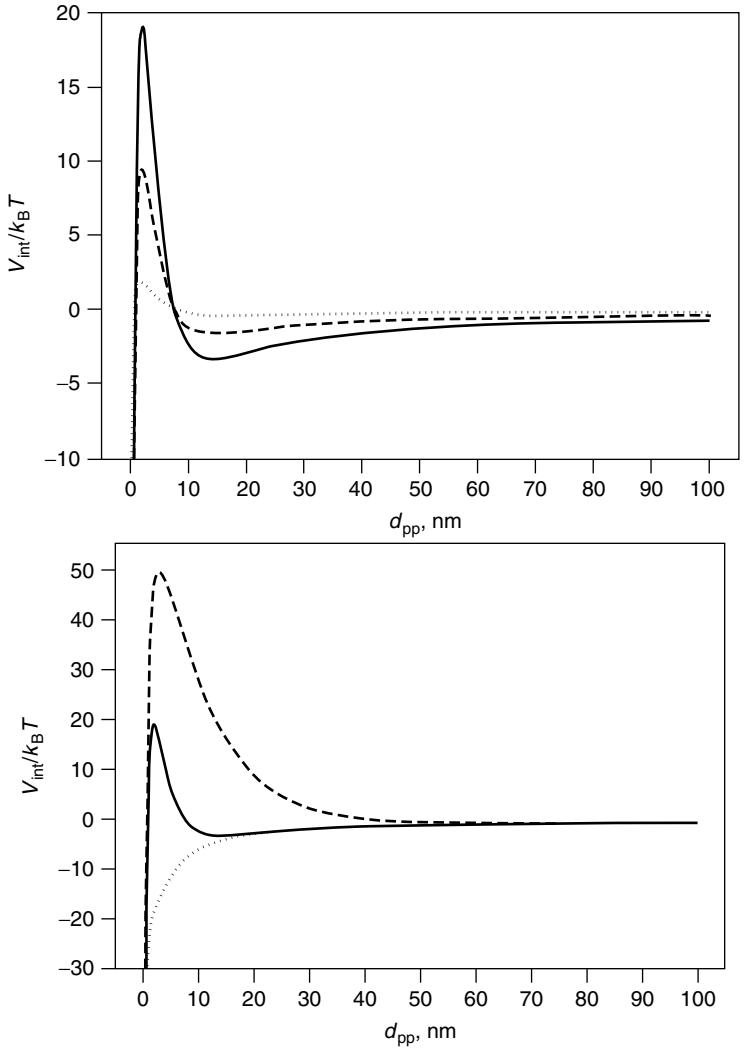

Fig. 30. (**a**) Interaction potential of charged stabilized particles calculated according to equations (37a–c) for particles of different size. Other parameters: $\Phi = -45$ mV, $C_{salt} = 1 \times 10^{-2}$ M, $A_{eff} = 6 \times 10^{-20}$ J. — $D = 100$ nm; --- $D = 50$ nm; (10) $D = 10$ nm. (**b**) Interaction potential of charged stabilized particles calculated according to equations (37a–c) for particles at various ionic strengths in the continuous phase. Other parameters: $\Phi = -45$ mV, $D = 100$ nm, $A_{eff} = 6 \times 10^{-20}$ J. — $C_{salt} = 10^{-2}$ M; $\cdots$ $C_{salt} = 10^{-1}$ M; --- $C_{salt} = 10^{-3}$ M;

local shear field. The kinetic energy of the particles can be approximated by equation 38, where ρ_{dp} is their density and v_{rel} is the relative velocity in collision, which is proportional to the shear gradient.

$$E_{kin} = \frac{1}{2} D^3 \rho_{dp} v_{rel}^2 \tag{38}$$

The important conclusion for heterophase polymerization where shear fields are applied is that in the case of electrostatically stabilized particles the tendency to coagulation increases with both increasing stirrer speed and particle size (particle mass). Furthermore, purely electrostatically stabilized particles are more stable in dispersion media of high permittivity (polar liquids or water) against orthokinetic flocculation.

Stabilization by Tethered Polymers. As discussed in the case of lyophilic colloids, interactions between the polymer forming the dispersed phase and the dispersion medium may contribute considerably to stability. This means that polymers that are able to interact with both the continuous phase and the particles can act as stabilizers as well. If the lyophilic groups are uncharged, it is called *steric stabilization* (288,290) and if these groups are charged it is called *electrosteric stabilization*. Polymer dispersions that are stabilized by either kind of polymers possess very special properties. Particles of this kind consist of a polymeric core surrounded by a stabilizer layer of the thickness ΔR. Inside this layer the concentration of lyophilic polymer per unit volume is $C_{S,L}$. The origin of the stability can be enthalpic or entropic or a combination of both and is theoretically treated within the framework of polymer solution theories. If the continuous phase is a nonpolar liquid and the interactions with the stabilizing polymer are only weak, stabilization is dominated by entropic effects (configurational entropy). In contrast, enthalpic effects are more important in polar continuous phases. A simplified discussion just to outline the principles is given below. It is based on a consideration of the change in the energy of mixing of the soluble polymer in the overlap region of approaching particles, where the concentration of lyophilic polymer is $2C_{S,L}$. This increase in concentration gives rise to an osmotic force, sucking in continuous phase liquid into the overlap region and pushing the particles away. A steric repulsion potential can be formulated as in equation 39, (290,305).

$$V_{st} \propto \frac{C_{S,L}^2}{v_{cp}\rho_{S,L}^2}\left(\Psi_1 - \chi_{S,cp}\right)\left[\left(\Delta R - \frac{d_{pp}}{2}\right)^2\left(3\frac{D}{2} + 2\Delta R + \frac{d_{pp}}{2}\right)\right] \tag{39}$$

In equation 39, v_{cp} is the molar volume of the continuous phase, $\rho_{S,L}$ is the density of the lyophilic polymer, Φ_1 is an entropy parameter for mixing of the overlap region, and $\chi_{S,cp}$ is the interaction parameter between the lyophilic polymer and the dispersion medium. The interaction of the stabilizer layers on approaching particles gives rise to large repulsive forces, which start to act suddenly. However, any change in the solution state of the lyophilic polymer leads to an influence on the stability of the dispersion. In this sense an important parameter for steric stabilization is the temperature. The stabilizing ability of lyophilic polymers can be lost if the temperature is close to their critical solution temperature where the molecules start to become lyophobic. A similar situation can occur in the case of aqueous dispersions upon the addition of electrolytes when the interaction between polymer and continuous phase molecules is decreased with increasing ionic strength. Donald Napper and co-workers have carried out an intense investigation of the thermodynamics of steric stabilization (304). Whether or not flocculation occurs upon changing the thermodynamic conditions of the stabilizing polymer

depends on the change in the free energy. ΔG_f, the free energy describing the flocculation process (cf eq. 40), must be positive to ensure stabilization (that is, flocculation is thermodynamically not favored), and if it becomes negative, the dispersion will flocculate.

$$\Delta G_f = \Delta H_f - T\Delta S_f \tag{40}$$

Equation 40 quantifies the above statement that both enthalpic and entropic effects contribute to steric stabilization, that is, one can easily find conditions when either ΔH_f or ΔS_f or both at a given T and pressure lead to $\Delta G_f > 0$. Flocculation is thermodynamically impossible if ΔH_f is positive and ΔS_f is negative. This is called combined enthalpic–entropic stabilization and is observed in dioxane–water and methanol–water mixtures as the continuous phase for dispersions stabilized with poly(vinyl alcohol) and poly(ethylene glycol), respectively. If the magnitude of $T\Delta S_f$ is larger than that of ΔH_f and both ΔS_f and ΔH_f are negative, it is called entropic stabilization because the large negative entropy causes stability. However, entropically stabilized systems may flocculate upon cooling as ΔG_f might become smaller than zero. In the case of an enthalpically stabilized system, which might become unstable upon heating, the magnitude of ΔH_f is larger than that of $T\Delta S$, and both ΔH_f and ΔS_f are greater than zero. The stabilization of dispersions in toluene or *n*-heptane with polystyrene and poly(12-hydroxy stearic acid), respectively, is entropic,. whereas poly(vinyl alcohol) in 2 *M* sodium chloride aqueous solution and polyisobutylene in 2-methylbutane act as enthalpic stabilizers. Note that poly(ethylene glycol) can act in entropic, enthalpic, and combined stabilization in methanol, 0.48 *M* aqueous magnesium sulfate solution, and methanol–water mixture, respectively.

Depletion Interactions. A polymer need not necessarily be adsorbed to impart stability to a colloidal dispersion. This kind of interaction, is described as depletion interaction, emphasizing the nonadsorbed (or the depleted particle–water interface) state of the lyophilic polymers. The interaction between dispersed particles and dissolved polymers can be described by means of phase diagrams showing regions of stability and instability depending on the concentration and size of both species. Again a simple but vivid picture can be used to explain the principle of this kind of interaction. The action of dissolved polymers on dispersed particles depends on two characteristic lengths: the size of the dissolved polymer (D_{ee}) and the average distance between the particles (d_{pp}, cf above). If $d_{pp} \gg D_{ee}$, that is a stable situation as the particle density is low and both particles and polymers move freely in the continuous phase. If the particle concentration increases and d_{pp} decreases such that $d_{pp} > D_{ee}$, a situation may possibly be reached where the local concentration of the polymer in the vicinity of two particles is higher than that in a region of lower particle density. Thus, an osmotic force arises, and in order to dilute this region, continuous phase fluid soaks in and pushes the particles apart. However, if $D_{ee} > d_{pp}$ and the concentration of dissolved polymer is larger outside an interstitial volume between particles, the flux of continuous phase fluid, which tries to dilute the local high polymer concentration, presses the particles together and hence, leads to coagulation of the dispersion. An analogous situation to depletion interaction, purely entropically driven, might also exist in neat colloidal suspensions of hard monodisperse spheres, that is, in good

approximation in purely nonionically stabilized particles possessing cutoff or hard repulsive potential. In the case of such particles, a higher degree of order must not necessarily mean a loss of entropy. In random close packing at space filling of 64%, direct contact between the particles occurs. In contrast, in a crystalline hexagonal arrangement at maximum space filling of about 75%, free volume exists between the particles and hence, each sphere has freedom of movement (mainly rotation). This entropy of the free volume outweighs the configurational entropy (with regard to the sphere center) at 54.5% space filling and crystallization starts purely driven by the gain of configurational entropy. In a mixture of a few large and many small spheres (a situation that is comparable with the above particle plus dissolved polymers) both entropy-driven attraction and repulsion can occur. Around each large sphere is an excluded volume for the smaller particles with a thickness of their size. If the distance between the larger spheres is below the size of the smaller spheres, the excluded volume regions can overlap and hence, the effective volume for the smaller spheres is increased by Δv_c, which causes an entropy gain $\Delta S_{sl} = k_B N_{ss} \ln[(v_c + \Delta v_c)/v_c]$, where v_c is the volume of continuous phase and N_{ss} the number of small particles. This entropy gain causes a decrease in the free energy and the existence of an attractive force for the larger particles. In the reverse case, if the distance between the larger drops is greater, then an entropic repulsive force exists. This is because before another particle fits in the gap the volume of continuous phase has to increase and then it might be larger per particle within the gap than outside. This again causes a gain in entropy and a loss in free energy (307). Obviously, dissolved polymers with large D_{ee} can lead to so–called bridging flocculation if they are able to strongly interact with colloidal particles. Such processes are carried out commercially in breweries or in wastewater treatment facilities with water-soluble polymers prepared by means of heterophase polymerization in organic media.

Combinations of Electrostatic and Steric Stabilization. From the application point of view in heterophase polymerizations, steric stabilization does not require the presence of high molecular weight polymers and can also be realized by low molecular weight nonionic stabilizer based on poly(ethylene glycol) as hydrophilic groups (low molecular weight means a molar mass below 10^3–10^4 g/mol). The simplest case, which indeed is frequently applied, is the joint application of ionic and nonionic low molecular weight surfactants. Advantage can be taken from the fact that the combination of electrostatic and steric stabilization gives on the one hand additional stability at low electrolyte concentrations and on the other hand the dispersion remains sterically stabilized at higher electrolyte concentrations (290). The effect of steric stabilization caused by adsorbed poly(ethylene glycol) chains has been clearly demonstrated by Napper and co-workers (308,309). The remarkable results of these studies are as follows: First, the critical coagulation concentration of sterically stabilized poly(vinyl acetate) dispersions against magnesium sulfate is increased by two orders of magnitude compared with purely electrostatic stabilized dispersions (3.9×10^{-1} versus 6.2×10^{-3} M $MgSO_4$ at 298 K). Second, for poly(vinyl acetate) latexes with diameters between 30 and 230 nm stabilized with poly(ethylene glycol) moieties (chain length of about 220), the point of incipient flocculation is independent of the particle size. Third, the electrolyte stability of particles stabilized jointly by electrostatic and steric components is governed by the steric contribution. Moreover, the flocculation conditions

are independent of the poly(ethylene glycol) chain length. Fourth, if once flocculated sterically stabilized particles can easily be redispersed if the conditions that have caused flocculation are removed, provided the stabilizer is strongly adsorbed. In other words, dispersions with only poorly anchored steric stabilizers may be flocculated more easily and may not be redispersed. Fifth, increasing the molecular weight of the steric stabilizer can kinetically retard the displacement of weakly anchored stabilizer. Sixth, both nonaqueous and aqueous dispersions stabilized with polymers require for stability that the continuous phase liquid is better than a Θ solvent for the stabilizing chains. This is the application of Bancroft's rule and later refinements (cf above) to polymeric stabilizers. Compared with low molecular weight surfactants, polymers possess more degrees of freedom regarding the modification of their properties. There are many possibilities, such as the molecular weight or molecular weight distribution and in the case of random copolymers their composition and the distribution of chemically different groups along the chain. Block copolymers can offer additional possibilities with regard to various architectures such as linear block copolymers, or star-shaped block copolymers, or graft block copolymers. Furthermore, polymers can stabilize dispersions via all stabilization mechanisms (electrostatic and steric stabilization) and offer additional possibilities by a combination of various mechanisms in a single molecule. In the sense of combined stabilization, block copolymers made of one polyelectrolyte and one strong anchor block offer another possibility of so–called electro–steric stabilization absent in the above simply joint application of both ionic and nonionic stabilizers. A great deal has been done during the last few years with regard to both theoretical and experimental investigations of the behavior of polyelectrolytes on surfaces in dependence on various parameters such as concentration, chain length, geometry of the surface, and the ionic strength (C_{salt}) in the continuous phase. The use of such block copolymers with strong acid groups (such as sulfonates) as stabilizers in aqueous heterophase polymerization has, compared with poly(carboxylic acid) blocks, the advantage that the stability is practically independent of the pH. Pincus derived, for strong polyelectrolyte tethered to spherical particles and forming a corona of thickness ΔR, a scaling relation that predicts a dependence of $\Delta R \propto C^{\alpha}{}_{\text{salt}}$, with $\alpha = -1/5$ (310). This relation predicts an extraordinary electrolyte stability compared with low molecular weight stabilizers, which show an exponential dependence on the ionic strength (cf equations 37a–37c). Indeed, the extraordinary stability against electrolytes was experimentally observed for various types of polyelectrolyte block copolymers such as poly(alkyl methacrylate-*b*-sulfonated glycidyl methacrylate) (311) but also for poly(ethyl ethylene-*b*-styrene sulfonate) (312) as stabilizers for polymer dispersions. Moreover, in the latter case a Pincus brush behavior ($\Delta R \propto C^{\alpha}{}_{\text{salt}}$) was observed but with clear experimental evidence that the exponent α depends on the ratio of corona thickness to particle size. If the ratio $2\Delta R/D$ is lower than 0.7, α is about -0.1, but at larger corona thickness in relation to particle size, the Pincus behavior ($\alpha = -0.2$) is observed (313). A shrinkage of the corona with over several orders of magnitude increase in ionic strength was also observed for triblock copolymer particles composed of poly(styrene sulfonate-*b*-*N*-isopropyl acrylamide-*b*-styrene), which were directly prepared by heterophase polymerization as described in Reference 48. Furthermore, experimental evidence is given that the shrinkage of the corona is directly related to the polyelectrolyte

behavior of the poly(styrene sulfonate) hairs because in case of nonionic sterically stabilized particles of poly(ethylene glycol-*b*-*N*-isopropyl acrylamide-*b*-methyl methacrylate), the corona thickness remains unchanged under the same conditions.

Optimum Stabilization and Heterophase Polymerization Technique. In summary, effective stabilization of particles during heterophase polymerization requires, besides some theoretical knowledge in physical and polymer chemistry, a lot of experience also and is always dependent on to the particular polymerization process. Aqueous and nonaqueous heterophase polymerizations require not only different stabilization mechanisms but also different stabilizers. Another expression of Bancroft's rule of thumb for emulsions that are for many heterophase polymerizations the starting point is that the liquid with the highest solubility for the stabilizer forms the continuous phase wherein the other liquid is dispersed. In principle, there are no limitations for the choice of a stabilizer for heterophase polymerizations if only the above general rules are complied—anionic, cationic, amphoteric, or nonionic, monomeric or polymeric, organic or inorganic, linear or branched, comb-like or star-like all, reactive or nonreactive, single or mixed systems, monofunctional or multifunctional, naturally occurring or synthetic—and even colloidal solid spheres have been applied as stabilizers. In the case of colloidal solid spheres, so–called Pickering stabilizers, which have practical meaning for suspension polymerizations, the starting emulsion is a three-phase rather than a two-phase system. The interaction between a Pickering stabilizer and the continuous phase is expressed by means of the contact angle. Droplets of a second liquid are stabilized in a continuous phase if the contact angle between the continuous phase and the sphere is below 90°, whereas if the contact angle is above 90° the inverse emulsion is preferably formed (314,315). During heterophase polymerizations, as well as during storage of the dispersions, stabilizers are needed to maintain the colloidal state and to guarantee the maximum possible benefit from that state. However, during the final application when the colloidal state is no longer needed, they may lead to problems as they are in general not compatible with the polymer produced. For example, in case of hydrophobic coatings made from aqueous polymer dispersions, low molecular weight stabilizers have a tendency to assemble in hydrophilic domains and finally can cause failure of the coating. One strategy to solve this problem is the use of stabilizers that are fixed in place. This is possible either by the use of polymeric or reactive surfactant that can participate in the polymerization reaction. A summary of recent developments in this field where a great deal has been done during the last decade can be found in Reference 316. Recently, the possibility of tailoring polymeric surfactants has been demonstrated as poly(ethylene glycol-*b*) (partly sulfonated olefin) have been synthesized and successfully applied as stabilizers in aqueous heterophase polymerization. These polymeric stabilizers combine all kinds of stabilization mechanisms in one molecule, that is, electrostatic, steric, and electrosteric stabilization together with reactivity in radical polymerization (152). The development of stabilizers for heterophase polymerization is an ongoing topic. But, for any new surfactant or stabilizer one faces with the problem that it is only an auxiliary material that has to meet strict cost requirements and has to improve existing solutions in two, frequently contradictory, fields, that is, during polymerization and during application of the solid products.

Copolymerization

The majority of polymers prepared by heterophase polymerizations are copolymers. Copolymerization is an effective way to tailor polymer properties for a variety of applications with only a limited construction set of monomers. The hierarchical or modular assembly of polymer dispersions, which goes in descending order with regard to size from dispersion via particles to polymer molecules and finally to monomer units offers almost unlimited possibilities to tailor required properties. For general considerations concerning copolymerization mechanism, the reader is referred to standard textbooks such as References 317–319 (see also BLOCK COPOLYMERS and GRAFT COPOLYMERS). In general, the composition of the copolymer chain is a function of the reactivity ratios and of the instantaneous concentrations of the monomers at the reaction loci. Considering a binary copolymerization, which means that there are two kinds of growing chains, one ended with a radical of monomer 1 (P_1) and the other ended with a radical of monomer 2 (P_2), equations 37b as defined below are frequently used. In these equations f_1 and f_2 are the mole fractions of monomers 1 and 2, respectively, at any time in the reaction loci ($f_1 + f_2 = 1$), F_1 and F_2 are the mole fractions of monomer 1 and 2, respectively, in the copolymer formed at that time ($F_1 + F_2 = 1$), M_1 and M_2 are the monomer concentrations of both monomers in the reaction loci at any time, r_1 and r_2 are the reactivity ratios, k_{11}, k_{22} , k_{12}, and k_{21} are the rate constants for the possible four propagation reactions $P_1 + M_1$, $P_2 + M_2$, $P_1 + M_2$, and $P_2 + M_1$, respectively.

$$F_1 = \frac{(r_1 - 1)\, f_1^2 + f_1}{(r_1 + r_2 - 2)\, f_1^2 + 2\,(1 - r_2)\, f_1 + r_2} \qquad r_1 = \frac{k_{11}}{k_{12}} \qquad r_2 = \frac{k_{22}}{k_{21}} \tag{41}$$

F_1 and F_2 are the instantaneous copolymer compositions and depend on the particular conditions at a given time in a given reaction loci in the heterogeneous reaction system. The overall or cumulative copolymer composition is the sum over all times and reaction loci, and may be different from that obtained in a homogeneous reaction system. The application of equations 41 for heterophase polymerization requires the knowledge of the relative concentrations of both monomers in the reaction loci or their partitioning behavior between the different phases. An additional complication arises from the fact that heterophase copolymerization is carried out with monomers that differ markedly in their solubility in the different phases. For instance, in many industrially important emulsion polymerizations, acrylic or methacrylic acid is used as comonomer to impart useful properties to latex particles during polymerization and application. This means that the composition of the monomer mixture in water and in the monomer-swollen polymer particles differs considerably. Thus, the composition of the copolymers formed in both phases differs as well. Wang and Poehlein investigated the composition of cooligomers formed during styrene–acrylic acid batch emulsion copolymerization (318). The cooligomers were isolated by precipitating a dioxane solution of dried latex samples in an excess of water (1/15 v/v). After separating the precipitated copolymer the water phase was dried and the residual solids (a mixture

[a]Polymerizations at 50°C with SDS as stabilizer and potassium peroxodisulfate as initiator 320; 1: styrene; 2: acrylic acid; MW: molecular weight without end groups, in g/mol; n_1, n_2: number of styrene and acrylic acid units per cooligomer.

of cooligomers, inorganic salts, and emulsifier) were dissolved in ethanol in order to isolate the cooligomers. They found that the composition of these products depends, besides on the starting monomer ratio, mainly on the presence or absence of seed particles. The data are summarized in Table 15 with the same abbreviations as used for equation 41. The values for f_1 and f_2 refer to the overall concentrations in the reactor and not to the reaction locus, which is the aqueous phase. These data confirm on the one hand the importance of identifying and characterizing the particular reaction loci in heterophase copolymerizations and on the other hand the necessity to carry out future work in order to understand the role of reactions in the continuous phase that are crucial although only a minor part of all monomers is converted there. Despite these problems, it is proved in many examples that the main reaction locus in heterophase polymerization is the monomer-swollen dispersed phase, and if the concentration of monomers in the whole reaction system is allowed to adjust according to the partition coefficients and f_1/f_2 can be estimated in the reaction locus, then there is good agreement between experimental and calculated compositions using equation 41 and r values derived from homogeneous kinetics. This is the case even for monomers with huge differences in their water solubility, such as styrene and acrylonitrile, as long as monomer droplets are present (321). For further information on emulsion copolymerization, the reader is referred to References 322–324. It is the general case for batch polymerizations that $F_1 \neq f_1$, that is, both monomers are not consumed with equal rates, which means that the less reactive monomer will be accumulated in the remaining monomer mixture as the reaction proceeds. In the case of an azeotropic point in the F_1–f_1 diagram, the mutual reactivity of both monomers changes, that is, if $F_1 > f_1$ the monomer 1 is more reactive, whereas if $F_1 < f_1$ the monomer 2 is more reactive. Thus, the composition of the copolymer is shifted, or a composition drift occurs, during copolymerization in accordance with equation 41. This composition drift cannot be avoided during batch or discontinuous heterophase copolymerizations where the monomers are fed into the reactor only at the beginning. However, the shift in the copolymer composition can be compensated if proper feeding strategies are applied. If the goal is constant copolymer composition throughout the whole reaction, the monomers have to feed into the reactor according to their consumption. In order to do so it is very

helpful to know the instantaneous copolymer composition or the f values in the reaction loci. For instance, the f values can be determined by gas chromatography (321), and the cumulative copolymer composition by nuclear magnetic resonance spectroscopy (325), from which the instantaneous copolymer composition can be deduced. Both methods need much longer times to deliver results than the characteristic growth time of a copolymer molecule, which is on the order of a minute (cf above). Notwithstanding these difficulties a lot of experimental data is a prerequisite for successful modeling. An example is the work of Jean Guillot on emulsion copolymerization (326). Starting from monomer-swollen particles as the main reaction loci he examined two possibilities to calculate f values. The first approach is based on experimental partition coefficients and the second on more general consideration with regard to thermodynamics of polymer solutions. Another way to control heterophase polymerization reactors is based on mathematical modeling in connection with reaction calorimetry, which means in the simplest case monitoring reactor temperature. To combine copolymer composition with reactor temperature control is of special benefit for large-scale, industrial reactors owing due to the exothermic polymerization reaction. A summary of possibilities to control emulsion polymerization reactors can be found in References 327–330. Composition control is by far more complicated in heterophase copolymerizations because of the more compartmentalized nature than in homogeneous copolymerizations. This situation may tempt researchers to the question whether it will ever be possible to model heterophase copolymerizations. Some of the problems toward satisfying models of emulsion copolymers, especially with respect to obtaining reliable kinetic constants and other model parameters, have been discussed in an overview paper by van Herk and German (331). As accurate, detailed models to solve the problem are not available today a possible way out is the use of hierarchical fuzzy-logic model based controllers as described for styrene–butadiene emulsion copolymerization in Reference 332 or neural networks as developed for a batch polymerization of methyl methacrylate (333). From the point of view of materials science, heterophase copolymerization is extremely important because it is the method of choice to tailor application properties of polymer dispersions and that of the products made thereof. Mechanical properties of the polymers such as glass-transition temperature or film formation temperature, elasticity, durability, tensile strength, water uptake, adhesion, light resistance, or solvent resistance, and also colloidal properties such as stability against electrolyte or temperature changes (freeze–thaw stability), surfactant adsorption, or interaction with pigments and other fillers are influenced by copolymer composition in the particle interior and on the surface, respectively. The diversity of monomers allows the preparation of polymers with desired glass-transition temperatures, somewhere in between 150 and -100°C by radical heterophase polymerization techniques (cf T_g values of homopolymers in Table Table 16). Provided the copolymerization behavior is known, the comonomer mixture to realize a particular glass-transition temperature can be approximated fairly well from the T_g's of the homopolymers according to equation 42, where the w's are weight fractions of the monomers in the random copolymer.

$$\frac{1}{T_g} = \sum_i \frac{w_i}{T_{g,i}} \tag{42}$$

Equation 42 is an empirical relation, which is based on the experimental observation that the T_g values of a binary copolymer ($i = 2$) vary monotonically with composition. T_g values are important because they determine many application properties of polymers and in relation to the application temperature whether it is rubbery or glassy. In case of film formation and coatings applications of polymer dispersions, the T_g values determine at which temperature interdiffusion of polymer molecules across particle boundaries can start. Besides this application as building blocks for the main polymer (which is a random copolymer) comonomers are also applied to act with the aim either to contribute to colloidal properties or to allow subsequent chemical reactions. Monomers frequently employed in radical heterophase polymerizations are put together in Table 17. The monomers listed in Tables 9, 10, 16, and 17 suggest that there is an almost infinite number of combinations that can be applied in radical heterophase copolymerizations.

The individual comonomers used in a particular comonomer mixture employed in commercial heterophase polymerization have to fulfill different tasks. The main monomers, ie the monomers of greater molar portion in the copolymers are responsible for the mechanical properties such as glass-transition temperature, film formation temperature, mechanical strength, elasticity, and so on. Functional monomers, which are only a minor part of the monomer mixture, have nevertheless to fulfill important tasks. They are in most cases more lyophilic than the main monomers and hence may contribute to latex stability. The most important examples in this sense, for aqueous continuous phases, are carboxylic acid monomers, with several benefits. These groups can exist in both ionized and un-ionized form; depending on pH, their copolymers contribute in ionized form to colloidal stabilization as electrosteric stabilizers; they can be used to adjust dispersion viscosity in dependence on pH; in case of latex paints they improve adhesion as well as incorporation of pigments; and finally carboxylic acid groups are available as reactive sites for further reactions. Possibilities to carry out reaction either between particles or polymer molecules are crucial for a variety of applications. One of the technically important fields for post-polymerization reactions is cross-linking of the polymer during film formation in order to increase the properties of coatings (259,332–336). With regard to chemical diversity there are virtually no limitations in heterophase polymerization for reactive groups.

Some of the most important reactive groups used as cross-linking sites in latex paints are listed in Table 18, together with some additional information regarding reaction conditions (cf Table 17 also for functional comonomers).

Particle Morphology

The development of inhomogeneous particle morphology is certain to happen in all kinds of heterophase polymerizations, not only with regard to the molecular weight of the polymers formed at different times during the polymerization but also with regard to chemical composition. This radial distribution of properties from the core to the periphery of the particles is a direct consequence of the heterogeneous nature of the reaction system and cannot be avoided. Driving forces are differences in the compatibility caused by enthalpic or entropic effects of various species, which differ either with regard to size or composition. In this sense hydrophilic and hydrophobic groups tend to assemble at the particle water interphase and in the interior of the particles, respectively. Consequently, the question arises to what extent a particular particle morphology represents an equilibrium structure. This is mainly governed by the mobility of the chains and hence, on the particular polymerization conditions such as T_g of the polymer, polymerization temperature, degree of swelling, degree of polymerization, and whether cross-linking occurs or not. In other words, the particle morphology is basically determined by competition between thermodynamic and kinetic factors during the particular heterophase polymerization process. Modeling morphology development during particle growth is complicated mainly by difficulties in treating the mobility of the polymer chains inside the particles in a proper way. During homopolymerization the situation is comparatively easy, as on the one hand low molecular weight species try to stay in place in less dense parts of the particle where they can gain more configurational entropy, and on the other hand hydrophilic end groups try to reach the aqueous phase in order to minimize

interaction energy. The situation is different for composite particles, where the interaction energy must be additionally considered; this is mainly the interfacial energy between chemically different components. Torza and Mason (339) pioneered this type of investigation when they determined the final morphology of a three-component heterophase emulsion (three mutually immiscible liquids, where mobility effects play no major role) by minimizing the interfacial free energy given by equation 43.

$$\Delta G_{\mathrm{I}} = \sigma_{1,2}A_{1,2} + \sigma_{1,3}A_{1,3} + \sigma_{2,3}A_{2,3} \tag{43}$$

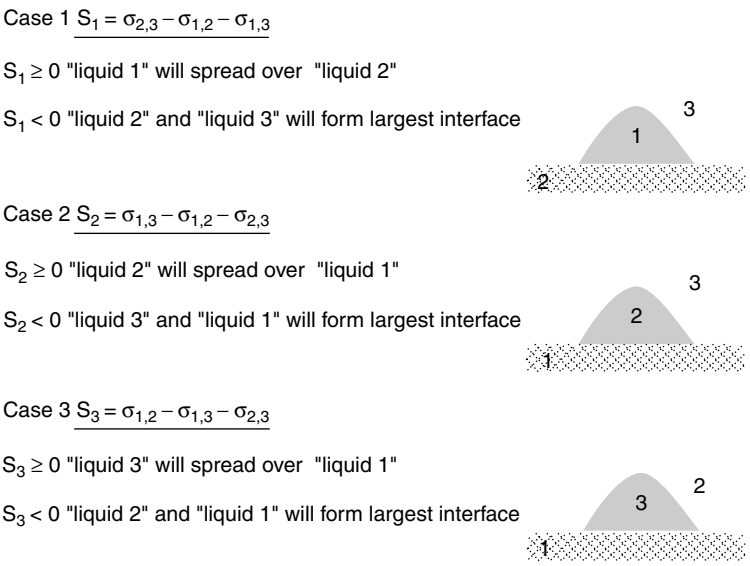

Fig. 31. Illustration of the spreading-coefficients approach to determine the thermodynamically favored morphology by means of the wetting picture, where a drop (gray) sits on a surface (patterned) both surrounded by a third component (white).

The σ's are the interfacial tension and the A's are the interfacial area between the liquids 1, 2, and 3. The conventions were made that phase 1 is chosen so that $\sigma_{1,2} > \sigma_{2,3}$ (which means that $S_1 < 0$), and that liquid 2 forms the continuous phase in which drops of both liquid 1 and liquid 3 are present. The analysis has been carried out by means of spreading coefficients for each liquid (S), which are defined by equation 44 and illustrated in Figure 31 by means of the well-known phenomenon of wetting. In this sense spreading coefficients greater than zero mean the drop wets the surface and forms a thin film, while for negative S's the liquid forms a lens, and interfacial contact between all three phases is thermodynamically favored. Spontaneous spreading or wetting means that the contact angle between the corresponding phases is zero and that the spreading molecules adhere to the substrate molecules more strongly than they cohere with one another.

$$S_1 = \sigma_{2,3} - \sigma_{1,2} - \sigma_{1,3} \quad S_2 = \sigma_{1,3} - \sigma_{1,2} - \sigma_{2,3} \quad S_3 = \sigma_{1,2} - \sigma_{1,3} - \sigma_{2,3} \tag{44}$$

Knowing the spreading coefficients it is now possible to predict thermodynamically favored morphologies. The predicted morphologies in Table 19 are easy to imagine with the information in Figure 31. According to the above convention that liquid 2 forms the continuous phase and $S_1 > 0$ is excluded, there are only three equilibrium morphologies possible, that is, core shell, single drops, and partial engulfing. This analysis revealed that the interfacial tensions between the phases are key factors that govern the final morphology. For practical applications, equilibrium interfacial tensions, for which one nneds to consider mutual

Table 19. Effect of Spreading Coefficients (Interfacial Tensions) on Mixed Particle Morphology[a]

Spreading coefficient	Largest interface between liquids	Spreading	Resulting morphology

[b]Either no interface is formed or no spreading occurs.

solubilities and swellabilities of all components, must be used because initial spreading can be very different from equilibrium spreading. According to equation 43, it is necessary to also consider the interfacial areas with regard to minimizing the free energy. In other words, the final morphology also depends on the relative amounts of the components. Methods to estimate the morphology in dependence on both the interfacial tensions and the volume fractions of the dispersed phases were developed and applied by several groups such as Sundberg (340–344), Törnell (345,346), El-Aasser (347,348), and Waters (349) to tailor particle morphology. The results can be summarized as follows. In order to determine the thermodynamically favored morphology, which is that with the lowest free energy, it is necessary to compare ΔG_1 for as many as possible morphologies. To show the principle, two simple cases are considered in context with Figure 31. The continuous phase is formed by liquid 2; lyophobic liquid 3 is present in the form of seed particles, with size D_3; and lyophilic liquid 1 is added to form composed particles of size D_t as a result of interaction with the seed particles. First, the change in free interfacial energy for the formation of normal core shell particles ($\Delta {G_1}^{cs}$) with the lyophilic liquid 1 forming the shell is given by equation 45. This is the normal or expected core shell morphology because the lyophilic phase forms the shell. The reference or starting free energy state is that for the lyophobic seed particles, which also forms the core in the final particles.

$$\Delta G_I^{cs} = \sigma_{1,3}\pi D_3^2 + \sigma_{1,2}\pi D_t^2 - \sigma_{2,3}\pi D_3^2 \tag{45}$$

It is advantageous to reduce $\Delta {G_1}^{cs}$ by $\Pi \times {D_3}^2$ and to ascribe the change in the free energy per unit area of seed particles to interfacial tension. This leads to equation 46.

$$\frac{\Delta G_{\mathrm{I}}^{\mathrm{cs}}}{\pi D_3^2} = \Delta\sigma^{\mathrm{cs}} = \sigma_{1,3} + \sigma_{1,2}\frac{D_{\mathrm{t}}^2}{D_3^2} - \sigma_{2,3} \tag{46}$$

Second, the reduced free energy change for the formation of inverted core shell particles (α) with the lyophobic liquid 3 and the lyophilic liquid 1 in the shell and the core, respectively, leads to equation 47. Note that the same reference state is assumed as above.

$$\Delta\sigma^{\mathrm{ics}} = \sigma_{1,3}\frac{D_1^2}{D_3^2} + \sigma_{2,3}\frac{D_{\mathrm{t}}^2}{D_3^2} - \sigma_{2,3} \tag{47}$$

Equations 46 and 47 clearly show the influence of the amount of material forming a particular phase on the thermodynamically favored morphology. It is possible to consider simple morphologies other than these and examples can be found in References 340–349. The sizes of the phases can be expressed as volume fractions, leading to equations, that are independent of particle size. The crucial point to use this type of equations in predicting particle morphology is to get reliable data for the various surface tensions. In general, these results mean for aqueous two-stage heterophase polymerizations that the more hydrophilic polymer that has the lower interfacial tension to water tends to form the particle shell (normal core–shell structure). This is absolutely true from the thermodynamic point of view but the influence of the particular polymerization conditions can lead to a variety of morphologies in between such as raspberry-, sandwich-, or acorn-like structures, or occlusions ("salami"-like structures), and even inverted core-shell structures are possible.

The influence of the polymerization procedure was demonstrated impressively in a series of experiments carried out by Lee and Rudin (350). The authors showed that if styrene is polymerized onto poly(methyl methacrylate) seed particles under conditions maintaining a high core viscosity or low mobility, that is, with a redox initiator at low temperatures with a slow monomer feed (no swelling), composite particles with an inverted core-shell morphology are formed, as the more hydrophilic poly(methyl methacrylate) should, from a thermodynamic point of view, form the shell. In contrast, if the polymerization is conducted in a way that favors higher mobility in the seed particles (no monomer feed but batchwise monomer addition with swelling of the seed particles before initiation with potassium peroxodisulfate at 60°C), the result is a salami-like morphology showing occlusions of polystyrene subparticles and that large parts of the poly(methyl methacrylate) core have been moved at the water interface. The morphology formation in the course of heterophase polymerization in seed particles swollen with a second-stage monomer is extremely interesting, as phase separation and nucleation processes take place either consecutively or in parallel. These processes are influenced strongly by polymerization kinetics and thermodynamics of phase separation and hence, the final morphology is determined by the chain mobility inside the particles, which to some extent is the result of a competition between thermodynamics and polymerization kinetics. Note that, whereas the influence of polymerization kinetics ends sometime or other, thermodynamics acts as long as the particles exist. Indeed some authors describe change in particle morphology

during storage of polymer dispersions (344). An interesting approach to model this behavior is described by Gonzales-Ortiz and Asua in a series of papers (351–353). They treated the polymerization of monomer 1 in seed particles of polymer 2. Phase separation leads to the formation of clusters. The motion of the clusters inside the particles is determined by a balance between van der Waals and viscous forces. Furthermore, cluster coalescence is allowed and polymerization is assumed to take place in both domains inside the particles. The authors simulated methyl methacrylate polymerization in polystyrene seed particles and found that the final particle morphology depends strongly on the polymerization kinetics and that the slower the rate of polymerization, the closer the final morphology is to the equilibrium structure. The formation of particles with a particular morphology is not only impossible to avoid but is moreover an advantage of heterophase polymerization processes, because by means of controlling morphology formation application properties can be tailored to very specific needs.

The following examples of practical importance should illustrate these possibilities for aqueous heterophase polymerizations. In this case it is practically impossible to avoid the concentration of hydrophilic groups at the particle–water interface, which means that it is difficult not to build up particles with a core–shell structure. Hydrophilic groups can arise from initiators or comonomers, or sidereactions such as hydrolysis of ester groups in monomers [acrylic or methacrylic acid ester monomers or vinyl acetate cf (93)] or oxidation reaction in the aqueous phase in connection with initiator decomposition (92,237,354–356). The first example is comonomers with functional groups, which are mostly of polar, hydrophilic character (cf Table 18) and which are employed in concentrations of a few percent relative to the main monomers in order to prepare polymer molecules with reactive sides for post-polymerization modifications such as cross-linking to increase mechanical properties of coatings. It might be of interest to control the distribution of these comonomers over the entire particle volume rather than to have them accumulated at the particle–water interface. There are two general and one specific possibility to do so in dependence on the properties of the hydrophilic comonomer (cf (337,357,358). The first of the general possibilities is the use of main monomers with a higher solubility in water (ethyl acrylate, instead of butyl acrylate, for instance, cf Table 9) leads to the formation of more hydrophobic copolymer with these reactive comonomers and favors a more equal distribution in the particle volume. The second general possibility is the control of the hydrophilic comonomer content in the monomer mixture during feed procedures. The amount of hydrophilic comonomer units at the particle–water interface is the lowest if the whole amount of this comonomer is added at the beginning of the feed process; it is in a middle range if it is equally distributed over the entire feed duration; and it is highest if it is added only at the end of the monomer feed period. The third principle can be additionally applied if the hydrophilicity of the comonomers can be easily controlled, such as in case of carboxylic acid comonomers by changing the pH value. These comonomers are much more hydrophobic in the acid form than in the carboxylated form and hence, at high pH-values they will preferably be accumulated at the particle–water interface. Note that emulsifier adsorption depends strongly on the polarity of the particle-water interface and is the lower with regard to the adsorbed amount the higher the polarity (cf above, Solubility and Solubilization) (255,336,357).

Another example of desired core-shell morphologies are polymer particles composed of regions with different mechanical or optical properties. For instance, impact modifiers for hard and brittle plastic materials are core-shell latex particles with a cross-linked rubbery core and a hard shell. The shell polymer should be identical to the hard material and must be grafted to the rubber core in order to prevent phase separation. Only in this case the modifier particles can effectively absorb tensile stresses and impart additional impact strength. Impact modifiers are used to improve mechanical properties of various commodity polymers such as polystyrene, poly(vinyl chloride), and poly(methyl methacrylate). The problem of impact modification is more complex if the optical properties such as transparency, clarity, and glass-like appearance of the polymeric material should not be changed. This necessitates an adaptation of the refractive indices between the bulk material and the modifier particles. However, the problem is not that easy to solve, as the refractive index is strongly temperature-dependent, especially for particle sizes with good stress-absorbing properties. Making the particles smaller may solve the problem with regard to the temperature dependence of the refractive index but at the expense of a decrease in mechanical properties. The solution of this problem is multilayered particles, where the core and the outer shell are composed of the hard polymer and in between both is the cross-linked rubber layer, which is on the one hand thick enough to impart the required impact modification and on the other hand thin enough to retain unchanged the optical properties over a larger range of temperatures. The morphology can be specifically tailored by multiple arrangements of rubber layers followed by hard polymer layers, where it is unimportant what the core material consists of provided the thickness of the rubber layers is smaller than the wavelength of visible light to ensure only a slight dependence of the refractive index on temperature. However, this example elucidates that it is important to have strategies to prepare well-defined core–shell transitions. In extension of Sütterlin (237), the following conditions can be formulated in order to get well-defined or less-defined shells (Table 20). Note that the preparation of core-shell morphologies requires a heterophase polymerization technique that allows the application of consecutive monomer addition.

A specific core-shell morphology is given when the core is a void (hollow particles), that is, the particle is a porous material. In the dried state these particles

Table 20. Conditions to Prepare Polymer Particles with Shells of Different Properties

Sharp core shell transition	Diffuse core shell transition
Polymerization rate $\gg$ monomer feed rate	Monomer feed rate $\gg$ polymerization rate
Avoid swelling of core polymer	Allow swelling of core polymer
Cross-linked core	Non-cross-linked core
More lyophobic core on more lyophilic shell	More lyophilic core on more lyophobic shell
More incompatible core and shell	More compatible core ad shell
Lower stabilizer concentration	Higher stabilizer concentration
More lyophilic emulsifier	Less lyophilic emulsifier
Lower polymerization temperature	Higher polymerization temperature
More lyophilic initiator	Less lyophilic initiator
Higher initiator concentration	Lower initiator concentration

can be considered as polymer gas (mostly air) composites. From the synthetic point of view it is necessary to distinguish between particles with a single hole and really porous particles consisting of a network of pores and channels. Single hollow particles find for instance application as synthetic low density pigments (due to the large difference of refractive index between polymer and air) in the paint and paper industry or as UV protection filters in cosmetic industry, whereas porous particles find application as the stationary phase in separation processes (chromatography).

There are several ways to make hollow particles. The first way (cf 337,359) is a multistep process, which starts with the preparation of particles with a high content of carboxylic acid groups. These hydrophilic particles are used as seed in a subsequent polymerization and covered with a more hydrophobic shell made of polymer with T_g above the desired service temperature of the composite material. In a next step the pH is increased at a temperature above the T_g of the shell, which causes the particles to swell considerably and to fill with water. This structure can be frozen in by decreasing the temperature again and after drying and dewatering, the carboxylic acid rich polymer in the core collapses onto the shell and air diffuses into the particles. Another possibility of making hollow particles, which is interesting from the general viewpoint of the various possibilities offered by heterophase polymerization techniques, requires the exchange of the continuous phase. Core–shell particles composed of a low molecular weight polymer in the core and a slightly cross-linked shell are transferred from a continuous phase in which both the core polymer and the shell polymer are insoluble into a medium that is a good solvent for the core and a swelling agent for the shell. Under these conditions the core polymer diffuses into the continuous phase if the cross-link density of the shell is properly adjusted and by ultrafiltration the core can be drained (360,361). A summary of the work done over the last decades on preparation of voided particles by encapsulation of an organic liquid, which is a nonsolvent for the polymer, can be found in Reference 362. It is a two-stage process, where the first stage is a batch process leading to encapsulation of a mixed liquid drop with a polymer layer and the second stage is stabilization of the drops by further polymerization in the shell with a monomer feed process containing cross-linking monomers. The formation of the polymer shell surrounding the liquid drops requires low molecular weight polymers and hence the polymerization is carried out in the presence of mercaptans as chain-transfer agents. Shell formation takes place at a certain degree of conversion when the nonsolvent (isooctane) monomer (styrene) mixture becomes a progressively poorer solvent for the polymer (polystyrene). Phase separation takes place predominantly at the drop–water interphase owing to energetic reasons, as the polystyrene–water interfacial tension (32.7 mN/m, cf Table 10) is lower than that for isooctane–water [the value for *n*-octane–water is 51.5 mN/m (363)]. The authors performed some thermodynamic calculations (equilibrium model based on Flory–Huggins theory) that were successful in characterizing the initial and final stages of the process. The process conditions can be adjusted in a way that particles either with a single void or with diffusive microvoids are obtained. A procedure to prepare multihollow particles by a stepwise treatment of polymer particles consisting of carboxylic acid copolymers was developed by Okubo and co-workers. The process of hole formation is similar to the one above based on core-shell particles. Increasing the pH

at elevated temperatures leads to a swelling of the particles with water and the subsequent decrease in pH leads to a collapse of the chains, followed by void formation. Deceasing the temperature below T_g causes the structure to freeze, as explained in Reference 364. The authors showed that this principle is virtually universal as they were able to obtain similar morphologies also with copolymer particles containing dimethyl 2-amino ethyl methacrylate instead of methacrylic acid upon the reverse order of pH changes (365). Multihollow particles can also be prepared by so–called double emulsion, that is, an emulsion droplet is itself an emulsion and hence a host for smaller drops. In a water-in-oil-in-water emulsion (w/o/w), drops that are water-in-oil emulsions are dispersed in an aqueous continuous phase. This type of emulsion needs two sets of emulsifiers: hydrophobic ones (smaller HLB values) designed to stabilize the interface of the internal water-in-oil emulsion, and emulsifiers with a higher HLB value to stabilize the external interface of the oil-in-water emulsion. If the oil in the water-in-oil emulsion is a monomer, hollow particles should result after polymerization and drying where the water has acted practically as porogen. To control void concentration and droplet stability is not that easy because stability has to be controlled for both kinds of dispersed droplets. It was found that stability is improved if a urethane macromonomer as viscosity enhancer was incorporated in the monomer mixture (methyl methacrylate and ethylene glycol dimethacrylate as cross-linker). The results clearly show that increasing the amount of urethane macromonomer up to 15 W% relative to the monomer mixture increases both the yield of particles with holes and the number of holes per particle (366).

Another way of making porous particles is the application of so–called porogens, which are liquids that are essentially immiscible with the continuous phase and nonsolvent for the polymer but solvents for the monomers. This procedure leads exclusively to porous (multihollow) particles and requires, as in the case of encapsulation of liquid drops, the polymerization to start from an emulsion or highly swollen seed particles. This technique is the application of the principle of macroscopic gel formation to heterogeneous polymerization techniques. Porous polymeric materials, either macroscopic or beads, are prepared by copolymerization in the presence of a cross-linker such as radical polymerization of styrene in presence of divinylbenzene, which is the very “classical system.” Materials of this kind are porous only upon swelling. To control pore size and porosity an inert substance is added, which is only responsible for pore formation and which will be recovered before the material is used. The former procedure leads to materials that are porous only in the swollen state, whereas the latter results in permanent porosity (367). The inert component can either be a nonsolvent for the polymer or a linear polymer, preferably of the same kind as the network polymer but uncross-linked, where its molecular weight controls the pore properties. In general, the pore size is controlled by both the concentration of cross-linker and inert component. The larger the amount of inert component for a given amount of cross-linker, the larger is the pore size, whereas the pore size decreases with increasing cross-linker concentration at given ratio of inert component. Furthermore, the poorer the interaction between porogen and polymer, the easier the phase separation occurs and hence, the larger the pores. These principles are more than 50 years old, but remarkable developments have taken place during the 1990s. The “classical” poly(styrene-*co*-divinylbenzene) beads are very hydrophobic, but

as separation tasks are more and more shifted toward aqueous systems more hydrophilic beads are needed. One example is permanently porous hydrogel beads made of poly(vinylpyrrolidinone-*co*-ethylene dimethacrylate), which were prepared by aqueous suspension polymerization (vinyl pyrrolidinone/ethylene dimethacrylate = 1.5 w/w) with a mixture of cyclohexanol and dodecan-1-ol (4:l w/w) as inert diluent (150 w-% relative to the amount of monomers). In order to carry out the heterophase polymerization, the composition of the aqueous phase and the stabilizing system employed were rather unusual. The aqueous phase was a 20 w-% solution of sodium chloride containing 7 w-% magnesium chloride. This high ionic strength is needed to avoid polymerization in the continuous phase. At polymerization temperature, before inserting the organic phase, 1 *M* sodium hydroxide was added drop wise under stirring, thus forming the stabilizer, which is colloidal magnesium hydroxide. Then the organic phase, containing 2,2-azobisisobutyronitrile, was added and the polymerization allowed to proceed until final conversion. At the end of the polymerization the magnesium hydroxide stabilizer was dissolved by adding HCl (368).

Another modern development in the field of polymer beads as stationary phases for separation techniques is their equipment with chiral properties, thus enabling the separation of enantiomers. Examples are described in References 369 and 370 in which the authors do not use suspension polymerization, but rather highly swollen polymer particles, prepared via Ugelstad's activated swelling method. In brief, the process is as follows: A monodisperse polystyrene seed (prepared by emulsifier-free emulsion polymerization) was activated by swelling with dibutyl phthalate, which was added in the form of an aqueous emulsion stabilized with sodium dodecylsulfate. The monomer mixture containing the chiral monomer, initiator, cross-linker, and toluene was sonicated in an aqueous sodium dodecyl sulfate solution and added to the activated seed particles. After the emulsion drops were sucked up by the activated particles, poly(vinyl alcohol) was added as polymeric stabilizer and the polymerization started by heating. After washing and drying, the particles were treated with toluene to extract the linear polystyrene. The polystyrene acts in this case as both seed polymer and porogen.

Another new development during the last decade is the use of supercritical CO_2 as porogen, which has the advantage that macroporous polymer beads can be synthesized in aqueous suspension polymerization in the absence of any organic solvents. The results show that the pressure, which is applied to adjust the solvency of the supercritical CO_2 together with the stirring speed, controls the pore size (371). All these processes for hollow or porous particle preparation are multistep procedures, but there are also results indicating that hollow particles can be obtained in single-step polymerizations. An interesting possibility, which is also of general importance for heterophase polymerizations, is described in Reference 372. The authors investigated suspension polymerization of styrene in the presence of divinylbenzene as cross-linker, with gelatin and poly(diallyl dimethyl ammonium chloride) as stabilizer, and either 2,2′-azobisisobutyronitrile or dibenzoyl peroxide as initiator. The reaction was started after emulsification at 40°C by increasing the temperature to its final value (between 60 and 80°C). If the polymerization reaction takes place predominantly in the outer shell of the droplets, then porous particles with a single hole in the center are obtained. The copolymers produced early during the polymerization have a higher degree of cross-linking

due to the reactivity ratios and form a dense shell at the droplet water interface. For geometric reasons this cross-linked shell cannot shrink as much as required by the density change from monomer to polymer. As polymerization proceeds the swelling of the shell with monomer will change gradually in dependence on cross-linking (cf eq. 48) and consequently the core depletes in monomer until finally a hole is formed (cf Shrinkage and Fig. 28). Hole formation was observed at high polymerization rates, that is, at higher temperatures and higher initiator concentrations. Phase separation that takes place inside the confined space of latex particles can also cause the formation of hollow or voided particles. For instance, hollow particle formation, besides other morphologies, was observed in styrene emulsion polymerizations either initiated with poly(ethylene glycol)–azo initiators (312) or in the presence of poly(ethylene glycol) macromonomers (373). Also, ionic groups, if they are present at high concentrations, can cause phase separation and the formation of multihollow morphologies. Such behavior was observed in the case of low molecular weight polystyrene latex particles and is discussed in detail in References 92 and 374.

Also, for pure homopolymers particle morphology can be an issue, such as in the case of vinyl chloride polymerization. Poly(vinyl chloride) particles are by no means homogeneous, but rather possess a complicated morphology, which is determined by various parameters. The properties of poly(vinyl chloride) grains prepared by suspension polymerization such as size, density, and porosity are primarily determined by the nature and concentration of the stabilizer and initiator and by the hydrodynamic conditions in the reactor. These grains can have a size up to a few hundred micrometers and are in fact aggregates of a number of droplets with a size of some ten micrometers. Each of these particles is composed of smaller ones with a size of only a few micrometers, which are aggregated into a porous network. These smaller particles consist of still smaller domains (69,156). But these smaller particles also have an internal structure and so on. The smallest substructures have a size of about 10 nm and were identified by of electron microscopy of particles, which were etched with gas molecules (375–377). All investigations regarding the morphology of poly(vinyl chloride) particles, regardless of the polymerization procedure, are in conformity with a hierarchical structure composed of domains with various sizes. The morphology of poly(vinyl chloride) grains is not only determined by the polymerization process but for dispersions prepared by emulsion and microsuspension polymerization also by the conditions during spray-drying, which is used to isolate the polymer (69,156). Control of the grain morphology is very important as for many applications the grains are dispersed in plasticizers that, before further processing can occur, have to swell the grains.

Controlled Aggregation

Besides the methods of morphology formation during the polymerization process, the morphology of polymer colloids can also be changed after polymerization by controlled aggregation processes, as already briefly mentioned above. Such processes require close contact between latex particles and hence, they always face the problem of stability control because at the end there should still be a colloidal

polymer dispersion and not a completely coagulated system. From the thermodynamic stability point of view the process of decreasing the interfacial area is always favored. One possibility to carry out such processes is heterocoagulation in aqueous dispersions (water is phase 2 according to Fig. 31) of small particles (phase 3) on oppositely charged larger ones (phase 1) as described by Ottewill and Waters (378–380). Combined stability with ionic and nonionic stabilizers is advantageous in order to ensure stability during the whole process. The application of above principles of minimization of free energy (the reference state is characterized by both kinds of particles being separated) and introducing volume fractions (ϕ_1, ϕ_3) in equation 48 defines conditions for engulfment of smaller particles (phase 3) by larger particle (phase 1).

$$\frac{\sigma_{2,3} - \sigma_{1,3}}{\sigma_{1,2}} > \frac{1 - \phi_1^{2/3}}{\phi_3^{2/3}} \tag{48}$$

Equation 48 reveals the influence of several variables on the thermodynamics of the engulfment. The process is favored the more hydrophobic the smaller particles the more hydrophilic the larger particles, the less the interfacial tension between both polymers, and the larger the volume fraction of the smaller particles that are forming the core in the composite particles. The applicability of these kinds of predictions as well as of the whole process to prepare composite latex particles has been successfully demonstrated (290,378–380). In a comprehensive study the possibilities of controlled aggregation processes to enlarge the particle size of polymer dispersions were investigated (381–383). Such processes might also be of technical importance as it is possible to produce aggregates with a narrowly distributed size of a few micrometers (up to 15 μm). The aggregation process of negatively charged latexes was induced by the addition of a cationic surfactant under stirring. If the concentration of the cationic surfactant is in a proper range, which causes only partial charge neutralization, the final aggregates are stable and still possess a negative surface potential. This indicates that the surfactant binding to the primary particles is a cooperative process, and besides being controlled by electrostatic interaction is also controlled by hydrophobic interaction of the surfactant tails. The whole aggregation is a three-step process, starting with formation of a gel-like network, which is broken up by shear forces and finally leads to smaller but compacter primary aggregates. These can further agglomerate into larger, secondary aggregates. Their size is mainly determined by the stirring speed and the surface chemistry of the particles (stabilization). Narrow size distribution of the secondary aggregates was only observed for latexes prepared in the presence of acrylic acid, which causes additional stabilization because of the formation of an electrosteric layer. Another kind of controlled aggregation is described in Reference 384. The authors describe the pH-induced coagulation of two rubbery latexes, poly(butyl acrylate) and poly(styrene-co-butadiene), both stabilized by stearic acid. Controlling the decrease in the pH leads to coagulation of the poly(butyl acrylate) particles onto the more hydrophilic poly(styrene-*co*-butadiene) particles.

Particle Morphology and Application. The morphology of the particles is the main key controlling their properties and application fields. Although in many practical cases the particle morphology, which builds up during the polymerization process, is not known in detail, it is the specific particle morphology that makes a dispersion suited for a particular application. Table 21 gives a few general examples of how certain particle morphologies can contribute to solution of application problems.

Hybrid Polymer Dispersions. Particle morphology is not only an issue in the case of heterophase copolymerization or seeded polymerizations but also so–called hybrid systems are arousing increasing interest. *Hybrid systems* mean in the widest sense the combination of materials arising from different manufacturing processes, such as a combination of more than one generic class of polymers (polyurethanes–acrylics or epoxy–acrylics) or also a combination of heterophase polymerizations with inorganic materials. The former class of hybrid systems plays an important role in the preparation of paints (336). The most widely utilized technique is the application of seed polymers, which are not prepared by heterophase polymerizations but by other techniques, in aqueous emulsion polymerizations. The seed can be either directly water–dispersable owing to hydrophilic functional groups or can be emulsified in water using a combination of surfactants and high shear; if necessary or possible, it can also be dissolved in the monomer mixture prior to emulsification. This kind of sequential polymerization can lead to superior products because totally different properties can be combined on nanometer size scales first in the particles and after application in the final coating. An example of this kind of hybrid heterophase polymerization is given in Reference 385. The colloidal size scale makes heterophase polymerizations a promising tool to prepare hybrid materials with inorganic components. Table 22 lists some recently published examples prepared by polymerization of the particular monomer or monomer mixture in the presence of inorganic material. Composites offer unusual combinations of mechanical properties (stiffness, strength, weight and cost reduction) that are hard to attain from the individual components alone. Heterophase polymerization in this context means not only the encapsulation of inorganic material (as most of the examples given in Table 22) but also the polymerization inside layered structures in the inorganic material, such as silicates (montmorillonites). This so–called intercalation polymerization leads to modification on size scales of a few nanometers and to additional benefits compared to microcomposites or reinforced plastics on millimeter length scales (401). Preparation of nanocomposites also requires specific interactions between the polymers and the inorganic material in order to avoid phase separation (with regard to short–term and long–term storage or use) and to profit form modifications on nanometer length scales.

Nonclassical or Novel Developments

In the kind of heterophase polymerizations considered so far, except microemulsion polymerization, the stabilizers are used to impart colloidal stability to the disperse phases, which are either monomer droplets or polymer particles in spherical shape. In addition to these “classical” heterophase polymerizations there are also

Table 21. Selection of Core Shell Particle Morphologies for Particular Applications

Application	Monomers	Morphology	Benefit
Adhesive	Styrene/(meth)acrylates	Core: high T_g Shell: low T_g	Core: cohesion Shell: adhesion
Pressure-sensitive adhesives	(Meth)acrylates/styrene	Core: (meth)acrylates	Retention of adhesive strength; warp resistance
Thermoset coatings	Various plus reactive methylol groups	Core: $T_{pol} > 60^{\circ}C$ Shell: $T_{pol} < 60^{\circ}C$	Cross-linking
Paper coating	Styrene butadiene plus polar monomers	Core: styrene butadiene Shell: acrylic acid, acrylamide, acrylonitrile	Increased water resistance and higher gloss
Hydrophilic filler	Hydrophobic plus (meth)acrylic acid	Core: hydrophobic Shell: plus acrylic acid	Water retention in plastics
Galenical polymer	Methyl methacrylate plus (meth)acrylic acid	Core: methyl methacrylate; Shell: (meth)acrylic acid	Redispersable Powder
Diagnostic material	Hydrophobic monomer plus reactive monomer	Core: high; T_g Shell: reactive, activated	High stability coupling of proteins
White finish	Hard and soft monomers	Composite morphology, no statistical copolymer	High elasticity and low caking
Glue	Polyurethanes polyester polyols	Secondary dispersions in water	Crystalline parts give high strength
Mortar	Vinyl acetate plus various comonomers	Poly(vinyl alcohol) as protective colloid	Redispersable powder
Research products	Various amphiphilic block copolymers	Core: hydrophobic Shell: hydrophilic	Redispersable pure solids

Table 22. Polymeric–inorganic Hybrid Composites Prepared with Heterophase Polymerization Techniques

Inorganic material	Heterophase polymerization	Reference
Magnetite	Suspension, styrene/divinyl benzene	386
Pfizers magnetite	Suspension, monomer mixture	387
Na–montmorillonite	Emulsion, methyl methacrylate	388
$LiClO_4$, fumed silica	Poly(ethylene glycol)dimethacrylate	389
$CaCO_3$	Emulsion, styrene	390
$CaCO_3$	Miniemulsion, styrene	391
TiO_2	Miniemulsion, styrene	392
SiO_2, Al_2O_3, TiO_2	(Mini)emulsion, *n*-butyl acrylate	393,394
Carbon black	Miniemulsion, styrene	395
Magnetite	Inverse emulsion, hydroxyethyl methacrylate, methacrylic acid	396
Na–montmorillonite	Emulsion, aggregation, styrene	397
SiO_2	Emulsion, 4-vinyl pyridine plus *n*-butyl acrylate or *n*-butyl methacrylate	398
Montmorillonite	Emulsion, acrylonitrile plus butadiene plus styrene	399
Layered silicate	Emulsion or suspension, Methyl methacrylate	400

heterophase polymerizations where the stabilizer determines the morphology and the shape of the disperse phase. To illustrate this, Figures 32 and 33 show illustrations of binary and ternary surfactant phase diagrams, respectively (402). The surfactant concentrations for all the "classical" heterophase polymerizations is in the left part of both phase diagrams, that is, in regions where surfactants form

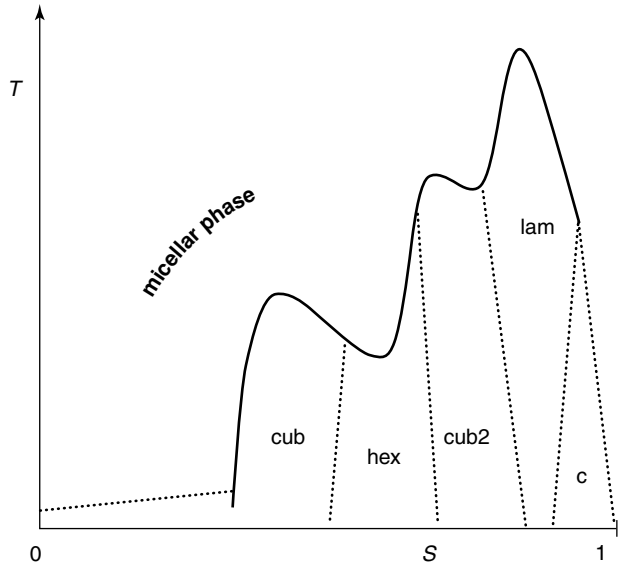

Fig. 32. Illustration of a binary phase diagram of a surfactant solution. *S*: weight fraction, surfactant; *T*: temperature; cub: cubic phase built up of discrete globular micelles; hex: hexagonal phase; cub2: bicontinuous cubic phase; lam: lamellar phase; c: crystalline phase.

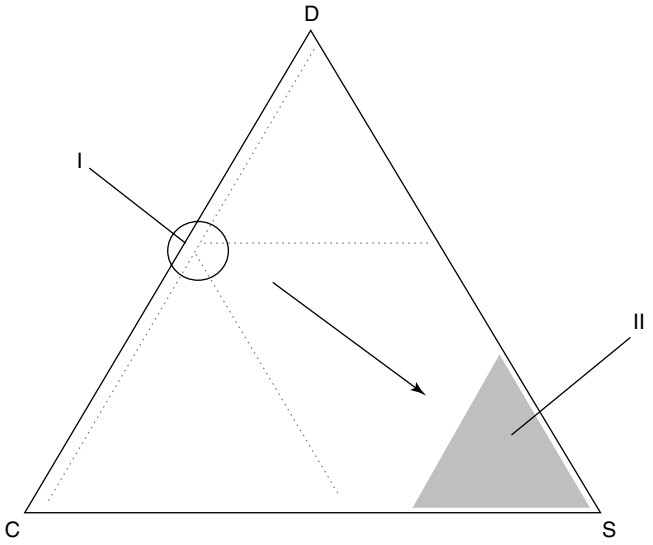

Fig. 33. Schematic drawing of a ternary phase diagram for heterophase polymerizations (part of the ternary phase prism at constant temperature). *I*: range for "normal" heterophase polymerizations; *II*: range for heterophase polymerizations in lyotropic phases.

only micelles. Searches have been inspired by the question as to what will happen if polymerizations are carried out in cubic, hexagonal, or lamellar phases, that is, at much higher surfactant concentrations. Basically, there are two possibilities: first, the use of normal monomers as third phase, which swell the surfactant phase (ternary case), and second, the use of reactive, that is polymerizable surfactants (binary case). In either case the interesting question is whether or not it will be possible to replicate the surfactant phase by polymerization. There is no general answer for either case. For the binary case, it was shown in a comprehensive study that for retention of surfactant lyotropic liquid crystalline phases during polymerization, the best position of the polymerizable group is neither at the end of the hydrophobic chain nor within the hydrophilic head group but rather a position where on the one hand chain mobility is reduced and on the other hand head group interactions are not able to prevent polymerization (403). The latter point means that in the case of ammonium surfactants, methacryloyloxyethyl groups attached to the nitrogen behave more readily than allyl groups. Similar results were obtained for (2-methacryloyloxyethyl)dodecyldimethyl ammonium bromide in comparison with 11-(methacryloylundecyl)trimethyl ammonium bromide. Whereas the former polymerizes readily in all phases (cubic, hexagonal, and lamellar) the polymerization of the latter one ceases in the hexagonal phase at about 60%. But both surfactants polymerize under retention of the macroscopic order (404). The situation for the ternary case is more complicated. Here the interesting question is whether or not it might be possible to use the swollen lyotropic phases as templates for the final polymer phase. It has been shown that the very first formed polymer changes the bicontinuous phase structure. Although a direct templating does not seem possible, the kind of lyotropic starting phase influences the final structure (405).

A review describing the state of the art using templates (including lyotropic surfactant phases) to prepare organic polymeric networks has recently been published (406).

