elutes in TREF. Therefore, the distribution of the longest ethylene sequences, and not the chemical composition distribution, is used to model the fractionation with Crystaf and TREF. This approach led to modest success for some ethylene/1-octene copolymers, but was later found not to be generally applicable to a broader range of polymer samples. It is certain that crystallization kinetics play a very important role in both Crystaf and TREF fractionations and that models that rely simply on thermodynamic equilibrium assumptions are not capable of describing these techniques quantitatively (18). Much more research is still required to obtain reliable phenomenological models for these two fractionation techniques.

Size-Exclusion Chromatography

Size-exclusion chromatography (SEC), also known as gel-permeation chromatography (GPC), is currently the standard technique to fractionate polymers according to molecular weight due to its short analysis time and good reproducibility (see CHROMATOGRAPHY, SIZE EXCLUSION). There exist many excellent reviews and book chapters covering different aspects of SEC fractionation (29–35). SEC is a standard liquid chromatographic technique and, as such, involves the transport of a polymer sample dissolved in a mobile phase through a packed column. Even though SEC can be run in preparative mode using large columns to fractionate sizeable polymer samples, it is much more commonly operated in analytical mode with small columns and only a few milligrams of polymer.

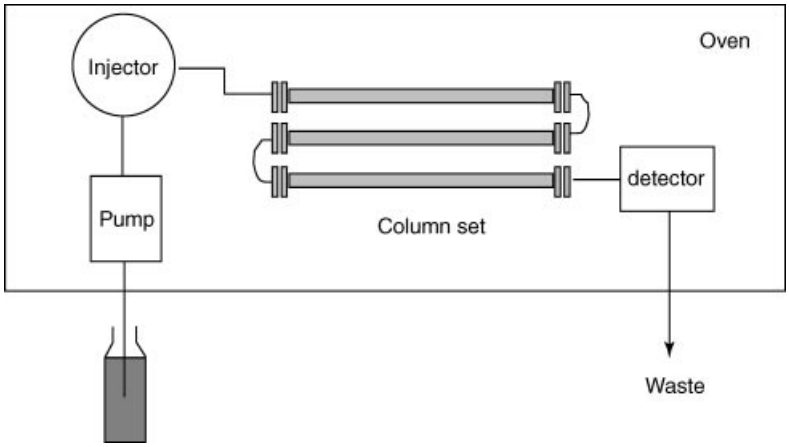

Fig. 23. SEC schematic.

SEC is commonly referred as *room-temperature SEC* or high temperature SEC, but the separation mechanism for both techniques is the same. As the name indicates, room-temperature SEC is used for polymers that are soluble at room temperature in the mobile phase; tetrahydrofuran is a commonly used solvent in this case, but many other solvents are equally adequate. High temperature SEC is mostly used for polyolefins and their copolymers since they are only soluble at temperatures from 120 to 150°C in solvents such as trichlorobenzene. In general, solvent type does not play a very important role in SEC, provided that it does not interfere with the column pore structure (when cross-linked polymer beads are used) and with the on-line detectors at the exit of the columns. However, care must be taken to avoid non size-exclusion effects, particularly for room-temperature SEC.

Figure 23 shows a schematic of SEC. The principle of SEC operation can be succinctly described as follows: the polymer sample, present as a dilute solution in a vial, is injected into the mobile phase as a narrow pulse and continuously flows through a series of columns containing packing with variable pore sizes. The elution time of the polymer chains depends on their size in solution or hydrodynamic radius: chains with higher volumes penetrate into fewer pores and elute first, while chains with smaller volumes penetrate into more pores (or penetrate deeper into the pores) and elute later. An on-line detector at the exit of the columns, most commonly a refractive index detector, is used to monitor the concentration of polymer chains eluting from the last column in the series, and a calibration curve is applied to relate elution volumes to molecular weights. *Retention time* is the time taken by a polymer fraction to elute from the columns. Likewise, *elution volume* is the volume of mobile phase required to elute a given polymer fraction from the columns.

In reality, even if all the pores were of the same diameter, fractionation by size would still take place since, because of solute-to-wall exclusion effects inside the pores, the available pore volume is higher for smaller chains than for larger ones, as illustrated in Figure 24. In practice, columns with a range of pore sizes are always used.

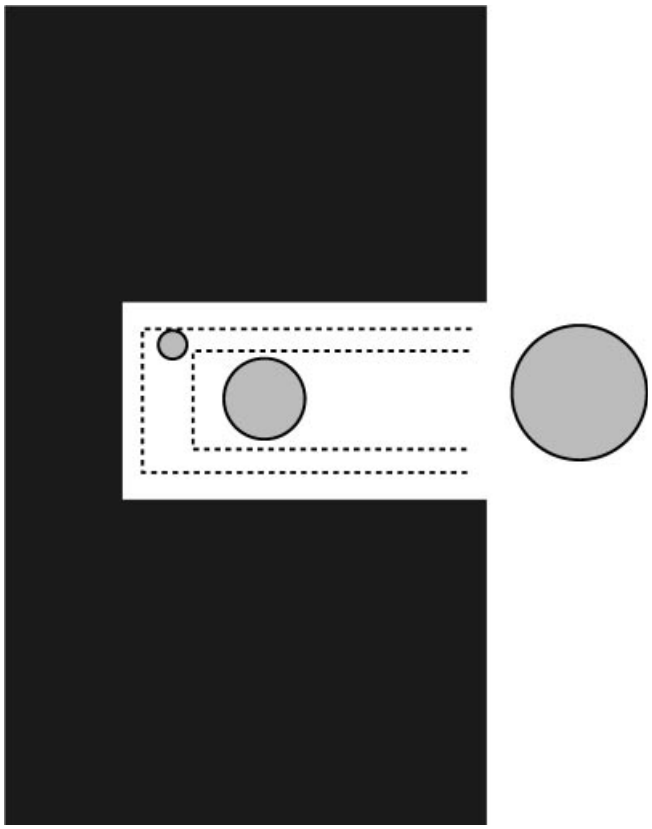

Fig. 24. Mechanism of SEC separation. Dotted lines indicate solution-to-wall exclusion volumes.

The relation between elution volume in the column and chain size in solution can be described with the simple equation:

$$V_R = V_i + KV_p \tag{19}$$

where V_R is the total elution volume, V_i is the interstitial volume between the packing particles, V_p is the pore volume of the packing particles, and K is a partition coefficient for the polymer chains between the stationary and the mobile phases. The partition coefficient K depends on the sizes of pores and polymer chains. It is equal to zero ($K = 0$) for chains that are too large to penetrate into any of the pores (*total exclusion limit*), and equal to one ($K = 1$) for chains that are small enough to diffuse into all pores (*total permeation* or *penetration limit*). These two limits, indicated in Figure 25, set the boundaries for polymer size resolution in SEC. Chains whose sizes are below the total permeation limit or above the total exclusion limit cannot be fractionated by SEC. Some mathematical models have been proposed to relate the value of K to pore sizes and radius of gyration of the polymer chains (32,36).

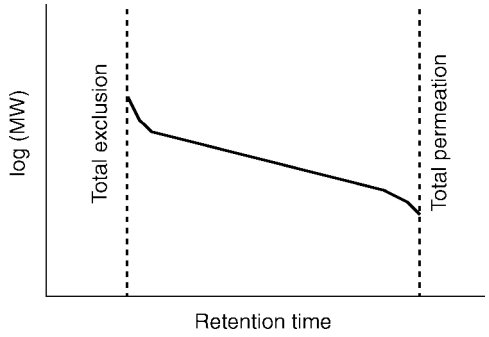

Fig. 25. An SEC calibration curve, showing the total permeation and total exclusion limits.

The partition coefficient can also be understood from a thermodynamic point of view with equation (37):

$$K = \exp\left(-\frac{\Delta G}{RT}\right) = \exp\left(\frac{\Delta S}{R} - \frac{\Delta H}{RT}\right) \tag{20}$$

Ideally, enthalpic effects are completely absent and SEC fractionation takes place on a size-exclusion basis only, ie

$$K \cong \exp\left(\frac{\Delta S}{R}\right) \tag{21}$$

Therefore, the value of K is proportional to the decrease in entropy experienced as the polymer chains diffuse into the pores of the packing and $0 \leq K \leq 1$.

The size of polymer chains in solution is a function of their chain length and topology, as well as solvent type and temperature. For linear chains, the size in solution is directly proportional to chain length, but for chains containing long-chain branches this relation depends on the type, number, and topology of the branches, making the quantification of SEC results significantly more complex (33).

In principle, SEC can be calibrated with standards of narrow molecular weight distribution of the polymer that one wishes to analyze. In this way, a calibration curve relating molecular weight to elution volume is obtained, in a fashion similar to what is done for the calibration of TREF or crystallization analysis fractionation. This approach, however, suffers from the limitation that the calibration curve is only applicable to one specific polymer. Additionally, narrow standards are not available for many different types of polymers. In principle, the batch fractionation techniques discussed above could be used to obtain such narrow standards, but these processes are time-consuming and, as explained, do not permit the isolation of samples with very narrow molecular weight distributions.

One of the great advantages of SEC is that it can be calibrated using a *universal calibration curve* that is independent of polymer type, provided that the chains behave like random coils in solution. This remarkably elegant solution to a rather complex problem is often taken for granted, but it is perhaps the most important reason why SEC is so widely applicable to different polymer types. The

universal calibration curve relies on the principle that polymer chains with the same volume in solution will elute at the same time from an SEC column. In other words, chains with the same hydrodynamic volume have the same retention time and elution volume.

The product of the molecular weight M and the intrinsic viscosity $[\eta]$ is called the *hydrodynamic volume* and is proportional to the size of polymer chains in solution:

$$[\eta]M = \Phi\left(\bar{r_0^2}\right)^{3/2}\alpha^3 \tag{22}$$

In equation 22, $\bar{r_0^2}$is the root-mean-square end-to-end distance of the polymer chain, and α and Φ are constants that depend on the type of solvent and polymer (30). When the logarithm of the hydrodynamic volume is plotted as a function of elution volume, an elegant relationship arises that is independent of polymer type, as illustrated in Figure 26 (31).

According to equation 22, polymers with the same root-mean-square end-to-end distances have the same hydrodynamic volume. Polystyrene standards spanning a wide range of molecular weight averages with very narrow molecular weight distributions (with polydispersity indices typically below 1.1) can be produced via living anionic polymerization and are, therefore, ideal calibration standards for SEC. The hydrodynamic volume of an unknown polymer, x, can be compared to that of a polystyrene standard, ps, with the equation:

$$M_{\mathrm{ps}}[\eta]_{\mathrm{ps}} = M_x[\eta]_x \tag{23}$$

The choice of a polystyrene standard is one of mere convenience; in principle, any other polymer standard with narrow molecular weight distribution could be used to generate the universal calibration curve. Equation 23 can be made more useful by substituting the Mark–Houwink relationship,

$$[\eta] = KM^a \tag{24}$$

and solving for M_x to obtain

$$\log M_x = \left(\frac{1}{1+a_x}\right)\log\frac{K_{\mathrm{ps}}}{K_x} + \frac{1+a_{\mathrm{ps}}}{1+a_x}\log M_{\mathrm{ps}} \tag{25}$$

Calibration curves for polystyrene narrow standards are very often linear functions in the general form,

$$V_{\mathrm{R}} = a - b\log M_{\mathrm{ps}} \tag{26}$$

where a and b are positive constants determined empirically. Higher degree polynomials are used when a simple linear regression is not adequate. The experimentally-measured SEC elution profile for polymer x is converted into the molecular weight distribution as follows: for each retention volume V_{R}, the

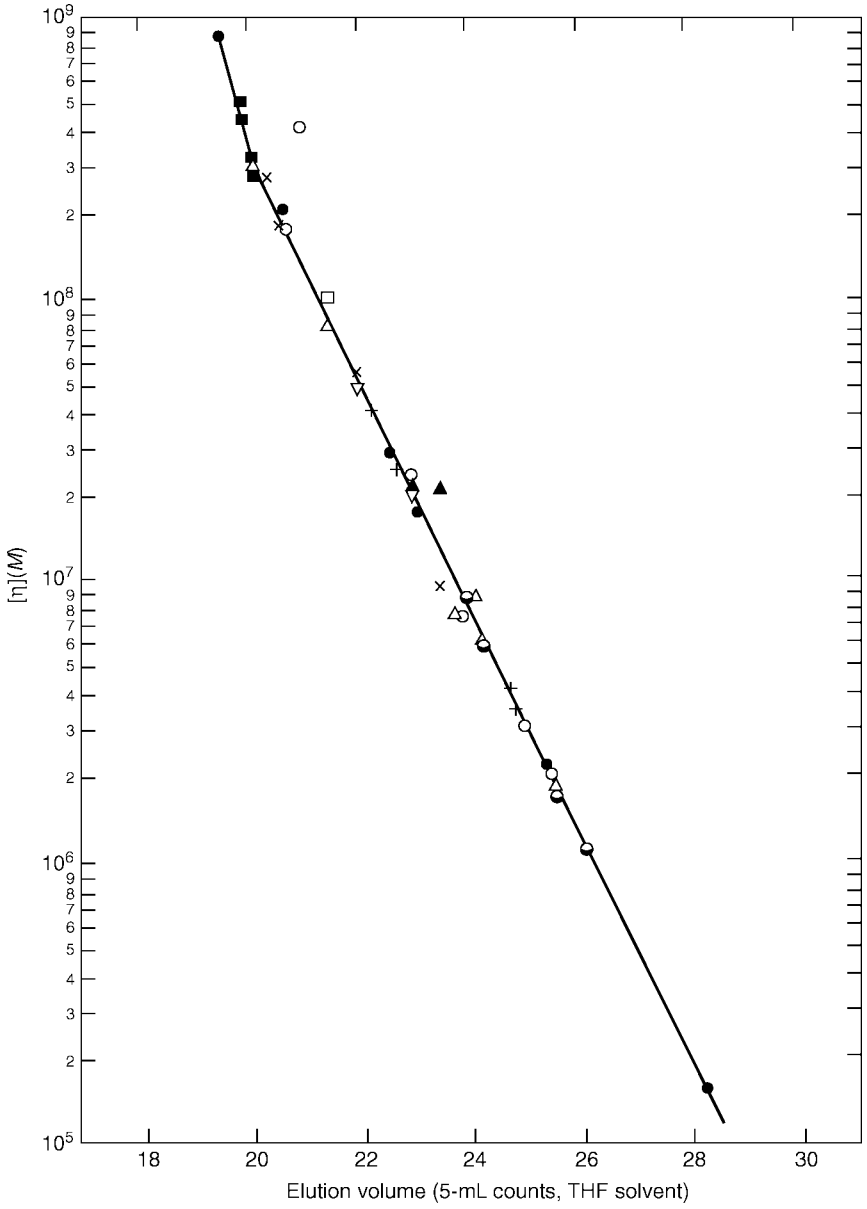

Fig. 26. Universal calibration curve for SEC. ● Polystyrene (linear); ○ polystyrene ("comb"); + polystyrene ("star"); △ polystyrene–poly(methylmethacrylate) copolymer (heterograft); × poly(methylmethacrylate) (linear); ◒ poly(vinylchloride); ▽ polystyrene–poly(methylmethacrylate) copolymer (graft-comb); ■ poly(phenyl siloxane); ▲ polystyrene–poly(methylmethacrylate) copolymer (statistical-linear); □ polybutadiene. From Ref. 31.

polystyrene-equivalent molecular weight, M_{ps}, is calculated using the universal calibration curve (eq. 26). This value is then substituted into equation 25 and the molecular weight of the sample, M_x, is calculated provided that the Mark–Houwink constants are known for polystyrene and the polymer sample at the

required analysis temperature and solvent. Calibration curves using broad standards may also be used, but are less common than the ones that use narrow standards (30).

Once the molecular weight distribution is established, molecular weight averages are calculated according to the following expressions:

$$M_n = \frac{1}{\int \frac{w(M)}{M}\,\mathrm{d}M} \tag{27}$$

$$M_w = \int M w(M)\,\mathrm{d}M \tag{28}$$

$$M_z = \frac{\int M^2 w(M)\,\mathrm{d}M}{\int w(M)\,\mathrm{d}M} \tag{29}$$

$$M_v = \left[\int M^\alpha w(M)\,\mathrm{d}M\right]^{1/2} \tag{30}$$

where $w(M)$ is the differential molar mass distribution measured by the mass on-line detector:

$$w(M) = \frac{\mathrm{d}W_V}{\mathrm{d}M} = \frac{\mathrm{d}W_V}{\mathrm{d}V}\frac{\mathrm{d}V}{\mathrm{d}(\log M)}\frac{\mathrm{d}(\log M)}{\mathrm{d}M} = \frac{\mathrm{d}W_V}{\mathrm{d}V}\frac{\mathrm{d}V}{\mathrm{d}(\log M)}\frac{1}{M} \tag{31}$$

The term $\frac{\mathrm{d}W_V}{\mathrm{d}V}$ is the height of the chromatogram and $\frac{\mathrm{d}V}{\mathrm{d}(\log M)}$ is the slope of the calibration curve, both measured at the elution volume V.

Many modern SEC instruments are provided with on-line viscometers to measure the intrinsic viscosity of the polymer sample during the analysis. In this case, the Mark–Houwink constants are estimated during the SEC analysis and do not need to be known *a priori*.

Many round-robins have been performed to test the intra- and inter-laboratory reproducibility of SEC. D'Agnillo and co-workers (38) reviewed the previous literature in the area and provided the most recent round-robin for high temperature SEC.

Fractionation Equipment. The main requirements for a commercial SEC unit are as follows: (*1*) reliable solvent pumps to keep a constant flow of mobile phase; (*2*) fractionation columns in the right range of porosity to fractionate a wide range of molecular weights; (*3*) an injection system capable of injecting the polymer sample without significantly disturbing the flow of the mobile phase; (*4*) an efficient mass detector and, optionally, chain-length or composition-sensitive detectors; and (*5*) an automated data acquisition system. All of the commercially available SEC units have incorporated these required features.

A reliable high pressure liquid pumping system (generally reciprocating-dual piston design to avoid pressure fluctuations) is one of the most important parts of SEC. Since SEC calibration is based on the retention time in the columns and the logarithm of the molecular weight varies very often as a linear function

of the elution volume or retention time, any fluctuation in flow rate will lead to significantly inaccurate molecular weight distributions. Pump pressures generally vary from 1000 to 4000 psi. These high pressures are required to overcome the pressure loss in the columns due to the small particle sizes of the packing. The flow rate of the mobile phase is kept in the range of 1–3 mL/min.

The injection system should be able to inject a small sample aliquot with precision, with injection volumes usually varying from 10 to 200 μL. The polymer sample solutions are commonly prepared with concentrations varying from 0.05 to 0.1% wt/vol. For high temperature SEC, polymer solutions are generally prepared directly in the injection compartment under spinning and filtering, if required. Off-line sample preparation setups are also available. The sample injection systems are provided with a sample carousel to permit the sequential injection of several samples.

SEC columns are commonly packed with microporous glass beads or cross-linked styrene–divinylbenzene gels, the latter being more common especially for applications involving chains soluble in organic solvents. Several other, less commonly used packings, are also available (33,39). The column packing can have pores of constant size or a distribution of pore sizes; the latter are called linear columns since they generally lead to a linear calibration curve. For polystyrene–divinylbenzene columns, the pore sizes depend on the degree of cross-linking since they are formed by swelling the packing with solvent. Pore sizes in the range of 50 to 10^7 Å correspond to the effective size range of most polymer molecules in solution. The size of the particles in the packing is also important: gel particle sizes in the range of 5–10 μm allow good packing and minimum channeling; 3-μm particles with increased pore volume packing, providing enhanced resolution at low molecular weights, are also available. SEC columns are generally 300–600-mm long and 7.5 mm in diameter, but shorter mini-bore columns 250-mm long and 4.6 mm in diameter can also be used to decrease solvent usage. Generally two or three columns are used in series, preceded by a shorter guard column to filter polymer gels and other impurities that may plug or damage the columns. All columns will degrade with usage, particularly polystyrene/divinylbenzene columns used at high temperatures. Column degradation alters their porosity and, consequently, polymer retention time. Because of this, SEC columns must be recalibrated at regular intervals to ensure that the results are reliable. It is common practice to monitor the state of the columns by injecting broad and narrow standards during the analysis of other unknown samples. Eventually, column degradation will lead to peak broadening and loss of resolution.

Differential refractive index detectors are the standard SEC mass detectors. They have the advantage of being able to respond to all polymer types, provided that the choice of solvent is adequate. To maximize detector response, the refractive indices of the polymer and solvent should differ significantly. Infrared and ultraviolet detectors have also been used successfully as mass detectors. Viscometers can be added to allow the calculation of the intrinsic viscosity of unknown polymer samples. They are also essential for the analysis of polymers with long-chain branches. Light-scattering detectors permit the direct measurement of the weight-average molecular weight of the polymer fraction present in the detector cell and can, therefore, be used to determine molecular weight distributions as an absolute technique dispensing the use of calibration curves. The combination of

SEC with refractive index, viscosity, and light-scattering detectors is referred to as *triple detector system*. This powerful configuration has found many applications in industry and academia, but it is also more complex to operate than single-detector SEC systems.

As any other liquid chromatographic technique, SEC analysis can be influenced by peak broadening due to axial dispersion and flow irregularities. A description of this phenomenon is beyond the scope of this article. For more information, see the brief summary presented by Styring and Hamielec and the related references cited by these authors (33).

SEC of Complex Polymers. For the case of linear homopolymers and linear and chemically homogeneous copolymers, there exists a direct relationship between the size of the polymer chains in solution and molecular weight. In this case, the separation mechanism operative in SEC will lead to fractionation by molecular weight only. On the other hand, complex polymers may have long-chain branches and, in the case of copolymers, are heterogeneous in chemical composition. Since the radius of gyration (or size in solution) is affected by both long-chain branching and chemical composition, chains with different molecular weights may have the same retention volume, and consequently the species present in the detector cell may have a distribution of molecular weights. In this case, other microstructural factors besides molecular weight affect SEC fractionation. Interaction chromatography (IC) is sometimes used to resolve these polymers. IC makes use of the enthalpic term of equation 20 to achieve the fractionation. Since the enthalpic term is influenced by the chemical nature of the polymer, chains with distinct chemical compositions can be fractionated. Chang recently published a comprehensive review on this subject (37).

Field Flow Fractionation

The power of field flow fractionation (FFF) lies in the simplicity of the design of its main component, the FFF separation channel. In FFF, a pulse of a polymer solution is injected into a carrier liquid and flows through a rectangular thin channel. An external physical field is applied perpendicularly to the axial flow, acting as a driving force for the fractionation of the polymer molecules according to molecular weight and/or other microstructural properties. Figure 27 shows a schematic of a FFF channel. Contrarily to chromatographic techniques such as SEC, the FFF channels contain no packing and can, therefore, be used to analyze polymer chains with a broader range of hydrodynamic radii from 1 nm to 100 μm. Several books and reviews have been recently published on this topic (40–45). The reader is referred to the review by Cölfen and Antonietti (43) for a comprehensive and up-to-date overview of principles, techniques, and applications of several FFF methods.

The nature of the external field determines the type of fractionation achieved in FFF. Even though many different types of fields have been examined, the most common are thermal, flow, and gravitational/centrifugal. Figure 28 summarizes some types of FFF methods with their respective dates of invention.

The fractionation mechanism in FFF is as simple as it is elegant (Fig. 29). Since the axial flow is laminar, a parabolic velocity profile is established in the rectangular channel. Consider first the case of flow-FFF (*Fl*-FFF) of a linear

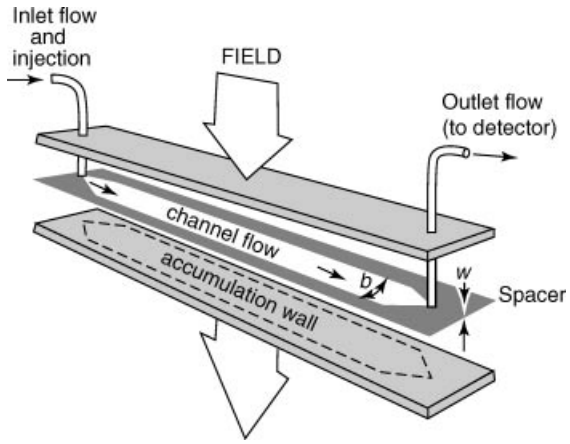

Fig. 27. Schematic of a FFF channel. From Ref. 40.

homopolymer: the carrier liquid flows perpendicularly through the porous walls of the channel, establishing an external flow field that is normal to the axial flow (*cross flow*). A narrow pulse of polymer solution is injected at one end of the column and the axial flow is stopped for a short period of time. The cross flow forces the polymer molecules to accumulate near the opposite wall (*accumulation wall*), generating a transversal polymer concentration gradient. According to Fick's law, this concentration gradient will act as the driving force for molecular diffusion in the opposite direction of the external field. After a short time, a

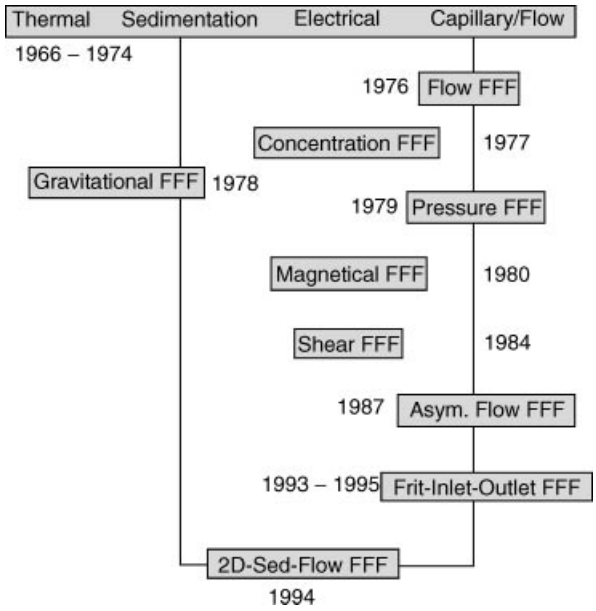

Fig. 28. Some types of FFF with their times of invention. From Ref. 43. Copyright (2000) Springer-Verlag.

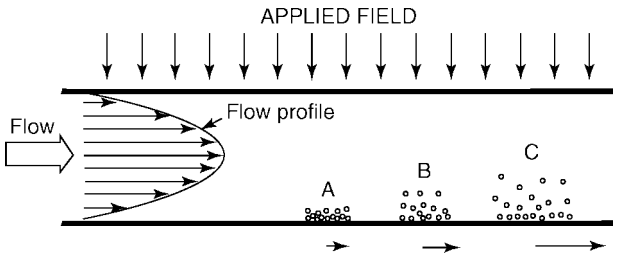

Fig. 29. FFF flow profiles and mechanism of fractionation. The molecular weight of the particles increases in the order A > B > C. From Ref. 40.

steady state is reached in a process called *relaxation* with the establishment of a polymer layer of a given thickness near the accumulation wall. Chains with smaller hydrodynamic radii (smaller molecular weights) have higher diffusion coefficients and will move farther away from the accumulation wall than chains with higher hydrodynamic radii. When the axial flow is restarted, generating a parabolic velocity profile inside the channel, smaller chains will, on average, be transported with higher axial velocities than larger chains and will consequently elute from the channel at shorter residence times (or shorter elution volumes). This mode of operation, where the intensity of the driving force is constant throughout the channel, is called the *classic* or *normal* model of operation. The intensity of the driving forces can be varied as a function of analysis time to permit the fractionation of polymers with broad molecular weight distributions. This mode of operation is called *field intensity programming*. Some other FFF modes of operation include steric-FFF (46), hyperlayer-FFF (47), and focusing-FFF (48). Hydrodynamic chromatography can also be seen as a special case of FFF where the external driving forces are absent (43). More details about these modes of operation can be found in the cited references.

Among all FFF techniques, *Fl*-FFF is the most universal, since the separation relies only on the difference between the diffusion coefficients of the solute species. It can be applied to fractionate polymers (down to molecular weights of 10^3 g/mol), colloids, and particles with hydrodynamic radii from 1 nm to 50 μm in either water or organic solvents, although it has been used much more frequently for water-soluble polymers. The transversal flow driving force has the same effect on molecules of all chain lengths, and thus forces them towards the accumulation wall regardless of their sizes. However, since Fick's diffusivity is inversely proportional to molecular weight, the shorter chains will diffuse away from the accumulation wall faster than the longer ones. As a consequence, in *Fl*-FFF the fractionation mechanism is regulated mainly by molecular weight. In symmetric *Fl*-FFF, the two walls are permeable to the transversal flow, while in asymmetric *Fl*-FFF only one of the walls is permeable. Figure 30 shows an example of *Fl*-FFF used in the fractionation of proteins.

In thermal-FFF (*Th*-FFF), a temperature gradient is imposed on the FFF channel (generally 10–100 K), causing the chains to diffuse towards the cold wall by a mechanism called thermal diffusion (Soret effect). *Th*-FFF is commonly used to fractionate synthetic polymers soluble in organic solvents with molecular weights from 10^4 to 10^7 g/mol. In principle, it can also be used to fractionate

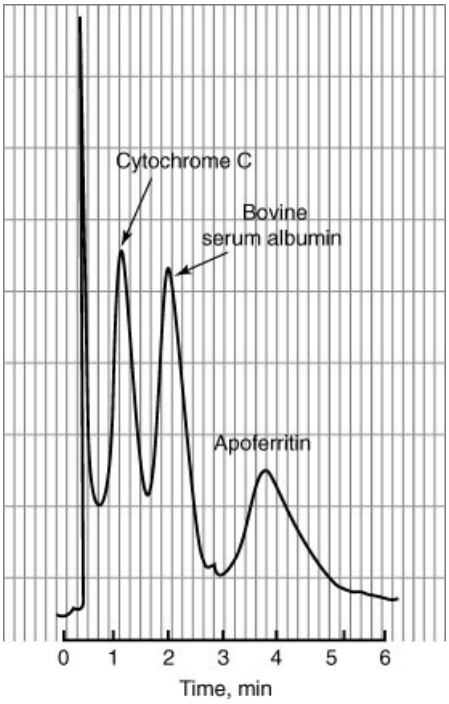

Fig. 30. *Fl*-FFF fractionation of three proteins. From Ref. 40.

hydrophilic polymers, but in practice *Fl*-FFF is the predominant technique for these polymers. *Th*-FFF is very useful for shear-sensitive chains with very high molecular weights or macromolecular aggregates. Unfortunately, the fractionation of shorter polymer chains requires the use of very high temperature gradients that may cause several operational problems.

The ratio of the thermal diffusivity D_T, to the molecular diffusivity D is the main fractionation parameter in *Th*-FFF. D_T depends on polymer and solvent composition, but it is virtually independent of chain length and long-chain branching. For random copolymers, D_T varies linearly with monomer composition, but more complex behavior is observed for block copolymers. In principle, this dependency on chemical composition can be used to fractionate copolymers according to their composition, as is beautifully illustrated in Figure 31 (49).

Gravitational or centrifugal forces are used to promote fractionation in sedimentation FFF (*S*-FFF). *S*-FFF is applicable for polymers with molecular weights higher than 10^6 g/mol and colloids or particles with diameters larger than 30 nm, both in water and organic solvents. The fractionation is regulated basically by the differences in density and the intensity of the centrifugal forces. It is mostly used to fractionate large biopolymers, polymer latexes, inorganic particles, emulsions, biological cells, etc. Figure 32 shows the schematic of an *S*-FFF channel coiled around a centrifugal rotor. An example of fractionation of polystyrene latex beads by *S*-FFF is illustrated in Figure 33.

Theoretical Considerations. The laminar flow patterns inside the FFF channel are well understood from basic fluid dynamic models and permit a very

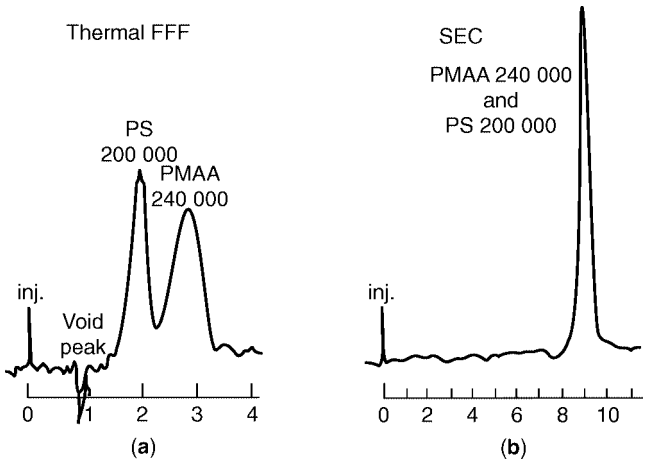

Fig. 31. *Th*-FFF according to chemical composition. From Ref. 49. Copyright (1989) Springer-Verlag.

elegant theoretical treatment for different FFF modes of operation, as opposed to chromatographic techniques where the internal packing generates flow patterns that are difficult to describe rigorously with simple mathematical models. Because of this precise mathematical treatment, FFF can be used not only as a fractionation technique, but also to determine fundamental physicochemical properties of the sample under analysis. This also allows a new concept for a universal

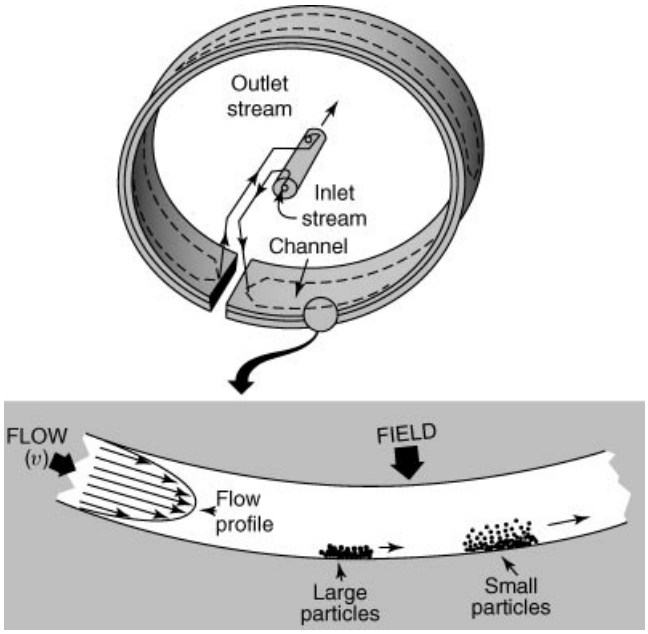

Fig. 32. *S*-FFF channel. From Ref. 40.

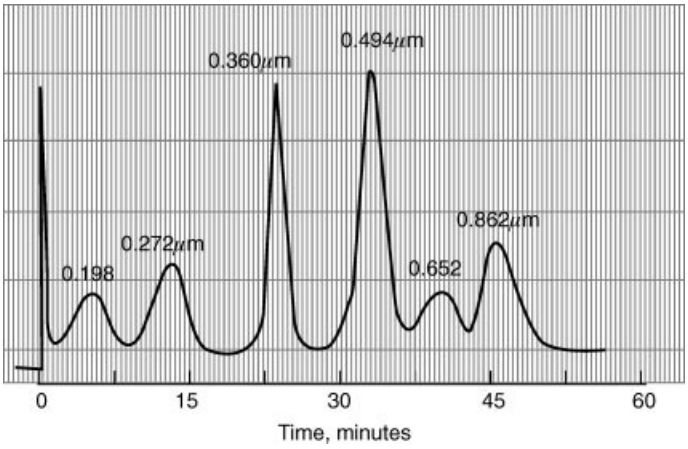

Fig. 33. *S*-FFF of polystyrene beads of different diameters. From Ref. 40.

calibration curve for fractionation by molecular weight. Basic mathematical relationships for *Th*-FFF, *Fl*-FFF, and *S*-FFF will be developed in this section, but the readers should be aware that significant deviations from this ideal behavior may occur during actual fractionation experiments. For a more elaborate mathematical treatment of these techniques, the reader is referred to the review by Cölfen and Antonietti (43).

Very concise expressions can be developed for FFF if the following assumptions are made: (*1*) the FFF channel can be modeled as the space between two parallel infinite plates, (*2*) the flow profile is parabolic, (*3*) a steady state concentration profile is established in the channel, and (*4*) the external field is uniform. With these assumptions, a simple mass balance across the cross section of the channel leads to the expression for the transversal flux J_x,

$$J_x = u_x c(x) - D\frac{\mathrm{d}c(x)}{\mathrm{d}x} \tag{32}$$

where u_x is the drift velocity of the chains toward the accumulation wall caused by the external field, $c(x)$ is the concentration profile of solute molecules as a function of the distance x from the accumulation wall, and D is their diffusion coefficient. The diffusion coefficient of polymers is a function of their molecular weight and other microstructural characteristics.

Solving this equation at the steady state, ie $J_x = 0$, leads to an exponential solution for $c(x)$,

$$c(x) = c_0 \exp\left(-\frac{x|u_x|}{D}\right) \tag{33}$$

where c_0 is the polymer concentration at the accumulation wall. Therefore, the normal mode of operation generates an exponential concentration profile with thickness inversely proportional to the molecular weight of the polymer solute. (In the case of focusing FFF, the external forces are varied in such a way as to balance

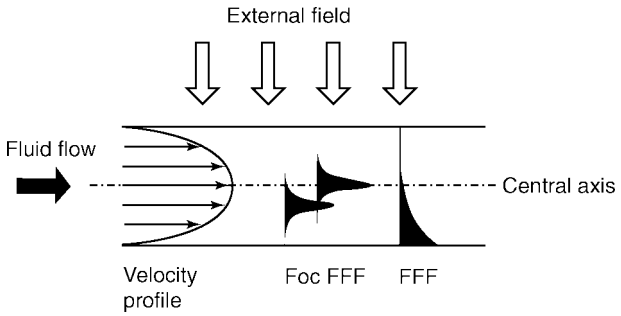

Fig. 34. Concentration gradients in classical and focused FFF. Reprinted from Ref. 45 by courtesy of Marcel Dekker, Inc.

the opposing diffusional forces, creating a focused band at a defined position above the accumulation wall where the external force is exactly counterbalanced, as illustrated in Figure 34.)

The two most important parameters in FFF are the dimensionless retention parameter λ and the ratio of the retention time of an unretained solution to the retention time of a retained solution, $R = \frac{t_0}{t_r}$. An unretained solution is one whose retention time is not affected by the external field (the carrier liquid, for instance). The retention parameter is defined by the equation

$$\lambda = \frac{l}{w} = \frac{kT}{Fw} \tag{34}$$

where l is the thickness of the solute separation layer, w is the width of the FFF channel, k is Boltzmann's constant, T is the temperature, and F is the transversal force that acts on the solute molecules. The parameter λ is, therefore, the fraction of the channel width occupied by the solute molecules.

The parameter λ cannot be measured directly, but must be related to R via the equation

$$R = \frac{t_0}{t_r} = \frac{V_0}{V_r} = 6\lambda\left[\coth\left(\frac{1}{2\lambda}\right) - 2\lambda\right] \tag{35}$$

where V_0 is the volume of the separation channel and V_r is the retention volume for the retained solution.

Since $\lambda \ll 1$ for most cases, the following approximation applies:

$$R \cong 6(\lambda - 2\lambda^2) \cong 6\lambda \tag{36}$$

Once λ is estimated from an experimentally-measured value of R, it can be used to calculate the values of several physicochemical parameters for the polymer chains. For *Fl*-FFF, the following expression holds:

$$\lambda = \frac{Dw}{\dot{V}_c} \tag{37}$$

where $\dot{V}_c$ is the transversal flow rate. The equivalent expressions for *Th*-FFF and *S*-FFF are as follows:

$$\lambda = \frac{D}{D_T(\mathrm{d}T/\mathrm{d}x)w} \tag{38}$$

$$\lambda = \frac{RT}{\varpi^2 rM\left(1 - \frac{\rho}{\rho_s}\right)w} \tag{39}$$

where D_T is the thermal diffusion coefficient, $\mathrm{d}T/\mathrm{d}x$ is the temperature gradient across the channel, $\varpi^2 r$ is the centrifugal acceleration, M is the molecular mass of the solute, R is the gas constant, and ρ and ρ_s are the solvent and solute densities, respectively. Equations 37 to 39 are very helpful to understand the basic physical parameters that affect separation inside FFF channels. Notice that the layer thickness, as estimated by the parameter λ, is always inversely proportional to the field strength, ie, $\dot{V}_c$, $\mathrm{d}T/\mathrm{d}x$, or $\varpi^2 r$. This permits the fractionation of a very broad range of molecular sizes by simply decreasing the intensity of the external field, as done in the mode of operation called *field intensity programming*. For instance, the analysis of a sample with broad molecular weight distribution can be started at high field intensity. If this intensity was kept throughout the fractionation, very large elution times would be required to elute the highest molecular weight species. Decreasing the field intensity in a programmed way leads to a reduction of the retention time of larger chains, thus shortening the analysis time. This procedure, however, increases the complexity of the analytical procedure and may also lead to undesirable secondary relaxation phenomena: solute–solute and solute-accumulation wall interactions at high field strengths.

Use of *Fl*-FFF and *Th*-FFF for Molecular Weight Fractionation. *Th*-FFF and SEC have been often compared since both techniques are generally used to obtain the molecular weight distribution of synthetic polymers in organic solvents. Nonetheless, SEC is much more widely used than FFF, despite the fact that these techniques can be seen as complementary. One of the advantages of SEC is the existence of a universal calibration curve applicable to all polymer types. Even though universal calibration curves can also be obtained for FFF, their concept is radically different from that of the universal calibration curve for SEC. For SEC, the universal calibration curve can be used for all polymers in the same SEC instrument and column set, but will differ from instrument to instrument. Even in the same instrument, the calibration curves will "drift" as the columns age and change their pore structure, particularly for high temperature SEC. Contrarily, the universal calibration curve for FFF is applicable, in principle, to a given polymer–solvent combination in all FFF setups, but will be different for each polymer–solvent system. Another practical advantage of SEC that may explain its predominance over FFF is a more straightforward mode of operation. Many of the operation modes of FFF, while very efficient, require considerably more expertise from the analyst.

In general, SEC is capable of analyzing lower molecular weight chains (using packing with small pore radii) but has limitations for very high molecular weight chains that can suffer chain scission because of the high shear stresses inside the

SEC columns and/or generate very high viscosities and pressure drops. On the other hand, *Th*-FFF is not very effective for fractionating low molecular weight chains because a very high temperature gradient is required (D is large for small chains, cf eq. 38), but becomes more attractive for higher molecular weight chains. Additionally, a series of SEC columns can be used to fractionate samples with very broad molecular weight distributions (up to five decades or more) since the elution volume in SEC is a linear (or quasi-linear) function of the logarithm of the molecular weight. Calibration curves for FFF, however, show a now-linear relation between elution volume and the logarithm of the molecular weight, as indicated in equation 40 below. This implies that in the normal mode of operation, FFF fractionation is limited to samples with narrow molecular weight distributions. As we have seen, this limitation can be reduced by operating FFF in the field programming mode, but at the price of a more elaborate analysis procedure (43).

FFF molecular weight calibration curves can be represented by the relation

$$\log V_r = a + S_m \log M \tag{40}$$

where V_r is the retention volume, M is the molar mass of the polymer, and a and S_m are constants for a given polymer–solvent system. The power of this approach is that the calibration constants can be related to the characteristics of the FFF equipment used to obtain the calibration curve and then extended to any other FFF setup. In other words, after equation 40 is determined for a given polymer-solution system in one FFF setup, in principle it can be used in any other FFF setup, even if some of the operation conditions and channel dimensions are different. This procedure will be outlined in the next paragraphs.

The following expressions apply for linear or uniformly branched polymers:

$$\frac{D}{D_T} = \varphi_0 M^{-n} \tag{41}$$

$$D = AM^{-b} \tag{42}$$

where the parameters φ_0, n, A, and b are universal constants for a given polymer–solvent system. Substituting equation 42 in equation 41, the following expression results:

$$\frac{AM^{-b}}{D_T} = \varphi_0 M^{-n} \tag{43}$$

Since it is know that D_T is nearly independent of molecular weight, then $b \approx n$ provided that the measurements are made at the same temperature.

Equations 41 and 42 can be substituted into their respective definitions of λ, equations 38 and 37, to obtain

$$\lambda = \frac{\varphi_0 M^{-n}}{(dT/dx)w} = \frac{\varphi_0 M^{-n}}{(\Delta T/w)w} = \frac{\varphi_0}{\Delta T} M^{-n} \tag{44}$$

$$\lambda = \frac{wA}{\dot{V}_c} M^{-b} \tag{45}$$

The parameter λ can be calculated from the experimentally-measured value of R using equation 35. Using the approximation $R = 6\lambda$ (accurate within 2% when $R < 0.06$), it is possible to obtain closed-form expressions for the dependency of the retention volume on molecular weight:

$$V_r = \frac{V_0 \Delta T}{6\varphi_0} M^n \text{ for } Th\text{-FFF} \tag{46}$$

$$V_r = \frac{V_0 \dot{V}_c}{6Aw} M^b \text{ for } Fl\text{-FFF} \tag{47}$$

Comparing equations 46 and 47 with the universal calibration curve, equation 40, the following expressions for the calibration constants are obtained:

$$a = \log \frac{V_0 \Delta T}{6\varphi_0} \text{ and } S_m = n \text{ for } Th\text{-FFF} \tag{48}$$

$$a = \log \frac{V_0 \dot{V}_c}{6Aw} \text{ and } S_m = b \text{ for } Fl\text{-FFF} \tag{49}$$

The beauty of these equations is that they are related only to the dimensions of the FFF channel, w and V_0; the strength of the external fields, ΔT or $\dot{V}_c$; and the polymer–solvent specific constants, φ_0, A, n and b. (For more rigorous calibrations, some corrections of these equations may be required.) They can, therefore, be applied to analyze a known polymer–solvent system in different FFF instruments under a wide range of experimental conditions (50).

Fractionation Equipment. The basic setup of FFF is essentially the same required for chromatographic techniques, with the chromatographic columns replaced by the FFF channel. The same requirements for precise sample injection, stable flow of the carrier liquid, and adequate sample detection described for SEC also apply to FFF.

FFF channels are usually 50- to 500-μm thick, 10- to 100-cm long, and have an aspect ratio of 20 to 200 (width/thickness). Particular details such as materials of construction, geometry of the channels, and specific arrangements of flow inlets and outlets can vary among different setups and operation modes. Details for several equipment configurations can be found in the references cited in this section.

Differential refractive index detectors are the most common choice for FFF mass detectors. As also the case for SEC, the use of multiple detectors is becoming increasingly important with FFF. Low angle laser light scattering (LALLS) and multiangle laser light scattering (MALLS) detectors are used for absolute determination of molecular weights. Many other detectors (UV, ICP-MS, differential viscometer, IR, electrospray mass spectroscopy) have also been used with FFF.

FFF is manly an analytical technique, but some effort has be made to run it in preparative or at least micro-preparative mode. The use of modified continuous FFF techniques or SPLITT channels (where the incoming polydisperse sample is split into two outlet flows with narrower distributions) is briefly described by Cölfen and Antonietti (43).

Continuous Polymer Fractionation

Continuous polymer fractionation (CPF) is a liquid–liquid extraction technique developed to fractionate large amounts of polymer (51). It was originally developed to fractionate homopolymers by molecular weight and has been applied for polyvinyl chloride (52), polyisobutylene (53,54), polyethylene (55), and polycarbonate (56). Recently, attempts to extend CPF to copolymers have been made (57) and it was shown that, under certain operational conditions, fractionation by chemical composition could also be achieved (58).

Being continuous, the advantage of CPF over the other techniques previously discussed lies in the fact that larger polymer samples can be fractionated in relatively shorter times. This is particularly important if large fractions with narrow MWD or CCD are required for the establishment of structure-property relationships or to remove, on a technical scale, chain populations that are undesirable for a given application of specialty polymers.

In a CPF liquid–liquid extraction column, the feed stream containing the polymer solution (polymer rich phase) flows countercurrently to the eluent stream containing the extracting agent. Chains with low molecular weight present in the polymer-rich phase (gel phase) are extracted by the eluent stream (sol phase), and the two phases exit from the bottom and top of the column because of their density differences. Mixed (solvent/nonsolvent) or single solvents can be used with CPF, but mixed solvents provide more flexible operational conditions. The same principles discussed before for batch fractionation can be extended to CPF. Weinmann and co-workers provide detailed theoretical treatment of CPF (56). Naturally, a single pass through a CPF column only permits the fractionation into two low–high molecular weight fractions. If more fractions are required, it is necessary to use columns in series, in which case successive extractions of the low molecular weight components can be achieved by changing the solvent/nonsolvent ratio or column temperature in the series.

A recent article describes two configurations for CPF columns (57): both were glass columns with high diameter ratios of 2.4 m/3.5 cm and 1.9 m/1.5 cm. The larger column was filled with glass beads of 8- and 10-mm diameter in a 1:1 ratio, while the smaller one with glass beads of 6 and 8 mm in a 3:1 ratio. The feed inlet was positioned at 3/4 of the total column high, since theoretical and experimental results indicate that this placement increases the separation efficiency (56). In this case, the temperature of the upper $\frac{1}{4}$ of the column can be decreased, creating a reflux effect that is beneficial to the fractionation. Two to three theoretical plates per meter and a fractionation capacity of 10–100 kg of polymer per hour and square meter of cross section have been reported for these columns (51).

A related technique for the fractionation of large amounts of polymer, continuous spin fractionation (CSF), has also been recently disclosed (59).

Mass Spectrometry

Traditional mass spectrometry techniques involving the study of ions in the gas phase are not adequate for the analysis of polymers because of their very low vapor pressures and their tendency to suffer chain scission during ionization. On the

other hand, recent developments on soft ionization techniques such as electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) mass spectrometry have found many applications in the polymer field (60–63). Since ESI is more commonly used with biopolymers (63) and most common applications of mass spectrometry (qv) for synthetic polymers use MALDI, we will restrict our discussion in this section to the later technique.

Mass spectrometry experiments consist of two equally important steps: ionization/vaporization and detection. Although traditional techniques such as electron impact ionization are too harsh and lead to the fragmentation of polymer molecules, the softer ionization technique of MALDI can be successfully used to fractionate polymers of narrow molecular weight distribution. The ionized analyte is accelerated through a magnetic field with voltage V, acquiring a velocity that is proportional to its mass-to-charge ratio (m/z). Time-of-flight (TOF) analyzers have been found to be the most adequate for polymer analysis. In the TOF spectrometer, the ions are separated according to their velocities and their m/z is evaluated on the basis of the time it takes for the ionized molecules to travel a flight path of length L to the detector (64):

$$t = \left(\frac{m}{2zeV}\right)^{1/2} L \tag{50}$$

Commercial MALDI-TOF instruments in the range up to 10,000 g/mol can have a resolution of up to 4 g/mol, which permits a remarkable resolution of molecular weight distributions (65). This impressive resolution is illustrated in Figure 35 for the molecular weight distribution of a polymethylmethacrylate sample (66).

The original promise of obtaining the complete molecular weight distribution of polymers with MALDI-TOF did not hold true except for polymers with very narrow distributions (polydispersity indices less than 1.2), in which case the analysis can be very accurate and reproducible (67). The reasons for this are complex and mainly caused by the fact that both the ionization process and the detector are mass-sensitive and discriminate towards the shorter chains in the population. The detector effect can be easily understood from inspection of Figure 1, where the number and weight chain length distributions of a polymer that follows Flory–Schultz's most probable distribution are compared. It is clear that the number of shorter chains greatly exceeds the number of longer chains, but the longer chains account for a much higher mass fraction of the sample. The signal of refractive index detectors, commonly used with SEC and FFF, is proportional to the mass of the polymer in the detection cell and is therefore very sensitive to the high molecular weight end of the distribution. On the other hand, the TOF detector is sensitive to the number, not the weight, of chains, and therefore the signal for the longer chains is quickly lost in the background noise. This is elegantly illustrated in Figure 36, where the molecular weight distributions of three polydimethylsiloxane samples measured by MALDI-TOF are much narrower and shifted to the low molecular weight end of the distribution than the ones measured by SEC.

In order to circumvent this limitation but still preserve the detailed molecular weight information generated by this powerful detection technique, MALDI-TOF has been used as an absolute detector, both on-line and off-line, for

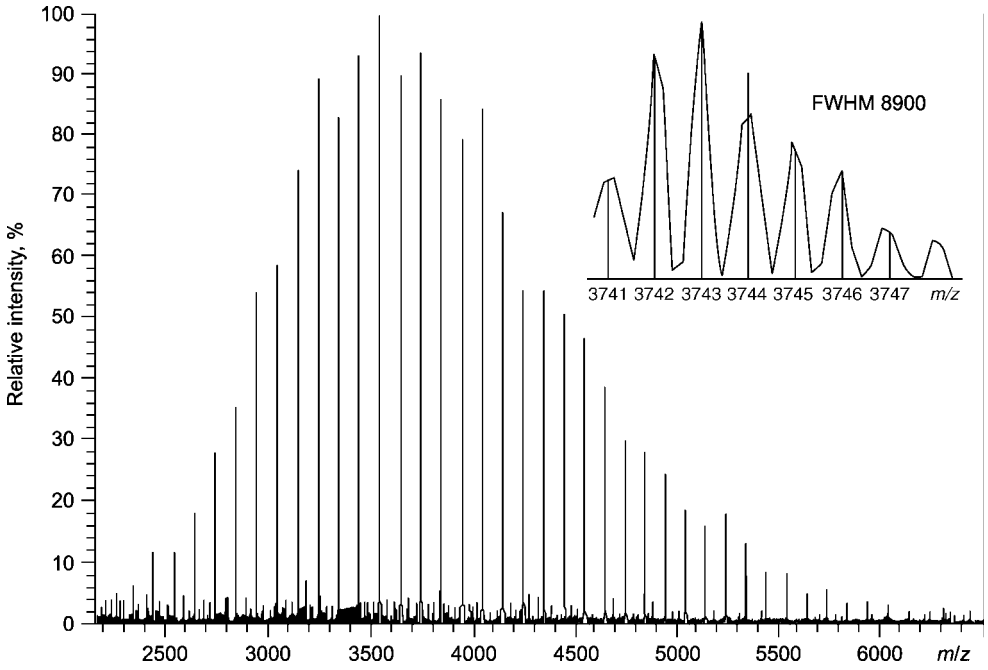

Fig. 35. MALDI analysis of a polymethylmethacrylate resin. _____ Raw data; ..... Theoretical isotope distribution. From Ref. 66.

narrow molecular weight fractions obtained by SEC (65,69,70). When applied to molecular weight measurements of homopolymers alone, MALDI-TOF brings little advantages to the already sophisticated SEC triple detector systems discussed above. However, when applied to copolymers, this approach permits the simultaneous estimation of the bivariate distribution of molecular weight and chemical composition, as explained by Suddaby and co-workers (65) and illustrated in Figure 37. In brief, this methodology consists in matching the molecular weights of the MALDI peaks for each SEC fraction to combinations of the molar masses of the comonomers using a polymerization kinetics model. Therefore, SEC/MALDI-TOF may have the potential to surpass any other known technique for the elucidation of the microstructure of synthetic copolymers.

Moreover, even though the complete molecular weight distribution for broad polymers may not be accurately recovered by MALDI-TOF alone, the very detailed molecular weight information provided for the lower molecular weight species is ideally suitable for the study of polymerization reaction mechanisms, chain end types, dendrimer analyses, and polymer identification (60–63,68).

Mass spectrometry experiments in general, and MALDI-TOF in particular, require the sample to be in the gas phase and ionized. Ionization is commonly achieved by the complexation of a cation with the polymer molecule. Polymers containing heteroatoms such as polyethers, polyamides, polyesters, polymethylmetacrylates, polysiloxanes, and polycarbonates are reasonably simple to be cationized by the addition of sodium or potassium salts. Apolar polymers containing double bonds such as polystyrene, polybutadiene, and polyisoprene can also

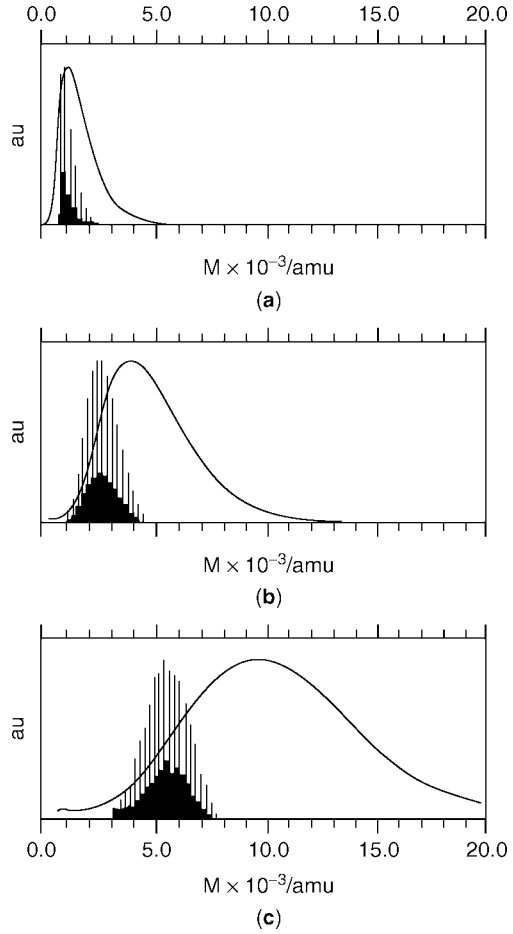

Fig. 36. Overlay of SEC and MALDI-TOF profiles for three poly(dimethylsiloxane) samples. From Ref. 67. Copyright (2000) Wiley-VCH.

be cationized with silver or copper salts. Until recently, apolar polymers with no functional groups, such as polyethylene and polypropylene, could not be analyzed by MALDI [with the exception of low molecular weight waxes and long alkanes (67)], but some alternative routes involving the functionalization of their terminal double bonds have been developed and seem to lead to sound analytical results (71–74). This is particularly attractive for the analysis of polyethylene made with metallocene catalysts that generally contains a large fraction of vinyl-terminated chains. Unfortunately, polymer–cation interactions are still the subject of much debate, even for polymer containing heteroatoms. For instance, varying the cation type in the analysis of polymethylmethacrylate samples can cause changes of 20–35% in their estimated molecular weight distributions (60).

The selection of the matrix for MALDI analysis is also far from trivial. In his comprehensive review, Nielen listed a table with more than 200 polymer/matrix/solvents entries for MALDI-TOF analysis. Homogeneous

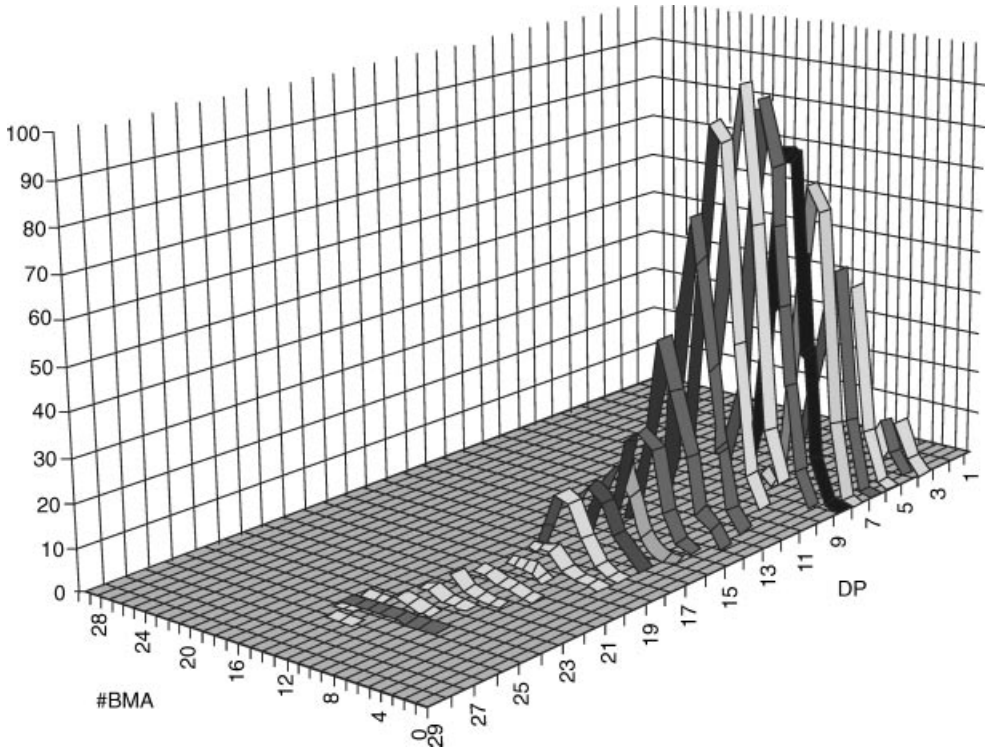

Fig. 37. Bivariate distribution of degree of polymerization (DP) and chemical composition for a copolymer of methylmethacrylate and *n*-butylmethacrylate determined by SEC–MALDI. Reprinted with permission from Ref. 65. Copyright (1996) American Chemical Society.

cocrystallization of matrix and polymer sample is essential for accurate analysis with MALDI. Generally, it is recommended that the polarities of matrix and polymer be close, but often a trial-and-error process is required. Several methods also exist for transferring the mixture of matrix, salt, and sample solutions onto the MALDI target, with electrospray deposition being considered the best approach (60).

Interaction Chromatography and Other Polymer Fractionation Techniques

The fractionation techniques described above are the ones that have proved to be applicable to the widest class of synthetic polymers over the last decades. Evidently, many more fractionation techniques have been used with many polymer types. Some of these methods will be described very briefly in the next paragraphs.

Ultracentrifugation has been used mainly for the characterization of biopolymers and gels in aqueous solutions. Some recent equipment developments have

stirred renewed interest in this fractionation method (75,76). Ultracentrifugation can be used in three main modes of operations: sedimentation velocity, equilibrium, and density gradient. In the *sedimentation-velocity* method, the centrifuge is operated at high rotational speed (above 40,000 rpm), generating a concentration profile in the fractionation cell that can be correlated to the molecular weight distribution of the polymer. In the *equilibrium* method, the centrifuge is operated at lower rotational speeds and long analysis times are required to establish the equilibrium between sedimentation and diffusion. The *density-gradient* method is mainly used to estimate the chemical composition or tacticity distributions of polymers and involves the use of two solvents of different densities. More details on centrifugation methods, including the description of new equipment apparatuses can be found in Borchard and co-workers (75).

Turbidimetric methods have also found some applications for the detection of polymer fractionation. In this case, polymer precipitation is promoted via the addition of a nonsolvent or temperature variation, according to the methods described for batch fractionation, and the turbidity created by the precipitation of the polymer chains is measured with a photometer. Both molecular weight and chemical composition fractionations can be achieved, based on the precipitation method utilized. However, only qualitative information about the distributions of molecular weight or chemical composition of the samples can be achieved by this method, because it is very difficult to relate the detector response to the actual microstructural distributions. Since this method of detection does not require the recovery of the individual polymer fractions, it may be very attractive for samples that form very viscous solutions, such as high molecular weight polymers, or samples containing inorganic fillers that would otherwise clog continuous fractionation equipment such as TREF, Crystaf, or SEC. *Cloud-point titration* is a variation of this method, used for the detection of incipient turbidity in a polymer solution. It is especially useful for the determination of the theta composition of polymer solutions. The principles of turbidimetric methods have been reviewed by Elias (77).

Many variations of interaction or adsorption chromatography have also been used to fractionate polymers. Although powerful, they are very often polymer-specific and beyond the scope of the present review. The reader is referred to the chapter of fractionation of polymers in the *Polymer Handbook* for an overview of some of these techniques (78) and to the review by Chang (37) for more details.

The power of interaction chromatography techniques will be briefly illustrated with a well-designed example for the fractionation by molecular weight of the six polystyrene samples shown in Figure 38 (79). The samples were analyzed in a high performance liquid chromatography (HPLC) system equipped with C18 bonded silica columns with various pores sizes using a solvent mixture containing a good solvent, CH_2Cl_2, and a poor solvent, CH_3CN, for polystyrene. At the highest concentration of the good solvent (65% CH_2Cl_2 by volume) the entropic effects dominate (recall eq. 20) and size exclusion is the main mechanism of separation. Thus, the chains with higher molecular weight have lower retention times. As the fraction of the good solvent CH_2Cl_2 decreases to 57%, the fractionation resolution is totally lost and all samples elute at the same retention time. At this operation condition, called the *chromatographic critical point* or the *adsorption-size exclusion transition point*, enthalpic and entropic effects cancel each other and

no separation takes place. For higher concentrations of nonsolvent, solute-support interaction effects start to dominate, increasing the enthalpic term in equation 20. At these conditions, longer chains having more repeating units interact strongly with the support and are retained longer in the columns, reversing the sequence of retention times observed during the size-exclusion mode of fractionation. A similar behavior is observed when the solvent mixture composition remains the same (CH_2Cl_2/CH_3CN: 57/43, the chromatographic critical point at 30.5°C) and the temperature is allowed to vary. According to equation 20, it is expected that the enthalpic effects will decrease as the temperature increases, and therefore fractionation by size exclusion will predominate at higher fractionation temperatures. This is indeed observed in the series of fractionations varying from 20 to 50°C, as indicated in Figure 38.

Interaction chromatography can also be used to fractionate model polymers according to long-chain branching. An application for star-shaped polystyrenes was presented by Chang and co-workers (79).

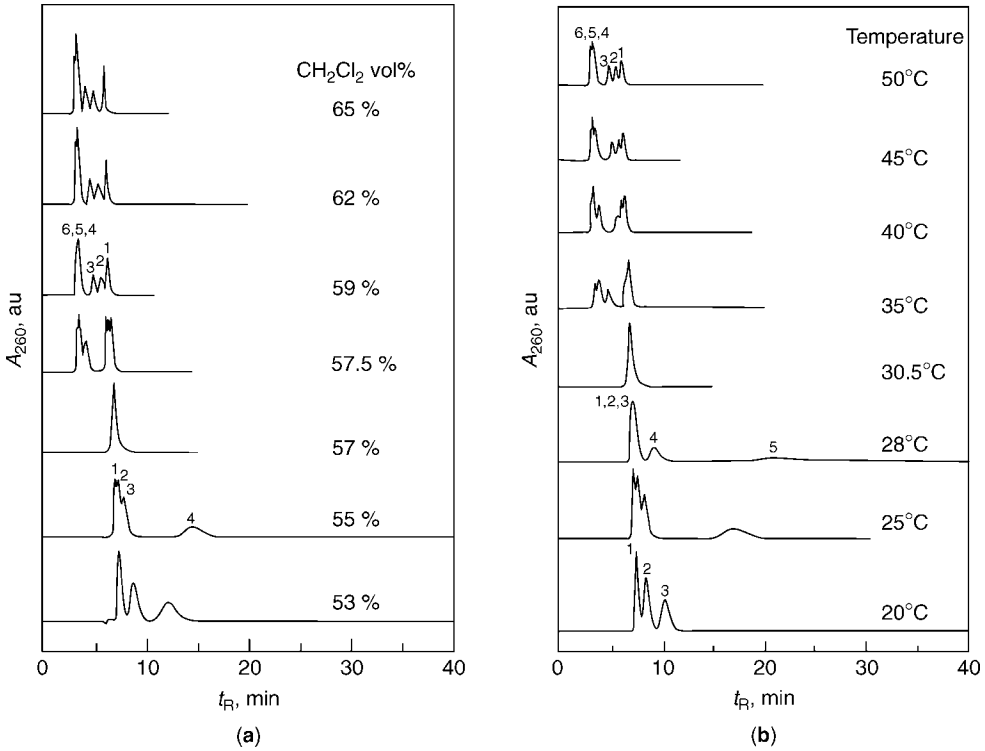

Fig. 38. Solvent composition and temperature effects for the fractionation of six polystyrene samples of different molecular weights M_w: (*1*) 2.5×10^3, (*2*) 12×10^3, (*3*) 29×10^3, (*4*) 165×10^3, (*5*) 502×10^3, and (*6*) 1800×10^3. The solvent mixture is CH_2Cl_2/CH_3CN. CH_2Cl_2 is a good solvent and CH_3CN is a poor solvent for polystyrene. The chromatograms on the left were measured at a constant temperature of 30.5°C and the ones on the right were measured at a constant ratio CH_2Cl_2/CH_3CN of 57/43 (vol/vol). From Ref. 79. Copyright (1996) Wiley-VCH.

Cross-Fractionation Chromatography and Related Techniques

Cross fractionation, also called *orthogonal fractionation*, is a term that can be applied to any technique that permits the fractionation of polymers according to two or more microstructural characteristics. For instance, polymer chains can be first separated into several fractions with narrow chemical composition distributions by TREF and each fraction can then be analyzed by SEC to recover their molecular weight distributions. When done off-line, these TREF–SEC fractionations are very time-consuming but can generate a wealth of information on polymer microstructure (80,81).

The term *cross-fractionation chromatography* (CFC) has been lately applied to a more specific method that combines TREF and SEC fractionation in an automated cross-fractionation instrument. The TREF fractions are collected in stepwise mode at predetermined temperature intervals and directly injected into the SEC columns (82). This system is very attractive because it permits the direct estimation of the bivariate distribution of molecular weight and chemical composition distribution of semicrystalline polymers. Evidently, all the considerations made above for the fractionation of complex polymers with TREF and SEC must be kept in mind when interpreting the results of these fractionations, since the separation mechanisms are not truly based on molecular weight and chemical composition but rather on hydrodynamic volume and crystallizability. CFC has been used in a large number of investigations, especially to study the polymerization mechanism of ethylene, propylene, and higher α-olefins with single- and multiple-site catalysts (83–89). Figure 39 shows the bivariate distribution of an ethylene/propylene copolymer measured by CFC and illustrates well the potential of this technique.

Interaction chromatographic separation methods that are sensitive to chemical composition have also been coupled with SEC to achieve similar cross-fractionation results for other polymer types (90–94), and fully automated instruments have been developed for HPLC–SEC orthogonal fractionations (95). It is generally preferred that the samples be first fractionated according to chemical composition by HPLC and then separated according to molecular weight by SEC.

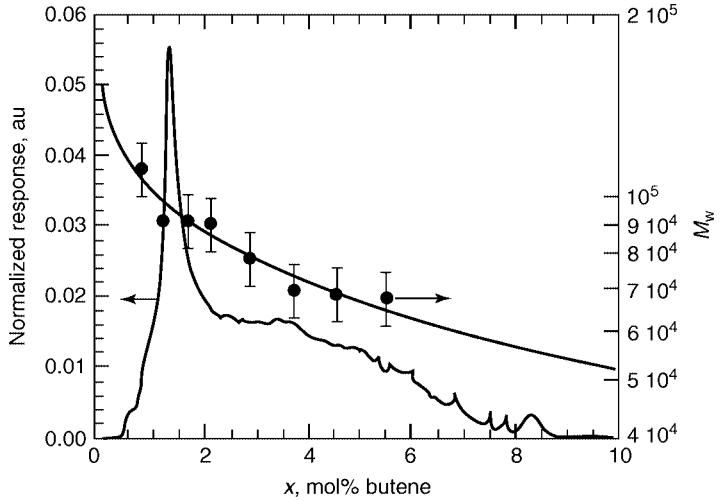

Fig. 40. Molecular weight distribution and average comonomer content for an ethylene/1-butene sample made with a Ziegler–Natta catalyst. Reprinted from Ref. 99. Copyright (2001), with permission from Elsevier.

The advantage of this sequence lies in the fact that SEC of complex copolymers responds to both molecular weight and chemical composition, while the influence of molecular weight on HPLC fractionation can be minimized by the selection of adequate analysis conditions. The importance of polymer cross-fractionation techniques is increasing because of the rapidly growing use of polymers with complex microstructures and would require a separate chapter for complete discussion. The interested reader is referred to the article by Pasch for a review on recent advances in the field of cross fractionation of polymers (96).

A simpler approach to CFC consists in measuring the average chemical composition of polymer eluting from SEC columns using an on-line Fourier transform infrared (FTIR) detector. Even though liquid flow cells can be used, signal-to-noise ratio problems may arise because of the low concentration of polymer species in the detector cell. Alternatively, the SEC effluent can be sent to a solvent evaporative interface where the polymer is deposited as a thin layer onto the surface of a germanium disk. After SEC fractionation, the disk is attached to an infrared spectrometer and the polymer microstructure is analyzed as a function of elution time (97,98). Unfortunately, this technique is not free of experimental difficulties either because it is very often difficult to obtain a uniform film deposited onto the disk. The type of information that can be obtained with SEC–FTIR is illustrated in Figure 40 for an ethylene/1-butene copolymer made with a heterogeneous Ziegler–Natta catalyst.

The SEC–FTIR combination, although attractive due to its simplicity, is not able to recover the bivariate distribution of molecular weight and chemical composition, but can only measure average composition as a function of molecular weight. Consequently, it is not a true cross-fractionation technique. A method to recover the chemical composition component of the distribution was proposed for the case of polyolefins made with single and multiple-site catalysts using a

polymerization kinetics model and molecular weight distribution deconvolution techniques (99,100).

GEL POINT

Introduction

The gel point (GP) marks the transition of a material from liquid to solid. The transition is caused by the growth of structure in the material, a structure that correlates molecular or supramolecular motion over large distances. At GP, the correlation length diverges to infinite size. This appearance of long-range connectivity is most easily seen in a rheological experiment (1).

The growth of connected structure is called *gelation* and its opposite, the decay of connectivity, is called *reverse gelation*. Depending on connectivity mechanism, the wide variety of gels can be grouped into two classes (2,3), the three-dimensionally connected networks and all the others for which the connectivity mechanism is less clearly defined. This second group of gels goes under many different names such as "jamming," "soft glass," "colloidal glass," "self-assembly," "granular gel" to mention a few. For lack of a specific term, here we call this second group the *glassy gels* since they often involve nonequilibrium states. As a common property of both classes of gels, the material structure immobilizes as it assumes a state of minimal internal energy that would get disturbed by flow. GP is marked by the divergence of regions of immobile structure to infinite size. Below GP connectivity, the material is able to flow and to relax while, beyond the gel point, a yield stress needs to be overcome before flow may happen.

Since a polymer at its gel point is in a critical state (4–9), it commonly is called a *critical gel* (10) to distinguish it from the various materials that are commonly called gel. It is interesting to explore the properties of the critical gel and use these as reference for describing the properties in the vicinity of the gel point. The critical gel affords universal rheological properties that are intermediate between liquid and solid, including the temperature shift factors that are also in between (11). It combines extreme ductility and fragility when subjected to large strain. Its

high adhesion strength (tackiness) is also an expression of the intermediate state; the critical gel still maintains the wetting properties of the liquid (low molecular weight polymer) while starting to gain the cohesive strength of the solid. The adhesion behavior must be accounted for when designing experiments with gels. It also suggests future applications of gels as adhesives.

The information most needed can be summed up in the following questions:

(1) When does GP occur?
(2) How soft or stiff is the material at GP?
(3) How fast does the material pass through GP?

These questions can be answered with the knowledge of the properties at GP. The simplicity and universality of the GP behavior, as shown below, suggests the use of the critical gel as reference state for developing soft materials.

Rheological Properties of the Critical Gel

The evolution of equilibrium mechanical properties during gelation is schematically shown in Figure 1 (using the example of chemical gelation). The steady shear viscosity of the liquid state grows as the connectivity increases. In the approach to GP, the steady shear viscosity diverges (ie, an infinite time would be necessary for the flow to reach steady state). Beyond GP, the equilibrium modulus starts to grow. At GP, the viscosity is infinite while the equilibrium modulus is still zero

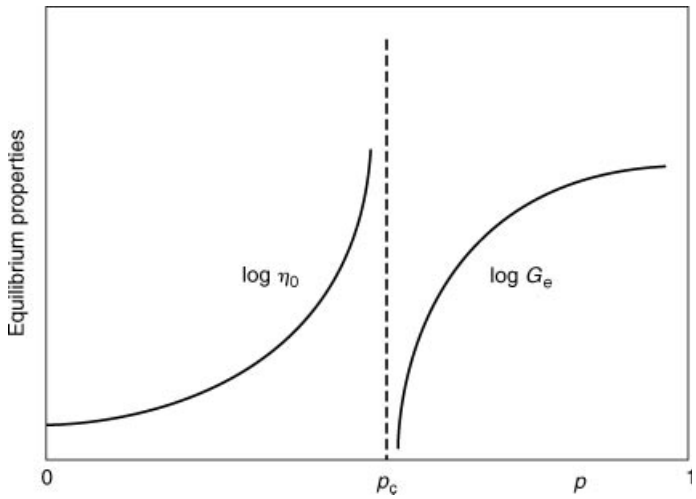

Fig. 1. Evolution of mechanical properties of a cross-linking polymer as a function of extent of cross-linking p (schematic). Representative properties are the steady shear viscosity for the liquid state (sol) and the equilibrium modulus for the solid state (gel). All viscoelastic liquid states are in between the Newtonian liquid ($p = 0$) and the critical gel ($p = p_c$). Equivalently, all viscoelastic solids are in between the critical gel and the Hookean solid ($p = 1$).

because the stress in a deformed critical gel can still relax completely. This shows that the conventional equations for a liquid (characterized by a steady shear viscosity) or for a solid (characterized by an equilibrium modulus) do not apply at GP. The critical gel has its own rheological behavior (1). The critical gel

a. requires infinite time to relax and
b. relaxes in a broad distribution of shorter modes which are self-similar.

This expresses itself in slow power law dynamics for both the linear relaxation modulus $G(t)$ and the relaxation time spectrum $H(\lambda)$ (12–14)

$$G(t) = St^{-n_c}; \qquad H(\lambda) = \frac{S\lambda^{-n_c}}{\Gamma(n_c)} \quad \text{for} \quad \lambda_0 < t < \infty \tag{1}$$

This rheological pattern seems to be a universal rheological property, since it occurs with both network gels and glassy gels at GP. Experiments with a large variety of chemically or physically gelling materials show this self-similar behavior without exception. The gamma function $\Gamma(n_c)$, arises naturally in the conversion of $G(t)$ into $H(\lambda)$. The two material parameters are the stiffnes S and the relaxation exponent n_c. Subscript c is used here to identify the critical state at the gel point. λ_0 is a crossover time to small-scale dynamics of the building blocks of the critical gel.

In comparison, a power law behavior has been predicted for molecules of self-similar (fractal) structure (15,16), suggesting that the critical gel is self-similar over a wide range of length scales (10,17). It also has been shown, without use of an analogy, that the onset of rigidity in a randomly cross-linked system is a continuous phase transition (18); at the transition, the correlation length diverges and the system is necessarily self-similar. The scaling behavior is then an automatic consequence of statistical thermodynamics (qv). Several theories have been proposed for the critical gel behavior (19–22).

The relaxation exponent n_c may assume values in the range $0 < n_c < 1$ (21). Its value cannot be predicted since a systematic study of the effect of molecular architecture on the value of the relaxation exponent is still missing. Typical experimental values are as follows:

$n_c \cong 0.5$ for end-linking networks with balanced stoichiometry (12,14,23)
$n_c \cong 0.5$–0.7 for end-linking networks with imbalanced stoichiometry (12,13,24)
$n_c \cong 0.7$ for epoxies (25)
$n_c \cong 0.8$ for PVC plastisol (26)
$n_c \cong 0.3$ for radiation cross-linked polyethylene (27)
$n_c \cong 0.5$ for micellar block polyelectrolytes (28)

The gel strength S depends on the value of n_c. A large value of S is always associated with a small value of n_c. Very little information is available about n_c of glassy gels.

The dynamic modulus of the critical gel, as described by equation 1, is also a power law:

$$G^*(\omega, p_c) = \Gamma(1 - n_c)\, S(i\omega)n_c \tag{2}$$

The real (the storage modulus G') and imaginary (loss modulus G'') parts are related as

$$G'(\omega, p_c) = \frac{G''(\omega,p_c)}{\tan(\frac{n_c\pi}{2})} = \Gamma(1 - n_c)S\omega^n \cos\left(\frac{n_c\pi}{2}\right) \tag{3}$$

The phase shift δ as defined by the loss tangent $\tan\,\delta = G''/G'$, is proportional to the slope of the dynamic modulus at GP (13):

$$\delta_c = \frac{n_c\pi}{2} \tag{4}$$

Introduced into a general constitutive equation for linear Viscoelasticity (qv) (29,30), the above relaxation modulus results in the constitutive equation for critical gels, the Winter–Chambon gel equation: (12,13)

$$\tau(t) = S\int_{-\infty}^{t} \mathrm{d}t'(t - t')^{-n_c}\dot{\gamma}(t') \tag{5}$$

The gel equation predicts all known rheological properties of critical gels, such as infinite viscosity and zero equilibrium modulus, as long as the applied strain is small. For large strains, a suitable strain measure must be introduced (12). Large strain behavior and breaking of the structure (reverse gelation by mechanical field) is not included in this equation. The breaking of critical gels (31) is a topic which needs to be investigated more closely in the future.

Chemical Gel Point

Chemically cross-linking polymers belong to the group of network gels. Molecules cross-link into large clusters through covalent bonds. The independent variable of the cross-linking process is the extent of reaction, p, which can be understood as bond probability. The polymer reaches the GP at a critical extent of the cross-linking reaction, $p \rightarrow p_c$. At GP, the second moment of the cluster size distribution diverges (7) and the molecular weight distribution is infinitely broad ($M_w/M_n \rightarrow \infty$) as molecules range from the smallest unreacted oligomer to the infinite cluster. The molecular motions are correlated over large distances but the critical gel has no intrinsic size scale. The liquid polymer before the GP, $p < p_c$, is called a *sol* because it is soluble in good solvents. The solid polymer beyond the GP, $p_c < p$, called a *gel* is not soluble any more, even in a good solvent. However, unattached molecules (sol fraction) are still extractable from the gel.

Prediction of the Chemical Gel Point. The classical mean field theories (32–34) are able to predict the critical conversion p_c quite accurately (35,36). The

predictions are mainly based on the assumptions that all functional groups of the same type are equally reactive, all groups react independently of one another, and no intramolecular reactions occur in finite species. The threshold p_c depends on the geometry of the network-forming species. Special cases follow.

Case 1. Homopolymerization of similar f-functional molecules:

$$p_c = \frac{1}{f-1} \tag{6}$$

The same relation is found for the end-linking of molecules of low functionality ($f = 3$ or 4) and for the vulcanization of long molecular chains. The average number of cross-linking sites along the chain is defined as

$$f = \frac{\sum_i f_i^2 n_f}{\sum_i f_i n_f} \tag{7}$$

with n_f being the number of molecules of functionality f_i.

Case 2. Cross-linking of f-functional molecules A_f with g-functional molecules B_g, which are mixed at a molar ratio

$$r = \frac{f(A_f)}{g(B_g)}$$

reaches the gel point at a conversion

$$p_{A,c} = [r(f-1)(g-1)]^{-1/2} \tag{8}$$

with $p_B = r p_A$. For the formation of a gel, the stoichiometric ratio must be chosen between a lower and upper critical value:

$$r_l = [(f-1)(g-1)]^{-1} \quad \text{and} \quad r_u = 1/r_l \tag{9}$$

Otherwise the reaction stops before reaching the gel point. The relations in equation 9 follow from equation 8 when considering species A_f or species B_g fully reacted, respectively.

Instead of the extent of reaction, the *stoichiometric ratio* is often chosen as independent variable of a chemical gelation experiment. Consider a system that consists of cross-linker A (average functionality $f = 3$ or $f = 4$, etc) and chain extender B (functionality $g = 2$). Assuming that the reaction is always brought to completion, the degree of cross-linking would depend on the stoichiometric ratio r (ratio of cross-linker sites to chain extender sites). The stoichiometry dependence of equilibrium mechanical properties is sketched in Figure 2. The cross-link density is a maximum for balanced stoichiometry. The viscosity diverges at a lower and an upper critical ratio r_l and r_u of equation 9. Solid behavior is found everywhere at intermediate stoichiometry $r_l < r < r_u$. Critical gels are formed at $r = r_l$ and $r = r_u$.

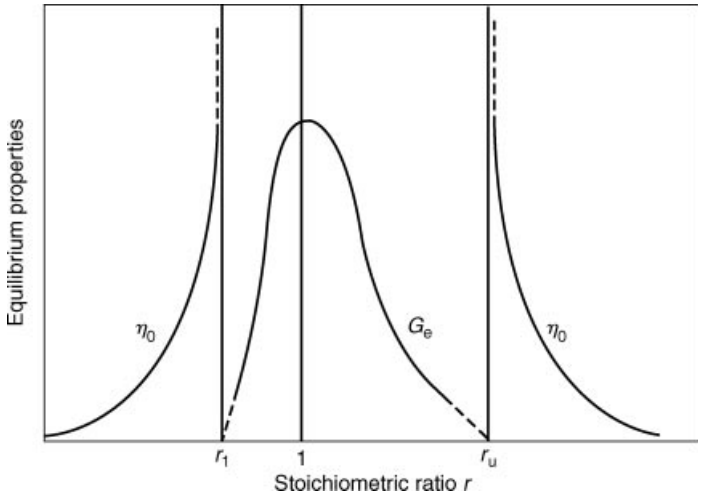

Fig. 2. Steady-state mechanical properties (schematic) of cross-linking polymers with different stoichiometric ratios r, defined as ratio of cross-linking sites of two reacting polymers. The reaction is presumably brought to completion. Steady critical gel behavior is found at the lower and the upper critical values, r_l and r_u.

Physical Gel Point

Physical gels are able to form sample-spanning, supermolecular structures. Connectivity has been found with a wide range of mechanisms which have been reviewed extensively by te Nijenhuis (37), Larson (38), and Nishinari (39). Physical gels come as both network materials (associative networks) and glassy gels. Such glassy gels can energetically associate into a sample-spanning structure, by repulsion as well as by attraction, leading to nonequilibrum states (soft glasses) (3,28). In analogy to chemical gelation, the physical gelation is defined by the growth of physically connected aggregates and the physical gel point is reached when the correlation length of molecular (or supramolecular) motion diverges to infinity. For temperature-dependent connectivity these materials are called *thermoreversible* (40); however, other variables might determine the connectivity such as pH value, concentration of connecting component, charge density, or stress level.

The principal differences between chemical and physical gels lie in the lifetime and the functionality of the junctions. Chemical bonds are considered to be permanent while the physical junctions have finite lifetimes. Physical junctions are constantly created and destroyed, however, at very low rates so that the network appears to be permanently connected if the time of observation is shorter than the lifetime of the physical network. For longer times of loading, the material flows and is characterized as a liquid even beyond its gel point. The analogy between chemical and physical gelation applies very well to systems with long-living bonds. It becomes less defined when renewal of physical bonds occurs on the time scale of observation and the system behaves as a liquid. In this case, a characteristic renewal time, λ_{pg}, of the physical bonds determines long-time ordering processes and rheology of a physical gel.

The analogy between physical and chemical gelation applies only to time scales shorter than the characteristic renewal time. Equation 1 changes into

$$G(t) = S_c t^{-n_c} \quad \text{for} \quad \lambda_0 < t < \lambda_{pg} \tag{10}$$

Physical gels typically have a yield stress beyond which the structure gets broken and liquid behavior sets in. Below the yield stress, the physical gel is a solid at experimental times shorter than the renewal time and it is a liquid at experimental times longer than the renewal time.

Range of the Power Law

The power law of the critical gel of a cross-linking polydimethylsiloxane (PDMS) was found for G' and G'' to extend over a frequency range of more than five decades (13,14), the entire experimental range. A lower frequency limit is given by the correlation length, which is the linear size of a typical cluster of the self-similar structure. This correlation length diverges at GP and the lower frequency limit of the power law could theoretically be extended to zero. However, a practical lower frequency limit is given by the finite sample size, ie, at a scale of observation that exceeds the size of the sample in the rheometer. The upper frequency limit of the power law behavior very much depends on the small scale structure of the critical gel.

For chemical gelation, the upper frequency limit (and the corresponding lower time limit, λ_0, of eqs. 1 and 10) typically depends on the following two molecular sizes:

(1) *Size of the chains between cross-links*: The randomly coiled chains exhibit self-similar behavior and the transition from the self-similar critical gel to the self-similar chain (between network junctions) is difficult to detect experimentally.
(2) *Glass length*: At very high frequency, the scale of observation decreases below the lower scaling length of the polymer called the *glass length*. The *glass length* is given by the size of the network element that determines the transition to glassy behavior at low temperature. This smallest network element depends on the specific molecular structure. It could be the distance between cross-links or the length of a chain unit. At this small-length scale, vitrification becomes important and deviation from equilibrium self-similar behavior is expected. In this description of chemical gelation, it is tacitly assumed that the scale of observation is sufficiently larger than the glass length. The details of the molecular structure are neglected by neglecting the high frequency transition to the glass behavior of the chemical networks.

Physical critical gels typically have a very limited power law region. The slow dynamics is governed by the transition to flow behavior as an expression of the finite lifetime of the physical junctions. The faster dynamics undergoes transition to the dynamics of the structural building blocks. These building blocks

are typically quite large in physical gels so that their dynamics can be seen at already low frequency. Between these two phenomena, little may remain of the self-similar dynamics of the critical gel. General relations are difficult to find because of the large variety of connectivity mechanisms, especially is glassy gels. Nonequilibrium states make the power law parameters path-dependent, ie they depend on the history of the glassy gel formation.

Vicinity of the Gel Point

The power law region seems to stretch out and then contract again, having its widest range at GP. The slope gradually decreases during gelation. This phenomenon is visible on cross-linking of PDMS (13,14), and it is very pronounced for radiation cross-linking of polyethylene (27). It is found in physical gels (26,28,41–44) as well as in chemical gels.

The longest relaxation time λ_{max} first grows to infinity and then decays again. In the vicinity of GP, this may be expressed in power laws (45):

$$\lambda_{max} \sim \begin{cases} (p-p_c)^{-s/(1-n_c)} & \text{for} \quad p<p_c \\ (p_c-p)^{-z/n_c} & \text{for} \quad p_c<p \end{cases} \tag{11}$$

These equations hold for small introduce absolute value signs $|p - p_c|$, ie, in the vicinity of GP. Materials near GP are often called *nearly critical gels*. The exponents depend not only on the dynamic critical exponent (relaxation exponent n_c) but also on the dynamic exponents s and z for the viscosity $\eta \sim (p_c - p)^{-s}$ and the equilibrium modulus $G_e \sim (p - p_c)^z$. If one, in addition, assumes symmetry of the diverging λ_{max} near the gel point

$$\frac{s}{1-n_c} = \frac{z}{n_c} \tag{12}$$

then the critical exponents are related as (45,46)

$$n_c = \frac{s}{s+z} \tag{13}$$

Into these relations one may introduce specific values (s, z) from percolation theory or from branching theory and determine the corresponding values for n_c. The wide range of values for the relaxation exponent $0 < n_c < 1$ lets us expect that the dynamic exponents s and z are nonuniversal. Since s and z can be predicted from theory (47), n_c values can be calculated from equation 13. This result, however, relies on the symmetry hypothesis, which does not seem to be generally valid, at least not for highly entangled polybutadienes (48).

The slow dynamics of a system, for which the relaxation time goes through a singularity, can be described with a discrete relaxation time spectrum with a

longest relaxation time $\lambda_{max}(p)$ that diverges at GP:

$$G(t,p) = G_e + \frac{S}{n\ \Gamma(n)\lambda_{max}^n} \sum_{i=1}^{\infty} \exp\left(- \frac{ti^{1/n}}{\lambda_{max}} \right) \tag{14}$$

Its four parameters G_e, S, λ_{max}, and n all depend on the bond probability p. In the liquid below GP and at GP, the equilibrium modulus is equal to zero, $G_e = 0$. For $n = 0.5$ and $G_e = 0$, this spectrum reduces to the well-known Rouse spectrum. It is remarkable that depending on the value of λ_{max}, the Rouse spectrum describes a viscoelastic liquid that includes the Newtonian liquid ($\lambda_{max} \to 0$) and the critical gel ($\lambda_{max} \to \infty$) as limiting cases.

Alternatively to equation 14, a cutoff function $F(t, \lambda_{max})$ may be applied to the equation of the critical gel, equation 1:

$$G(t,p) = G_e + St^{-n}F(t, \lambda_{max}) \tag{15}$$

The model reduces to the power law at the gel point $F(t, \lambda_{max}) \to 1$ for $\lambda_{max} \to \infty$. The stretched exponential cutoff function (49)

$$F(t, \lambda_{max}) = e^{-(t/\lambda_{max})^{\beta}} \quad \text{with} \quad 0 < \beta < 1 \tag{16}$$

was found to give good results with a curing epoxy (50).

Measurements of Instant of Gelation

Equilibrium Rheological Measurements. The appearance of an equilibrium modulus or the divergence of the steady shear viscosity might be used to estimate the position of the gel point by extrapolation. Extrapolation is necessary because these measurements fail in the close vicinity of GP. Measurement of the equilibrium modulus (51,52) is extremely difficult because its value remains below the detection limit for a considerable time and it, theoretically, requires an infinite time to perform the measurement. The diverging steady shear viscosity (53–55) indicates the location of GP. The simplicity of this experiment may lead to neglect of the severe shortcomings that can be summed up as follows:

(1) GP is found by extrapolation of an experiment which never can reach steady state since the longest relaxation time diverges at GP.
(2) The network structure near GP is very fragile and most probably gets broken during the viscosity measurement, causing an apparent delay in gelation or may induce reverse gelation.

For these reasons, steady-state measurements give only an apparent gel point. The real and the apparent gel point might be close together, but additional experiments will be needed for confirming such an assumption.

Transient Rheological Measurement. The nature of the critical gel suggests transient measurements, which are possible even if the longest relaxation

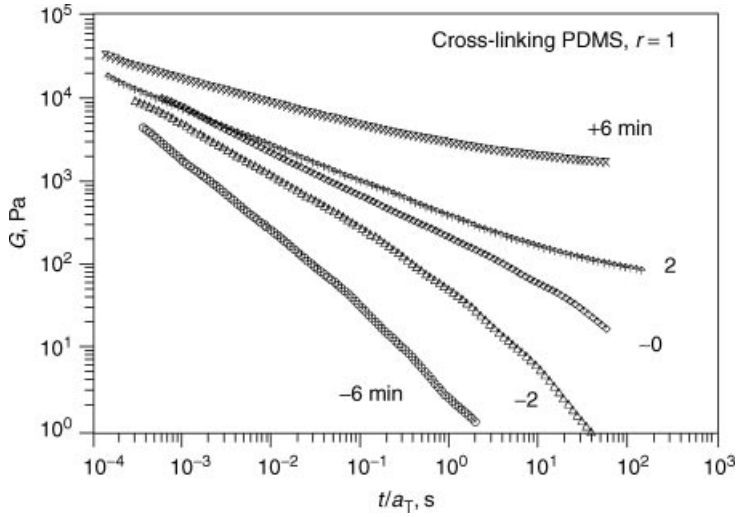

Fig. 3. Evolution of relaxation modulus of a cross-linking polymer as shown with five samples of increased cross-link density. Parameter is the reaction time distance from the gel point ($t - t_c$). The values are calculated from dynamic mechanical data (13). The power law relaxation is limiting behavior for the liquid and the solid. One of the samples is very close to the critical gel. However, at very long times it deviates from the power law behavior. It is still a fluid.

time diverges. A typical evolution of the relaxation modulus is shown in Figure 3. The power law is distinguished from the other states by being a straight line. It shows that the entire relaxation time spectrum is affected by the gel transition. It is surprising to find that intermediate relaxation modes, which are accessible to experiment, are affected by the diverging longest relaxation time in a way that makes it possible to distinguish between a sol and a gel (1,13,14). It is not necessary to measure the diverging longest relaxation time; measurement of intermediate relaxation modes suffice for detecting the gel point in many different ways. Three examples are as follows:

(1) the loss tangent $\tan \delta = G''/G'$ of the critical gel is independent of the frequency of the dynamic experiment. GP is detected by the intersect of $\tan \delta$ curves (see Fig. 4). A multifrequency experiment has been designed for detecting the GP based on this approach (56).

(2) For start-up of shear flow at constant rate, the transient viscosity grows in a power law with time. This might be utilized for detecting GP. The total strain must be kept small because, near GP, stress relaxation is infinitely slow and shear modification cannot be avoided even at extremely low rates of deformation.

(3) It is especially simple to detect the instant of gelation of a material whose critical relaxation exponent n_c is known. For any frequency (within the power law region) and any temperature, in a small amplitude oscillatory shear experiment at constant ω_0, GP is reached at the instant at which functions $G'(\omega_0, t)/\cos(n_c\pi/2)$ and $G''(\omega_0, t)/\sin(n_c\pi/2)$ intersect (see eq. 3).

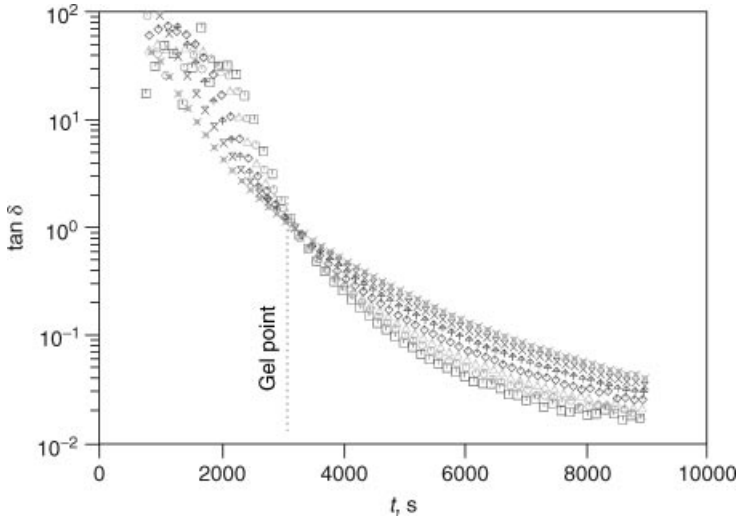

Fig. 4. Loss tangent of a chemically cross-linking polybutadiene as function of reaction time (48). Data were taken at several frequencies. The GP is marked by the instant at which the loss tangent is independent of frequency. All data are taken at low frequencies where the self-similar behavior prevails.

In the special case of $n_c = 0.5$, this relation simplifies even further. It should be noted that an intersect of G' and G'' is not necessarily indicating a gel point in spite of many published claims to the contrary.

With dynamic mechanical experiments, the instant of gelation can be measured as precisely as the accuracy of the rheometer permits, a significant advantage over extrapolation methods. An additional advantage is that the strain is kept small and shear modification of the molecular structure is avoided. The main limitation is the experimental time that tends to get long as low probing frequency is chosen. Rapidly gelling materials do not give sufficient time to the experimentalist to perform mechanical spectroscopy near the gel point.

Nonrheological Methods. Dynamic light scattering has been developed as nondestructive and real-time determination of GP for both chemical and physical systems (57–59). Time-resolved dynamic light scattering not only allows one to determine the gelation threshold but also to investigate critical dynamics near the gelation threshold. At GP, a power law appears in the intensity–time correlation function. Specific features originate from some unique aspects of gels: nonergodicity, frozen inhomogeneities, in addition to the divergence of the connectivity correlation.

Specific Methods for Chemical Gelation. The predictability of the threshold p_c suggests that GP can be found by monitoring the degree of cross-linking until it has reached the theoretical p_c value. However, the degree of cross-linking is difficult to measure accurately. Side reactions that parallel the cross-linking reaction (60,61) might interfere with the measurement. For practical purposes, these difficulties are avoided by saying that the polymer is before the gel point (sol state) if it can be completely dissolved in a good solvent and beyond the gel

point (gel state) if it cannot be dissolved completely. Numerous solution swelling experiments have confirmed that the rheologically observed GP coincides with the transition from a completely soluble state to an insoluble state (13,14,23).

Applications

For many applications in polymer processing, it is sufficient to know when the liquid–solid transition occurs for the purpose of avoiding it. For example, shaping must occur before the gel point while the polymer is still able to flow and the stress can relax to zero. Polymers around the gel point are used in a broad spectrum of applications such as gel processing, reactive processing (gel as intermediate state), and the development of new polymeric materials (adhesives, absorbents, porous catalysts, vibration dampers, membranes, colloidal glasses). They are also important outside the polymer field, for example, in food technology or in blood clotting.

GENETIC METHODS OF POLYMER SYNTHESIS

Introduction

Polymers have found enormous technological significance in a variety of areas including plastics, resins, fibers, and biomaterials. Both the chemical nature of the polymer and its structure are critical in determining its properties; the importance of polymer structure in dictating function has, for many decades, fueled the development of synthetic strategies for creating well-defined macromolecules. During the past 15 years, the application of biosynthetic strategies has gained increasing prominence as a polymer synthetic method, owing to the fact that the biosynthesis of macromolecules offers precise control of monomer sequence and macromolecular structure. This control is the source of the information storage, hierarchical assembly, mechanical strength, and enzymatic properties of natural macromolecules such as nucleic acids and proteins, which serve as an inspiration to the polymer chemist. Genetic methods of polymer synthesis have therefore been used to create protein-based polymeric materials inspired by natural molecules such as collagen, silk, and elastin, as well as materials comprising amino acid sequences with no natural counterpart. The macromolecules produced by these strategies exhibit novel and well-controlled properties, and genetically directed synthetic methods promise the contribution of additional advanced materials in the future.

Properties of Synthetic Polymers

Synthetic polymers, used here to describe polymers produced by chemical (ie, nonbiological) methods, have enjoyed great technological success since the beginning of their development in the early 20th century. A nearly limitless set of monomers can be polymerized by a vast variety of chemical transformations, which has contributed to the successful application of polymers in disparate applications, such as textiles, high temperature materials, and biomaterials. The properties of polymers are controlled by their chemical composition and by structural parameters such as polymer chain length, stereochemistry, monomer sequence, and topology. Because chemical polymerizations are statistical processes, synthetic polymers exist as a population of different molecules of varying structure, rather than as a collection of identical molecules. The properties of a synthetic polymer can therefore only be characterized with respect to the average properties of the chain

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

population and the distribution around this average. Such heterogeneity has not adversely affected the use of these macromolecules in bulk application, but does have profound consequences when attempting to engineer polymer properties on the nanometer length scale. In this regime, important parameters such as functional group placement and macromolecular assembly are directly affected by variations in molecular weight, sequence, stereochemistry, and topology.

There have been many advances in synthetic polymer chemistry that have increased the control of polymer structure. These advances began most notably in the 1950s with the implementation of Ziegler–Natta polymerizations (1,2) and living polymerizations (3–5), which permitted, for the first time, control over architectural parameters such as stereochemistry and molecular weight, respectively. The development of these methods was critical to developing an understanding of structure–property relationships in polymeric materials and for the production of useful plastics, fibers, and elastomers. Since that time, a variety of novel chemical strategies for controlling polymerizations have continued to evolve, including the use of organometallic catalysts to control stereochemistry in olefinic polymers; atom-transfer radical polymerizations that permit living free-radical polymerization; living *N*-carboxyanhydride polymerizations; and living ruthenium-catalyzed ring opening metathesis polymerizations (2,6–15). These methods have been extremely important for producing stereoregular materials, synthetic macromolecules with unusual self-assembly properties and phase separation behavior, polymers with triggered and controlled response, and functionalized polymers with controlled molecular weight. Despite these advances, precise control of functional group placement remains elusive in polymers produced by chemical methods, which can limit their utility in applications where precise molecular recognition, catalysis, and assembly is desired. Because genetically directed methods of polymer synthesis offer precise control over molecular weight, stereochemistry, and sequence, they have been increasingly applied over the last 15 years toward the synthesis of exactly defined protein based materials that have potential uses in materials, biomedical, and nanotechnology applications.

Biosynthesis of Proteins

The control over protein synthesis in living organisms is derived from the templated nature of the genetically directed polymerization (Fig. 1). A DNA message encoding an amino acid sequence—naturally derived or artificial—is transcribed (converted) to a messenger RNA (mRNA) sequence. This sequence is translated (decoded) by transfer RNA (tRNA) molecules, which deliver amino acids to the ribosome. At the ribosome, the corresponding amino acid sequence is linked together enzymatically to form the protein. The tRNA molecules carry the appropriate amino acid to its exactly specified location along the protein chain via codon–anticodon pairing, and are charged with the appropriate amino acid by a highly selective class of enzymes, the aminoacyl tRNA synthetases. These enzymes exhibit an extremely small error frequency in amino acid incorporation—fewer than one in 10,000 errors (16)—so the amino acid sequence is preserved with great fidelity during protein biosynthesis; this permits the exact control of the placement of over 20 different amino acids along the protein backbone. This primary sequence

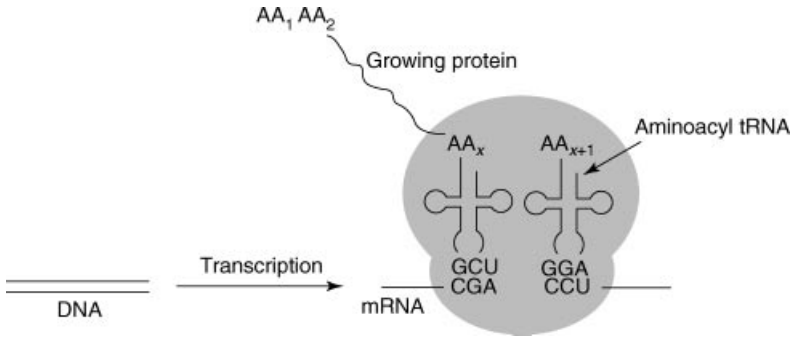

Fig. 1. Schematic of protein biosynthesis.

directs the formation of regular secondary structure (helical, coil, or sheet) and mediates the 3-D structure, assembly, and molecular recognition that are the hallmark of biological materials and the source of their remarkable properties. The strict sequence control, then, allows the synthesis of a remarkably diverse set of materials from a single set of building blocks. For example, the range of properties of Silk (qv), Collagen (qv), and elastin, which are each synthesized from the same set of 20 natural amino acids, arises from differences in their primary sequences and consequently different conformations and assembly.

The mechanical properties of these natural proteins, which can be comparable to and sometimes exceed those of high performance synthetic materials (Table 1), coupled with their potential biological activity, have been a motivation for the synthesis of polymers via genetic methods. Capturing these properties in genetically engineered artificial protein polymers offers the possibility of biologically derived performance materials and other protein materials that can be engineered with properties not currently found in the natural protein repertoire (eg, novel folding motifs and assemblies). Furthermore, the exact molecular weight control and precise specification of amino acid position of genetically directed methods provides materials that carry sufficient information to exactly control their folding and assembly. Because proteins assume thermodynamically stable structures in solution, the 3-D placement of functional groups on the atomic

Table 1. Representative Properties of Several Natural Proteins and Synthetic Fibers[a]

Material	UTS, MPa	Modulus, GPa	% Strain at break
B. mori silk	740	10	20
N. clavipes silk	875–972	11–13	17–18

[b]From Ref. 18.

length scale, with assembly controlling placement on longer length scales, is possible; the advantages of this assembly include the purposeful control of the mechanical, chemical, and biological properties of the artificial protein polymer chain. The variety of amino acid sequences that can be constructed and produced in cellular hosts via protein engineering methods provides access to a wide variety of protein polymers with diverse properties. Additionally, the incorporation of non-natural amino acids in these polymers has also significantly broadened the versatility of *in vivo* protein synthesis as a route to producing polymeric materials.

Genetically Directed Synthetic Strategies

Recombinant DNA methods have been traditionally used in site-directed mutagenesis studies designed to probe protein folding or enzymatic activity. The ease with which genetic sequences can be constructed has, however, led to the increased use of these methods for the synthesis of proteins with repetitive sequences. Naturally occurring materials with desired properties can be produced in organisms such as bacteria and yeast, simply by transferring the DNA encoding the natural protein into the appropriate expression host. Alternatively, short, repetitive amino acid sequences that are found in naturally occurring proteins can be linked together to form an artificial protein (one that does not exist in nature). Finally, since the folding of certain amino acid motifs is understood, amino acid sequences not found in nature can be designed from scratch (*de novo* design) to produce artificial proteins with desired chemical, biological, and/or physical behavior.

The production of naturally occurring proteins, such as silk, collagen, or elastin, is motivated by their excellent mechanical properties. In one approach for producing these proteins, the cDNA encoding the natural protein is isolated from an organism that produces the protein of interest and is cloned into an expression plasmid that carries the necessary genetic information to direct the expression host to produce both RNA and protein. While this approach guarantees that the polymer sequence will match that of the natural protein, difficulties with gene stability and protein synthesis can be encountered when the genes are extremely long and repetitive and when the coding preferences of the organism from which the DNA is isolated are different than those of the expression host. In many cases, it is not possible or necessary to construct a single amino acid sequence that encodes the full-length protein, and so shortened DNA sequences from the natural protein can be used.

Since many natural structural proteins comprise highly repetitive amino acid sequences, strategies to produce artificial repetitive proteins with properties analogous to those of the natural proteins have also been developed. The artificial repetitive proteins are either based on naturally occurring amino acid sequences or on sequences identified via *de novo* design. The overall strategy for gene design and expression is summarized in Figure 2. Synthetic genes encoding the artificial proteins are produced via standard molecular biological protocols; the genes for short amino acid sequences (30–40 amino acids, 90–120 base pairs) are first produced by solid-phase chemical synthesis and are then ligated into circular plasmid DNA, which serves as a source of the DNA "monomer" for future experiments. The initial solid-phase synthesis of the short genes permits use of DNA sequences

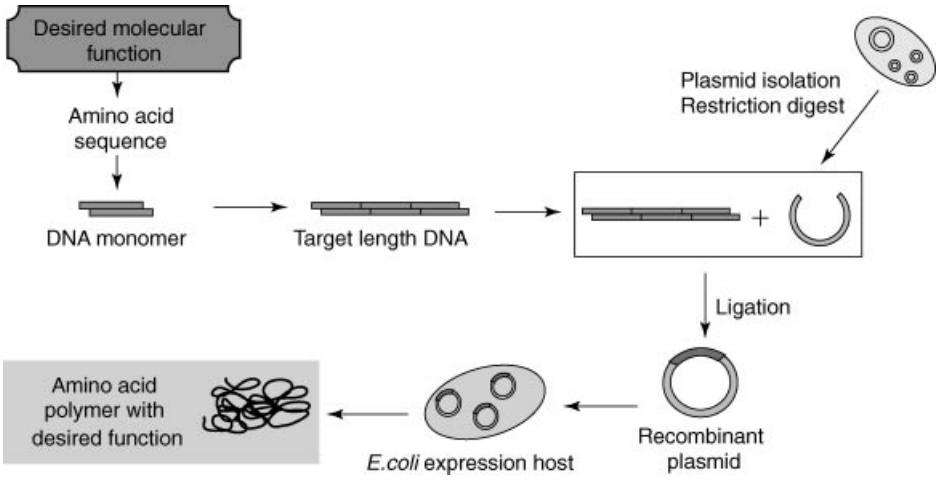

Fig. 2. Protein engineering strategy for the genetically directed synthesis of protein polymers.

that reflect the natural coding preferences of the organism in which the protein will be expressed and allows reduction of repetition in codon usage. It also permits the inclusion of amino acids with desired chemical functionality, or the insertion of biologically active sequences, to capture a variety of desired materials properties in the resulting protein. After the sequence of the gene in the plasmid in confirmed, the monomer is isolated from the plasmid and multimerized enzymatically. The multimerization proceeds in a head-to-tail orientation to form genes that can have lengths of up to 5000 base pairs (approximately 1675 amino acids); these genes are ultimately ligated into an expression plasmid (*vide infra*).

There are several different strategies (random, iterative, and recursive) that have emerged for the construction of multimers, as outlined in Figure 3, although the use of one strategy is not exclusive of another; ie, a combination of these approaches can be used in the construction of a single artificial gene (19). In random approaches, as the general one described above, DNA monomers are oligomerized in a single step, creating a population of oligomers of different lengths. In iterative approaches, a DNA segment is oligomerized in a series of uniform steps, each step adding one DNA segment to the growing oligomer. In recursive approaches, the DNA monomers are joined sequentially, with the length of the ligated segments doubling at each step. Random approaches offer the advantage of rapid creation of a library of repetitive genes of different lengths in a single step. Although this method does not guarantee the synthesis of a specific gene of desired length, it has been the most widely adopted of the multimerization strategies, owing to its simplicity and the fact that ligation conditions can be controlled to increase the probability of obtaining multimers of a given molecular weight range. Iterative and recursive approaches offer the advantage of production of genes with a specific and predetermined molecular weight, which is desirable if the effects of sequential changes in molecular weight or the impact of a precise and alternating block copolymer architecture are of interest. These methods requires repetitive cloning steps, the exact number depending on the desired

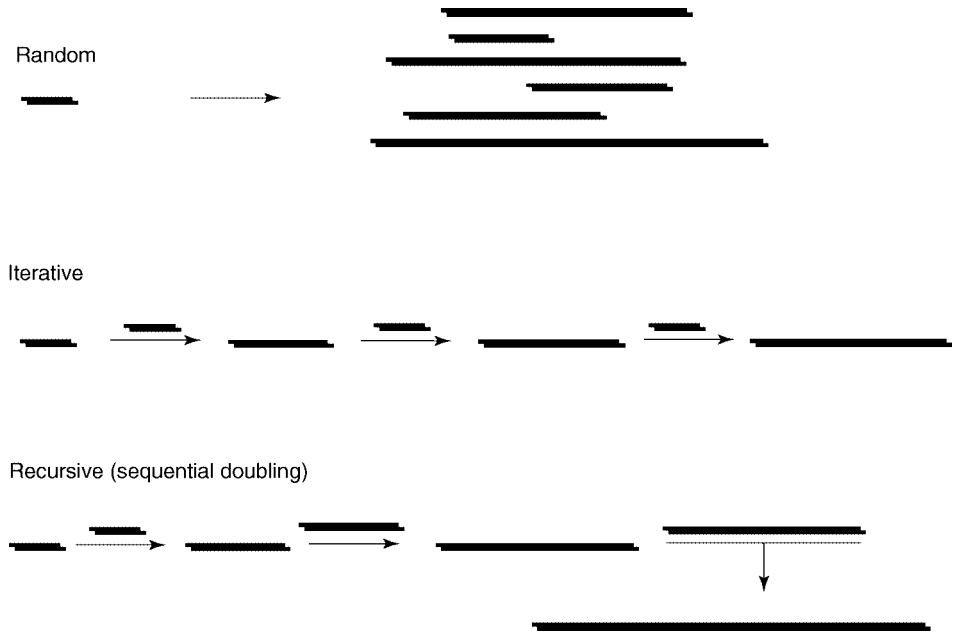

Fig. 3. Multimerization strategies employed for the construction of artificial genes. Adapted from Ref. 19, with permission from Elsevier.

length of the gene. The different approaches are used depending on the requirements of a specific macromolecular design, and demonstrate the flexibility of genetic methods of polymer synthesis for the production of varied types of polymer architectures.

Once the appropriate gene library is constructed, individual genes are incorporated into an expression plasmid, which is then incorporated into an expression host, most commonly *E. coli*. Because only one type of plasmid is maintained per cell, the plasmid DNA of individual bacterial colonies can be screened to identify and isolate a specific synthetic gene of desired length. The chosen synthetic gene is expressed from an expression plasmid (Fig. 2), which directs the synthesis of mRNA and protein in the cell. The expression plasmid also contains a promoter that regulates protein production and that can be controlled by inexpensive external means (eg, addition of chemicals, change in temperature). During protein expression, host cells are grown to a desired density, and then protein synthesis is initiated by simple addition of chemicals or change in temperature. Protein polymers can be produced at high levels in host cells; protein generally accumulates intracellularly (although it can also be transported out of the cell) and is then isolated from the cellular proteins via cell lysis, washing, precipitation, and chromatographic methods. The proteins are analyzed via amino acid analysis, chromatographic methods, mass spectrometry, NMR, and immunochemical analysis to confirm their identity; the pure product is absolutely homogeneous in both molecular weight and sequence. A variety of protein polymers based on silk, collagen, elastin, mussel adhesive proteins, and viral spike proteins have been produced by these methods, and there are also reports of the production of

hybrid polymeric materials comprising synthetic polymers coupled to genetically engineered motifs. There are limited reports of the synthesis of the mussel adhesive and viral spike protein polymers (20,21) and the hybrid polymers (22–24). The vast majority of materials have been produced from silk, collagen, elastin, and artificial amino acid sequences (Table 2); research in the design, synthesis, and characterization of these materials will therefore by presented below.

Silk-Like Protein Polymers

Naturally occurring silk (qv) is produced by a variety of organisms such as the silkworm (eg, *Bombyx mori*), spider (eg, *Nephila clavipes*), and scorpion, and the toughness and mechanical properties of the silk fiber has interested materials scientists for its use as a lightweight, high performance fiber, and in composite applications. Of all the silks, those from *B. mori* and from the dragline of *N. clavipes* have been the most extensively studied. The silk from the silkworm *B. mori* has been cultivated for centuries and used as a textile fiber. Spider silks, in contrast, are a family of proteins, in which there are multiple types of silk; for example, *N. clavipes* has seven different types of silk, each of which is tailored for a specific function. All silks have a highly repetitive amino acid sequence, which is characteristic of the fibrous proteins (eg, silk, collagen, and elastin) that serve a mechanical or structural function; globular proteins that serve catalytic or molecular recognition functions do not contain such repetitive sequences. The exact nature of the repetitive amino acid sequence depends on the type of silk, but includes alanine- and glycine-rich regions that have a high propensity for β-sheet formation via intrachain hydrogen bonding, interrupted by less crystalline or amorphous domains. The crystalline region from *B. mori* fibroin, for example, has the sequence [GAGAGSGAAG(SGAGAG)$_8$Y], and it is estimated to occur approximately 70 times within the protein (101). The repeated motifs from spider silk are less conserved, but a 13 amino acid repeat, (YGGLGSQGAGRGG), based on cDNA sequences, has been identified (102); this consensus region is generally followed by a short polyalanine sequence. The novel mechanical properties of silks are believed to arise from the folding of the protein into small β-sheet crystallites that are dispersed in a noncrystalline matrix (103); shear forces during fiber spinning permit processing and alignment of the crystallites to produce excellent fiber properties. The dragline of *N. clavipes*, for example, dissipates energy over a large surface area and balances stiffness (modulus of 10–50 GPa), strength (tensile strength of near 1.0 GPa), and extensibility (elongation to break of 10–30%) (104) (Table 1). These mechanical properties compare will to those of synthetic high performance materials, with a high tensile strength that approaches that of Kevlar, a toughness 3 times that of aramid fibers, and a strength 5 times that of steel by weight.

Protein engineering strategies have been widely employed for the production of silk-like proteins, both in research investigations aimed at understanding the molecular basis for the excellent mechanical properties of silk, as well as in commercial applications that employ protein engineering methods as a source of specialty materials (or potentially materials for bulk fiber applications). Protein engineering of silk is motivated in large part by the difficulty of isolating

[a] One-letter abbreviations of the amino acids are employed except as noted in the table. The letter X indicates positions in which several different amino acids have been encoded. Only general consensus repeats are given; minor linker regions, fusion tags, random sequences of amino acids, and minor substitutions in isolated repeats are deleted for simplification.

[b] The A and G residues are dispersed randomly throughout the sequence to reduce gene repetition.

[c] A blocks: $[VPGEG(IPGAG)_4]_{14}$, $[(APGGVPGGAPGG)_2]_x$, $[VPGVG(IPGVGVPGVG)_2]_{19}$, $[VPGEG(VPGVG)_4]_{30}$, $[VPGEG(VPGVG)_4]_{48}$, $[(VPGMG)_5]_x$; B blocks: $[VPAVG(IPAVG)_4]_{16}$, $[VPGFG(IPGVG)_4]_{14}$.

[d] CS5 = GEEIQIGHIPREDVDYHLYP; CS5 is a cell-binding domain from fibronectin.

[e] Helix = SGDLENEVAQLEREVRSLEDEAAELEQKVSRLKNEIEDLKAE.

these proteins in large quantities from the predatory spider, which cannot be cultivated like the silkworm. Despite advances in recombinant DNA methods, no complete cDNA or genomic DNA sequence of a natural silk protein has been successfully utilized for protein expression. The difficulties arise primarily because of the extreme length and repetitiveness of these genes, and also potentially because of the poor codon correspondence between the animal and the expression host, which places an unbalanced demand on aminoacyl-tRNA pools during bacterial protein expression. As a result of these difficulties, genetic deletions and/or premature termination during protein synthesis are often observed. However, the relatively simple, repetitive amino acid sequences that comprise silk proteins can be easily used to construct artificial silk-like proteins, and this approach has addressed the instability and poor production of protein from the expression plasmids prepared from the natural cDNA. Indeed, these approaches have been used to produce silk-like protein polymers containing nearly 1000 amino acids from bacterial expression systems, and somewhat longer polymers in yeast, indicating the flexibility of the method. Limitations in predicting protein polymer structure and function from the properties of the repetitive amino acid sequences can occur, but have not caused serious problems in the design of silk-like artificial proteins; the repetition of consensus sequences of natural silks provides protein-based polymers in which the conformational properties of the original protein are well preserved.

The instability of long cDNA sequences has limited their lengths to less than 2.5 kb. Recently, a 1.5-kb partial cDNA fragment of *N. clavipes* dragline silk has been cloned and the 43-kDa protein has been expressed from *E. coli* (25). However, most work has focused on the bacterial expression of silk-like proteins from synthetic genes, as mentioned above. Earliest reports of this approach date back to the work of Cappello and co-workers in 1990 (26). In these initial studies, a variety of different silk-like protein sequences with the repetitive sequence $(GAGAGS)_n$ were constructed, (where G is glycine, A is alanine, and S is serine) on the basis of the *B. mori* silk fibroin. The 108-bp monomer, flanked by Ban I restriction sites which permit only head-to-tail ligation of monomers, was multimerized enzymatically, and the multimers were fractionated and ligated into an expression system controlled by a strong, temperature-sensitive promoter that permits induction of protein expression by simply raising temperature to above 40°C. The $(GAGAGS)_n$ sequence proved intractable because of the formation of very stable and insoluble β-sheet structures, and so more complex sequences with improved solubility have been produced via introduction of noncrystalline regions dispersed between the β-sheet crystalline regions. For example, artificial proteins designed to contain both the crystalline segments of silk fibroin and the cell adhesion domain of fibronectin have also been synthesized by Cappello and co-workers, and have been shown via wide-angle X-ray scattering and molecular simulations to crystallize according to the models for Silk I (27). More recently, a sequence that alternates the $(GAGAGS)_4$ repeat from *B. mori* with a $(VPGVG)_8$ repeat from elastin has been produced, and the protein maintains excellent materials properties based on the combination of crystallinity and elasticity imparted by the two repetitive domains of the 832-amino acid artificial protein (105). Copolymers of the crystalline region of *B. mori* silk fibroins with the unordered glycine-rich region of *Samia*

cynthia ricini have also been produced to improve the tractability of the *B. mori* crystalline domain (28).

Similar success has been observed for the expression of repetitive artificial proteins based on spider silk amino acid sequences. Genes for partial amino acid sequences from *N. clavipes* have been generated, and repetitive genes of these sequences have been produced via recursive multimerization strategies. Proteins comprising 8 or 16 repeats of a poly(alanine) β-sheet hard segment with either interspersed (GXG) variants or (GPGGY) and (GPGQQ) alternating pentamers as the soft segment have been expressed in both *E. coli* and *Bacillus subtilis* by Fahnestock and co-workers (29–31). When expressed in *E. coli* under control of the strong promoter of the bacteriophage T7, approximately 10–30% of the soluble cell protein is the expression target sequence, although some truncated products are formed in these expression systems. The proteins are easily purified via chromatographic methods or via solubility differences between the artificial repetitive protein and other cellular proteins (31,32). When expressed in the yeast *Pichia pastoris*, from genes employing the codon preferences for *Pichia* (33), truncated products are eliminated and protein yields are increased, with silk-like proteins comprising 10% of the total protein (yields of 1 g/L). A chromosomal integration strategy is used to establish the genes in *Pichia* by homologous recombination, and expression is controlled by the strong promoter AOX1, which is induced by addition of small amounts of methanol. Fusing the target protein to secretion signals and prosequences of *Saccharomyces cerevisiae* permits efficient secretion of the target protein from the cell and into the extracellular medium, although at much lower yields. The advantages of this system include the fact that *P. pastoris* is a useful host for large-scale fermentation, and that extracellular localization of an expression protein target has many potential advantages for low cost production (simpler recovery, purification, and the potential for expression from immobilized cells). Circular dichroism (CD) characterization of these proteins in dilute aqueous solution indicates that the protein polymer adopts a random coil conformation, with increasing β-sheet content upon drying, consistent with the reported behavior of natural silk proteins upon spinning into fibers.

The production of other synthetic genes based on the amino acid sequences of dragline silk from *N. clavipes* has also been achieved by Kaplan and co-workers. From the partial cDNA sequences of this silk, two consensus repeats (NCMAG1 and NCMAG2, abbreviated for *N. clavipes* major ampullate gland) have been identified: (GGAGQGGYGGLGSQGAGRGGLGGQGAG), followed by a polyalanine region, and (GPGGYGPGQQGPGGYAPGQQPSGPGS), also followed by a polyalanine region. Repetitive proteins with sequences based on NCMAG1 and NCMAG2 have been produced from *E. coli* via expression of artificial repetitive genes from a pQE9 expression vector under control of a bacteriophage T5 promoter (34); these proteins contain a hexahistidine fusion to facilitate purification via metal chelate affinity chromatography. Yields of approximately 15 mg/L have been observed, although the yield of the silk-like repetitive proteins decreases with increasing length. Characterization via CD confirms the expected presence of β-sheet structure in these proteins. Additional silk-like proteins, also modeled after the dragline silk of *N. clavipes*, have been produced in *E. coli* by other research groups (35,106); in general, these proteins have molecular weights ranging

from 10 to 160 kDa (molecular weights of natural spider silk proteins can reach 740 kDa), with yields of purified protein ranging from 2 to 20 mg/L.

In addition to expression from bacterial and yeast expression hosts, silk proteins have also been expressed from transgenic hosts, motivated in part by the low expression yields obtained in microorganisms. Tobacco and potato plants have been successfully utilized as transgenic hosts for producing silk-like proteins based on dragline silk (36,37). In these investigations, at least 2% of the total soluble protein in the endoplasmic reticulum of the tobacco and potato leaves and potato tubers is reported to be silk. In addition, partial cDNA clones of the silk protein from *Araneus diadematus* and from *N. clavipes* have been expressed in mammalian cells [baby hamster kidney (BHK) cells] to yield several grams of protein that is recovered in soluble form by ammonium sulfate precipitation. The 25–50-mg/L yields provide an ultimate yield of more than 12 g of material purified from conditioned culture media (38). For production of larger amounts of these recombinant silk-like proteins, expression from goat milk may prove a viable alternative, and is currently under development; transgenic goats that express silk proteins in their milk have been produced by Nexia Biotechnologies, Inc., and methods to purify these proteins have been developed (39,107–109).

Additional areas of active research have been to mimic the fiber spinning conditions of the spider and to control β-sheet assembly in order to produce artificial silk protein materials that have mechanical properties similar to those of the natural silk protein fibers. In general, the spinning of recombinant, silk-like artificial proteins requires dissolution in harsh solvents such as hexafluoroisopropanol, formic acid, or 9 *M* lithium bromide. For example, fibers have been spun from solutions of these proteins in hexafluoroisopropanol with quenching in methanol and wet drawing. Such fibers exhibit the properties [tenacities of 2 g/denier (gpd) and 8–10% elongation] of traditional textile fibers, but do not match the properties of natural dragline silk (110). Silk proteins produced from bacterial sources have also been spun into fibers from more benign aqueous processing conditions that better mimic those of the spider. In 2002, Arcidiacono and co-workers reported the aqueous solution spinning of silk sequences derived from *N. clavipes* dragline silk and expressed from *E. coli* (40). The proteins are produced via expression of the C-terminal cDNA of *N. clavipes* dragline (42.9 kDa), or via expression of the consensus sequences NCMAG1 and NCMAG2 of *N. clavipes* (55 kDa). The key to the successful spinning of these proteins from aqueous solution has been to eliminate the drying of the protein at any stage of purification and processing, by increasing protein concentration via removal of water during purification, with processing in dilute denaturing buffer (160 m*M*–1 *M* urea). The content of β-sheet structure in the fibers increases with time, as expected, and fiber diameters range from 10 to 60 μm in diameter, depending on the weight percentage of the spin dope and the identity of the protein. Fibers are insoluble in water and birefringent, indicating the formation of oriented fibers, although no mechanical property measurements have been reported. The *A. diadematus*-derived protein produced in mammalian cells (38) has also been processed in a similar manner—first concentrated into an aqueous spin dope exceeding 23% (w/v) protein, coagulated in methanol/water, and exposed to wet draw conditions. The fibers isolated via these methods exhibit a tenacity of 2.26 gpd and 55–130% extensibility, which yield a toughness equivalent to that of silk, although the properties do not exactly mimic

natural silk fibers, which have a tenacity of 7–11 gpd and an extensibility of 30% (*vide supra*).

The difficulties in processing silk proteins is largely a result of the spontaneous assembly into β sheets of the poly(alanine) sequences of dragline silk, especially under conditions of shear. In an effort to understand the architectural variables that will permit purposeful control of β-sheet formation and hierarchical assembly during processing, protein engineering methods have been employed toward the design and synthesis of silk protein sequences in which amino acids and amino acid sequences are included for control of β-sheet formation. Incorporating sequences that can trigger β-sheet assembly, for example, as demonstrated by Kaplan and co-workers, has been one approach to control protein properties. In one design, methionine residues have been included to flank the (AAAAA) units of the NCMAG1-based repetitive proteins (41–43). Under reducing conditions, these polymers readily form β-sheet structures as assessed by CD and Fourier transform infrared (FTIR) spectroscopies; β-sheet assembly is disrupted upon oxidation of methionine to the larger and more hydrophilic sulfoxide. These researchers have also introduced sites of enzymatic phosphorylation that flank the alanine-rich sequences, in order to alter the size and charge of serine residues and control β-sheet formation (41,44). When the serine hydroxyl group in the sequence RGYSLG is phosphorylated by cAMP protein kinase, β-sheet formation is prevented; upon dephosphorylation by alkaline phosphatase, the ability to form β sheets is recovered. In other investigations aimed at controlling solubility and processability of silk-like proteins, Asakura and co-workers (45) have designed a chimeric sequence that combines the crystalline polyalanine sequence $(Ala)_{18}$ of *Samia cynthia ricini* silk with a noncrystalline (GX)-rich sequence (GVGAGYGAGAGYGVGAGYGAGVGYGAGAGY) found in the silk fibroin of *B. mori*. The introduction of the glycine-rich noncrystalline sequence in the protein results in improved solubility of this silk-like protein and prevents β-sheet formation in the polyalanine region of the protein, as assessed via solid-state ^{13}C CP/MAS NMR studies.

The materials properties of other members of the spider silk family are also becoming of increasing research interest. Sequences based on the flagelliform silk protein, which produces the unique elastomeric properties of the capture spiral of spider webs, have been recently studied by Conticello and co-workers (46). A protein containing 11 repeats of the flagelliform-derived amino acid sequence $\{(GPGGSGPGGY)_2GPGGK\}$ can be expressed in *E. coli*, and has been characterized by a combination of techniques including CD, FTIR, and NMR, which indicate that these molecules adopt a β-turn conformation. These results suggest that the elastomeric properties of the flagelliform sequence may have similar origins as those found in other β-turn-forming proteins such as elastin. The mechanical properties of protein polymers that contain flagelliform-like amino acid sequences can also be controlled by the inclusion of peptide motifs that are known to form β-sheet crystallites but that are not naturally found in silk proteins.

Conticello and co-workers (47) have also produced alternating block copolymers containing a flagelliform-like sequence $(GPGQQ)_6$, which is derived from the *A. diadematus* dragline silk fibroin, and the amphiphilic sequence $(AEAEAKAK)_2$. Although the (AEAEAKAK) sequence is not a silk-derived sequence, it has been shown to form very stable β-sheet structures in aqueous solution (111). Proteins

containing these sequences assemble into β-sheet linked membranes from concentrated aqueous solution, and membrane formation is responsive to conditions that alter the conformation of the (AEAEAKAK) units in the polymer (47).

The application of silk-like protein polymers in many disparate applications such as textiles, medical applications, and cosmetics will be possible, given their demonstrated synthesis and favorable properties. One difficulty to be overcome in the synthesis of artificial silk-like proteins from bacterial hosts is the generally low expression yields, which can be as low as 1–10 mg/L. Yeast systems offer advantages in this regard, with potential yields of 300–1000 mg/L possible, although difficulties in purifying the protein from these expression hosts have been encountered. While the mechanical properties of spider silk are a desirable goal, it has remained difficult to reproduce the properties in the laboratory environment, although continued progress is being made in this direction, owing to increased understanding of the processing of these proteins and the ability to control the solubility of the proteins via protein engineering strategies. Improved understanding of the impact of synthesis and processing on the resulting mechanical properties of silk-like materials will increase the number of applications in which these polymers will find use. Coupled with the fact that silk-like proteins can also be useful in supporting cell growth and tissue function, the proteins will find use in both materials science and medical applications, such as in fibers, threads, membranes, and scaffolds. The genetic tailoring of their sequence and the ability to include repeats of other structural proteins such as collagen or elastin (*vide infra*) has also resulted in a variety of silk-based proteins that can be useful in varied materials applications, including fiber reinforcement, controlled release, and scaffolds for tissue engineering, and will continue to expand the number of uses in which these polymers will find application.

Collagen-Like Protein Polymers

Collagen (qv) is another important fibrous structural protein that has been produced by protein engineering methods for applications in materials science and biology. The collagens comprise a highly abundant family of extracellular matrix proteins that are found in all connective tissues. They represent 30% of the total body proteins in mammals and are found in tendons, ligaments, cartilage, bone, and skin. Although there are at least 20 genetically distinct types of collagen (the most abundant in mammals being types I–III), all are composed of three helical chains that have the general amino acid sequence Gly-X-Y, in which X is primarily proline, and Y is primarily hydroxyproline. The monomeric helical sequence first assembles into a triple helix with dimensions of 300 nm in length and 1.5 nm in diameter, which then forms larger-scale hierarchical structures that ultimately assemble into high strength elastic fibers that form connective tissue (112). In addition to its structural role, collagen is also involved in a variety of important biological events such as early development, cell attachment and proliferation, wound healing, and tissue remodeling. This combination of mechanical strength, higher order assembly, and biological activity of collagen has made it a broadly used protein-based biomaterial. Collagen I, in particular, is the most abundant structural protein in animals, and has been

widely exploited for medical use, cosmetics, therapeutics, and also as its denatured form (gelatin) in food and photographic emulsions. Although collagen is available in large quantities from mammalian sources, extraction from animal tissues poses the risk of contamination by viral or infectious agents, which has become of increasing concern in recent years. Owing to this potential risk, the simplicity of the repetitive sequence, the wide biological and materials uses of collagen, and the ability to tailor collagen amino acid sequences, protein engineering strategies have become more prevalent for the production of recombinant collagen.

In contrast to the production of silk-like proteins, recombinant production of collagen-like proteins has focused primarily on the production of cDNA sequences isolated from natural sources. Fibrillar collagens have been produced in mammalian cells (113,114), insect cells (48,49), yeast (51,115–118), and transgenic animals (51,52,118) and plants (119,120). Yields generally range from 15 to 500 mg/L, although a triple-helical, 160-kDa human type I collagen has been produced in mouse milk at 1–8-mg/mL yields (52), and a 21-kDa fragment of mouse collagen I (from cDNA fragments) can be produced from *P. pastoris* at yields of 14.8 g/L of clarified broth (53).

To obtain correctly assembled collagen fibrils, most organisms employ extensive post-translational modification of procollagens, and the enzymes that mediate these modifications have been incorporated into expression systems for collagen production. One of the most important considerations is the hydroxylation of proline residues to 4-hydroxylproline via the action of the tetrameric (α_2 β_2) enzyme prolyl 4-hydroxylase. In almost all collagens (with the exception of some marine invertebrate collagens), hydroxylation of the proline is required for correct fibril formation and to maintain the melting temperature of the collagen at physiologically relevant levels (approximately 40°C). A lack of hydroxylation reduces (and can, under physiological conditions, eliminate) the propagation of banded fibril formation, lowers the melting transition temperature, and can render the collagen useless for biological applications (120). Most bacterial and yeast expression hosts do not contain the genes for prolyl 4-hydroxylase, and some insect and mammalian expression hosts do not generate sufficient amounts of this enzyme. Coexpression of collagen with the subunits of prolyl 4-hydroxylase has therefore been used to permit recombinant production of functional collagen. Another consideration in collagen expression is that the protein is generally expressed as procollagen, which contains N- and C-terminal peptides to impart solubility. The genes for the proteolytic enzymes N-proteinase and C-proteinase are also often included in expression hosts to allow processing of the procollagen, via removal of the N- and C-terminal peptides, into the assembling collagen form. It has been recently reported, however, that human type I collagen proteins lacking the propeptides can be produced from *S. cerevisiae* expression hosts that lack the genes for the prolyl 4-hydroxylase (117) and can still correctly fold. Generally, in expression systems in which the proteinases are not included, procollagen can be cleaved with pepsin post-translationally to liberate the N- and C-terminal propeptides and permit fibrillar assembly of collagen.

Vuorela and co-workers (50) have demonstrated that coexpression of subunits of human prolyl 4-hydroxylase with the proα1 (III) chains of human type III procollagen in *P. pastoris* yeast expression systems permits production of

approximately 15 mg/L of properly folded homotrimeric type III procollagen that is resistant to pepsin digestion. The yeast expression hosts also demonstrate an expected increased level of prolyl 4-hydroxylase activity, and can be used in the large-scale production of different types of recombinant collagen. Similar strategies have also been employed for the production of high levels of human type I collagen in *P. pastoris* (121). In these investigations, the genes for the proα1 and proα_2 chains of type I procollagen are expressed, along with the genes for both the α and β subunits of prolyl 4-hydroxylase. The correct assembly of proα1 and proα_2 chains is observed (2:1 ratio), and high expression yields of 500 mg/L are obtained. In contrast to these other yeast systems, properly hydroxylated, 28-kDa mouse α1 (I) collagen fragments can be expressed from the yeast *Hansenula polymorpha* without coexpression of prolyl 4-hydroxylase (54). Successful expression of the procollagen chains from insect cells has also been observed. Proα1 chains of human type III collagen have been expressed from baculovirus vectors in *S. frugiperda* Sf9 or High Five cells (48), as have wild-type and modified proα chains of human type I collagen (55). With coexpression of human prolyl 4-hydroxylase, correctly assembling procollagen molecules can be produced at yields of 10–20 mg/L.

Mammary gland expression has also been explored as a route to produce procollagens, although this has been more limited in scope and use to date. The general method involves the expression of genomic or cDNA transgene sequences in conjunction with mammary-gland–specific promoters, which drives the expression of the proteins in milk. It has been achieved for procollagen via two different approaches. In one strategy, the cDNA encoding a shortened version of recombinant pro α_2 procollagen chains has been integrated into the mouse genome, and the procollagen has been coexpressed with the α and β subunits of prolyl 4-hydroxylase. The expression of a thermally stable triple helical artificial α_2(I) homotrimer at 50–200 mg/L is possible in this system (51). In another instance, transgenic mice were generated that contained the αS1-casein mammary-gland–specific promoter linked to a 37-kb segment of the human α1(I) procollagen structural gene. Very high levels of triple helical procollagen are produced via this system (8 mg/mL) (52). An advantage for transgenic expression of protein polymers in milk is that the expression levels of proteins can be increased via the use of a species with a higher volume production of milk (eg, mouse to rabbit to pig or goat).

Although recombinant natural collagen sequences have been of significant academic and commercial interest (115,122,123), the production of collagen-based proteins with additional functions has also been explored. For example, in an effort to design advanced biomaterials, Fertala and co-workers (124) have identified specific regions in collagen that are responsible for particular biological activity. These researchers have developed a cDNA cassette expression system (125) that allows systematic removal of specific amino acid sequences in collagen II. By removal of certain D blocks in collagen II, followed by expression of the modified protein in mammalian cells (HT-1080 cells), purification, and assessment of human chondrocyte (cartilage cell) spreading and migration, the amino acid region 704-938 has been identified as critical for the spreading of chondrocytes (124). The studies demonstrate that collagen (II) domains differ in their ability to support attachment and migration of chondrocytes, and suggest that advanced collagen-based materials could be designed to present multiple copies of the critical domains, permitting support of a greater number of cells and potential improvements in

tissue regeneration. In other efforts to produce collagen-based materials with improved biological activity, Hayashi and co-workers have produced a collagen III epidermal growth factor (EGF) chimeric protein from Sf9 insect cells (126). The proteins maintain the fibril-forming properties of the collagen domain, and films of the protein also improve cell growth via the action of the EGF; the chimeric protein may therefore be useful for cell culturing, wound healing, and tissue engineering applications. Together, these studies point to the utility of protein engineering strategies to identify and to produce materials containing multifunctional domains that impart desired biological and materials properties.

In addition to protein engineering investigations that have been based on natural collagen sequences, there is also significant interest in creating artificial collagen-like sequences with novel chemical and physical properties. Accordingly, genetically directed methods have been employed to produce artificial protein polymers containing the collagen-based GXY repeat, with substitutions in the X and Y positions to impart desired chemical functionality. The proteins have been expressed in yeast and bacterial systems. For expression from yeast (*Saccharomyces cerevisiae*) and certain bacteria (*Bacillus brevis*), fusion of the α-mating factor secretion signal permits secretion of the collagen-like proteins (CLPs) into the medium (53,56,57), which simplifies purification and points to the feasibility of commercial scale production of the proteins. Kajino and co-workers (57) have designed DNA sequences encoding human α1 collagen repeats $(GESGREGAPGAEGSPGRDGSPGAKGDRGET)_6$ and $(GAPGAPGAPGPVGPAGKSGDRGETGPAGPP)_{8,10}$ according to the codon usage of *B. brevis*. The proteins are expressed in *B. brevis* at estimated yields of 500 mg/L, and they exhibit reversible sol-gel behavior similar to that of native gelatin. Nonhydroxylated gelatins, with sequences based on partial cDNA sequences from mouse type I and rat type III collagen, have been produced in higher yields of 14.8 g/L from *P. pastoris*, using the *S. cerevisiae* α-mating factor (53). Completely synthetic, 36.8-kDa collagen sequences that are rich in GXP and GXQ sequences can also be produced, without degradation, in *P. pastoris* at high yields of approximately 3–6 g/L (58).

Expression from *E. coli* has not been as successful as the yeast and *B. brevis* expression systems. In early attempts to express CLPs from bacterial expression systems (59,60), a 22-kDa CLP with the sequence $(Gly\text{-}Pro\text{-}Pro)_{32}$ was produced in *E. coli* under control of a thermally inducible promoter. The resulting protein degraded in this cellular host, although use of an appropriate mutant host minimized this problem. Reducing the proline content of the collagen-like proteins appears to minimize stability problems, as less proline-rich proteins with sequences such as $\{GAP(GPP)_4\}_x$ and $\{\{GAP(GPP)_4\}_2GPAGPVGSP\}_x$ have been successfully produced from *E. coli* by Ferrari and Cappello (61). Recently, the sequence $(GAPGAPGSQGAPGLQ)_{52}$, which has an even lower proline content than previously produced CLPs, has been expressed in *E. coli*; the protein can be expressed in soluble form, at 100–200-mg/L yields, in low cell density, small-scale experiments (62,63).

The tensile strengths and availability of type I collagen render it the most widely used natural polymer in the medical field, with uses in tissue engineering, delivery systems, and cosmetic surgery; the denatured form of collagen (gelatin) finds widespread use as a food additive and photographic emulsion. In addition to

minimizing risks associated with isolation of collagen from animal sources, genetically directed strategies for the production of recombinant collagen-like protein polymers are also appealing as a result of the potential for CLPs in the above applications. The progress toward expression of collagen-like proteins from bacterial and other expression systems may permit the rational design of artificial CLPs with specialized materials uses; for example, understanding the individual roles of collagen domains in eliciting biological responses may result in the design of CLP-based scaffolds for directed interactions with cells. The ability to produce designer collagen and gelatin polymers via genetically directed methods may therefore drive the growth of these strategies as a large-scale source of recombinant human collagens and artificial collagen-like polymers for a variety of additional applications in nanotechnology, materials science, and medicine.

Elastin-Like Protein Polymers

Elastin is another protein found in connective tissues, and provides strength, flexibility, and elasticity to organs and tissue. When expressed in tissue, elastin is produced as the 750–800 amino acid protein tropoelastin, which then assembles into microfibrils, is modified via hydroxylation of proline, and is cross-linked via lysyl oxidase oxidation of lysine-rich domains (127). This assembly and insolubilization of tropoelastin results in the mature elastin network, which confers elastic and biological functionality to tissue. Elastin is composed of large, mobile, highly hydrated hydrophobic domains and smaller alanine-rich regions. The hydrophobic domains of elastin contain proline, alanine, valine, leucine, isoleucine, and glycine, with valine and glycine being most abundant. The sequence of the hydrophobic domain is highly repetitive, containing repeats of the general sequences GX, PX, GGX, or PGX (X = G, A, V, L, or I); the common repeat in mammalian elastin is VPGVG, with up to 11 consecutive pentapeptide repeats (127,128). In contrast to silk and collagen, elastin, even at high molecular weights, is soluble in aqueous solution, which, along with the highly repetitive nature of the hydrophobic regions of this functional protein, has fueled an enormous amount of interest in the use of elastin-based repeats in genetically engineered protein polymers. Whereas protein engineering has been employed in the production of tropoelastins for studies of biological activity, essentially all materials investigations have focused on the biosynthesis of elastin-like proteins (ELPs) comprising repetitions of the VP(LCST)GVG motif.

One unique feature of the VPGVG sequence is that, although it is generally soluble, it exhibits a lower critical solution temperature (LCST), which causes aqueous solutions of the protein to separate into solvent-rich and polymer-rich phases upon heating. This transition is analogous to that of the well-known poly(*N*-isopropylacrylamide) polymers, in which an entropy-driven dehydration of the polymer chain results in phase separation above a critical temperature. The ability of elastin-like polymers to undergo an LCST transition is conserved as long as the glycine and valine residues are present. The LCST transition is observed even with substitution, in the repeat sequence VPGXG, of any amino acid X (except proline); indeed, choice of the amino acid residue X can be used to control the LCST of the protein. This unique behavior of elastin confers mechanical properties

that make it a versatile platform for the engineering of protein-based materials for a variety of applications such as biomaterials, drug delivery, responsive silica membranes, and tissue engineering.

Because of this versatility, both chemical and protein engineering methods have been used widely for the synthesis of elastin-based protein materials based on the VPGXG sequence. A single repeat of the VPGVG unit is sufficient to observe the random coil to β-turn transition (129), which has made chemical strategies accessible for the synthesis of elastin-based peptide materials. However, limitations of solid-phase peptide synthesis plague these materials at higher molecular weights, since the presence of hard-to-purify deletion products significantly alters the properties of the materials (64). Protein engineering methods have therefore been used widely for synthesis, with relatively high yields (generally 50–100 mg/L, and up to 800 mg/L) facilitating the characterization and use of these materials for commercial applications. Elastin-like proteins have been produced in *E. coli* (64–68), fungi (69), chloroplasts (70), and plants (71), although most materials investigations with elastin-like proteins utilize bacterial expression.

The broad range of interest in elastin-like protein polymers has fueled the development of new genetic strategies for the assembly of the genes encoding the elastin repeats (70,74). Seamless cloning methods (72) permit the assembly of high molecular weight genes, in a controlled head-to-tail fashion, directly into the expression vector. Clones of up to 5000 bp (200 kDa) have been prepared via these strategies, with yields commonly on the order of 200–800 mg/L. Since the multimerization is random in nature, seamless cloning results in the formation of a library of genes of different lengths, although the exact length of the genes cannot be controlled purposefully. Recursive strategies have therefore also been applied for the synthesis of repetitive artificial proteins with specific and predetermined chain lengths (68) to enable control of elastin-like protein transition temperature via purposeful control of ELP molecular weight and block architecture. By sequential cloning steps, gene products carrying a specified number of repeats can be produced. A variety of $(VPGXG)_n$ ELPs have been produced via these strategies, with molecular weights up to 130 kDa (330 pentapeptide repeats).

The elastin-like proteins produced by genetic methods have proven useful for a number of applications in biotechnology, materials science, and medicine. In early demonstrations by Urry and co-workers (64), ELPs with the general sequence G–$(VPGVG)_{19}$–VPGV have been expressed from *E. coli*, are easily purified from cellular proteins, and exhibit a sharp LCST at approximately 48°C, as expected for a VPGVG sequence of this molecular weight. By appropriate design of the elastin-like polymer, thermal, chemical, and electrochemical stimuli can all be used to alter and control the LCST of ELPs (64). Urry and coworkers have demonstrated, for example, that substitution of any of the natural amino acids in the fourth position of the VPGVG pentapeptide provides a range of LCST transitions. Attachment of redox-active cofactors such as FAD/$FADH_2$ (flavin adenine dinucleotide) or NAD/NADH (nicotinamide adenine dinucleotide) to glutamic acids in a VPGEG repeat permits electrochemical control over the hydrophobic collapse of the protein (73). Upon reduction of FAD to $FADH_2$ or of NAD to NADH, the increased hydrophobicity of the pentapeptide results in the hydrophobic collapse of the elastin-like polymer at substantially lower temperatures (73). If the two different states of the ELP (oxidized and reduced) have LCSTs

above and below room temperature, the electrochemical transition can stimulate an observable transition under ambient conditions.

Following up on the extensive body of work by Urry (74,75,130), others have also taken advantage of the control of LCST possible for these elastin-like polymers in the design of ELPs for drug delivery applications. In one example, Chilkoti and co-workers (19,68,76) have produced a family of polymers of the general sequence VPGXG in *E. coli*, where X = V, A, and/or G. The ratios of V:A:G are varied in order to tune the LCST, with one library containing no A or G, and two others containing the residues in ratios of 5:2:3 and 1:8:7. The A and G substitutions in the fourth position of the pentamer are dispersed throughout the sequence to reduce the repetition within the gene. These polymers have 120 to 330 pentapeptide repeats and molecular weights of 50 kDa to 130 kDa, and the LCST of the polymers is dependent on both the molecular weight and the guest residue sequence. Transition temperatures that vary smoothly between approximately 28°C and 78°C are obtained, demonstrating the potential for genetically designing an ELP with a desired transition temperature for drug delivery applications. In addition, ELPs designed to exhibit an LCST at 35°C (131) exhibit complex shear moduli similar to those observed for collagen and hyaluronan at physiological temperature, and are able to support cartilaginous cell growth. The combination of these results suggests that these materials may also be useful as injectable scaffolds for cartilaginous tissue repair (131), although chemical crosslinking would likely be required to impart sufficient mechanical integrity upon gel formation. These investigators have also designed block copolymers based on the VPGXG sequences, with one block comprising 64 repeats of the V:A:G composition 1:8:7 (LCST > 90°) and the other comprising 60 repeats of VPGVG (LCST = 35°C). Upon heating, these block copolymers form 40–100-nm size nanoparticles, owing to the hydrophobic collapse and aggregation of the VPGVG block. The mechanical, chemical, and/or biological properties can be tuned to enable self-assembly with incremental changes in temperature, pH, and ionic strength, making these block copolymers attractive candidates for controlled delivery, tissue engineering applications, and stimuli responsive surfaces and membranes (132,133).

Genetically directed synthetic strategies also permit the preparation of other complex block copolymers with tunable properties. Conticello and co-workers (77,78) have designed and synthesized a series of elastin-mimetic diblock (AB) and triblock (BAB) copolymers for assembly on the mesoscopic scale, and have expressed these polymers in *E. coli*. The B blocks consist primarily of the hydrophobic elastin repeats $\{VPAVG(IPAVG)_4\}_{16}$, and the A blocks comprise more hydrophilic repeats such as $\{VPGEG(IPGAG)_4\}_{14}$, $\{VPGEG(VPGVG)_4\}_{30}$, and $\{VPGEG(VPGVG)_4\}_{48}$ (see Table 2). The hydrophobic B blocks exhibit an LCST below 37°C, which is desired so that collapse of the hydrophobic block occurs under physiologically relevant conditions. The substitution of alanine (A) in place of glycine (G) in position three of the pentamer results in a change of mechanical properties of the material from elastomeric to plastic, which permits control of the mechanical properties of the block. The hydrophilic blocks are chosen because of their high LCST values, so that phase separation of the two blocks occurs at physiological conditions to form ordered polymeric structures. Indeed, BAB block copolymers with an A block comprising $\{VPGEG(VPGVG)_4\}_{30}$ undergo a reversible sol–gel transition at 23°C. The same group has demonstrated

that diblock copolymers of the general sequence $\{VPGEG(IPGAG)_4\}_{14}VPGEG–\{VPGFG(IPGVG)_4\}_{16}VPGFG$ assemble into spherical particles and beaded filaments in water at 25°C (79).

There are also significant opportunities for controlling the mechanical properties of ELP materials via covalent cross-linking strategies. Several different strategies have been employed to cross-link soluble elastin molecules into a cross-linked, elastomeric network. Early work by Urry employed γ irradiation for cross-linking, which yields elastomeric networks with an elastic modulus very similar to native elastin. Although this method does not require a specific amino acid for cross-linking, it affords little control over the position of cross-linking and can also result in chain scission. Therefore, in addition to γ irradiation (134), other radical-based cross-linking methods employing dicumyl peroxide have been developed, as well as chemical cross-linking strategies such as carbodiimide coupling (80) and chemical reactions with electrophilic reagents. Chemical cross-linking approaches, explored by several groups, offer the advantage of control of the positions of the chemically reactive cross-linking sites, which can in turn control cross-linking density, molecular weight between cross-links, and resultant mechanical properties. Elastin-like proteins with the repetitive sequences $\{(VPGVG)_4VPGKG\}_{39}$ have been produced by the Conticello group; the lysines are reacted with the electrophilic *N*-hydroxysuccinimide esters of bifunctional carboxylic acids, bis(sulfosuccinimidyl)suberate (in phosphate buffer), or disuccinimidylsuberate (in DMSO) to produce cross-linked gels (67). The elastin-mimetic hydrogels exhibit expected elastomeric behavior, with a reversible contraction (62.4%) and expansion upon cycling between 10 and 45°C. Trifunctional tris-succinimidyl aminotriacetate has also been used by other groups to cross-link elastin-like polymers $\{VPGKG(VPGVG)_6\}_n$ (with $n = 56$, 112, and 224) and $\{VPGKG(VPGVG)_{16}\}_n$ (with $n = 51$, 102, and 204) (81). The mechanical properties of the cross-linked hydrogels are dependent on molecular weight, the density of lysine residues, and temperature, and range from 0.24 to 15 KPa. Cross-linked elastin-like polymer hydrogels exhibit an LCST, although one that is gradual, as compared to the abrupt LCST transition observed for soluble elastin-like polymers. In additional studies by Urry and co-workers (80), polymers with the general sequence $\{(GVGVP)_2(GXGVP)(GVGVP)_2\}_n$, with X = lysine or glutamic acid, have been mixed and cross-linked via carbodiimide-mediated coupling. The swelling of the cross-linked materials varies as a function of the cross-linking reaction temperature, and filamentous structures are formed in elastin-like polymers cross-linked above their LCST.

Methods to produce elastomeric fibers from ELPs have also been investigated. Uncross-linked polymers can be spun into fibrous mats via electrospinning protocols (135), with long uniform fibers resulting from spinning solutions greater than 10 wt% in polymer; tensile strengths of 35 MPa and a material modulus of 1.8 GPa are possible via these strategies. Acrylate groups have been incorporated via reaction with the lysine (K) amines to permit production of cross-linked elastin-mimetic fibers (136), which exhibit increased tensile strengths and moduli that are similar to those reported for native elastin.

Alternate strategies to control the mechanical properties of elastin-like proteins, via combination with amino acid sequences from different fibrous proteins, have also been explored. Combining the temperature-responsiveness

of elastin-based repeats with the excellent mechanical properties of silk-like proteins (*vide supra*) yields protein polymers that have properties similar to those observed in segmented polyurethanes, with the advantage of controlled sensitivity to stimuli (pH and temperature). Cappello and co-workers have combined the (GVGVP) repeat from mammalian elastin with the (GAGAGS) sequence from *B. mori* silk to create copolymers of over 10 different compositions (82). The relative lengths of the silk-like and elastin-like blocks are varied, and the ionic sensitivity of the polymers is controlled via the selection of amino acids in the elastin-like block. Representative copolymer compositions include the sequences $\{(GVGVP)_4(GEGVP)(GVGVP)_3(GAGAGS)\}_{16}$ and $\{(GVGVP)_4(GXGVP)(GVGVP)_4(GAGAGS)\}_{11}$, where X is either glutamic acid or valine (83,84); these silk-elastin-like polymers (SELPs) are easily expressed from *E. coli* hosts. Characterization of the physical behavior of these proteins via turbidity measurements indicates that the transition temperature (LCST) of the polymers containing glutamic acid is sensitive to pH, and that the LCST of both the glutamic acid- and valine-containing polymers can be modulated with changes in ionic strength, temperature, polymer concentration, and polymer length (83,84). The simultaneous control over amino acid sequence and molecular weight afforded by genetically directed methods of polymer synthesis therefore provides opportunities for fine-tuning the stimuli-responsive behavior of these polymers. The materials have potential applications as injectible urethral bulking agents for treating incontinence, cell culture coatings, drug delivery systems, or soft-tissue augmentation or bone repair.

Cappello and co-workers have also investigated polymers in which the number of silk-like domains in the polymer is increased to produce polymers that spontaneously form hydrogels in aqueous solution. For example, the sequence $\{(GVGVP)_4(GKGVP)(GVGVP)_3(GAGAGS)_4\}_{12}$ undergoes an irreversible sol-gel transition in aqueous solution of physiological pH and ionic strength, mediated by hydrogen-bond controlled crystallization of the silk-like domains (85), unlike the polymers above, which contain fewer silk-like repeats and do not form hydrogels. The hydrogels (12 wt%) exhibit mechanical and swelling properties that do not change as a function of temperature, as the presence of the silk domains eliminates their temperature sensitivity (86). X-ray diffraction patterns of SELP polymers are very similar to those of simple silk-like polymers (SLPs), confirming the presence of similar crystalline arrangements of silk-like blocks in both SELPs and SLPs. Crystalline silk-fibroin domains are also observed, via NMR, in the solid state of other SELPs (137). Proteins and DNA can be delivered from the hydrogels without loss of activity (85,87,138,139); bioactive DNA can be released from the gels for up to 28 days, with the rate of release for 2.6–11-kb plasmids being dependent on the size of the plasmid DNA (87,139). DNA released from these gels can also be delivered in the active form in a mouse breast cancer model (139). These results suggest the potential use of these polymers as *in situ* gel-forming implants for protein and gene delivery applications (140,141).

Protein engineering strategies have also allowed the incorporation of biological function into elastin-like protein polymers and SELPs. The incorporation of cell-binding amino acid sequences, such as RGD (82,142) and REDV (from the CS5 domain of fibronectin) (66) (Table 2), permits endothelial cell adhesion to

these materials for their application in tissue engineering. Tirrell and co-workers have also incorporated cross-linking domains into biologically active elastin-like polymers (Table 2) to permit the production of biologically active, cross-linked materials with mechanical properties similar to those of native elastin. The incorporation of lysine residues at the termini or in the VPGXG repeat of elastin-CS5 copolymers permits cross-linking via gluteraldehyde or *N*-hydroxysuccinimide activated suberic acids (88,89). Molecules of the general sequence RKTMG{LD-CS5-G$(VPGIG)_{20}VP\}_x$LEKAAKLE, with $x = 1$, 3, and 5, have been cross-linked via reaction with gluteraldehyde. The observed molecular weight between cross-links (M_c) and mechanical properties of the cross-linked polymers approximate those of elastin (0.3–0.6 MPa), with elongation-to-break values of 100–220% (88). A broader range of mechanical properties can be obtained from elastin-based proteins in which lysine residues are incorporated in the VPGXG repeats. Proteins of the general sequence $\{LD\text{-}CS5\text{-}G((VPGIG)_2(VPGKG)(VPGIG)_2)_4VP\}_3$, when cross-linked via reaction with NHS-activated suberic acids, yield cross-linked materials with Young's moduli ranging from 0.07–0.97 MPa, with M_c values of 3,000–38,000 (89). These values span the range of mechanical properties of natural elastins and vary as expected with measured extents of cross-linking. Films prepared from these proteins have also been shown to support endothelial cell adhesion under shear stresses that mimic those in blood vessels (143). The polymers are therefore being considered for applications in engineered artificial grafts for the surgical reconstruction of small- and medium-diameter blood vessels.

Overall, the applications for elastin-based protein polymers are numerous, given their useful elastomeric properties, biological behavior, and low immunogenicity. The versatility of these systems includes the ability to engineer the LCST behavior of $(VPGXG)_n$ polymers via choice of the X residue, to produce cross-linked elastomeric gels, and to synthesize elastin-like block copolymers that assemble into nanoparticles. The amino acid sequence of these polymers can also be engineered to allow the incorporation of biologically active domains. Their possible applications as drug and gene delivery vehicles, membranes, elastomeric fibers, and vascular grafts have continued to motivate interest in their scientific and technological potential, and a variety of academic and industrial research groups continue to investigate these polymers.

Artificial Proteins Designed *de Novo*

In addition to the design of protein polymers based on repetitive amino acid sequences found in naturally occurring proteins, *de novo* design has also been applied to the production of artificial proteins with desired conformational properties. Knowledge of the secondary structure preferences (ie, α-helix, β-sheet, coiled-coil, reverse turn, etc) of amino acids and amino acid sequences has permitted the design of completely artificial proteins with prescribed structures, chemical reactivity, and assembly. These short amino acid sequences are encoded into genes and multimerized into target polymer lengths via the genetic strategies previously described. Proteins are expressed from *E. coli*, purified by appropriate protocols, and their structure and assembly is characterized. A variety of novel protein materials, such as crystalline lamellar solids, smectic-like liquid crystals, and reversible

hydrogels have been produced via these methods, and showcase the control over macromolecular structure and function that can be achieved by genetically directed polymer synthesis.

The earliest example of this approach involved the design and synthesis of crystalline lamellar solids by Tirrell and co-workers. Although the folded chain lamellar crystal is a well-known motif in polymer science, this architecture is formed in synthetic polymers for largely kinetic reasons. The trapping of the polymer chain into a folded conformation upon cooling makes it essentially impossible to precisely control the thickness and surface chemistry of such chain-folded lamellar structures. The genetic engineering approach, however, has afforded such folded structures in which both variables can be controlled, simply by controlling the sequence of amino acids in a protein polymer. Polymers with the general sequence $\{(AG)_xEG\}_y$(with x ranging from 3 to 6, and y ranging from 5 to 54) have been designed on the basis of the knowledge that alanyl–glycyl dyads form thermodynamically stable β-sheets in natural silk proteins. When precipitated from formic acid, this family of proteins forms crystalline solids with primarily β-sheet structure, as ascertained from infrared and Raman spectroscopic analysis, cross polarization/magic angle spinning NMR, and wide-angle X-ray diffraction (WAXD) (90,144). X-ray diffraction investigations indicate that the lamellar thickness is always shorter than the chain length of the polymers, as expected for the chain-folded architecture, and consistent with this observation, X-ray structure refinement identifies an antiparallel β-sheet arrangement of the chains as the best fit to experimental X-ray data. The glutamic acid residues of this sequence would be expected to lie at the lamellar surface, and indeed, deprotonation of the carboxylic acid groups does not cause any change in the chain conformation or intersheet packing distance as observed via vibrational spectroscopy and WAXD, respectively (145). Consistent with these results, X-ray diffraction characterization of crystalline lamellar solids of $\{(AG)_3XG\}$ sequences (with X = Asn, Phe, Ser, Val, or Tyr) demonstrates that the interlamellar spacing increases linearly with the increasing volume of the amino acid side chain in position X (91), but that neither the turn length nor the intrasheet packing distance is altered. These results suggest that crystal surface functionality can be designed via the choice of the amino acid in position X of the $\{(AG)_3XG\}_y$ sequences.

The self-assembling properties of certain β-sheet-forming peptides have also been captured in protein polymers. Sequences of alternating polar and nonpolar residues comprise a prevalent sequence motif in the antiparallel β-sheet regions of natural proteins, and accordingly, the peptide $(AEAEAKAK)_2$ has been demonstrated by Zhang and co-workers to self-assemble into an organized supramolecular structure (111). Protein polymers of the sequence $(AEAEAKAKAEAEAKAK)_9$ have been produced by Goeden-Wood and co-workers in an effort to capture the self-assembling characteristics of the peptides while improving the mechanical properties of the supramolecular gels (146,147). The proteins (which contain a decahistidine fusion sequence) can be expressed from *E. coli* and purified via metal-chelate affinity chromatography with yields of approximately 5 mg/L. The protein is shown, via CD and FTIR investigations, to adopt a stable β-sheet structure, and is suggested to form β-sheet fibrils via Congo Red dye binding assays and characterization by scanning electron microscopy (SEM). Under physiological conditions, the protein forms hydrogels with a storage modulus of approximately

100 Pa, suggesting the potential application of these polymers in soft tissue engineering or drug delivery applications.

In addition to the *de novo* design of β-sheet forming protein polymers in which self-assembly is controlled by monomer sequence, the design of helical proteins in which assembly is controlled by molecular weight has also been demonstrated. Helical rods form well-defined self-assembled structures; one particularly well-studied example is poly(γ-benzyl-α,L-glutamate) (PBLG), which forms oriented films and liquid crystalline solutions. The large dipole moment along the helical axis permits orientation of these rod-like polymers via the use of an electric field to yield materials with interesting piezoelectric and nonlinear optical properties. Since the conventional approach for making these molecules utilizes the ring-opening polymerization of *N*-carboxy-α-amino acid anhydrides, molecules made by this method have broad molecular weight distributions, and therefore form cholesteric liquid crystalline phases in which there is orientational order but no longitudinal registry of individual chains. Smectic liquid crystalline phases, in which there is both orientational order and longitudinal registry, are not observed for PBLG synthesized by the chemical methods. In contrast, genetically directed synthetic strategies permit the synthesis of monodisperse poly(α,L-glutamic acid) (PLGA), which can be chemically benzylated to form biosynthetically derived PBLGs capable of forming smectic-like liquid crystalline phases in solution (92,93). Monodisperse polypeptides with the sequence $ED(E_{17}D)_xEE$ (referred to as PBLG-*x* after benzylation), where $x = 3$–6, have been produced in *E. coli* (93,94). Aspartic acid (D) is included periodically to provide recognition sites for the enzyme *BbsI* and to preserve the genetic stability of the repetitive glutamic acid sequence. The biosynthetically produced PLGAs are benzylated by alkylation of the PLGA with phenyldiazomethane, and analysis by NMR indicates 94–98% benzylation. Small-angle X-ray diffraction patterns of films dried from solutions of PBLG-4 and PBLG-5 (in a 97/3 mixture of chloroform and trifluoroacetic acid) show well-defined spacings of 114.5 and 140 Å, respectively. These values almost exactly match the expected lengths of the monodisperse PBLG helices (114.5 and 141 Å) (92,93), suggesting alignment of the helical molecules in a smectic-like liquid crystalline phase. The films are thought to specifically orient in a twisted grain boundary (TGB)-like phase, owing to the superposition of a smectic-A layering (from the monodisperse PBLG) and the chirality of the helical rod (148).

Additional helical polymers in which assembly is controlled by monomer sequence have also been designed by Tirrell and co-workers and by Kaplan and McGrath, and have proven fruitful for assembly of protein-based materials. Helical coiled-coil motifs (comprising leucine zipper peptides) are found in transcription factors and play an important role in controlling protein dimerization and DNA binding; related helical motifs are also found in structural proteins such as keratin (the main structural protein in hair and nails). The primary structural feature of the leucine zipper peptides is the heptad repeat sequence *abcdefg*, in which hydrophobic amino acids occupy positions *a* and *d* (*d* is primarily leucine), while charged residues generally occupy positions *e* and *g*. Under appropriate pH and temperatures, these amino acid sequences adopt helical conformations that array the hydrophobic residues *a* and *d* along a single face of the helix. Assembly of these helices, most often in the form of dimeric coiled-coils, is controlled by aggregation of the hydrophobic face, with the stability of specific associations

modulated by the charged residues *e* and *g*. The coiled-coil stability, aggregation number, and aggregate specificity can be manipulated though control of the heptad amino acid sequence and the chain length. Thus, these helical motifs serve as versatile structures for the assembly of novel protein-based materials.

Earliest work in this area by Kaplan and McGrath focused on the synthesis of a variety of isolated leucine zipper peptides with controlled assembly properties (149,150). Expanding the approach, Tirrell and co-workers have designed hydrogel-forming, triblock copolymers carrying short leucine zipper end blocks flanking a water-soluble polyelectrolyte domain (95). In this triblock copolymer, there are three main considerations in the design of the protein sequence: (*1*) the hydrophobic face of the leucine zipper block is modeled after the a/d residue pattern of the *Jun* oncogene product; (*2*) the *b*, *c*, and f positions are chosen on the basis of the residues that most commonly reside in those positions in naturally occurring coiled-coil proteins; and (*3*) nine of the 12 *e* and *g* positions in the sequence are occupied by Glu residues in order to facilitate pH control of gelation and viscoelastic behavior. The triblock protein polymer comprises two leucine zipper end blocks of six heptad repeats, with a central polyelectrolyte block of the sequence $\{(AG)_3PEG\}_{10}$. It has been expressed in *E. coli*, and CD characterization of the purified protein confirms the presence of both helical and random coil structures. At low pH and ambient temperature, these materials form elastic gels; increases in pH or temperature produce a viscous solution of nonassociated protein (95). Solid-state NMR investigations of the protein hydrogel show that the central polyelectrolyte domain is isotropically mobile on the microsecond time scale, while the leucine zipper domains are rigid, which is consistent with the association of the leucine zippers as the basis for hydrogel formation (151). On the millisecond time scale, the leucine zipper domains exhibit rigid body motion, which supports the hypothesis that the domains act as continuously exchanging physical cross-links.

Alteration of the composition of these proteins via genetic methods may prove to be a successful strategy for modulating the physical behavior of protein-based hydrogels. For example, alteration of the acid/base balance in the helical domains (positions *e* and *g*) can alter the stability of the coiled-coil association, which will in turn control the stability of the hydrogel network and alter the pH and temperature at which these macromolecular structures assemble into hydrogels. Inclusion of cross-linking or lysis domains and/or cellular or molecular recognition sequences will permit the design of hydrogels with predetermined physical and biological properties and may expand their uses as reagents for encapsulation and controlled delivery.

Genetically directed synthetic methods are also being exploited for the structure-based design of protein polymers that display desired functional groups. Kiick and co-workers have designed a series of functionalized, alanine-rich helical proteins with the general sequence $\{(AAAQ)_x(AAAE)(AAAQ)_x\}_h$, in which the position and number of the glutamic acid residues (E) can be varied systematically. Members of this family of proteins can be produced in *E. coli* and are easily purified via metal chelate affinity chromatography at yields of 10–20 mg/L. The proteins are shown, via CD spectroscopy, to be highly helical under ambient conditions (96), and, along with related random coil sequences, have intended applications for purposeful display of biologically active groups and/or organic moieties.

In all of the cases described above, genetically directed methods have been used to produce protein polymers with predesigned secondary structures that control the folding, assembly, and/or the mechanical and biological properties of the resulting polymer. However, genetically directed methods of polymer synthesis have also been applied to the production of protein polymers in which a lack of regular secondary structure is desired. Recursive multimerization strategies have been used by Won and Barron (97) to produce genes that encode random coil protein polymers of the general sequence $(GKGSAQA)_x$, with molecular weights up to 46.25 kDa. Protein polymers of this repetitive, nonnatural sequence have been produced in *E. coli* at yields of approximately 15 mg/L, and CD studies confirm the random coil nature of the protein. The ultimate goal of this line of investigation is the creation of long, repetitive water-soluble proteins for diverse biomaterials and tissue engineering applications. Inclusion of the lysine residues (K) at regular intervals in this random-coil, water-soluble protein is intended for the attachment of bioactive factors or for cross-linking.

Multisite Incorporation of Nonnatural Amino Acids

A very important recent development in these synthetic methods is the expansion of their chemical versatility via the incorporation of nonnatural amino acids. Standard methods of *in vivo* protein synthesis employ the 20 naturally occurring amino acids normally encoded by the mRNA templates. This repertoire of amino acids includes carboxylic acids, amines, and thiols as the primary chemically reactive sites, which limits the chemical versatility of protein polymers. Accordingly, there has been a great deal of interest in incorporating functional groups such as alkenes, alkynes, halogens, or azides into proteins. Such incorporation would permit chemical modification of protein polymers via reactions that are orthogonal to those of the natural amino acids and would also afford opportunities to alter surface properties, impart photosensitivity, and control association of protein polymers. However, investigations of this kind have been challenging owing to the strict controls over the fidelity of protein biosynthesis exerted by the aminoacyl-tRNA synthetases (aaRS), the class of enzymes that controls the incorporation of amino acids into proteins *in vivo*.

There are several strategies for incorporating nonnatural amino acids into proteins that circumvent the discriminatory power of the aaRS; for example, nonnatural amino acids can be incorporated directly into polypeptides via chemical synthesis strategies. Whereas the number of nonnatural amino acids that can be incorporated in this fashion is essentially limitless, there are several disadvantages. In solution-based *N*-carboxyanhydride polymerizations (13), sequence control is lost, while in solid-phase peptide synthetic methods (152), the less than perfect efficiency of the amino acid coupling step limits peptide length to approximately 50–75 amino acids, which is generally insufficient for materials applications.

A second strategy that avoids the synthetases combines both chemical and biological synthesis. Chemical aminoacylation methods were introduced by Hecht and co-workers in the late 1970s (153) and have since been exploited by a variety of other investigators (154–157). In these strategies, the nonnatural amino acid is

chemically attached to a suppressor tRNA, which decodes a single stop codon that is engineered into the mRNA sequence of a target protein. The nonnatural amino acid is then incorporated into the protein by suppression (decoding) of the stop codon by the suppressor rRNA during *in vitro* translation. This method permits the site-specific incorporation of nonnatural amino acids into proteins, and the chemical aminoacylation step permits the incorporation of essentially any nonnatural amino acid. The *in vitro* translation protocols, however, yield only microgram quantities of protein. To address these low protein yields, *in vivo* strategies employing heterologous synthetases have been developed for the site-specific incorporation of nonnatural amino acids into proteins produced from *E. coli* and from yeast (158–163); these methods have proven a versatile strategy for the site-specific incorporation of electrophilic, acetylenic, azido-functionalized, and redox-active amino acids into proteins (164–166). Such strategies require the inclusion, in the expression host, of both a suppressor tRNA that decodes the stop codon during protein synthesis (and is not recognized by any of the *E. coli* aaRS) and a synthetase that will aminoacylate only the suppressor tRNA (and none of the endogenous *E. coli* tRNAs) with only the nonnatural amino acid. A recent advance in this line of investigation is the generation of a bacterial expression host that carries the heterologous synthetases necessary for site-specific, *in vivo* incorporation of a nonnatural amino acid and that can also synthesize the nonnatural amino acid from basic carbon sources (167).

Although suppression-based methods permit the incorporation of a variety of nonnatural amino acids, modest suppression efficiencies limit the incorporation of the nonnatural amino acid to a single site in the protein. Whereas in many instances it may be desirable to limit incorporation to a single site (eg, studies of protein folding or enzymatic activity), multisite incorporation has many distinct advantages in the synthesis of protein polymer materials, in which alteration of bulk material properties is desirable. In multisite incorporation strategies, nonnatural amino acids are incorporated into protein polymers at some or all of the positions normally occupied by the natural amino acid, generally via the utilization of the nonnatural amino acid by the protein biosynthetic apparatus of the expression host. These strategies therefore also afford the opportunity to control the placement of the nonnatural amino acids in the protein polymer, which offers additional advantages in macromolecular synthesis.

Perhaps surprisingly, given the extremely high fidelity of amino acid incorporation during protein biosynthesis, it has been known for decades that a number of nonnatural amino acids are able to replace natural amino acids in bacterial proteins. For example, selenomethionine is incorporated in place of methionine in *E. coli*, can be used in all steps of protein biosynthesis, and supports cell growth (168–170). Amino acids that differ in structure and functionality from the natural amino acids, such as *p*-fluorophenylalanine, norleucine, and trifluoroleucine, have also been known for decades to replace the natural amino acids in bacterially synthesized proteins (170–172). Over the past several years, a variety of additional nonnatural amino acids bearing novel chemical functionality have also been incorporated into protein polymers *in vivo* (Fig. 4). Unsaturated, azido-functionalized, and ketone-decorated analogues have been incorporated and subsequently modified via chemical strategies that are orthogonal to the chemistries of natural amino acid side chains (173–175). Fluorinated amino acids offer opportunities for

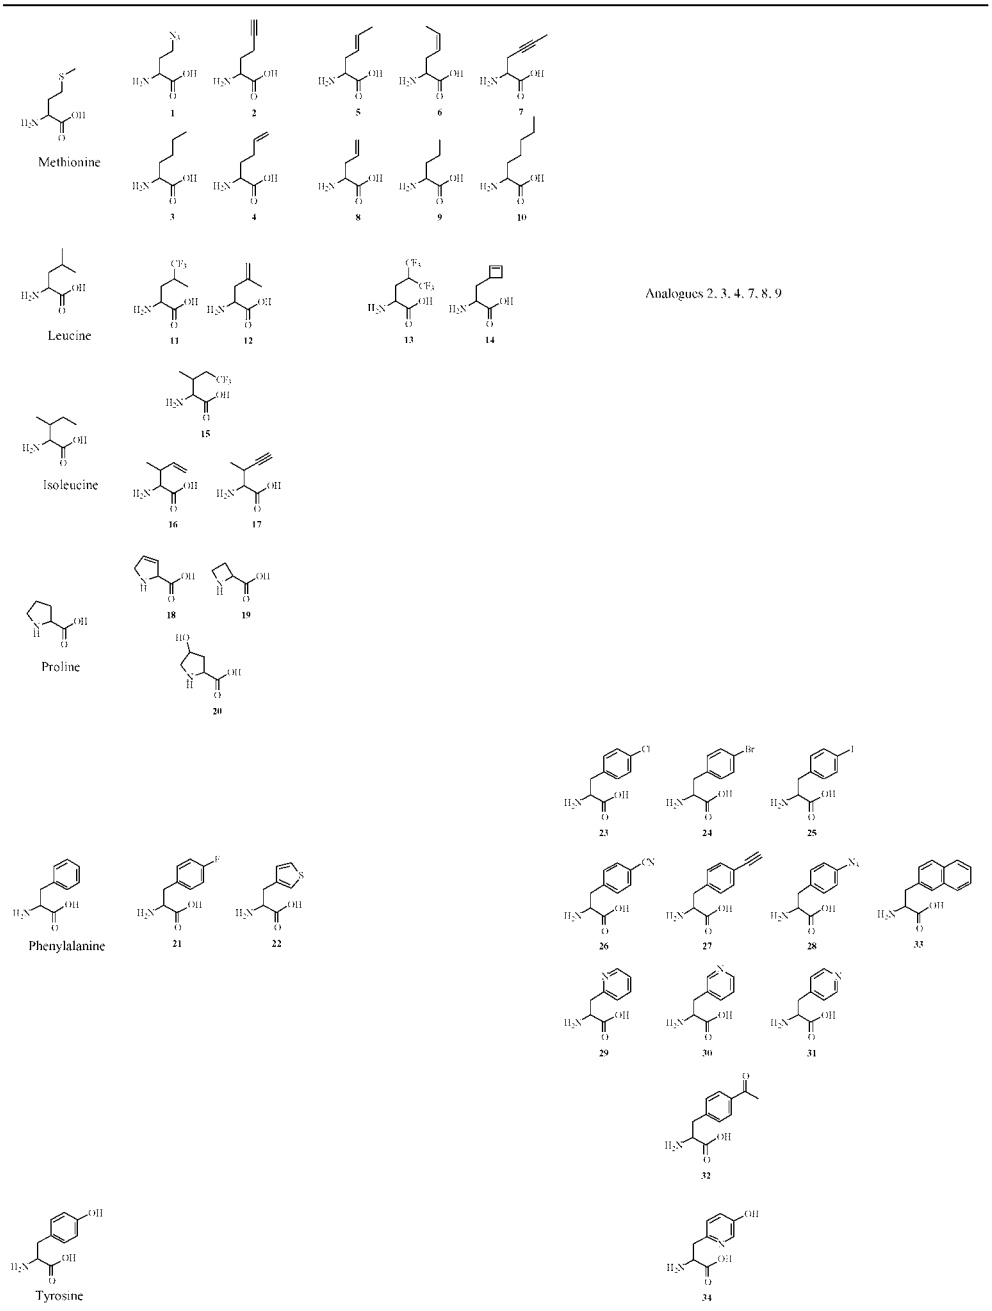

Fig. 4. Nonnatural amino acids and the strategies used for their multisite incorporation into proteins.

controlling the surface properties of protein films (98), and also afford strategies for increasing the thermodynamic stability of protein assemblies (176). Incorporation of aryl halide function permits chemical modification of proteins via palladium-catalyzed reactions, and also offers new opportunities for protein structure determination (177,178).

The incorporation of nonnatural amino acids into proteins *in vivo* requires that the nonnatural amino acid meet several criteria. First the analogue must be transported across the cell membrane into the cell, either by amino acid specific or general transport mechanisms, and it must not be degraded once inside the cell. Second, the nonnatural amino acid must be recognized by the aaRS during translation, and must also be able to form a stable aminoacyl-tRNA that is not subject to the aaRS editing mechanisms that normally prevent misacylation of tRNA. Finally, the nonnatural amino acid must be an efficient substrate for the elongation factor Tu (EF-Tu) and must be accepted at the ribosomal A site. Transport into the cell does not appear to be limiting, based on the number of nonnatural amino acids that have been demonstrated to replace natural amino acids in biosynthetically derived proteins. Recognition of the misacylated-tRNA by EF-Tu and acceptance at the ribosomal A site are also not suggested to be limiting factors, based on the enormous number of nonnatural amino acids that can be incorporated into proteins by *in vitro* translation protocols. Many different investigations have indicated that the key determinant to the success of the *in vivo* approach, therefore, is the ability of the nonnatural amino acid to be charged to a tRNA by an aminoacyl-tRNA synthetase.

The high specificity and efficiency that the aaRS exhibit for the natural amino acids requires that the concentration of natural amino acid in the culture medium during protein expression must be strictly limited relative to the concentration of the nonnatural amino acid, so that incorporation of the nonnatural amino acid will be favored. This requires that the natural amino acid that will be replaced must be chosen prior to protein expression, and the appropriate bacterial auxotroph (a strain that is unable to synthesize the chosen natural amino acid) must be obtained/produced. The general experimental procedure for nonnatural amino acid incorporation involves several steps. The auxotroph is grown first in medium that contains the natural amino acid (to maximize the number of protein-producing cells), and then at a desired cell density the cells are centrifuged and washed quickly in order to remove the natural amino acid, and are then resuspended in a medium that contains the nonnatural amino acid but not the natural amino acid. Protein expression is then induced, and in cases where the nonnatural amino acid supports protein biosynthesis, the protein is isolated and purified. The extent of amino acid replacement (ie, nonnatural amino acid incorporation) can be determined via amino acid analysis, Edman degradation analysis, mass spectrometry, tryptic digest/mass spectrometry, and/or NMR, depending on the identity of the nonnatural amino acid.

One of the more recent developments in the *in vivo* incorporation of nonnatural amino acids has been the correlation of the activation of a nonnatural amino acid by an aaRS with the ability of the nonnatural amino acid to support protein biosynthesis (ie, to be incorporated into proteins *in vivo*). The covalent attachment of an amino acid to its cognate tRNA proceeds in two steps, activation and

aminoacylation:

$$\text{aaRS} + \text{aa} + \text{ATP} \rightleftharpoons [\text{aaRS} : \text{aa}{\sim}\text{AMP}] + \text{PP}_i$$
$$[\text{aaRS} : \text{aa}{\sim}\text{AMP}] + \text{tRNA}^{\text{aa}} \rightleftharpoons \text{aaRS} + \text{AMP} + \text{aa}{\sim}\text{tRNA}^{\text{aa}}$$

where aaRS is the aminoacyl-tRNA synthetase, aa is the amino acid, ATP is adenosine triphosphate, AMP is adenosine monophosphate, PP_i is pyrophosphate, aaRS:aa∼AMP is the aminoacyladenylate complexed with the enzyme, and aa∼$tRNA^{aa}$ is the aminoacyl-tRNA. The rate of activation of the amino acid by the enzyme can be measured in assays that monitor the rate at which radiolabeled pyrophosphate is incorporated into ATP (the reverse of the top reaction). The rate of ATP–PP_i exchange is measured as a function of analogue concentration, and the data are fit to a standard Michaelis–Menten model to determine $k_{\text{cat}}/K_{\text{m}}$, which can be used to compare the relative rates of activation of different amino acids by a given aaRS. The measured rates of activation of a variety of nonnatural amino acids by the appropriate aaRS have been shown by Tirrell and co-workers to correlate well with the ability of the bacterial host to utilize the amino acids during protein biosynthesis.

The quantitative establishment of the direct role of the aaRS in the multisite incorporation of nonnatural amino acids has resulted in the development of several strategic approaches that can be taken to control incorporation. The first relies on the ability of the wild-type biosynthetic apparatus to utilize nonnatural amino acids, and uses a standard auxotrophic expression host for protein synthesis. The second approach relies on increasing the level of activity of the wild-type aaRS in the bacterial host by engineering the host to produce extra copies of the desired enzyme. In the third approach, the aaRS is also engineered; the active site can be altered to permit activation of a broader set of nonnatural amino acids, and/or the editing activity of the aaRS can be abolished so that misacylated tRNAs are no longer destroyed by the editing pathway of the enzyme. The mutant aaRS is then overexpressed in the bacterial host. An additional strategy, which permits simultaneous incorporation of both a nonnatural amino acid and its natural counterpart in specified positions, expands the genetic code by the expression of a heterologous aaRS/tRNA pair. The aaRS with desired new activities can be identified via evolutionary-based mutagenesis strategies and/or by rational computational approaches. The application of these methods, as described in more detail below, has resulted in a large set of nonnatural amino acids that can be incorporated into proteins *in vivo* (Fig. 4).

Strategies for Nonnatural Amino Acid Incorporation that Employ the Wild-Type Biosynthetic Apparatus

Methionine. Of the investigations on the incorporation of nonnatural amino acids into proteins, the incorporation of methionine analogues is among the earliest studied. Methionine has been an interesting target for replacement by nonnatural amino acids, as the promiscuity of the biosynthetic apparatus toward methionine has been known for decades, and a variety of methionine analogues

are able to replace methionine during protein biosynthesis. There are no editing mechanisms for hydrolysis of misacylated $tRNA^{Met}$, which suggests that methionine analogues of varying side-chain structures and chemical function may be readily incorporated into proteins. In addition, methionine-rich interfaces are known to mediate a variety of protein–protein assembly processes, and the replacement of methionine may therefore provide opportunities for purposeful manipulation of protein–protein interactions.

The first report of multisite inclusion of nonnatural amino acids into genetically engineered protein polymers was reported by Tirrell and co-workers in the early 1990s, with the inclusion of selenomethionine (in place of methionine) into the repetitive β-sheet-forming polypeptide $\{(GA)_3GM\}_9$ (99). A methionine auxotroph was transformed with an expression plasmid that contained the DNA sequence encoding the polypeptide. The ratio of selenomethionine to methionine in the product protein, as determined via radiolabelling assays, correlated linearly with the ratio in the growth medium, indicating that selenomethionine is capable of essentially perfect replacement of methionine. Standard auxotrophic expression hosts were used to produce the selenomethionine-containing proteins, with the wild-type protein biosynthetic machinery accepting selenomethionine in place of methionine in every stage of protein biosynthesis.

In addition to the selenomethionine example above, telluromethionine, norleucine, trifluoromethionine, and ethionine have all demonstrated translational activity in wild-type bacterial hosts as well (179–181). The translational activity (ie, ability to support protein biosynthesis) of several additional chemically novel methionine analogues (**1-10**) has therefore been investigated (Figure 4). In all of these studies, the incorporation of methionine analogues into the target protein murine dihydrofolate reductase (mDHFR) has been determined; mDHFR carries methionine in 8 positions, and therefore serves as a reasonably stringent test of incorporation of methionine analogues. The mDHFR is encoded in a commercially available pQE15 expression plasmid, which is transformed into an *E. coli* methionine auxotroph.

Methionine analogues **1**, **2**, **3**, and **4** have been shown to replace methionine *in vivo* in these conventional bacterial expression hosts (174,182,183); the remaining methionine analogues, **5-10**, do not support protein biosynthesis under similar assay conditions. Analogues **1** (azidohomoalanine, Aha) and **2** (homopropargylglycine, Hpg) replace methionine quantitatively, as assessed via amino acid analysis, Edman degradation, and mass spectrometry. Furthermore, cultures supplemented with these analogues support the production of mDHFR in the same yields as cultures supplemented with methionine (approximately 40 mg/L) (174,183). Analogue **4** (homoallylglycine, Hag) replaces methionine at levels of approximately 92%, although yields of mDHFR from cultures supplemented with Hag are approximately 28% of those from cultures supplemented with methionine. Further assessment of the activation of the methionine analogues by MetRS has also been conducted and has suggested additional strategies for the incorporation of analogues **5–10** (*vide infra*).

These results suggest that the replacement of methionine by chemically reactive analogues can be used in the synthesis of chemically and physically novel protein polymers. Indeed, mDHFR decorated with the azido-functionalized Aha

(**1**) can be selectively modified by Staudinger-type reactions with triarylphosphine reagents (174), in both its purified form as well as in whole cell lysates. Cell-surface proteins equipped with Aha can also be efficiently modified with alkyne-functionalized biotinylating reagents via copper(I)-catalyzed triazole formation (184). Upon incubation with an avidin-functionalized fluorescent agent after biotinylation, cells decorated with Aha can be differentiated from cells decorated with methionine via flow cytometry methods (184). These results suggest opportunities for chemical modification of protein polymers and for labeling of proteins *in vivo*.

Fluorinated Amino Acids. Synthetic fluoropolymers exhibit many useful surface properties, such as low surface energy, low friction coefficient, excellent solvent resistance and hydrolytic stability, and chemical and biological inertness, and this has enabled these polymers to find use in many disparate applications, such as Teflon-coated pans, self-lubricating parts, pipe liners, membranes, and vascular grafts. The possibility of imparting similar properties to well-defined protein architectures has been of long-term research interest. Fluorinated leucine analogues have been of particular focus owing to leucine's abundance in natural proteins, and substitution by leucine analogues may provide a general strategy for controlling protein folding and function. Furthermore, 5,5,5-Trifluoroleucine (Tfl, **11**) has been known for over 30 years to support bacterial cell growth and to be incorporated into proteins in the absence of leucine. Tfl has been incorporated into β-sheet forming polypeptides with the general sequence $\{(GA)_3GL\}_{12}$, via protein expression in a standard leucine auxotroph, in an attempt to produce protein materials with similar surface characteristics as fluoropolymers. The incorporation of Tfl significantly lowers the surface energy of resulting protein films; contact angles of hexadecane on fluorinated protein films (70°) are much higher than those on the unfluorinated, leucine-containing protein (17°) (98). The fluorinated analogue *p*-fluorophenylalanine (Pff, **21**) can also be incorporated into the similar sequences $\{(GA)_3GF\}_{13}$ (98). FTIR and WAXD studies of protein solids containing Tfl or Pff confirm the antiparallel β-sheet architecture, suggesting that the fluorinated surface may be formed by presentation of the fluorinated amino acids in the fold regions of the β-sheet proteins.

The incorporation of fluorinated amino acids into proteins also confers other potential materials property advantages. Since many organofluorine compounds exhibit lower solubility in water than their hydrocarbon equivalents, fluorinated amino acids may act as hyper-hydrophobic analogues of the hydrophobic amino acids, which may impart increased stability to assembled protein structures stabilized by hydrophobic interactions. The fact that the fluorinated amino acids are nearly isosteric to their natural counterparts also suggests that fluorinated amino acids could be incorporated into proteins without disrupting protein structure. These factors have motivated the investigation of the effect of fluorinated analogues of leucine on the assembly and stability of coiled-coil proteins produced *in vivo*. In experiments to test Tfl incorporation, the pQE9-derived expression plasmid encoding the leucine zipper protein (*vide supra*) is transformed into a leucine auxotroph, and the cells are grown on cultures supplemented with Tfl (**11**). As might be expected on the basis of many previous reports of the translational activity of Tfl, the analogue supports the synthesis of the leucine zipper protein (176), with a maximum level of incorporation of 92%, as indicated by

amino acid analysis and MALDI-MS. Varying the ratio of leucine to Tfl in the culture medium permits various amounts of each amino acid to be incorporated into the protein, although the yields of protein decrease steadily to 20 mg/L (from 40 mg/L) as the percentage of Tfl in the culture medium is increased to 100%. Analysis of the purified proteins via CD indicates that the protein outfitted with Tfl exhibits essentially identical secondary structures as the leucine-containing protein, with greater than 90% helicity. Additionally, the proteins show increasing stability to thermal and chemical denaturation with increasing degrees of fluorination, with "melting" temperatures increased to a maximum of 67°C as compared to 54°C for the leucine-containing protein (176). The increased stability of these assembled structures with respect to thermal and chemical denaturation may have important consequences on controlling the stability and stimuli-responsiveness of not only leucine zipper based, but other types of protein-based materials as well.

Similar strategies have also been employed to incorporate trifluoroisoleucine (Tfi, **15**) into proteins *in vivo* (185). The analogue Tfi was used to supplement cultures of an *E. coli* isoleucine auxotroph equipped with a pQE-15-derived expression plasmid encoding mDHFR (which contains 14 Ile residues). In this bacterial expression host, Tfi was shown to support protein synthesis, with levels of replacement of 93% (185). In an effort to deduce the impact of the incorporation of fluorinated amino acids on protein function, Tfi was also incorporated into murine interleukin-2 (mIL-2), which contains five isoleucine residues in the helical core of the protein. Fluorinated mIL-2 elicits an equivalent maximal proliferative response as the wild-type mIL-2, which indicates that the fluorinated protein still folds into an active, native structure. The combination of the results for the isoleucine and leucine analogues suggests that at least some protein domains will tolerate side-chain fluorination without loss of function. They also indicate the potential for maintaining desired secondary structures and biological activity in repetitive artificial proteins equipped with nonnatural amino acids.

Unsaturated and Structural Amino Acids. The earliest investigations of the incorporation of unsaturated analogues into genetically engineered proteins were conducted in the 1990s. Unsaturated proline analogues were of initial interest for their potential ability to modify protein folding behavior and present reactive chemical functionality at fold surfaces; the potential for substitution of proline had been indicated by earlier studies indicating incorporation of proline analogues into cellular proteins (186). Polymers of the repeating unit $\{(AG)_3PEG\}_x$ had been successfully produced in *E. coli* hosts (100) but were difficult to crystallize, presumably because the conformationally restricted proline residue prevents alignment and hydrogen bonding of the alanylglycyl diads in the repetitive polymer. The incorporation of the analogues dehydroproline (Dhp, **18**) and azetidine-2-carboxylic acid (Aze, **19**) has therefore been assessed via expression of $\{(AG)_3PEG\}_{16}$ in cultures of a proline auxotroph grown on media supplemented with Dhp or Aze (173,187). The Dhp is most readily incorporated (nearly 100%), while the Aze is incorporated at levels of approximately 40%, as determined by ^{1}H NMR spectroscopy and amino acid analysis.

The physical properties of the Dhp variant are qualitatively very similar to those of the proline-containing variant; both form optically clear, amorphous

solids and are water-soluble, indicating a lack of crystallization. The chemical properties of the Dhp variant, however, are strikingly different, as reaction of the protein with H_2O_2 or Br_2 produces hydroxylated and brominated forms of Dhp in quantitative reactions, as determined by the loss of the alkene resonance in the NMR spectrum of the modified protein (173). Whereas the Aze variant is not chemically reactive, the physical structure of this protein is very different than the proline-containing protein, with FTIR spectroscopy indicating β-sheet structure (187). The smaller size of the Aze appears to increase the chain flexibility sufficiently to permit folding; the fact that the addition of only 4 to 6 Aze residues out of 148 amino acids can cause such a pronounced change in physical properties may also have important consequences for purposeful control of polymer physical and chemical behavior. Incorporation of the unsaturated leucine analogue **12** and isoleucine analogues **16** and **17** into the test protein mDHFR has also been reported and may have similar potential for modification of protein folding and reactivity (188,189). The isoleucine analogues can support protein synthesis at levels of approximately 50% of that observed in cultures supplemented with isoleucine, and can replace isoleucine with extents of replacement of 80% (**16**) and 70% (**17**).

The modification of protein structural properties via incorporation of nonnatural amino acids has also recently been realized for human type I collagen expressed in *E. coli*. Proline residues in collagen are hydroxylated to permit folding and to improve the stability of the collagen triple helix (*vide supra*). In mammalian systems, this enzymatic post-translational modification permits the accumulation of correctly folded protein. In prokaryotic systems, however, these enzymes are not present, and thus the modification of the proline has been accomplished via the introduction of the enzyme prolyl 4-hydroxylase in the expression host. The direct incorporation of trans-4-hydroxyproline (Hyp, **20**) in place of proline would obviate the need for the introduction of such additional enzymatic pathways. Buechter and co-workers have demonstrated the feasibility of this approach by the expression, in *E. coli*, of a protein with a sequence derived from the α_1 fragment of human type I collagen; the protein contains 64 Gly-X-Y repeating units and 52 proline residues in both positions X and Y (190). The protein has been expressed in an *E. coli* proline auxotroph, under conditions in which the auxotroph is grown in proline-depleted cultures that contain hydroxyproline and hyperosmotic concentrations of sodium chloride (500 m*M*). Mass spectrometry and amino acid analysis of the protein indicate quantitative replacement of Pro by Hyp in proteins isolated from these cultures. Hyp is activated 5 orders of magnitude less efficiently than Pro by ProRS *in vitro* (190), and therefore does not support protein biosynthesis under normal culture conditions. However, subjecting *E. coli* to hyperosmotic conditions increases the intracellular Hyp concentration sufficiently to recover its ability to support protein biosynthesis; it may be accumulated via mechanisms similar to those that cause active accumulation of Pro under hyperosmotic conditions (191). The Hyp-containing collagen fragments fold into the correct triple-helical structure, as assessed via CD spectroscopy (190), indicating that the global substitution of Hyp for Pro does not appear to destabilize the triple helix, even though Hyp is normally only found in the Y position of Gly-X-Y repeats in vertebrate collagens. Full-length fragments of α_1(I) chain, with

338 G-X-Y repeats and 255 proline residues, have also been expressed in proline-depleted cultures supplemented with Hyp under hyperosmotic conditions, and although the extent of Hyp substitution has not been quantitatively determined, these results suggest that Hyp can replace Pro in even very large numbers of Propositions.

Electroactive Amino Acids. Conducting polymers have been actively investigated for decades because of their potential applications in lightweight batteries, electrodes, nanowires, and nerve regeneration. The production of conducting polymers, however, is often plagued by the insolubility of the highly conjugated, rigid polymer. The incorporation of electroactive amino acids into genetically engineered protein polymers has been explored as a strategy for circumventing these solubility issues, as well as for generating biomedically relevant materials with combined biological and electrical function useful for nerve regeneration. Early investigations explored the incorporation of 3-thienylalanine (3TA, **22**) into the repetitive sequence $\{(GA)_3GF\}_{13}$; protein polymers were expressed from a pET-derived plasmid in a phenylalanine auxotroph grown on media supplemented with 3TA. The 3TA replaces Phe at levels of approximately 85%, as determined by ^{1}H NMR spectroscopy, amino acid analysis, and UV spectroscopy (192). The 3TA analogue alone can be oxidatively polymerized to produce conjugated systems (193), which could be used for the formation of electroactive films or the direct electropolymerization and attachment of biologically active motifs to electrode surfaces.

Nonnatural Amino Acid Incorporation via Overexpression of Wild-Type Aminoacyl-tRNA Synthetases

The examples above demonstrate the flexibility of the wild-type translational apparatus for the incorporation of nonnatural amino acids. Nevertheless, the range of chemical functionality available via utilization of a wild-type bacterial host is substantially more limited than that available via chemical polymerization methods, which has prompted further investigation of the promiscuity of the aaRS in the incorporation of nonnatural amino acids. Such investigations have relied on developing an understanding of the relationship between the rates of activation of a nonnatural amino acid by its cognate aaRS and the ability of the nonnatural amino acid to be incorporated into proteins *in vivo*.

Studies by Kiick and Tirrell have demonstrated the correlation between the kinetics of MetRS-catalyzed analogue activation *in vitro* and methionine analogue incorporation into proteins *in vivo*. The results of ATP-PP_i activation assays indicate that the translationally active analogues **1**, **2**, **3**, and **4** are activated by *E. coli* MetRS, although they are 390-, 500-, 1050- and 1850-fold poorer substrates for the enzyme than methionine, respectively (174,194). In the case of analogues **1** and **2**, the lower rates of activation do not impede the rate of protein synthesis or the extent of incorporation of the analogue (*vide supra*). At the sufficiently lower rates of activation of analogues **3** and **4**, however, the yield of protein recovered from cultures supplemented with the analogue correlates with the rate of activation of

the analogue (57% and 28% yields, respectively). Analogues **5-10** are increasingly poor substrates for the MetRS, consistent with their lack of translational activity in a conventional bacterial host (195).

Overexpression of MetRS in a bacterial expression host has been successfully employed as a strategy for incorporation of methionine analogues **5-10**. In this approach, the *E. coli metG* gene and its promoter are ligated into the expression plasmid pQE-15; bacterial hosts equipped with this plasmid (pQE15-MRS) exhibit approximately 50-fold increased rates of methionine activation. When this modified bacterial expression host is grown in cultures supplemented with analogue **5**, the rate of activation of analogue **5** is increased sufficiently to permit its incorporation into proteins at levels of replacement of approximately 92% (with protein yields of approximately 12 mg/L) (196). The analogues **6-10**, which are activated up to 340,000 more slowly than methionine, can also be incorporated into proteins via similar strategies (195), although the engineered expression host must be grown in medium supplemented with large amounts of the analogue (500 mg/L). In protein produced under these conditions, the level of methionine replacement by analogues **6-10** is 60–98%. Overexpression of the MetRS has also been shown to increase protein yields from cultures supplemented with poor substrates of MetRS.

Overexpression of wild-type aaRS has also been used to expand the number of fluorinated amino acid analogues that can be incorporated into proteins (197). The successful modification of protein properties via incorporation of Tfl, **11**, suggests fluorination as a strategy for modifying surface properties and assembly, and substitution by Hfl, **13**, which carries six fluorine atoms, may have a correspondingly greater impact on protein stabilization. ATP-PP_i exchange assays indicate that Tfl is only 240-fold poorer a substrate for LeuRS relative to Leu, consistent with its ability to replace Leu in proteins produced by a conventional bacterial host. These assays, however, show that Hfl is approximately a 4000-fold poorer substrate for LeuRS versus leucine. Overexpression of the wild-type LeuRS in an engineered expression host has therefore been employed as a strategy to permit incorporation of Hfl (197). The *E. coli leuS* gene and its promoter were ligated into the expression vector pQEA1 (which encodes the leucine zipper motif), to yield plasmid pA1EL. Bacterial hosts equipped with the pA1EL plasmid exhibit LeuRS activity that is elevated approximately 8 times that of unmodified bacterial hosts. Leucine zipper proteins produced from Hfl-supplemented cultures of this bacterial host show a maximum level of Hfl incorporation of 74%, as assessed via amino acid analysis and MALDI-MS. CD measurements confirm that the Hfl-containing protein is >90% helical, and that the melting transition temperature for this fluorinated protein is elevated to 76°C [which is 22°C greater than that of the leucine-containing protein and 9°C greater than that of the Tfl containing protein (*vide supra*)]. The Hfl-containing protein remains 100% folded in urea concentrations up to 4 *M* (197). Overexpression of the LeuRS has also permitted the incorporation of cyclobutenylglycine, **14**, into leucine zipper proteins (198); the side-chain functionality of this analogue may have uses for chemical modification or graft polymerization via ring-opening metathesis polymerization methods. Combined, these results suggest that overexpression of a wild-type aaRS is a general strategy for expanding the set of nonnatural amino acid analogues that can be incorporated into proteins *in vivo*.

Nonnatural Amino Acid Incorporation via Overexpression of Mutant Aminoacyl-tRNA Synthetases

Active Site Mutations. Alteration of the amino acid specificity of the aminoacyl-tRNA synthetases offers another strategy for incorporating into proteins nonnatural amino acids that are not utilized by the wild-type translational apparatus. Such alteration was initially demonstrated in investigations focused primarily on altering the specificity of an aaRS for different natural amino acids (199,200). More recently, investigations by Tirrell and co-workers have expanded the number of nonnatural amino acids that can be incorporated into proteins via mutagenesis of the active site of PheRS (175,177,178). Wild-type PheRS is active toward phenylalanine and *p*-fluorophenylalanine (Pff, **21**), but not toward *p*-chlorophenylalanine (Pcf, **23**), presumably because the additional steric bulk of the chlorine substituent precludes acceptance of Pcf at the active site of PheRS. In 1991, an engineered mutant form of this enzyme that charges $tRNA^{Phe}$ with Pcf was reported (201); the enzyme carries the mutation A294G, in which the alanine residue at position 294 has been mutated to glycine. This mutation effectively enlarges the active site and permits the activation of phenylalanine analogues that carry larger substituents in the *para* position; indeed, investigations indicated that the mutant PheRS permitted incorporation of Pcf into proteins *in vivo* (202). Overexpression of this mutant PheRS in *E. coli* has also permitted the multisite incorporation of a larger set of chemically diverse phenylalanine analogues into target proteins; analogues incorporated include *p*-bromo (**24**) (177), *p*-iodo (**25**), p-cyano (**26**), *p*-ethynyl- (**27**), and *p*-azido-phenylalanine (**28**), and 2-, 3-, and 4-pyridylalanine (**29-31**) (178).

To achieve these results, the mutant α subunit of PheRS is encoded on an expression plasmid that also encodes the target protein mDHFR (which contains nine Phe residues). The resulting plasmid is transformed into an *E. coli* phenylalanine auxotroph (177), and the auxotroph is grown in media depleted of Phe and supplemented with one of the phenylalanine analogues (250–500 mg/L). Target protein isolated from these cultures is then characterized to determine the level of analogue incorporation. The analogue *p*-Br-Phe, **24**, is incorporated into mDHFR at levels of replacement of 88% (as determined via amino acid analysis), with protein yields of 20–25 mg/L (approximately 70% of the expression levels of cultures supplemented with Phe) (177). The other phenylalanine analogues, **25-31**, can be incorporated into mDHFR with levels of replacement ranging from 45 to 90%, with protein yields of 6–18 mg/L (178). The UV spectra of proteins outfitted with analogues **27**, **28**, **29**, **30**, or **31** show peaks whose positions and intensities are consistent with those of the free amino acid analogues, indicating that the functional groups are not modified by the bacterial host during protein biosynthesis or modified by photodegradation.

The introduction of these functional groups provides numerous opportunities to engineer protein polymer properties. Introduction of aryl halide functionality into engineered proteins, for example, opens possibilities for a variety of controlled chemical modifications of proteins via chemistries that are orthogonal to existing methods of protein modification, such as transition metal-catalyzed coupling, amidation, and cyanation. The aryl azide side chain provides the capacity for intramolecular photoactivated cross-linking via the liberation of an amine group

upon exposure to UV light. The use of such modification strategies would allow new approaches to side-chain modification, immobilization on surfaces, cross-linking, and synthesis of graft copolymers. Several of the phenylalanine analogues also show distinct photophysical behavior in the X-ray, UV, and IR regions that may facilitate crystal structure determination via X-ray diffraction and biophysical studies of protein folding and assembly. Bromination, for example, has been explored as a new tool for use in X-ray diffraction studies of protein structure via multiwavelength anomalous diffraction methods.

The potential for incorporating additional Phe analogues via further mutagenesis of the PheRS has also been investigated by the Tirrell group. The crystal structure of the *Thermus thermophilus* wild-type PheRS complexed with Phe (203) has served as a starting point for the design for additional mutant *E. coli* PheRS. Computational approaches have been used to identify important cavity-forming mutations in the *T. thermophilus* enzyme (175), and show that mutation of Ala314 (Ala294 in *E. coli*) to Gly, and Val261 (Thr251 in *E. coli*) to Gly, enlarges the active site. Overexpression of the double mutant PheRS (A294G and T251G) in a bacterial expression host (via similar strategies as those above) permits incorporation of *p*-acetophenylalanine (Paf, **32**) into mDHFR, at levels of replacement of approximately 80% and yields of 20 mg/L (60% of those obtained from cultures supplemented with Phe) (175). The Paf-containing mDHFR has been shown to be active toward hydrazide reagents, without chain cleavage. These studies demonstrate the power of computational approaches for the design of aaRS that permit incorporation of new nonnatural amino acids. They also demonstrate the versatility of the biosynthetic apparatus for production of proteins containing chemically novel nonnatural amino acids.

In addition to these investigations of PheRS, other investigations have suggested the potential for altering the amino acid specificity of TyrRS (199,204) to permit incorporation of tyrosine analogues. An active site mutant of TyrRS, F130S, shows an increased specificity for azatyrosine, **34**, via *in vitro* assays of aminoacylation. The mutant TyrRS is overexpressed in *E. coli* expression hosts, and when cultures of the host are grown on media supplemented with radiolabelled ^{3}H-azatyrosine, azatyrosine is incorporated into *E. coli* cellular proteins, as assessed via SDS-PAGE with detection via film exposure (204). The results for cellular protein uptake are likely to be generally applicable to the incorporation of similar analogues into artificial repetitive protein polymers.

Editing Site Mutations. Mutations of aaRS editing sites have also been a target for increasing the number of nonnatural amino acids that can be incorporated into proteins. IleRS, LeuRS, and ValRS all exhibit an editing mechanism in which a separate editing domain of the aaRS controls hydrolysis of noncognate aminoacyladenylates and misaminoacylated tRNAs on the basis of the size and hydrophilicity of the noncognate amino acid side chain. LeuRS, in particular, employs this editing mechanism to prevent the incorporation of methionine and isoleucine in place of leucine during protein biosynthesis. Tang and Tirrell have reported the generation of a T252Y editing site mutant of *E. coli* LeuRS with impaired editing activity, as assessed via *in vitro* aminoacylation assays (205). A leucine zipper target protein (*vide supra*) has been produced in cultures of a leucine auxotroph that overexpresses the mutant LeuRS; the cultures are supplemented with various nonnatural amino acids but are depleted of leucine,

methionine, isoleucine, and valine. Analysis of the target protein via amino acid analysis and tryptic digest mass spectrometry indicates that the methionine analogues norleucine (**3**) and norvaline (**9**) are incorporated at the leucine sites in the leucine zipper protein at levels of 91 and 79%, respectively (205), consistent with the attenuation of the editing activity of LeuRS against methionine. The analogues also replace methionine at levels of 92 and 68%, respectively (205), as is expected on the basis of the reported ability of these analogues to replace methionine *in vivo* (*vide supra*). Overexpression of the mutant LeuRS also permits the incorporation of the unsaturated methionine analogues homopropargylglycine (**2**), homoallylglycine (**4**), 2-butynylglycine (**7**), and allylglycine (**8**), at levels of 74, 37, 37, and 76%, respectively, as assessed via mass spectrometric analysis. In other investigations, mutations at the editing site of valyl-tRNA synthetase have also been demonstrated to permit the incorporation of aminobutyrate in place of valine in cellular proteins produced by *E. coli* (206). Modulation of the editing activities of select aaRS therefore provides an additional strategy for incorporation of novel amino acids into proteins *in vivo*.

Nonnatural Amino Acid Incorporation via Introduction of Heterologous aaRS/tRNA Pairs

The multisite incorporation of nonnatural amino acids in protein polymers has relied on the replacement of a given natural amino acid by a desired nonnatural amino acid. Protein polymers that contain both a natural amino acid and its analogue can be produced via methods in which the ratio of the amino acids in the culture medium is controlled (*vide supra*). These strategies, however, do not permit precise control of the placement of the natural and nonnatural amino acids in the protein chain, since the nonnatural amino acid must "share" codons with the natural amino acid it replaces. The degeneracy of the genetic code, which arises from the use by the protein biosynthetic apparatus of 61 mRNA sense codons to direct the templated polymerization of 20 amino acid monomers, can be used to overcome this limitation. The ability to reassign degenerate triplet codons to nonnatural amino acids offers possibilities for expanding the combinations of building blocks (natural and nonnatural) that can be used to construct artificial proteins. Tirrell and co-workers have recently demonstrated the feasibility of this strategy for the simultaneous incorporation of phenylalanine and its analogue 3-(2-naphthyl)alanine (Nal, **33**) at specified positions in a target protein (207).

Phenylalanine is encoded by two codons, UUC and UUU, and both codons are read by a single $tRNA^{Phe}$, which carries the anticodon GAA. Introduction of a $tRNA^{Phe}$ with an AAA anticodon, therefore, offers a strategy to incorporate nonnatural amino acids only at phenylalanine positions encoded by UUU, while maintaining the incorporation of Phe at positions encoded by UUC. To achieve this experimentally, Kwon and co-workers have introduced a heterologous PheRS and its cognate $tRNA^{Phe}$ into an *E. coli* expression host (207). Specifically, the investigations have employed a yeast $tRNA^{Phe}$ (with an AAA anticodon, $ytRNA^{Phe}_{AAA}$), which is not charged by *E. coli* PheRS, and a mutant yeast PheRS (T415G) that charges only the yeast $tRNA^{Phe}$ and preferentially activates Nal over Phe (Fig. 5).

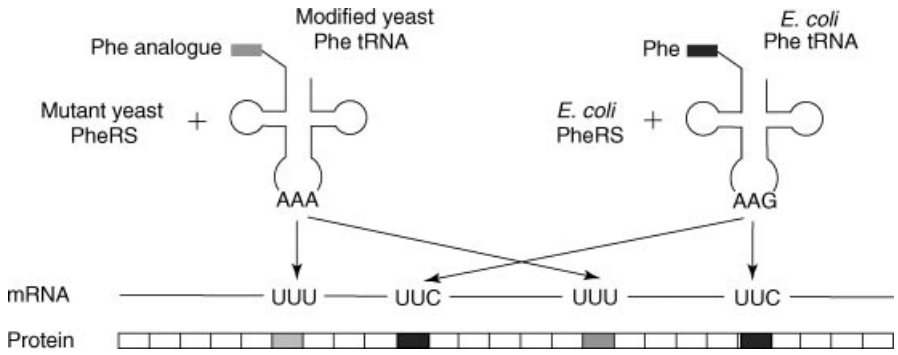

Fig. 5. Strategy for specific multisite incorporation of both natural and non-natural amino acids. Adapted, with permission, from Ref. 208.

The mutant yeast PheRS gene is encoded on an expression plasmid that also encodes the target protein mDHFR, which contains four Phe residues encoded by UUC and five by UUU; the yeast $tRNA^{Phe}_{AAA}$ is encoded on the repressor plasmid pREP4. Protein expression is induced in cultures of a Phe auxotroph that is equipped with these plasmids; the culture medium is supplemented with Nal and depleted of Phe. Amino acid analysis of the isolated target protein indicates that 4.4 of the 9 Phe residues are replaced by Nal, and mass spectral analysis shows replacement of 5 phenylalanine residues by Nal, which corresponds exactly with the number of UUU codons present in the mDHFR gene. Analysis, via MALDI-MS, of tryptic digest fragments of mDHFR indicates that Nal is indeed incorporated at positions encoded by UUU, while Phe is incorporated at positions encoded by UUC (207). This approach will have important consequences for the engineering of protein polymers, particularly upon the identification of additional heterologous aaRS that can charge specific tRNAs with desired nonnatural amino acids.

The versatility of nonnatural amino acid incorporation afforded by overexpression of mutagenized aaRS suggests the potential of evolutionary-based and rational strategies for the design of aaRS with engineered activity toward specific nonnatural analogues. Directed evolution strategies developed by Arnold (209) can be applied to the random mutagenesis of aaRS, followed by appropriate screening to identify aaRS that can charge its tRNA with a desired nonnatural amino acid. Such evolutionary strategies have been applied by Schultz and co-workers to the production of heterologous aaRS that can aminoacylate suppressor tRNAs with nonnatural amino acids *in vivo* (158,162–167); similar strategies should be applicable to the design of aaRS/tRNA pairs for multisite incorporation as well. Rational methods are also potentially powerful approaches to aaRS design. Goddard and co-workers have recently applied computational methods for the determination of Phe analogue/PheRS binding energies, and have demonstrated the correlation between computationally determined binding energies and the incorporation of the Phe analogues into proteins *in vivo* (210). Given the expanding kinetic data now available for a variety of nonnatural amino acid/aaRS pairs, these computational methods can be further developed to allow the rational design of new sets of amino acid/aaRS pairs that will find application in protein polymer engineering. The prospects are therefore promising for utilizing both evolutionary and rational

approaches to engineer the biosynthetic apparatus for the purposeful production of chemically and physically novel protein polymers.

Prospects and Commercial Viability

The expansion in the design and synthesis of *de novo* designed protein polymers over the last decade has had important consequences in polymer science. The genetically directed synthesis of protein polymers has allowed elucidation of structure-function relationships in protein polymers and has experienced enormous growth as an approach to the design of new polymeric materials, with both interesting academic and commercial applications. Protein polymers modeled after natural fibrous proteins have shown novel mechanical, assembly, and biological properties. Artificial protein polymers that exhibit controlled chain folded architectures, liquid crystalline phases, and self-assembled hydrogels on the basis of sequence and molecular weight control have been produced. The development of additional artificial protein polymers will offer continued opportunities for the production of novel materials that display functional groups in a manner that controls materials assembly, mediates interactions with biological targets, and yields polymers with interesting mechanical, biological, and/or surface properties. The expansion of the synthetic methods to include the incorporation of a wide array of nonnatural amino acids also suggests a variety of new strategies for macromolecular synthesis.

In addition to the functional advantages offered by protein-based polymers, continued interest in exploring their commercial use is motivated by the fact that the polymers are produced from renewable resources and are environmentally friendly materials from production through disposal. Practically, the relative cost and amount of time required to design and synthesize a protein polymer with desired physical and chemical characteristics can be much higher than the costs of designing and producing a chemically derived polymer. However, once the protein is designed and methods for its reliable production are defined, the costs of producing the protein polymer via fermentation is generally independent of the complexity of the polymer produced, and can therefore be much lower than the costs of chemical synthesis of complex macromolecules, since chemical synthesis costs increase quickly with increasing polymer complexity and control of monomer sequence. The costs associated with the biosynthesis of protein-based polymers depend on the costs of the materials used in synthesis and the scale of the synthesis; the raw materials are often as simple as glucose or methanol, ammonia, and salts. Larger-scale synthesis is achieved via the use of high cell density fermentation procedures, in which oxygen, glucose, and pH levels are controlled to allow high cell density growth in large quantities of culture medium; in the laboratory, multigram quantities ($>$25 g) of protein can be produced from *E. coli* via such strategies, and yields as high as 15g/L are possible from yeast. Given that commercial fermentations can be scaled to thousands of liters of culture, yields of proteins suitable for technological and market applications are possible. Hundreds of tons of protein per year can be produced via technologies currently in place for the production of amino acids, antibiotics, and protein therapeutics.

The costs of purification of protein polymers can be high if purification requires multiple chromatographic separations; however, most repetitive protein polymers have physicochemical properties very different from cellular proteins, and can be separated from these proteins by selective precipitation methods involving changes in temperature and pH. Similarly, protein polymers whose sequences alone may not permit such simple purification strategies can be expressed with fusion tags that facilitate purification. Secretion into the culture medium can also simplify purification and provide opportunities for less complicated large-scale syntheses, as expression hosts could be immobilized on a solid support, and protein removed in a continuous fashion without the requirement to turn over the culture entirely.

Recombinant enzymes have been produced and purified via these methods at market costs as low as $23/lb (110); these costs are likely acceptable for protein polymers with a primary commercial use as a high value biomedical material. For large commercial materials applications, however, lower cost production and purification will be required. Additional advances in fermentation, such as the use of secretion, may help drive costs down, although currently the yields of protein obtained by protein secretion systems have generally tended to be much lower than those of the standard intracellular accumulation systems.