The monomer solubility in the continuous phase plays in heterophase polymerization, a crucial role as long as diffusion processes through the continuous phase are necessary. This is for instance the case during emulsion polymerization. where the monomer has to diffuse from the reservoir (either droplets or tank in case of batch or feed procedures, respectively) to the particles. However, if the goal is to restrict the polymerization to droplets formed by diminution techniques (for instance suspension or miniemulsion polymerization) a zero solubility in the continuous phase is desirable because Ostwald ripening and bleeding of the drops is impossible (cf above). For some applications very hydrophobic polymers are needed. It is difficult to bring highly hydrophobic monomers such as lauryl methacrylate or stearyl acrylate through the aqueous phase into the particles as the main reaction loci during technically important emulsion polymerization. Recently it was found that β-cyclodextrins, which are cyclic oligosaccharides made up of seven glucopyranose units, can form inclusion complexes with hydrophobic substances. One example is the application of cyclodextrin instead of surfactants for emulsion polymerization of moderately hydrophobic monomers such as butyl methacrylate (407) or emulsion homopolymerization of very hydrophobic monomers such as dodecyl and octadecyl methacrylate, also in the absence of emulsifying agents (408). These hydrophobic monomers led to massive coagulation and incomplete conversion during emulsion polymerization in the presence of common sulfonate surfactants. Another example is the application of cyclodextrins as "transport shuttle" for hydrophobic monomers in emulsion copolymerization (409,410). This application is of interest also in order to increase the hydrophobicity of polymeric materials.

Process Models. The demands in industry on increasing product quality and constancy, on most efficient use of reaction space, and on cost reduction require increasing efforts with regard to process and product quality control. Much progress has been made in this field during the last decade. One way to meet industrial requirements is the development and application of process models, which are often applied together with on-line data acquisition systems. In order to completely master a polymerization process a multidisciplinary approach that considers kinetic and polymer property models (rate of polymerization, copolymer composition, particle size, and molecular weight distributions), hardware and software sensors, nonlinear observers for the data interpretation, and easily tuneable, robust controllers (411,412) are needed. The complexity of heterophase polymerization processes makes them difficult to model in detail, especially because the estimation of model parameters is the crucial point. There are basically two ways out of this dilemma in order to fulfill the demand of reactor and product control: First, the development of on-line techniques, that allow a fast determination of important product properties in time frames fast enough to allow remediation when problems occur during the polymerization. Second, the development of mathematical algorithms that provide accurate estimates of the properties of the reactor content. An example of the state of the art, and how to design such an observer, can be found in References 413. The authors developed a continuous–discrete observer that accurately estimates parameters for emulsion copolymerization and

that has been applied for batch copolymerization of styrene and butyl acrylate as well as for semibatch copolymerization of methyl methacrylate and butyl acrylate.

The control of batch heterophase polymerizations is a difficult task owing to the gel effect and the absence of lasting stable operation conditions. Frequently in these cases an adapting, self-tuning controller is applied. An example of this for a styrene batch suspension polymerization can be found in Reference 414. The application of a nonlinear predictive controller for a batch vinyl chloride suspension polymerization is given in Reference 415. All these controllers and software techniques require input data on the polymerization reactions. An important application property of a polymer is its molecular weight and hence, its control during polymerization is of special importance. Because of the lack of on-line methods (hardware sensors) a software sensor was developed that calculates the feed streams of monomer and chain-transfer agent required to get a desired molecular weight distribution (416). The control strategy uses a nonlinear-model–based controller and experimental data of both unreacted monomer and chain-transfer agent obtained with gas chromatography. Also, another strategy was developed, which is based on reaction calorimetry data (417). Recently it was shown that it is possible to carry out on-line monitoring of molecular masses during polymerization reactions. To perform this a diluted reactant stream from a polymerization reactor was made to flow through a series of detectors comprising refractive index, ultraviolet absorbance, and time-dependent static light scattering. This combination of detectors allows the determination of the absolute weight-averaged molecular weight of polymers (418). In order to get viscosity data it is also possible to include single-capillary viscometer in the series of detectors (419). The methodology was further improved to allow the finding of instantaneous weight-averaged molecular mass distributions during polymerization reactions and hence, it allows the on-line monitoring of polydispersity (420). Using this technique it was possible to analyze acrylamide polymerization in aqueous solution and to deduce from on-line data important kinetic parameters such as reaction orders and initiator decomposition rate constant (421). Reviews of on-line techniques to get required data can be found in References 422–424).

Reaction Calorimetry. The easiest way to follow a polymerization is to monitor the temperature of the reaction mixture or to use reaction calorimetry (cf above). Landau gives an excellent review on reaction calorimetry, its principles and application in chemical research in Reference 425. Table 23 summarizes papers dealing with reaction calorimetry of heterophase polymerizations. Reaction calorimetry gives on-line information with regard to the overall heat released during the reaction. This heat release is directly connected with the monomer conversion (eq. 49).

$$H_F \equiv r_p = -\frac{dM}{dt} = \frac{dV_P}{dt} \propto \left(D^3 \frac{dN}{dt} + ND^2 \frac{dD}{dt} \right) \tag{49}$$

Equation 49 can be considered as the basic relation in the case of on-line monitoring of compartmentalized polymerizations. H_F is the heat flow, r_p is the rate of polymerization, M is the overall monomer concentration, t is the time, V_P is the total polymer volume, D is the average particle diameter, and N is the particle

Table 23. Reaction Calorimetry in Heterophase Polymerizations

Characteristics	Reference
Feed policies to maximize productivity, principles, modeling semi-batch emulsion polymerization	426
Adiabatic calorimetry, radical heterophase polymerization, data acquisition, mass balances, parameter estimation	427
Kinetics styrene emulsion polymerization, varying emulsifier and initiator concentration (sodium dodecyl sulfate and potassium peroxodisulfate)	428–431
Suspension polymerization of styrene, thermokinetic parameters for scale-up	432
Heterophase polymerization, different monomers, initiators and emulsifiers, reaction rate profiles	433
Semi-batch acrylate emulsion polymerization, isoperibolic calorimetry, increase reactor performance	434
Isoperibolic calorimetric investigation of styrene heterophase polymerization with polyurethane emulsifiers	435

concentration. Equation 49 leads immediately to two important conclusions: First, the heat flow practically contains all information about the polymerization process. Second, for a compartmentalized polymerization this information can be extracted only if an additional on-line method is applied. The second method should preferably be a method for the analysis of the particle size or better yet the particle size distribution (PSD). Such a combination is described in References 436 and 437. A small aliquot of dispersion was withdrawn from the reactor with a sampling loop and passed through an on-line density meter (to determine the monomer conversion) and capillary hydrodynamic fractionation apparatus (to measure the PSD). The methods described so far with the *terminus technicus* "on-line" require the removal of an aliquot of the reaction to carry out the analysis. The only exception is reaction calorimetry, where the temperature is measured either inside the reactor or through its walls.

There is another group of techniques available, so–called in-line techniques, which neither require the removal of reaction mixture nor its destruction or dilution. The majority of these techniques is based on various kinds of radiation and hence mainly comprise spectroscopic methods. Owing to the rapid progress in the recent years with regard to optical fiber techniques, and computer techniques these techniques are ready to use inside closed reactors. A summary of papers dealing with in-line techniques to investigate heterophase polymerizations is given in Table 24. These selections suggest that there are a variety of in-line techniques under development or already available to monitor almost all characteristic quantities of heterophase polymerizations. Most of the techniques are only useful to investigate special features in laboratory experiments at low solids content (high dilution) such as transmission measurements, fluorescence spectroscopy, or surface tension. For some others the equipment is very expensive and the gain of additional information frequently does not justify the enormous price and running costs of these methods such as nuclear magnetic resonance or electron spin resonance spectroscopy. In contrast, other methods such as infrared and Raman spectroscopy or ultrasound are very promising.

Table 24. Selection of In-Line Methods to Analyze Heterophase Polymerizations

Method	Application	Reference
Near-infrared spectroscopy (short wavelength 700–1100 nm)	Styrene emulsion polymerization conversion monitoring	438,439
Near-infrared spectroscopy (wave-length 1500–1800)	suspension polymerization evaluation of average particle size	440,441
Near-infrared spectroscopy	Emulsion polymerization, detection of monomer droplets upon addition of butyl acrylate and methyl methacrylate individually and in mixtures	442
Raman spectroscopy	Emulsion polymerization of methyl methacrylate and copolymerization of styrene/butyl acrylate	443
Raman spectroscopy	Styrene suspension polymerization (signal evaluation)	444
Raman spectroscopy	Emulsion copolymerization of styrene and butadiene, determination of styrene monomer in the reactor	445
Ultrasound	Emulsion homo- and copolymerization principles of applications, conversion	446,447
Ultrasound	Conversion (from velocity) and particle size distribution (from attenuation) for poly(vinyl chloride) and polyterafluoroethylene dispersions	448
Ultrasound velocity and attenuation	All kinds of dispersions, to determine particle size distribution and zeta potential	449–453
Electron spin resonance (ESR)	Radical concentrations during emulsion polymerization, lifetime of radicals in reaction compartments	454–456
Time–resolved fluorescence	Emulsion polymerization of styrene spectroscopy pyrene–labeled macroinitiators; dynamics in polymerizing particles	457,458
Solid–state nuclear magnetic resonance spectroscopy	Emulsion polymerization of butyl acrylate in D_2O, conversion	459
Surface tension	Emulsion polymerization of styrene and methyl methacrylate, emulsifier-free	93,95
Combination of turbidity and conductivity, surface tension, Fourier-transformed infrared spectroscopy	Nucleation during emulsion polymerization of styrene, vinyl acetate, and methyl methacrylate; continuous emulsion polymerization of methyl methacrylate, phase transition of polystyrene oligomers with Fourier-transformed infrared spectroscopy	93

From Batch to Continuous Operation. A last point to mention here is that over the last few years technological developments took place in order to transfer classical batch heterophase polymerization processes such as suspension, miniemulsion, and microemulsion polymerization into semibatch or even continuous operation. In the case of suspension (cf Table 6) and miniemulsion polymerization (460,461) this is done in order to increase reactor productivity. The polymerization inside preformed drops requires for continuous operation more than one continuous stirred-tank reactor or plug flow reactors in order to realize residence time distributions, which are as much as possible similar to that of batch reactors. This is necessary in order to achieve an almost equal conversion in all droplets. Continuous stirred-tank reactors possess an exponential residence time distribution whereas the residence time distribution in batch reactors is an orthogonal function. For microemulsion polymerization the goal to develop semibatch procedures is primarily to improve the yield with regard to emulsifier usage as at the end of batch operations polymer particles coexist with empty micelles. The high emulsifier concentration at the start, which was necessary to form the microemulsion, is at the end of the process much too high to ensure particle stability. It is now well established to start monomer feed and if necessary some initiator at the end of the batch period in order to increase the solids content and hence also the emulsifier yield (217,259,270,462). The average particle size stays small (a small increase in average particle is observed, because besides new nucleation and growth seed polymerization also takes place as a result of swelling of the first generation of particles), because there is enough emulsifier available to stabilize newly formed particles. If the fed monomer differs from the first-stage monomer, a special kind of composite particle is obtained that possesses interesting mechanical properties, compared with products from common emulsion polymerization (274) owing to the smaller particle sizes.

In final conclusion, heterophase polymerization is a generic term that describes a complex field of polymer science, that spans preparation of both organic and inorganic polymer and mixtures thereof and that is not restricted to a certain polymerization mechanism or technology. It is among the oldest areas in polymer chemistry but it is developing with ever-increasing speed and comprises nowadays more than "classical" emulsion and suspension polymerization techniques.

Abbreviations

A: Hamaker constant (general)
$A_{1,2}$, $A_{1,3}$, $A_{2,3}$: interfacial areas between phases 1–2, 1–3, and 2–3, respectively
A_{eff}: effective Hamaker constant of interacting particles
A_m: Hamaker constant of the medium between interacting particles
A_p: total surface/interface of dispersed phase material
A_p: Hamaker constant of interacting particles
a_s: area covered by a surfactant molecule
A_{spec}: specific surface/interface of dispersed phase either per unit mass or volume of either dispersed phase or water (eq. 1)
C: capacity of a conducting sphere
C_0: solubility of the dispersed phase material in the continuous phase
C_I: initiator concentration
C_{LC}: concentration of the lyophob in the continuous phase
C_{LC0}: solubility of the lyophob in the continuous phase
C_M: monomer concentration

$C_{M,p}$: monomer concentration inside dispersed phase particles
cmc: critical micelle concentration of surfactant/stabilizer
C_{MC0}: solubility of the monomer in the continuous phase
C_S: surfactant/stabilizer concentration
$C_{S,C}$: critical surfactant concentration for stabilization of particles after nucleation
$C_{S,L}$: concentration of stabilizing polymer (lyophilic polymer) in the volume of the hydrodynamic layer
C_{salt}: ionic strength in the continuous phase
D: diameter of dispersed phase material
D_0: diameter of seed particles
D_d: droplet diameter
$D_{d,c}$: critical droplet diameter for which Ostwald ripening stops (eq. 25)
$D_{d,e}$: droplet diameter at equilibrium
D_{dp}: size of dispersed phase molecule
D_{ee}: characteristic length of a dissolved polymer molecule
d_h: diameter of a single hole
D_m: monomer droplet diameter
D_{MC}: diffusion coefficient of monomer in the continuous phase
D_p: monomer particle diameter
d_{pp}: interparticle distance (eq. 3)
D_t: diameter of final composite particles
e: type of end group
E_{kin}: kinetic energy of particles in a shear field (approximation)
f: radical efficiency for starting polymerization
f_1, f_2: mole fractions of monomer 1and 2 in a comonomer mixture
F_1, F_2: mole fractions of monomer 1 and 2 build in the copolymer
FG: solids content in parts per 100 parts dispersion
h: Planck's constant
H: geometrical function of interacting particles
j: chain length
$k_{11}, k_{22}, k_{21}, k_{12}$: propagation rate constants of M_1 with P_1, M_2 with P_2, M_1 with P_2, and M_2 with P_1, respectively
$k_{abs,i}$: rate constant of primary radical absorption by particles of dispersed phase
k_B: Boltzman's constant
$k_{d,d}$: rate constant of initiator decomposition in the dispersed phase
$k_{d,w}$: rate constant of initiator decomposition in the continuous phase
k_{des}: rate constant of radical desorption
k_L: London interaction constant
k_p: propagation rate constant
$k_{t,d}$: termination rate constant in dispersed phase
$k_{t,w}$: rate constant of radical termination in the continuous phase
M_1, M_2: concentration of both comonomers
M_{mon}: molecular weight of the monomer
M_S: molecular weight of surfactant/stabilizer
N: number of particles of dispersed phase material (eq. 2)
n: number of growing centers per particle of dispersed phase
N_A: Avogadro's number

n_I: number of initiator molecules per particle of dispersed phase
N_n: number of particles of dispersed phase with n growing centers
$n_{R,equ}$: number of radicals per particle of dispersed phase at steady state (eq. 7)
n_S: number of molecule of disperse phase at the surface/interface (eq. 5)
N_{ss}: number of small spheres in the mixture with large spheres
P: concentration of propagating radicals
p': vapor pressure outside the drop (eq. 29)
p_0: bulk vapor pressure of the liquid forming a drop (eq. 29)
P_1, P_2: growing chain ended with a radical of monomer 1 and growing chain ended with a radical of monomer 2, respectively
P_d: pressure inside dispersed phase particle
$P_{j,e,w}$: concentration of radicals of chain length j and end group e in the continuous phase
P_n: average degree of polymerization
P_{SW}: swelling pressure
Q: concentration of interacting centers per unit volume
R: gas constant
r: radius of swollen particles
r_0: radius of unswollen particles
r_1, r_2 reactivity ratios (eq. 41)
r_{abs}: absorption rate of radicals from the continuous phase into particles
$r_{i,d}$: rate of initiation in the dispersed phase
$r_{i,w}$: rate of initiation in the continuous phase
r_p: overall rate of polymerization (eq. 9)
S_1, S_2, S_3: spreading coefficients of phase 1, 2, and 3, respectively (eq. 44)
T_g: glass-transition temperature
$T_{g,i}$: glass-transition temperature of a homopolymer of monomer i
v: particle volume
v'': molar volume of the liquid forming a drop (eq. 29)
V_A: attractive potential (eq. 32)
v_c: volume of continuous phase
$v_{c,p}$: molar volume of the molecules forming the continuous phase
V_{int}: interaction potential between charge–stabilized spheres (eq. 37a)
$v_{m,p}$: monomer volume in swollen particles
v_{mon}: molar volume of the monomer
$v_{p,p}$: polymer volume in swollen particles
$V_{R,B}$: Born's repulsion potential
$V_{R,es}$: repulsion potential between equally charged spheres
v_{rel}: relative velocity of two approaching particles in a shear field
V_{st}: steric repulsion potential
w_i: weight fraction of monomer i in a copolymer
$W_{surf,t}$: amount of surfactant relative to the total mass of organic phase (or dispersed phase) (eq. 4)
Z: number of electrons in the outer shell of a molecule
z: stoichiometric valency of the electrolyte dissolved in the continuous phase
ΔD: decrease in diameter caused by shrinkage during polymerization
ΔG_f: free energy of the flocculation process
ΔG_I: interfacial free energy (eq. 43)

ΔH_f: change in enthalpy during flocculation
ΔP_d: Young–Laplace pressure
ΔR: hydrodynamic stabilizer layer thickness
ΔS_f: change in entropy during flocculation
ΔS_{sl}: entropy gain between interacting small and large hard spheres
Δv_c: increase in the effective volume for the smaller spheres due to overlap of the excluded volume regions of the larger spheres
$\Delta \mu_1$: chemical potential of swelling agent (monomer)
Θ: theta condition of a dilute polymer solution (in the limit of infinite molecular weight, the situation where $\Delta \mathrm{H} = T\Delta S$)
Ψ: surface potential
α: exponent in the scaling relation between the hydrodynamic layer thickness (ΔR) and the ionic strength (C_{salt})
α_0: static polarizability of molecules
$\chi_{m,p}$: Flory–Huggins interaction parameter between monomer and polymer
$\chi_{S,cp}$: Flory–Huggins interaction parameter between the stabilizing polymer and the continuous phase
ε: permittivity
ϕ_1: monomer volume fraction inside swollen particles.
ϕ_1, ϕ_3: volume fractions of phase 1 and 3, respectively (eq. 48)
ϕ_2: polymer volume fraction inside swollen particles
ϕ_L: volume fraction of the lyophob inside dispersed phase droplets
$\phi_{L,e}$: volume fraction of the lyophob inside dispersed phase droplets in equilibrium
$\phi_{L,i}$: volume fraction of the lyophob inside dispersed phase droplets just after comminution
ϕ_{MC0}: molar solubility fraction of monomer in the continuous phase
ϕ_{SE}: fraction of free surface energy relative to total free energy of a particle of dispersed phase (eq. 6)
γ: interfacial tension liquid vapor
ψ_{dp}: volume fraction of dispersed phase
κ^{-1}: Debye's screening length (eq. 37b)
ν_c: frequency of fluctuations
π_s: osmotic pressure of a bulk gel
ρ_{dp}: density dispersed phase
ρ_{m1}: monomer density
ρ_{p1}: polymer density
σ: interfacial tension dispersed fluid continuous fluid phase
$\sigma_{1,2}$, $\sigma_{1,3}$ $\sigma_{2,3}$: interfacial tension between phases 1–2, 1–13, and 2–3, respectively
τ_{ex}: exchange time of a droplet during Ostwald ripening
τ_{pol}: duration to form an average polymer molecule (eq. 8)
$\bar{n}$: average number of radicals per particle
$k_{abs}^{j,e}$: rate constant of absorption of propagating radicals with chain length j and end group e
$k_{abs}^{t,e}$: rate constant of radical termination in the continuous phase with chain length j and end group e
$\bar{D}_{d,i}$: average droplet diameter just after comminution

$\bar{M}_C$: average molecular weight between two cross-links
v_{mol}^{mon}: volume per monomer molecule
v_{mol}^{ru}: volume per repeating unit of the monomer in the polymer
ΔG_{cs}^{I}: change in interfacial free energy for the formation of core–shell particles (eq. 45)
$\Delta\sigma^{cs}i$: change in reduced interfacial free energy for the formation of core–shell particles or inserted core-shell particles (eqs. 46 and 47)
$2fk_d$: initiator decomposition rate constant, including efficiency for initiating polymerization (f)

IMPACT RESISTANCE

Introduction

Impact resistance is a measure of the ability of a material, specimen, or structure to withstand a sudden load without failure. The impact resistance of a specimen or structure is therefore a complex function not only of intrinsic factors such as the mechanical properties of the material but also of extrinsic factors such as geometry, mode of loading, load application rate, environment, and, quite importantly, the definition of failure.

The issue of stress geometry or mode of loading is all-important: a material highly resistant to failure in one mode of loading can fail catastrophically in another. Therefore, the impact resistance of a structure is relevant only with respect to a particular mode of loading. A soundly designed structure can fail unexpectedly if the geometry of a structural component is altered by the gradual change of shape, material wear, or crack growth, or if the mode of loading is changed, as when a force is applied in an unforeseen manner. Thus, it is often necessary to test the material or structure under conditions more severe than those of actual use. It is also prudent to follow certain well-established design guidelines. Last but not least, the use of damage tolerant materials may contribute to the avoidance of catastrophic failure.

Impact often implies a high loading rate, but the type of failure usually associated with impact can also occur under apparently innocuous conditions, even at low rates of loading. In addition to high strain rates, low temperatures and sharp notches tend to reduce fracture resistance. When the rate of strain energy accumulation is higher than can be contained in or dissipated by the material in the vicinity of a crack or a flaw, sudden and unstable fracture can occur, often entailing crack speeds of hundreds of meters per second. Higher

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

speeds are more likely to cause unstable fracture, other conditions being equal, for then even small flaws, less severe geometries, or milder temperatures can become critical. This is partly due to the viscoelastic nature of polymers. Under truly high speed conditions, ie, when inertial effects are involved, the deformation and fracture behavior are complicated by wave propagation and constraint effects (1–4).

In contrast to impact resistance, the fracture toughness of a solid polymer is much better defined for a given set of quasi-static low strain rate testing conditions (see also FRACTURE; FATIGUE and ASTM D5045-99). Toughness can often be improved by the incorporation of a soft, elastomeric phase into the rigid polymer matrix. The art and science of material modification for the purpose of toughening is extremely complex (5). Enhancement of toughness improves impact resistance.

The performance of a material or a structure also depends on local variations due to processing conditions, such as cooling rate, shear stress, and melt-flow paths, which result in orientation and residual stress. Multiphase materials can exhibit even greater local variations in material properties than those observed in single phase polymers. A structure produced by a given process may possess significant morphological differences from test specimens. Ultimately, it may be necessary to test the impact resistance of components.

Since the impact toughness of a material, as it is commonly called, depends on the technique of measurement, the testing instruments and the technique must be considered first.

Testing Machines and Techniques

Several types of machines are in use for different types of tests, offering advantages and disadvantages as well as different information. Impact strength is measured by many different empirical methods, some of which may not be appropriate for the performance evaluation of finished products. More sophisticated and meaningful testing devices are under development but remain mostly in research laboratories. The following is a description of the machines and techniques that have gained wide currency. However the foregoing should serve to warn the reader to be cautious about the validity of the results for applications. For this and other reasons a number of standardized test methods are used to approximate actual use conditions.

Standard Test Methods. Many impact tests are sufficiently standardized to have ASTM designations (see Table 1).

Pendulum-Type Instruments. Pendulum-type machines are used for notched or unnotched specimens that may be of different sizes and supported as a cantilever (Izod) or as a bar supported at its ends (Charpy). These tests are also referred to as flexed-beam impact tests.

The Izod impact test is based on an old, established test originally designed for metals in which a notched-bar specimen is tested in cantilever fashion with an excess energy pendulum machine. Izod (ASTM D256), Charpy (ASTM D6110 and Research Report D20-1034, to become a new standard), and the tensile-impact (ASTM D1822) tests can be performed with pendulum machines.

Table 1. Standard Tests for Impact Resistance[a]

Test	Designation	Description
Brittleness temperature	ASTM D746	The temperature is determined at which plastics and elastomers exhibit brittle failure under impact.
Falling weight	ASTM D3029	Impact resistance indicated by energy to break or crack rigid plastics by means of a falling weight (tup); constant drop height and variable weight (tup)[b] are recommended.
Falling weight	ASTM D1709	Similar to D3029 but for measuring impact resistance of polyethylene film by free-falling round-headed dart.
Falling weight	ASTM D2444	For impact resistance of thermoplastic pipe and fittings by falling weight (tup).[b]
Fracture toughness	ASTM D5045	For plane-strain fracture toughness.
High rate stress/ strain (tension)	ASTM D2289	Area under stress–strain curve measures impact resistance at testing speeds up to 254 m/min.
Izod impact	ASTM D256[c]	Energy to break a notched cantilever beam specimen upon impact by a pendulum. Notch tends to promote brittle failure. Unnotched impact strength is obtained by reversing the notched specimen in the vise. Notch sensitivity can be determined by using Method D.
Charpy impact	ASTM D6110 (also, Research Report D20-1034)	Similar to Izod impact test. Notched specimen is supported on two ends and struck by a pendulum in the middle, a three-point-bend setting.
Tensile impact	ASTM D1822	Recommended for plastic materials too flexible, too thin, or too rigid to be tested by ASTM D256. Measures energy to break by "shock in tension" imparted by a swinging pendulum.

[a] Ref. 6.
[b] Designation of the weight.
[c] Includes Charpy impact testing.

In these machines a mass is attached to the end of an arm that rotates about a pivot point; a striker is attached to a mass. The arm is raised to a predetermined position. When the arm is released, it swings downward and strikes the specimen, which is mounted rigidly in a vise or a fixture. The precise mounting position and the type of fixture depends on the test. The mass, length of the arm, and angle at the raised position determine the amount of available energy. The total energy must be high enough to give a complete break. Typical pendulum machines of the Izod and Charpy types are depicted in Figures 1 and 2, respectively; specimen geometries are shown in Figure 3. After the striker breaks the specimen at the bottom of its swing, it continues to swing upward until all the kinetic energy is

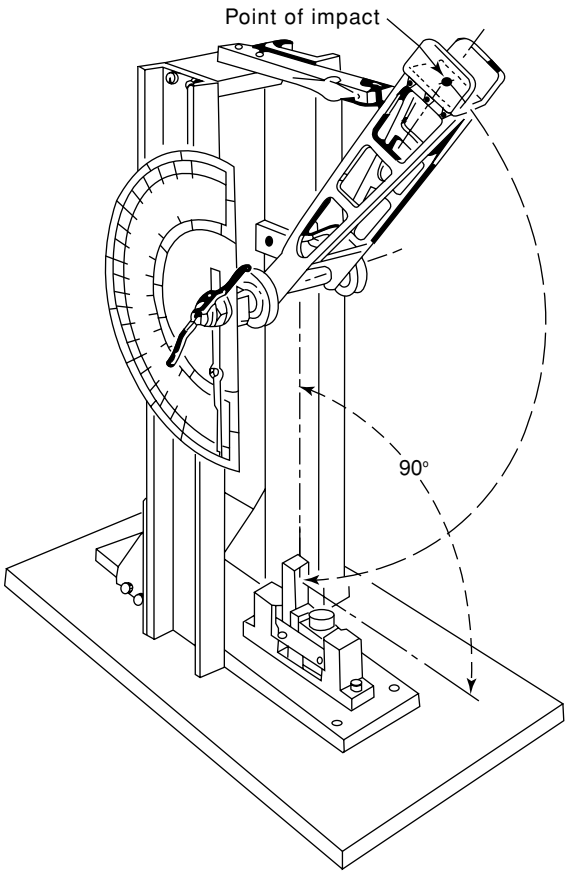

Fig. 1. Izod-type pendulum impact machine, ASTM D256.

converted to potential energy. The energy absorbed by the specimen, E_s, is found by

$$E_{\mathrm{S}} = E_I - E_{\mathrm{R}} - E_{\mathrm{F}} - E_{\mathrm{w}}$$

where E_{I} is the initial energy available, E_{R} the energy at the maximum angular travel, E_{F} the energy dissipated by friction, and E_{w} the kinetic energy to remove the broken, detached half-specimen as it is thrown forward by the pendulum. The last one is usually small; E_{F} can be found by performing the test without a specimen in place. Machines are usually equipped with a dial with calibration marks mounted in the plane of rotation in such a way that E_{I} and E_{R} can be read directly. An "instrumented" pendulum machine is equipped with a load cell, usually a piezoelectric quartz device for high frequency response, mounted on the striker or on the mounting block to which the specimen vise is attached. The electric signal from the load cell is amplified, digitized, and recorded by electronic memory. The energy is calculated from the load–time relationship by a computer connected to the instrument. The total energy can be displayed by a digital readout, or the

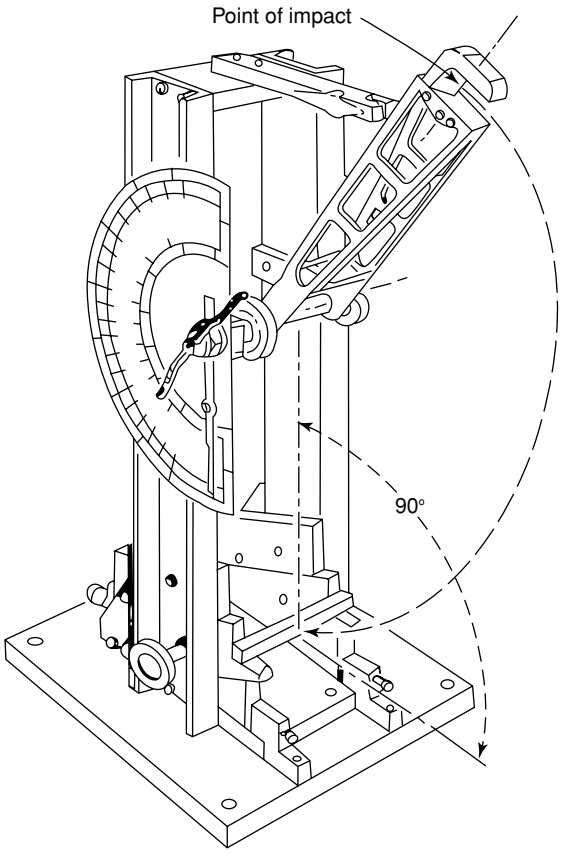

Fig. 2. Charpy-type pendulum impact machine, ASTM D256.

entire load–time trace can be displayed on a cathode-ray tube screen. In the latter instance, a microcomputer is attached and the information can be processed as desired.

The Izod test is used mostly in the United States and the United Kingdom [British Standard (BS) 2782, Method 306A]. The notched specimen is firmly clamped in a vertical position in a vise fixed in the base of the apparatus (Fig. 1). A pendulum fitted with a striker head of 3.2-mm radius, falling from a height of 0.61 m (ASTM) or 0.31 m (BS), hits the specimen horizontally at a point above the notch. At least 10 samples are required to obtain a satisfactory assessment of impact strength.

The U.S. test method has now been accepted as an International Standardization Recommendation ISO/R180, 2000. The material from which the test pieces are cut must be prepared under carefully controlled conditions to ensure development of full strength and freedom from strain caused by uneven heating or rapid cooling. The cutting of the notch requires special care, particularly with notch-sensitive materials. Small variations in the notch can give wide variations in impact values. The notch should be cut with a tool in good condition and shaped smoothly and accurately to the dimension called for in the test specification. Errors are caused

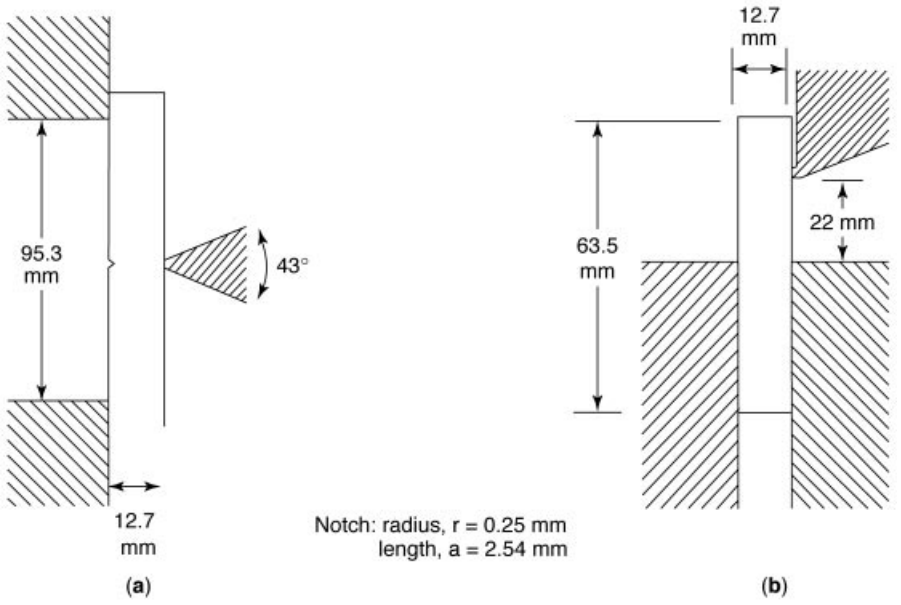

Fig. 3. Geometry of testing and specimen support arrangement for (**a**) Charpy and (**b**) Izod tests specified in ASTM D256 (7). Courtesy of Applied Science Publishers Ltd.

by variations in clamping pressure, failure to strike the specimens squarely, and the condition of the cutter and the cutting techniques for machining notches (8,9). Impact strength decreases linearly with increasing clamping pressure. A taper of 13 min of an arc on the specimen induces errors up to 25% of the expected impact strength of a perfectly parallel specimen. Variations in excess of 10% in expected impact strength were observed from differences in the notch cutter. Torsional stresses caused in the Izod specimen by skewness between the pendulum striker head and the surface of the specimen increase impact strengths even for small angles of skewness (Table 2).

Table 2. Effect of Skew Striking on Impact Strength of Poly(methyl methacrylate) Sheet[a,b]

Angle of skewness	Impact strength, J/m[c] of notch[d] at clamping pressure	
	16.5 MPa[e]	49.6 MPa[e]
10′	26.05	22.42
50′	27.75	25.78
1°10′	28.02	26.95
4°50′	29.78	29.36
5°10′	29.78	29.52

[d]Crack propagation to crack initiation.

The total breaking energy as measured by the Izod test comprises the following: energy to initiate fracture; energy to propagate fracture across the specimen; energy for plastic deformation; energy to throw the broken fragment away from the test piece; and energy lost through friction and vibration (9).

The energy to initiate and propagate fracture depends largely on the notch geometry. The energy for plastic deformation is important in materials that, even when notched, break by ductile failure. The energy to separate the broken fragments is important in materials of low impact strength and high density, eg, mineral filled phenolic resin. The effect is corrected by placing the fragment on the striker head of the machine, striking it again, and subtracting the energy absorbed from the original apparent impact strength. However, in being thrown forward the fragment may adopt different modes of movement, and may rotate only under the first strike. For high impact, low density materials, this source of error is less important. Points of increased stress or of stress concentration can be introduced during machining; their effect is less for the ASTM specimen than for the BS specimen (8).

As can be seen in Table 3, in the ASTM test the energy required for crack propagation in PMMA is more than twice of that required for crack initiation; in the BS test they are about equal. Therefore the ASTM test results are much less likely to be affected by the specimen preparation than are BS test results. The BS specimens are more susceptible to imperfections in the notch surface and to the direction of machine marks (ie, stress-concentrating imperfections). Moreover, since a machined surface is never as smooth as a molded surface, molded (notched) specimens are expected to give higher values. This has been confirmed with specimens prepared from PMMA moldings where molded notch values are higher than machined notch values by a factor of 1.8. In addition, specimens with molded notches, especially those from crystalline polymers, exhibit higher impact strength than those with machined notches because of the difference in morphology or thermal stresses due to rapid cooling near the surface and slower cooling in the interior.

In the Charpy impact tester the specimen is mounted on a span support and struck centrally with a swinging pendulum (see Fig. 2). The results are expressed in terms of breaking energy per unit of cross-sectional area.

The Charpy pendulum impact test is most commonly employed in the European continent. Both the standard test bar and the small standard test bar are specified in the German Standard DIN 53453. The sample is notched and is

supported horizontally against the stops at either end. The pendulum striker hits the sample centrally behind the notch and the excess energy of the pendulum is measured by the angle of the subsequent swing. A large number of tests is necessary to give an average value. The Charpy-type test used in the United States is ASTM D6110 (Research Report D20-1034); in the United Kingdom, it is BS 2782, Methods 306 D and E.

Although the Charpy impact test is accurate and reproducible, significant errors may occur (10). Testing and machine variables tend to produce abnormally high values, since they retard the pendulum swing or otherwise cause excess energy losses. The recorded energy may be in error by as much as 100–200% at low energy and 15–20% at high energy levels. Differences are usually caused by the condition of the test machines; methods of machining and finishing the specimens; and cooling and testing (5). With strict controls and carefully prepared specimens, an average impact value should be accurate to within 5% for values up to 27.1 J (20 ft·lbf).

Pendulum-type machines are inexpensive and simple to use and maintain. Data can be produced from which fracture toughness G_{Ic} (more correctly known as the critical strain-energy release rate in Mode I) can be calculated (see FRACTURE and ASTM D5045-99 and later in this article). However, these machines are limited in the range of impact speeds, with a maximum of 3.4 m/s. Furthermore, the common practice of reporting only the total energy does not allow easy interpretation of the data, which can be overcome by using the instrumentation described previously. The use of instrumentation as described previously is often helpful for this purpose.

Falling-Weight Impact Instruments. Falling-weight methods are usually employed for sheet specimens. The weight may be gradually increased in mass, or dropped from increasing heights on the same specimen or onto a series of specimens. Like the pendulum tester, the machine is driven by gravity. The specimen, ordinarily in the form of sheet, is subjected to a direct blow from a falling weight. The weight is raised to a known height and is allowed to fall almost freely inside a guide tube or along a set of guide rails (see Fig. 4). A striker is mounted beneath the weight or in a guide resting on top of the specimen; the Gardner impact tester, usually preferred, is of the latter type. In recent years drop towers of considerable height have become commercially available. However, as the terminal velocity depends on the square root of the drop height, the maximum velocity that can be conveniently obtained is limited. In the case of the drop tower an arrangement similar to that described for the instrumented pendulum impact tester is necessary to determine the load applied to the specimen and the terminal velocity. Since the maximum velocity achieved with this type of machine is considerably higher than that available from the pendulum-type machine, vibration and inertial effects can interfere with the recording of the load signal. Therefore all supporting components must be as rigid as possible, and the piezoelectric load cell assembly must be of low mass and high rigidity to produce a high natural frequency. In addition to the load, the velocity of the falling weight must be determined. Frictional effects can result in significant errors when calculating the velocity by assuming free fall. The velocity must therefore be measured directly by a linear array of, for example, photoelectric sensors positioned near the end of the fall, just above where the specimen is struck. An accelerometer attached to the falling weight

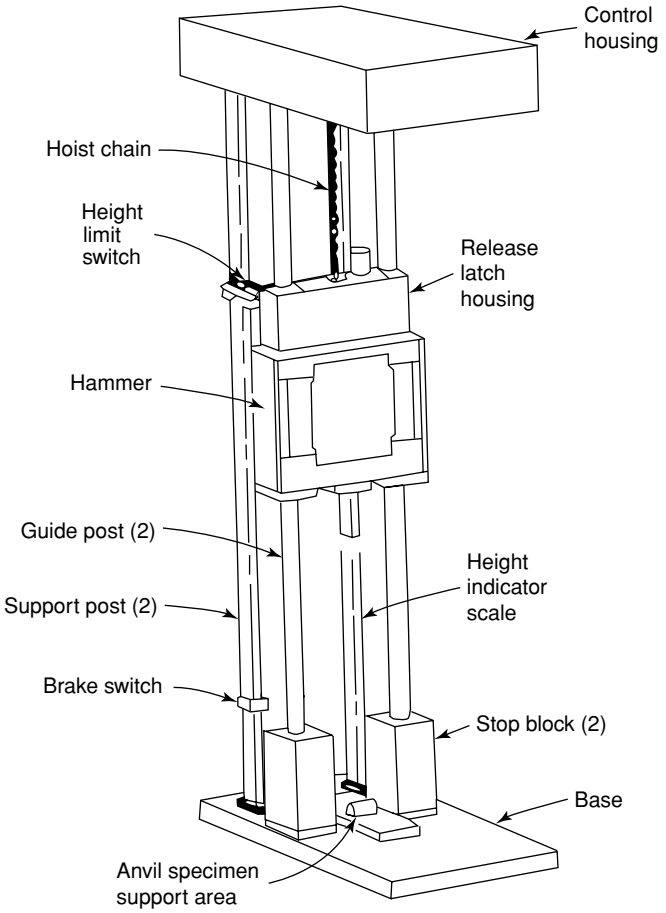

Fig. 4. Typical drop-weight testing machine (11). Courtesy of ASTM.

measures load and velocity separately. The electric signal from the accelerometer is recorded digitally as before. The absorbed energy and the force are calculated from the change in velocity caused by the impact. The results are obtained by processing the acceleration signal in the computer. The accelerometer must be mounted near the tip of the striker to minimize interference from reflected shock waves. An accelerometer is preferred over a load cell at high test velocities.

In the falling-weight test (BS 2782, Method 306B) also known as a dart-drop test or Gardner impact test, a spherical ball striker, 12.7 mm in diameter, is fastened to a load-carrying device to which weights can be attached. The striker assembly slides freely in vertical guides and is released from a predetermined height to strike centrally on a specimen, which is supported on the base of the equipment. In the so-called staircase method the load is increased by fixed increments on successive specimens, each struck once, until a specimen fails. The weight is then reduced by fixed increments until a specimen withstands the impact, after which it is increased again by fixed increments until a specimen fails again. This procedure is repeated on at least 20 samples to determine the energy

level at which 50% of the specimens break; the result is quoted as the impact strength for 50% failure (F_{50}) (see Fig. 5). An important source of uncertainty in this test is the criterion used to determine failure. Sometimes failure is obvious, as when the specimen shatters; other times failure is indicated by a small crack. As this is usually a visual test, whether or not failure has occurred depends on the judgment of the testing technician.

In the Probit method (13), a set of energy levels for the falling weight is selected. A series of specimens is tested at each level, and the failure–impact energy relation determined. With the help of a detailed failure–impact energy curve a simple control test can be carried out by testing a small number of specimens at a single fixed energy level. This procedure is far more reliable and economical than the F_{50} values.

In the common drop-weight test, force and displacement are not recorded by electronic instruments. On the other hand, in fully instrumented procedures a weight–height combination at which the specimen is consistently broken is found by trial and error, or by choosing a height that produces a desired terminal velocity and adjusting the weight to break the specimen consistently. A number of drop tests are then performed under identical conditions. Each test is recorded by an electronic instrument. The exact number of tests required depends on the divergence of the data and the confidence limit desired. This method requires fewer specimens. The velocity can be varied as desired (within the limits of the tester), and an entire set of data can be obtained at the same velocity. The deformation behavior, including the point of crack initiation, can in many cases be deduced from the load–deflection curve, reducing operator errors. Furthermore, the ability of a material to decelerate a moving mass can be assessed.

Many materials that give low Izod impact values on notched specimens fail in a ductile manner when tested in sheet form. Notched impact strength and the impact properties of sheet are not correlated because the stress states and the material responses differ.

The cause of failure of sheet material in practice is more likely to be revealed by a falling-weight impact test than by an Izod test (14). Falling-weight tests thus

give a better guide to practical behavior unless the molded article contains ribs, sharp corners, and similar geometry. Any anisotropy present, such as excessive orientation leading to weakness in a given direction, is revealed in the test. For example, an oriented injection-molded specimen may fail with a single straight crack at a low energy, whereas a substantially unoriented compression molded specimen of the same material would fail with cracks in several directions after having withstood much higher impact energies.

In falling-dart testers impact is produced by means of a pointed weight or dart. This method assesses the toughness of plastic film under certain specified conditions, such as sample geometry, dimensions of the dart head, and velocity. In one such apparatus, a perfectly flat specimen is clamped by a vacuum and held in uniform tension. The flat test film is placed over the specimen holder and kept wrinkle-free by the vacuum. The dart is automatically released from an electromagnet as soon as the correct pressure differential is reached. Darts of various weights are dropped, and the percent failure is plotted against dart weight on probability graph paper. A straight line is drawn through the plot. The intersection of the line with 50% failure is the weight in grams for F_{50} impact failure. ASTM D1709 gives a formula for the calculation of impact strength without a graph. In the examination of tubular film the edge fold as well as the face of the film may be tested. The U.S. specification for the falling-dart method (ASTM D1709-01) refers specifically to polyethylene film, whereas the U.K. standard (BS 2782, Method 306F) covers all flexible plastic film. In an equipment modification two electromagnetic counters are provided: one records the number of specimens tested and the other, which is operated by a push switch, the number of breaks. For tests of thick film, a clamping ring is provided in addition to the vacuum clamping to prevent film slippage, which is especially important in this case. In both specifications the dart, which has a 38-mm-diameter hemispherical head, falls freely 0.66 m to strike the specimen. The weight of the dart is adjusted with loose weights to determine the limit required to fracture 50% of the specimens. Other more recent versions are commercially available, usually equipped with digital recording devices and computer analysis of the results.

Tensile-Impact Instruments. A standard Izod impact-testing machine, a variation of the swinging pendulum, is easily adapted at little cost to tensile impact testing. The conventional Izod vise is replaced by one capable of holding the fixed end of a tensile specimen and a metal crosshead is secured to the other end of the specimen (see Fig. 6). The swinging pendulum strikes the crosshead removing both the crosshead and half of the specimen. Development of this instrument led to the specification ASTM D1822-99 (tensile impact energy to break plastics and electrical insulating material). This method can be used to measure the impact resistance of test pieces cut from actual moldings, and help to assess directional differences in stress that arise from flow-induced molecular orientation produced during mold filling. It is also very useful for the evaluation of very small samples. The energy required to produce failure can be obtained by varying the height of fall or the mass of the falling weight or by measuring the excess swing of the pendulum. Transducers and electronic instruments can provide load–deflection curves. The results show reasonable correlation with the falling-weight test of film and with the performance of moldings and sheet. Tensile impact instruments require less material than the usual falling-weight impact test. At relatively low

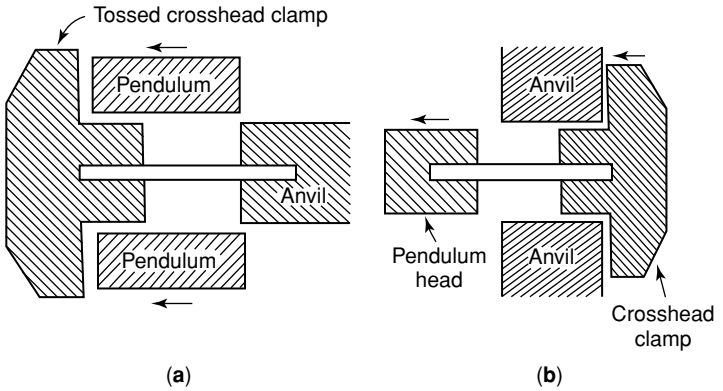

Fig. 6. Tensile impact machines. (**a**) Specimen in base; (**b**) specimen in head.

speeds they often give good correlation with falling-weight tests. This correlation is due to the fact that in both tests the tensile mode of stress is generated by the testing geometry. The falling-weight test, however, generates a biaxial tensile stress that can more easily give rise to failure. This is a consequence of the higher component of hydrostatic tensile stress in the biaxial tensile test, which favors the cohesive mode of failure.

Special Test Machines. Hydraulically and pneumatically driven machines have found increasing use in research and quality control laboratories; ASTM standards have not yet been established. These machines require higher operator skills and are more expensive, but offer better control and produce more information.

Hydraulic and pneumatic impact testing machines differ in the way in which the impact energy is derived, in the amount of energy and maximum velocity that can be developed, and in the amount of deceleration suffered by the striker. A hydraulic fluid or a gas under high pressure is stored in an accumulator. Upon receiving an electrical signal, a valve is opened, and the fluid or gas is transferred to a cylinder, wherein a low friction piston is connected to the load application device. The pressure difference between the two sides of the piston causes acceleration to a high velocity. Different designs in the valve and pressure return arrangement, and, increasingly, high speed digital electronics and signal processors allow the velocity to be controlled to varying degrees of success. The maximum load capacity of the testing machine depends on the pressure of the fluid, piston area, and pressure drop in the valve and upon expansion. The maximum velocity depends on the pressure, the flow rate allowed by the valve, the size of the accumulator, the inertia of the moving mass, and the distance allowed for acceleration. Commercial hydraulically driven impact testers are now capable of generating a maximum speed of 22 m/s at a maximum load of 900 kg (see Fig. 7); different designs are available including computers for control and data acquisition and analysis. Possible tests include tensile impact, puncture (flexed-plate) impact, and flexed-beam impact. A pneumatic machine is shown in Figure 8; anvils for various types of impact tests are shown in Figure 9. The high compressibility of gases means that the striker could decelerate significantly if the force required to deform the test specimen is high.

Fig. 7. Hydraulic high speed impact tester. (**a**) Specimen enclosed in environmental chamber; (**b**) hydraulic drive unit at the end of the rails for component testing. Courtesy of Instron Corp., Canton, Mass.

A principal advantage of hydraulic pneumatic machines employing feedback control is that a higher fixed velocity can be maintained. Much depends, of course, on the specifics of the design.

In pendulum machines the velocity upon striking the specimen is initially constant at 2.4 m/s in the Izod test, and 3.4 m/s in the Charpy test. After the specimen is struck the velocity decreases, depending on the amount of energy absorbed. This problem is more serious in tough specimens. In drop-weight tests, the velocity upon impact depends on the drop height, and yet the test results often report only the product of weight and drop height, ignoring the impact velocity. Since polymeric materials are rate sensitive in their mechanical behavior, tests using gravity-driven machines could produce misleading results because the terminal velocity just prior to striker contact with the specimen could vary widely. The use

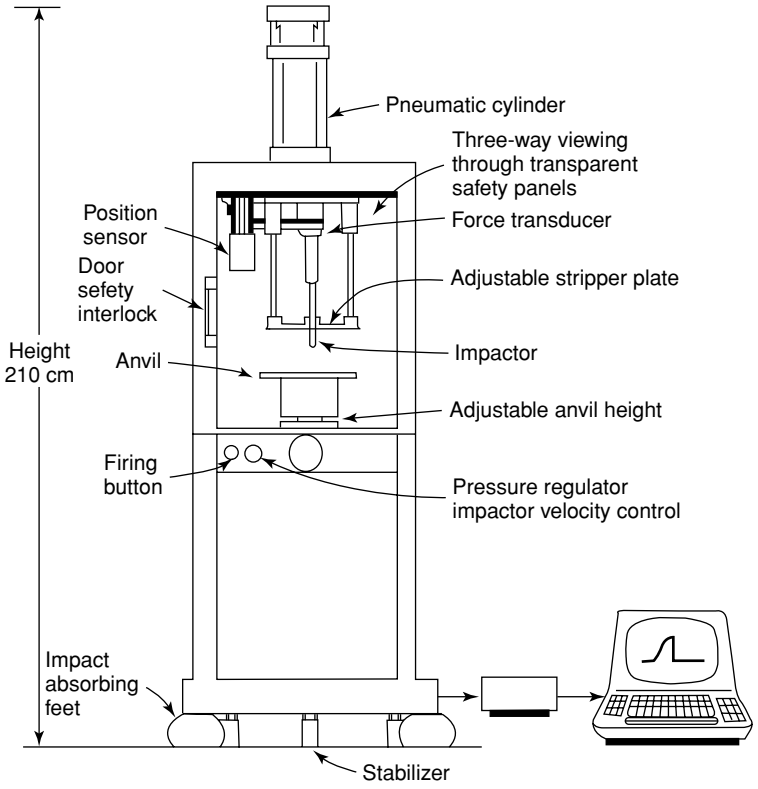

Fig. 8. Pneumatic impact tester. Various types of impactors, anvils, and force transducers are available for different applications. Courtesy of ICI Australia Operations Pty Ltd., Dingley, Victoria, Australia.

of the special machines described here avoids such problems. (This test standard has been discountinued in 1992.)

Product Testing. Standardized specimens are specially prepared for falling weight tests, swinging-pendulum tests, tensile impact tests, and others. However, frequently results from such tests fail to predict the performance of actual fabricated components in service. For this reason, the conventional forms of impact testing are more useful as control or material comparison tests. This limitation has become more serious in recent years with the rapid introduction of many new polymers and their blends. One reason for the difference in performance is the fact that the fabricating process can influence impact strength. A typical example is the effect of flow-induced orientation in thin-walled moldings. The flow behavior of the material during the filling of the mold may be more important than the basic impact properties of the unoriented material in governing the impact behavior of the thin-wall moldings. Specimen geometry is also important because the stress state and rate of stress buildup are governed by the size and shape of the article. Therefore the impact strength of the finished product may need to be tested under appropriate conditions in addition to the usual control and quality tests.

Mechanical Behavior

Tensile Impact. The tensile impact test subjects a specimen to uniaxial tension at a strain rate of approximately $10^2 s^{-1}$. This strain rate is 3–6 orders of magnitude higher than that encountered in conventional uniaxial tension testing (7,15,16). The effect of strain rate on uniaxial tensile behavior depends on the scale of deformation and the temperature range. At small strains the tensile modulus E increases with strain rate, but the magnitude of change depends on the temperature range. If the relaxation process is significant, eg, the glass transition or a strong secondary relaxation occurs near the test temperature, the modulus would also be rate dependent. The change can be about a factor of 2 for a secondary relaxation, and an order of magnitude or more for a temperature somewhat below T_g. If no significant relaxation occurs near the test temperature, E can be unaffected by the strain rate. At room termperature, PMMA has a strain-rate senstitive modulus whereas PC has not, although at sufficiently high rates strain-rate sensitivity develops. At strains beyond 1–2%, some materials become brittle even at low strain rates. An example is commercial PS, which typically contains small amounts of foreign material that serves as nucleation centers for craze initiation. Pure PS without surface flaws may be susceptible to shear yielding; increasing strain rate reduces flaw tolerance. If the material is not brittle enough to fracture, it eventually reaches a yield point defined as the maximum in the load–elongation curve. This yield point is not necessarily due to shear yielding. Impact-modified polystyrene, for example, exhibits a yield point independent

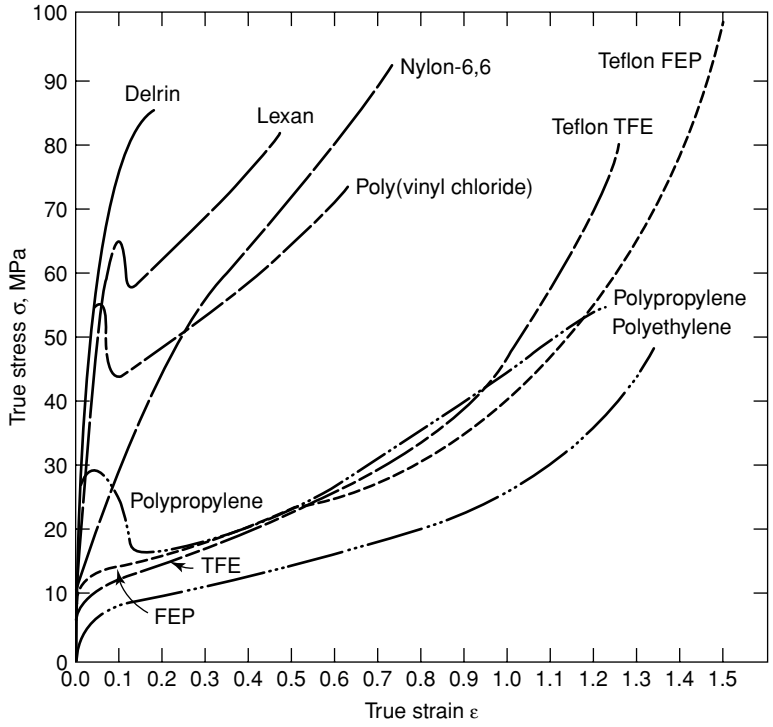

Fig. 10. True stress–true strain behavior of polymers. Delrin is an acetal resin; Lexan, a polycarbonate; Teflon TFE designates the tetrafluoroethylene homopolymer; Teflon FEP is a copolymer of tetrafluoroethylene and hexafluoropropylene (17). To convert MPa to psi, multiply by 145. Courtesy of Polymer Engineering and Science.

of shear yielding. If the load maximum is due to shear yielding, further straining results in a neck because of strain softening (16). Some crystalline polymers do not exhibit a maximum in the load–elongation curve but merely a knee because of the strengthening effect of the spherulites. Yield strength usually increases with strain rate (15,16). The strain-rate sensitivity of the shear yield stress behaves in much the same fashion as the modulus; it also depends on a significant relaxation process near the test temperature. After neck formation the strain-rate sensitivity stabilizes and neck extension occurs (16). On the other hand, thinning of the neck results in ductile fracture, which can also be due to high strain rates.

Examples of uniaxial tensile true stress–true strain behavior of polymers deformed at low strain rates are shown in Figure 10. Common engineering stress–strain curves cannot be used to determine the elongational strain because the shape for a given set of testing conditions depends on the specimen geometry. Some polymers show ductile deformation after yield by a process of necking and cold drawing. The apparent neck extension depends on the length of the specimen gauge section if the conventional method of calculating engineering strain $\varepsilon = \Delta l/l_0$ is used, where Δ_1 is the elongation and l_0 the original gauge length. The true value of the extensional strain can be ascertained only by direct measurement of the strain in the necked section. If the specimen dimensions are identical and

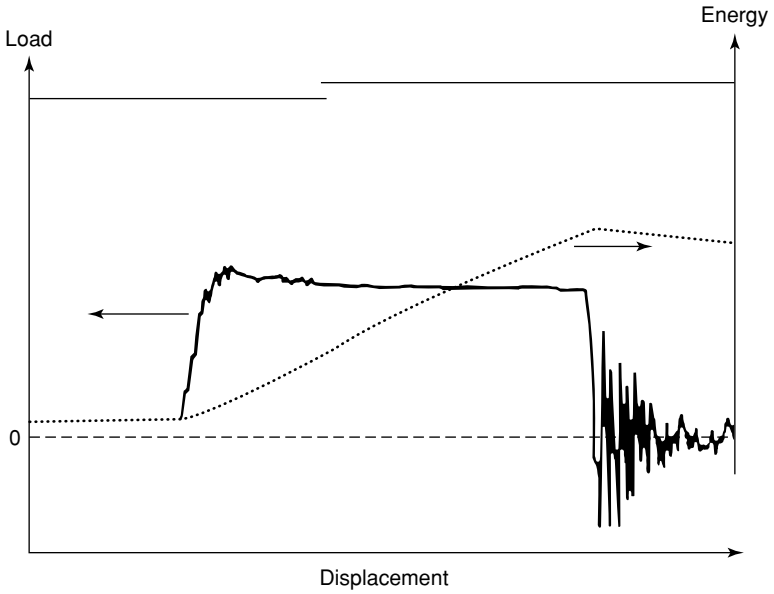

Fig. 11. Typical load and energy data from tensile impact test on polypropylene using an instrumented pendulum tester. The dotted line shows the accumulated energy as the deformation increases. Courtesy CEAST SpA, Torino, Italy.

the extents of necking comparable, the apparent maximum engineering strain can be used as a relative ductility index. Ductility usually decreases with strain rate or decreasing temperature. At a given strain rate and temperature, ductility depends on molecular weight and amount of filler or impurity in the material. Stresses applied orthogonal to the principal stress direction can also affect ductility. *Tensile impact toughness*, a measure of the total energy absorbed by a dog-bone-shaped specimen in uniaxial tension, is the integrated value of the typical force–elongation curve. It is highly sensitive to the ductility of the material at the testing rate. The tensile impact behavior of polypropylene is shown in Figure 11. The curve is typical of a pendulum impact tester equipped with transducers and digital storage instruments. The strain-softening behavior is clearly discernible even at such a high strain rate. The advantage of electronic instrumentation can be seen immediately.

Flexed-Plate Impact. In flexed-plate impact, a ball, dart, or striker is driven by gravity or pressure into a thin plate supported by or clamped over an annular area. The nose of the dart is usually hemispherical, though sometimes square. A flex-plate impact test corresponds closely to conditions of actual use. However, geometric factors, such as specimen thickness and dart-to-annular opening ratio, cannot be readily standardized, and furthermore, the geometry itself can cause a change in the deformation mode (14). The progression of deformation processes associated with the load–deflection curve can be seen in Figure 12. In Figure 12A the specimen failed in a ductile manner and the plastic deformed extensively around the dart nose. The remaining unsupported material was cold drawn. Partially deformed specimens and finite-elements analysis reveal yielding

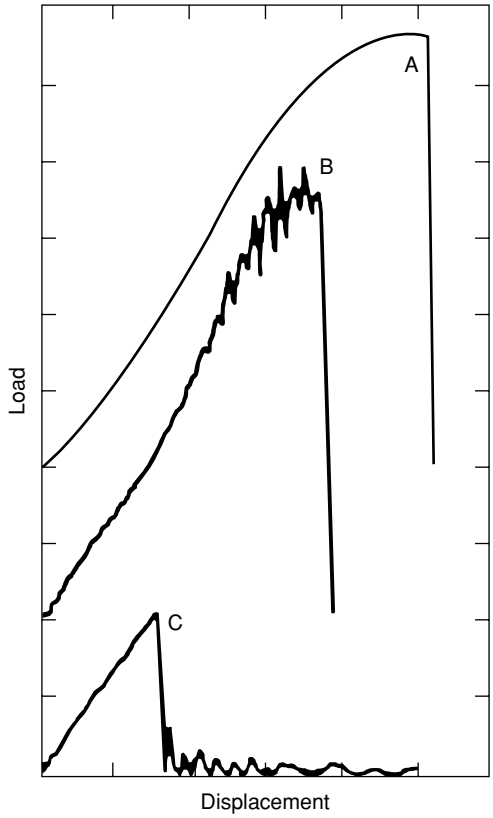

Fig. 12. Typical load–deflection data from puncture impact tests. (A) ductile failure; (B) cracking started at about 50% of the maximum load; (C) brittle failure (18).

under the dart early in the deformation process, at about 25% of the maximum load. This initial yielding is marked by a slight decrease in the slope. Subsequently a yielded zone in the shape of a hemispherical dome develops around the dart nose. As deflection continues, the net area undergoing yielding also increases, which results in geometric hardening, ie, the load increase is due to the change in specimen geometry as described above. The processes of material softening and geometric hardening eventually combine to result in a slight increase in slope. At this stage of the deformation the unsupported area of the specimen is akin to that of a membrane rather than a plate. The stress in the membrane is essentially uniaxial tension in the radial direction. Finally, excessive thinning takes place somewhere in the specimen, the exact location being dependent on the geometry, and rupture causes the load to drop precipitously (18,19). Thus, the total energy absorbed, which is the area under the load–deflection curve, depends in a very complex manner on both the testing geometry and the yield and deformation behavior of the material. The curve of Figure 12B is obtained when the specimen develops a crack during the membrane-stretching process. The sudden release of elastic energy upon cracking causes the load-cell assembly to vibrate at its natural frequency and results in the "ringing" signal. The crack is stabilized by the

specimen geometry and does not propagate. Consequently the specimen is able to carry an increasing load even though, by some definitions, the specimen would be considered to have failed (18). The curve in Figure 12C is obtained when the specimen fails in a totally brittle manner; no decrease in the slope of the load–deflection curve is discerned. Cracking occurs on the tension side opposite the area where the dart or striker contacts the plate. Little or no plastic deformation occurs anywhere on the specimen. Brittle fracture of this type occurs more readily in thick plates even for materials normally considered to be ductile. This observation serves to warn against treating such test results as material properties. Clearly, the test specimen and specimen holding fixture contribute importantly to the test results.

In addition to plate thickness, decreasing temperature, increasing deformation rate, or environmental aging can transform ductile-type failure (Fig. 12A) to brittle-type failure. In the case of a ball or a hemispherical dart impact test, it is commonly assumed that the resultant stress state at the center of the plate is biaxial tension. This assumption is erroneous because the normal force on the plate is significant and could lead to over optimistic values on ductile-to-brittle transition conditions, whether expressed as a critical temperature or aging time. This behavior is caused by normal stress suppressing brittle failure (15,18,20).

Flexed-Beam Impact. Flexed-beam impact tests are sometimes carried out on unnotched specimens, though notched specimens are preferred. The Izod and Charpy tests are examples of flexed beam tests. These two testing geometries are different, but both types of notches create a severe stress concentration. Many materials that are tough in the tensile and flexed-plate impact tests become brittle in notched flexed-beam tests because the stress state near the base of the notch favors a brittle response due to the high component of hydrostatic tensile stress mentioned above. For a given specimen thickness, the impact toughness depends on the notch tip radius (see Fig. 13). Subjecting a thin, notched specimen to bending creates a tensile stress concentration along two orthogonal directions: the main one along the specimen length, the other parallel to the notch or crack direction. The magnitude of the former depends on the notch sharpness. The minor stress is due to constraints created by notch-free sections of the specimen, which are at a lower stress. Because the specimen is thin, it contracts freely in the thickness direction; a state of plane stress is said to exist in this instance. The biaxial tension state is more favorable than the uniaxial tension state for craze or crack formation because of the larger hydrostatic or dilatational stress component in the former case. Many polymers that are ductile in uniaxial tension exhibit brittle behavior in this stress state; other polymers are able to shear-yield. Shear yielding creates a large plastic zone at the notch tip, and subsequent failure is due to ductile tearing of the material. This mode of failure usually absorbs a large amount of energy. Some impact-modified materials are able to form a plastic zone ahead of the notch containing of a high density of crazes. Considerable energy can be absorbed by this mechanism. The load–deflection behavior of tough plastics is illustrated in Figure 14.

Subjecting a thick notched, notch-sensitive specimen to bending creates a tensile stress component that is perpendicular to the specimen faces. This third stress is due to constraint in the thickness direction because the material ahead of

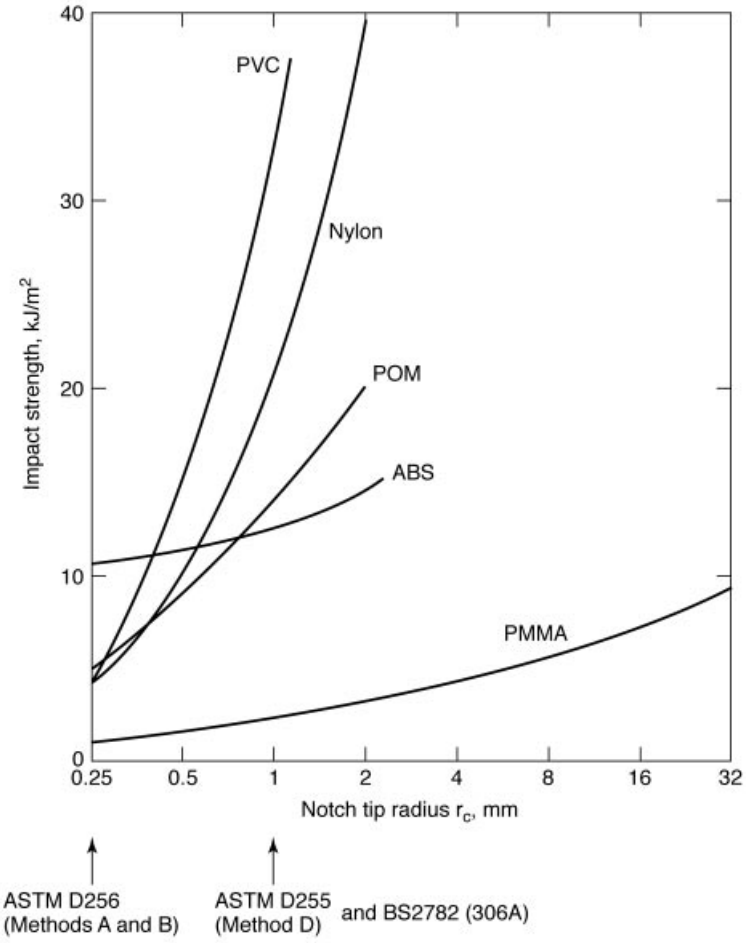

Fig. 13. Impact strength as a function of notch tip radius for different polymers (21). To convert kJ/m^2 to $ft{\cdot}lbf/in.^2$, divide by 2.10. POM = polyoxymethylene. Courtesy of The Plastics and Rubber Institute.

the notch is unable to contract freely in this direction; the constraint effect is said to be due to plane strain. The triaxial tension state is even more favorable than the biaxial tension state for the formation of crazes, again because of the larger dilatational stress component in the former. With sufficiently large thickness and sharp cracks few unmodified polymers are able to deform in a completely ductile manner owing to the intrinsically low cohesive strength of polymers relative to their yield strengths. The fracture is due to craze formation and rapid crack propagation. At intermediate thicknesses or notch radii the specimen can deform in mixed mode: plane-strain in the specimen center and plane-stress near the surfaces. In the plane-stress region, plastic deformation zones are often found. Their size determines the amount of energy absorbed by the specimen; the plane-strain zone, by contrast, absorbs little energy.

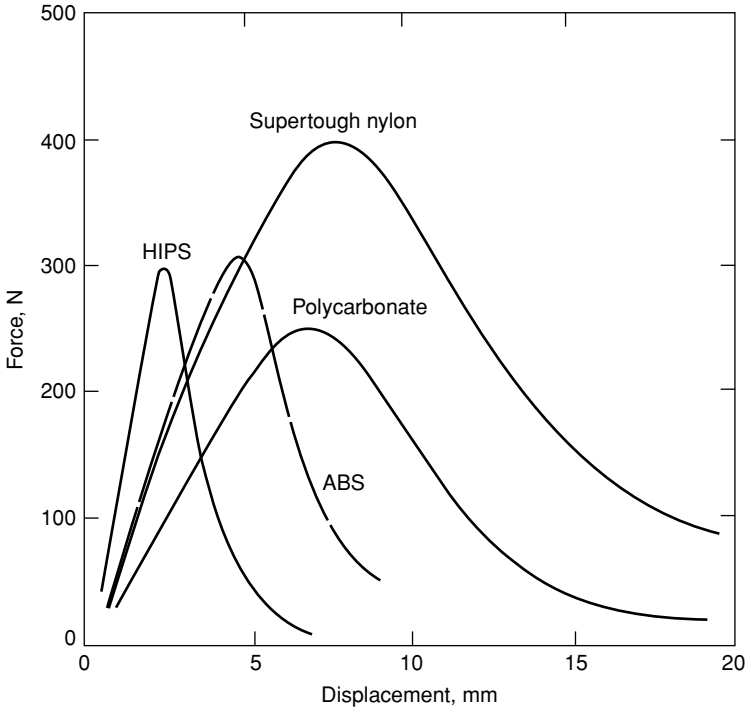

Fig. 14. Load–deflection behavior of a number of tough polymers tested in the notched Charpy geometry at low rates (22). To convert N to kgf, multiply by 0.102. Courtesy of the Society of Plastics Engineers.

The impact toughness of a material, as measured by a flexed-beam test on a notched specimen, depends on the thickness of the specimen and the radius of the notch, and therefore cannot be considered a material property. Furthermore, the transition from predominantly plane-stress to predominantly plane-strain is unpredictable when complex geometries are encountered in structural components. Because this transition can create unexpected and catastrophic failures, some polymers normally considered to be very tough and ductile may benefit from impact modification. The modified versions are less sensitive to geometric variations.

The transition from plane-stress to plane-strain can also be brought about by impact rate (23), temperature (Fig. 15), molecular weight, and thermal history (24). The effects of thickness and rate are shown by an example in Figure 16. In this example notched polycarbonate (PC) specimens are tested at various bending speeds. The thick (6.4 mm) specimens are uniformly brittle, whereas the thin (3.2 mm) specimens are uniformly ductile. The intermediate thickness (4.4 mm) specimens exhibit a ductile-to-brittle transition at about 0.3 cm/s. In toughened PC even the 6.4-mm-thick specimens are tough up to about 40 cm/s (see Fig. 17).

Fracture Toughness from Flexed-Beam Impact Tests. As stated above, the so-called impact toughness values obtained from Izod and Charpy tests are not material properties because they depend on specimen thickness, notch depth, notch radius, and other factors unrelated to material properties. These

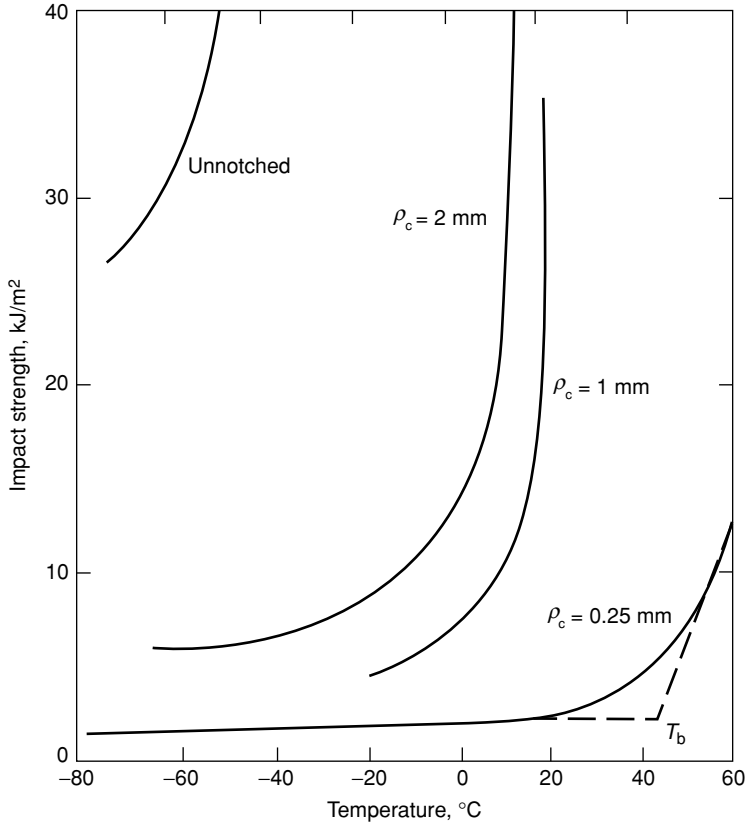

Fig. 15. Effect of test temperature on the impact strength of PVC specimens containing various notch radii (21). T_b = brittle temperature. To convert kJ/m^2 to ft·lbf/in.^{2}, divide by 2.10. Courtesy of The Plastics and Rubber Institute.

values are therefore useful only for the comparison of different materials, and are useless for design calculations. By contrast, fracture toughness (ASTM D5045-99), which is a material property, is useful in design calculations. Consequently it is desirable to have fracture toughness values that are taken under impact conditions, and especially if they could be obtained from the Izod or Charpy test machines.

The fracture toughness G_{Ic} can be determined from the impact energy U if the geometry of the specimen is known (25) and if the specimen fails in plane-strain. To determine if the latter condition is satisfied one could examine the fracture surface. If the top edges of the fracture surface remain in the planes of the sides of the specimen and no sign of large-scale plastic drawing in front of the notch tip is observed then this condition is probably satisfied. Another signature for plane-strain fracture is the load–deflection curve, which would have the shape of a right triangle. This points out the desirability of using an instrumented tester.

In this analysis it is assumed that linear elastic fracture mechanics (LEFM) applies. When a specimen containing a sharp notch of depth a is subjected to

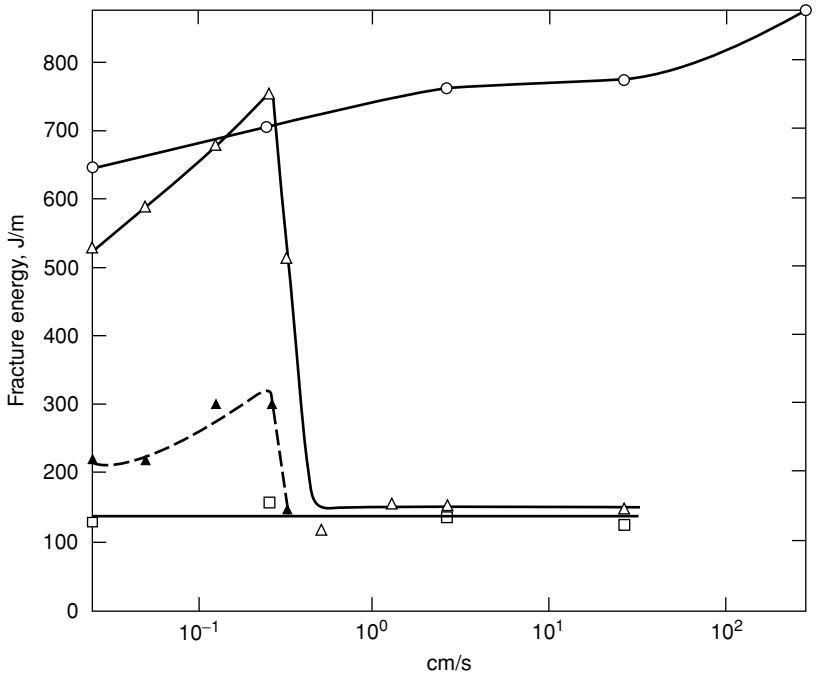

Fig. 16. Effect of test speed on the fracture energy of polycarbonate specimens of various thicknesses tested in the notched Charpy geometry. ○, 3.2 mm; △, 4.4 mm; ▲, energy up to load maxima for 4.3 mm; □, 6.4 mm (22). To convert J/m to ft·lbf/in., divide by 53.38.

bending with a load P, a deflection x results. The energy U stored is given by

$$U = Px/2 \tag{1}$$

When the crack grows, compliance $C = x/P$ increases as the stored energy is released. Thus, if it is known how C changes with a the strain-energy release rate G can be calculated from equation 1

$$U = P^2C/2 \tag{2}$$

For a specimen of uniform thickness B,

$$G = \frac{1}{B}\frac{\mathrm{d}U}{\mathrm{d}a} = \frac{1}{B}\frac{\mathrm{d}U}{\mathrm{d}C}\frac{\mathrm{d}C}{\mathrm{d}a} \tag{3}$$

When fracture occurs, the critical strain-energy release rate G_c is calculated:

$$G_c = \frac{P^2}{2B}\frac{\mathrm{d}C}{\mathrm{d}a} \tag{4}$$

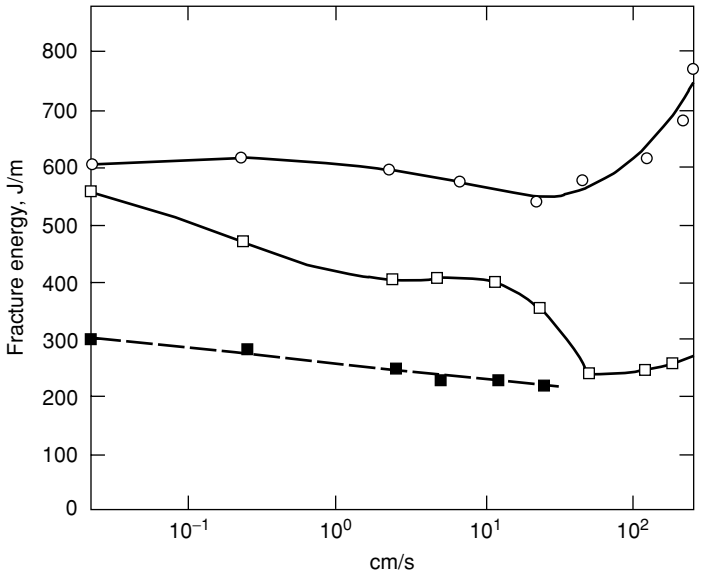

Fig. 17. Effect of test speed on the fracture energy of an impact-modified PC as in Figure 16. ○, 3.2 mm; □, 4.4 mm; ■, energy up to load maxima for 6.4 mm (22). To convert J/m to ft·lbf/in., divide by 53.38.

In an impact test, usually only the energy U is determined. Combining equations 2 and 4 gives

$$U = G_c B \frac{C}{\mathrm{d}C/\mathrm{d}a} \tag{5}$$

In practice, U is determined for a series of specimens with various notch depths a. It is therefore more convenient to express equation 5 in terms of

$$G_c = \frac{U}{BDC} \frac{\mathrm{d}C}{\mathrm{d}(a/D)} \tag{6}$$

where D is the specimen width. The dimensionless compliance function

$$\phi = \frac{C}{\mathrm{d}C/\mathrm{d}(a/\mathrm{D})}$$

can be determined experimentally from quasi-static bending tests, and has been calculated analytically for this geometry (26). Equation 6 can then be rewritten as

$$U = G_c B \mathrm{D} \phi \tag{7}$$

predicting that a linear relationship should exist between the impact energy U and $BD\phi$, the slope of which should be equal to G_c. G can then be obtained by

determining U for a series of specimens with various notch depths if the relationship is indeed linear. If the impact tester is instrumented, a further criterion would be a rapid drop in load P after reaching a peak, ie, the load–deflection curve should have the shape of a right triangle. If the notch is too blunt and a significant amount of plastic flow occurs, which would cause the top of the load–deflection curve to round off, a correction factor may be needed, ie, the crack length a is increased by the plastic zone size r_P (25,27):

$$a_f = a + r_P$$

The plastic zone size can usually be determined from the appearance of the fracture surface and is distinguished by a whitened or very rough area directly ahead of the original notch tip. The G_c, values for some plastics for both the Izod and Charpy geometries (25) are in Table 4. With the same method, the G_{Ic} of a number of polymers was determined (3) at different rates (Fig. 18).

The procedure outlined above can be useful if the specimens are prepared carefully to ensure that LEFM applies. The specimen should be as thick as is practicable, and the notches should be very sharp. If a razor blade is used for cutting, a compressive plastic zone must be avoided at the notch tip. This can be accomplished by slicing the notch tip rather than by pressing the blade into the notch. If the fracture surface contains plastic flow, the crack size most likely has

to be corrected. The method for determining fracture toughness can be extended to tensile impact of a notched specimen (28).

Improving the Impact-Resistance of Materials

Impact resistance is not an absolute term. It depends on the design of the structure as much as it does on the intrinsic material toughness. Nevertheless the impact resistance of a material can be increased by modifying it with toughening. This increase is sometimes at the cost of reduced modulus and strength, and perhaps fatigue resistance. The impact toughness of commercial plastics is shown in Table 5.

High Impact Polystyrene (HIPS), Acrylonitrile–Butadiene–Styrene Copolymer (ABS), and Modified Poly(xylenol ether) (PXE). Polystyrene is a transparent, rigid, easily processable, inexpensive material. Its chief disadvantages are extreme brittleness and high susceptibility to crazing by organic liquids. It was also among the first materials to be produced in a toughened form, commonly known as HIPS, in order to allow the material to be used in applications with moderate loadings such as electrical applicances.

In the most common production method rubbery polybutadiene (PBD) is precipitated from a styrene–polybutadiene solution in styrene during the polymerization of styrene. The precipitated phase itself typically contains 2–10-μm particles consisting of a rubbery sphere containing spheroidal polystyrene inclusions that are separated by thin membranes of PBD rubber (see Fig. 19). It is believed that this type of composite particle has an advantage over solid rubber spheres because for a given weight fraction, it maximizes the effective volume fraction of the rubbery phase, thus enhancing the impact toughness without causing undue reduction in modulus. The rubbery phase can also be introduced by blending PS with

a triblock copolymer such as poly(styrene–butadiene–styrene) (SBS). The toughening is believed to be due to the nucleation and controlled growth of extensive crazing at the rubber–PS interface (29). The appearance of stress-whitening is due to the high density of crazes generated by deformation. The stress–strain behavior of ABS, PS, and a typical HIPS are shown in Figure 20. It is readily apparent that HIPS has much lower modulus and tensile strength, but much higher elongation

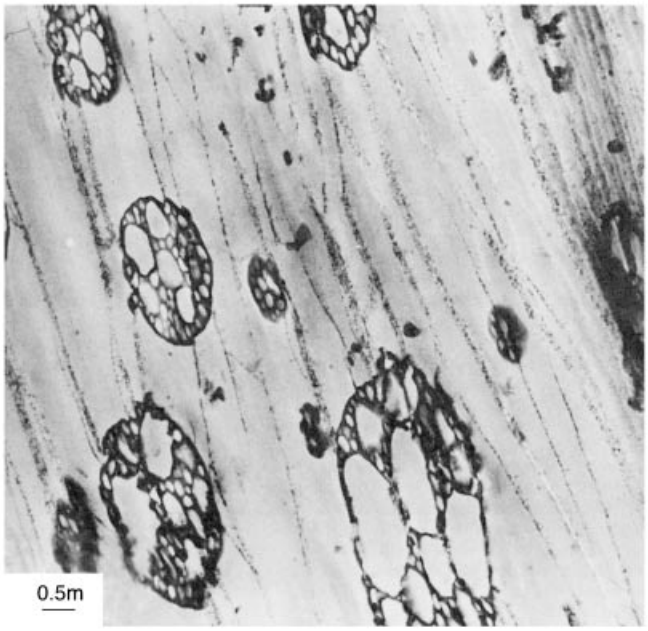

Fig. 19. Electron micrograph of an osmium tetroxide stained ultrathin section of HIPS. This micrograph shows the typical morphology of the dispersed rubber particles. The thin lines connecting the particles are crazes formed after the material has undergone deformation.

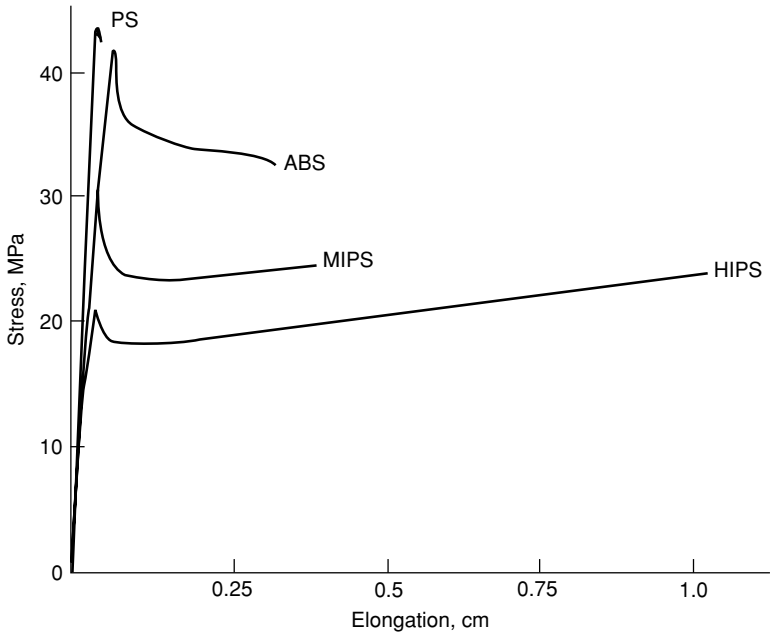

Fig. 20. Typical uniaxial tensile stress–strain behavior of PS, medium-impact PS (MIPS), high-impact PS (HIPS), and ABS (30). To convert MPa to psi, multiply by 145. Courtesy of Springer-Verlag.

than PS. At the cost of a decrease in modulus and strength, ductility and impact toughness are greatly enhanced because of the higher volume fractions of rubber particles in the tougher materials.

Acrylonitrile–butadiene–styrene polymers (qv), the impact-modified version of SAN (styrene–acrylonitrile copolymer), are produced in the same manner as HIPS. Block copolymers such as SBS may also be used as the second phase. The morphologies of ABS and HIPS are very similar except that for optimal impact toughness the rubber particles in ABS are smaller than those in HIPS, ca 1–5 μm in diameter. The difference between ABS and HIPS, as far as mechanical behavior is concerned, is due to the fact that SAN is more ductile than PS. Consequently, the impact toughness of ABS is higher than that of HIPS. Because of compositional and morphological differences, these materials exhibit a range of mechanical properties. For a given volume fraction of rubber particles in ABS, higher AN (acrylonitrile) content enhances toughness. The toughening mechanism is believed to consist of the formation of numerous shear bands in addition to massive crazing (29); both are due to the presence of the rubber particles. In certain ABS grades deformation in tension causes the formation of cavities inside the rubber particles, leading to the formation of shear bands from these cavitated particles (31).

The toughest member in this category of plastic materials is a blend of poly(xylenol ether) [PXE, poly(2,6-dimethylphenylene oxide)] and PS and a rubbery impact modifier; PXE is also known as PPO [poly(phenylene oxide)] (Table 6). However, PPO, a registered trademark, can be confused with poly(propylene oxide), and therefore PXE is the preferred abbreviation. PXE is completely miscible with PS and forms a true solid solution (32); T_g is high and the material is ductile. Melt viscosity is also very high. Processability is improved by blending with PS; the viscosity of the mixture is approximately the weighted average of the two components, whereas T_g varies with the composition (32). Compared with the weighted average, moduli and yield strengths are higher but the fracture toughness is lower (32,33). Commercial grades are usually impact-modified by a dispersion of rubbery particles, which are sometimes obtained by directly blending PXE with HIPS instead of PS. The stress–strain behavior of HIPS/PS/PXE blends is shown in Figure 21. The PXE/HIPS blends exhibit a good overall combination of mechanical properties. The toughening mechanism is believed to be a combination of shear banding and massive crazing (29). The PXE/HIPS blends are much more expensive than HIPS or ABS. Furthermore, they require precise

Table 6. Composition of HIPS/PS/PXE Blends (wt%) Investigated

Blend	HIPS	PS	PXE
A	50	50	0
B	50	37.5	12.5
C	50	25	25
D	50	12.5	37.5
E	50	0	50

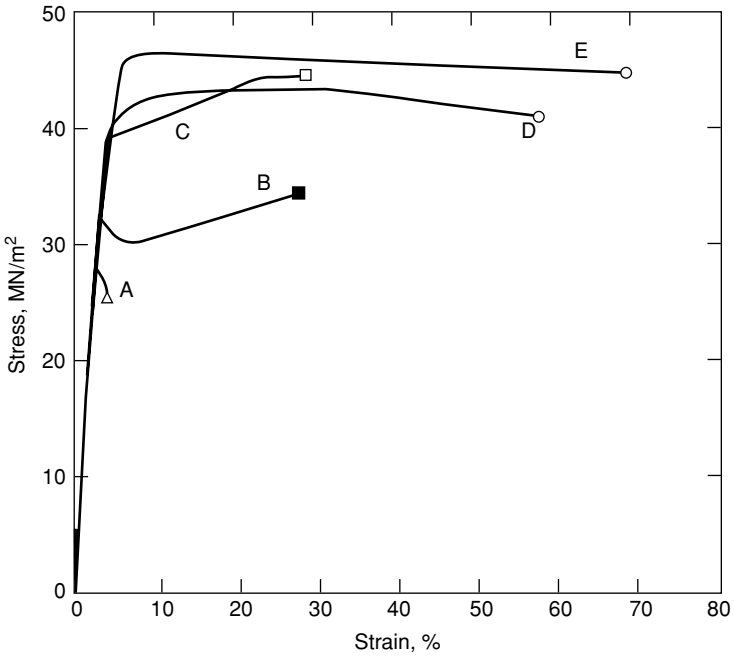

Fig. 21. Uniaxial tensile stress–strain behavior of HIPS/PS/PXE blends at 20°C showing the effects of matrix composition. Strain rate 4×10^{-4} s^{-1} (29). To convert MN/m^2 to psi, multiply by 145. Courtesy of Applied Science Publisher Ltd.

processing control in injection molding because of the relatively high melt viscosity of commercial PXE.

The terms HIPS, ABS, and PXE refer to families of polymers, within which there are variations in composition, morphology, and properties. This is especially true of PXE blends, which exhibit behaviors in between those of HIPS and PXE. Processing and applications must be specific to each grade. As in other materials, pigments, flame retardants, and especially reinforcing fillers can have significant effects on impact toughness. The relevant properties must be determined for each composition.

Since the toughness of these materials depends on the presence of rubber particles, the destruction or oxidation of these particles reduces impact toughness. Excessively high temperatures or shear rate during processing and prolonged exposure to oxidative environments destroy or cross-link the rubber and must be avoided. Prolonged exposure to ultraviolet radiation degrades these materials because of the decomposition of the PBD rubber and sometimes PXE. Saturated elastomers resist oxidative degradation better than unsaturated PBD. In such instances, the low temperature impact toughness of the material might be impaired because the T_g of the saturated rubber is usually higher than that of PBD. UV stabilizers may improve the resistance of PXE to sunlight. The rubber particles act as effective sites for the nucleation of crazes in cyclic fatigue.

Therefore fatigue initiation occurs more readily in the impact-modified versions than in the unmodified versions; crack propagation is slower in the former (30).

Polycarbonates, Other Ductile Glassy Polymers, and Their Impact-Modified Versions. A number of glassy polymers possess some degree of ductility at or near room temperature at moderate rates of strain ($<100\%\ s^{-1}$). Ductility is defined here as the percentage of permanent elongation after yield in a uniaxial tension test. These polymers include polycarbonate (PC), polysulfone (PSU), polyethersulfone (PES), some polyesters, and others as well as copolymers derived therefrom. Some low T_g difunctional epoxies also belong in this category. Poly(vinyl chloride) (PVC), which may possess a low degree of crystallinity, and which loses its ductility more readily under adverse external conditions such as low temperatures and impact rates than other members in this category, may be included here. The class of materials discussed here, whether impact-modified or not, generally exhibits high values of tensile-impact toughness compared with the styrenic materials discussed previously. Drop-weight impact toughness may also be high. However, a flexed-beam impact test (ie, Izod or Charpy) performed on notched specimens of these materials may produce brittle behavior. Using typical notched Izod impact geometries (notch depth of 2.5 mm, notch tip radius of 0.25 mm) and a specimen thickness of 3.2 mm, some of these materials fail in a brittle mode and exhibit impact toughness values that are surprisingly low, given the fact that these same materials are ductile in uniaxial tension. Other materials, PC for example, fail in a ductile mode and absorb large amounts of energy when the specimen thickness is 3.2 mm or less, but dramatically change to the brittle fracture mode when the specimen thickness is increased or the temperature lowered. The specimen thickness effect is due to the difference in constraints at the surfaces and in the interior of the specimen. The temperature effect is not well understood, but is undoubtedly due to the different temperature dependencies of the shear yield stress and crazing stress. These dependencies may be correlatable to molecular relaxations.

The need for impact modification of this type of materials is not based on brittleness but on notch sensitivity. Impact modification does not necessarily enhance toughness when tensile impact and drop-weight impact tests are the criteria. Impact modification is achieved by melt blending a second soft, usually elastomeric, phase, which may be in the form of a dispersion of spherical particles or a network-like structure. To aid the dispersion of the second phase, compatibilization is usually required; that is, the elastomer is copolymerized or altered chemically to reduce the interfacial energy between the two polymer phases. Inadequate compatibilization can lead to unstable morphologies after melt processing, which can in turn produce weak knit lines in injection-molded articles, or skin and core morphologies that interfere with the proper functioning of the processed article and reduce the impact resistance of the molded articles.

It appears that the toughening effect near a crack tip occurs as follows: after initial deformation, cavitation occurs within or around the soft phase in a zone surrounding the crack tip. This zone is known as the process zone. The newly created surface around these cavities in the process zone allows the latter to grow plastically, thus absorbing some energy. Localized shear deformations, often referred to as shear bands, may also grow from these cavities. If the volume fraction

of the soft phase is sufficiently large, these shear bands may merge or coalesce. Since the localized deformation in shear bands cannot be recovered, it is known as plastic deformation. If the plastically deforming material is adjacent to a surface, eg, a crack, then the unloading that occurs there absorbs additional energy (34). The latter may be a significant mechanism of energy absorption in materials that exhibit this mechanism. However it may not occur if the crack growth is terminated by unstable fracture, which often occurs, due to the geometry of crack growth or to very high rate of deformation.

Cavitation in or around the soft phase causes stress-whitening, which is often observed at and near the fracture surface of broken specimens. Stress-whitening is sometimes mistakenly attributed to crazing. While profuse crazing could certainly give rise to intense whitening, the latter could also be due to the occurrence of numerous cavities associated with the rubber phase. Cavitation (including crazing) is an essential step in the toughening process because it relieves the triaxial tension around each cavity initially built up at the crack tips. After the triaxial tension is relieved by cavitation, the stress that remains is more favorable for shear yielding. Since these materials are more prone to shear yielding than to crazing, ductile fracture is restored.

Evidence for the initial deformation process described above can be seen in the three micrographs of an epoxy toughened with elastomer, shown in Figure 22. In Figure 22a, cavitated rubber particles can be seen in a scanning electron micrograph of the fracture surface. In Figure 22b, the cavitated rubber particles can be clearly discerned beneath the fracture surface. The shear bands between the rubber particle cavities are revealed by viewing the specimen between crossed-polarizers in Figure 22c.

Semicrystalline Polymers and Their Toughened Versions. Semicrystalline polymers are different in mechanical behavior from glassy polymers. Conventional melt processing techniques may produce semicrystalline morphologies in many polymers. The polymers in this category include high density polyethylene (HDPE), polypropylene (PP), polyacetals (POM), polyamides (PA, or nylons), poly(ethylene terephthalate) (PET), poly(butylene terephthalate) (PBT), and more recent materials such as poly(phenylene sulfide) (PPS), and polyetheretherketone (PEEK). Low modulus polymers such as low density polyethylene (LDPE) and certain thermoplastic elastomers can be included. Crystallinity is typically between 30 and 40%, though it can be as low as a few percent and as high as 80% in HDPE. Mechanical behavior of semicrystalline polymers depends strongly on the degree and distribution of crystallinity and the differential cooling rates between the surface and the interiors of the specimens. In molded articles, the interior of a thick section contains many large spherulites. Since, in the presence of a notch, the interior is in plane-strain, resulting in triaxial tension, large spherulites invariably cause brittleness, apparently due to weak interspherulitic boundaries. In very thick sections voiding can also occur during the crystallization process. Sometimes, in the mistaken belief that larger cross-sections provide greater strength and a more gentle radius reduces stress concentration, a designer specifies very thick sections at the junction between two surfaces. This causes the growth of very large spherulites and voids, resulting in brittleness. Brittleness in this circumstance may be avoided by using thin sections. Stiffness can be overcome by the proper choice of cross-sectional geometries.

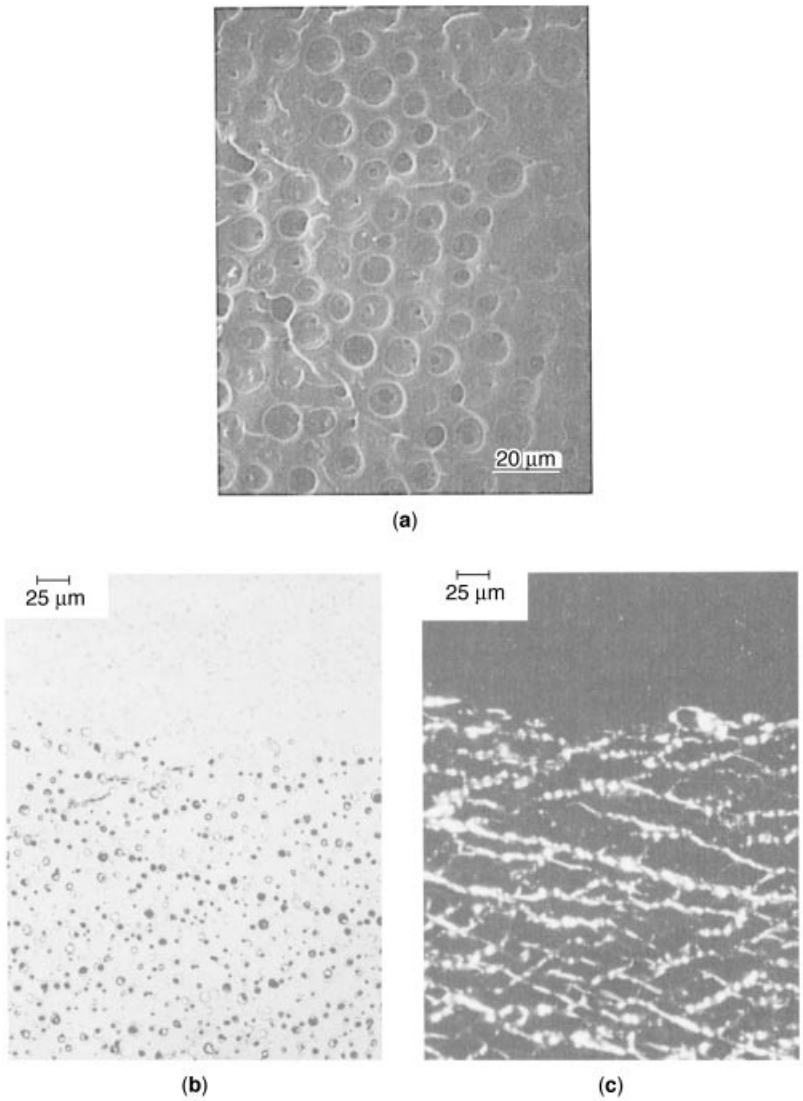

Fig. 22. (**a**) Scanning electron micrograph of the fracture surface of an elastomer-modified epoxy. (**b**) Optical micrograph of a thin section of the same epoxy. (**c**) The same optical micrograph viewed between crossed-polarizres.

Enhancement of impact toughness in some semicrystalline polymers is similar to techniques used for some glassy polymers. Usually an elastomeric phase is melt-blended into the host polymer, resulting in a dispersion of spheroidal elastomeric particles or a network. Compatibilization is obtained by copolymerization or chemical reaction at the interface. The toughening mechanisms may include both massive crazing and cavitation-plastic deformation, depending on the polymer blend, morphology, and degree of adhesion. The elastomeric phase may alter

the morphology of the semicrystalline phase, for example, by nucleating additional spherulites, perhaps of a different crystalline structure, thus improving the inherent toughness of the crystalline phase by reducing the spherulitic size. If toughening is caused by the formation of shear bands, deformation of spherulites contributes to energy absorption.

Incompatible Blends of Rigid Polymers. Some blends are composed of rigid polymers, one or both of which may be rubber-modified. Examples of these materials include PC/ABS, PVC/ABS, PC/PBT, and nylon/PXE. Other combinations are also possible. An important difference between these materials and the PS/PXE blend described above is that the latter is thermodynamically compatible, and behaves as a homogeneous material, whereas the former are thermodynamically incompatible. The incompatibility causes the components, though intimately mixed, to form a continuous-dispersed phase morphology, or a cocontinuous morphology; in the latter neither component can be considered a dispersion. The ABS blends are tough, presumably because the ABS component is already toughened. The commercial versions of the other two examples contain an elastomeric impact modifier. The morphologies and mechanical behaviors of these materials have not yet been studied in detail. However, because of the potential for being able to combine the desirable properties of each of the components, this type of material will undoubtedly become increasingly important.

INITIATORS, FREE-RADICAL

Introduction

Free-radical initiators are chemical substances that, under certain conditions, initiate chemical reactions by producing free radicals:

$$\underset{\text{Initiator}}{\text{I}} \longrightarrow \underset{\text{Radical}}{\text{I}\cdot} \qquad (1)$$

Initiators contain one or more labile bonds that cleave homolytically when sufficient energy is supplied to the molecule. The energy must be greater than the bond dissociation energy (BDE) of the labile bond. Radicals are reactive chemical species possessing a free (unbonded or unpaired) electron. Radicals may also be positively or negatively charged species carrying a free electron (ion radicals). Initiator-derived radicals are very reactive chemical intermediates and generally have short lifetimes, ie, half-life times less than 10^{-3} (1).

The principal commercial initiators used to generate radicals are peroxides and azo compounds. Lesser amounts of carbon–carbon initiators and photoinitiators, and high energy ionizing radiation are also employed commercially to generate radicals. Emerging technologies use *N*-alkoxyamines as free-radical initiators or employ atom or group transfer facilitated by transition metals.

Free-Radical Formation and Use

There are three general processes for supplying the energy necessary to generate radicals from initiators: thermal processes, microwave or ultraviolet (uv) radiation

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

processes, and electron transfer (redox) processes. Radicals can also be produced in high energy radiation processes. Initiators are sometimes called radical catalysts. However, initiators are not true catalysts because they are consumed in amounts ranging from substoichiometric up to stoichiometric or greater when they are employed as initiators in chemical reactions. True catalysts such as enzymes are not consumed in the chemical reaction they catalyze.

Once formed, radicals undergo two basic types of reactions: propagation reactions and termination reactions. In a propagation reaction, a radical reacts to form a covalent bond and to generate a new radical. The three most common propagating reactions are atom abstraction, β-scission, and addition to carbon–carbon double bonds or aromatic rings. In a termination reaction, two radicals interact in a mutually destructive reaction in which both radicals form covalent bonds and reaction ceases. The two most common termination reactions are coupling and disproportionation. Because the propagation reaction is a chain reaction, it has become the most significant aspect of commercial free-radical chemistry. Radical chain reactions are involved in many commercial processes.

Radicals are employed widely in the polymer industry, where their chain-propagating behavior transforms vinyl monomers into polymers and copolymers (see RADICAL POLYMERIZATION). The mechanism of addition polymerization involves all three types of reactions discussed above, ie, initiation, propagation by addition to carbon–carbon double bonds, and termination: Initiation

$$\mathrm{I} \longrightarrow \mathrm{I}\cdot \tag{2}$$

$$\mathrm{I}\cdot + \mathrm{M} \longrightarrow \mathrm{I{-}M}\cdot \tag{3}$$

Propagation

$$\mathrm{I{-}M}\cdot + n\mathrm{M} \longrightarrow \mathrm{I{-}M_{\mathit{n}}{-}M}\cdot \tag{4}$$

Termination

$$2\ \mathrm{I{-}M_{\mathit{n}}{-}M}\cdot \longrightarrow \mathrm{I{-}M_{\mathit{n}}{-}M{-}M{-}M_{\mathit{n}}{-}I} \tag{5}$$

$$2\ \mathrm{I{-}M_{\mathit{n}}{-}M}\cdot \longrightarrow \mathrm{I{-}M_{\mathit{n}}{-}M'} + \mathrm{I{-}M_{\mathit{n}}{-}M''} \tag{6}$$

In these equations, I is the initiator and I· is the radical intermediate, M is a vinyl monomer, I–M· is an initial monomer radical, I–M_nM· is a propagating polymer radical, and M′ and M″ are polymer end groups that result from termination by disproportionation. Common vinyl monomers that can be homo- or copolymerized by radical initiation include ethylene, butadiene, styrene, vinyl chloride,

vinyl acetate, acrylic and methacrylic acid esters, acrylonitrile, *N*-vinylimidazole, *N*-vinyl-2-pyrrolidinone, and others (2).

Two other important commercial uses of initiators are in polymer cross-linking and polymer degradation. In a cross-linking reaction, atom abstraction, usually a hydrogen abstraction, occurs, followed by termination by coupling of two polymer radicals to form a covalent cross-link:

$$\mathrm{P{-}H + I\cdot \longrightarrow I{-}H + P\cdot} \tag{7}$$

$$\mathrm{2\,P\cdot \longrightarrow P{-}P} \tag{8}$$

P—H is a polymer with covalently attached hydrogen, I· is the initiating radical, and P—P is a cross-linked polymer. Cross-linking is a commercially important reaction of thermoplastics (such as polyethylene) and elastomers. In polymer degradation, hydrogen abstraction is followed by β-scission that results in breakage of the polymer chain:

$$\mathrm{P{-}\underset{\displaystyle R}{\overset{|}{C}}H{-}CH_2{-}P' + I\cdot \longrightarrow I{-}H + P{-}\underset{\displaystyle CH_2{-}P'}{\overset{\displaystyle R}{\overset{|}{\underset{|}{C}}}}\cdot} \tag{9}$$

$$\mathrm{P{-}\underset{\displaystyle CH_2{-}P'}{\overset{\displaystyle R}{\overset{|}{\underset{|}{C}}}}\cdot \xrightarrow{\beta\text{-scission}} P{-}\underset{\displaystyle R}{\overset{|}{C}}{=}CH_2 + P'\cdot \longrightarrow P'H} \tag{10}$$

I· is the initiating radical, P′· is the chain-propagating polymer radical that subsequently abstracts a hydrogen atom from another polymer molecule, P—CHR—CH_2—P′ is the polymer before, and P—CR=CH_2 and P′—H are polymer chains after degradation. Polymer degradation is important in facilitating the commercial processing (molding and extruding) of polypropylene (the degradation is more commonly called controlled rheology or vis-breaking). In the β-scission reaction the first-formed radical cleaves to a polymer radical and to an electronically neutral molecule (polymer with an unsaturated end group) by scission of a carbon–carbon bond β to the atom bearing the initial radical center.

Other common radical-initiated polymer processes include curing of resins, eg, unsaturated polyester–styrene blends; curing of rubber; grafting of vinyl monomers onto polymer backbones; and telomerizations.

A typical example of a nonpolymeric chain-propagating radical reaction is the anti-Markovnikov addition of hydrogen sulfide to a terminal olefin. The mechanism involves alternating abstraction and addition reactions in the propagating steps:

Initiation

$$\mathrm{I} \longrightarrow \mathrm{I}\cdot \tag{11}$$

$$\mathrm{I}\cdot + (\text{excess})\ \mathrm{H_2S} \longrightarrow \mathrm{I{-}H} + \mathrm{HS}\cdot \tag{12}$$

Propagation

$$\mathrm{HS}\cdot + \mathrm{CH_2{=}CH{-}R} \longrightarrow \mathrm{HSCH_2{-}\overset{\displaystyle H}{\underset{\displaystyle R}{\overset{|}{\underset{|}{C}}}}\cdot} \tag{13}$$

$$\mathrm{HSCH_2{-}\overset{\displaystyle H}{\underset{\displaystyle R}{\overset{|}{\underset{|}{C}}}}\cdot} + \mathrm{H_2S} \longrightarrow \mathrm{HSCH_2CH_2R} + \mathrm{HS}\cdot \tag{14}$$

Termination

$$\mathrm{HS}\cdot \longrightarrow \text{Nonradical sulfur compounds} \tag{15}$$

Other nonpolymeric radical-initiated processes include oxidation, autoxidation of hydrocarbons, chlorination, bromination, and other additions to double bonds. The same types of initiators are generally used for initiating polymerization and nonpolymerization reactions. Radical reactions are extensively discussed in the chemical literature (3–20).

Structure–Reactivity Relationships. Much has been written about the structure reactivity of radicals. No single unifying concept has satisfactorily explained all radical reactions reported in the literature. A long standing correlation of structure and reactivity involves comparisons of the energies required to homolytically break covalent bonds to hydrogen. It is assumed that this energy, the hydrogen BDE, reflects the stability and the reactivity of the radical coproduced with the hydrogen atom (21–24). However, this assumption should really be limited to radical reactivity and selectivity in hydrogen atom abstraction reactions, and can be particularly misleading for reactions with polar transition states, in which radicals can behave either as nucleophiles or electrophiles (25). Solvent interactions with transition-state species can also influence the reactivity (26–30). Nevertheless, the correlation of radical reactivity with BDE is quite useful. Table 1 shows some general BDE values for the formation of various carbon and oxygen radicals from various precursors. According to the theory, the higher the BDE, the higher the reactivity and the lower the stability of the radical formed

Table 1. Bond Dissociation Energies

Precursor	BDE, kJ/mol[a]
$(R)_3C—H$	381
$(R)_2CH—H$	406
$RCH_2—H$	418
$CH_3—H$	439
RO—H	439
RCOO—H	444
$C_6H_5—H$	469
HO—H	498

[a]To convert kJ/mol to kcal/mol, divide by 4.184.

by removal of a hydrogen atom. Thus bulky *tert*-alkyl radicals are more stable and less reactive than less bulky secondary alkyl radicals that in turn are more stable and less reactive than primary alkyl radicals. Hydroxyl radicals are the most reactive radicals listed. Methyl radicals are more reactive than other primary alkyl radicals and are about as reactive as alkoxy radicals. Lower stability and increased reactivity correspond to less discriminating radical behavior, resulting in faster and less-selective radical reactions with other molecules. In organic systems, this reaction is usually hydrogen atom abstraction. Consequently, methyl radicals and oxy radicals (carboxy, alkoxy, hydroxy) are considered good hydrogen-atom-abstracting radicals, and are suitable for cross-linking, grafting, and degradation reactions. Enhanced stability and reduced reactivity correspond to more discriminating radical behavior, resulting in slower and more selective subsequent reactions. Therefore, reactions other than hydrogen abstraction are favored. Substituted carbon radicals, such as the ethyl radical, are ineffective hydrogen-abstracting radicals; thus these radicals are more likely to react with carbon–carbon double bonds. Initiators that generate these types of radicals are suitable for vinyl monomer polymerizations that avoid undesirable side reactions (cross-linking, grafting, etc).

The BDE theory does not explain all observed experimental results. Addition reactions are not adequately handled at all, mostly owing to steric and electronic effects in the transition state. Thus it is important to consider both the reactivities of the radical and the intended coreactant or environment in any attempt to predict the course of a radical reaction (31). Application of frontier molecular orbital theory may be more appropriate to explain certain reactions (32,33). Radical reactivities have been studied by esr spectroscopy (34–36) and modeling based on general reactivity and radical polarity (37). Recent radical trapping studies have provided considerable insight into the course of free-radical reactions, particularly addition polymerizations, using radical traps such as 2,4-diphenyl-4-methyl-1-pentene (α-methylstyrene dimer, MSD) (38–44) and 1,1,3,3-tetramethyl-2,3-dihydro-1*H*-isoindol-2-yloxyl (45–49).

The choice of an initiator for a given radical process depends on the reaction conditions and the reactivity of the initiator. These two factors must be balanced so that the reaction is successful. Knowing the decomposition behavior of initiators is important to ensure proper selection. The stabilities or reactivities of initiators

such as organic peroxides and aliphatic azo compounds are significantly affected by structural variations close to the labile bond or bonds, ie, the oxygen–oxygen bond in peroxides and the carbon–nitrogen bonds in aliphatic azo compounds. The reactivity differences, resulting from structural differences between initiators, are due to several electronic and steric factors. Alkyl and aryl substituents stabilize carbon radicals through resonance and field effects. These substituent effects on radical stability are reversed for initiator stability. Initiators that decompose to produce highly alkylated or arylated carbon radicals are less stable (more reactive) than those that decompose to less alkylated or arylated carbon radicals. Electronic factors introduced by electron-donating or electron-withdrawing substituents can also affect initiator stability–reactivity; electron-donating substituents stabilize, whereas electron-withdrawing groups destabilize incipient carbon radicals. Initiators with bulky groups on either side of the labile, radical-forming bonds are less stable (more reactive) than initiators with less bulky groups since decomposition to radicals relieves ground-state steric strain (50).

Activation Parameters. Thermal processes are commonly used to break labile initiator bonds in order to form radicals. The amount of thermal energy necessary varies with the environment, but absolute temperature T is usually the dominant factor. The energy barrier, the minimum amount of energy that must be supplied, is called the activation energy E_a. A third important factor, known as the frequency factor A_3 is a measure of bond motion freedom (translational, rotational, and vibrational) in the activated complex or transition state. The relationships of A, E_a, and T to the initiator decomposition rate k_d are expressed by the Arrhenius first-order rate equation (eq. 16), where R is the gas constant, and A and E_a are known as the activation parameters.

$$k_d = A\, e^{(-E_a/RT)} \quad \text{or} \quad \ln k_d = \ln A - E_a/RT \tag{16}$$

Increasing temperature increases initiator decomposition rate. When a single labile bond is broken in the rate-determining step, the frequency factor is high. When multiple bonds are broken, the activated complex is restricted, the frequency factor is low, and the rate of decomposition is reduced (assuming no change in activation energy). Generally, slower rates of decomposition of the initiator mean higher activation energy values. Steric and electronic factors affect the activation energy of the initiator. Factors that enhance the stabilities of the incipient radicals reduce the activation energy and thus increase the decomposition rate.

The activation parameters for an initiator can be determined at normal atmospheric pressure by plotting $\ln k_d$ vs $1/T$ using initiator decomposition rates obtained in dilute solution (0.2 M or lower) at several temperatures. Rate data from dilute solutions are required in order to avoid higher order reactions such as induced decompositions. The intercept for the resulting straight line is $\ln A$ and the slope of the line is $-E_a/R$; therefore both A and E_a can be calculated. Activation parameters can also be determined by differential scanning calorimetry (51), although consideration must be given to the influence of decomposition products on the values obtained.

Initiator Half-Life. Once these activation parameters have been determined for an initiator, *half-life times at a given temperature*, ie, the time required

for 50% decomposition at a selected temperature, and *half-life temperatures for a given period*, ie, the temperature required for 50% decomposition of an initiator over a given time, can be calculated. In selecting appropriate initiators for radical applications such as vinyl monomer polymerizations and polyolefin cross-linking, care must be exercised in the use of calculated half-life data for temperatures, pressures, and solvents different than those used in determining the activation parameters. Half-life data are useful for comparing the activity of one initiator with another when the half-life data are determined in the same solvent and at the same concentration and, preferably, when the initiators are of the same class. Because producers of initiators and their customers roughly correlate the thermal stability of initiators with temperature, it is useful to express this stability in terms of 1- and 10-h half-life temperatures, ie, the temperatures at which 50% of the initiator has decomposed in 1 and 10 h, respectively. An extensive compilation of rate data for initiators is available (52). Half-life temperatures are usually provided in manufacturers' product catalogs (53,54). Rate data for commercial organic peroxide initiators are often available from special manufacturers' half-life bulletins (55).

Although a variety of methods for generating radicals by one or more of these three methods are reported in the literature, commercial initiators are primarily organic and inorganic peroxides, aliphatic azo compounds, certain organic compounds with labile carbon–carbon bonds, and photoinitiators.

Peroxides

Organic Peroxides. Organic peroxides are compounds possessing one or more oxygen–oxygen bonds. They have the general structure ROOR′ or ROOH, and decompose thermally by the initial cleavage of the oxygen–oxygen bond to produce two radicals:

$$\mathrm{ROOR'} \longrightarrow \mathrm{RO\cdot} + \mathrm{\cdot OR'} \tag{17}$$

Depending on the peroxide class, the rates of decompositions of organic peroxides can be enhanced by specific promoters or activators, which significantly decrease the energy necessary to break the oxygen–oxygen bond. Such accelerated decompositions occur well below a peroxide's normal application temperatures and usually result in generation of only one useful radical, instead of two. An example is the decomposition of hydroperoxides with multivalent metals (M), commonly iron, cobalt, or vanadium:

$$\mathrm{ROOH} + \mathrm{M^{n+}} \longrightarrow \mathrm{RO\cdot} + \mathrm{HO^-} + \mathrm{M^{(n+1)+}} \tag{18}$$

Solvent polarity also affects the rate of peroxide decomposition (56). Most peroxides decompose faster in more polar or polarizable solvents. This is true even if the peroxide is not generally susceptible to higher order decomposition reactions. This phenomenon is illustrated by various half-life data for *tert*-butyl peroxypivalate [927-07-1]. The 10-h half-life temperature for *tert*-butyl peroxypivalate varies from 62°C in decane (nonpolar) to 55°C in benzene (polarizable) and 53°C in methanol (polar).

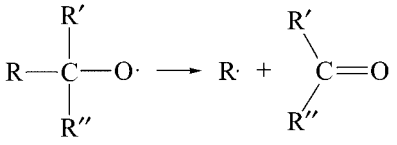
Following radical generation, the radicals produced (RO· and R′·) can initiate the desired reaction. However, when the radicals are generated in commercial applications, they are surrounded by a solvent, monomer, or polymer "cage." When the cage is solvent, the radical must diffuse out of this cage to react with the desired substrate. When the cage is monomer, the radical can react with the cage wall or diffuse out of the cage. When the cage is polymer, reaction with the polymer can occur in the cage. Unfortunately, other reactions can occur within the cage and can adversely affect efficiency of radical generation and radical reactivity. If the solvent reacts with the initiator radical, then solvent radicals may participate in the desired reaction.

Two secondary propagating reactions often accompany the initial peroxide decomposition: radical-induced decompositions and β-scission reactions. These intermolecular and intramolecular radical reactions compete kinetically with the desired reaction. Both reactions affect the reactivity and efficiency of the initiation process. Peroxydicarbonates and hydroperoxides are particularly susceptible to radical-induced decompositions. In radical-induced decomposition, a radical in the system reacts with undecomposed peroxide, eg:

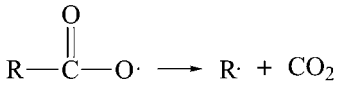
$$R^{\cdot} + ROOR \longrightarrow ROR' + RO\cdot \tag{19}$$

Radical-induced decomposition is an inefficient method of generating radicals, since the peroxide is induced to decompose without adding radicals to the system. Such decompositions are suppressed in vinyl monomer polymerizations, since the vinyl monomers quickly and efficiently scavenge radicals. In nonscavenging environments, eg, in nonolefinic solvents, induced decompositions occur with those peroxides that are susceptible, and they become more pronounced as the peroxide concentration increases. Although the homolysis of organic peroxides is a first-order reaction, the radical-induced decomposition is generally a higher-order reaction. Therefore, in those peroxide systems where induced decomposition is occurring, decomposition rates are significantly higher than the true first-order decomposition rates.

The other secondary propagation reaction that occurs during initiation is β-scission, as shown in equations 20 and 21:



(20)



(21)

Although reaction 21 is a β-scission reaction, it is more commonly termed decarboxylation. In both reactions, the energetics and other properties of the radicals are changed. The initially formed oxygen radicals become carbon radicals. The earlier discussion of relative BDEs for the two types of radicals is applicable here.

Steric and temperature effects are also important in β-scission. In equation 20, the newly formed alkyl radical R· is generally derived from the bulkiest alkyl group of the alkoxy radical, and it is usually the most stable radical. An exception here is the phenyl radical, which does not form upon β-scission of α-cumyloxy radicals, owing to its high energy. Instead, β-scission of the α-cumyloxy radical gives methyl radical and acetophenone. For *tert*-alkoxy radicals, the difference in generation of a *tert*-butoxy radical or a *tert*-amyloxy radical from a *tert*-alkyl peroxide can make a significant difference in the course of the resulting radical reaction. β-Scission of the *tert*-butoxy radical produces a methyl radical having about the same energy (as indicated by BDE) and reactivity as a *tert*-butoxy radical. β-Scission of the *tert*-amyloxy radical produces an ethyl radical having significantly lower energy and reactivity than the *tert*-amyloxy radical.

In equation 21, only one alkyl radical is possible; however, the rate of β-scission is greatly influenced by the bulk of the R group. As with β-scission of α-cumyloxy radicals, benzoyloxy radicals do not decarboxylate as readily as other acyloxy radicals, owing to formation of high energy phenyl radicals. If the R group is sufficiently bulky, decarboxylation occurs simultaneously with scission of the oxygen–oxygen bond. Increased temperatures enhance β-scission. For more thermally stable peroxides, the higher decomposition temperatures result in increased β-scission. Solvent interaction with the transition state for β-scission also facilitates the reaction (26–30).

Approximately 100 different organic peroxide initiators, in well over 300 formulations (liquid, solid, paste, powder, solution, dispersion), are commercially produced throughout the world, primarily for the polymer and resin industries. Considerable published literature exists that describes the synthesis, chemical properties, and utility of organic peroxides (57–68). A multiclient study covers the commercial producers and users of organic peroxides as well as other initiators, and their commercial markets and applications (69).

The eight classes of organic peroxides that are produced commercially for use as initiators are listed in Table 2. Included are the 10-h half-life temperature ranges (nonpromoted) for the members of each peroxide class.

Peroxide half-life data provide useful guidance for comparing the activity of one peroxide with another in a given application, if the previously discussed limitations of half-life data are considered. Several producers of organic peroxides provide customers with extensive half-life data on commercial and developmental organic peroxides (56,70). In addition, customer guidance is provided for selection of organic peroxides for various commercial applications, eg, vinyl monomer polymerizations, curing of unsaturated polyester resins, cross-linking of elastomers and polyolefins, and reactive extrusion, based on peroxide type and half-life criteria. This information is available in a manufacturer's half-life bulletin and associated personal computer interactive software (56), and in many available application-focused brochures (71–77).

Table 2 shows that commercial organic peroxides are available with 10-h half-life temperature activity varying from about room temperature to about 130°C. Organic peroxide classes such as diacyl peroxides and peroxyesters show a strong correlation between structural variation and 10-h half-life temperature activity. Other organic peroxide classes, eg, peroxydicarbonates and monoperoxycarbonates, show very little change in activity with structural variation. The

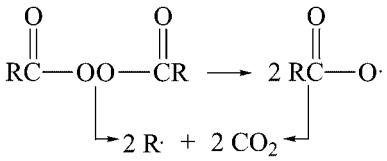
Table 2. Commercial Organic Peroxide Classes[a]

Organic peroxide class	Structure	10-h $t_{1/2}$, °C[b,c]
Diacyl peroxides		21–75
Dialkyl peroxydicarbonates		49–51[d]
tert-Alkyl peroxyesters		38–107
OO-tert-Alkyl *O*-alkyl monoperoxycarbonates		99–100
Di(*tert*-alkylperoxy)ketals		92–110
Di-*tert*-alkyl peroxides		115–128
tert-Alkyl hydroperoxides		—[e]
tert-Alkyl hydroperoxides	 + other structures	—[e]

[a] $x = 0$ or 1.
[b] Temperature at which $t_{1/2} = 10$ h.
[c] In benzene, unless otherwise noted.
[d] In trichloroethylene (TCE).
[e] Not applicable.

diperoxyketals and dialkyl peroxides show a moderate change in activity with variation in peroxide structures. In the cases of hydroperoxides and ketone peroxides, precise half-life data are difficult to obtain owing to the susceptibilities of these thermally stable peroxide classes to induced decompositions and transition-metal catalysis. Furthermore, radicals are usually generated from these two classes of peroxides at lower temperatures using activators (or promoters), and first-order decomposition rates have no significance. Although the low temperature acyl sulfonyl peroxide, acetyl cyclohexanesulfonyl peroxide (ACSP) [3179-56-4] (with a 10-h half-life temperature of 42°C), is still used to some extent commercially, it is only produced captively; hence its peroxide class was not included in Table 2.

Diacyl Peroxides. Table 3 lists several commercial diacyl peroxides and their corresponding 10-h half-life temperatures, determined in benzene and other solvents (78). Although diacyl peroxides cleave at the oxygen–oxygen bond, decarboxylation can occur, either simultaneously or subsequently (eq. 22):



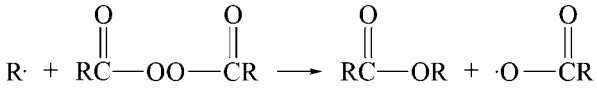
(22)

Table 3. Commercial Diacyl Peroxides

Name	CAS registry number	Structure	10-h $t_{1/2}$, °C[a]	Solvent
Dibenzoyl peroxide	[94-36-0]		73	Benzene
			72	TCE[b]
Dilauroyl peroxide	[105-74-8]		62	Benzene
			64	TCE
Succinic acid peroxide	[123-23-9]		66	Acetone
Diisononanoyl peroxide	[58499-37-9]		61	TCE

[a]Temperature at which $t_{1/2} = 10$ h.
[b]TCE is trichloroethylene.

The extent of decarboxylation primarily depends on temperature, pressure, and the stability of the incipient R· radical. The more stable the R· radical, the faster and more extensive the decarboxylation. With many diacyl peroxides, decarboxylation and oxygen–oxygen bond scission occur simultaneously in the transition state. Acyloxy radicals are known to form initially only from diacetyl peroxide [110-22-5] and from dibenzoyl peroxides (because of the relative instabilities of the corresponding methyl and phenyl radicals formed upon decarboxylation). Diacyl peroxides derived from non-α-branched carboxylic acids, eg, dilauroyl peroxide, may also initially form acyloxy radical pairs; however, these acyloxy radicals decarboxylate very rapidly and the initiating radicals are expected to be alkyl radicals. Diacyl peroxides are also susceptible to induced decompositions:

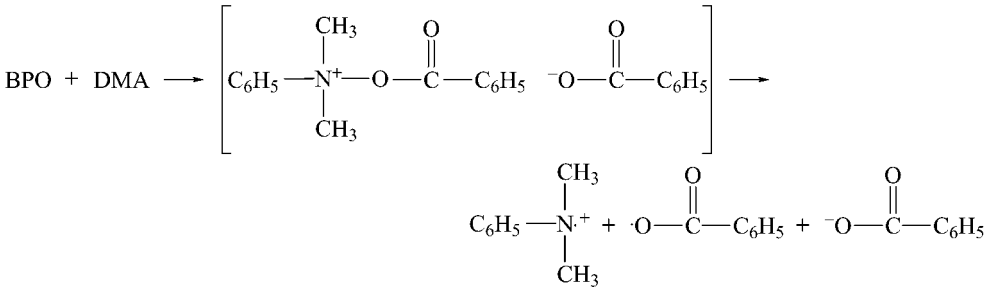


(23)

Diacyl peroxides are used in a broad spectrum of applications, including curing of unsaturated polyester resin compositions, cross-linking of elastomers, production of poly(vinyl chloride), polystyrene, and polyacrylates, and in many nonpolymeric addition reactions. The activities of acyloxy radicals in vinyl monomer polymerization (79,80) and under high-pressure conditions (81,82) have been investigated.

Aromatic diacyl peroxides such as dibenzoyl peroxide (BPO) [94-36-0] may be used with promoters to lower the useful decomposition temperatures of the peroxides, although usually with some sacrifice of radical generation efficiency. The most widely used promoter is dimethylaniline (DMA). The BPO–DMA combination is used for hardening (curing) of unsaturated polyester resin compositions, eg, body putty in auto repair kits. Here, the aromatic *tert*-amine promoter reacts with the BPO to initially form *N*-benzoyloxydimethylanilinium benzoate (ion pair), which

subsequently decomposes at room temperature to form a benzoate ion, a dimethylaniline radical cation, and a benzoyloxy radical that, in turn, initiates the curing reaction (83):

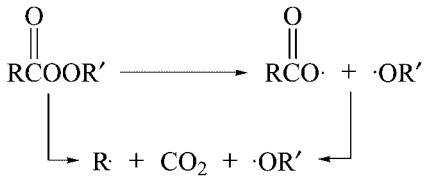


(24)

Although the BPO–DMA redox system works well for curing of unsaturated polyester blends, it is not a very effective system for initiating vinyl monomer polymerizations, and therefore it generally is not used in such applications (83). However, combinations of amines (eg, DMA) and acyl sulfonyl peroxides (eg, ACSP) are very effective initiator systems at 0°C for high conversion suspension polymerizations of vinyl chloride (84). BPO has also been used in combination with ferrous ammonium sulfate to initiate emulsion polymerizations of vinyl monomers via a redox reaction (85). Decompositions of BPO using other promoters have been reported, including organoaluminum compounds (86), chromium(II) acetate (87), nitroxyl radicals (88), tin(II) chloride with *o*-sulfonic benzoylimide (89), benzoyl thiourea [614-23-3] (90), and other reducing agents (91).

***tert*-Alkyl Peroxyesters.** Table 4 lists several commercial *tert*-alkyl peroxyesters and their corresponding 10-h half-life temperatures (determined in dodecane and other solvents) (92). Only *tert*-alkyl peroxyesters are commercially available. As illustrated in Table 2, the peroxyester class offers the broadest range of temperature activity of any of the peroxide classes.

Peroxyesters undergo single- or multiple-bond scission to generate acyloxy and alkoxy radicals, or alkyl and alkoxy radicals and carbon dioxide:



(25)

Acyloxy radicals can decarboxylate, as noted above for the diacyl peroxides. The alkoxy radicals (R′·) can undergo the β-scission reaction, leading to greater radical reaction selectivity. Variation of the R group or the R′ group provides a convenient means of altering the relative activity of peroxyesters. For example, increasing the steric bulk of either or both of R and R′ generally lowers the thermal stability of a peroxyester. Thermal stability decreases as follows: for R,

[d] In trichloroethylene (TCE).
[e] In ethylbenzene.

$CH_3 > RCH_2 > R_2CH > R_3C$; for R′, *tert*-butyl > *tert*-amyl > *tert*-octyl > α-cumyl > 3-hydroxy-1,1-dimethylbutyl. By way of example, *tert*-butyl peroxyacetate [107-71-1] is more thermally stable than 3-hydroxy-1,1-dimethylbutyl peroxyneodecanoate [95718-78-8]. Although other factors affect thermal stability, the trends shown can be used to qualitatively predict peroxyester reactivity trends. The order of activity of the R′ group in peroxyesters is also observed in other *tert*-alkyl peroxy-containing compounds. The mechanism of decomposition of *tert*-alkyl peroxypivalates has been studied by use of a nitroxyl compound to trap the radicals formed (93). The behavior of peroxyesters under pressure has been investigated (94–98).

Peroxyesters, particularly those with α-hydrogens or conjugated double bonds, are susceptible to induced decomposition under certain conditions, but they are generally less susceptible than diacyl peroxides. Lower molecular weight peroxyesters that have some water solubility can be hydrolyzed.

The more selective nature of the radicals produced by *tert*-amyl peroxyesters and other *tert*-amyl peroxides has led to their use in commercial polymer applications requiring discriminating radicals, such as polyol grafting and high solids acrylic resin production (99,100). *tert*-Amyl peroxides have been replacing aliphatic α-cyanoazo initiators in these applications. Owing to their diverse structures and associated reactivities, peroxyesters are also used in many other applications, including polymerization of ethylene, vinyl chloride, styrene and acrylate esters, and curing of unsaturated polyester resins.

Monoperoxycarbonates. Some commercially available *OO-tert*-alkyl *O*-alkyl monoperoxycarbonates and their corresponding 10-h half-life temperature (determined in dodecane) are listed in Table 2 (92). Monoperoxycarbonates are related to peroxyesters and also generate alkoxy radicals, ·OR′, which again as above can undergo β-scission.

$$RO-\overset{\overset{O}{\|}}{C}-OOR' \longrightarrow RO-\overset{\overset{O}{\|}}{C}-O\cdot + \cdot OR' \qquad (26)$$

Changing the structure of R′ affects the activity of monoperoxycarbonates as previously discussed for peroxyesters. The other cogenerated radical is an alkoxycarbonyloxy radical. The nature of the R group has practically no effect on the reactivity of monoperoxycarbonates having the same *OO-tert*-alkyl group. The 10-h half-life temperature remains at 100°C for almost all *OO-tert*-butyl *O*-alkyl monoperoxycarbonates.

Monoperoxycarbonates are similar in thermal stability to *t*-alkyl peroxybenzoates and can be used in applications where there is concern that benzene will be formed as a by-product of peroxybenzoate initiation. For example, *OO-tert*-butyl *O*-(2-ethylhexyl) monoperoxycarbonate [34443-12-4], with a 10-h half-life temperature of 99°C, can be used in place of *tert*-butyl peroxybenzoate, with a 10-h half-life temperature of 104°C, for the polymerization of styrene with only slight changes in reaction conditions.

Recently, poly(monoperoxycarbonates) have been introduced for the commercial polymerization of vinyl monomers (101). They provide improved productivity in existing polymerization processes. Perhaps more interesting are possibilities of

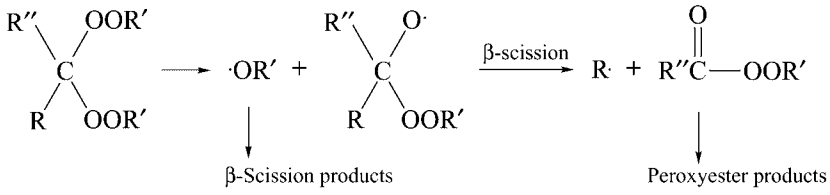
forming polymers with enhanced molecular weight and enhanced properties due to the formation of polyradical initiating species.