Nevertheless, production of protein-based materials continues to progress in the areas of biomedically related polymers and fibers, and both prokaryotic and eukaryotic expression systems are used commercially. Since 1988, Protein Polymer Technologies, Inc (PPTI) has been a pioneer in protein polymer design and synthesis, and has extensive patent literature in the area of silk-based and elastin-based polymeric materials. The high molecular weight, genetically engineered biomaterials are processed into products with properties tailored to specific clinical needs; over 50 protein polymer sequences have been designed by PPTI for commercial application, and some can be produced in kilogram quantities. Targeted products include urethral bulking agents for the treatment of stress urinary incontinence, dermal augmentation products for cosmetic and reconstructive surgery, tissue adhesives and sealants, scaffolds for wound healing and tissue engineering, and depots for local drug delivery. The first commercial product of PPTI combined the *B. mori* silk motif with a cell adhesion sequence of fibronectin to yield protein polymers that form autoclavable, stable coatings on plastic and glass via adsorption of the β-sheet blocks of the polymer; these polymers are now sold as cell-culture products by Sanyo Chemical Industries. Silk-elastin-like proteins are used for injectable hydrogels; after injection, stable, water-insoluble hydrogels are formed via β-sheet hydrogen bonding and can be used for both surgical and drug delivery applications. In addition to medical applications, industrial applications are also of interest for the protein polymers, and Genencor International, Inc has obtained a worldwide exclusive license to develop PPTI's protein polymers in both industrial and personal care applications. Nexia Biotechnologies Inc manufactures complex recombinant proteins with industrial and medical applications; its lead product, BioSteel, is based on recombinant spider-silk proteins, and production of these proteins from transgenic goats is under continued development. Targeted applications for these materials include medical sutures, surgical meshes, and artificial ligaments, as well as materials applications such as technical sporting gear (eg, biodegradable fishing lines), soft body armor, and composites.

The challenges facing commercial implementation of protein polymers has not quenched motivation for research and technological progress in this area. In fact, many important contributions have been published first as patent applications because of their potential commercial significance. Numerous patents have been awarded, with topics focused on natural protein sequences, construction and expression of artificial genes/proteins, specific application needs addressed by the unique properties of protein materials, and the incorporation of nonnatural amino acids.

List of Abbreviations and Symbols

Natural amino acids, three-letter and one-letter abbreviations

Ala, A	alanine
Arg, R	arginine
Asn, N	asparagine
Asp, D	aspartic acid
Cys, C	cysteine
Gln, Q	glutamine
Glu, E	glutamic acid
Gly, G	glycine
His, H	histidine
Ile, I	isoleucine
Leu, L	leucine
Lys, K	lysine
Met, M	methionine
Phe, F	phenylalanine
Pro, P	proline
Ser, S	serine
Thr, T	threonine
Trp, W	tryptophan

Tyr, Y	tyrosine
Val, V	valine
	Other abbreviations and symbols
AAA	adenine adenine adenine
CCU	cytosine cytosine uracil
cDNA	complementary deoxyribonucleic acid
CGA	cytosine guanine adenine
DNA	deoxyribonucleic acid
GAA	guanine adenine adenine
GCU	guanine cytosine uracil
GGA	guanine guanine adenine
k_{cat}	turnover number
K_m	Michaelis constant
mRNA	messenger ribonucleic acid
RNA	ribonucleic acid
SDS–PAGE	sodium dodecyl sulfate–polyacrylamide gel electrophoresis
tRNA	transfer ribonucleic acid
UUC	uracil uracil cytosine
UUU	uracil uracil uracil

HIGH PERFORMANCE FIBERS

Introduction

High performance fibers are generally characterized by remarkably high unit tensile strength and modulus as well as resistance to heat, flame, and chemical agents that normally degrade conventional fibers. Applications include uses in the aerospace, biomedical, civil engineering, construction, protective apparel, geotextiles, and electronic areas.

For many years, plastics reinforced with polymer fibers have been utilized in the manufacture of boats and sports cars. More recently, ultrahigh strength, high modulus fibers have been invented and combined into composites whose strength and stiffness on a specific basis are unmatched by conventional construction materials. Composites are now replacing metals in such crucial applications as aircraft and the space shuttle. The polymeric composites contain carbon or aramid fibers several times stiffer, weight for weight, than steel. In composite materials, the fibers support the load which is distributed by the plastic which also prevents fatigue and failure (1–4) (see COMPOSITE MATERIALS).

In addition to their role in composites, high performance fibers are also found in coated and laminated textile products, three-dimensional fabric structures, multifunctional property improvement, and intelligent or self-adaptive materials.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

In this article, the preparation and properties of typical high performance fibers are discussed, then their applications are classified and detailed. The principal classes of high performance fibers are derived from rigid-rod polymers (qv), gel-spun fibers, modified carbon fibers (qv), carbon–nanotube composite fibers, ceramic fibers, and synthetic vitreous fibers.

Rigid-Rod Polymers

Rigid-rod polymers are often liquid crystalline polymers classified as lyotropic, such as the aramid Kevlar (DuPont), or thermotropic liquid crystalline polymers, such as Vectran (Celanese) (see POLYAMIDES, AROMATIC; LIQUID CRYSTALLINE POLYMERS, MAIN-CHAIN; LIQUID CRYSTALLINE THERMOSETS).

Liquid Crystallinity. The liquid-crystalline state is characterized by orientationally ordered molecules. The molecules are characteristically rod- or lathe-shaped and can exist in three principal structural arrangements: nematic, cholesteric, smectic, and discotic (5,6).

In the nematic phase, within volume elements of the macroscopic sample, the axes of the molecules are oriented on average in a specific direction in various domains. The centers of gravity of the molecules are arranged in a random fashion, and consequently no positional long-range order exists. The molecules are arranged in essentially parallel arrays. Without the presence of an orienting magnetic or physical force, the molecules exist in random parallel arrays. When an orienting force is applied, these domains orient easily. The nematic phase is amenable to translational mobility of constituent molecules.

The cholesteric phase may be considered a modification of the nematic phase since its molecular structure is similar. The cholesteric phase is characterized by a continuous change in the direction of the long axes of the molecules in adjacent layers within the sample. This leads to a twist about an axis perpendicular to the long axes of the molecules. If the pitch of the helical structure is the same as a wavelength of visible light, selective reflection of monochromatic light can be observed in the form of iridescent colors.

In the smectic phase, the centers of gravity of the rod-like molecules are arranged in equidistant planes, ie, the ends of the molecules are correlated. The planes may move perpendicular to the layer normal, and within layers different arrangements of the molecules are possible. The long axes of the molecules may be parallel to the layer normal or tilted with respect to it. A two-dimensional short- or long-range order may exist within the smectic layers. The smectic modifications are labeled according to the arrangement of the molecules within the layers using the symbols A–K.

In the smectic A phase, the director is perpendicular to the planes, while in the smectic C phase, the director is tilted at an angle less than 90° to the planes. In the smectic A and C phases, the molecules diffuse randomly and as a result, no positional order exists within the planes (positional order exists only in one dimension). However, other smectic liquid crystal phases exist in which the molcules have some degree of order within each plane that results in three-dimensional positional order (or quasi-three-dimensional order). In this case, molecules diffusing through the plane spend more time at certain locations than at other locations.

The smectic B phase is a more ordered analog of the smectic A phase in which the molecules adopt hexagonal order over distances of ca 150–600 Å (6). The hexagonal S_B phase has two tilted analogs called the smectic I and smectic F phases, in which the hexagonal lattices tilt toward the apex and the side, respectively. In the crystal B phase, the molecules adopt hexagonal order similar to that of the smectic B phase; however, the hexagonal lattices show long-range (three-dimensional) positional order. Crystal J and G phases represent hexagonal lattices with long-range positional order which are analogs of S_I and S_F, respectively. The crystal E phase results from contraction of a hexagonal lattice which leads to a herringbone-like structure with restricted rotation. Crystal K and H phases are the respective tilted analogs of the crystal E phase.

In the discotic phase, disclike molecules form liquid crystal phases in which the axis perpendicular to the planes of the molecules, orients along a specific direction. The nematic discotic phase has orientational order but no positional order. In the columnar discotic phase, the disclike molecules form columns and therefore exhibit orientational and positional order. In a chiral discotic liquid crystal, the director rotates in a helical path throughout the system.

Poly(1,4-benzamide) (PBA) (7) was the first nonpeptide synthetic polymer reported to form a liquid crystalline solution. In order to obtain liquid-crystalline solutions of poly(1,4-benzamide), it was first necessary to prepare the polymer in the proper solvent. Preparation of the polymer in *N,N*-dialkylamide solvents at low temperatures from *p*-aminobenzoyl chloride hydrochloride produces tractable PBA polymers with inherent viscosities of as much as 5 dL/g. In solvents such as *N,N*-dimethylacetamide [127-19-5] and *N,N,N′,N′*-tetramethylurea [632-22-4] a coupled polymerization–spinning process in liquid-crystalline solution has been developed. If polymerization is initiated at temperatures greater than 25°C, lower molecular weight polymer is formed. Above 25°C, chain termination by reaction of acid chloride chain ends with *N,N*-dialkylamide is significant. To obtain high molecular weights, a lithium base such as lithium hydride, lithium carbonate, or lithium hydroxide is added to the polymerization solution after the first 1–2 h of reaction time to neutralize the hydrogen chloride generated. As the reaction proceeds, the polymerization rate decreases because the increasing amounts of hydrogen chloride consequently produce fewer free-terminal amine groups.

When pure needle-like crystals of *p*-aminobenzoyl chloride are polymerized in a high temperature, nonsolvent process, or a low temperature, slurry process, polymer is obtained which maintains the needle-like appearance of monomer. PBA of inherent viscosity, 4.1 dL/g, has been obtained in a hexane slurry with pyridine as the acid acceptor. Therefore, PBA of fiber-forming molecular weight can be prepared in the solid state.

In 1975, the synthesis of the first main-chain thermotropic polymers, three polyesters of 4,4′-dihydroxy-α, α'-dimethylbenzalazine with 6, 8, and 10 methylene groups in the aliphatic chain, was reported (8). Shortly thereafter, at the Tennessee Eastman Co. thermotropic polyesters were synthesized by the acidolysis of poly(ethylene terephthalate) by *p*-acetoxybenzoic acid (9). Copolymer compositions that contained 40–70 mol% of the oxybenzoyl unit formed anisotropic, turbid melts which were easily oriented.

Polyesters such as poly(*p*-phenylene terephthalate), which would be expected to form liquid crystalline phases, decompose at temperatures below the melting point. Three principal methods have been used for lowering the melting

temperatures of thermotropic copolyesters: (*1*) the use of flexible groups as spacers to decouple the mesogenic units and reduce the axial ratio; (*2*) the use of unsymmetrical groups on mesogenic units; and (*3*) the copolymerization of rigid units with nonlinear, bent units which add a "kink" to the rod-like system.

According to patents obtained by Carborundum (10–12), Celanese (13), DuPont (14–17), and Eastman (9,18) most industrial main-chain thermotropics are prepared by condensation polymerization involving transesterification. Hydroxy-substituted monomers are acetylated before polymerization by acetic anhydride in the presence of a suitable catalyst. The transesterification reactions involve acetylated diol, or monosubstituted hydroxybenzoic or hydroxynaphthoic acids, and diacids. The polymerizations are carried out in an inert atmosphere to prevent oxidation. A stainless steel stirrer is utilized to improve mixing and to accelerate the release of the reaction by-products. The polymerizations are carried out at 50–80°C above the melting point of the highest melting monomer. After a low melt viscosity prepolymer is obtained, a vacuum is applied to remove the additional acetic acid and increase the molecular weight of the polymer. Finally, solid-state polymerization under reduced pressure or in nitrogen at a temperature of 10–30°C below the melting point may be utilized to increase the molecular weight. The heat treatment of spun fibers under these conditions leads to spectacular increases in tensile strength and modulus.

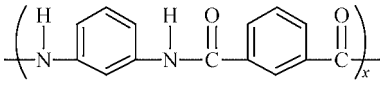
Researchers at DuPont used hydroquinone asymmetrically substituted with chloro, methyl, or phenyl substituents and swivel or nonlinear bent substituted phenyl molecules such as 3,4- or 4,4′-disubstituted diphenyl ether, sulfide, or ketone monomers. For example, poly(chloro-1,4-phenylene-*trans*-hexahydroterephthalate) and related copolymers were prepared in a melt-polymerization process involving the reaction of molar equivalents of the diacetoxy derivatives of diphenols and hexahydroterephthalic acid (19). During polymerization, a phase transition from isotropic to anisotropic occurred soon after the rapid melting of the intermediates to form a clear, colorless liquid.

Also in 1972 (20), Carborundum researchers described a family of aromatic copolyesters that were recognized later to form liquid-crystalline melts. The polymers are based on a bisphenol monomer. In 1976, in a patent assigned to Carborundum, a hydroxybenzoic acid–terephthalic acid–bisphenol system, modified and softened with isophthalic acid, was reported to be melt spinnable to produce fiber (21).

Industrial Lyotropic Liquid-Crystalline Polymers (Aramid Fibers). The first polyaramid fiber (MPD-1) was based on poly(*m*-phenylene isophthalamide) [24938-60-1]. The fiber was not liquid crystalline but was the first aramid fiber to be commercialized by DuPont under the trade name Nomex nylon in 1963 and changed to Nomex aramid in 1972 (22). The principal market niche for Nomex (DuPont) was as a heat-resistant material. Teijin also introduced a fiber (trademark Conex) based on MPD-1 in the early 1970s. Fenilon, also based on MPD-1, was produced in the former USSR for civilian, military, and space exploration applications. In 1970, DuPont introduced an aramid fiber, Fiber B, for use in tires, which was probably based on polybenzamide PBA spun from an organic solvent. Fiber B had high strength and exceptionally high modulus. Another version of Fiber B, based on poly(*p*-phenylene terephthalamide) [24938-64-5] (PPT) was introduced in the 1970s. This version of Fiber B was spun from sulfuric acid and had a tensile strength approximately twice that of the Fiber B based on MPD-1.

An even higher modulus fiber based on PPT, in which the modulus was increased by the drawing of the as-spun fiber, was introduced under the name PRD-49 for use in rigid composites. The undrawn and drawn fibers were later announced as Kevlar-29 and Kevlar-49, respectively. In 1975, Akzo of the Netherlands reported the commercialization of an aramid fiber, Twaron (Akzo), based on PPT.

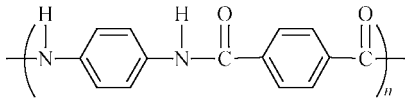
Nomex. This fiber was commercialized for applications requiring unusually high thermal and flame resistance. Nomex (DuPont) fiber retains useful properties at temperatures as high as 370°C. Nomex has low flammability and has been found to be self-extinguishing when removed from the flame. On exposure to a flame, a Nomex fabric hardens, starts to melt, discolors, and chars thereby forming a protective coating (23). Therefore an outstanding characteristic is low smoke generation on burning. The limiting oxygen index (LOI) value (top down) for Nomex fabrics is 26.0 (24). Nomex has a tga weight loss of 10% at 450°C and a use temperature of 370°C. Nomex has good to excellent strength, a tenacity of 0.42–0.51N/tex (4.8–5.8 gf/den) (25), good extendability, and a modulus greater than that of nylon-6,6. The density is 1.38 g/cm^3 (26). Nomex is more difficult to dye than nylon, but the use of dye carriers allows dyeing to proceed at high temperatures with temperature-resistant basic dyes (27). The structure of Nomex may be represented as follows:



Nomex

MPD-1 fibers may be obtained by the polymerization of isophthaloyl chloride [99-63-8] and *m*-phenylenediamine [108-45-2] in dimethylacetamide with 5% lithium chloride (26). The reactants must be very carefully dried since the presence of water would upset the stoichiometry and lead to low molecular weight products. Temperatures in the range of 0 to −40°C are desirable to avoid such side reactions as transamidation by the amide solvent and acylation of *m*-phenylenediamine by the amide solvent. Both reactions would lead to an imbalance in the stoichiometry and result in forming low molecular weight polymer. Fibers may be either dry spun or wet spun directly from solution.

Kevlar. In the 1970s, researchers at DuPont reported that the processing of extended chain all para-aromatic polyamides from liquid crystalline solutions produced ultrahigh strength, ultrahigh modulus fibers. The greatly increased order and the long relaxation times in the liquid crystalline state compared to conventional systems led to fibers with highly oriented domains of polymer molecules. The most common lyotropic aramid fiber is poly(*p*-phenyleneterephthalamide) (PPT) which is marketed as Kevlar by DuPont. Aramid fiber is available from Akzo under the trade name Twaron. These fibers are used in body armor, cables, and composites for sports and space applications. Kevlar has the following structure:



Kevlar

PPT of high molecular weight (inherent viscosity of 22 dL/g, corresponding to a molecular weight of 123,000) can be prepared by low temperature polymerization in various solvents (28). PPT is less soluble in amide solvents than PBA and the most successful polymerization solvents are a mixture of hexamethylphosphoramide [680-31-9] (HMPA) and *N*-methylpyrrolidinone [872-50-4] (NMP) or NMP-containing calcium chloride (29,30). These solvent systems yield fiber-forming polymer. As the molecular weight increases rapidly during the first few seconds of the polymerization, the critical concentration is exceeded and the solution develops the opalescence characteristic of the liquid-crystalline state. The critical factors influencing the molecular weight include stoichiometry, solvent composition, temperature, and solids concentration (31). At low monomer concentrations, side reactions can occur between the acid chloride chain ends and the amide solvents. At higher solids concentrations, gelation acts to limit the development of high molecular weights. It is of critical importance to keep the initial temperature low in order to prevent the reaction of the amide solvents with the acid chloride groups.

The preparation of high molecular weight PPT in HMPA/NMP shows a strong dependence of inherent viscosity on reactant concentrations. In 2:1 (by volume) HMPA/NMP, the highest inherent viscosity polymer is obtained when each reactant is present in concentrations of ca 0.25 *M* (32,33); higher and lower concentrations result in the formation of polymer of lower inherent viscosities. A typical procedure (31) is as follows: 1,4-phenylenediamine [106-50-3], HMPA, and NMP are added to an oven-dried resin kettle equipped with a stirrer and stirred for ca 15 min with cooling to −15°C, followed by the addition of powdered terephthaloyl chloride [100-20-9] to the rapidly stirred solution. The reaction mixture changes to a thick, opalescent, paste-like gel in ca 5 min.

The manufacturing process utilized (34,35) is continuous polymerization in order to minimize cost. A continuous stream of *p*-phenylenediamine solution is added to a continuous stream of molten terephthaloyl chloride. Volumetric control is easily achieved because both reactants are in the liquid state. Residence time in the mixing apparatus is on the order of 1 s. Next, the reactants enter a high shear, continuous screw mixer, in which the inherent viscosity of the polymer increases to 4–4.5 dL/g. The minimum inherent viscosity required for fiber spinning in sulfuric acid is 4 dL/g. The residence time is less than 15 s so the polymer solution which enters the third stage is still a fluid. The third stage is a high shear, twin-screw mixer with blades positioned for a number of recycle zones within the mixer, thereby achieving lower temperatures, higher residence times, and higher molecular weights.

An alternative polymerization process utilizes a slurry of calcium chloride in NMP as the polymerization medium (30). The solubility of calcium chloride is only 6% at 20°C; however, the salt continues to dissolve as conversion of monomers to polymer proceeds and calcium chloride/polyamide complexes are formed. Polymer molecular weight is further increased by the addition of *N,N*-dimethylaniline [121-69-7] as an acid acceptor. This solvent system produces fiber-forming polymer of molecular weights comparable to that formed in HMPA/NMP.

Since PPT melts with decomposition at ca 560°C (36), melt spinning cannot be employed. Thus, solution spinning techniques (31) must be used to prepare fibers. Although dry, wet, and dry jet-wet spinning methods have all been used to

prepare fibers, ordinarily PPT is spun from nematic sulfuric acid solutions using the dry jet-wet spinning process with cold water as the coagulant. In the dry spinning process, a polymer solution is passed through a spinnerette followed by flash evaporation of the solvent in a heated chamber and subsequent winding of the fiber produced on a bobbin. In the wet spinning process, the polymer solution is passed through a spinnerette located in a coagulation bath. The fiber formed is then drawn to increase molecular orientation, tenacity, and modulus. In dry jet-wet spinning, the polymer solution is allowed to flow through a spinnerette into a separated coagulation bath. Therefore, the temperatures of the spinnerette and coagulation baths may be independently controlled. The liquid crystalline nature of the PPT dopes and the dry jet-wet spinning technology are principally responsible for the development of commercial high performance Kevlar fibers.

Drawdown of the coagulated fiber is an essential element in high performance fiber technology (31). Under shear, the unoriented domains become oriented in the direction of stretch. In the fiber manufacturing process, the unoriented liquid-crystalline domains are oriented in the spinnerette, followed by retention and perfection of the highly ordered nematic phase by the elongational forces in the air gap and further drawdown in the coagulation medium (37). Coagulation sets the high degree of orientational order achieved by stretching. Tenacity increases with increasing drawdown and inherent viscosity as well as decreasing air gap (between the spinnerette and coagulation bath). Modulus increases with increasing drawdown and total spinning strain.

Because of their rigid-chain structure, PPT and related *p*-aramids exhibit liquid-crystalline behavior in solution. The rod-like molecules aggregate in nematic, ordered domains. When solutions of these materials are exposed to shear, these ordered domains tend to orient in the direction of flow. On passing through a spinnerette, liquid-crystalline solutions retain the high degree of orientation acquired in the spinning process, leading to as-spun fibers with extraordinary degrees of crystallinity and orientation. As-spun fibers of PPT, obtained by spinning a 20% solution of PPT in 100% sulfuric acid, have a crystalline orientation angle of ca 12° (determined from wide-angle X-ray diffraction) and a modulus of ca 72 GPa (38). Heat treatment increases the degree of crystalline alignment. Correspondingly, heat-treated fibers have an orientation of ca 9° and a modulus of ca 120 GPa.

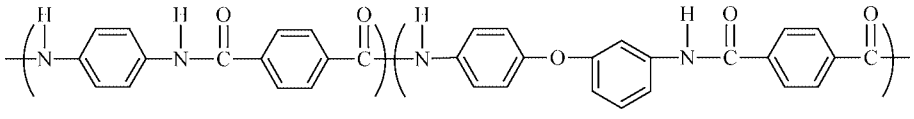
In a typical commercial dry jet-wet spinning process, PPT polymer of inherent viscosity 6.0 dL/g is added to 99.7% sulfuric acid in a water-jacketed commercial mixer in a ratio of 46 g of polymer to 100 mL of acid (39). The mixture is sealed in a vacuum of 68.5–76 mL of mercury. Mixing takes place for 2 h at temperatures of 77–85°C. The dope is then transferred to a glass-lined, water-jacketed kettle at 90°C. Any air or bubbles caused by the transfer are removed under vacuum for about 30 min. The dope is then pumped through a heated (90°C) transfer line to an electrically heated spinning block with an associated gear pump. The gear pump then meters the dope through a heated (80°C) 1.25-cm diameter spinnerette containing 100 holes of 51 μm diameter. The dope is extruded from the spinnerette at a velocity of ca 63 m/min vertically through a 0.5-cm layer of air (air gap) into water at a temperature of 1°C. The yarn is wound on a bobbin under a 50°C water spray. The bobbin is then submerged in 0.1 *N* $NaHCO_3$ solution and then further extracted with water at 70°C.

Dramatic increases in the mechanical properties of aramid fibers are observed on heat treatment under tension. Tenacity and modulus increase exponentially with increasing temperature (and draw ratios) of wet spun fibers at temperatures of ca 360°C (the glass-transition temperature, T_g) to 550°C (the melting temperature). Dry jet-wet spun yarns heat treated under tension show substantial increases in modulus at temperatures greater than 200°C; the already high values of tenacity remain essentially unchanged. An intermediate modulus, high tenacity dry jet-wet spun yarn is thus converted into high modulus, high strength fiber.

Because the inherent viscosities of the heated yarns remain constant, it is postulated that the changes are physical. Yarns with as-spun moduli of 8.8–88 N/tex (100–1000 gf/den) may be obtained directly by dry jet-wet spinning. Yarns with as-spun tenacities of greater than 1.8 N/tex (20 gf/den) are obtained by dry jet-wet spinning. Kevlar-29 has a tenacity of ca 2.5 N/tex (28 gf/den) and a specific modulus of ca 41 N/tex (464 gf/den) (40). Kevlar-49 has a tenacity of ca 2.5 N/tex (28 gf/den) and a specific modulus of ca 86 N/tex (980 gf/den). A relatively new fiber, Kevlar-149, is the highest tensile modulus aramid fiber currently available. Its specific modulus is ca 126 N/tex (1430 gf/den) and tenacity ca 2.3 N/tex (26 gf/den).

The crystal structure of PPT is pseudo-orthorhombic (essentially monoclinic) with $a = 0.785$ nm; $b = 0.515$ nm; c (fiber axis) $= 1.28$ nm and $\gamma = 90°$ (41). The molecules are arranged in parallel hydrogen-bonded sheets. There are two chains in a unit cell and the theoretical crystal density is 1.48 g/cm^3. The observed fiber density is 1.45 g/cm^3. Based on electron microscopy studies of peeled sections of Kevlar-49, the supramolecular structure consists of radially oriented crystallites. The fiber contains a pleated structure along the fiber axis, with a periodicity of 500–600 nm.

Technora. In 1985, Teijin Ltd. introduced Technora fiber, previously known as HM-50, into the high performance fiber market. Technora is based on the 1:1 copolyterephthalamide of 3,4′-diaminodiphenyl ether and *p*-phenylenediamine (42). Technora is a wholly aromatic copolyamide of PPT, modified with a crankshaft-shaped comonomer, which results in the formation of isotropic solutions that then become anisotropic during the shear alignment during spinning. The polymer is synthesized by the low temperature polymerization of *p*-phenylenediamine, 3,4′-diaminophenyl ether, and terephthaloyl chloride in an amide solvent containing a small amount of an alkali salt. Calcium chloride or lithium chloride is used as the alkali salt. The solvents used are hexamethylphosphormide (HMPA), *N*-methyl-2-pyrrolidinine (NMP), and dimethylacetamide (DMAc). The structure of Technora is as follows:



Technora

The polymerization is carried out at temperatures of 0–80°C in 1–5 h at a solids concentration of 6–12%. The polymerization is terminated by neutralizing

agents such as calcium hydroxide, calcium oxide, calcium carbonate, or lithium hydroxide. Inherent viscosities of 2–4 dL/g are obtained at 3,4′-diaminodiphenyl ether contents of 35–50 mol%. Because of the introduction of nonlinearity into the PPT chain by the inclusion of 3,4′-diaminodiphenyl ether kinks, the copolymer shows improved tractability and may be wet or dry jet-wet spun from the polymerization solvent. The fibers are best coagulated in an aqueous equilibrium bath containing less than 50 vol% of polymerization solvent and from 35 to 50% of calcium chloride or magnesium chloride.

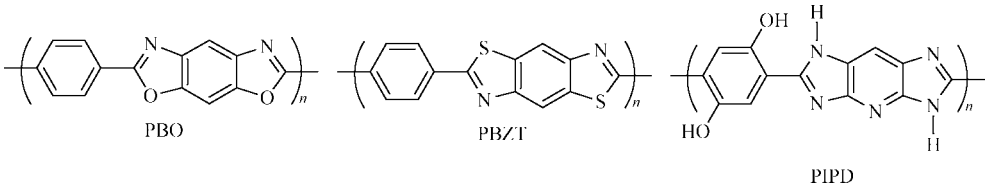
The copolymer fiber shows a high degree of drawability. The spun fibers of the copolymer were highly drawn over a wide range of conditions to produce fibers with tensile properties comparable to PPT fibers spun from liquid-crystalline dopes. There is a strong correlation between draw ratio and tenacity. Typical tenacity and tensile modulus values of 2.2 N/tex (25 gf/den) and 50 N/tex (570 gf/den), respectively, have been reported for Technora fiber (42).

Heterocyclic Rigid-Rod Polymers.

PBO, PBZ, and PIPD. PBZ, a family of *p*-phenylene-heterocyclic rigid-rod and extended chain polymers includes poly(*p*-phenylene-2,6-benzobisthiazole) [69794-31-6] (*trans*-PBZT), poly(*p*-phenylene-2,6-benzobisoxazole) [60871-72-9] (*cis*-PBO), and poly[2,6-diimadazo[4,5-b:4′,5′-e]pyridinylene-1,4(2,5-dihydroxy)phenylene (PIPD). PBZT and PBO were initially prepared at the Air Force Materials Laboratory at Wright–Patterson Air Force Base, Dayton, Ohio (43). PBZT was prepared by the reaction of 2,5-diamino-1,4-benzenedithiol dihydrochloride with terephthalic acid [100-21-0] in polyphosphoric acid (PPA) and PBO by the reaction of 4,6-diamino-1,3-benzenediol dihydrochloride with terephthalic acid in PPA. The PIPD was prepared by the reaction of 2,3,5,6-tetraaminopyridine with 2,5-dihydroxyterephthalic acid. PIPD was initially prepared at Akzo Nobel Central Research (44).

Although the crystal structures of the 2,6-diphenyl- *cis*- and *trans*-benzobisoxazole compounds have colinear exocyclic bonds with the coplanar condensed rings (45), and the phenyl rings coplanar with the heterocycles (46), the central ring of the 2,6-diphenyl-*cis*-benzobisthiazole system is bent (47). The exocyclic bonds of the 2,6-diphenyl-*cis*-benzobisthiazole system are bent out of linearity. The central, condensed ring system of 2,6-diphenyl-*trans*-benzobisthiazole is planar with the exocyclic bonds showing a deviation of only 0.06 nm from colinearity. The phenyl rings of 2,6-diphenyl-*trans*-benzobisthiazole deviate from planarity with a dihedral angle of ca 23°. The phenylene rings in the *trans*-PBZT polymers are coplanar with the central condensed heterocyclic ring system. Wide-angle X-ray diffraction studies of PIPD revealed a hydrogen bonding scheme consisting of intramolecular O–H–N hydrogen bonds and intermolecular N—H—O hydrogen bonds. The crystal structure of heat-treated PIPD fiber (M5 fiber) showed monoclinic symmetry (48). Crystal structure analysis showed that the neighboring chains are shifted along the *c*-axis (chain axis) relative to one another by 2.0 Å units. Each polymer chain is linked by bidirectional intermolecular hydrogen bonds to its four axially shifted neighbors. The presence of bidirectional intermolecular hydrogen bonding in PIPD is considered to be the basis for the exceptionally good compressive properties of PIPD. The relatively high compressive strength of PPT as compared to PBO and PBZT (4) is attributed to interchain hydrogen bonding. The additional bidirectional hydrogen bonding in

PIPD compared to PPT would explain the exceptionally high level of compressive strength for PIPD. Sikkema and co-workers (49) reported that while other polymers have compressive strengths between 0.2 and 0.6 GPa, M5 fiber spun from PIPD has a compressive strength of 1.7 GPa. The structures of PBO, PBZT, and PIPD are as follows:



The early syntheses of *cis*-PBO and *trans*-PBZT were conducted at polymer concentrations of 3 wt% or less. Since these isotropic solutions had high bulk viscosities, polymerizations had to be carried out at low solids concentrations to maintain tractability. When the concentration of *trans*-PBZT was raised to 5–10 wt%, nematic solutions were formed and polymers with intrinsic viscosities as high as 31 dL/g were obtained. Initially, the formation of *trans*-PBZT solutions of concentrations greater than 10% caused foaming problems during the polymerization and low molecular weights. The discovery of the P_2O_5 adjustment method was the breakthrough that resulted in the production of nematic spinnable dopes.

The P_2O_5 adjustment method involves adding P_2O_5 to the PPA polymerization solvent to maintain an effective PPA composition as the PPA acts as solvent, catalyst, and dehydrating agent. PPA acts as the solvent for monomer, oligomers, and polymer. PPA also activates the functional groups for polymerization and removes the water of condensation. Also, P_2O_5 is added at the end of the polymerization to achieve the viscosity necessary for spinning. At the end of the polymerization process, the P_2O_5 content must be greater than 82% to keep all the components in solution and less than 84% to give a solution of the proper viscosity for spinning. The temperatures of the PBO and PBZT polymerizations are raised in steps from 100 to 200°C to avoid decomposition of monomers. The temperature of the PIPD polymerization was raised stepwise from 100 to 180°C.

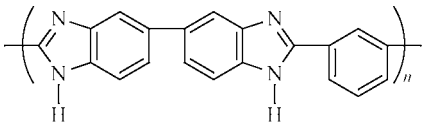
These rigid-rod polymers are spun using the dry jet-wet spinning technique also used for the spinning of aramid dopes. The solution is extruded under heat and pressure through a single or multihole spinnerette and an air gap into a coagulation bath, followed by washing, drying, and heat setting. PBO and PBZT have been spun in PPA and methanesulfonic acid. Water, dilute phosphoric acid, methanol, and ammonia have been used as coagulants. Heat treatment involves temperatures of 500–700°C with residence times on the order of a few seconds to several minutes. The nematic PPA solution formed in the polymerization may be used as the spinning dope. The typical molecular weight range used to spin fibers is 50,000–100,000 daltons. PIPD as-polymerized solutions of M_w 60,000–150,000 were air-gap wet spun at 180°C into a water or dilute phosphoric acid bath, followed by washing to a low phosphorus content and drawing at a temperature above 400°C to produce the final high modulus M5 fiber.

In thermogravimetric analyses (50) of the ordered polymers, the extrapolated onset of degradation of PBO and PBZT is reported to be 620°C in air. The

extrapolated onset of degradation of PBO in helium is over 700°C. In isothermal aging studies in air at 343°C, PBO and PBZT retain ca 90% of the weight after 200 h. At 371°C in air, PBO and PBZT retain ca 78 and 71% of the original weight, respectively. PBZ polymers degrade without the observation of crystalline melting points or glass-transition temperatures. The onset of thermal decomposition in air for PIPD was reported to be 530°C.

Toyobo (Zylon) has marketed the PBO fiber and Magellan Systems International has brought M5 fiber to the marketplace. PBO fibers have the highest reported tensile modulus of any known polymeric fiber, 280–360 GPa (41–52 $\times$ 10^6 psi). PBO and PBZT are among the most radiation-resistant polymers. Although the compressive strengths of PBO and PBZT are approximately an order of magnitude less than the tensile strengths, alloys of these fibers with high compressive strength fibers can be produced. The polymers are now being evaluated for other applications such as nonlinear optics. Possible PBO applications include reinforcing fibers in composites, multilayer circuit boards, athletic equipment, marine applications, woven fabrics, and fire-resistant fibers (1). Magellan Systems International reports a tenacity of 5.3 GPa, a modulus of 350 GPa, and a compressive strength of 1.6 GPa for M5 fiber (51). Possible M5 applications include advanced lightweight composites, hard and soft ballistic armour, high strength cables, advanced fabrics and textiles, and high performance fire retardant materials.

Polybenzimidazole (PBI) Fibers. Poly[(2,2′-*m*-phenylene)-5,5′-bisbenzimidazole] [25734-65-0] is a textile fiber originally marketed by the Celanese Corp. (52) which does not form liquid-crystalline solutions due to its bent meta backbone monomeric component. PBI (Celanese) has an excellent resistance to high temperature and chemicals.



PBI

PBI is being marketed as a replacement for asbestos and as a high temperature filtration fabric with excellent textile apparel properties. The synthesis of wholly aromatic polybenzimidazoles with improved thermal stabilities was reported in 1961 (53). The Non-Metallic Materials and Manufacturing Technology Division of the U.S. Air Force Materials Laboratory, Wright–Patterson Air Force Base, awarded a contract to the Narmco Research and Development Division of the Whittaker Corp. for development of these materials into high temperature adhesives and laminates.

Poly[2,2′-(*m*-phenylene)-5,5′-bisbenzimidazole] was chosen as the most promising candidate for further development as a fibrous material. Under the terms of an Air Force contract, DuPont was able to spin fibers from both dimethylsulfoxide and dimethylacetamide solutions to form relatively strong, thermally stable fibers. In 1963, an Air Force contract was awarded to Celanese Research Co. for the development of a manufacturing process for the scale-up of PBI production. PBI fiber of tenacities 0.31–0.44 N/tex (3.5–5.0 gf/den) were produced in sufficient quantity for large-scale evaluation. The fiber was discovered to have

a soft hand in addition to possessing a high degree of nonflammability. In the limited oxygen index (LOI) test, the concentration of oxygen required for sustained, steady-state burning was 41%. A new development program was started at Celanese with funding from NASA and the Air Force to develop a flight suit material, fabrics for fatigues worn in space capsules, and utility equipment such as ropes and bungee cords.

Further field tests demonstrated that in spite of the excellent thermal and fire resistance, shrinking of the fabrics occurred above the glass-transition temperature which might expose the wearer to flames. Based on the results obtained in an Air Force contract at Dynatech Co., the Celanese Research Co. developed a two-stage process that reduced the shrinkage from 50 to 6%. The process was also amenable to on-line processing. The sulfonated derivative is the fiber which was marketed by the Celanese Corp. Some end uses include replacement of asbestos, thermal and chemical safety apparel, and stack gas filter bags, airline seat covers, firemen turn coats, and race car driver suits.

Development efforts at Celanese Research Co. established solid-state polymerization as the most practical process for engineering scale-up. Homogeneous solution polymerization of PBI in polyphosphoric acid was eliminated because of the need to work with low solid compositions (in the range of 3–5%) during the precipitation, neutralization, and washing steps required for isolation of the product.

In the first stage of the engineering scale-up process (54), a 189 L oil-jacketed, stainless steel reactor is charged with diphenyl isophthalate [744-45-6] (DPIP) and 3,3′,4,4′-tetraaminobiphenyl (TAB). The reactor is deoxygenated by alternative application of vacuum and filling with nitrogen three times, followed by agitation and heating to 250°C under a stream of nitrogen, followed by heating at 290°C for 1.5–3.0 h in the absence of agitation before cooling. In the second stage of the process, the polymer obtained in three to four runs is ground to 0.84 mm (20 mesh) and charged into a 38 L oil-heated stainless steel reactor for a final heating step with agitation at 370–390°C for 3–4 h. Initially, large amounts of foam were produced in the first stage of the process. Foam reduction involves the addition of 10–20% by weight of an organic additive such as diphenyl ether. At the lower temperature of the first stage, the additive acts to prevent foaming and the additive is then removed at the higher temperatures involved in the second stage. Although the foam volume is significantly reduced, the additive residues are removed only with considerable difficulty.

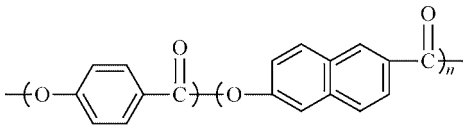
The spinning process used to produce PBI fibers is dry spinning (55). The preferred solvent for dry spinning of PBI is dimethylacetamide (DMAc). The powdered polymer is dissolved in DMAc at high temperatures (ca 250°C) to form ca 23% wt/wt concentration spinning dopes. The spinning dope is fed by a metering pump through a spinnerette (following filtering) into a countercurrent of hot nitrogen gas in the spinning column. Nitrogen gas is used to prevent oxidation of the oxidatively sensitive filaments formed as the hot gas evaporates the DMAc. The filaments pass to a godet roll and then onto a winder. Washing of the fiber takes place on perforated bobbins to remove lithium chloride stabilizer and residual solvent. The fiber is drawn to achieve improved mechanical properties by passing it from feed rolls to draw rolls through an oven set at temperatures greater than 400°C while under a positive nitrogen pressure. Acid treatment to minimize

shrinkage involves the use of aqueous sulfuric acid to produce an acid salt followed by heat treatment to form sulfonic acid groups. If all the imidazole rings were substituted, the final stabilized product would contain 8% sulfur; however, the level of sulfur ordinarily obtained (ca 6%) is sufficient for the required improvement in dimensional stability.

Typical properties of stabilized PBI (56) are a tenacity of 0.27 N/tex (3.1 gf/den), a fiber breaking elongation of 30%, an initial modulus of 3.9 N/tex (45 gf/den), a density of 1.43 gf/cm^3, and a moisture regain of 15% (at 21°C and 65% relative humidity).

Solution dyeing of PBI is necessary (57) because the glass-transition temperature (T_g) of PBI is greater than 400°C, and as a result dye molecules only slowly diffuse into the PBI fiber structure. Since the pigments are added to the spinning dope, the pigments must be capable of withstanding the high temperatures used in the various fiber-forming processes.

Industrial Thermotropic LCPs. Vectran (Celanese), poly(6-hydroxy-2-naphthoic acid-*co*-4-hydroxybenzoic acid) [81843-52-9], was the first thermotropic fiber to become commercially available (58). Vectran is synthesized by the melt acidolysis of *p*-acetoxybenzoic acid and 6-acetoxy-2-naphthoic acid.



Vectran

First, *p*-hydroxybenzoic acid (HBA) [99-96-7] and 6-hydroxy-2-naphthoic acid (HNA) [16712-64-4] are acetylated to produce the low melting acetate esters which are molten at 200°C. In an inert gas, the two monomers are melted together at 200°C. The temperature is raised to 250–280°C and acetic acid is collected for 0.5–3 h. The temperature is raised to 280–340°C and additional acetic acid is removed in vacuum for a period of 10–60 min. The opalescent polymer melt produced is extruded through a spinning jet, followed by melt drawdown. The use of the parallel offset monomer, acetylated HNA, results in the formation of a series of random copolyesters of different compositions, many of which fall within the commercially acceptable melting range of 250–310°C. Characteristically, these nematic melts show the persistence of orientational order under the influence of elongational flow fields which results in low melt viscosities under typical fiber formation conditions even at high molecular weights.

Axial orientation develops quickly during melt drawdown with a concomitant increase in fiber modulus. At a drawdown ratio of ca 10, the fiber achieves a maximum modulus in the range of 44.1–61.7 N/tex (500–700 gf/den). Neither cold drawing nor annealing led to additional increases in modulus. The high level of mechanical properties is the result of the comparative ease of axial orientation of the nematic phase leading to a highly oriented rod-like fiber structure. This is borne out by X-ray fiber analysis which shows well-defined meridonal maxima characteristic of highly oriented parallel arrays of polymer chains with poor lateral spacing.

Heat treatment of the as-spun fibers results in an increase in tenacity but no attendant increase in modulus. Typically, the as-spun fibers are heat treated in an inert environment at temperatures 10–20°C below the melting point for from 10 min to several hours. There is a corresponding increase in chemical resistance and melting temperatures, presumably due to increases in molecular weight rather than improvements in structural perfection. This is in agreement with X-ray fiber diagram results which show no increase in orientation of mesophases during the heat-treatment process. Vectran HS fibers are reported to have typical tensile strength and modulus values of 2 N/tex (23 gf/den) and 46 N/tex (550 gf/den) (59), respectively. The melting point and density are reported to be 330°C and 1.4 g/cm^3. The fibers have an excellent chemical resistance except for their resistance to alkali.

Gel-Spun Fibers

In the mid-1970s, it was discovered at the Dutch States Mines Co. (DSM) that through an ingenious new method of gel spinning ultrahigh molecular weight polyethylene it was possible to produce fibers having twice the tenacity of Kevlar, which was then considered to be the strongest known fiber (60). The discovery was important not only because of the exciting 3.8 N/tex (44 gf/den) strengths these new fibers displayed, but also because it clearly demonstrated that factors other than monomer polarity were critical in controlling fiber performance characteristics. These high performance polyethylene fibers (HPPE) produced by the DSM subsidiary company Stamicarbon were called Dyneema and those produced by the Allied Signal Corp. in the United States are sold under the trade name of Spectra 1000. The commercial products have somewhat lower strengths than the laboratory fibers but still are in the high 2.6 N/tex (30 gf/den) range (61).

Process. In the gel spinning process, 1–8% solutions of polyethylene are prepared by dissolving polymer of molecular weights of 1–4 million in hot hydrocarbon liquids such as decalin, melted waxes, or mineral oils at ca 150°C. These hot solutions are then screw extruded through spinnerettes having holes of 0.5–2.0 mm diameter and an L/D ratio of 25 to control the viscoelastic flow properties of the fluid. The fibers are spun into a cooling bath which yield disoriented highly crystalline gel fibers of sufficient stability to be wound onto a first godet at several meter per minute. These gel fibers are then processed in solvents at about 50°C to remove the hydrocarbons. The solvent-free gels are then stretched in progressively hotter zones at temperatures from 120 to 160°C with an overall final windup/extrusion speed of about 1000/1 or whatever is required to give the final desired strengths of 1.7–3.5 N/tex (20–40 gf/den) (62).

The patent literature indicates that the AlliedSignal process uses lower boiling solvents such as chlorofluorocarbons as the cooling/extraction baths (63), whereas the processes of Stamicarbon indicate the use of decalin solvent followed by cooling and slow removal of the decalin in successively hotter chambers while stretching (64).

Properties. Fiber property comparisons for the different products are given in Table 1.

Table 1. Properties of Commercial HPPE Fibers[a]

Fiber	Tenacity, N/tex	Initial modulus, N/tex	Elongation at break, %
Dyneema	1.01–3.57	57–128	3–7
Spectra 1000	3.4–3.57	162–171	3–7

[a] Refs. 63 and 64.

The attributes of HPPE fibers include high strength; high abrasion resistance; high UV stability as compared to other synthetics; high resistance to acids, alkali, organic chemicals, and solvents; and low density. Disadvantages are a low melting point of about 150°C (1), which means performance is limited to no more than 120°C; difficult processing; and poor surface adhesion properties.

It is difficult to process HPPE staple fibers mechanically because of so-called married fibers which are bundles of 4–6 fibers that firmly adhere to each other and resist separation by conventional processing. Although HPPE fibers like to adhere to each other, they exhibit poor adhesion to other materials.

It is possible to modify HPPE to overcome the poor adhesion of the fiber surfaces by using corona discharge in an oxygen atmosphere previously developed for polyolefin films or by the addition of fillers to the polymer solution prior to spinning. The melting point of HPPE fibers embedded in polymer matrices is increased by about 8°C (65,66). Temperature performance can also be enhanced by wrapping the HPPE fibers with other fire-resistant or fire-retardant fibers (67,68). Other ultrahigh molecular weight polymers have also been spun via the gel spinning process. These include polypropylene, polyacrylonitrile, poly(vinyl alcohol), and nylon-6. However, the property improvements in these cases evidently have not warranted commercialization.

Modified Carbon Fibers (Elongatable Carbonaceous Fiber)

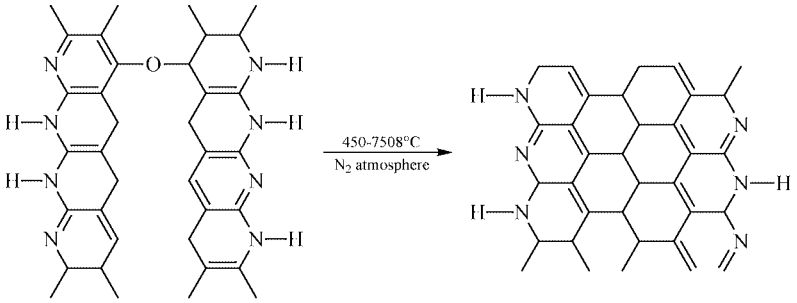
Carbon Fibers (qv) are made by the nonoxidative high temperature pyrolysis of fibers originally spun from either rayon, polyacrylonitrile (PAN) [25014-41-9] or mesomorphic hydrocarbon tar (MT or pitch) materials. Of these three staring materials the most work has been done with rayon because the carbon fibers produced from rayon have the best overall physical and performance characteristics (69).

For example, rayon-based carbon fibers have the lowest density followed by those from PAN, with those from the tar base having the highest density. A similar trend is found in physical strength test results. Of paramount importance for space vehicle use, the carbon fibers from rayon exhibit the best ablative performance with the least loss of weight during re-entry into earth's atmosphere. The carbon fibers used in space projects require a special classified type of rayon and special carbonizing conditions to reach peak performance. During the early 1990s such rayon was in short supply due to the closing of the main producer having effluent pollution problems. However, a second new supply was developed with no delay to the space program. Due to their low elongation and resulting high brittleness, essentially all rayon-based carbon fibers are used as reinforcement fibers for laminate structures with polyphenolic and other resins. Carbon fiber

cloth can only be woven on special types of textile looms. Acrylonitrile copolymers and terpolymers can be used to make carbon type fibers with higher elongations that are much more applicable for textile operations.

Liquid-crystalline mesophase pitch is employed for high modulus carbon fiber production by stress graphitization. Carbon fibers prepared from this process were commercialized in the early 1980s (1). Petroleum, coal tar, and poly(vinyl chloride) are common sources of the pitch used in the preparation of carbon fibers.

It is difficult to weave or knit regular carbon fiber. For any fiber to be considered as a satisfactory textile fiber it should have an elongation of at least 3% and preferably more in the range of 5–8%. The extreme brittleness, high modulus, and low elongation of standard carbon fibers restrict them to be woven only on a special type of rigid rapier loom. To overcome these drawbacks, an exciting new modification of carbon fiber technology was developed; by using less stringent carbonizing conditions and only partially carbonizing the precursor fibers, improved textile fiber properties have been achieved (70).



OPF EDF

Process. Any standard precursor material can be used, such as oxidized polyacrylonitrile (PAN) fiber (OPF). This OPF (Dow) is treated in a nitrogen atmosphere at 450–750°C, preferably 525–595°C, to give fibers having between 69 and 70% C, 19% N; density less than 2.5 g/mL; and a specific resistivity under $10^{10}\ \Omega \cdot$cm. If crimp is desired, the fibers are first knit into a sock before heat treating and then de-knit. Controlled carbonization of precursor filaments results in a linear Dow fiber (LDF), whereas controlled carbonization of knit precursor fibers results in a curly carbonaceous fiber (EDF) (Dow). At higher carbonizing temperatures of 1000–1400°C the fibers become electrically conductive (71).

Properties. Unlike regular carbon fibers, these new products do not conduct electricity, but do exhibit good textile processing properties and possess exceptional ignition-resistant, flame-retardant, and even fire-blocking properties. The limiting oxygen index (LOI) defines the percentage of oxygen necessary in an oxygen/nitrogen mixture before a material supports combustion. Typical LOI values for various fibers are given in Table 2.

Previous results with ignition-resistant (IR) blends, where such fibers as aramids or PBI (Celanese) are used as the high LOI fibers, show that they need at least 65% and typically 85% fiber content to pass the vertical burn test for lightweight nonwoven batting. In contrast only 7–20% of either the Dow EDF or LDF mixed with flammable natural and synthetic fibers allow the blends to

Table 2. Limiting Oxygen Values of Fibers[a]

[a] Refs. 70 and 71.

pass such tests while still retaining most of the base natural or synthetic fiber properties. Blends of 50/50 EDF/polyester also passed the stringent FAA airlines ignition resistance tests with zero flame length and no after-burn, whereas other blends of 65% LOI fiber/40% synthetic blends gave burn lengths of 20 cm and 15 s after-burn, clearly demonstrating the superiority of the lower level carbonaceous fiber as a flame blocker (71,72). Such nonwoven batting has exceptional thermal and sound insulation properties and has been successfully tested by the U.S. Navy for pilot's arctic wear.

Carbon–Nanotube Fibers

In 2000, Poulin and co-workers reported a carbon–nanotube spinning method (73) in which surfactant-dispersed single-walled nanotubes were injected at a rate of 10–100 ml/h into a cylindrical container holding a 5% poly(vinyl alcohol) (PVA) aqueous solution. The cylinder was rotated at speeds of 30–150 rpm. By pumping out the PVA solution, meter-long ribbons were obtained. After the ribbons were washed and rinsed with pure water to remove PVA and surfactant and drying, fibers several tens of centimeters long were made by slowly pulling the ribbons out of water. Young's moduli of the fibers varied between 9 and 15 GPa.

In 2003, Baughman and co-workers reported that by modifying the Poulin process (74), they were able to spin 100-m lengths of nanotube composite fiber in a continuous process at a rate of more than 70 cm/min. In their process, the spinning gel was injected into a cylindrical pipe in which a a PVA coagulation solution was allowed to flow, resulting in collapse of the spinning solution into nanotube fiber subsequently wound on a mandrel. The second stage of the process

involved unwinding the fibers on a series of godets that transport them through an acetone wash-bath, followed by drying and wrapping on a mandrel.

Baughman reported that these composite fibers were tougher than any natural or synthetic fibers described to date. The composite fibers were approximately 50 μm in diameter and contained ca 60% single-wall nanotubes by weight. They reported a tensile strength of 1.8 GPa (which is comparable to that of spider silk) and an energy-to-break of 570 J/g that is higher than that of spider dragline silk (165 J/g), Kevlar fibers (33 J/g), and graphite fiber (12 J/g). Baughman and co-workers have used the nanotube composite fibers to make nanotube supercapacitors which were woven into textiles. Suggested potential applications for the carbon–nanotube fibers include distributed sensors, electronic interconnects, electromagnetic shields, and attennas and batteries.

Silicon Carbide Ceramic Fibers

The commercially produced continuous and multifilament Nicalon (Hercules) fiber is produced from polydimethylsilane; however other organosilicon polymers have been used for the production of silicon carbide fiber. Polydimethylsilane is first distilled to remove the low molecular weight components, and polymer of average molecular weight 1500 is melt spun at 280°C and cured in air at 200°C. The fiber is then heat treated between 800 and 1500°C in nitrogen or vacuum. Optimum mechanical properties are achieved at ca 1250°C. Listed properties of the Nicalon fiber are modulus: 200 GPa; and tensile strength: 2.8 GPa (1).

Continuous SiC fibers can also be prepared by using chemical vapor deposition (CVD). For this process, tungsten or a carbon substrate fiber and vapors of CH_3SiHCl_2, $C_2H_5SiCl_3$, or CH_3SiCl_3 have been used. A SiC fiber with a reported modulus of 400 GPa and tensile strength of 3.45 GPa (1) is produced in a tubular glass reactor by a CVD process on a carbon monofilament substrate melt-spun from coal tar pitch. The process is carried out in two steps : (*1*) approximately 1 μm thick pyrolytic graphite is deposited to render the substrate fiber smooth and enhance its electrical conductivity, and (*2*) the coated substrate fiber is exposed to the silane vapors. Decomposition at the surface occurs at temperatures of ca 1300°C to form β-SiC continuously on the substrate.

Silicon carbide has high thermooxidative stability and good thermal and electrical insulation properties. In composite applications, this fiber can be used to reinforce polymer, metal, and ceramic matrices.

Vitreous Fibers

Man-made vitreous fibers (MMVF) comprise a number of glass and specialty glass fibers and also refractory ceramic fibers. The vitreous state in glass is somewhat analogous to the amorphous state in polymers. However, unlike organic polymers, it is not desirable to achieve the crystalline state in glass. Glasses are produced from glass-forming compounds such as SiO_2, P_2O_5, etc, which are mixed with other intermediate oxides such as Al_2O_3, TiO_2, or ZnO, and modifiers or fluxes like MgO, Li_2O, BaO, CaO, Na_2O, and K_2O (1).

The purpose of the fluxes is to break down the SiO_2 network so that the molten glass has the proper viscosity characteristics to allow it to cool to the desired vitreous state. Glasses with large fractions of noncross-linking monovalent alkaline fluxes allow the melts to form at lower temperatures but correspondingly have lower chemical resistance. For example, sodium silicate glasses with larger amounts of Na_2O are sold as water solutions (water glass).

A wide range of glass compositions is available to suit many textile fiber needs; the three most common glass compositions are referred to as E, S, and AR glasses. AR glass is a special glass with higher contents of Zr_2O designed to resist the calcium hydroxide in the cementitious products where it is used. S glass is a magnesium–aluminum–silicate cross-linked glass used where high mechanical strength or higher application temperatures are desired. E glass is a member of the calcium–aluminum–silicate family containing less than 2% alkali (see composition in ASTM specification D578-89a) and is the predominant glass used to make textile and continuous filament fibers.

Glass fibers $<3\ \mu$m are to be avoided because these are classified as respirable fibers which can enter and damage lung passages. Most glass fiber products have sufficient fiber lengths to prevent lung entry even if their diameters are $<3\ \mu$m.

Manufacture. Vitreous fibers are produced by several processes (75).

Continuous Drawing Process. Textile glass filaments are made by a process different from that used for making discontinuous fibers, but literally parallel to a standard organic polymer melt spinning operation that does not employ a screw extruder. Premelted glass or glass marbles are fed into an electrically-heated furnace called a bushing which contains platinum nozzles. The exiting glass filaments are drawn down into the desired diameters, water sprayed, coated with a sizing, and the multiple filaments are collected as bundles of strands which are then wound onto a suitable cone.

Rotary Process. This process is much like the making of cotton candy except that molten glass is used in place of molten sugar. The melted glass is dropped into a rotating spinner with sidewall perforations and the exiting glass filaments are drawn to a fine diameter by the centrifugal force. These fibers are collected and coated with a protective spray containing either lubricants, binders, or antistatic and wetting agents. Other versions of the rotary process are (*1*) the wheel centrifugal process where molten glass is cascaded over spinning wheels and the formed fibers are stretched and broken by variations in the wheel speeds prior to being collected, and (*2*) the Downey process where molten glass is dropped onto a centrifuge wheel and then exits into a stream of high velocity air much like the melt blown process for making textile nonwovens.

Flame Attenuation. This process closely resembles the continuous drawing process except that the melted strand is not wound onto a cone. Rather, the exiting strand is blown at right angles with a high velocity gas burner so as to remelt and reform the glass as small fibers, which are collected as a mat onto a moving belt. A modification of this process simply uses the high velocity flame at right angles to a dropping melted stream of glass to fibrillate the mass into minute fibers.

Properties. Glass fibers made from various compositions have softening points in the range 650–970°C. Fiber length and diameter distributions are significant factors in determining thermal and acoustical insulation properties. Slag wool and rock wool fibers are prepared from the slag from pig iron blast furnaces.

They contain significant amounts of iron oxides and have a glass-transition temperature of 760–870°C. Slag and rock wool fibers are used to prevent fires from spreading. At temperatures above 850°C, these fibers partially devitrify and form polycrystalline material that melts at 1225–1360°C, which is high enough to contain the fires for several hours. Seventy percent of the slag wool in the United States is used for ceiling tiles.

Refractory Ceramic Fibers (RCF). These MMVF materials constitute only about 1% of the vitreous fiber market but have exceptional high temperature performance characteristics. They are produced by using high percentages of Al_2O_3 about 50/50 with SiO_2 as is or modified with other oxides like ZrO_2 or by using Kaolin clay which has similar high amounts of Al_2O_3. Different compositions result in modifying end use temperatures from about 1050°C or higher for the kaolin-based products to 1425°C and above for the zirconium-containing materials. At temperatures above 1000°C these ceramic fibers tend to devitrify and partially crystallize. Specially prepared ceramic fibers are used to protect space vehicles on re-entry and can withstand temperatures above 1250°C.

Structure/Property Classification

Commercial high performance fibers and high technology textile products have become an increasingly important segment of fiber and textile consumption worldwide. Although breakdown of the numerous applications by weight and/or economic value is impractical, one review indicated that high technology textile uses would account for 50% of all worldwide fiber consumption by the year 2000 compared to 10–15% in 1990 (76). In some instances various technologies and concepts are combined or refined to produce a textile product for the desired application(s). Thus, sophistication and enhancement of properties may be introduced at the fiber, yarn, and/or fabric levels.

The relationship between structure and properties of textile or fibrous substrates and their applications is one method of classifying nontraditional or high technology textiles. At the fiber level, the distinguishing high performance characteristics are high tenacity/strength fibers, hollow fibers, very fine or microtex (microdenier) fibers (hollow or nonhollow), fibers with unique porosities, bicomponent and biconstituent fibers, and fibers with superior resistance to extreme heat, flame, and/or chemical agents (Table 3). At the fabric or product level, the classes may be described as coated and laminated fabrics, composites and fiber-reinforced materials, three-dimensional fabric structures, and fabrics containing polymers or structural features that impart multifunctional properties or allow the fibrous substrate to act as an intelligent material. Although some of these fiber and fabric characteristics also apply to conventional textile uses and products, many of these concepts have evolved from the production and use of high performance fibers and products.

Fiber Properties.

High Strength Fibers. Super fibers or fibers with very high tenacities and Young's moduli have been defined as those with a tenacity of at least 2.5 GPa (255 kgf/mm^2) and a modulus of at least 55 GPa (5600 kgf/mm^2) (77). Fibers meeting these criteria are glass fibers, aramids such as Kevlar and Twaron, gel spun

Table 3. Classification of High Performance Fibers and High Technology Fibers by Properties[a]

Property	Fiber types	Applications
High tenacity and modulus	Aramids, gel spun polyethylene, PBO, PIPD, polyarylate	Tires, antiballistics, ropes, optical cables
Resistant to heat and flame	Aramids, PEEK (Victrex), PBI, polyimides, EDF	Protective clothing for various applications
Resistance to chemical agents	Fluorocarbons, polyolefins	Filters, geotextiles, marine applications
Microtex and hollow fibers	Most synthetics and regenerated fibers	Filtration, leisure, insulation, biomedical fashion, fragrances
Intricate shapes and porosities	Most synthetics and regenerated fibers	Antimicrobial, fiber optics, specialty wipes

[a]Ref. 3.

polyethylene such as Dyneema and Spectra, and various carbon fibers and aromatic liquid-crystalline polyesters such as Vectran. Representative applications are for antiballistic clothing, building materials, aerospace, and as reinforcing material in composites for various applications.

Heat-Resistant Fibers. Inherently flame- and heat-resistant fibers have other criteria for performance in addition to high tenacity and modulus. These fibers must be suitable for protective clothing or for use as a material in a particular application such as firefighters' uniforms, race car drivers apparel for protection from hot metals and gas explosions, and as components in commercial and military aircraft. Dimensional stability and strength retention on exposure to intense heat sources as well as a limiting oxygen index (LOI) above 30 are essential for most of these applications. Fiber types and blends meeting these criteria are various aramids such as Nomex and Kevlar, polybenzimidazole (PBI), poly(phenylene sulfide) (PPS) such as Ryton (Phillips Petroleum), Dow's EDF, and wool blends with these various inherently flame-resistant fibers.

Chemically-Resistant Fibers. Fibers with excellent chemical resistance to corrosive and/or chemical warfare agents or extreme pH conditions (eg, very acidic or very alkaline) were initially used for protective clothing. However, applications for filtration of gases and liquids in numerous industrial facilities are now more important. For example, PPS is suitable for use in filter fabrics for coal-fired boilers because of its outstanding chemical and heat resistance to acidic flue gases and its excellent durability under these end use conditions. Many high tenacity fibers are also chemically inert or relatively unaffected under a variety of conditions. Aramids, gel spun polyethylene, polypropylene, fluorocarbon, and carbon fibers meet these criteria and have been used or are being considered for applications where chemical resistance is important.

Fine and Hollow Fibers. Controlling and designing the geometry, fineness or denier, and porosities of fibers (and occasionally of yarns) have led to novel and high technology textile products for diverse applications. Hollow fibers derived from regenerated cellulose or from synthetic fibers have been used in the development of artificial body organs such as the kidney, pancreas, and lung. Hollow fibers

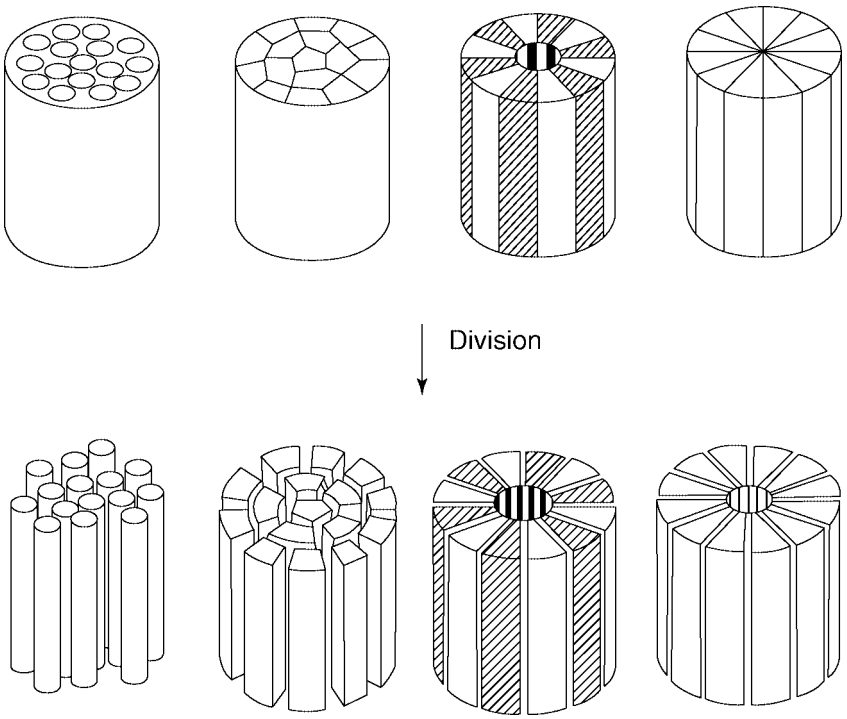

Fig. 1. Ultrafine fibers are produced by spinning bicomponent or biconstituent polymer mixtures, highly stretching such products to ultrafine deniers, and extracting or otherwise removing the undesired matrix carrier to release the desired ultrafine fibers (78). For example, spinning polyester islands in a matrix of polystyrene and then, after stretching, dissolving the polystyrene to leave the polyester fibers; cospinning polyester with polyamides, then stretching, removing the polyester by caustic treatment, leaving 100% nylon ultrafine fibers.

have also frequently been employed to increase the insulation value of garments due to the benefits of the air trapped inside the fiber cavity. A variety of ultrafine fibers, ranging in tex (denier) from as little as 0.0011 (0.01) up to 0.011 (0.1) have been commercialized (primarily in Japan) to impart various surface characteristics that change fabric hand and appearance. Because spinning ultrafine fibers directly is technically difficult, such fibers may be produced by spinning bicomponent or biconstituent polymer mixtures, highly stretching them to form ultrafine deniers, and extracting or otherwise removing the undesired matrix carrier material to release the desired ultrafine fibers (Fig. 1) (78). Another technique used to prepare ultrafine (nanofibers) fibers is electrospinning (79). Controlling the porosity of fibers has been advantageously used to release antimicrobial agents at different rates for specific applications. Novel core/sheath yarns that control selective distribution of both components are being evaluated for numerous applications.

Product Types.

Composites. Various composite materials have evolved over the years as a significant class of high performance textile products. The prototype composite is carbon fiber with an epoxy resin matrix for structural aircraft components

and other aerospace and military applications. Carbon fiber composites are also used in various leisure and sporting items such as golf clubs, tennis rackets, and lightweight bicycle frames. However, other types of applications and composites are also entering the marketplace. For example, short cellulose fiber/rubber composites are used for hoses, belting, and pneumatic tire components.

3D Structures. Three-dimensional textile structures have been developed primarily for architectural, civil engineering, and aerospace applications. Such structures fall into four different categories: nonwoven orthogonals (straight, continuous fibers arranged in three directions with no interlacing); multilayer woven (multiple layers interlaced at selected points); multilayer knitted or stitched (multiple layers of yarns stitched in diverse or desired directions); and three-dimensional braids (intertwining of multiple yarns so that a particular yarn follows a path taking it completely across the structure several times) (80).

Multifunctional Materials. Multifunctional property improvement by binding of specific polymers to fibers and fibrous products has been extensively investigated and reviewed (81). With poly(ethylene glycol) as the bound polymer, functional and aesthetic property improvements include thermal comfort, liquid absorbency/repellancy, increased wear life, soil release, resistance to static charge, antimicrobial activity, and resiliency. Numerous applications such as sportswear/ski wear, protective clothing for health care workers, durable and nondurable hygienic items, work uniforms, and space suits are being commercialized and evaluated.

Smart Materials. The field of intelligent or self-adaptive materials is in its infancy, particularly with regard to textile products. Conceptually, any material that is responsive to one or more external stimuli (heat, force, light, moisture, electrical current) and that responds to such exposure by changing shape or related characteristics is classified as an intelligent material. Synthetic gels that act like artificial muscle and fabrics that self-repair to avoid tensile and other forms of mechanical failure are examples of ongoing research and uses (82).

Classification by Types of Application

Another way to classify high performance fibers and high technology textile materials or products is by types of applications. A scheme of 10 main categories has been adopted (Table 4) and is similar to several classification schemes previously reported (76).

Transportation. High performance fibers and high technology textile products have many applications in the transportation area. Composites are increasingly used as structural materials in aircraft components such as horizontal stabilizers, fins, landing gear doors, fan blades, and nose spin cones. In addition to carbon and glass fibers in composites, aramid and polyimide fibers are also used in conjunction with epoxy resins. Safety requirements by the U.S. Federal Aeronautics Administration (FAA) have led to the development of flame- and heat-resistant seals and structural components in civilian aircraft cabins. Wool blend fabrics containing aramids, poly(phenylene sulfide), EDF (Dow), and other inherently flame-resistant fibers and fabrics containing only these highly heat- and flame-resistant fibers are the types most frequently used in these applications.

Table 4. Classification of High Performance and High Technology Textiles by Types of Applications[a]

Application class	Subcategories	Examples of specific products
Transportation	Civilian and military aircraft, traffic	Components of aircraft, air bags, seats in planes and cars
Manufacturing	Electronics, information, and communication	Optical fibers for telecommunications and computers, printed circuit boards, industrial filters and belts
Agriculture and forestry	Horticulture, erosion control, barriers	Greenhouse covers, control of drainage, land nets cultivation of plants
Civil engineering and construction	Geotextiles and geomembranes architectural	Road reinforcement, pond liners, and dams, fabric roofs, soil stabilization
Fishery and marine	Pollution containment, aquatic life, industrial and leisure marine equipment and vehicles	Breeding of corrosion resistant composites, conveyers floating backwaters, screens for fish breeding, speedboat components
Protective clothing	Chemical/environmental/biological security, heat and flame	Firefighters' uniforms, bulletproof vests, protection from toxins and diseases
Sports and leisure	Sporting goods and vehicles, spas and pools	Golf clubs, tennis rackets, snowmobiles, bicycle frames, spa and pool parts, ski wear and sportswear, luxury apparel
Biomedical and health care	Devices, artificial organs, sutures, wound care, prostheses	Kidneys and artificial limbs, bioimplants, dressings for wounds, hydrogel composites
Defense and aerospace	Chemical/biological protection, camouflage, components for weapons	Chemical/biological warfare protection composites for armour and other weapons, space suits and materials for space travel
Energy use and conversion	insulation, containment of hazardous waste, shields from high energy sources	All types of insulation, waste containers, electromagnetic shielding

[a]Ref. 76.

The introduction of air bags into automobiles represented a new and enormous market for high performance textiles. Polyamide-coated fabrics are primarily used because of the high strength of the polyamide, but there have been marketing and technical studies that indicate the feasibility of using high tenacity polyester as the base fabric. Performance requirements for air bags include tear; tensile, seam, and bursting strength; dimensional stability;

resistance to puncture, abrasion, and buckling; flame resistance; and resistance to delamination (83). It has been estimated that by the end of the century more than 41×10^6 m^2 of coated fabrics would be used in the United States alone to make automobile air bags (84).

Manufacturing. The use of advanced textile materials in manufacturing is a diverse and expanding market. Optical fibers are being increasingly used in telecommunications, computers, cable television, and to facilitate process control in the nuclear, petrochemical and chemical, and food industries. Although most optical fibers are glass or of related inorganic composition, there are optical fibers for special applications comprised of poly(methyl methacrylate), polystyrene, and polycarbonate that are coextruded with fluorinated acrylate polymers. Polyacetal, ie, poly(oxymethylene) fiber has also been used as a reinforcing material for optical fibers. Basic fiber properties required for an optical fiber are (*1*) a structure with a high refractive index core and a low refractive index cladding (sheath bonded to core under high temperature and pressure); (*2*) fiber with a low attenuation or low power loss of light over distance; and (*3*) fiber with low dispersion or pulse broadening as light travels down the fiber (85).

Electronics and electrical insulation are other manufacturing areas in which advanced fibers are extensively used. Manufacturing of computer components such as printed circuit boards and printed wiring boards require use of reinforced fibers that have good dielectric properties, thermal and dimensional stability, chemical resistance, and low moisture regain. For electrical insulation applications, fiber requirements are high dielectric strength, low power loss, and good thermal and chemical resistance. Although inorganic fibers are extensively used for both electronic and electrical applications, aramid fibers are also now used for both types of applications. A variety of natural and synthetic fibers are also used for various electrical applications (86).

A third area that has rapidly expanded in the manufacturing sector is the demand for clean room working garments. The primary electronics and computer industries have the most stringent requirements for cleanliness in their manufacturing environments; clean room garments are also used by personnel in the pharmaceutical, food, precision engineering, and biotechnology/biomedical industries. Requirements for clean room garments and the increasingly stringent standards for both particle size and number of acceptable particles have been critically reviewed and discussed (87). Required properties for garments in clean rooms include fabrics or materials that are dustproof, antistatic, durable to laundering and sterilization procedures, and that are comfortable. Garments have been designed with ability to filter air by mechanical or electrostatic concepts and collect fine particles. Microtex polyester fibers are most frequently used to make these clean room garments. Diameters of particles to be removed have progressed from about 1 μm in the early 1970s to only 0.1 μm in the 1990s. Industry standards for the corresponding degree of cleanliness (particles/m^3) have decreased from 35,000 to 35 (10,000 to 1 per ft^3). Thermal comfort of many of the garments is unacceptable due to their low moisture content, but some efforts are being made to develop microporous coatings to provide both comfort and function required for this application.

The fourth area of manufacturing for advanced fibrous materials is that of filtration of liquids and gases. Filters have diverse requirements for different

industries and environments to which they are exposed. The use of cellulose acetate and aramid hollow fibers to desalinate water by a reverse osmosis process is an example of one of the earlier applications for filtration. Important fiber properties for such filtration are hydrolytic, oxidative, and biological stability over wide pH ranges. Separation of gases by ultrafiltration for a variety of industries is another example of the importance of advanced fibrous substrates. Because of the diversity of exposure to extreme temperature changes and corrosive chemical agents, many of the high temperature, high tenacity, and inert fibers are replacing more conventional types of fibers for such filtration. Poly(phenylene sulfide), polysulfone, aramids, polyimide, PEEK (Victrex), fluorocarbon, and related fibers are examples of high performance fibers effective for gas and liquid filtration under extreme and rapidly changing environmental conditions.

Agriculture and Forestry. Agricultural and silvicultural applications for high performance textile materials range from geotextile and geomembrane materials to horticultural uses to facilitate the growth, yield, and production of edible and ornamental plants. Geotextile structures, either permanent or biodegradable, are inexpensive alternatives to more expensive, conventional concrete or other materials for prevention and control of gully formation. Also, drainage and soil erosion control on farm acreage have been facilitated by geotextiles. Wind fences and other geotextile barriers have also been advantageously used.

If the geotextile is above ground, it should be stable to sunlight, air pollution, rot, and mildew-producing fungi besides having mechanical integrity and dimensional stability. If the textile is below ground, it should be dimensionally stable and inert to most chemical agents and have good long-term permeability so that it does not become easily clogged with soil particles.

Other examples of agricultural applications are flexible and lightweight silos constructed from geotextiles that hold grain, manure, or any other agricultural commodity of interest. Polypropylene fiber is used primarily in most geotextile (agricultural, civil engineering, and other applications) structures because of its excellent inertness to chemical and biological agents and its dimensional stability over long periods of use. Polyester and glass fibers are also used to some extent in geotextiles.

Horticultural applications include use of greenhouse thermal screens, rowcrop and turf covers, conveyer belts to process agricultural products, and other similar items. High performance fibers are not normally used in these applications, but high strength fibers are preferable for conveyer belts. Environmentally inert low cost fibers such as polypropylene are used for many of the outdoor horticultural applications.

Civil Engineering and Construction. These textile applications can be classified as civil engineering applications (also commonly referred to as geotextiles) and architectural applications. High performance fibers are not currently used to any great extent in these applications due to their high unit cost. However, mechanical and environmental requirements for such applications demand that even conventional fibers withstand challenging structural demands and sustained long-term performance outdoors. Polypropylene fibers have captured a sizable portion of the geotextile market because of their excellent dimensional stability and chemical inertness. Polyester and glass fibers are two other types of fibers used in geotextile applications. Reinforcement of highways and roadbeds is by far the

principal use of geotextiles. Their primary function is to serve as a soil stabilizer by spreading the impact load of vehicles over a larger area thus prolonging the useful life of roadways. As in agricultural applications, geotextiles are also used to prevent or minimize soil erosion and facilitate drainage. These materials have been utilized in important projects such as reinforcement of dikes in Holland and to construct dams in the United States. Mechanisms for geotextile failure have been critically evaluated and discussed (88). The types of failure must be evaluated relative to the function of the geotextile. Failure modes include piping of soils through or clogging of the geotextile, reduced tensile resisting force, deformation of the fabric, reduced resistance to puncture, and reduced in-plane flow of liquids.

Most architectural fabrics are usually flexible composites comprised of glass fibers coated with fluorocarbons to resist wind, mechanical forces, and outdoor environmental degradation. The airport terminal in Saudi Arabia, and the roofs for the Hubert Humphrey Dome in Minneapolis and the Tokyo Dome Stadium are a few examples of the successful use of architectural fabrics.

Fishery and Marine. Marine applications for textiles include (*1*) those concerned with fishing and fishing industries, (*2*) leisure items and components, and (*3*) industrial, including control of various types of environmental pollution and influences (89,90). The earliest use of textiles in fishery and marine applications were for high strength nets, lines, and ropes. Conventional natural and synthetic fibers are being replaced by high performance fibers such as aramids, gel spun polyethylene, and polyacetal. However, cost is still a factor because the latter fibers are still much more expensive than the conventional fibers. More advanced applications for fishing and marine industries include the construction of artificial seaweed beds comprised of synthetic fiber membranes that facilitate fish breeding.

Advanced composites and fiber-reinforced materials are used in sailcloth, speedboat, and other types of boat components, and leisure and commercial fishing gear. Aramid and polyethylene fibers are currently used in conveyer belts to collect valuable offshore minerals such as cobalt, uranium, and manganese. Construction of oil-adsorbing fences made of high performance fabrics is being evaluated in Japan as well as the construction of other pollution control textile materials for maritime use. For most marine uses, the textile materials must be resistant to biodeterioration and to a variety of aqueous pollutants and environmental conditions.

Protective Clothing. Protection against adverse chemical and biological environments, from heat and/or flame, and antiballistic protection are the principal applications of protective clothing. Several high performance fibers are finding increasing use in many protective clothing applications due to their high strength, resistance to cutting and firearms, and their ability to withstand temperature extremes and corrosive chemical agents. Aramids such as Kevlar and polyethylene fibers such as Spectra are used in many bulletproof vests and other types of security garments. PBI is used in firemen turn coats and race car driver suits.

Aramids are also used in firefighters' uniforms for their excellent flame resistance. The new Dow Curlon EDF fibers have exceptional flame resistance both by themselves and in combination with other flammable fibers. At only 20% by weight, Curlon has been shown to totally prevent the flaming of polyester and other similar flammable materials. This property along with Curlon's good textile processibility will undoubtedly lead to many new applications in the protective

garment area (70–72). Garments derived from blends of polybenzimidazole (PBI) and aramid fibers have excellent chemical resistance and a low propensity to severe burns as shown by tests in a gas pit where temperatures could rise as high as 1100°C (91).

There are distinct performance differences for garments that are resistant to flame alone compared to those that are resistant to both heat buildup and flammability. Appropriate tests have been devised that measure the thermal protective performance of fabrics when exposed to a radiant heat source. Sophisticated constructions against biohazards need further development to produce materials that are both thermally comfortable and impermeable to blood-borne pathogens and other deleterious microorganisms. The most promising approaches are materials that are laminated or coated fabrics that are permeable to vapor but impermeable to liquids. Statistics included in recent OSHA standards for protection against blood-borne pathogens (eg, hepatitis and AIDS viruses) estimate that currently close to six million persons in the United States (health care workers and many other occupations) require protective clothing and other types of safeguards against these biohazards (92).

Sports and Leisure. The application of high technology fiber properties and complex structures for sports and leisure are identifiable in three areas: components for sporting goods, boats, and other rigid structures; high technology sportswear and ski wear; and luxury apparel. Although most components for sporting goods (such as tennis rackets, golf clubs, lightweight bicycle frames, spa components, speedboat components) are usually carbon–fiber reinforced composites, the high performance aramids and polyethylene are now being used to manufacture items such as bicycle helmets and other sports items. For these end uses, impact and overall tensile strength, dimensional stability, and resistance to specific environmental agents are required. High technology sportswear and ski wear evolved with the advent of Gore Tex.

Gore-Tex. Gore-Tex (WL Gore) was the first fabric comprised of a microporous polytetrafluoroethylene film laminated to a polyamide fabric. The microporosity of the film allowed the garment to be breathable or allow passage of water vapor yet be waterproof or resistant to liquid penetration. Since that time, a variety of microporous materials or related structures have been developed in the United States and Japan. Another example for high technology sportswear is the latent heat and high water absorbency of a cross-linked poly(ethylene glycol) coating on fabrics that makes it possible for the garment to be thermally adaptable in hot and cold environments (81). Also, microencapsulation of zirconium carbide into polyamide or polyester fibers produces a ski wear garment (called Solar-α) that absorbs sunlight and converts it into heat.

Numerous high touch fibers have been produced and commercialized (primarily in Japan) for luxury apparel. Conceptually, the geometry and fineness of the fibers are carefully modified and controlled to produce fabrics with desirable sensual responses of touch, sight, sound, comfort, and even odor (78,93). There are several techniques for producing ultrafine fibers and this has led to the production and commercialization of materials such as Ultrasuede, artificial leather and silk, fabrics with a peach-fuzz sensation, perfumed hosiery, fabrics that change color due to microencapsulation of cholesteric liquid crystals, and numerous other luxury and novelty textile products.

Biomedical and Health Care. This area is an extremely diverse and expanding market for high performance fiber concepts and their reduction to the desired end use performance. Although the complexity of the human body and its physiological functions are difficult to mimic with artificial materials, significant progress has been made in the introduction of biomaterials and related health care products. The numerous uses of fibers in medicine have been critically and concisely reviewed, including nonimplantable items (such as surgical dressings, gowns, drapes, pressure bandages), extra corporeal devices (components of dialyzers and oxygenators, catheters) and implants (sutures, vascular grafts, artificial organs, fibers and fabrics for surgical reinforcement, optical fibers for medical procedures, and orthopedic devices) (94). In addition to having the desired mechanical and functional integrity for the particular biomedical application, the fibrous product must be nonallergenic, usually nonthrombogenic, noncarcinogenic, sterilizable, and biocompatible. Nonimplant items are usually derived from conventional fibers and fabrics, except for clean room garments. Examples of extra corporeal devices or components are regenerated hollow cellulose fibers for the artificial kidneys or dialyzers and hollow fibers or flatsheet fibrous membranes derived from polypropylene, polytetrafluoroethylene, and various coated fabrics in blood oxygenation devices.

Implants generally can be classified as those that are designed to be bioabsorbable (eg, sutures) and those that are designed for more permanent function (nonabsorbable sutures, vascular grafts, and artificial organs). Bioabsorbable materials have been critically reviewed with emphasis on sutures and related fibrous products (95). Bioabsorbable sutures were originally derived from catgut or collagen, but now a variety of poly(glycolic acid) homo- and copolymers as well as poly(dioxanones) are used. Hydrogel fibrous composites have become important as wound dressings and as implants. Many of these hydrogel composites are poly(ethylene oxide) homopolymers and/or copolymers of poly(acrylic acid), polyacrylamide, or other related structures (96). Nonabsorbable sutures and reinforced structures for vascular grafts and artificial organs are derived from high tenacity polyamide, polypropylene, polyester, polytetrafluoroethylene, and various coated fibers and fabrics. Optical fibers for endoscopy and angioplasty procedures are usually composed of glass or poly(methyl methacrylate). In addition to these classifications, the production of biomimetic fibers, ie, fibrous materials that are specifically designed to mimic physiological and other anatomical functions of living organisms, has been described (97). Applications include artificial cells, nerves and muscles, biosensors, and artificial bones and teeth.

Defense and Aerospace. Military applications for high performance fibers and high technology textiles generally parallel those discussed earlier for civilian aircraft and protective clothing. Protective clothing is usually designed to be impermeable to chemical and biological warfare agents such as nerve and mustard gas. Design of protective clothing for these purposes is usually classified information, but it is reasonable to assume that the clothing assembly consists of microporous membranes and elaborate filtration devices. Another military application is the design of combat uniforms that are dyed in such a manner that they provide effective camouflage and are not detectable by night surveillance devices. Not surprisingly such materials have been adapted to civilian use by hunters to give better camouflage against deer and turkeys, which see UV reflections. Printing of aramid fabrics for this purpose has been described (98).

Requirements for space suits are more complex and frequently involve garments that can circulate water and/or air through the fibrous assembly. Laminated and/or coated garments with specific requirements to pressure, radiation, temperature, and humidity are more structurally complex as a textile product relative to the types of fibers used in this aerospace fabrication.

Fiber composites and three-dimensional textile structures are frequently used in advanced military weapons and aircraft such as extended use armor tracks, materials for engine parts (nose spin cones and fan blades), and primary and secondary structural components of aircraft (main wings, horizontal tail and stabilizer, speed brakes, high performance gaskets, fins, and ailerons). Although many of these materials are carbon fiber–epoxy resin composites or glass fiber–epoxy resin composites, there is an increase in the use of aramid, polyimide, and polytheretherketone (PEEK) fibers because of their excellent strength and thermal/oxidative and chemical stabilities.

Energy Use and Conservation. A variety of materials are needed for high performance thermal insulation, particularly as components of nuclear reactors. Replacements for asbestos fibers are needed for components such as reactor core flooring, plumbing, and packaging. The fibers must be very resistant to high temperatures with outstanding dimensional stability and resistance to compression.

Filters for nuclear fuel reprocessing and replacement of fibrous composites to reduce or prevent radiation leaks are two other areas of application. Advanced fiber composites, aramids, and high tenacity polyethylene for specific applications are types of high performance fibers and structures being considered (3). Metal-coated fibers and fabrics have been effective in electromagnetic shielding applications. High performance fabrics have also been used for containment of hazardous waste in addition to being used for conservation of energy and improving the safety of nuclear power plants (99). The same considerations that apply to geotextiles for other applications also apply to geotextiles used for waste containment. However, there are additional performance requirements such as excellent resistance to municipal waste leachate. Thus, polypropylene and to a lesser extent polyethylene fibers are used in the construction of geotextiles for this type of application.

INTELLIGENT POLYMER SYSTEMS

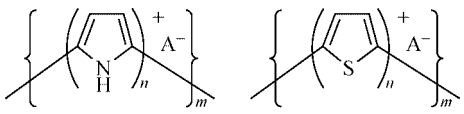
Introduction

Intelligent polymer systems possess the ability to sense, process information, and actuate responses. Energy is usually required to implement these functions and so energy conversion/storage capabilities are desirable if the system is to be truly autonomous. Ideally, these functions would be integrated at the molecular level.

It has been clearly demonstrated over the past 20 years that inherently conducting polymers (ICPs) are capable of providing all of the above functions and as such they have a critical role to play in the development of intelligent polymer systems (see ELECTRICALLY ACTIVE POLYMERS).

This article briefly reviews the properties of ICPs and their ability to function as sensors, processors, actuators, and energy conversion/storage systems.

To illustrate the ability of ICPs to provide the range of functions required for intelligent polymer systems, we will draw on examples that utilize polypyrroles (**1**) or polythiophenes (**2**).



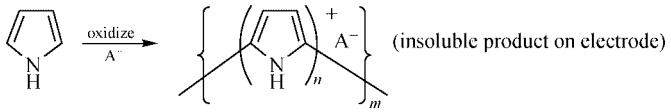
1 **2**

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

For polypyrroles and polythiophenes, n is usually ~3–4 for optimal conductivity; ie, there is a positive charge on every third or fourth pyrrole or thiophene along the polymer chain, near which the dopant anion A^- is electrostatically attached.

Polyanilines are also of interest but they are less amenable to use in a wide range of environments because of the need to retain protonation to ensure conductivity. Consequently, most of the examples here will focus on polypyrrole and polythiophene.

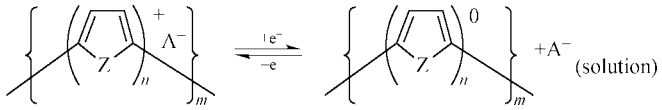
Each of these materials may be produced via either chemical or electrochemical oxidation of the appropriate monomer (1). For polypyrrole the electrodeposition process is described simplistically in equation 1.



(1)

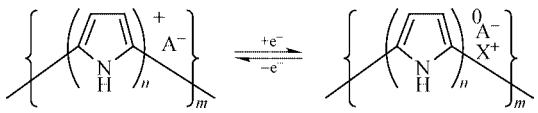
A dopant counterion (A^-) is incorporated during electrosynthesis to balance the charge on the polymer backbone. A wide range of dopants can be incorporated using this approach. Common chemical oxidants such as $FeCl_3$ and $(NH_4)_2S_2O_8$ may also be used and these provide the anion from the oxidant, as the dopant anion A^-. In general, chemical oxidation provides ICPs as powders, while electrochemical synthesis leads to films.

An important feature of ICPs is that they are amenable to oxidation/reduction processes that can be initiated at moderate potentials. For polypyrroles and polythiophenes, two oxidation states can be reversibly switched, as shown in equation 2 (Z = NH or S). The oxidized forms exhibit good electrical conductivity (σ = 1–100 $S \cdot cm^{-1}$), while the reduced forms have very low conductivity ($\sigma \sim 10^{-8}$ $S \cdot cm^{-1}$).



(2)

If the dopant anion A^- is small and mobile (eg, Cl^-) and the polymer has a high surface-area-to-volume ratio, then upon reduction the anion will be efficiently ejected from the polymer. However, if the dopant is large and immobile (eg, if A^- is a polyelectrolyte such as polystyrene sulfonate) then an electrically induced cation-exchange process occurs, according to equation 3:



(3)

where the cation (X^+) is incorporated from the supporting electrolyte solution (2). The exact nature of the reduction process has a dramatic effect on the physical and

chemical properties of the polymer. These changes are important in determining the sensing, information processing, and actuation capabilities of the systems as discussed below.

Sensing

Nature has developed recognition systems that are able to discriminate on the basis of highly specific molecule–molecule interactions generating a unique signal. Alternatively, nature utilizes arrays of less specific sensors to collect information that is deciphered using pattern recognition processes carried out in the brain. Both approaches have also been pursued using ICPs in the development of synthetic sensors, as both chemical and physical sensors.

As chemical sensors, specificity can be induced by using molecular recognition components from nature. For example, the ICP may be used as an immobilization platform for enzymes (3–5), antibodies (6–10), oligonucelotides (11–13), or even whole living cells (14,15). The bioactive component may be incorporated during the polymerization process and the ICP provides signal transduction and transmission capabilities (Figure 1**a**). The majority of enzyme-containing ICP sensors generate a signal because of the enzymatic generation of an electroactive product (eg, H_2O_2) or the consumption of an electroactive product (eg, O_2). Alternatively, the bioevent may trigger a change in pH of the analyte solution that alters the resistance of the polymer (16). The mechanism of signal generation with antibody-containing conducting polymer sensors appears to be associated

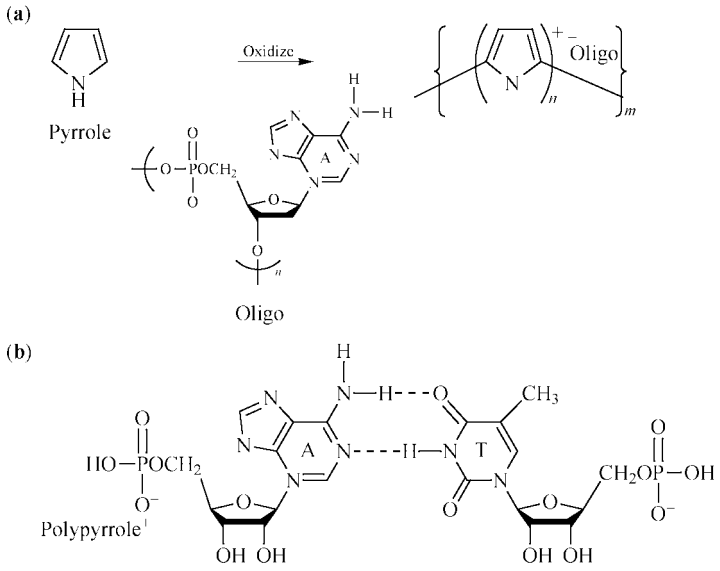


Fig. 1. (**a**) Polymeriztaion of polypyrrole onto an electrode using an oligonucleotide (A) as the dopant. The oligonucleotide is physically entrapped within the polymer during synthesis. (**b**) As a target oligonucleotide (T) passes across the surface of the oligonucleotide (A) doped polypyrrole electrode, a hybridization reaction occurs (indicated by the dashed lines). This results in a change in the current/potential response observed at the electrode.

with the modification of cation movement into and out of the polymer upon oxidation/reduction in the presence of the antigen (17,18). In the case of complementary oligonucleotide binding, only limited examples use direct electrochemical signal transduction (19,20), and here the mechanism of signal generation is not clear (Figure 1**b**).

The selective detection of metal ions has also been achieved by the covalent attachment of molecular recognition moieties to the ICP backbone. The usual approach has been to synthesize a monomer or dimer containing the appropriate recognition group and this is subsequently polymerized (21). Swager (22) have prepared polythiophenes containing crown ethers and calixarenes covalently bound to the bithiophene repeat units, which exhibit controllable selectivity toward Li^+, Na^+, and K^+ ions.

An alternative route to appropriately functionalized ICPs is the use of sulfonated species containing the desired molecular recognition/receptor site as the dopant anion for the conducting polymer chains. For example, calixarene-containing polypyrroles (23) and polyanilines (24) have recently been prepared via the use of sulfonated calixarenes as dopant anions. Similarly, the incorporation of metal complexing agents such as sulfonated 8-hydroxyquinoline as dopants in polypyrroles provides a simple route to metal ion-selective ICPs (25).

ICPs have also been assembled as microsensing arrays with a view to collecting less specific data subsequently deciphered using pattern recognition software. The so-called electronic noses are based on this principle (26–30). A range of conducting polymers with differing molecular selectivity respond (by changes in electronic resistance of the polymer) to a complex mixture to produce a unique pattern of responses. This approach has been used to differentiate beers (26), to detect microorganisms (28,29), for wastewater management (31,32), and for wine characterization (33). Stuetz and co-workers (31) demonstrated the ability of a nonspecific sensor array (consisting of 12 conducting polymers) to detect changes in the organic content of a wastewater sample. These researchers were able to draw a comparison between the odor profiles of sewage liquids and corresponding BOD, GOD, and TOC measurements using this sensor array. Using a nonspecific conducting polymer sensor array, Bourgeois and co-workers (32) developed an on-line continuous measurement system that monitored changes in water and wastewater quality. By analyzing the headspace gas from sparged samples, which flowed over the sensor array, they were able to successfully monitor samples both in a laboratory and in field setting. Guadarrama and co-workers (33) used the response of a conducting polymer sensor array to characterize varieties of Spanish wine. Using static and dynamic headspace sampling combined with statistical analysis utilizing pattern recognition techniques, they were able to characterize these wines by considering the sensitivity of the polymer films to moisture and ethanol content.

The array approach has also been developed for amperometric sensing when used in solution. Change in amperometric responses in the presence of different ions is used as the signal transduction method. This has been used by us to discriminate between simple ions (34,35) and even proteins (36). The approach used is similar to the “electronic nose” in that none of the sensing elements is specific; however, each polymer has a different selectivity series, giving rise to a unique pattern of responses for any given protein.

Actuating

ICPs are capable of undergoing transformations at the molecular level through to the macro-molecular level. The former can be used to build responsive molecule release systems, while the latter forms the basis of artificial muscles. A change in oxidation state of the polymer (see equations 2 and 3) is accompanied by dramatic changes in chemical and physical properties. Chemical changes have been studied at the molecular level using a technique known as *inverse chromatography* both in solution (37,38) and in gas phase (39,40). These studies revealed that, at least when the dopant A^- is small and mobile, reduction decreases the anion-exchange capacity of the polymer and increases the hydrophobicity of the polymer backbone. The dopants can be chosen so that the release process has the desired effect on the chemical composition of the immediate environment. For example, Miller described the triggered release of glutamate (41) and salicylate (42) among other compounds.

The movement of ions has also been tracked using electrochemical quartz crystal microbalance techniques (43–45). As ions move in and out of the polymer matrix, upon oxidation and reduction, a resonant frequency shift is observed for the polymer coated quartz crystal. The magnitude of the frequency shift is indicative of the amount of ions moving either in or out of the polymer. The direction of ion flow has been shown to be dependent upon the nature of the dopant bound within the polymer. Small spherical-like anions are known to move easily in and out of the polymer matrix. When the polymer is oxidized the backbone becomes cationic (p-type) and anions move into the polymer, effectively doping the polymer. Upon reduction of the polymer backbone, the cationic characteristics of the polymer are lost and the anions are expelled under the negative electric field of the reduction potential. Ion flux can be reversed by the incorporation of large anion species into the polymer during the growth phase, such as dodecylbenzene sulfonate (46,47) or polyelectrolytes such as polystyrene sulfonate (48). Upon reduction of the polymer the bulky anion cannot be expelled while the polymer backbone looses its net cationic charge, resulting in the bulk material having an anionic character. The result of this process is that cation species are incorporated into the polymer to achieve electrostatic balance.

The incorporation of either anions or cations during redox cycling results in polymer swelling. This principle has been exploited in applications such as polymer actuators. These incorporation/exclusion events at the molecular level also result in changes in the overall volume (dimensions) of the polymer (49). It was these volume changes that led Baughman and colleagues to the concept of electromechanical actuators (artificial muscles) based on conducting polymers.

Massoumi and Entezami (50,51) utilized conducting polymer bilayers to demonstrate that active cations and electrolyte cations (ie, sulfosalicylic acid and 2-ethylhexyl phosphate) can be transported in to and out (controlled release) of the bilayer outer film.

Pyo and Reynolds (52,53) reported the selective releasing of ions, such as adenosine 5′-triphosphate and heparin respectively, from conducting polymer bilayer structures. Piro and co-workers (54) successfully incorporated oligonucleotides into conducting polymer films using a two-step polymerization process. The release of these trapped oligonucleotides was also investigated, where the

release exhibited a three-step profile: a "burst" period during the first 5 min, followed by an intermediate and a very slow release stage lasting up to several days. The uptake and release of dopamine were investigated with a quinone-containing conducting polymer film (55). This study found that dopamine, once incorporated into the polymer, could be released by applying an oxidative potential. Pernaut and Reynolds (56) studied the controlled release of a polypyyrole membrane "loaded" up with adenosine triphosphate (ATP). Electrochemical triggering allowed ATP to be delivered with a variety of release profiles and adjustable rates.

Controlled-release devices that utilize the unique properties of conducting polymer membranes can also be configured. It has been shown that the transport properties of ICPs are dependent on the oxidation state of the membrane. This has been demonstrated both in solution (57) and for transport of volatiles (58). Extraordinary selectivity factors have been reported for the separation of some volatiles; for example, selectivity factors of 3590 for H_2/N_2, 30 for O_2/N_2, and 336 for CO_2/CH_4 were reported (59). With membranes operational in solution, the controlled transport of simple ions (60), metal ions (61,62), small organic molecules (63), and even proteins (64,65) has been demonstrated.

The transitions that occur within the conducting polymers also result in dramatic changes in physical properties. For example, upon reduction the materials become more transparent (66), making them useful in electrochromic devices (67,68).

By producing simple laminated membrane structures (Figure 2) containing the ICP, force generation occurs upon oxidation/reduction of the active polymers, and movement follows. A number of detailed studies on the effect of polymer composition, supporting electrolyte and rate of stimulation on the forces generated, have been carried out (69–72).

In recent studies it has been shown that the electrolyte used for ICP-based devices including artificial muscles is critical (73). Subsequent to this, it was discovered that a new class of electrolytes, ionic liquids, have characteristics that are particularly useful for ICPs (74,75).

Ionic liquids (ILs) have received a great deal of attention in recent years (see Ionic Liquids, Polymerization in). ILs have unique solvent properties and low volatility that provide advantages over conventional electrolyte systems with a wide range of application in green chemistry. Attention has been mainly directed toward modifying ILs to manipulate the solvent and electrical properties. Properties that are unique to ionic liquids include tunable hydrophobicity (76) and

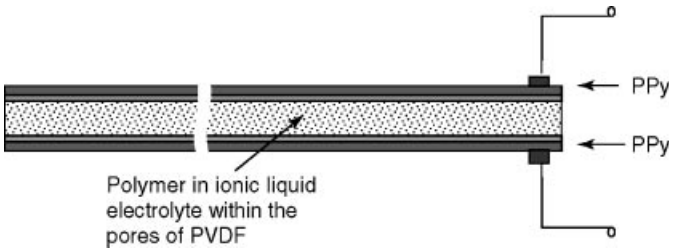

Fig. 2. Cross section of a polypyrrole double-sided PVDF [poly(vinylidene fluoride)] electromechanical actuator, with the pores of PVDF filled with electrolyte.

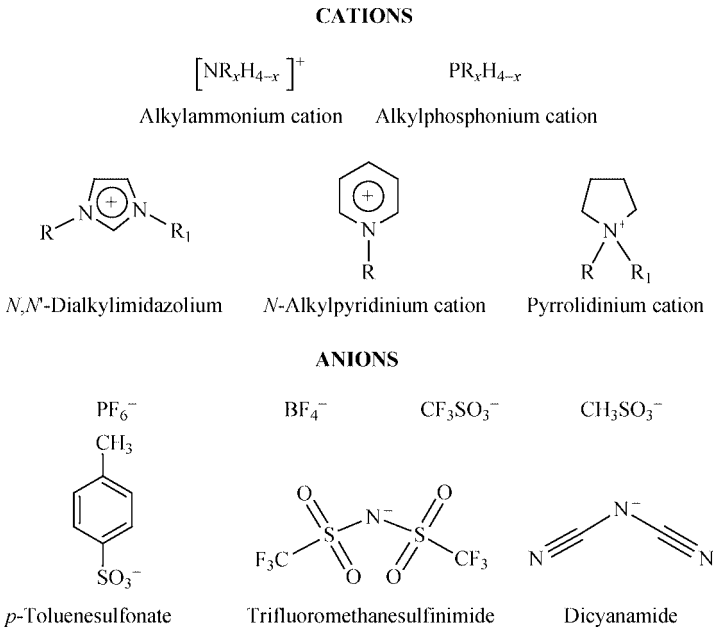

Fig. 3. Typical ionic liquid ions.

choice of anion (77). ILs generally have excellent thermal stability (78) and low volatility (79) and, in some instances, offer unique solubility properties as a result of following different dissolution rules with respect to common organic solvents (80). The minimal vapor pressure they exhibit also leads to good environmentally stability. ILs also offer wide electrochemical potential windows, which can be manipulated by choice of the anion and cation system (81,82). There are potentially thousands of IL systems yet to be discovered based on the combination of organic cation structures with the myriad of anions that are potentially available. Figure 3 shows a number of cation systems that have been reported with anions such as PF_6^-, BF_4^-, NO_3^-, Cl^-, $CF_3SO_3^-$, and trifluoromethanesulfonimide, to list but a few.

Given the intimate interaction of ICPs with the electrolyte, especially during oxidation/reduction of the polymer the chemical nature of the ionic liquid is also important. The versatility of ionic liquids in this regard has proven extremely useful. For example, the use of imidazolium cations during oxidation/reduction of PPy PF_6 used as electromechanical actuators has been shown to not only give markedly improved stability (increasing cycles length from hundreds to hundreds of thousands of cycles) but also increased performance. The latter feature arises from the inclusion of the imidazolium cation during reduction, a process that apparently preserves the inherent modulus of the materials (83).

Another interesting form of these electrolytes involves their use as solid electrolytes. By performing polymerization in the ionic liquid a solid can be produced (84). A highly stable, easily handled actuator can be constructed using this electrolyte.

All of the above responses (actuators) are initiated by creating an appropriate electrical potential that causes the polymer to change form. This is usually achieved by imposition of a potential from an external source.

Electrochromic Devices

Electrochromic devices (ECDs) have been extensively researched as potential large area electrochromic windows. The technology is in direct competition with liquid crystal display devices. ECDs have a distinct advantage over the LCD in that the device color remains even after the driving potential has been removed (68) (see Electrochromic Polymers). The use of ICPs in electrochromic devices has been discussed and reviewed in a number of recent articles (85–88). The observed color changes of these devices are ideally reversible and can undergo thousands of cycles without degradation. Device scale-up is strongly dependent upon the electrochemical behavior of the polymer in the electrolyte, which has a strong influence upon the redox reversibility of the polymer. Solvent-based electrolytes, although shown to be effective in the laboratory, suffer from component evaporation, often leading to device failure. Sealing the unit to prevent solvent leakage has also proven to be a challenge. This issue has been addressed by the adoption of solid polymer electrolyte systems. More recently, the application of nonvolatile ionic liquids (74–91) to electrochromic devices has produced devices capable of millions of cycles, with little loss of performance over the device lifetime (92).

Electrochromic effects in conducting polymers are achieved by varying the band gap (HOMO − LUMO) of the π–π^* transition and is associated with π-bond conjugation. Band gap, and therefore color, is influenced by the type of monomer repeat unit, the polymer conjugation length, and, ultimately, the level of polymer oxidation. Copolymerization of different monomers has also been used as a method of modifying these band gaps. Polypyrroles have a color shift from blue-violet (670 nm) to yellow-green (420 nm) when oxidized and reduced respectively. Polyanilines have three redox states that are yellow when fully reduced to the leucoemeraldine state (300–400 nm), green in the mid-oxidation emeraldine salt state (400 and $>$750 nm), and blue when fully oxidized as the pernigraniline salt (600 nm). Polythiophene is blue when oxidized (730 nm) and red when reduced (470 nm) (93).

The challenge that remains for conducting polymer electrochromic applications is clearly in the domain of device scale-up. The application of these materials to large area devices, such as windows, requires uniform real-time switching of the polymer oxidation state to access different color regions. Although this has been demonstrated for small-scale devices, it is difficult at larger scales.

Information Processing

The use of inorganic, silicon-based materials in the development of complex circuitry that is capable of processing vast amounts of information is a well-developed

industrial technology. The concept of plastic electronics has only attracted considerable interest in recent years.

Polymers are increasingly being utilized as new materials for electronics and optics. Necessary elements for this imperative are of course the functional properties but with the added advantage of polymer processability and flexibility in structural design (94). In fact, replacement of traditional inorganic semiconductors by organic molecules, polymeric or even biological materials have recently been termed as *molecular electronics* (ME) (95). Rambidi (96) identified one of the main directions in the development of devices for molecular information processing to be based on the concept of distributed molecular (chemical) information processing media. It has been proposed that the electrical conduction in ICPs occurs via nonlinear (or topographic) defects (solitons/polarons) generated either during synthesis or as a result of doping. Solitons and polarons have recently been shown to have implications in the technical development of molecular electronic devices (97).

To realize molecular electronics, one of the key issues is how to fabricate the ordered structures in a planned manner since various properties of organic molecules are of anisotropic nature, and consequently the functions of molecular assemblies depend strongly on the way molecules are arranged in them (97). Much research has been done on the molecular engineering of these assembly processes, namely Langmuir–Blodgett film (98,99) and self-assembly techniques (100,101). Pal and co-workers (102) used the Langmuir–Blodgett technique to develop polymeric light-emitting diodes (LEDs) (see LANGMUIR-BLODGETT FILMS). Both dc and ac LEDs were fabricated with a precise thickness ranging from a few molecular layers to tens of layers. In dc LEDs, they showed that as few as three layers of active polymer can yield the same luminance as the thicker ones. Zhang and co-workers (103) fabricated binary DNA/surfactant-modified arrays on a heterogeneous patterned surface through a controlled condensation and dewetting process using the SAM (self-assembled monolayers) technique. Studies on the formation of DNA SAMs at surfaces were driven by an inherent interest in understanding different aspects of this molecule and its importance in biomimetic materials science and molecular electronics.

ICPs have been studied for their application to such molecular electronic devices as diodes (104,105), field effect transistors (FETs) (106,107), and light emitting diodes (LEDs) (108,109) (Figure 4). Rectifying junctions are the basic element of many electronic components. Since their discovery, ICP rectifying junctions such as p–n junction and Schottky junction have been studied (97). Chen and Fang (111) found that the acid doping of free-standing polyaniline film can cause a higher rectifying behavior and photovoltaic conversion. It has been shown that increased diode performance is observed when the device is fabricated from regioregular polymers having a short alkyl substituent and/or by the presence of electron-withdrawing groups (97).

The performance of ICP-based FETs are quite encouraging and recent use of these devices in logic circuits or active matrix emissive displays has geared up the research in this direction immensely (112,113). In conventional semiconductor devices, "field effect" has been used to improve performance (114). Control of current passing through a "gate electrode" using the field-effect phenomenon opens the possibility of a transistor action without requiring the existence of p–n junctions,

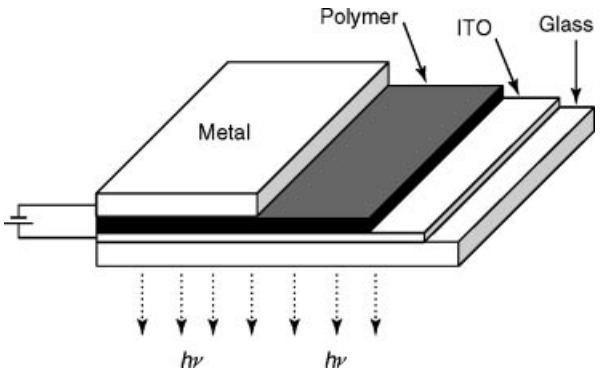

Fig. 4. Schematic of a polymer LED device configuration (110).

which in turn improves the device characteristics (97). Koezuka and co-workers (106) were the first to use this phenomenon to fabricate ICP-based FETs.