Diperoxyketals. Some commercially available di(*tert*-alkylperoxy)ketals and their corresponding 10-h half-life temperatures (determined in dodecane) are listed in Table 5 (102). Diperoxyketals thermally decompose by cleavage of only one oxygen–oxygen bond initially, usually followed by β-scission of the resulting alkoxy radicals (103–107). For acyclic diperoxyketals, β-scission produces an alkyl radical and a peroxyester.



(27)

Owing to similarity of thermal stability, the peroxyester decomposes, as discussed previously. Cyclic diperoxyketals such as 1,1-di(*tert*-butylperoxy)cyclohexane cleave the cycloalkyl ring during β-scission to give an alkyl radical with an attached peroxyester group. The effect, after peroxyester decomposition, is the production of two monoradicals (·OR′), a diradical (·R′—R·), and carbon dioxide. Because of the generation of diradicals, cyclic diperoxyketals such as 1,1-di(*tert*-butylperoxy)cyclohexane are effective in enhancing polymer molecular weight or increasing polymer productivity when employed as initiators in commercial vinyl monomer polymerizations (108,109). Diperoxyketals are used commercially in styrene polymerizations, curing of elastomers, and in elevated

temperature curing of unsaturated polyester resin compositions. *tert*-Amyl diperoxyketals are good initiators for acrylics, especially in the preparation of high solids coatings resins (110).

Di(*tert*-alkyl) Peroxides. Some commercially available dialkyl peroxides and their corresponding 10-h half-life temperatures in dodecane are listed in Table 6 (111). Dialkyl peroxides initially cleave at the oxygen–oxygen bond to generate alkoxy radical pairs:

$$R_3C{-}OO{-}CR_3 \longrightarrow 2\ R_3C{-}O\cdot \xrightarrow{\beta\text{-scission}} 2\ R\cdot + 2\ R_2C{=}O \qquad (28)$$

Because high temperatures are required to decompose dialkyl peroxides at useful rates, β-scission of the resulting alkoxy radicals is more rapid and more extensive than for most other peroxide types. When methyl radicals are produced from alkoxy radicals, the dialkyl peroxide precursors are very good initiators for cross-linking, grafting, and degradation reactions. When higher alkyl radicals such as ethyl radicals are produced, the dialkyl peroxides are useful in vinyl monomer polymerizations. The behavior of di(*tert*-butyl) peroxide [110-54-4] under high pressure has been investigated (112,113).

Dialkyl Peroxydicarbonates. Some commercially available dialkyl peroxydicarbonates and their corresponding 10-h half-life temperatures (determined in trichloroethylene solutions) are listed in Table 7 (114). These peroxides are active at low temperatures and initially undergo homolytic cleavage to produce

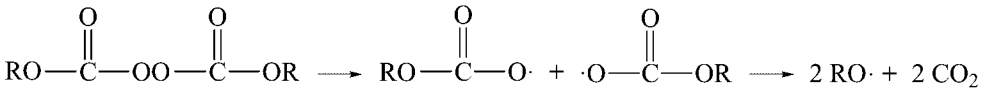
[b] In trichloroethylene (TCE).

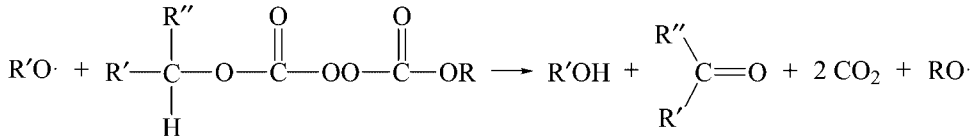
alkoxycarbonyloxy radical pairs that may subsequently decarboxylate to produce alkoxy radicals:



(29)

Table 7 shows that the nature of the alkyl group, whether primary alkyl, secondary alkyl, or cycloalkyl, does not affect the 10-h half-life temperatures of dialkyl peroxydicarbonates in trichloroethylene (TCE) [79-01-6]. All peroxydicarbonates have about the same 10-h half-life temperature in TCE (48–50°C).

As a peroxide class, dialkyl peroxydicarbonates are very susceptible to radical-induced decompositions:



(30)

Decomposition rate studies on dialkyl peroxydicarbonates in various solvents reveal dramatic solvent effects that primarily result from the susceptibility of peroxydicarbonates to induced decompositions. These studies show a decreasing order of stability of peroxydicarbonates in solvents as follows: TCE > saturated hydrocarbons > aromatic hydrocarbons > ketones (69). Decomposition rates are lowest

in TCE where radicals are scavenged before they can induce the decomposition of peroxydicarbonate molecules.

Peroxydicarbonates are efficient polymerization initiators for most vinyl monomer polymerizations, especially for monomers such as acrylates, ethylene, and vinyl chloride. They are particularly good initiators for less reactive monomers such as those containing allyl groups. They are also effective for curing of unsaturated polyester molding resins. In order to increase the shipping and handling safety of peroxydicarbonates, stabilized formulations have been developed and commercialized (115–120).

***tert*-Alkyl Hydroperoxides.** Some commercially available *tert*-alkyl hydroperoxides (121) are listed in Table 8. Hydroperoxides can decompose thermally to initially form alkoxy and hydroxy radicals:

$$\mathrm{ROOH} \longrightarrow \mathrm{RO}\cdot + \cdot\mathrm{OH} \qquad (31)$$

However, because of the high temperature nature of this class of peroxides (10-h half-life temperatures of 133–172°C) and their extreme sensitivities to radical-induced decompositions and transition-metal activation, hydroperoxides have very limited utility as thermal initiators. The acid-promoted decomposition to produce radicals has been reported (122). The oxygen–hydrogen bond in

hydroperoxides is weak [368–377 kJ/mol (88.0–90.1 kcal/mol) BDE] and is susceptible to attack by higher energy radicals:

$$\mathrm{ROOH} + \mathrm{R'}\cdot \longrightarrow \mathrm{R'{-}H} + \mathrm{ROO}\cdot \tag{32}$$

Further reactions of the alkylperoxy radical (ROO·) depend on the environment but generally cause generation of other radicals that can attack undecomposed hydroperoxide, thus perpetuating the induced decomposition chain. Radicals also can attack undecomposed peroxide by radical displacement on the oxygen–oxygen bond:

$$\mathrm{R'}\cdot + \mathrm{ROOH} \longrightarrow \mathrm{R'OH} + \cdot\mathrm{OH} \text{ or } \mathrm{R'OH} + \mathrm{RO}\cdot \tag{33}$$

This is basically the same type of induced decomposition that occurs with other peroxide classes, eg, the dialkyl peroxydicarbonates and diacyl peroxides.

Hydroperoxides are more widely used as initiators in low temperature applications (at or below room temperature) where transition-metal (M) salts are employed as activators. The activation reaction involves electron-transfer (redox) mechanisms:

$$\mathrm{ROOH} + \mathrm{M}^{n+} \longrightarrow \mathrm{RO}\cdot + \mathrm{OH}^{-} + \mathrm{M}^{(n+1)+} \tag{34}$$

$$\mathrm{ROOH} + \mathrm{M}^{(n+1)+} \longrightarrow \mathrm{ROO}\cdot + \mathrm{H}^{+} + \mathrm{M}^{n+} \tag{35}$$

Either oxidation state of a transition metal (Fe, Mn, V, Cu, Co, etc) can activate decomposition of the hydroperoxide. Thus a small amount of transition-metal ion can decompose a large amount of hydroperoxide. Trace transition-metal contamination of hydroperoxides is known to cause violent decompositions. Because of this fact, transition-metal promoters should never be premixed with the hydroperoxide. Trace contamination of hydroperoxides (and ketone peroxides) with transition metals or their salts must be avoided.

Transition-metal ions also react with the generated radicals to convert the radicals to ions:

$$\mathrm{RO}\cdot + \mathrm{M}^{n+} \longrightarrow \mathrm{RO}^{-} + \mathrm{M}^{(n+1)+} \tag{36}$$

This reaction is one example of several possible radical–transition-metal ion interactions. The significance of this and similar reactions is that radicals are destroyed and are no longer available for initiation of useful radical reactions. Consequently, the optimum use levels of transition metals are very low. Although the hydroperoxide decomposes quickly when excess transition metal is employed, the efficiency of radical generation is poor.

Ketone Peroxides. These materials are mixtures of compounds with hydroperoxy groups and are composed primarily of the two structures shown in Table 2. Ketone peroxides are marketed as solutions in inert solvents such as nonvolatile esters. They are primarily employed in room-temperature-initiated curing of unsaturated polyester resin compositions (usually containing styrene

monomer) using transition-metal promoters such as cobalt naphthenate. Ketone peroxides contain the hydroperoxy (—OOH) group and thus are susceptible to the same hazards as hydroperoxides. By far the most popular commercial ketone peroxide is methyl ethyl ketone peroxide [1338-23-4]. Smaller quantities of ketone peroxides such as methyl isobutyl ketone peroxide [28056-59-9], cyclohexanone peroxide [12262-58-7], and 2,4-pentanedione peroxide [37187-22-7] are used commercially (123).

The cyclic trimer ketone peroxides (eg, methyl ethyl ketone peroxide cyclic trimer [24748-23-0]) have been selectively prepared in dilute solution (in a safety solvent due to the shock sensitivity of the pure peroxide) for use as unpromoted, thermal initiators (124,125). They have been shown to effectively modify polyolefins under certain conditions in a manner similar to dialkyl peroxides.

Selection of organic peroxides for various commercial applications has been reviewed (55,126,127), particularly for vinyl chloride polymerizations (72). Recent innovations in peroxide technology include new promoted systems (128,129), peroxide-containing surfactants (130–133), and peroxides bonded to inorganic fillers (134).

Inorganic Peroxides

Inorganic peroxide–redox systems have been employed for initiating emulsion homo- and copolymerizations of vinyl monomers. These systems include hydrogen peroxide–ferrous sulfate, hydrogen peroxide–dodecyl mercaptan, potassium peroxydisulfate–sodium bisulfite, and potassium peroxydisulfate–dodecyl mercaptan (85,135). Potassium peroxydisulfate [7727-21-2], $K_2S_2O_8$, (or the corresponding sodium or ammonium salt), is an inorganic peroxide that is used widely in emulsion polymerization (eg, latexes and rubbers), usually in combination with a reducing agent. Without reducing agents, the peroxydisulfate ion decomposes to give sulfate ion radicals:

$$S_2O_8^{2-} \longrightarrow 2\,{\cdot}SO_4^- \tag{37}$$

With transition-metal activators, the initiation process is postulated as

$$S_2O_8^{2-} + Fe^{2+} \longrightarrow Fe^{3+} + {\cdot}SO_4^- + SO_4^{2-} \tag{38}$$

The reaction with mercaptans is believed to generate initiating sulfur radicals:

$$K_2S_2O_8 + 2\,RSH \longrightarrow 2\,KHSO_4 + 2\,RS{\cdot} \tag{39}$$

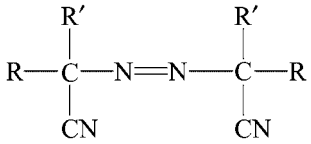
Hydrogen peroxide, in combination with reducing agents (transition metals), also is used in those applications where its high water and low oil solubility is not a problem or is easily overcome.

Peroxide Safety. When handling and using peroxide initiators, care should be exercised since they are thermally sensitive and decompose (sometimes

violently) when exposed to excessive temperatures, especially when they are in their pure or highly concentrated states. However, they are useful as initiators because of their thermal instability. What may be a safe temperature for one peroxide can be an unsafe temperature for another, since peroxide initiators encompass a wide activity range. Because some peroxides are shock or friction sensitive in the pure state, they are generally desensitized by formulating them into solutions, pastes, or powders with inert diluents and dispersions or emulsions with aqueous diluent. All manufacturers' literature should be carefully scrutinized and the peroxide safety literature should be reviewed before handling and using specific peroxide initiator compositions (71–78,92,102,111,114,121,123,127,136–140).

Azo Compounds

Generally, the commercially available azo initiators are of the symmetrical azonitrile type:



The symmetrical azonitriles are solids with limited solubilities in common solvents (141,142). Some commercial aliphatic azo compounds and their 10-h half-life temperatures are listed in Table 9.

Azo initiators decompose thermally by cleavage of the two carbon–nitrogen bonds, either stepwise or simultaneously, to form two alkyl radicals and a nitrogen molecule:

(40)

In commercial azo initiators, *tert*-alkyl-type radicals are generated, which are generally more stable than most of the radicals generated from peroxide initiators. Thus when azonitriles are used as initiators for vinyl monomer polymerizations, the primary initiator radicals generally do not abstract hydrogens from polymer backbones as can sometimes occur when peroxide initiators are employed. Therefore branch grafting is suppressed and linear polymers having reduced long-chain branching are obtained.

Azonitriles are not susceptible to radical-induced decompositions (142) and their decomposition rates are not usually affected by other components of the environment. Cage recombination of the alkyl radicals occurs when azo initiators are used, and results in the formation of toxic tetrasubstituted succinonitrile derivatives (142). This can be a significant drawback to the use of azo initiators. In contrast to some organic peroxides, azonitrile decomposition rates show only minor solvent effects (141,142) and are not affected by transition metals, acids, bases, and many other contaminants. Thus azonitrile decomposition rates are predictable. Azonitriles can be used as thermal initiators for curing resins that

[a]Temperature at which $t_{1/2} = 10$ h.

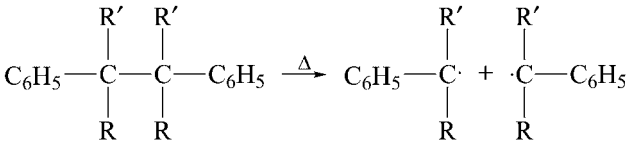
contain a variety of extraneous materials since cure rates are not affected. In addition to curing of resins, azonitriles are used for polymerization of commercial vinyl monomers.

tert-Amyl peroxides are viable commercial alternatives to azo initiators and can produce low energy ethyl radicals that are similar in initiating and hydrogen-abstracting properties to those produced by aliphatic azo compounds. *tert*-Amyl peroxides have been replacing aliphatic azo compounds in many commercial polymer applications, eg, production of high solids acrylic resins (99,100).

Care should be exercised in handling and using azo initiators in their pure and highly concentrated states because they are thermally sensitive and can decompose rapidly when overheated. Although azonitriles are generally less sensitive to contaminants, the same cautions that apply to peroxides should also be applied to handling and using azo initiators. The manufacturers' safety literature should be read carefully (141). The potential toxicity hazards of decomposition products must be considered when using azonitriles. Such hazards are present primarily when pure or highly concentrated azonitrile solutions are decomposed in poorly ventilated areas. The chemistry of aliphatic azo compounds has been reviewed (15,143–146).

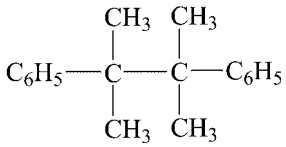
Carbon–Carbon Initiators

Carbon–carbon initiators are hexasubstituted ethanes that undergo carbon–carbon bond scission when heated to produce radicals. The thermal stabilities of the hexasubstituted ethanes decrease rapidly with increasing size of the alkyl groups (147). The 10-h half-life temperature range of this class of initiators is very broad, extending from about 100°C to well above 600°C. An extensive compilation of half-life data on carbon–carbon initiators has been published (147). The commercially available carbon–carbon initiators are tetrasubstituted 1,2-diphenylethanes that undergo homolyses to generate low energy, *tert*-aralkyl radical pairs:

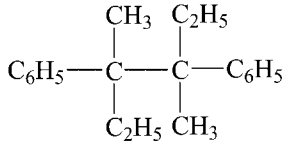


(41)

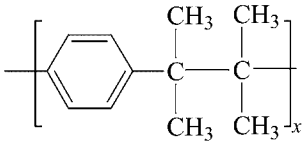
Three carbon–carbon initiators are currently available commercially: 2,3-dimethyl-2,3-diphenylbutane [1889-67-4] (**1**), 3,4-dimethyl-3,4-diphenylhexane [10192-93-5] (**2**), and poly(1,4-diisopropylbenzene) [25822-43-9] (**3**).



(**1**)



(**2**)



(**3**)

Initiators (**1**) and (**2**) have 10-h half-life temperatures of 237 and 201°C, respectively. It has been reported that, unlike organic peroxides and aliphatic azo compounds, carbon–carbon initiators (**1**) and (**2**) undergo endothermic decompositions (54). These carbon–carbon initiators are useful commercially as fire-retardant synergists in fire-resistant expandable polystyrenes (148). Accelerators for the thermal decomposition of diphenylethane initiators have been reported (149).

Initiators for Mediated Radical Reactions

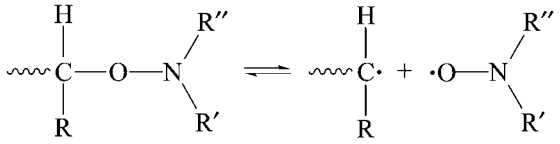
Recently, there has been considerable interest in controlling the generation of free radicals in polymerization reactions both initially and throughout the course of the reaction (150). There are many reasons for this: controlling the polydispersity of the polymer formed ($M_n/M_w < 1.5$), control of polymer end groups, prevention of side reactions, preparation of block copolymers, chemical control of the reaction kinetics, design of new polymer architectures, and controlled graft modification of polyolefins (151,152).

Early work to control radical polymerization involved initiators that generated one radical capable of initiating a polymer-forming chain reaction and one radical that reversibly reacted with the propagating polymer radical. This reversible termination established an equilibrium between propagating and dormant polymer chains, and retarded irreversible termination reactions such as coupling and disproportionation. An initiator that provided mediated polymerization was called an *iniferter*, a combination of *ini*tiator, trans*fer* agent, and *ter*minator. Known photochemical iniferters are sulfides and disulfides (particularly thiuram disulfides, eg, tetraethylthiuram disulfide [97-77-8]). Thermal iniferters can be carbon–carbon initiators (eg, tetraphenylethanes, *vide supra*) and certain azo compounds (eg, phenylazotriphenylmethane [981-18-0]). Using iniferters, telomers, block copolymers, and other polymer architectures have been prepared using free-radical reactions (153,154).

More recently, refinements and new approaches for controlling radical polymerization have been described (155). Two of the most studied methods feature either stable counter-radicals, eg, nitroxyl-mediated polymerization (NMP), or reversible activation of carbon–halogen bonds by transition-metal species in a

process called atom-transfer radical polymerization (ATRP) (see LIVING RADICAL POLYMERIZATION).

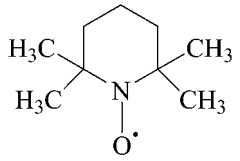
In NMP, the nitroxyl radicals, either alone or in the presence of additional modifiers, react reversibly with the propagating polymer radical to establish an equilibrium between active and dormant propagating radicals present in the system (156):



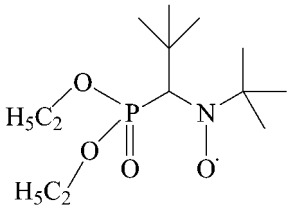
(42)

New monomer units are thus added to the active radicals of the growing chain in a controlled manner, and when the monomer is completely consumed the usual termination reactions (coupling and disproportionation) are prevented by the presence of the nitroxyl, allowing the polymer chain to continue "living." Thus, in effect, each growing polymer chain becomes a polymerization initiator for continued reaction according to the equilibrium between dormant and active species, which is controlled by the structures of the polymer and nitroxyl radicals, the solvent, and the temperature (157–164). The resulting product from nitroxyl-mediated polymerization of a single monomer can be used as a macroinitiator for copolymerizing one or more new monomers, resulting in block copolymers or other designed molecular architectures.

NMP can be achieved in either of two ways: (*1*) by adding a stable nitroxyl radical to the polymerization reaction initiated by traditional initiators (peroxides or azo compounds) to generate an alkoxyamine *in situ*, or (*2*) by preparing an alkoxyamine to be used as the initiator. Two widely studied examples of stable nitroxyl radicals are 2,2,6,6-tetramethylpiperidinyl-1-oxyl [2564-83-2] (**4**, TEMPO) or 4-substituted derivatives thereof and *N*-*tert*-butyl-*N*-[1-(diethylphosphono)-2,2-dimethylpropyl]nitroxide [188526-94-5] (**5**) (165–172).



(**4**)

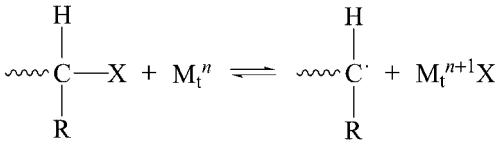


(**5**)

Many mono- and poly(*N*-alkoxyamines) have been synthesized and investigated in NMP reactions (161,173–185). Halogen-terminated polymers have been converted into alkoxyamine macroinitiators (186).

NMP has been studied mostly for polymerization of styrene and acrylates. It is limited in its application because of the equilibrium conditions, particularly high temperature, required to achieve a reasonable polymerization rate. A variation of this system does not use conventional free-radical initiators, using instead only the nitroxyl compound, an alkyl or aryl metal compound (such as an alkyl aluminum), and an appropriate strongly binding ligand (187). Nitroxyl-mediated polymerizations can be promoted by organic acids (188,189), organic salts (190), and acylating agents (191).

In ATRP, the growing polymer radical is deactivated to prevent termination reactions by reversible transfer of an atom or group (eg, halogen) between the propagating polymer radical and a transition-metal compound, thus providing controlled, equilibrium concentrations of growing polymer chains and dormant chains:



(43)

In this equation M_t^n represents a transition metal of valence n and X represents a halogen atom. The most studied system of this type involves three components: an alkyl or aryl halide, a metal catalyst, and specific ligands (192–195), eg, 1-phenylethyl chloride [672-65-1], copper(I) chloride, and 2,2′-bipyridine [366-18-7]. In these systems, concentrations of propagating and dormant species must be carefully controlled for successful polymerization and narrow polydispersity to be achieved. The concept of "reverse" ATRP, involving conventional peroxide and azo initiators and the oxidized form of the metal catalyst [eg, copper(II) chloride], has also been reported (196). Like NMP, ATRP has been studied mostly for the polymerization of styrene and acrylic monomers, although other monomers have been polymerized successfully, eg, vinylidene difluoride (197). Other metal catalysts have been reported, such as bis(ortho-chelated) arylnickel(II) complexes (198) and porphyrin cobalt(III) organometallic complexes (199).

Various other approaches to mediated radical polymerization have been investigated. A living system has been reported, wherein borinate radicals react reversibly with the growing chain and are generated by autoxidation of trialkylboranes through an alkylperoxyborane intermediate (200). Organochromium–macrocyclic polyamine systems and peroxide–trialkylphosphite systems (201) have also been investigated. Photochemical-mediated systems involving polymerization of acrylate monomer using alkyl cobaloximes as photoinitiators have been reported (202).

Other Radical Generating Systems

There are many chemical methods for generating radicals reported in the literature, that involve unconventional initiators (91,203–224). Most of these radical-generating systems cannot broadly compete with the use of conventional initiators

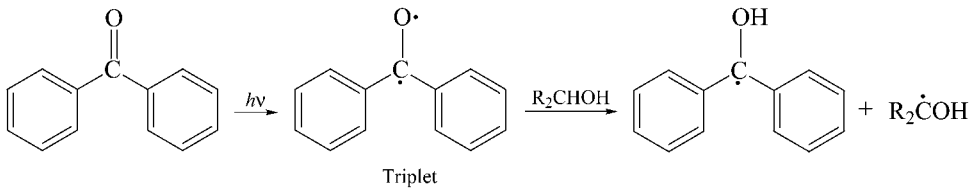
in industrial polymer applications owing to cost or efficiency considerations. However, some systems may be well-suited for initiating specific radical reactions or polymerizations, eg, grafting of monomers to cellulose using ceric ion (225).

Initiation through Radiation and Photoinitiators

High energy ionizing radiation sources (eg, x-rays, γ-rays, α-particles, β-particles, fast neutrons, and accelerator-generated electrons) can generate radical sites on organic substrates (226). If the substrate is a vinyl monomer, radical polymerization can occur (227). If the substrate consists of a polymer and a vinyl monomer, then polymer cross-linking, degradation, grafting of the monomer to the polymer, and polymerization of the monomer can all occur (228). Radical polymerizations of vinyl monomers with ionized plasma gases have been reviewed (229). Ultrasonic polymerization of vinyl monomers using special initiators (eg, dodecanethiol) has been described (230).

Initiation of radical reactions with uv radiation is widely used in industrial processes (231). In contrast to high energy radiation processes where the energy of the radiation alone is sufficient to initiate reactions, initiation by uv irradiation usually requires the presence of a photoinitiator, ie, a chemical compound or compounds that generate initiating radicals when subjected to uv radiation. There are two types of photoinitiator systems: those that produce initiator radicals by intermolecular hydrogen abstraction and those that produce initiator radicals by photocleavage (232–239).

In the case of intermolecular hydrogen abstraction, a hydrogen (H) atom donor is required. Typical donors have an active H atom positioned alpha to an oxygen or nitrogen, eg, alcohols (R_2CHOH), ethers (R_2CHOR), and *tert*-amines (R_2CHNR_2), or an active H atom directly attached to sulfur, eg, thiols (RSH). Some of the commercial photoinitiators that undergo intermolecular H abstraction from the H atom donor upon excitation by uv radiation are listed in Table 10. A reaction illustrating this photoinitiation process is given below for benzophenone (photoinitiator) and an alcohol (H atom donor):



(44)

Upon exposure to uv light, ground-state benzophenone is excited to the triplet state (a diradical), which abstracts an alpha H atom from the alcohol, resulting in the formation of two separate initiating radicals. With amine H atom donors, an electron transfer may precede the H transfer, as in triplet exciplex formation between benzophenone and amine (eq. 46):

Table 10. Photoinitiators That Abstract Hydrogen

Name	CAS registry number	Structure
Benzophenone	[119-61-9]	4-Phenylbenzophenone	[2128-93-0]	Xanthone	[90-47-1]	Thioxanthone	[492-22-8]	2-Chlorothioxanthone	[86-39-5]	4,4′-Bis(*N*,*N*′-dimethylamino) benzophenone (Michler's ketone)	[90-94-8]	Benzil	[134-81-6]	9,10-Phenanthraquinone	[84-11-7]	9,10-Anthraquinone	[84-65-1]	

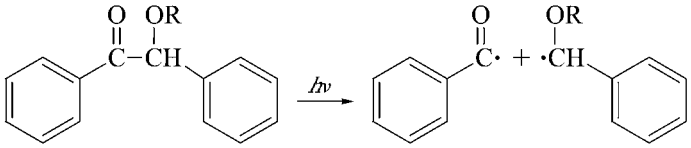
(45)

Some commercial photoinitiators (Table 11) undergo a photocleavage to form two initiating radical fragments directly, eg, benzoin ethers:



(46)

In many photoinitiated processes, a photosensitizer may be used. A photosensitizer absorbs light and subsequently transfers the absorbed energy to an energy acceptor, which then can produce initiator radicals by H abstraction or by photocleavage. The energy-transfer agent (photosensitizer) usually undergoes no net change. A variety of photosensitizers have been used such as eosin, chlorophyll, methylene blue, and thioxanthone. In photosensitized processes, the energy acceptor often is referred to as a co-initiator. These co-initiators do not absorb light but accept energy from the excited photosensitizer, which distinguishes them from the photoinitiators listed in Tables 10 and 11. Typical co-initiators that undergo H abstraction are the H donors mentioned above. An example of a co-initiator undergoing photocleavage is quinoline-8-sulfonyl chloride [18704-37-5] photosensitized by thioxanthone (233).

The peroxide and azo thermal initiators also are photochemically unstable and have been used as radical sources at well below their normal thermal decomposition temperatures. However, their industrial use as photoinitiators has been limited because their light-absorption characteristics frequently are unsuitable and because of the obvious potential complication owing to their slow thermal decomposition, which leads to poor shelf life and nonreproducible photoactivity in given formulations (237).

Economic Aspects

The principal worldwide producers of organic peroxide initiators (trade names and available Internet addresses) are Atofina Chemicals, Inc. (Lupersol, Luperox, http://www.luperox.com); Akzo Nobel (Trigonox, Perkadox, Cadox, Cadet, Laurox, Liladox, Kenodox, Lucidol, Butanox, Cyclonox, http://www.polymerchemicals.com); Degussa-Hüls AG (formerly LaPorte companies), which includes Aztec Peroxides, Inc. (in the United States) (Aztec) and Peroxid-Chemie GmbH (in Europe) (Interox) (http://www.degussa-initiators.com, http://www.laporteplc.com); Crompton Corp. (formerly Witco Corp.) (Esperox, Esperal, USP, Quickset, Hi Point, http://www.cromptoncorp.com); Nippon Oil & Fats Co.

Table 11. Photoinitiators That Undergo Photocleavage

Name	CAS registry number	Structure
α,α-Dimethyl-α-hydroxyacetophenone	[7473-98-5]	1-(1-Hydroxycyclohexyl)phenylmethanone	[947-19-3]	Benzoin methyl ether	[3524-62-7]	Benzoin ethyl ether	[574-09-4]	Benzoin isobutyl ether	[22499-12-3]	α,α-Dimethoxy-α-phenylacetophenone	[24650-42-8]	α,α-Diethoxyacetophenone	[6175-45-7]	1-Phenyl-1,2-propanedione, 2-(*O*-benzoyl)oxime	[17292-57-8]	Diphenyl(2,4,6-trimethylbenzoyl) phosphine oxide	[75980-60-8]	α-Dimethylamino-α-ethyl-α-benzyl-3,5-dimethyl-4-morpholinoacetophenone	[119313-12-1]	
(Nyper, Perbutyl, Percumyl, Perhexa, Permek, Peroyl, http://www.nof.co.jp); The Norac Company, Inc. (Benox, Norox, http://www.norac.com); and GEO Specialty Chemicals (formerly Hercules Inc.). (DiCup, VulCup, http://www.geosc.com). Worldwide the three leading producers of organic peroxides are Akzo Nobel, Atofina Chemicals Inc., and Degussa-Hüls (formerly LaPorte). Sales volumes and value are difficult to estimate because of the many initiator formulations and dilutions that are available. Particularly for dialkyl peroxides, there are many small formulators and distributors that purchase a peroxide from a primary

manufacturer and formulate it for a particular end-use application. Approximate North American sales of organic peroxide initiators in 2000 were valued at $\sim\$300 \times 10^6$; worldwide sales were valued at $\sim\$800 \times 10^6$.

The principal worldwide producers of organic azo initiators (trade names, Internet address) are DuPont (Vazo, http://www.dupont.com/vazo/), Atofina Chemical Inc. (AZDN, http://www.atofinachemicals.com), and Wako Pure Chemical Industries, Ltd. (Wako, http://www.wako-chem.co.jp/egaiyo/). The worldwide market for organic azo initiators is small, being only about 10% of the market for organic peroxide initiators.

Ciba Speciality Chemicals, Inc. (Darocur, Irgacure, http://www.cibasc.com) and Sartomer (distributor of Lamberti S.p.A. Esacure photoinitiators, http://www.sartomer.com, http://www.esacure.com) are significant suppliers of photoinitiators. Ciba Specialty Chemicals supplies alkoxyamines (Chimassorb). Nitroxyl radicals are available from Aldrich and Degussa-Hüls. Sales figures on photoinitiators are not readily available. The market for these initiators has been reviewed (240). Because most of the consumption of organic peroxides and azo initiators is in the developed countries, market growth in 2000 and beyond is expected to be modest, ie, 2–3% annually.

IONOMERS

Introduction

In the 1950s it was already known that the presence of carboxylate ionic groups had a strong influence on the properties of elastomers; the early work on the carboxylic elastomers has been documented in a review (1). Since then, it has been recognized that the ionic interaction is one of the very important factors in modifying polymer properties, giving to the polymers many of the properties of vulcanized and filled systems.

The origin of the word *ionomer* dates back to 1965 (2), when it was used for the first time to describe a class of thermoplastics (Surlyn, E. I. du Pont de Nemours & Co., Inc.) consisting of ethylene and partly neutralized methacrylic acid. Historically, the definition of the ionomer referred to thermoplastic polymers of low dielectric constant, containing a relatively small amount of ionic groups (<15 mol%). Later, however, Eisenberg and Rinaudo, who noticed that ionomers in solution sometimes showed polyelectrolyte behavior, proposed another definition; (3) *ionomers* are polymers whose bulk properties are governed by ionic interactions in discrete regions of the material (ionic aggregates). Typical examples of the structures of random ionomers [ie, poly(styrene-*co*-sodium methacrylate), P(S-*co*-MANa) (**1**) and poly(styrene-*co*-sodium styrenesulfonate), P(S-*co*-SSNa) (**2**)] are depicted below.

(**2**)

There are several ways of expressing ion concentration in ionomers. In the case of vinyl polymers, the easiest way of expressing ion content is mole percent (mol%), which means the ratio of the number of repeat units containing ionic groups to the total number of repeat units (multiplied by 100). For example, in the case of the P(S-*co*-MANa) and P(S-*co*-SSNa) ionomers, chemical structures **1** and **2**, the ion content is $[100 \times n/(n + m)]$ mol%. However, in the case of highly aromatic or rigid chain systems, for example, milliequivalent per unit weight or moles per liter might be more convenient. In this article mol% is generally used for expressing ion content.

The following four cases are probably useful to illustrate the effect of ionic interactions on the properties of ionomers; they involve the glass-transition temperature, mechanical properties, transport, and melt viscosity. The first case is the glass transitions of inorganic polymers. In 1965, it was found that the glass-transition temperature (T_g) of poly(phosphoric acid), $(HPO_3)_x$, was $-10°C$, but that neutralization of the polymer with Na^+ increased the T_g to 280°C (4). In the case of the ionomer neutralized with Ca^{2+}, the T_g increased further to 520°C. Thus, it was concluded that the increase in the T_g was strictly ascribed to the neutralization of the acid groups (ie, ionization) and to the ionic interaction between anions and cations. The T_g can be related to the strength of the ionic interaction through a q/a effect, where q is the cation charge and a is the distance between the centers of an anion and a cation. The q/a value suggests that the T_g is proportional to the electrostatic work needed to separate the anion from the cation (5). The magnitude of the change in the T_g values (from -10 to 520°C) indicates the importance of ionic interactions on the T_g of polymers. A similar relation was observed for the 100% ionized silicates (6), acrylates (7), and ionenes (8). A number of theories of the T_g and q/a effect in ionomers have been developed (9–11).

The second case is the mechanical properties as a function of temperature for P(S-*co*-MANa) ionomers. Shown in Figure 1 are the storage modulus (E') and loss tangent (tan δ) for P(S-*co*-MANa) ionomers (12,13). The behavior of the P(S-*co*-MANa) ionomer containing 5.4 mol% of ions resembles that of a phase-separated blend or a block copolymer in which the volume fraction of a high T_g (ca 200°C) phase is ca 50%. The volume fraction of the phase can be calculated from the relative area under two loss tangent peaks. In addition, the calculated activation energies for the glass transitions are characteristics of those for glass transitions of nonionic polymers. In the case of the ionomer containing 9.6 mol% of ionic groups, the low T_g phase becomes a minor component, while the high T_g phase becomes dominant. The low and high T_g's of the 9.6 mol% ionomer are ca 150 and 230°C, respectively. It should also be noted that in the 9.6 mol% ionomer, ca 90% of the material is still styrene. Finally, for the 21.6 mol% ionomer, the loss tangent peak at low temperatures disappears, while the

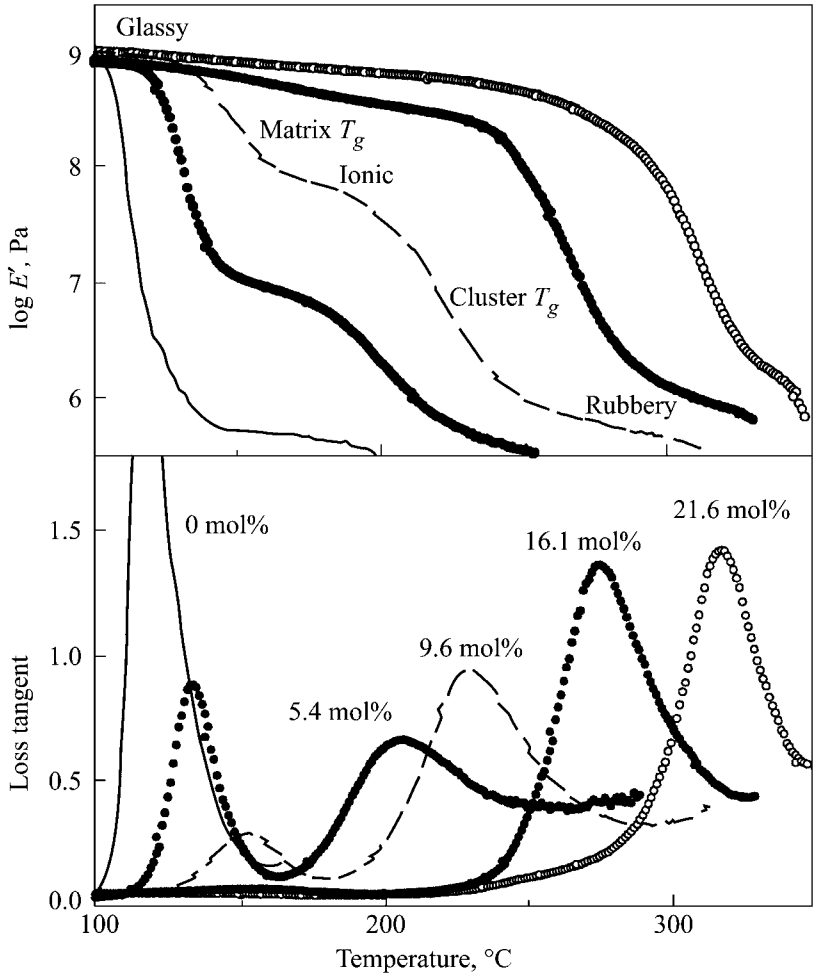

Fig. 1. Storage moduli (E') and loss tangent measured at 1 Hz as a function of temperature for P(S-*co*-MANa) ionomers with ion contents marked near each plot (data were obtained from Refs. 12 and 13).

peak at high temperatures shows its maximum at ca 320°C. At this point it should be mentioned that the estimated T_g of poly(sodium methacrylate) is ca 310°C (14), and thus it is clear that the 21.6 mol% ionomer possesses a T_g very close to that of the poly(sodium methacrylate). This result implies that unusual copolymerization effects must be taken into account. The presence of ions also affects ionomer modulus significantly. For example, at 200°C polystyrene is a viscous material. However, the modulus of the 5.4 mol% ionomer is ca $10^{6.3}$ Pa, and that of the material containing 21.6 mol% of ions is ca $10^{8.8}$ Pa. This behavior is partly due to an increase in the T_g of the ionomer. It should also be noted that for the ionomers of intermediate ion contents, the modulus value changes from the glassy modulus, through the glass transition of the matrix phase, through the "ionic" modulus, through the glass transition of the ion-rich phase, through the rubbery modulus, to modulus for flow behavior.

The third case demonstrates the effect of ions on the transport properties of polymers, especially conductivity. Since their first appearance, the perfluorosulfonate (eg, Nafion, E. I. du Pont de Nemours & Co., Inc.) (15) and perfluorocarboxylate ionomers (eg, Flemion, Asahi Glass Inc.) (16) have been recognized as becoming conductive in the presence of water. The high conductivity has been attributed to the hydration of ionic aggregates, resulting in the formation of percolative ionic domains containing water that allow the ionomers' high conductance. Similar results were also obtained in methyl methacrylate-based (17) and styrene-based ionomers (18) in the presence of water. For example, in the case of poly(methyl methacrylate-*co*-sodium methacrylate) ionomers, conductivity percolation, ie, abrupt insulator–conductor transition, was achieved at the ion content of 5 mol% (17). Above that ion content the ionomer exhibited a conductivity of ca $10^{-2}\ \Omega^{-1}\cdot cm^{-1}$, which was comparable to that of semiconductors.

The last case illustrates the melt viscosity of ionomers. The melt viscosity of polystyrene homopolymer was found to be 400 Pa·s (4×10^3 P) at 220°C (19). However, the melt viscosity of identical molecular weight polystyrene containing 3 mol% of carboxylate ionic groups increased to 7×10^4 Pa·s (7×10^5 P). In the case of a sulfonated sample, the melt viscosity increased further to 9×10^7 Pa·s (9×10^8 P), ie, an increase of over 5 orders of magnitude. As expected, the melt viscosity also increased with increasing ion content. These four cases mentioned above are typical significant effects encountered whenever ionic interactions are introduced into polymers. Ionic interaction and ion aggregation, being responsible for all of the effects mentioned above, have received considerable attention from industrial and academic arenas.

Ionomer Models

In 1970, it was suggested that ions in media of low dielectric constants form aggregates (20). This ion aggregation is one of the major features in the study of ionomers, and is the fundamental basis of the discussion of morphology. The ionic aggregates, termed *multiplets* (20), frequently give rise to a pronounced peak in the small-angle region of the x-ray scattering profile (see Fig. 2). The ionic species has a high atomic number, which gives the scattering centers a high electron density (21). Since the appearance of the first article, published in 1968 (21), dealing with this "ionomer" peak of the ethylene ionomer, a very wide range of morphology studies has confirmed the existence of the ionomer peak in most ionomers, at least under some conditions. However, the interpretation of this ionomer peak is not straightforward and has been a theoretical challenge; as a result, different models have been proposed. Among them, two models based on ionomer morphologies and the so-called Eisenberg–Hird–Moore (EHM) model will be discussed below.

Hard-Sphere Model. In 1973, it was suggested that the ionomer peak is ascribed to the distance between ionic aggregates, with the contrast provided by the difference in the electron density between the ionic aggregates and the hydrocarbon phase (22). The scattering centers are considered to be points on a paracrystalline lattice. In 1983, a refined model was proposed (23); in this hard-sphere model, the multiplets have liquid-like order and the distance of closest approach

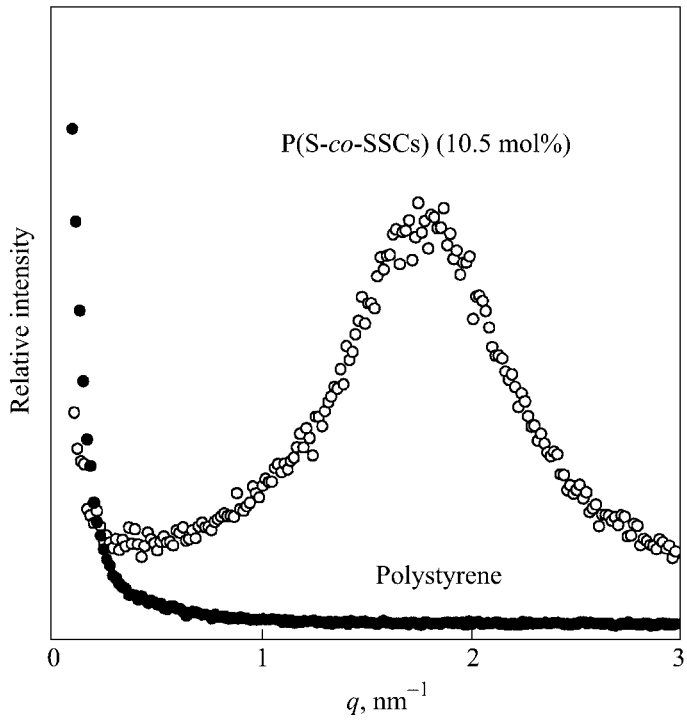

Fig. 2. Small-angle x-ray scattering data as a function of q ($=4\pi \sin\theta/\lambda$, θ is half the scattering angle and λ is the x-ray wavelength) for polystyrene and poly(styrene-*co*-cesium styrenesulfonate) ionomer containing 10.5 mol% of ions.

is governed by the thickness of a layer containing polymer chains on the surface of each multiplet.

Core–Shell Model. In 1974, the observed small-angle x-ray scattering (saxs) peak was interpreted (24) as resulting from the characteristic intraparticle distances. In that model, called core–shell model, an ionic core of ca 1 nm radius is surrounded by a shell of hydrocarbon material containing no ionic groups, and is, in turn, surrounded by a shell of polymeric materials of somewhat higher ion content. In contrast to the hard-sphere model, the core–shell model suggests that the distance between the two ion-rich regions, ie, the core and the outer shell, gives rise to the ionomer peak. This model was elaborated in 1980. It was found that the saxs profiles of the ethylene ionomers depended on sample elongation, and thus it was postulated that the ionic core might not be spherical but lamellar (25).

EHM Model. The Eisenberg–Hird–Moore (EHM) model or multiplet/cluster model, incorporating both morphological and mechanical features, is also based on the existence of ionic aggregates, ie, multiplets (26). In the EHM model, it is assumed that the saxs peak is a result of interparticle scattering along the line suggested in References 22 and 23.

The primary ionic aggregates consist of several ion pairs, and the size of a multiplet is limited by a number of factors (20). The most important factor is a

steric effect of the polymer chain segments adjoining the ion pair, which cannot get out of the way when the aggregates are formed. This effect, which leads to an upper limit on the size, arises from the fact that each ion pair is attached through primary bonds to a polymer chain or to a spacer, and that all the ionic groups must be inside a multiplet, while the organic polymer segments must be outside the multiplet.

Naturally, a number of other factors also influence the size of multiplets, such as the size of ion pairs (27), the dielectric constant of polymers (4), the distance between an ionic group and a polymer backbone (28), and an ion content (28,29). For example, small ion pairs attached to a relatively bulky chain backbone would lead to small multiplets, while large ion pairs attached to a very flexible backbone are expected to form large multiplets. If the dielectric constant of the polymer were high enough, as is the case of the polyphosphates, the ions would be solvated, and thus no multiplet would be found.

In the case of polystyrene ionomers, in which an ionic group is attached to the para position of benzene ring through a flexible alkyl side chain, the effect of the distance between the pendant ion and the backbone on the multiplet size was studied by using a saxs technique (28). Shown in Figure 3 are the relationships

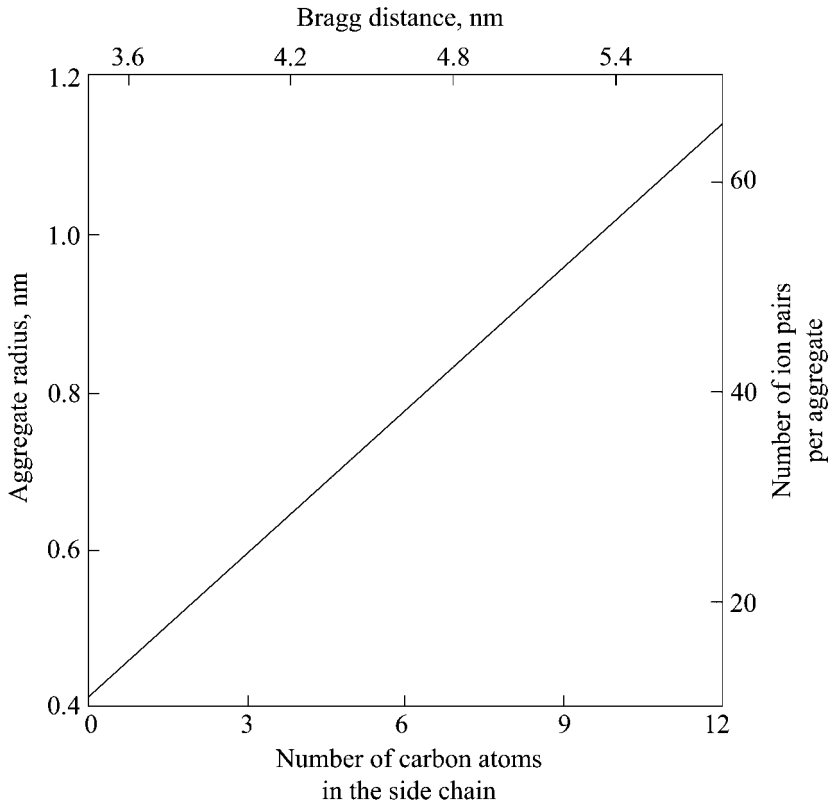

Fig. 3. Aggregate radius–number of carbon atoms in the side chain–number of ion pairs per aggregate–Bragg distance relationships in alkyl side-chain ionomers (data were obtained from Ref. 28).

between the aggregate radius of the alkyl side-chain ionomers containing 7.5 mol% of ions, the number of carbon atoms in the side chain, the number of ion pairs per aggregate, and the Bragg distance. It is shown that the Bragg distance (the distance between aggregates) is a linear function of the number of carbon atoms. The number of ion pairs per aggregate could be calculated for ionomers containing side chains of 2 carbons, 6 carbons, and 11 carbons; they are 21, 37, and 60 ion pairs, respectively. In the figure, it is also shown that the radius of the aggregate increases linearly with increasing the side-chain length, extrapolating to a value of ca 0.4 nm for the cesium–methacrylate system. In the case of the ionomer containing the alkyl chain of 11 carbons, the radius of the aggregate is ca 1.1 nm.

In the case of P(S-*co*-MANa) and P(S-*co*-SSNa) ionomers, every ion pair in the multiplet has two chains emanating from it. Thus, the spherical multiplets, consisting of a few of ionic groups, resemble physical cross-links. A novel feature of the EHM model is a reduced mobility of the polymer chains in the immediate vicinity of the multiplets (26). The chains emanating from the multiplet will be restricted in their mobility, with the restriction decreasing as the distance between the polymer chain segments and the multiplet increases (30,31). Because the chains are anchored rigidly to the multiplets, the mobility of polymer chains surrounding the multiplets is believed to be considerably lower than that of the chains in nonionic polymers. Other mechanisms leading to a reduction of chain mobility were also proposed. Bridging between neighboring multiplets through polymer chains is expected to put the polymer chains under tension, causing a decrease in the chain mobility. The crowding of polymer chains would also affect the mobility; it has been suggested that crowding may possibly be the dominant factor in the reduction of chain mobility (32). Thus, with considerations of the three mechanisms mentioned above, one would expect that the chains in the vicinity of the multiplets do not move as easily as the chains in nonionic bulk polymers. Regarding the restricted mobility of polymer chains, a considerable amount of supportive evidence has been collected by using nuclear magnetic resonance, dynamic mechanical techniques, and other methods (30,31,33–37).

The EHM model postulates that the thickness of the layer of reduced mobility is of the order of the persistence length of the polymer chain (eg, ca 1 nm for polystyrene). Thus, the size of the reduced mobility region of a material including the multiplet is of the order of 3 nm or less (see Fig. 4). However, a certain critical dimension, probably in the range of 5–10 nm, must be exceeded for a polymer to have its own glass transition, and thus the size of the reduced mobility region of ca 3 nm is too small to show its own glass transition.

As the ion content increases, the number of multiplets also increases, and regions of restricted mobility start overlapping. As a result, the sizes of these regions become large enough to exceed a threshold value for independent phase behavior. These large regions of reduced mobility are called *clusters* (26). This overlapping of reduced mobility regions results in the appearance of a second T_g at a temperature higher than that of the normal T_g. As the ion content increases further, the clustered regions become dominant and even continuous.

Apart from the three models described in this section, many other models and morphologies have been proposed; other attempts have also been made to describe the morphologies of ionomers. Interested readers are referred to the original literature (38–73).

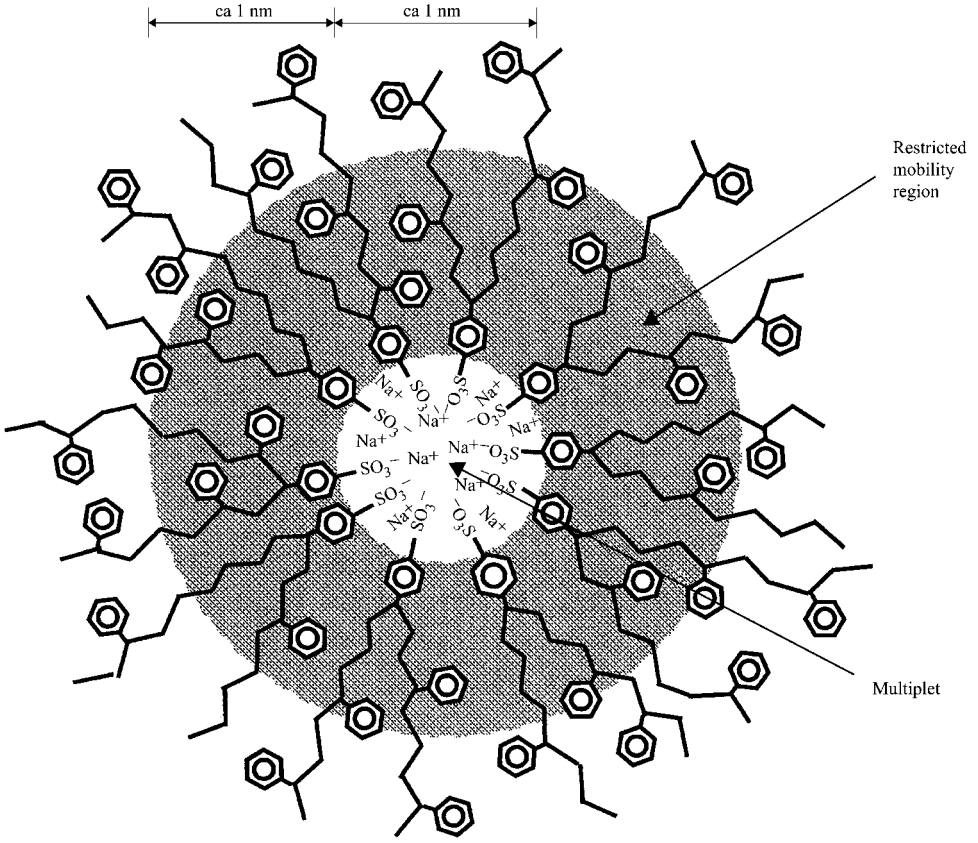

Fig. 4. Representative scheme of a multiplet and of the region of restricted mobility surrounding it in a P(S-*co*-SSNa) ionomer.

It should also be mentioned that the ionomer morphologies were investigated by other techniques rather than saxs, which include transmission electron microscopy (tem) (74–77) and scanning transmission electron microscopy (stem) (78–80). It is worth noting that different sample preparation methods can lead to different morphologies. For example, spherical aggregates were found in the polystyrene-based ionomers by using a tem technique (76), but in some cases, vesicular aggregates were observed by using stem technique (80). In addition to the tem and stem methods, a small-angle neutron scattering technique was also used to study the interphase morphology of ionomers as well as chain conformation (81–90). It should also be mentioned that an extended x-ray absorption fine structure technique was employed to determine the structure around the neutralizing cations in multiplets (91–98).

Recently, the multiple morphologies of block ionomers in solution have been investigated extensively (99–101). The equilibrium, near-equilibrium, and nonequilibrium morphologies observed to date are spheres, rods, bicontinuous rods, bilayers, lamellae, vesicles, inverse bicontinuous rods, large compound micelles, aggregates of spheres, large rod-shaped compound micelles, large compound vesicles, and many others (101).

Glass-Transition Temperatures

In polystyrene-based ionomers, two glass transitions (T_g's) are observed, especially by dynamic mechanical techniques. In the plots of modulus vs. temperature for pure polystyrene and the P(S-*co*-MANa) ionomer containing 21.6 mol% of ions (see Fig. 1), it is shown that the two polymers have only one loss tangent peak at 120°C and at 320°C, respectively. The activation energies obtained from Arrhenius plots of a maximum of the peak at different frequencies are 520 kJ/mol for the polystyrene and 640 kJ/mol for the 21.6 mol% ionomer (13). These values imply that these two peaks indeed represent glass transitions. The ionomers of intermediate ion contents show two drops in the modulus curves as a function of temperature and two loss tangent peaks. The positions of the peaks as a function of ion content for the P(S-*co*-MANa) system are shown in Figure 5 along with those obtained from P(S-*co*-SSNa) ionomers (13,102,103). It is clear that there are two groups of lines; the lower and higher T_g's are referred to as the matrix and the cluster T_g's, respectively. Several other investigations have been performed to bear on the duality of the glass transitions in polystyrene ionomers by using a differential scanning calorimeter (13,102,104–107) and by measuring the volume of ionomers as a function of temperature (108) (see GLASS TRANSITION).

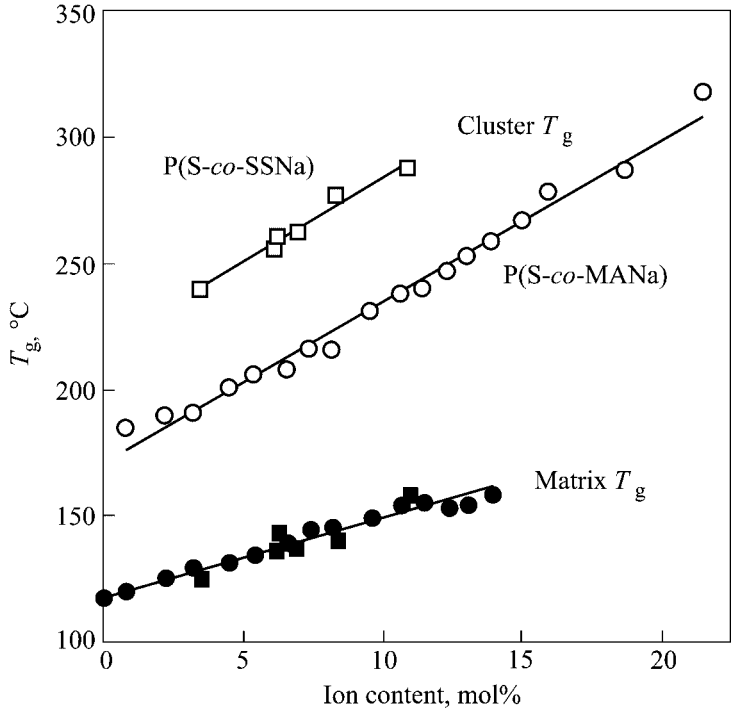

Fig. 5. Glass-transition temperatures of matrix and clustered regions vs ion content for P(S-*co*-MANa) and P(S-*co*-SSNa) ionomers (some of data were obtained from Refs. 13,102, and 103).

Glass-Transition Temperature of Unclustered Regions. A study (109) of the effect of the degree of neutralization on the T_g of poly(ethylene-*co*-sodium methacrylate) ionomers suggested that the loss tangent peak at ca 0°C was due to a β relaxation occurring in the amorphous branched polyethylene phase from which most of the ions had been depleted. The peak position was found to shift to lower temperatures with the increasing degree of neutralization. It was found that the T_g of the poly(ethylene-*co*-sodium acrylate) ionomers increased with increasing ion content (110).

In the case of the P(S-*co*-MANa) ionomers, it was reported that the T_g increased slowly up to ca 6 mol% of ions, but took a sharp turn above that ion content (111). According to the EHM model, the reason for the increase in the matrix T_g is following: in polystyrene ionomers, isolated multiplets and the surfaces of clusters would act as cross-links, and thus the matrix T_g naturally increases with increasing ion content (26).

At this point, it should be noted that the T_g does not always increase with ion content. When poly(styrene-*co*-styrenesulfonic acid) copolymers are quaternized with various amines, in which at least one of the substituents on the nitrogen is an alkyl chain, the T_g decreases with increasing ion content if the alkyl chain is long enough (112). As can be expected, in that system the long alkyl chain acts as an internal plasticizer.

An investigation (113) of the T_g of the poly(styrene-*co*-vinylpyridine) copolymers quaternized with iodoalkane found that the T_g increased with increasing ion content, but that the increasing rate of the T_g with ion contents (dT_g/dc) depended on the length of an alkyl chain. For example, dT_g/dc for the ionomer quaternized with iodomethane was ca 3.2°C/mol%, while for the ionomer quaternized with iododecane it was only ca 1.1°C/mol%.

Glass-Transition Temperature of Clustered Regions. Regarding the cluster T_g, the most extensively investigated system is the P(S-*co*-MANa) ionomers (13). At low ion contents, the cluster T_g increases almost in parallel with the matrix T_g, but only along the temperatures ca 60°C higher than the latter (see Fig. 5). However, with increasing ion contents, the cluster T_g increases more sharply so that for the ionomer containing 15 mol% of ions the difference between the two T_g's now widens to ca 110°C. It is also found that the type of ionic groups changes the temperature difference between the two T_g's. For example, the cluster T_g of the P(S-*co*-SSNa) ionomers is much higher than that of the P(S-*co*-MANa) ionomers (see Fig. 5) (102,103,114,115). In the case of the sulfonated ionomer containing 3.5 mol% of ions, the difference between the matrix and cluster T_g's is ca 115°C, but for the 11 mol% ionomer it widens to ca 130°C. It has been suggested that the ionic interaction of a sodium sulfonate ion pair is much stronger than that of a sodium carboxylate ion pair owing to the difference in the three-dimensional arrangement of the cation and the anion (115).

In terms of the cluster T_g, one very interesting system is the poly(styrene-*co*-*N*-methyl-4-vinylpyridinium iodide) copolymers (27,116). Although the matrix T_g increases with increasing ion content in exactly the same way as it does for other polystyrene-based ionomers, the loss tangent peak for the cluster T_g is not observed. This implies that this system is unclustered. The reason for the absence of clustering in vinylpyridinium ionomers is that the *N*-methyl vinylpyridinium cation and the iodide anion are too large for strong

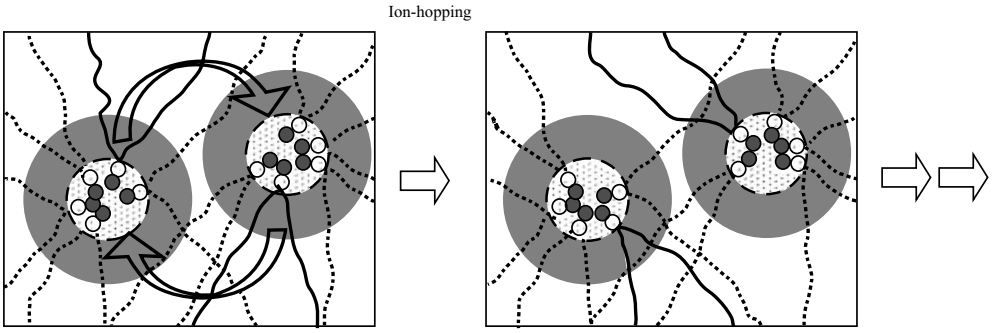

Fig. 6. Schematic drawing of the "ion-hopping" mechanism. Inner circles represent multiplets containing several ion pairs, indicated by smaller black and white circles. The shaded area represents restricted mobility regions. The thicker curved lines are polymer chain segments, which are subjected to move from one multiplet to the other.

ionic interactions. In addition, the T_g of the polymer matrix is too high for those ionic groups to form a sufficient number of multiplets. Therefore, no clustering is observed. Above the matrix T_g, only the chain entanglement governs the ionomer properties. However, when the ionomer is plasticized, which lowers the T_g of the polymer (leading to a decrease in the thermal energy kT_g of polymer chains), clustering is induced in this system (27), and thus, two loss tangent peaks are now observed.

While the mechanism of the matrix glass transition is the same as that of nonionic polymer, the mechanism of the cluster glass transition is still rather ambiguous. An *ion-hopping mechanism* (the actual removal of ion pairs with sufficient thermal energy from multiplets; see Fig. 6) was proposed to occur at and above the cluster T_g (103,117). According to this possibility, the glass transition can only be encountered when ion pairs can move out of the multiplets at a fast rate. Furthermore, the activation energies for ion hopping in the P(S-*co*-MANa) system are generally higher than those in the P(S-*co*-SSNa) system despite the opposite trend in the strength of ionic interaction (13,103). Thus, the strength of the ionic interaction influences the cluster T_g, but is not directly related to the activation energies for ion hopping (13).

As was mentioned before, the polyphosphates show only one glass-transition behavior. In that system, based on electrostatic considerations the T_g should be determined by the strength of ionic interactions, since the polymers have a high dielectric constant and a high T_g. Thus, the separation of ionic species, ie, ion hopping, determines the mobility of polymer chains, and a q/a dependence should be expected.

Properties of Styrene Ionomers

Stress Relaxation. In a study (111) of stress relaxation behavior of P(S-*co*-MANa) ionomers, it was found that below ca 6 mol% of ions, time–temperature superposition was applicable. However, above that ion content,

time–temperature superposition broke down. This could be understood: Below the percolation threshold (ca 5.4 mol% for this system) (13) for the connectivity of clustered regions, the matrix phase was responsible for the behavior. Above the percolation threshold, however, both the clustered and unclustered regions caused the results, and thus time–temperature superposition failed.

Dynamic Mechanical Properties and Filler/Percolation Concepts. One of the detailed dynamic mechanical studies of the P(S-*co*-MANa) ionomers in terms of storage modulus and loss tangent as a function of temperature has already been discussed (see Fig. 1). In the plot of modulus as a function of temperature, the ionomers of intermediate ion content showed two inflection points. The modulus values at a higher inflection point, called the "ionic" modulus, were in the range of ca $10^{6.5}$ to $10^{8.5}$ Pa, depending on the ion content, and the modulus value at a lower inflection point was ca $10^{5.5}$ Pa, which was independent of the ion content. Since the modulus–temperature curves of the ionomers resembled those of the filled materials, the ionic modulus might be interpreted as due to a filler effect. With the volume fraction of a clustered regions obtained from the areas under the loss tangent curves, the value of ionic modulus was calculated by the Guth equation [$E^* = E(1 + 2.5V_f + 14.1V_f^2)$, where E^* was the Young's modulus of the filled regions, E was that of the unfilled regions, and V_f was the volume fraction of filler] (118), assuming that the filler effect was operative here. Then, one could find that the calculated ionic modulus values were close to the experimental points, up to ca 3 mol% of ions (ca 45 vol% of a clustered phase) (13). This implied that clusters acted as fillers in the temperature range between the two T_g's of the ionomers, when the ion content was below the percolation threshold.

When one looks at the morphological picture given in the EHM model, one might suggest that the percolation concept is applicable to the clustering in ionomers (13). Thus, the ionic modulus of the P(S-*co*-MANa) system was attempted to be fitted with percolation theory. It was found that the log(ionic modulus) yielded a straight line when it was plotted against log $(f - f_c)^n$, where f was the volume fraction of clustered regions, f_c was the critical volume fraction at the percolation threshold, and n was the critical exponent (13). The slope of the plot, ie, critical exponent n, was found to be ca 1.3. This value is very close to the universal value for conductivity percolation (ca 1.5), which means that the percolation concept is indeed applicable.

Sulfonate vs Methacrylate vs Carboxylate. A comparison study (19) of the melt viscosity values of polystyrene ionomers, either randomly carboxylated or sulfonated in the para position of a benzene ring, showed that the melt viscosity values at 220°C of the two ionomers were significantly different. For example, at 2 mol% of ions, the melt viscosity of sodium sulfonated polystyrene ionomer was more than 2 orders of magnitude higher than that of the sodium carboxylated polystyrene ionomer.

The storage moduli against temperature for the P(S-*co*-SSNa) and P(S-*co*-MANa) ionomers containing ca 6 mol% of ions are shown in Figure 7. One can find two differences. First, the "ionic plateau" extends to higher temperatures for the P(S-*co*-SSNa) ionomer. Since the ionic interaction between the sodim sulfonate ionic groups is stronger than that between sodium methacrylate, it is expected that the ionic plateau of the sulfonate ionomer persists to higher temperatures. Second, the height of the ionic plateau is lower for the P(S-*co*-SSNa)

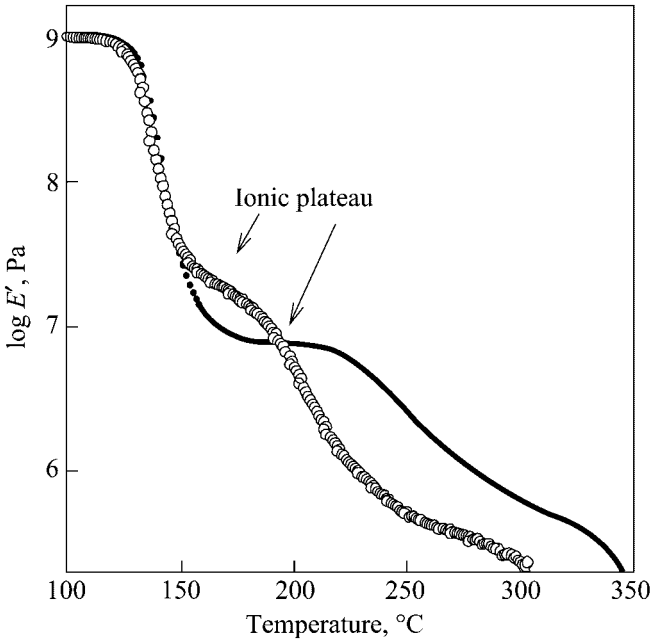

Fig. 7. Storage moduli (E') measured at 1 Hz as a function of temperature for P(S-*co*-MANa) (○) and P(S-*co*-SSNa) (●) ionomers containing 6.5 and 6.3 mol% of ions, respectively.

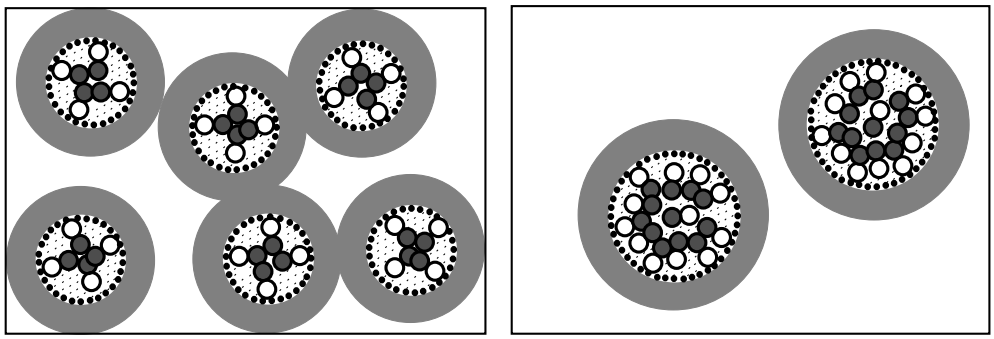
ionomer than for the P(S-*co*-MANa) ionomer. This can be understood: The ionic groups in the sulfonated ionomer are located in the para position of the benzene ring, while in the methacrylate ionomer they are directly attached to the main chain (103). Thus, larger multiplets form in the sulfonated systems because the distance between the ionic group and the main chain is longer, leading to less steric hindrance for the ionic groups to form multiplets. Since the multiplets are larger, there are fewer multiplets; since the thickness of the restricted mobility layer is presumably the same in the two systems, the total volume of restricted mobility regions is lower in the sulfonates (see Fig. 8). At this point, it is worth recalling that the strength of the ionic interaction also changes the multiplet size; that is, the stronger ionic interaction is, the more ion pairs in the multiplets are. This also enlarges the multiplet size of the P(S-*co*-SSNa) ionomer, compared to that of the P(S-*co*-MANa) ionomer (103).

Comparison of the dynamic mechanical properties of the *p*-carboxylated polystyrene ionomers and those of the P(S-*co*-MANa) ionomers shows a more subtle difference. For the *p*-carboxylate ionomers the ion pairs are farther from the polymer backbone than for the P(S-*co*-MANa), and thus form larger multiplets (102,103). Again, since the size of multiplets is smaller for the P(S-*co*-MANa), the total number of multiplets is larger, which results in the smaller amount of reduced mobility regions for the carboxylated polystyrene system, at a comparable ion content. As a result, the ionic modulus should be lower in the *p*-carboxylate system than in the methacrylate system.



(a) (b)

Fig. 8. Schematic diagrams of restricted mobility regions (shaded area) in ionomers containing multiplets that are smaller in their size but larger in their number (**a**), and that are larger in their size but smaller in their number (**b**). The thickness of the restricted mobility layer was assumed to be the same. The white and black circles represent ionic groups.

In the case of the *p*-sulfonated polystyrene ionomer, the ion pairs are at the same distance from the backbone as in the *p*-carboxylated polystyrene ionomer. As was mentioned above, however, the ionic interaction in the sulfonated ionomer is stronger than that in the carboxylated ionomer. Thus, at the identical ion content, the modulus–temperature curves show longer ionic plateau, and the volume fraction of reduced mobility regions for the *p*-sulfonated ionomer is smaller than for the *p*-carboxylated ionomer (103), leading to less clustering for the *p*-sulfonated ionomers.

Physical Properties of Other Ionomers

A wide range of ionomers based on other polymer backbones has also been studied. Even though an extensive discussion of properties of partly crystalline ionomers as well as the other ionomer families is beyond the scope of the present review, it will be useful to discuss very briefly the properties of some of them. In partly crystalline polyethylene-based and perfluorinated ionomers the degree of crystallinity makes the interpretation of experimental results difficult.

Polyethylene-Based Ionomers. Since their appearance in 1965 under the trade name Surlyn, ethylene ionomers have been studied extensively (2,21,24,38–40,109,110,119–123), and are well known for their flexibility, transparence, toughness, and melt processibility. An example of stress relaxation behavior of an ethylene-based ionomer is shown in Figure 9 (38). It is shown that the rate of stress relaxation is very slow, and a sharp glass-transition region is not observed. The shapes of the curves are different from those obtained from amorphous styrene ionomers. However, the results are very similar to those of some amorphous ionomers of very high ion content or highly crystalline nonionic polymers. When superposition of the individual curves is carried out, it is found that the shift factors are not the WLF (Williams–Landel–Ferry) type, and that master curves cannot be constructed since more than one mechanism may be involved in the relaxation of the material.

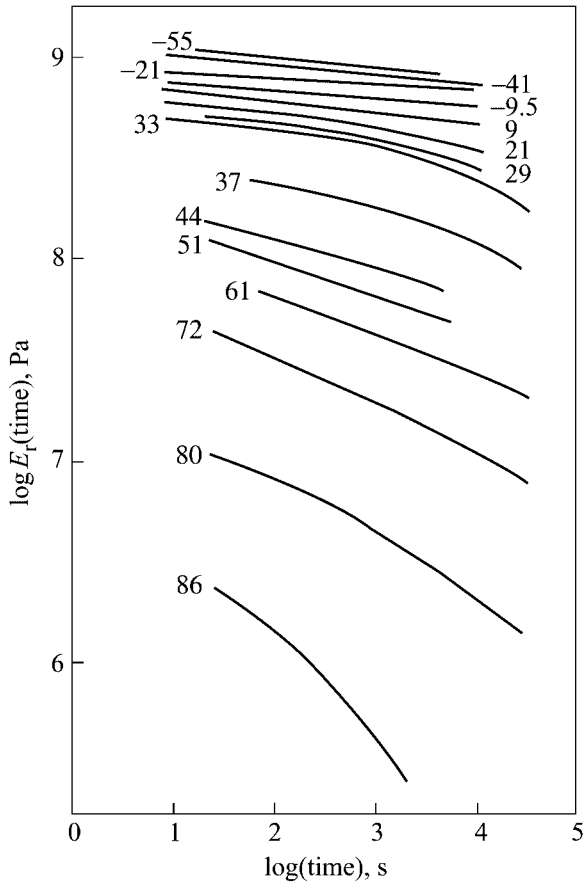


Fig. 9. Stress relaxation curves for an annealed poly(ethylene-*co*-methacrylate) ionomer containing 8 mol% of acid groups, 47% of which were neutralized with NaOH (modified from Ref. 38).

One experiment provides another case in point in the relaxation behavior of polyethylene ionomers (109). In the plots of decrement against temperature, four peaks were observed. The first peak (γ) at ca -120°C was assigned to the crankshaft motion of short hydrocarbon segments in the amorphous phase. The second peak (β) was shown in the temperature range of -20 to 0°C. The peak height increased slightly, but its position remained at a constant temperature in spite of the increasing degree of neutralization. Similar results were also found in the ethylene ionomers of various ion contents (120). Thus, the peak was ascribed to a relaxation in the amorphous branched polyethylene phase having no ionic group. In the case of the third peak (β') (0–50°C), with increasing degree of neutralization, its intensity decreased; however, the peak position remained at a constant temperature. This peak was assigned to micro-Brownian motion of polymer chains, occurring in the amorphous polymer having hydrogen bonds. The fourth peak (α) at high temperatures ($>50^{\circ}$C) shifted to even higher temperatures with increasing degree of neutralization, which was attributed to micro-Brownian

motions of relatively large segments of polymer backbone. This peak was also assumed to reflect the dissociation of the ionic aggregates. At a relatively high degree of neutralization, an additional relaxation, the α' relaxation peak at ca 50°C, was identified (121). Since the peak was not sensitive to frequency, it was assigned to an order–disorder transition of ionic clusters.

Polytetrafluoroethylene-Based Ionomers. Studies on the properties of perfluorosulfonate ionomers have been carried out extensively (124–128). In one of the studies, the nonionic precursor containing $-SO_2F$ groups at the end of the side chain, was compared with the ionomer of an equivalent weight of 1155 (125). It was found that if the degree of crystallinity in both the precursor and the acid-type polymers were low, time–temperature superposition of stress relaxation curves, measured over 4 orders of magnitude of time, could be applicable. In the case of a potassium-neutralized ionomer, time–temperature superposition broke down up to ca 180°C, but above that temperature it became applicable again (124). In the plots of the 10 second tensile modulus values of the precursor, the acid form, and the potassium-neutralized ionomer as a function of temperature, it was found that the two step drop in the modulus was not observed (125). This was probably due to the crystallinity and the different morphology in the tetrafluoroethylene ionomers, compared to styrene ionomers.

The loss tangent curves of the acid form of Nafion and the completely neutralized Cs ionomer are shown in Figure 10 as a function of temperature (124). Three peaks are shown. The peak at highest temperature (α) is ascribed to the glass transition in ionic cluster regions, the β peak at intermediate temperature is attributed to the glass transition in the matrix regions, and the peak at lowest temperature (γ) is due to local motions of CF_2 groups of the polymer main chains

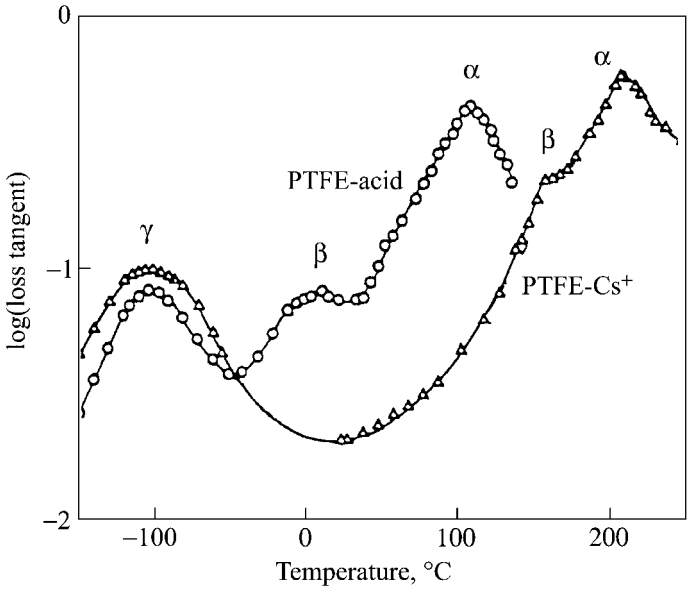

Fig. 10. Loss tangent vs temperature for Nafions (PTFE) in the acid and Cs^+ ionomer form (modified from Ref. 124).

in noncrystalline regions of polytetrafluoroethylene. Also the α peak was found to shift to higher temperature with the increasing degree of neutralization (126).

In the study of the effect of crystallinity on the 10 second tensile modulus, it was found that the modulus curve of the amorphous Nafion (prepared by melting Nafion by heating and subsequently quenching it) was essentially parallel to that of the crystalline Nafion, but only moved along the temperatures ca 40°C lower than the latter (126,128). Thus, it was concluded that the small degree of crystallinity, ie, ca 7%, in perfluoroethylene ionomers shifted the modulus–temperature curve to ca 40°C higher.

In the case of the perfluorocarboxylate ionomers (129), in addition to the three main peaks, a β' peak was also identified, but the mechanism for the relaxation was not identified. A γ' peak between temperatures for the β and γ relaxation was assigned to local motions of the polar side groups in the matrix.

Block Ionomers. The block ionomers to be discussed are of AB or ABA type, in which one of the blocks is ionic (eg, sodium methacrylate) and the other consists of nonionic units (eg, polystyrene). While ionic block copolymers in a micelle form in both aqueous and nonaqueous solutions have been studied extensively (99–101,130,131), the viscoelastic properties of block ionomers in bulk have not received much attention (132–137). If the short ionic blocks formed micelle-like aggregates, which were surrounded by nonionic blocks, the viscoelastic properties of the diblock ionomers would be very similar to those of stars or polymers of low molecular weight (136). Thus, above the T_g of the nonionic blocks, as the temperature increased the modulus dropped rapidly with a very short rubbery plateau. For example, in a dynamic mechanical study, it was found that a homopolymer containing 490 styrene units showed a T_g at ca 115°C, and started to flow at ca 150°C. However, in the case of a diblock ionomer containing 490 styrene units and 40 sodium methacrylate ionic units showed a T_g at ca 116°C, and flow behavior was observed above ca 165°C, which was only 15°C higher than that of nonionic polystyrene (135).

Triblock polystyrene ionomers exhibited an extended rubbery plateau, and the height of the rubbery plateau increased with increasing the length of the ionic block (135). For the triblock ionomer with ionic endblocks of 22 units and a polystyrene midblock of 490 units, the rubbery modulus was ca 10^6 Pa, while for the triblock ionomer with ionic endblocks of 44 units and a midblock of an identical block length, the rubbery modulus increased by approximately 1 order of magnitude; it was suggested that trapped entanglements of chains influenced the modulus more significantly for the longer ionic block ionomer than for the shorter ionic block ionomer. It was also observed that the onset of flow occurred at ca 250°C for the ionic block of 8 units and at ca 290°C for the ionic block of 22 units. For the ionomer of a block length of 44 units, the significant flow behavior was not observed below the decomposition temperature. As expected, however, in the case of the acid triblock ionomers the second drop in the modulus was seen at ca 200°C, at which the acid polymer began to flow (135).

Triblock ionomers consisting of lightly sulfonated styrene endblocks connected by hydrogenated butadiene (ie, ethylene/butylene) midblock have also been investigated (134). It was found that the ion association increased the T_g of polystyrene phase, and that a new modulus plateau region appeared above the T_g. It was also observed that the modulus values between the T_g's of the

ethylene/butylene-rich and polystyrene-rich phases decreased with the increasing level of sulfonation.

Telechelic Ionomers. Telechelic ionomers are polymers containing ionic groups placed at both ends of the polymer chain. Telechelics have been actively studied (49,138–143); even though those studies have mainly been devoted to solution properties, in some cases bulk properties have also been investigated (138,139,142,143). The findings to this date show that the viscosities of the telechelics are higher than those of the nonionic polymers because of the presence of aggregation of ionic groups at the ends of polymer chain (138). Naturally, the type of cation affects viscoelastic properties appreciably, since it changes the degree of association of ionic groups. In addition, a study of molecular weight effect demonstrates that the lowest molecular weight yields a well-developed rubbery plateau, supporting the importance of ionic interactions for the behavior (139).

Star Ionomers. The star ionomers have mainly been studied by a few research groups (144–151). One example of the star ionomers consisted of a central benzene ring, from which three polyisobutylene chains containing a terminal sulfonate ionic group emanated. In the penetration depth–temperature plots of the unfunctionalized tri-arm star of 14,000 molecular weight, a sharp drop in the modulus, that was characteristically found in the modulus of polymers of very low molecular weight, was observed (148). However, when the ends of tri-arm star were terminated with a sulfonic acid group, a rubbery inflection point at a relatively low level was observed. Furthermore, if the acid groups were neutralized with potassium, a modulus increased to a much higher value. It was also found that the modulus increased by decreasing the polydispersity of molecular weight but that the elongation at break decreased (150). Recently, star block ionomers were also prepared and investigated (151).

Since it is not possible to describe all the ionomer families in this article, we will just name a few more extensively studied ionomers here; polyurethane ionomers (152–155), polypentenamers (156,157), ionenes (158–160), polysiloxane dizwitterionomers (161,162), ethyl (or butyl) acrylate zwitterionomers (163,164), ethyl acrylate ionomers (165–167), methyl methacrylate ionomers (168–171), and liquid crystalline ionomers (172–179). An area which has been a subject of considerable investigation but not discussed here is ionomer blends. Some reviews summarize this subject, and thus interested readers are referred to those review articles (180–183). It should also be mentioned that even though the solution properties of ionomers are of great importance, the discussion on the topic is omitted; readers who are interested in the topic can look up other review articles (184–187).

Plasticization

Since ionomers have the amphiphilic nature, it should be possible to plasticize independently the ionic regions and the regions of low polarity, ie, the hydrocarbon-rich regions, in ionomers by using plasticizers of high or low polarity, respectively. An early example of such a study on dual plasticization is Reference 188. It was found that the ion-rich regions in the sulfonated polystyrene ionomers containing 1–5 mol% of ions could be plasticized by using a polar

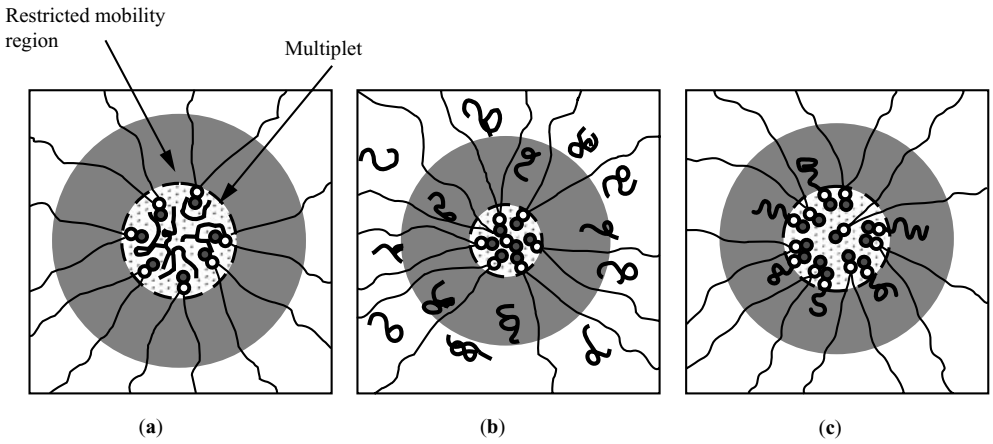

Fig. 11. Schematic diagrams of a multiplet and restricted mobility region surrounding it for plasticized ionomers: (**a**) polar plasticization, (**b**) nonpolar plasticization, and (**c**) amphiphilic plasticization. The thicker curved lines represent plasticizer molecules.

plasticizer such as glycerol. The polar plasticizer weakens the ionic interactions, leading to the fast rate of ion hopping, which decreases the cluster T_g (see Fig. 11). As a result, the bulk viscosity of the ionomer decreases substantially. A nonpolar plasticizer such as dioctylphthalate is, however, probably distributed quite evenly throughout both the matrix and cluster regions, interacts with the nonpolar hydrocarbon regions of ionomers, and thus lowers both the matrix and cluster T_g's. Because of the importance of plasticizers in ionomers for processing, this section is devoted to this topic. The section is divided into three parts dealing, respectively, with polar, nonpolar, and amphiphilic plasticizers.

Polar Plasticizers. At low concentrations, polar plasticizers enter ionic aggregates, shield ionic groups, which decreases the strength of ionic interactions to the point where the ionic core becomes mobile, and thus reduces the energy for ion hopping (see Fig. 11a). As a consequence, ions can be removed at a fast rate. Therefore, the cluster T_g shifts to lower temperature, and the melt viscosity decreases. At sufficiently high concentration, the multiplets may even be disrupted completely. However, the polar plasticization has little effect on the matrix T_g (188).

It was found that the addition of methanol to sulfonated polystyrene ionomers lowered the saxs intensity and shifted the saxs peak to a lower angle at low plasticizer contents; at somewhat high plasticizer contents (ca 10 wt%), the addition of methanol depleted the saxs peak completely (189). Thus, it was suggested that the addition of polar plasticizer increased the size of the ionic core, leading to the reduction of the electron density difference between the ionic core and the hydrocarbon-rich phase. However, in the case of the Zn-sulfonated polystyrene ionomer plasticized with water, it was found that with the increasing amount of water, the x-ray peak shifted to a lower angle, but its intensity increased (190). It was suggested that the water swelled the ionic core and induced a morphological

rearrangement, leading to the change in the fraction of ionic groups that formed ionic aggregates and in the number of the multiplets in the ionomer.

Nonpolar Plasticizers. Plasticizers of low polarity, such as diethylbenzene or dioctylphthalate, are miscible with polymers of low polarity, such as polystyrene. Since both cluster and unclustered regions of the polystyrene ionomer are primarily polystyrene, a nonpolar plasticizer should exist almost evenly in the cluster and matrix regions (see Fig. 11b). For example, it was found that both loss tangent peaks for the matrix and cluster T_g's shifted to lower temperatures as the amount of diethylbenzene increased; in some concentration range, the two T_g's were depressed in parallel (191). In the morphology study of plasticized ionomers, it was found that the saxs peaks did not change much with the different amounts of plasticizer (192). As was mentioned before, in ionomer systems while a polar plasticizer lowered the melt viscosity strongly, but had little effect on the matrix T_g, nonpolar plasticizer lowered the melt viscosity slightly, but lowered the matrix T_g substantially.

Amphiphilic Plasticizers. In one study (193) when ethylene–propylene terpolymer containing Zn-sulfonate (Zn-EPDM) (0.6–1.4 mol% of ions) was mixed with Zn-stearate, clustering was not observed because of the very low ion content. However, as the amount of the plasticizer increased, the matrix T_g and rubbery modulus of the polymer increased slightly. In addition, the temperature at which the modulus started to decrease, which accompanied the flow and was presumably associated with the onset of ion hopping, descended with the increasing amount of plasticizer. Above 120°C, a dramatic decrease in the modulus occurred over a narrow temperature range, which might be associated with the melting of the Zn-stearate. Some of the Zn-stearate could be present in microphase-separated forms as micelles or highly crystalline regions, possibly acting as fillers below their melting temperature. Thus, the matrix T_g increased slightly with increasing the amount of Zn-stearate. Subsequently, it was confirmed that the excess Zn-stearate formed small crystalline regions, with a size of less than ca 0.5 μm (194). On the other hand, the rest of Zn-stearate partitioned into the multiplets, in which the ionic groups of the Zn-stearate presumably aggregated directly with the multiplet, and the stearate hydrocarbon chains resided in the matrix phase. It should be noted that the ionic group attached to the stearate was a carboxylate group, while the ionic group of the ionomer was a sulfonate group. Thus, the carboxylate head group, which was incorporated into the sulfonate aggregate, would plasticize the multiplet to some extent, and thus decreased the modulus even further. Recently, it was found that the saxs peak at $q = 1.6\ \text{nm}^{-1}$ ($d_{\text{Bragg}} = 3.9$ nm) due to the presence of crystalline Zn-stearate disappeared at temperatures between 115 and 130°C, depending on the amount of the Zn-stearate (195). It was proposed that the saxs peak corresponded to the long period of a bilayer crystal of Zn-stearate chains tilted ca 27°.

When the P(S-*co*-SSNa) ionomer was plasticized with a surfactant, sodium dodecylbenzenesulfonate, the hydrophilic head group of which was the same as that of the pendant ionic group of the ionomer (196), the matrix T_g decreased only slightly, whereas the cluster T_g decreased significantly. It was suggested that the head ionic group of the surfactant was incorporated into the multiplet without disrupting or plasticizing it, since the ionic groups of the surfactant and the ionomer

were identical, and that the hydrocarbon tail of the surfactant resided in the restricted mobility regions surrounding the multiplets (see Fig. 11c). Therefore, the main effect of the addition of the surfactant was an increase in the mobility of the chains in the immediate vicinity of the multiplets.

A styrene oligomer (molecular weight = ca 800), one end of which contained Cs- and Ba-neutralized *p*-carboxylate unit, could be used to plasticize the ionic domains of *p*-carboxylated polystyrene (69). The short carboxylated styrene oligomer, again, plasticized the restricted mobility regions surrounding the multiplet, and thus eliminated or suppressed the reduced mobility layer, resulting in a reduction of clustering.

Applications of Ionomers

At present, ionomers are used in a broad range of applications, and the aim of this section is to describe some of the more interesting applications. The particular examples are selected mostly for illustrative purposes to suggest the scope of the applications. Regarding applications of ionomers, extended abstracts appeared in 1988 (197), and several review articles deal with, sometimes in part, the ionomer applications (198–210); interested readers are referred to the original articles.

Membranes. One of the most useful applications of ionomers is their use as a membrane of superpermselectivity (206,211) (see MEMBRANE TECHNOLOGY). The most important ionomer in this category is the perfluorinated ionomers, eg, Nafion, which are copolymers of tetrafluoroethylene and a perfluorinated monomer containing a sulfonate group at the end of a long side chain. The perfluorinated ionomers can allow water transport and the diffusion of cations at a fast rate. Because the cation is in an environment of pendant anions, the pendant sulfonate groups directly attached to the polymer backbone limit the diffusion of anions through the membrane. Since polytetrafluoroethylene is well known for its high dimensional and thermal stability, the perfluorinated ionomers also show high stability. Thus, these ionomers find extensive applications in the chlor-alkali industry, in which the ionomer membranes are used to separate the cathode and anode compartments for the electrolysis process of NaOH. The use of these membranes saves the cost of electricity considerably, and produces pure NaOH.

The perfluorinated ionomers can also be used in fuel cells (206,207). In the fuel cells, the energy generated from chemical reactions can be converted into electrical energy, and thus the fuel cells can be used as electric power sources for transportation. The fuel cell employing the H_2/O_2 (a fuel/an oxidant) reaction consists of anode and cathode compartments, which are separated by an electrolyte; the electrochemical reactions between H_2 and O_2, producing water and electricity, take place at the electrodes. The stationary electrolyte for fuel cells should not contain corrosive liquids and have high energy efficiency per unit mass and long-term stability, eg, ca 1×10^4 h at ca 90°C. For such cells, ionomers as cation-exchange resins can be used as membrane electrolytes. The perfluorosulfonate ionomers such as Nafion are promising candidates for the cell membranes because of their thermal and dimensional stability. However, Nafions are too expensive to be used in fuel cells, and thus extensive researches have been going on to understand why the Nafions are excellent as the membrane and to find the ways to produce other membranes that are less expensive.

Plastics. Ionomers have found extensive applications as plastics, which include golf ball covers, bowling pin covers, bumper guards and body side molding strips of automobiles, shoe parts, bottle stoppers, and ski boot shells. Among them, perhaps the most well-known application is golf ball covers (206,212). In general, two properties are required as ionomer plastics: toughness and moldability. The blend of partly Zn-neutralized and partly Na-neutralized ethylene-based ionomers satisfies these two requirements. The injection molding can be used for the blend to make golf ball covers. In addition, by blending both Zn-neutralized and Na-neutralized ionomers, problems encountered in ionomers containing single cation, eg, the cold crack problem in Na-ionomers and the low rebound problem in Zn ionomers, can be solved effectively. Other examples of applications of the ethylene-based ionomers include packaging materials, impact modifiers, rheology modifiers, modifiers for glass-reinforced thermoplastics, and ionomer foams.

Elastomers. The Zn-EPDM can be used as a self-vulcanizing rubber. The ion aggregation in these ionomers makes it unnecessary to vulcanize the polymer chemically, in contrast to normal elastomers. These ionomers can be used as roofing materials (206,213). Since the material is thermoreversibly cross-linked, a certain degree of creep is inevitable while the ionomer is being used; however, the problem of rupture can be avoided. This type of materials assures advantages for the sealing of rubber sheets through thermal treatment and for the reprocessing of ionomers by simply heating and subsequently molding them.

Catalysis or Catalytic Supports. Ionomers have been used as catalysts. Perfluorosulfonated ionomers have been used as superacid catalysts in various reactions (214–216). In addition, the ionic aggregates can serve as microreactors, implying a wide range of potential applications in this area. Thus, active ions or metals in the phase-separated regions of the ionomer can be used as catalysts (206). For example, when various gases are catalyzed by cations in the multiplets, amines, hydrides, and carbonyls are formed (206,217,218). The cations in the multiplets can also be reduced, and converted to metallic particles which can also act as catalysts (219–225).

Drilling Fluids. Sulfonated polystyrene and sulfo-EPDM have been used as drilling fluid (226–228). The purpose of the ionomer in this application is to improve the suspension property of various agents. It should be remembered that in the drilling operation, the drilling fluids are exposed to very severe shear conditions at high temperatures. Thus, the ionomers are expected to keep the drilling products as well as elements necessary to assist the drilling under the harsh conditions. In addition, the ionomers have advantages for extending an applicable temperature of drilling fluids to much higher temperatures than nonionic polymers.

Coating for Fertilizers. The application of ionomers as a coating for agricultural fertilizers enhances the effectiveness, for example, by improving release properties. A case in point is the Zn sulfo-EPDM ionomers which are used as a coating material for slow release of fertilizers (229). The volatile polar solvent plasticizes multiplets, causing a significant decrease in the solution viscosity, which, in turn, allows easy spraying of ionomer solutions on the urea fertilizers. As the polar solvent evaporates very rapidly, the aggregation of the ionic groups yields a strong film with uniform thickness and high melt strength. Using this idea, various release patterns can be obtained, depending on the size of fertilizer particles and

film thickness. When the urea fertilizers are exposed to water, the water molecules diffuse through the coating layer, and dissolve the urea particles, resulting in a sharp increase in the osmotic pressure of water inside the coating layer. As the amount of water increases, and the pressure on the coating layer increases to a point where damage to the coating layer occurs, then the urea solution is released through the crack of the coating layer. Because of the variation in the average thickness of the coating layers, the release of the urea solution occurs over long time. Thus, ionomeric-coating technique on the fertilizer particles allows that the appropriate amount of fertilizers can be released on the time when they are most needed.

ISOCYANATE-DERIVED POLYMERS

Introduction

Organic diisocyanates and polymeric diisocyanates are widely used as monomers in reaction polymerization reactions (1,2). By far their widest use is in the manufacture of polyurethanes produced by an addition reaction from macroglycols and isocyanates. Modification of polyurethanes (qv) by partial trimerization of the isocyanate group is used in the manufacture of rigid cellular plastics (polyurethane isocyanurate foams), and in the molding of solid cross-linked elastomers, using the RIM (reaction injection molding) process. Also, poly(urethane ureas) are produced by using a diamine extender or a macrodiamine as one of the comonomers. An example is the use of diethyltoluenediamine as an extender in the RIM of automotive parts. The use of amine monomers, which react very rapidly with isocyanates, increases the reaction rates in the corresponding molding processes. Also, diamine extender or macrodiamines are used in spray applications and in the manufacture of elastic Spandex fibers. Poly(urethane isocyanurates) and poly(urethane ureas) are treated adequately under polyurethanes (qv), and they are not included in this article (see POLYURETHANES).

The homopolymerization of diisocyanates is only useful for specialty diisocyanates, such as aliphatic 1,2- or 1,3-diisocyanates (3) and aromatic *o*-diisocyanates (4), which polymerize via cycloaddition processes. Anionic homopolymerization of monoisocyanates takes place by addition across the C=N bond to form nylon-1 polymers. Polyamides are also obtained from diisocyanates and enamines or ketenaminals. This reaction proceeds by a $[2+2]$ cycloaddition reaction with subsequent ring opening to form polyamides. $[2+4]$ cycloaddition polymerization to form heterocyclic polymers is observed with carbonyl diisocyanate (5). Ring-opening polymerization occurs in the reaction of bis-epoxides

with aromatic diisocyanates to give poly(2-oxazolidinones). Vinyl isocyanates undergo addition polymerization across their vinyl group to give polyisocyanates with a very high isocyanate content, which are difficult to handle. Copolymerization of vinyl isocyanate with other vinyl monomers allows the synthesis of useful polyisocyanates. Other difunctional nucleophiles, such as bis-mercaptans, hydrazine, dihydrazides, or dioximes, are also used as comonomers in polyaddition processes.

Reaction polymerization reactions of isocyanates with suitable monomers can be performed in an extruder or in a RIM machine. In the latter reaction thermosets (cross-linked polymers) are produced. In an extruder usually linear polymers are manufactured. For example from methylene di-*p*-phenylene isocyanate (MDI), with some macroglycols and 1,4-butanediol as extenders, segmented polyurethane elastomers are produced in an extruder (6). However, linear condensation polymers are also produced in a vented extruder. For example from MDI, with macrodicarboxylic acids and dicarboxylic acids as extenders thermoplastic block copolyamide elastomers are produced. The by-product of the condensation reaction, carbon dioxide, is removed in the vented extruder. The polycondensation process can also be performed in solution. For example, MDI can be added to a solution of dicarboxylic acids in tetramethylene sulfone, with simultaneous removal of the carbon dioxide. Tetramethylene sulfone is the solvent of choice for solution polymerization of isocyanates (7). In addition to dicarboxylic acids trimellitic acid anhydride and benzophenonetetracarboxylic acid dianhydride (BTDA) are utilized as monomers for condensation polymers. With these monomers poly(amide imides) and poly(imides) are produced. The diisocyanate-derived commercial polycondensation products are listed in Table 1.

Often it becomes necessary to lower the melting points of the derived polymers to allow processability. This is best achieved by using mixtures of the diisocyanates. For example, high temperature fibers (PI 2080) are produced using 80% 2,4-TDI and 20% MDI and BTDA. Also, poly(amide imides) are modified with 20% isophthalic acid, and azelaic acid is often used as comonomer to reduce the crystallinity of the derived polymers. The utilization of comonomers

Table 1. Condensation Polymers Derived from Diisocyanates and Suitable Monomers

Isocyanate	Comonomers	Polymers
MDI	Polyester dicarboxylic acids, azelaic acid	Segmented poly(amide) elastomers
MDI	Isophthalic acid, azelaic acid	Engineering thermoplastic poly(amides)
MDI	Azelaic acid	Semicrystalline engineering plastic poly(amide)
MDI, TDI	Trimellitic acid anhydride, isophthalic acid	Copoly(amide imide) films
MDI, TDI	Benzophenonetetracarboxylic acid dianhydride	Poly(imide) fibers and films
MDI, TDI	—[a]	Poly(carbodiimide)

[a]A phospholene oxide catalyst is used in this polycondensation reaction.

allows the manufacture of numerous condensation polymers from diisocyanates. Segmented thermoplastic polyamide elastomers and some engineering thermoplastic polyamides are available from Dow, and Lenzing AG in Austria has produced PI 2080 fibers. Oligomeric carbodiimides obtained from sterically hindered aromatic diisocyanates are used as stabilizers for polyesters, polyester-based polyurethanes, and polyether-based poly(urethane ureas) (8). The mechanism of stabilization of polyesters with oligomeric carbodiimides is based on the rapid reaction of carbodiimides with carboxylic acids generated in the hydrolysis of a polyester. Oligomeric carbodiimides can also function as chain-mending agents, preventing loss of molecular weight. The carbodiimide oligomers derived from sterically hindered aromatic diisocyanates are commercially available under the trade name Stabaxol from Rhein Chemie, a subsidiary of Bayer.

Diisocyanates have also been used as monomers in the manufacture of thermally stable addition/condensation heterocyclic polymers. For example, reaction of dihydroxyaryl-dicarboxylic acid esters with diisocyanates produce poly(benzoxazindiones), which are useful as high performance wire coatings (9). The addition/condensation procedure was also used in the manufacture of poly(parabanic acid) from MDI and hydrogen cyanide (10). The use of the toxic hydrogen cyanide as monomer has prevented the commercialization of this useful polymer.

Monomers

Diisocyanates are usually synthesized by phosgenation of the corresponding diamines. A tabulation of diisocyanates synthesized up to 1972 with pertinent methods of synthesis is available (11). Instead of the toxic phosgene gas, the liquid trichloromethyl chloroformate (diphosgene) (12) or the solid bistrichloromethyl carbonate (triphosgene) (13) can be used in the laboratory (see PHOSGENE). Also, oligomeric *t*-butylcarbonates are used to convert diamines into diisocyanates (14).

The principal commercial aromatic isocyanates are toluene diisocyanate (TDI), polymeric isocyanate (PMDI), and its coproduct (MDI), but some specialty aromatic isocyanates and some aliphatic diisocyanates are also available. The latter are used in the manufacture of color stable polyurethanes. TDI is mainly produced as a 80:20 mixture of the 2,4- and the 2,6-isomers, but a 65:35 mixture of the same isomers, pure 2,4-TDI and a crude partially trimerized product, are also available. PMDI is a mixture of the MDI isomers and their higher oligomers, and MDI is mainly the 4,4′-diisocyanate. The principal commercially available isocyanates are listed in Table 2.

Sulfonyl diisocyanates, such as *m*-phenylenedisulfonyl diisocyanate, are used as monomers for base-soluble polymers (15). 4-Isocyanatobenzenesulfonyl isocyanate can also be used as a monomer for base-soluble polymers. Reaction of *p*-toluenesulfonyl isocyanate with polymers having amide units in the backbone structure affords sulfonyl urea derivatives, which on hydrolysis with 1 *N* NaOH degrade the polymer to carboxylic acids (16). Likewise, polymerization of the monomer derived from acrylamide and *p*-toluenesulfonyl isocyanate affords a homopolymer, which on hydrolysis with 1 *N* NaOH affords poly(acrylic acid) (17).

Table 2. Major Aromatic Isocyanates

Name	Boiling point, °C/kPa[a]	Melting point, °C	Structure	Producer
PPDI	110–112/90	94–96		Akzo
TDI	120/75	14		BASF, Bayer, Dow, Lyondell
MDI	171/7.5	37		BASF, Bayer, Dow
PMDI		— [b]		BASF, Bayer, Dow
NDI	244/0.98	130–132		Bayer
TODI	160–170/3.75	71–72		Nippon Soda

[a] To convert kPa to mm Hg, divide by 7.5.
[b] Light to dark brown liquid.

Some aliphatic diisocyanates are also commercially available and they are listed in Table 3.

Because of its relatively low boiling point HDI is currently only supplied in the form of derivatives (trimer, allophanate, biuret, etc) (18). Polymeric aliphatic isocyanates are obtained by copolymerization of 2-isocyanatoethyl methacrylate and styrene (19). Hydroxyalkyl acrylates and methacrylates are used as monomers to form hydroxyl group containing polymers, which are cross-linked with diisocyanates or blocked diisocyanates (20). The elusive parent diisocyanate, O=C=N–N=C=O, is only stable at −75°C, and therefore it is not suitable as a monomer or comonomer in polymerization reactions (21).

The market for polyurethanes in 2000 was of the order of 8 million tons per year. Therefore, diisocyanates and polymeric isocyanates are readily available at reasonable cost, and their use as monomers for other addition and condensation polymers is indicated.

Blocked isocyanates can be used in the cross-linking of hydroxyl group containing polymers in the formulation of powder coatings. Blocking agents include phenol, caprolactam, ketoximes, and 3,5-dimethylpyrazole. The latter has the lowest dissociation temperature (22). Currently, virtually all automobiles produced use a blocked isocyanate in the formulation of cationic electrodeposition coatings (23). The [2 + 2] cycloadduct derived from MDI and diarylketenes is used as an initiator in the nylon RIM process (24).

Table 3. Major Aliphatic Isocyanates

Name	Boiling point, °C/kPa[a]	Structure	Producer
HDI	130/98	$OCN(CH_2)_6NCO$	Bayer
TMHDI	149/75	$OCNCH_2C(Me)_2CH_2CH(Me)CH_2CH_2NCO$ $OCNCH_2CH(Me)CH_2C(Me)_2CH_2CH_2NCO$	Huels
CHDI	122–124/90		Akzo
H_6XDI	110/7.5		Takeda

IPDI	153/75		Bayer, Huels
$H_{12}MDI$[b]	179/6.75		Bayer

[a] To convert kPa to mm Hg, divide by 7.5.
[b] Mixture of stereoisomers.

Also, isocyanates are used in the formulation of interpenetrating polymer networks (IPNs) (25). A polyester–polyurethane IPN with a ratio typical for sheet molding compound (SMC) is obtained from MDI, poly(caprolactone triol), an unsaturated polyester resin, and styrene monomer (26). IPNs are also reviewed under polyurethanes.

Isocyanates in general are toxic chemicals and require great care in handling. Oral ingestion of substantial quantities of isocyanates can be tolerated by the human body, but acute symptoms may develop from inhalation of much smaller amounts. The suppliers Material Safety Data Sheets (MSDS) have to be consulted for the most current information on the safe handling of isocyanates.

Homopolymerization

The anionic homopolymerization of monoisocyanates proceeds by addition across their C=N double bond to give nylon-1 polymers (27). The reaction is generally conducted in dimethyl formamide (DMF) at −50°C, using sodium cyanide as the initiator. The infrared spectra of the nylon-1 homopolymers show a strong absorption band at 1700 cm^{-1} (C=O) and a band from 1280 to 1390 cm^{-1}, indicating a disubstituted amide structure. The nylon-1 polymers obtained in the anionic polymerization reaction are listed in Table 4.

Table 4. Nylon-1 Polymers Obtained by Anionic Polymerization of Monoisocyanates

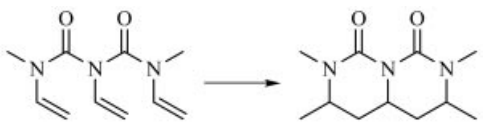
Isocyanate	Yield, %	Softening temp., [a] °C	Melt temp., °C
Vinyl			300
Ethyl	48		250
Allyl	10	180	260–290
n-Propyl	70	180	250
n-Butyl	75	180	209
Isobutyl	18	173	210–220
n-Amyl	67	145	209
n-Hexyl	85	120	195
n-Nonyl	100		
n-Undecyl	70	45	155
n-Octadecyl	2	40	94
9-*n*-Decenyl	75	75	180–240
Benzyl	50		250
Phenyl	28		197
m-Tolyl	60		200
p-Tolyl	25		
p-Methoxyphenyl	35		212–214
m-Dimethylaminophenyl			315

[a]Temperature at which the polymer first become plastic without sticking on a metal temperature-gradient bar.

The melt temperature of nylon-1 polymers depends on the legth of the side chain. The longer the side chain, the lower the melting point of the polymer. Steric requirements for the homopolymerization of monoisocyanates are severe. No homopolymers are obtained from isopropyl, cyclohexyl, *o*-methoxyphenyl, and α-naphthyl isocyanate. All alkyl nylon-1 polymers, with the exception of poly(allyl isocyanate), have a low order of crystallinity as shown by X-ray diffraction. However, the polymerization of *n*-butyl isocyanate and phenyl isocyanate in various solvents at -78°C, initiated by lithium or sodium alkyls, produces crystalline polymers (28). The mechanism of the sodium cyanide catalyzed polymerization in DMF involves intermediates having a spiro structure (29).

The solution properties of alkyl poly(isocyanates) in a variety of solvents indicate an unusual chain stiffness similar to the α-helical poly(α-amino acids) (30). Optically active poly(isocyanates) are obtained by anionic polymerization of the optically active monomers (31). The temperature-dependent optical activity and circular dichroism suggest a large preference of one of the helical senses (32).

Vinyl isocyanate is polymerized across the isocyanato group to give the nylon-1 polymer **1**. Treatment of **1** with azoisobutyronitrile and UV light at room temperature produces the ladder polymer **2** (33).



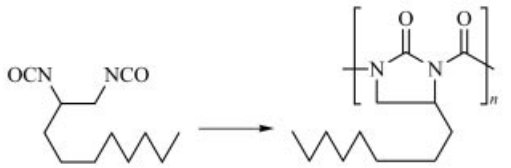
1 **2**

The double bond also survives in the homopolymerization of 2-isocyanatoethyl methacrylate (34).

The nylon-1 polymers are thermally not stable because unzipping occurs on heating, giving rise to the formation of monomers and cyclic trimers. The decomposition temperature of poly(alkyl isocyanates) is about 140°C. The main fragmentation products from alkyl nylon-1 polymers are the cyclic trimers, while aryl nylon-1 polymers afford mainly the monomers. The unzipping of the homopolymers can be prevented by using $Cl_3TiOCH_2CF_3$ to stabilize the living ends of the homopolymer. When the homopolymers contain functional groups, $CpTi(OCH_2CF_3)Cl_2$ can be used for this purpose (35). Poly(isocyanatocarboxylic acid esters) are obtained by conducting the polymerization at −40°C in toluene in the presence of *n*-butyllithium (36). Silylated isocyanato carboxylic acids are likewise polymerized, and the protecting group is removed using HF in ethanol (37). The rapid degradation of the nylon-1 polymers has been used to create raster images upon treatment with electron beams (38). Poly(isocyanates) with chiral azo chromophores can undergo photoisomerization of the chiral side chain. This reaction can be used as a switch, whose effect is amplified in the polymer backbone (39). A review article on nylon-1 polymers appeared in 1976 (40).

The homopolymerization of aliphatic diisocyanates across their C=N bond is limited to aliphatic 1,2- and 1,3-diisocyanates and cyclohexane-1,2 and 1,3-diisocyanate (3). These diisocyanates are cyclopolymerized by an alternating, intermolecular–intramolecular propagation mechanism, using sodium cyanide as the catalyst. The cyclopolymers obtained in this manner are listed in Table 5.

The cyclopolymerization of 1,2-diisocyanatodecane (**3**) in the presence of $CpTiClN(CH_3)_2$ affords the cyclopolymer **4**, which is soluble in many organic solvents (41).



3 **4**

Aromatic *o*-diisocyanates, such as 2,3-TDI, are also homopolymerized via a cycloaddition mechanism (4). The anionic homopolymerization of 2,4-TDI in DMF, using sodium cyanide as the initiator, occurs only through the nonhindered isocyanato group to give linear polymers containing free isocyanato groups (42). Homopolymers are also obtained by coupling polymerization of MDI, using samarium iodide to induce the electron transfer necessary to achieve the polymerization (43). Condensation homopolymerization of PMDI affords low density poly(carbodiimide) foams (see later under Condensation Polymers).

4-Vinylphenyl isocyanate also undergoes homopolymerization across the C=C double bond. This reaction is conducted in toluene at 60°C, using 3 mol% of AIBN as the catalyst (44). Ruthenium catalysts are used to convert *p*-nitropolystyrene in the presence of methanol into the corresponding methyl carbamate, which is a masked polyisocyanate (45).

Table 5. Cyclopolymers Derived from 1,2- and 1,3-Diisocyanatoalkanes

Monomer	Polymer structure	Mp, °C	Inherent viscosity,[a] dL/g
1,2-Diisocyanatoethane		365	0.85
1,2-Diisocyanatopropane		287	1.35
1,2-Diisocyanatocyclohexane		303	0.38
1,2,3-Triisocyanatopropane		365–400	0.28[b]
1,3-Diisocyanatopropane		420–425	—
1,3-Diisocyanatocyclohexane		224–265	0.1

[a]Concentration 0.5% w/v in tetrachloroethane/phenol (40/60).
[b]In conc. sulfuric acid.

When a group reactive with the isocyanate group is attached to an aryl isocyanate A–B homopolymers are obtained. For example, from isocyanatophenols, polyurethanes are obtained. Substituents next to the isocyanate or hydroxyl group increase the stability of isocyanatophenols (46). Polyurethanes are also obtained from α,γ-aminoalcohols and di-*t*-butyldicarbonate, and the intermediate α,γ-hydroxyalkyl isocyanates are polymerized using $Zr(acac)_4$ as catalyst (47). Polyamides are obtained from sterically hindered aliphatic aminoisocyanates (48) and poly(imides) are obtained from 4-isocyanatophthalic anhydride (49). Polyamides are also obtained by interfacial polymerization of 4-isocyanatobenzoyl chloride. Reaction of isocyanatocarboxylic acid chlorides with glycols gives poly(ester urethanes) (50). Similarly, reaction of 4-isocyanatobenzenesulfonyl chloride with diamines affords poly(sulfonamide ureas) (51).

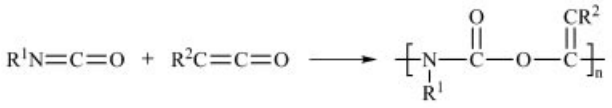
When two reactive groups are attached to the aryl isocyanate, hyperbranched homopolymers are obtained. For example, 3,5-dihydroxyphenyl isocyanate,

generated from 3,5-dihydroxybenzoyl azide, undergoes polymerization with network formation (52). Hyperbranched polyurethanes are also constructed using phenol blocked 1,3-diisocyanatobenzene with a CH_2OH group in the 5-position in combination with 4-methylbenzyl alcohol for end capping. Homopolymerization proceeds by thermally unblocking the isocyanato groups (53).

Copolymers

Copolymerization of 4-vinylphenyl isocyanate and styrene at 60°C in toluene in the presence of AIBN affords the expected copolymers (44). Also, 1:1 copolymers from vinyl isocyanate and maleic anhydride are known (54). The copolymeriation of *n*-butyl isocyanate with a variety of olefins is conducted in toluene/THF at −80°C, using sodium biphenyl as initiator (55). Anionic copolymerization of styrene and hexyl isocyanate affords rod–coil block copolymers. The styrene polymer forms the coil block, while the polyisocyanate block assumes the rod shape (56). Vinyl-, 9-decenyl-, or β-allyloxyethyl isocyanate undergoes copolymerization reactions with styrene or methyl methacrylate (57).

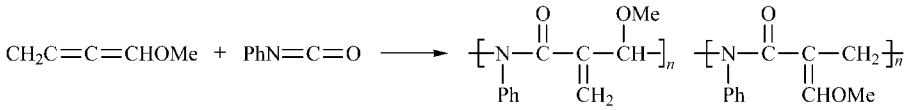
The anionic copolymerization of isocyanates and ketenes is conducted in DMF at −60°C, using sodium cyanide as initiator. This method gives copolymers of dimethylketene and isocyanates (58) and diphenylketene and phenyl isocyanate (59). The structure of the copolymers **5** was elucidated by spectral and degradative studies (60).



5

The sterically hindered *o*-methoxyphenyl isocyanate does not copolymerize with ketenes. Copolymers derived from isocyanates and ketenes are listed in Table 6.

Alkoxyallenes **6** and aryl isocyanates undergo copolymerization at 80°C to give alternating polyamide copolymers **7** (61).



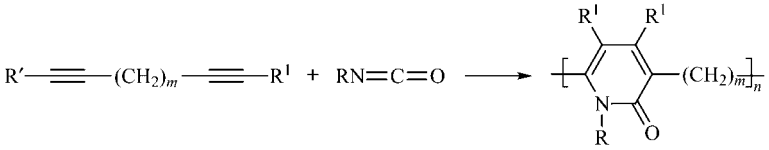
6 **7**

The same alternating copolymers are obtained from methoxyallene and *p*-chlorophenyl isocyanate. Initiators are not required in this copolymerization reaction (62).

Copolymers of diynes **8** with phenyl isocyanate afford poly(2-pyridones) **9**. This copolymerization reaction uses nickel(0) complexes as initiators (63).

Table 6. Copolymers from Isocyanates and Ketenes

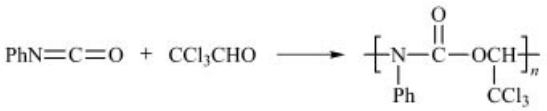
Ketene	Isocyanate	Ratio	Yield, %	Melt temp., °C
Diphenyl	Phenyl		70	179–186
Phenylmethyl	Phenyl		30	200–204
Phenylethyl	Phenyl	0.84:1	4	170–179
Phenylethyl	Phenyl	1.3:1	12	186–197
Phenylethyl	Phenyl	2:1	40	189–199
Phenylethyl	Phenyl	3.2:1	51	201–220
Phenylethyl	*p*-Chlorophenyl	1:1	45	152–167
Phenylethyl	*m*-Chlorophenyl	1:1	18	148–156
Phenylethyl	*p*-Methoxyphenyl	3:1	22	174–185
Phenylethyl	*p*-Methoxyphenyl	4:1	35	178–192
Phenylethyl	*p*-Methoxyphenyl	6.5:1	63	203–209
Phenylethyl	*m*-Methoxyphenyl	1:1	7	167–175
Phenylethyl	*m*-Methoxyphenyl	1.5:1	29	180–192
Phenylethyl	*m*-Methoxyphenyl	2:1	46	167–182



8 **9**

From diethynylbenzene and aromatic or aliphatic isocyanates also copolymers are obtained. Aryl isocyanates produce 1:1 copolymers using equimolar amounts of the monomers. An excess of aliphatic isocyanates is necessary to give the 1:1 copolymers (64). Similarly, from 1,4-bis(phenylethynyl)benzene and alkyl- or aryl isocyanates rigid poly(2-pyridones) are obtained (65). Soluble ladder poly(2-pyridones) are obtained from macrocyclic diynes and aryl- or alkyl isocyanates (66).

Anionic copolymerization of isocyanates with chloral (67), cyanopropionaldehyde (68), and acrolein dimer (69) is also known. For example, reaction of phenyl isocyanate with chloral in DMF at −68°C, using potassium cyanide as initiator, affords chloroform-soluble copolymers **10**, which melt at about 230°C (67).



10

Copolymers produced in diethyl ether with *n*-butyllithium as initiator are insoluble and melt as high as 329°C. The infrared and melting point data indicate a marked difference in crystallinity of the differently initiated copolymers.

The reaction of cyanopropionaldehyde with methyl isocyanate, initiated with the benzophenone dilithium complex at −78°C affords a 1:1 copolymer (68). Also,

copolymerization of acrolein dimer with methyl-, ethyl-, or phenyl isocyanate at 15°C in toluene affords 1:1 copolymers (69). The copolymerization of ethylene oxide with aromatic isocyanates is conducted in toluene at −78°C, using triethylaluminum as initiator.The shown acetal structure **11** is proposed for the copolymer (70).

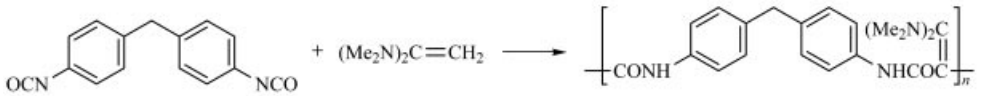
11

Alkyl isocyanates do not copolymerize with ethylene oxide.

Block copolymers are obtained from aromatic diisocyanates and vinyl monomers, such as styrene, isoprene, and methyl methacrylate via anionic polymerization, using *n*-butyllithium as initiator (71). Since TDI undergoes selective reaction through the nonhindered isocyanato group poly(butadiene-*block*-imide) block copolymers are obtained (72).

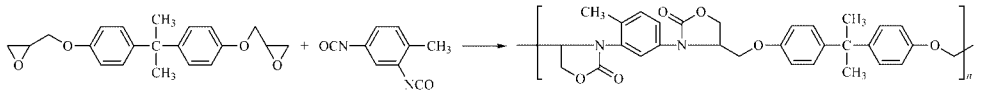
Addition Polymers

The reaction of MDI with enamines produces polyamides by a [2+2] cycloaddition reaction across the C=C bond. Ring opening in the initial reaction forms an amide bond and regenerates the double bond, which undergoes the same reactions again (73). With formic acid in DMF the enamine polymer hydrolyzes to give the corresponding keto polymer (74). From MDI **12** and ketene aminals **13**, polyamides **14** are formed in a similar manner (75). These reactions can be performed in a RIM machine.



12 **13** **14**

Glycidyl ethers derived from bisphenol A (**15**) or diglycidyl tetrephthalate can also be used as monomers in diisocyanate reactions. The reaction of 2,4-TDI with **15** proceeds by ring-opening [2+3] cycloaddition polymerization across the 1,3-dipol generated from the bis-epoxides to form a linear poly(2-oxazolidinone) (**16**) (76).

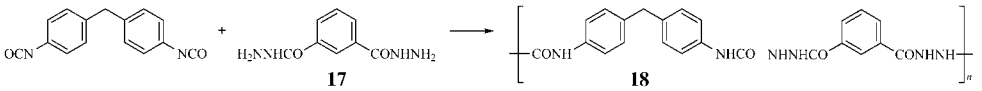


15 **16**

The reaction of bis-epoxides with aromatic diisocyanates can also be conducted in DMF in the presence of lithium chloride (77).

Diisocyanates also react with other difunctional nucleophiles to give addition polymers. The use of hydrazine as extender in the manufacture of Spandex fibers

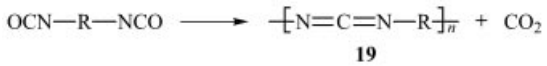
is discussed under polyurethanes. Reaction of MDI with isophthalic dihydrazides **17** in DMSO affords poly(semicarbazides) **18** (78). Dioximes and diisocyanates react in a similar manner to give polyaddition products (79).



The polyaddition reaction of MDI with benzyloxamine in dimethylacetamide (DMAc) in the presence of 1,8-diazabicyclo [5-3-0] undec-7-ene (DBU) affords a poly(biuret) (80).

Condensation Polymers

Polycarbodiimides **19** are obtained from diisocyanates by the phospholene oxide catalyzed condensation–elimination sequence (81).



The reaction proceeds at room temperature at a sufficiently fast rate to allow fabrication of polymers from liquid monomers. However, only thermosets are produced because of cross-linking of the linear poly(carbodiimides). The generated carbon dioxide can be utilized as a blowing agent and low density cellular products are readily obtained from PMDI (82). Copolymerization of diisocyanates and monoisocyanates, the latter as chain stoppers, affords processable oligomeric carbodiimides. For example, polymerization of MDI with controlled amounts of phenyl isocyanate in xylene at 120°C, using 1-phenyl-3-methyl-2-phospholene oxide as the catalyst, affords low molecular weight linear carbodiimides (83). The reaction of HDI with a phospholene oxide catalyst affords low molecular weight trifunctional oligomers, in which the isocyanate and the carbodiimide groups are cotrimerized with the generated carbon dioxide (84).

Carbodiimide groups undergo a [2+2] cycloaddition reaction with isocyanates to form four-membered ring cycloadducts. This reaction is used to convert the low melting MDI into a liquid commercial product (Isonate 143-L) (85) The liquid MDI is used in RIM applications.

The manufacture of polyamides by reaction polymerization of MDI with macrodicarboxylic acids, dicarboxylic acids, and trimellitic acid anhydride was pioneered in the 1970s at the D.S. Gilmore Research Labs of the Upjohn Co (86). Some of these products are commercially available from Dow. For example, segmented polyamide elastomers are obtained in the reaction of MDI with dicarboxylic acids and a carboxylic acid terminated aliphatic polyester, polycarbonate, or polyether prepolymer with an average molecular weight of M_n 500–5000 (87). The dicarboxylic acid serves as the hard segment chain extender and the macrodicarboxylic acid forms the soft-segment matrix for the polyamide elastomers. The reaction is conducted in a polar solvent, using a phospholene oxide catalyst. Preferrably, a

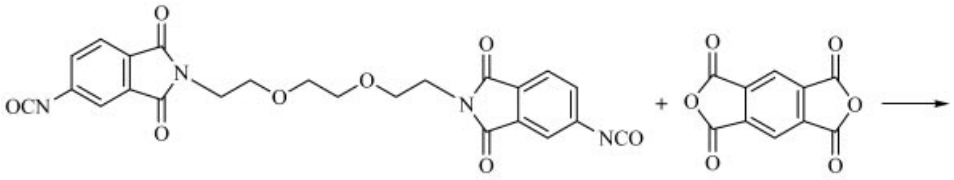
continuous reaction in a vented extruder is used. The polyamide elastomers produced in this manner have light yellow to brown color and they are soluble in polar solvents. Molecular weights in inherent viscosity terms range between 0.8 and 1.1 dL/g measured as 0.5 wt% solution in *N*-methylpyrrolidinone (NMP). Polyamide elastomers retain useful tensil properties where most other thermoplastic elastomers cannot even be tested. Polyesteramide elastomers are also resistant to dry heat aging at 150°C. Alloys of poly(ethylene adipate) (PEAs) with nylon-66 and poly(butylene terephthalate) (PBT) display useful high temperature properties and improved impact properties, respectively.

Homopolymers derived from MDI and azelaic acid are semicrystalline engineering plastics with a T_g of 135°C and a T_m of 290°C (88). Copolymers of MDI with azelaic acid, containing 20–30 mol% of adipic acid show a eutectic T_m of approximately 240°C. These amorphous or slightly crystalline copolymers have mechanical properties comparable to transparent nylons or polycarbonates. Although injection molded samples are transparent, they will crystallize and turn opaque. Copolyamides derived from MDI and aromatic dicarboxylic acids are more difficult to prepare. Because of the very high T_m (420°C) of the isophthalic acid/MDI block it was necessary to prevent the formation of any appreciable crystalline blocks, which was accomplished by prereacting a portion of the isophthalic acid (15–20 mol%) with 2,4-TDI. In this manner crystallization of the isophthalic acid/MDI blocks was surpressed (89). Thus, copolyamides containing IPA/azelaic acid (50:50) are obtained with thermal and mechanical properties similar to polysulfone.

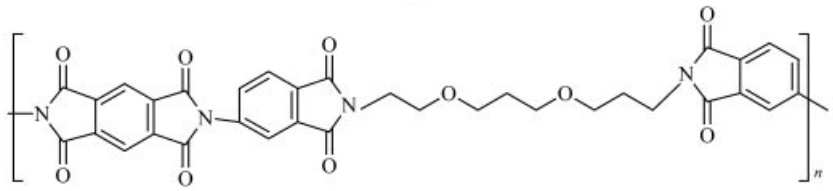
The preparation of poly(amide imides) from isocyanates was explored by Rhone Poulenc, Amoco, and Upjohn (now Dow). For example, MDI was reacted with trimellitic acid anhydride in NMP and the solutions were directly converted into films (Rhodeftal) or fibers (Kermel). When the polymer is isolated it crosslinks, and it can no longer be redissolved. Upjohn produced poly(amide imides) from MDI and trimellitic acid anhydride or from MDI, trimellitic acid anhydride, and various dicarboxylic acid as comonomers in tetramethylene sulfone (90). In this manner high molecular weight polymers are obtained, which can be redissolved in polar solvents, such as DMF or NMP after isolation. As an example, PAI 8020 was made by reacting a 80:20 mol% mixture trimellitic acid anhydride/isophthalic acid with MDI. PAI 8020 would not injection mold by itself unless modified by copolymerization or alloying with other thermoplastics. Its high temperature properties can be further enhanced by blending with polyimide 2080 (see below). Films of PAI 8020 are useful as cable and wire wrap and in other high temperature applications. Poly(amide imide) foams have also been prepared from PMDI and trimellitic acid anhydride (91,92).

Polyimides are also obtained in one step in the reaction of diisocyanates with tetracarboxylic acid dianhydrides. As an example, BTDA is reacted with a mixture of 2,4-TDI and MDI in DMF (93). This copolyimide, PI 2080, is used as a high temperature fiber and it is also sinter molded into solid shapes with exceptional mechanical properties. From PMDI and benzophenone-tetracarboxylic acid dianhydride polyimide foams with outstanding thermal properties and flame resistance are produced (94). Polyimides derived from *p*-phenylene diisocyanate (PPDI) or naphthalene diisocyanate (NDI) and pyromellitic dianhydride or BTDA are also synthesized using DMAc as solvent (95).

An A–B polyimide is also obtained from 4-isocyanatophthalic anhydride (49). Processable polyimides **21** are obtained from the diisocyanate **20** and pyromellitic dianhydride (96).



20

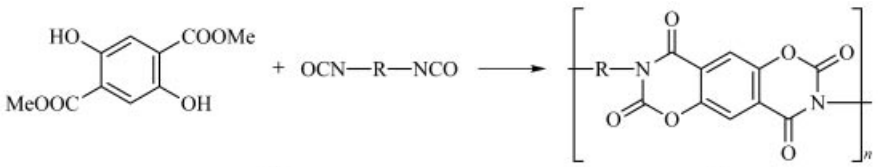


21

Poly(arylene ethers) are obtained from *n*-propyl isocyanate blocked highly aromatic bisphenols and difluoroarenes. In this manner polymers containing hole (electron) transport moieties are obtained (97).

Addition/Condensation Polymers

High temperature resistant heterocyclic polymers are obtained from diisocyanates and suitable monomers containing groups which undergo addition polymerization, followed by condensation polymerization reactions with neighboring groups. For example, dihydroxydicarboxylic esters **22** react with MDI in DMSO, in the presence of a tertiary amine catalyst, to form linear addition polymers, which undergo subsequent cyclization to produce poly(benzoxazindiones) **23** (9).

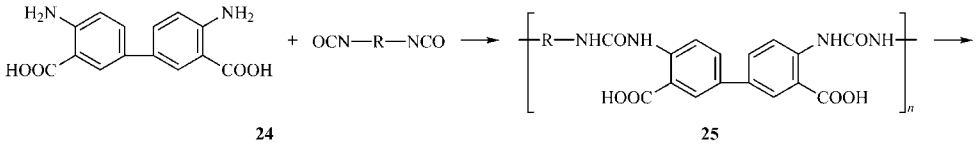


22 **23**

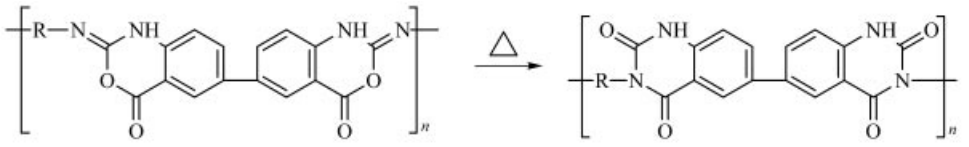
The addition/condensation polymers derived from dihydroxybiphenyl dicarboxylate and diphenylether-4,4-diisocyanate have outstanding thermal stability (−180 to 300°C). The hydrolytic stability of poly(benzoxazinedione) films to concentrated acids and dilute bases is excellent.

Similarly, 4,4′-diaminobiphenyl-3,3′-dicarboxylic acid (**24**) reacts with diisocyanates to produce linear polyureas **25**, which on dehydration at 160–180°C give the condensation polymers **26**. Further heating of **26** to 230–250°C causes

rearrangement to give poly(quinazolinediones) **27**, a polymer exhibiting outstanding thermal stability (98). The polymerization can also be conducted in polyphosphoric acid.

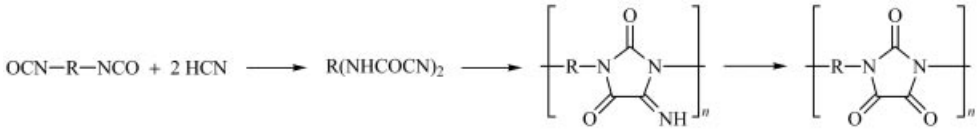


24 **25**



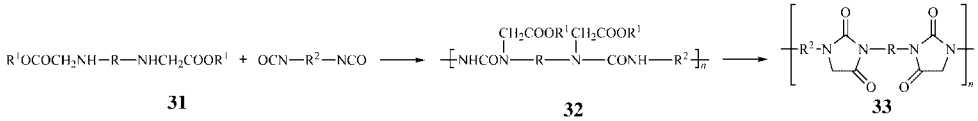
26 **27**

Reaction of MDI with hydrogen cyanide gives linear cyanoformamidines **28**, which cyclize to give poly(iminoimidazolidinones) **29**. The latter are hydrolyzed to poly(parabanic acids) **30** (10).



28 **29** **30**

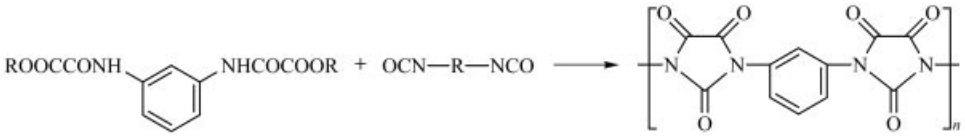
The reaction of diisocyanates with difunctional glycinates **31** affords linear polymers **32**, which cyclize to form poly(hydantoins) **33**. Phenol and cresol are the preferred solvents, and the cresol solutions of **33** can be used directly for wire coating and other applications (99).