ICPs have been demonstrated to exhibit light emission in the entire visible spectrum, quantum efficiency over 4%, fast response time, brightness of 10^6 cd $\cdot$ m^{-2}, and device lifetime more than 2 months (97). Heeger (115) reported that the operating life of polymer LEDs, with an initial brightness of 400–500 cd $\cdot$ m^{-2} at room temperature, approached several thousand hours. This equates to operating lifetimes in excess of 10^4 h at display brightness. The current interest in exploring the luminescent properties of ICPs is for flat-panel displays used in information processing devices, such as laptop computers, cellular telephones, small handheld devices, large panel displays, and notebook computers (97). The main advantages of these ICP materials over conventional luminescent materials are the tuning of wavelength emitted by chemical modification, low operating voltages, flexibility, easy processing, low cost, possibility of making large area device, and output color in whole visible spectrum (97).

Energy Conversion/Storage

The intelligent polymer system must also be capable of converting energy from a natural source, such as sunlight, and storing it until required. ICPs that are capable of carrying out these functions have potential as a replacement for Si photovoltaic cell technology as well as energy storage in rechargeable battery systems.

Polymer Photovoltaics. The potential of making lightweight, low cost, and flexible solar cells has driven growing interest in device development. It has been demonstrated that ICPs are capable of functioning as the active layer in photovoltaic devices (116–120). Upon irradiation of the ICP electron–hole pairs (excitons) are generated. If these excitons are transported to an interface where they can be split before recombination occurs, then electrical energy is generated. Both Schottky devices (121) and photoelectrochemical cell (122–124) configurations have been used. Photovoltaic responses were obtained early on from a variety of ICPs in single-polymer Schottky devices with quantum efficiencies up to

Table 1. Summary of Photovoltaic Performance of Some Conducting Polymers

Polymer system	Device	Voc,[a] V	Isc,[b] mA/cm^2	FF,[c]	Y,[d] %
Polyacetylene (PA)	n-Si/p-PA	0.53	18.18	0.32	4.3

1% (125–127); the best results have been obtained using interpenetrating blends of functionalized polyphenylenevinylenes (128,129) and/or polythiophenes (130) with quantum efficiencies up to 29% and energy conversion efficiencies up to 2%. The addition of dyes (131–133) and electron acceptors (134–136) to such devices has also increased the overall power conversion efficiency to around 3%. Performance parameters for some typical conducting polymers are listed in Table 1. Although the performance of these materials is significantly low than what has been achieved for traditional silicon-based technologies, the production of these devices are still highly attractive as device manufacture can be undertaken without the need for a clean room, the relatively low cost with respect to silicon, technology, and the potential for large-scale flexible cells.

Energy Storage. A number of strategies have been adopted for the utilization of conducting polymers as rechargeable battery devices. Many studies have looked at the potential of replacing either the anode or cathode electrode with a conducting polymer, more typically the cathode, as tradition metal anodes have significantly higher energy densities, gravimetrically, than do polymers (137). A more interesting possibility is the development of all polymer batteries where an electroactive polymer comprises both the ahde and cathode supported on inert conducting supports such as graphite and platinum. Killian and co-workers were the first group to report the assembly of an all-polymer battery structure (138) utilizing both p- and n-dopable polypyrrole with a specific charge capacity of 22 mAh $\cdot$ g^{-1} at a cell potential of 0.4 V. The cells showed no loss in capacity when cycled 100 times. The observed cell potential was clearly limited by the n-doping ability of the cathode.

More recently, an all-polymer battery based on derivatized polythiophenes supported on graphite-coated supports was described (139). In this instance, polythiophene functioned more effectively in the n-doping region and provided an improved cell discharge voltage of 2.4 V and capacities of 9.5–1.5 mAh $\cdot$ g^{-1}. A recent approach is the development of a polymer/polymer battery based on polyaniline anode and poly-1-naphthol cathode (140). This device has been reported with an impressive cell voltage of 1.4 V, a specific capacity of 150 Ah g^{-1}, and a loss of 15% of cell capacity after 100 cycles. Other attempts at fabricating battery systems have been made (141) with polyacetylene, polypyrrole, and polyaniline (142),

where the batteries were shown to compare favorably on a gravimetric basis. On a volumetric basis, more traditional inorganic insertion compound electrodes were found to outperform these systems. The application of conducting polymers as either a cathode or anode combined with more traditional inorganic or metallic electrodes has been extensively reviewed by others (137,139).

Polymer Processing

All of the foregoing applications of ICPs have significant commercial potential. However, in most cases, exploitation has been limited because of the lack of convenient polymer processing and device fabrication protocols. For example, polypyrroles exhibit the desirable properties mentioned above; however, polymerization usually results in the formation of an insoluble, infusible material not amenable to subsequent fabrication. Conducting polythiophene salts are similarly intractable. Several approaches have recently been employed to overcome this problem of intractability.

Solubility has been induced for polypyrroles by attaching alkyl (143,144) or alkyl sulfonate (145,146) groups to produce 3-substituted pyrrole monomer prior to polymerization. This results in markedly enhanced solubility in organic or aqueous medias respectively. Polythiophenes can also be rendered either organic-solvent-soluble (147) or water-soluble (148) using these derivitization approaches. These improvements in solubility achieved above via ring substitution generally result in significant loss in electrical conductivity of the final polymer. Consequently, formation of colloidal dispersions is an attractive alternative route to solution processing in water, as this allows for post-synthesis handling while retaining reasonable conductivity.

Conducting polymer colloids can be produced by chemical (149) or electrochemical (150,151) oxidation of monomer in the presence of a steric stabilizer. Colloids produced electrochemically are formed by intercepting the polymer deposition on the electrode surface utilizing hydrodynamic control. This is facilitated by the presence of a steric stabilizer in solution. The electrochemical approach is advantageous in that the polymer properties can be altered by accurate control of the oxidation potential during polymerization. This technique also allows a wide range of dopants to be incorporated into the polymer to give different properties. For example, proteins can be incorporated into conducting polymers while retaining their biological integrity (151).

Emulsion polymerization is the most appropriate method for producing submicrometer (nano) particles owing to its versatility and relative simplicity. Formation of ICP nanodispersions consisting of highly conducting nanoparticles dispersed in either organic or aqueous solution has been achieved using polyaniline (152), polypyrrole (153), and regioregular polythiophene (154). Jang and Oh (155) used thermodynamically stable microemulsion micelles as nanoreactors to synthesize, at low temperatures, polypyrrole nanoparticles with dimensions of several nanometers. Deng and co-workers (156), using a core–shell approach, synthesized magnetic and conducting Fe_3O_4–polypyrrole nanoparticles (30–40 nm in diameter) in the presence of Fe_3O_4 magnetic fluid (core material) in aqueous solution containing sodium dodecylbenzenesulfonate as a surfactant and dopant.

The successful polymerization of polythiophene nanoparticles has been plagued by the insolubility of most thiophene monomers, and their subsequent polymer. Although advances have been made in solubilizing the monomer, in particular the utilization of surfactants, polymerization normally results in either precipitated powders or deposition of solid films. In recent times the substituted thiophene, poly(3,4-ethylenedioxythiophene) (PEDOT) has received much attention owing to its excellent environment stability. Baytron (PEDOT/PSS), a polythiophene dispersion commercially available from Bayer Corp., is widely used in electrochromic and antistatic device fabrication (157). Advances in substituted thiophene monomer synthesis are now providing a means of polymerizing polythiophenes that are stable as nanoparticle solutions. Edder and Frechet (158) recently synthesized a series of bridged oligothiophenes where their novel molecular architecture is expected to improve their utility as electroactive surfactants for semiconducting nanoparticles or organic electronics.

Device Fabrication

For the final device, the functional properties of ICPs must be integrated within a host structure that provides the mechanical/physical properties required.

ICPs have been assembled inside a number of host polymers including polyacrylonitrile, polyvinyl alcohol, and others (159). A number of attempts have been made to form composites with improved processability and mechanical properties while maintaining the inherent properties of the conducting polymer (160). Conducting polyaniline blends and composites are prepared mostly via the chemical oxidation route, although electrochemical synthesis is also employed in some cases (161,162). Using the chemical approach *in situ* polymerization of monomer in the presence of a host polymeric matrix has been reported (163–165). Polyaniline–poly(ethylene terephthalate) (163) and polyaniline–polystyrene (164) composites have been prepared using this approach.

Emulsion polymerization in heterogeneous systems (166) has been used to prepare processable conductive composites of polyaniline–poly(alkyl methacrylate). Polyaniline composites have also been prepared via dispersion polymerization (167–169). In such studies colloidal dispersions of electrically conductive polyaniline particles have been prepared using vinyl methyl ether (168) or methyl cellulose (170) stabilizers.

ICPs have also been assembled inside hydrogels, retaining both the electronic properties of ICPs and the water adsorption properties of gels (171,172).

Conducting polymers have also been prepared as coatings on both natural and synthetic fibers and fabrics. For example, silk and wool (173,174) or nylon (175) have been coated. Electrospinning (176,177) is another method for the production of ICP composite fibers and nanofibers. This simple approach is based on the electrostatic fiber spinning of composite fibers of polyaniline with polyethylene oxide, polystyrene, and polyacrylonitrile. These fibers are formed when a high electric field (5–14 kV) is placed between the tip of a metallic anodic spinning needle loaded with the dissolved polymer solution (0.5–4 wt% PAn and 2–4 wt% host polymer) and an opposing cathode plate separated by 20 cm. The presence of the high electric field results in the surface tension of the polymer-loaded solution

at the needle tip to be exceeded, expelling a polymer fiber from the surface toward the opposing cathodic plate. The transit time from anode tip to the cathode plate is accompanied by a desolvation and drying process in part assisted by the electrostatic charges placed upon the solvent molecules which undergo electrostatic repulsion processes. The resulting nanofiber composite is reported to have lengths in the meter range collected as an interwoven mesh with large surface to volume ratios ($\sim 10^3$ $m^2 \cdot g^{-1}$). Fiber dimensions of less than 100 nm have been routinely produced by this technique. More recently (176) fibers of PAn have been directly spun from a 20 wt% solution of polyaniline (Versicon, JGB Enterprises, Inc., Liverpool, NY) in 98% sulfuric acid at 5 kV.

The ability to provide more processable ICPs, as described above, enables new approaches to device fabrication, including ink-jet printing (178) and screen printing (179). Photolithography has also been used to produce ICP patterns (180–182), while spin coating has been used to produce thin, even films (183).

Screen printing is a simple and environmentally friendly way to produce electronic circuitry and make interconnections (184). Bao and Lovinger (185) used screen printing to develop organic transistors with high field-effect mobilities (approx 0.015–0.045 $cm^2 \cdot V^{-1} \cdot s^{-1}$) using regioregular poly(3-hexylthiophene). Garnier and co-workers (186) have demonstrated the usefulness of printing in organic FET fabrication, while Gustafsson (187) showed it was possible to print polyaniline to form the gate electrode. While screen printing is a highly efficient and relatively simple way to fabricate intricate electronics and circuits, this technique suffers from low resolution; in most instances, screen printing is used to pattern the parts of the circuits that do not demand high resolution (188).

Because of the ability to print, typically at higher resolution, ink-jet printing has emerged as an attractive patterning technique for conjugated polymers in areas such as LEDs (189). Patterning of organic molecules by ink-jet printing can be achieved either by printing a solution of the molecule (in organic solvent) or by printing dispersions of the molecule in water or organic solvents. Magdassi and Ben Moshe (190) have demonstrated the concept of direct patterning of water-insoluble organic molecules in the form of nanoparticles contained in a microemulsion droplet, which are converted into organic nanoparticles upon impact with the substrate surface due to evaporation of the volatile solvent. Rogers and co-workers used microcontact printing techniques to fabricate various electronic components, such as transistors (191) and logic gates (192) from conducting polymer dispersions and conducting polymer composites. While these printing techniques mentioned above offer higher resolution than conventional screen printing techniques, these still suffer from resolution limitations for some circuit designs. Sirringhaus and co-workers (193) developed a method to print high-resolution all-polymer transistor circuits utilizing hydrophobic surface patterning which confines the spreading of water-based conducting polymer ink droplets upon ink-jet printing.

INTERCALATION POLYMERIZATION

Introduction

The term *intercalation* is used by chemists to describe the insertion of mobile guest species (atoms, molecules, or ions) into a crystalline host lattice containing an interconnected system of empty lattice sites (□) of appropriate size, according to the general equation (see Reference 1)

$$x\,\text{Guest} + \square_x\,[\text{Host}] \longleftrightarrow (\text{Guest})_x[\text{Host}]$$

Usually reversible and occurring near room temperature, intercalation reactions are considered as topochemical processes, since the structural integrity of the host lattice is formally conserved. A wide range of inorganic host lattices have been found to undergo these intercalation reactions including (2) (Fig. 1) (*1*) framework lattices made of interconnected or parallel isolated channels and (*2*) layered lattices and chain-type structures made of inorganic slabs or chains, respectively. The framework lattices (zeolite-type structures, tungsten bronzes, etc) are characterized by rigid vacant channels with constant pore volume. Therefore, the uptake of guest species is limited by the minimal channel cross section which results in guest shape selective intercalation behavior ("molecular sieve" phenomenon). On the other hand, the structures resulting from the weak association of slabs or chains provide flexible "pores," since the dimensions of the interslab or interchain spaces can adapt to the dimensions of the guest species. In practice, the chain structures, such as $(NbSe_3)_8$, $(Mo_3Se_3)_8$, and $(RuBr_3)_8$, have low structural stability and therefore relatively few studies have been carried out on their intercalation chemistry (1).

Thus, the present review is mainly devoted to the synthetic aspects of the intercalation of organic monomers in layered inorganic lattices and their *in situ*

polymerization leading to hybrid monophasic compounds, also called layered nanocomposites, made of the alternation of inorganic and polymer layers. Nevertheless, it may be noticed that these topochemical reactions are not the only routes to obtain such layered nanocomposites (Fig. 2): the synthesis of the mineral slabs from soluble precursors in a macromolecular solution (3,4) or the mineral slab exfoliation and their subsequent restacking after adsorption of macromolecules (encapsulative precipitation) (5,6) are other already investigated routes, which will not be reported in this article.

Under specific experimental conditions, such materials may be obtained as delaminated (or exfoliated) nanocomposites, which may be described as single inorganic slabs uniformly and randomly dispersed within a polymer matrix. Readers interested by the synthesis and the properties of these delaminated nanocomposites, especially in the field of clays, should see Nanocomposites, Polymer–Clay and other recent reviews (7–9). These materials have unusual and versatile properties, such as barrier materials and reinforced materials, (see BARRIER POLYMERS; REINFORCEMENT).

Nevertheless, considerable interest has also focused in recent years upon the synthesis of layered nanocomposites. Polymer-layered nanocomposites have advantages over their small-molecule analogues in compositional stability and mechanical strength, which make them more suitable for applications. On the other hand, it is expected that the thermal or oxidative stability of the polymer could be enhanced through encapsulation. The constrained environment is also expected to lead to a higher degree of polymer ordering, which would enhance their properties by orders of magnitude (ie, electronic conductivity or nonlinear optical susceptibility for conjugated polymers). A more potentially rewarding benefit arises, however, when the two lattices have ionic and/or electronically conductive

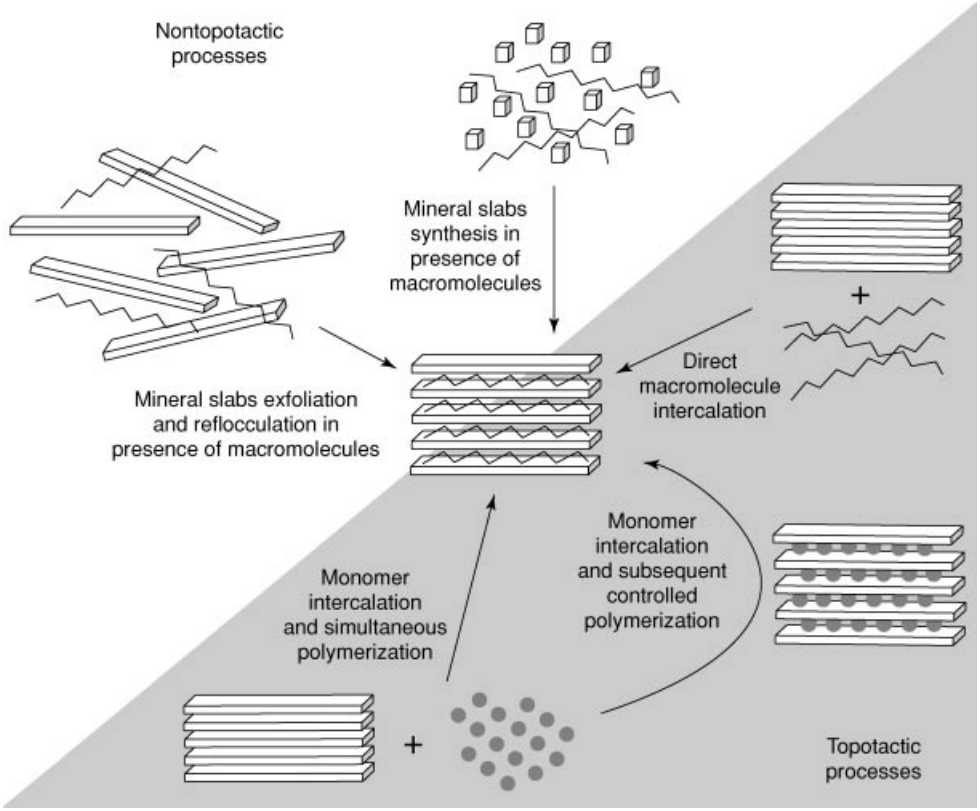

Fig. 2. Schematic representation of the synthetic routes leading to polymer-layered nanocomposites (where ○ and □ symbolize organic monomer and inorganic slab precursor, respectively).

properties. The goal is to design systems such that two lattices interact in such a way so as to enhance the properties of both.

The advantages of the polymer-layered nanocomposites are not only connected to the properties of the materials themselves. The presence of intercalated macromolecules may provide also a unique interslab environment for photofunctional molecules or probes. The photoluminescent behavior of tris(2,2′, -bipyridine)ruthenium(II) is gratefully enhanced in the interslab space of fluorotetrasilicic mica by the presence of poly(vinylpyrrolidinone)(PVP) (10). Moreover, layered nanocomposites may also be the precursors of inorganic ceramics (β-sialon, SiC, AlN, $Al_4Si_2C_5$, etc) through carbothermal reduction, because inorganic slabs and organic substances can contact at a molecular level and therefore prevent phase separation phenomena and the crystallization of parasitic phases (11). Lastly, from the viewpoint of the polymer chemist, polymerization reactions carried out in the confined 2-D space between inorganic slabs may further the synthesis of (*1*) macromolecules with stereospecific sequences, if the arrangement of intercalated monomers may be controlled through their interactions with the inorganic slabs and/or with cointercalated species, and (*2*) planar macromolecules

by using the interslab space as a polymerization nanoreactor where the polymer growth is prevented in the third direction by the slab presence.

Inorganic Layered Hosts and Intercalation Driving Forces

The majority of layered phases are characterized by strong intralayer covalent bonding and weak interlayer interactions. The slabs may be electrically neutral or may possess an overall charge which may be either positive or negative (Table 1). In molecular layered compounds, the slabs are electrically neutral and stacked on each other by Van der Waals forces or hydrogen bonds and the interslab space is a connected network of empty lattice sites. In the charged layered systems, the slabs are held together by weak electrostatic forces and the interslab spaces are partially or completely filled by ions or by a combination of ions and solvent molecules. The interslab distance, corresponding to the first line at lower 2θ values on x-ray diffraction (XRD) patterns, is directly affected by the presence, the concentration, and the conformation of any guest intercalated species. It should be noticed that this interslab distance corresponds to the basal spacing which is indeed the sum of the thickness of the interslab space and the thickness of the slab itself (Fig. 3). It is generally the first recorded parameter for checking the intercalation success and determining the guest arrangement.

Intercalation Through Electron Transfer. The direct intercalation of electrically neutral molecules in layered neutral crystals is only possible if these guest molecules are Lewis bases (organic amines, phosphines, thiols, etc) or strong electron donors (alkali metals) and if the host lattice is reducible. Indeed, the electron transfer mechanism from the intercalated guest to the host lattice is governed

Table 1. Examples of Some Layered Host Structures That Exhibit Intercalation Reactions[a]

Lattice Type	Illustrative examples[b]	Slab charge
Metal chalcogenides	$\mathbf{MX_2}$ where M = Ti, Ta, Mo, etc; X = S, Se	Neutral
	$\mathbf{MPX_3}$ where M = Mn, Cd, etc; X = S, Se	Neutral
Metal oxides	$\mathbf{MoO_3}$	Neutral
	$\mathbf{V_2O_5}$ or $\mathbf{V_2O_5} \cdot n\mathrm{H_2O}$ (xerogel)	Neutral
Metal oxy-halides	**MOX** where M = Fe, Ti, V, etc; X = Cl, Br	Neutral
Metal halides	α-$\mathbf{RuCl_3}$	Neutral
Hydrous metal oxides	$[\mathbf{M^{II}_{1-x}M'^{III}_x(OH)_2}]^{x+}[A^{n-}_{x/n}]^{x-} \cdot n\mathrm{H_2O}$ where M = Mg, Ni, etc; M′ = Al, Co, Fe, etc; A = Cl, NO_3, CO_3, etc	Positive
Metal hydrogen phosphates	$\mathbf{M(HOPO_3)_2} \cdot \mathrm{H_2O}$ where M = Ti, Zr, Hf, Ce, Sn	Neutral
Hydrogen uranyl phosphate	$\mathrm{H}\mathbf{UO_2PO_4} \cdot 4\mathrm{H_2O}$	Negative
Metal phosphates	$\mathbf{MOPO_4}$ where M = Ti, V, etc	Neutral
Smectite clays and silicates	Kaolinite $\mathbf{Al_4Si_4O_{10}(OH)_8}$	Neutral
	(Fluoro)Hectorite $\mathrm{Na_{0.6}}\mathbf{(Li_{0.6}Mg_{5.4})Si_8O_{20}(OH,F)_4}$	Negative
	Montmorillonite $\mathrm{Ca_{0.35}}\mathbf{(Mg_{0.7}Al_{3.3})Si_8O_{20}(OH)_4}$	Negative

[a] For their crystalline structure and intercalation chemistry, see for instance Ref. 1.
[b] The chemical component in bold type constitutes the slab (the other ones are in the interslab space).

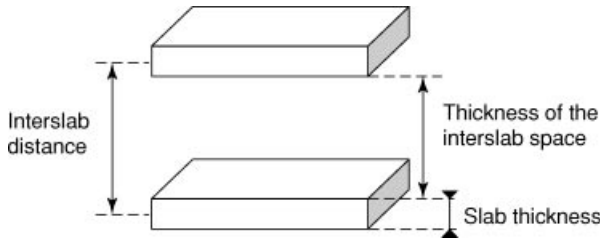

Fig. 3. Schematic representation of the characteristic distances describing the interslab space: the interslab distance is directly derived from XRD patterns (distance corresponding to the first line at lower 2θ values); the thickness of the interslab space is derived from the latter after deduction of the slab thickness.

by the oxidizing power of the metal within the slabs: the layered structure is generally preserved if the guest molecules are just on the reducing side of the host. Intercalation reactions are performed under anhydrous conditions at temperatures up to 200°C with neat reactants, if the potential guests are liquid or low melting solids. Solid guests are dissolved in polar organic solvents (toluene, acetonitrile, dimethoxyethane, dimethylformamide, etc) which often accelerate the intercalation process, but may also cointercalate with the guest molecules. On intercalation, the electric band structures of the layered crystals are changed greatly: some layered semiconductors are changed into metallic compounds and even changed into superconductors (12).

Intercalation Through Ion Exchange. Such mechanisms are observed in layered lattices made of negative or positive slabs, where the net charge is balanced in the interslab space by the presence of cations or anions, respectively. These ions can often be replaced by immersing the material in a concentrated solution of other ions of the same charge. These exchange reactions are driven by the great excess of the replacement ion. Intercalation reactions involving clay hosts all generally proceed by cation-exchange processes, with various kinds of inorganic as well as organic cations, such as voluminous quarternary alkyl ammonium ions.

Intercalation Through Dipole–Ion Interactions. Neutral polar molecules can also directly intercalate into the interslab spaces of ion-exchangeable layered crystals. The driving force for the intercalation is mainly due to dipole–cation interactions similar to the interactions involved in the solvation of cations in an electrolyte solution. The intercalation occurs only if such interactions are strong enough to compensate the energy necessary for the guest molecules to spread the slabs.

Surfactant-Mediated Intercalation. In general, nonpolar molecules are not able to intercalate between the slabs of pristine inorganic layered materials. The preintercalation of ionic surfactants by ion-exchange reactions is the only route allowing to make the interslab space sufficiently open and organophilic for accommodating non polar guest molecules. This route is especially used in the field of clays with commercial organically modified clay precursors, called organoclays.

Intercalation Through Acid–Base Interactions. Such mechanisms are observed in layered host lattices (metal phosphates; layered perovskites $HCa_2Nb_3O_{10}$, $HCa_2Nb_2MO_9$ with M = Al, Fe, $HMM' O_6 \cdot H_2O$ with M = Nb,

Ta and M′ = W, Mo), where acidic protons, present within or between the slabs, may be neutralized by guest Brønsted bases.

Intercalation Through Guest Displacement. Kaolinite is atypical among silicates, because neither cations nor anions are present in the interslab space and the inherent hydrogen bondings between the slabs limit the intercalation chemistry. Today, the most effective technique for kaolinite is a guest displacement reaction, in which preintercalated organic species (DMSO, NMF, methanol, etc) can be displaced with various types of organic molecules. Multistep displacement is also possible by using these compounds as second intermediates (11).

Direct Intercalation of Preformed Macromolecules

In addition to the rapidly expanding field of exfoliated clay–polymer nanocomposites (see NANOCOMPOSITES, POLYMER-CLAY), direct intercalation of macromolecules into inorganic layered materials with retention of the layered nature is also an excellent way of constructing nanocomposites with original properties. The synthetic pathways have to overcome large entropic barriers.

One of the first successful attempts for intercalating preformed macromolecules was reported in the field of clays (13). Poly(ethylene oxide)(PEO) macromolecules ($M_w = 6 \times 10^2 - 6 \times 10^5$ g/mol) were intercalated from acetonitrile solutions into montmorillonite or hectorite where interslab cations were Li^+, Na^+, K^+, Ba^{2+}, etc. The resulting compounds exhibit good chemical and thermal stability, preserving their ion-exchange properties. The corresponding increase in the interslab distance (between 0.6 and 0.8 nm according to the cation nature) does not depend on the PEO molar mass and is consistent with a single-layer intercalated polymer adopting a helical conformation in the interslab space (Fig. 4). Such an arrangement, checked by IR, ^{13}C, and ^{23}Na NMR spectroscopies, indicates that interslab cations remain associated with the PEO oxygen atoms and this allows one to infer that the intercalation driving force is the well-known PEO affinity for cationic species (dipole–cation interaction) (14,15). PEO–clay nanocomposites show higher ionic conductivities than the parent silicate (up to $10^{-5} - 10^{-4}$ S/cm in the direction parallel to the layer plane) and their potential use as polymer electrolyte in solid-state lithium batteries as a substitute for conventional PEO–salt complexes is argued by the fact that in these nanocomposite systems the typical problem of ion pair formation is avoided, because only the cations are able to move (16). Similar routes, based on the PEO affinity for cations, were also successfully investigated with MPS_3 (with M = Mn, Cd) (17,18) or MoO_3 (19) materials preintercalated with alkali cations. In transition-metal phosphorous trisulfides, the concept was extended to poly(ethylene imine) (20) and PVP (21).

Cation exchange reactions, as intercalation driving force, were investigated with ionomer macromolecules such as poly(*p*-xylylene-α-dimethylsulfonium chloride) ($M_w = 10^5$ g/mol) in MoO_3 after the preintercalation of hydrated alkali cations and partial swelling in water (22). The ionomer was *in situ* converted to poly(*p*-phenylenevinylene) (PPV) by heating up to 250°C for eliminating HCl and $S(CH_3)_2$ (eq. 1). The interslab distance is in good agreement with an orientation of the aromatic ring planes perpendicularly to the oxide slabs. The increase of electronic

conductivity, together with x-ray photoelectron spectroscopy (XPS) data, is consistent with the formation of p-doped PPV in the oxide lattice.

(1)

Another example of direct macromolecule intercalation is the insertion of hydrophilic chains, such as PEO, PVP, poly(propylene glycol) (PPG), and

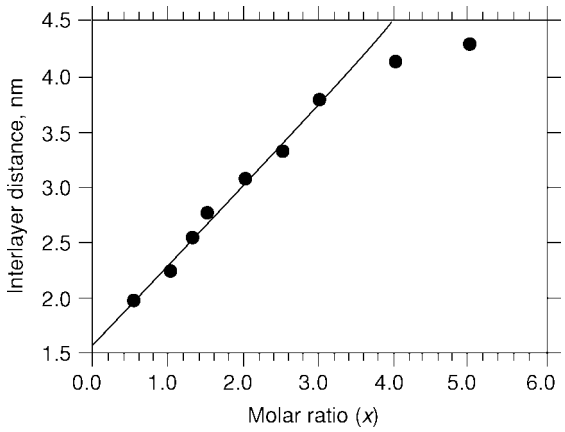

Fig. 5. Variation of the interslab distance as a function of x in $(PVP)_xV_2O_5 \cdot nH_2O$ nanocomposite. From Ref. 24, with permission.

methylcellulose, between the slabs of vanadium oxide xerogel, which is infinitely swellable in water (23–25). In practice, the nanocomposites were carried out by mixing aqueous solutions of macromolecules with a $V_2O_5 \cdot nH_2O$ solution in various stoichiometries and obtained as red self-supporting films. It may be noticed that, in the case of $(PVP)_xV_2O_5 \cdot nH_2O$ materials, single phases are obtained when $1 \leq x \leq 5$. Interestingly, as x increases, the interslab distance increases continuously and linearly up to $x = 3$ with the increment being 0.7 nm per mole of PVP (Fig. 5). At $x > 3$, significant deviations from the linear relationship begin to appear, showing that the interslab space become saturated and that any additional polymer deposits outside the host. Moreover, the nanocomposite films are flexible with methylcellulose, but brittle with PPG and PVP.

Last typical examples, which may be taken in the literature, are surfactant-mediated intercalation with the incorporation of poly(*p*-phenylene) into MoO_3 (26) (Fig. 6) or poly(ethylene glycol)–kaolinite (27) and PVP–kaolinite (28) by refined guest displacement methods.

The main disadvantage of the route based on the direct intercalation of preformed macromolecules is the slow kinetics for the transport of macromolecules in the interslab spaces. In practice, the intercalation experiments require several days to complete at room temperature and their duration is inversely proportional

to the molar mass of macromolecules. Another limit is the inability of this method for accommodating nonlinear and insoluble macromolecules, such as the majority of conducting organic polymers. That is why parallel efforts have been focused on two-step routes, such as monomer intercalation and *in situ* polymerization. Further advantage of such synthetic routes based on polymerization in constrained environment is that, in theory, they offer the possibility for designing: (*1*) macromolecules with stereospecific sequences, if the arrangement of intercalated monomers may be controlled through their interactions with the inorganic slabs and/or with cointercalated species and (*2*) two dimensional macromolecules by using the interslab space as a polymerization nanoreactor where the polymer growth is prevented in the third direction by the slab presence.

Monomer Intercalation and Simultaneous Polymerization

In a significant number of cases, the contact between organic monomers and inorganic layered materials leads to the spontaneous polymerization of the monomers between the slabs. Even if all the mechanisms involved are not completely elucidated, it is possible to distinguish several scenarios.

Spontaneous Polymerization in Layered Aluminosilicates. Layered aluminosilicates are known not only to intercalate organic species but also to trigger spontaneous polymerization of some organic monomers. Brønsted acidity and/or transition-metal cations populating the surface of the slabs have been reported to be responsible for initiating the polymerization.

Forty years ago, it was shown that bringing into contact Na-montmorillonite and 4-vinylpyridine at ambient temperature leads to the formation of an intercalated monolayer of poly(4-vinylpyridine) whose aromatic rings are oriented perpendicularly to the slabs (29). Melted acrylamide was also successfully intercalated and polymerized, but the attempted intercalation/polymerization of styrene was less conclusive. At the time, the assumption of an ionic polymerization mechanism initiated by chemisorbed hydronium or hydroxyl ions derived from water was made.

In the case of transition-metal-exchanged smectite clays such as montmorillonite or hectorite, the interaction of the organic monomer with the transition-metal ions is followed by a relatively slow electron transfer reaction which produces reactive organic free radicals (30). These radicals then serve to initiate polymerization of guest monomers, such as benzene, aniline, pyrrole, and thiophene on hectorite films. According to the nature of the monomer and therefore to the strength of its interaction with the transition cation, the polymerization occurs on the film surface and/or in the interslab spaces, as checked by scanning force microscopy (SFM) and x-ray diffraction (XRD). For example, aniline vapor readily polymerizes in both sites of Cu^{2+}-exchanged hectorite (31). On the basis of the results of electron spin resonance (ESR) experiments, a plausible polymerization mechanism was proposed, where the first step is the oxidation of one aniline molecule by Cu^{2+}, leading to an aniline radical-cation able to initiate the polymerization. Atmospheric O_2 is also involved in the propagation step, with the subsequent formation of polyaniline in the leucoemeraldine form. Other easily oxidized monomers, such as pyrrole and thiophene, react in a similar way. On

the other hand, with benzene, the extent of polymerization is much lower, with macromolecules essentially located between the slabs (30).

The intercalative polymerization of aniline may also be carried out using a Cu^{2+}-exchanged synthetic hectorite (fluorohectorite) (32). The electronic absorption spectrum of the resulting nanocomposites showed the characteristic insulating poly(aniline) form (ie the emeraldine base). To obtain conducting materials it is necessary to dope the nanocomposite by exposure to HCl vapors. As a consequence of this treatment, the emeraldine salt is formed within the interslab space and a significant increase in the electrical conductivity is observed, which reaches high in-plane d.c. conductivity values (0.05 S/cm) with an anisotropic ratio $\sigma_{\parallel}/\sigma_{\perp}$ close to 10^5. Similar experiments are also successful with pyrrole, leading to polymerized nanocomposites where the variation in the basal spacing is consistent with heterocyclic rings oriented parallel to the silicate slabs (33). A broad infrared band extending from about 1800 cm^{-1} into the near-infrared region is indicative of the presence of polarons/bipolarons in conducting polypyrrole. Doping of polypyrrole–fluorohectorite nanocomposites with iodine vapors produces a strong increase in the d.c. conductivity from 2×10^{-5} to 0.12 S/cm. The electrical conductivity increases with temperature in the 100–400 K range, but above 400 K the observed dramatic decrease is interpreted as strong oxidation of polypyrrole (16).

Methyl methacrylate (MMA) and styrene, adsorbed on transition-metal-exchanged hectorite, may undergo polymerization by mechanisms that do not involve electron transfer and the reduction of the metal cation in the interslab spaces. This type of polymerization occurs relatively slowly (3 days to a week) compared with the redox reactions previously described and the resulting polymer seems, in most cases, to be primarily located on the surface of the clay film or in defects in this film (34). The ESR technique showed no evidence for the formation of organic free radicals during the polymerization. A possible cationic mechanism would rely on the enhanced Brønsted acidity of the intercalated transition metals, due to the high degree of dissociation of the water molecules associated to these metals, and the potential for the stabilization of cationic species by the negatively charged silicate slabs. While cationic polymerization of MMA may be unusual, this species could act as a Lewis acid, and in the presence of small amounts of water as a Brønsted acid (30).

A last example concerns the spontaneous polymerization of 2-ethynylpyridine within the interslab spaces of montmorillonite with different exchangeable cations (35,36). When the colorless acetylenic monomer is added into the aluminosilicate suspension in benzene, the color of the mixture readily turns reddish brown and darkens gradually. The macromolecules may be liberated through dissolution of the clay with hydrofluoric acid and on their infrared spectrum a strong band at 1630 cm^{-1}, due to —C=C— stretching, is observed, indicating the formation of a polymer with extensive conjugation. Additional evidence for polymerization is provided by the large bathochromic shift in the UV–vis absorption spectrum of the polymer, with an absorption peak at 470 nm, while poly(2-ethynylpyridine) from thermal polymerization in bulk absorbs at 370 nm, indicating a more extensively conjugated structure of the former. Thermogravimetric experiments show that the macromolecules confined to the interslab spaces have a higher thermal stability than the liberated polymer. The

polymerization rate of 2-ethynylpyridine increases with acidity of the montmorillonites, consistently with a spontaneous mechanism wherein the acetylenic triple bond would be activated via quaternization of the pyridine nitrogen. These sources of protons could be polarized water molecules on the surface of aluminosilicates, particularly water molecules associated with compensating cations.

Redox Intercalative Polymerization in Highly Oxidizing Hosts. The *in situ* redox intercalative polymerization (RIP) reaction is a direct and topotactic intercalation method (37). This type of reaction requires a strongly oxidizing host to provide the driving force to pull the monomers into the interslab spaces and oxidize them into polymers. In addition, the host should be able to distribute efficiently those electrons throughout the structure. These hosts are essentially FeOCl, V_2O_5, $VOPO_4$, and α-$RuCl_3$. The monomers may be polymerized through an oxidative mechanism, and therefore they mainly derive from aniline, pyrrole, thiophene, or furan structures, leading to conductive macromolecules. Generally prepared through chemical or electrochemical routes, the electronically conductive polymers are obtained as amorphous and insoluble powders, whose microstructure morphology characteristics (overall chain conformation and packing, degree of cross-linking, etc) are largely uncontrollable. Therefore, the charge transport mechanisms remain poorly understood and the following examples result from synthesis efforts for designing well-defined 2-D architectures isolated from each other through the use of the interslab spaces as nanoscale templates. Moreover, it has been clearly shown according to spectroscopic data that the role of the oxidizing transition-metal ions (such as Fe^{III} in FeOCl or V^{IV} in $VOPO_4$) determines the conducting form of the polymer and, therefore, the electrical behavior of the resulting nanocomposite (38,39).

The transition-metal oxyhalide FeOCl was the first investigated host (38). In a typical synthesis, a mixture of FeOCl and monomer (neat or in acetonitrile solution) is stirred at ~40–50°C for several days. The violet solid turns brown-black gradually with a shiny metallic luster and, few days later, it is recovered by filtration, washed, and dried. The success of the redox intercalative polymerization is strongly dependent on the first anodic potential (E_{pa}) of the heterocyclic monomers with respect toward the reduction potential of the inorganic phase. Although the precise redox potential of FeOCl under the reaction conditions is not known, it may be inferred from RIP experiments with different monomers that this value is comprised between 1.32 and 1.86 V versus SCE (40). These lower and upper bounds indeed correspond to the E_{pa} of the most oxidizible monomers which are readily polymerized within the slabs of FeOCl (2,2′-bithiophene) and the E_{pa} of the less oxidizible monomers which cannot be polymerized in similar conditions, respectively (Fig. 7). The fact that pyrrole and 2,2′-bithiophene may be spontaneously intercalated and polymerized, contrarily to thiophene (structurally very close to pyrrole), suggest that thermodynamic rather than kinetic factors are important in these intercalative polymerization reactions. It should be also pointed out that for RIP to occur in a five-membered ring heterocycle, the 2 and 5 positions must not be blocked by substituents. For example, use of 2,5-dimethylpyrrole, which has a less positive E_{pa} than pyrrole itself, does not form a conductive polymer nor an intercalation compound. This of course derives from the fact that polymerization proceeds through coupling at the 2 and 5 positions. Elemental analyses were consistent with the stoichiometries $(C_4H_3N)_{0.34}FeOCl$ and $(C_4H_2S)_{0.28}FeOCl$ and

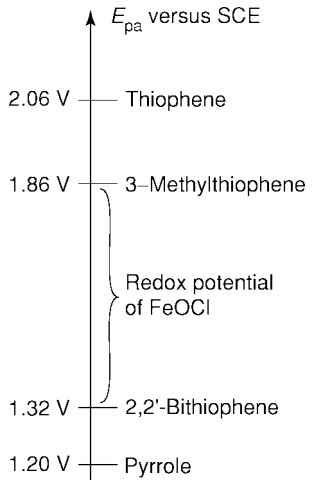

Fig. 7. Thermodynamic factors explaining why the redox intercalative polymerization in FeOCl is possible for pyrrole and 2,2′-bithiophene and not for 3-methylthiophene and thiophene.

XRD patterns with heterocyclic rings oriented perpendicular to FeOCl slabs. If the intercalation reaction is carried out at higher temperatures (>80°C) and for longer times (>2 weeks), the scanning electron microscopy (SEM) photographs show what appears to be amorphous polymeric film covering the crystal surfaces. XRD patterns of these overreacted samples show broad diffraction peaks, suggesting considerable decrease in the crystallite size and/or severe disorder resulting from the disruption of the FeOCl lattice. The ^{57}Fe Mössbauer spectroscopy allowed to check the partial reduction of FeOCl. Consistently with the RIP mechanism, electrons are transferred to the host slabs and are delocalized over all Fe sites, thus yielding an average formal oxidation state of Fe less than +3. Four-probe electrical conductivity data (in the range 4–300 K) measured on compressed pellets of the pyrrole or 2,2′-bithiophene based nanocomposites show a decrease in conductivity with falling temperature, with room temperature, conductivity of about 1 S/cm.

FeOCl host was also investigated for the redox intercalative polymerization of aniline (41). The success of this reaction strongly depends on the experimental conditions of the reaction: the most defined nanocomposites are obtained with acetonitrile as solvent and with a mole ratio of aniline to FeOCl > 8 in order to drive the reaction to completion. The reaction is accelerated by raising the temperature and/or performing it under air, indicating that oxygen is involved in the RIP mechanism. When large single crystals of FeOCl (as long as 0.5 mm) are used, the reaction rate is much slower, but the resulting products contain amounts of poly(aniline) similar to the microcrystalline samples. Elemental analyses show stoichiometry $(C_6H_4NH)_{0.3}FeOCl$ which corresponds to the maximum value calculated on the basis of the molecular sizes of FeOCl and poly(aniline). The macromolecules may be extracted from the nanocomposite by dissolution of the mineral slabs in HCl. Molecular weight studies via size exclusion chromatography (SEC) analysis suggest $M_w \sim 6100$ and $M_n \sim 3500$ versus $M_w \sim 69000$ and $M_n \sim 7700$ observed for polyaniline obtained independently in bulk. So, chain

lengths obtained in the interslab spaces are shorter than those obtained in bulk conditions, but show narrower length distribution. Infrared spectra of the intercalated macromolecules show the characteristic fingerprint of the emeraldine positive form, whose counter anions are the reduced FeOCl slabs.

Vanadium pentoxide is one of the most extensively studied inorganic layered host in the field of conductive polymers (35). The inorganic starting matrix could be either crystalline V_2O_5 or the quasi-amorphous $V_2O_5 \cdot nH_2O$ xerogel materials obtained by drying the gel resulting from the acidic hydrolysis of vanadate. Nevertheless, V_2O_5 gels can form highly oriented films that yield characteristic powder XRD patterns with enhanced 00l peaks. The strongly oxidizing character of the oxide induces the redox polymerization of the organic monomer. It is worth remarking that while the intercalated polymer is effectively p-doped (partially oxidized) during this process, the V_2O_5 suffers itself a partial reduction that renders it an n-doped (partially reduced) electrically conductive mixed-valence (V^{IV}/V^{V}) oxide. Such redox intercalation reactions alter the band structure of vanadium oxide forming bronze-like electrically conductive materials with mixed electronic charge-transport properties. So, these nanocomposites could be characterized as conductive polymer bronzes by analogy to alkali metal or molecular bronzes (42). First attempts of RIP experiments in V_2O_5 were performed with pyrrole and *N*-methylpyrrole (43), 2,2′-bithiophene (44), 2,5-dimercapto-1,3,4-thiadiazole (45), 3,4-ethylene dioxythiophene (46), and aniline (42,47,48). In this last case, the redox intercalation reaction and the subsequent spontaneous polymerization were studied in detail. In practice, it occurs instantly upon contact of the xerogel with aniline and is associated with an immediate and dramatic color change to dark blue. Despite this, the reaction takes several hours to go to completion because of the diminishing diffusion of the growing guest species into the interslab spaces. As neat aniline is not able to swell the xerogel and as other solvents such as DMSO or DMF are too readily cointercalated, water seems to be the most suitable solvent because a lot of it is expelled from the slightly hydrophobic interslab space, allowing more polymer to be inserted. When a wet xerogel (preswollen by water) of V_2O_5 is used, the reaction is complete within minutes but the final product is nearly amorphous, and sometimes the V_2O_5 framework is severely disrupted as checked by the dramatic changes on the V—O stretching region of the infrared spectrum. Experiments carried under air show that in such conditions the reaction completion times are shorter and the products tend to possess better lamellar order. The reaction steps of aniline and V_2O_5 in air are very complicated and could be summarized by the following overall equation:

$$x\ C_6H_5NH_2 + V_2O_5 \cdot nH_2O + (2x - 3y)/2\ O_2 \rightarrow$$
$$[(C_6H_4NH)_{x-y}(C_6H_5NH_3)_y]V_2O_5 \cdot mH_2O + (2x - 3y)/2\ H_2O_2 + (n - m)H_2O$$

Aging the samples in the presence of O_2 causes simultaneously the partial reoxidation of the reduced V_2O_5 framework and the oxidative coupling of polyaniline oligomers and anilinium ions inside the interslab spaces to form longer chains. So, oxygen acts as an electron acceptor during the *in situ* reaction and long after intercalation is complete. Further experiments carried out with 4-anilinoaniline or 4-anilinoanilinium iodide as monomers in $V_2O_5 \cdot nH_2O$ xerogel leads to the

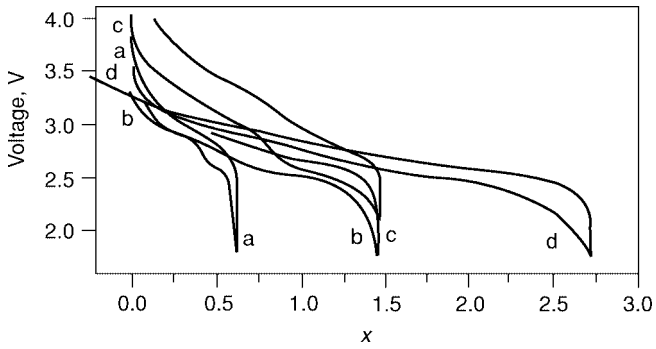

Fig. 8. First discharge curves of (a) V_2O_5 xerogel dried at 100°C, (b) poly(aniline)–V_2O_5 nanocomposite as prepared, without treatment, (c) V_2O_5 xerogel dried at 250°C, and (d) poly(aniline)–V_2O_5 nanocomposite treated at 80°C for 5 h, as a cathode material by coupling with a lithium metal anode using 1 *M* $LiClO_4$ in a 1:1 mixture of ethylene carbonate/dimethoxyethane as electrolyte (note: x is the ratio intercalated Li^+/V_2O_5). From Ref. 51, with permission.

intercalation of 4-anilinoanilinium cation moieties, followed by their polymerization (49). The oligomers obtained through this route exhibit a relatively low molecular weight dispersion, which cannot be obtained by the oligomerization reactions of 4-anilinoaniline in liquid phase. Electrochemical Li insertion into these polyaniline/V_2O_5 nanocomposites is enhanced because the intercalated conductive macromolecules facilitate Li diffusion kinetics and increase the capacity (50). The electrochemical performance indeed is very sensitive to the nature of the conductive polymer, the synthesis conditions, and subsequent treatments. For example, O_2 treatment, which has an important effect on the final molecular weight of the macromolecules and on the oxidation state of the oxide, is of great help in controlling the specific capacity of these nanocomposite cathodes, which can reach values as high as 300 A · h/g (measured at a low discharge rate) (51) (Fig. 8). So, there are features like this increased capacity or the improved diffusion of lithium [Li^+ diffusion coefficients were found to be one order of magnitude higher in the nanocomposites than in pristine V_2O_5 (50)] that make the performance of the nanocomposite materials superior to the sum of its components (52). Unfortunately, owing to the possible presence of benzidine moieties in the polyaniline backbone, the application of such nanocomposites is limited since they might yield toxic (carcinogenic) products upon degradation. So, the intercalation of the more "environment-friendly" poly(3,4-ethylene dioxythiophene) (PEDOT) in vanadium pentoxide was investigated (46). These experiments were performed with crystalline V_2O_5 and 3,4-ethylene dioxythiophene in water refluxing for 12 h. Interestingly, as a function of the EDOT amount, the interslab spacing of V_2O_5 expands in two stages, consistently with the intercalation of a first monolayer of PEDOT for low monomer concentration and the intercalation of a second monolayer for higher concentrations. The application potential of these nanocomposites as cathode materials in rechargeable lithium batteries was demonstrated by the electrochemical insertion of lithium, showing a discharge capacity superior to 300 mA · h/g (compared to 140 mA · h/g for pristine V_2O_5) with a better

reversibility, presumably because of the structural stabilization of the crystalline oxide as the consequence of the polymer presence between its slabs (53).

Oxovanadium phosphates, $VOPO_4$ and more expanded α-$VOPO_4 \cdot 2H_2O$, are layered compounds obtained by refluxing V_2O_5 in phosphoric acid and also known for accommodating organic and organometallic compounds between their slabs through redox reactions. Methyl-substituted pyrrole derivatives (3-methylpyrrole and 3,4-dimethylpyrrole) can be oxidatively polymerized in the $VOPO_4$ interslab space, whereas pyrrole is polymerized only on the grain surface without intercalation (54). The oligomerization indeed would occur at the interface of the $VOPO_4$ lattice and the intercalation of these oligomers would indeed depend on the regularity of their chain structure: poly(3-methylpyrrole) and poly(3,4-dimethylpyrrole) form a straight-chain structure which would be suitable for intercalation, whereas partially branched chains of polypyrrole could not be inserted (Fig. 9). Indeed, further experiments showed that intercalated polypyrrole can be obtained more readily in cast films by contact with pyrrole vapors (39). In the case of aniline (but also of 4-anilinoaniline and 4-anilinoanilinium iodide), its intercalation as anilinium cation was shown, but it does not polymerize spontaneously in the interslab space (49) or it gives short oligomers unable to enhance the electrical conductivity of the nanocomposite (55). So, the reactivity of $VOPO_4$ would be likely different from that of V_2O_5 xerogel and it was suggested that a possible reason could be the longer distance between intercalated monomer and the nearest-neighboring vanadium

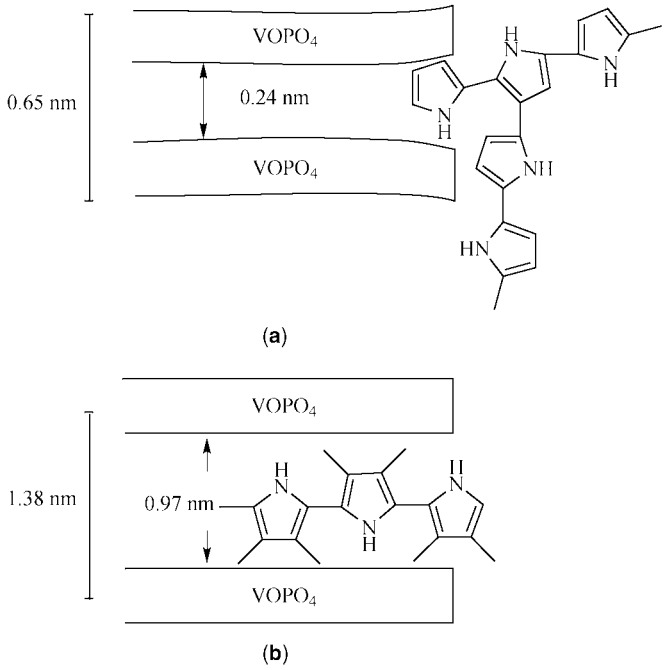

Fig. 9. Schematic representation of the intercalation of (**a**) polypyrrole and (**b**) poly(3,4-dimethylpyrrole) moieties into the $VOPO_4$ interslab space. Reproduced from Ref. 54, with permission of The Royal Society of Chemistry.

atoms in the case of the phosphate (49). Nevertheless, the *in situ* polymerization of aniline may be achieved by treatment with Cu^{2+} ions ($CuCl_2$) (56).

In contrast to layered metal chalcogenides, oxides, and thiophosphates, layered transition-metal halides have not received much attention in the study of intercalation, because most of them are not very stable, even under mild conditions in which they are generally hydrolyzed, solubilized, or decomposed. α-$RuCl_3$ is a notable exception and is very stable under these conditions. Cations can be intercalated reductively or through ion exchange, while neutral polar molecules can be incorporated through solvent exchange. It was recently demonstrated that it is also a suitable host for macromolecules (encapsulative precipitation) (57) and in particular for polyaniline through a RIP process (37). The reaction is carried out from a solution of aniline in acetonitrile in open air at ambient temperature for 1 week. XRD and infrared spectroscopy data are consistent with the formation of the conductive polymer (emeraldine salt form) in the interslab space. Similar to the intercalative polymerization of aniline into FeOCl and V_2O_5, the presence of oxygen is key to a successful outcome of the reaction. So, heating the product at 120°C in air for 5 days allows to complete the polymerization. On the other hand, a control experiment in the absence of air or oxygen showed that no intercalation reaction occurred after 23 days. The electrical conductivity of the nanocomposite at room temperature is ~2 S/cm, three orders of magnitude higher than that of α-$RuCl_3$. Moreover, in contrast to pristine α-$RuCl_3$, which shows antiferromagnetic ordering below 15.6 K, the nanocomposite does not exhibit this transition, because of the presence of diamagnetic Ru^{2+} centers (due to the partial reduction of Ru^{3+} through the RIP process) and the increased separation of the $RuCl_3$ slabs. The potential applications of such polyaniline/α-$RuCl_3$ nanocomposites will probably be derived from the combination of the high conductivity of polyaniline and the wide-ranging catalytic properties of $RuCl_3$, providing new materials with valuable electrocatalytic properties.

Monomer Intercalation and Subsequent Controlled *In Situ* Polymerization

The observation of the spontaneous polymerization of intercalated monomers is essentially limited to the cases of very oxidizing hosts accommodating monomers able to oxidatively polymerize (leading to electroactive polymers) or to very acidic and/or transition-metal-exchanged aluminosilicates. In all other cases, the polymerization is generally not spontaneous and it has to be initiated or catalyzed in a second step through the use of an external compound.

Oxidative polymerization. In Na-exchanged or Cs-exchanged montmorillonites, anilinium chloride may be readily intercalated by ion-exchange reaction at ambient temperature in a few hours. The oxidative polymerization may be performed by electropolymerization (58): the anilinium/montmorillonite nanocomposite is used as electrode and electrolyzed galvanostatically at 20 $\mu A/cm^2$ in 2 *M* HCl up to 20 mC/cm^2. The clay-modified electrode changes its color from white to blue and this blue color cannot be removed (even by washing with organic solvents) suggesting that the intercalated aniline is polymerized during the electrolysis. Another polymerization route consists in using an external oxidant

such as ammonium peroxodisulfate at 0°C for 1 day in water, where the nanocomposite is dispersed (59). Peroxodisulfate may also be used for oxidizing aniline in other layered hosts, whose intrinsic redox potential is not sufficient: MoO_3 (60) or layered Brønsted acids, such as $HCa_2Nb_3O_{10}$, $HCa_2Nb_2MO_9$ (M = Al, Fe) (61), and $AlH_2P_3O_{10} \cdot 2H_2O$ (62), where aniline is previously intercalated through acid–base interaction. In other examples, the aniline intercalated in MoO3 is oxidized by iron(III) chloride (63), aqueous H_2O_2, or iodine vapor (64). These oxidants are generally used in the proportion of 2 equiv per equivalent of aniline. Sometimes, atmospheric oxygen through a thermal treatment at 130°C in air is efficient enough, for instance when aniline is intercalated in layered metal phosphate $HUO_2PO_4 \cdot 4H_2O$ (65,66) or α-$M(HOPO_3)_2 \cdot H_2O$ (M = Zr, Ti) (66) and in trirutile-like layered oxides $HMWO_6 \cdot nH_2O$ (67) or $HMMoO_6 \cdot H_2O$ (68) (M = Nb, Ta).

Free-Radical Polymerization. The earliest works in these layered nanocomposites are also more complete from the point of view of the polymer chemistry (69). These studies concerned the adsorption of MMA monolayers (through dipole–ion interactions) between the slabs of Na-exchanged montmorillonite and the free-radical polymerization MMA initiated by thermolysis of cointercalated benzoyl peroxide or azobisisobutyronitrile or with γ-ray initiation. It was shown that γ-ray doses or initiator concentrations necessary to induce the polymerization are higher than those allowing comparable bulk polymerizations. The polymerized nanocomposites appeared to resist thermal degradation under conditions at which complete degradation of free polymer was found (70). This effect would be due to steric factors hindering the thermal motion of the macromolecule segments sandwiched between the slabs of montmorillonite. Moreover, it would appear that the macromolecules liberated by dissolution of the mineral by HF have a greater thermal stability than macromolecules made in a conventional free-radical technique. An NMR spectroscopy study of the liberated macromolecules showed a pronounced isotactic component which is weak in the reference PMMA (71). Isotacticity increases as the monomer intercalation yield decreases and it reaches a plateau for yields corresponding to a monolayer arrangement between the slabs, indicating that the mechanism which leads to stereospecificity is confined to the interslab space. A model was proposed where the exchangeable cations (such as sodium), which randomly populate the interslab space, interact through dipole–ion interactions with the carbonyl group of two monomers (Fig. 10). Thus coordinated, both

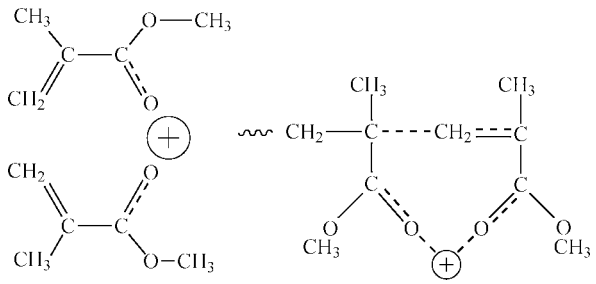

Fig. 10. Schematic representation showing how in the interslab space the dipole–ion interactions between two MMA monomers and one exchangeable cation would lead to the formation of an isotactic diad. From Ref. 71, with permission.

monomers would lead to the formation of an isotactic diad, increasing therefore the stereoregularity of the macromolecules. By varying the nature of the exchangeable cations, it was observed that the percentage of isotactic triads increases with increasing strength of the dipole–ion interactions (72). At least, the polymerization conversion yield depends strongly on the nature of the exchangeable cations: $Na^+ < K^+ < Cs^+$ and $Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$, ie, with increasing interaction energy (73). The polymerization rate does not depend significantly on monomer surface concentration up to a critical value below which the rate drops dramatically. The overall energy of activation was found to be similar to the value for bulk polymerization and it was suggested that steric effects, reducing the mobility of monomer molecules within the interslab space, are responsible for the decrease in polymerization rates. A further example of γ-ray-initiated polymerization was reported with vinyl acetate intercalated in Na-exchanged montmorillonite (74).

Propargylamine and aminoacetonitrile may be readily intercalated through acid–base interaction within the interslab spaces of α-$M(HOPO_3)_2 \cdot H_2O$ (M = Zr, Sn) (75). Their subsequent thermal treatment (150–180°C for 24 h in air) or UV irradiation (550 W medium pressure Hg lamp for 11 days) results in polymerization of the guest molecules. However, if the photochemical reaction does not reduce the crystallinity of the initial materials, its extent is more limited, as observed by ^{13}C CP-MAS NMR spectroscopy. In all cases, these polymerized nanocomposites are insulators as pressed powder pellets ($\sigma < 10^{-8}$ S/cm). Heating these compounds to 300°C in argon turns them black and at temperature over 750°C the graphitization reaction leads to conductivities up to 1 S/cm.

Last examples are taken in the fields of layered double hydroxides (LDH) whose general formula is $[M^{II}_{1-x}M'^{III}_x(OH)_2]^{x+}_{\text{slab}}\,[A^{n-}_{x/n} \cdot mH_2O]^{x-}_{\text{interslab space}}$ and the structure derives from the natural hydrotalcite (M = Mg; M′ = Al, $A^{n-} = CO_3^{2-}$ and $0.22 < x < 0.33$). Partial M^{II} to M^{III} substitution induces a positive charge for the layers, balanced with the presence of exchangeable anions A^{n-} between the slabs. So, acrylate anions were intercalated through anion exchange and subsequently polymerized by thermal treatment at 80°C in the presence of potassium peroxodisulfate (76). The interslab distance was found to slightly decrease from 1.38 to 1.34 nm. Infrared data confirmed the disappearance of the C=C vibration band. Acrylate anions are also readily intercalated in nickel-based LDH, leading to $[Ni_{0.7}M'_{0.3}(OH)_2]^{0.3+}[(\text{acrylate})^-_{0.3} \cdot \frac{1}{2}H_2O]^-$ where M′ = Fe or Co, through the reduction of the corresponding layered γ-oxyhydroxide in dispersion in an aqueous solution of acrylate (77,78). The nature of the substituting cation in the slabs appears to strongly influence the polymerization mechanism. When M′ = Fe, the LDH containing monomer anions may be isolated and then interslab free-radical polymerization of acrylate anions was successfully initiated by potassium peroxodisulfate. On the contrary, a one-step process occurs if M′ = Co, leading straight to LDH containing polyacrylate anions. The true role of the substituting cation M′ is not yet well understood, nevertheless it would seem that in this last case, a free-radical polymerization mechanism could also be suggested, but involving a redox initiation step where a few acrylate anions would be oxidized during the intercalation reaction and would lead to the formation of radical carbonium ions. The *in situ* polymerized macromolecules were extracted from interslab spaces by anionic exchange, derivatized into poly(methyl acrylate),

and analyzed by SEC. Only oligomers were detected with weight-average molar masses ranging from 300 to 2900 g/mol vs. polystyrene standards (79).

Miscellaneous Polymerization. Pioneering works demonstrated the feasibility of the intercalation of 6-aminocaproic acid between the slabs of various Na^+-, Ca^{2+}-, Mg^{2+}-, Co^{2+}-, and Cu^{2+}-exchanged montmorillonites, where it arranges as a monolayer or a bilayer as a function of the intercalated amount (80). It was found from infrared data that Cu in Cu^{2+}-exchanged nanocomposites was strongly bonded to the amino acid. In a second step, 6-aminocaproic acid was *in situ* polymerized by thermal treatment at 250°C for 1 h in nitrogen flow. A step polymerization mechanism was suggested with the condensation of protonated $-NH_3^+$ groups with —COOH ones. Thermogravimetric results showed that the thermal stability of the polymerized nanocomposites is lower in Cu^{2+}-exchanged montmorillonite than in the other materials, probably because of a lesser degree of polymerization partially inhibited by the strong bonding between cations and monomers. Similar results were observed in α-$Zr(HOPO_3)_2 \cdot H_2O$, where the head-by-tail arrangement of the 6-aminocaproic acid monomers organized by the host matrix is conducive to polyamide formation (81). Evidence for *in situ* polymerization came again from thermogravimetric analysis, infrared spectroscopy, and ^{13}CCP-MAS NMR spectroscopy data. From differential thermal analysis results, it was found that, in contrast to the bulk polymer, which shows a melting transition at 229°C, the polyamide-based nanocomposite shows no thermal events over the range 80–320°C. This difference in behavior between bulk and confined macromolecules is attributed to inhibited formation of polymer crystallites within a spatially restricted environment of a layered matrix. More recently, negatively charged aspartic acid was intercalated within the interslab space of LDH based on magnesium and aluminum through a coprecipitation technique involving simultaneous formation of the inorganic slabs and intercalation of the anionic species (encapsulative precipitation) (82). *In situ* thermal polycondensation of aspartate monomer was performed at 220°C in air for 24 h leading to a poly(α,β-aspartate) based nanocomposite. The observed decrease in basal spacing and structural order was attributed at once to the polycondensation reaction and to the loss of intercalated water molecules. A last example concerns the intercalation of β-alanine into kaolinite by the guest displacement method using ammonium acetate based kaolinite as the intermediate (83). Zwitterionic β-alanine was ordered in a monolayer arrangement between the layers. Although the intercalated monomer was mostly polymerized by thermal treatment at 250°C for 10 h under nitrogen atmosphere, a part of the guest species was decomposed to acrylic acid and NH_3 gas.

The *in situ* thermal polymerization of ε-caprolactone in Cr^{3+}-exchanged fluorohectorite was also reported (84). The basal spacing observed prior to polymerization was found to be consistent with the orientation of the ε-caprolactone ring perpendicular to the silicate layers (Fig. 11). After polymerization, the decrease in the basal spacing is consistent with the dimensional change accompanying the ring-opening polymerization. The polymerization reaction appears to proceed through cleavage of the acyl-oxygen bond catalyzed by the interslab Cr^{3+} ions. It may be noticed that, in that example, between the monomer intercalation step at room temperature and the polymerization step at 100°C, the excess monomer was not removed. Therefore, the final material may be described as poly(ε-caprolactone) intercalated silicate particles embedded in the same polymer matrix. In similar

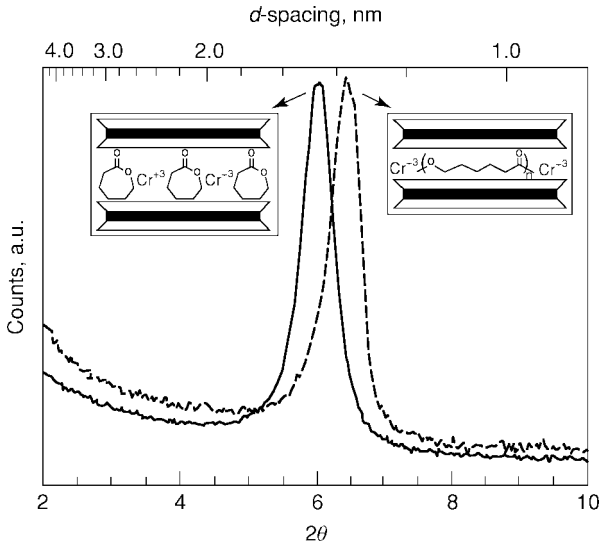

Fig. 11. Powder XRD patterns of ε-caprolactone–fluorohectorite nanocomposite before (solid line) and after (dashed line) polymerization. cases, the delamination is often observed leading to delaminated (or exfoliated) nanocomposites, especially in the field of aluminosilicates (see NANOCOMPOSITES, POLYMER-CLAY).

In this article, a great number of synthetic pathways leading to polymer-layered nanocomposites have been reported. The structure and the original properties of these new materials were greatly investigated, in particular from the viewpoint of their ionic or electron conductivity and their thermal stability. Nevertheless, only a small part of these works were focused on the study of the polymerization mechanisms at work and/or on the thorough analysis of the stereoregularity and the skeletal structure of intercalated macromolecules. So, a lot of research remains to be carried out in order to fully understand these factors and to prove that such routes are of industrial interest for the synthesis of well-defined polymers.

INTERPENETRATING POLYMER NETWORKS

Introduction

An *interpenetrating polymer network*, IPN, is defined as a combination of two polymers in network form, at least one of which is synthesized and/or cross-linked in the immediate presence of the other (1). An IPN is distinguished from other multipolymer combinations such as Polymer Blends (qv), blocks, and grafts in two ways: (*1*) An IPN swells, but does not dissolve in solvents; and (*2*) creep and flow are suppressed (see BLOCK COPOLYMERS; GRAFT COPOLYMERS).

The above represents the classical definition of an IPN. The term *interpenetrating polymer network* was coined before the extent or consequences of phase separation were fully realized. This article covers sequential and simultaneous types of IPNs made in bulk and also includes such materials as IPNs based on latexes and suspension-sized particles; thermoplastic IPNs, which contain physical cross-links in one or both polymers, and hence may be (partly) soluble; and a number of other closely related materials.

Some applications of IPNs of note include sound and vibration damping, biomedical applications, natural products and renewable resources, tough and impact-resistant materials, etc. IPN review articles include those by Sperling and Hu (2), Lipatov (3), and Athawale and co-workers (4). There are also papers of note by Srivastava and co-workers (5), and edited books by Klempner and co-workers (6), and Kim and Sperling (7). Two older books review early references, and develop the concepts of IPNs (1,8).

Nomenclature. The IPNs have a well-developed nomenclature (9), as do most multicomponent polymeric materials (10). Thus, a cross-linked polymer network is indicated by the prefix *net-*, and an IPN is indicated by the connective *-ipn-*. Thus, an IPN of polybutadiene and polystyrene is written as

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

(*net*-polybutadiene)-*ipn*-(*net*-polystyrene)

and if copolymers and/or two-worded mer structures are needed, brackets are employed:

{*net*-poly(styrene-*stat*-butadiene)}-*ipn*-{*net*-poly(ethyl acrylate)}

Synthesis and Structure of IPN and SIN Materials

Figure 1 models the structure of interpenetrating polymer networks and related materials. Solid and dotted lines indicate polymer 1 and polymer 2, respectively. The dots indicate cross-links. Structure a indicates a polymer blend, where the two polymers are mixed, but not bonded together anywhere. Structure b indicates a graft copolymer (qv), where polymer 2 is bonded along the side of polymer 1. Structure c indicates a block copolymer (qv), where polymers 1 and 2 are bonded end-on-end. These three structures are all thermoplastic, in that, not being cross-linked, they flow if heated above their glass transition and/or melting temperatures.

Structure d illustrates an AB–cross-linked copolymer. In this case, polymers 1 and 2 are bonded to each other. Structure e indicates an IPN, sometimes called a

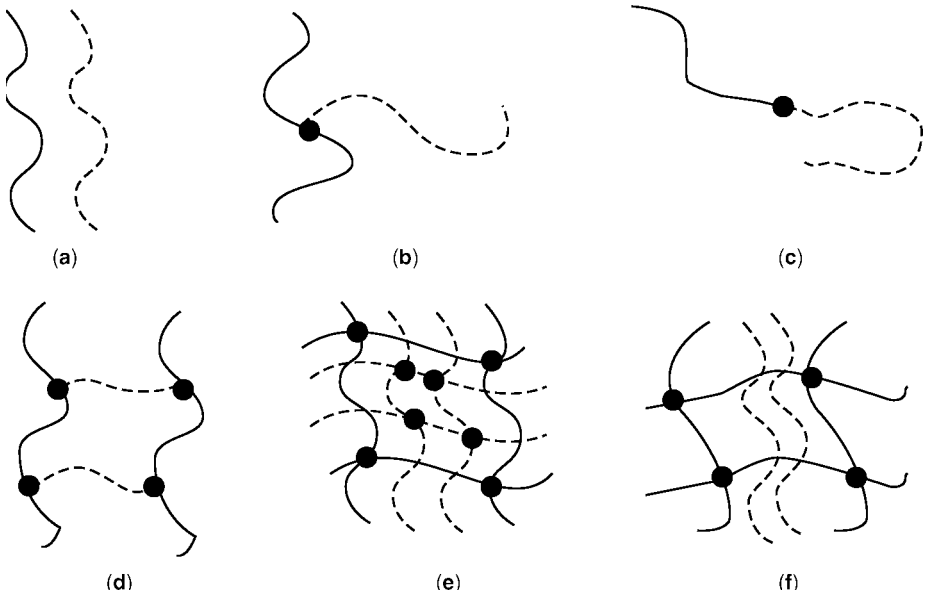

Fig. 1. Six basic combinations of two polymers, represented by solid and dashed lines, respectively, and the dots representing covalent bonds. (**a**) A polymer blend, with no bonding between the chains; (**b**) a graft copolymer, with the dashed polymer bonded to the side of the solid line polymer; (**c**) a block copolymer, where the chains are bonded end-on-end; (**d**) an AB-cross-linked copolymer, where one polymer is bonded to the other, but not to itself; (**e**) an interpenetrating polymer network of two cross-linked polymers; (**f**) a semi-interpenetrating polymer network, where only one of the polymers is cross-linked.

full IPN, where both polymers are cross-linked. Structure f illustrates a semi-IPN, where one polymer, but not both, are cross-linked. These last three structures are all thermoset, because at least one polymer network pervades the entire material. Thus, they will not flow on heating.

Of course, one may imagine many related structures and/or more complex topologies. By simple analogy, three or more polymers may coexist in any one of the topologies of Figure 1. Some quite different materials include the polyrotaxanes, where rings encircle a polymer chain (11); catenanes (12), where a series of rings form a chain (13); and dendrimers. These latter are hyperbranched, fractal-like structures emanating from a central core and containing a large number of terminal groups (14) (see DENDRONIZED POLYMERS). Noting that the polyrotaxanes, catenanes, and dendrimers are usually one-phase polymers, their behavior is quite different from that of any of the structures shown in Figure 1.

Figure 2 (15) outlines the two basic methods of IPN synthesis. In Figure 2, the boxes indicate monomers, the X's indicate cross-links, and the subscripts indicate whether it goes to make up polymer 1 or polymer 2. As in Figure 1, the lines indicate the polymers and the dots indicate cross-links. The P_1 and P_2 above the arrows indicate polymerization of polymer 1 and polymer 2, respectively.

The general procedure to synthesize a sequential IPN calls for mixing monomer 1 and cross-linker 1 and polymerizing to form network 1. Then, monomer 2 and cross-linker 2 are swollen in, and polymerized *in situ*.

A simultaneous interpenetrating network, SIN, as the name suggests, starts with a mix of both monomers and both polymers. These are polymerized simultaneously, but by different routes, such as chain and step polymerization. Thus, while reacting, the two polymers do not interfere with each other, but merely dilute

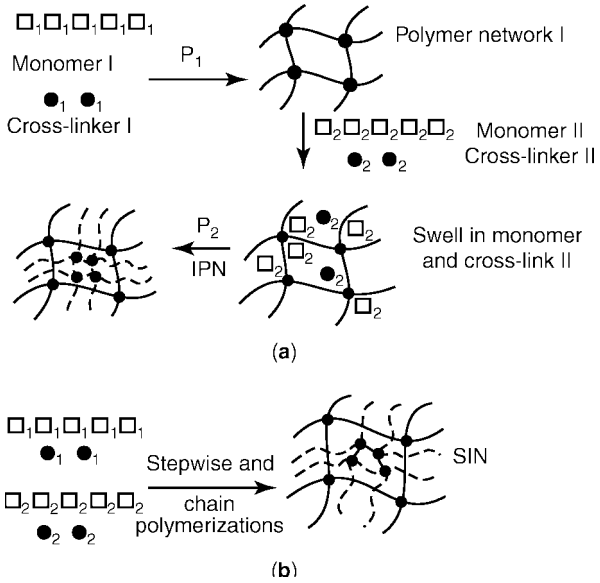

Fig. 2. Two basic synthetic methods of preparing IPNs, sequentially and simultaneously. (**a**) Sequential IPNs; (**b**) simultaneous interpenetrating network (SIN).

each other. Of course, the rates of the two reactions need not be equal. As explored below, if one polymer or the other reacts faster, different morphologies may result, with concomitant different physical and mechanical behavior patterns.

Besides sequential and simultaneous IPN synthetic methods, there are several other methods of preparation:

Latex IPNs. The polymers are made via emulsion polymerization, each particle constituting a micro-IPN. Frequently, one monomer and cross-linker are polymerized, followed by addition of a second monomer and cross-linker, which is also polymerized. Depending on the rates of monomer addition relative to the rates of polymerization, various degrees of interpenetrating and/or core-shell morphologies may result.

Gradient IPNs. The overall composition and/or cross-link density of the material varies from location to location on the macroscopic scale. One way of preparing these materials involves partial swelling of the first polymer network by the second monomer mix, followed by rapid polymerization before diffusional equilibrium takes place.

Thermoplastic IPNs. These materials utilize physical cross-links rather than chemical cross-links. Thus, the materials may be made to flow at elevated temperatures. As such, they are hybrids between polymer blends and IPNs. Such cross-links may involve block copolymers, ionomers, and/or semicrystallinity.

Semi-IPN. As illustrated in Figure 1**f**, a semi-IPN is composed of a cross-linked polymer and a linear polymer. If one is making a sequential synthesis, the terminology semi-I and semi-II IPNs refers to having the first or second polymer cross-linked, respectively.

Homo-IPNs. These materials consist of two networks prepared from substantially the same cross-linked polymer.

Special Considerations in IPN and SIN Synthesis. Most of the IPNs and SINs made to date rely on chain and/or step polymerization, although other methods, such as anionic polymerization, have been occasionally employed. Of course, appropriate cross-linkers, initiators, and so forth must be added.

For very many IPN and SIN syntheses, except for phase separation aspects, the interaction between the two materials during polymerization has often been ignored. However, to greater or lesser extents in real systems, of course, there is some interaction. A few examples are helpful:

(1) In sequential IPNs, if polymer I is based on a diene, and monomer II (such as styrene) is polymerized *via* free-radical polymerization, some grafting will occur. Of course, this grafting is important for interfacial bonding in such related materials as high impact polystyrene (HIPS) and acrylonitrile–butadiene–styrene (ABS) materials.

(2) If polymer I is an acrylic, the labile hydrogen may be abstracted, providing another type of grafting site.

(3) In a SIN polymerization, the high viscosity of one of the polymers, or its lack of high viscosity as a slow-polymerizing component, may alter the phase morphology or other features.

(4) Vitrification of one of the polymers may slow or stop the polymerization of the other component.

Some specific investigations of the chemical interactions include the following:

Tabka and Widmaier (16,17) undertook the study of the interactions of azo-bis(isobutyronitrile) (AIBN), free-radical initiators with stannous and stannic organotin polyurethane catalysts. These workers found a synergistic effect of stannous octoate on the AIBN on the radical polymerization (qv) of methyl methacrylate, increasing the reaction rate and shortening the gelation time. While there was a severe deactivation of the tin(II) atom by the AIBN, there was no measurable effect using organotin(IV) stannic catalysts.

Michal'chuk and co-workers (18) investigated the changes in mobility during formation on the basis of epoxy and allylic oligomers. Using pulse NMR spectroscopy, these workers concluded that SIN formation results in mutual hindrances to the full conversion of the reactive groups, and a concomitant increase in the number of defects in the IPNs. This results in greater molecular mobility in the final materials than might otherwise be expected.

Polymer Blend and IPN Classification Scheme. Of course, all of the various compositions of matter composed of two polymers are related to each other. Figure 3 (19) illustrates how the major kinds of polymeric materials based on two kinds of mers are related to each other. The IPNs are shown here under the *occasional grafts* heading, because many of the preparations have a few grafts between the two polymers as a consequence of free-radical chemistry, etc. Since one network of these materials is always polymerized in the presence of the other

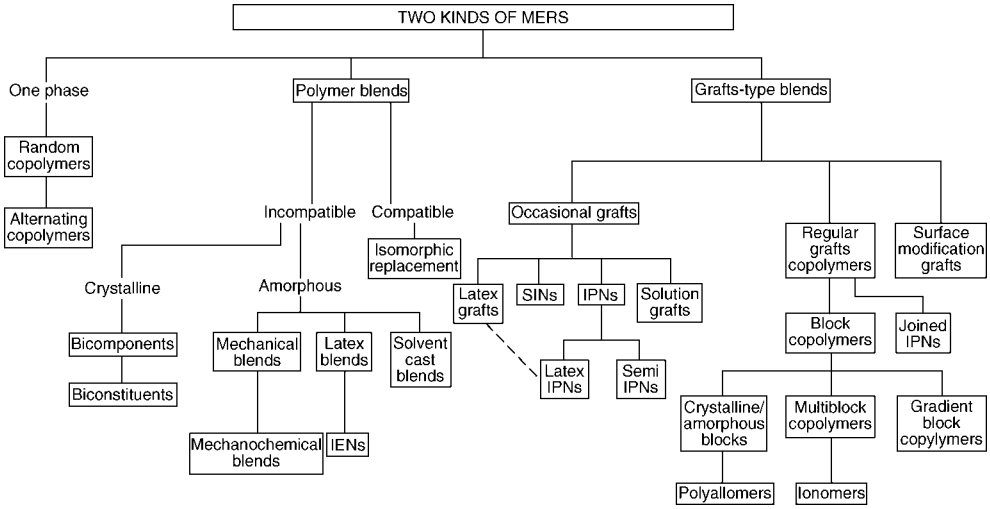

Fig. 3. A polymer blend classification scheme.

network, some grafting is hard to avoid, and in many cases is desired. However, an IPN (or SIN) can be distinguished from a graft copolymer (qv) because the morphology (qv) and mechanical behavior are primarily controlled by the cross-links rather than the grafts.

IPN Morphology and Physical Behavior

Most compositions of matter made up of two polymers (see Fig. 1) exhibit some degree of phase separation. This is caused by the very small entropy of mixing two high molecular weight materials, and the very frequent positive heat of mixing of two different chemical structures. In simple polymer blends (qv), the mixing tends to be relatively coarse, although many routes to complex and relatively finely divided morphologies have been developed. Block copolymers (qv) domain sizes are largely controlled by the molecular weight of the individual blocks, and the domain shape by the relative proportions of the two blocks (20,21).

Electron Microscopy Studies. In sequential IPNs and semi-IPNs, the size and shape of the polymer II domains are controlled by the cross-link density of polymer I and the relative proportions of the two polymers. Figure 4 illustrates

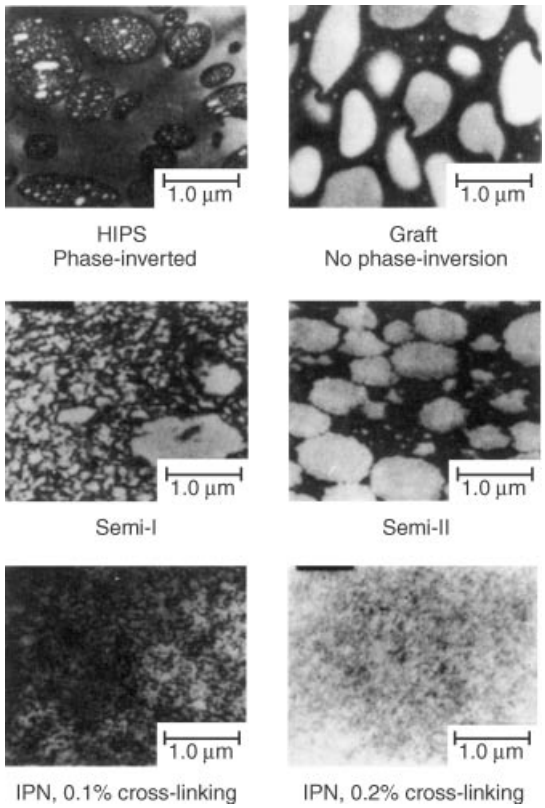

Fig. 4. Transmission electron microscopy of OsO_4-stained polybutadiene and polystyrene (white) combinations.

the two-phased morphology of IPNs, semi-IPNs, and polymer blends prepared from styrene-butadiene copolymers (qv) (SBR) and polystyrene (22) (see STYRENE POLYMERS). The double bonds in the butadiene polymers (qv) are stained dark with osmium tetroxide. In this series of transmission electron micrographs, the samples are sliced to about 60 nm thickness, sometimes called *salami slices*.

The upper left photo in Figure 4 is of HIPS, a material known for its toughness (23). This material is a type of polymer blend made by dissolving polybutadiene or SBR in styrene monomer, and polymerizing *with stirring*. The SBR is first soluble in the styrene monomer, but phase separates after a few percent conversion. Part of HIPS toughness comes from having grafts between the polybutadiene and the polystyrene, and part of the toughness comes from a phase-within-a-phase-within-a-phase morphology (24). Shortly after polymerization is initiated, the growing quantity of polystyrene makes the SBR insoluble in the mix. At first, the SBR phase is the continuous phase. On continued polymerization, the growing volume and increasing viscosity of the polystyrene-rich phase causes a phase inversion, helped by the stirring.

Of course, the styrene within the polybutadiene droplets is also polymerizing, but cannot get out. It forms a very fine structure, also visible in the upper left photo of Figure 4.

HIPS gets its toughness in part from this fine structure, and in part from the grafting that takes place between the SBR and the polystyrene, increasing the interfacial bond strength. (Commercially, block copolymers of polybutadiene and polystyrene are often added to further increase the interfacial bond strength.)

The upper right photo has substantially the same composition as that in the upper left, but was made without stirring. This material was first made in 1927 (25). It did not undergo phase inversion, and hence the SBR remains the continuous phase. This material is adhesive in nature, but not commercial.

The corresponding sequential IPN morphology of the same overall composition is shown in the lower left photo. In this case, a sheet of SBR was cross-linked, followed by swelling in styrene plus divinyl benzene and polymerizing *in situ*. The phase domains are of the order of 100 nm, with both phases exhibiting co-continuity. An increased cross-link level for the SBR results in a finer phase domain structure, as shown in the lower right of Figure 4.

The two semi-IPNs are shown in the middle left and right photos of Figure 4. The semi-I IPN resembles the full IPN, but the morphology is coarser. The semi-II IPN resembles the upper right morphology. Of significant interest here was that the HIPS exhibited a toughness value of about 80 J/m (1.5 ft·lb/in.) of notch, while the middle left had about 160 J/m (3.0 ft·lb/in.), and the lower left had about 267 J/m (5.0 ft·lb/in.) of notch.

The development of the morphology in both the HIPS-type material and the IPNs requires several steps (see Fig. 5) (26). The original polymer I swollen with monomer II solution first has one phase. After a few percent of polymerization, it phase separates via nucleation and growth kinetics. This tends to produce spheroidal-shaped particles, the white material in Figure 5**a**. (Super-saturated salt solutions often follow nucleation and growth phase separation kinetics.) On further polymerization, the phase separation kinetics follows spinodal decomposition, leading to interconnected cylinders (Fig. 5**b**) (27–29). Close examination of both the HIPS and IPN morphologies strongly suggests that spinodal

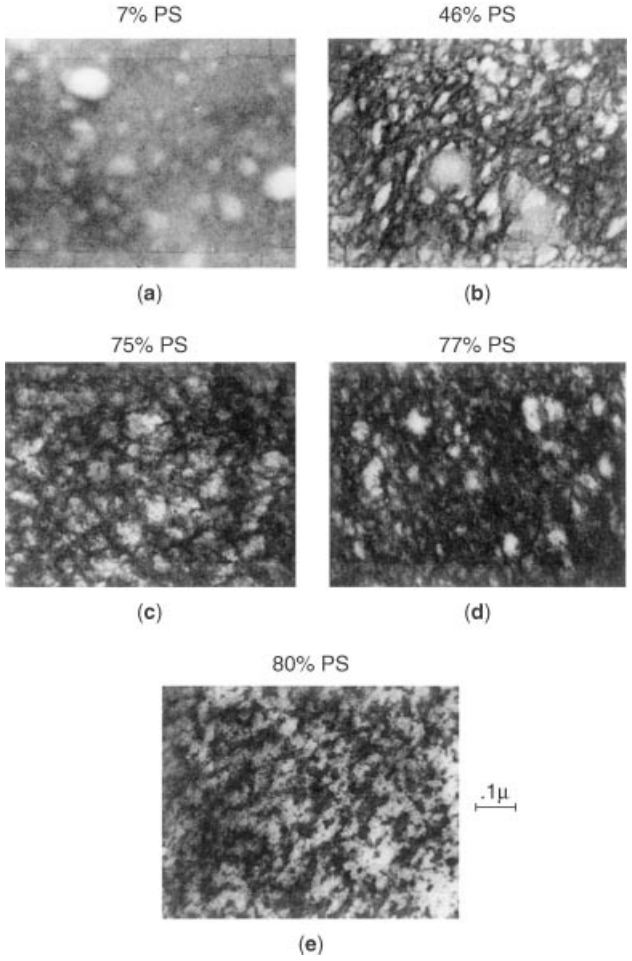

Fig. 5. Transmission electron microscopy of the polymerization of substantially the same composition as shown in the lower left portion of Figure 4.

decomposition plays a strong role in the final morphology of these materials. (Note that a thin section of a cylinder cut at an angle looks like an ellipsoid.) Figures 5**c**, 5**d**, and 5**e** have something of an appearance of a snowstorm, because the continued cross-linking limits phase separation.

Thus, as illustrated in Figure 6, the initial mix first has one phase, then undergoes a region of nucleation and growth. Then, the composition enters the spinodal decomposition region, arriving at the final morphology. Note that if phase separation is more or less complete, the final composition will be a mix of nearly pure polymer I and polymer II, with the final composition being an average.

Phase diagrams of IPNs have also been researched. Sophia and co-workers (30) found that the phase diagram of a semi-IPN indicates a lower critical solution temperature for these materials (Fig. 7), similar to that of polymer blends. Seemingly strange, these materials are more mutually soluble at lower temperatures than at higher temperatures, a consequence of their low entropy of mixing.

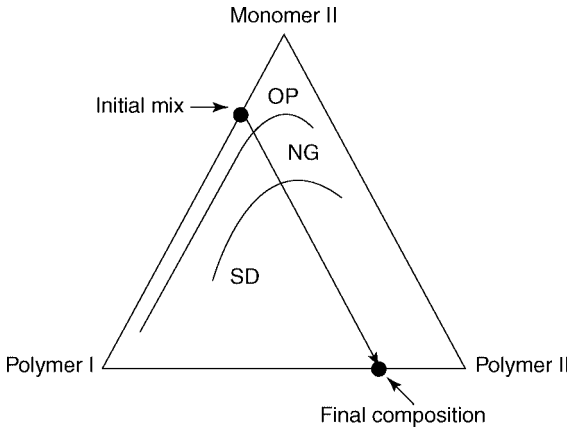

Fig. 6. A generalized phase diagram for the polymerization shown in Figure 5. OP = One phase, NG = nucleation and growth, and SD = spinodal decomposition.

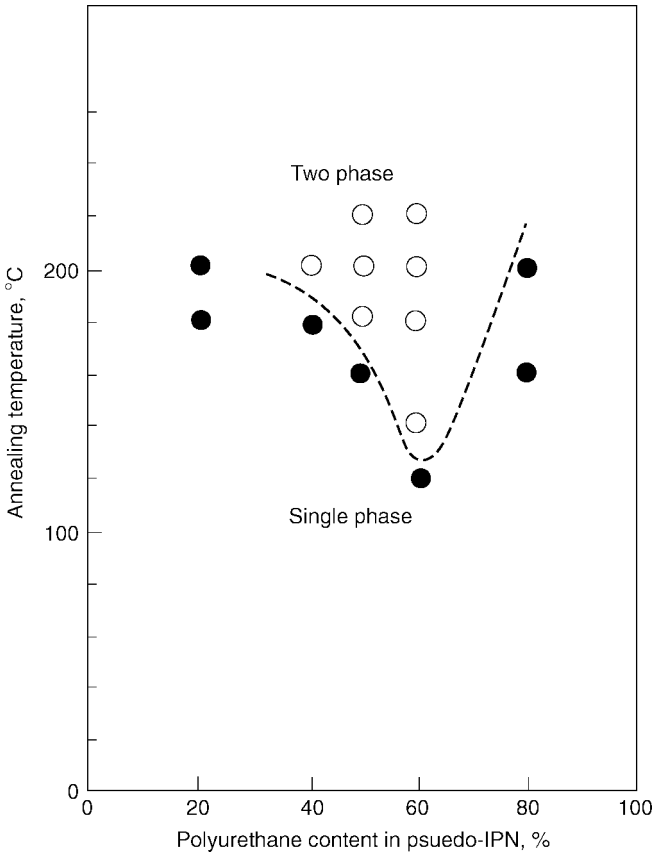

Fig. 7. A phase diagram of a polyurethane–poly(vinyl chloride) semi-IPN, showing a lower critical solution temperature.

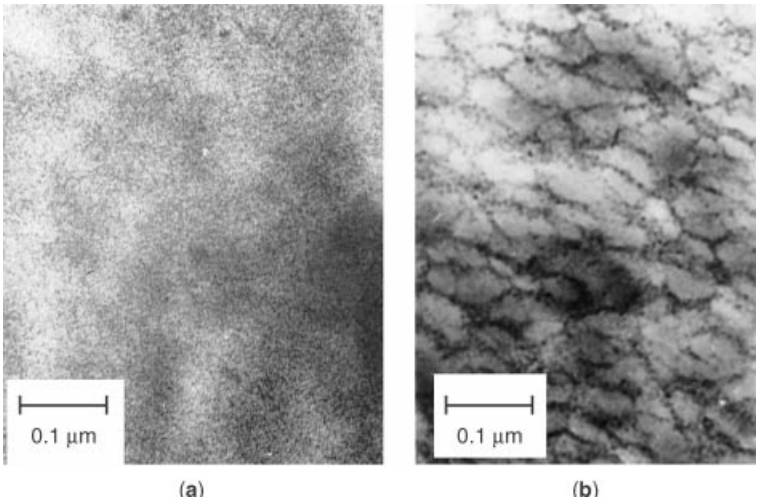

Fig. 8. A comparison of two possible morphologies of IPNs, based on (**a**) {poly(ethyl acrylate)}-*ipn*-{poly(methyl methacrylate)} and (**b**) {poly(ethyl acrylate)}-*ipn*-polystyrene.

The relative miscibility (qv) of the two polymers in IPNs is controlled not only by the thermodynamics of mixing, but to some extend also by the cross-link density and exact method of preparation. Huelck and co-workers (31) learned that while IPNs of poly(ethyl acrylate) and polystyrene exhibited two distinct glass transitions (qv) and two observable phases via transmission electron microscopy, the corresponding {*net*-poly(ethyl acrylate)}-*ipn*-{*net*-poly(methyl methacrylate)} compositions, being isomeric, had a microheterogeneous morphology (see Fig. 8).

Ma and Tang (32) showed that increasing cross-link density of SINs of poly(*n*-butyl acrylate) and epoxy 10:90 compositions tends to increase molecular interpenetration, and thus entanglement between the two networks.

Glass-Transition Behavior. Sánchez and co-workers (33) studied the system {*net*-poly(methyl acrylate)}-*ipn*-{*net*-poly(methyl methacrylate)}, which is not chemically isomeric, but close to being so. They varied the cross-linking level of both polymers of these sequential IPNs. When the poly(methyl acrylate) was cross-linked with 10% of ethylene glycol dimethacrylate (EGDMA), dynamic mechanical studies on midrange compositions showed that the system had a single glass transition, showing it to be substantially miscible (see Fig. 9) (33). The poly(methyl acrylate) network was polymerized first with 0.1% (open circles), 0.5% (squares), and 10% (triangles). In each case, the PMMA network contained 10% EGDMA.

It must be noted that this apparent miscibility is only mechanical in nature, a product of the high cross-link level of a sequential IPN. Sánchez and co-workers (33) note that the key factor controlling the apparent miscibility in sequential IPNs is the cross-linking density of the network polymerized first.

In related work, Dueñas and co-workers (34) found a similar effect with the system poly(butyl acrylate) and poly(butyl methacrylate). At 10% cross-linking level, the forced miscibility was sufficient to allow the glass transitions of the IPNs to follow the Fox equation (35).

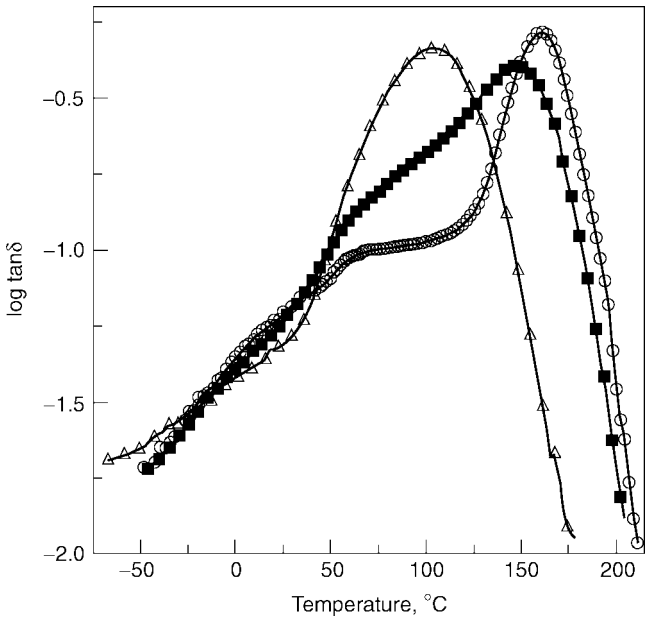

Fig. 9. Sequential IPNs of poly(methyl acrylate) and poly(methyl methacrylate) as a function of cross-linking level with EGDMA.

In block copolymers composed of random-coiled polymers, the molecular weight of the blocks and their relative proportions controls the domain size and shape (36,37). A somewhat similar relationship exists in IPN.

Domain Size Theory. Assuming spherical domains, Yeo and co-workers (38) derived equations for the domain size in sequential IPNs. The domain diameter of polymer II, D_{II}, was related to the interfacial tension γ, the absolute temperature T times the gas constant R, and the concentration of effective network chains, c_I and c_{II}, occupying volume fractions v_I and v_{II}, respectively:

$$D_{II} = \frac{4\gamma}{RT(Ac_I + Bc_{II})} \tag{1}$$

where

$$A = \frac{1}{2v_{II}}\left(3v_I^{1/3} - 3v_I^{4/3} - v_I \ln v_I\right) \tag{1a}$$

and

$$B = \frac{1}{2}\left(\ln v_{II} - 3v_{II}^{2/3} + 3\right) \tag{1b}$$

The quantity γ is experimentally determined from the work to create a unit interface. For many polymer/polymer interfaces, the value is in the range of 20–60 J/μm^2 (39). Although equation 1 was derived for spheres, it yields a reasonable estimation of the cylindrical diameter of spinodally phase-separated IPNs.

Phase Continuity in Sequential IPNs. The question has been repeatedly raised: Do IPN morphologies really exhibit dual phase continuity? Evidence for dual phase continuity in sequential IPNs was examined by Widmaier and Sperling (40,41). A series of sequential IPNs were prepared from poly(*n*-butyl acrylate) and polystyrene. Two cross-linkers were used, divinyl benzene (DVB), which forms ordinary covalent cross-links, and acrylic anhydride (AA), which forms labile cross-links. The AA cross-links were cut by soaking the samples in a 10% aqueous ammonium hydroxide solution for about 12 hours.

Some of the samples had the AA cross-links in the acrylic component and some of them had it in the styrenic component. After de–cross-linking one component or the other, the materials were subjected to a Soxhlet extractor. The remaining materials were examined by scanning electron microscopy. The density of the remaining material was also determined.

For both types, nearly the whole amount of de–cross-linked polymer could be extraced, indicating a low level of chemical grafting between the two polymers, and/or little entrapped material. When polymer II (polystyrene) was de–cross-linked and extracted, one still recovered polymer I (the acrylic) without substantial damage as shown by its density, equilibrium swelling degree, and scanning electron micrographs.

When polymer network I was de–cross-linked and extracted, the remaining network II presented a porous structure as indicated by reduced density and scanning electron microscopy. The void regions, corresponding to the location of the poly(*n*-butyl acrylate) before extraction, appeared interconnected. However, the extent of continuity of polymer II depended on its concentration. For midrange compositions, there was good evidence for dual phase continuity. However, when the amount of polymer II was decreased below 30%, the sample crumbled by itself, indicating a macroscopically discontinuous second phase. At a microscopic level, though, some degree of connectivity could still be detected. In summary, greater than 20–30% of polymer network II, its phase domain structure was continuous. Throughout the composition range studied, polymer network I was continuous.

The foregoing finding was important especially in the light of transmission electron micrograph studies, resulting in thin salami slices of osmium tetroxide stained samples. The observation of polymer network II could be interpreted as spherical domains in many such cases, but suggestive of ellipsoidal structures in others. The above discussion leads to the conclusion that the spherical and/or ellipsoidal structures, being two-dimensional, are better interpreted as interconnecting structures containing spheroidal and other morphologies (26,42). The modulus evidence for dual phase continuity will be presented below.

Modulus vs Composition. The modulus of IPNs as a function of composition yields information about their relative phase continuity. The first such study on polyacrylate/polyurethane latex interpenetrating elastomeric networks (IENs) was carried out by Matsuo and co-workers (Fig. 7) (43). Note that in the midrange of composition, the modulus begins to follow the parallel Takayanagi model (44). This suggests that the stiffer acrylic phase is becoming a continuous phase, as predicted from percolation models of three-dimensional mosaics of compressed spheroidal structures.

Yeo and co-workers (Fig. 10) (45) compared several models of phase continuity with the behavior of {*net*-poly(butyl acrylate)}-*ipn*-(*net*-polystyrene). The

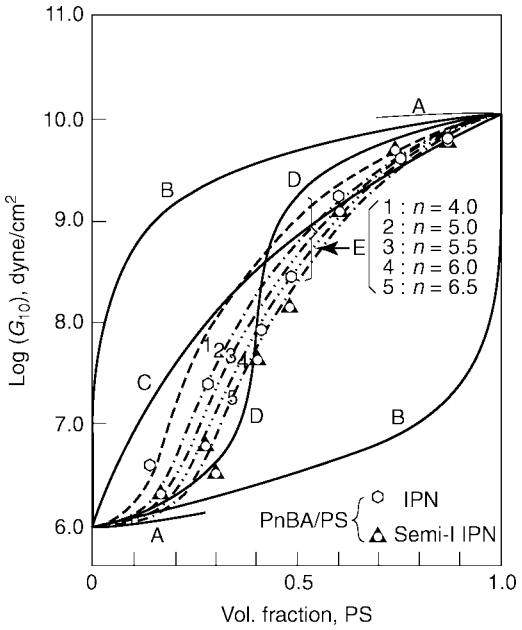

Fig. 10. Sequential IPNs of poly(butyl acrylate) and polystyrene as a function of composition. **A**: Upper–Lower Bound Model; **B**: Hashin–Shtrikman Model; **C**: Davies Model; **D**: Budiansky Model; and **E**: Coran–Patel Model. dyne/cm^2 = 0.1 Pa.

S-shaped curve has the greatest slope near the 50/50 composition. The Budiansky model (46,47) was the only model to follow the S-shaped curve.

Ramis and co-workers (48) made a similar study of SINs prepared from unsaturated polyester–styrene mixes with MDI-poly(propylene glycol). When the storage modulus, E', was plotted through a range of compositions, the Budiansky equation (47) was again found to fit better than several other relationships.

Phase Separation and Gelation Studies. A phase diagram of linear poly(ethylene oxide) (LPEO) and divinyl benzene (DVB) cross-linked poly(methyl methacrylate) as a function of polymerization of the latter was also researched by duPrez and co-workers (49) (Fig. 11). The temperature of measurement was also a variable, but the curve separating the one-phased system from the two-phased system did not change much in the narrow temperature range covered.

A time–temperature-transformation (TTT) diagram (50,51) study on a poly(ether sulfone)-*ipn-net*-epoxy semi-II IPN was carried out by Kim and coworkers (Fig. 12) (52). Note the several regions delineated by the progressive polymerization and cross-linking of the epoxy. Several steps in the transformation during polymerization were identified:

(1) Onset of phase separation
(2) Gelation of the epoxy
(3) Fixation of the phase-separated morphology
(4) End of phase separation
(5) Vitrification (glass forming) of the epoxy phase.

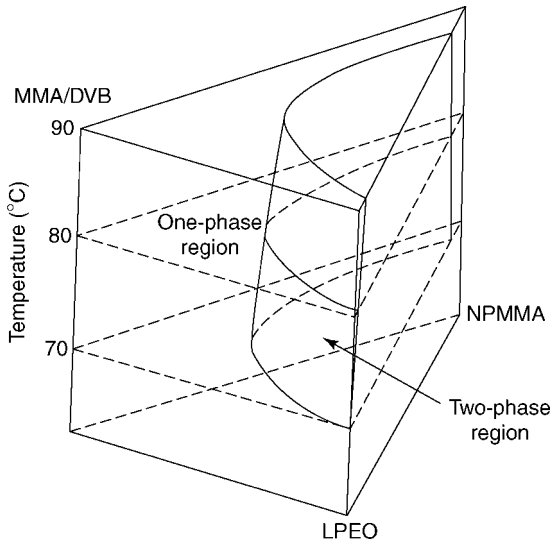

Fig. 11. A ternary phase diagram of the semi-IPN based on methyl methacrylate, poly(methyl methacrylate), and linear poly(ethylene oxide).

These workers also found that the lower critical solution temperature for the material was at 265°C.

The development of SINs requires three steps: gelation of polymer I, gelation of polymer 2, and phase separation of 1 from 2. Since these three events may occur

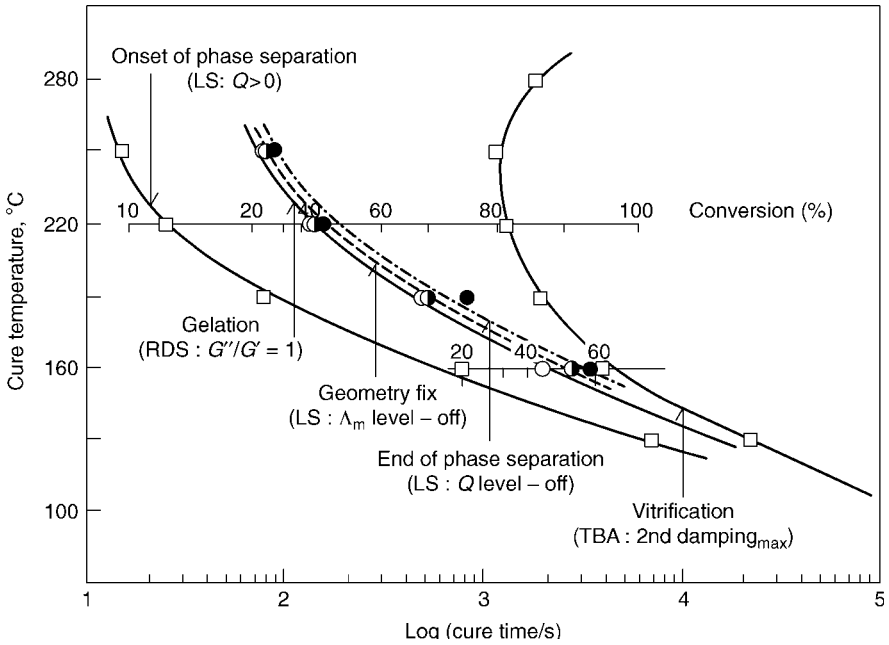

Fig. 12. A time–temperature-transformation (TTT) cure diagram for the system poly(ether sulfone)-*ipn*-epoxy.

in any order depending on concentration, cross-linker level, initiator, temperature, etc, there are 3! = 6 different morphologies and physical behavior patterns that may be observed.

This led to the development of a series of metastable phase diagrams for (*net*-polyurethane)-*ipn*-{poly(methyl methacrylate)} SINs (see Figs. 13 and 14) (53). The term *metastable* derived from the realization that none of the IPNs or SINs are truly at thermodynamic equilibrium relative to phase separation. Two figures were utilized to illustrate the phenomena more clearly. Since both monomers and both polymers needed to be represented, a tetrahedron structure was utilized, where the four pure components occupy the four vertices. The four triangular faces of both figures represent the ternary systems delineated by the compositions indicated in the vertices. Since the methyl methacrylate mix contained 0.5% tetraethylene glycol dimethacrylate as a cross-linker, it gelled after about 8% conversion, indicated by the G_1-U-PU plane in Figure 13. The phase separation curve for the ternary system MMA-PMMA-"U" on polymerization of only the methyl methacrylate is indicated by the points C-D-A-E. In a similar fashion, the phase separation curve for the MMA-PMMA-PU system, rear triangle in Figure 13, is shown by the points J-B-K-L. The entire tetrahedron volume is divided into two regions: one phase-separated and the other single-phased, separated by C-D-A-E-L-K-B-J. Tracing the sail-like characteristics of this surface aids in following the separation of the two regions of space. The curvilinear line A-B indicates the intersection of the PMMA gelation plane with that of the phase

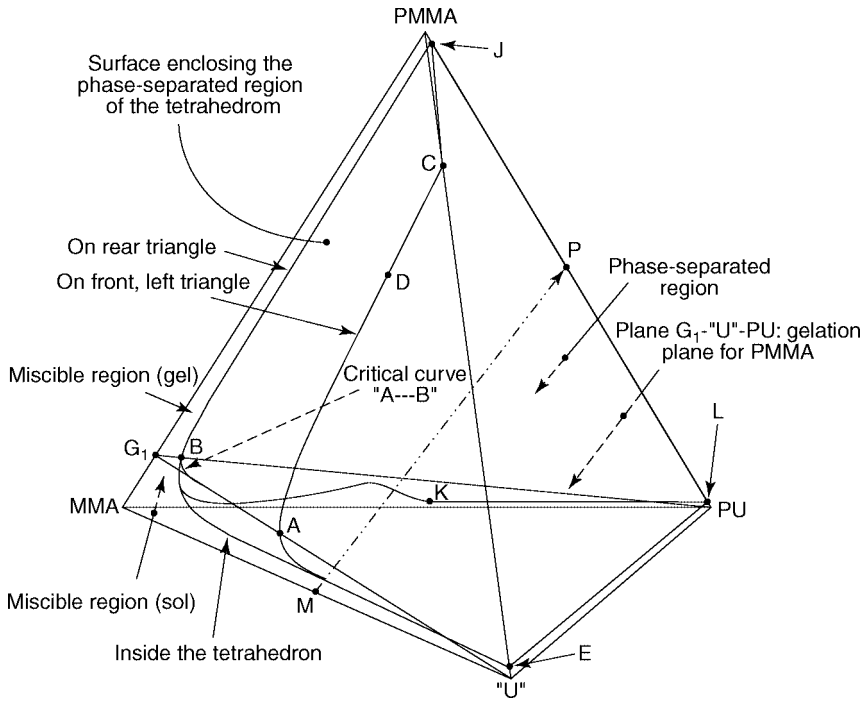

Fig. 13. A tetrahedron metastable phase diagram for the SIN polymerization of poly(methyl methacrylate) and polyurethane.