31 **32** **33**

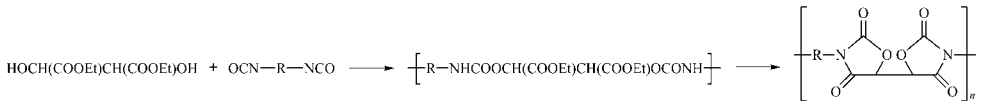
Another approach to poly(hydantoins) involves cyclization of α-cyanoalkyl substituted polyureas, obtained from aromatic diisocyanates and the corresponding nitriles. Hydrolysis of the resultant poly(iminoimidazolidinones) affords poly(hydantoins) (100).

The reaction of aromatic diisocyanates with *N*,*N*-arylenedioxamide acid esters **34** affords poly(2,4,5-trioxoimidazolidines) **35** (101).



34 **35**

Poly(oxazolininediones) **36** are obtained from α-hydroxy acid esters and aromatic diisocyanates (99).



36

In the reaction of *N*,*N*′-bis(2-carbomethoxyethyl)-1,6-hexanediamine (**37**) with aromatic diisocyanates poly(hydrouracils) **38** are formed. The intermediate linear poly(ureas) are cyclized in polyphosphoric acid (100).

LANGMUIR–BLODGETT FILMS

Introduction

Langmuir–Blodgett (LB) films, one of the earliest examples of smart materials, provide the opportunity to control the structure of thin films at the molecular level. In this method, a single layer of molecules is first organized on a liquid surface, usually water, before being transferred onto a solid support to form a thin film whose thickness is a constituent molecule. If the process is repeated, multilayered films can be prepared. The layer of molecules on a liquid surface is termed a *Langmuir monolayer*, and after transfer it is called a *Langmuir–Blodgett film*. The ability to control the thickness of an organic film at the molecular level and to control the placement of molecules in multilayer assemblies forms the basis of many "smart" applications of LB films. Applications include electronics, optics, microlithography, and chemical sensors, as well as biosensors and biochemical probes. Many comprehensive review articles and books exist on the subject of LB films (1–4).

History

The technique is named after Irving Langmuir and Katharine Blodgett, researchers at the General Electric Co. in the first half of the twentieth century. Langmuir, who was awarded the Nobel prize for chemistry in 1932 for his studies of surface chemistry, used floating monolayers to learn about the nature of intermolecular forces. In the course of his studies, Langmuir developed several new techniques that are still used today in studying monomolecular films. Together with Langmuir, Katharine Blodgett refined the method of transferring the floating monolayer onto solid supports. In addition to treating many practical details of LB

methods, publications and patents by Langmuir and Blodgett cover a number of potential applications, including controlling the reflectivity of glass, a step gauge for optically measuring the thickness of thin films, submicrometer mechanical filters, and biosensing.

Although the methods are commonly named after Langmuir and Blodgett, numerous observations and experiments on floating organic films predate them (1,5,6). The practice of pouring oil on water to calm choppy seas has been known for centuries. Benjamin Franklin, however, who was aware of the effect, is credited with the earliest scientific account of spreading oil on water, which he reported in a paper presented to the Royal Society and published in 1774. An extract from that paper reads as follows (1):

> At length being at Clapham where there is, on the common, a large pond, which I observed to be one day very rough with the wind, I fetched out a cruet of oil, and dropped a little of it on the water. I saw it spread itself with surprising swiftness upon the surface. . .
> In these experiments, one circumstance struck me with particular surprise. This was the sudden, wide and forcible spreading of a drop of oil on the face of water. . . it spreads instantly, many feet around, becoming so thin as to produce the prismatic colors, for a considerable space, and beyond them so much thinner as to be invisible, except in its effect of smoothing the waves at a much greater distance. It seems as if a mutual repulsion between its particles took place as soon as it touched the water. . .

In the late 1800s, Lord Rayleigh became interested in surface layers on water. When Langmuir determined that certain films on water indeed had the thickness of only one molecule, it confirmed an earlier suggestion by Rayleigh. After publishing on the way overlayers on water influenced surface tension, he received a communication from Agnes Pockels who had quantified that the surface tension of water depended on the surface coverage of "contaminant." Building on Pockels's method of measurement, Rayleigh went on to estimate the size of an olive oil "molecule."

Modern studies of floating monolayers and LB films fall largely into two areas. The first area includes detailed fundamental studies of the physical nature and structure of Langmuir monolayers and LB films. The second involves applications that take advantage of thin films that have controlled thickness and composition. Much of the current work on applications derives inspiration from the pioneering work of Hans Kuhn in the 1960s (7). Kuhn used LB methods to control the position and orientation of functional molecules within complex assemblies, an elegant early example of what is currently being called "supramolecular assembly." To acknowledge Kuhn's contributions, some authors now use the term Langmuir–Blodgett–Kuhn (LBK) films for transferred films of functional molecules.

Equipment

References 1 and 2 both discuss common equipment. Essentially, all LB film work begins with the Langmuir–Blodgett trough (alternatively called Langmuir trough

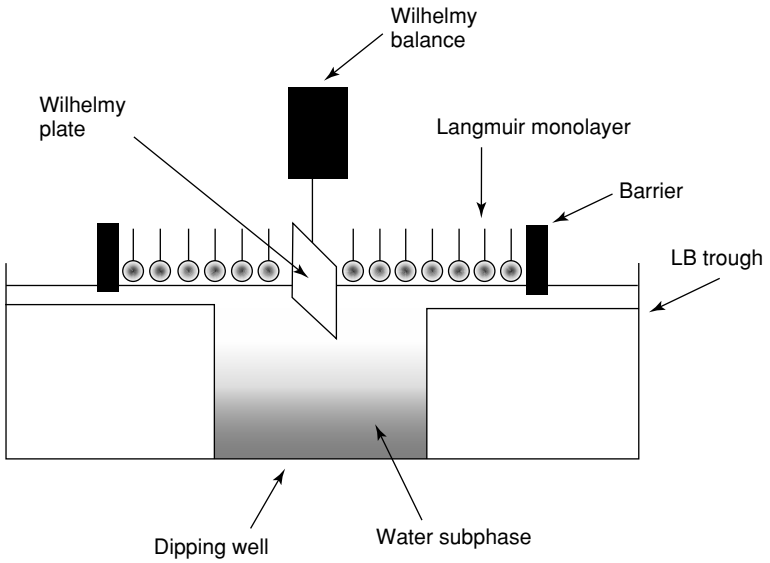

Fig. 1. Schematic of a Langmuir trough and its components.

or Langmuir film balance), which, save for modern materials and electronics, is similar in design and function to the early apparatuses of Pockels and of Langmuir. The trough that contains the subphase is normally about 1 cm deep. The surface area can range from about 100 cm^2 for smaller troughs to more than 1 m^2 for larger systems, designed primarily for transferring large amounts of material. Modern troughs are generally inert and hydrophobic, for example, made from or coated with Teflon or a similar polymer. Moveable barriers that can skim the surface of the subphase permit controlling the surface area available to the floating monolayer. The simplest approach is a bar that moves across the top of a rectangular trough, as shown in Figure 1. For transfer onto solid supports, troughs contain a dipping well—a section that is deep enough to allow immersing the substrate into the subphase—and a sample holder that can vertically displace the substrate. A photo of a complete LB film system is shown in Figure 2.

The rectangular trough that has a moveable barrier is the most common design, but other systems are also widely used. Some variations include circular troughs, systems that use a continuous flexible belt for compression, moving-wall troughs, and troughs designed for continuous deposition or alternate layer deposition. All systems are equipped with a mechanism for monitoring the state of the monolayer on the water surface during the course of experiments, usually, by measuring the surface pressure using either a Wilhelmy plate or Langmuir balance.

Film-Forming Molecules and Polymers

The classic "LB active" molecules are fatty acids such as stearic acid (**1**). The long-chain examples, *n*-octadecanoic (stearic), *n*-eicosanoic (arachidic), and *n*-docosanoic (behenic) acids constitute the best-studied class of Langmuir monolayers and LB films; work dates back to the original papers by Langmuir and

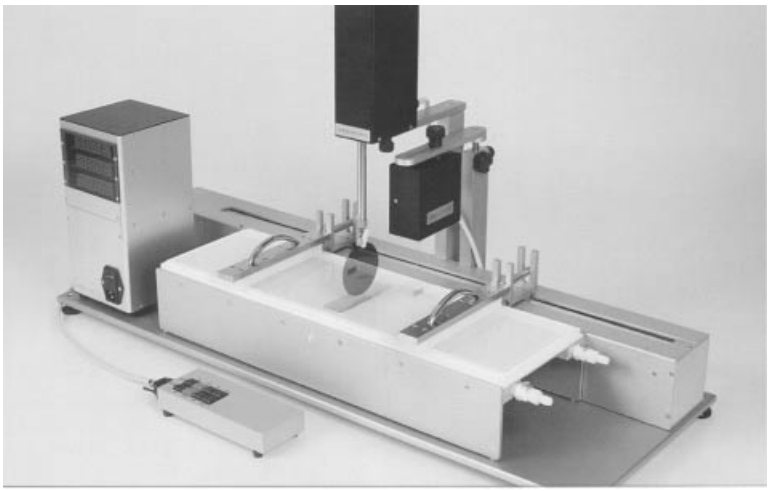

Fig. 2. Photograph of a modern Langmuir–Blodgett system. Courtesy of KSV Instruments.

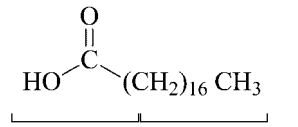
Blodgett. These molecules can be used to demonstrate most of the principles involved in floating monolayers. However, Langmuir monolayers can be prepared from many variations of straight-chain molecules, polymerizable molecules, polymers, and conductive materials (1,2,4,8).



Hydrophilic head group — Hydrophobic chain

1

Fatty Acids. Fatty acids possess clearly defined hydrophilic (carboxylic acid) head groups and hydrophobic (linear alkane) tails. The amphiphilic nature of these molecules leads to a preferred orientation at the air–water interface, where the hydrophobic tails extend from the water surface. Other film-forming molecules normally possess similar hydrophobic and hydrophilic parts. For example, replacing the carboxylic acid by other functional head groups leads to alkylamines, amides, nitriles, esters, alcohols, and phosphonic acids, all of which form Langmuir monolayers. In addition to the head groups, the hydrophobic tail can be modified. Double bonds, triple bonds, and aromatic groups can normally be incorporated into the hydrophobic tail, and the film-forming properties are retained. In addition to hydrocarbon amphiphiles, molecules that have fluorocarbon tails also form Langmuir monolayers.

Phospholipids and Related Biomolecules. The structural features of phospholipids that lead to naturally occurring bilayer structures, such as those found in biological membranes, also make them good film-forming amphiphiles.

The double hydrocarbon chains can be saturated, or they can contain double bonds. The state of the monolayer, whether it is expanded or condensed, at a given temperature depends on the length and nature of the hydrocarbon chains. The polar head groups vary, but all contain phosphate groups that are anionic at neutral pH. Phosphatidic acids, phosphatidylethanolamines (cephalins), phosphatidylcholines (lecithins), and phosphatidylserines are some of the many types of phospholipids studied as Langmuir monolayers. Other components of biological membranes also form Langmuir monolayers. Derivatives of sterols (such as cholesterol), naturally occurring pigments (porphyrins and carotenes) (9), cellulose (10), vitamin B_{12} (11), and proteins have been incorporated into monolayers as single-component films or as mixtures. Commonly, fatty acid molecules are employed in mixtures to stabilize monolayers of compounds that may not form stable monolayers alone.

Polymers. Polymeric monolayers are formed either by spreading preformed polymers or by polymerizing reactive monomers on the water surface. A large variety of preformed polymers has been studied, including polyacrylates and polymethacrylates, poly(vinyl butyral), poly(vinyl methyl ether), poly(vinyl acetate), poly(vinyl fluoride), poly(vinylidene fluoride), (12), silicone copolymers, maleic anhydride copolymers, and polypeptides (1). Monomers that have been successfully polymerized at the air–water interface include derivatives of aniline (13), vinyl alcohol (14), and styrene (15). In addition to the interesting chemistry and the two-dimensional structural control, polymer LB films are much more robust than films formed from straight-chain amphiphiles.

Langmuir Monolayer Formation

To form a Langmuir monolayer, the molecule of interest is dissolved in a volatile organic solvent (frequently chloroform or hexane) that will not react with or dissolve in the subphase (1,2,4). A quantity of this solution is placed on the surface of the subphase, and as the solvent evaporates, the surfactant molecules spread and alter the surface pressure of the water surface. A barrier designed to measure this surface pressure (Π), relative to that of the pure subphase, is the principle behind the Langmuir balance. Alternatively, the surface pressure is measured as the difference between the surface tension (γ) of the monolayer and that of the pure subphase (γ_0), $\Pi = \gamma_0 - \gamma$. A common method for measuring surface tension involves using a Wilhelmy plate, usually a piece of platinum or paper that is wetted by the subphase, suspended from a balance. As the monolayer is compressed by using the moveable barrier to reduce the surface area, the surface pressure increases. A plot of the surface pressure versus surface area is called a pressure versus area isotherm (or Π–A isotherm). Isotherms are normally plotted in terms of area/molecule, and the units of surface pressure are mN/m.

A representative pressure versus area isotherm is shown in Figure 3. As the pressure increases, the two-dimensional monolayer goes through different phases that have some analogy to three-dimensional gas, liquid, and solid states. If the area/molecule is sufficiently high, the floating film is in a two-dimensional gas phase where the surfactant molecules are not interacting. As the monolayer is compressed, the pressure rises, signaling a change in phase. The molecules begin

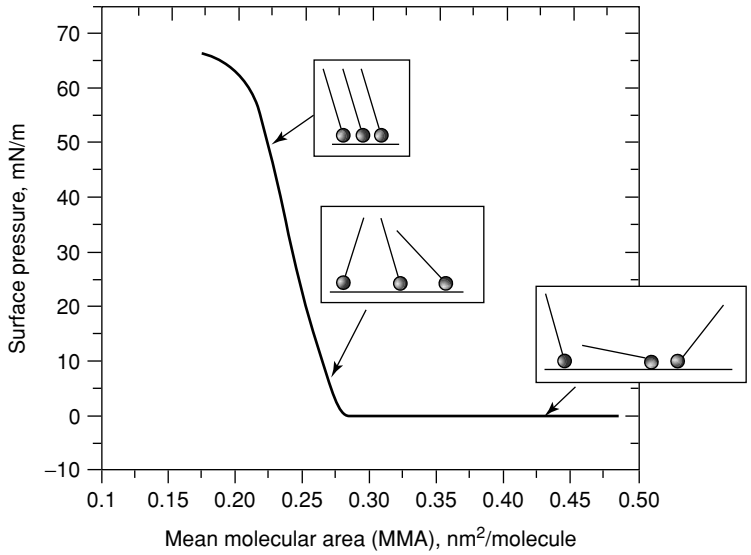


Fig. 3. A representative pressure vs. area isotherm. The cartoons represent idealized gas-analogous, liquid-expanded, and liquid-condensed phases of the monolayer. Two phases often coexist at a given temperature and surface pressure.

to interact, forming a two-dimensional phase, called a liquid-expanded (LE) phase, which is analogous to a three-dimensional liquid. Upon further compression, the pressure begins to rise more steeply, as the liquid-expanded phase gives way to a condensed phase (or a series of condensed phases). This transition, analogous to a liquid–solid transition in three dimensions, does not normally result in a true two-dimensional solid. Rather, condensed phases tend to be liquid crystalline in nature and are called liquid-condensed (LC) phases. Condensed phases have low compressibility, so the slope of the Π–A curve becomes quite steep. As the pressure is increased further, the monolayer eventually collapses under the pressure and either slides over upon itself or folds under into the subphase. When two phases such as gas and LE or LE and LC phases are in equilibrium, the surface pressure plateaus across a range of mean molecular areas. An image of two phases in equilibrium is shown in Figure 4.

The mean molecular area of an amphiphile is determined foremost by the size of the hydrophilic head group and its interactions with counterions in the subphase and with other head groups within the plane. Once these interactions are at an energetic minimum, the alkyl chains pack to maximize both van der Waals interactions and alkane density. By extrapolating the steepest part of the curve before the collapse at zero pressure, a minimum cross-sectional area per molecule can be found. This approach was one of the original methods used in attempts to measure the size of a molecule.

Isotherms differ from one molecule to another, and they also differ as a function of temperature. Monolayers, like three-dimensional substances, undergo temperature-dependent phase transitions. At any given temperature, the monolayer may pass through several phases during compression, or only a couple. The various states of monolayers can be detected in a number of ways, including surface potential measurements, optical spectroscopy, and optical imaging. One imaging

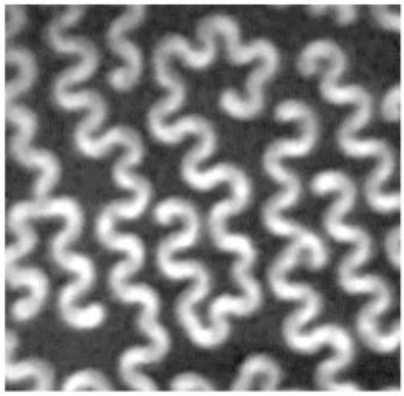

Fig. 4. Brewster angle micrograph of stearylamine on a water/glycerol subphase, showing contrast between liquid-expanded (darker regions) and liquid-compressed (lighter regions) phases. Photo courtesy of C. Mingotaud.

method is fluorescence microscopy, which involves adding to the subphase a fluorescent probe molecule that will be either included or excluded from the surface layer, depending on the state of the monolayer. Imaging the surface yields the structure of domains of phases in equilibrium. Brewster angle microscopy (BAM) is an imaging technique that does not depend on a probe molecule. Laser light is reflected from the subphase surface and is detected by a CCD camera. The light is reflected at the *Brewster angle* of water, the minimum angle where light is totally internally reflected. As the monolayer is compressed, its refractive index changes, leading to reflection of the laser light. Different phases will have different optical properties, leading to clear images of the state of the monolayer (Fig. 4). Grazing incidence x-ray diffraction (gixd) has been used to identify the structures of condensed phases. Highly collimated x-rays from a synchrotron source sample the monolayer at a low angle of incidence. The in-plane packing and tilt angles of the alkyl tails of many fatty acid phases have been determined in this way.

Langmuir–Blodgett Films

According to one reference (16), the "resulting degree of control over film thickness and molecular architecture (using LB deposition) is unsurpassed by any other deposition technique." The term Langmuir–Blodgett film traditionally refers to Langmuir monolayers that have been vertically transferred from the water subphase onto a solid support such as glass, silicon, mica, or quartz. Vertical deposition is the most common method of LB transfer; however, horizontal lifting of Langmuir monolayers onto solid supports is also possible through the Langmuir–Blodgett–Schaefer method.

Monolayer or Multilayer Transfer. Highly hydrophilic or highly hydrophobic substrates are desirable for preparing LB films. Rigid Langmuir monolayers are difficult to transfer, so some flexibility in the monolayer is necessary. When hydrophobic, the substrate originates above the water surface. After the monolayer has been spread and compressed to the desired transfer pressure, the substrate is dipped vertically through the monolayer; transfer is by hydrophobic

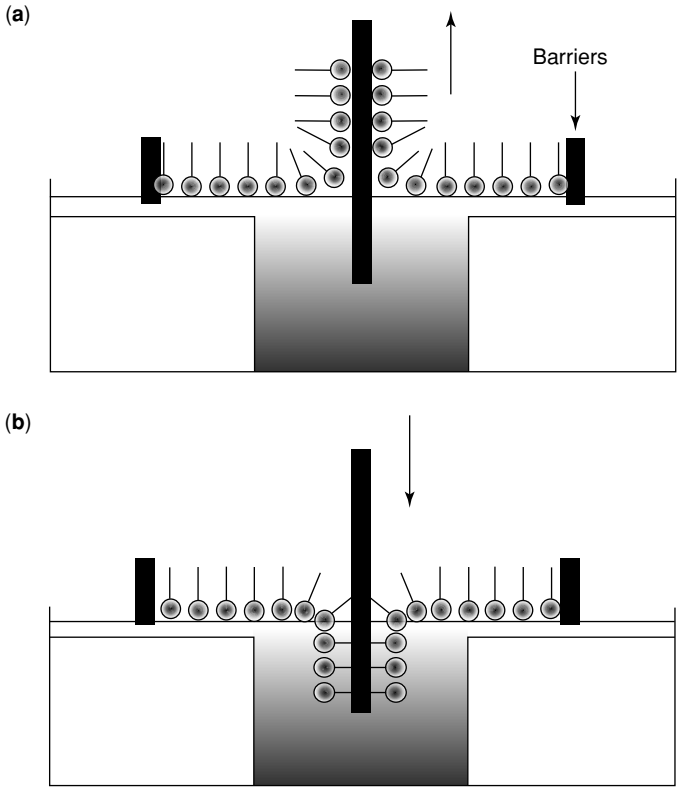

Fig. 5. Schematic of Langmuir–Blodgett transfers. The gray circles represent the hydrophilic head groups, and the thin black lines represent the alkyl chains. The molecules have been spread on an aqueous subphase. (**a**) A hydrophilic substrate is being withdrawn from the dipping well and is attracting the hydrophilic head groups that drive the film transfer. (**b**) A hydrophobic substrate is being pushed down through the monolayer. The alkyl chains are transferred, and the monolayer is pulled off the surface by hydrophobic interactions.

interactions between the alkyl chains and the surface. A hydrophilic substrate is submerged in the aqueous subphase before spreading and compressing the monolayer film. After the monolayer is stabilized, the substrate is withdrawn from the subphase, and the hydrophilic interactions drive the transfer (Fig. 5).

Three common film architectures can result from vertical deposition (Fig. 6). In X-type LB films, a Langmuir monolayer is consistently transferred onto a hydrophobic substrate so that it maintains head–tail interactions. In Z-type LB films, the monolayer is transferred onto a hydrophilic substrate that also forms head–tail interactions. X- and Z-type films are not common but can be prepared on a specially designed trough. However, some amphiphiles prefer this type of interaction, and upon regular dipping these structures form spontaneously. Y-type multilayers are most common, can be prepared on either hydrophilic or hydrophobic substrates, and are typically the most stable due to the strength of the head–head and tail–tail interactions. Even when films of some amphiphiles have been deliberately transferred by an X or Z method, the spacing between the hydrophilic

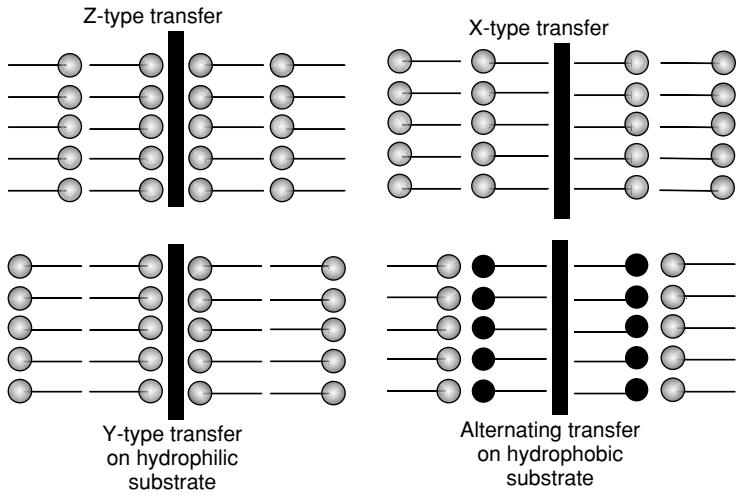

Fig. 6. Representations of X-, Y-, and Z-type LB films. Z-type LB films have head–tail interactions between layers and are transferred onto hydrophilic substrates. X-type LB films also have head–tail interactions but are transferred onto hydrophobic substrates. Y-type films can be transferred onto either hydrophilic or hydrophobic substrates but involve head–head and tail–tail interactions between layers. Alternating films can be transferred by using specially designed "double troughs."

head groups shows packing similar to Y-type films, implying that some molecular rearrangement occurs during or shortly after deposition. Ultimately, the molecular structure of the amphiphile determines the preferred method of dipping; multilayers can be built by repeating the vertical deposition procedure.

The quality of the transferred film is first indicated by the transfer ratio (τ), which is a measure of the change in the area of the floating monolayer versus the area of the substrate coated by the transferred monolayer. A transfer ratio of unity indicates that the monolayer transferred has the same area per molecule as it occupied on the water surface. Assuming that the monolayer on the water surface was stable and the monolayer was not reorganizing significantly during transfer, τ should be between 0.95 and 1.05 to be considered a successful transfer. A consistent deviation from unity could imply a change in organization upon transfer, but if the transfer ratio is irregular or significantly different from unity, the transferred film is most likely of poor quality.

Characterization of Transferred Films. Many analytical techniques are used to study transferred films. The film characteristics typically of interest are thickness, interlayer spacing, molecular orientation and packing, film coverage, surface topology, chemical composition, and optical and magnetic properties. The techniques used to study these parameters are well described in the literature (1,2,4).

Film Thickness and Layered Structure. X-ray diffraction is a reliable technique for probing interlayer spacing, and film thickness can be inferred from interlayer spacing. This technique is very sensitive to long-range periodicity. Many orders of 00l Bragg peaks, indicative of a well-defined layered architecture, are often observed for LB films. Neutron diffraction is similar to x-ray diffraction in

that both result in interference effects that can lead to an understanding of film organization. Film thickness can be determined by ellipsometry, which compares the amplitude and phase of s- and p-polarized light reflected from a film. Differences in amplitude and phase of the reflected light between the coated surface and the untouched substrate can be related to the film thickness.

Molecular Orientation and Molecular Packing. Grazing incidence x-ray diffraction was mentioned earlier as a method for determining the arrangement of molecules within a floating Langmuir monolayer. The same methods can be applied to transferred films. Transmission electron diffraction has also been observed in LB films and used to determine molecular packing, although the organic films are mostly unstable to the electron beam. Atomic force microscopy (qv) (afm) at molecular scale resolution has also been used to observe the arrangement of molecules in transferred monolayer and multilayer films (17).

Chemical Composition. Standard spectroscopic methods, including ftir, Raman scattering, and uv–visible absorption can be used to study the chemical makeup of films vibrational spectroscopy. These methods are often sensitive enough to be applied even to monolayer films. In the Raman scattering, the signal can be enhanced by preparing the LB film on a noble metal substrate, such as Au or Ag, or by interacting the film with surface plasmons. For each of these techniques, polarization studies can be used to determine the orientation of chromophores within the transferred films. Solid-state nmr has also been applied to LB films. Studies have included ^{1}H, ^{13}C, and ^{31}P magic-angle spinning experiments (18). NMR is complicated by the small amount of materials available, so these studies are not routine. The elemental composition, and possibly atomic proportions, within a film can be determined by x-ray photoelectron spectroscopy (xps), which measures the energy of an expelled electron as the surface is bombarded by a monochromatic x-radiation source. Binding energies are unique to each element in the film, as well as to that element's chemical environment and oxidation state. The intensities of the xps peaks can be used to determine the relative ratios of the elements present and can indicate the type of crystalline lattice formed. However, the intensities of the xps peaks are sensitive to many parameters, such as the element's electron escape depth, which can complicate determination of the elemental ratios (19).

Imaging. Imaging of the film is sometimes possible by using a transmission electron microscope (tem). Films are either transferred directly onto a tem-appropriate surface, such as a Cu grid, or are removed from the original substrate by, for example, submerging the film in highly diluted hydrofluoric acid and lifting it onto a grid surface for imaging by tem. Scanning probe microscopy, including atomic force microscopy (afm) and scanning tunneling microscopy (stm), can be used to obtain direct nanometer-scale images of surfaces without significant film degradation, which plagues some other imaging techniques (17) (see MICROSCOPY).

Applications

A wide range of potential applications exists for materials formed by the LB technique. A few examples include coatings, chemical or gas sensors, conducting LB films, NLO and SHG materials, and magnetic films.

LB coatings have been used as photoresists. In the area of ultrathin (single molecule) photoresists, spin-coated polymers tend to lack the consistency in structure and thickness necessary for these applications. However, preformed polymer LB films or polymerized monomeric LB films are extremely uniform, and can be used in these applications. Photo-cross-linking of poly(*p*-phenylene) and photopolymerization of ω-tricosenoic acid and methacrylic acid LB films have been investigated (20,21). Etching resulted in patterns that had resolutions of ca 60 nm. (see LITHOGRAPHIC RESISTS)

Chemical or gas sensors have been prepared by the LB technique. Sensing LB films often comprise chromionophores that have two functionally different groups on the same molecule. The ionophore component senses the presence of specific ions, and the chromophore component translates information from the ionophore into an optical signal. Gas sensors can translate oxidation or reduction by an atmospheric gas into an optical signal. Porphyrin, porphine, and phthalocyanine LB films have been studied for gas sensing of NH_3, I_2, O_2, CO, and NO_x (22–25). However, chemical sensing does not have to trigger an optical change. LB films of redox materials such as polythiophene and polypyrrole, ferrocene, TTF, and metallo porphyrins, as well as fullerenes and Schiff bases, have been used to modify electrodes for electrochemical sensing of a guest molecule or ion (26).

Conductivity has been studied in organic LB films based on porphyrins, phthalocyanines, and charge transfer complexes of derivatives of the electron donor, tetrathiafulvalene (TTF), and electron acceptor, TCNQ (2). Partially filled conduction bands can be achieved by forming films of nonstoichiometric mixtures of the donors and acceptors or by using donors and acceptors that have incomplete electron transfer, and electrical conduction is possible. Because LB films are not completely crystalline in the plane of the film, electrical conductivities are averages across crystalline domains (2). Films of TTF derivatives have been successfully prepared whose in-plane dc conductivities ranged from 10^{-3} to 10^{1} S cm^{-1} (27). LB films of conducting polymers, such as poly- and oligo(arylarenes) have also been fabricated (see ELECTRICALLY ACTIVE POLYMERS). LB films have been used as active and inactive layers in heterostructured electronic devices, including diodes and field effect transistors (28–30). Fullerene LB films have been investigated for their photovoltaic and charge transfer properties (31).

A material that can interact with electromagnetic radiation to generate new waves that have a different phase, frequency, or other propagative characteristics is called a nonlinear optical (NLO) material. Some NLO materials react in second-order processes that lead, for example, to frequency-doubling of laser radiation and electro-optic modulation of light (see ELECTROOPTICAL APPLICATIONS). Materials with such NLO behavior are called second-harmonic-generation (SHG) materials. To be suitable for NLO applications, the material should be typically highly conjugated and have an asymmetrical charge distribution along the primary molecular axis. The solid-state structure must also be noncentrosymmetric. The LB technique can enable the control of molecular architecture to build noncentrosymmetric crystalline environments. Nonlinear optical materials are prepared by either LB transfer of asymmetrical molecules, noncentrosymmetric transfers, such as X- or Z-type transfers, or by transfer of alternating films of NLO active and passive amphiphiles (1,2,4). Additionally, diluting an NLO active molecule in a fatty acid matrix can lead to noncentrosymmetric aggregation that can enhance

NLO or SHG effects. In a related application, LB films have been used as thin film optical waveguides (2).

Some derivatives of poly(*p*-phenylenevinylene) (qv) coupled with poly(pyridine) derivatives behave as a light-emitting layer and an electron-transport layer, respectively, (see LIGHT EMITTING DIODES) (32). Dye molecules are pervasive in the LB literature. Azobenzenes have been studied in LB films along with their trans–cis isomerization properties (33). Anthracene, pyrene, and numerous heterocyclic long-chain derivatives have been studied in LB films. Kuhn studied cyanine dyes as one of his original examples of energy transfer molecules incorporated into multilayer films, and hemicyanine dyes are studied for photoelectric conversion (34). Porphyrins and phthalocyanines, which are important in biological energy transport systems, have been extensively studied in LB films for their in-plane electrical conductivity and interplane charge transfer properties (35,36). Quinolinium salts, which are electron acceptors, can be bridged to electron donors (such as naphthalene), and it has been observed that they operate as multifunctional dyes that exhibit SHG and photoelectric conversion behavior (37). Electroluminescent devices have also been prepared using LB films of quinolinium salts (38).

By incorporating functional inorganic layers into the polar part of LB bilayers, phenomena typical of an inorganic solid state have been engineered into these normally organic assemblies (39). For example, LB films can be formed from organophosphonic acids, and if metal ions are bound to the head groups, a continuous inorganic lattice is formed in the polar part of the film. The inorganic lattice energy greatly stabilizes the films. Although LB films are often unstable to heat and solvents, mixed organic/inorganic metal phosphonate films can be thermally cycled to more than 100°C and are stable to both organic and aqueous conditions (40,41). When the inorganic ions are Mn^{2+} or Cu^{2+}, these films—it has also been shown—order magnetically. Another example of a magnetic LB film is a mixed organic–inorganic film that incorporates a Prussian blue lattice.

Some LB films exhibit a temperature-dependent pyroelectric coefficient that makes them candidates for thermal imaging applications (1). Both X- and Z-type films and alternating Y-type films (Fig. 6) can be built with permanent polarization, whose magnitude is often temperature-dependent. Their pyroelectric coefficient p is small relative to standard semiconducting and ceramic materials, but so is their permittivity ε; this makes their ratio p/ε, the figure of merit, comparable to that as for currently employed inorganic materials. The advantage of LB methods is that they can be used to prepare very thin, very uniform films.

LITHOGRAPHIC RESISTS

Introduction

Lithography in its original meaning describes a method of printing where a master pattern or design is first formed on a stone or metal surface using a hydrophobic material, the pattern is wetted with a hydrophobic ink, and finally the inked pattern is transferred to paper to produce copies of the master. Today, the meaning of the term has broadened to include a number of methods for replicating a predetermined pattern on a substrate, for an increasing variety of purposes. In most cases, replication is effected by first coating the substrate with a photosensitive polymer film termed a *lithographic resist*, and then exposing the film to a pattern of light (1–3). Photochemically induced changes in areas of the film exposed to light alter solubility to such an extent that either exposed or unexposed areas can be selectively dissolved to reveal portions of the substrate surface. If the exposed areas of resist become insoluble, then the resist is termed negative-acting; if solubility of the exposed regions increases, then the resist is termed positive-acting.

In certain applications, the resist film becomes a permanent, functional component of the device being constructed, typically serving as an electrical insulator or protective encapsulant. In such cases the patterned film often will be treated to enhance chemical resistance and mechanical properties (4). Most commonly, however, the resist pattern is a temporary template, and is removed or stripped after the image has been transferred to the substrate. Numerous methods of image transfer have been practiced, including plating and deposition (*additive* processing), chemical etching or physical milling to erode the exposed substrate (*subtractive* processing) or bombardment with energetic ions that become implanted in the substrate surface. Figure 1 summarizes the steps comprising the lithographic process.

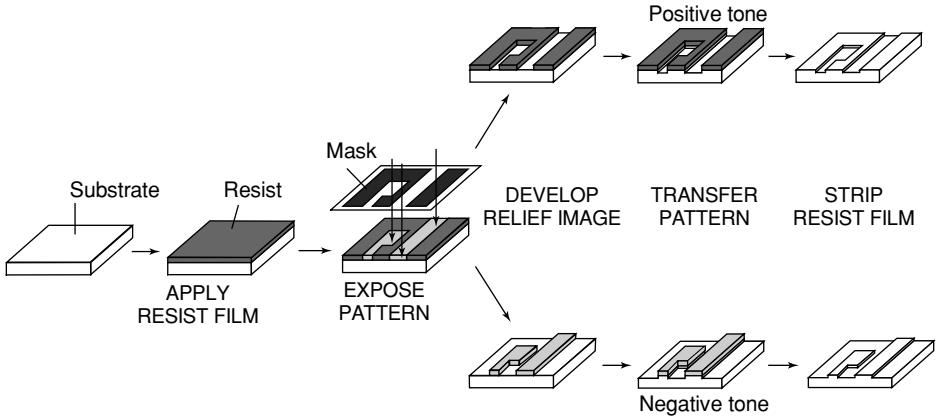

Fig. 1. The lithographic process. A substrate is coated with a photosensitive polymer film called a resist. A mask with transparent and opaque areas directs radiation to predetermined regions of the resist film. Depending on resist characteristics, exposed or unexposed portions of the film are removed using a developer solvent. The resulting pattern is then transferred to the substrate surface and the resist is stripped.

Lithographic resists enable a host of technological advances that have had far-ranging impact. For example, the rapid progress in microelectronics technology in large part stems from refinement of the lithographic techniques used to fabricate computer integrated circuits. The ability to pack ever-increasing numbers of discrete electronic components in a given area of an integrated circuit, when coupled with the economies of scale that result from high volume manufacturing, has led to both improved performance and lower cost with each succeeding device generation (5). In calendar year 2000, the annual global market for semiconductors exceeded US$200 billion.

The advantages of miniaturization are now being exploited in areas beyond microelectronics. Adaptation of materials and processes originally devised for semiconductor manufacture has allowed fabrication of sensors (for example, pressure meters and accelerometers used in the automotive industry) (6,7), complex optical (8) and micromechanical (6,7,9) assemblies, and devices for medical diagnostics (6,7,10), all using lithographic resists.

Essential Attributes of Lithographic Resists. Regardless of the specific application, all resists must display certain fundamental functional properties:

(1) The resist composition must form *uniform, defect-free films* on the substrate of interest. To achieve this, the resist components must be soluble in and inert toward the selected coating solvent or medium, the formulation must form glassy films without component precipitation, separation or dewetting, and must be stable during post-application heating steps. A variety of different coating techniques have been applied, including spray coating, curtain coating, spin coating or whirling, dip coating, dry-film lamination, and most recently, electrodeposition onto a conducting substrate from an aqueous emulsion of resist components.

(2) The coated film must display *adequate* adhesion to the substrate after coating, and through the develop and image transfer steps. Adherence is influenced by resist composition, substrate surface composition, preparation and cleanliness, coating conditions, develop and etch process details, and, with negative cross-linking resists, by the exposure dose. Adhesion loss in mild cases is manifested by the lifting of a resist pattern at its perimeter (often visible under microscopic examination as a contrasting band or color at the edge of the image) and in extreme cases by complete detachment of the resist pattern.

(3) The resist must have suitable *radiation sensitivity*. Today's exposure tools are so costly that tool throughput is a key measure of performance. The overall time to expose a resist film is the sum of the times to load and position the substrate in the exposure tool, to align the substrate and the mask, to irradiate the film, and to unload the completed part. In the optimum case the resist exhibits sufficient radiation sensitivity so that the fraction of the overall cycle apportioned to irradiate the film does not limit the overall throughput.

(4) The resist must provide *high fidelity reproduction* of the mask image on the substrate. This attribute is generally quantified as the resist's *resolution*, that is, the smallest feature that can be consistently printed, and its *contrast*, which is a fundamental measure of how the resist response changes with increasing radiation dose. In high resolution lithography, diffraction and imperfections in the optical system cause stray radiation to be scattered into regions of the resist pattern that nominally are unexposed. A resist with high contrast can effectively reject the stray radiation and yield a more accurate replica of the original mask. Resist contrast is fundamentally related to the dissolution properties of the polymer matrix and is influenced by resist composition, and by process conditions and exposure tool characteristics.

(5) The patterned resist must provide an effective *protective barrier* during image transfer. The image transfer step frequently includes harsh chemical or physical treatments that erode or otherwise degrade the resist pattern. A resist's capacity to withstand the more vigorous image transfer processes (for example plasma etching) can vary widely with its composition.

(6) After image transfer, the patterned resist must be readily and completely *removable* without substrate damage. The pattern often can be stripped from the substrate with a mild organic solvent. Proprietary stripper formulations or plasma oxidation treatments are utilized when the imaging chemistry or image transfer process has insolubilized the pattern.

Physics of Image Formation. Spatially directed radiation chemistry is the basis of all modern lithographic processes. While numerous approaches for the localized activation of chemical processes have been pursued, by far the predominant means for fabricating microdevices today employs optical *projection photolithography* to bring about photochemical reactions in the resist film in an imagewise fashion (11). In this technique, a light image of the desired pattern, transmitted through a mask, is reduced in size and precisely focused onto a resist-coated wafer using a system of lenses (Fig. 2). Because of diffraction and

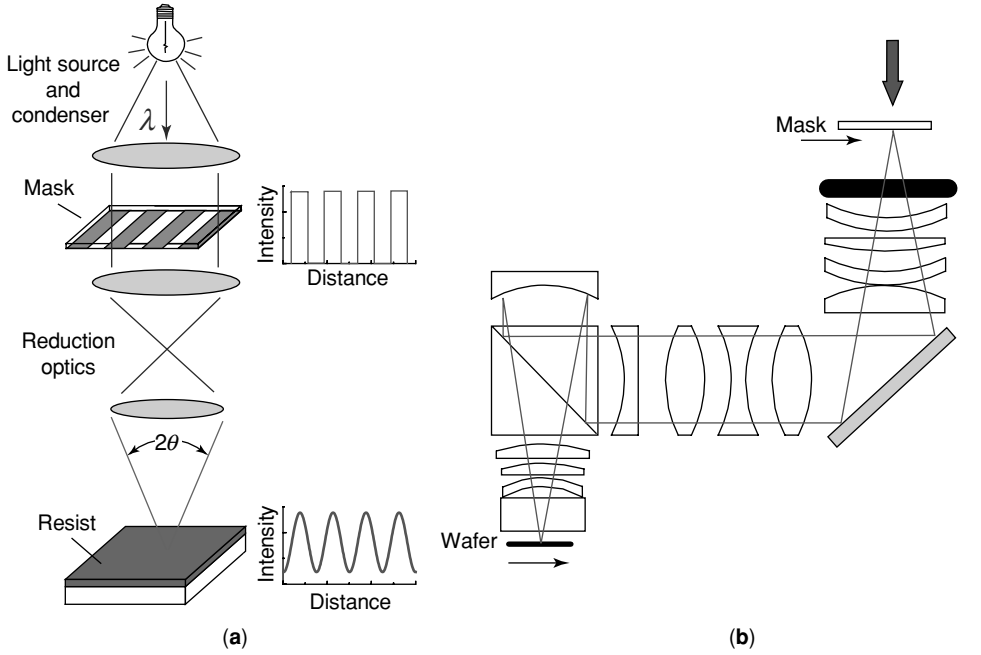

Fig. 2. Projection lithography. (**a**) Schematic diagram illustrating the essential components in a projection exposure tool. (**b**) Optical elements in a modern projection exposure tool used for device manufacturing. The additional components enhance the precision of the projected light image by correcting for optical aberrations and distortions (12).

slight imperfections in the optical components, a nominally square wave pattern of light intensity is presented as a sinusoidal pattern of light at the wafer plane. The ratio of light intensity in the nominally bright and dark regions, a measure of the *aerial image contrast*, varies with the wavelength and optical characteristics of the exposure tool. Since this ratio determines how the extent of photochemical reaction of the nominally exposed and unexposed areas of the resist film differs, it controls the ability to selectively dissolve one of these areas during the develop step. As the aerial image contrast decreases, differentiation during development between exposed and unexposed regions grows increasingly difficult and ultimately determines the limits of spatial resolution.

The minimum resolution R achievable with projection lithography is governed by the relation

$$R = k_1 \lambda / \mathrm{NA} \tag{1}$$

where λ is the wavelength of exposing radiation, k_1 is a process- and material-dependent parameter in the range of 0.4–1, and NA is the numerical aperture, equal to the refractive index of the surrounding medium ($\sim$1 for air) times the sine of the angle θ subtended by the objective lens of the system (13).

The depth of focus (DOF) for the same tool is given by the equation

$$\mathrm{DOF} = k_2 \lambda / (\mathrm{NA})^2 \tag{2}$$

where k_2 is a process-dependent parameter of the order of 0.5–1, and λ and NA are defined as before. A large value for DOF is desired as it increases the tolerance of the process to deviation of the substrate surface from perfect planarity.

The evolutionary refinement of projection optical lithography since its introduction can be understood by consideration of these equations. The overall goal is improved resolution while maintaining a maximum DOF. Resolution improvements may be realized by increasing the NA, by reducing the exposure wavelength λ, or by process and tool refinements that reduce the value of k_1. There are practical limits to each of these approaches, however.

To improve resolution by increasing the NA of the lens system, either the diameter of the lens must be increased or the focal length reduced. The net overall result is a lens system of increased size, mass, complexity, and cost. Since the NA appears as a squared term in the equation for DOF, a resolution improvement achieved via increased NA is accompanied by a proportionately larger decrease in DOF. Moreover, complex polarization effects arise as the angle θ exceeds $\sim 45^\circ$ (an NA of ~ 0.7) (14).

According to equations 1 and 2, improving resolution by reducing the exposing wavelength does not incur as great a penalty in DOF, but brings the requirement that a suitable photoresist, light source, and selection of optical lens materials be available for the decreased wavelength. The development of new generations of photoresists for leading-edge microlithographic applications has been driven in large part by the need for imaging materials optimized for a specific exposure wavelength.

The first projection exposure tools, introduced in the mid-1970s, were designed to print features at the >2000-nm scale, using light of 400–450-nm wavelength (15). Improvements in optical fabrication and design allowed the use of the resist systems designed for this wavelength range for an extended period, with increases in the NA as the primary means for realizing improved resolution. In the mid-1980s, as feature dimensions decreased below 1000 nm, a shift to exposure tooling based on an illumination wavelength of 365 nm signaled the start of the now-familiar trend where improved resolution derives in large part from reduction of exposure wavelength. This was soon followed by the development of exposure tools based on ultraviolet (uv) excimer lasers operating at 248-nm (KrF) and later at 193-nm (ArF) wavelengths. Current research and development activities are exploring the issues that accompany the use of 157-nm illumination from a F_2 excimer laser as a source in projection lithography.

Several less evolutionary routes to achieving improved resolution through wavelength reduction are also being pursued, including x-ray proximity lithography ($\lambda \sim 1$ nm) (16), extreme-uv lithography ($\lambda \sim 13$ nm) (17), and lithography using charged-particle beams of electrons (18) or positive ions (19). In the latter two technologies the particle deBroglie wavelengths are so small that resolution is limited by aberrations in the ion optics and ion–ion repulsion rather than diffraction. Each of these approaches brings with it unique requirements for optical components, masks, and resists; intensive research and engineering activities have been pursued for a number of years in the attempt to bring each of these approaches to practical implementation.

Modern Resists for Microlithography

Most modern lithographic resists are evolved from materials first developed for the printing industry (20). Increasingly specialized resists and processing techniques have been introduced as applications of lithographic technology have grown in scope and sophistication. Today the market for photoresists used in the manufacture of integrated circuits is estimated to be US$1.4 billion annually, with diazonaphthoquinone–cresol novolac (DNQ-novolac) resist products accounting for about two-thirds of this. Commercial resist systems designed for deep-ultraviolet applications are now being used to build the critical levels of most leading-edge semiconductor products, however, and use of such advanced materials is expected to grow at the expense of the older DNQ-novolac systems.

DNQ-Novolac Photoresists. The bulk of the world's semiconductor processing is carried out using DNQ-novolac resin based photoresists and exposure tools equipped with mercury arc lamp illumination sources (producing uv wavelengths of 365 or 436 nm) (21). These photoresists consist of a photoactive DNQ dispersed in a phenolic matrix resin (a low molecular weight condensation product of formaldehyde and cresol isomers known as *novolac*) (Fig. 3). The phenolic structure renders the novolac polymer weakly acidic, and readily soluble in aqueous alkaline solutions. In admixture with an appropriate DNQ the polymer's dissolution rate is sharply decreased, typically by 2–3 orders of magnitude. Photolysis causes the DNQ to undergo a multistep reaction sequence (a photochemical Wolff

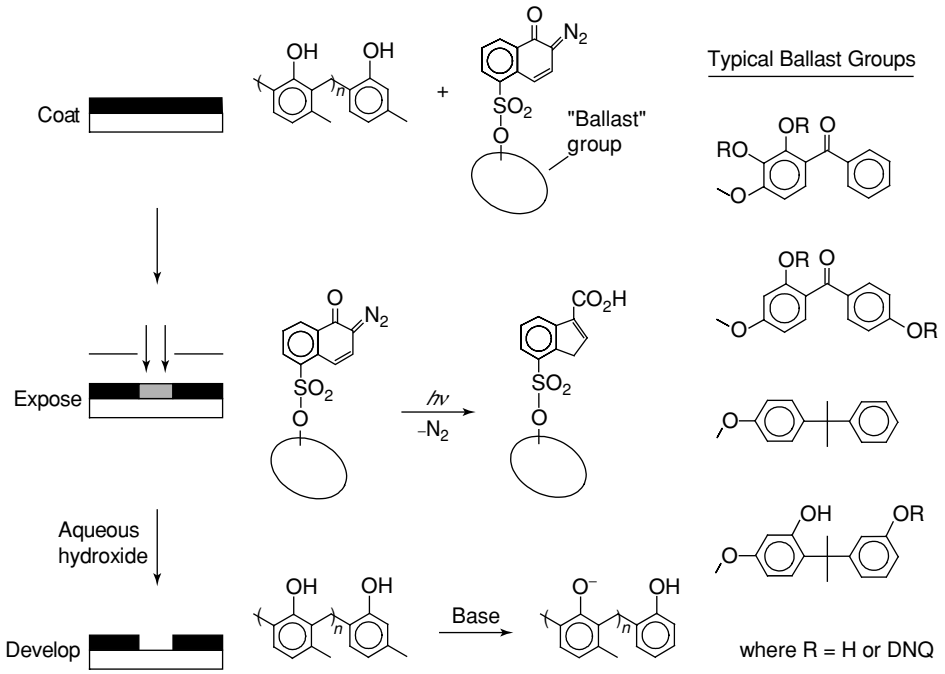

Fig. 3. Chemistry of diazonaphthoquinone–cresol novolac positive-acting resist. During patternwise exposure, the DNQ undergoes photolysis that destroys its inhibitory effect on film dissolution.

rearrangement), ultimately forming a base-soluble carboxylic acid that does not inhibit film dissolution. Immersion of a patternwise-exposed film of the resist in an aqueous solution of hydroxide ion (typically containing 0.2–0.3 *N* tetramethylammonium hydroxide) leads to rapid dissolution of the exposed areas and only very slow dissolution of unexposed regions. Since the polymer itself undergoes no reaction during the image formation process, the film solubility is controlled by *chemical* and *polarity* differences rather than molecular size.

DNQ-novolac resist chemistry has proved to have remarkable flexibility and extendibility. First used in electronic manufacturing applications in the 1960s, the performance of these materials has been continually improved by careful optimization of the polymer and DNQ dissolution inhibitor. Today, highly optimized DNQ-novolac resists are used to manufacture integrated circuits with device geometries on the 350-nm scale.

Deep-Ultraviolet Chemically Amplified Resists Based on Acid Catalysis. Unfortunately DNQ-novolac resists are not suitable for use at deep-ultraviolet (DUV) wavelengths ($\lambda \sim 250$ nm), the succeeding evolutionary step in the progression of optical lithography tools to higher resolution. There are two principal reasons for this. The first can best be understood by consideration of

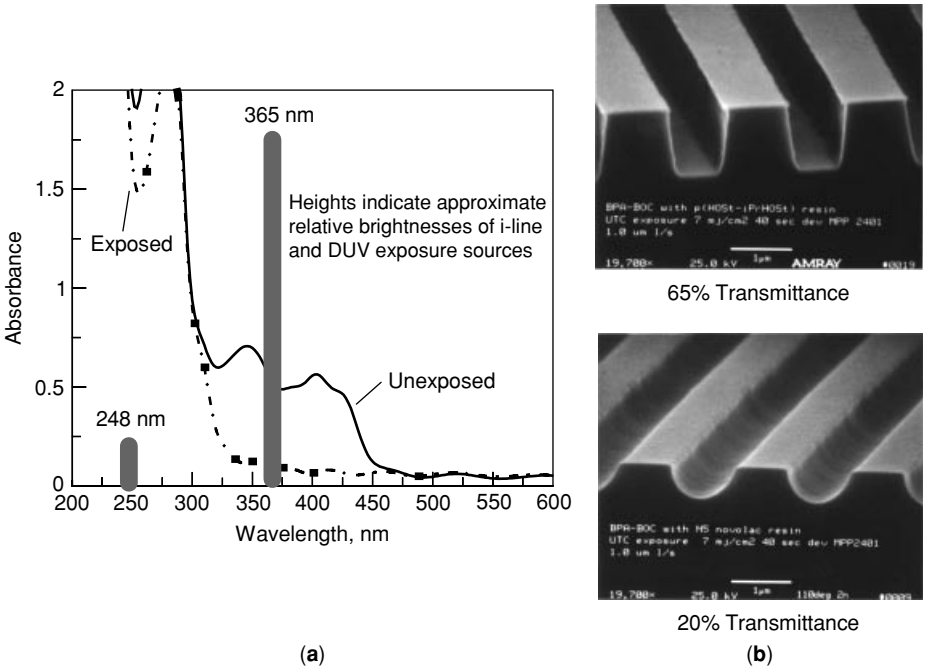

Fig. 4. Impact of optical absorption on resist performance. (**a**) optical absorption spectrum of a typical DNQ-novolac resist before and after exposure. (**b**) Impact of optical absorbance on photoresist imaging properties. Shown are scanning electron micrographs of relief images obtained using two different photoresist formulations, processed under identical conditions. The formulations are functionally identical but differ in the transparency of the film at the exposing wavelength (22). (top) image obtained when the film is weakly absorbing; (bottom) image obtained when the film absorbs strongly at the exposing wavelength. Note the incomplete development to substrate and the sloping sidewalls.

resist optical properties. Figure 4a shows the optical absorption spectrum of a typical DNQ-novolac photoresist film before and after exposure with 365-nm light. The absorption band at long wavelengths (300–450 nm) is that of the DNQ sensitizer. As the DNQ is photolyzed this characteristic absorption decreases. The increased transparency facilitates efficient photolytic conversion of the sensitizer throughout the depth of the film. If such a film is exposed at 248 nm, however, the strong nonbleaching absorbance at that wavelength (due in part to the novolac matrix polymer, and in part to the DNQ and its photoproduct) sharply attenuates the beam as it passes through the film. The result is highly nonuniform photolysis of photosensitizer in the resist film, with insufficient conversion near the substrate interface to effect solubilization. Figure 4b illustrates the damaging effect of this on resist imaging properties. As will be seen in later sections, the need to circumvent excessive resist absorbance is a repeating theme in the evolution of resist materials.

Second, the overall brightness of light sources available for DUV exposure is much less than that of mercury arc lamps used for 365-nm imaging. Although KrF excimer lasers are generally regarded as powerful sources of uv light, the spectral output line is relatively broad. Limitations of available lens materials make correction for chromatic aberration difficult, and so the source output beam must span only a very narrow wavelength range. Introduction of optical line narrowing elements into the beam leads to a large overall attenuation. Figure 4a illustrates the relative intensities at the wafer plane for typical 365- and 248-nm exposure tools. Roughly speaking, a photoresist designed for use with current DUV exposure tooling must be at least 10 times more efficient in its utilization of absorbed photons than a DNQ-novolac resist. Since the quantum yield for DNQ-novolac systems is of the order of $\sim$0.3, a 10-fold improvement in efficiency is a considerable challenge, and obviously calls for a different approach.

One means of attaining this increased efficiency is by the photochemical generation of an initiating species or catalyst that is active in a subsequent thermal reaction. A familiar example of this is found in photoinitiated free-radical polymerizations, and this approach has seen extensive application in photoresists intended for use in the production of printed circuit boards (23). Each single photochemical event (formation of a free radical) can result in the polymerization of a large number of olefin monomers, giving an effective quantum yield for bond formation that is much higher than that of the initiating photochemical reaction and which can exceed unity. Such photopolymerization resists are not well-suited for use in microlithographic applications because of their limited resolution, a consequence of excessive solvent swelling during the develop step.

This "chemical amplification" (CA) concept can be extended to catalytic reactions. In 1982, it was recognized that if a photosensitizer producing an acidic product is photolyzed in a polymer matrix containing acid-labile groups, the acid could serve as a spatially localized catalyst for the formation or the cleavage of chemical bonds (24). An early practical example of this concept is shown in Figure 5. The acid-generating sensitizer is an onium salt, a class of compounds that efficiently generate a Brönsted acid upon photolysis. The polymer is poly(*tert*-butoxyoxycarbonylstyrene) (PTBOCST). Photolysis forms a small quantity of acid in those areas exposed to radiation. During a later heating step the acid catalyzes thermolysis of pendant *tert*-butoxyoxycarbonyl (TBOC) groups, largely

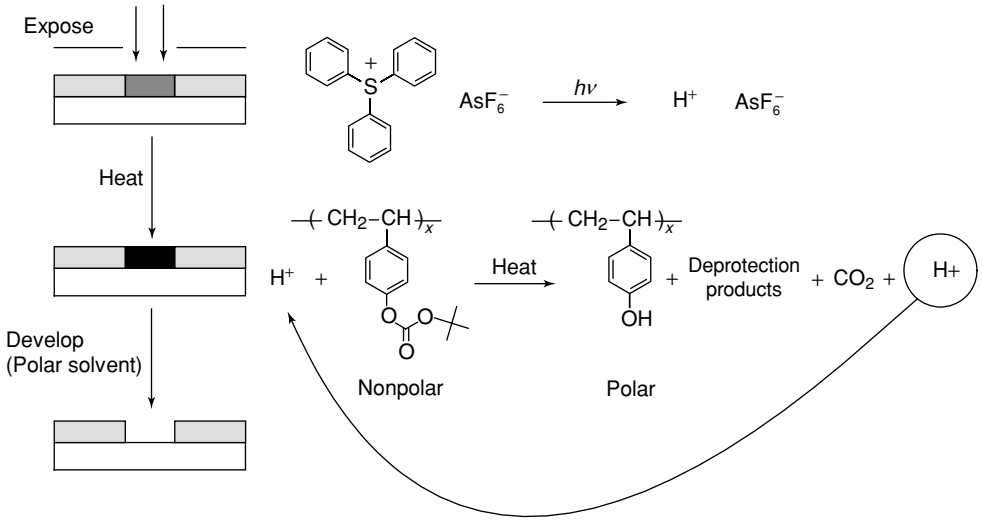

Fig. 5. Chemistry of PTBOCST chemically amplified resist. In the first step, patternwise exposure creates small quantities of acid. In a second heating step, pendant TBOC groups are cleaved under acid catalysis. The exposed and deprotected areas can be selectively dissolved in a polar solvent.

converting the nonpolar PTBOCST into the polar poly(hydroxystyrene) (PHOST) and gaseous products, while regenerating the initial acid. The converted latent image can be developed either in positive tone by selecting a polar solvent or in negative tone by selecting a nonpolar solvent as the developer. The catalytic chain length for this system, that is, the average number of TBOC groups fragmented by each acid molecule, has been measured to be in the range 800–1100 (25). Therefore an extremely low exposure dose (in the range of 1–5 mJ/cm^2) is needed to image this system, roughly 2 orders of magnitude more photosensitive than typical DNQ-novolac resists.

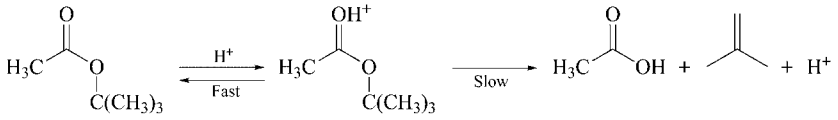
Since the original proof of concept, and a later demonstration of its practical use in semiconductor manufacturing (26), applications and extensions of this concept have proliferated. CA resists now find use in virtually all leading-edge photolithographic manufacturing processes, and it is anticipated that this dominance will continue into the foreseeable future regardless of the specific exposure technologies. In the following sections the general characteristics of CA resists are discussed using as examples those targeted for 248-nm exposure. Following that, the key factors that ultimately limit extendibility of lithographic resists are enumerated. Finally, examples are provided of how CA resists are being tailored to suit the requirements of specific future exposure technologies. Throughout the discussion that follows, the relation between functional properties and resist composition is emphasized.

Characteristics of CA Photoresists for 248-nm Exposure. CA DUV photoresists differ from DNQ-based resists in a fundamental way. In the latter, the dissolution inhibitor component (the DNQ) is itself photoactive (Fig. 3). Typically in a CA resist the photoactivity and solubilization functions are separate. The photolysis of the photo-acid generator (PAG) does not of itself significantly promote dissolution [although exceptions to this have been noted (27)]. Reaction of the acid

with the protected phenols bound to the polymer backbone must take place to achieve a significant change in polymer solubility. The nature and the efficiency of the imaging chemistry are dictated by the reactivity of the acid-labile functional groups, the properties of the polymer and PAG, and by lithographic processing conditions. We detail here how these factors shape the imaging characteristics of CA resists.

Acid-Catalyzed Chemistry. Acid-catalyzed reactions form the basis for essentially all CA resist systems for microlithographic applications. These reactions can be generally classified as either cross-linking/photopolymerization or deprotection/rearrangement reactions. Polymer cross-linking and photopolymerization reactions lead to increases in molecular weight. Since this causes a reduction in the film solubility, these find application in negative-tone resist systems. Deprotection and rearrangement reactions are typically used to unmask acidic functionality such as pendant phenolic or carboxylic acid groups. These impart solubility in aqueous alkaline solution and therefore such reactions are used in positive-tone resists. Representative examples of each type of chemistry are described below.

Positive-Tone Imaging Chemistry. The ester, carbonate, and ketal acidolysis reactions that form the basis of most positive tone CA resists are thought to proceed by specific acid catalysis (28). In this mechanism (type AAL1), illustrated here for the hydrolysis of *tert*-butyl acetate (29), the first step is a rapid equilibrium where the proton is transferred between the photogenerated acid and the ester:



The rate of the reaction in such case is $R = k[PH^+]$, where PH^+ is the protonated *tert*-butyl ester. In the corresponding polymeric resist system, PH^+ is the repeat unit bearing the acid-labile protecting group.

In formulated resist systems the situation is more complex. The photogenerated acid can be so strongly acidic that it dissociates completely upon formation. In such a case, the proton will reside on other basic components of the resist film, which can include polymer functionality (ie, pendant ester or ether groups), and adventitious impurities such as water or residual casting solvents, as well as additives such as coating aids. The reactant PH^+ will be in equilibrium with all other protonated species in the resist film. The concentration of each protonated species is then determined by the basicity of its unprotonated conjugate. As deprotection proceeds, the concentrations of the basic resist components will change, shifting the equilibria and influencing the overall kinetics. Substitution of an acid of different strength, or introduction of a basic impurity or additive, will perturb the concentration of PH^+ and thereby the imaging behavior of the resist.

Figure 6 lists representative acid-labile protecting groups that have been incorporated in positive-tone CA resist systems. These groups can be pendant to the matrix polymer chain, can be attached to a monomeric or polymeric additive that acts as a dissolution inhibitor (30–32), or even can be appended to the PAG structure (33).

Negative-Tone Imaging Chemistry. In many negative-tone CA resists cross-linking is employed to effect insolubilization of the exposed pattern. In the

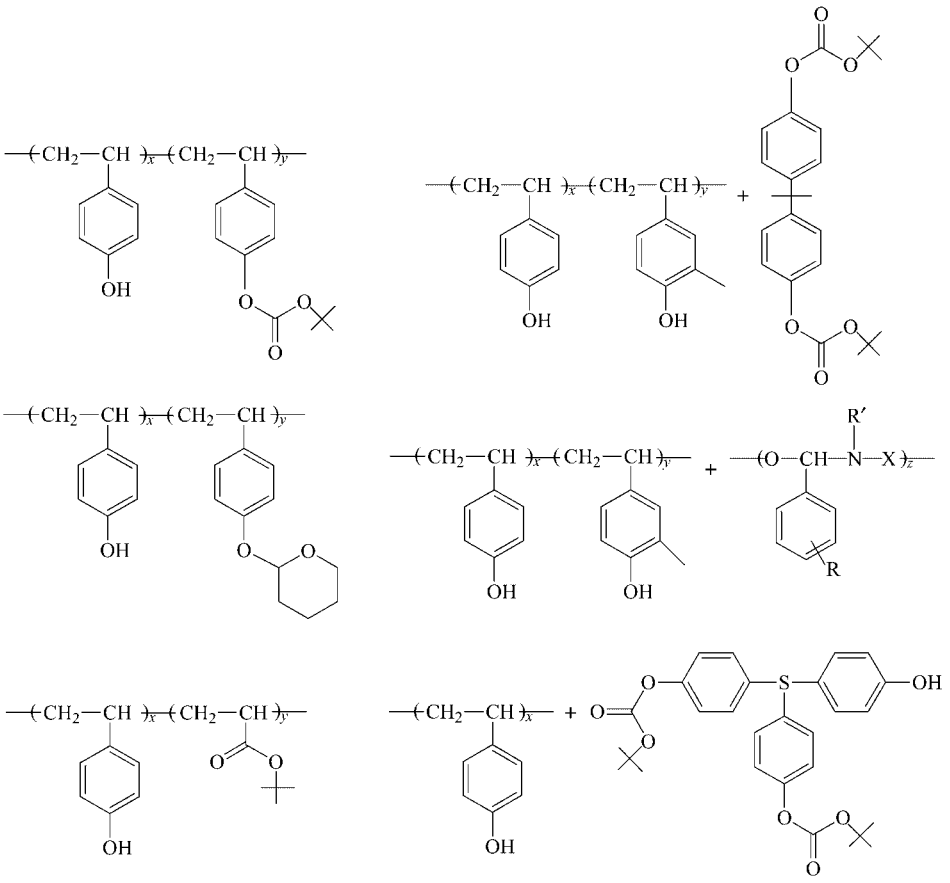


Fig. 6. Representative polymers and protecting groups used in positive-tone CA resists. On the left are shown three examples where the acid-labile protecting groups are pendant to the polymer chain; the right column provides three examples where the acid-labile groups are found on small molecules added to the polymer film.

limiting case, an acid-catalyzed bond-forming reaction can convert the polymer film from a glassy matrix of individual polymer strands into a three-dimensional network that is effectively a single molecule bound to the substrate surface. Full cross-linking is not always required, however. A small increase in molecular weight due to partial cross-linking, or simply a change in polarity stemming from grafting of the cross-linking agent to the polymer chain, can cause a change in dissolution properties that is adequate for imaging.

One of the first CA resist systems described in the chemical literature is based on the acid-catalyzed cross-linking of epoxy groups (top reaction of Fig. 7) (34). While such resists display excellent photospeed, they suffer from solvent-induced image distortion during development, the result of swelling of the cross-linked polymer during development. Careful attention to formulation and process conditions is required to achieve high resolution imaging. This difficulty, coupled with the practical problems associated with the use of organic solvents in a manufacturing setting, has limited the acceptance of such resists.