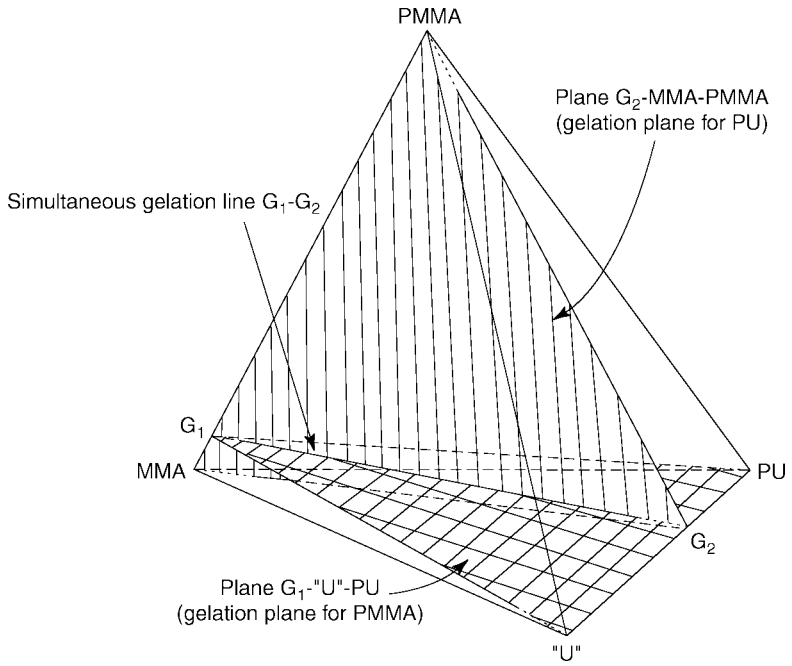

Fig. 14. Continuation of Figure 13, illustrating the gelation planes of both the poly(methyl methacrylate), G_1 and polyurethane, G_2.

separation sail-like surface. It represents the critical line along which there is simultaneous gelation of the PMMA and phase separation of the PU from that of the PMMA. Thus, reactions moving to the left of this curve will have the PMMA gel before phase separation, while reactions to the right of A-B phase separation before gelation.

Figure 14 illustrates the gelation plane of the polyurethane, G_2-MMA-PMMA, as well as the G_1 gelation plane of the PMMA (also shown in Figure 13). The intersection of the two planes, G_1-G_2, indicates the line of simultaneous gelation of both polymers. The line G_1-G_2 also intersects the line A-B of Figure 13, not shown. This intersection represent a triple critical point. Here, both polymers simultaneously gel and phase-separate. This defines an ideal SIN synthesis.

All SIN and IPN polymerizations must begin somewhere along the edge of the line MMA-"U", and end along the edge line PMMA-PU. However, the lines need not be straight or even single lines. When phase separation ensues, the line divides into two portions, ending at points J and L of Figure 13.

Since the polymerization rates can be controlled, and in general will not be equal, and the cross-linker levels independently control the gelation planes, all six possibilities of SIN morphologies can be envisioned. Also, as an extreme, a sequential IPN synthesis can also be traced on these figures. The semi-IPNs will clearly lack one of the gelation planes. A polymer blend polymerization will have only the phase separation curvilinear plane, without either gelation plane. Thus, Figures 13 and 14 provide a kind of map to determine how and why different morphologies and concomitant physical and mechanical behavior patterns emerge.

Of course, these maps serve as a guide to bring about specific morphologies and concomitant behavior profiles of the IPNs.

Following the work of Mishra and co-workers (53), Dean and co-workers (54,55) investigated the SIN syntheses of dimethacrylate- and epoxy-based materials by near-infrared and other methods. The rates and order of the polymerizations were systematically altered. The final conversion of the dimethacrylate was limited by the vitrification or topological restraint of the SIN. Whether one or two glass transitions are observed depends on the relative rates and order of the polymerizations.

Of course, the relative reaction rates of the two polymers in SINs may be controlled by the quantity of cross-linker, temperature, initiator level, concentration of the two monomers, level of light intensity, time and completeness of phase separation, etc. The above assumes that there is no interference between the two reactions, except for the mutual dilution effect.

Thermoplastic IPNs

Thermoplastic IPNs are hybrids between the polymer blends and the IPNs. Often, physical cross-links are used to bond the chains in one or both polymers. In other cases, one of the phases actually has chemical cross-links, but it constitutes a discontinuous phase so as to allow flow. In this latter case, the discontinuous case is often cylindrical in shape, highly elongated.

The most important commercial thermoplastic elastomers are based on polypropylene (PP) and ethylene–propylene–diene monomer (EPDM) elastomer (see ETHYLENE-PROPYLENE ELASTOMERS). The diene portion of the elastomer is cross-linked, frequently by dynamic vulcanization, ie, chemical cross-linking during melt shearing.

The PP/EPDM thermoplastic elastomer was modeled by Kresge (56) to show the morphology of the material after crystallization (see Fig. 15). To allow for extraction of the elastomer, he used EPM, lacking in chemical cross-linking. The PP clearly exhibits phase continuity, resembling an open-celled sponge with micron-sized porosity. Careful examination of the micrograph indicated that the voids were also continuous. (Otherwise, the EPM could not have been extracted.) Therefore, the material formed an interpenetrating two-phased structure. However, it is probable that the increase in viscosity of the EPDM phase, brought about by cross-linking, would reduce the continuity of the elastomer phase.

Coran and Patel (57) point out several examples of the improvements achieved:

(1) Reduced permanent set
(2) Greater ultimate mechanical strength
(3) Greater fatigue resistance
(4) Improved fluid resistance to hot oils
(5) Greater high-temperature stability
(6) Greater stability of the phase morphology in the melt; the phase domain size does not increase.

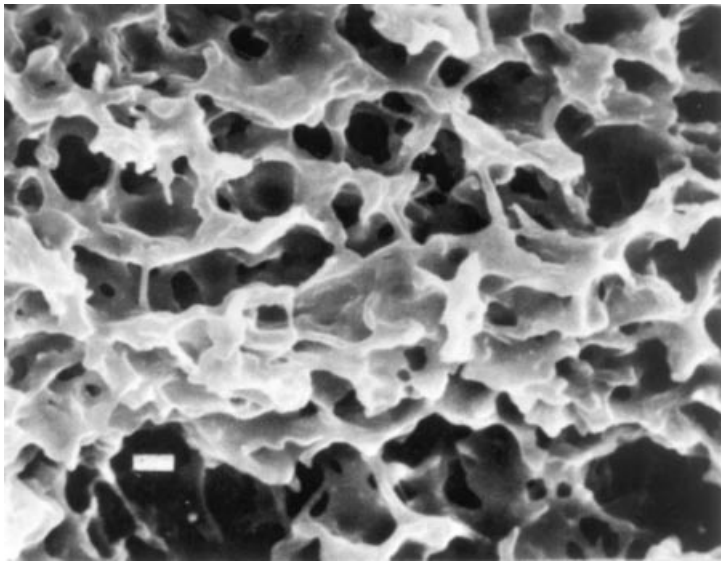

Fig. 15. A scanning electron micrograph of a model thermoplastic IPN based on a binary (70/30) blend of EPM and polypropylene. The EPM phase was removed, then the sample fractured under liquid nitrogen to illustrate the dual phase continuity of the material.

(7) Greater green strength, ie, greater melt strength
(8) More reliable fabricability

The PP/EPDM materials are most famous for being tough, energy-absorbing materials, which led them to be used as the plastic component of automotive bumpers.

Davison and Gergen prepared thermoplastic IPNs based on block copolymers and semicrystalline polymers (see Table 1) (58). Here, a hydrogenated version of the styrene–butadiene–styrene triblock copolymer was utilized, ie, SEBS, where the EB stands for ethylene-butylene (saturated 1,2-polymerized butadiene mers).

Table 1. Composition of Co-Continuous Interlocking Network Phases

	Composition by parts	
Component	A	B
25,000-100,000-25,000 SEBS	100	100
Poly(butylene terephthalate)	100	70
Shellflex 790 extending oil	100	–
Tuffto 6050 oil	–	50
Polypropylene	10	10
Irganox 1010 antioxidant	0.2	0.2
Dilaurothiodipropionate antioxidant	0.5	0.5
TiO_2	5	5

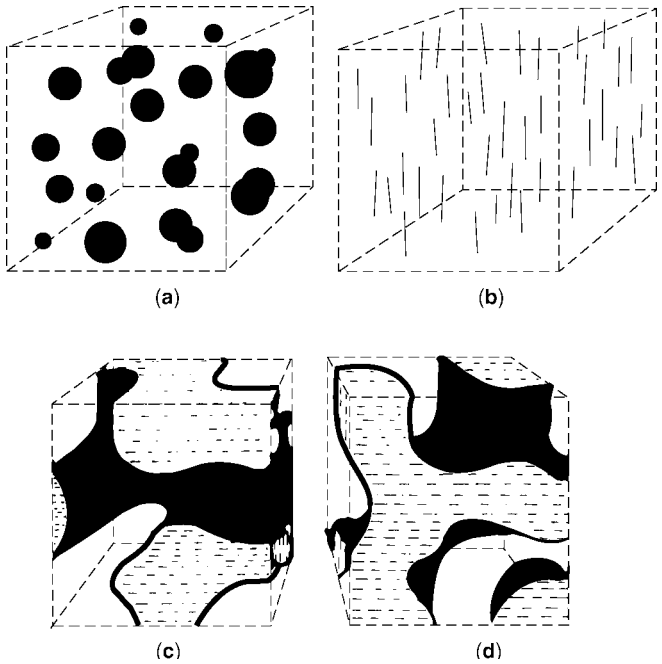

Fig. 16. Various morphologies illustrating the development of dual-phase continuity. (**a**) Dispersed sphere, clearly discontinuous in space; (**b**) dispersed fibers or cylinders. Figures (**c**) and (**d**) together illustrate dual-phase continuity, where both phases are interlocked in a kind of three-dimensional puzzle.

By blending these polymers, taking care to match melt viscosities and volume fractions (see eq. 2 below), dual-phase continuity can be achieved (see Fig. 16) (59). In Figure 16**a**, droplets of material are dispersed in a continuous matrix, a morphology observed in rubber-toughened plastics. Figure 16**b** illustrates dispersed fibers, observed in liquid crystal polymers and some thermoplastic elastomers. If the fibers or cylinders are infinitely long, they exhibit one-dimensional phase continuity.

Figures 16**c** and 16**d** constitute the important figures that model the materials in Table 1. These two figures together depict a co-continuous morphology, where the two phases are interlocked or interpenetrating. Note that three polymers are presented in Table 1. The major components are the SEBS and the poly(butylene terephthalate). The third polymer is the polypropylene, used as a compatibilizer. It appears at the interfaces between Figures 16**c** and 16**d**. Thus, *three* co-continuous phases are formed in this material! These materials are useful as under-the-hood electrical insulators because they have substantially constant modulus between the glass transition of the EB center block and the melting temperature of the poly(butylene terephthalate).

The requirements for both dual phase continuity and phase inversion for polymer blends and thermoplastic IPNs alike require the specification of the melt viscosity and the volume fraction of each component. Some melt shearing is assumed. These concepts were formulated quantitatively by Paul and Barlow (60)

and Jordhamo and co-workers (61):

$$\frac{V_1}{V_2} \times \frac{\eta_2}{\eta_1} = X \tag{2}$$

where if

$X > 1$, phase 1 is continuous
$X \approx 1$, dual phase continuity or phase inversion
$X < 1$, phase 2 is continuous

In equation 2, V represents the volume fraction and η represents the melt viscosity of phase 1 or 2, as per subscript. Equation 2 is true in the limiting case for zero shear. Utracki (62) proposed somewhat more complex relationships for finite shear rates.

However, in many experimental and industrial situations, equation 2 provides a reasonable approximation, as reviewed by Jordhamo and co-workers (see Fig. 17) (61). Note especially the dual phase continuity region in Figure 17. If the shearing action is stopped while the composition is within this region, it may remain dual phase continuous. Here, the phase continuity of a number of materials was examined and plotted. It must be noted that dual-phase continuity and/or phase inversion took place over about a factor of 4 in the data. Thus, some aspect of dual phase continuity exists via equation 2 as X varies from about 0.5 to about 2.

Thermoplastic IPN technology was also explored by Han and co-workers (63). In this case, thermoplastic IPNs based on polypropylene (PP) and EPDM were prepared using supercritical solution technology. Propane was used as the supercritical fluid. The synthesis steps were as follows:

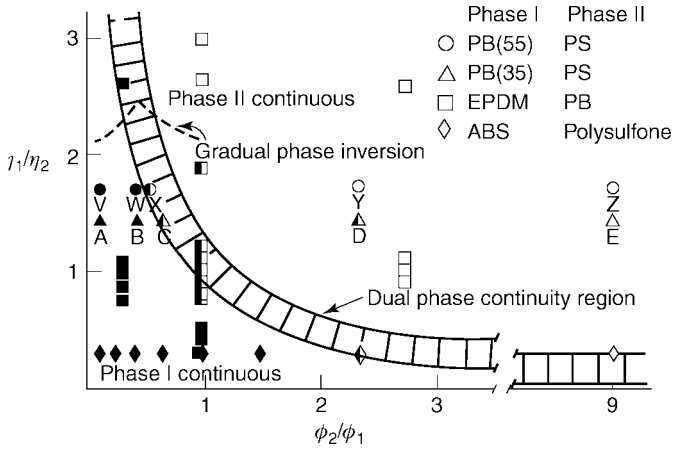

Fig. 17. Phase continuity and inversion diagram for polymer blends and IPNs during polymerization and under shear.

(1) PP and EPDM were dissolved in propane; a homogeneous solution was formed.
(2) *t*-Butyl peroxide was injected.
(3) EPDM was cross-linked for one hour at 175°C and 65 MPa.
(4) The polymers could be precipitated by two independent methods:
    a. Reducing the pressure below the cloud point, followed by lowering the temperature; or
    b. Isobaric cooling to ambient temperature, then reducing the pressure.
(5) Residual solvent was vented.
(6) Dried thermoplastic IPN was recovered.

The morphologies using the 4a route were fibrous in nature (64); those utilizing route 4b resulted in a porous spheroidal structure for the PP phase (65). In all cases, the morphology was significantly finer than that available with the then commercial routes of preparing PP/EPDM thermoplastic IPNs.

Siegfried and co-workers (66,67) investigated thermoplastic IPNs based on SEBS triblock copolymers with a polystyrene ionomer. Two subclasses of thermoplastic IPNs were identified: those prepared by a sequential polymerization method, and those prepared by mechanically blending separately synthesized polymers. In each case, a polystyrene acid sulfate was neutralized dynamically in the melt with a concentrated solution of sodium hydroxide. The water steamed off rapidly under the reaction conditions. The first subclass resulted in lower melt viscosities, but more nearly equal dual-phase continuity was achieved with the second subclass. The subject of thermoplastic IPNs was recently reviewed by Sperling (68).

Latex IPNs

Latex IPNs, by definition, have their origin in emulsion polymerization. Several types of latex IPNs exist. If one blends two kinds of latex particles, followed by film formation and cross-linking of both polymers, the material is called an *interpenetrating elastomeric network*, IEN. Usually, IENs form a three-dimensional mosaic structure (69,70).

Latex IPNs are often made by sequential polymerization of two (or more) cross-linked polymers utilizing emulsion polymerization (71). For core-shell latex IPN synthesis, first a cross-linked seed latex of polymer 1 is synthesized (2). Then, a second monomer and cross-linker are added to the system, usually with no added surfactant. Often, a starved polymerization route is employed, ie, the rate of polymerization equals or exceeds the rate of monomer addition. This reduces the swelling of the seed latex by the monomer 2 mix, producing a two-layer latex having a spherical core, and an overlaying shell. Obviously, multiple shells can be added for different purposes.

Some possible morphologies of latex IPNs having three polymers are illustrated in Figure 18 (72). Note that in Figure 18**a**, the monomer B mix first dissolves

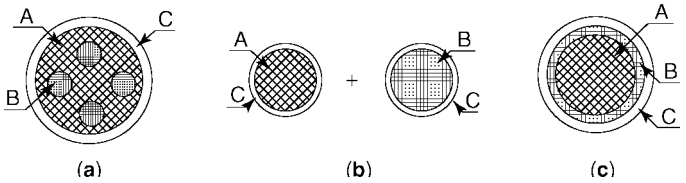

Fig. 18. Some possible latex IPN particle morphologies. (**a**) IPN core/shell particles; (**b**) separated core/shell particles; and (**c**) multilayered particles.

in polymer A, then polymerizes and phase separates to form internal domains. Then, polymer network C forms a shell around the A-B core.

If the glass transitions of the three polymers are sufficiently different, and the three polymers are phase-separated, then one obtains three glass transitions, as illustrated in Figure 19 (73). In this case, the three polymers were obtained by blending two latexes having different cores but the same shell, as in Figure 18**b**. G' and G'' represent the dynamic shear modulus. Both latexes have a core of poly(butadiene-*stat*-styrene), with some of the latexes having a SAN shell and some having a shell of poly(ethylhexyl methacrylate-*stat*-styrene). In both cases, the polymerizations were carried out under starved conditions.

Silverstein and co-workers (74), Silverstein and Narkis (75), and Nemirovski and Narkis (76) studied the morphology and rheological behavior of latex IPNs and related materials (see Fig. 20) (75). After water evaporation, some degree of phase continuity of individual phase domains is achieved in this case. All of these compositions were based on polyacrylates and polystyrene. After polymerizing and drying, the latex particles do not interdiffuse to form a monolithic solid because of the cross-links in each latex particle. However, being moderately soft, they flow together as modeled in Figure 20 (75). The solid black spheres represent polystyrene domains, and the cross-hatched material represents an acrylic

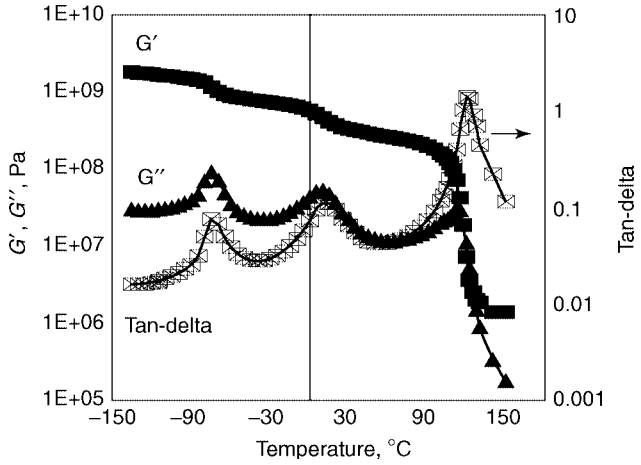

Fig. 19. The dynamic mechanical behavior of a mix of two latexes or the morphologies represented by Figure 18**b**.

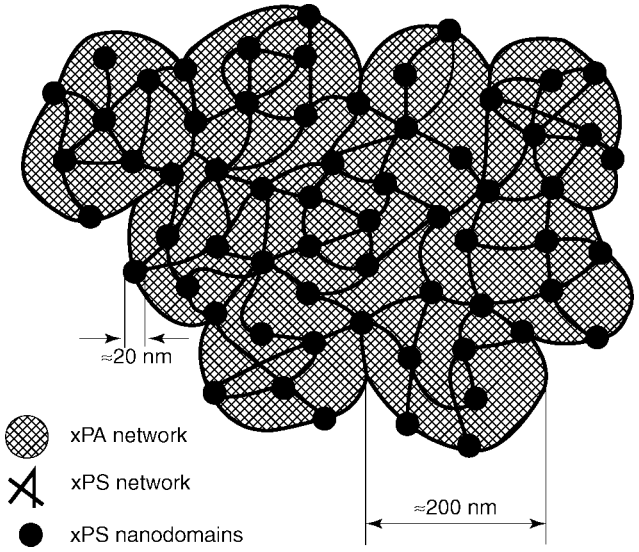

Fig. 20. Model of a latex IPN.

network. The rheological behavior of these materials resembles the flow behavior that might be expected for a room full of underinflated beach balls.

Sound and Vibration Damping Behavior

Sound and vibration damping are important throughout the world today for the automotive industry, appliances, aircraft, tall buildings, submarine technology, etc. However, the frequencies of the sound or vibration differ greatly, from a fraction of a Hertz for tall buildings to 10^3–10^4 Hz for cars and appliances. This is important, because the WLF equation shows that the glass transition increases some 6–7°C with each decade of frequency increase (77). One of the most important methods of damping involves polymeric materials in or near their glass transitions temperatures where the loss tangent tan δ and/or the loss modulus E″ are high.

Many IPNs exhibit a microheterogeneous morphology. When the domains are of the order of 10–20 nm, the whole system becomes substantially all interphase material, ie, it is extensively but incompletely mixed, with different microregions having different compositions (see Fig. 8) (31). In the transmission electron micrograph of Figure 8**a**, the microheterogeneous morphology is made from the isomeric pair, poly(ethyl acrylate) and poly(methyl methacrylate). When polystyrene is used as the second polymer, the cellular structure in Figure 8**b** emerges.

Whereas an immiscible IPN pair will have two distinct glass transitions, the microheterogeneous morphology often results in one broad glass transition, covering the temperature range between both homopolymer glass transitions. Thus, more or less constant E″ or tan δ can be obtained.

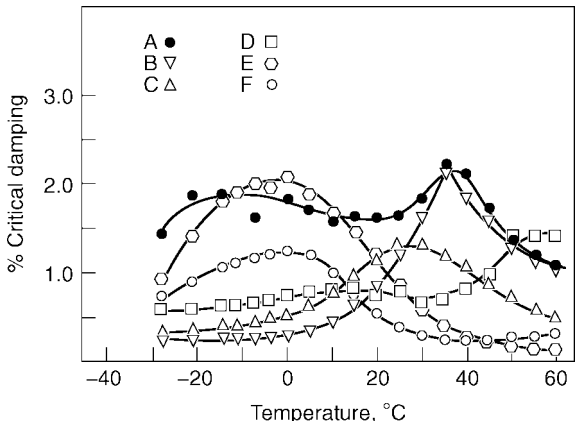

Fig. 21. Damping effectiveness as a function of temperature for several commercial materials compared to an IPN, composition A.

There are two basic engineering mechanisms for the use of damping polymers:

(1) Extensional damping, where a polymer is placed as a free layer on the resonating vibrating system; and
(2) Constrained layer damping, where a stiff material is placed on the top of the damping polymer to increase the shearing action. Sometimes a simple sandwich arrangement is used, where two thin layers of sheet metal (the bread) have a thin layer of polymer between them (the jelly).

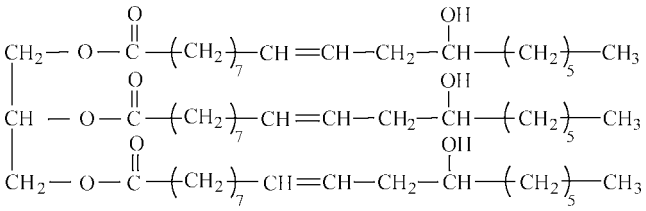
The damping of an IPN constrained layer system based on an acrylic/methacrylic IPN and an epoxy constraining layer is compared with several other commercial homopolymers and statistical copolymers in Figure 21 (78). Hitachi Chemical has a high temperature sound and vibration damping material based on vinyl–phenolic compositions (79).

Natural Products/Renewable Resource-Based IPNs

Of increasing importance in modern society are polymeric materials that either originate from plants or animals, are naturally degradable, or both. One of the major approaches utilizes triglyceride oils with functionality other than double bonds. For example, most of the edible oils such as corn oil are triglycerides containing one or more double bonds in the side chains. Usually, the double bonds are structurally *cis*. An exception is tallow, which is a saturated oil.

Castor Oil-Based IPNs. Those triglyceride oils with functionality other than double bonds such as hydroxyl or carbonyl groups are generally considered inedible, although they are sometimes used for medicinal purposes. Prime among

these materials is castor oil, containing one hydroxyl group per side chain (see eq. 3):



(3)

In medicinal applications, the hydroxyl group irritates the stomach lining. Chemically, the hydroxyl group can react to form urethanes or esters, and hence form a polymer network. Polyurethane foam rubber frequently contains large amounts of reacted castor oil, for example. The glass transition of castor oil polyesters are of the order of −50°C (80).

If styrene (or other vinyl monomer) plus cross-linker is swollen in and polymerized, an IPN is formed. The products tend to be tough, leathery materials. Research on castor oil-based IPNs began in 1974 as a cooperative research program between the Universidad Industrial de Santander, Bucaramanga, Colombia, and Lehigh University in the United States (81,82).

Castor oil hydroxyl groups can be easily reacted with either isocyanate groups to form polyurethanes, or with carboxyl groups to form polyesters. The synthesis scheme for forming polyester-based SINs from castor oil is illustrated in Figure 22 (80). Here, sebacic acid (itself a derivative of castor oil) is reacted with

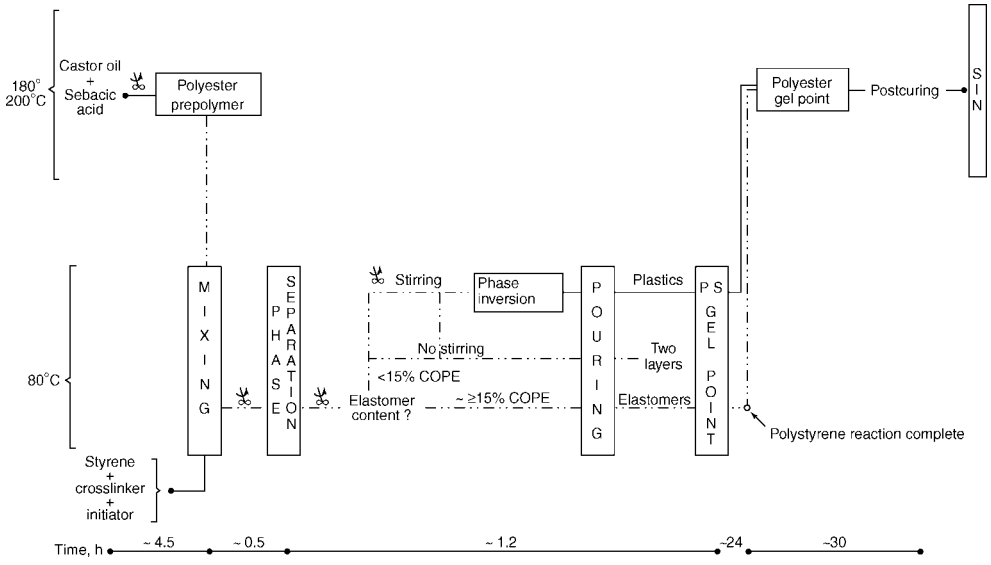


Fig. 22. A synthesis scheme for castor oil-polyester based SINs with polystyrene being the second component. ▬ ▪ ▬ ▪ ▬ = polyester is the continuous phase; ▬▬ = polystyrene is the continuous phase; and ⁂ = Stirring.

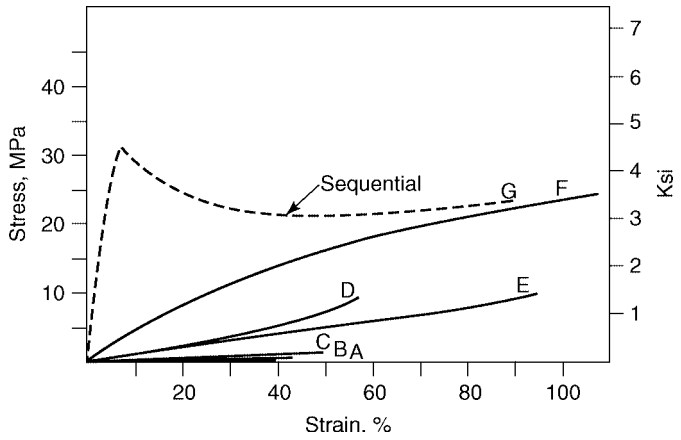

Fig. 23. Stress–strain curves for several castor oil (CO), polyester (PE), polyurethane (PU), and polystyrene network (PSN) materials. A: COPEN; B: COPEUN; C: COPUN; D: 40/60 COPEN/PSN; E: 40/60 COPEUN/PSN; F: 40/60 COPUN/PSN; and G: 40/60 COPUN/PSN.

castor oil. Note that stirring is required after phase separation to obtain phase inversion.

A number of polyester, polyurethane, and mixed structures were made into IPN. Stress–strain curves on these compositions are illustrated in Figure 23 (83). In some cases, the castor oil was first reacted with a diacid, then finished with an isocyanate to form a urethane. Here, COPEN stands for castor oil polyester network, U stands for urethane, and EU stands for the mixed ester–urethane derivative. PSN stands for polystyrene network. Compositions 1, 2, and 3 are relatively soft and weak. Compositions 4 and 5 are somewhat higher modulus, more energy-absorbing materials. Composition 6 is much tougher. The sequential IPN, composition 7, is identical to composition 6, except that the sequential mode of IPN formation replaced the SIN mode. The yield point in the stress–strain curve of composition 7 suggests greater phase separation with the polystyrene being a more continuous phase. It must be pointed out that composition 6 is tough enough to make long-lasting shoe heels.

Castor oil has also been made into semi-IPNs with poly(ethylene terephthalate) (PET). Typical time–temperature reaction conditions are shown in Figure 24 (84). Since the castor oil is an ester as well as the PET, significant bond interchange takes place at elevated temperatures, as indicated. If the material is heated too long, a statistical copolymer will result. Under the given reaction conditions, the mix goes from a two-phase mix to a one-phase mix. On cooling, it phase separates again.

Tan (85) investigated SIN compositions based on castor oil polyurethanes and styrene–acrylic mixes. Under these conditions, there is considerable grafting. Abrasion resistance to jetting sand was very high, leading to a coating application of the Ge Zhou Ba hydroelectric power station dam in the desert region of western China (86).

Other triglyceride oils that are being investigated as IPN monomers include vernonia oil and lesquerella oil. Vernonia oil, a naturally epoxidized oil,

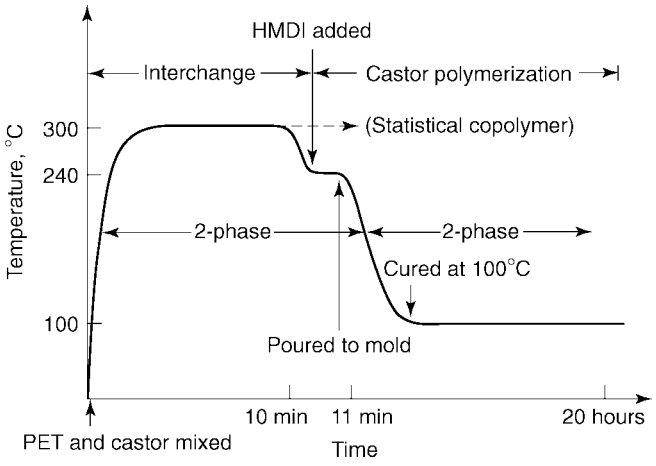

Fig. 24. A typical time–temperature cure cycle illustrating bond interchange and phase behavior of castor oil/urethanes and poly(ethylene terephthalate) semi-IPNs. Axes not drawn to scale.

was combined with poly(ethylene terephthalate) to make semi-IPNs (87). Lesquerella oil comes from a wild flower growing in the desert of southwest United States and Mexico. It, too, makes tough IPNs (88). It is thought that lesquerella could be grown where no crop exists today. Other functionalized oils of interest include crambe, epoxidized linseed oil, and epoxidized soybean oil (89).

Natural Rubber Latex-Based IPNs. Another kind of natural product IPN is based on natural rubber latexes. After processing, this rubber is in wide use today for truck and aircraft tires (see RUBBER, NATURAL). While still in the latex form, these latexes can be treated just like their synthetic counterparts and used as the core material for IPN production. An interesting material, prepared by polymerizing methyl methacrylate in the rubber latex, is called Hevea Plus MG (90–92). This makes an impact-resistant composition somewhat resembling ABS. Polystyrene as well as PMMA was used variously as the second polymer. Notched Izod impact strengths were increased over those of the pure plastics by a range of 10–15, reaching over 30 kJ/m^2.

Polysaccharide-Based IPNs. Cellulose (qv) and cellulose derivatives have been the largest tonnage single polymer sold in the world since the beginning of civilization until the present. Kamath and co-workers (93) prepared IPNs and related AB–cross-linked copolymers using compositions such as allyl cellulose cinnamonate and cross-linked acrylics, polystyrenes, or vinyl acetates. An improved thermal stability was noted. Hydrogel materials prepared from cellulose esters and polyacrylamide have also been investigated (94) (see HYDROGELS).

Combinations of both polysaccharides and castor-oil–based polyurethanes have also been investigated. Semi-IPNs of castor-oil–based polyurethanes and nitrokonjac glucomannan (NKGM) were investigated by Gao and Zhang (95). The konjac glucomannan is a natural polysaccharide, and was nitrated for these studies. Possible substitution of the semi-IPN for some petrochemical products was mentioned, along with biodegradability. Films made from the semi-IPN were found to be highly transparent, with a breaking strength of some 30 MPa.

Table 2. History of IPNs and Related Materials

Event	Investigators	Year	Ref.
Vulcanization of rubber	Goodyear	1844	96
First IPN	Aylsworth	1914	97
Macromolecular Hypothesis	Staudinger	1920	98

History of Interpenetrating Polymer Networks and Related Materials

The patent literature shows that IPNs were invented over and over again, beginning in 1914 (see Table 2). Each time, the idea was lost and reinvented.

Aylsworth (97) was the first person known to invent an IPN. In 1914 he combined the then new phenol–formaldehyde compositions with natural rubber and sulfur. Of some historical interest is that Jonas Aylsworth was Thomas Edison's chief chemist (110). Edison had just switched from the cylinder-type record to the platter, using the new phenol–formaldehyde materials. However, these phenol–formaldehyde materials were brittle, and the first phonograph records had to be made very thick to prevent breakage.

In effect, by adding natural rubber and sulfur, Aylsworth made not only the first IPN, but also the world's first rubber-toughened plastic. This was decades before rubber-toughened styrenics were commercial. The West Orange, NJ, Edison Museum has evidence that Aylsworth's composition was used for toughening phonograph records from 1914 to 1929, stopping only when Edison left the phonograph record business. Then, the idea was apparently lost.

Aylsworth's patent (97), however, does not mention IPNs and polymer networks, or even use the term polymer. Note that that date was six years prior to H. Staudinger's enunciation of the macromolecular hypothesis, which was, of course, the first statement that certain colloids had the structure of long chains.

Several other independent discoveries of IPNs followed. J. J. Staudinger (son of H. Staudinger) and Hutchinson have a 1951 patent (with a 1941 application date!) to smooth the surfaces of transparent plastic sheeting for esthetic purposes (99). These men took sheets of cross-linked polystyrene or PMMA and swelled the

sheets with the same monomer mix as the first network. This stretched the sheets, and after polymerization of the second monomer mix the waviness or surface imperfections of the original material were reduced. These were the first homo-IPNs.

The next independent invention of IPNs was by Solt in 1955 (111). Solt invented anionic–cationic ion exchange resins with the idea of having both charges on the *same* suspension-sized particle. The idea was that the exchange efficiency would be improved if both charges were in juxtaposition, but still separated in space. Indeed, the charges must be separated, even by a fraction of a nanometer, to prevent coacervation.

The term *interpenetrating polymer network* was first coined by Millar in 1960 (102). These were polystyrene–polystyrene homo-IPN suspension-sized particles. The idea was that some particles, the *fines*, were too small. On adding more monomer and cross-linker, larger and more satisfactory particles could be made. Early works by Shibayama and Suzuki (112), Lipatov and Sergeeva (105), Frisch and co-workers (107), and Sperling and Friedman (106) set the pace for the modern development, founding the field of IPNs (1).

In Table 2, there is an apparent gap of two decades (1977–1997) between thermoplastic IPNs and the modern IPN nomenclature; in fact many people were busy characterizing a number of new materials and developing their applications, as described above. Application-oriented papers and patents are delineated below.

Actual or Proposed IPN Applications

A number of commercial IPN materials and their applications are summarized in Table 3. The value of IPNs to society, of course, lies in their usefulness. IPNs can and are being made into rubber-toughened plastics and a special value seems to lie in their capability of forming tough but flexible materials. IPNs often have another unusual property: that of forming co-continuous, very finely divided phases. These tough but flexible materials have suggested biomedical applications.

Biomedical Applications. Dillon (114) synthesized IPN membranes from polytetrafluoroethylene (PTFE) and poly(dimethyl siloxane) (PDMS) (see PERFLUORINATED POLYMERS, POLYTETRAFLUOROETHYLENE; SILICONES). These flexible membranes are used for a variety of medical purposes, especially second-degree burn care. These materials are commercially available under the trade name Silon. The PDMS component rapidly transports body fluids away from the burn site, while the PTFE provides mechanical strength. The PTFE is also waterproof, so that when the wound area is washed, water beads up on the film. An additional valuable feature is that the films are highly transparent, so that the doctor can observe the wound area easily, making early treatment of any infection or other problem possible.

Salmerón Sánchez and co-workers (115) prepared sequential IPNs based on {*net*-poly(ethyl acrylate)-*ipn*-{*net*-poly(hydroxyethyl acrylate)}. These two polymers differ primarily in the presence or absence of a hydroxyl group. Investigation via differential scanning calorimetry indicated three qualitatively different kinds of thermograms depending on the initial quantity of water present. The water present is primarily associated with the poly(hydroxyethyl acrylate), but the

Table 3. Selected Commercial IPN Materials[a]

Manufacturer	Trade Name	Composition	Application
Shell Chemical Co.	Kraton IPN	SEBS–polyester	Automotive parts
LNP Plastics	Rimplast	Silicone rubber–nylon or PU	Gears or medical
DSM N.V.	Kelburon	PP–EP or rubber–PE	Automotive parts
Uniroyal (Reichhold Chemical Co.)	TPR	EPDM–PP	Auto bumper parts
Rohm & Haas	–	Anionic–cationic	Ion-exchange resins
Monsanto	Santoprene	EPDM–PP	Tires, hoses, belts, and gaskets
BF Goodrich	Telcar	EPDM–PP or PE	Tubing, liners, and wire and cable insulation
Exxon	Vistalon	EPDM–PP	Paintable automotive parts
Cook Composites	Acpol	Acrylic–urethane–polystyrene	Sheet molding compounds
Dentsply International	Trubyte, Bioform	Acrylic–based	Artificial teeth
Hitachi Chemical	–	Vinyl-phenolics	Damping compounds
Bio Med Sciences	Silon	PDMS–PTFE	Burn dressing, scar abatement

[a]Updated from Table 10.5 in Ref. 113.

poly(ethyl acrylate) component clearly interferes with water transport and freezing. Whereas this was a basic study of hydrogel behavior, other systems examined below have several potential applications, particularly to the biomedical field (see HYDROGELS).

Polymer gels based on poly(*N*-isopropylacrylamide) [P(N-iPAAm)] in aqueous media undergo a temperature-induced collapse of the chains from a perturbed random coil to a globular structure known as a *coil-to-globular transition*. This is macroscopically observable as a sudden decrease of the degree of swelling at a sharp first-order phase transition known as a *lower critical solution temperature* (LCST) at 32°C. The P(N-iPAAm) gels exhibit the sharpest transition of the class of thermosensitive alkylacrylamide polymers examined (116) (see ACRYLAMIDE POLYMERS).

Since this LCST occurs between room temperature and body temperature, there has been great interest in this and related materials from a biomedical point of view. In order to adjust the LCST to meet various proposed objectives, a number of copolymers and IPNs of P(N-iPAAm) and have been prepared.

Zhang and Peppas (117) examined sequential IPNs of poly(methacrylic acid) (PMAA) and P(N-iPAAm) hydrogels as a function of pH and temperature. pH is critically important to studies involving PMAA, since the carboxyl group is ionized at higher pH but in the acid form below about 5.5. The IPNs had a swelling/deswelling transition in a range that included that of pure P(N-iPAAm), 32°C, but was broader.

An important possible use of such IPNs involves drug delivery. A number of model drugs was examined by Zhang and Peppas (117). As expected, higher

permeability was observed for the smaller model drug compounds (see CONTROLLED RELEASE TECHNOLOGY).

At low water contents, the LCST depends on the water concentration for P(N-iPAAm) (118), being constant for high swelling ratios (as most often needed), but shifting to higher temperatures when the initial water concentration is below 50%. Hydrophilic poly(acrylic acid) (PAA), when added in IPN form, tends to increase the LCST. In the case of P(N-iPAAm) and PAA sequential IPNs, the association between the complementary binding sites produces complexes that decrease the ability of the hydrogel to swell in water. For the various copolymers and IPNs, a major effect was the broadening of the transition.

The first-order LCST of P(N-iPAAm) leads to many possible applications in the biomedical field. Wu and Jiang patented an IPN hydrogel based on {*net*-poly(*N*-isopropylacrylamide)}-*ipn*-{*net*-gelatin} (119). These materials also swell greatly at room temperature, but can be made to undergo a rapid reduction in volume at blood temperature, 37°C. When formed into a tube, these hydrogels can be placed over the cut ends of a blood vessel. The material shrinks rapidly as the material increases in temperature from room temperature to body temperature, grasping both ends of the blood vessel and allowing blood to be temporarily transported in a normal manner.

There are two ways of bending light. The most common is to present the light with a material surface at an angle to the direction of the light's travel. However, light waves can also be *bent* by changing the refractive index internally in the material. This latter fact has been used to prepare gradient IPN compositions in soft contact lenses. By using computer-controlled laser polymerization of polymer II in gradient IPNs (polymers of two different refractive indices), it is possible to have improved astigmatism control (120,121).

Another class of IPNs are the homo-IPNs, made of two more or less identical polymers. An example are the homo-IPNs prepared from cross-linked poly(methyl methacrylate) (PMMA) (122,123). In this case, densely cross-linked material of suspension-sized PMMA particles are prepared. These are mixed with a very similar monomer mix, and polymerized. Some, but not all, of the second monomer mix swells into the suspension particles.

Homo-IPNs of PMMA are used commercially for artificial teeth, the kind that come out at night (122,123). One trade name is Bioform IPN (Table 3). In one example, suspension-sized particles of cross-linked PMMA were mixed with linear PMMA, MMA monomer, cross-linker, and initiator. After polymerization, the teeth have two superior properties. First, because a suspension polymerization route is used, the dentist can grind the teeth to a fine powder. This is important when fitting the new teeth to the opposing set of teeth. They can be ground better because the interface between the suspension-sized particles and the surrounding phase is slightly weaker than the bulk material. A single network of a similar composition may char under the dentist's drill.

Second, a densely cross-linked polymer is required. Salad oil, butter, and similar materials are excellent plasticizers (qv) for linear PMMA, which cause the teeth to swell.

Smart Materials. Eck and co-workers (124) developed a smart material for solar energy management. It seems that the use of solar energy to heat water in some tropical areas results in water that is *too hot*. Usually, the water pipes to

be heated are in a panel covered by glass, and exposed to the sun. The material of Eck and co-workers makes use of a lower critical solution temperature (see Fig. 7 for example) with an IPN based on {*net*-poly(propylene oxide)}-*ipn*-{*net*-poly(styrene-*stat*-2-hydroxymethyl acrylate)}. A film of this material is placed on the underside of the glass. At low temperatures, the film is clear, transmitting the light. When the temperature exceeds a certain value, the film clouds up, increasing reflection back into the atmosphere.

A polymer blend of the same or similar composition cannot be used because the phase domains that will form will become large enough to take many hours to diffuse back to a single phase. The IPN forms domains of only some tens of nanometers, allowing diffusion back and forth between one phase and two phases in minutes. Interestingly, this appears to be the only application suggested for the LCST of polymer blends or IPNs.

Pervaporation Membranes. Pervaporation membranes for separation of ethanol and water and other types of solutions are being investigated by Kim and his students (125,126). Some of these membranes are anionic/cationic IPNs. Starting with a 10% ethanol feed, after three stages the retentate is 94% ethanol. Water vapor passes through the membrane as the pervaporate.

Other Applications. Another new material, developed by Lipatov and Karbanova (127) and Bukhbinder and Kosjakov (128) flies under the designation gradans. Cylindrical glass or polymer fibers are widely used to transmit light or other electromagnetic energy for communication purposes, optoelectronics, integrated optics, and medical engineering. A major problem is that the electromagnetic energy tends to leak out of the surface of the fiber, shortening the useful path. If the fiber is made so that its refractive index has an increasing gradient from the center to the surface, the energy will be bent back towards the center as it moves through the fiber. One way to accomplish this is through making a gradient IPN, with the second monomer making a polymer of higher refractive index than the first.

Some of the materials mentioned in Table 3 have already been discussed. The reader will recognize the Silon and Bioform materials described above. Kraton IPN is also discussed above (see Figs. 16**c** and 16**d** and Table 1). Several of the materials manufactured are based on EPDM–PP thermoplastic IPNs.

Current Literature Suggestions and Applications. In 2004, the production of IPN-based papers is averaging about 100 papers a year. This contrasts to the fact that up to 1979, there was a *total* of about 125 scientific papers and about 75 patents issued on the subject. The number of IPN-related patents has also increased accordingly.

Many of the most recent papers mention possible applications (see Table 4). Again, possible medical applications stand out the most.

Kim and Kim describe a most interesting material in Reference 134 of Table 4. The need for synthetic blood vessel sections is great. A blood vessel must be both flexible and strong. However, a major problem with materials has been that the inner surface may abrade red blood cells and cause adsorption of materials such as the fibrinogens and platelets, important in coagulating blood. (The lifetime of red blood cells passing various surfaces is inversely related to the modulus of the material of contact.) Fibrinogen is one of the most important globular proteins circulating in the blood, playing a central role in the regulation of hemostasis

Table 4. Actual and Proposed IPN Applications from Select Recent Literature

Composition	Application	Ref.
Biomedical/Pharmaceutical		
Poly(ε-caprolactone) semi-homo-IPNs	Bone implant composites with hydroxyapatite	129
Poly(*N*-isopropylacrylamide-*stat*-acrylic acid) + grafted polyacrylamide copolymers	Engineered cartilage, polymer scaffolds	130
Acrylic resin IPNs	Acrylic false teeth	131
Poly(acrylic acid) + cross-linked gelatin	Hydrogel drug release systems.	132
Segmented polyurethane + poly(2-methacryloyloxyethyl phosphoryl chloride)	Blood compatibility, no platelet adhesion	133
Polyurethane + polystyrene with pendant poly(ethylene oxide) chains	Blood compatibility; adsorption of fibrinogens and platelets suppressed.	134
Chitosan + poly(ethylene oxide) semi-IPN	Drug release	135
Sodium alginate + cross-linked gelatin or egg albumin	Controlled release of medication	136
Poly(vinyl alcohol) + poly(dimethyl siloxane) hydrogels	Drug release	137
Chondroitin + poly(acrylic acid) semi-II IPN	Controlled drug release	138
Polyurethane + polystyrene IPNs	Adhesion of endothelial cells	139
Poly(hydroxyethyl methacrylate) + poly(ethylene glycol) semi-IPN	Antithrombogenic material	140
Polypropylene + polyacrylamide mix	Controlled release of drugs	141
Poly(vinyl alcohol) + poly(2-hydroxyethyl methacrylate)	Prosthetic disc nucleus	142
Poly(2-hydroxyethyl methacrylate) + chitosan	Lysozyme adsorption	143
Polysiloxane + poly(vinyl alcohol) with ferromagnetic derivate	Immobilize antigens	144
Electrical		
Polystyrene or poly(methyl methacrylate) + modified epoxy	Underfill adhesive for electronic applications	145
Castor oil-based polyurethane + poly(methyl methacrylate) + polyaniline	Electrical conducting properties	146
Polyaniline + poly(vinyl alcohol) semi-IPN	Electrical conducting materials	147
Poly(vinyl alcohol) + chitosan hydrogel	Bends in electric field; smart material	148
Polyaniline + poly(vinyl acetate) semi-II IPN	Electrical conductivity	149
Polyaniline + melamine-urea	Electrical conductivity	150
Poly[methoxyoligo(oxyethylene) methacrylate] + poly(methyl methacrylate)	Electrochemical conductivity	151
Poly(sodium acrylate) + poly(*N*-isopropyl acrylamide) semi-II IPN	Intelligent hydrogels, thermovolume sensitive, heavy metal ion recovery	152

Composition	Application	Ref.
Poly(vinyl alcohol) + poly(diallyl dimethyl ammonium chloride)	Samples bend in electric field	153
Damping		
Vegetable oils	Damping materials	154
Polyester + epoxy with carbon black	Heat-resistant damping	155
Poly(dimethyl siloxane) + polyacrylates + polymethacrylates	High temperature damping	156
Polysiloxanes + poly(methyl methacrylate)	Sound and vibration damping	157
Ion exchange		
Sulfonated polystyrene + poly(vinyl chloride) semi-I IPNs	Cation exchange membranes	158
Poly(hydroxyethyl methacrylate) + chitosan	Removal of heavy metal ions from aquatic systems	159
Poly(vinyl chloride) + polystyrene with cation exchange groups	Cation exchange membrane	160
General		
Polyimides + alkoxysilane dye	Second-order nonlinear optics	161
Epoxy + unsaturated polyester	Rubber-toughened plastics	162
Poly(vinyl alcohol) grafted with acrylamide + sodium alginate	Pesticide release	163
Poly(acrylic acid) + poly(butyl methacrylate-*stat*-methyl methacrylate)	Pervaporation membrane	164
Natural rubber + polystyrene	High transport membranes	165
Carboxymethyl cellulose + poly(ethylene glycol) + cross-linked polyacrylamide	Controlled release of KNO_3 agricultural fertilizer	166
Unsaturated polyester + poly(2-hydroxyethyl methacrylate)	Improved flame resistance	167

and thrombosis. It participates in blood coagulation and facilitates adhesion and aggregation of platelets. The result might be thrombosis in the patient.

Mother Nature makes the inner lining of blood vessels very soft, so that the probability of coagulation is far reduced. The hydrophilic pendant poly(ethylene oxide) (PEO) chains, described in Reference 134, stick out from the inner side of the blood vessel, creating a soft gel environment. The presence of the pendant PEO chains significantly suppresses the adhesion of fibrinogens and platelets on the surface of the polymeric blood vessel by steric repulsion. In these IPNs, the blood compatibility increases with both the length of the pendent chains and the density of grafting.

Thus, the polyurethane and polystyrene, main components of the IPN, provide both the strength and the flexibility, and the grafted PEO provides a soft, gelatinous inner surface, mimicking Mother Nature. Besides possible use as artificial blood vessels, there is a wide range of blood-handling equipment now in use for surgery, etc, as possible applications.

A similar effect arises in the materials described in Reference 133 of Table 4. Segmented polyurethanes, of course, are a type of block copolymer. These

materials are very strong elastomers, which are in wide use as the elastic fiber in undergarments, bathing suits, etc. The poly(2-methacryloyloxyethyl phosphoryl chloride) forms a highly swollen, soft gel partly exposed on the IPN blood vessel surface.

However, there are possible applications to optoelectronics, agriculture, and other topics as well. References 148, 152, and 153 in Table 4 mention smart materials, particularly those that bend in an electric field. These are widely being investigated as sensors of various kinds.

Concluding Comments

In a certain sense, the term *interpenetrating polymer networks* is a misnomer, since most of these materials phase separate, rather than being mutually soluble on the molecular level. One could argue that the phases interpenetrate, and/or that true molecular interpenetration takes place at the interphase. However, the term describes the general synthesis and structure of the materials.

The field of interpenetrating polymer networks now takes its place parallel to the fields of polymer blends, grafts, and blocks. Indeed, most of these materials are useful because they undergo some kind of phase separation. Many IPNs seem to work best when the degree of phase separation is only partial or the size of the domains is in the tens of nanometer range. Those IPNs composed of an elastomer and a plastic to make flexible materials seem to be the most unique among these materials.

LATEX TECHNOLOGY

Introduction

Latex technology encompasses colloidal and polymer chemistry in the preparation, processing, and conversion of natural and synthetic latices into useful products.

Latex technology vernacular is not always consistent. By definition a *latex* is a colloidal suspension of polymer particles stabilized by dispersing agents in an aqueous medium. The dispersing agents are conventional ionic or nonionic surfactants or polymeric surfactants made from block or graft copolymers derived from monomers with different hydrophobicities. An *emulsion* (1) is a dispersion of two or more (2) immiscible liquid phases (one being water) stabilized by amphiphilic materials. A latex is a specific type of emulsion; one where the organic phase is a polymer particle. The terms latex and emulsion are often used interchangably partly because emulsion polymerization is the principal synthetic route to latices. Emulsion polymerization is one type of heterophase polymerization involving organic and aqueous phases. Others include suspension, dispersion, and precipitation polymerization which generate water-borne particles different from latices. Heterophase Polymerization (qv) can also involve two immiscible organic phases as in nonaqueous polymer dispersions and polymer microgels. Finally, polymers prepared via homogeneous polymerization, whether in solution or neat, can be inverted into a polymer dispersion in water using surfactants. Similar to latices, these materials can have very different molecular weight and functional group distributions and thus form a separate class of materials.

Latices have been in use for a very long time and the history of latices and polymer development are closely linked. The Mayas (3), around 1600 BC, used the sap of trees like the sparse *Hevea brasiliensis* of South America (4) to make rubber products and waterproof clothing. The Mayas called the sap "caa o-chu," literally translated as "weeping tree." *Caoutchouc* is now the French word for rubber. The

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

natural rubber derived from this sap was shown to be 93–95% *cis*-1-4-isoprene by Faraday (5) in the early 19th century. Goodyear's invention of vulcanization, and later the automobile, increased natural rubber demand through the beginning of the 20th century (6). Large rubber plantations in Malaya, Ceylon, Indonesia, and Indochina increased the world's natural rubber production to 200,000 t by 1920. Enhanced supply led to rapid growth of natural rubber products and improvements in latex processing. The Allied blockade of Germany during World War I led to the first process for making synthetic latex (7). Gottlob (8) and others were early developers of emulsion polymerization (at first using methods to duplicate how natural rubber is produced in nature). Soon thereafter, U.S. companies began producing commercial synthetic latices: Buna S (butadiene–styrene copolymer), also known as Government Rubber–Styrene or GR–S rubber; Neoprene (polychloroprene) (9); and Thiokol (polysulfides) (see STYRENE-BUTADIENE COPOLYMERS). Japan's seizure of the Southeast Asia rubber plantations during World War II led to intensive research in synthetic rubber production (10). Today synthetic latex production accounts for 60% of the 18×10^6-t total rubber market (11,12) which has been growing at 2–5% over the last decade. Synthetic latices account for ca 2.5% of the world polymer market (13,14). Allergic reactions to proteins in natural latex and other natural latex market drivers have recently created more opportunities for synthetic latices (15). Over 70% of the natural latex market is converted to solid polymer for use in tires.

Many synthetic latices exist (16–18). They contain butadiene and styrene copolymers (elastomeric), styrene–butadiene copolymers (resinous), butadiene and acrylonitrile copolymers, butadiene with styrene and acrylonitrile, chloroprene copolymers, methacrylate and acrylate ester copolymers, vinyl acetate copolymers, vinyl and vinylidene chloride copolymers, ethylene copolymers, fluorinated copolymers, acrylamide copolymers, styrene–acrolein copolymers, and pyrrole and pyrrole copolymers. Many of these latices also have carboxylated versions.

Traditional applications for latices are adhesives, binders for fibers and particulate matter, protective and decorative coatings (qv), dipped goods (especially without allergens), foam, paper coatings including water-proofing paper (19), backings for carpet and upholstery, modifiers for bitumens and concrete, and thread and textile modifiers to improve feel or properties such as flame retardence. More recently latices have found use in biomedical applications as protein immobilizers; as visual detectors in immunoassays, as release agents in drug delivery (20), wound treatment, and synthetic blood (21), in electronic applications as photoresists for circuit boards; in batteries, conductive paint, copy machines; as key components in molecular electronic devices; in specialty coatings for seeds (22), in artificial turf plastics; and as an important component of oil recovery techniques (23). The application of even more specialized latices can be surprisingly complex (24).

Latex Properties

The observable properties of a latex, ie, stability, rheology, film properties, interfacial reactivity, and substrate adhesion, are determined by the colloidal and polymeric properties of the latex particles. Important colloidal properties include ionic charge, stability, particle size and morphology distribution, viscosity, solids,

and pH. Important polymer properties include molecular weight distribution, monomer sequence distribution, glass-transition temperature, crystallinity, degree of cross-linking, and free monomer. Methods for analyzing each of these properties exist, depending on the end use of the product. Overviews of the various polymer colloid characterization methods are available (25–27) (see also COATINGS).

Stability. For a latex to be a useful product, control of polymer isolation is crucial. The individual polymer particles must be stable enough to avoid coagulation resulting from perturbances like high temperature, freeze–thaw cycles, high shear in handling, electrolyte addition, and organic solvent addition during processing, but not so stabilized that polymer isolation is impossible. Stability is related to the surface properties of the latex particles, and these are usually determined during latex manufacture (28). Visual detection of coagulation is easy; more sophisticated optical techniques are possible (29). The types of initiator, emulsifier, and monomers used are the key determinants.

Electrostatic Stabilization. The electrical charges on the surface of a latex particle are balanced by an electrical double layer of oppositely and then similarly charged counterions. The outer layer is known as the diffuse electrical double layer, and its potential controls the colloidal stability of the latex particles (30). The diffuse electrical double-layer potential is closely related to the zeta potential. Electrophoresis measurements at various pH and ionic strengths are a means of calculating the zeta potential (31,32). As two particles approach, their individual diffuse double layers begin to overlap and the particles repulse one another. As the particles get even closer, attractive forces build and the particles coagulate. The energy required to overcome the repulsive forces depends on the ionic strength of the bulk phase, the temperature, and the nature of the ions balancing the latex particle charge. Latex particles coagulate at zeta potentials close to zero and are very stable at zeta potentials above 50 mV. One way to coagulate particles is to reduce the energy barrier between particles by adding electrolyte. The Derjaguin–Landau–Verwey–Overbeek (DLVO) theory (33) is a method for predicting the amount of electrolyte needed to coagulate a latex by first predicting the critical coagulation concentration. DLVO theory does not account for the chemical nature of the electrolyte nor the interaction of the ions with water. Additional mechanisms must often be added to the extended DLVO theory to model more complicated systems (34). Aluminum compounds, such as aluminum alginate, coagulate latices with varying effectiveness depending on the pH of the latex system (35). Protein behavior (36) and even nonaqueous stabilization can be modeled in a similar fashion (37).

Steric Stabilization. Nonionic surfactants, usually containing ethylene oxide units, are able to stabilize particles by adsorbing their hydrocarbon chain ends on the hydrophobic polymer zones of the surface of the latex particle. The ethylene oxide groups extend into the water phase. These compounds suffer from temperature and dilution sensitivity. A–B block copolymers where A is compatible with the latex polymer and B with the dispersion medium offer a more robust method of steric stabilization. Triblock and star block methacrylate copolymers can also act as surfactants providing steric stabilization (38). Reactive macromonomers with affinity toward the dispersion medium copolymerized with hydrophobic monomer offer a chemical way of grafting the stabilizer to the surface of the latex particle (39). Organic solvent addition is used to coagulate sterically stabilized latices (40).

Addition of soluble homopolymer can lead to reversible and irreversible flocculation by depletion and bridging flocculations (41).

In general, electrostatic stabilization leads to smaller and more uniform particle size when compared with syntheses involving similar amounts of steric stabilizers. An advantage of non-ionic surfactants over electrostatic stabilization is improved humidity resistance (42). A given class of stabilizer can provide both electrostatic and steric stabilization depending on the length of the steric moieties in the surfactant molecule (43).

Other Stabilizers. In addition to anionic, cationic, and nonionic surfactants used in manufacture of the latex, other specialized surfactants can be added or compounded to the latex after manufacture to increase the stability of the latex. For example, amphoteric surfactants such as *c*-cetyl betaine are used to improve the mechanical stability of low pH anionic compounds. Quaternary ammonium salts are used to improve the mechanical stability of cationic latices and their compounds. They are used either alone or in combination with a nonionic surfactant. Sequestrants (44) such as sodium silicate, sodium polyphosphate, and the sodium salt of ethylene diamine tetraacetic acid are added to anionic latices to retard the destabilizing action of cations that get leached slowly from compounding ingredients containing multivalent ions. The addition of these ingredients is also beneficial if the use of hard water is unavoidable in making and using the anionic latex compound. Care must be taken to avoid shocking the latex during compounding with these additional surfactants.

Rheology. Flow properties of latices are important during processing and in many latex applications such as dipped goods, paint, and fabric coatings. Rheology is used to characterize the stability of latices (45). For dilute, nonionic latices, the relative latex viscosity is a power–law expansion of the particle volume fraction. The terms in the expansion account for flow around the particles and particle–particle interactions. For ionic latices, electrostatic contributions to the flow around the diffuse double layer and enhanced particle–particle interactions must be considered (46). A relative viscosity relationship for concentrated latices was first presented in 1972 (47). A review of empirical relative viscosity models is available (46). In practice, latex viscosity measurements are carried out with rotational viscometers (see RHEOLOGICAL MEASUREMENTS).

It is possible to increase the viscosity of a latex after manufacture using thickeners. Thickening occurs through increases in medium viscosity or polymer particle aggregation. If considerable aggregation occurs without a corresponding increase in medium viscosity, undesirable separation or creaming occurs. Methylcellulose, caseinates, and polyacrylate salts are typical thickeners. Ease of adding the thickener, ability to maintain viscosity, and undesirable side effects must be considered when selecting a thickener. Some thickeners slowly hydrolyze in the latex and lose their effectiveness over time. The full range of the effects of adding thickener develops over time; some of them are much faster than others. To avoid exceeding the desired viscosity, it is advisable to add thickener in small increments, waiting after each for the viscosity to reach equilibrium before adding the next one.

The viscosity of the latex can also be dependent on pH. In the case of some latices, lowering the pH with a weak acid such as glycine is an effective method for raising the viscosity without destabilizing the system. Latices made with

poly(vinyl alcohol) as the primary emulsifier can be thickened by increasing the pH with a strong alkali.

Particle size influences the viscosity of a latex, and the industrial demand for high solids latices has led to bimodal and multimodal particle-size distributions (48). Solids levels approaching 70 wt% are possible. The smaller the particle size, the higher the viscosity.

Particle Size. The particle-size distribution of a latex is a determinant of its performance in application. Particles are almost always spherical, although nonspherical particles are possible (49,50). Particle-size distributions are now routinely measured using scattering methods, light scattering being the most common and most effective on particles >300 nm. Small-angle neutron scattering (SANS) is useful for concentrated latices and smaller (< ca 300 nm) particle sizes (51). Microscopic techniques are also a reliable method. Two of the newer techniques are sedimentation field-flow fractionation (52) and capillary hydrodynamic fractionation (53). The particle-size distribution has an impact on stability, rheology, morphology, and film-forming properties. Stability is predicted for larger particles, with broadly distributed particle sizes showing a greater tendency to coagulate owing to interactions between the smaller particles (54). Viscosity effects are weighted to the larger particles. Morphology is affected by particle size, as in the case where the particle size of the polystyrene latex used to seed polystyrene core–poly(ethyl methacrylate) shell particles determined the morphology of the final latex. When the seed was less than 200 nm in diameter, the final particles were prolate spheroids of near-hemispherical polystyrene and poly(ethyl acrylate) domains. When the seed was 300 nm in diameter, spherical polystyrene particles embedded with circular patches of poly(ethyl methacrylate) were the result (55). A review of the fundamental aspects of morpology control has been written by Sundberg and Durant (56).

Film Properties. Dehydration (57) at temperatures above the polymer glass-transition temperature is the principal means for forming film from latex. Interdiffusion of the polymer chains between particles is thought to be the limiting step in film formation (58). The final properties of the film depend on the polymer in the latex particles. Significant differences can exist between films made from solution polymer and latex polymer, respectively, because of the colloidal debris remaining on the latex polymer (59). Important film properties include hardness, flexibility, clarity, conductance, impact strength, and toughness. Core–shell particles have seen extensive use as rubber-toughening agents.

Improving Properties Through Compounding. The potential value of most polymers can be realized only after proper compounding. Materials used to enhance polymer properties or reduce polymer cost include antioxidants (qv), cross-linking agents, accelerators, fillers (qv), plasticizers (qv), adhesion promoters, pigments, etc. Antioxidants are essential to retard degradation in unsaturated polymers. Cross-linking agents are used to build modulus, resistance to permanent deformation, and greater solvent resistance in many types of polymers. Accelerators are frequently used to reduce the time and temperature required to affect the cross-linking. Fillers, such as carbon black (qv) and clays, do not reinforce latex polymers as they do their dry polymer counterparts. Rather, they are used in most latex applications to adjust processing rheology and to lower raw material costs of the product, or to impart specific effects, eg, aluminum trihydrate to increase resistance to flame degradation, or carbon black to increase resistance

to UV degradation. Plasticizers and oils are used to soften and increase flexibility at lower temperatures, improve resistance to crystallization, or depress the brittle point of the product. Hydrocarbon process oils, glycols, vegetable oils, ester plasticizers, and low melting point resins are some of the common materials used. Many types of resins are added to enhance the tackiness of polymers. Generally, within a class of tackifying resins, the lower the melting point, the greater the tack developed in the compounded polymer. The optimum amount of any resin for maximum tack depends on the type of polymer to which it is added. Resins added as solvent-cut emulsions rather than as solventless emulsion or dispersions develop more tack in the polymer, because the residual solvent in the polymer contributes to the tack of the polymer resin blend. Pigments and dyes are used to impart color. Some pigments with some polymers also impart other effects such as improved water resistance or reduced flammability.

Latex Applications

Adhesives. Latices are used as additives (qv) in the construction market, in tires and belt fabrication, in furniture manufacture, in packaging, and in tapes, labels, envelopes, and bookbinding. The adhesives are used in wet or dry laminations. In wet lamination, the adhesive is not dried before assembly; hence at least one of the substrates must be porous to allow for the water to evaporate. Wet lamination has the advantage that the surfaces to be adhered can be repositioned during assembly, provided the solids content remains below the level at which the adhesive begins to form a film. The disadvantage of wet lamination is the slower development of cohesive strength in the adhesive film and the need for closer control of timing when the two substrates are to be brought together; if this occurs too soon, the adhesive film is too weak to hold the assembly together, and if it occurs too late, the adhesive is too dry to effect a satisfactory bond.

Binders. Latices are used as fiber binders in the paper and textile industries. The two principal methods of application are (*1*) wet-end addition, wherein the ionic latex is added to a fiber slurry and then coagulated in the slurry prior to sheet formation; and (*2*) saturation of the latex into a formed fiber web, wherein the latex is coagulated by dehydration. Latices are also used as binders for particulate matter such as rubber scrap.

Coatings. Latices are used in residential and industrial paints, coated paper and paperboard, seeds (60), fabric coatings, backing for carpet, upholstery, and drapery; as basecoats for wallpaper and flooring; and in insulation coatings (see COATINGS). Application methods include brushing, squeegee, spraying, dipping, and frothing (see COATING METHODS, SURVEY).

Dipped Goods. Latices are used in various dipping processes to produce balloons, bladders, gloves, extruded thread, and tubing. Manufacturing techniques include multiple dip and dry, and coagulant dipping employing a colloidal destabilizer (61,62).

Foam Products. Latices are made into foams for use in cushioning applications. The latices are frothed with air and then chemically coagulated for thick applications, or heated to induce coagulation for thinner applications. The latter method allows for infinite pot life during production (see CELLULAR MATERIALS).

Modifiers. Latices are added to bitumens, mortars, and concrete to improve impact resistance and reduce stress cracking. Key to the use of latices in these technologies is compatibility between the latex and the construction materials.

Synthetic Latex Manufacture

The history of emulsion polymerization has been well documented (63). Early efforts to produce synthetic rubber coupled bulk polymerization with subsequent emulsification (64). The first attempts at emulsion polymerization arose from problems controlling the heat generated during bulk polymerization. In emulsion polymerization, hydrophobic monomers are added to water, emulsified by a surfactant into small particles, and polymerized using a water-soluble initiator. The result is a colloidal suspension of fine particles, 50–1000 nm in diameter, usually comprising 30–50 wt% of the latex product. By 1935 emulsion polymerization became the method of choice in making synthetic rubber because of its many advantages (65): (*1*) the reaction mass viscosity remains low throughout the polymerization, providing for improved heat transfer, agitation, and product handling; (*2*) the sensible heat of the water in the emulsion balances the heat of reaction generated by free-radical polymerization; and (*3*) the rate of reaction is rapid, while producing very high molecular weight.

Kinetics and Mechanisms. Early researchers misunderstood the fast reaction rates and high molecular weights of emulsion polymerization (66). In 1945 the first recognized qualitative theory of emulsion polymerization was presented (67). This mechanism for classic emulsion preparation was quantified (68) and the polymerization separated into three stages: nucleation, particle growth while monomer droplets exist, and particle growth once monomer droplets have disappeared.

Stage I: Particle Nucleation. During stage 1 of a typical emulsion polymerization, the reaction mass consists of an aqueous phase containing small amounts of soluble monomer, small spherical micelles, and much larger monomer droplets. The micelles are typically 5–30 nm in diameter and are saturated with monomer emulsified by the surfactant. The monomer droplets are larger, 1000–10,000 nm in diameter, and are also stabilized by the surfactant.

Water-soluble initiator is added to the reaction mass to generate radicals which can enter the very small diameter micelles. Polymerization starts in the mcielle, converting it into a growing polymer particle. As monomer within the particle converts to polymer, it is replenished by diffusion from the monomer droplets. The concentration of monomer in the particle remains high (5–7 M), as long as monomer droplets exist. The growing polymer particles require more surfactant to remain stable, supplied from the uninitiated micelles. Stage I is complete once the micelles have disappeared, usually at or before 10% monomer conversion. Typically, 1 in 100 micelles are converted into latex particles, the others sacrificing their surfactant to the larger latex particles.

Primary radicals generated from water-soluble initiator rarely enter a micelle (69) because of differences in surface-charge density. The radicals formed from decomposition of water-soluble initiator are ionic in nature and very soluble

in the aqueous phase. The ionic radical water solubility is reduced by polymerization with monomer dissolved in the aqueous phase, a key first step, and the growing ionic oligomer chains become less soluble in the aqueous phase and readily enter the micelles. Radical entry is a thermodynamic balance based on solubility (70). Other theories exist to explain how water-soluble radicals enter micelles (71). The micelles are presumed to be the principal locus of particle nucleation (72) because of the large surface area of micelles relative to the monomer droplets.

However, in the case of miniemulsion, processing methods reduce the size of the monomer droplets closer to the size of the micelle, leading to significant particle nucleation in the monomer droplets (73) and therefore lack of dependence on monomer tranpsort across the aqueous phase. Intense agitation, cosurfactant, and dilution are used to reduce monomer droplet size. Additives such as cetyl alcohol are used to retard the diffusion of monomer from the droplets to the micelles, in order to further promote monomer droplet nucleation (74). The benefits of miniemulsions include inclusion of hydrophobic moieties in latex particles (75), faster reaction rates (76), improved shear stability, and the control of particle-size distributions to produce high solids latices (77). Microemulsion Polymerization (qv) (78) employs very high surfactant levels to make very small latex particles.

An expression for the number of particles formed during stage I was developed, assuming micellar entry as the formation mechanism (68), where k is a constant varying from 0.37 to 0.53 depending on the relative rates of radical adsorption in micelles and polymer particles, r_i is the rate of radical generation, m is the rate of particle growth, a_s is the surface area covered by one surfactant molecule, and S is the total concentration of soap molecules.

$$N_\mathrm{p} = k(r_i/m)^{0.4}(a_\mathrm{s}S)^{0.6} \tag{1}$$

During stage I, the number of polymer particles range from 10^{13} to 10^{15} per mL. As the particles grow they adsorb more emulsifier and eventually reduce the soap concentration below its critical micelle concentration (CMC). Once below the CMC, the micelles disappear and emulsifier is distributed between the growing polymer particles, monomer droplets, and aqueous phase.

The Smith–Ewart expression (eq. 1) accurately predicts the particle number for hydrophobic monomers such as styrene and butadiene (79), but fails to predict the particle number (80) for more hydrophilic monomers such as methyl methacrylate and vinyl acetate. A new theory based on homogeneous particle nucleation, called the HUFT theory after Hansen, Ugelstad, Fitch, and Tsai, was developed (81) to explain the hydrophilic monomer data yielding more accurate particle number predictions. The HUFT theory has been extended to include precursor and mature latex particle formation (82,83). In homogeneous coagulation theory (82), very small diameter precursors, containing only small amounts of monomer, transform into mature particles through coagulation. Mature particles form only near the end of the nucleation stage and positively skewed particle-size distributions are the result (83).

The debate as to which mechanism, controls particle nucleation continues. There is strong evidence that the HUFT and coagulation theories hold true for the more water-soluble monomers. What remains at issue are the relative rates of

micellar entry, homogeneous particle nucleation, and coagulative nucleation when surfactant is present at concentrations above its CMC. It is reasonable to assume that each mechanism plays a role, depending on the nature and conditions of the polymerization (84).

Whatever the nucleation mechanism, the final particle size of the latex is determined during stage I, provided no additional particle nucleation or coalesence occurs in the later stages. Monomer added during stages II and III only serves to increase the size of the existing particles.

Stage II: Growth in Polymer Particles Saturated with Monomer. Stage II begins once most of the micelles have been converted into polymer particles. At constant particle number the rate of polymerization, R_p, as given by Smith–Ewart kinetics is as follows: (85)

$$R_p = \frac{10^3 N k_p [M] \bar{n}}{N_A} \tag{2}$$

where k_p is the propagation rate constant, $[M]$ is the concentration of monomer in the particle, N is the concentration of growing polymer particles, $\bar{n}$ is the average number of radicals per particle, and N_A is Avogadro's number.

During stage II the growing particles maintain a nearly constant monomer concentration. The concentration of monomer is particle-size dependent, with smaller particles having lower concentrations (86).

During stages II and III the average concentration of radicals within the particle determines the rate of polymerization. To solve for $\bar{n}$ the fate of a given radical was balanced across the possible adsorption, desorption, and termination events. Initially, a solution was provided for three physically limiting cases. Subsequently, n was solved for explicitly without limitation using a generating function to solve the Smith–Ewart recursion formula (87). This analysis for the case of very slow rates of radical desorption was improved on (88), and later radical readsorption was accounted for and the Smith–Ewart recursion formula solved via the method of continuous fractions (89). More recently, an algebraic solution (90) to the Smith–Ewart recursion formula was put forth that greatly simplifies the calculation.

The nature of the radical within the latex particle determines its fate; ie, its propensity to desorp, propagate, chain transfer, or terminate. It seems reasonable that an ionic radical will not penetrate deeply into a latex particle but rather anchor its ionic head on the surface or palisade of the latex particle, much the way a surfactant molecule does. Once anchored, the nonpolar tail containing the radical will penetrate into the particle, and reactively diffuse throughout the polymer and monomer solution until either the ionic radical desorbs back into the aqueous phase, the ionic radical terminates with another radical within the particle, or the ionic radical undergoes a chain transfer event with either the monomer, polymer, or a chain-transfer agent within the latex particle. Once a chain transfer event occurs, the new radical becomes nonionic and has a markedly different solublity in the particle and aqueous phases. As the nonionic radical grows in chain length within the particle, it becomes even less soluble in the aqueous phase and becomes less likely to desorb. Such a qualitative description of radical fate was quantified

(91) and used to properly calculate the rate of polymerization in a macromonomer-mediated emulsion polymerization of methyl methacrylate.

As the particles grow, they require more soap to remain stable. If soap is not available the particles can destabilize, causing product and process problems.

Stage III: Growth in Polymer Particles with a Decreasing Monomer Concentration. Stage III begins once the monomer droplets disappear. The rate of polymerization decreases with reduced particle monomer concentration. At high monomer conversion, diffusion control of termination can cause an apparent increase in the rate of polymerization (92). Still further conversion can lead to diffusion control of propagation and a marked reduction in rate of polymerization (93). High free monomer in the final latex can result (94–96) causing product odor and handling problems.

The Smith–Ewart kinetics described assume homogeneous conditions within the particle. An alternative view, where monomer polymerizes only on the surface of the particle, has been put forth (97) and supported (98). The nature of the intraparticle reaction environment remains an important question.

Basic Components. The principal components in emulsion polymerization are deionized water, monomer, initiator, emulsifier, buffer, and chain-transfer agent. A typical formula consists of 20–60% monomer, 2–10-wt% emulsifier on monomer, 0.1–1.0-wt% initiator on monomer, 0.1–1.0-wt% chain-transfer agent on monomer, various small amounts of buffers and bacteria control agents, and the balance deionized water.

Water. Latices should be made with deionized water or condensate water. The resistivity of the water should be at least $10^5\Omega$. Long-term storage of water should be avoided to prevent bacteria growth. If the ionic nature of the water is poor, problems of poor latex stability and failed redox systems can occur. Antifreeze additives are added to the water when polymerization below 0°C is required (99). Low temperature polymerization is used to limit polymer branching, thereby increasing crystallinity.

Monomers. A wide variety of monomers can be used, and they are chosen on the basis of cost and ability to impart specific properties to the final product. Water solubilities of industrially important monomers are shown in Table 1 (100). The solubility of the monomer in water affects the physical chemistry of the polymerization. Functional monomers such as methacrylic and acrylic acid, infinitely soluble in water, are also used. These monomers impart long-term shelf stability to latices by acting as emulsifiers. The polymerization behavior of some monomers, such as methacrylic acid, as well as the final latex properties are influenced by pH. For optimum results with these acids, polymerization is best performed at a pH of ca 2. After polymerization, the latex is neutralized to give adequate shelf stability at tractable viscosities.

When monomers of drastically different solubility (101) or hydrophobicity are used or when staged polymerizations (102,103) are carried out, core–shell morphologies are possible. A wide variety of core–shell latices have found application in paints and impact modifiers, and as carriers for biomolecules. In staged polymerizations, spherical core–shell particles are made when polymer made from the first monomer is more hydrophobic than polymer made from the second monomer (104). When the first polymer made is less hydrophobic than the second, complex

Table 1. Water Solubilities of Monomers Common to Latex Production

Monomer	CAS Registry Number	Solubility in water at 25°C, mM
n-Octyl acrylate	[2499-59-4]	0.34
Dimethylstyrene		0.45
Vinyltoluene	[25012-15-4]	1.0
n-Hexyl acrylate	[2499-95-8]	1.2
Styrene	[100-42-5]	3.5
n-Butyl acrylate	[141-32-2]	11
Chloroprene	[126-99-8]	13
Butadiene	[106-99-0]	15
Vinylidene chloride	[75-35-4]	66
Ethyl acrylate	[140-88-5]	150
Methyl methacrylate	[80-62-6]	150
Vinyl chloride	[75-01-4]	170
Vinyl acetate	[108-05-4]	290
Methyl acrylate	[96-33-3]	650
Acrylonitrile	[107-13-1]	1600
Acrolein	[107-02-8]	3100

morphologies are possible including voids and half-moons (105), although spherical particles still occur (106).

Surfactants. Surfactants perform many functions in emulsion polymerization, including solubilizing hydrophobic monomers, determining the number and size of the latex particles formed, providing latex stability as particles grow, and providing latex stability during post-polymerization processing.

Emulsification is the process by which a hydrophobic monomer, such as styrene, is dispersed into micelles and monomer droplets. A measure of a surfactant's ability to solubilize a monomer is its CMC. Below the CMC the surfactant is dissolved in the aqueous phase and does not serve to solubilize monomer. At and above the CMC the surfactant forms spherical micelles, usually 50–200 soap molecules per micelle. Many properties, such as electrical conductivity, interfacial tension, surface tension, refractive index, and viscosity, show a sudden decrease at the CMC (107). The CMC is temperature- and chain-length-dependent for a given class of surfactants (108). The CMCs of nonionic surfactants are higher than those of ionic surfactants (109).

Surfactants also stabilize the growing polymer particles by overcoming the attractive forces between particles. Anionic and cationic surfactants use electrostatic repulsion forces to negate the attraction. Nonionic surfactants use steric forces to repel the attraction. Figure 1 compares the two stabilizing mechanisms. The ability of a given surfactant to stabilize latex particles is dependent on many factors (110), including surfactant type and concentration, aqueous solubility of the monomer and polymer, agitation and shear rate, temperature, surface tension, ionic strength, and concentration of the monomer and polymer (111).

An a priori method for choosing a surfactant was attempted by several researchers (112) using the hydrophile–lipophile balance or HLB system (113). In the HLB system a surfactant soluble in oil has a value of 1 and a surfactant soluble in water has a value of 20. Optimum HLB values have been reported

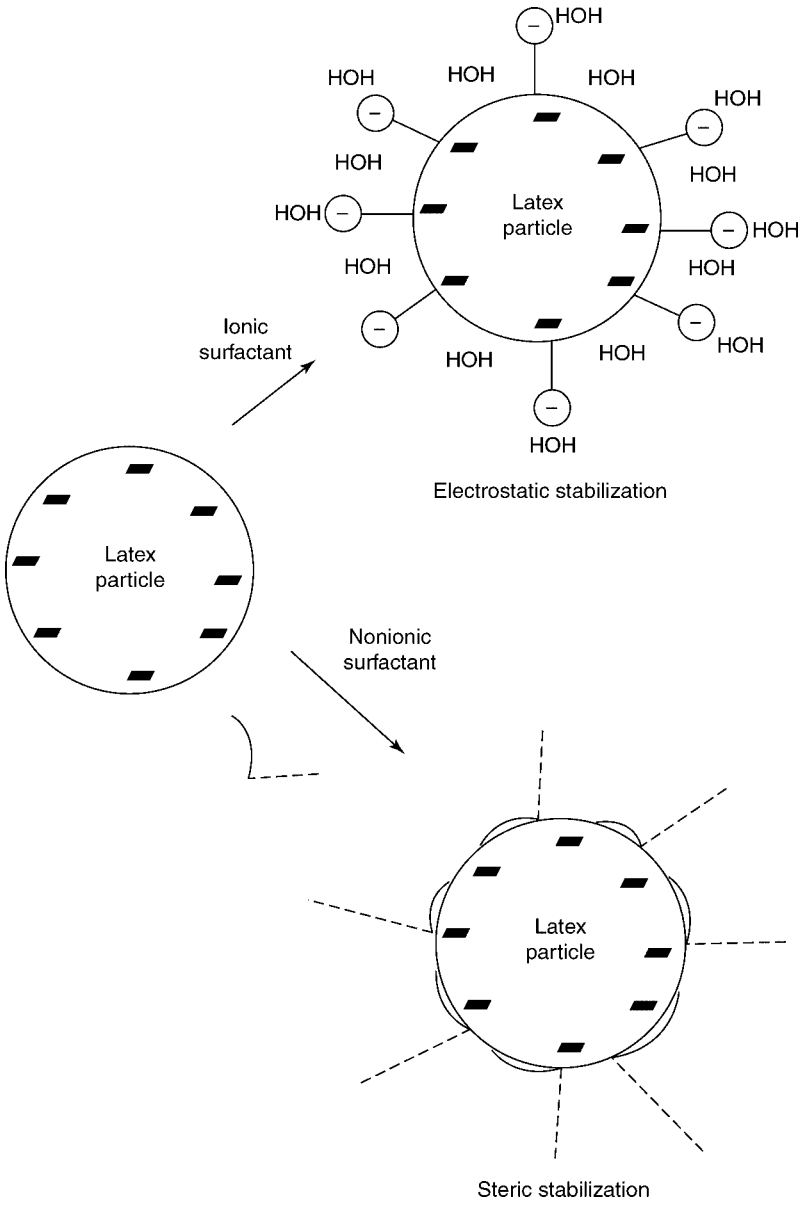

Fig. 1. Surfactant stabilization mechanisms.

for latices made from styrene, vinyl acetate, methyl methacrylate, ethyl acrylate, acrylonitrile, and their copolymers and range from 11 to 18. The HLB system has been criticized as being imprecise (114).

Three generations of latices as characterized by the type of surfactant used in manufacture have been defined (115). The first generation includes latices made with conventional (*1*) anionic surfactants such as fatty acid soaps, alkyl carboxylates, alkyl sulfates, and alkyl sulfonates (116); (*2*) nonionic surfactants such as

poly(ethylene oxide) or poly(vinyl alcohol) used to improve freeze–thaw and shear stability; and (*3*) cationic surfactants such as amines, nitriles, and other nitrogen bases, rarely used because of incompatibility problems. Portland cement latex modifiers are one example where cationic surfactants are used. Anionic surfactants yield smaller particles than nonionic surfactants (117). Often a combination of anionic surfactants or anionic and nonionic surfactants is used to provide improved stability. The stabilizing ability of anionic fatty acid soaps diminishes at lower pH as the soaps revert to their acids. First-generation latices also suffer from the presence of soap on the polymer particles at the end of the polymerization. Steam and vacuum stripping methods are often used to remove the soap and unreacted monomer from the final product (118,119).

The second generation includes latices made with functional monomers such as methacrylic acid, 2-hydroxyethyl acrylate [818-61-1], acrylamide [79-06-1], 2-dimethylaminoethylmethacrylate [2867-47-2], and sodium *p*-vinylbenzenesulfonate [98-70-4] that create *in situ* polymeric emulsifier. The initiator decomposition products, such as the sulfate groups arising from persulfate decomposition, can also act as chemically bound surfactants. These surfactants are difficult to remove from the latex particle.

The third generation are latices made with independently prepared surfactant to mimic the *in situ* prepared functional monomer surfactant. These emulsifiers are often A–B block polymers where A is compatible with the polymer and B with the aqueous phase. In this way, surface adsorption of the surfactant is more likely.

Any of these surfactant classes can involve surfactants that react onto the latex particle. These surfactants are known as *surfmers*. If the surfactant also acts as a chain-transfer agent, it is dubbed a *transurf*. Reversible addition fragmentation agents can act as transurfs (120).

Initiators. The initiators most commonly used in emulsion polymerization are water-soluble although partially soluble and oil-soluble initiators have also been used (121). Normally only one initiator type is used for a given polymerization. In some cases a finishing initiator is used (122). At high conversion the concentration of monomer in the aqueous phase is very low, leading to much radical–radical termination. An oil-soluble initiator makes its way more readily into the polymer particles, promoting conversion of monomer to polymer more effectively.

The most common water-soluble initiators are ammonium persulfate, potassium persulfate, and hydrogen peroxide. These can be made to decompose by high temperature or through redox reactions. The latter method offers versatility in choosing the temperature of polymerization with −50 to 70°C possible. A typical redox system combines a persulfate with ferrous ion:

$$S_2O_8^{2-} + Fe^{2+} \rightarrow Fe^{3+} + SO_4^{2-} + SO_4^{-} \quad (3)$$

Reducing agents are employed to return the Fe^{3+} to Fe^{2+}. By starting at a lower temperature, the heat of reaction can be balanced by the sensible heat of the water in the emulsion. Temperature profiles from 20 to 70°C are typical for such systems. Care must be taken when working with redox systems to eliminate oxygen from the reactor before beginning the polymerization. The effectiveness of

the redox system can be pH-dependent, with the optimum pH range depending on the type of the redox system (123). For higher temperature polymerizations, eg, above 70°C, thermal decomposition of the initiator is used.

A third source of initiator for emulsion polymerization is hydroxyl radicals created by γ-radiation of water. A review of radiation-induced emulsion polymerization detailed efforts to use γ-radiation to produce styrene, acrylonitrile, methyl methacrylate, and other similar polymers (124). The economics of γ-radiation processes are claimed to compare favorably with conventional techniques although worldwide industrial application of γ-radiation processes has yet to occur. Use of γ-radiation has been made for laboratory study because radical generation can be turned on and off quickly and at various rates (125).

The ionic nature of the radicals generated, by whatever technique, can contribute to the stabilization of latex particles. Soapless emulsion polymerizations can be carried out using potassium persulfate as initiator (126). It is often important to control pH with buffers during soapless emulsion polymerization.

Chain-Transfer Agents. The most commonly employed chain-transfer agents in emulsion polymerization are mercaptans, disulfides, carbon tetrabromide, and carbon tetrachloride. They are added to control the molecular weight of a polymer, P_n, by transferring a propagating radical to the chain-transfer agent AX (127):

$$P_n^{\bullet} + \mathrm{AX} \rightarrow P_n\mathrm{X} + \mathrm{A}^{\bullet} \tag{4}$$

The newly formed short-chain radical $\mathrm{A}^{\bullet}$ then quickly reacts with a monomer molecule to create a primary radical. If subsequent initiation is not fast, AX is considered an inhibitor. Many have studied the influence of chain-transfer reactions on emulsion polymerization because of the interesting complexities arising from enhanced radical desorption rates from the growing polymer particles (128,129). Chain transfer reactions are not limited to chain transfer agents. Chain transfer to monomer is in many cases the main chain termination event in emulsion polymerization. Chain transfer to polymer leads to branching which can greatly impact final product properties (130).

Other Ingredients. During polymerization and post-processing, the pH of the emulsion is important. Increasing the pH to improve latex stability is achieved usually by adding sodium hydroxide, potassium hydroxide, or ammonia. To avoid causing any localized flocculation because of a rapid increase in electrolyte in a confined area, these ingredients must be added as dilute solutions of around 3% with mild agitation. In some cases, some surfactant may be required to be added along with the dilute alkali. Antimicrobial agents are added for protection against bacteria attack.

Process. Commercial processes (131) manufacturing latex can be divided into batch, semibatch, and continuous methods. A schematic of typical equipment is shown in Figure 2. The reactor is usually glass-lined, including agitator and thermowell. The remaining tanks are constructed of stainless steel. The reactor is jacketed to allow for heating and cooling between 0 and 100°C. Reactor agitation is chosen to provide adequate mixing while avoiding shear-induced coagulation. The reactor is equipped with a small condenser; reflux is to be avoided to prevent coagulum from forming. A monomer–soap solution is emulsified by a centrifugal pump

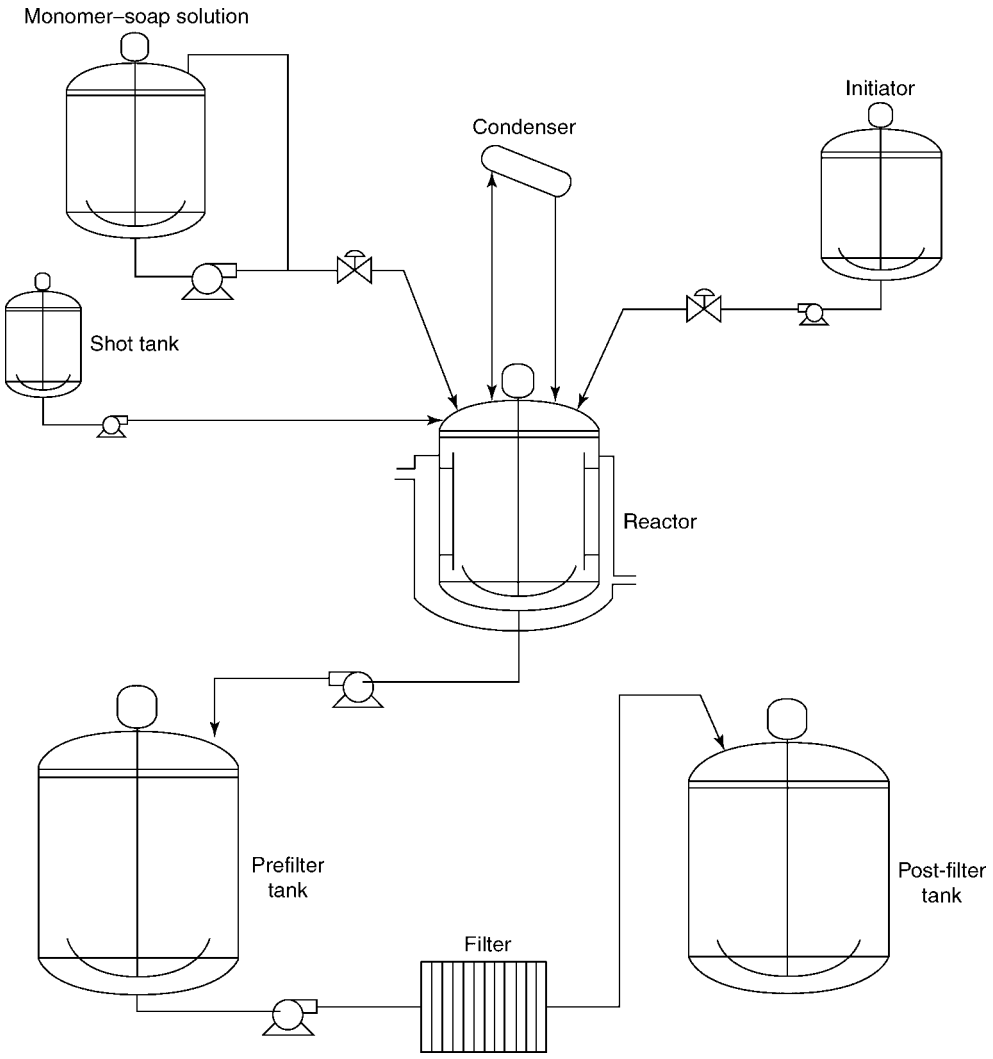

Fig. 2. Typical latex manufacturing equipment.

and fed to the reactor along with initiator, using suitable flow control. Premixing monomer and initiator is to be avoided to prevent premature polymerization in the feed tank. A shot tank is usually required to allow for addition of ingredients in minor amounts.

In the most common production method, the semibatch process, about 10% of the preemulsified monomer is added to the deionized water in the reactor. A shot of initiator is added to the reactor to create the seed. Some manufacturers use master batches of seed to avoid variation in this step. Having set the number of particles in the pot, the remaining monomer and, in some cases, additional initiator are added over time. Typical feed times are 1–4 h. Lengthening the feeds tempers heat generation and provides for uniform comonomer sequence distributions (132). Sometimes skewed monomer feeds are used to offset differences in monomer

reactivity ratios. In some cases a second monomer charge is made to produce core–shell latices. In-line instruments can help determine monomer consumption rates and are becoming more frequently employed, especially in the development of new materials (133). At the end of the process, pH adjustments are often made. The product is then pumped to a prefilter tank, filtered, and pumped to a post-filter tank where additional processing can occur. When the feed rate of monomer during semibatch production is very low, the reactor is said to be monomer-starved. Under these conditions, monomer droplets are not present, and intraparticle polymerization takes place under high polymer–low monomer concentrations. These conditions can lead to branched polymer with bi- and trimodal molecular weight distributions (134).

The batch process is similar to the semibatch process, except that most or all of the ingredients are added at the beginning of the reaction. Heat generation during a pure batch process makes reactor temperature control difficult, especially for high solids latices. Seed, usually at 5–10% solids, is routinely made via a batch process to produce a uniform particle-size distribution. Most kinetic studies and models are based on batch processes (135).

Continuous processes have been developed for many of the larger volume synthetic latices (136–140). Most of these processes involve the use of several continuously stirred tank reactors (CSTR) in series. The exponential residence time distribution of a CSTR is broad relative to a batch reactor, leading to broad particle-size distributions. By placing many CSTRs in series, the effective residence time and corresponding particle-size distributions are narrowed. CSTR processes can also suffer from sustained oscillations and multiple steady states, leading to poor reactor and product performance (141). The cause of the oscillations is related to new particle formation. To avoid such oscillations, many processes use a seed latex in the feed stream (142). If premanufacture of seed is not desirable, a tubular reactor can be used to produce seed of uniform particle size (143). Tubular reactors have also been used as loop reactors, where feeds enter and leave a tubular loop in which the circulating flow is much greater than the throughput (144). Cooling water is sprayed directly on the tube to control the reaction temperature. Recently, coagulum has been successfully controlled during tubular production of a latex using pulsatile flow (145).

Foaming represents a persistent problem in the processing and handling of latices. The most effective way to eliminate the presence of foam is to simply avoid its generation. Ways to reduce foam include eliminating the free fall of latex by using dip-pipes, not stirring air into the latex by not agitating with exposed impellers, and not adding dry ingredients laden with adsorbed air directly to the latex. There are many proprietary additives for minimizing generation of foam (antifoaming agents) or eliminating foam (defoaming agents), but there is no one type that works for all latices (see ANTIFOAMING AGENTS). Only by trial and error can the most effective agent be found for a given compound or process. With any of them, the minimum amount required should be used since their addition tends to cause localized flocculation, poor wetting, lower water resistance, and "fisheyes" in films. Many antifoam agents get absorbed into the polymer or other ingredients in the compound and thus lose their effectiveness over time, particularly if the compound is being recirculated during processing. These conditions necessitate augmentation with additional amounts of antifoaming agent to counter these effects.

Process Modeling. The complexity of emulsion polymerization makes reliable computer models valuable. Many attempts have been made to simulate the emulsion polymerization process for different monomer systems (146–148).

Other Routes.

High Solids Emulsions. Latices are made at the highest possible solids content consistent with acceptable viscosity. Latices solids can be increased by centrifuging, creaming, electrodecantation, or evaporation. The latter two techniques, however, are not of commercial importance. Natural rubber latex, 25–40-wt% solids to start, is concentrated to about 60-wt% solids by centrifuging with milk/cream separator equipment. Creaming is commonly used with synthetic polymer latices. Creaming is accelerated by adding solutions such as ammonium alginate and surfactant to the latex. Depending on the initial solids content and type of latex, solids contents of 58–65 wt% are possible.

Soap-starved recipes have been developed that yield 60-wt% solids low viscosity polymer emulsions without concentrating. It is possible to make latices for application as membranes and similar products via emulsion polymerization at even higher solids (149). Solids levels of 70–80 wt% are possible. The paste-like material is made in batch reactors and extruded as product.

Inversion of Nonacqueous Polymers. Many polymers such as polyurethanes, polyesters, polypropylene, epoxy resins, and silicones that cannot be made via emulsion polymerization are converted into latices. Such polymers are dissolved in solvent and inverted via emulsification, followed by solvent stripping (150). Solid polymers are milled with long-chain fatty acids and diluted in weak alkali solutions until dispersion occurs (151). Such latices usually have lower polymer concentrations after the solvent has been removed. For commercial uses the latex solids are increased by techniques such as creaming.

MECHANICAL PERFORMANCE OF PLASTICS

Introduction and Scope

Since 1950 or so revolutionary developments have taken place in synthesis, characterization, structure–property relations, performance, and applications of synthetic polymers. Applications of these materials have permeated all aspects of our daily life, including health, medicine, clothing, transportation, housing, defence, energy, electronics and photonics, information technology, employment, and trade (1). This has been possible because of unique attributes of polymer-based materials including low density, high specific strength and modulus, high corrosion resistance, full ranges (from very low to very high) of electrical and thermal conductivities, easy and low energy processing into intricate shapes by fast processing techniques (such as injection molding or extrusion), moth and fungus resistance, controlled biodegradability, low permeability of water vapors and other gases, and great aesthetic appeal. One property alone, namely low densities, causes gradual conversion in automotive, aviation, aerospace, and other industries from metal parts to polymer-based parts.

On top of the above attributes, polymer materials are generally less expensive than most alternative materials. Mechanical properties are most important in the design and selection of engineering plastics because all applications require necessarily a certain degree of mechanical loading.

Consider now polymer-based materials from the point of view of a materials user. A user can be an industrialist who buys truckloads of polymer-based components for his plant, a housewife, a little girl playing with a plastic doll—in fact anybody. The user typically has no interest (and little knowledge) of chemical synthesis of polymers, thermodynamics, polymer processing—in fact of any

of the areas of polymer science and engineering. There is only one aspect of interest common to scientists, engineers, and laymen alike—and that is the *performance*. Since performance involves mechanical properties, there will be necessarily certain overlaps with other articles of this *Encyclopedia* which in various ways deal with these properties, eg, Elasticity, Rubber-like (qv), Viscoelasticity (qv), Fracture (qv), Fatigue (qv), Impact Resistance (qv), Dynamic Mechanical Analysis (qv), Micromechanical Properties (qv), and Yield and Crazing (qv). The present article focuses on performance and its constituent *reliability*.

Problems in polymer science and engineering can be solved on the basis of information acquired in experiments, by developing models and theories, and also by performing computer simulations. All these three kinds of approaches are useful when dealing with performance and reliability.

Relaxational and Destructive Processes: Chain Relaxation Capability

The Importance of Reliability. The reliability of a material or component—not necessarily polymeric—constitutes its most important characteristics. The two questions concerning polymer-based materials that are being asked the most often are

(1) Will a material or component serve as much time as I need it, or will it fail prematurely?
(2) Is there a material or component with better properties?

Although both questions are often asked simultaneously, the second question deals with development of new materials and will be considered in other articles. The first question shows that failure is related to prediction of service performance under given service conditions.

Chain Relaxation Capability. What is the key factor of deciding whether a material will serve—rather than deform and fracture into pieces? To answer this, we need to remember that polymer-based materials are viscoelastic. The "face" each polymer shows to the observer—elastic, viscous flow, or a combination of both—depends on the rate and duration of force application as well as on the nature of the material and external conditions including the temperature. Later there will be a more detailed discussion of the nature of viscoelasticity. At this point let us stress that properties of viscoelastic materials vary with time—while for elastic materials time plays no role at all.

A component in service is "attacked" from the outside, perhaps by an impact (in impact testing we are actually hitting the specimen with a hammer) or else by slow extension (as in tensile testing). In general, forces with various duration, direction(s), and application rate

$$U = U_0 - U_b - U_r \tag{1}$$

Here U is the energy provided from the outside which at a given time has not yet been spent one way or the other; U_b ("b" for bond breaking) at the same time

has been spent on destructive processes (such as crack formation or propagation); U_r at the given time has been dissipated, in other words spent on nondestructive processes. Dissipation in a viscoelastic material is largely related to relaxational processes; the subscript "r" stands for relaxation. The quantities in equation 1 may refer to the material as a whole, but it is usually more convenient to take them as pertaining each to a unit weight of polymer such as 1 g.

The question whether the component will survive in fact hinges on U_r. The energy U_r is related to the chain relaxation capability (CRC) which has been defined (2–4) as the amount of external energy dissipated by relaxation in a unit of time per unit weight of polymer.

We shall use the abbreviation CRC for the concept and the symbol U_{CRC} for the respective amount of energy. Thus, at a given time t

$$U_r = \int_0^t U_{CRC}\, dt \tag{2}$$

It takes approximately 1000 times more external energy to break a primary chemical bond (such as a carbon–carbon bond in a carbonic chain, what corresponds to U_b and to crack propagation) than to execute a conformational rearrangement. This is the basis of the following key statement (2–4): Relaxational processes have priority in the utilization of external energy. The excess energy, which cannot be dissipated by such processes, goes into *destructive* processes.

In other words, the viscoelastic material will try to relax rather than fracture—as long as it can go on relaxing. Unless there is a high concentration of external energy at a particular location, so that a number of primary chemical bonds will break starting a crack, that energy will be dissipated. In contrast to metals and other nonchain materials, when we pull at a polymeric chain, we gradually engage all segments of it; this by itself lowers the probability of local concentration of the external energy and thus the probability of destruction.

We can distinguish at least four constituents of CRC (2–4):

(1) Transmission of energy across the chain, producing intensified vibrations of the segments;
(2) Transmission—mainly by entanglements but also by segment motions—of energy from the chain to its neighbors;
(3) Conformational rearrangements (such as cis into trans) executed by the chains;
(4) Elastic energy storage resulting from bond stretching and angle changes. This last factor is often excluded from considerations even though for a number of processes, it might be quite important.

Chain relaxation capability depends strongly on free volume, that is the amount of space in which polymer chain segments can move around and relax. This connection will be explored and used to advantage later on in this article.

The concepts defined above will serve to evaluate reliability of polymer-based materials, but first methods of experimental determination of mechanical properties and also the responses of materials to deformation should be reviewed (5).

Quasi-Static Mechanical Testing

Types of Applied Stress. Mechanical behavior of polymer-based materials depends on composition, structures, and interactions at molecular and supermolecular levels (5–7). The structures are much dependent on primary chemical (mostly covalent) bonding inside the chains and secondary bonding (dispersion: van der Waals, induction, electrostatic, and hydrogen bonding, the last being the strongest in this category) forces in between chains (8). The composition often includes additives aimed at an improvement of a particular property.

When a body is subjected to an applied force F, the resultant stress σ induces a finite deformation or strain ε within the body. The deformation can be recoverable (elastic) irrecoverable (plastic), gradually partly recoverable (viscoelastic) and can lead to fracture of the body, depending on amplitude of load, rate of deformation, and temperature. The recoverable deformation may be instantaneous, small (energetic elastic in nature due to the bending and stretching of the interatomic bonds of plastic materials), or large (rubbery or entropic, also elastic in nature due to coiling and uncoiling of polymer chains). The irrecoverable or plastic deformation may lead to permanent deformation or may be recoverable after heating the polymeric material above its glass-transition temperature T_g. The viscoelastic deformation is generally a function of temperature T since it depends on free volume v^f (much more of which is discussed later).

Simple *fracture* is the separation of the body into two or more parts in response to an imposed stress that can be acting slowly (for instance the gravitational field of the earth), rapidly (impact), or anything in between.

The applied stress may be tensile, compressive, shear, hydrostatic, or torsional (see Fig. 1). Two fracture models are possible, *ductile* and *brittle*. In ductile materials fracture is preceded by substantial plastic deformation with high energy absorption. By contrast, there is normally little or no plastic deformation and low energy absorption accompanying a brittle fracture. The ductility is a function of temperature of the material, the strain rate, and the stress state. Depending on these factors, a material considered ductile material may actually fail in a brittle manner.

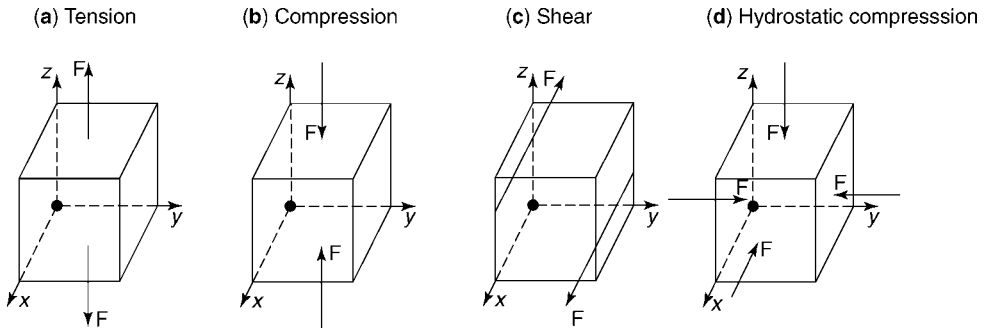

Fig. 1. Typical modes of stress application to polymeric materials: (**a**) Tension, (**b**) Compression, (**c**) Shear, (**d**) Hydrostatic pressure.

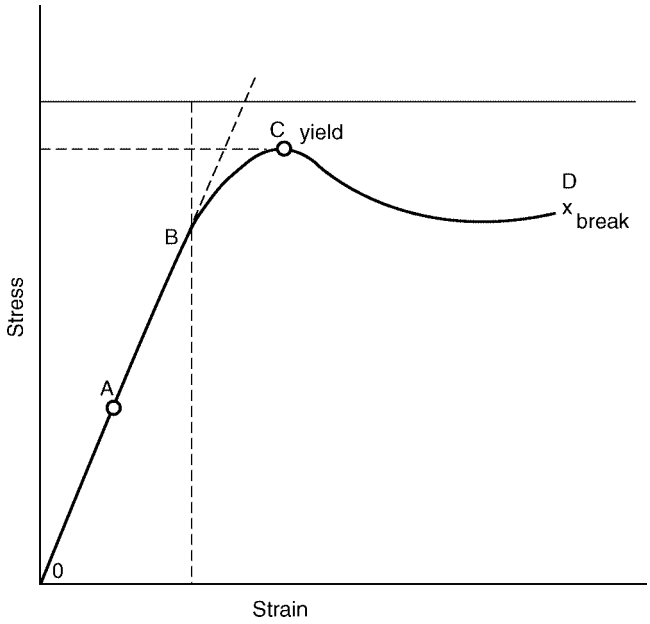

Fig. 2. A stress–strain curve in tension typical for engineering plastics.

Stress–Strain Behavior. The determination of stress–strain behavior in tension is one of the most important test methods for mechanical properties of engineering plastics and is of high importance to the design engineer (see ENGINEERING THERMOPLASTICS, OVERVIEW). The tensile test is usually performed by monitoring the force that develops as the sample is elongated at a constant rate of extension. An often encountered stress–strain curve of a plastics material at equilibrium with any environment can be represented as depicted in Figure 2.

The behavior seen in Figure 2, typical as it is, is by no means the only one. A hard and brittle material such as a phenolic resins (qv) is characterized by a high modulus of elasticity, no well-defined yield point, and low strain at break (Fig. 3**a**). It may not yield before break. A hard and strong material is characterized by a high modulus, high yield stress, and high strength with low strain at break, such as a polyoxymethylene (Fig. 3**b**). A hard and tough material such as polycarbonate (qv) is characterized by high modulus, high yield stress, and high elongation at break (Fig. 3**c**). A soft but tough material such as polyethylene (PE) exhibits low modulus and low yield stress with very high elongation at break (Fig. 3**d**) (see ETHYLENE POLYMERS, HDPE; ETHYLENE POLYMERS, LDPE; ETHYLENE POLYMERS, LLDPE). A soft and weak material, such as polytetrafluoroethelene (PTFE, Teflon) is characterized by low modulus and low yield stress with moderate elongation at break (see PERFLUORINATED POLYMERS, POLYTETRAFLUOROETHYLENE).

The area under stress–strain curve is proportional to the energy required to break and is a measure of the *toughness* of the material. Typical engineering plastics exhibit curves characteristic of hard and strong or hard and tough materials.

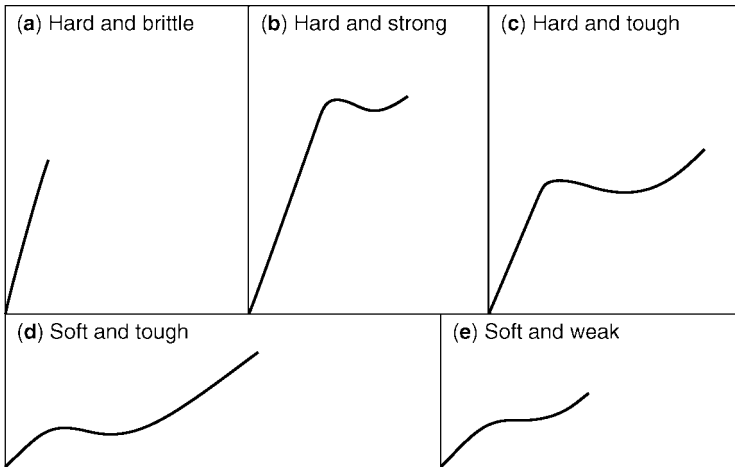

Fig. 3. Tensile stress–strain curves for several categories of plastics.

Elastic Modulae. The mechanical behavior is in general terms concerned with the deformation that occurs under loading. Generalized equations that relate stress to strain are called *constitutive relations*. The simplest form of such a relation is Hooke's Law which relates the stress s to the strain e for uniaxial deformation of the ideal elastic isotropic solid:

$$\sigma = E\,\varepsilon \tag{3}$$

E is the Young's modulus and is clearly a measure of resistance of the material to deformation; the reciprocal of the modulus $D = 1/E$ is called *compliance*.

In reality, the mechanical behavior of polymeric solids deviates from equation 3. The following factors are at play:

(1) Only at very small deformations the stress is exactly proportional to the strain and Hooke's Law is obeyed. In general, the constitutive equations are *nonlinear*. Unlike metals, polymers can recover from strains beyond the proportional limit without any permanent deviations.

(2) The loading rate and time affect the deformations in polymeric solids. As already pointed out, viscoelastic materials show simultaneously the "face" of an elastic solid and that of a flowing viscous liquid. This implies that the simplest constitutive relation for a polymeric solid should, in general, contain *time* and *frequency* as variables in addition to stress and strain.

(3) There is incomplete and time-dependent recovery when loads are removed.

(4) Polymer-based materials are often anisotropic—as in cases of films and synthetic fibers.

(5) Temperature and other environmental factors affect the mechanical behavior. Thus, polymers can show all features of a glassy brittle solid, an elastic rubber, or a viscous liquid depending on the temperature and time scale of measurements. At low temperatures or high frequencies, a polymeric

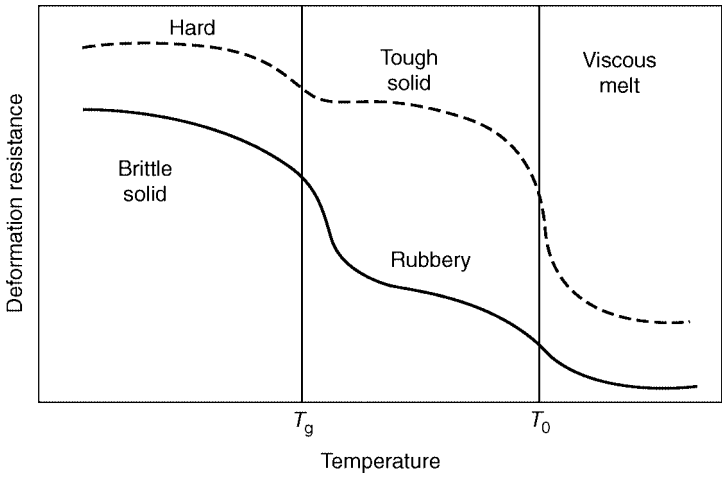

Fig. 4. Variation of Young's modulus with temperature for amorphous (solid line) and semicrystalline (broken line) polymers.

material may be glass-like with the Young's modulus of 10^9–10^{10} N/m^2 and will break or flow at strains greater than 5%. At high temperatures or low frequencies, the same polymeric material may be rubber-like with a modulus of 10^6–10^7 N/m^2 withstanding large extensions (≈100%) without permanent deformation. At still higher temperatures, permanent deformation occurs under load and the material behaves like a highly viscous liquid. In an intermediate temperature or frequency range (glass-transition range), the material is not glassy or rubber-like. Here it shows an intermediate modulus (viscoelastic modulus) and may dissipate a considerable amount of energy on being strained. Figure 4 shows the variation of Young's modulus with temperature. Note that the diagram pertains to uncross-linked elastomers (=rubbers) since in the cross-linked ones the plateau in the middle part remains also at high temperatures; see next section for more on elastomers. The glass-transition temperature is also highly influential in semicrystalline plastics where a brittle-tough transition in the solid state can be observed in response to an applied stress. Young's modulus decreases drastically on traversing the melting temperature T_m as melt is formed. The extent of crystallization determines the rate of change of the modulus—providing temperature characteristics both across and within the primary thermal transition.

(6) The whole range of the behaviors shown in Figure 5 can be displayed by a single polymer, depending on the temperature and strain rate. The figure displays the load extension behavior of a single polymer at various temperatures. At the lowest temperature we observe low extensibility followed by brittle behavior (Fig. 5**a**). Figure 5**b** shows a distinct yield point (maximum load) with subsequent failure by neck instability. Necking and cold drawing is seen in Figure 5**c** with orientational hardening and eventual failure in the highly oriented neck at high strain levels exceeding often 300%. Behaviors

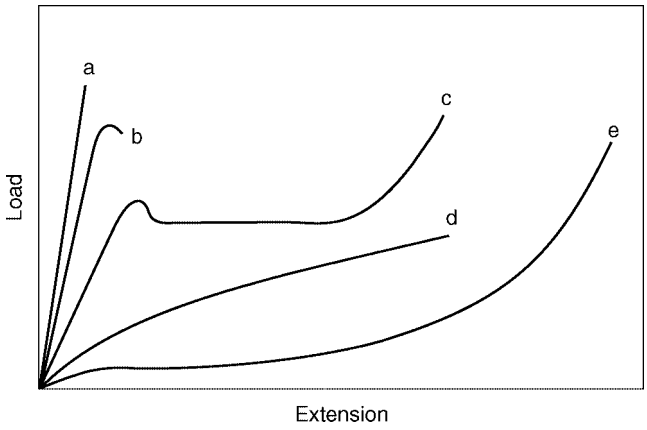

Fig. 5. Stress–strain curves at various temperatures (increasing from a to e): (**a**) low extensibility followed by brittle fracture at the lowest temperature; (**b**) localized yielding followed by fracture; (**c**) necking and cold drawing; (**d**) homogeneous deformation with indistinct yield; (**e**) rubber-like behavior.

seen in Figures 5**d** and 5**e** are characteristics of rubber elastic response, which is typical for amorphous and low crystalline materials at temperatures just above the glass-transition temperature T_g. These deformations are mainly elastic—characterized by low stress and high extensibility—unless there is significant stress-induced crystallization during drawing process.

(7) Similar curves can be obtained by changing the strain rate rather than temperature (see Fig. 6).

The elastic modulus E is only one of four elastic constants or modulae (8). Another one is the Poisson ratio ν defined as

$$\nu = -\varepsilon_r/\varepsilon \tag{4}$$

where ε_r is the linear strain in the direction perpendicular to the tensile stress σ producing the strain ε along the direction of the force application. ε_r has the opposite sign to that of ε, and hence the minus sign is incorporated in the definition to make ν positive for most materials. On application of a tensile stress on one pair of perpendicular faces of unit cube (Fig. 7**a**), the cube transforms to the shape seen in Figure 7**b**.

The bulk modulus k_b is defined by

$$k_b = -V\,dP/dV = -dP/(dV/V) \tag{5}$$

Here V is the volume of material and dP is the hydrostatic pressure applied from all sides. The negative sign has again been introduced to render the modulus positive.

The shear modulus G, the last of the four modulae, is defined in terms of the shear strain θ divided by the shear stress σ. Assuming θ to be very small

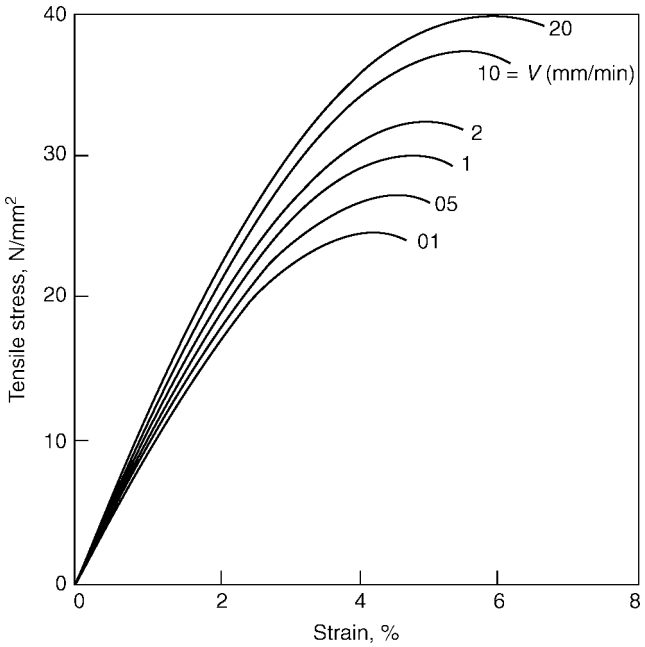

Fig. 6. Tensile stress–strain curves up to the yield point at various strain rates.

(see Fig. 7**c**), we have

$$G = \sigma/\theta \tag{6}$$

The linear theory of elasticity provides relationships between the modulae:

$$E = 2G(1+\nu) = 3\,k_b(1-2\nu) \tag{7}$$

The forces involved in the elasticity of amorphous polymers (qv) are not only of the van der Waals (dispersive) type but involve a high proportion of bonded interactions between atoms. The conformations of the polymer chain are "frozen in" so that the forces required in order to stretch bonds, change bond angles, and rotate segments of polymer chain around bonds are very important in determining the elastic properties. These forces are stronger than van der Waals forces and cause higher modulus.

Calculation of the modulae of semicrystalline polymers (qv) is fairly tedious and involves several operations: (*1*) calculation of modulae of amorphous polymers; (*2*) calculation of the elastic constants of anisotropic crystalline polymers; (*3*) averaging of elastic constants of the crystalline materials to provide an effective isotropic modulus; (*4*) the averaging of the isotropic amorphous and crystalline modulae to obtain the overall modulus. Only the second of these steps is accurate, the other are approximate.

In a semicrystalline material the chains are constrained because of the crystallization process. The constraints give the material different properties from those of a purely amorphous rubbery polymer. The states of stress and strain

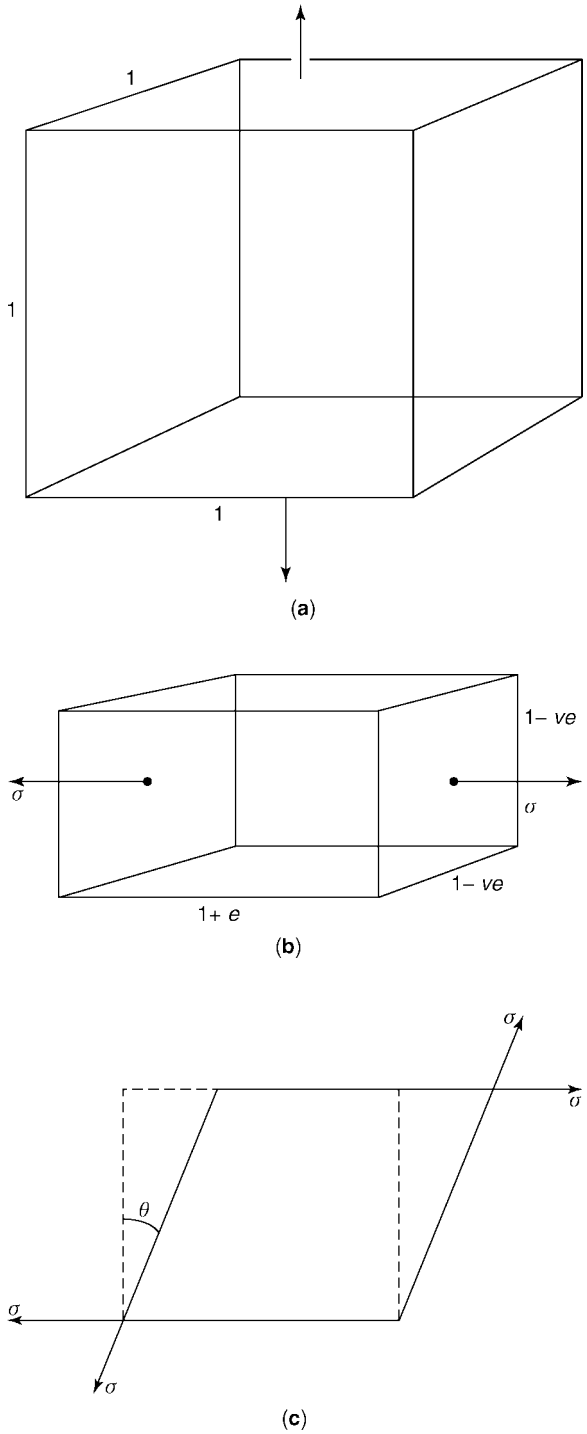

Fig. 7. The effect of application of tensile stress σ on a unit cube before (**a**) and after (**b**); (**c**) the application of shear stress τ to the unit cube.

are not homogeneous in a material comprising components with different elastic properties. In the operations just described, the assumption of uniform stress gives results closer to the experiment than does the assumption of uniform strain.

Rubber Elasticity

Unlike ordinary plastics, elastomers (also called rubbers) are capable of undergoing very large recoverable deformations under the influence of very small loads. A typical rubber may be stretched up to 10 times of its original length with essentially no visual or nonrecoverable strain. The rubber-like materials consist of relatively long polymeric chains that have a high degree of flexibility and mobility and are joined into a network structure. That structure leads to solid-like features where chains are prevented from flowing relative to each other under external stresses. The phenomenon is known as *rubber elasticity*. It is entropy-driven and is endowed with a thermoelastic effect. Rubber elasticity has been discussed by Gedde (9) and in much detail by Mark and his colleagues (10–12) (see ELASTICITY, RUBBER-LIKE). Important facts include

(1) A stretched rubber sample subjected to uniaxial load contracts reversibly on heating.
(2) The rubber sample gives out heat reversibly when stretched.
(3) The elastic forces are due to changes in conformational entropy. The long-chain molecules are stretched out to statistically less favorable states. The instantaneous deformation occurring in rubbers is due to high segmental mobility and thus results in rapid changes in chain conformation of the molecules. The energy barriers between different conformational states must be therefore small compared to the thermal energy.

The above features of rubbery materials have long been known. The quantitative measurements of mechanical and thermodynamic properties of natural and other elastomers go back to 1805 and some of the studies were conducted by luminaries like Joule and Maxwell. The first molecular theory in polymer science dealt with the rubber elasticity (9–12).

The first rubbery material discovered was natural rubber obtained from latex of the tree called *Hevea brasiliensis*. At this writing we have quite a variety of synthetic rubber or synthetic elastomers. The double bonds in natural rubber are all in cis configuration; a change in molecular conformation corresponding to a rotation around any of three single bonds per repeat unit requires very little energy. There are many single bonds in the backbone and there are no stiffening groups such as ring structures and bulky side chains. Another important feature is that the glass-transition temperatures T_g for all these materials are low and below the room temperature; hence they are in the rubbery state at ambient temperatures. Elastomers typically have low melting temperatures but some of them do undergo crystallization upon sufficiently large deformations.

Examples of typical elastomers include natural rubber, butyl rubber, poly(dimethyl siloxane), polyethyl acrylate, styrene–butadiene copolymer, and ethylene–propylene copolymer. Some polymers are not elastomers under normal

conditions but can be made so by raising the temperature or adding plasticizers (qv).

Quantitative statistical theories of rubber elasticity are based on the premise that contributions to the elasticity from to changes in the internal energy on stretching are negligible compared with the contributions due to changes in entropy (9–12). (see STATISTICAL THERMODYNAMICS). Essentially, the aim of the statistical theory is the calculation of the change in entropy when a rubber is deformed. By relating the change of entropy to the work done, strain energy function can be derived for isothermal stretching. Currently, one typically assumes that the network consists of phantom Gaussian chains, that all network changes are entropic, that the volume remains constant, and that one needs to take into account interchain interactions. In the phantom network theory, the positions of junctions are allowed to fluctuate about the mean positions prescribed by the affine deformation ratio. One finds that the modulus is proportional to the absolute temperature and also increases with increasing cross-link density.

The network theory gives a good representation of the experimental results only for moderate strains ($\varepsilon < 1.5$). For larger extensions, the theory overpredicts the stress because the conformational states are no longer adequately represented by the Gaussian distribution. At still higher extensions ($\varepsilon > 6$), the observed stress rapidly rises because of development of strain-induced crystallization [see Fig. 8 (here λ = strain ε)].

The values of Young's modulus for isotropic glassy and semicrystalline polymers are typically two orders of magnitude lower than those of metals. These materials can be either brittle with fracture at strains of a few percent or ductile leading to large but nonrecoverable deformation. Young's modulae for elastomers are typically four orders of magnitude smaller than, say, steel—which is how recoverable extensions up to ≈1000% are possible.

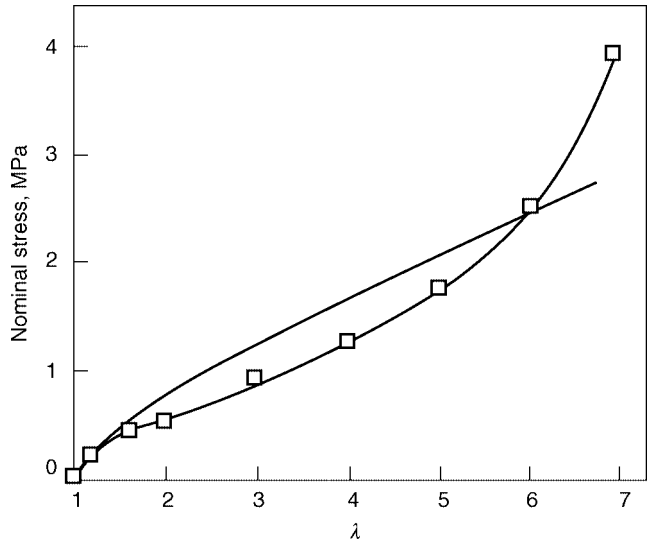

Fig. 8. Variation of nominal stress with extension ratio in a cross-linked rubber. —□— Experimental; ———Theoretical.

Creep, Stress Relaxation, and Dynamic Mechanical Behavior

Viscoelasticity. As already noted, the time-dependent properties of polymer-based materials are due to the phenomenon of viscoelasticity (qv), a combination of solid-like elastic behavior with liquid-like flow behavior. During deformation, equations 3 and 6 above applied to an isotropic, perfectly elastic solid. The work done on such a solid is stored as the energy of deformation; that energy is released completely when the stresses are removed and the original shape is restored. A metal spring approximates this behavior.

In contrast, a viscous liquid has no definite shape and flows irreversibly under the action of external forces; the work done by shearing stress is dissipated as heat. The so-called perfect liquid obeys the law of Newton:

$$\sigma = \eta \, \mathrm{d}\gamma/\mathrm{d}t \tag{8}$$

where $\mathrm{d}\gamma/\mathrm{d}t$ is the rate of change of shear strain with time t; the proportionality factor η is the shear viscosity. A dashpot is quite often used to represent the ideal viscous flow behavior according to equation 8. A dashpot is full of a purely viscous liquid; the plunger moves through the liquid at a rate proportional to the stress.

Since by definition the viscoelastic material in shear exhibits both the behavior governed by equation 6 and than represented by equation 8, the constitutive relation for the linear viscoelastic solid can be written as

$$\sigma = G\gamma + \eta \, \mathrm{d}\gamma/\mathrm{d}t \tag{9}$$

We have to remember that equation 9 applies only at small strains.

The linear viscoelastic materials obey the so-called Boltzmann Superposition Principle. As noted by Tschoegl (13), this was the only foray of the Viennese statistical physicist Ludwig Boltzmann into mechanics. The principle states that in linear viscoelasticity effects are simply additive; it matters at which instant an effect is created and it is assumed that each increment of stress makes an independent contribution.

Two manifestations of linear viscoelasticity are *creep* and *stress relaxation*; the respective two testing methods are known as *transient tests*. One can also apply sinusoidal load, an increasingly more used method of study of viscoelasticity by dynamic mechanical analysis (qv) (DMA). We shall now briefly discuss each of these three approaches.

Creep. Creep is a time-dependent strain increase under a constant stress. As already mentioned, the constant stress can be quite simply provided by a gravitational field of the earth. The creep behavior is most often analyzed in terms of the Kelvin–Voigt model in which a spring and a dashpot are parallel. The model is characterized by a constant representing the elastic (modulus) and viscous flow (viscosity) deformations. From the geometry of model, individual strain in each element is equal to total strain and applied stress is supported jointly by the spring and dashpot.

In nature viscoelasticity rarely follows the Kelvin–Voigt model. A way out is to make a combination of springs and dashpots so as to describe the observed behavior. Such combined models are convenient for calculations. Needless to say,

they do *not* explain anything. The explanation has to be found in the morphology of the phases present and still deeper at the level of chemical structures and interactions between chain segments.

Stress Relaxation. The phenomenon of stress relaxation is the time-dependent stress decay under a constant strain condition. There exists a simple Maxwell model of the process, which consists of a spring and dashpot in series. If a fixed strain is applied, the spring is immediately extended and a stress is produced in it. The dashpot begins to be displaced. The strain and stress in the spring thus decay to zero as dashpot is displaced at decreasing rate until the displacement becomes equal to the original strain of the spring. Thus the stress relaxes to zero according to the model.

In reality, the stress decays to a constant value called the *residual stress* (14–16). Moreover, Kubat has discovered a curious phenomenon (14,15): the stress σ vs time t curves for stress relaxation of metals and polymers look practically the same. This in spite of claims by some hardened metallurgists that plastics should not be even called materials and in spite of behavior of some polymer scientists who simply ignore metals and alloys. Kubat has shown that even the slope of the large central descending part is virtually independent of the kind of material.

Trying to expain this curious phenomenon, Kubat has assumed that the relaxation occurs in *clusters*. That is, neither individual atoms in metals nor the polymer segments relax individually, but both kinds of units relax collectively. On the basis of this assumption, Kubat succeeded in developing a general theory of stress relaxation that provides predictions agreeing precisely with experiments (16).

Every theory makes certain assumptions. Computer simulations of polymers provide us with information inaccessible experimentally (17); the section Fracture Mechanics and Crack Propagation deals more on this subject. The simulations also make possible testing theoretical models. If there is a disagreement between the behavior of a computer-generated material and the prediction, one cannot blame it on errors of the experiment.

Molecular dynamics computer simulations have been used to test the basic assumptions of the Kubat theory (18,19). At first, the right shape of the stress vs time curve was seen, but the residual stress was seen after 1.5 decades of time; in reality for both metals and polymers it takes 4.3 or so decades of time. The computer-generated materials had no defects; to make the materials more realistic, some 2 or 3 vol% of defects were introduced. Then the stress relaxation curves took more than 4 decades of time—in agreement with the experiment (see Fig. 9).

More importantly, the molecular dynamics simulations show that the metal atoms and polymer chain segments rarely relax individually. They relax in clusters—just as Kubat has assumed. This is why it does not matter whether the material is a metal or a polymer. Kubat has also derived an equation for the distribution of cluster sizes (16). Simulations show that his size distribution equation is close to the behavior of computer-simulated materials (20). This is a beautiful example where experiments, theory, and computer simulations all coincide.

Dynamic Mechanical Analysis (DMA). Dynamic mechanical analysis (DMA) consists in imposition of a sinusoidal stress at a specified angular frequency ω and temperature T. In elastic materials strains are in the same phase

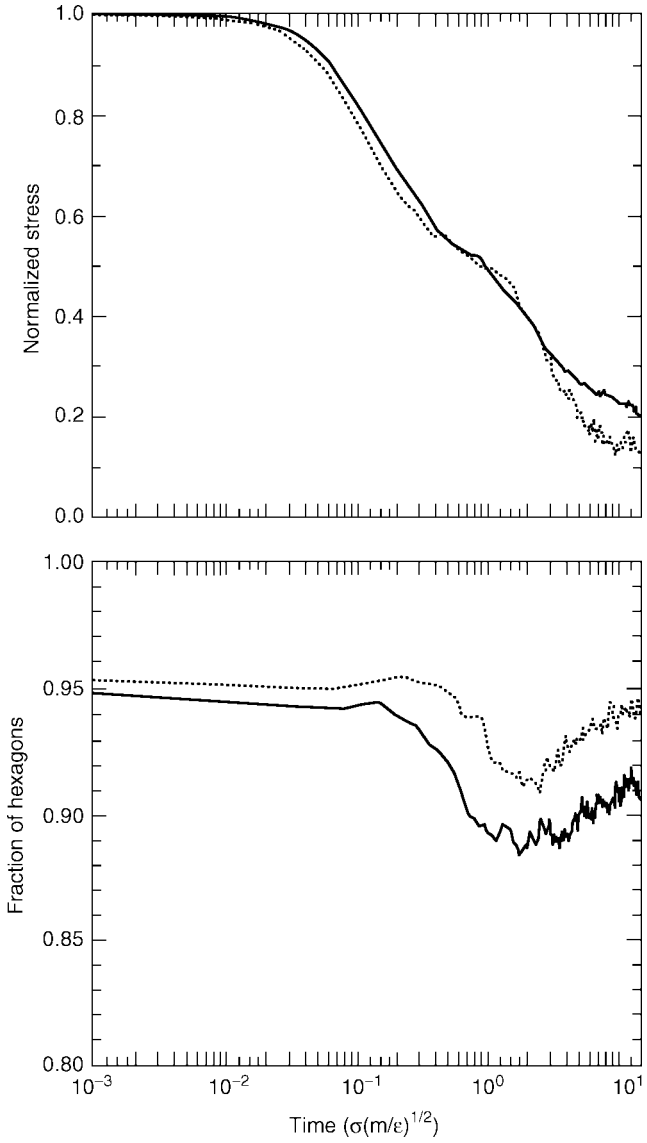

Fig. 9. Computer simulation of stress relaxation; after. ——— Polymer; . . . . . Metal (15).

as stresses and are related by a unique modulus value. By contrast, in viscoelastic materials there is a strain lag. The more liquid-like the material is, the larger the lag; the more solid-like it is, the smaller the lag. This is why DMA is a technique *par excellence* to characterize viscoelasticity of polymer-based materials. The experiment can be represented by

$$\varepsilon = \varepsilon_0 \exp(i\omega t) \tag{10a}$$

$$\sigma = \sigma_0 \exp\{i(\omega t + \partial)\} \tag{10b}$$

where ∂ represents the lag. The complex modulus is defined by

$$G^* = \sigma/\varepsilon = (\sigma_0/\varepsilon_0)\exp(i\partial) = (\sigma_0/\varepsilon_0)(\cos\theta + i\sin\theta) = G' + iG'' \tag{11}$$

Convenient parameters to work with are G' and G''. The former is called the *storage modulus* and represents the elastic solid-like contribution to the viscoelastic response of the material. The latter is called the *loss modulus* and represents the liquid-like response.

Some researchers like to work with just one parameter to characterize viscoelastic behavior, either G^* defined above or the so-called *loss factor*

$$G''/G' = \tan\partial \tag{12}$$

We find it more convenient to deal with G' and G'' separately. However, when one deals simultaneously with many polymer-based materials then one diagram per material might be sufficient. An example of behavior of a polymer is shown in Figure 10 as a function of the logarithmic angular frquency. Here G' is called G_1, G'' is called G_2, and tan ∂ is also displayed.

It can be shown that the energy ΔU dissipated per cycle per unit volume of the material is given by

$$\Delta U = \Pi G'' \varepsilon_0^2 \tag{13}$$

As more and more polymer-based materials are in use, their viscoelastic characteristics become more and more important. Some industry practitioners are apprehensive of imaginary and complex quantities such as those that appear in equations 10a, 10b and 11. Fortunately, a unique book on DMA (21) is aimed

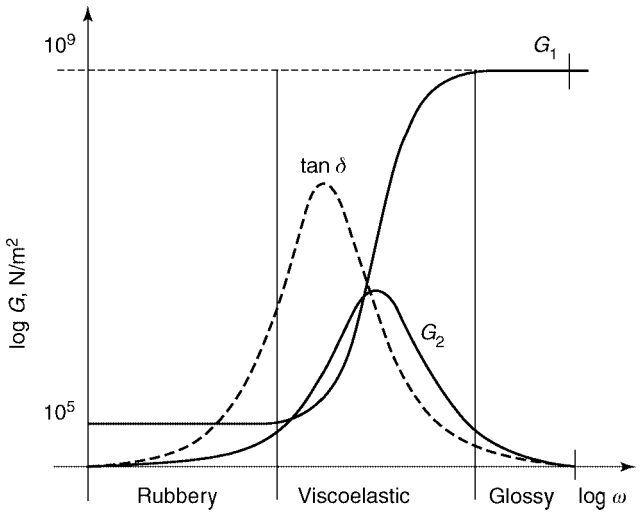

Fig. 10. DMA characteristics of a polymer. The variations of G', G'', and tan ∂ with the logarithmic frequency ω. Explanations in text.

precisely at the apprehensive practitioners—although it provides a wealth of information for the initiated as well. A much shorter story on the subject also by Menard can be found as a chapter in a collective book (22).

Yield Behavior

Yield Stress. For ideal linear viscoelastic material, if the load is removed at any time, the material recovers fully. These conditions are approximately satisfied at low stresses for several polymers. The elastic strains occur because of increase in the intermolecular distances, the bond angles, or a small shifting (without destruction) of the fluctuation network linkage points. At a certain stress level called the *yield stress*, the strain increases without a further increase in the stress. If the material has been strained beyond the yield stress, a nonrecoverable strain remains. Thus the yield point of a material is the highest stress that it can endure without manifesting a permanent strain upon unloading (see YIELD AND CRAZING).

The phenomenon of yielding occurs in all materials, including semicrystalline and glassy polymers. Yielding is associated with stress levels necessary to produce the initial permanent strain called the *plastic strain*. However, as so much in mechanics, also this definition has been first devised for metals. For polymers it is not unique because under some conditions polymers will manifest a strain after unloading which may persist only for a certain period of time. Thus the definition of what is the permanent strain in polymer-based materials from a practical point of view is arbitrary. For those materials whose stress–strain curves are monotonic, the 0.2% offset method is often used to determine yield stress. A line is constructed parallel to the elastic portion of the stress–strain curve at the offset strain such as 0.002. The stress corresponding to the intersection of this line with the stress–strain curve as it bends over into the plastic region is then defined as the yield strength σ_y. When the material exhibits a maximum in the stress–strain curve just beyond the elastic region, in this case the maximum stress is recognized as the yield stress.

Most of polymers except for the glass-transition region exhibit a maximum in the stress vs strain curve and it is this maximum stress that is usually referred as the yield point in what follows. At the yield point, molecular chain segments are able to slip past each other and the deformation process occurring either in crystalline or amorphous phase is entirely irreversible and is exemplified by a sharp drop in the stress–strain curve. The lateral sample dimensions are immediately narrowed; this observation has become known as *necking* and is most often seen in semicrystalline polymers above T_g. True stress (load/actual area of cross section at the particular load) rises in vicinity of the necked region, so that further deformation may occur preferentially in the elements of materials close to this point. However, the molecules become highly aligned in the direction of applied stress. Local stiffness increases as a result and a point is reached where the enhanced resistance to deformation in the plastically deformed anisotropic region compensates the simultaneous increase in true stress. The post-yield necking process becomes stable in this way; further deformation results in neck propagation along the waist of the material. This process is called *cold drawing*; it occurs at a drawing stress often independent of strain level. At the point where the relatively

compliant and isotropic material has all been highly strained because of formation of chain-extended crystalline morphology during cold drawing, the load rises since the applied deformation is resisted by the uniaxially oriented microstructure of high stiffness. The strength and stiffness properties have been enhanced parallel to the draw direction. The adjacent segments of the parallel chains are generally held only by secondary bond forces giving rise to fibrillization as precursor to eventual fracture when the material in the remaining cross section is unable to support to applied load.

The shapes of stress–strain curves for various temperatures are shown in Figure 11. The yield stress decreases with increasing temperature. The segments shift in the process of cold drawing of flow of a glassy polymer under the effect of stress—not because of thermal motion, but because the latter is almost absent in the glassy state. However, there is definite storage of thermal energy in the polymer even when $T < T_g$. With the elevation of temperature in the region below T_g, the storage of energy in the segments grows and a smaller and smaller external mechanical energy is needed to shift the segments and to develop cold

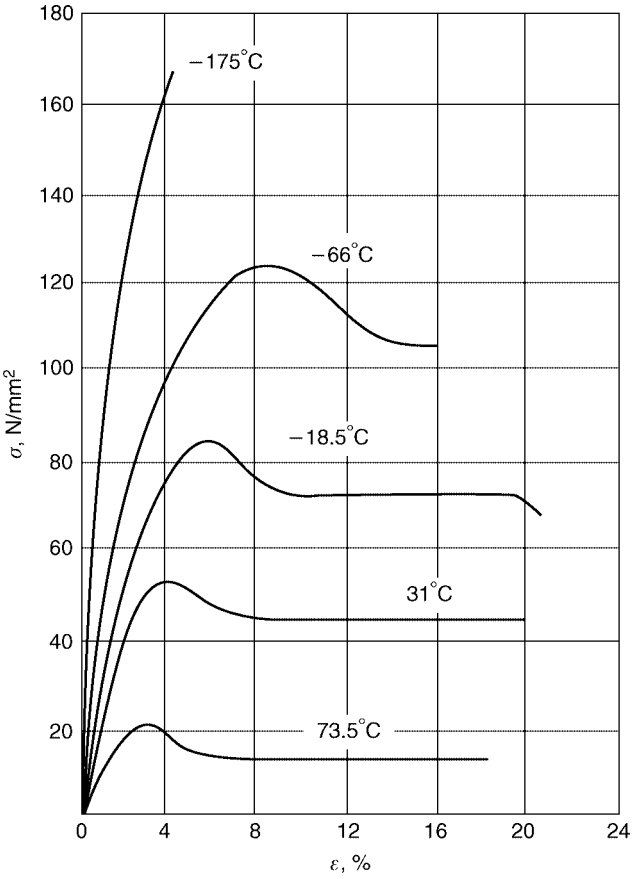

Fig. 11. The tensile stress–strain curves for poly(vinyl chloride) (PVC) at several temperatures.

flow. Lowering of temperature causes not only an increase in yield stress but also straightening of curve and diminution of yielding. The specimen may fail even before the yield stress is reached. The failure occurs at very low strain such as fraction of 1%. This means that the polymer at low temperatures behave like a brittle one that is not capable of not only highly elastic strains but also of cold flow.

After withdrawal of high stresses below T_g, the large strains do not disappear. However, if the polymer is then heated above T_g, the specimen recovers its original size completely. Thus the deformation of glassy polymers is recoverable.

Shear Yielding. In consideration of yielding of polymer-based materials, a major distinction must be made between two different microstructural phenomena, *shear yielding* and *craze yielding*. Shear yielding basically involves the shear flow with little or no change in density up to the yield point. Craze yielding or dilatational yielding is highly localized in the form of thin crazes which consist of a very porous fibrillar region.

The yielding of solids under multiaxial stresses gives rise to question about the yield criteria. One of the simplest yield criteria was proposed by Tresca already in 1864. It states that yielding occurs when the maximum shear stress exceeds a critical value. In terms of principal stresses we have (23):

$$(\sigma_1 - \sigma_3)/2 > \sigma_y \tag{14}$$

Here $\sigma_1 > \sigma_2 > \sigma_3$ so that σ_1 is the largest principal stress. A negative stress is always smaller than a positive one and σ_y is the shear yield point. Since the criterion holds for all possible values of the principal stresses, it also holds for the uniaxial stress field. In this case the criterion reduces to

$$(\sigma_1 - \sigma_3) > \sigma_y \tag{15}$$

The Tresca criterion works well for polycrystalline materials. It has been observed that the following criterion proposed by van Mises is somewhat better (23):

$$(\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_y \tag{16}$$

The differences between the two criteria is usually ≈15%. The Tresca criterion is often used because its form is simpler and because for engineering applications it gives a more conservative prediction for shear failure.

Both Tresca and van Mises criteria are not affected by the addition of hydrostatic pressure because that pressure simply adds a constant to each of the principal stresses and the two criteria depend only on the differences between the principal stresses. However, many experiments with multiaxial stresses show that the yield criteria for polymers have to include the hydrostatic component of the stress tensor $\boldsymbol{P}$, where

$$\boldsymbol{P} = (\sigma_1 + \sigma_2 + \sigma_3)/3 \tag{17}$$

$\boldsymbol{P}$ affects the yield stress as well as the shape of the stress–strain curve. This is reflected by the difference between uniaxial tension and compression stress–strain curves; a pure shear curve lies between them.

Given limited applicability of earlier equations, Brown and co-workers (23,24) have developed the following equation for uniaxially oriented polymers:

$$B_9(\sigma_2-\sigma_3)^2+B_{10}(\sigma_2-\sigma_1+\sigma_i)^2+B_{11}(\sigma_1-\sigma_i+\sigma_2)^2 + 2\mathrm{L}\tau_{23}^2+2M\tau_{32}^2+2N\tau_{12}^2=(1-\boldsymbol{QP})^2 \quad (18)$$

Here σ_i is the difference between the yield point in tension and in compression in the direction of orientation. Thus, according to equation 18, eight parameters are required to describe completely the yield stress of a uniaxially oriented polymer.

The crystalline regions become more prominent at low temperature relative to amorphous regions and they may permit easy slip at low temperatures probably via a dislocation mechanism. However, there is no evidence of dislocations in semicrystalline polymers. In PTFE the increase in yield point with decreasing crystallinity may be due to grain size effect. As the crystallinity is reduced, the lamella size also decreases. It is most likely that the direction of easy slip is parallel to the chain direction. Since the chains are parallel to the thin dimension of the crystal, it is likely that the lamella thickness should directly affect the yield point at low temperatures—as was observed experimentally (25).

Molecular Theories of Yielding. Several models of yielding of amorphous polymers are based on continuum mechanics invoking the concepts of free volume, springs and dashpots, and viscosity. Some of the theories take molecular point of view. Robertson (26,27) assumed chain bending as the fundamental mechanism for yielding. He postulated that the yield point corresponds to the state where the amount of bends produced by the stress were equivalent to the number of bends that occur at T_g.

In another molecular approach Argon (28) has proposed a theory of yielding for glassy polymers based on the concept that deformation at molecular level consists in the formation of a pair of molecular kinks. The resistance to double kink formation is considered to arise from the elastic interactions between chain molecule and its neighbors, ie, from intermolecular forces. This is in contrast to the Robertson theory, where intramolecular forces are of primary consideration. We need to recall that the intramolecular forces are by several orders of magnitude stronger than the intermolecular ones—except for entanglements which operate as if they were primary chemical bonds.

Brown (24,29) proposed a model of homogeneous yielding based on the Mie (Lennard–Jones) interaction potential. According to Brown, there are three types of molecular motions in an amorphous polymer up to shear yield strain:

(1) shearons which consist of the motion of molecular segments whose covalent bonds lie in the plane of shear;
(2) rotons which are like shearons except that covalent bonds make an angle with the plane of shear; and
(3) tubons which require a force parallel to the covalent bond that allows the molecular segments to move along the shear plane.

The macroscopic yield point is calculated in the Brown model on the basis of cooperative and nearly homogeneous motion of all molecular segments. The value of the yield point is calculated from the friction and shear resistance of each type of molecular motion produced by shearons, rotons, and tubons.

Crazing. As noted in the beginning of the Shear Yielding section, shear yielding is different from craze yielding. We need also to note that crazes constitute one source of cracks. Crazes are observed in glassy polymers except thermosets. Originally, it was thought that crazes are just tiny cracks, but this turned out not to be true. We now recognize three kinds of these structures: surface crazes, internal crazes, and crazes at the crack tip. All three kinds consist of elongated voids and fibrils. The fibrils are composed of highly oriented chains and each fibril is oriented approximately at 90° to the craze axis. The fibrils span the craze top to bottom, resulting in an internal sponge-like structure (see Yield and Crazing).

Extensive studies of crazes and their behavior under loads have been conducted by Kramer and co-workers (30–40). We know from this work that there are two unique regions within the craze: (*1*) the craze/bulk interface, a thin (10–25 nm) strain-softened polymer layer in which the fibrillation (and thus craze widening) takes place and (*2*) the craze midrib, a somewhat thicker (50–100 nm wide) layer in the craze center, which forms immediately behind the advancing craze. The relative position of the midrib does not change as the craze widens. By contrast, as the phase boundaries advance, continuously new locally strain-softened regions are generated, while strain-hardened craze fibrils are left behind.

In general, externally provided energy in excess of CRC may be absorbed by crazing, shear yielding, or cracking. Therefore, we need to compare crazing to shear yielding. In the latter, oriented regions are formed at 45° angles to the stress. The shear bands are birefringent; in contrast to crazes, no void space is produced.

Of course, cracks are the "really dangerous" ones. We talk more about cracks as such in the following section. The crazes are capable of bearing significant loads thanks to the fibrils. Therefore, the question arises, under what conditions can crazes transform into cracks? The fibril breakdown must precede crack nucleation. Kramer and his colleagues have established that an important variable governing craze fibril stability is the average number of effectively entangled strands n_e that survive the formation of fibril surfaces. Equations for calculating the original number of strands n_0 as well as the number n_e have been provided by Kramer and Berger (36). It turns out that polymers with $n_e > 11.0 \times 10^{25}$ strands/m^3 and concomitantly a short entanglement length I_e are ductile and deform by shear yielding. Such materials exhibit strains up to $\varepsilon = 0.25$ or even more prior to macroscopic fracture. Polymers with $n_e < 4 \times 10^{25}$ strands/m^3 and thus with large I_e are brittle and deform exclusively by crazing. For polymers with intermediate values of n_e (and I_e), competition between shear deformation and crazing is observed.

The presence of liquids or vapors in the environment of a polymeric component affects the response to external mechanical forces (24,41). Thus, for instance polyarylate under uniaxial extension exhibits exclusively shear yielding without crazing. However, exposure to organic vapor (methyl ethyl ketone) results in crystallization, embrittlement, and conversion of the response to deformation from shear yielding to crazing (41).

Fracture Mechanics and Crack Propagation

Stress Concentrators and Stress Concentration Factor. Just as all materials, polymer-based materials exhibit structure imperfections of various kinds. They appear already in processing, during handling in transport, as well as in service. Because of the presence of crazes, scratches, cracks, and other imperfections, mechanical properties of real polymeric materials are not as good as they theoretically could be. In this section we deal particularly with stress concentrators such as *cracks* (which appear although we did not want them) and *notches* (which are made on purpose to have well-defined cracks).

As said, imperfections appear already in processing. We have *knit lines*: areas in injection-molded parts made of thermoplastics in which, during manufacturing, separate polymer melt flows arise, meet, and melt more or less into one another. Consequences of the presence of knit lines on mechanical properties are discussed by Criens and Moslé (42). They also discuss methods of mitigating effects of knit lines on performance. The simplest such method, namely raising the processing temperature, is also a costly one.

The deteriorating effects of cracks and notches on material properties are represented by the *stress concentration factor*

$$K_t = 1 + 2(h/r)^{1/2} \tag{19}$$

Here h is the depth (length) of the crack or notch, or one-half of the length of the major axis in an elliptical hole; and r is the radius of curvature at the bottom (tip) of the notch, or at each end of the major axis of an elliptical crack. The name stress concentration factor is very appropriate. Tensile tests were discussed under Quasi-Static Mechanical Testing. Consider again a tensile test with the stress σ applied to the ends of the specimen. The lines of force applied to these ends cannot go through the air; they must go through the material—and therefore around the crack. As a consequence, when the lines meet (or separate, depending on the direction) at the crack tip, that tip is subjected not to the nominal stress σ but to the stress which is K_t time larger. Equation 19 is also applicable in everyday life, not only in an industrial plant or a testing laboratory. When one wants to cut a plastic sheet into halves, a small incision in one side of the sheet helps. Such an incision is in fact a notch, and creates the stress concentration defined by equation 19.

Stress Intensity Factor. In some applications, a somewhat different measure of the "evil" produced by a crack or notch called the stress intensity factor is in use:

$$K_I = \alpha^* \Pi^{1/2} \sigma h^{1/2} \tag{20}$$

K_I characterizes the stress distribution field near the crack tip. The Roman one, I, refers to the opening or tensile mode of crack extension; α^* is a geometric factor appropriate to a particular crack and component shape; the remaining symbols are the same as in equation 19. It is unfortunate that K_t and K_I have similar symbols, similar names, and are expressed in terms of the same quantities—but we do not propose to fight the existing habits in this article. For an infinite plate in

plane stress, the geometric factor $\alpha^* = 1$. *Plane stress* means that the stress along the z-axis perpendicular to the plate surface is almost—although not exactly—equal to zero. For other geometries there exist tabulations of α^* values (43).

Griffith's Theory of Fracture. Fracture (qv) of polymers and polymer-based composites is of course a subject on which entire books have been written. General fracture mechanics has been presented fairly succinctly by Pascoe (44). Here we shall quote the most important results.

Already in 1921 Griffith (45,46) considered for elastic bodies the question: when will a crack propagate? Starting with basic thermodynamics, he replied: this will happen if the crack growth will lower the overall energy. He considered three contributions to the energy:

(1) the potential energy of the external forces which are doing work on the body deforming it;
(2) the stored elastic strain energy; and
(3) the work done against the cohesive forces as the new crack surfaces are formed.

On this basis Griffith derived an equation which in modern notation can be written as

$$\sigma_{cr} = (2\Gamma E/\Pi h)^{1/2} \tag{21}$$

σ_{cr} is the stress level at and above which the crack will propagate; Γ is the surface energy per unit area (corresponds to the last of the three factors just named); E is the elastic modulus; and h is the same as in equations 19 and 20.

Thus, if the actual stress imposed $\sigma < \sigma_{cr}$, the material will sustain that stress without the crack growing. The equation is identical for both constant load and constant displacement conditions, and hence it should work also for any intermediate conditions. Equation 21 has been the inspiration for much further work. Pascoe (44) provides a fairly detailed discussion of the Griffith theory.

Crack Propagation and Its Prevention. To begin with, there is a need to distinguish rapid crack propagation (RCP) and slow crack propagation (SCP). RCP is a dangerous process; velocities of 100–400 m/s (that is 300–1400 ft/s) have been observed in PE pipes. Since such pipes are being used for distribution of fuel gas within localities, RCP might be accompanied by an explosion of the gas pressurized inside. However, a criterion was developed which allows prediction of whether RCP will occur (47); the criterion is also discussed in Reference 4. Briefly, from the determination of impact strength of the material, that is, the energy absorbed by the material when fracturing under impact, one can predict whether RCP will or will not occur. The criterion is based on CRC concepts; the impact strength is used here as the appropriate measure of the CRC for rapid crack propagation.

Slow crack propagation is not limited to fuel plastic pipes, not at all spectacular, and "quiet" and insidious. The crack propagation rate dh/dt might be only, say, 1 mm per month; an observation for, say, 2 weeks after installing a polymeric component in service might not show anything.

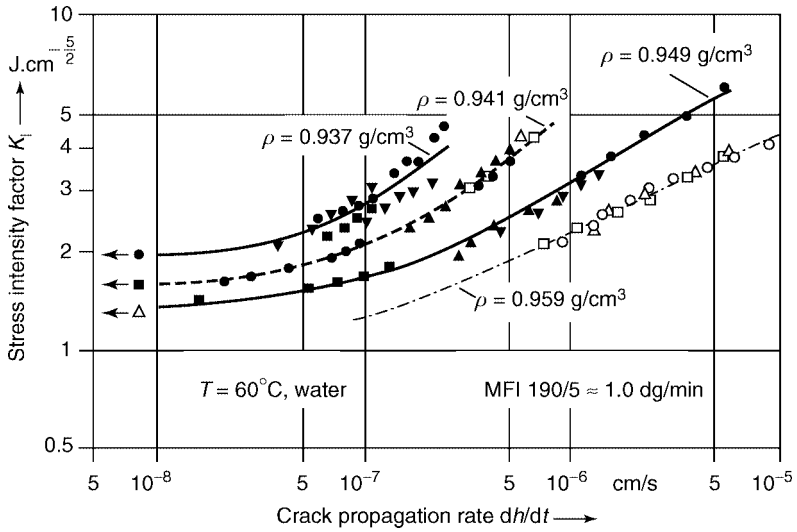

Fig. 12. Crack propagation rate vs the stress intensity factor for Hoechst polyethylenes (48).

Experimentalists customarily present the dh/dt rates as a function of the logarithmic stress intensity factor log K_{I} as defined by equation 20. The problem of relating dh/dt to K_{I} was solved by using the CRC approach (48) in conjunction with the Griffith fracture mechanics including our equation 21. The result is

$$\log K_{\mathrm{I}} = \frac{1}{2}\log\left(\alpha^{*2} 2\Gamma E\right) + \frac{1}{2}\log[1 + (1/\beta h_{\mathrm{cr}})\mathrm{d}h/\mathrm{d}t] \tag{22}$$

Here β is a time-independent factor characteristic for a material. In the derivation of the last equation, both the stress level σ and the initial crack length h_0 were used (48). However, these quantities canceled out—with the unexpected result that the crack propagation rate is independent of both.

The experimental results support equation 22—as shown for instance in Figure 12 for Hoechst PEs studied under tension in water medium at 60°C. Each kind of symbol pertains to a different stress level and a different original notch length. We have called SCP "insidious." The lowest crack propagation rate shown in the figure is $\mathrm{d}h/\mathrm{d}t = 10^{-8}$ cm/s; this is only 0.315 cm per year, but the crack does grow. This fact gives us an idea of the usefulness of equation 22.

As mentioned, equation 22 was derived on the basis of the CRC concept. The larger is the CRC, the better the material defends itself against external forces. We can write a series of approximate proportionalities (4):

$$\mathrm{CRC} \sim v^{\mathrm{f}} \sim T \sim \omega^{-1} \sim \rho^{-1} \tag{23}$$

where ρ is the mass density and ω is the frequency used in the Dynamic Mechanical Analysis Section. The expression (23) will be discussed more in a later section. Now we see that Figure 12 provides a direct proof of validity of the CRC approach

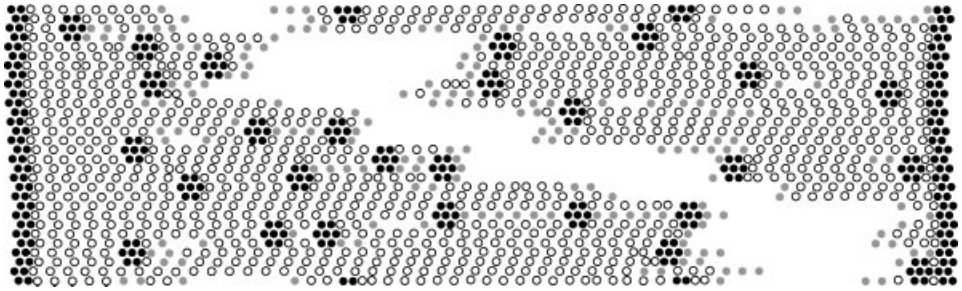

Fig. 13. Tensile deformation leading to crack propagation in a two-phase (PLC islands + flexible matrix) polymer (51).

and of the expression 23. The material with the lowest density has necessarily the highest free volume v^f and, therefore, the lowest crack propagation rate dh/dt.

Computer Simulation of Crack Propagation. A typical experimental procedure for investigating fracture consists in looking at the fracture surface with a scanning electron microscope (SEM) or a transmission electron microscope (TEM) (49,50). This provides us with the morphology at the time of fracture, which is useful information. However, the microscopic techniques do not tell us where and how the crack(s) which eventually led to fracture had started.

The whole story from the crack initiation to fracture can be seen in molecular dynamics (MD) computer simulations (51–53). We have already talked about MD simulations of stress relaxation in a previous section. The question to be answered by MD was: where in two-phase materials formed by polymer liquid crystals (PLCs) the cracks start? They could start in the flexible polymer matrix because it is relatively weak, or inside the LC-rich *islands* which are more brittle, or at the interface from the matrix side, or else at the interface from the island side.

An example of the answer is shown in Figure 13 (51). A large crack which is going to cause fracture is formed at the interfaces on the matrix side. The beauty of computer simulations is that we can watch the cracks form and propagate until fracture. Animations of this process are made for added perspicuity.

Ductile–Brittle Transition. As seen in expression 23, CRC is also proportional to the temperature T. At low temperatures polymer-based materials are brittle and more prone to crack propagation. There exists the *ductile–brittle impact transition temperature* below which the material is brittle and above which ductile. A successful method of prediction of that temperature as a function of the stress concentration factor (eq. 19) is described in Reference 3.

Crack Healing. Finally, let us mention that *crack healing* takes place. Experiments of this kind have been conducted by Wool and his collaborators and described in detail (54,55). As Wool says, when two similar pieces of a bulk polymer are brought into contact at a temperature above the glass transition, the interface gradually disappears and mechanical strength develops as the crack—or weld—heals. This takes place in both cracks and welds in spite of the differences between them. Healing is mainly due to the diffusion of chains across the interface. This fact is the origin of a method of crack healing with *molecular nails*—also discussed by Wool (54,55).

Healing manifests itself not only in mechanics but also in tribology; see Section on Tribology.

Long-Term Service Prediction

Free Volume as the Prediction Tool. For obvious reasons, prediction of long-term performance from short-term tests is needed. Such prediction methods exist and are in fact quite powerful. Unfortunately, numerous papers and reports are still based on a false assumption that *nothing can be predicted and therefore everything has to be measured*. Much information can be obtained from a limited amount of experimental data—and also from computer simulations discussed at various locations in this article.

To be able to make long-term predictions, some definitions are needed. We have already noted that the more the free volume v^f, the larger is the maneuvering ability of the chains, and the higher CRC. Using specific quantities (typically per 1 g), we write

$$v = v^* + v^f \tag{24}$$

where v is the total specific volume and v^* is the characteristic (incompressible or hard-core) volume. The last two names are based on the qualitative picture of applying an infinitely high pressure so that all free volume is "squeezed out" and only v^* remains. Some people like to work instead with the reduced volume defined as

$$\tilde{v} = v/v^* = 1 + v^f/v^* \tag{25}$$

Equation 24 or 25 is usable only in conjunction with a specific equation of state of the general form $P = P(v, T)$. We also need two more reduced parameters defined in an analogous way as in equation 25:

$$\tilde{P} = P/P^* \quad \tilde{T} = T/T^* \tag{26}$$

P denotes pressure and T (thermodynamic) temperature; P^* and T^* are, like v^*, characteristic (hard-core) parameters for a given material. T^* constitutes a measure of the strength of interactions in the material. It has been found repeatedly that good results are obtained when using the Hartmann equation of state (56–58):

$$\tilde{P}\tilde{v}^5 = \tilde{T}^{3/2} - \ln \tilde{v} \tag{27a}$$

At the atmospheric pressure the term containing $\tilde{P}$ becomes negligible, and we have simply

$$\tilde{v} = \exp(\tilde{T}^{3/2}) \tag{27b}$$

Evaluation of the necessary characteristic parameters in equation 27a proceeds as follows. One can use the thermomechanical analysis (TMA) in the expansion mode and determine at the atmospheric pressure, the dependence of specific volume v on temperature T. By fitting the experimental results to equation 27b one obtains the characteristic parameters v^* and T^*. If one performs full P–V–T determination [this can be done with the so-called Gnomix apparatus (59) used also by us to advantage (60)], then one represents experimental results by equation 27a and finds by a least-squares procedure the parameters P^*, v^*, and T^*.

Time–Temperature Correspondence. The next step consists in using the so-called correspondence principles. The most often used is the principle of time–temperature correspondence advocated and used extensively by Ferry (61). To formulate the correspondence (also called equivalence) principle, consider a conformation rearrangement in the chain so fast that we cannot record it at the room (laboratory) temperature. What we can do is to lower the temperature. At a temperature low enough, the process will be slowed down to the extent that we shall be able to "catch" it. This approach works in the opposite direction as well. Instead of conducting experiments for 100 years at the ambient temperature, we can go to a higher temperature, thus produce higher free volume v^f in the material, and "catch" within, say, 10 h the same series of events. This is the basis for the time–temperature correspondence.

As discussed earlier, we can perform DMA by applying an oscillating force to a polymer-based material. If the frequency ω of the oscillations is low, the chains will be able within one half-cycle to adjust better to the externally imposed field, just as they do at higher temperatures. The inverse is true also: high frequencies will provide very little opportunity for such rearrangements, just as if the free volume was low and the temperature low also. We infer that high frequencies cause similar effects as low temperatures and also vice versa. This is the reason for the series of proportionalities (eq. 23) provided above and also for the time–frequency correspondence principle.

To see how one makes long-term predictions, consider for instance dependence of tan ∂ for high density polyethylene (HDPE) as a function of the logarithmic reciprocal frequency log ω^{-1} (62). One can make a series of isothermal measurements of this quantity. Then, taking advantage of the time–frequency correspondence, one can shift the isothermal curves—except for one—so that they would form a single curve. This is shown (62) in Figure 14. The diagram is called the *master curve* and pertains to the reference temperature T_0 for which the curve was *not* moved.

We see in the axis explanation for Figure 14 the *shift factor* a_T. It tells us how much a given isothermal curve needs to be shifted; thus, a_T is the key to the long-term prediction. One of us has derived a general equation for a_T (2,3):

$$\ln a_T = A_T + B/(\bar{v} - 1) \tag{28}$$

where A_T and B are material constants; B is called the Doolittle constant since it comes from the Doolittle equation connecting viscosity and free volume (see also Reference 62 for the cases involving predrawing). Since the reduced volume as defined in equation 25 appears in equation 28, we also need an equation of state such as the Hartmann equation (eq. 27a).

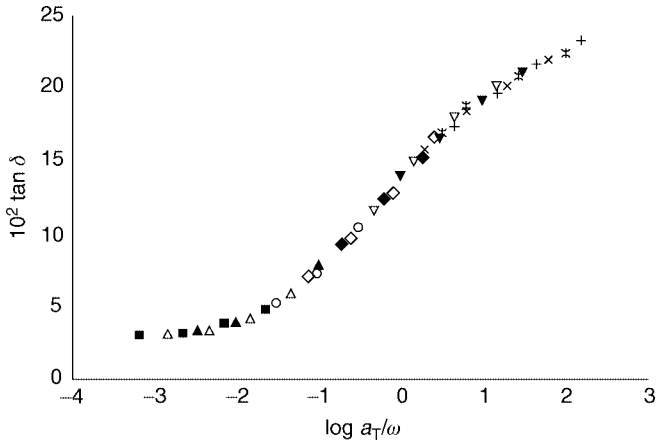

Fig. 14. The master curve of tan ∂ vs log ω^{-1} for HDPE at 40°C (62). Each kind of symbols pertains to a different isotherm.

The master curve for HDPE shown in Figure 14 was obtained using equation 28 in conjunction with equation 27a. In Figure 15 we see the results of the calculation presented as a continuous curve. The experimental points have been obtained by shifting the curves until the best visual fit. Clearly the equation works.

The correspondence principles accomplish an important goal: prediction of long-term behavior from short-term tests. However, some polymer scientists and engineers do not believe that the prediction methods work apparently, because they think that the time–temperature equivalence is the same thing as the so-called WLF equation of 1955 (63) for the shift factor a_T. Ferry who co-created WLF warned (61) that the use of that equation is limited to a temperature range

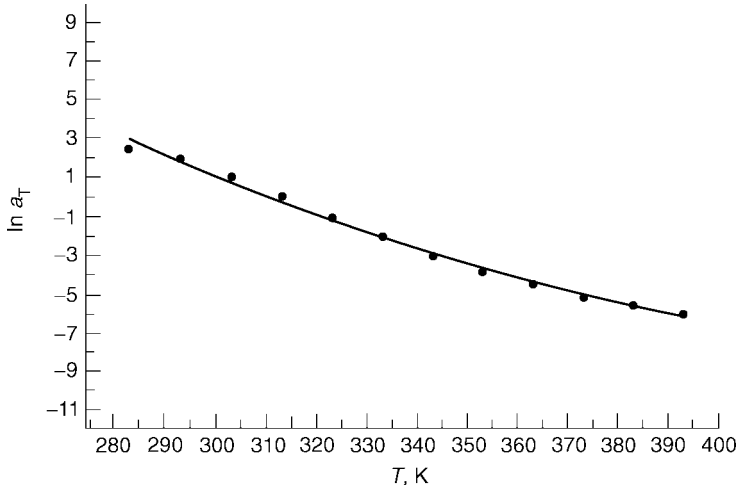

Fig. 15. The temperature shift factor a_T as a function of the temperature T for the master curve shown in Figure 14; filled circles are the experimental points from creep, the continuous line calculated from equation 28 together with equation 27a (62).

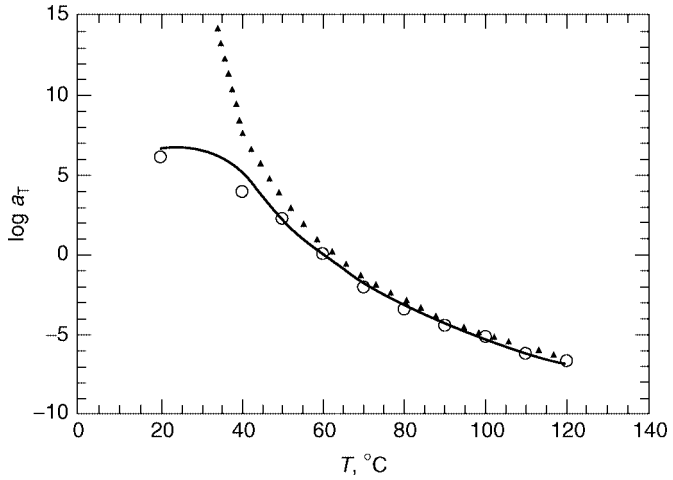

Fig. 16. The temperature shift factor a_T (T) for PET/0.6PHB polymer liquid crystal (PET = poly(ethylene terephthalate, PHB = *p*-hydroxybenzoic acid, 0.6 = mole fraction of PHB in the PLC copolymer). Explanations in text (64).

from the glass temperature T_g to $\approx (T_g + 50)$ K. When the WLF equation is used outside of its applicability range, bad results are likely.

The prediction methods are applicable not only to one-phase polymer-based materials, but also to multiphase systems. A polymer liquid crystal which forms *four phases* in its service temperature range has been studied and predictions accomplished over 16 decades of time. Each experiment was made over 4 decades only (64) and the same equations 27a and 28 were used. Let us look at the diagram of the logarithmic temperature shift factor log a_T as a function of the temperature T for that PLC in Figure 16. The circles are the experimental values corresponding to shifting resulting in a 16 decade master curve. The continuous line was calculated from equations 27a and 28. We include also as triangles values of a_T calculated from the WLF equation. We see that at higher temperatures the WLF results agree well with the experiment—the reason why that equation is still in use. We also see that at low temperatures the WLF equation leads to disastrous results.

There is also the issue whether the temperature shift factor a_T depends on the technique used or is it a property of the material independent of the kind of experiments performed. In derivation of equation 28 it was assumed that a_T is a material property (2,3). This is confirmed by experiments. The continuous line seen in Figure 16 agrees with the experimental shift factors obtained from creep (shown as circles) equally well as with a_T values obtained from stress relaxation results (64).

Time–Stress Correspondence. In 1948 O'Shaughnessy demonstrated experimentally the existence of a different equivalence principle, namely between time and stress (65). Several compliance D values for rayon at different stress levels were shifted forming what we now call a master curve. Some work on this basis was performed at the Latvian Institute of Polymer Mechanics in Riga and is described by Goldman (5). However, generally the O'Shaughnessy principle attracted much less attention than the time–temperature–frequency correspondence. The

reason was that there was no equation which would enable calculations based on this principle—not even a bad one.

In 2000 (66) an equation was derived for the stress shift factor:

$$\ln a_\sigma = A_\sigma + \ln v(\sigma)/V_{\text{ref}} + B/(\bar{v}-1) + C(\sigma - \sigma_{\text{ref}}) \tag{29}$$

where the index "ref" pertains to the reference state for which no shifting occurs. The parameter A_σ is analogous to A_T in equation 28; B is the same Doolittle constant; and C is another material parameter.

Actually in Reference 66 a more general shift factor equation was derived which deals with changes of both the temperature T and stress σ:

$$\ln a_{T,\alpha} = A_{T,\sigma} + \ln T_{\text{ref}}/T + \ln v/v_{\text{ref}} + B(\bar{v}-1) + C(\sigma - \sigma_{\text{ref}}) \tag{30}$$

When we assume a constant stress $\sigma = \sigma_{\text{ref}}$ then equation 30 reduced to equation 28 as it should. When we need a shift factor dependent on the stress level σ only for $T = T_{\text{ref}} =$ constant then equation 30 reduced to equation 29 as it also should.

Equation 29 was tested experimentally with good results (67,68). However, we defer showing an example of its application to the following section.

Long-Term Predictions from a Minimum of Data. One problem with the use of the correspondence principles to make long-term prediction seemed unresolved: the amount of data needed. Thus, in Reference 64 experimental creep and stress relaxation results for the PET/0.6PHB PLC were obtained at 10 temperatures. Similarly, in Reference 67 creep compliance was determined at 9 stress levels. Can we get away with doing experiments at two or three temperatures—or at two or three stress levels—and get valid predictions? The answer is yes, and procedures for that purpose have been developed. When one works with the time–stress correspondence, then the minimum data procedure (68) is naturally based on equation 29. Similarly, when we use the time–temperature correspondence, the minimum data procedure (69) is based on equation 28.

Here is an example of the minimum data procedure for the application of the time–stress correspondence. In Figure 17 we show creep compliance of the same PET/0.6PHB PLC as a function of logarithmic time. This is a master curve—and only two sets of experimental data (for two stress levels) have been used to create it.

As a proof of the validity of the prediction, in Figure 18 we show the stress shift factor a_σ as a function of the stress level σ. The continuous curve with asterisks has been calculated using all experimental results available, that is 9 sets for 9 stress levels. The broken line with open circles is based on two extreme sets of results only, for 10 J/cm^3 and 50 J/cm^3, the same as seen as points in Figure 17. Both curves have been obtained from experimental data via equation 29. We see that the differences are small. The values calculated from two stress levels deviate from those based on the full set on the average by $\pm 0.73\%$ (68). Thus, not only prediction of reliability and long-term behavior from short-term tests seems possible for many polymer-based materials. The amount of experimental data needed for the prediction is lower than widely believed.

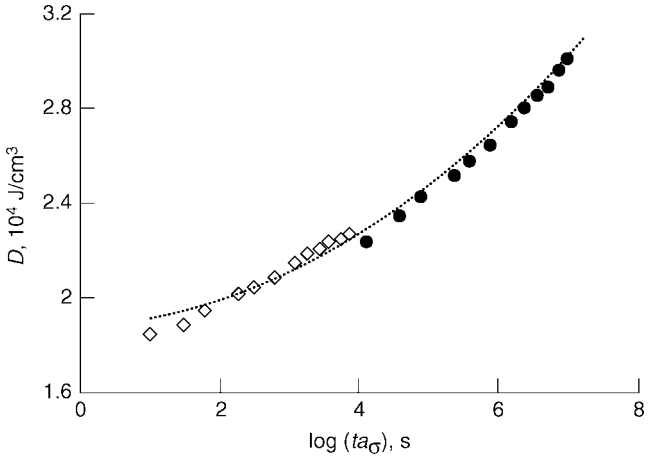

Fig. 17. Master curve of creep compliance of PET/0.6PHB for $\sigma_{ref} = 10$ J/cm^3 (= 10 MPa = 10 MN/m^2). Open circles are experimental points for 10 J/cm^3, filled circles for 50 J/cm^3 (68).

Tribology: Scratch and Wear Resistance

In the section under Fracture Mechanics and Crack Propagation, cracks and notches were discussed as stress concentrators. Scratches are also stress concentrators which affect the reliability. Therefore, we now need to move from the mechanics of polymer-based materials to their tribology. Tribology deals with friction, wear, scratch resistance, and design of interactive surfaces in relative motion (70). It is an underappreciated science. Rabinowicz (71) says the following about the so-called Jost report on tribology prepared for the British Government:

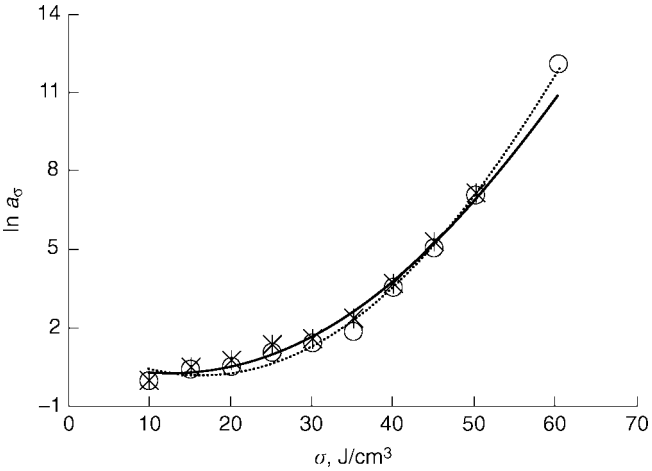

Fig. 18. Logarithmic stress shift factor a_σ as a function of stress level σ for the master curve shown in Figure 17. The continuous line is based on experimental results for nine stress levels; the discontinuous one on two levels only, 10 J/cm^3 and 50 J/cm^3. -✳- Experimental; -⊖- Calculated (10–50) (68).

"At the time the Jost Report appeared it was widely felt that the Report greatly exaggerated the savings that might result from improved tribological expertise. It has now become clear that, on the contrary, the Jost Report greatly underestimates the financial importance of tribology. The Report paid little attention to wear, which happens to be (from the economical point of view) the most significant tribological phenomenon" (see SCRATCH BEHAVIOR OF POLYMERS).

Scratch testing involves the determination of the instantaneous depth (penetration depth R_p) caused by an indentor and also of the final (*after healing*) residual depth R_h. Healing is a consequence of viscoelasticity. It is clear that in terms of reliability, R_h (rather than R_p) is important; the shallower the residual depth, the higher the scratch resistance.

Can we improve the scratch resistance of polymer-based materials? Fortunately, the answer is yes. One way is to apply a low concentration additive to a given polymer-based material. This is much easier said than done—but possible (72,73). In Figure 19 we see the residual depth R_h in a commercial epoxy as a function of concentration of an added fluoropolymer for various forces applied by

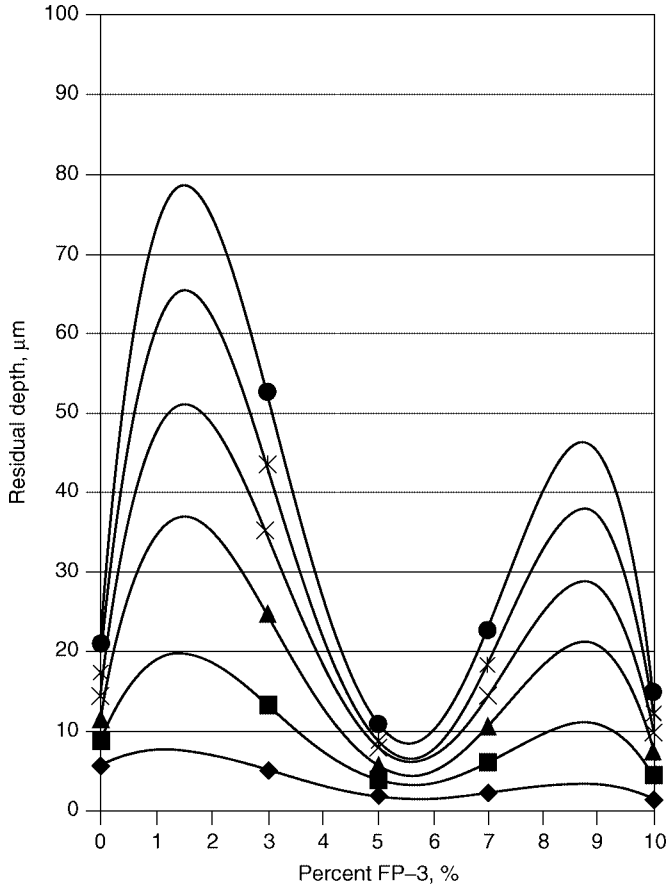

Fig. 19. The residual depth R_h of a commercial epoxy as a function of weight % concentration of a fluoropolymer additive; after (73). ◆ 2N, ■ 4N, ▲ 6N, × 8N, ⁎10N, ● 12N.

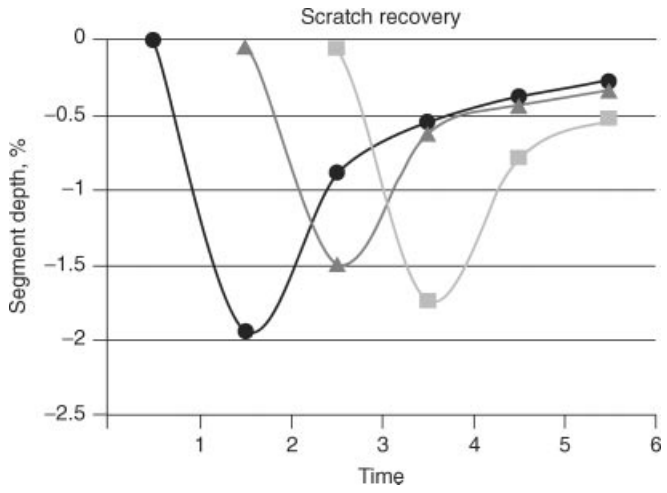

Fig. 20. Changes with time of vertical locations of surface segments in scratch testing simulation. —●— Segment 1, —▲— Segment 2, —■— Segment 3 (76).

a diamond indentor. We see that first the curves go through maxima. That is, if somebody would stop experiments at 3 wt% of the additive, one would conclude that the additive lowers the scratch resistance instead of enhancing it.

Wear can be defined as the unwanted loss of material from solid surfaces owing to mechanical interaction (71). When dealing with metal surfaces, one often uses external lubricants. For polymers and polymer-based materials this is not advisable. The polymer might absorb the lubricant and swell; the results would be worse than without the lubricant.

One option of lowering wear which is widely used is lowering the friction. *Friction* can be defined as the tangential force of resistance to a relative motion of two contacting surfaces (71). One distinguishes *static friction* which appears when starting relative motion and *dynamic friction* which manifests itself when sustaining the motion. Again, an appropriate additive might lower the friction. This has been done also for a commercial epoxy with a fluoropolymer additive (74).

Another option of lowering wear has been discovered recently. It turns out that multiple scratching might result after 15 times or so in *polymer hardening* so that consecutive scratch runs do not make the groove any deeper (75). This has been found for instance for polypropylene and also for TFPE (Teflon). This in spite of the fact that Teflon is a material with notoriously low scratch resistance—as known to anybody who has ever used frying pans.

As in other topics discussed above, molecular dynamics computer simulations also here elucidate the phenomena that take place. In Figure 20 we show the first ever computer simulation of scratch testing (76).

MELAMINE–FORMALDEHYDE RESINS

Introduction

Melamine-based resins represent an important class of aminoplastic resins (1–6) and are made by the reaction of formaldehyde with mainly melamine, using urea, phenol, or other components as comonomers. The raw material and the basic chemistry of melamine–formaldehyde (MF) resins, their history, their basic industrial manufacturing procedures, as well as their use as laminating resins, molding compounds, coatings, textile finishes, and other applications have been described earlier (7,8) (see AMINO RESINS). This article concentrates on melamine-based resins used as wood adhesives, which is by far the biggest area of application, as well as on various special chemical aspects such as cocondensation and analysis (see also WOOD COMPOSITES). SciFinder (1960–2003) comprises approximately 2500 citations for MF resins (all types), implying the still high significance of research in this area.

For most applications as wood adhesives, the melamine resins are in liquid form; for special applications powdered (spray dried) types are used. The resins consist of linear or branched oligomeric and polymeric molecules in an aqueous solution, and sometimes partly as a dispersion of molecules in an aqueous phase. The resins show duroplastic hardening behavior, leading to three-dimensional cross-linking and hence to insoluble and nonmeltable networks. The resins, however, always contain some residual monomers, especially free formaldehyde, even in the hardened state.

Even with only the three monomers melamine, formaldehyde, and urea, a variety of different types of resins exists which can fulfill nearly all requirements given in the wood-based panels industry. This field of application involves the production of wood-based panels like particleboards, medium density fiberboard (MDF), oriented strand board (OSB), plywood, blockboards, and others. In rare cases the resins and panels are also used in the furniture industry. According to the raw materials used, various types of melamine resins are possible:

MF	melamine–formaldehyde resin
MUF	melamine–urea–formaldehyde cocondensation resin
mUF	melamine-fortified UF resins
MF + UF	mixture of a MF and an UF resin
PMF	phenol–melamine–formaldehyde cocondensation resin
MUPF, PMUF	melamine–urea–phenol–formaldehyde cocondensation resin

Composition of the Resins and Basic Reactions

The generation of melamine–formaldehyde resins usually follows a two-step mechanism (Fig. 1). The first step (methylolation step) leads to the formation of

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

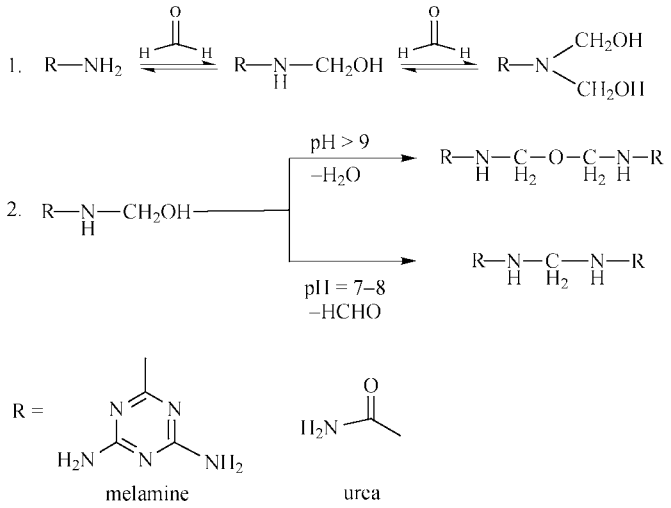

Fig. 1. Reaction mechanism for the formation of formaldehyde-based amino resins. 1, methylolation; 2, condensation.

methylolated melamine species by reaction with formaldehyde. The second step (bridging) forms ether or methylene bridges by condensation, either water or free formaldehyde is generated depending on pH. Both steps can be either base- or acid-catalyzed and are equilibrium reactions.

The most important parameters for the melamine–formaldehyde resins are

(1) the type of the monomers (melamine, urea, phenol)

(2) the molar ratio or mass ratio of the various monomers in the resin:

F/M	Molar ratio of formaldehyde to melamine
$F/(NH_2)_2$	Molar ratio of formaldehyde to amide groups, whereby urea counts for two NH_2 groups, and melamine for three NH_2 groups
M/U	Molar ratio of melamine to urea
F/U/M	Triple molar ratio
% melamine	Mass portion of melamine in the resin: (a) based on the liquid resin, (b) based on the resin solids content, or (c) based on the sum of urea and melamine in the resin

(3) the purity of the different raw materials, eg residual methanol or formic acid in formaldehyde or ammeline/ammelide in melamine (9,10), with ammeline–melamine–formaldehyde resins described in the literature (11,12)

(4) the "cooking" procedure, which usually is a multi step procedure with both alkaline and acidic steps:

a. pH-program

b. temperature program

c. types and amounts of alkaline and acidic catalysts

d. sequence of addition of the different raw materials

e. duration of the different steps of the cooking procedure

The melamine molecule contains three primary amine groups, each of which has the potential of reacting with two moles of formaldehyde forming up to a hexa-substituted product if the molar ratio F/M is high enough. Because of the significant higher reactivity of these melamine amine groups towards substitution with formaldehyde than urea, the melamine resins show the ability to form polymer structures with a much higher cross-link density compared to UF resins.

The production of pure MF resins is usually performed by the reaction of melamine with formaldehyde in an aqueous solution yielding a precondensate mixture of different monomeric as well as short linear and branched oligomeric melamine–formaldehyde compounds; all these reactions are determined mainly by temperature, length of condensation, pH of condensation, as well as the order and time course of heating and reagent addition (13). Usually all types of methylolated melamine species together with oligomeric parts (usually more than six melamine residues are linked from the beginning of the reaction) are present in the reaction mixture (see Fig. 2). Kinetic investigations (14–17) indicate the following order of reactivity towards methylolation of functional groups : (a) the rate of the methylolation decreases with increasing number of methylol groups/melamine; (b) the methylolation of secondary nitrogens is favored over tertiary nitrogens; and (c) secondary nitrogens (ie, already methylolated $-NH_2$ moieties) deactivate the methylolation of neighbored nitrogen atoms. Further important parameters

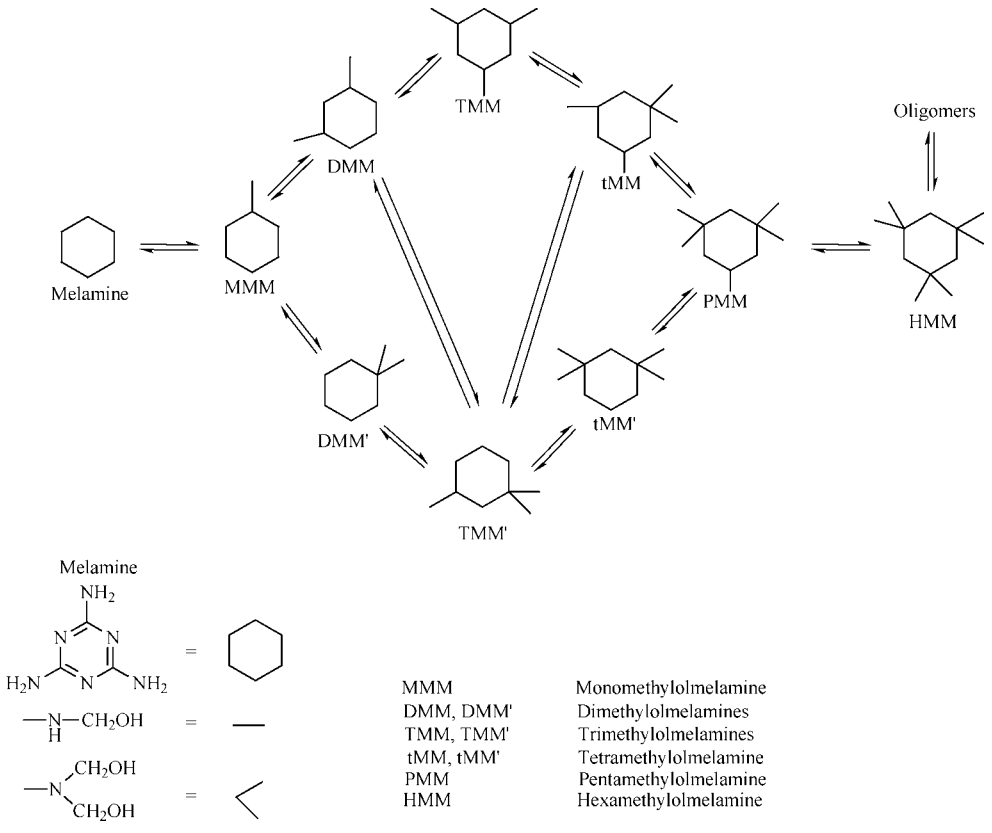

Fig. 2. Formation pathways of methylolated melamines.

are changes in the pH due to parallel running Canizarro reactions and the grain size of the melamine used (18,19).

The obtained liquid resins are colorless and normally of low viscosity. Such MF solutions are cured in a second stage by the application of heat, pressure, or an acid catalyst to give an insoluble, highly cross-linked resin. The long-term storage stability of the resins mainly requires stable rheological properties. Possible thixotropic behavior during storage at room temperature and chemical cross-linking or alterations due to further condensation are the drawbacks (20,21).

The molar mass distributions of melamine-based condensation and cocondensation resins are much broader than for other synthetic polymers. The low molar mass monomers comprise free formaldehyde (M = 30 g/mol) as well as residual and nonreacted post-added urea (M = 60g/mol). Monomeric methylols are generated, eg, in the case of MUF resins, by the reaction of this post-added urea with the free formaldehyde. The oligomeric compounds with two to five molecules of melamine are linked by methylene or methylene ether bridges. Free formaldehyde in the resin has positive and negative effects: on the one hand it induces the hardening reaction by reaction with the aminoplastic hardener and functions as an additional cross-linker; on the other hand it causes formaldehyde emission during the press cycle. Addditionally the residual formaldehyde leads to the displeasing subsequent formaldehyde emission from the pressed boards. Because of the stringent formaldehyde emission regulations worldwide, especially Germany/Austria and Japan ["E1"; "E Zero"; "Super E Zero"/"Four star" (22)] and hence the necessity to limit the subsequent formaldehyde emission, the molar ratio $F/(NH_2)_2$ has been decreased drastically within the last two decades.

The molar ratio of formaldehyde/reactive amino groups [$F/(NH_2)_2$] distinctly determines reactivity, the possible degree of cross-linking, and hence the bonding strength. If the molar ratio is decreased in order to lower the formaldehyde emission, the reactivity as well as the degree of hardening (degree of cross-linking) decreases (see Table 1).

An increase in the M/U molar ratio at a fixed F/(M + U) molar ratio enhances the bond performance. MUF resins with high melamine content have a more highly branched cross-linked structure and free melamine compared to

Table 1. $F/(NH_2)_2$ Molar Ratio of Melamine-Based Resins[a]

1.20 to 1.35	Resins for water-resistant plywood; addition of a formaldehyde catcher is necessary
0.98 to 1.15	E1-particleboard- and E1-MDF-resin for water-resistant boards (PB: EN 312-5 and 312-7; MDF: EN 622-5). Especially for MDF production, formaldehyde catchers are added.
Distinctly below 1.00	Special resins for boards with a very low subsequent formaldehyde emission

[a] (mUF, MUF, MUPF, and others) currently in use in the wood-based panels industry.

resins with low melamine content even if there is no significant difference in the linkage structure (23).

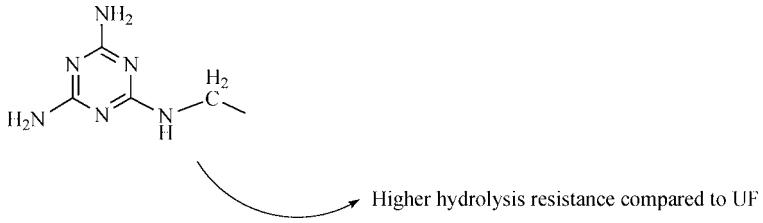
Influence of the Degree of Condensation. The higher the degree of condensation (higher molar masses), the higher is the viscosity at the same solid content. Besides a reduced water dilutibility of the resin, the flowing ability and the penetration into the wood surface are diminished. Additional effects are a decreased wetting behavior of a wood surface and a reduced distribution of the resin on the wood surface (particles, fibers). For mixtures MF + UF the degrees of condensation of the two components determine the viscosity of the mix according to the composition.

Correlations between the molar mass distribution (degree of condensation) and mechanical and hygroscopic properties of the produced boards are rather uncertain. The influence of the degree of condensation shows itself during the application and the hardening reaction (wetting behavior, penetration into the wood surface in dependence of the degree of condensation, drying out behavior after the application of the resin onto the surface).

Hydrolysis Resistance. The deterioration of a bond line, and hence its durability under the conditions of weathering, is determined essentially by

(1) failure of the resin (low hydrolysis resistance, degradation of the hardened resin causing loss of bonding strength);
(2) failure of the interface between the resin and wood surface due to the replacement of physical bonds between resin and reactive wood surface sites by water or other nonresin chemicals; and
(3) breaking of bonds due to mechanical forces and stresses: the influence of water causes swelling, and therefore movement of the structural components of the wood-based panels (cyclic stresses due to swelling and shrinking, including stress rupture).

The different behavior and resistance against hydrolysis depends on the type of the formaldehyde based resin and is determined at the molecular level. The aminomethylene links in urea–formaldehyde resins (UF) are susceptible to hydrolysis and therefore not stable at higher relative humidity or increased moisture contents, especially at elevated temperatures (24,25). A higher hydrolysis resistance can be achieved by incorporating melamine into the resin (melamine fortified UF resins, MUF, PMF, MUPF, PMUF), whereby the bonding between the nitrogen of the melamine and the carbon of the methylol group shows an increased stability against hydrolysis. The stabilization of the C—N bond arises from the conjugated double bonds of the aromatic ring structure of the melamine. An additional stabilization effect is exerted by the slower decrease of the pH in the bond line due to the buffering capacity of melamine (26).



Because of the high costs of melamine as raw material, the costs for melamine-based resins are, however, much higher than for UF resins. Therefore the content of melamine in these resins is always as high as necessary but as low as possible. Pure melamine–formaldehyde resins are found mainly in mixtures with UF resins. The possible higher hydrolysis resistance as the most important advantage of these pure MF resins is counteracted by their low storage stability in liquid form and their exceedingly high price. The melamine content in the resins can vary between a few percent in melamine-fortified UF glue resins and more than 30%. Additionally, the mode of incorporation of the melamine can be very different. This knowledge is usually proprietary, and therefore description in the literature is rare (27,28). The higher the content of melamine, the higher is the stability (hydrolysis resistance) of the hardened resin against the influence of humidity and water (2, 29, 30). The stability of a resin against hydrolysis can be evaluated by monitoring the formaldehyde emanation during hydrolysis caused by boiling water or the influence of diluted acids at higher temperatures (31).

The reaction progress and end point can be monitored *in situ* under actual reaction conditions using FTIR spectroscopy for functional groups in real time, whereby the concentration of key reaction species can be followed directly using their isolated IR bands (32).

Melamine-fortified resins with a melamine content of up to approximately 10% based on liquid resin are used for various applications where straight UF resins cannot provide the desired combination of processing tolerance, formaldehyde emission, and specific board properties such as a low thickness swelling. MUF resins with higher content of melamine (up to 30% based on liquid resin) find applications in enhanced performance grade boards for use in humid conditions (moisture-resistant application).

Cocondensation Resins. Cocondensation of MF resins with urea, phenols, and other components is possible in many ways. One of the most interesting tasks is to clarify whether there is a real cocondensation within these resins or rather whether two independent, interpenetrating networks are formed (see INTERPENETRATING POLYMER NETWORKS). Cocondensation between urea and melamine via methylene bridges and methylene ether bridges has been strongly suggested or proven (33), but precise analysis cannot always be attained (34).

The production of MUF resins of various content of melamine can follow various paths:

(1) Direct cocondensation of melamine, urea, and formaldehyde in a multistep reaction with varying sequences of addition of the components (35–41), in particular of melamine and urea (27). Subsequent partial etherification leads to improved storage stability of the MUF resins with a low content of formaldehyde (42) and an improved reactivity (43).

(2) Direct mixing of an MF resin with a UF resin (28,44–46).

(3) Addition of melamine in various forms (pure melamine, MF/MUF-powder resin) to a UF resin during the application of the resin. In the case of the addition of pure melamine, the UF resin must have a rather high molar ratio of at least F/U = 1.5 approximately. Otherwise there is not enough formaldehyde available to react with the melamine in order to incorporate it into the resin.

(4) Melamine can also be added in the form of melamine salts, such as acetates, formiates, or oxalates (47–53), which decompose in the aqueous resin mix at higher temperatures. The melamine is then incorporated into the UF resin, forming an MUF resin and generating acids as latent hardeners. Furthermore it has been reported that using this procedure with melamine salts, the amount of melamine needed is much lower than in other MUF resins (47–52). MUF resins can also contain various other compounds that can react with formaldehyde such as urea derivatives, guanamines, or amides (54,55).

MUPF resins (PMUF resins) are mainly used for the production of particleboards according to DIN 68763 and EN 312 (quality P5 and P7, option 2 "V100"), as well as of OSB (quality type OSB3 and OSB4 according to EN 300). They usually contain small amounts of a phenol component. Production procedures are described in patents and in the literature (56–66). Newly developed MUPF resins enable a distinct reduction of the necessary resin consumption in the OSB face layers (67,68).

PMF/PMUF resins usually contain little or no urea. The analysis of the molecular structure of these resins has shown that there is no cocondensation between the phenol and the melamine, but that there exist two separate networks (69–72). This can be explained on the basis of a different reactivity of the phenol methylols and the melamine methylols, depending on the existing pH.

Under acidic conditions there are two steps in the hardening of a PMF resin (73): in the first, quick step, the condensation of the melamine dominates; in the second, rather slow step, the phenol is incorporated into the network. Under alkaline conditions a cocondensation between phenol and melamine could be detected (74,75). A PMUF resin with a distinctly higher portion of phenol and also a high content of melamine can be produced by starting with a PF condensation, followed by addition of melamine and further formaldehyde; urea is then added at the end of the procedure to decrease the molar content of free formaldehyde (76).

There are interesting niche markets for resins with very low content of formaldehyde and hence boards with extremely low subsequent formaldehyde emission. Since pure UF resins are too weak to be used for this purpose (low mechanical strength, high thickness swelling), melamine-fortified resins or MUF resins are used. The necessary content of melamine in these resins can vary distinctly and depends on the level of subsequent formaldehyde emission, on the board type as well as on other board requirements; eg, a certain thickness swelling (77–80).

Melamine-based resins with extreme low molar ratios [$F/(NH_2)_2 < 0.5$] can be used as so-called formaldehyde scavenger resins (81). They are mixed mainly with UF resins during the application for the production of wood-based panels with low subsequent formaldehyde emission.

MUF honeymoon adhesive systems for bonding of timber of high moisture content (wet gluing) to produce laminated wood (glulam) and finger-jointing are composed of two components: (*1*) a MUF resin at a pH of approximately 10 with no fillers added, and (*2*) a low pH aqueous solution of carboxymethylcellulose and formic acid lacking resorcinol in the system (82–85).

Correlations Between the Composition of Melamine Resins and Properties of Hardened Glue Lines and Wood-Based Panels

Only a few investigations have been done concerning the prediction of adhesive bond strengths and other properties based on the composition of the resin. Equations for evaluating a possible correlation between the chemical structures in various MUF resins with different molar ratios $[F/(NH_2)_2]$ and different types of preparation and the achievable internal bond together with the subsequent formaldehyde emission have been investigated. For this purpose, various structural components have been determined by means of NMR, and several ratios of the amounts of the various structural components have been calculated, eg,

(1) for MF resins (86):
   a. unreacted melamine to monosubstituted melamine
   b. unreacted melamine to total melamine
   c. methylene bridges related to methylol groups
   d. degree of branching: number of branching sites at methylene bridges related to total number of bondings at methylene bridges

(2) for MUF-resins (87,88) typical ratios determined are
   a. sum of unreacted melamine and urea to the sum of substituted melamine and urea
   b. methylene bridges related to methylols or to the sum of methylene bridges and methylols.

Applications

Depending on the various requirements different resin types are selected for use. Boards with low requirements (interior use) are usually UF-bonded. The incorporation of melamine (MUF, MF + UF), and sometimes phenol (MUPF), improves the low resistance of UF bonds to the influence of humidity, water, and weather. Fields of application for the various melamine-based wood adhesives resins are boards with reduced thickness swelling; eg, as laminate flooring cores and boards for use in humid conditions [according to EN 312 for particleboard, EN 300 for OSB, EN 622-5 for MDF, EN 314 for plywood and prEN 12775, prEN 13353, prEN 13017, and prEN 13354 for blockboard (solid wood panels)].

Impregnation of wood with MF impregnating resins has shown considerable potential to improve various wood properties such as surface hardness and weathering resistance. Using UV micro spectroscopy, it has been shown that water-soluble MF resins diffused well into the secondary cell wall and the middle lamella of wood (89–92).

Laminate floorings require a very low long-term (24 h) thickness swelling of the MDF/HDF- or particleboard cores. Requirements usually are less than 8% or 10%, respectively, sometimes less than 6% or even lower. Such a low thickness swelling usually cannot be obtained with UF resins; the incorporation of melamine is a suitable way to achieve the desired results. The necessary melamine content

[k]eg, Ammonium sulfate in powder form.

in the resin depends on various parameters; eg, the type of wood furnish, the pressing parameters (pressure profile, density profile), and the resin consumption. Another important parameter is the cooking procedure of the resin, which considerably influences the thickness swelling of the boards even at the same gluing factor and the same content of melamine. It is especially important to use the formaldehyde present in the system as efficiently as possible by maximizing the content of methylene bridges compared to methylene ether bridges.

Combination of Melamine Resins with Other Adhesives. PMDI can be used as an accelerator and as a special cross-linker for MUF resins, with additions of approximately 1–2% based on dry particles (46,93–95).

For the purpose of special effects, combinations of adhesives or glue resins might be used; eg, the combination of adhesives in the particleboard or OSB production with PMDI in the core layer and a MU(P)F resin in the face layer.

Glue Resin Mixes for the Application of Melamine Resins. Table 2 summarizes some glue resin mixes for different applications in the production of particleboard, MDF, and plywood.

Hardening of Melamine Resins

During the curing process of a thermosetting adhesive resin, a three-dimensional network is built up. This yields an insoluble resin which is no longer thermoformable. The acid hardening conditions can be adjusted (*1*) by the addition of a so-called latent hardener (eg, ammonium sulfate or ammonium nitrate), or (*2*) by the direct addition of acids (maleic acid anhydride, formic acid, phosphoric acid and others) or of acidic substances, which dissociate in water (eg aluminium

sulfate). Ammonium sulfate reacts with the free formaldehyde in the resin to generate sulfuric acid, which decreases the pH. These acidic conditions hence enable the condensation reaction to restart, and finally the gelling and hardening of the resin. The rate of decrease of the pH during the hardening process depends upon the amount of available free formaldehyde and on the amount of hardener. An acceleration of the hardening process is achieved by heat (26,96), whereas the addition of melamine to a UF resin slows down the pH drop after the addition of the hardener (26) and thus yields an increase in the gel time.

The mechanism of the hardening reaction of MUPF/PMUF resins is not entirely clear. Such resins harden under similar acid conditions as MUF resins, whereas phenolic resins have a minimum of reactivity under these conditions; hence the phenolic portion of the resin might not really be incorporated into the aminoplastic portion of the resin during hardening (66).

During the hardening of PMF resins, no cocondensation reaction occurs. Therefore in the hardened state, two independent interpenetrating networks exist (69–72,97). Indications for a cocondensation via methylene bridges between the phenolic nucleus and the amido group of the melamine have been found by ^{1}H NMR only in model reactions between methylolated phenols and melamine (97).

The hardening of MUF resins can be enhanced by the addition of formaldehyde-based accelerator mixtures and monitored via rheology, gel time measurements, as well as the so-called ABES tests (98,99). Analyses indicate that cured MUF resins are mainly composed of separate MF and UF networks. Thus particleboards glued with an MUF/accelerator mixture exhibit improved mechanical properties compared to boards produced with commercially used MUF adhesives. The swelling properties of particleboards glued with an MUF/accelerator mixture are comparable to boards made from a commercial MUF resin (100).

Imino-amino methylene base intermediates obtained by the decomposition of hexamethylenetetramine (hexamine) stabilized by the presence of strong anions (hexamine sulfate) have been shown to markedly improve the water and weather resistance of hardened MUF resins used as wood adhesives (101–105). Even with only small additions between 1% and 5% the use of MUF resins of much lower melamine content with constant performance of the boards is possible.

Analytical Chemistry of MF Resins

The analytical chemistry of MF resins requires modern and sophisticated analytical methods because of the chemical complexity of the resin mixture. Several tens of components, ranging from defined low molecular component to oligomeric and polymeric components, can be identified within the resin mixture. Usually analytical methods are performed to achieve information on the following points : (*1*) the detailed composition (structure and amount) of low molecular components, (*2*) the estimation of the amount of characteristic functional moieties, and (*3*) the structure of the hardened thermoplastic networks. A complete overview of analytical methods concerning MF resins can be found in the literature (1).

Nuclear Magnetic Resonance (qv) (86,106) in the liquid state has proven one of the most efficient and valuable tools for analyzing the composition of MF and related resin materials. Besides ^{1}H NMR (16,107) spectroscopy, whose

resolution is limited by the small spectral range (~15 ppm), ^{13}C NMR spectroscopy (15,108,109) (spectral range ~200 ppm) is very effective for the analysis of hydrated or lyophilized samples in dimethyl sulfoxide (DMSO) or aqueous solution. Table 3 and Table 4 show the relevant resonances together with the assignment to the corresponding structural units (17,110). Values are shown for methylolated as well as methoxylated MF resins. Additional information on MUF (87) and M(U)PF resins (69–71,111) is reported in the literature. Degrees of branching as well as distinct molecular species can be identified with this method. The molecular mobility of resins components can be analyzed by gel-phase NMR spectroscopy on native MF resins (13). The changes of the concentration of various structural elements during the condensation of an MF resin can be followed by ^{13}C NMR (112).

[a] ^{13}C Chemical shift in 40% DMSO/60% H$_2$O.

The lower the pH during the condensation, the higher is the portion of methylene bridges compared to ether linkages.

Hardened MF resins can be analyzed by solid-state NMR spectroscopy (113,114) detecting ^{13}C NMR and ^{15}N nuclei (requiring ^{15}N-enriched material). The chemical shift values from Table 3 and Table 4 are valid because of the equivalence between chemical shifts in solution and solid-state NMR spectra. The usual limited resolution of these spectra, however, limits the detailed analysis possible by liquid NMR spectroscopy. An analysis of molecular mobility within the hardened networks can be achieved by ^{13}C solid-state NMR spectroscopy.

IR spectroscopy is used frequently for the analysis of MF-type resin materials. Despite its broad use and availability, the information is quite limited for the analysis of distinct chemical species because of broad bands and overlap with water signals (see VIBRATIONAL SPECTROSCOPY). Information on cocondensation between phenolic resins and melamine (72,115), the structural analysis of hydroxymethylated melamines (116,117), as well as the chemistry of hardening (118) can be followed.

The analysis of MF resins as well as alkoxylated MF resins by chromatographic methods has been described vastly in the literature (119,120) and allows the separation and identification of oligomeric methylolated melamines by conventional UV- or refractive index based detection. The most direct method for the determination of methylolated melamines within a MF resin is the coupling between HPLC methods and Mass Spectrometry (qv), enabling the direct structural analysis by HPLC-MS methods on methoxylated (121–124) and butoxylated MF resins (see CHROMATOGRAPHY, HPLC) (125). Favored ionization methods use ESI-MS ionization methods to achieve an efficient ionization process. The detection of up to pentameric melamine units can be achieved by this method.

High pressure DSC coupled with both HPLC and GPC can characterize the polymerization or cure of MF resins (126). DSC was used to calculate the kinetics of the reaction resin during curing, and GPC monitored the change in molar masses.

The effects of cure temperature and amount of catalyst on the rheokinetical behavior of an MF resin can be followed using dynamical mechanical techniques (127), and time–temperature–transformation (TTT) cure diagrams can be constructed using the results of these methods (127–129) (see DYNAMIC MECHANICAL ANALYSIS).

Other, more historic methods for analyzing the chemical composition of MF resins rely on size-exclusion chromatography (SEC) (130,131) and thin-layer chromatography (132) (see CHROMATOGRAPHY, SIZE EXCLUSION).

Economic Aspects

Out of the approximately 6.5 million ton of formaldehyde-based resins (in dry form) used as adhesives in the wood-based panels industry, more than 900,000 ton are based on melamine (133). The resins are produced mainly by the chemical industry itself, as well as partly by the wood-based panels industry on its so-called megasites. In 1999 approximately 28%, or 196,000 ton, of the melamine that was produced worldwide was converted into wood adhesives (133).

MOLECULAR RECOGNITION IN DENDRIMERS

Introduction

Dendrimers are highly branched polymers that can be obtained with a very high degree of control (1–10). The degree of control that is obtainable in dendrimers is often touted as being matched by those only seen with biopolymers. Ever since the first report of dendrimer synthesis (11), a number of possible applications for these molecules were envisioned (7,12). Several of those imaginative ideas are being brought to practice with these new macromolecular architectures. The seminal work of Newkome and Tomalia also has to be credited for bringing this area of research to the forefront (13,14). A particular theme that has emerged out of these new molecules is to use these scaffolds for molecular recognition (15). Structurally, dendrimers have three different locations of interest: a core, highly branched interior building blocks, and functionalities in the periphery. The features that render these macromolecules as ideal candidates for molecular recognition are that (*1*) dendrimers can be obtained in a highly monodisperse form, ie, with a high degree of control over molecular weight; (*2*) They adapt a globular conformation at higher generations, thereby generating space in its interior for binding guest molecules; (*3*) The core of the dendrimer is often well-encapsulated from the solvent environment; (*4*) The ability to functionalize the periphery of the dendrimers allows for a high density presentation of functionalities.

Binding events between two molecules (a host and a guest) occur due to certain attractive forces. These could be dispersion forces such as π-stacking, metal–ligand interactions, hydrogen bonding, hydrophobic interaction, ionic interaction, or other electrostatic attractions. In this article, we will focus mainly on hydrogen-bonding-based recognition and hydrophobic forces. We will make occasional reference to ionic interactions and π-stacking within the two topics above. Dendrimers based on metal–ligand interactions are not included in this review and interested readers are referred to other recent review articles on this topic (6,16,17) (see also DENDRONIZED POLYMERS).

Synthesis of Dendrimers

Syntheses of dendrimers can be achieved mainly through two complementary methods: (*1*) a divergent approach and (*2*) a convergent approach (18). Both approaches use AB_n monomer units and utilize protection–deprotection (or masking–unmasking methodologies) to grow the dendrimer. The divergent synthesis starts from the core and the periphery grows as more synthetic iterations are performed on the same molecule (Fig. 1). Therefore, the reactive functionalities are always in the periphery of the dendrimer. In the convergent synthesis, the dendritic growth occurs at the focal point of the dendron or dendrimer, since the growth takes place from the periphery to the core (Fig. 2). The divergent approach and the convergent approach are shown schematically in Figures 1 and 2, respectively.

There are advantages and disadvantages to both of these approaches. Since the reactive functionalities are in the periphery of the growing dendrimer in the divergent approach, the reactivity of these groups is retained even at high generations. However, in the convergent synthesis, since the reactive functional group is at the focal point of the dendrimer, this functionality tends to get encapsulated at higher generations. Therefore, it becomes less reactive and it is difficult to

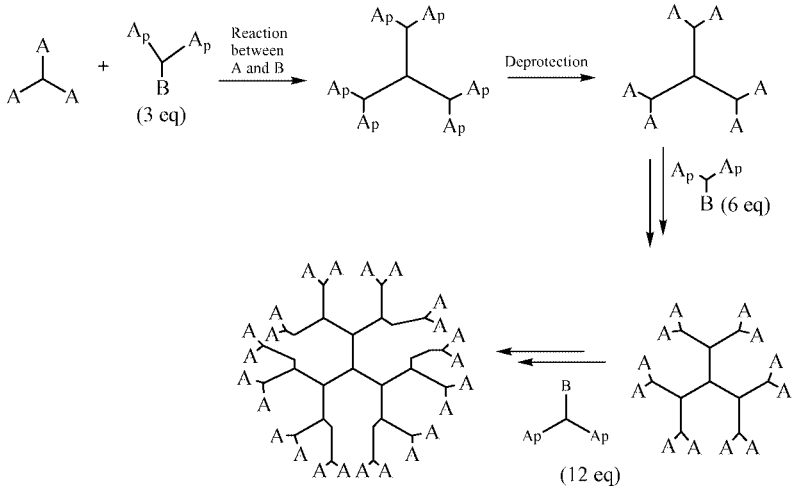

Fig. 1. Schematic representation of the divergent approach.

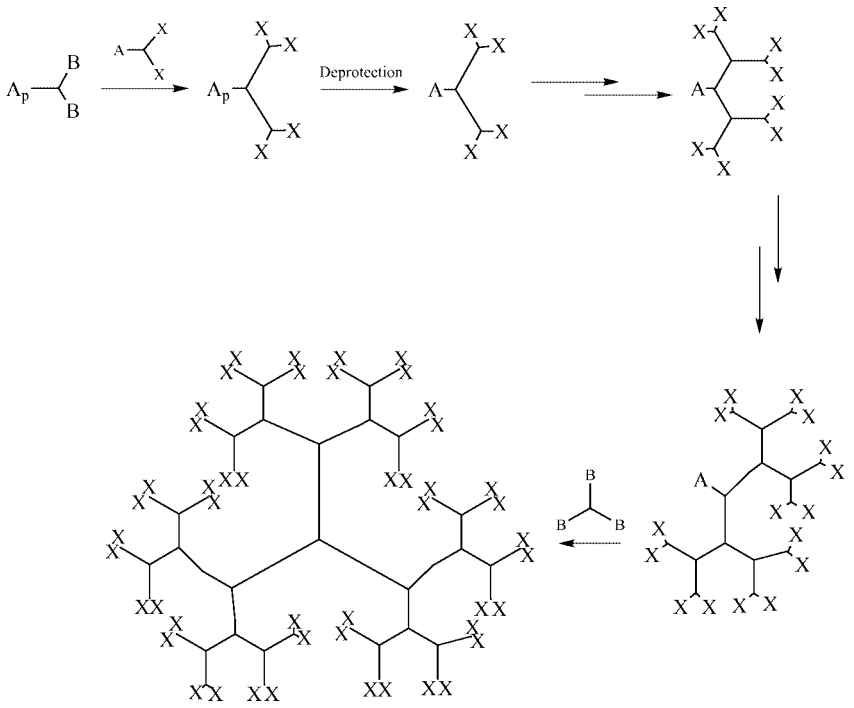

Fig. 2. Schematic representation of the convergent approach.

produce very high generations using the convergent approach. Also, note that the number of reactions that needs to be done on a single dendrimer molecule doubles with each generation in the divergent synthesis (Fig. 1). This results in defects in the dendrimer structures at higher generations. In the convergent synthesis, the number of reactions to be performed in a particular molecule always remains the same, independent of the generation. Therefore, achieving a pure, monodisperse dendrimer is more likely. Dendritic systems such as the commercially available polyamidoamine (PAMAM) and poly(propylene)imine (PPI) dendrimers are synthesized through a divergent approach. Dendrimers such as the Newkome dendrimer, silane-based dendrimers, and the phosphorus based dendrimers are also made using a divergent approach (13,19,20). Benzyl ether and phenylacetylene dendrimers are the two main classes of dendrimers that have been synthesized using a convergent approach (4,5).