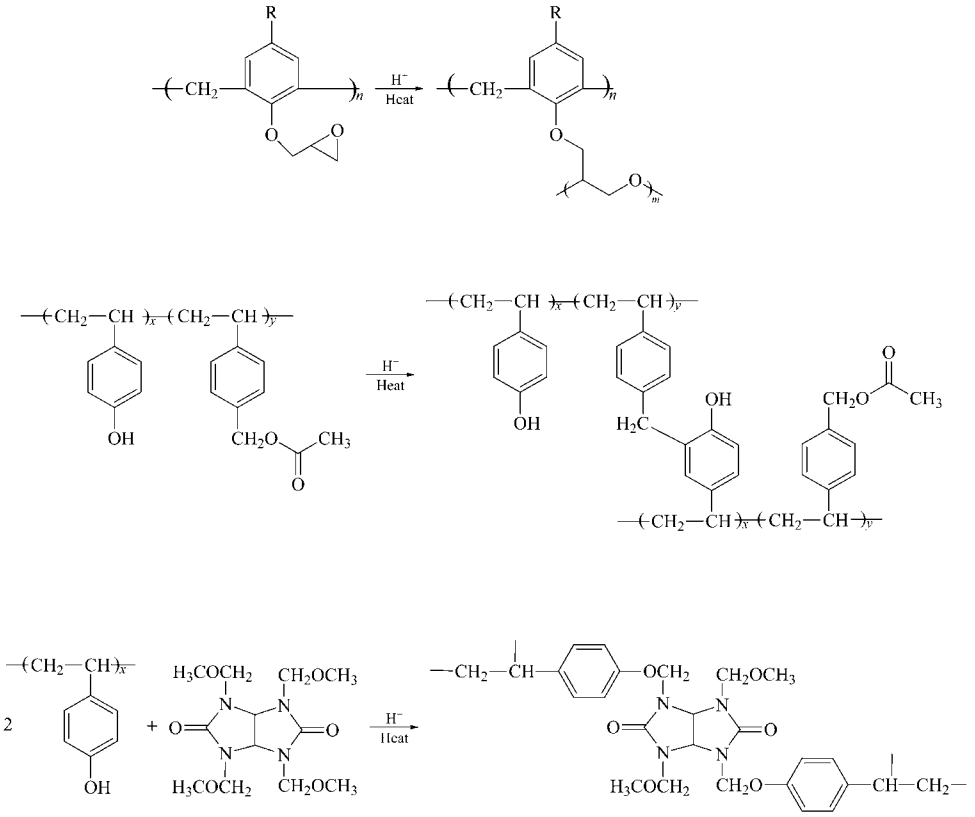

Fig. 7. Representative imaging chemistry employed in negative-tone CA resists: (top) epoxy polymers requiring organic solvent development; (center) PHOST-based cross-linking systems requiring aqueous development; and (bottom) monomeric cross-linking agents used in PHOST matrix polymers.

Several CA negative-tone photoresists exploit the high reactivity of aromatic structures toward electrophilic substitution by incorporating the cross-linking chemistries shown as the middle and bottom reactions of Figure 7. In these examples the phenolic structure renders these systems developable in aqueous alkaline solution. Since the dissolution properties for such polymers closely resemble the surface-limited etching found in DNQ-novolac positive resists, image distortion due to solvent swelling is not observed. Systems have been described where the active cross-linking group is covalently bound to the polymer (35,36), or is incorporated as a nonpolymeric additive (37). Bond formation can take place at the hydroxyl site or on the ring (36).

While cross-linking systems have been most widely studied, negative-tone patterning can be achieved by exploiting the polarity change that accompanies deprotection. The PTBOCST resist (Fig. 5) is a familiar example, since use of a nonpolar developer solvent produces negative-tone images. In a second example, a pinacol rearrangement changes a polar diol into a less polar carbonyl group, allowing negative-tone imaging when developed in an appropriate organic solvent (38).

Polymers for 248-nm CA Resists.

Optical Properties. It was noted earlier that novolac-based resists absorb too strongly in the 248-nm spectral region to be used for exposure at that wavelength. Experience has shown that the optimum optical absorbance for a nonbleaching photoresist is about 0.3–0.4 absorbance units at the required film thickness (typically 600–1000 nm for 248-nm resists), representing a balance between conflicting requirements for high transparency to provide uniform illumination through the depth of the film, and high absorption to suppress thin-film optical reflectivity effects that reduce process latitude (39,40). To maximize light absorption by the photosensitizer, the polymer should be as transparent as possible at the exposure wavelength. A rule of thumb is that polymeric component's contribution to the absorbance should not exceed 0.2 at the required film thickness. A number of different polymer families are transparent at this wavelength; Figure 8 compares the optical absorption characteristics of an acrylic polymer and PHOST to that of a *meta*-cresol novolac resin. The acrylic polymer in particular appears well-suited for 248-nm exposure, and early work in DUV resists took advantage

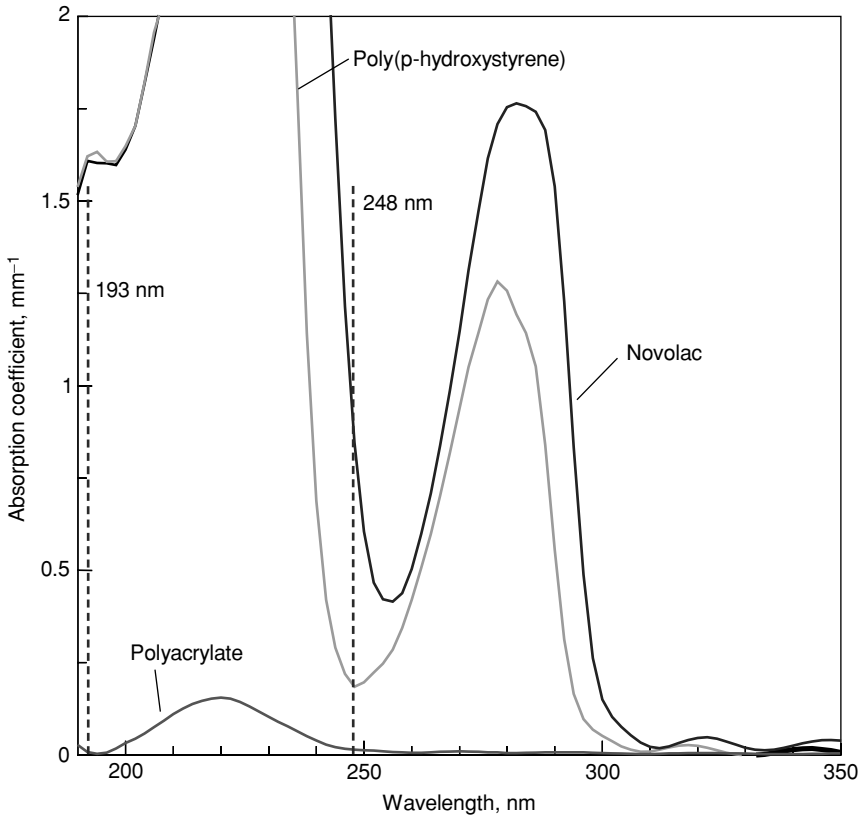

Fig. 8. Optical absorption spectra of thin, 1000-nm-thick films of novolac, poly(hydroxystyrene), and poly(acrylate) polymers. The novolac resin is transparent only above 300 nm. While poly(hydroxystyrene) also absorbs strongly below 300 nm, it exhibits a region of adequate transparency centered near 248 nm. The acrylate polymer is quite transparent over the uv range.

of that characteristic (41). While suitable for wet-etch image transfer processes, acrylic-based polymers have such poor resistance to the plasma etch image transfer processes now commonly used in semiconductor fabrication that their use is impractical (42). Materials based on the PHOST structure are far more robust toward plasma etching, and many derivatives of PHOST are sufficiently transparent at 248 nm to provide a useful polymer platform for resist design.

Polymer Synthesis. Typically the resists used in 248-nm DUV lithography are based on copolymers of hydroxystyrene and an acid-labile comonomer as depicted in the examples of Figures 6 and 7. These polymers are almost always produced by free-radical solution polymerization of a derivative of 4-hydroxystyrene (HOST), and thus are usually medium molecular weight (5000–100,000) polymers with relatively narrow polydispersities (between 1.5 and 2.5) (43). Although structurally similar, the functional properties of phenolic resins based on HOST bear little resemblance to those of novolac, whose unique properties stem in part from the unusual step-growth polymerization mechanism (44), which produces substantial quantities of oligomeric products and high molecular weight branched polymer.

Poly(hydroxystyrene) (PHOST) is often prepared by polymerization of 4-acetoxystyrene, followed by base-catalyzed hydrolysis (Fig. 9a). The acetoxystyrene monomer's stability and polymerization kinetics allow production of PHOST of higher quality than is easily obtained via direct radical polymerization of HOST. The PHOST homopolymer formed thereby is then partially or fully derivatized with an acid-cleavable functionality to produce the final resist component. In some instances the resist polymer can be prepared in a single step by direct polymerization of the protected monomer(s) (23,45), entirely avoiding the intermediate PHOST. HOST-containing resist polymers have also been prepared by free-radical copolymerization of a latent HOST and a stable, acid-labile monomer, for example, the copolymerization of acetoxystyrene with *tert*-butyl acrylate, followed by selective removal of the acetoxy group (46) (Fig. 9b).

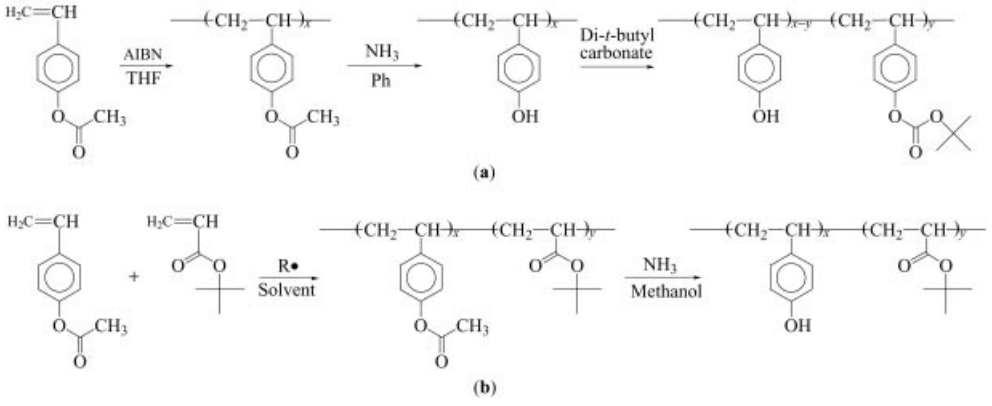

Fig. 9. Examples of synthetic methods for the preparation of polymers for 248-nm CA resists. (**a**) Synthesis of PHOST from acetoxystyrene monomer, followed by partial protection with an acid-labile pendant group to form poly(*tert*-BOCstyrene-*co*-hydroxystyrene); (**b**) synthesis of the acid-labile copolymer poly(hydroxystyrene-*co*-*tert*-butylacrylate) by radical copolymerization using a latent HOST, followed by selective deprotection.

Relating Polymer Properties and Lithographic Properties. While the nature of the imaging chemistry is a central element determining the functional characteristics of a CA resist composition, the impact of other polymer properties must also be considered in resist design. Polymer molecular weight (47,48) and molecular weight distribution (49,50) exert a strong influence on the solubilization properties of phenolic polymers in aqueous base, and therefore must be carefully controlled to ensure a reproducible and optimum dissolution response to the imaging chemistry. There is evidence that the polymer molecular weight can also impact the fine-scale definition of the final developed resist image (51,52) (the line-edge roughness, discussed later in greater depth). The dissolution of base-soluble copolymers is influenced both by the relative amounts of each monomer incorporated in the polymer and by how the different monomers are distributed along the chains (53,54).

Free-radical polymerization chemistry, and the transition metal catalysis chemistry used to make some 193-nm resist polymers (discussed later in this article), places fragments of the initiating species at the terminuses of the polymer chains. Although their effective concentration in a resist film is low relative to the polymer repeat unit, these end groups can have a discernible impact on its functional lithographic properties. End groups can have several independent effects (55,56). First, if the initiator fragment absorbs uv light, an undesirable decrease in the transparency of the polymer can occur. The efficiency of acid-catalyzed deprotection is influenced by the choice of initiator, presumably a consequence of an acid–base interaction of the initiator residue with the photogenerated acid. In some instances, eg, with polymers prepared by cationic polymerization, the end groups can render the chains susceptible to acid-catalyzed depolymerization. Finally, properties of the end group can influence dissolution behavior of the final polymer; nonpolar groups can suppress aqueous base dissolution compared to the same polymer prepared with a polar initiator. Since the concentration of the end groups is directly related to the number of polymer chains in a given volume or mass, their effects are accentuated as polymer molecular weight is decreased and their effective concentration is increased.

Photoacid Generators. The chemical and physical properties of the PAG component play an important role in determining the functional behavior of a CA resist. A variety of PAG compounds (both ionic and nonionic structures) have been developed as researchers have sought to optimize the photochemical properties of the initial PAG (quantum yield of acid generation, wavelength response) and the properties of the photogenerated acid (pK_a, volatility, mobility), while maintaining acceptable solubility, thermal stability, low manufacturing cost, and low toxicity.

Ionic Photoacid Generators. The application of onium salts as photochemical sources of catalyst for acid-catalyzed polymerization was first reported in the 1970s (57). Sulfonium and iodonium salts have become the most widely used members of this group because of ease of synthesis, high thermal stability, and high quantum yield. Representative examples are depicted in structures **a–d** in Figure 10 (58–61).

The properties of the photoacid can be readily modified by varying the counterion in these salts, generally accomplished through a metathesis reaction. This exchange usually has no significant impact on the photochemical reactivity of the

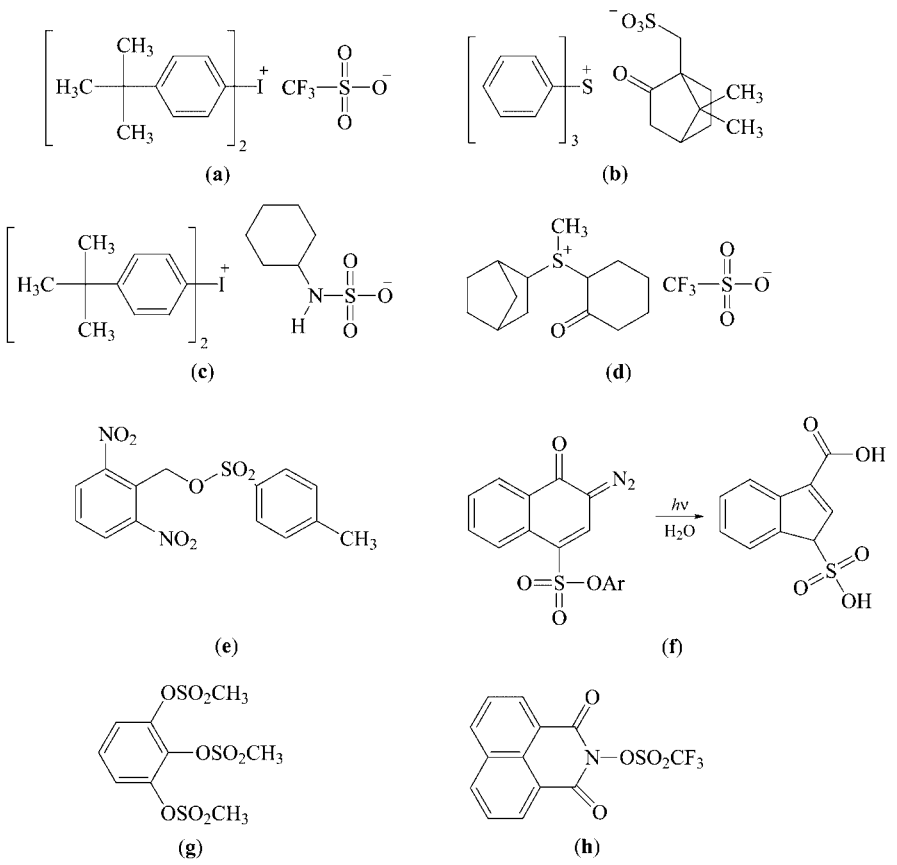

Fig. 10. Typical examples of the photoacid generators used in CA resist formulations; **(a)–(d)** are examples of onium salts; **(e)–(h)** are nonionic PAGs.

cation. In this way the acid strength of the photogenerated acid can readily be adjusted from that of so-called *super acids* to the comparatively weak organic acids (62). Modifying the acid strength can shift acid–base equilibria within the film. Since the catalyzed deprotection occurs via a protonated intermediate species, its concentration will be affected by this shift and thereby the concentration of that intermediate and the rate of deprotection can be manipulated.

The solubility of the PAG in the solid polymeric matrix can influence CA resist performance (63). This is a particular issue for the ionic onium salts; if the polarities of polymer and PAG are sufficiently different, phase segregation will occur, and the poor mixing of photoacid and polymer effectively reduces the efficiency of catalyzed deprotection. Additionally, resist contrast can be affected when the solubility of the photoproducts differs from that of the original onium salt. In fact onium salts can serve as dissolution inhibitors in novolac polymers, analogous to diazonaphthoquinones, even in the absence of any acid-sensitive chemical function on the polymer (27).

Simple aryl onium salts (structures **a–c** in Fig. 10) absorb in the wavelength range of 200–330 nm, making them well-suited for applications requiring DUV

exposure. Spectral response can be shifted to longer wavelengths either by varying substituents or by sensitization. The absorption properties also can be shifted to shorter wavelengths by replacing the aromatic groups in the onium cation with aliphatic groups (e.g., structure **d** in Fig. 10). These latter materials have been used in resists designed for exposure with 193-nm light, where aryl-substituted onium salts are claimed to increase absorption of the formulated resists to unacceptably high values (59).

There is evidence for several mechanistic pathways leading to formation of acid products from photolysis of onium salts: a direct irradiation route and two photosensitization routes proceeding either through a triplet intermediate or an electron-transfer mechanism. In the direct route, radicals, cations, and radical cations all have been proposed as reactive intermediates. The latter two species are believed to be immediate precursors of the photogenerated acid (top reaction of Fig. 11) (64). In the case of electron-transfer photosensitization (bottom reaction of Fig. 11), aromatic radical cations (generated from the photosensitizer) are believed to be a proton source as well (65). The electron-transfer route provides a convenient means to shift an onium salt's wavelength response and to tune its photospeed at the shifted wavelength without the need for chemical synthesis. By careful selection of aromatic hydrocarbon sensitizers with low oxidation potentials, the activity of triaryliodonium salts can be shifted to wavelengths >500 nm via electron-transfer sensitization (66).

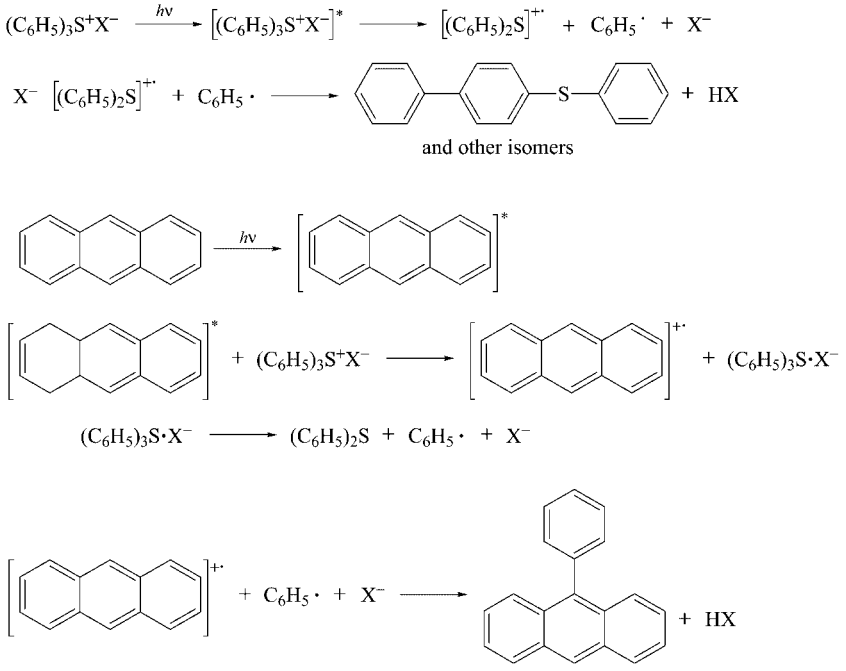

Fig. 11. Proposed photochemical mechanisms for the generation of acid from sulfonium salt photolysis. The top scheme illustrates photon absorption by the onium salt (direct irradiation) and the bottom scheme is an example of electron-transfer sensitization, initiated by irradiation of an aromatic hydrocarbon.

Nonionic Photoacid Generators. A number of nonionic compounds have been demonstrated to produce a Brönsted acid upon irradiation. Some examples are depicted by structures **e–h** in Figure 10 (67–70). The photochemical rearrangements leading to acid production vary. As one example, irradiation of the 2,6-dinitrobenzyl ester (structure **e** in Fig. 10) induces an intramolecular rearrangement [the well-known *ortho*-nitrobenzyl rearrangement (71)], ultimately producing toluenesulfonic acid (62). Unlike onium salts, in this case no radical flux is produced upon photolysis, minimizing the potential for cross-linking side reactions that can cause resist scumming or even negative-tone behavior in positive resist systems. 4-Sulfonyl DNQ sulfonic acid generators, shown in structure **f** of Figure 10, have been used as PAGs in CA resists, most effectively at exposure wavelengths longer than 300 nm (70).

In another example of photosensitization, electron-transfer from a photoexcited phenolic moiety of the polymer matrix to a PAG such as structure **g** in Figure 10 leads to the formation of methanesulfonic acid (68). Sulfonic acids can also be produced from *N*-hydroxyimide derivatives (such as structure **h** in Fig. 10) (69) by such an electron-transfer route, or by direct excitation.

Processing Characteristics of CA Resists. While the increased radiation sensitivity afforded by CA resists offers enormous practical advantages, it brings the need for far more stringent control of the lithographic process. Any factor that influences the course of the catalytic reaction will have an effect that is amplified by a factor equal to the catalytic chain length.

Post-Exposure Boke (PEB) Temperature Control. Experience has shown that precise temperature control is required to achieve reproducible high resolution imaging with CA resists. A typical PEB process calls for heating the exposed film coated on a silicon wafer substrate with a hot plate at a specified temperature in the range of 90–140°C for a 60-s period. To achieve acceptable dimensional control in the final resist images, the temperature across the entire wafer (which in today's manufacturing processes can be up to 300 mm in diameter) must be uniform, varying not more than 0.5°C, during PEB. The sensitivity of a CA resist's PEB process to small changes in temperature has been assessed by measuring the shift in the width of a printed image with temperature (72–74). Such image blur or spreading is the result of a complex interplay between the initial acid profile, the acid mobility, and the chemical kinetics of the acid-catalyzed reaction. The activation energy (E_a) for deprotection, which characterizes how its rate changes with temperature, has a large impact on CA resist processing characteristics. Correlations between the E_a of the deprotection reaction and the magnitude of the image dimensional shift with temperature have been noted. The image shift in PTBOCST resist (E_a for deprotection ~28 kcal/mol) has been measured to be 40 nm/°C (72), while the image shift for a CA resist based on acid-catalyzed acetal deprotection ($E_a \sim 15$ kcal/mol) shows essentially no dimensional shift with temperature (74). These "low activation energy" systems typically undergo deprotection at room temperature upon exposure, and so another of their potential advantages is a reduced dependence on the precise timing of process steps (75,76) since there is in effect no delay between the exposure and postbake steps. Deprotection at room temperature is not always desirable, however (see later under Outgassing of Resist Components), and the intrinsically higher reactivity can reduce the stability of the formulated resist solutions during storage (ie, its shelf life). As with

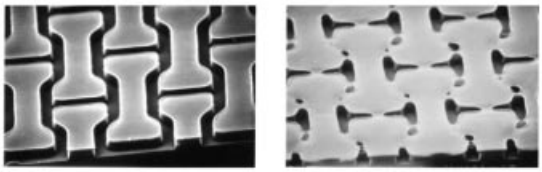

Fig. 12. Scanning electron micrographs illustrating the effects of airborne basic chemical contamination. The image on the left was formed when a positive-tone CA resist was processed without any delay after coating. The image on the right was formed when an identical film was stored after coating for 15 min in an atmosphere containing 10 ppb of *N*-methylpyrrolidone, and then processed identically to the first.

PAGs, the choice of the best protecting group for a specific system calls for a balancing of functional properties to optimize overall resist performance.

Processing Delay Time Effects. A critical and at-first puzzling problem was encountered during early manufacturing trials of CA resists. Sporadically, severely distorted resist profiles would be formed in positive-tone CA resists, displaying what seemed to be a cap on the upper surface of the resist image (Fig. 12). In severe cases this cap or "T-top" would appear as a skin or crust over the entire wafer surface that prevented development of the pattern. The magnitude of the effect varied dramatically between laboratories and appeared to grow more severe as the time interval between exposure and postexposure bake was increased.

Ultimately, it was demonstrated that contamination of the resist surface by airborne basic impurities present at parts-per-billion levels caused neutralization of the photogenerated acid near the resist–air interface, locally suppressing the acid-catalyzed chemistry and producing the observed effects. *N*-methylpyrrolidone (NMP), a common solvent used in semiconductor manufacturing as a stripping and coating solvent, was the first basic contaminant to be identified in laboratory air (77,78). Even though an amide like NMP is generally considered to be a weak base (the pK_a of protonated NMP is ~ -1.0), when compared to the basicity of the polymer matrix (the pK_a of most protonated esters, ethers, and phenols is in the range of -6 to -7) NMP is sufficiently basic to effectively compete for the proton catalyst, slowing the rate of the deprotection reaction (and the overall extent of conversion) in the contaminated region of the resist film. Other sources of airborne clean-room contaminants now have been identified (77). These include paints, adhesives, and sealants, materials that, like NMP, cannot be readily eliminated from the semiconductor manufacturing process.

The impact on negative CA resists of airborne base contamination differs qualitatively from their positive-tone counterparts. Suppression of acid-catalyzed chemistry at the surface of a negative resist results in some film erosion at the top of the exposed fields and in some cases an apparent loss of photosensitivity, but in general the relief images formed exhibit the expected cross-sectional profile. This is in sharp contrast with the typical behavior seen with positive-tone CA resists, where suppression of acid-catalyzed chemistry at the surface causes an insoluble surface skin.

Much attention has been given to means of reducing susceptibility of CA resists to airborne contamination. Process engineering changes such as the addition of special activated carbon filters to the environmental chambers surrounding

the exposure tools (77,79), overcoating the resist with a soluble protective film to isolate the resist from the environment (78,80,81), or modifications of the process flow to minimize the time interval between exposure and postexposure bake have been shown to improve CA resist processability. Resist materials modifications have also been pursued. For example, researchers have purposely introduced basic additives into the resist formulation (82,83) with the notion that a resist already containing added base should be less affected by the absorption of further small amounts of basic contaminants. A side benefit of this approach is improved resolution through a reduction in image blur (see under Limits of Extendibility for Lithographic Resists).

Resist process stability in the presence of airborne bases has also been improved by carefully tuning the polymer characteristics to reduce the rate of contaminant absorption. For example, the rate of NMP uptake was found to vary by almost a factor of 50 depending on the polymer structure in a study using radiotracers to quantify the kinetics and extent of contaminant absorption (84). The contaminant uptake of each polymer could be related to its solubility parameter (which characterizes contaminant solubility in the film) and the T_g of the polymer. Films with T_g values below the post-apply bake temperature undergo polymer film annealing during post-apply baking, leading to a reduction in free volume (present as a consequence of the nonequilibrium nature of the spin coating process), which reduces diffusant mobility. The practical conclusion that can be drawn from this result is that susceptibility to airborne chemical contaminants can be minimized if a CA resist film is baked after coating at a temperature at or above its T_g. By deliberately selecting polymers, protecting groups, and PAGs with thermal properties and stability in mind, CA resists have been designed that can be heated without thermolysis at or above T_g (85,86). Such resists display sharply improved environmental stability compared to analogous systems processed below T_g.

Outgassing of Resist Components. The evolution of reactive volatile organic material from CA resists during exposure has been recognized to be a significant issue. Deposition of volatilized substances on optical surfaces degrades the projected image, and if the deposited material undergoes radiation chemistry during exposure then permanent damage can result (87). Mass spectral analysis of the material evolved upon exposure (88) provides evidence that the contaminants originate from both PAG and polymer: the PAG radiation chemistry (Fig. 11) generates volatile, low molecular weight, reactive products, and a small degree of polymer deprotection and/or chain fragmentation takes place on the timescale of the exposure. The degree of outgassing is strongly tied to the polymer and PAG structures.

Limits of Extendibility for Lithographic Resists

Image Blur in CA Resists. The mobility of the acid catalyst in the film influences CA resist performance. At the molecular level, the proton must move from site to site to effect acid-catalyzed reactions in the resist film. If the mobility is too great, however, the initial spatial profile of photogenerated acid will be blurred and the final developed resist image will appear distorted. The problem becomes more acute at finer resolution. In those situations where diffusion of the

positively charged proton causes a net displacement of positive charge, as is the case for diffusion in a concentration gradient, it must be accompanied by diffusion of the anion so as to maintain overall charge neutrality. In such cases the proton movement is coupled to that of the anion, and those properties of the anion that affect its mobility, for example its volumetric size, will influence the overall acid transport. The use of onium salts bearing sterically bulky counterions [eg, where camphorsulfonate anion (Fig. 10**d**) is used rather than methanesulfonate] has been examined as a means for reducing acid mobility (89).

While excessive acid diffusion leads to image blur, even in cases where diffusion has been suppressed to an insignificant level (e.g., by means of an immobile anion), significant image spreading will still occur during PEB (90). When imaging at dimensions near the resolution limit of a projection exposure tool, diffraction leads to partial illumination, and therefore generation of some amount of acid, in areas of the resist that nominally are unexposed. Because of this, the deprotection reaction proceeds rapidly at the center of the exposed image but also at a significant, although slower, rate in the nominally unexposed regions. This causes the width of the deprotected region—which ultimately defines the shape of the developed image—to spread beyond the desired boundaries. This can be suppressed by purposely adding to the resist formulation a small amount of a basic substance such as an amine or an organic hydroxide (82,83,91). The amount of base is calculated to slightly exceed the amount of acid formed in the dark areas of the pattern, suppressing image spreading there with minimal impact on the chemistry in the exposed areas.

Line-Edge Roughness. Random fluctuation in the width of a resist feature, termed line-edge roughness or LER, is anticipated to be a significant source of line-width variations that could ultimately limit the extendibility of conventional lithographic resists to nanoscale fabrication. Analyses of imaged resists have revealed LER values that vary over a wide range (51,52,92–94). Potential sources of LER include the molecular weight and molecular weight distribution of the resist polymer (51), the molecular structure of resist components (94), inhomogeneity in the distribution of resist components within the film (63), statistical effects influencing film dissolution (95), and intrinsic properties of the imaging chemistry (96).

The standard dimensional tolerance used in semiconductor fabrication is $\pm 10\%$ of the minimum feature size; for example, a minimum dimension of 50 nm will require dimensional control of the order of 5 nm. In resist patterns prepared under optimal imaging conditions, for a wide range of resist chemistries the minimum LER was found to be in the range of 2–7 nm (52). This minimum roughness is of the order of the molecular size of polymers typically used in resist formulations, as estimated by the radius of gyration for polymers with molecular weights in the range of 5000–100,000. One factor that strongly influences the degree of LER is the sharpness of the aerial image (Fig. 13); the more blurred the light image, the greater is the LER of the final resist image. This correlation is taken as evidence that nanoscale inhomogeneity in solubility properties is present at the intermediate dose range of the resist line-edge and is replicated in the developed image.

Characterization of the origins of LER and the design of strategies to minimize LER are today active areas of research. In recent work, experimental electron beam resist formulations comprising nonpolymeric materials (eg, liquid crystals

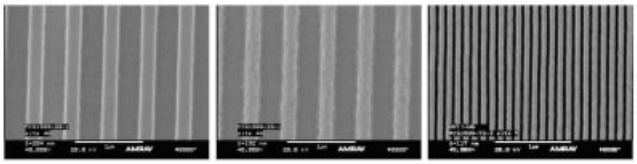

Fig. 13. Top-down scanning electron micrographs of developed resist images depicting line-edge roughness; (left) low LER obtained when printing 250-nm lines and spaces with a sharply defined aerial image in a commercial CA photoresist; (center) increased LER obtained with the same resist when exposed with a degraded aerial image; (right) LER obtained on the same resist when printing 50-nm lines/spaces with a sharply defined aerial image.

or fullerene derivatives) (97,98) have displayed very high resolution (10-nm feature sizes) accompanied by very low LER (∼1 nm or less).

Image Collapse. Although resist feature dimensions have undergone continuing reductions in line width, image thickness has not scaled proportionately. This is because significant erosion of the resist occurs during image transfer. While refinement of plasma etch processes has significantly reduced resist erosion, the improvements have not kept pace with the line-width shrinkage. As a result the *aspect ratio* required of resist features, that is, the ratio of its height to its width, has increased with time as line widths have grown smaller. The extent to which the aspect ratio can increase ultimately is limited by mechanical failure of the images during processing, typically manifested as image collapse. Figure 14 shows a typical example of this.

Studies of this problem have shown that the image collapse occurs following post-develop rinsing of the nascent resist images (99,100). During the post-rinse drying step, unequal surface tension forces from the rinse liquid trapped between

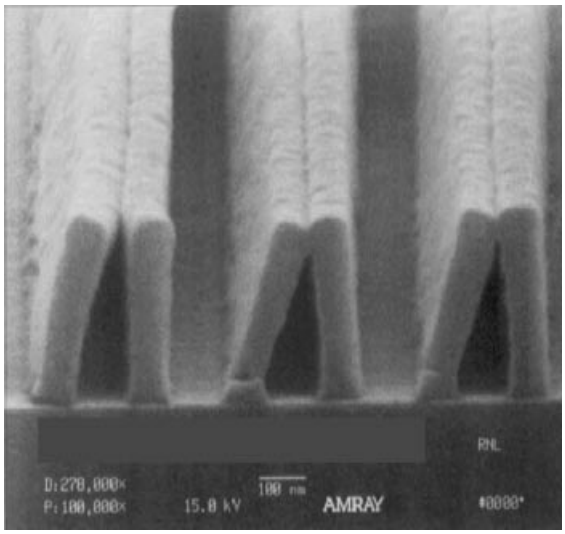

Fig. 14. Scanning electron micrograph of a CA resist pattern illustrating image collapse during postdevelop drying. Note the fracture of the resist structure near its base. Courtesy of D. Medeiros of IBM.

features distort and then fracture the fragile structures. Isolated lines, which are not subjected to unsymmetrical forces, do not show image collapse.

The propensity for image collapse depends on the width and proximity of the features, its aspect ratio, the substrate surface, and the mechanical properties of the imaged resist. Two characteristic failure modes have been identified: deformation, where fracture occurs within the resist structure, and adhesion loss, where the resist feature separates from the substrate at their interface. Low surface-tension rinse liquids [in the extreme, supercritical fluids (101)] and the use of rigid and highly adhesive resists reduce the frequency of image collapse.

Resists for Emerging Exposure Technologies

Photolithography at 193-nm Wavelength. Projection photolithography using 193-nm light is anticipated to find initial implementation in semiconductor manufacturing processes in the year 2002. The design of resists for this exposure technology has proved to be a significant challenge. Existing resist materials developed for use at longer wavelengths were found to be too opaque for exposure at 193 nm, a circumstance reminiscent of the earlier shift from 365- to 248-nm exposure tools. This triggered a decade-long large-scale development effort to devise suitable 193-nm resist materials. A particularly demanding aspect of this undertaking is that the first use of 193-nm resists will be to fabricate device levels whose minimum feature sizes are 130 nm, a dimension substantially smaller than the exposure wavelength. The first large-scale use of 248-nm resists was with the 500-nm device generation, that is, at a feature size of twice the exposure wavelength. With evolutionary materials and optical improvements, 248-nm resists have been applied to devices with increasingly smaller features, now reaching dimensions below 150 nm through the use of complex (and costly) optical resolution enhancement techniques that sharpen the projected light image (102). One implication of this is that a first-generation 193-nm resist must be at a level of refinement equivalent to a fourth-generation 248-nm resist.

Phenolic polymers in many respects are ideal for microlithographic resists as they provide predictable, well-controlled dissolution behavior, excellent adhesion properties, and acceptable plasma etch resistance. But the strong absorption of phenolic polymers at 193 nm (illustrated in Fig. 8) precludes their use at that wavelength, and 193-nm resist efforts can be characterized as the pursuit of new transparent polymer systems that combine these three functional attributes as effectively as do their phenolic counterparts.

193-nm Resist Design Strategies. For a typical target thickness of ~400 nm, the optical density of the formulated resist should be of the order of 0.2–0.3. This transparency requirement precludes the use of unsaturated functionality such as aromatics and vinylics, but aliphatic, cycloaliphatic, carboxylic ester and acid, ether, nitrile, and sulfone groups exhibit acceptable optical properties. Using such building blocks, resist chemists have worked to achieve both good plasma etch resistance and good lithographic performance. Experience has shown that this calls for a balancing of the at-times-conflicting properties of the building blocks through copolymerization and blending.

Analyses of the relation between polymer structure and plasma etch resistance have led to a set of guidelines applicable to resist design (103–105). Polymer materials with "cyclic carbon," ie, those having a significant mass of carbon in the repeat unit incorporated as ring structures with high C—C connectivity, exhibit improved etch resistance (103). In 193-nm resist materials, the restriction against incorporating aromatic structures reduces this to a simple rule: maximize the alicyclic groups (aliphatic rings) in the polymer to maximize etch resistance. The alicylic structure can be integrated into the polymer chain, or can be incorporated as inert or acid-labile pendant groups (105).

Perhaps the most significant challenge in the design of 193-nm resists is the control of dissolution properties in 0.26 N aqueous tetramethylammonium hydroxide, the industry-standard developer solution. Transparent, base-labile functional groups such as carboxylic acids and anhydrides and lactones have emerged as functional substitutes for phenols. The dissolution behavior of carboxylic acids differs markedly from that of phenols, presumably because of the much stronger acidity of the former, which affects the extent of ionization and therefore the polarity of the ionized chains when contacted by developer. While the inclusion of a large proportion of alicyclic groups improves polymer etch resistance, the added hydrophobic character further complicates its dissolution behavior. By reaching the proper hydrophilic/hydrophobic balance it is possible to achieve a large difference in solubility between exposed (deprotected) and unexposed resist, at useful dissolution rates and without swelling. To further tune solubility properties, low molecular weight aliphatic dissolution inhibitors (often cholate esters) frequently are added to 193-nm resist formulations (106). The inclusion of such compounds allows more flexible control of dissolution properties and acts to plasticize the film, a benefit at times since several of the polymer systems under study for 193-nm resists have very high glass-transition temperatures (200°C or more) (Table 1).

Research efforts in 193-nm resists in large part have focused on three polymer families: poly(acrylates), poly(cycloolefins), and cyclic olefin–maleic anhydride (COMA) copolymers. The main characteristics of each of these are detailed below.

Photoresists Based on Acrylic Polymers. Acrylate and methacrylate polymers as a class are quite transparent in the 193-nm spectral range (Fig. 8). Positive-tone CA resists based on acrylic polymers, although first designed for printed circuit fabrication where minimum dimensions are 50 μm or more, have been demonstrated to produce high resolution images using 193-nm exposure tooling (107).

The methacrylate terpolymer shown in Figure 15a typifies this class of material. In the terpolymer, each monomer type imparts specific characteristics to the polymer, providing a mechanism for precise balancing of functional properties. The polymer contains a protecting group (acid labile), a more polar group that improves adhesion and solubility of the PAG in the film, and a smaller amount of a carboxylic acid to modify film polarity and dissolution. Such polymers are prepared by simple free-radical solution polymerizations that are readily scalable to manufacturing levels. The copolymerization properties of methacrylate monomers, where the ester groups exert little influence on reactivity toward polymerization, make it straightforward to optimize resist properties by synthesizing ter- or tetrapolymers.

Table 1. Generalized Strategy for 193-nm Resist Design

Polymer	Protecting group	Photo-acid generator	Additives
FUNCTIONAL PROPERTIES			
Film forming	Polarity switch	Efficiency	T_g modifier
Etch resistance	Shrinkage	Acidity	Dissolution modifier
Optical transparency	Thermal stability	Volatility	Resolution enhancement
Adhesion	Outgassing	Size	Coating aid
Thermal stability		Interfacial distribution	
MATERIALS SET			
Acrylate	Acetal/ketal	Aryl sulfonium salts	Additive material chemical classes
Methacrylate	*tert*-Butyl ester	Aryl iodonium salts	Amines
Cyclic olefin	Alicyclic ester	Alkyl sulfonium salts	Organic ionic hydroxides
Alternating copolymer	Inert modifiers	Nonionic PAGs	Surfactants
Cyclopolymer			Cholate esters
Hybrid (eg, acrylic/alternating)			

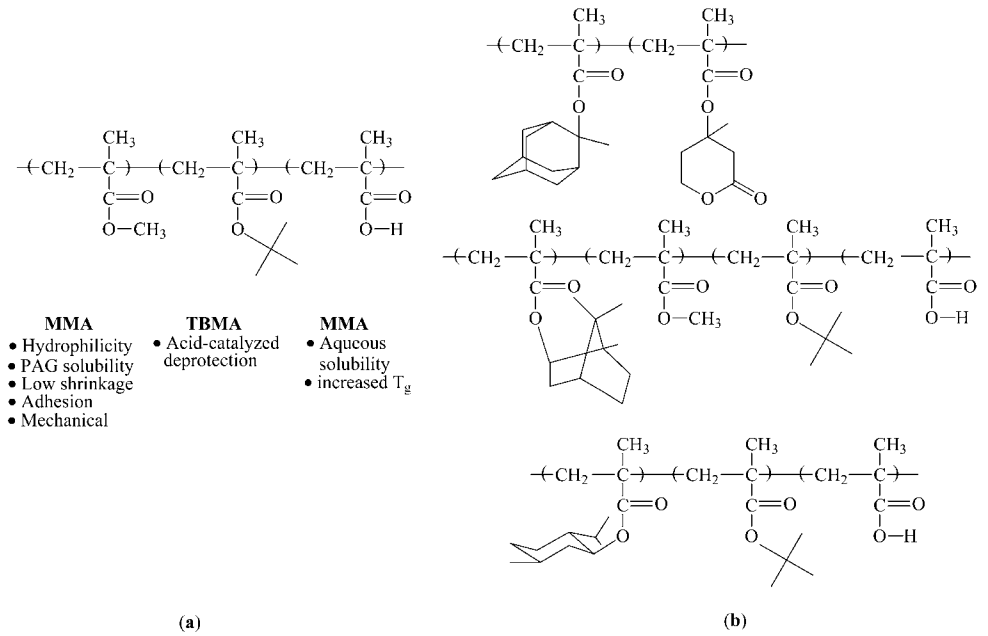

Fig. 15. Candidate polymers for 193-nm resists. (**a**) An acrylic terpolymer designed for chemically amplified resist applications. The properties each monomer contributes to the final polymeric structure are enumerated. (**b**) Examples of acrylic copolymer structures that have been applied in 193-nm CA photoresists.

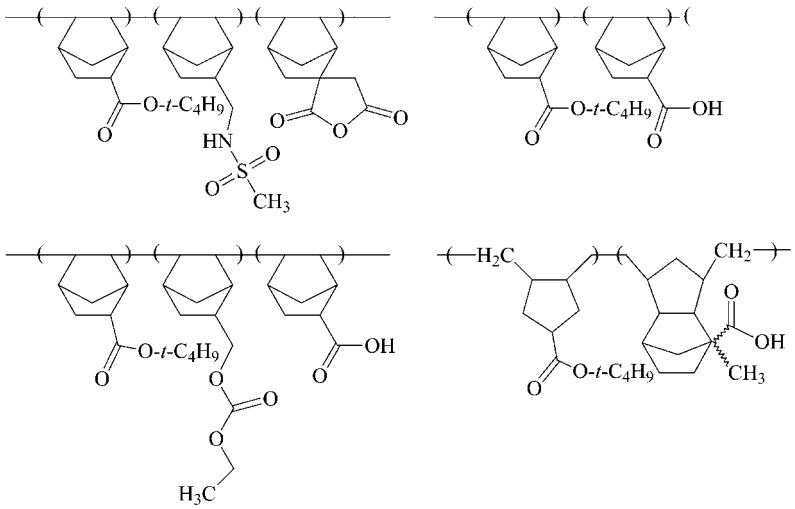

Fig. 16. Cyclic olefin copolymers evaluated for 193-nm resist applications.

The etch resistance of common acrylic polymers is poor but can be improved without reducing 193-nm optical transparency by the attachment of alicyclic pendant groups to the backbone. For example, a 1:1 copolymer of *tert*-butyl methacrylate and adamantyl methacrylate (108) exhibits a nearly twofold reduction in plasma etch rate compared to the *tert*-butyl methacrylate homopolymer. Figure 15b provides examples of alicyclic ester groups that have been assessed (109–111).

Acrylate polymers slowly undergo chain scission upon irradiation with uv light and electron beams. While this property has been used to advantage [acrylic polymers such as poly(methyl methacrylate) have seen use as high resolution but low sensitivity electron beam and DUV resists], in this instance it is undesirable as it compromises plasma etch resistance, and complicates the metrology of acrylate resist patterns when using scanning electron microscopy (112).

Photoresists Based on Cyclic Olefins. These resists have received significant attention, as the base polymers are extremely robust in plasma etch processes (113). Figure 16 depicts illustrative examples of this class of polymer that have been examined for 193-nm lithographic applications (114–116). The polymers typically are prepared by means of a metal-catalyzed addition or ring-opening metathesis polymerization process using substituted norbornene monomers. Polymers prepared by the metal-catalyzed addition have relatively low molecular weight (3000–10,000), polydispersities of ∼1.5, and very high glass-transition temperatures (>250°C). In the ring-opening process, product molecular weight can be controlled over a wide range by the addition of α-olefins to the polymerization mix. Cyclic-olefin-based resists have been notable for their atypical development properties in aqueous base (a tendency toward significant swelling), but nonetheless have been used to formulate resists capable of high resolution imaging properties.

Photoresists Based on COMA Copolymers. Introduction of an anhydride linkage into the cyclic olefin polymer structure leads to a significant and useful improvement in dissolution properties: COMA copolymers require a much lower

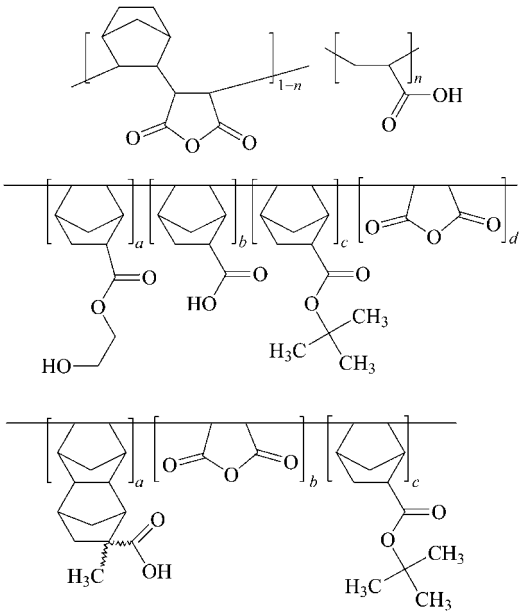

Fig. 17. Cyclic olefin–maleic anhydride copolymers for 193-nm lithographic applications.

proportion of carboxylic acid to achieve aqueous dissolution, and that dissolution proceeds without the substantial swelling that is characteristic of cyclic olefin polymers (116). Hydrolytic ring opening of the anhydride during development, producing a hydroxyl group and a carboxylate anion in the alkaline developer medium, occurs synchronously with development. Presumably the additional ionization of the backbone increases its rate of dissolution such that swelling is minimized.

COMA polymers (Fig. 17), synthesized by conventional radical polymerization, have a 1:1 alternating structure, a consequence of the preference for each radical to react exclusively with the other monomer. As a rule, the products are high T_g materials; for example poly(norbornene-*co*-maleic anhydride) has a $T_g > 300^\circ$C. The polymerization allows the incorporation of small amounts of other vinyl monomers (e.g. acrylic acid) without disruption of the alternating structure (117). Substituted norbornenes can be included in the polymerization mixture to incorporate acid-labile functionality, to modify polymer polarity, and to improve film adhesion (118). Cholate dissolution inhibitors can be added in the formulated resist to further modify functional properties (119).

Vinyl ether monomers also have been combined with maleic anhydride to prepare alternating copolymers. Conceptually similar to COMA systems, these polymers have lower glass-transition temperatures and possibly improved imaging properties (120).

Photolithography at 157-nm Wavelength. As recently as 1997, 157-nm lithography was not regarded as a viable manufacturing technology, primarily because of concern about the availability of suitable materials for optical components and masks (121). Because of that view, no significant resist R&D efforts had been undertaken up to that time. Recent improvements and innovation in optical materials (122) and increasing concern about the timing of availability of complex new nonoptical lithographic technologies (see below) have fostered an intense interest

in 157-nm technology as the immediate successor to 193-nm lithography (123). At this time (early 2001) technical solutions to the issues of laser sources, optical design, and contamination control are considered to be well in hand, and the primary challenge is regarded to be the design of polymers for the new resists this exposure technology will require.

Like their 193-nm counterparts, 157-nm resists will be first used for printing feature sizes (100–70 nm) well below the exposure wavelength. The requirement for very high resolution coupled with the intrinsically low transparency of organic polymers makes the design of these resist systems particularly challenging. Consideration of the factors that dictate resist thickness, such as focus latitude, etch resistance, and mechanical stability of the features, suggests a target thickness of ~200 nm for a 157-nm single layer resist used to print 70-nm features. Using the optical absorbance of current 248-nm resists (of the order of 0.30, or 50% transmission) as a guide, a resist for 157-nm exposure must therefore have an optical density of no greater than 1.5/μm. As a rule, 248- and 193-nm resist polymers have optical densities at 157 nm in the range of 6–8/μm, much too high for lithographic applications (124). This stringent requirement has dictated the direction of materials R&D for 157-nm lithography.

Molecular Absorption at 157 nm. This wavelength (63,700 cm^{-1}, 7.89 eV) falls in the middle of the vacuum ultraviolet (VUV) region of the electromagnetic spectrum. At such energies the electronic transitions of organic molecules include excitations into Rydberg orbitals along with the familiar valence shell transitions (ie, the π–$\pi*$ transitions of aromatic molecules) found at longer wavelengths (125). Molecular Rydberg transitions, in which the excited electron occupies a diffuse orbital large compared to the size of molecule, can have easily identifiable sharp atomic-like features but can also appear as broader transitions difficult to distinguish from valence shell excitations. While a significant body of work (both experimental and theoretical) has been compiled on the VUV spectroscopy of organic molecules in the gas phase (126) there is less data on the absorbance properties in solution or solid phase. Simple extrapolations from absorption spectra of small molecules in the gas phase to polymeric systems are complicated by the fact that Rydberg transitions are usually shifted or absent in condensed media.

Some generalizations are possible, however. It is well known that replacement of hydrogen with the highly electronegative fluorine atom can cause spectral shifts to shorter wavelength (higher energy) through perturbation of the sigma-bonded framework (126). This effect can influence adjacent atomic centers in the framework, leading, for example, to a decrease in the oxygen atom's contribution to 157-nm absorption in fluorinated alcohols and esters. A survey of polymers of different structural types does show that fluorinated resins as a class exhibit suitable transparency (124). A second polymer class identified as potential 157-nm resins in this survey was the silsesquioxanes with minimal hydrocarbon content (127). At present these two material families serve as the basis for 157-nm resist development.

Single-Layer 157-nm Resists. As with other CA resists, the design of a 157-nm photoresist material must include functionality that confers aqueous base solubility, plasma etch resistance, and efficient imaging based on acid catalysis. Although the phenolic and carboxylate groups that provide these functions in 248- and 193-nm CA resists are not well-suited for 157-nm lithography, fluorinated variants that offer improved optical transparency show promise.

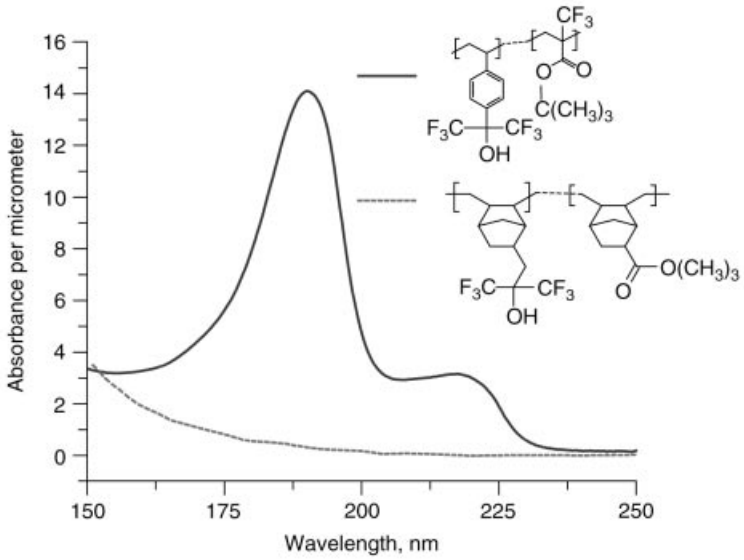

Fig. 18. Polymers for 157-nm resists containing HFIPA units. The structures and VUV absorption properties are shown for two copolymers that typify the materials now under investigation.

Fluorinated alcohols such as hexafluoroisopropyl alcohol (HFIPA) have good transparency at 157 nm [and in fact have been used as solvents for VUV spectroscopy (128)]. Their acidity ($pK_a \sim 11$) is roughly equal to that of the phenolic groups upon which most 248-nm resists are based, and they exhibit similar solubility behavior in aqueous base (52). Like phenols, fluoroalcohols can be coupled to acid-labile protecting groups such as carbonates or ketals. Some recent examples of candidate polymers for 157-nm resists can be viewed as fluorinated analogues of 248-nm CA resists, for example, copolymers of HFIPA–styrene, either with its protected form poly(TBOC–HFIPA–styrene-*co*-HFIPA–styrene) or with α-trifluoro-*tert*-butylmethacrylate (129,130). Figure 18 shows the structure of this last polymer (upper structure) and its VUV absorption spectra.

Other experimental 157-nm resists can be considered to be derived from 193-nm CA resists. The homopolymer poly(HFIPA–norbornene) has an optical density of 1.8/μm (130). First used in 193-nm resist polymers (131), HFIPA–norbornene monomer can be incorporated into cyclic olefin polymers prepared via organometallic catalysis, and can be copolymerized with vinyl monomers such as acrylates or fluorinated acrylates using standard free-radical polymerization to give products with optical densities of less than 3/μm (Fig. 18, lower structure) (132,133). Still other fluorinated monomers can be employed in 157-nm resists, and resist systems based on polymers of fluorinated olefins and vinyl alcohols have been described (134,135). In general, it appears that incorporation of fluorine compromises the etch resistance of resists when compared with their hydrocarbon analogues (136).

The development of practical 157-nm resists brings its share of challenges. Achieving the proper dissolution characteristics in polymer systems containing

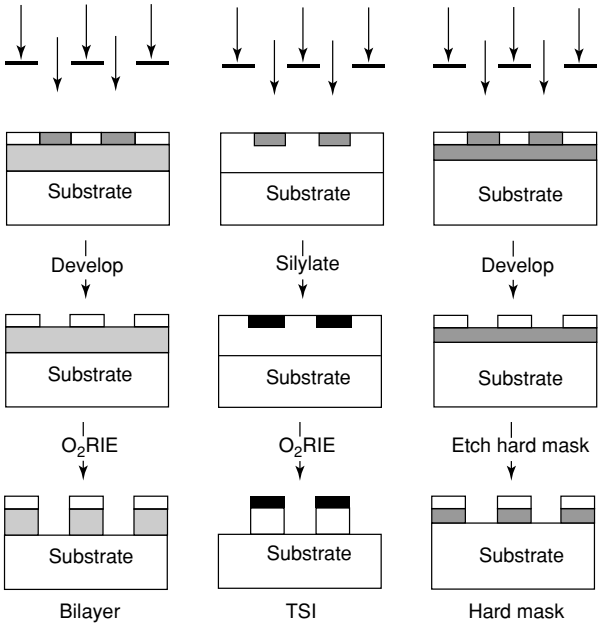

Fig. 19. Schematic diagram of three approaches to multilayer resist imaging.

a high proportion of fluorine can be difficult, a problem analogous to that encountered with 193-nm resists. Because of the high photon energies at 157 nm (183 kcal/mol, which far exceeds C—C single bond strengths) there is the potential for significant photochemical degradation of the polymer (ie, backbone scission or side-chain cleavage), with the attendant problems due to resist outgassing.

Multilevel 157-nm Systems. One flexible approach that allows optimization of optical absorbance without compromising etch resistance is to decouple the two properties into separate thin-film layers. This *multilevel resist* or *thin-film imaging* approach was first introduced in the 1970s (137) and many variants on the concept have since been described (138). Examples of current interest include silicon-based *bilayer* resists (139), *top surface imaging* (TSI) processes (140), and the combination of *ultrathin resists* (UTR) with inorganic *hard masks* (141) (Fig. 19). In each of these approaches the lithographically formed image is confined to a thin film, or a thin layer within a film, and is then transferred into a second nonimaging layer that serves as the etch-resistant mask for final substrate etching. The initially formed image typically is replicated into the underlayer using a selective anisotropic etch step. By careful selection of etch chemistries and materials design, the final relief image can provide a robust barrier for the final image transfer. The added complexity of multilevel resist approaches compared with a single-layer resist process is a drawback but is offset by the advantages that accrue from (*1*) imaging very thin films, which eases the requirements for high transparency and reduces the impact on image quality of drifts in focus; and (*2*) forming thicker, high aspect ratio films, which improves the integrity of the protecting pattern while circumventing the problem of image collapse. Until now, the added complexity has generally outweighed the intrinsic benefits, and

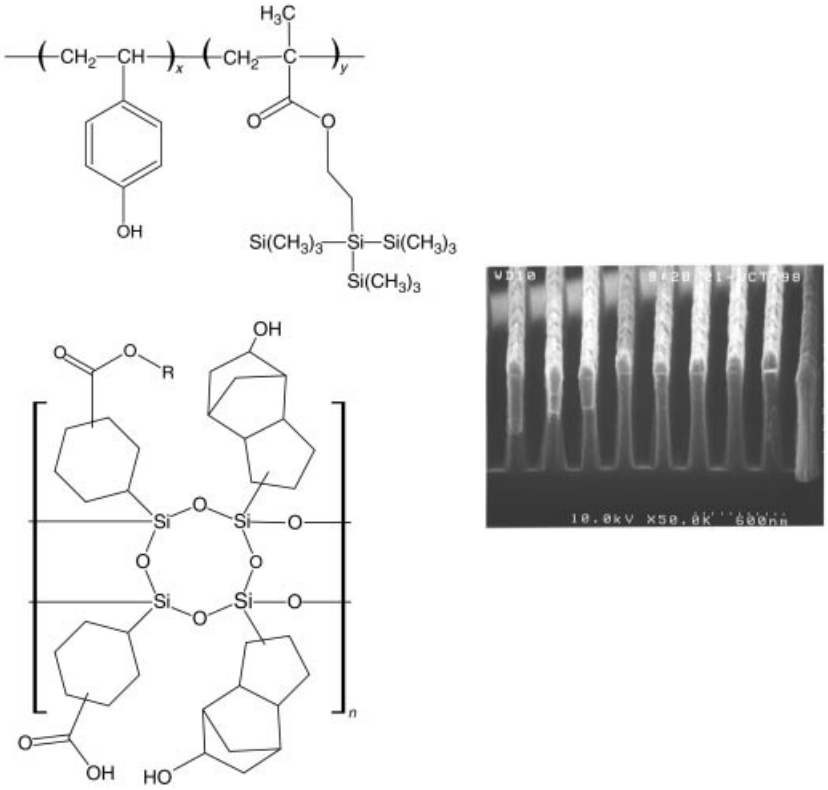

Fig. 20. Examples of silicon-containing polymers for use in bilayer resist formulations. The top structure is used in a 248-nm bilayer CA resist. The scanning electron micrograph shows the high aspect ratio images that can be obtained using 248-nm projection lithography with a bilayer resist based on this polymer. The bottom structure shows an example of a silicon-containing polymer designed for use in 193-nm lithography.

so multilevel resists have not yet seen widespread manufacturing use. The limited selection of polymeric materials suitable for 157-nm resist formulation has brought renewed interest in multilevel systems.

Figure 20 provides examples of silicon-containing polymers specifically designed for use in CA bilayer resists. Silsesquioxane polymers (eg, the lower structure in Fig. 20) have seen extensive use in bilayer resists developed for both 248- and 193-nm applications (142–144). Fluorocarbinol derivatives of silsesquioxanes have particularly good transparency at 157-nm wavelengths. Positive-tone resists can be prepared from such polymers by protecting the hydroxyl group with an acid-labile group such as *tert*-butoxycarbonate. Negative-tone silsesquioxane resists have been formulated by incorporating the acid-catalyzed cross-linking chemistry described earlier.

A high silicon content in the resin is advantageous as it provides the basis for etch selectivity in an oxygen plasma. When a thin film of a resist containing silicon is patterned atop a polymer underlayer containing no silicon, and then immersed in an oxygen plasma, the imaged film immediately forms a highly etch-resistant layer of SiO_2 while the unprotected underlayer rapidly erodes. In general, the greater the silicon content, the more effectively this silicon oxide barrier resists the

plasma. Using a specialized variant of plasma etching, termed reactive ion etching, the underlayer etch can be performed anisotropically, transferring the pattern of the top film vertically into the thick underlayer. The final etched bilayer pattern serves as a resist relief image useful for pattern transfer to substrate. Figure 20 provides an example of the high aspect ratio features that can be formed using bilayer imaging, in this instance using 248-nm lithography.

The TSI scheme shown in Figure 19 exploits the high optical absorption of the polymer to confine the imaging chemistry, and a subsequent reactive silylation step, to a thin layer at the top of the film. Since an oxygen plasma etching step is used to form the relief image, TSI offers benefits similar to the bilayer resist approach. In the past, pronounced line-edge roughness has restricted practical implementation of the TSI technique (145). Recent modifications to the reactive ion etch procedure and the transparency of the polymers employed in 193-nm imaging systems have been reported to minimize LER (146,147) and these efforts are being extended to the more challenging 157-nm TSI systems (148).

Resists for "Next-Generation Lithography" Applications. As recently as 1999, five different technologies were being evaluated as possible successors to optical lithography (149). Because of the economics and infrastructure of the semiconductor industry it is likely that only one or at most two different lithographic technologies can be fully developed and supported by the worldwide manufacturing community. The current consensus, based on a collection of factors including evaluations of the extensibility of each approach, is that extreme ultraviolet (EUV) lithography (17) will be the successor to 157-nm lithography for high volume manufacturing, and that electron projection lithography (EPL) (150,151) may be used in certain other types of manufacturing applications. On the basis of the projected brightness of the radiation sources, it is anticipated that CA resists will be a requirement for both exposure technologies.

Photolithography at EUV Wavelengths. EUV projection lithography uses light of wavelengths in the range of 10–14 nm (the soft x-ray region), produced by a plasma source. Since no materials have significant transmission at such wavelengths, EUV technology uses a series of curved mirrors and a reflective mask to project the light image. In this wavelength range the absorption coefficient of any material depends on the atomic weight percent and the density of each element in the absorbing material, and can be calculated from the mass absorption coefficients of the individual elements (17). Phenolic and acrylate-based resists absorb strongly at this wavelength (although less so than at 157 nm), and there is little likelihood that polymer structural modifications will lead to a significant increase in transparency at EUV wavelengths (152). As a consequence, current development is focused on developing hard mask processes (Fig. 19) that use 248 nm resists modified for higher EUV sensitivity, at thicknesses of 100–120 nm where transparency is adequate (141).

Resists for Electron-Beam Lithography. In *direct-write* electron-beam lithography a finely focused beam of high energy (1–100 keV) electrons is scanned in a pattern across a resist-coated substrate. This technique, used extensively in the manufacture of photomasks, is capable of exquisite resolution (~10 nm or less), but the serial nature of the exposure limits its throughput. A variant on this technique, termed *electron projection lithography* (EPL) (15,150), employs a thin membrane or stencil mask, patterned with a material that strongly scatters electrons, to project a high contrast image through an aperture onto the

resist-coated substrate. The inherent parallelism of this approach provides much higher throughput while maintaining some of the resolution capabilities of the direct write systems. EPL technology is now being refined for use in future semiconductor manufacturing.

At the high accelerating voltages commonly used, the exposing beam readily penetrates through the depth of a resist film, and so resist "transparency" is not considered an issue. Because the source current must be limited to suppress beam blur due to electron–electron repulsions, electron-beam lithographies targeted for high throughput (such as EPL) require very sensitive (CA) resists. To date, development activities for EPL resists have focused on the modification of existing 248-nm resist chemistries to enhance electron-beam sensitivity (153–155). On the basis of pulse radiolysis studies, it has been proposed that electron-beam irradiation of a CA electron-beam resist produces a polymer-based radical cation that undergoes an electron-transfer reaction with the PAG to produce an acidic product, akin to the electron-transfer sensitization mechanism proposed for dye sensitization in CA photoresists (156).

LIVING RADICAL POLYMERIZATION

Introduction

Conventional free-radical polymerization (FRP) is characterized by the continuous formation of radicals (initiation) and continuous disappearance of radicals (termination) (see RADICAL POLYMERIZATION). The statistical nature of the FRP process leads to relatively polydisperse polymers, with a typical instantaneous polydispersity index (PDI) of 1.5 or 2, depending on the mode of termination (1). The complete growth of an individual chain in FRP takes typically in the order of seconds. The molar mass distribution (MMD) of an FRP product consists of an accumulation of instantaneous MMDs formed over the course of the reaction. Hence the final PDI may have a value significantly larger than 1.5 or 2. FRP is a versatile technique that allows the polymerization of monomers with various functional groups. Furthermore, the polymerization can be carried out in a variety of reaction media, ranging from bulk monomer, via solution polymerization, to heterogeneous media, eg emulsion and suspension polymerization, and polymerization in supercritical carbon dioxide. One of the main disadvantages of FRP is the poor control over the microstructure of the synthesized macromolecules. This includes the relatively high PDI, and also the practical impossibility to synthesize block copolymers, and other advanced structures.

Advanced structures can be synthesized via living polymerization techniques. Notable example of these techniques is anionic polymerization (2), which is known to allow the synthesis of low PDI materials as well as block copolymers. The

main disadvantages of anionic polymerization are the limited choice of monomers, and the extremely demanding reaction conditions.

In order to overcome the disadvantages of FRP without sacrificing the above-mentioned advantages, it was recognized that a living character had to be realized in conjunction with the free-radical mechanism. At present three main mechanisms exist that ensure this living character by establishing an equilibrium between active (radical) and dormant chains. In a typical living radical polymerization (LRP), all chains are started early in the reaction, and are allowed to grow throughout the reaction. How this is achieved for individual LRPs will be detailed below. In general, the result of a successful LRP will be a polymer with low PDI, and predetermined (number-average) molar mass.

In this overview, the historical development of techniques will be summarized. In addition, the mechanisms and kinetics of the main three techniques will be highlighted. Finally, scope and limitations of the three techniques will be discussed on the basis of a number of examples.

Historical Overview

Probably the first publication that dealt with LRP already appeared in the late 1960s (3). In the 1970s and 1980s it was realized that the main drawback in FRP, ie, the broad polydispersities, and the inability to form block copolymers could be overcome by the introduction of reversible deactivation of the active radical. Otsu reported on several attempts to introduce this reversibility (4,5). The iniferter technique was developed, which comprises a UV-labile or thermally labile link that can be reversibly cleaved, and used for monomer insertion (6,7). Otsu showed that the technique allowed the synthesis of block copolymers, albeit with a PDI around 2. Currently it turns out that the iniferter technique may still have advantages over the more recent developments, eg when the synthesis of multiblock copolymers is aimed for (8).

In the mid-1980s, the first technique that relies on the reversible termination of radicals with a stable free radical was developed in the group of E. Rizzardo at CSIRO in Australia. Rizzardo and co-workers found that nitroxide-stable free radicals were able to add to carbon-centered radicals to form alkoxy amines (9). In certain cases these alkoxy amines are thermally unstable, so that they enter into an equilibrium between (transient) carbon-centered radical and (persistent) nitroxide radical on one side, and alkoxy amine on the other side. TEMPO was initially the most frequently used nitroxide in conjunction with the polymerization of styrene and its derivatives. The TEMPO–polystyrene adduct requires temperatures of 120°C or above in order to establish an equilibrium at which polymerization takes place. Around the mid-1990s Georges and co-workers focused on the TEMPO-mediated polymerization of styrene (10), and developed various strategies to overcome intrinsic weaknesses of the system. They used camphor sulfonic acid to enhance the rate of polymerization (11). This rate enhancement was later elucidated to be due to the destruction of excess nitroxide that builds up during the polymerization.