Since dendrimers are often pursued as globular protein mimics, it is useful to be able to vary each monomer unit from the other, ie introduce sequences within dendrimers. For achieving such a possibility, the convergent approach is an ideal synthetic protocol. The Thayumanavan group has developed two synthetic protocols in which the peripheral functionalities of the dendrimers are all different from each other (21,22). In the first approach, we used an AB_2 monomer unit in which one of the B units is protected. This approach was demonstrated by the monoprotection of one of the phenolic groups of 3,5-dihydroxybenzyl alcohol with an allyl moiety. The resultant monomer was treated with one alkylating agent to

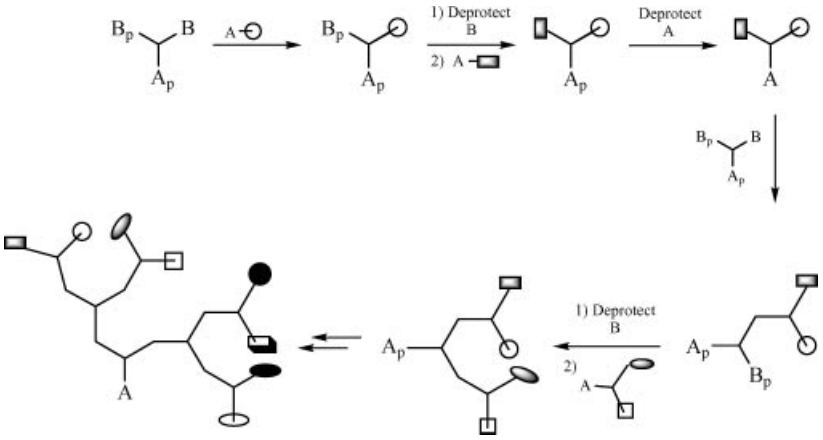

Fig. 3. Schematic representation of ABB_p sequencing methodology.

cleanly afford the monosubstituted compound. The allyl group was deprotected and the resultant phenol was then treated with a second electrophile to afford the differentially substituted G1 dendron. Conversion of the hydroxymethyl moiety to bromomethyl group and iterations of the above-mentioned steps resulted in higher generation dendrons, as schematically shown in Figure 3.

In an alternate approach, an ABB′ monomer was used as the building block unit. In this monomer, under a certain condition the functionality B reacts with A selectively, while A can react with B′ under a different set of conditions. The repeat unit used for this purpose was ethyl 3-hydroxy-5-hydroxymethylbenzoate. Here B is the phenol, B′ is the primary alcohol, and the masked form of A is the ester group. This approach is schematically shown in Figure 4. Another facile route that is capable of introducing sequences within dendrimers was developed by Simanek, where three different functionalities can be reacted one at a time with a traizine core (23).

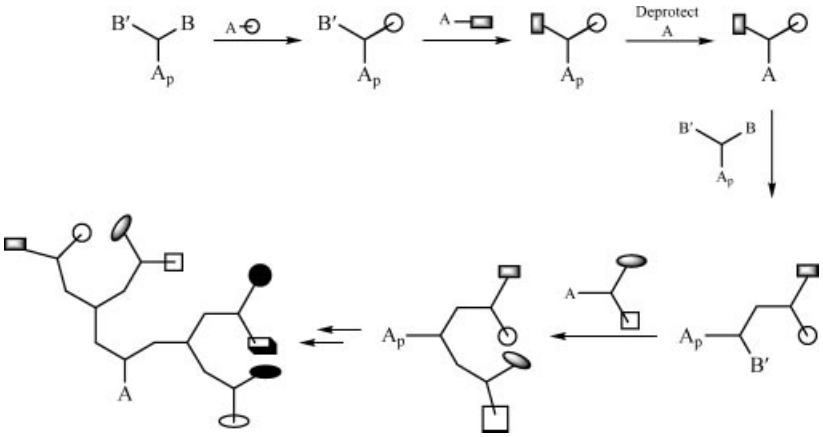

Fig. 4. Schematic representation of ABB′ sequencing methodology.

Hydrogen Bonding

Hydrogen bonding has been a fascinating tool for molecular recognition for chemists, since it is ubiquitous in nature's recognition processes and is highly directional. The directional nature of hydrogen bonds allows control over the relative orientation of the host–guest molecular framework. Hydrogen-bonding-based interactions are often weak in the presence of polar and/or protic solvents or in the presence of other competitive guest molecules. This feature has led to the design of the reversible incorporation of guest molecules that could find use in applications such as catalysis, separations, and controlled drug release.

Hydrogen Bonding within Dendritic Interiors. Newkome and co-workers incorporated 2,6-diaminopyridine units as the host recognition functionalities within dendrimers (24). The dendrimer host containing the donor–acceptor–donor (DAD) hydrogen-bonding receptor was able to bind glutarimide containing the complementary acceptor–donor–acceptor (ADA) units with 1:1 functional stoichiometry (Fig. 5). The apparent association constant was found to be about 62–70 M^{-1}. Newkome also noted that the analysis was complicated by additional complexation sites within the dendrimer backbone, as they weakly compete for the guest molecule. Similarly, Santo and Fox have also studied the hydrogen-bonding interaction between dendrimers and several heterocyclic guest molecules (25). These authors noticed that the binding efficiency depends on the nature of the peripheral functionalities of PAMAM dendrimers. It is also interesting to note that PAMAM dendrimers have been shown to be capable of accommodating guest molecules such as 2-naphthol in their interior, which can then be released upon a pH change (26). These interactions are presumed to be due to hydrogen bonding.

Specific binding between a dendrimer host and a complementary guest molecule was also achieved by Zimmerman and co-workers, where they used benzyl ether or phenyleneethynylene dendrimer backbone (27). In this work, naphthyridine units were incorporated into the focal point of dendrimers, and complementary benzamidinium-based molecules were used as guests (Fig. 6). The authors found the association constant (K_a) of this host–guest interaction to be independent of the dendrimer generation and is dependent only on the nature of the solvent in which it is measured. These results were taken to suggest

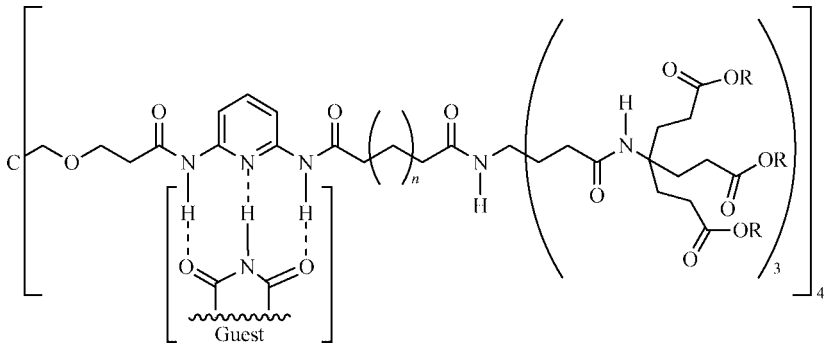

Fig. 5. Structure of the Newkome dendrimer that binds glutarimide.

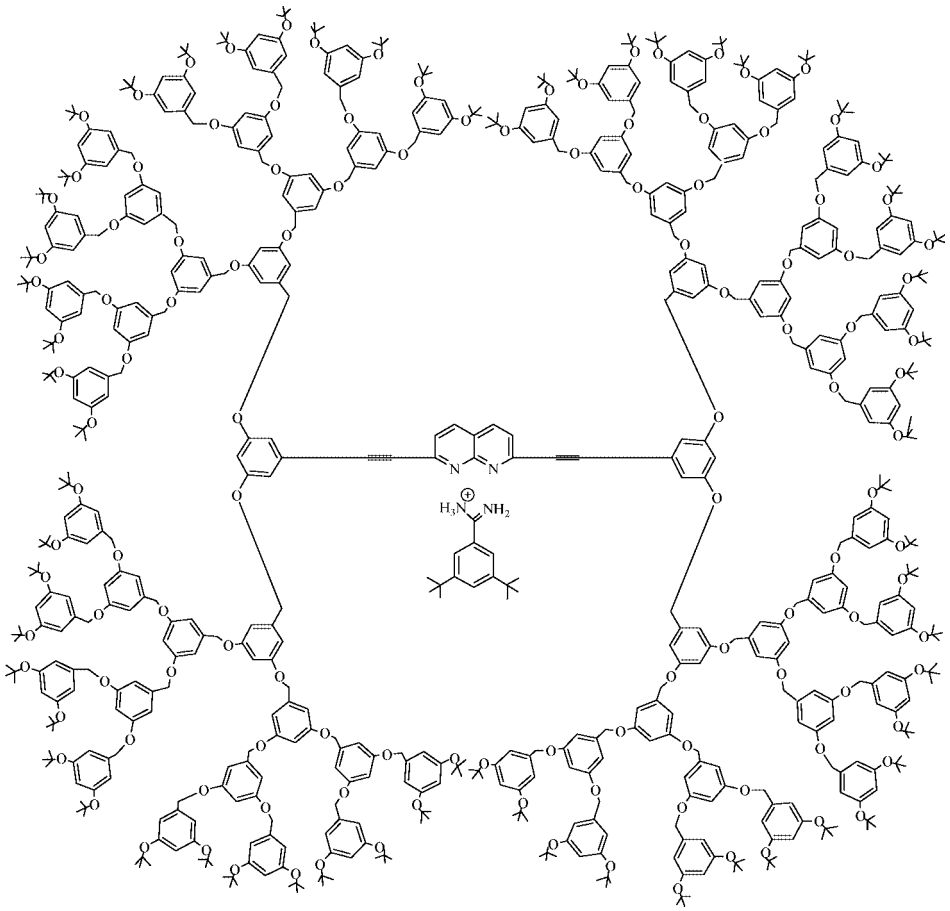

Fig. 6. Structure of the dendrimer with a naphthyridine core.

that dendrimers are highly porous in nature and that the dendritic interiors are solvent-filled. This is an interesting result, considering the report by Fréchet, where the solvatochromic shifts of a chromophore incorporated in the core suggests that the polarity of the dendritic interior is dictated by the dendrimer backbone and not the bulk solvent (28).

Diederich and co-workers incorporated optically active binaphthol at the core of benzyl ether dendrimers (29). The diol moiety in the core was converted to the corresponding phosphates, which were used for carbohydrate recognition (30). Although, they observed a 1:1 association with glycosidic guest molecules, the binding selectivity was observed to be weak. Also, the association strength did not change significantly with dendrimer generation. This observation is consistent with Zimmerman's results mentioned above. Fluorescence-based enantioselective recognition of amino alcohols was also attempted with BINOL-cored dendrimers (31). The proof-of-principle for such a possibility is reported, although the enantiodiscrimination using these dendrimers is moderate. The fact that the fluorescence quenching is not dependent on amino alcohol concentration leads to the

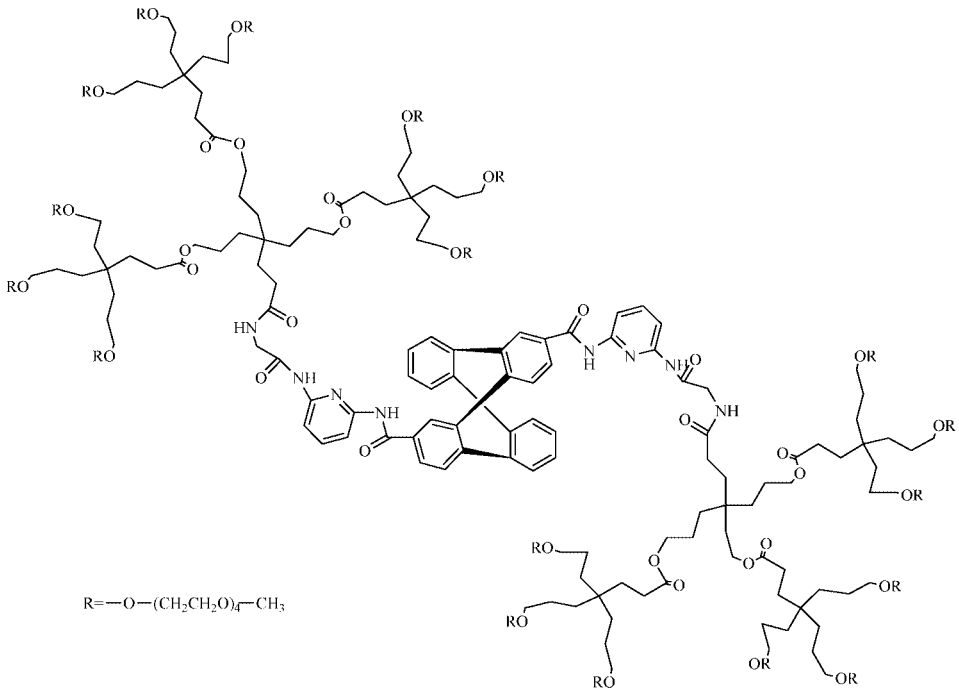

Fig. 7. Structure of a dendrocleft.

conclusion that the quenching occurs because of the hydrogen bonding between the core of the dendrimer and the amino alcohols.

Carbohydrate recognition has also been achieved with dendrimers by Smith and Diederich (32). These so-called dendroclefts are made up of a 9,9′-spirobi[9*H*-fluorene] initiator core containing 2,6-di(carboxamido)pyridine moieties (Fig. 7). Upon increasing the dendrimer generation, it was noted that the discrimination of enantiomeric guest molecules became poorer, whereas discrimination between diastereomeric guest molecules became better. This was attributed to the difference in steric demands of the dendritic shell or to the possible participation of the peripheral functionalities in the host–guest hydrogen-bonding network.

Molecularly imprinted polymers have been approached as a possible mode of performing host–guest chemistry in recent years (33). However, the limitations of these methods include incomplete template removal, broad guest affinities, and slow mass transfer. The molecular homogeneity, monodispersity, and large solubility of dendrimers make them good choice for the molecular imprinting process. Recently, Zimmerman and co-workers used their cored-dendrimer concept (34) to template porphyrins with benzyl ether dendrimer (35). The hollow core of the dendrimer contained eight carboxyl groups inside the dendritic core, capable of hydrogen bonding with complementary guest molecules. They showed that different porphyrin-based guest molecules can bind reversibly to the host structure (Fig. 8) (36).

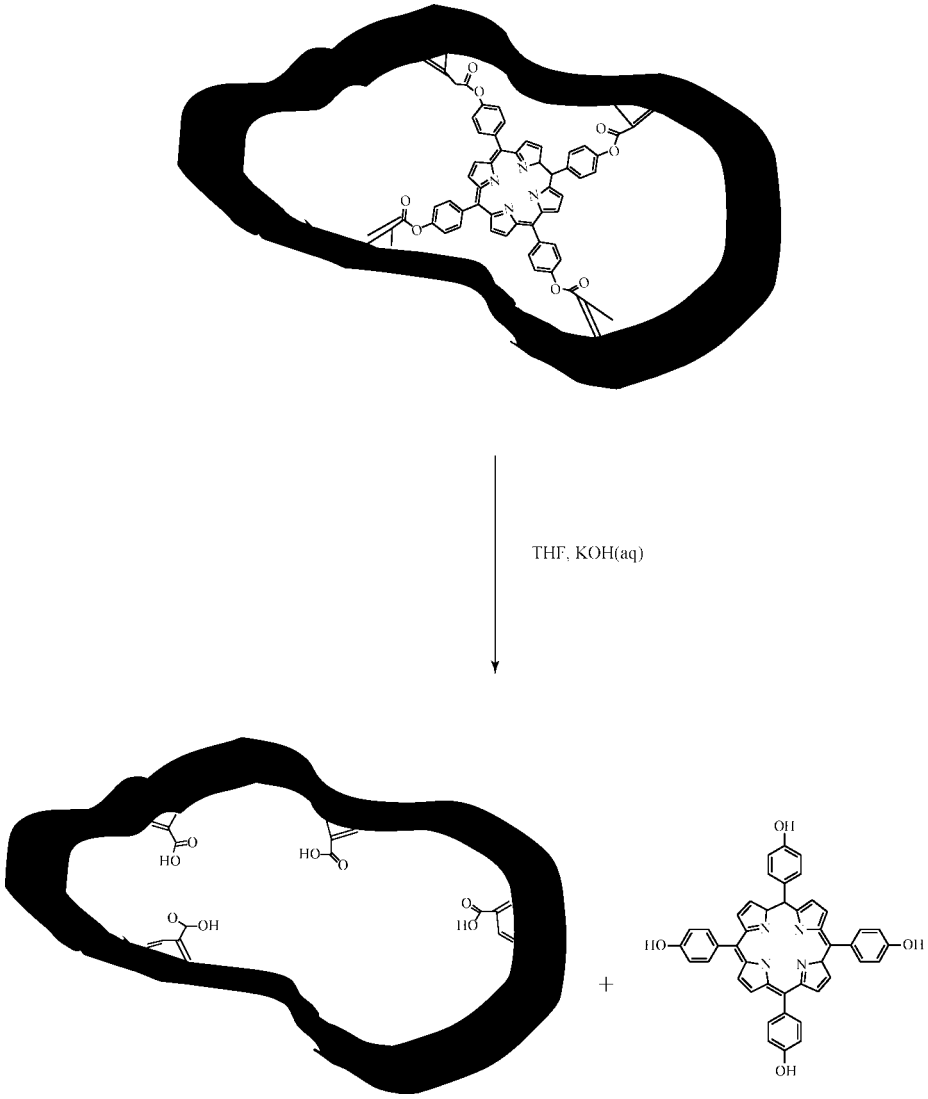

Fig. 8. Molecularly imprinted dendrimers.

Hydrogen Bonding in the Dendritic Periphery. While host–guest interaction in the dendritic interior is interesting because of the unique environment that dendrimers often provide in their interiors, reversible modification of dendritic periphery is also interesting. Meijer and co-workers showed that PPI dendrimers with modified urea functionalities can be utilized to bind guest molecules that are also urea-based (37). It was also shown later that a thiourea-based host functionality is better than urea itself for the urea-based guests (Fig. 9) (38). The observation was confirmed by isothermal calorimetry studies. Since both host and guest molecules are based on urea functionalities and since the periphery of the dendrimers contains a high density of the urea functionalities, there is

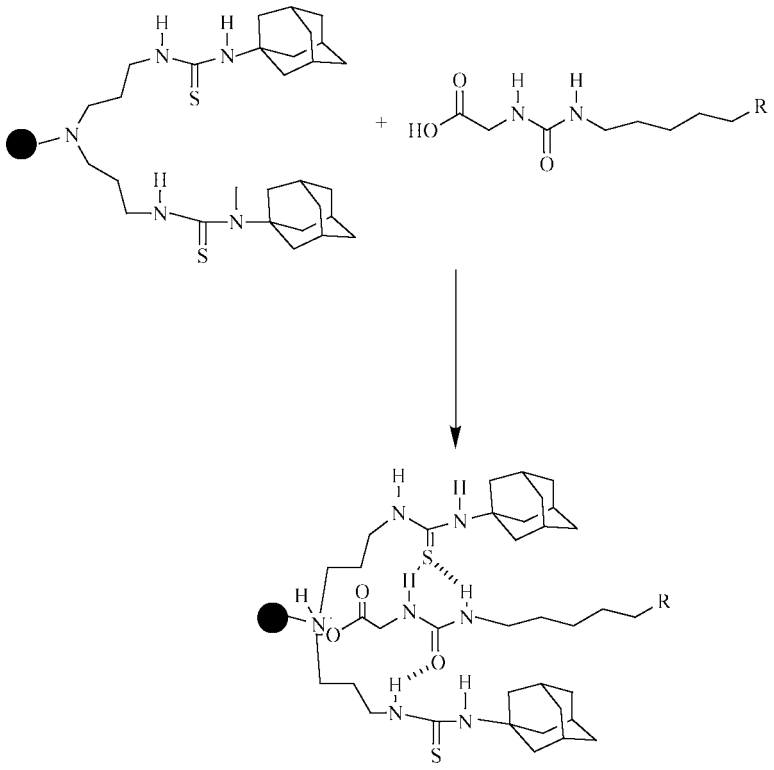

Fig. 9. Binding of urea guest molecules with thiourea functionalities in the dendritic periphery.

an obvious opportunity for intramolecular hydrogen bonding in these dendrimers. When there is an increased intramolecular hydrogen-bonding interaction, it was observed that the host–guest interaction is weaker. The authors attributed this observation as the probable reason for thiourea being a better host. They suggest that the soft interaction between the molecules owing to the presence of sulfur compared to oxygen provides a less dense structure, which is more accessible to guest molecules.

An elegant application of this method was shown by Reek and Meijer, where this type of dendrimer was used as catalytic support for palladium-catalyzed allylic amination reactions (39). The periphery of the dendrimer contains many adamantyl-functionalized urea groups (Fig. 10), and the catalyst was designed to have complementary hydrogen-bonding elements along with a triphenyl phosphine moiety, a ubiquitous ligand in organometallic catalysis. The presence of multiple catalytic sites in a single dendrimeric support did not hamper the reaction rate, showing that the phosphine ligands were independent of each other. It was also easy to recover the ligand from the support, which could then be reused.

An interesting work by Kim showed that the periphery of the dendrimers can be reversibly manipulated through noncovalent interactions (40). They used Cucurbituril as the molecular bead that encapsulates the amino butane peripheral units (Fig. 11). The pseudorotaxane-terminated dendrimers not only gave a

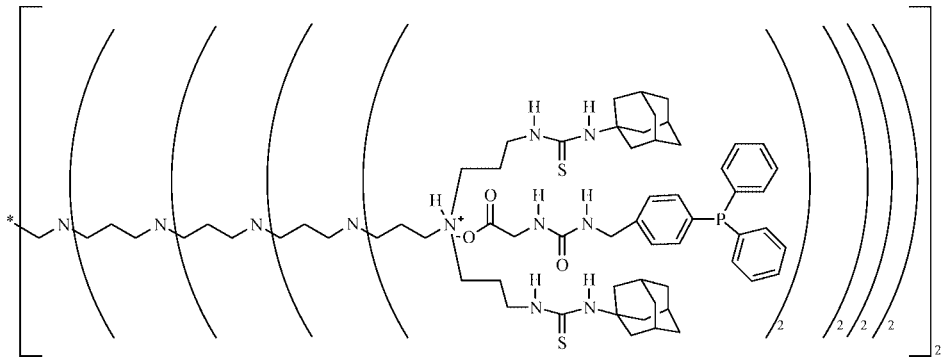

Fig. 10. A recoverable catalyst using hydrogen-bonded host–guest dendrimer.

topologically novel dendritic structure but also suggested that these structures can be useful for applications such as drug delivery upon appropriate redesign.

Intramolecular hydrogen bonding among the periphery units in dendrimers has been effectively used for binding guest molecules. Meijer's group has shown that the intramolecular hydrogen bonding among the peripheral units can be used to construct a so-called dendritic box. Intramolecular hydrogen bonding is

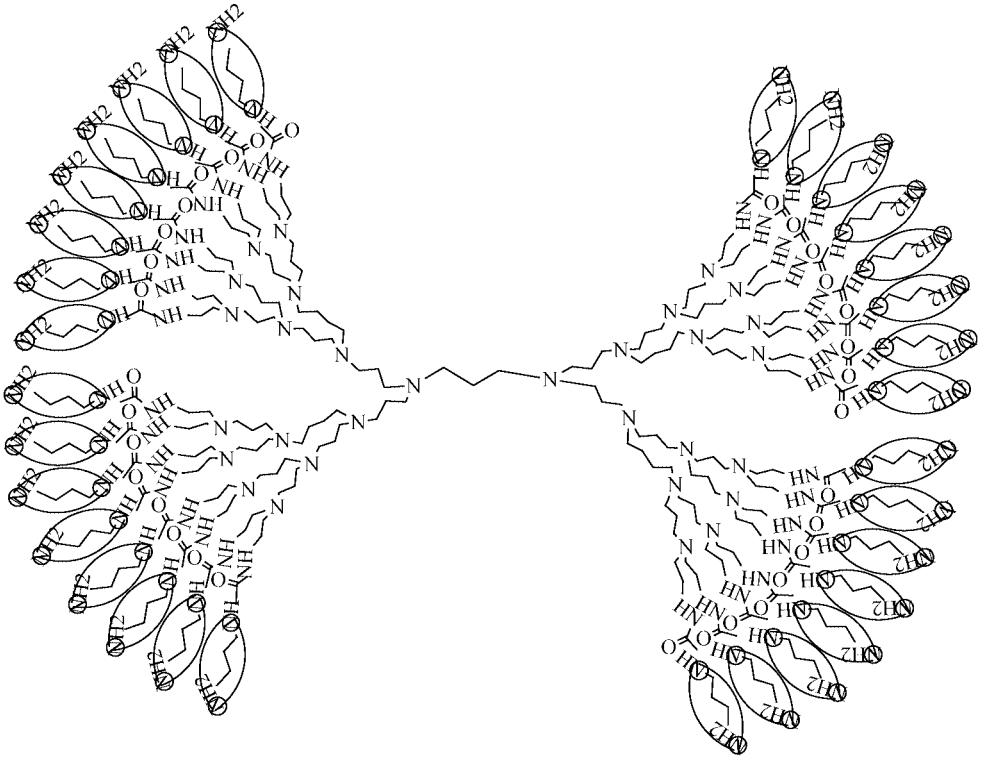

Fig. 11. Dendrimers with noncovalently bound cucurbiturils (the cylindrical objects denote cucurbiturils).

shown to result in dendrimers with a solid-shell structure and a flexible core (41,42). The hydrogen bonding units were generated from the derivatization of the primary amino groups in PPI dendrimers with Boc-protected amino acids. Guests were incorporated inside the dendrimers while functionalizing the peripheral amino groups. Typical guest molecules used include 3-carboxy-PROXYL radical, erichrome black, and rose bengal. All these guest molecules contain carboxylic or sulfonic acid functionalities, which bind to the dendritic interior containing tertiary amines presumably through acid–base interactions. Note that the role of hydrogen-bonding periphery in these dendrimers is not to provide specific interactions with the guest molecules, but rather to provide a solid shell to trap the guest molecules. Meijer noted that size-selective release of the trapped guest molecules is possible by first deprotecting the Boc groups and then by hydrolyzing the amino acids from the dendrimer under rather harsh conditions (Fig. 12) (43,44).

Biomimetic Materials. The large structure of dendrimers and their globular shape has attracted significant attention because of its potential application as biomimetics, especially as enzyme mimics. The work by Aida and co-workers showed the function of dendrimers as a hemoglobin mimic (45). Aryl ether dendrimers were used to encapsulate iron(II)–porphyrin 1-methylimidazole complex (Fig. 13). The oxygen-binding ability of the complex increased with the dendrimer generation where the dioxygen molecule binds to the complex, instead of the μ-oxo-dimer formation observed for lower generations of the dendrimers. Another important result from this study was that the oxygenated complex was very stable toward carbon monoxide, which holds exciting possibilities in itself. However, in this work, the use of 1-methylimidazole apparently complicated the study of oxygen affinity measurements.

Interestingly, Collman and co-workers used 1,2-dimethylimidazole (dimim) which formed 1:1 high spin iron(II) adduct (Fig. 14) (46). It was found that the ratio of the two binding constants K_{CO}/K_{O2} of this complex was very low, as compared to T-state hemoglobin and the picket fence Fe(II)–dimim complex. The probable reason is that the bound dioxygen molecule formed hydrogen bonding with the amide NH-groups of the dendritic backbone used. The destabilization of the CO ligand was thought to be an unfavorable steric interaction between the CO and the dendritic branch. These results were further supported in a later publication, where the O_2 binding studies were performed (47). It was noted that the complexation of first and second generation of the amide-based dendrimers show efficient O_2 binding, whereas the control molecule without the amide bonds showed reduced stability for the dioxygen complex. Also for the first and second generation of the amide-based dendrimer, it was seen that in the presence of solvents like water, the oxygen affinity of these compounds decreased, clearly showing the effect of competing hydrogen bonding between water and the dendritic branches.

The emission properties of tryptophan (Trp) have been widely used in biophysical studies of proteins. Recently, Smith and Müller used Trp to probe the dendritic microenvironment by attaching the amino acid to polyether dendrimers and studying their fluorescence spectra (Fig. 15) (48). It was observed that in the presence of non-hydrogen-bonding solvents, the dendritic effect (shift of λ_{max}) was profound. The argument was that in presence of non-hydrogen bonding solvents, there was effective hydrogen-bonding interaction between the amide H-atom of

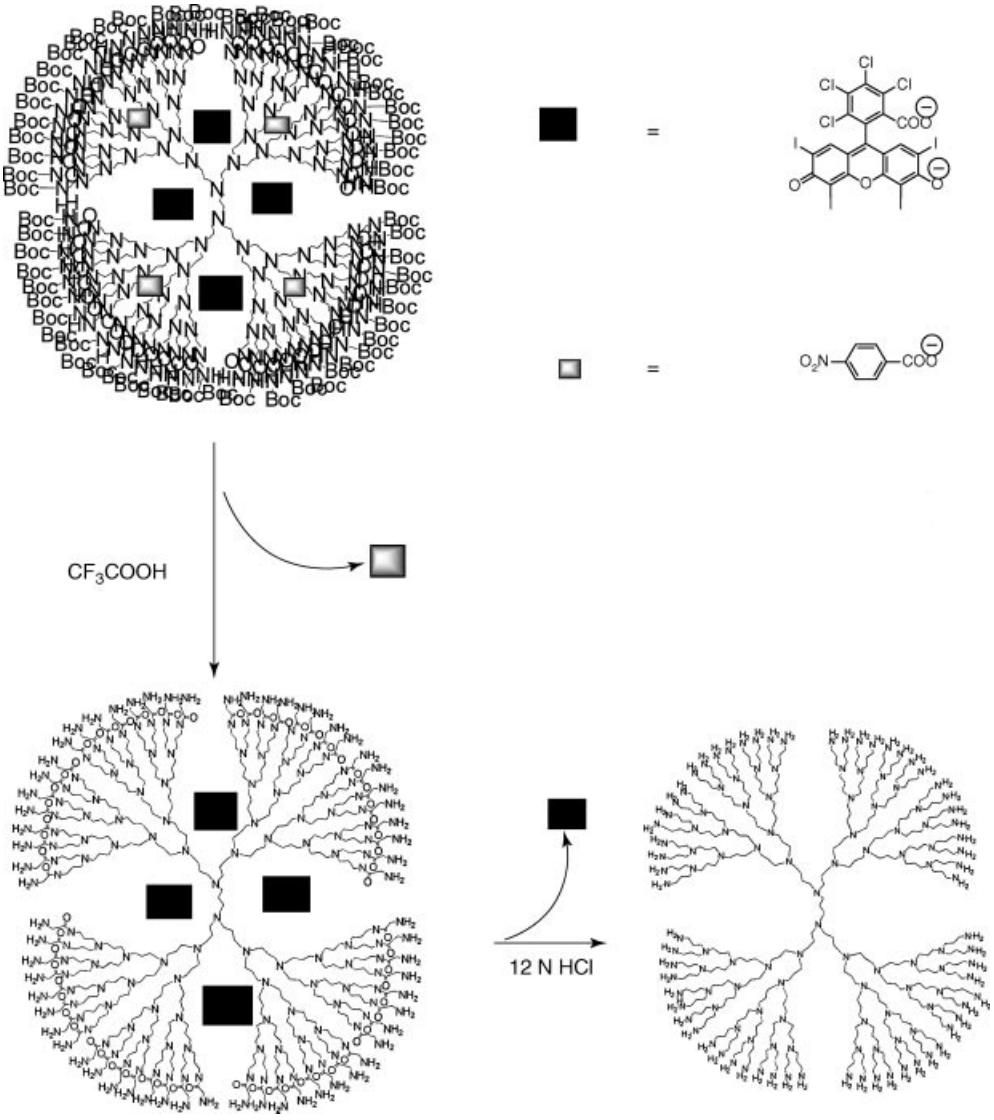

Fig. 12. Dendritic box and selective guest release.

Trp and the carbonyl groups of the dendrimer, which leads to the shift in the emission spectra. It was seen that the hydrogen bond acceptor solvents do not change the character of the spectra much, which is understandable. Also, the hydrogen bond donor–acceptor solvents showed negative dendritic effect owing to the competition faced by the Trp, from the solvents. It was proposed that strong hydrogen bonding between the Trp and dendritic branch resulted in a change of the polarity of Trp's microenvironment, resulting in an emission shift. This proposal was further supported in a later publication where they took Trp along with another compound where the —NH group of the indole ring has been changed to N—Me (49). No dendritic effect was observed in this case.

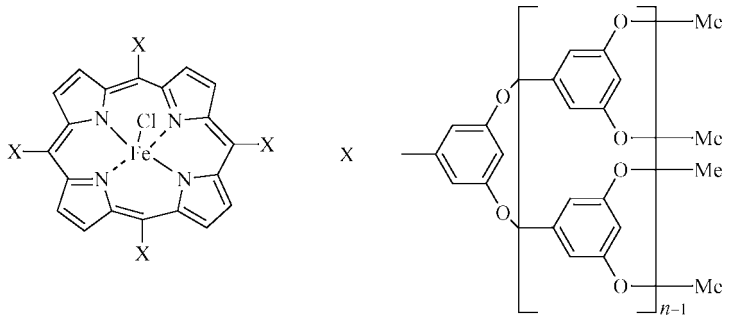

Fig. 13. Porphyrin dendrimer with oxygen-binding ability.

Parquette and Huang showed that the hydrogen-bonding effects within the dendritic interior could result in a particular helical bias in a dendrimer, and that the chirality can be transferred from the core to the periphery. Working with pyridine-2,6-dicarboxamide, they first showed the synthesis and characterization of dendrimers whose conformations at different levels are somewhat restricted because of intramolecular hydrogen bonding (Fig. 16) (50). The stability of helical secondary structure in these dendrimers is dramatically enhanced by linking each generational shell through an anthranilamide turn unit (51). Circular dichroism studies on these intramolecularly hydrogen-bonded dendrimers revealed that the interconversion between the two diastereomeric helical conformations (M and P helices) relating a pair of anthranilamide termini depends on solvent, temperature, and dendrimer generation (52). More recently, they have shown that the compaction levels of these dendrimers can be modified by varying the linkers in the central core of the dendrimer (53).

Sensors. An obvious application of molecular recognition is in the area of sensory materials. Several aspects described above can be exploited to generate sensors. There have been a particular interest in anion sensing with dendritic structures. Significant contributions in this field have been made independently by Astruc and Kaifer. Astruc and co-workers studied the binding effect of several anions, including HSO_4^-, $H_2PO_4^-$, and Cl^-, on different dendrimer generations (54). The dendritic effect was most pronounced with $H_2PO_4^-$ anions. Using polyamido ferrocene dendrimers, they showed that with increase in generations, the $E_{1/2}$ value for ferrocene wave increased with the addition of the $H_2PO_4^-$ anions (Fig. 17). It was proposed that the $H_2PO_4^-$ anion interacts with the dendrimers via a synergy between electrostatic and hydrogen-bonding interactions. The fact that more $H_2PO_4^-$ anions are needed for higher generations of dendrimer was taken to suggest that the $H_2PO_4^-$ units are interacting with the amide moieties present in the dendritic backbone. The sensory effect was maximum for the dendrimer with 18 ferrocene units, indicating that the steric factors become important in larger generations. This work was extended further by attaching AB3 phenol units *p*-OH—$C_6H_4C(CH_2CH{=}CH_2)_3$ and *p*-OH—$C_6H_4C[(CH_2)_3SiMe_2{-}CH_2NHCOFc]_3$, with different generations of polypropyleneimine dendrimers (55). The molecules here were assembled by hydrogen bonding. The characterization by cyclic voltammetry (CV) and NMR methods proved that the

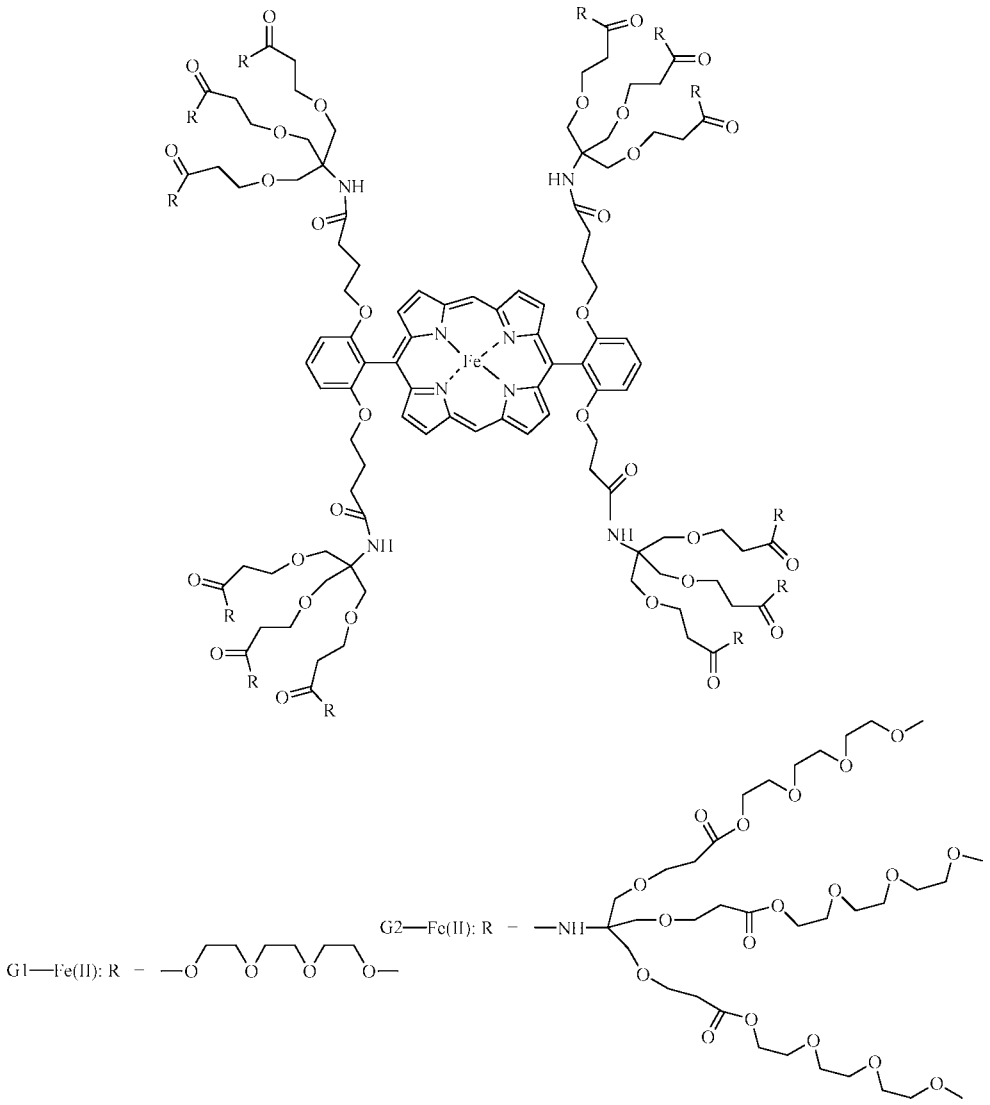

Fig. 14. Iron–porphyrin dendrimer by Collman and Diederich.

sudden wave changes, alterations of half stoichiometry, and decrease of peak intensity in CV are all affected by dendrimer generations. On a similar note, Kaifer and co-workers showed that similar hydrogen-bonding-mediated anion sensing can be performed via ferrocenyl urea dendrimers (56). The results here are significant since all the studies were done in DMSO, where the competing solvent effects would seem to make the anion sensing less feasible.

Dendrimer Assemblies. Supramolecular assembly is not a new area of research and chemists have been involved in this field for a long time. However, controlled assembly of well-defined macromolecules is often seen only in nature. Dendrimers are ideal scaffolds as artificial proteins and enzyme mimics, since

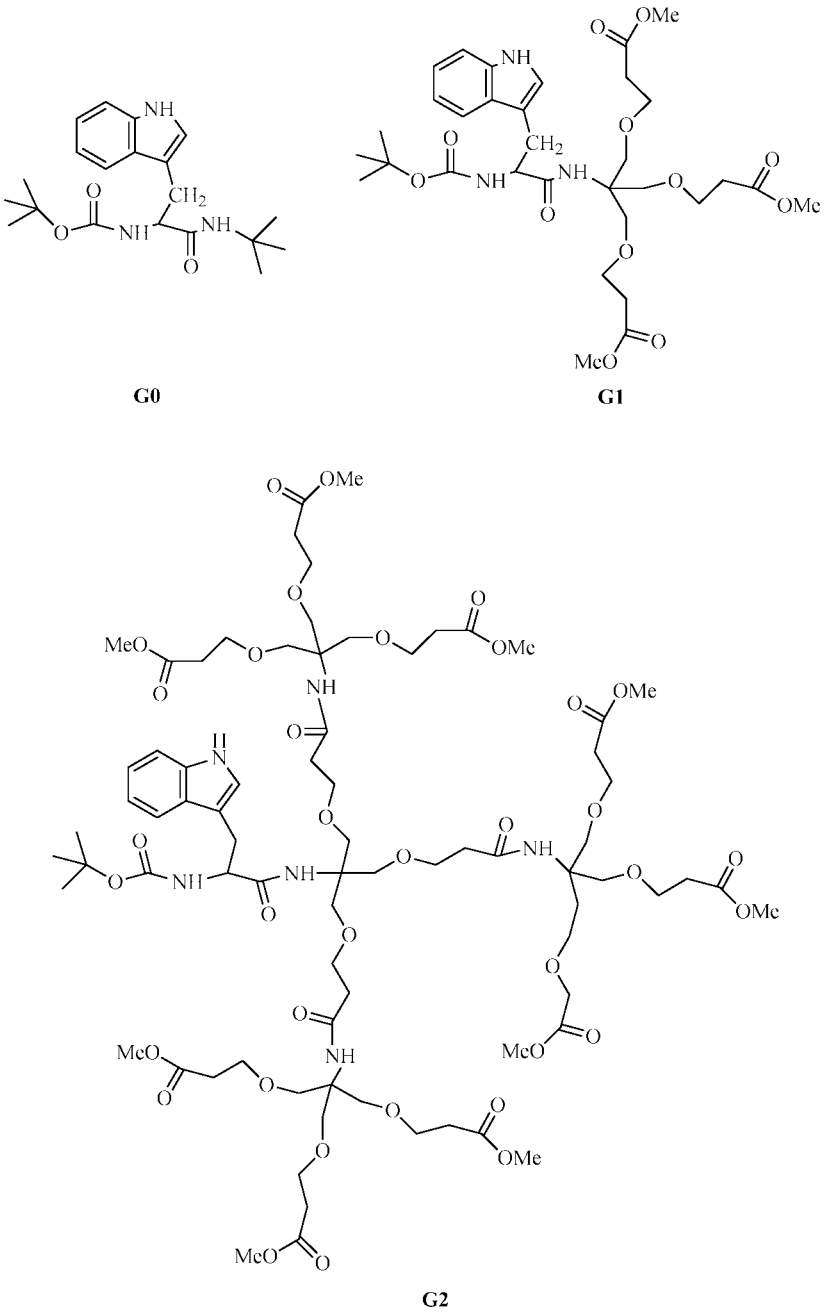

Fig. 15. Tryptophan dendrimers.

they have large molecular weights, are monodisperse, and are easy to functionally manipulate. Zimmerman showed that hydrogen-bonding-mediated assembly of didendrons can be achieved by complexing monodendrons with a 1,9,10-anthyridine core and ditopic complementary guest molecule (Fig. 18). A 2:1 complex was

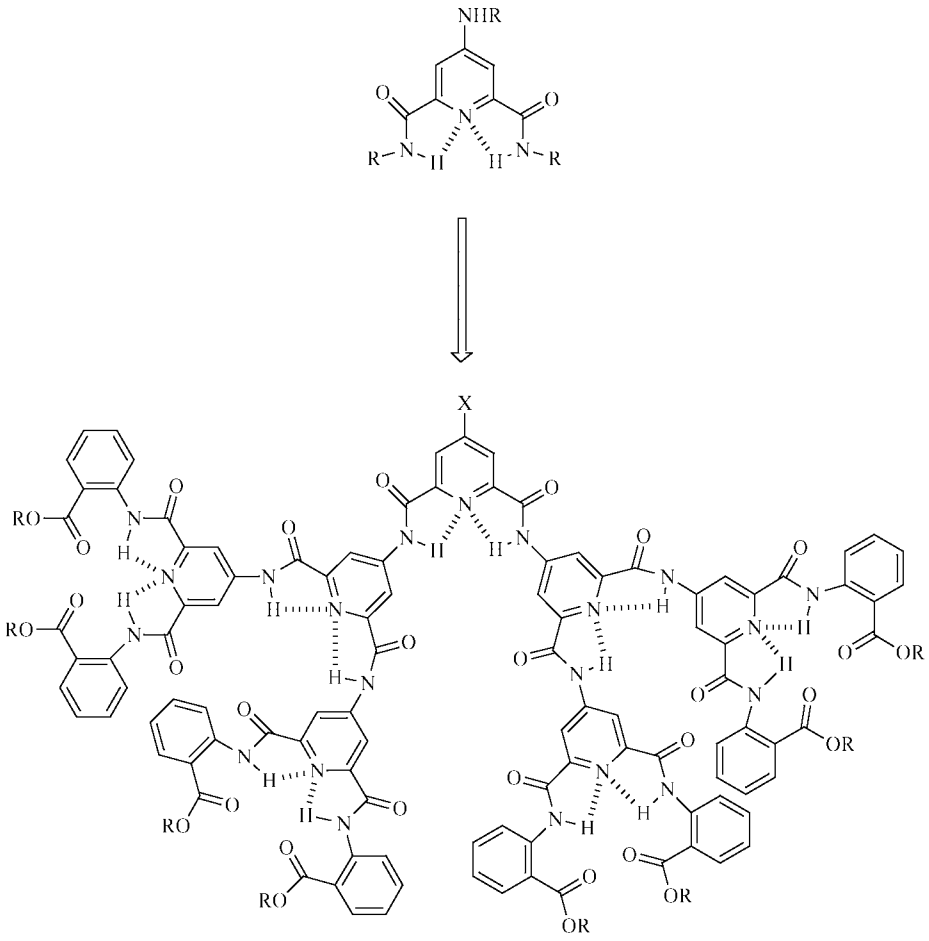

Fig. 16. Dendrimers with helical bias due to intramolecular hydrogen bonding.

observed between the anthyridine core with three hydrogen bond acceptor functionalities (AAA) and guest molecules containing benzamidine groups with two hydrogen bond donor abilities (DD). High association constants were observed between these complementary hydrogen-bonding motifs. A small molecule containing two benzamidine group was used to assemble two dendrons containing the naphthyridine core (57).

Similarly, Smith and co-workers showed the scope of dendritic assembly through the interaction between a crown-ether core and divalent ammonium ions (58). Lysine-based dendrons were built with crown ethers at the focal point. These dendrons assembled into didendrons upon a 2:1 binding with a guest molecule containing two ammonium moieties. This supramolecular assembly of dendrons was easily dislodged using K^+ ions, as the latter competes for the crown ether (Fig. 19). In a later publication, the same group reported the supramolecular assembly of the similar dendrimers based on aliphatic diamines (59). The two-component gel-phase materials reported here are attributed to the length

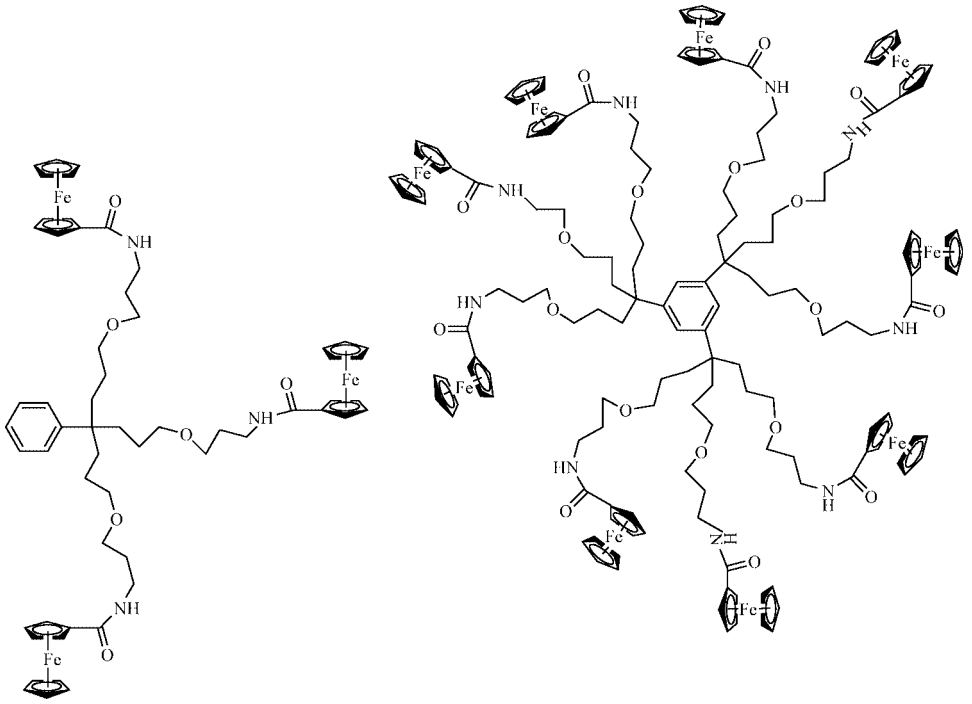

Fig. 17. Anion sensing ferrocene dendrimers.

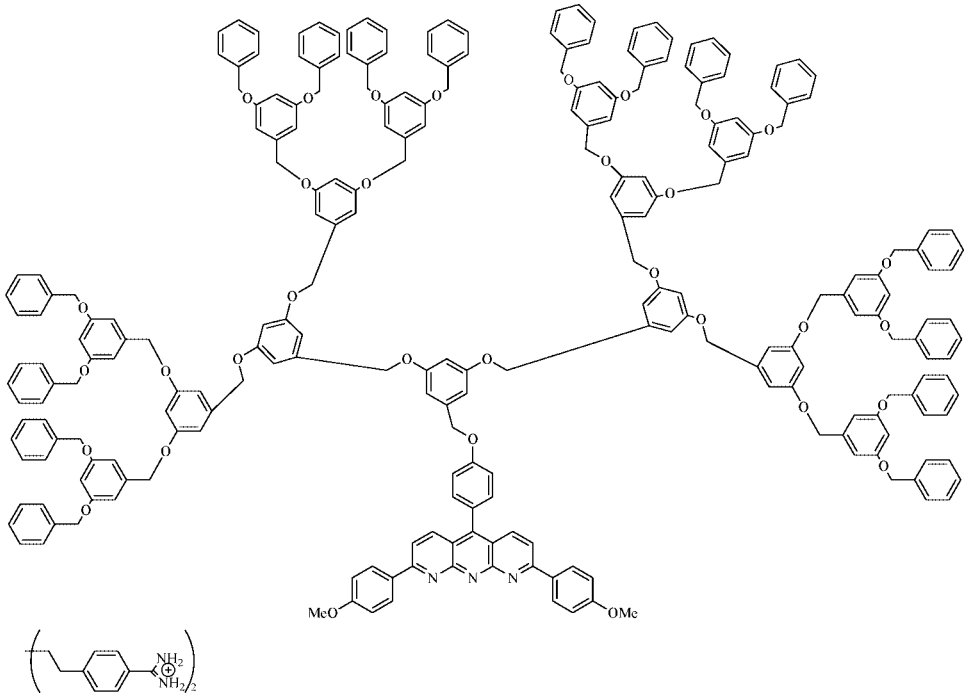

Fig. 18. Dendron with the DDD motif and the complementary guest.

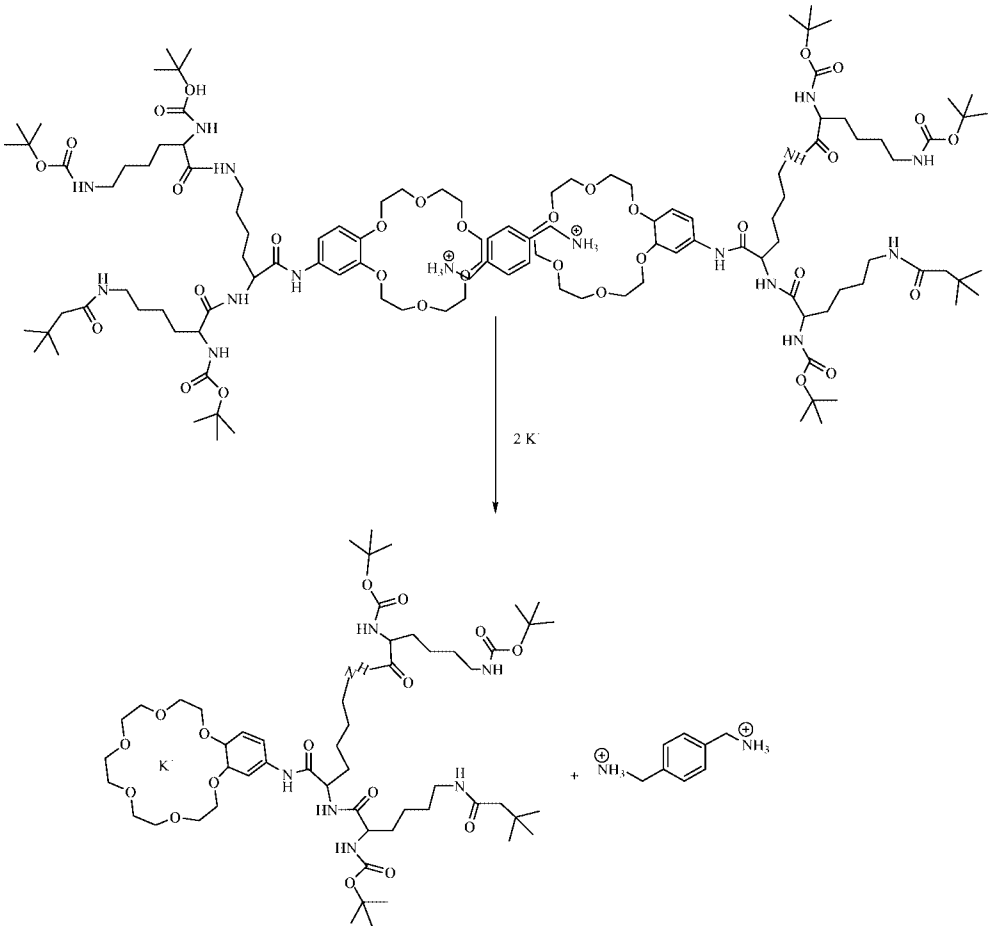

Fig. 19. Deaggregation of crown-cored dendrons.

of the hydrophobic spacer and the potential hydrogen-bonding units within the amino acid branches. Similarly, Gibson reported a tritopic $R_2NH_2^+$ moiety, which exhibited the ability to assemble dendrons cooperatively (60,61).

Another interesting dendrimeric assembly strategy was shown by Stoddart and co-workers, where they introduced the concept of mechanically interlocked branching units in the dendrimer (62,63). Here the dendrons are attached to particular components, which are involved in mechanical bonding with catenanes or rotaxanes. A bis-dibenzo[24]crown-8 core was attached to $R_2NH_2^+$ type compound, where R is a benzylic group. The association constant for those assemblies was found to be quite high. After association, benzyl ether dendrimers were attached while maintaining the association in good yield (Fig. 20). Stoddart also reported a similar assembly of dendrimers by a slippage methodology (64).

Assemblies higher than dimeric and trimeric ones have also been reported with dendrimers. Zimmerman attached benzyl ether dendrimers to a core containing two-isophthalic acid units (65). The self-complementary nature of carboxylic acids is expected to provide either a polymeric or a hexameric aggregate

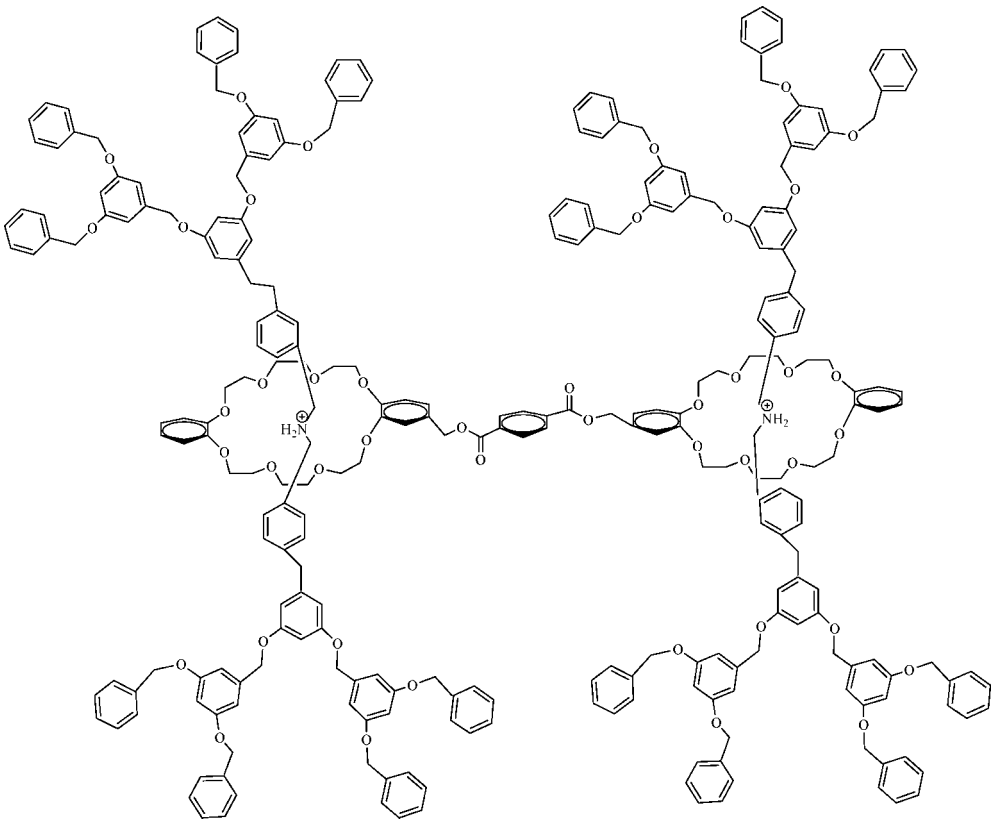

Fig. 20. Dendrimers with mechanical branching.

via hydrogen bonding (Fig. 21). The SEC and NMR data showed the hexameric structure to be predominant. An advantage for the hexamer aggregation was the subtle interplay between favorable hydrogen bonding and van der Waal's interaction, and the unfavorable steric interactions between the adjacent dendrimers in competing aggregates. The hexameric aggregate structure was further supported by SANS (small-angle neutron scattering) studies (66).

The hexameric assembly based on carboxylic acid moieties mentioned above exhibited low stability in moderately competitive solvents like THF. Also, only certain generations of dendrimers (G2 and G3) formed hexameric aggregates, while G1 did not form any stable hexameric assembly. Keeping this in mind and also the fact that nature has chosen heterocycles to form hydrogen bonds in nucleic acids, Zimmerman and Kolotuchin synthesized and characterized a new molecule capable of forming hexameric assemblies (Fig. 22) (67). This compound formed hexameric aggregates and were stable in dilute THF solutions. Encouraged by this result, they attached different generation dendrons to this species and characterized the assemblies (68). From NMR titration data, it was shown that the stability of the hexameric assemblies was (A)6-G1 > (A)6-G2 > (A)6-G3. Also when (A)6-G1 and (A)6-G3 were mixed together, they formed one structure out of about 13 possible structures. This indicated that the discrete aggregates were

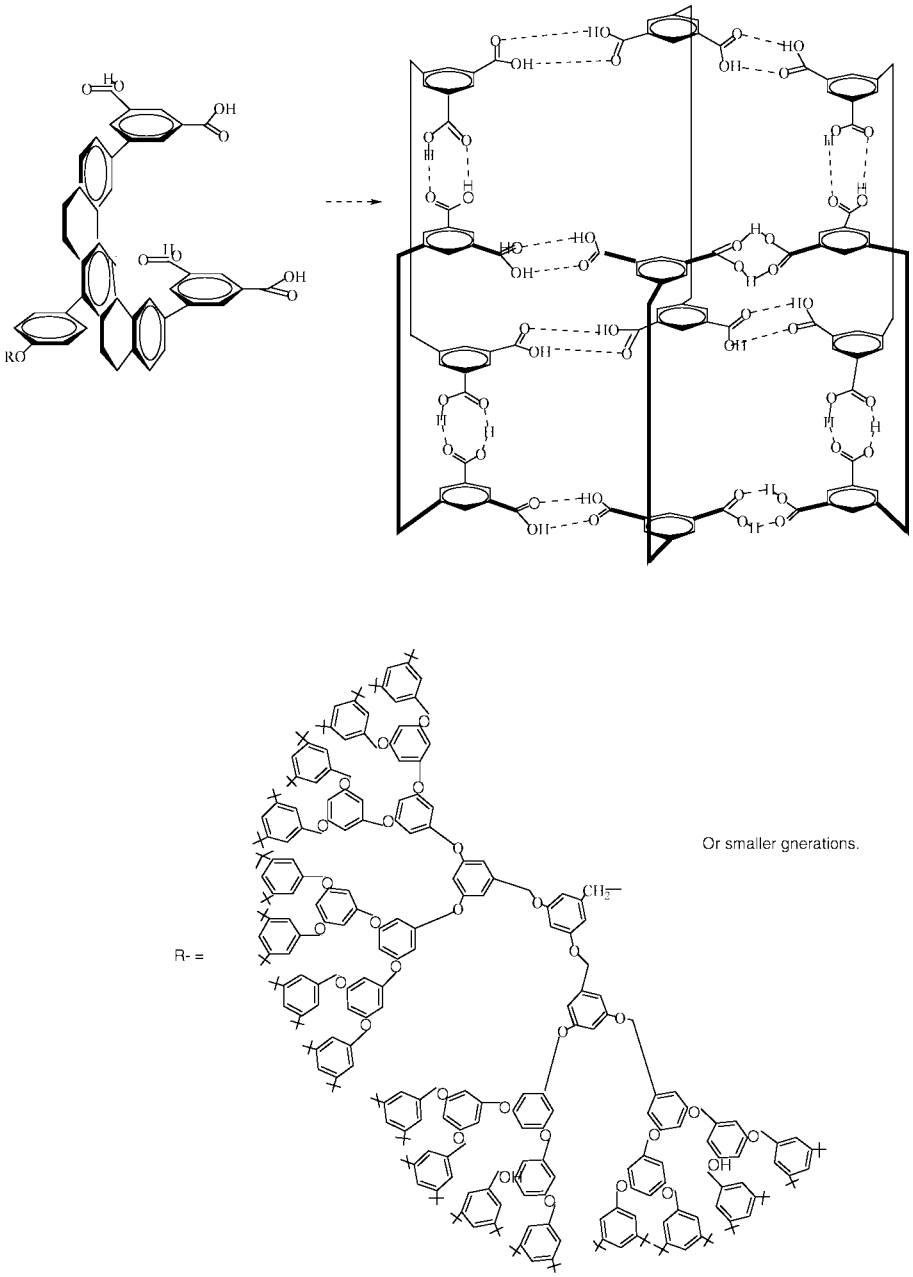

Fig. 21. Carboxylic acid based hexameric dendrimer assembly.

self-selected, and one can play with the supramolecular structures by making subtle variations in different parameters like temperature, solvent, and steric effects (69). Even higher order assemblies using liquid crystalline dendrimers have been achieved by the elegant work of Percec and co-workers (70,71). Discussion of those structures is beyond the scope of this review. Similarly, dendrimers also have been

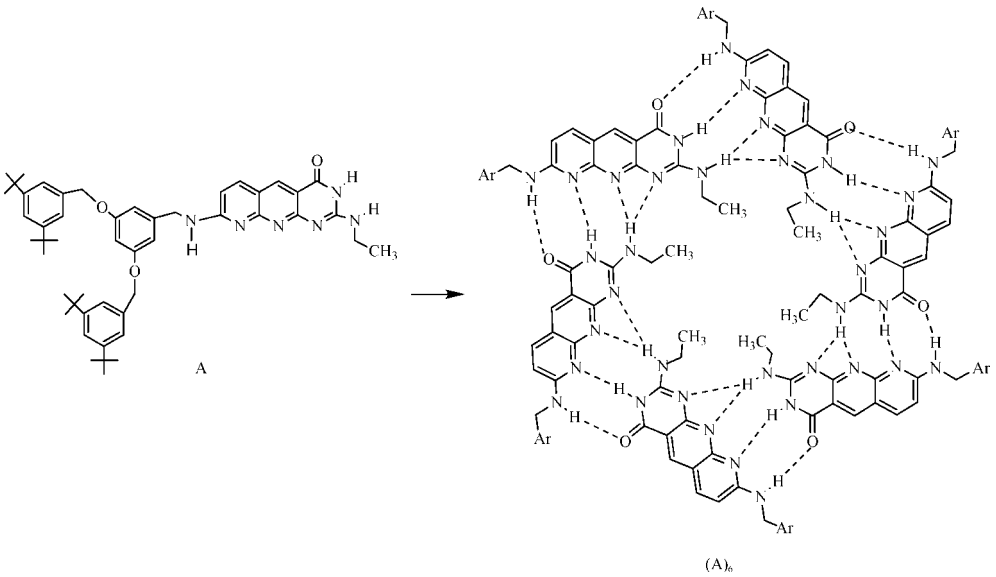

Fig. 22. Stable hexameric assemblies designed by Zimmerman.

shown to form hydrogen-bonding-based network assemblies with themselves or with other polymers, the discussion of which is not included in this article (72–77).

Host–Guest Interaction Based on Amphiphilicity

The globular nature of dendrimers at high generations provides significant opportunities for dendrimers to be used as hosts in a variety of ways. One of the most prominent interactions involves the formation of dendrimers with micellar or inverse-micellar characteristics. In this section, we will discuss host–guest interactions based on hydrophobic or solvophobic pressure. We will also discuss binding based on ionic attractions including acid–base interactions within this section, since these have been used along with amphiphilicity to enhance binding in several cases.

Dendrimers as Micelles. In their seminal work, Newkome and coworkers designed and synthesized a dendrimer called micellanoic acid with an all-hydrocarbon interior and carboxylic acid periphery (Fig. 23) (78). They showed that these dendrimers are water-soluble and are capable of sequestering hydrophobic substituents in their interior. The guest molecules include spectral probes such as phenol blue, naphthalene, pinacyanol chloride, and diphenylhexatriene. By comparison with classical amphiphiles such as SDS, it was shown that the critical micelle concentration (cmc) of these dendrimers is very low. Therefore, they called these dendrimers as unimolecular micelles (79). Binding abilities of some of these amphiphilic dendrimers have also been investigated using electrokinetic chromatography and electrochemistry (80–83).

Similarly, amphiphilic dendrimers with carboxylic acid peripheral groups and benzyl ether interior were synthesized by Fréchet and co-workers (Fig. 24)

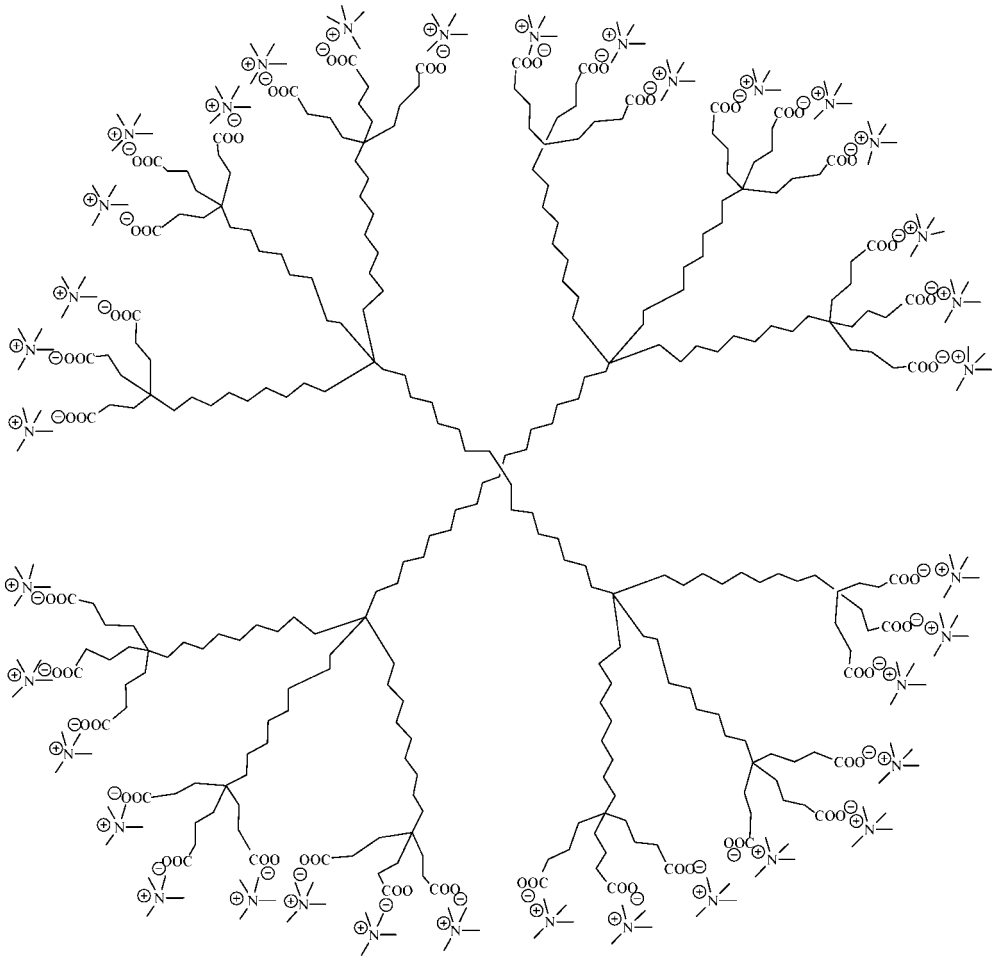

Fig. 23. Structure of micellanoic acid.

(84). The carboxylate salts of these dendrimers are water-soluble and are capable of sequestering apolar guest molecules, such as pyrene. Spectral analysis indicated that about 0.45 molecules of pyrene was found per dendrimer. Fréchet also demonstrated that this could be increased to 0.7 molecule of pyrene per dendrimer by increasing the ionic strength of the solvent. This is a significant number and is comparable to classical micelles based on small molecule amphiphiles. The cmc values for these dendrimers seem to be nonexistent or below the detectable limits, reiterating the ability of dendrimers to function as unimolecular micelles. These dendrimers also demonstrated the ability to act as recyclable solubilizing agents.

Kraska and Seyferth synthesized water-soluble carbosilane dendrimers based on simple hydrosilation and alkylation reactions (19). The sulfonate-terminated and tetralkylammonium-terminated amphiphilic dendrimers have been shown to act as micelles. These dendrimers are capable of sequestering alkyl benzenes (toluene, ethyl benzene, or propyl benzene). It was estimated that a

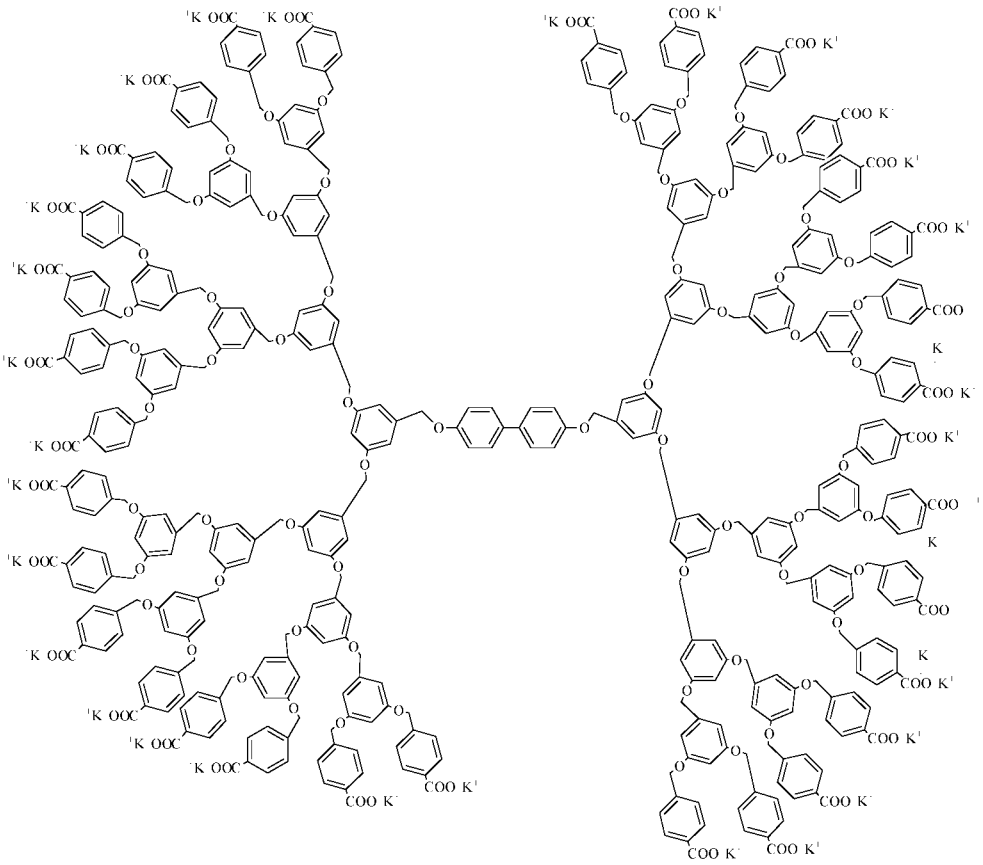

Fig. 24. Structure of micellar benzyl ether dendrimer.

second-generation dendrimer with 16 sulfonate groups in the periphery was able to sequester about two to three alkyl benzene molecules in its interior.

Turro and co-workers studied amphiphilic PAMAM dendrimers with different alkyl chain lengths at their core (85). Specifically, diamino derivatives of ethane, butane, octane, and dodecane were studied. The amino groups were placed at the terminal carbons of these *n*-alkanes. The ability of these dendrimers to sequester hydrophobic derivatives was studied by using Nile red as the guest molecule. They observed that the sequestering ability depends both on the dendrimer generation and the length of the alkyl chain in the core. They were able to demonstrate that the dye molecule is bound closer to the alkyl chain at the core, in case of long alkyl chains. It was also shown that the ability of the dendrimers to sequester apolar guest molecules is enhanced by adding a surfactant to the aqueous solution of the dendrimer. The location of the dye molecule in this case also depends on the length of the alkyl chain at the core, as shown in Figure 25. Note that the ability to generate both amine-terminated and carboxylic-terminated PAMAM dendrimers render them capable of sequestering guest molecules based on ionic interactions. This capability has been exploited by the research groups of Turro and Tomalia (86,87).

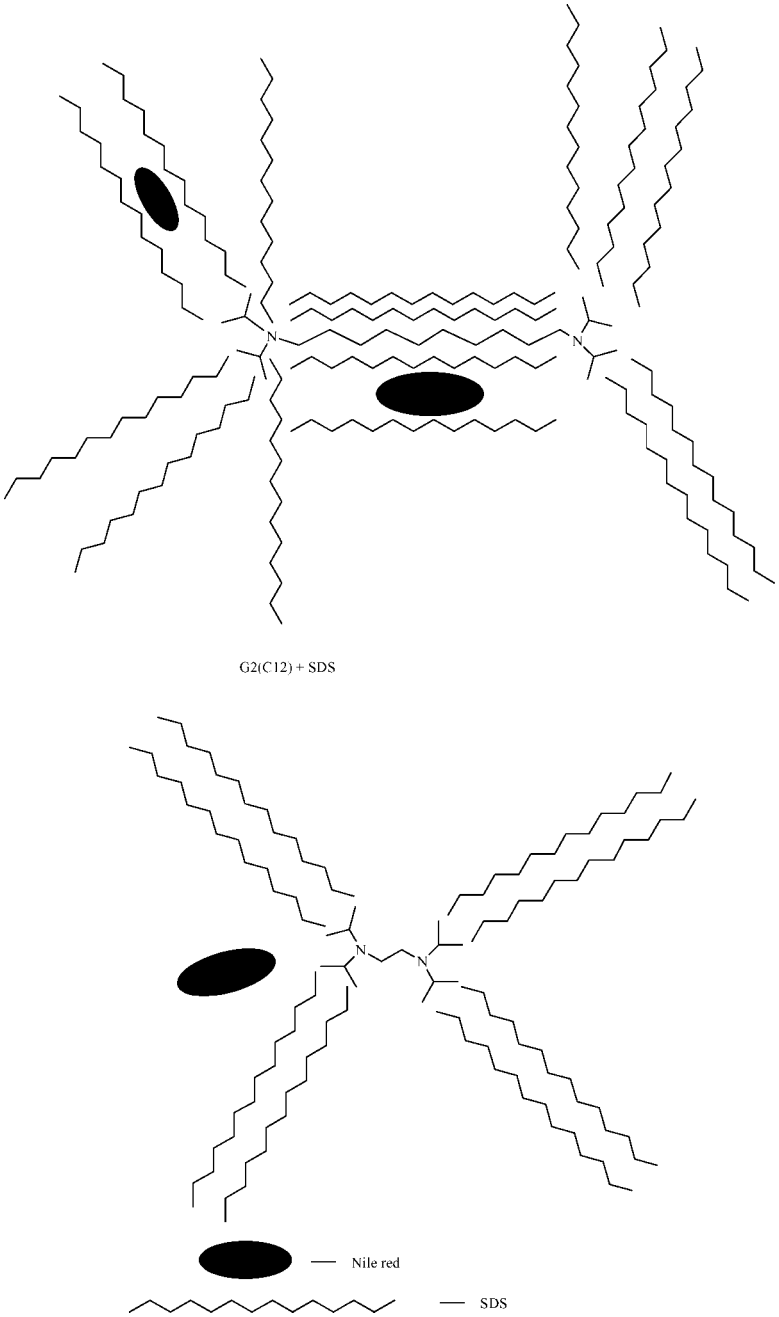

Fig. 25. Location of the dye in amphiphilic PAMAM dendrimers and surfactant mixture.

An interesting variation to the amphiphilic dendrimers shown above was synthesized by Pan and Ford (88,89). PPI dendrimers were derivatized at their periphery with both alkyl chains and triethyleneglycol monomethyl ether (TEG) moieties (Fig. 26). They observed that these dendrimers are not soluble in water,

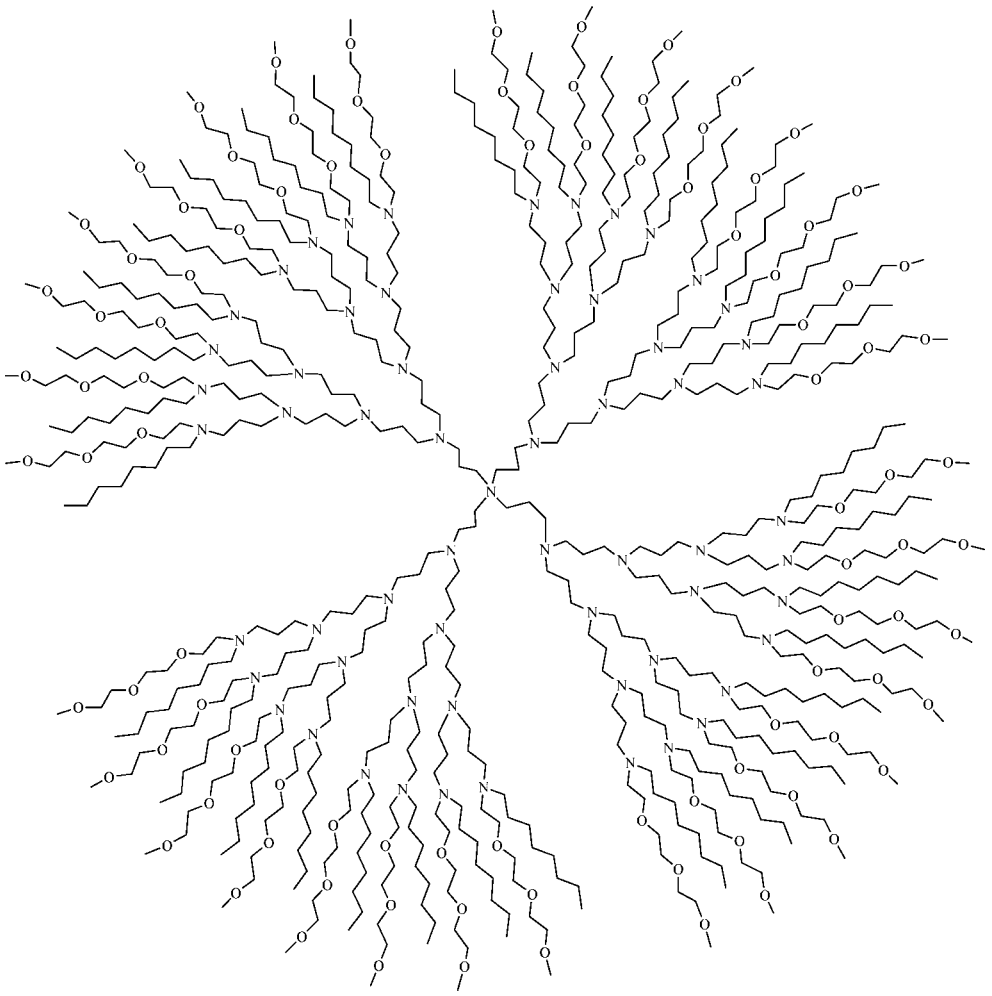

Fig. 26. Structure of amphiphilically modified peripheries designed by Ford.

surprisingly even at low pH. However, they were able to render these dendrimers soluble in water by further derivatizing these dendrimers into quaternary ammonium salts. Aqueous solutions of these dendrimers were able to accommodate apolar guests such as pyrene or Reichardt's dye. Furthermore, these dendrimers also exhibited the ability to catalyze the decarboxylation reaction of 6-nitrobenzoisoxazole-3-carboxylate ion. A rate increase of 200–500 times was observed in the presence of the dendrimer, compared to the rate of the reaction in pure water.

In proteins, almost all the side chains of hydrophobic amino acids are directed toward the interiors in globular proteins. Similarly, the hydrophilic amino acid side chains are directed toward the exterior of these proteins with significant consistency. These biomacromolecules can therefore be also considered as unimolecular micelles as well. Noting this structural theme in proteins, it is clear that an important structural requirement that will further enhance dendrimers' repertoire

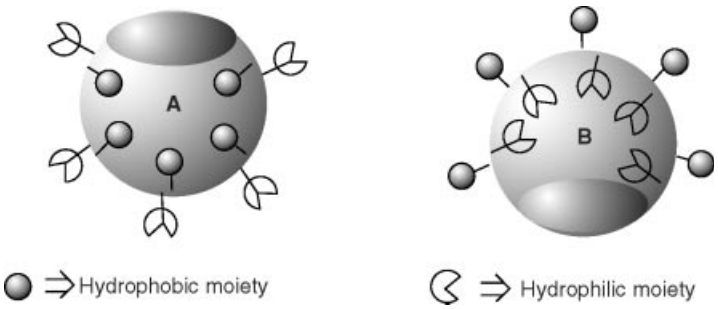

Fig. 27. The possible conformations (**A** and **B**) of the amphiphilic dendrimer in polar and apolar solvents respectively.

in this arena involves the ability to selectively functionalize the concave interiors of these macromolecules, ie, selectively direct functional groups toward the interior of the globular dendrimer. A flexible backbone is a prerequisite to obtain globular shape at high generations. Attaining conformational control over the orientation of the functional groups is nontrivial, when the molecules are built with flexible linkers. Thayumanavan and co-workers proposed an approach to achieve control over functional group orientation by rendering the macromolecules facially amphiphilic (90). In this design, the dendrimers are uniformly amphiphilic over the entire globular surface; that is, when the convex face of the dendrimer is hydrophilic, the concave face will be hydrophobic and vice versa. The nature of the functional groups directed toward the concave interior of the dendrimer will be driven by solvophobic interactions. In this design, the inherent flexibility of the dendritic backbone can be expected to yield the different solvent-dependent conformations 27**A** and 27**B**, as shown in Figure 27.

The monomer design involves a unit that has the AB_2 functional groups for the dendrimer growth and the amphiphilic functional groups in orthogonal planes (Fig. 28). The amphiphilic substituents are placed on opposite sides of the plane containing the AB_2 moieties. Such relative placement of the functional groups dictates that the amphiphilic moieties are in a plane perpendicular to that of the macromolecular backbone upon assembly of the dendrimer. The geometric arrangement of the dendrimer also dictates that the hydrophobic and the hydrophilic functionalities are in opposite faces of the globular dendrimer, and thus the structures 27**A** and 27**B** should result (Figs. 27 and 28). A monomer unit that satisfies these structural requirements is represented by the biphenyl molecule shown in Figure 28, in which the hydrophilic unit is a TEG moiety and the hydrophobic unit is an *n*-butyl group. Synthesis of dendrons up to the fourth generation has been reported. However, solubility problems hampered the studies that would support the structural hypothesis proposed. Experiments are under way to modify the functional groups and render the dendrimers soluble in both polar and apolar solvents.

In addition to utilizing dendrimers themselves as micelles, there have been several reports on utilizing block-*co*-polymers containing a hydrophilic linear polymer and a hydrophobic dendrimer. These studies are not included in this review. We recommend some key references in this area for an interested reader (91–104).

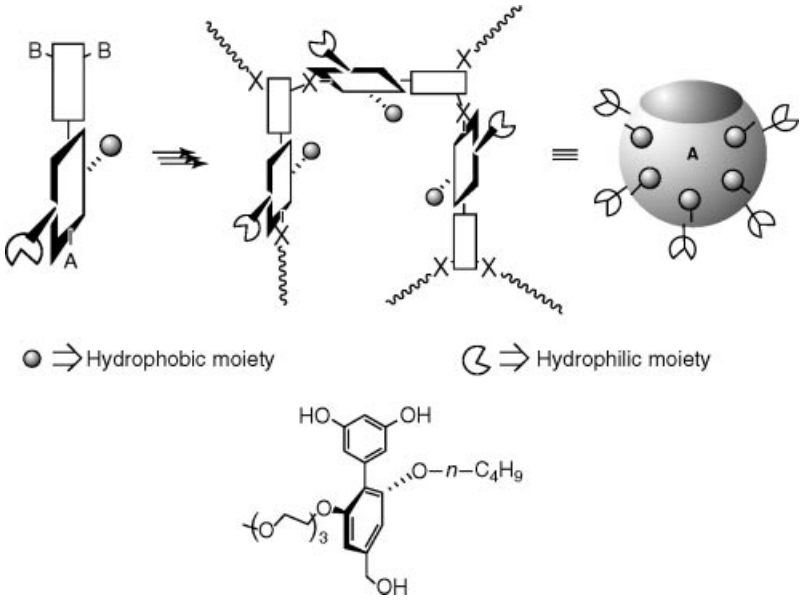

Fig. 28. Cartoon of the AB_2 monomer with the amphiphilic groups on the orthogonal plane, the dendrimer growth, and its conformation in a hydrophilic solvent is represented.

Biomimetic Dendritic Amphiphiles. The active sites of globular proteins are often buried in their hydrophobic binding pockets. Inspired by globular proteins, Diederich has developed a class of dendrimers called dendrophanes (105). These are dendrimers that contain a hydrophobic cyclophane cavity and polar peripheral functionalities. Diederich showed that the size of the guest molecules that could be accommodated in these hydrophobic cavities depend on the size of the cyclophane core. Two different cyclophanes were reported; one that is capable of binding benzene and naphthalene guests and a larger one that is capable of binding large steroidal substrates (106,107). Guest molecules were shown to be bound specifically at the cyclophane core and the nonspecific binding, if any, is negligible. The binding constants were found to be independent of the dendrimer generation. The micropolarity of the cyclophane core is significantly reduced and is comparable to ethanol. The exchange kinetics of the host–guest binding events were found to be fast. The combination of these properties led to the idea of developing these molecules into possible artificial globular enzymes. In order to mimic the enzyme pyruvate oxidase, Diederich and co-workers incorporated thiazolium ions into the cyclophanes and studied the catalytic ability of these compounds in the oxidation of naphthalene-2-carboxyaldehyde to naphthalene-2-carboxylate (Fig. 29) (108). The observed acceleration of the reaction was attributed to both the reduced polarity in the dendritic interior and fast exchange rates.

More recently, Hecht and Fréchet have synthesized an amphiphilic dendrimer that is capable of acting as a photoreactor to catalyze a cycloaddition reaction between cyclopentadiene and singlet oxygen (109). In this case, an apolar functionality capable of sensitizing singlet oxygen (benzophenone) was attached to dendrons containing hydrophilic peripheral groups. The cyclopentadiene

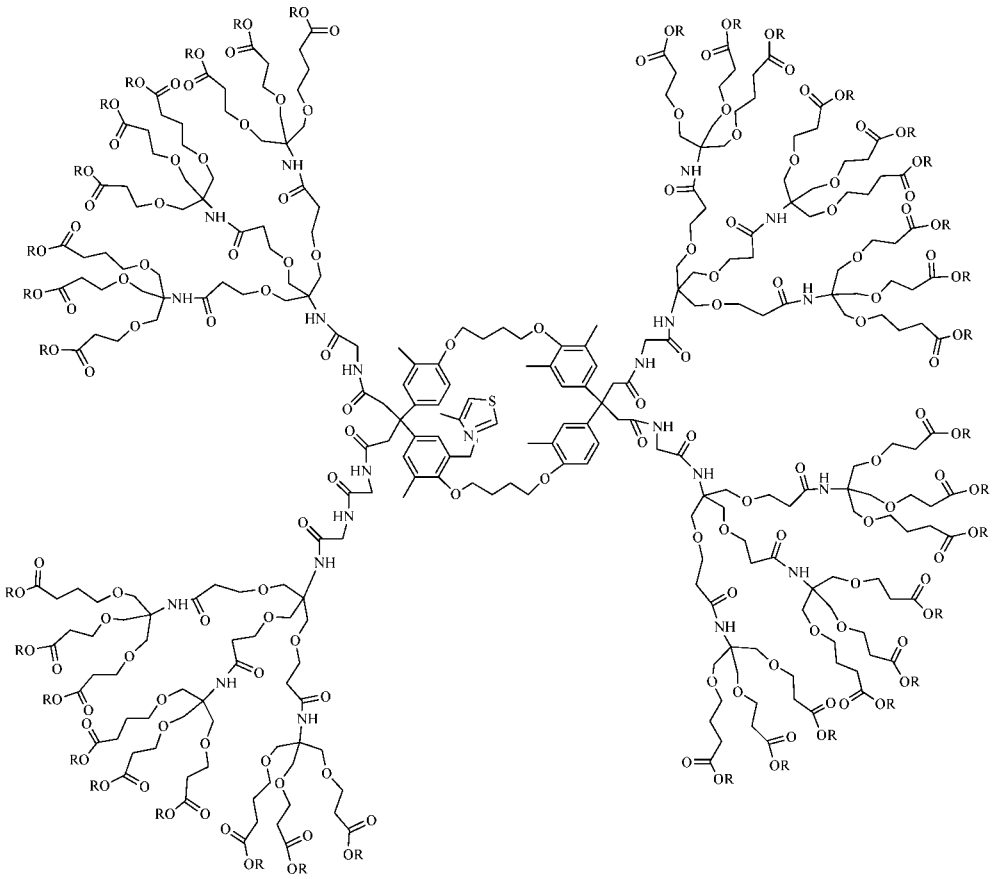

Fig. 29. Structure of the dendritic enzyme.

substrate was concentrated closer to the benzophenone core owing to the relatively apolar nature of the core. Since the singlet oxygen is also generated near the benzophenone core, the dendrimer was able to serve as a nanoreactor for this reaction (Fig. 30).

Dendrimers as Inverted Micelles. The inherently polar building blocks of PAMAM and poly(propylene imine) dendrimers make these molecules attractive candidates for the creation of unimolecular inverted micelles. Meijer modified the PPI dendrimers with apolar end groups such as the palmitoyl chains and studied the inverted micellar character of these dendrimers (Fig. 31) (110,111). These dendrimers are capable of sequestering anionic guest molecules from aqueous solutions. The binding process is attributed to the combination of hydrophobic effect, hydrogen bonding, and ionic interactions. It was also noted that the efficiency of binding is dependent on pH and were better at lower pH. It is also interesting to note that these dendrimers exhibited significant selectivity in the sequestration of guest molecules from the aqueous solution. For example, a fifth-generation dendrimer was able to extract only 1 or 2 molecules of fluorescein, whereas the same host was able to extract about 50 molecules of rose bengal. This selectivity is

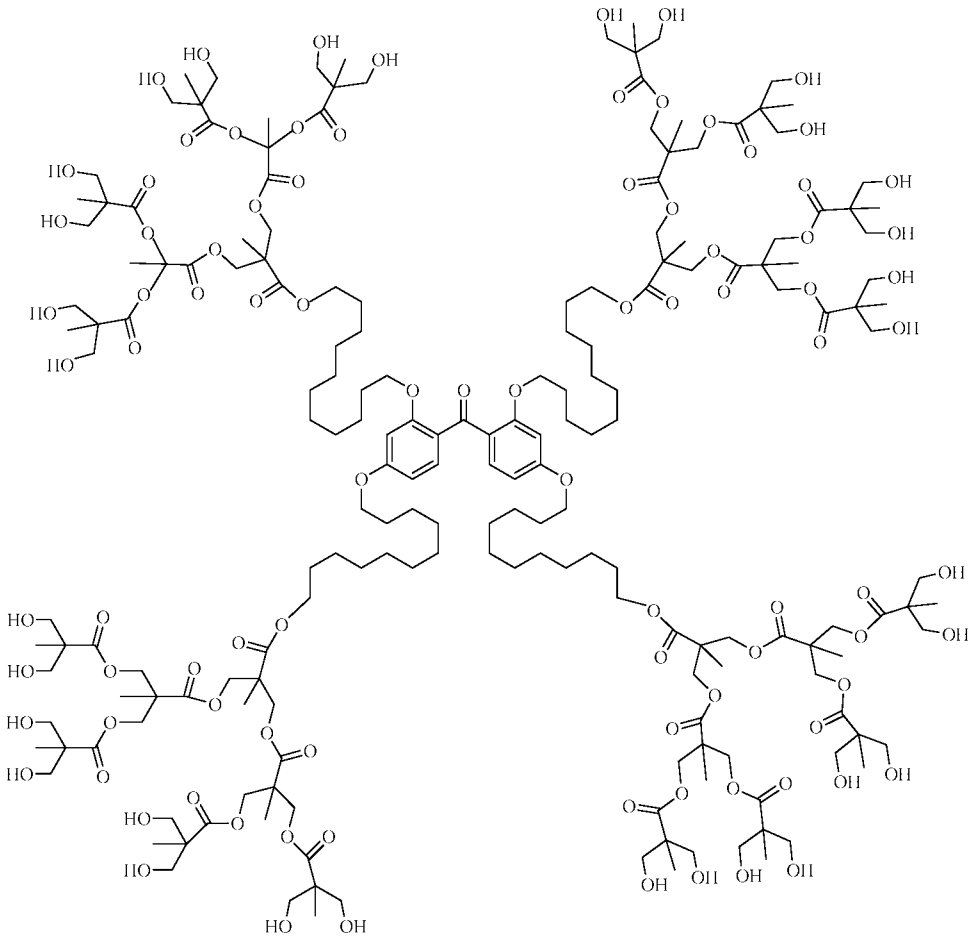

Fig. 30. Structure of the dendrimer with a singlet oxygen sensitizing core.

magnified in an experiment where it was demonstrated that even at pH 10, the dendrimer was able to selectively extract rose bengal out of a mixture containing a 10,000:1 ratio of fluorescein to rose bengal. Meijer also utilized PPI dendrimers that are modified with oligo(*p*-phenylenevinylenes) as the peripheral apolar functionality to study energy transfer in supramolecular assemblies containing the dendrimer host and an anionic dye molecule as the guest (112). Similarly, Balzani and Vögtle have shown that PPI dendrimers functionalized with dansyl groups in their periphery can extract eosin red from aqueous solutions into the organic layer (113,114). When dendrimers are functionalized with fluorocarbon chains at their periphery, these macromolecules were soluble in supercritical carbon dioxide and fluorocarbon solvents and were capable of solubilizing polar substrates in these solvents (115,116). This is of considerable significance, since this process could have implications in environmentally benign catalytic processes.

Tomalia and co-workers reported the hydrophobic modification of PAMAM dendrimers by treating the terminal primary amines with various epoxyalkanes (117). Similar to the PPI dendrimers reported above, these dendrimers also

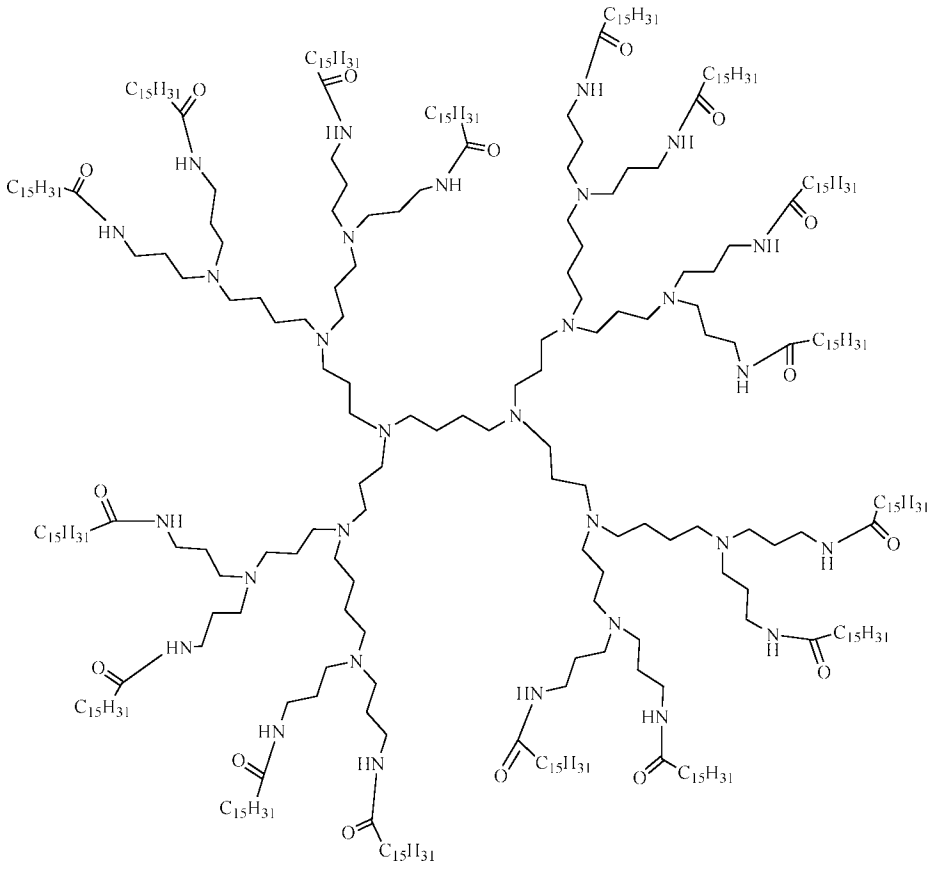

Fig. 31. Inverted micelles based on poly(propylene imine) dendrimer.

exhibited the inverted micelle properties that are capable of sequestering polar guest molecules. More specifically, Tomalia showed that these dendrimers are capable of transporting copper(II) ions from an aqueous solution into an organic phase.

An elegant experiment by Crooks showed that the hydrophobic modification of PAMAM dendrimers by noncovalent interactions could also result in macromolecules that behave like inverted micelles (118). The spontaneous assembly between the fatty acids and amino periphery of the PAMAM dendrimer was driven by ionic interactions (Fig. 32). These dendrimers were shown to be capable of extracting hydrophilic dyes such as methyl orange from water into toluene. Similarly, these dendrimers were also shown to be excellent molecular containers for catalytically active metal nanoparticles. The inverted micellar nature of various dendrimers have been used by Crooks and others for the preparation of a variety of nanoparticles (119–122). A related macromolecule, but an architecture with less of a control, is a hyperbranched polymer. Hydrophobically modified hyperbranched polymers have also been shown to be capable of acting as inverted micelles (123,124).

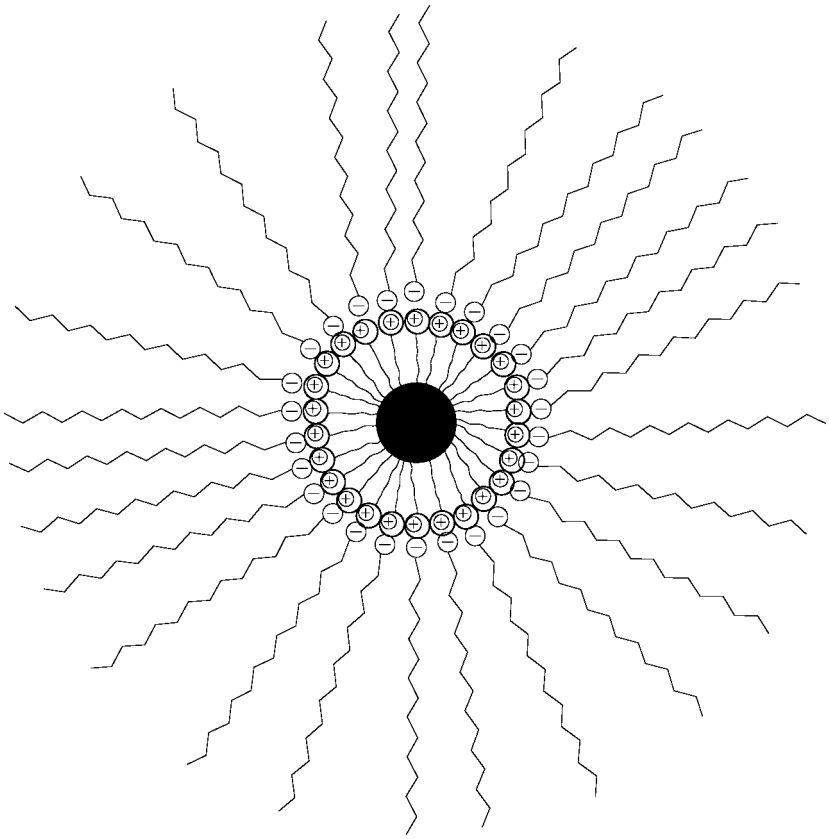

Fig. 32. Supramolecular assembly of inverted micelles by Crooks.

Binding at the Dendritic Periphery. Dendrimers with ferrocene substitutions at their periphery have been synthesized to achieve new electrochemical sensors for anions such as $H_2PO_4^-$ (54–56,125). These ferrocene dendrimers are often insoluble in aqueous media. However, if the peripheral ferrocenes are efficiently complexed with cyclodextrins, the resultant complex can be rendered water-soluble (Fig. 33). Kaifer and co-workers were able to demonstrate that such complexes are indeed more soluble (126). They also noted that the solubility depends on the efficiency of complexation, which decreased with increasing generation possibly because of steric crowding. Since the binding of ferrocene with cyclodextrin is based on the hydrophobic effect, there is a significant difference in binding between ferrocene and ferrocenium ions. The weaker binding of ferrocenium ions provides the opportunity to release these complexes with electrochemical control. Similarly, the difference in association constants between cobaltocenium ion and cabaltocene provides a system in which the binding increases upon an electrochemical trigger (127).

Similar to ferrocene, admantane is also considered an excellent guest moiety for β-cyclodextrin. Reinhoudt showed that adamantyl-terminated PPI dendrimers can bind to several β-cyclodextrin molecules (128–130). The complex was most

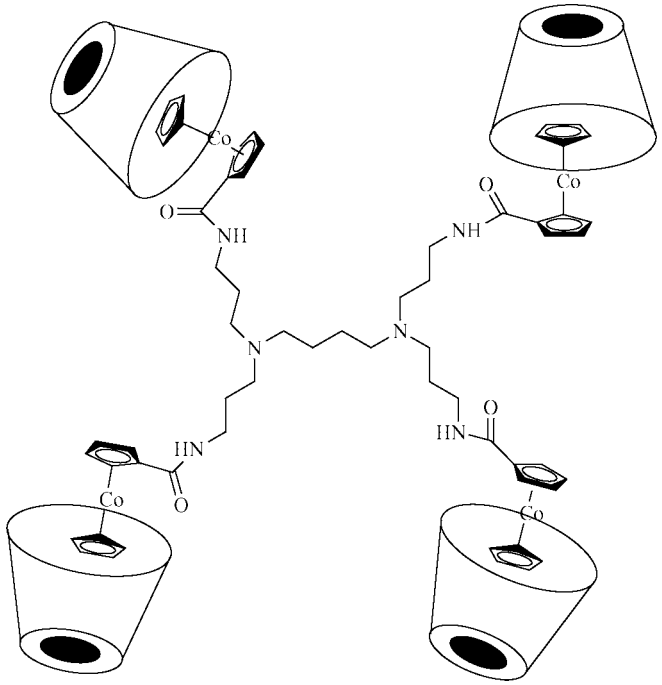

Fig. 33. Dendrimer with cyclodextrin caps.

stable at pH 2, at which point the internal tertiary amines are all protonated. The possible extended conformation of the protonated dendrimer is suggested to be responsible for the complete complexation of cyclodextrins with dendrimers up to the fourth generation. Reinhoudt was able to show that the stoichiometry of binding up to fourth-generation dendrimer between the cyclodextrin and adamantyl groups was 1:1. This ratio decreased in the fifth generation and is attributed to the possible steric crowding.

Small surfactant molecules also have been used as guest molecules to bind to the surface of the dendrimers, often through the combination of hydrophobic effect and ionic interactions (131–136). Ottaviani and co-workers studied the characteristics of the PAMAM dendrimers using noncovalently incorporated nitroxide radical based surfactant (131). The dendrimers were terminated with carboxylate moieties, while the nitroxide radical was functionalized with a quaternary ammonium functionality. They noted that the nitroxide surfactants were able to act as micellar hosts for low generation dendrimers. However, for higher generation dendrimers (>3.5), the dendrimer was able to act as a host for the nitroxide surfactant molecule. The binding was proposed to be due to ionic and hydrophobic interactions. Using EPR (electron paramagnetic resonance) studies, they were also able to show that the nitroxide radical probes are trapped in a restricted space in proximity to the dendrimer surface. On the basis of this observation, a mode of binding was proposed as seen in Figure 34 (132). Similarly, Majoral has utilized this strategy to functionalize the periphery of phosphorus-based dendrimers noncovalently with carbohydrates (136).

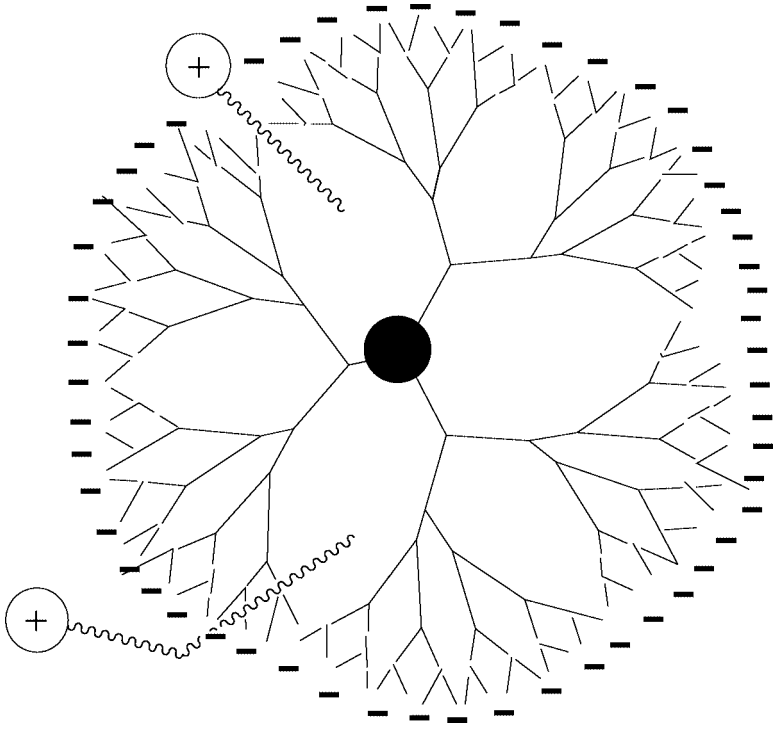

Fig. 34. Binding small molecule surfactants in dendrimers with hydrophobic chains buried inside.

Catalysis with Amphiphilic Dendrimers. An example of biomimetic catalysis with amphiphilic dendrimers has already been mentioned above (108). Similarly other micellar dendrimers have been used to catalyze reactions either within the hydrophobic interior or at the interface. An interesting example was provided by the research group of Rico-Lattes, in which PAMAM dendrimers were functionalized using D-gluconolactone (137–139). The resultant chiral dendrimers were tested for their capabilities in the asymmetric reduction of prochiral ketones using sodium borohydride as the reagent. While these dendrimers provide moderate or poor asymmetric induction in a homogeneous phase (water), the chiral induction was very high in THF. The selectivity is attributed to the supramolecular ordering of the prochiral ketone at the chiral solvating interface. The third-generation dendrimer was found to be a particularly suitable vehicle for this chiral induction. Similarly, binding based on hydrophobic interaction is also attributed to the catalysis of aminolysis reactions of *p*-nitrophenyl esters using amine-terminated PAMAM dendrimers (140,141).

Hawker and co-workers reported the synthesis of unimolecular inverse micelles based on benzyl ether dendrimers with hydroxyl groups in its interior (142). They showed that this dendrimer was able to catalyze the E1 elimination reaction of 2-iodo-2-methylheptane. The tridendron of G4 seems to be particularly effective in catalyzing this reaction. The conversions to products were found to be greater than 90%. The regioselectivity of the elimination was moderate. Turnover

numbers as high as 17,400 were observed with these dendrimers. The catalysis of the dendrimer was attributed to the ability of the internal hydroxy groups to stabilize the cationic transition state of the elimination reaction.

Dendrimer Assembly Based on Hydrophobic Interactions. Noncovalent assembly of dendrimers using hydrogen-bonding interactions was discussed earlier in this article. Noncovalent assembly of dendrimers based on hydrophobic interactions is also very attractive, since these assemblies can be achieved in aqueous solutions or other polar solvents. The strong association between adamantyl groups and β-cyclodextrin is a well-known phenomenon. Newkome and co-workers used this interaction in an attempt to assemble dendrimers (83). They synthesized a bis-ester of admantane carboxylic acid with tetraethyleneglycol and attempted to complex this bis(adamantane ester) to a β-cyclodextrin derivatized with amide dendrons (Fig. 35). On the basis of a dye-displacement assay, the efficiency of the dendrimer assembly was found to be not very high. They attributed this to the possible steric encumbrance of the bis(admantane ester) owing to the chain compaction by the sodium ions present in solution.