By the end of the 1990s, Hawker and Tordo independently developed alternative nitroxides that allowed polymerization at temperatures below 100°C, and also allowed the polymerization of acrylates (12,13).

A parallel development was initiated by the first publications from Sawamoto and Matyjaszweski. They reported independently on the transition-metal–catalyzed polymerization of various vinyl monomers (14,15). The technique, which was termed atom transfer radical polymerization (ATRP), uses an activated alkyl halide as initiator, and a transition-metal complex in its lower oxidation state as the catalyst. Similar to the nitroxide-mediated polymerization, ATRP is based on the reversible termination of growing radicals. ATRP was developed as an extension of atom transfer radical addition (ATRA), the so-called Kharasch reaction (16). ATRP turned out to be a versatile technique for the controlled polymerization of styrene derivatives, acrylates, methacrylates, etc. Because of the use of activated alkyl halides as initiators, the introduction of functional endgroups in the polymer chain turned out to be easy (17–22). Although many different transition metals have been used in ATRP, by far the most frequently used metal is copper. Nitrogen-based ligands, eg substituted bipyridines (14), alkyl pyridinimine (Schiff's base) (23), and multidentate tertiary alkyl amines (24), are used to solubilize the metal salt and to adjust its redox potential in order to match the requirements for an ATRP catalyst. In conjunction with copper, the most powerful ligand at present is probably tris[2-(dimethylamino)ethyl)]amine (Me_6-TREN) (25).

Many different polymer architectures have been synthesized via ATRP. These architectures include block copolymers (14), graft copolymers (26–29), star-branched polymers, etc. Some work was devoted to the reduction of the amount of catalyst used, or to the efficient removal of catalyst from the resulting polymer (30–33).

The third large development is, unlike nitroxide-mediated polymerization and ATRP, based on reversible chain transfer. Reversible degenerative chain transfer is a reaction in which chain-transfer activity is passed on from chain to chain. Although there are a number of examples of techniques that rely on this principle (34–37), the most noteworthy undoubtedly is reversible addition–fragmentation chain transfer (RAFT) (38,39). RAFT was developed by Rizzardo and co-workers in the late 1990s. Its most popular form makes use of thiocarbonylthio compounds that, depending on the activating substituent, can have very high chain-transfer values. Also, dependent on the activating substituent, the whole gamut of vinyl monomers can be polymerized in a controlled fashion, leading to low PDI materials. In contrast to NMP and ATRP, RAFT requires the continuous production of radicals to keep the polymerization going. Despite this continuous production of new chains, and the concomitant termination of growing chains, polymers with PDIs below 1.1 are readily achieved. Also, in this case, a wide range of polymer architectures has been synthesized.

Simultaneous with the first introduction of RAFT a similar development was introduced where specifically xanthates were employed as the reversible chain-transfer agent (40). The technique, called MADIX (macromolecular design via interchange of xanthates), can be seen as a special case of RAFT polymerization. Xanthates can be regarded as RAFT agents where the activating substituent is an alkoxy fragment. For most vinyl monomers, xanthates exhibit a low chain-transfer constant compared to some of the dithioesters. This leads to broader molar mass distributions, with PDIs around 2. A notable exception is the combination of vinyl esters with xanthates. Where it has proven very difficult to perform living polymerization of vinyl esters (eg vinyl acetate), the use of xanthates as RAFT agents

leads to poly(vinyl acetate) of predetermined molar mass, and low polydispersity (40).

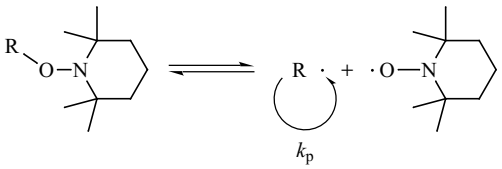
The latest development in living radical polymerization at this stage is the use of diphenylethylene (DPE) (41). In the continuous search for systems that lead to living polymerization in combination with a minimal disturbance of the conventional free-radical process, DPE could be an interesting alternative (42). There are specific difficulties associated with LRP in emulsion (see RADICAL POLYMERIZATION) (43). DPE, although not fully investigated yet, may prove to be a valuable addition to the existing LRP techniques.

Nitroxide-Mediated Polymerization (NMP)

Nitroxides have been investigated extensively to control the homo- and copolymerization of styrene. NMP proceeds via the reversible trapping of carbon-centered radicals as indicated in equation 1. The two most commonly used ways to start the polymerization are

(1) Generation of free radicals from a conventional free-radical initiator (eg, azo compound or peroxide), addition of one or a few monomer units, followed by trapping of the carbon-centered radical by the nitroxide compound (**1**). The trapping reaction produces an alkoxy amine, which contains a thermally labile C—O bond (44).

(2) Thermal decomposition of an alkoxy amine (**2**), which was synthesized in a separate reaction (45).



2 **1** (1)

Since the propagating species in LRP is a free radical, it may undergo the known reactions, including chain transfer and bimolecular termination. If bimolecular termination occurs, the equilibrium will gradually shift in the direction of the alkoxyamine. This is due to the gradual buildup of nitroxide. This process slows down the polymerization, and may lead to unacceptably long reaction times. Several approaches have been developed to overcome this phenomenon. In the early days of NMP, TEMPO was by far the most frequently used nitroxide. Because of the small equilibrium constant, the polymerization needed to be carried out at temperatures above 100°C. Under these conditions, styrene shows significant thermal (self)initiation. The presence of this additional radical source counterbalances the buildup of excess free nitroxide. Fukuda and co-workers measured the rate of TEMPO-mediated styrene polymerization, and found it to be identical to the conventional thermal polymerization of styrene (46). Workers at Xerox developed a method to increase the rate of polymerization by the addition

of camphor sulfonic acid (CSA) (11). Several explanations have been put forward for the mechanism of rate enhancement by CSA. Most likely the CSA degrades the excess free nitroxide, thus shifting the equilibrium more to the active species. An even more effective way to accelerate NMP consists of the addition of a slowly decomposing free-radical initiator (47,48).

Great improvements in NMP were brought about by the development of new nitroxides. Two independent groups worked on this topic. Tordo and co-workers developed β-phosponylated nitroxides, eg *N*-*tert*-butyl-*N*-(1-diethylphosphono-2,2-dimethylpropyl)nitroxide, which is commonly known as SG1 (13). Simultaneously, Hawker and co-workers synthesized a library of nitroxides and investigated their effectiveness in NMP (12). It turned out that the presence of a β-hydrogen greatly improves the performance of the nitroxide. *N*-*tert*-butyl-*N*-(1-diethylphosphono-2,2-dimethylpropyl)nitroxide and α-hydrido derivatives based on a 2,2,5-trimethyl-4-phenyl-3-azahexane-3-oxy skeleton, eg *N*-*tert*-butyl-*N*-(2-methyl-1-phenyl-propyl)nitroxide, both allow the NMP of acrylates. Furthermore, polymerization temperatures below 100°C are feasible, which greatly facilitates the use of NMP in emulsion polymerization. This will be discussed later.

In an NMP initiated by preformed alkoxyamines, the number-average degree of polymerization will be $\bar{P}_n = \Delta[M]/\left([R{-}T]_0 + 2\Delta[I]_0\right)$, where $[R{-}T]_0$ is the alkoxyamine at the start of the reaction, $\Delta[I]_0$ is the amount of (slowly decomposing) initiator converted (dissociated) and $\Delta[M]$ is the amount of monomer converted. The factor 2 associated with the amount of converted initiator accounts for the fact that one initiator molecule produces two radicals. This equation assumes the absence of chain-transfer reactions. Note that the occurrence of termination by disproportionation will not influence the number-average degree of polymerization, whereas termination by combination will lead to a (usually small) deviation from the predicted value. The PDI of the resulting polymer will obviously be influenced by the occurrence of any chain-breaking reaction (chain transfer or termination). Details on the prediction of the PDI will be given below.

In the group of Fischer, a considerable amount of work was dedicated to the kinetic description of NMP. They introduced the concept of the so-called persistent radical effect (PRE) (49,50). The PRE relies on the limited buildup of the concentration of deactivator, which in the case of NMP is the nitroxide, the persistent radical. On the basis of the PRE, it can be predicted which conditions will lead to narrow MMDs, and to a small fraction of irreversibly terminated "dead" chains.

Although many authors present linear relationships between $\ln([M]_0/[M])$ and time as one of the proofs that a polymerization is living, Fischer and co-workers show that $\ln([M]_0/[M])$ in many cases should scale with $t^{2/3}$, and that the persistent radical concentration increases with $t^{1/3}$.

In Figure 1 an experimental example from the work of Fischer's group is shown that obeys the kinetic relationship they introduced (51). If the kinetic model is accepted, the implication is a proper prediction of the PDI and the fraction of dead (irreversibly terminated) chains, etc. In other words, on the basis of kinetic parameters and relevant concentrations, a system can be optimized in terms of degree of livingness (low PDI and small fraction of dead chains).

For an overview of rate constants in NMP, the reader is referred to a review on the persistent radical effect by Fischer (52).

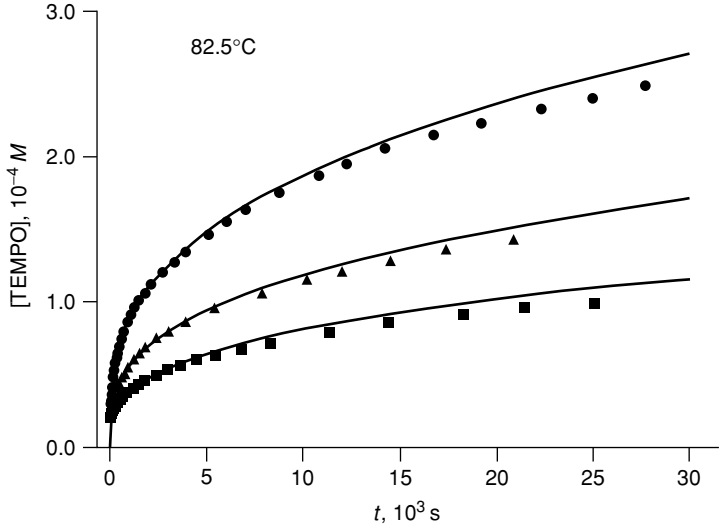


Fig. 1. Time dependence of the TEMPO concentration during thermolysis of cumyl–TEMPO: ● 1.16×10^{-2} M; ▲ 5.10×10^{-3} M; ■ 2.52×10^{-3} M.

Atom Transfer Radical Polymerization (ATRP)

ATRP is a more versatile technique than NMP, ie except for a few exceptions all vinyl monomers are susceptible to ATRP. Notable exceptions are unprotected acids (eg (meth)acrylic acid). Some other monomers may be difficult to polymerize since they exhibit side reactions, which may be affected by the choice of reaction conditions, nature of the catalyst, etc. An example of such a monomer is 4-vinyl pyridine (4-VP), which can undergo quaternization by the (alkyl halide) initiator (53). Nevertheless, successful polymerization of 4-VP has been reported.

In ATRP a transition-metal catalyst is used to reversibly activate halide-terminated dormant chains. The principal mechanism is outlined in equation 2.

$$\mathrm{R{-}X} + \mathrm{Cu^{(I)}X/ligand} \underset{+\mathrm{M}\ (k_p)}{\rightleftharpoons} \mathrm{R\cdot} + \mathrm{Cu^{(II)}X_2/ligand} \qquad (2)$$

The kinetic description of ATRP has received considerable attention. There is a similarity between the descriptions of NMP and of ATRP. Both rely on reversible activation of dormant chains, albeit the activation in the case of NMP is a unimolecular reaction whereas in the case of ATRP it is a bimolecular reaction. If the reaction medium is homogeneous, ie activator and deactivator are soluble in the reaction mixture, the monomer consumption as a function of time can be described as follows.

$$\ln\left(\frac{[\mathrm{M}]_0}{[\mathrm{M}]_t}\right) = \frac{k_\mathrm{p}k_\mathrm{a}[\mathrm{RX}]_0[\mathrm{Cu^I}]_0}{k_\mathrm{d}[\mathrm{Cu^{II}}]_0}t \tag{3}$$

$$\ln\left(\frac{[\mathrm{M}]_0}{[\mathrm{M}]_t}\right) = \frac{3}{2}k_p\left(\frac{k_\mathrm{a}[\mathrm{RX}]_0[\mathrm{Cu^I}]_0}{3\mathrm{k_d}\times 2k_\mathrm{t}}\right)^{1/3} t^{2/3} \tag{4}$$

Where $[\mathrm{M}]_0$ and $[\mathrm{M}]_t$ are the monomer concentrations at time zero and time t respectively. $[\mathrm{RX}]_0$ is the alkyl halide initiator concentration at time zero. $[\mathrm{Cu^I}]_0$ and $[\mathrm{Cu^{II}}]_0$ are the activator and deactivator concentrations, respectively, at time zero. $\mathrm{k_p}$ is the propagation rate constant, $\mathrm{k_a}$ is the activation rate constant, $\mathrm{k_d}$ is the deactivation rate constant, and $\mathrm{k_t}$ is the rate coefficient for bimolecular termination. Equation 3 applies to the situation where a pseudoequilibrium concentration of deactivator [Cu(II) in this case] is built up. In the case of many ATRP reactions where no deliberate addition of Cu(II) has taken place, equation 4 will provide a better match with experimental data. Fischer and co-workers have derived an expression for the concentration of deactivator necessary to switch from equation 4 to equation 3. The equation derived by Fischer reads (for ATRP):

$$[\mathrm{Cu^{(II)}}]_{0,t} = \sqrt{3K_\mathrm{eq}[\mathrm{RX}]_0[\mathrm{Cu^{(I)}}]_0\frac{k_\mathrm{t}}{k_\mathrm{p}}} \tag{5}$$

This theoretically derived concentration was experimentally confirmed in a study by Zhang and co-workers (54). In Figure 2, the experimental data as well as the theoretical fits to the data are shown from the study by Zhang. It is clear that the crossover from a $t^{2/3}$ to a linear dependence on time exactly coincides with the theoretical prediction. In the figure it is obvious that an inhibition period is observed, which increases with increasing concentration of Cu(II). The origin of the inhibition period is not completely clear.

In many cases the catalyst complex consists of a Cu(I) halide with multidentate aliphatic tertiary amines as ligands (eg *N*,*N*,*N*′,*N*″,*N*″-pentamethyl diethylene triamine, PMDETA). This ligand is cheap and provides relatively high rates of polymerization with still a reasonable degree of control. One of the peculiarities of this ligand is the fact that the Cu(II) complex has very limited solubility. In a study by Snijder and co-workers it is shown by ESR that a ceiling Cu(II) concentration is reached early in the polymerization of MMA. When this happens, the equations 1 and 2 no longer describe the monomer conversion versus time properly. On the basis of the experimental observation of constant deactivator concentration, Snijder derived a new expression that adequately describes monomer conversion versus time (55).

$$\ln\left(\frac{[\mathrm{M}]_0}{[\mathrm{M}]}\right) = \frac{k_\mathrm{p}[\mathrm{Cu^{II}X_2}]_c}{2k_\mathrm{tD}k_\mathrm{eq}}[3\xi t + [\mathrm{PX}]_0^{-3}]^{1/3} - \frac{k_\mathrm{p}[\mathrm{Cu^{II}X_2}]_c}{2k_\mathrm{tD}k_\mathrm{eq}[\mathrm{PX}]_0} \quad \text{with} \quad \xi = 2k_\mathrm{tD}\left(k_\mathrm{eq}/[\mathrm{Cu^{II}X_2}]_c\right)^2. \tag{6}$$

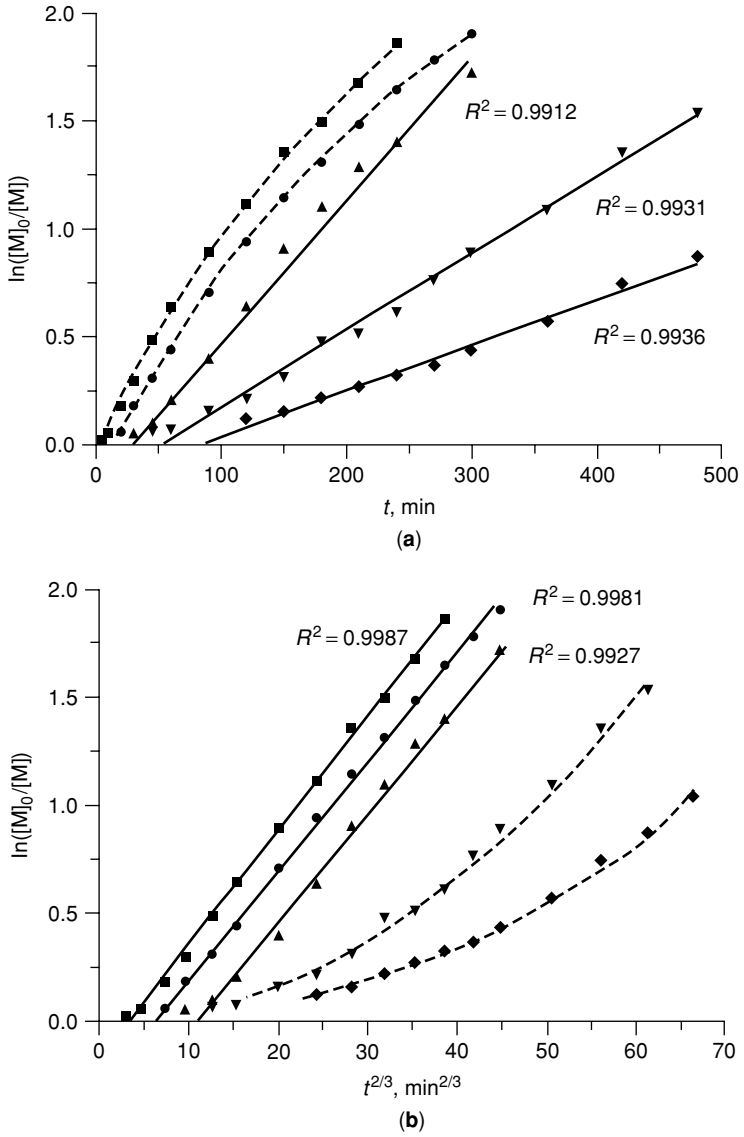

Fig. 2. Plots of $\ln([M]_0/[M])$ versus reaction time (t and $t^{2/3}$) for the ATRP of MMA in toluene at 90°C using different amounts of initially added $CuBr_2$. $[MMA]_0 = 2.8879\ M$, $[HEBIB]_0 = 0.0959\ M$, $[CuBr]_0 = [NHPMI]_0/3 = 0.0969\ M$. $[CuBr_2]_0/[CuBr]_0$: ■ 0; ● 0.05; ▲ 0.1; ▼, 0.2; ◆ 0.3.

As indicated above, the majority of work on ATRP has been conducted using copper as the transition metal. An enormous variety of nitrogen-based ligands have been used in conjunction with Cu(I) halide. The most popular ligands are

(1) Multidentate aliphatic tertiary amines (PMDETA, Me_6-TREN).
(2) Substituted bipyridines.
(3) Alkyl pyridylmethanimine.

The initial work by Matyjaszewski and co-workers largely concentrated on the use of substituted bipyridines (14). Although this ligand provides good living character to the polymerization, the rates of polymerization are quite low. In more recent work by Matyjaszewski and co-workers as well as in the research of other groups, more emphasis is placed on the use of multidentate aliphatic tertiary amines (24). The higher rates of polymerization, and to some extent the heterogeneous character of the polymerization, have certain advantages, which will be detailed under Scope and Limitations. The alkyl pyridylmethanimines were introduced by Haddleton and co-workers (23) and are mainly used for the polymerization of methacrylates.

Apart from copper-based complexes several other metals have been used as well. Fe (56–59), Ni (60), Ru (15), etc have been used to some extent. Especially noteworthy here is the work by Sawamoto and co-workers. As indicated in the Introduction, Sawamoto and Matyjaszewski simultaneously pioneered ATRP. Matyjaszewski started off with the use of copper, whereas Sawamoto spent most of his efforts on ruthenium-based catalysts. Recent work from Sawamoto and co-workers shows that the Ru-based complexes can compete with the Cu-based systems on many fronts. Although not yet perfect it seems that a specific Fe-based catalyst is the first to polymerize vinyl acetate via an ATRP mechanism (61).

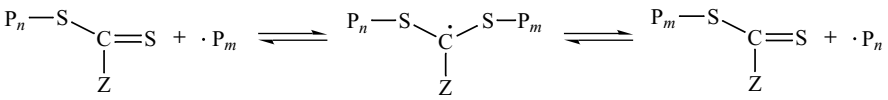
The initiation in ATRP may occur in one of two different ways. The common way to initiate is via the reaction of an activated (alkyl) halide with the transition-metal complex in its lower oxidation state. Typical examples would be the use of ethyl 2-bromoisobutyrate and a Cu(I) complex for the initiation of a methacrylate polymerization (62), or 1-phenylethyl chloride for the initiation of a styrene polymerization (14). In addition, there are initiators like 2,2,2-trichloro-ethanol (63) that appear to be very efficient, and that result in hydroxy-functional polymer chains. Percec and co-workers reported on the use of sulfonyl chlorides as universal initiators in ATRP (64). Also the use of di-, tri-, or multifunctional initiators is possible, which will result in polymers growing in two, three, or more directions. All these variations open up possibilities to well-defined architectures.

The alternative way to initiate ATRP is via a conventional free-radical initiator, which is used in conjunction with a transition-metal complex in its higher oxidation state. Typically one would use AIBN in conjunction with a Cu(II) complex. Upon formation of the primary radicals and/or their adducts with a monomer unit, the Cu(II) complex very efficiently transfers a halogen to this newly formed chain. In doing so the copper complex is reduced, and the active chain is deactivated. It is easily envisaged that the system will arrive at the same equilibrium as depicted in equation 2, but now approaching it from the right-hand side. This alternative way of initiation was termed “reverse ATRP” (65,66).

Reversible Addition–Fragmentation Chain Transfer (RAFT)

In terms of polymerizable monomers, RAFT is at present the most versatile technique for conducting LRP. In contrast to the previously described NMP and ATRP, this system relies on chain transfer for the exchange between active and dormant chains. The chain end of a dormant chain carries a thiocarbonylthio moiety, which is chain-transfer–active. Upon chain transfer, the thiocarbonylthio

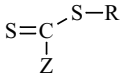
moiety is transferred to the previously active chain, which now becomes dormant, and the previously dormant chain carries the radical activity and is able to propagate. In equation 7, the basic mechanism of this exchange reaction via chain transfer is depicted. As can be seen in equation 7, in between the two states of dormant and active chains there is an intermediate radical, which will undergo the subsequent fragmentation reaction (67). In the present literature there is some controversy about the possible fates of this intermediate radical. Starting point of the controversy is an observed retardation in some examples of RAFT polymerization compared to the equivalent free-radical polymerization in the absence of the RAFT agent. Davis and co-workers explain the retardation by a slow rate of fragmentation, which leads to the buildup of a relatively large concentration of (intermediate) radicals (68,69). On the other hand, Monteiro and co-workers explain the retardation by irreversible termination of the intermediate radical (70). The remarkable point about this controversy is that the difference in the rate constants of fragmentation between Davis' and Monteiro's approaches is some 7 orders of magnitude. Fukuda and co-workers carried out independent rate measurements, which seem to support Monteiro's view (71). However, at present nobody has ever been able to detect the presence of three- or four-armed stars, which should result from the intermediate radical termination.



(7)

A whole variety of thiocarbonylthio compounds have been synthesized and used in RAFT polymerization. The initial work was focused to some extent on the use of dithioesters. More recently the range of RAFT agents is expanded to trithiocarbonates, dithiocarbamates, and xanthates.

To some extent the choice of RAFT agent determines the degree of control obtained. The general structure of a RAFT agent can be depicted as in structure (**3**), where the Z group is the activating group, and R is the homolytically leaving group.



To a large extent the Z group determines the rate of addition, and the R group determines the rate of fragmentation. The choice of Z and R groups is dependent on the nature of the monomer to be polymerized. In Figure 3 an overview is given of different Z and R groups and the monomers that can be polymerized in a controlled fashion using these Z and R groups (72).

Although already in the initial patent from CSIRO the application of RAFT in emulsion is reported (38), it appeared to be quite troublesome to carry out a well-controlled reaction in emulsion.

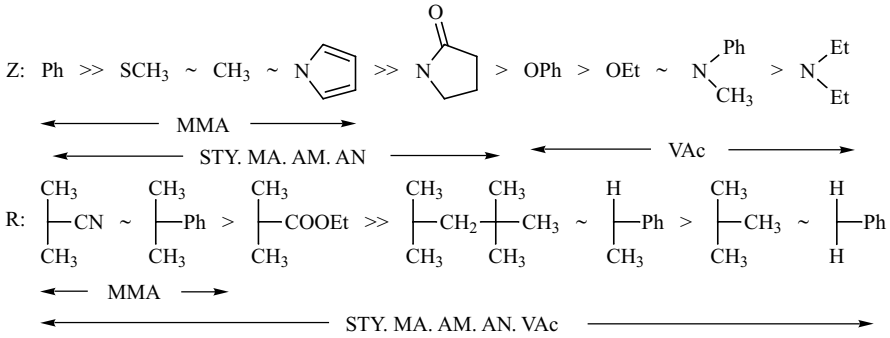


Fig. 3. Requirements for Z and R groups of RAFT agent for the controlled polymerization of styrene (STY), methyl methacrylate (MMA), methyl acrylate (MA), acrylamide (AM), acrylonitrile (AN), and vinyl acetate (VAc).

Scope and Limitations

Living radical polymerization (LRP) is developed on the basis of conventional free-radical polymerization (FRP). The main idea behind this development is to overcome intrinsic shortcomings of FRP without sacrificing any of its strengths. These strengths are

(1) Wide range of monomers, including functional ones (hydroxyl, epoxy, carboxylic acid, etc.).
(2) Nondemanding in terms of reaction conditions.
(3) Widely applied in academia as well as in industry for (co)polymer synthesis.

The intrinsic shortcomings are

(1) Poor control over chain length (distribution).
(2) Poor control over chain topology (block copolymers and more advanced topologies are virtually impossible to synthesize efficiently).
(3) No, or hardly any, control over tacticity.

To what extent did the efforts in LRP up till now lead to success in overcoming the shortcomings of FRP? The one shortcoming that has only been solved very recently is the control over tacticity. Matyjaszewski and co-workers have recently shown that the addition of lanthanides to an ATRP results in control over tacticity (73).

Various classes of monomers have been polymerized via LRP. Styrene and its derivatives can be polymerized using any of the three main techniques. Under the appropriate conditions NMP, ATRP, and RAFT all lead to polymers with a predetermined molar mass, and a low PDI. Also the synthesis of block copolymers where one of the blocks is poly(STY) has successfully been accomplished. Styrene is the monomer that poses the smallest demands on the choice of nitroxide in NMP. TEMPO has been used frequently, but

one requires relatively high reaction temperatures (125–140°C). When *N-tert*-butyl-*N*-(1-diethylphosphono-2,2-dimethylpropyl)nitroxide or *N-tert*-butyl-*N*-(2-methyl-1-phenyl-propyl)nitroxide is used, the reaction temperature can be lowered to 80–90°C. Similarly, in ATRP a wide variety of transition-metal complexes can be used in combination with a large selection of initiators. Styrene appears to posses an equilibrium constant for the activation–deactivation equilibrium, which is quite favorable for conducting these reactions. Finally, for RAFT also, the choice of RAFT agent is not very critical in the degree of success obtained. Usually, large chain-transfer rate constants are obtained, which results in polymers with low PDIs.

Methacrylates form an important class of monomers. They are available with a large number of different ester side groups. NMP is not capable of polymerizing methacrylates in a controlled fashion. Most frequently the nitroxide will undergo a disproportionation reaction, with the propagating radical leading to a dead polymer chain with an unsaturated chain end and a hydroxylamine.

ATRP can in general be carried out on methacrylates. The initial work on MMA polymerization was reported by the group of Matyjaszewski (62), including work on high molar mass polymer (74), detailed kinetics (75), and on substituted methacrylates (76–78). Haddleton and co-workers focused largely on the polymerization of methacrylates, and used most frequently alkyl pyridylmethanimine ligands with copper halide as the catalyst. The only occasion where ATRP on methacrylates leads to difficulties is when the ester side chain contains functional groups that interfere with the copper complex. Many other groups have investigated the polymerization of methacrylates. A variety of transition-metal complexes have been utilized for this purpose. The parent compound of methacrylates (methacrylic acid) cannot be polymerized as such via ATRP. Armes and coworkers showed that the sodium salt of methacrylic acid can be polymerized in aqueous media (79). Other groups used approaches where the acid functionality is protected via various methodologies, eg via *tert*-butyl ester, via trimethylsilyl ester, or via the tetrahydropyranyl ester (80).

RAFT is probably the most versatile technique to polymerize methacrylates. Regardless of the nature of the ester side group, RAFT can be employed for the LRP of methacrylates. Also, methacrylic acid can be polymerized without protecting group chemistry. There are some requirements in terms of activating Z group and homolytically leaving R group of the RAFT agent that have to be met in order to have a successful polymerization.

Acrylates can be polymerized using NMP when the proper nitroxide is employed. *N-tert*-butyl-*N*-(1-diethylphosphono-2,2-dimethylpropyl)nitroxide and *N-tert*-butyl-*N*-(2-methyl-1-phenyl-propyl)nitroxide were proven to be capable of controlling the polymerization of butylacrylate.

ATRP of acrylates is easily achieved. The equilibrium between active and dormant chains is much more to the dormant side. This results in relatively low rates of polymerization even though the propagation rate constant of acrylates is quite large. Methacrylate polymerizations, although having a much smaller propagation rate constant, proceed faster in ATRP than do acrylate polymerizations under identical conditions. In general, polyacrylates will posses a somewhat larger PDI than polymethacrylates synthesized via ATRP, especially at low molar mass. The main reason of this phenomenon is that during an activation–deactivation

cycle acrylates will undergo multiple monomer additions, whereas methacrylates will only undergo single monomer addition. In the long chain limit this effect will diminish. Also, in the case of acrylates, acrylic acid can only be polymerized in the nonprotonated form (sodium salt or protected as indicated above).

Similar to the polymerization of methacrylates, acrylates can easily be polymerized using RAFT. In this case the choice of RAFT agent is less critical, and functional groups (including acid) are not known or expected to result in any problems. The only point of caution is that depending on the choice of the RAFT agent significant retardation or inhibition may occur.

Butadiene and isoprene have to date only been polymerized in a living radical fashion via NMP (81). The group of Hawker has shown that nitroxides with an alpha C—H bond to the nitrogen can successfully be applied in the polymerization of dienes. The result is a linear increase of molar mass with conversion, and a PDI below 1.1.

Vinyl acetate is the monomer that has required significant efforts in order to achieve LRP. The first successful attempt was using RAFT with xanthates as a RAFT agent (also known as MADIX). At a later stage it turned out that certain dithiocarbamates also were able to induce LRP of vinyl acetate. Of all the attempts to polymerize VAc using ATRP, only specific iron complexes used by Sawamoto and co-workers were claimed to be successful (61). However, the PDIs they claimed were relatively large compared to other monomer/catalyst combinations.

Although the synthesis of polymers with narrow molar mass distributions is interesting from an academic point of view, the potential applications are more likely to be found in polymers with specific topologies. The most basic topology in reach of LRP is the block copolymer. Although it may occur as a trivial exercise to synthesize an A–B block copolymer, there are some precautions that need to be taken into account. The trivial one is that a maximum degree of livingness should be obtained for the first block. In general this requires some limitations to the maximum conversion in the synthesis of the first block. The probability of bimolecular termination significantly increases if the polymerization would be carried out to (almost) complete monomer conversion. The other important precaution concerns the sequence of block copolymer synthesis. Whether A–B or B–A is the preferred sequence mainly depends on the rate of initiation of the second monomer by the first block macroinitiator. As an example, when poly(STY-*b*-MMA) is the target structure, it is either the initiation of STY polymerization by the poly(MMA) macroinitiator or the initiation of MMA polymerization by the poly(STY) macroinitiator. In the case of ATRP as the LRP technique of choice, and without the use of any advanced techniques (which will be outlined below) initiation versus propagation needs to be studied. For the proper synthesis of a block copolymer a clean transition is required. Hence, initiation should be fast compared to propagation. When poly(STY) is used to initiate MMA this requirement is not met. Initiation is relatively slow, since for poly(STY) the activation–deactivation equilibrium lies strongly to the dormant side. To some extent this means that each chain that has undergone the transition to block copolymer is more reactive than the poly(STY) macroinitiator. The former chains will start to grow with a relatively high rate whereas the remaining macroinitiators still wait to be activated. The result is a broad molar mass distribution, or in the case of a low molar mass poly(MMA) block, a large fraction of unreacted poly(STY) macroinitiator.

Conversely, when poly(MMA) is used as a macroinitiator, initiation is relatively fast since the equilibrium between active and dormant chains lies more to the active side. The chains that get converted into block copolymer are less reactive in this case. In the limit it can be explained as a situation in which all the macroinitiators get converted into block copolymer before the chain growth of the second block [poly(STY)] commences.

As indicated above, this scenario holds for ATRP when no special techniques are invoked. There is one relatively straightforward technique to circumvent this forced order of block copolymer synthesis. This technique is called halogen-exchange (83). It relies on the difference in bond strength between an alkyl chloride and an alkyl bromide. The carbon–bromine bond is weaker than the carbon–chlorine bond. The result of this in a so-called mixed halogen system is that carbon–chlorine bonds are preferentially formed. In halogen exchange experiments, this phenomenon is used to slow down propagation relative to initiation. In practice this would mean that poly(STY) is synthesized from a bromine functional initiator using copper(I) bromide as the catalyst. In the second step, where MMA is polymerized, the bromine functional poly(STY) macroinitiator is used in conjunction with copper(I) chloride. The macroinitiator chain gets activated and adds an MMA unit. Subsequently, it is deactivated by $CuCl_2$ (or CuClBr), which results in the formation of a carbon - chlorine bond, and thus a chlorine functional dormant block copolymer chain. Because of the difference in bond strength, the poly(STY)—Br is now more reactive than the poly(STY-*b*-MMA)—Cl. Hence, all the macroinitiator gets converted into dormant block copolymer chains, followed by propagation of the MMA block. Initially, the work by Matyjaszewski and co-workers on halogen exchange strongly emphasized the negative effect on propagation rate. This obviously leads to an increased ratio of initiation rate to propagation rate. At a later stage it was shown by Klumperman and co-workers that, apart from the effect on propagation rate, the use of copper chloride also leads to an increased rate of initiation (larger value of the activation rate constant of a bromine functional macroinitiator).

In Figure 4 it is shown how halogen exchange in block copolymer synthesis influences the resulting molar mass distributions (82).

Advanced Architectures

As indicated above, conventional free-radical polymerization is not very well suited for the synthesis of advanced polymer architectures. Even the synthesis of di- or triblock copolymers is hardly possible using this technique. The main reason is the continuous initiation and termination of chains. This results in the early generation of dead polymer chains that no longer participate in the polymerization process. The consecutive addition of monomers as employed in living anionic polymerization for the synthesis of eg poly(styrene-*block*-butadiene) will only lead to the synthesis of a mixture of two homopolymers.

Advanced architectures are possible via LRP. A large fraction of the chains in an LRP will grow throughout the polymerization process. The subsequent addition of a second monomer will lead to the formation of a block copolymer. Various examples of this process can be found in recent literature employing any of the

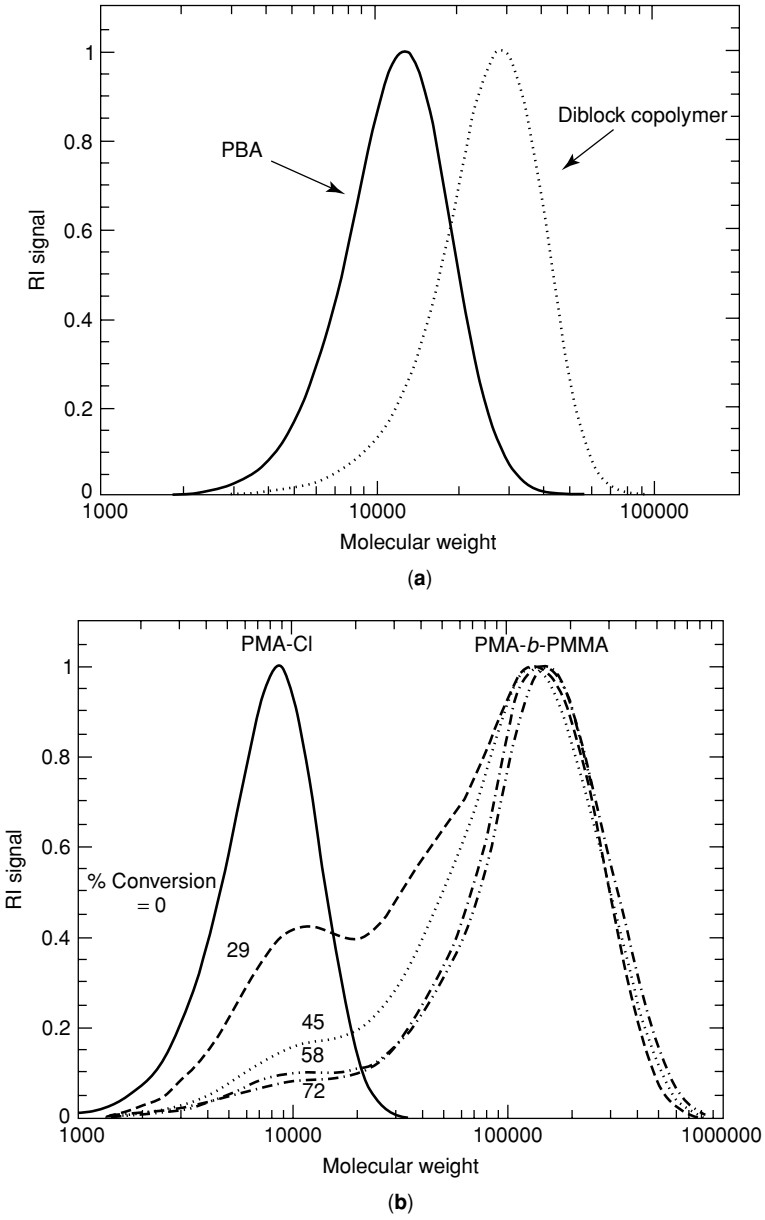

Fig. 4. Effect of halogen exchange on the molar mass distribution of an acrylate–methacrylate diblock copolymer. (**a**) Poly(BA-*b*-MMA) with halogen exchange; (**b**). Poly(MA-*b*-MMA) without halogen exchange (82).

known techniques ATRP, NMP, or RAFT (84,85). As indicated above, the sequence of the synthesis of a block copolymer may have a large influence on the degree of control.

The synthesis of an A—B—C triblock copolymer can be realized using an analogous procedure (86). Also, in this case the sequence of the comonomer additions

will influence the final result. However, in this case monomer B needs to be incorporated as the second block. Smart strategies, which include the proper choice of comonomer sequence and the possibility to employ halogen exchange in ATRP, are needed to optimize the resulting block copolymer. If the triblock copolymer is a symmetrical A–B–A copolymer, the most commonly employed synthetic strategy is the use of a difunctional initiator (NMP or ATRP) or transfer agent (RAFT). This allows the growth of the central B-block in two directions, and the subsequent addition of monomer A to synthesize the outer blocks. Here obviously the same precautions and limitations apply as in the synthesis of A–B diblock copolymers.

One of the more or less unique features of LRP in the synthesis of block copolymers is the possibility to incorporate a statistical copolymer as one of the blocks. Because of the very favorable reactivity ratios in radical polymerization compared to ionic polymerizations this is more easily achieved in LRP than in eg anionic polymerization. If the statistical copolymer is synthesized at its azeotropic conditions, there is little difference with the synthesis of a homopolymer block. If polymerization would take place under nonazeotropic conditions, the usual precautions need to be taken to avoid composition drift.

On the other hand, composition drift can be employed in LRP to synthesize gradient (or tapered) copolymers (87). The prediction of the composition drift can be carried out in exact analogy with composition drift in conventional free-radical copolymerization. The only, but important, difference is that in the case of LRP, the composition drift is superimposed on the growth of each individual chain. This then automatically leads to the formation of a gradient copolymer. In extraordinary cases the composition drift is such that a spontaneous block copolymerization will take place. One example that has been published in this regard is the synthesis of a poly(styrene-*block*-(styrene-*alt*-maleic anydride)). When a polymerization is started at a STY to MAnh molar ratio of 75:25, a copolymer with close to alternating monomer sequence is formed. This leads to a relatively fast depletion of MAnh, with the excess STY forming a homopolymer block. For the synthesis of alternating copolymers it turns out that the commonly used strategy in FRP of adding a Lewis acid to the copolymerization of styrene and acrylates can also be employed in ATRP (88)

Another class of architectures in reach of LRP are the so-called hyperbranched structures (see HYPERBRANCHED POLYMERS). The well known limit of these hyperbranched structures are dendrimers, where the consecutive growth of the polymer leads to (nearly) perfect globular macromolecules. The synthesis of dendrimers usually is a tedious multistep organic reaction. In the case of LRP, where monomers are polymerized that carry an initiator functionality as well, the synthetic procedure is quite straightforward. Examples have been reported on the basis of NMP (89) as well as on the basis of ATRP (90,91). It is very important to tailor the reactivities of initiator and monomer in this application. Two limiting cases can be recognized in that sense. If initiation is slow compared to propagation, linear chains will be formed that carry the initiator functionalities as pendent groups. In principle these polymers could be used for the synthesis of densely grafted polymers as described below. On the other hand, if initiation is very fast compared to propagation, monomers will be enchained in linear chains as well, but the polymer backbone now has a completely different architecture. In Figure 5, the two modes of polymerization are illustrated using *para*-vinylbenzylchloride.

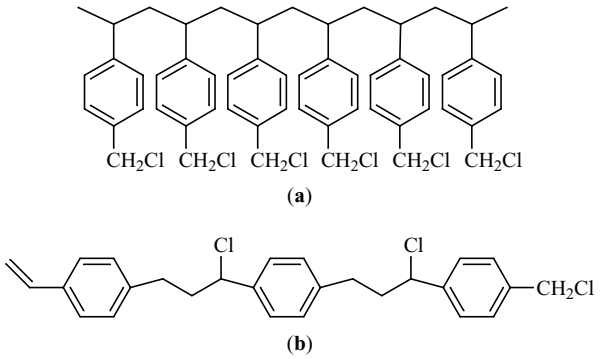

Fig. 5. Two modes of polymerization of *para*-vinylbenzylchloride, resulting from (**a**) fast propagation compared to initiation, and from (**b**) fast initiation compared to propagation.

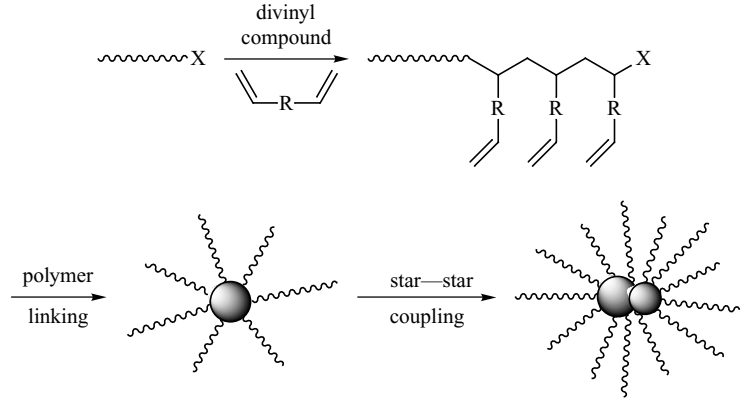

Fig. 6. Synthesis of star polymers via the "arm first" strategy (94).

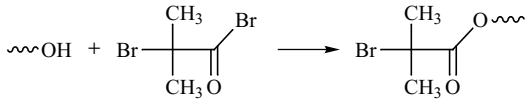
It needs to be stressed that Figure 5 shows the hypothetical two extreme cases outlined above.

The first examples of star polymers synthesized via LRP were reported by Matyjaszewski and co-workers (92,93). At a later stage they reported on the synthesis of star polymers via the so-called arm first procedure (94). In this approach polymer chains are synthesized with a reactive chain end that allows coupling to the core of the star (Fig. 6).

The statistical nature of the growth process of the hyperbranched structures will inevitably lead to a relatively large variation in degree of branching. The closest one could get to a dendritic structure is by carefully matching the initiation and propagation rates. Here it needs to be taken into account that in the example shown in Figure 5, the initial primary halide will be turned into a secondary halide after the first monomer addition. This will greatly affect its activation–deactivation equilibrium. Alternatives to true hyperbranched structures in some applications are star-branched structures with a fixed and known number of arms. In LRP these structures are readily accessible via multifunctional

initiators or transfer agents. Examples have been published using NMP, but more notably using ATRP. In the work of Matyjaszewski it has been shown that any hydroxy functionality can be turned into an ATRP initiator via esterification using 2-bromo-2-methyl-propionyl bromide, as indicated in equation 8 (95).



(8)

This approach was used by Haddleton and co-workers to synthesize multifunctional initiators and subsequently multiarm stars by using various sugars (96), and cyclodextrin (21-arm star) (97). The general advantages of LRP techniques also apply to the synthesis of the multiarm stars. This includes the possibility to synthesize block copolymer arms, gradient polymer arms, etc. One of the potential drawbacks is the enhanced tendency toward bimolecular termination, which in the case of termination by coupling leads to star–star coupling. It will be evident that the step from star–star coupling to network formation or cross-linking (gelation) is only a relatively minor one.

The final architecture that will be discussed here is that of densely grafted polymer chains. If the process described for the formation of hyperbranched structures is turned into a two-step process, it is possible to synthesize chains that contain a branch on each repeat unit of the polymer backbone. Because of the great steric congestion, these structures will behave like a rigid rod. The first example of a densely grafted polymer chain completely via LRP (ATRP) is based on the polymerization of trimethylsilyl-protected 2-hydroxyethyl methacrylate (HEMA-TMS) (77). In a post-polymerization reaction the trimethylsilyl groups are removed and the resulting hydroxy functionalities are turned into ATRP initiators by reaction with 2-bromoisobutyryl bromide to yield poly-(2-(2-bromoisobutyryloxy)ethyl methacrylate) (pBIEM). Subsequently, the densely grafted structure was obtained by polymerizing styrene or butyl acrylate as side chains from the initial backbone (pBIEM). In Figure 7 typical examples of these rigid rod structures are shown as observed by Atomic Force Microscopy (qv) (AFM).

Combined Mechanisms

LRP is a powerful tool for the synthesis of complex polymer architectures as was shown above. However, in some cases it is desirable to combine structures that are hardly or not at all accessible via radical polymerization techniques. In such cases it may be beneficial to combine LRP with another polymerization mechanism. Many examples have been reported so far. A few examples will be listed here. Polystyrene-*b*-polyisobutylene-*b*-polystyrene was synthesized via a combination of living cationic polymerization and ATRP (98). Polyolefin Graft Copolymers (qv) were synthesized by first polymerizing alkoxyamine-substituted olefins via metallocene catalysis, and subsequent polymerization of vinyl monomers via

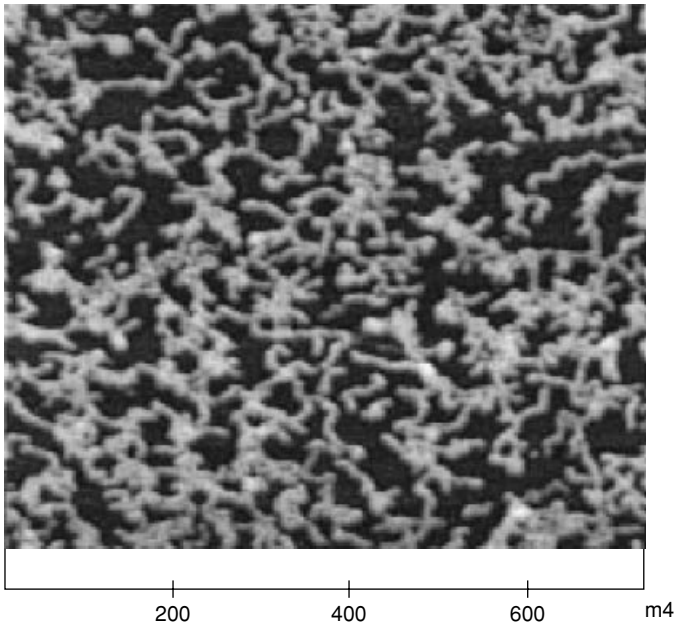


Fig. 7. AFM image of a densely grafted copolymer. Polystyrene grafted from pBIEM ($M_n = 55{,}500$; $M_w/M_n = 1.3$).

NMP (99). Living ring-opening polymerization of ε-caprolactone and lactides was combined with various LRP techniques (100). An approach to synthesize vinyl polymers with poly(vinyl ether) grafts is to make use of macromonomers. Cationic polymerization is used to synthesize the macromonomers with a methacryloyl pendent group. The macromonomers are then copolymerized via ATRP (101). Poly(ε-caprolactone)-graft-poly(methyl methacrylate) copolymers are prepared by the (co)polymerization of a cyclic ester containing an activated bromide functional group [γ-(2-bromo-2-methylpropionyloxy)-ε-caprolactone]. The activated bromide functionality is subsequently used to introduce the PMMA side chains via ATRP (102). Anionic Polymerization (qv) and ATRP are combined to synthesize eg A–B–C triblock copolymers (103). The same group demonstrated the versatility of end-group modification of various polymers into ATRP initiators (104,105). It needs to be stressed that this approach has been adopted by many research groups, and that probably the first attempts were published by Matyjaszewski and co-workers (18). Polyisoprene-*b*-polystyrene with a single fluorescent label at the junction between the two blocks is reported by Winnik and co-workers (106). They also use a combination of anionic polymerization and ATRP. Finally, LRP can be combined with enzymatic polymerization as shown by Meyer and co-workers (107). They use a bifunctional initiator (benzyl-3-(2-bromo-2-methylpropionyloxy)-2-hydroxymethyl-2-methylpropionate) with a primary hydroxy functionality to initiate the enzymatic ring-opening polymerization of ε-caprolactone, and an activated bromide functionality to initiate ATRP.

LRP in Emulsion

One of the great advantages of conventional FRP is the fact that the polymerization can be conducted in aqueous environment, viz suspension polymerization, emulsion polymerization (see HETEROPHASE POLYMERIZATION). Soon after LRP was first published, investigations were started to allow LRP to be carried out in aqueous media as well. This turned out to be far from trivial. Recently, the efforts to conduct LRP in emulsion were reviewed (108).

Bon and co-workers were the first to publish a successful attempt toward TEMPO-mediated LRP in emulsion (109). This first work was far from optimal, since it only worked in seeded emulsion polymerization, and temperatures above 100°C were required to obtain a dynamic equilibrium between dormant and active species. NMP improved quite significantly with respect to its applicability in emulsion polymerization when the above-mentioned developments led to polymerization temperatures below 100°C. Notable in this respect was the work by Charleux and co-workers, who employed *N*-*tert*-butyl-*N*-(1-diethylphosphono-2,2-dimethylpropyl)nitroxide as the mediating nitroxide for the LRP of styrene and butyl acrylate in emulsion (110,111).

ATRP in emulsion (112–116) and miniemulsion (117) was mainly investigated by Matyjaszewski and co-workers. The difficulties to remove the copper catalyst from the latex, and the low stability of the obtained latex were among the structural difficulties to develop an attractive alternative to the NMP-based systems.

RAFT polymerization in emulsion (118–121) and miniemulsion (122–125) received considerable attention. The initial results were not very promising. In many instances the stability of the emulsion during polymerization was very poor. Phase separation was often observed where the typical red color of the RAFT agent would disappear from the emulsion and form a sticky red layer on top of the emulsion. One of the alternatives to overcome this problem was the application of miniemulsion polymerization. In this technique, micron-size monomer droplets are absent. All the monomer is dispersed in submicron droplets, which are transformed into latex particles during the polymerization process. Stable latexes were obtained in a number of cases, where the polymers possess a reasonably narrow molar mass distribution. The disadvantage of miniemulsion polymerization is that relatively high surfactant concentrations and the use of a so-called cosurfactant or hydrophobe is required. It is therefore that further research was conducted to develop a strategy that allows LRP in conventional emulsion. At present the most successful attempt seems to be a two-stage process (126) in which a water-soluble monomer, eg acrylic acid, is polymerized in the presence of a RAFT agent in aqueous media. This polymerization is only conducted up to low molar mass. Subsequently, a monomer with low water solubility is dispersed in the reaction mixture, and further polymerization is carried out to yield a stable latex. Formally the polymer is a diblock copolymer, albeit with a short hydrophilic block. The polymer has a relatively low PDI.

The use of RAFT agents with a low activity (120,121) ie a low chain-transfer constant is another option that provides useful results. Xanthates represent a class of RAFT agents that are useful in this respect. The majority of polymer chains in such a system carry the xanthate as an end group. However, because of the

low chain-transfer constant the PDI of the polymer is around 2. In principle, the polymers can be used for chain extension, and for the synthesis of block copolymers (qv).

The final system that is worth mentioning in this chapter on LRP in emulsion is the use of 1,1-diphenylethylene (DPE) (127). DPE adds to a growing radical and forms a radical with a reactivity too low for propagation. The exact mechanism is not elucidated, but the incorporation of DPE leads to a chain that allows chain extension or block copolymer formation. More or less similar to what was described about the xanthates in RAFT polymerization, here also the molar mass distributions are relatively broad. The greatest advantage of DPE-mediated polymerization is the fact that it results in minimal disturbance of the polymerization process. The product latex does not contain any unusual extractable material (like the catalyst in ATRP), or polymer-bound colored moieties (like the thiocarbonylthio compound in RAFT). The obvious drawback is the limited control over chain architecture, and the limited understanding of the mechanistic details.

Future Directions

Presently, significant work has been done to develop and optimize various LRP techniques. Commercial applications are still scarce. The general expectation is that the products of LRP will mainly be employed in high-value-added products. These may include specialty coatings, adhesives, personal care products, biomedical applications, and optoelectronical applications. Examples of biomedical applications can be found in the work of eg, Müller (128), Haddleton (129), and Wooley (130,131). For materials in optoelectronical applications it is of great importance that many of the techniques from FRP can be adopted to LRP. An example is surface grafting from or onto various substrates, like silica (132) and gold (133). Much of the work of Hawker and co-workers is dedicated to the application of LRP in electronical applications (134).

MAGNETIC POLYMERS

Introduction

Typical behavior of small molecules or metal ions with unpaired electrons is that of a paramagnet, ie, magnetic interactions within the large ensemble of electron spins are negligible and a large external magnetic field is required to even partially align the electron spins. For ferromagnetism and other technologically useful types of magnetism, the quantum mechanical exchange interaction between electron spins is a prerequisite (1). In a ferromagnet, the exchange interactions within a three-dimensional structure align the spins in one direction, producing a large magnetic moment in magnetic domains of more than 10^4 electron spins, even in the absence of external magnetic field. The strength of this exchange interaction determines the *Curie temperature* (T_C), that is, the temperature above which the magnetic ordering is destroyed and the material becomes paramagnetic (1). (Analogously, T_C is referred to as ferrimagnetic Curie temperature in ferrimagnets).

Traditional magnetic materials are based upon metals (and metal ions) with partially filled *d*- and *f*-shells, ie, selected metals, metal alloys, and ceramics. Composite materials such as organic polymers filled with small metallic or inorganic magnetic particles fall into similar category (2).

The relatively recent magnetic materials, in which organic radicals function as the source of electron spin, are organometallic magnets and organic magnets. In organometallic magnets, the exchange interaction occurs between organic radicals or radical anions and metal ions. Many of such materials may be viewed as one-, two-, or three-dimensional coordination polymers (3–5). In organic magnets, based upon molecular solids of organic radicals (or radical ions), exchange interactions occur between molecules with unpaired electrons. Because

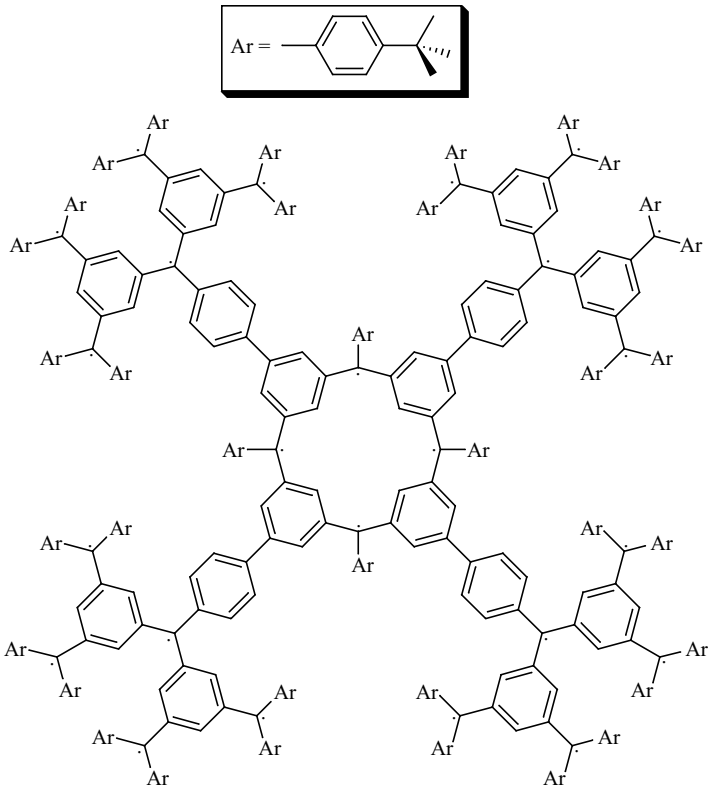
such through-space interactions are inherently weak, the T_C's for organic ferromagnets are typically below 2 K, with the exception of the C_{60}-TDAE [TDAE = tetrakis(dimethylamine)ethylene] radical ion salt which has $T_C = 16$ K (6–8).

Organic polymers, in which exchange interactions between radicals are mediated by π-conjugated system, provide an alternative approach to organic magnets. As early as 1968, Mataga proposed few structures for plausible one- and two-dimensional "ferromagnetic" polymers, based upon cross-conjugated diphenylcarbenes and triphenylmethyls (9). Studies of numerous model diradicals (and dicarbenes) established the importance of connectivity of π-system mediating exchange interaction between the radicals. For two radicals linked through *m*-phenylene, triplet (spin multiplicity, $2S + 1 = 3$, for $S = 1$, where S is the total spin quantum number) ground state is found, as long as the π-system is approximately planar. The energy gap (ΔE_{ST}), between the singlet excited state and the triplet ground state, exceeds RT at room temperature in several diradicals. The analogous p- or o-connectivity leads to the singlet ground state, ie, pairing of two spins-1/2 (10,11). Such pairwise exchange interactions leading to the triplet and singlet ground states are referred to as ferromagnetic coupling and antiferromagnetic coupling, respectively. Strong ferromagnetic couplings ($\Delta E_{ST} > RT$), when extended in a three-dimensional network, could lead to ferromagnetism at room temperature (10). This goal was recently brought a step closer by discovery of magnetic ordering in a highly cross-linked conjugated organic polymer (12), which is described in the next section.

One of the measures of progress toward magnetic polymers is the average value of S in the ground state of the paramagnetic macromolecule. (For n ferromagnetically coupled spin-1/2, $S = n/2$). Several problems need to be addressed in synthesis of such conjugated polymers. Connectivity between the radicals within the π-system of the macromolecule must be strictly controlled; typically, the head-to-tail polymerization provides adequate connectivity for ferromagnetic coupling. However, even a single head-to-head (or tail-to-tail) connection may result in spin pairing (or interruption of exchange interaction) and, consequently, low value of average S will be obtained. Analogously, a severe out-of-plane twist of the π-system may interrupt exchange coupling or change ferromagnetic coupling to antiferromagnetic coupling. This particular problem is amplified by the need for sterically hindered groups in the macromolecule to prevent radicals from dimerization or other chemical decomposition pathways of radicals. The placement of sterically bulky groups and overall connectivity of the π-system should allow for significant delocalization of spin density from radicals to the linking π-system; this is a prequisite for a significant through-bond exchange interactions, including ferromagnetic coupling between the neighboring radicals. The chemical yield for generation of radicals must be near quantitative or, if radical monomers are used for polymerization, the radicals should survive polymerization conditions intact.

It is clear that the synthesis of magnetic polymers poses an extreme challenge for polymer science and organic chemistry, especially in view of the fact that the ultimate goal is a macromolecule with large number (10^4 or more) of interacting radicals (12). Not surprisingly, until late 1990s, the highest values of S in organic molecules and polymers were attained for strictly monodisperse organic molecules, eg, polyarylmethyl **1** with $S = 10$, prepared by laborious multistep syntheses (13–15) (Fig. 1). Even though stable triplet ground state ($S = 1$) diradicals



(**1**)

Fig. 1. Dendritic-macrocyclic polyradical **1**.

are well known, most of the reported "magnetic" polymers did not even reach $S \approx 1$, ie, a ferromagnetic coupling of two spin-1/2 radicals on average. Spurious reports of "ferromagnets" showing hystereses at room temperature in organic polymers with radical concentration on the order of 1% radical/unit or less are ignored in this review; magnetic behavior of such "magnetic" polymers has been shown to be associated with metal purities (16).

Two limiting approaches have been developed for connectivity between the radicals within conjugated polymers: Class I polyradicals, in which the radicals are within the π-system mediating exchange interactions, and Class II polyradicals, in which radicals are pendant groups attached to the conjugated polymer backbone.

Class I Polyradicals

The discussion of Class I polyradicals is focused on conjugated polymers **2** in which *m*-phenylene groups are employed to attain through-bond ferromagnetic coupling (Fig. 2). They are by far the most important of all organic polymers studied for their magnetic properties.

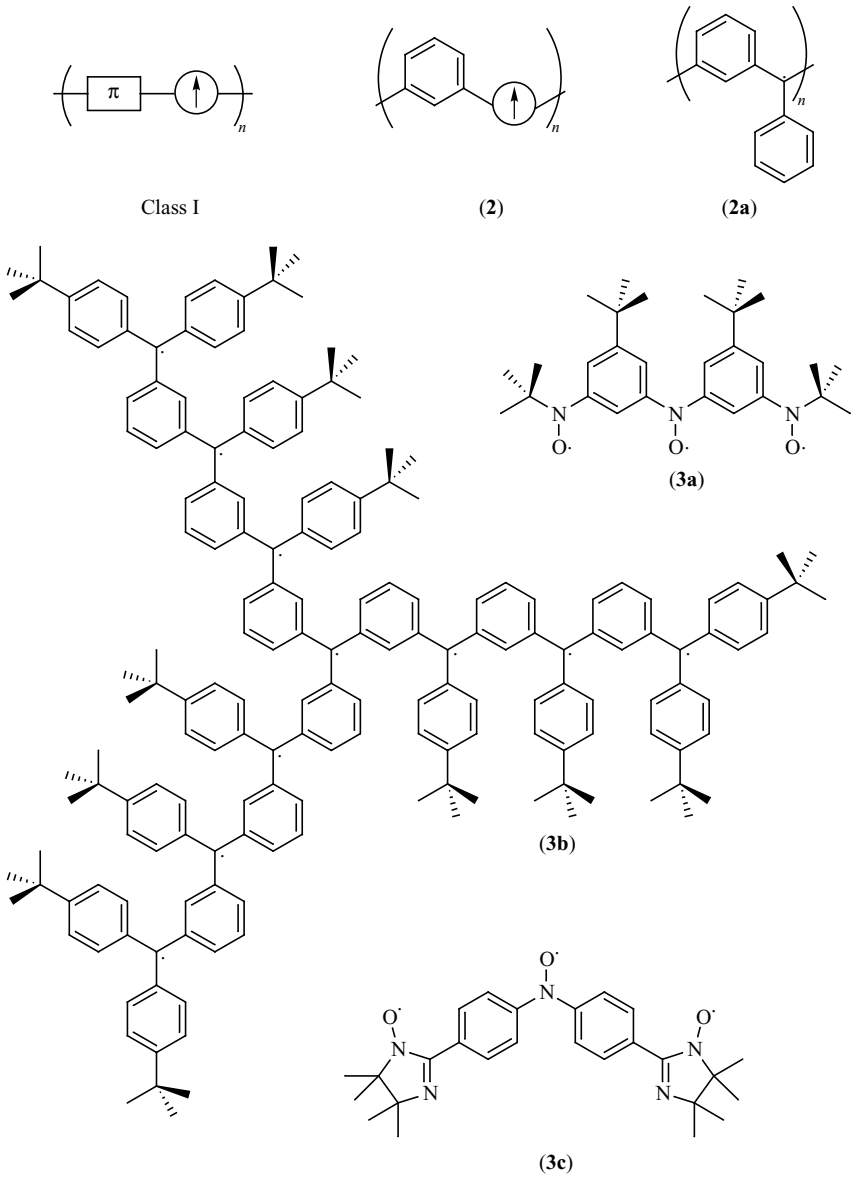


Fig. 2. Selected linear and branched neutral polyradicals with *m*-phenylene-like connectivities.

Linear polyarylmethyl polymer **2a** was prepared from the corresponding hydrocarbon with degree of polymerization (DP) of about 30. Magnetic studies showed an average value of $S \approx 2$; the radical concentration was not determined (17). The star-shaped model molecules had much higher values of S, eg, $S = 5$ for **3b**; oligoradicals **3** could be much better characterized compared to polymers **2** (Fig. 2) (18). Extension of star-shaped connectivity to dendrimers was not successful in improving the values of S (19).

While moderately sterically hindered polyarylmethyls can be handled in solution at low temperatures, the isoelectronic aminium radical cations and boride radical anions may offer stability at room temperature. However, such highly charged species may exist as complicated, medium-dependent oligomeric aggregates in solution. It is not uncommon that such intermolecular dimers and oligomers are diamagnetic, leading to overall very low radical concentrations. Nevertheless, the general idea of generating spin carrying polyradical polyions connected via *m*-phenylenes (or other ferromagnetic couplers) has attracted considerable interest ("polaronic ferromagnet") (20) (Fig. 3).

Electron spin resonance (ESR) spectra for disodium diboride (**4**) suggest triplet ($S = 1$) ground state or near degeneracy between the singlet and the triplet states; however, the resonance positions are highly solvent and counterion dependent (21). Such a complicated behavior for a simple diradical suggests that this system is not a promising candidate for magnetic polymers.

Bushby reported several aminium-based polymers (22). Polyamine **5a** ($M_w > 10^4$, GPC) was prepared by Suzuki reaction based polymerization, and then p-doped with antimony pentachloride. The resultant polyaminium polymer **5b** had radical concentration of ~0.5 radical/unit and an average value of $S \approx 4$ (22). The ferromagnetic coupling was rather weak, as expected for extended exchange pathway of *m*-phenylene with two *p*-phenylene spacers (Fig. 3).

ESR studies of numerous model aminium-based small monodisperse oligomers, eg, **6** and **7**, were reported in the past few years (Fig. 3) (23,24). For dications and trications, $S = 1$ and $S = 3/2$ states were detected (25–32). The $S = 3/2$ and $S = 1$ ground states for **6a** and **7b** were determined via spin nutation spectroscopy and magnetization study, respectively (Fig. 3) (24,32). For selected di- and trications bearing *p*-phenylenediamino-based radical cations, preliminary measurements of magnetic susceptibility using Evans NMR method suggested the low spin ground states ($S = 0$ and $S = 1/2$), though detailed studies with respect to medium and concentration effects for these highly charged species are needed (25–28). The $S = 1$ and $S = 3/2$ states were also detected for di- and trications derived from ylids **8a** and **8b**, respectively (Fig. 3) (33). There were reports of functionalized poly(*m*-aniline)s oxidized to the corresponding polyaminiums and polynitroxides; however, only values of $S \leq 1$ were obtained and, typically, radical concentrations were poor (34,35).