Diederich has used the previously described association between steroids and cyclophanes to noncovalently assemble dendrimers (143). A bis(testosterone) derivative that contains a rigid phenylacetylene-based linker is used as the ditopic ligand (Fig. 36). The linker contains positively charged amino groups, which are useful both to solubilize these compounds in aqueous solutions and to have ionic interactions with the negatively charged periphery of the dendrons. Using ^{1}H NMR, it was ascertained that the steroid, not the phenylacetylene linker, is bound to the cyclophane. The association constants for a 1:1 complex were high in all cases. However, the association for a 2:1 complex was dependent on the length of the bis(steroid) linker. It was observed that for higher generation dendrimers, the possible repulsion between the negative charges of the dendrons inhibits the

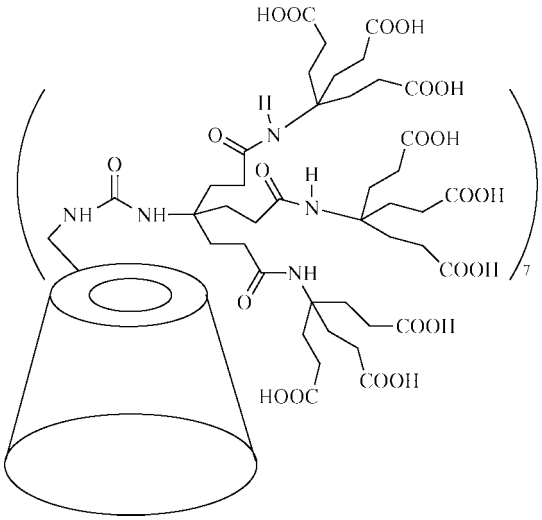

Fig. 35. Cyclodextrin cored dendrimer synthesized by newkome.

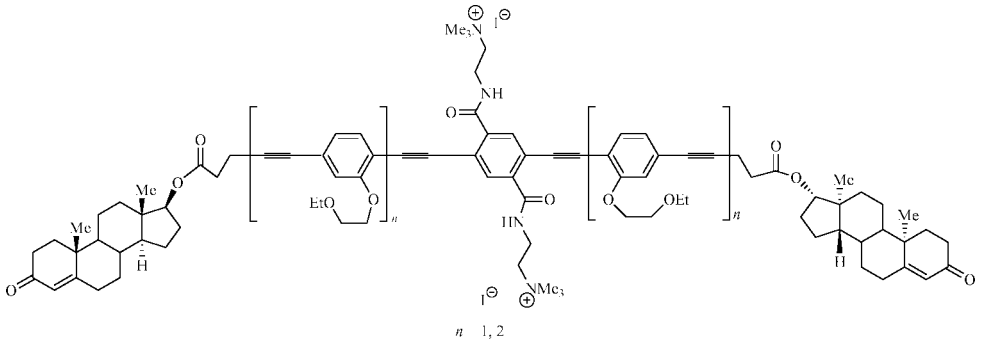

Fig. 36. Structure of the ditopic steroidal guest molecule (structure of the dendrimer is similar to the one shown in Fig. 29, but with a larger cyclophane core).

formation of a 2:1 complex. This repulsive interaction is reduced for dimerizing the dendrons by using a longer phenylacetylene linker.

Summary

Ever since the first reports on the synthesis of dendrimers, these macromolecules have attracted the attention of researchers from biology to engineering. The compactness of the three-dimensional architecture, the opportunity to present a high density of functional groups in the periphery, the opportunity to encapsulate functionalities in the core, and the globular structure of these molecules make them extremely versatile. Each of these features makes these molecules attractive for different applications in a variety of areas. Some of these features make them ideal architectures for binding guest molecules in its interior, periphery, or the interface. In this article, we have mainly discussed hydrogen bonding and amphiphilic interactions with frequent inference to ionic interactions. Molecular recognition using dendritic scaffolds will have lasting implications in nanotechnology and biology (144–154).

MOLECULAR SELF-ASSEMBLY

Introduction

Molecular self-assembly is an extremely versatile tool for the thermodynamically controlled generation of higher order constructs (1). Nature uses self-assembly extensively in biological systems with "lock and key" specificity to give the diverse range of highly ordered systems observed in living organisms. Applying the self-assembly strategy to the reversible synthesis and controlled aggregation of

macromolecules has garnered considerable interest in recent years. The utility of directional and highly specific noncovalent interactions has been demonstrated to be a particularly attractive method of controlling polymer aggregation, using the abundance of recognition elements developed by supramolecular chemists (1). The high degree of modularity makes this approach extremely versatile in that the assembling units can be precisely tuned with directed synthesis to customize the selectivity, directionality, and association strength of the noncovalent interaction. Also, the strength of the noncovalent interactions that embody molecular self-assembly is thermally dependent, allowing for reversible control over the assembly process which contributes to the design of unique material properties with defect correction and self-healing capabilities.

Recently, a number of contributions have been published that detail a growing field of synthetic polymer chemistry: supramolecular polymers/polymerization (2,3). Supramolecular polymers are macromolecules containing monomers held together by noncovalent interactions. As listed in Table 1, these interactions can be divided into six commonly used categories which include hydrogen bonding (4) (often multiple hydrogen bonds acting in tandem), π stacking of aromatic systems (5), metal–ligand interactions (6), London dispersion forces (7), electrostatics, and hydrophobics. As formed, these novel supramolecular polymers should exhibit similar material properties to their covalently bound counterparts with the added functionality of reversible binding. In addition to the supramolecular polymerization of main chain polymers, it is also conceivable to modify covalently bound linear polymers with pendant sidechains capable of noncovalent binding. In theory, this combination provides the most advantageous properties from both components: intrinsic materials properties dictated by the choice of polymer backbone with the reversible lock and key nature of supramolecular interactions.

Main-Chain Versus Side-Chain Supramolecular Polymers

The present concept of supramolecular polymers containing multiple hydrogen bonding units was first introduced over a decade ago by Jean-Marie Lehn (8). Three-point hydrogen bonds between bisfunctional diaminopyridine and thymine derivatives form supramolecular polymer chains exhibiting liquid crystalinity (Fig. 1**a**). Lehn and co-workers expanded the scope of this methodology to include bisfunctional molecules joined by chiral tartaric acid spacers (9) and rigid anthracene-based linkers (10). The utility of this approach has been demonstrated many times over in the years since, as can be ascertained by numerous contributions from many researchers (11,12).

Building upon Lehn's three-point hydrogen bound supramolecular polymers is the work done by E. W. Meijer using self-complementary ureidopyrimidinones, recognition elements capable of quadruple hydrogen bonding (Fig 1**b**). The quadruple hydrogen bonding system has two major differences with complementary three-point hydrogen bonding between thymine and diamidopyridines: an extremely high degree of association ($K_{\mathrm{dim}} > 10^6\ \mathrm{M}^{-1}$) and self-complementarity that eliminates stoichiometric concerns. The high dimerization constant of ureidopyrimidinone makes this an excellent system for supramolecular polymerizations, as the resulting polymers will possess a high degree of polymerization in

Table 1. Six Categories of Noncovalent Intermolecular Interactions[a]

Interaction	Description and bond strengths	Selected example
(London) Dispersion forces	> 4 kJ/mol. Temporarily induced dipole–dipole interactions	π–π stacking	8–12 kJ/mol (face–face), 12–21 kJ/mol (edge–face). Attractive forces between electron-rich interior with electron-poor exterior	Hydrophobic	4–42 kJ/mol. Association of nonpolar complements in aqueous or polar media	Hydrogen bonding	> 4kJ/mol (weak), 4–17 kJ/mol (moderate), 21–42 kJ/mol (strong). Donor–acceptor interaction involving hydrogen atom as proton donor and base (electron pair) as proton acceptor	Electrostatic	4–42 kJ/mol (dipole–dipole), 42–125 kJ/mol (ion–dipole), >188 kJ/mol (ion–ion). Coulombic attraction between opposite charges	Dative bonding	21–377 kJ/mol. Metal–ligand coordination. Ligand donates electron pair(s) to center	
[a]Association strengths are for systems in chloroform.

solution. The resulting macromolecules generate excellent materials that have many advantages, such as strongly temperature-dependent viscoelastic properties. However, substantially more energy is required to induce complete dissociation to overcome the high degree of association.

In contrast to the above supramolecular polymers, recognition groups covalently attached as pendant polymer side chains (13) have been investigated for their potential elastomeric properties, first by Stadler and co-workers (14) in 1986 to increase miscibility between incompatible polybutadiene and polyisoprene blends by employing the relatively weak dimerization of urazole moieties ($K_{\mathrm{dim}} < 10^2\ \mathrm{M}^{-1}$), and later in 2001 where G. W. Coates and co-workers

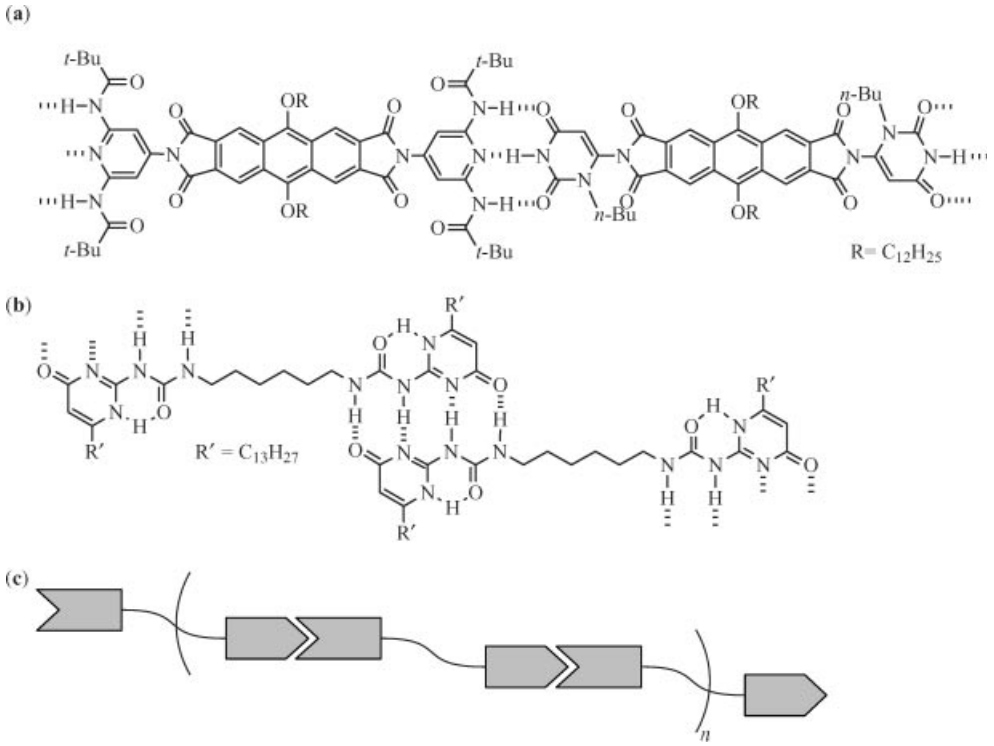

Fig. 1. Supramolecular polymers developed by (**a**) Lehn employing three-point hydrogen bonds between diamidopyridine and thymine residues and (**b**) Meijer employing self-complementary, quadruple hydrogen bonds. (**c**) A simplified schematic depicting the extended chain of repeating bisfunctional monomers fashioning the backbone of a supramolecular polymer.

(15) demonstrated the synthesis of elastomeric polyolefins equipped with thermoreversible cross-links between ureidopyrimidinone pendant groups. Kato and co-workers (16,17) have made large contributions to this field by exploring side-chain polymers as liquid crystalline materials. Furthermore, these motifs have been investigated by M. Weck and co-workers (18) for their dual functionality in catalysis and self-assembly, as well as by Sleiman and co-workers for their "DNA-mimetic" supramolecular aggregation properties yielding potentially functional morphologies (19).

As will be detailed in the following section, polymer assemblies can be formed very efficiently with moderate strength association constants $\sim$500–600 M^{-1} ($\sim$14.6 kJ/mol = 3.5 kcal/mol), especially when many of these interactions are working cooperatively. These moderate strength interactions contribute to overall constructs that are quite dynamic and require minimal amounts of energy for disassembly. These characteristics provide an elegant and potent means for controlling solution-state polymer structure, and applications are envisioned ranging in diversity including, but not limited to transport, encapsulation, delivery systems, sensors, devices, and other environmentally responsive materials.

"Plug and Play" Polymers

As mentioned earlier, the recognition elements inducing main-chain supramolecular polymerizations appear in many varieties. Analogously, these assembling units can also be effectively utilized as assembling units on polymer side chains. There exist two methods of generating pendant side chains containing supramolecular elements: (*1*) polymerizing or copolymerizing the monomer with a presynthesized recognition moiety, and (*2*) polymerizing a monomer with an active site that does not participate in the polymerization but is capable of post-polymerization modification. The latter scenario will be discussed throughout the rest of this article, as it avoids issues of blockiness (nonrandom blocks of functionality due to cooperativity during polymerization) and solubility associated with aggregation during copolymerization processes.

Supramolecular assembly is dynamic by nature. Further enhancing this characteristic is the modular nature of noncovalent interactions that permit a divergent approach to polymer structure, allowing multiple systems to be assembled using a single polymer backbone (Fig. 2). These polymers provide flexible backbones, are synthesized readily using free-radical–initiated polymerizations

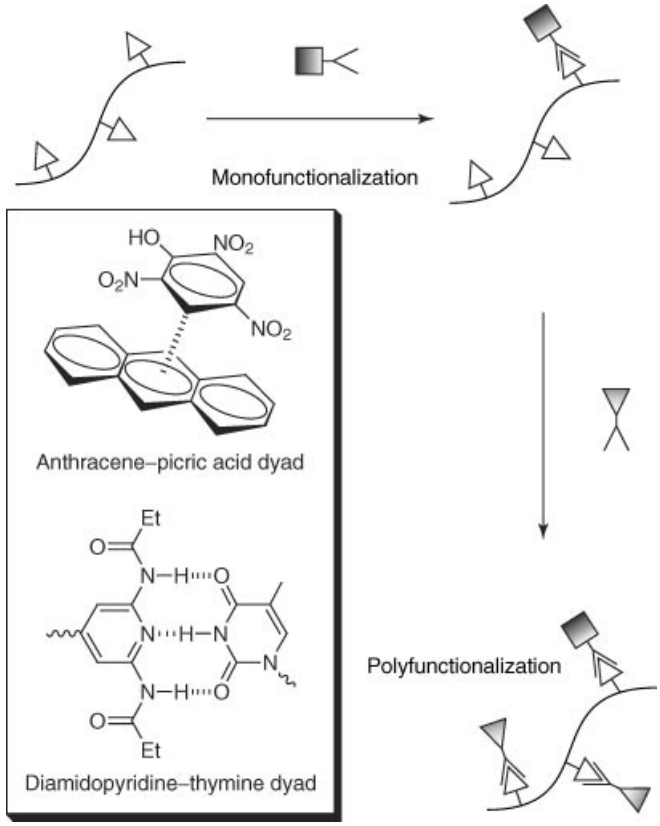

Fig. 2. Schematic representation of versatility of reversible, supramolecular side-chain modification, and selected examples of interactions that can be employed (inset).

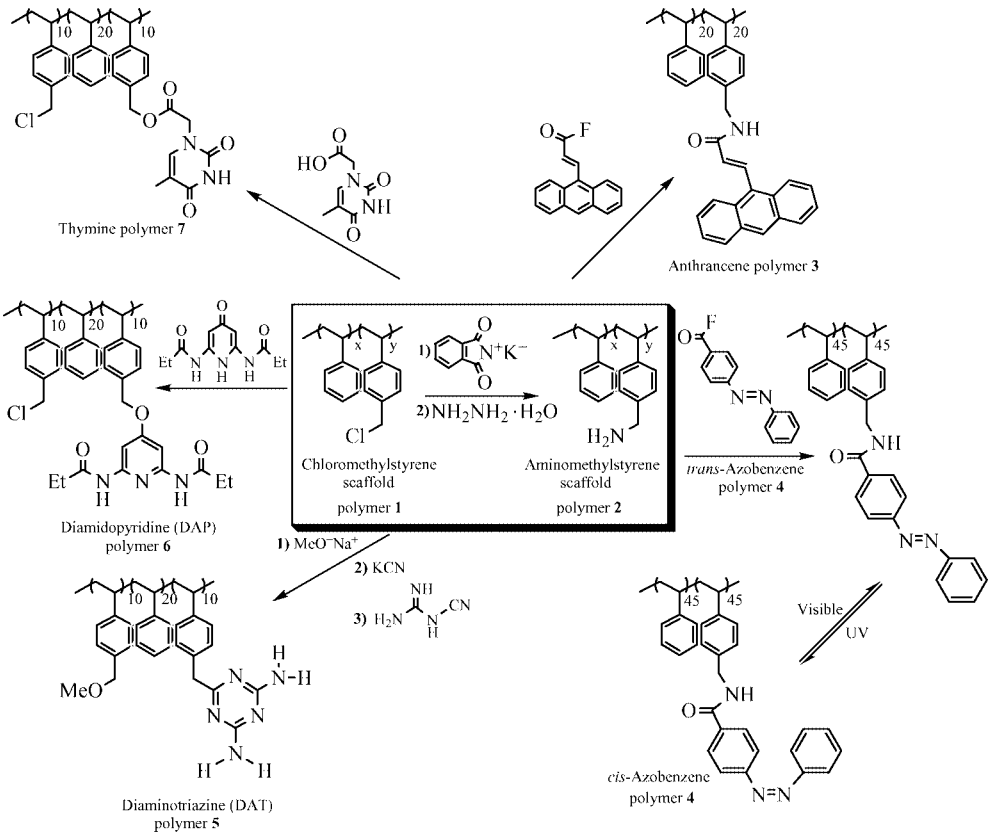

Fig. 3. Schematic illustration of versatile polymer scaffolds providing a divergent approach to polymer structure.

in multigram scales, and contain numerous monomers with sites for facile substitution. [Styrene and *p*-(chloromethyl)styrene polymerize with similar reactivity rates; therefore the desired 1:1 monomer ratio was achieved by initiating the polymerization in the presence of a 1:1 molar ratio of monomers]. The versatility of this polymer is demonstrated in Figure 3. For example, the chloromethyl sites can be directly functionalized via nucleophilic substitution, or easily converted to amines which react quantitatively with active esters, acid halides, or other electrophiles.

Our first investigations into polymer structural control were achieved utilizing aromatic stacking interactions. Employing polymers **3** and **4**, obtained from amine-functionalized polymer **2**, anthracene and azobenzene moieties were introduced quantitatively onto the styrene backbone. Anthracene polymer **3** adopts a highly folded, compact globular structure in solution because of numerous favorable anthracene–anthracene and anthracene–benzene interactions. (20) Capitalizing on the electron-rich nature of the pendant anthracene side chains, electron-deficient picric acid (Fig. 4**a**) was introduced into the system to induce a swelling of the polymer structure. The increased electrostatic interaction between the electron-rich anthracenes and electron-poor picric acid causes picric acid to

intercalate between anthracenes, affecting a swelling of the polymer globule. The hydrodynamic radius of the polymeric globule is dependent upon the concentration of picric acid, allowing for facile control over polymer size. Also, addition of picric acid causes this system to exhibit an increased thermal stability due to increased electrostatic interactions between anthracene–picric acid over anthracene–anthracene (Fig. 4).

Later, it was also demonstrated that pendant azobenzene units provide for photochemical control over polymer structure (21). Azobenzene is an extremely versatile photochrome; its structure can be controlled by the absorption of light,

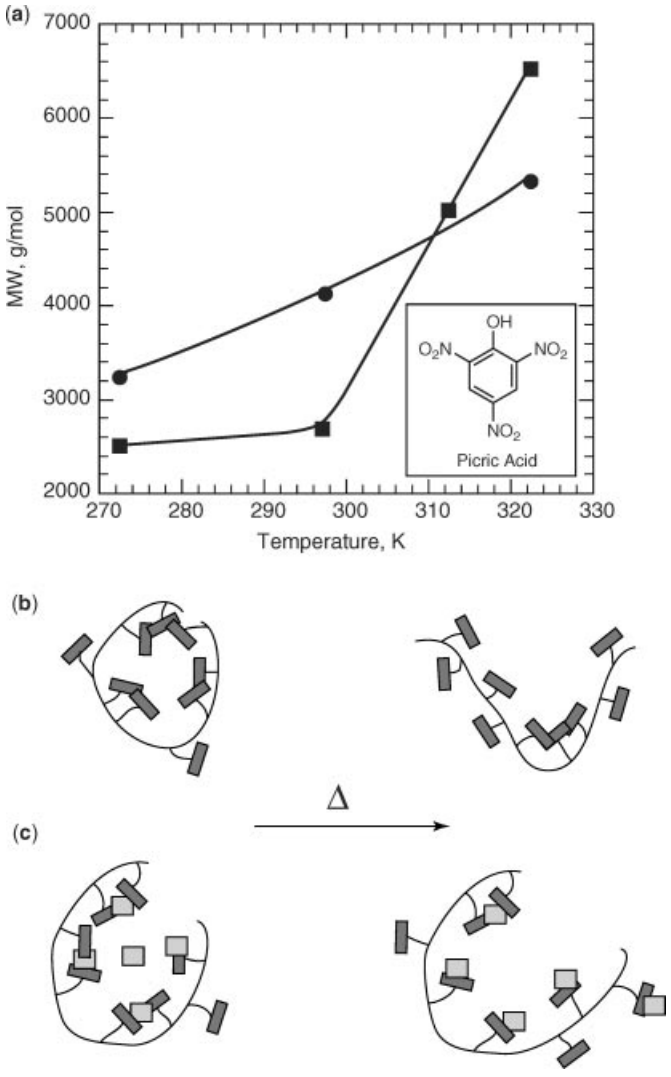

Fig. 4. Graphical and schematic illustrations of thermal unfolding process. (**a**) Variations in relative sizes of polymer **3** with and without picric acid. often used for the creation of light-driven devices. (22) Photochemical isomerization of the azobenzene chromophore (UV irradiation induces trans to cis isomerization) causes the hydrodynamic radius to decrease as a result of the more compact cis isomer allowing for a greater degree of side-chain–side-chain aromatic stacking (Figs. 5 and 6). This isomerization process is reversible and directly linked to the UV–vis behavior of azobenzene.

To extend the methodology and demonstrate the modularity of reversible side-chain modification using specific noncovalent interactions, recognition elements capable of three-point hydrogen bonding were attached to the polymer scaffold. Diaminotriazine is a suitable recognition element for noncovalent side-chain modification through its donor–acceptor–donor hydrogen bonding units. However, attachment of triazine to the chloromethylstyrene scaffold (polymer **1**), fashioning polymer **5**, generates a polymer with a highly folded, micelle-like structure in noncompetitive solvents such as $CHCl_3$ as a result of the multiple modes of intrapolymeric hydrogen bonding between diaminotriazine moieties (23). This compact macromolecular conformation creates a system that inefficiently

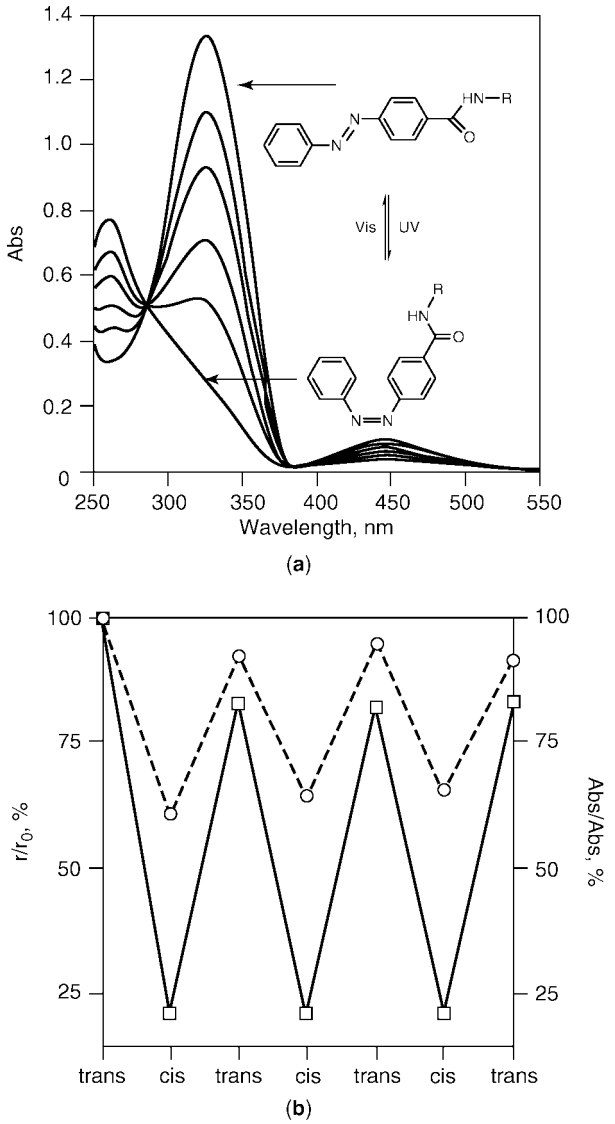

Fig. 6. (**a**) Absorption spectra variations of polymer **4** upon irradiation with UV and visible lights, and (**b**) variations in the relative radius of gyration (solid line) and absorption (dashed line) of **4** during irradiation.

complexes external guests because of competition between polymer–polymer and polymer–guest interactions. However, this conformation is very attractive for encapsulation since site isolation is a major advantage in catalysis and data storage. Specifically, ferroceneuracil **8** is able to penetrate the highly compact structure of **5** and bind multiple triazine units in the polar core (24). This guest is equipped with an additional hydrogen bond donor, N—H(1) in Figure 7, not in a linear array with the three-point DAD motif, creating a "wraparound" effect that maximizes favorable contacts between host and guest.

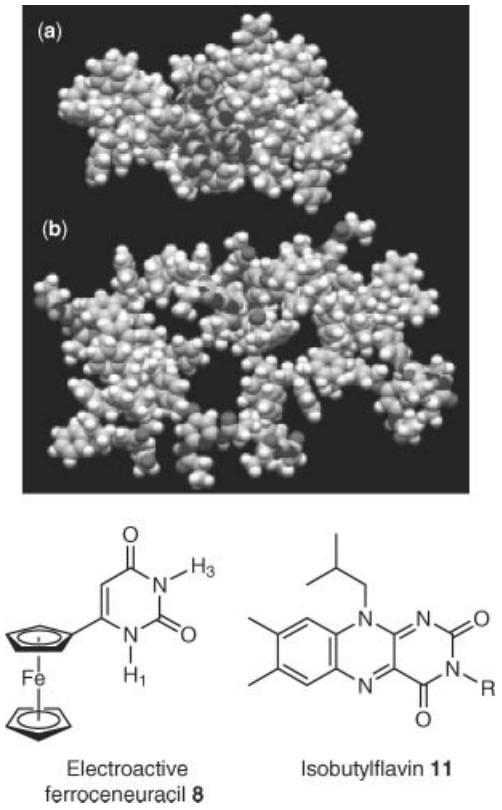

Fig. 7. Molecular dynamics runs (300 K, $CHCl_3$) of polymers (**a**) **5** and (**b**) **6** (40 repeat units each, schematically represented in Figure 3). Electroactive guest **8** and fluorescent guest **11** employed to probe binding efficiencies of **5** and **6**.

Efforts to provide more efficiency in guest complexation resulted in the replacement of diaminotriazine with diacyldiamidopyridine. Diacyldiamidopyridine is a highly analogous molecule containing the very same donor–acceptor–donor motif as diaminotriazine; however, diacyldiamidopyridine self-associates to a lesser extent resulting in a less-folded polymer capable of more efficient guest complexation.

To probe the binding efficiencies with the polymers above, a guest, isobutylflavin **11**, was employed. Isobutylflavin **11** contains the complementary acceptor–donor–acceptor recognition moiety required for specific complexation. Figure 8**a** shows that there is a significant reduction in binding efficiency of the triazine derivative compared to the diamidopyridine derivative. As previously mentioned, implicit in the bimolecular recognition of intrapolymerically associated triazine polymers is a decrease in the efficiency of interpolymeric binding. This inefficiency is explained by the requirement for polymer **5** to first uncoil prior to the recognition event (Fig. 8**b**).

The previous paragraphs have outlined a few methodologies by which we have demonstrated control over solution-state polymer structure by reversibly

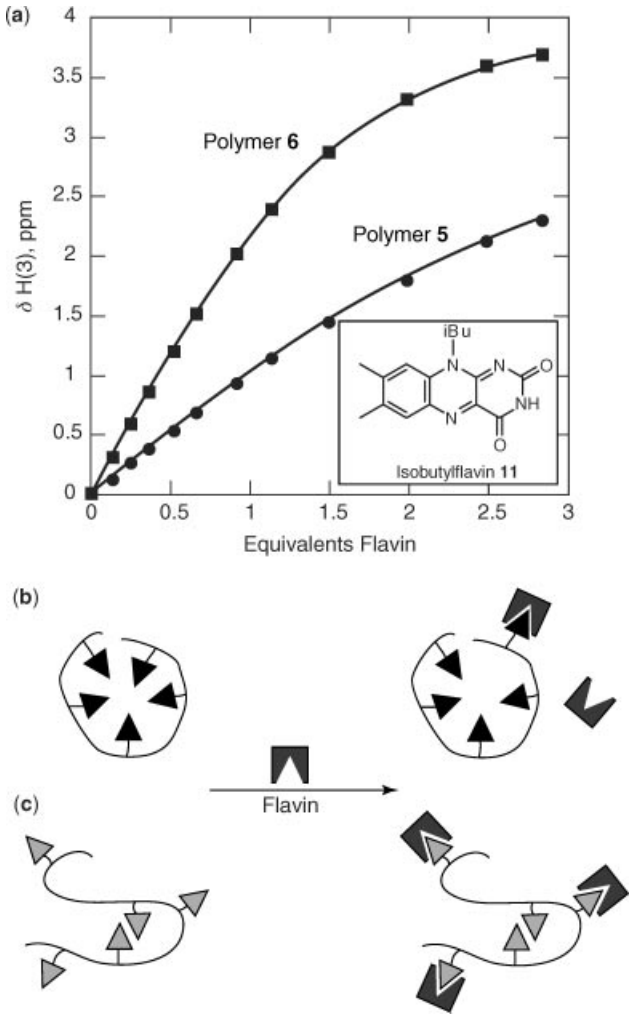

Fig. 8. (**a**) Graphical representation of the downfield shift of the imide proton of polymer **11** upon introduction to polymers **5** and **6**. Schematic representations of the recognition behavior of (**b**) polymers **5** and (**c**) **6** with **11**.

binding small guests to the pendant side chains of a flexible polymer scaffold or through reversible interactions of the pendant side chains with themselves. As such, this "plug and play" methodology has proven to be a very versatile approach to supramolecular polymer engineering.

Formation of Highly Structured, Functional Microscale Systems

Reversible side-chain modification has been demonstrated to be quite useful and very versatile at controlling the structure of single polymer strands in solution. This approach can also be very effectively used for solution-state assembly of

many polymer strands into higher order structures such as vesicles (25), micelles (26), and gels (27). As specific molecular recognition processes provide a tool for obtaining molecular-level control over higher order assembly processes (28), so too will integration of the "lock and key" selectivity with the phase-separated, three-dimensional nature of vesicular and micellar templates present a new opportunity for the creation of systems featuring novel structural and dynamic properties.

Combination of complementary diacyldiamidopyridine- and thymine-functionalized polymers **6** and **7**, respectively, in nonpolar media results spontaneously in the formation of giant vesicular aggregates, or recognition-induced polymersomes (RIPs). (Fig. 9) (29). In contrast to reports of di-block copolymer-based polymersomes that rely upon solvophobicity and phase

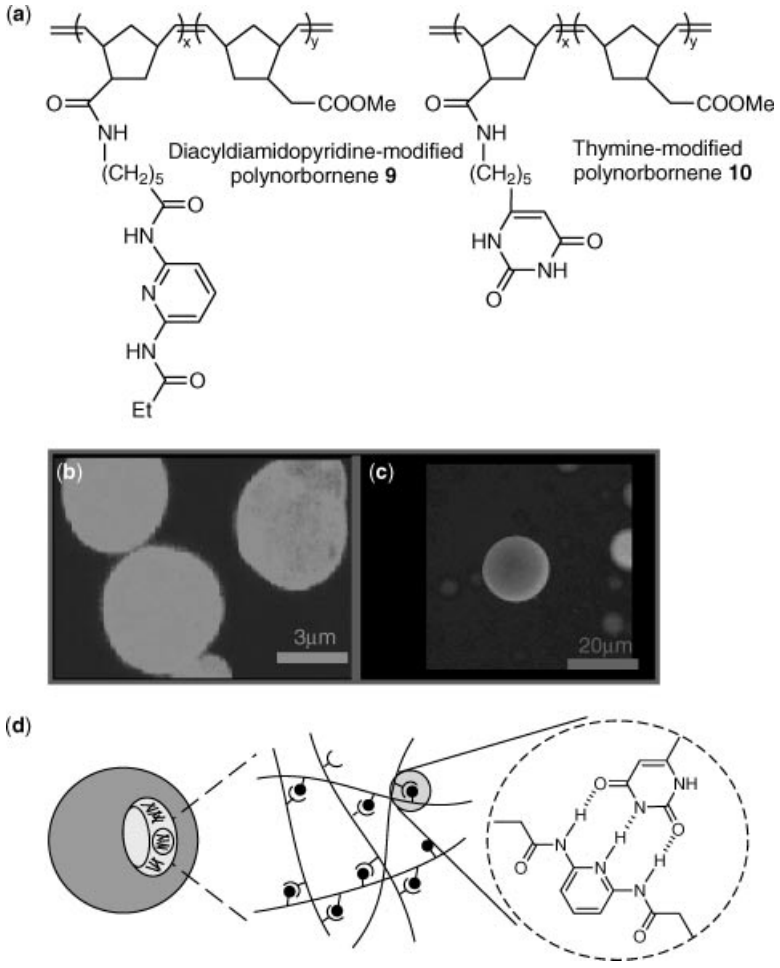

Fig. 9. (**a**) Random polynorbornene-based copolymers **9** and **10** that assemble into RIPs analogous to copolymers **6** and **7**. (**d**) Schematic illustration of specific interstrand hydrogen bonding driving polymersome formation.

segregation for self-assembly (18), these RIPs are formed through highly specific interactions between the complementary pendant side chains (Fig. 9**d**) as the polymers do not aggregate unless functionalized post-polymerization with recognition elements. Interestingly, these highly unusual, ordered microstructures from disordered, random copolymers are not unique to flexible polystyrene backbones; the more rigid polynorbornene scaffold, when derivatized with diacyldiamidopyridine (polymer **9**) and thymine (polymer **10**), also self-assembles in nonpolar media into RIPs (30) (Fig. 9**b**).

The formation of vesicular architectures from random copolymers lacking well-defined headgroups was unprecedented, proving a new method for the creation of supramolecular assemblies. This mode of assembly provides a new tool for the control of vesicle structure; complementary monovalent and multivalent guests would be expected to distort or disrupt vesicle structure through competitive binding to the polymer recognition sites (31). (see POLYMER VESICLES).

Initially, flavin was introduced into a solution of preformed RIPs to specifically and reversibly incorporate a fluorescent tag into the vesicular structure as an extension of our plug and play approach to polymer side-chain modification. As expected, the monodentate flavin caused a disruption in RIP structure appearing as an immediate swelling upon contact (Fig. 10**b**). However, this result was briefly lived as RIP diameter slowly returned to that of original, preformed RIPs (Fig. 11).

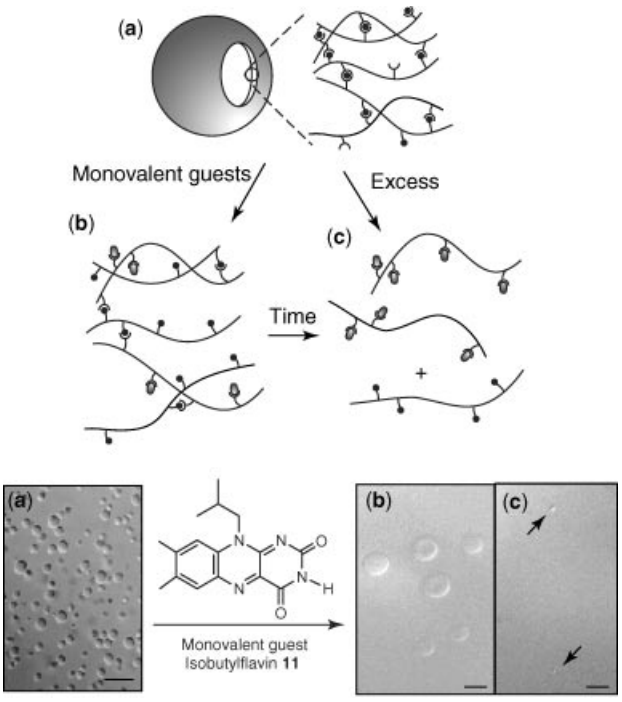

Fig. 10. Differential interference contrast micrographs of RIP–guest interactions with corresponding schematics: (**a**) native, undoped RIPs; (**b**) swollen RIPs 30 s after monovalent guest **11** addition; and (**c**) equilibrated RIPs 50 min after addition of 11. Scale bars represent 10 μm.

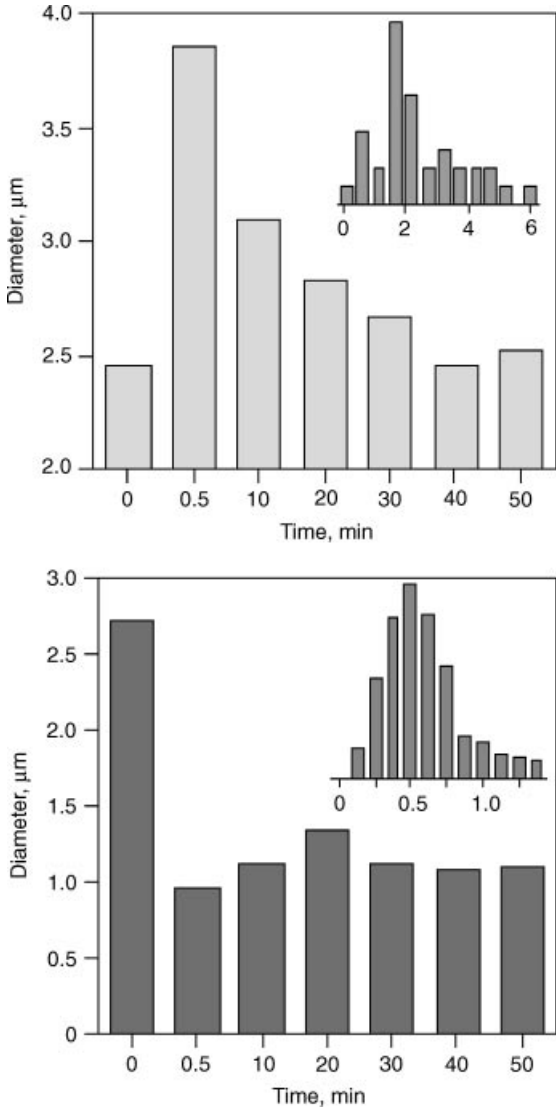

Fig. 11. Graphical representations of size changes occurring upon introduction of mono- and multivalent guests. Flavin (top) affects an immediate but temporary RIP swelling. Thy–Au (bottom) constricts polymer strands within RIPs resulting in submicrometer constructs. The insets on each graph are histograms of the equilibrated system 50 min after guest addition.

Presumably, this is due to the dynamic nature of these specific recognition processes. Flavin competitively binds with the DAP moiety of polymer **6**; over time, strands of polymer **6** become saturated with **11**, causing these polymers to leave the aggregate, in turn resulting in a return to original RIP size. Since RIP size distribution (Fig. 11**a**) and average diameter return to that of original, undoped RIPs firmly suggest that flavin is not incorporated into the final, equilibrated RIP system.

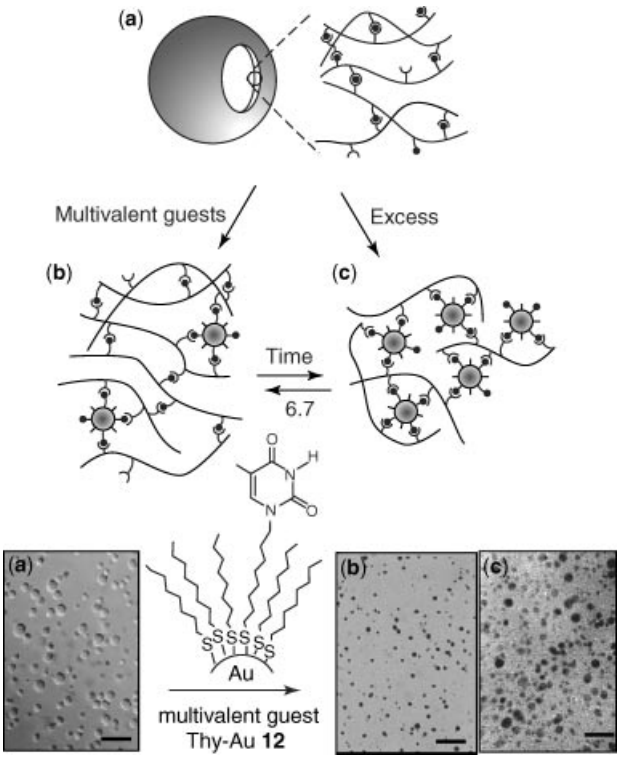

Fig. 12. Differential interference contrast micrographs of RIP–guest interactions with corresponding schematics: (**a**) native, undoped RIPs; (**b**) smaller RIPs 30 s after multivalent guest **12** addition (scale bars represent 10 μm); (**c**) submicrometer polymer–nanoparticle assemblies 50 min after Thy–Au addition. Scale bar represents 1 μm.

As already mentioned, multivalent guests were expected to act very differently with RIPs because of the greater number of contacts that, potentially, can be formed between the multifunctional Thy–Au and RIP (Fig. 12). In previous studies, we have demonstrated that analogous polymers interact specifically with Thy–Au to form solid spherical assemblies (32). The gold nanoparticles are excellent guests for these investigations because of their discrete structure, solubility in nonaqueous media, facile place exchange of ligands, and desired multifunctionality. From this, we predicted and confirmed that Thy–Au specifically embeds within the RIP and then causes a major reorganization of the component polymers. This process can followed qualitatively by phase contrast microscopy as RIPs are initially observed to be translucent in solution. The solution darkened upon addition of an aliquot of Thy–Au, but the solution cleared very rapidly ($\sim$30 s), indicating Thy–Au is rapidly incorporated into the RIP wall. However, this rapid incorporation was followed by an overall decrease in average diameter (Fig. 12**b**). Addition of Thy–Au constricts the component polymers, resulting in an immediate decrease in RIP diameter. However, the structures do not equilibrate back to original size, as seen in the flavin system, but rather new self-assembled spheres on the submicrometer scale forms.

To demonstrate the specific nature of these observed effects, highly analogous *N*-methylated versions of guests were synthesized and employed in the same capacity. The methyl groups cause only minimal changes in guest structure; however, these groups drastically change guest activity in solution as the methyl group effectively disrupts three-point hydrogen bonding, making these excellent molecules for control experiments. In both cases, no size changes or morphological effects were observed, clearly indicating the specific nature of these interactions.

Extension of this self-assembly approach to supramolecular engineering has led to an alternate motif for noncovalent cross-linking, a series of bisthymines that are complementary to the diamidopyridine side chains of polymer **6** (33). Upon combination in non-polar media thermally reversible, micrometer scale spherical aggregates were formed (Figs. 13**b** and 13**c**).

From the LCSM micrographs in Figure 13, the solid fluorescence profile of these spherical assemblies is indicative of a filled sphere rather than the vesicular morphology. Moreover, it is apparent that the fluorescence emission tapers off with microsphere radius; fluorescence is more intense in the microsphere center

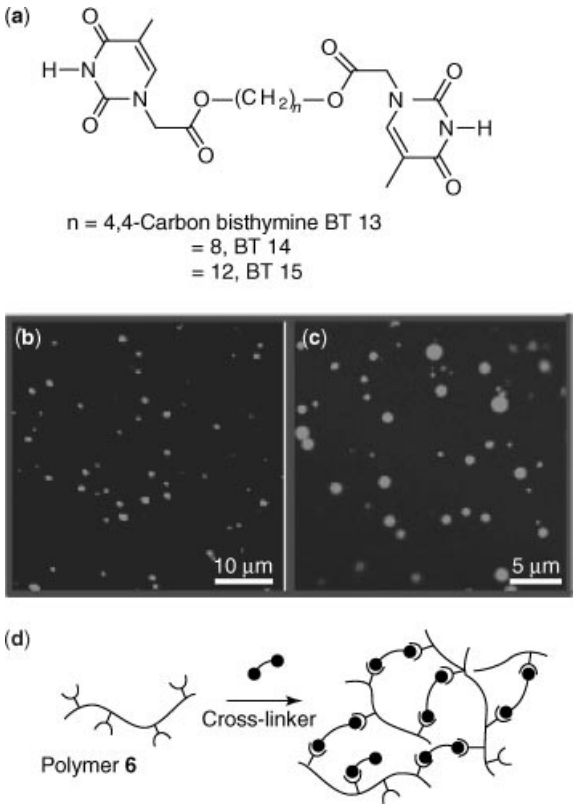

Fig. 13. (**a**) Bisthymine cross-linkers 13–15. (**b**,**c**) LCSM micrographs of microspheres generated from combination of polymer **6** and bisthymine (BT) **16**. (**d**) Schematic depiction of noncovalent polymer cross-linking.

indicating the presence of a microgel morphology. Also, the highly localized fluorescence observed in the micrographs indicates that very little flavin-tagged polymer exists free in solution, demonstrating the effectiveness of the cross-linking process.

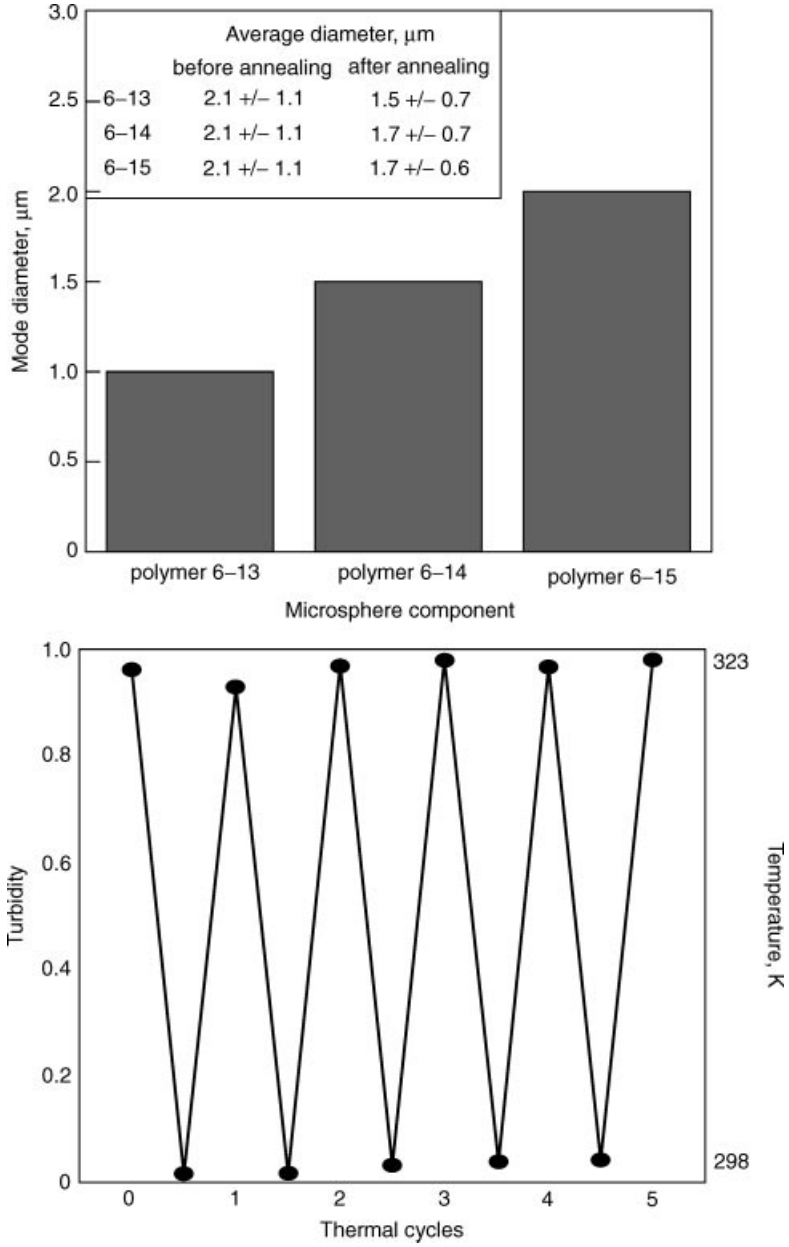

Fig. 14. Graphical representations of increasing microsphere diameter with increasing cross-linker length and average diameters (top) before and after thermal annealing cycles (inset), and solution turbidity during annealing cycles (bottom).

Interestingly, the overall size distribution of the resulting microspheres was found to be dependent on cross-linker preorganization; varying the alkyl spacer between thymines on the cross-linker translates into a stepwise growth in overall diameter on the microscale (Fig. 14). In accord with self-assembled systems, these microspheres could be thermally cycled, with complete disassociation of system components at elevated temperatures. Although small variations in turbidity are detected, microspheres after thermal annealing appear to retain less polydisperse, smaller overall diameters. Presumably, this change in distribution is the result of thermal cycling of the initial kinetic structures to thermodynamically more stable aggregates.

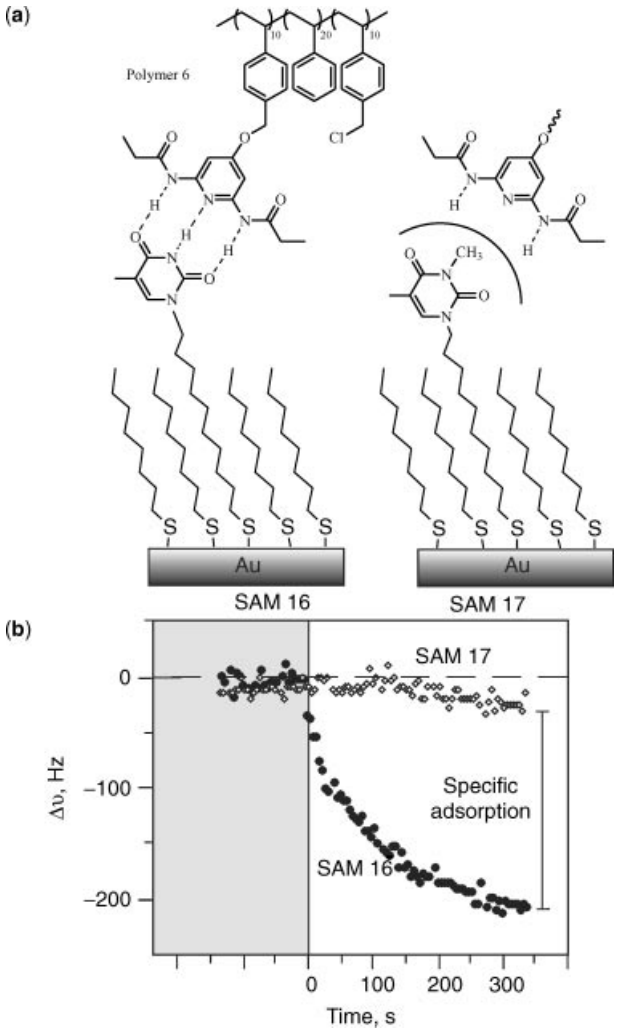

Fig. 15. (**a**) Self-assembled monolayers (SAMs) featuring imide functionality **16** and *N*-methylated control **17**. (**b**) Graphical representation clearly illustrating the essential role specific hydrogen bonding plays in polymer deposition.

Surface Modification

The concepts of supramolecular chemistry are also well suited to interactions at the solid–liquid interface. This provides an effective and efficient means of reversibly controlling the physical and chemical properties of a surface. There currently exist many well-established techniques for surface modification, such as electrostatics, ionic coordination, chemisorption, and Langmuir–Blodgett deposition; however, introducing specific hydrogen bonding interactions allows one to enhance the interfacial specificity between the surface and adsorbate while maintaining surface-charge neutrality, a prerequisite when designing materials with biocompatibility. To this end, self-assembled monolayers (SAMs) allow the incorporation of specific amounts of diverse functionality to investigate polymer deposition using noncovalent interactions (Fig. 15) (34).

Quartz crystal microbalance (QCM) is a well-established technique for monitoring surface deposition as the natural frequency of quartz decreases when mass is deposited onto the chip. This frequency change can be directly related to film formation and can be monitored in real time. The QCM experiment in Figure 15**b** depicts this phenomenon and indicates that polymer is rapidly adsorbed onto SAMs with the selectively expected from the DAP–Thy recognition dyad. These data also provide a method for determining the varying contributions of adsorption from nonspecific or specific interactions. Any frequency change in the case of *N*-methylated SAM **17** is due to nonspecific adsorption and can be subtracted from the response observed with SAM **16** to isolate the contribution of specific adsorption processes.

MOLECULAR WEIGHT DETERMINATION

Introduction

This article discusses the theory and methods for the determination of molecular weight averages and molecular weight distributions of oligomeric and polymeric materials. The more important methods are described in greater detail in separate articles (see CHROMATOGRAPHY, SIZE EXCLUSION; FRACTIONATION; CHARACTERIZATION OF POLYMERS).

Molecular Weight Averages and Distributions

Most polymeric materials are comprised of mixtures of molecules of various sizes. This distribution of molecular weights is a result of the statistical nature of the polymerization proces (1). A complete description of the molecular weight distribution of a homopolymer is necessary to understand its physical, rheological, and mechanical properties. Structural variations, such as chain branching, and copolymer or higher mer polymers with various degrees of structural randomness further complicate a complete description of the molecular ensemble. Copolymers and higher mer polymers also need to be characterized for molecular composition as a function of molecular weight. Block copolymers and polymer mixtures also offer significant challenges to evaluate their molecular weight distribution. Failure mechanisms and practical lifetimes of polymeric materials may also be established through molecular weight measurements.

Most classical techniques for molecular weight determination are only capable of yielding one of the molecular weight averages of the distribution. These traditional methods are used nowadays only on a limited basis, and only a limited number of commercial instrumentation is available.

These averages are defined in terms of the molecular weight M_i and the number of moles n_i or the weight w_i of the component molecules. The molecular weight averages are defined by equations 1-4.

Number-average molecular weight:

$$\bar{M}_{\mathrm{n}} = \frac{\sum n_i M_i}{\sum n_i} = \frac{\sum w_i}{\sum w_i / M_i} \tag{1}$$

Weight-average molecular weight:

$$\bar{M}_{\mathrm{w}} = \frac{\sum n_i M_i^{\,2}}{\sum n_i M_i} = \frac{\sum w_i M_i}{\sum w_i} \tag{2}$$

z-Average molecular weight:

$$\bar{M}_z = \frac{\sum n_i M_i^{\,3}}{\sum n_i M_i^{\,2}} = \frac{\sum w_i M_i^{\,2}}{\sum w_i M_i} \tag{3}$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

$(z + 1)$-*Average molecular weight*:

$$\bar{M}_{z+1} = \frac{\sum n_i M_i^4}{\sum n_i M_i^3} = \frac{\sum w_i M_i^3}{\sum w_i M_i^2} \tag{4}$$

Viscosity-average molecular weight:

$$\bar{M}_{\mathrm{v}} = \left[\frac{\sum n_i M_i^{1+a}}{\sum n_i M_i} \right]^{1/a} = \left[\frac{\sum w_i M_i^a}{\sum w_i} \right]^{1/a} \tag{5}$$

Equation 5 is an important practical molecular weight average derived from viscometry. To calculate this average, the exponent a and the constant K of the Mark–Houwink relationship relating intrinsic viscosity $[\eta]$ to molecular weight must be known.

$$[\eta] = KM^a \tag{6}$$

The value of a lies between 0.5 and 1.0 for random coils, depending on the solvent employed to determine the relationship of the intrinsic viscosity to molecular weight. For rigid rod molecules, the value of a is expected to be ~1.8. With these limits for a, it may be seen that $\bar{M}_{\mathrm{v}}$ is always larger than $\bar{M}_{\mathrm{n}}$ but can equal $\bar{M}_{\mathrm{w}}$ when the upper limit of a is reached for random coils.

If molecular weight is considered a continuous variable, the molecular weight distribution may be described by a set of moments μ_r given by the integrals

$$\mu_r = \int_0^x M^r f(M)\, \mathrm{d}M$$

where r = 0, 1, 2, 3, etc; $f(M)$ is the number-density distribution; and $f(M)dM$ is the number of moles of molecules with molecular weight between M and $(M + dM)$.

The average molecular weights are defined as

$$\bar{M}_{\mathrm{n}} = \frac{\mu_1}{\mu_0}$$
$$\bar{M}_{\mathrm{w}} = \frac{\mu_2}{\mu_1}$$
$$\bar{M}_z = \frac{\mu_3}{\mu_2}$$
$$\bar{M}_{z+1} = \frac{\mu_4}{\mu_3}$$

Molecular weight averages can be determined from these moments (2).

Molecular Weight Distribution Functions

Various mathematical functions have been employed to describe the distribution of molecular weights. Some of the more common functions are shown in Table 1 in terms of the mole fraction X. Further details are available (3).

Width of Molecular Weight Distributions. The width of the Gaussian distribution function may be expressed in terms of the standard deviation of the mole fraction MWD function σ_n or the mass fraction MWD function σ_w:

$$\sigma_n = (\bar{M}_w \bar{M}_n - \bar{M}_n)^{0.5}$$
$$\sigma_w = (\bar{M}_z \bar{M}_w - \bar{M}_w)^{0.5}$$

The standard deviation is an absolute measure of the width for the Gaussian function only. Widths of molecular weight distribution for other functions have to be calculated for each case from the distribution function itself.

The relationships between molecular weight averages and parameters in the molecular weight distribution functions are as follows:
which leads to

$$\exp(\sigma_w)^2 = \frac{\bar{M}_w}{\bar{M}_n} = \frac{\bar{M}_z}{\bar{M}_w}$$

Thus the ratios of two adjacent averages are constant.

Poisson distribution function.

The ratio of the weight-average to number average molecular weight is given by

$$\frac{\bar{M}_w}{\bar{M}_n} = 1 + \left(\frac{1}{\bar{M}_n}\right) - \left(\frac{1}{\bar{M}_n}\right)^2$$

Table 1. Molecular Weight Distribution Functions

Name	Function	Comments
Gaussian	$X(M) = \frac{1}{\sigma_n (2\pi)^{1/2}} \exp\left[\frac{(M - M_m)^2}{2\sigma_n^2}\right]$	M_m = median value equal to $\bar{M}_n$
Log-normal	$X(M) = \frac{1}{\sigma_n (2\pi)^{1/2}} \exp\left[\frac{(\ln M - \ln M_m)^2}{2\sigma_n^2}\right]$	M_m = geometric mean
Poisson[a]	$X(M) = \frac{\nu^{M-1}}{\Gamma(M)} \exp(-\nu)$	$\nu = \bar{M}_n - 1$
Flory–Schulz[b]	$X(M) = \frac{\beta^{k+1} M^{k-1} \bar{M}_n}{\Gamma(k+1)} \exp(-\beta M)$	k = degree of coupling $\beta = \frac{k}{\bar{M}_n}$

[a] $\Gamma(M) = \gamma$-function.
[b] $\Gamma(k+1) = \gamma$-function.

Gaussian distribution function
mole-fraction distribution function median value $= \bar{M}_n$
mass-fraction distribution function median value $= \bar{M}_w$

Log-normal distribution function
mass-fraction distribution function median value $= M_m$

$$\bar{M}_n = M_m \exp[(\sigma_w)^2/2]$$

$$\bar{M}_w = M_m \exp[3(\sigma_w)^2/2]$$

$$\bar{M}_z = M_m \exp[5(\sigma_w)^2/2]$$

and therefore depends only on $\bar{M}_n$.

Flory–Schulz distribution function
The molecular weight averages this function are related by

$$\frac{\bar{M}_n}{k} = \frac{\bar{M}_w}{k+1} = \frac{\bar{M}_z}{k+2}$$

where k is the coupling constant, defined as the number of independently growing chains required to form one dead chain.

Polydispersity
Traditionally, polydispersity Q has been defined as

$$Q = \bar{M}_w/\bar{M}_n = U + 1$$

where U, the molecular inhomogeneity, has a numerical value of one less than Q. The width of molecular weight distributions increases with increasing Q and U. Except for the Gaussian distribution function, the standard deviation is only a relative measure of distribution width (4,5).

Determination of Molecular Weight

Several books have been published since this article was last written (6–9).

Number-Average Molecular Weight.

End-Group Analysis. In end-group analysis the concentration of an end group is measured by a suitable technique, and then, from the known structure of the polymer, the value for $\bar{M}_n$ may be calculated (10–15). In condensation polymers one end of the polymer should have a specific group that can be titrated by appropriate means. Polyesters (13), polyamides (13), and polyurethanes (16) have been subjected to this analysis. Polyethers have been analyzed by hydroxyl-group titrations similar to those used for polyesters or by reaction with excess phenyl isocyanate followed by reaction with excess di-*n*-butylamine; the latter was back-titrated with perchloric acid (17). Nonaqueous titrations (18) have been used to

characterize polysulfones with $\bar{M}_n$ values of up to 25,000. Potentiometric titration in aqueous and nonaqueous media have been used to determine molecular weights of acrylamide and acrylonitrile polymers (19). Spectrophotometric analyses have also been widely utilized (14), notably uv–visible, infrared techniques, and NMR (20). Examples include the determination of phenolic end groups in polymers by uv spectroscopy (21) and potentiometric titration (18). Infrared spectroscopy has been used (22) to estimate carboxyl groups in the presence of carbonyl groups by reaction of the former with SF_4; the resulting thionyl halides were quantitatively measured. NMR spectroscopy (^1H) has been used to characterize $\bar{M}_n$ of hydroxyl end-capped polystyrenes (A. D. Edwards and M. J. R. Loadman, Malaysian Rubber Producers Research Association, unpublished data, 1976). Reaction of the single proton on the hydroxyl group yields a trimethylsilyl group containing nine protons. The enhanced sensitivity allows determination of $\bar{M}_n$ values of up to 80,000. A similar method has been reported for hydroxy-terminated polybutadienes (23), polyester polyurethanes (24), epoxides (25), and other polymers (26–28). Acid end groups in polyethylene terephthalate have been characterized (29) by reaction with hexafluoroisopropanol and ^{19}F NMR.

In certain cases extremely high sensitivity may be attained with radioactive labeling (30). Using radiolabeled (^{35}S) bisulfite initiator, the number-average molecular weight of Teflon samples was determined in the range of 389,000–8,900,000 (31). This is a particularly useful technique for insoluble polymers.

Measurement of Colligative Properties. Colligative properties are those that depend on the number of species present rather than on their kind (32,33). From thermodynamic arguments it may be shown that for very dilute ideal solutions

$$\ln a_1 = -X_2$$

where a_1 is the activity of the solvent and X_2 is the mole fraction of solute. From this relationship the solute molecular weight may be calculated if the weight fraction w_2 is known.

$$x_2 = \frac{n_2}{n_1} = \frac{w_2 M_1}{M_2 w_1}$$

This equation demonstrates that the activity, measurable by several methods, is proportional to the number of solute molecules. Thus in the case of polydisperse solutes, the number-average molecular weight is the average determined. At higher concentrations and molecular weights, the solutions become nonideal, and higher powers of the solute concentration are introduced into the equations. Measurements of several solute concentrations are required, and appropriate extrapolation techniques must be used.

Lowering of Vapor Pressure. The partial vapor pressure p_1 of solvent 1 over a solution is lower than the vapor pressure over the pure solvent $p_1{}^0$. This is expressed by Raoult's law:

$$P_1 = X_1 p_1{}^0$$

where X_1 is the mole fraction of the solvent.

For a binary solution containing a mole fraction X_2 of solute then,

$$X_2 = \frac{p_1^0 - p_1}{p_1^0} = \frac{\Delta p_1}{p_1^0} \tag{7}$$

For a dilute solution,

$$X_2 = \frac{n_2}{n_1} = \frac{w_2 M_1}{M_2 w_1} \tag{8}$$

Combining equations 7 and 8 yields

$$M_2 = w_2 \frac{M_1}{w_1} \frac{p_1^0}{\Delta p_1}$$

The unknown molecular weight of solute M_2 may be calculated from the lowering of the vapor pressure caused by the addition of w_2 grams of solute to form a binary solution; $\bar{M}_n$ values of up to 1000 may be determined (34–37).

A variation of this technique, the isopiestic method (38–40), was devised to avoid the difficulty of accurately determining the small difference in vapor pressure caused by the addition of solute. In this method (41) two limbs of a container joined by a common vapor space are filled, one with a reference solution of known weight concentration w_s and molecular weight M_s and the other with the unknown solution of known weight concentration w_2 and unknown molar concentration. The apparatus is immersed in a constant-temperature bath controlled to $\pm 0.001^\circ$C; the absolute temperature is not important. Distillation of the solvent continues until the vapor pressures above the solutions in each limb are equal, and thus the solutions contain equal mole fractions of solute. At equilibrium, which may require several weeks, the final volumes V_s, and V_2 of the known and unknown solutions are read from the calibrations on each limb.

$$\bar{M}_n = \frac{w_2 M_s V_s}{V_2 w_s}$$

$\bar{M}_n$values of up to 20,000 have been determined by this method.

Ebulliometry. Ebulliometry (34,42–47) is another technique for determining the depression of the solvent activity by the solute. In this case the elevation of the boiling point is determined. The boiling-point elevation ΔT_b is measured with sensitive thermocouples or matched thermistors in a Wheatstone bridge. The molecular weight $\bar{M}_n$ is calculated from

$$\bar{M}_n = \frac{K_b c}{\Delta T_b}$$

where c is the concentration of solute in g/1000 g of solvent and

$$K_b = \frac{R T_b^2 M}{1000\ \Delta H_v} \tag{9}$$

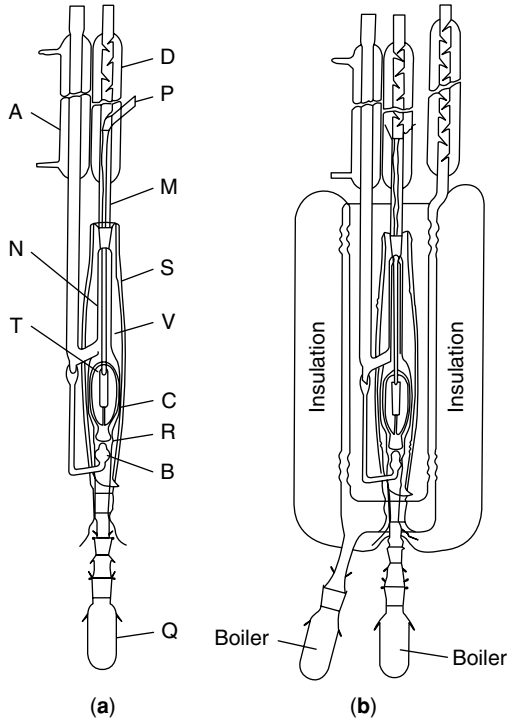

Fig. 1. (**a**) Ebulliometer design for molecular weight determination of up to $\bar{M}_n = 100{,}000$. A denotes ebulliometer cooler; B, boiler; C, Cottrell pump; D, adiabatic jacket cooler; M, thermopile; N, upper thermopile weldings; P, thermopile terminals connected with detector; Q, adiabatic jacket boiler; R, platinum resistance; T, lower thermopile weldings; and V, vacuum jacket circulated by solvent vapor. (**b**) Complete ebulliometer with adiabatic jackets and insulating apparatus (50). Courtesy of Huethig and Wepf Verlag.

is the molal ebullioscopic constant. M is the molecular weight of the solvent and T_b its boiling point; ΔH_v is the molar latent heat of vaporization of the solvent.

The ebullioscopic constant may be evaluated directly from equation 9 and thus provides an absolute method. However, the value for K_b is often determined by using a high purity solute of known molecular weight.

Currently, a sensitivity of 1×10^{-5}°C or 2.4×10^{-6}°C is attainable using a 160-junction thermocouple (48) or thermistors (49), respectively. The upper limit of molecular weight, which may be determined by this method, also depends on the solvent and solution nonideality. With careful measurements and good ebulliometer design, $\bar{M}_n$ values of up to 100,000 may be determined on isotactic polypropylene (50). The apparatus employed is shown in Figure 1. This technique has been applied to aqueous solutions (51). An ebulliometer of simple design having a temperature sensitivity of 50×10^{-6}°C has recently been reported (52). A rotating ebulliometer attempts to overcome the superheating problem (53). Errors in the methods for treating ebullioscopic data to obtain molecular weight have been discussed (54).

Cryoscopy. The freezing point of a solution is depressed below that of the pure solvent by an amount proportional to the mole fraction of solute. The value

for $\bar{M}_n$ is obtained from

$$\bar{M}_n = \frac{K_f c}{\Delta T_b}$$

where c is the concentration of solute in g/1000 g of solvent and

$$K_f = \frac{RT_m^2 M}{1000\ \Delta H_{fus}}$$

is the molal cryoscopic constant; M is the molecular weight of the solvent and T_m its melting point; ΔH_{fus} is the molar latent heat of fusion of the solvent.

Some materials, such as camphor, have very large cryoscopic constants and may be used to increase the sensitivity of the method. The method is used to determine $\bar{M}_n$ of polymers (55–59), such as polyesters (60) and ethylene-vinyl acetate copolymers (61).

A novel variation of this technique (62) involves depression of the first-order, nematic–isotropic melting transition of *N*-(*p*-ethoxybenzylidene)-*p*-*n*-butylaniline. Polystyrene and poly(ethylene oxide) are soluble in both phases, and $\bar{M}_n$ values of up to 10^6 have been studied.

Vapor-Pressure Osmometry. When a drop of solution is exposed to pure solvent vapor, the solvent vapor condenses onto the droplet, because the solute lowers the vapor pressure of the drop (63–68). The heat of condensation causes the temperature of the drop to rise, until theoretically the solution vapor pressure is increased to equal that of the solvent. In practice this does not occur, but a state of equilibrium is reached, where the heat losses from the droplet are matched by the heat of condensation (GB/T 6579-86). The temperature increase is proportional to the number of moles of solute present. A standardized method is available (H. Knauer, Berlin, unpublished data).

The design of a commercial instrument is given in Figure 2 (H. Knauer, Berlin, unpublished data). The temperature stability needed is 0.001°C. In another design, by Wescan Instruments, Inc., small platinum mesh screens ensure that a constant amount of solvent or solution is present on the thermistor. The resistance value ΔR, which is proportional to the temperature difference, is measured with a bridge circuit in all instruments. A calibration curve of ΔR vs molality m is determined by employing a solute of known molecular weight. After several minutes ΔR reaches a constant value; the calibration curve is often highly linear, but may not go through the zero point (66).

$$\Delta R = a + bm$$

The number-average molecular weight of the unknown sample may then be calculated from equation 10:

$$\bar{M}_n = \frac{bc}{\Delta R - a} \tag{10}$$

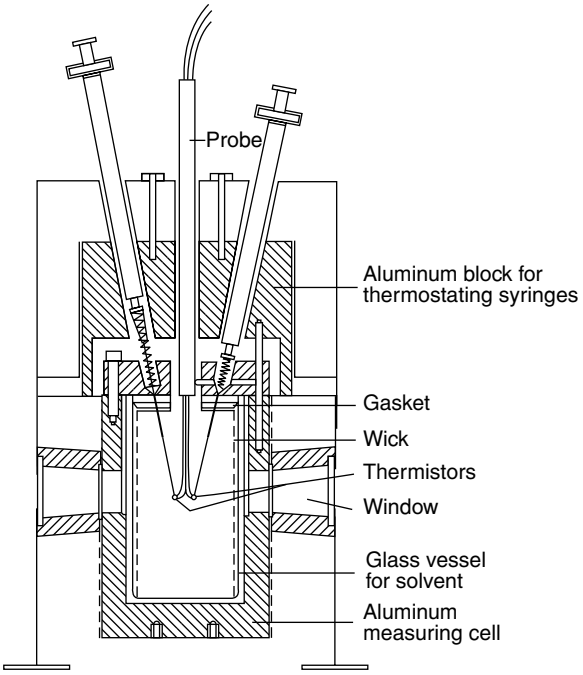

Fig. 2. Vapor-pressure osmometer apparatus (H. Knauer, Berlin, unpublished data, 1987). Courtesy of Dr. -Ing. Herbert Knauer GmbH.

where c is the concentration of solute in g/1000 g of solvent. In older osmometers the calibration curve depended on the material used to perform the calibration. For the Wescan instrument and another research vapor-pressure osmometer (69), both based on the same design (70), the calibration constant was independent of the material. These instruments have determined polystyrene $\bar{M}_n$ values of 400,000 (71), 100,000 (72), and 100,000 (69); polyolefins have been characterized at 140°C (73) and styrene/methylmethacrylate copolymers (32). For higher molecular weight solutes, the virial coefficients become important. In this case $\Delta R/c$ must be plotted against c in order to extrapolate the $\Delta R/c$ value to infinite dilution. When the plot is not linear, it is necessary to plot $(\Delta R/c)^{1/2}$ vs c to obtain a linear extrapolation to infinite dilution.

Membrane Osmometry. Membrane osmometry is a well-established technique (68,74–81). Commercial instrumentation is available (Gonotec GmbH, Knauer). A standardized method is available (GB/T 6596-86). The main problem is membrane permeation by lower molecular weight species (82). Improvements in membranes with well-defined, low molecular weight cutoffs can be expected as a consequence of the renewed interest in membrane-separation techniques (83,84) (see MEMBRANE TECHNOLOGY). Membrane osmometry has been applied to a wide variety of polymers, including operation at high temperatures for polymers difficult to dissolve. Comb-like polymers have been characterized and the results compared with those from gel permeation chromatography (GPC) (85). Preliminary results of an online osmometer for GPC detection have been described (86,87). The upper limit for molecular weight determination is ca 1×10^6. The lower limit

depends on the molecular weight distribution, ie, the details of the composition of the low molecular weight tail. In most cases the concentration dependence of osmotic pressure Π must be determined and Π/c extrapolated to zero concentration by plotting Π/c vs c, or $(\Pi/c)^{1/2}$ vs c.

Viscosity-Average Molecular Weight. The viscosity of dilute polymer solutions may be related to the molecular weight of the polymer by the appropriate calibration (see Viscometry). The polymer is usually separated into narrow molecular weight distribution fractions, which are characterized by absolute molecular weight methods. The molecular weight is related to the intrinsic viscosity $[\eta]$ by the Mark–Houwink relationship (eq. 6).

The intrinsic viscosity is obtained using viscometer types of viscometer tubes and plotting the reduced or inherent viscosity of a series of polymer solutions with various concentrations against the solution concentration. Extrapolation to zero concentration yields the intrinsic viscosity. The technique has found widespread application (88–92), and compilations of Mark–Houwink constants are available (93). A novel method to determine intrinsic viscosity using a flow piezoelectric quartz crystal has been developed (94). Static and continuous measurements of intrinsic viscosity using a differential viscometer (Viscotek) have been reviewed (95). If the Mark–Houwink constants are determined using narrow molecular weight distribution materials, the average molecular weight obtained from equation 6 is the viscosity-average molecular weight $\bar{M}_v$. The range of molecular weights that may be characterized is very large. Special precautions are required for extremely high molecular weight samples to avoid degradation during the solution process or the measurement (96). Dilute solution viscometry for measurement of molecular weight, branching, and other physical parameters have been reviewed (97). A method to calculate the viscosity average molecular weight from GPC for a polymer with unknown Mark–Houwink constants has been reported (98).

Weight-Average Molecular Weight.

Light Scattering. Laser Light Scattering (qv) is a technique (99–106) widely used to characterize polymeric materials. Standardized methods are available (ASTD D4001 and GB/T 6598-86). Commercial instrumentation is available to measure the light-scattering properties of polymer solutions and the refractive index increment (107). Older instrumentation includes the Brice Phoenix Photometer, the Sofica Light Scattering Photometer, as well as the Chromatix product. Wyatt Technology and Malvern Instruments currently produce instruments. Lasers are used as light sources to measure scattering at small angles to the beam. This is important since the data obtained must be extrapolated to zero concentration and zero scattering angle using Zimm plots (108). The weight-average molecular weight is determined by this technique, and the molecular weights accessible range from a few hundred to several million. The solutions employed must be free of dust and are usually subjected to filtration or centrifugation. Solutions of high molecular weight degradable polymers are the most difficult to clarify. The solvent is selected to give a reasonable difference in refractive index with the solute. The technique has been applied to determine the molecular weight of difficultly soluble polymers such as polyethylene (109,110) and of polytetrafluoroethylene and its copolymers with ethylene (111–113). Copolymers with homogeneous distribution of monomer units in the polymer chain may be analyzed by the same methods as homopolymers. If the composition varies as a function of molecular weight, the analysis is more complicated (114). Terpolymers have also been considered (115).

True molecular weights and heterogeneity of styrene-butyl acrylate copolymers have been determined using static low angle laser light scattering (LALLS) and GPC/LALLS (116) and styrene–polydimethylsiloxane block copolymers (117) using GPC/LALLS. Multi-angle laser light scattering (MALLS) has been used as a GPC detector to characterize molecular weight, molecular size, and branching of organic and water soluble polymers (118).

Dynamic light scattering (119) has been used to determine the number average molecular weight (120) and molecular weight distribution of polymers in solution (121–123). There are several mathematical approaches to determine the molecular weight distribution from PCS data. Comparisons with GPC and numerical simulation have been made (124). The resolution of bimodal distributions has been demonstrated (125).

Pulse-induced critical scattering (126,127), although not utilized as a method for molecular weight characterization, may be a sensitive procedure for detecting small differences in molecular weight distribution.

X-ray (128) and neutron scattering (qv) (129,130) may also be used to determine weight-average molecular weights. The main drawback is the greater expense and the lack of suitable facilities.

Ultracentrifuge. The ultracentrifuge is used to determine molecular weights (131–133). Sedimentation velocity employs a sufficiently high centrifugal field so that the sedimentation rate may be measured. The sedimentation coefficient S is empirically corrected for concentration and pressure effects to give S_0, the sedimentation coefficient at zero concentration. The method also requires the measurement of the diffusion coefficient at infinite dilution D_0. The molecular weight is calculated from the Svedberg equation

$$\frac{S_0}{D_0} = \frac{M(1 - \nu\rho)}{RT}$$

where ν is the partial specific volume of the solute and ρ the density of the solution. For a polydisperse solute the correct averages for S and D are combined in the Svedberg equation to yield a well-defined average molecular weight. If D is obtained from intensity-fluctuation spectroscopy (134) and combined with the weight average S value, the weight-average molecular weight is obtained. The application of the sedimentation velocity method to calculate molecular weight distribution is extremely complex, but has been successful in special studies (135).

In the sedimentation equilibrium method, a lower centrifugal field is maintained for a period of time in such a way that sedimentation is balanced by diffusion and an equilibrium distribution of polymer is established in the cell. Although $\bar{M}_w$ and $\bar{M}_z$ are easily determined, the length of time of the experiment is a disadvantage. In contrast to light scattering, this method is not affected by dust particles, and no calibration is needed. The molecular weight distribution may be obtained from the sedimentation velocity data, but not without mathematical difficulties (136) or requiring additional data at other rotor speeds (137,138). An improved detection system for the analytical ultracentrifuge has been reported (139,140). A new 8-cell rotor that allows increased throughput of samples has been described (141).

Improved data analysis has led to the simultaneous determination of the sedimentation coefficient and diffusion coefficient, and a calculation of the molecular weight from the Svedberg equation (142). The Svedberg method is capable of determining molecular weights of up to 40×10^6 (96) on an absolute basis. Sedimentation equilibrium in a density gradient has been used to determine the compositional analysis of copolymers, eg, butadiene-styrene (143).

Munk (144) has recently reviewed the use of sedimentation velocity and sedimentation equilibrium to characterize molecular weight. A new absolute method for the determination of molecular weight distribution based on band sedimentation and LALLS has been applied to water-soluble polymers (145).

Higher Molecular Weight Averages. Classical techniques often cannot be used for higher molecular weight averages ($\bar{M}_z$, $\bar{M}_{z+1}$, etc). These are usually measured by determining the molecular weight distribution by fractionation (qv) or affinity chromatography (qv) and back-calculating the averages from the distribution.

Determination of Molecular Weight Distribution

Fractionation. Polymers may be separated on the basis of molecular weight by precipitation or phase-separation techniques (146–149). The polymer that is originally in solution separates on the basis of molecular weight when the thermodynamic quality of the solvents is changed, ie, by changing the solvent composition or temperature. The principal techniques are *fractional precipitation* and *coacervate extraction*, both solution-based (Fig. 3). The former is based on the removal of material from the polymer-rich precipitated phase and the latter on the removal of fractions from the polymer-lean solution phase. Computer simulations and experimental results have shown the coacervate extraction technique (150) to yield narrower molecular weight distribution fractions than the fractional precipitation method (151–153).

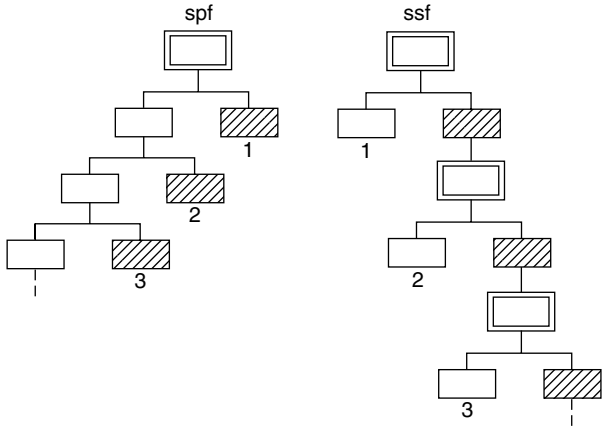

Fig. 3. Successive precipitation (SPF) and solution fractionation (SSF) (coacervate extraction): ▭, mother solution; ▭, polymer rich phase; and ▨, polymer-lean phase. Numbers denote fraction numbers (148). Courtesy of Society of Chemical Industry.

To obtain the molecular weight distribution, the fractions of known mass must be characterized by a molecular weight technique. The integral and differential molecular weight distribution may be evaluated using a method (154) that assumes no particular molecular weight distribution function for the fraction or treatments that assume a particular model for the molecular weight distribution of the fractions (155). Fractionation may also be achieved by crystallization from dilute solution (156).

In column fractionation (157,158) the polymer is precipitated onto an inert support, which is placed at the top of a packed column (159). A solvent mixture of increasing solvent power is pumped through the column; a temperature gradient is often maintained. This is known as *Baker–Williams fractionation* (160). This technique is applicable to all amorphous homopolymers and crystalline homopolymers above the melting point. For copolymers and more complex compositions, the same technique may be employed, but the analysis is considerably more difficult.

Temperature rising elution fractionation (TREF) (161,162) is a useful fractionation technique which gives information on the compositional distribution.

Chromatography. The determination of molecular weight distribution and chemical composition by chromatographic techniques has been discussed (163).

Gel Permeation (Size-Exclusion) Chromatography. GPC has been in use since the 1960s and has been a most important development in molecular weight determination (164–169). For this technique the polymer must be soluble, and calibration with suitable standards is required. The method is extremely efficient; it requires 0.5–2 h per sample and only a few milligrams of material. Standardized methods are available (GB/T 6599-86, ASTM D5296-97, and A83 ASTM D6747-99). Commercial instrumentation capable of operating up to 150°C is available from Waters and Polymer Laboratories. Detection is normally accomplished by differential refractometry, although uv and ir (170) absorption spectrometry have also been employed. The chromatographic columns are packed with spherical- or irregular-shaped porous beads. The packing may be a crosslinked polymer, a porous glass, or a silica material. The pore size distribution determines the separation range of the columns. Calibration is normally performed using well-characterized narrow MWD standards. Calibration can be performed using broad MWD materials (171). Typical calibration curves (172) are shown in Figure 4. By combining columns in series, a separation range may be achieved covering the molecular weight distribution of the sample. Mathematical treatments of the chromatogram and calibration curve to calculate the molecular weight distribution are given (173). Broadening by the chromatographic process must be calibrated for and corrections applied to produce true molecular weight distributions. *Chemimetrics* has been applied to GPC calibration equations (174) and helped to establish the best equations. Data reduction in GPC (175) has been described. A new solvent system which allows polyesters and polyamides to be characterized by GPC at room temperature has been developed (176). High speed GPC of low molecular weight polymers has been described (177).

The design and use of a continuous, viscometric detector (178,179) has further advanced the application of the GPC technique, and a commercial viscometric detector is on the market from Viscotek Corp (180,181).

Direct determination of the polymer molecular weight in the detector cell after separation by GPC is possible by LALLS. The technique (182–184) is applicable to the dilute polymer solutions emerging from the chromatographic column; commercial equipment is available, older models (Chromatix KMX6 and LSD100 from LDC/Milton Roy) and newer instruments (Wyatt and Polymer Labs). A review of prior development and a description of a methodology for correcting for dispersion in the concentration detector and the light scattering detector has been published (185). A review of GPC and the application of molecular weight detectors and related separation techniques has been published (186). The characterization of complex polymers by GPC and high performance liquid chromatography (HPLC) has been discussed (187). Quantitative high temperature GPC of polyolefins using refractive index and differential viscometer detection (188) and differential viscometer and light scattering detectors (189) has been reported. This method has been used for on-line molecular weight measurement and branching characterization of water-soluble polymers (185,190). Shear degradation during the chromatographic process may be a problem (191), but can be detected by viscometry and LALLS. A triple detector employing a concentration detector, a viscometer, and a light scattering detector is available (Viscotek). Three detectors, an evaporative light scattering detector to measure concentration, a refractometer, and LALLS, have been used to determine MWD of copolymers (EPM and EPDM) (192). LALLS has proven useful in detecting and eliminating aggregates in dilute polymer solutions which would affect the GPC results (193). Nuclear magnetic resonance,

NMR, has been employed as an on-line detector for GPC (194). Goldwasser (195) developed an analysis which allows the calculation of absolute values for $\bar{M}_n$ from the combined results from GPC and differential viscometry. Mass spectrometry has been coupled with GPC to characterize a variety of polymers (196–198). A comparison of the most probably peak value of polymer distributions has been evaluated between MALDI MS and GPC (199).

Analyses by GPC of block and statistical copolymers (200,201) and copolymers (202) and polymer mixtures (203) have been reported. Full copolymer characterization by combining GPC-NMR with GPC-MALDI has been demonstrated (204).

Other detectors that are capable of determining the polymer concentration in the effluent are based on dielectric constant (205) and density (206–213). Mass can be determined directly with a piezoelectric quartz sensor having a sensitivity of 10^{-10} g (214). A universal mass detector, evaporative light scattering Detector (ELSD) based on the formation of droplets in a nebulizer gas and detection by light scattering using a laser, has been developed and applied to GPC (215). Commercial ELSD units are available from Alltech, Varex Corp., and Polymer Laboratories.

A direct molecular weight method (216) employs the LALLS detector, but uses sedimentation velocity instead of GPC to separate the polymers.

Round robin tests for reproducibility of GPC results have been reported (217). Twenty-four laboratories used calibration standards from two different sources and three test polymers. The results for the three samples varied from 3 to 14% depending on which calibration was used. Similar results for number-average molecular weights have been documented (218). Round robin characterization of polyethylene by high temperature GPC in 15 laboratories has been documented (219).

High Performance Liquid Chromatography and Supercritical Fluid Chromatography. For lower molecular weights, HPLC and supercritical fluid chromatography (SFC) (220) offer higher resolution than GPC. Higher molecular weights may produce multiple peaks from monodisperse standards (221). The oligomers are resolved into individual peaks, and molecular weight averages are calculated (222). HPLC is more common and has been applied to phenol-formaldehyde resins (223), polyurethanes (224), polyesters (225), and polycarbonates (226). Since solvent gradients are often used in HPLC the refractometer detector cannot be used, and ultraviolet/visible spectrometers and/or ELSDs must be used. The ELSD may also be used in SFC. SFC can resolve higher oligomers than HPLC. Polystyrene oligomers of up to $n = 50$ may be resolved by SFC; the process requires 18 h (227). Several commercial SFC units are available and their availability should rapidly increase the application of this technique to characterize oligomeric species. A review of supercritical fractionation of polymers and copolymers has been published (228). Mass spectrometry has been used in conjunction with SFC and capillary GPC to characterize polypropylene glycol (229).

Liquid adsorption chromatography (LAV) and GPC have been used to determine chemical composition distribution (CCD) and MWD of styrene–methyacrylate copolymers (230).

Thin-Layer Chromatography. Thin-layer chromatography (TLC) is widely applicable to polymer characterization and has been used to characterize

molecular weight distribution and compositional distribution (231–233). Cellulose nitrate has been fractionated by this method on the basis of molecular weight or nitrogen content (234).

Mass Spectrometry. Advances in soft ionization techniques and developments in high resolution mass spectrometers has led to the possibility of determining intact molecular ions up to 1×10^6 Da and the measurement of the entire MWD (235,236). The application of mass spectrometry techniques to characterize polymer molecular weight distribution has evaluated (237–243). The MWD of polystyrene SRM 1487 and a narrow MND polymethylmethacrylate (MW 6300) determined by MALDI TOF mass spectrometry have been compared with results from the ultracentrifuge and GPC (244).

Phase-Distribution Chromatography. A chromatographic fractionation is achieved in this method (245,246), by partitioning a solute between a solvent flowing through a column, packed with a support coated with a thin layer of high molecular weight, non-cross-linked polymer. The temperature of operation is below the Θ-temperature of the solute, and separation efficiency increases sharply with decreasing temperature. A fully automated chromatograph has been designed (247), and applications have been reported (248–250).

Field–Flow Fractionation. Field-flow fractionation (FFF) employs a one-phase chromatographic system (251,252). Commercial instrumentation is available from Postnova Analytics and Tecan. Separation occurs in a thin channel containing a single moving fluid. The field applied across the channel may be selected on the basis of the solute. Possible fields include sedimentation, cross-flow, concentration, dielectric, thermal, and magnetic. A book (253) and a review (254) of this technique and its comparison with GPC for the characterization of polymer molecular weights have been published.

Thermal fields have been used for the separation of polymers in organic solvents (255). Methods for calculation of MWD from thermal FFF have been published (256). For aqueous systems a cross-flow of solvent has been used to separate polyelectrolytes (257) and high molecular weight polyacrylamides (258). Water-soluble polymers have also been characterized by this technique (259,260), in conjunction with LALLS detector (261) and MALLS (262). Extremely high molecular weights of up to 10^{12} can be determined (263); because no abrupt changes occur in the forces imposed on the polymer molecules, no degradation takes place. Sedimentation fields were investigated (264), and small samples were quickly fractionated. Compositional heterogeneity has been determined by sequential GPC and FFF (265).

Electrophoresis. Electrophoresis is widely practiced on biopolymers (266–268) for the determination of molecular weights of proteins and their subunits. Typically, a polyacrylamide bed is used to separate or characterize these solutes under the influence of an electric field, on the basis of charge and molecular size. The proteins are frequently denatured with sodium dodecyl sulfonate (SDS), and these subunit-SDS complexes are separated on the basis of molecular size. A densitometer employing a soft laser scanning device is commercially available to automate the data-reduction process (269).

Rheological Measurements. Some polymers are difficult to dissolve. Mechanical spectroscopy or rheological measurements (qv) offer a way to determine the molecular weight distribution of these materials. Mechanical spectroscopy has

been applied to characterize the MWD of polyolefins (270) Rheological data has been used to determine the MWD of polybutadiene and polypropylene (271). Measurements of ethylene–tetrafluorethylene copolymers using dynamic mechanical analysis of the melts showed broader distributions than those determined by high temperature laser light scattering (272).

Other Techniques. Atomization of polymer solutions to form single molecules deposited in a solvent-free state on a surface has been demonstrated for a wide variety of polymers (273). The electron microscope is used at 20,000–30,000 × after platinum shadowing to determine size and size distribution (274). The scanning transmission electron microscope is employed for biological macromolecules (275). For extremely high molecular weight polymers hydrodynamic chromatography (HDC) may be a viable technique. Columns are packed with solid spheres and the diameter determines the separation range. Solid particles between 5 and 300 nm may be separated. Columns are available from Polymer Laboratories, and using a high temperature infrared detector cell the composition of polyolefin copolymers can be characterized. A mathematical model for HDC and GPC for porous column packings has been published (276). Methods to characterize insoluble polymers have been discussed (277,278).

MOLECULAR WEIGHT DETERMINATION

Introduction

This article discusses the theory and methods for the determination of molecular weight averages and molecular weight distributions of oligomeric and polymeric materials. The more important methods are described in greater detail in separate articles (see CHROMATOGRAPHY, SIZE EXCLUSION; FRACTIONATION; CHARACTERIZATION OF POLYMERS).

Molecular Weight Averages and Distributions

Most polymeric materials are comprised of mixtures of molecules of various sizes. This distribution of molecular weights is a result of the statistical nature of the polymerization proces (1). A complete description of the molecular weight distribution of a homopolymer is necessary to understand its physical, rheological, and mechanical properties. Structural variations, such as chain branching, and copolymer or higher mer polymers with various degrees of structural randomness further complicate a complete description of the molecular ensemble. Copolymers and higher mer polymers also need to be characterized for molecular composition as a function of molecular weight. Block copolymers and polymer mixtures also offer significant challenges to evaluate their molecular weight distribution. Failure mechanisms and practical lifetimes of polymeric materials may also be established through molecular weight measurements.

Most classical techniques for molecular weight determination are only capable of yielding one of the molecular weight averages of the distribution. These traditional methods are used nowadays only on a limited basis, and only a limited number of commercial instrumentation is available.

These averages are defined in terms of the molecular weight M_i and the number of moles n_i or the weight w_i of the component molecules. The molecular weight averages are defined by equations 1-4.

Number-average molecular weight:

$$\bar{M}_{\mathrm{n}} = \frac{\sum n_i M_i}{\sum n_i} = \frac{\sum w_i}{\sum w_i / M_i} \tag{1}$$

Weight-average molecular weight:

$$\bar{M}_{\mathrm{w}} = \frac{\sum n_i M_i^{\,2}}{\sum n_i M_i} = \frac{\sum w_i M_i}{\sum w_i} \tag{2}$$

z-Average molecular weight:

$$\bar{M}_z = \frac{\sum n_i M_i^{\,3}}{\sum n_i M_i^{\,2}} = \frac{\sum w_i M_i^{\,2}}{\sum w_i M_i} \tag{3}$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

$(z + 1)$-*Average molecular weight*:

$$\bar{M}_{z+1} = \frac{\sum n_i M_i^4}{\sum n_i M_i^3} = \frac{\sum w_i M_i^3}{\sum w_i M_i^2} \tag{4}$$

Viscosity-average molecular weight:

$$\bar{M}_{\mathrm{v}} = \left[\frac{\sum n_i M_i^{1+a}}{\sum n_i M_i} \right]^{1/a} = \left[\frac{\sum w_i M_i^a}{\sum w_i} \right]^{1/a} \tag{5}$$

Equation 5 is an important practical molecular weight average derived from viscometry. To calculate this average, the exponent a and the constant K of the Mark–Houwink relationship relating intrinsic viscosity $[\eta]$ to molecular weight must be known.

$$[\eta] = KM^a \tag{6}$$

The value of a lies between 0.5 and 1.0 for random coils, depending on the solvent employed to determine the relationship of the intrinsic viscosity to molecular weight. For rigid rod molecules, the value of a is expected to be ~1.8. With these limits for a, it may be seen that $\bar{M}_{\mathrm{v}}$ is always larger than $\bar{M}_{\mathrm{n}}$ but can equal $\bar{M}_{\mathrm{w}}$ when the upper limit of a is reached for random coils.

If molecular weight is considered a continuous variable, the molecular weight distribution may be described by a set of moments μ_r given by the integrals

$$\mu_r = \int_0^x M^r f(M)\, \mathrm{d}M$$

where r = 0, 1, 2, 3, etc; $f(M)$ is the number-density distribution; and $f(M)dM$ is the number of moles of molecules with molecular weight between M and $(M + dM)$.

The average molecular weights are defined as

$$\bar{M}_{\mathrm{n}} = \frac{\mu_1}{\mu_0}$$
$$\bar{M}_{\mathrm{w}} = \frac{\mu_2}{\mu_1}$$
$$\bar{M}_z = \frac{\mu_3}{\mu_2}$$
$$\bar{M}_{z+1} = \frac{\mu_4}{\mu_3}$$

Molecular weight averages can be determined from these moments (2).

Molecular Weight Distribution Functions

Various mathematical functions have been employed to describe the distribution of molecular weights. Some of the more common functions are shown in Table 1 in terms of the mole fraction X. Further details are available (3).

Width of Molecular Weight Distributions. The width of the Gaussian distribution function may be expressed in terms of the standard deviation of the mole fraction MWD function σ_n or the mass fraction MWD function σ_w:

$$\sigma_n = (\bar{M}_w \bar{M}_n - \bar{M}_n)^{0.5}$$
$$\sigma_w = (\bar{M}_z \bar{M}_w - \bar{M}_w)^{0.5}$$

The standard deviation is an absolute measure of the width for the Gaussian function only. Widths of molecular weight distribution for other functions have to be calculated for each case from the distribution function itself.

The relationships between molecular weight averages and parameters in the molecular weight distribution functions are as follows:
which leads to

$$\exp(\sigma_w)^2 = \frac{\bar{M}_w}{\bar{M}_n} = \frac{\bar{M}_z}{\bar{M}_w}$$

Thus the ratios of two adjacent averages are constant.

Poisson distribution function.

The ratio of the weight-average to number average molecular weight is given by

$$\frac{\bar{M}_w}{\bar{M}_n} = 1 + \left(\frac{1}{\bar{M}_n}\right) - \left(\frac{1}{\bar{M}_n}\right)^2$$

Table 1. Molecular Weight Distribution Functions

Name	Function	Comments
Gaussian	$X(M) = \frac{1}{\sigma_n (2\pi)^{1/2}} \exp\left[\frac{(M - M_m)^2}{2\sigma_n^2}\right]$	M_m = median value equal to $\bar{M}_n$
Log-normal	$X(M) = \frac{1}{\sigma_n (2\pi)^{1/2}} \exp\left[\frac{(\ln M - \ln M_m)^2}{2\sigma_n^2}\right]$	M_m = geometric mean
Poisson[a]	$X(M) = \frac{\nu^{M-1}}{\Gamma(M)} \exp(-\nu)$	$\nu = \bar{M}_n - 1$
Flory–Schulz[b]	$X(M) = \frac{\beta^{k+1} M^{k-1} \bar{M}_n}{\Gamma(k+1)} \exp(-\beta M)$	k = degree of coupling $\beta = \frac{k}{\bar{M}_n}$

[a] $\Gamma(M) = \gamma$-function.
[b] $\Gamma(k+1) = \gamma$-function.

Gaussian distribution function
mole-fraction distribution function median value $= \bar{M}_n$
mass-fraction distribution function median value $= \bar{M}_w$

Log-normal distribution function
mass-fraction distribution function median value $= M_m$

$$\bar{M}_n = M_m \exp[(\sigma_w)^2/2]$$

$$\bar{M}_w = M_m \exp[3(\sigma_w)^2/2]$$

$$\bar{M}_z = M_m \exp[5(\sigma_w)^2/2]$$

and therefore depends only on $\bar{M}_n$.

Flory–Schulz distribution function
The molecular weight averages this function are related by

$$\frac{\bar{M}_n}{k} = \frac{\bar{M}_w}{k+1} = \frac{\bar{M}_z}{k+2}$$

where k is the coupling constant, defined as the number of independently growing chains required to form one dead chain.

Polydispersity
Traditionally, polydispersity Q has been defined as

$$Q = \bar{M}_w/\bar{M}_n = U + 1$$

where U, the molecular inhomogeneity, has a numerical value of one less than Q. The width of molecular weight distributions increases with increasing Q and U. Except for the Gaussian distribution function, the standard deviation is only a relative measure of distribution width (4,5).

Determination of Molecular Weight

Several books have been published since this article was last written (6–9).

Number-Average Molecular Weight.

End-Group Analysis. In end-group analysis the concentration of an end group is measured by a suitable technique, and then, from the known structure of the polymer, the value for $\bar{M}_n$ may be calculated (10–15). In condensation polymers one end of the polymer should have a specific group that can be titrated by appropriate means. Polyesters (13), polyamides (13), and polyurethanes (16) have been subjected to this analysis. Polyethers have been analyzed by hydroxyl-group titrations similar to those used for polyesters or by reaction with excess phenyl isocyanate followed by reaction with excess di-*n*-butylamine; the latter was back-titrated with perchloric acid (17). Nonaqueous titrations (18) have been used to

characterize polysulfones with $\bar{M}_n$ values of up to 25,000. Potentiometric titration in aqueous and nonaqueous media have been used to determine molecular weights of acrylamide and acrylonitrile polymers (19). Spectrophotometric analyses have also been widely utilized (14), notably uv–visible, infrared techniques, and NMR (20). Examples include the determination of phenolic end groups in polymers by uv spectroscopy (21) and potentiometric titration (18). Infrared spectroscopy has been used (22) to estimate carboxyl groups in the presence of carbonyl groups by reaction of the former with SF_4; the resulting thionyl halides were quantitatively measured. NMR spectroscopy (^1H) has been used to characterize $\bar{M}_n$ of hydroxyl end-capped polystyrenes (A. D. Edwards and M. J. R. Loadman, Malaysian Rubber Producers Research Association, unpublished data, 1976). Reaction of the single proton on the hydroxyl group yields a trimethylsilyl group containing nine protons. The enhanced sensitivity allows determination of $\bar{M}_n$ values of up to 80,000. A similar method has been reported for hydroxy-terminated polybutadienes (23), polyester polyurethanes (24), epoxides (25), and other polymers (26–28). Acid end groups in polyethylene terephthalate have been characterized (29) by reaction with hexafluoroisopropanol and ^{19}F NMR.

In certain cases extremely high sensitivity may be attained with radioactive labeling (30). Using radiolabeled (^{35}S) bisulfite initiator, the number-average molecular weight of Teflon samples was determined in the range of 389,000–8,900,000 (31). This is a particularly useful technique for insoluble polymers.

Measurement of Colligative Properties. Colligative properties are those that depend on the number of species present rather than on their kind (32,33). From thermodynamic arguments it may be shown that for very dilute ideal solutions

$$\ln a_1 = -X_2$$

where a_1 is the activity of the solvent and X_2 is the mole fraction of solute. From this relationship the solute molecular weight may be calculated if the weight fraction w_2 is known.

$$x_2 = \frac{n_2}{n_1} = \frac{w_2 M_1}{M_2 w_1}$$

This equation demonstrates that the activity, measurable by several methods, is proportional to the number of solute molecules. Thus in the case of polydisperse solutes, the number-average molecular weight is the average determined. At higher concentrations and molecular weights, the solutions become nonideal, and higher powers of the solute concentration are introduced into the equations. Measurements of several solute concentrations are required, and appropriate extrapolation techniques must be used.

Lowering of Vapor Pressure. The partial vapor pressure p_1 of solvent 1 over a solution is lower than the vapor pressure over the pure solvent $p_1{}^0$. This is expressed by Raoult's law:

$$P_1 = X_1 p_1{}^0$$

where X_1 is the mole fraction of the solvent.

For a binary solution containing a mole fraction X_2 of solute then,

$$X_2 = \frac{p_1^0 - p_1}{p_1^0} = \frac{\Delta p_1}{p_1^0} \tag{7}$$

For a dilute solution,

$$X_2 = \frac{n_2}{n_1} = \frac{w_2 M_1}{M_2 w_1} \tag{8}$$

Combining equations 7 and 8 yields

$$M_2 = w_2 \frac{M_1}{w_1} \frac{p_1^0}{\Delta p_1}$$

The unknown molecular weight of solute M_2 may be calculated from the lowering of the vapor pressure caused by the addition of w_2 grams of solute to form a binary solution; $\bar{M}_n$ values of up to 1000 may be determined (34–37).

A variation of this technique, the isopiestic method (38–40), was devised to avoid the difficulty of accurately determining the small difference in vapor pressure caused by the addition of solute. In this method (41) two limbs of a container joined by a common vapor space are filled, one with a reference solution of known weight concentration w_s and molecular weight M_s and the other with the unknown solution of known weight concentration w_2 and unknown molar concentration. The apparatus is immersed in a constant-temperature bath controlled to $\pm 0.001^\circ$C; the absolute temperature is not important. Distillation of the solvent continues until the vapor pressures above the solutions in each limb are equal, and thus the solutions contain equal mole fractions of solute. At equilibrium, which may require several weeks, the final volumes V_s, and V_2 of the known and unknown solutions are read from the calibrations on each limb.

$$\bar{M}_n = \frac{w_2 M_s V_s}{V_2 w_s}$$

$\bar{M}_n$values of up to 20,000 have been determined by this method.

Ebulliometry. Ebulliometry (34,42–47) is another technique for determining the depression of the solvent activity by the solute. In this case the elevation of the boiling point is determined. The boiling-point elevation ΔT_b is measured with sensitive thermocouples or matched thermistors in a Wheatstone bridge. The molecular weight $\bar{M}_n$ is calculated from

$$\bar{M}_n = \frac{K_b c}{\Delta T_b}$$

where c is the concentration of solute in g/1000 g of solvent and

$$K_b = \frac{R T_b^2 M}{1000\ \Delta H_v} \tag{9}$$

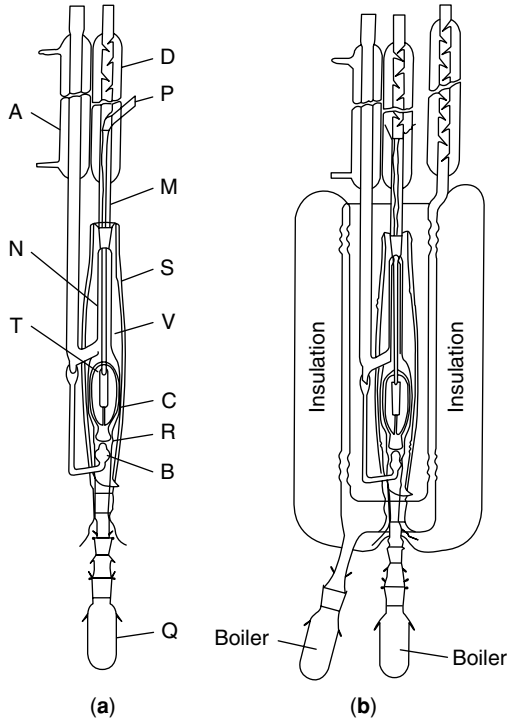

Fig. 1. (**a**) Ebulliometer design for molecular weight determination of up to $\bar{M}_n = 100{,}000$. is the molal ebullioscopic constant. M is the molecular weight of the solvent and T_b its boiling point; ΔH_v is the molar latent heat of vaporization of the solvent.

The ebullioscopic constant may be evaluated directly from equation 9 and thus provides an absolute method. However, the value for K_b is often determined by using a high purity solute of known molecular weight.

Currently, a sensitivity of 1×10^{-5}°C or 2.4×10^{-6}°C is attainable using a 160-junction thermocouple (48) or thermistors (49), respectively. The upper limit of molecular weight, which may be determined by this method, also depends on the solvent and solution nonideality. With careful measurements and good ebulliometer design, $\bar{M}_n$ values of up to 100,000 may be determined on isotactic polypropylene (50). The apparatus employed is shown in Figure 1. This technique has been applied to aqueous solutions (51). An ebulliometer of simple design having a temperature sensitivity of 50×10^{-6}°C has recently been reported (52). A rotating ebulliometer attempts to overcome the superheating problem (53). Errors in the methods for treating ebullioscopic data to obtain molecular weight have been discussed (54).

Cryoscopy. The freezing point of a solution is depressed below that of the pure solvent by an amount proportional to the mole fraction of solute. The value

for $\bar{M}_n$ is obtained from

$$\bar{M}_n = \frac{K_f c}{\Delta T_b}$$

where c is the concentration of solute in g/1000 g of solvent and

$$K_f = \frac{RT_m^2 M}{1000\ \Delta H_{fus}}$$

is the molal cryoscopic constant; M is the molecular weight of the solvent and T_m its melting point; ΔH_{fus} is the molar latent heat of fusion of the solvent.

Some materials, such as camphor, have very large cryoscopic constants and may be used to increase the sensitivity of the method. The method is used to determine $\bar{M}_n$ of polymers (55–59), such as polyesters (60) and ethylene-vinyl acetate copolymers (61).

A novel variation of this technique (62) involves depression of the first-order, nematic–isotropic melting transition of *N*-(*p*-ethoxybenzylidene)-*p*-*n*-butylaniline. Polystyrene and poly(ethylene oxide) are soluble in both phases, and $\bar{M}_n$ values of up to 10^6 have been studied.

Vapor-Pressure Osmometry. When a drop of solution is exposed to pure solvent vapor, the solvent vapor condenses onto the droplet, because the solute lowers the vapor pressure of the drop (63–68). The heat of condensation causes the temperature of the drop to rise, until theoretically the solution vapor pressure is increased to equal that of the solvent. In practice this does not occur, but a state of equilibrium is reached, where the heat losses from the droplet are matched by the heat of condensation (GB/T 6579-86). The temperature increase is proportional to the number of moles of solute present. A standardized method is available (H. Knauer, Berlin, unpublished data).

The design of a commercial instrument is given in Figure 2 (H. Knauer, Berlin, unpublished data). The temperature stability needed is 0.001°C. In another design, by Wescan Instruments, Inc., small platinum mesh screens ensure that a constant amount of solvent or solution is present on the thermistor. The resistance value ΔR, which is proportional to the temperature difference, is measured with a bridge circuit in all instruments. A calibration curve of ΔR vs molality m is determined by employing a solute of known molecular weight. After several minutes ΔR reaches a constant value; the calibration curve is often highly linear, but may not go through the zero point (66).

$$\Delta R = a + bm$$

The number-average molecular weight of the unknown sample may then be calculated from equation 10:

$$\bar{M}_n = \frac{bc}{\Delta R - a} \tag{10}$$

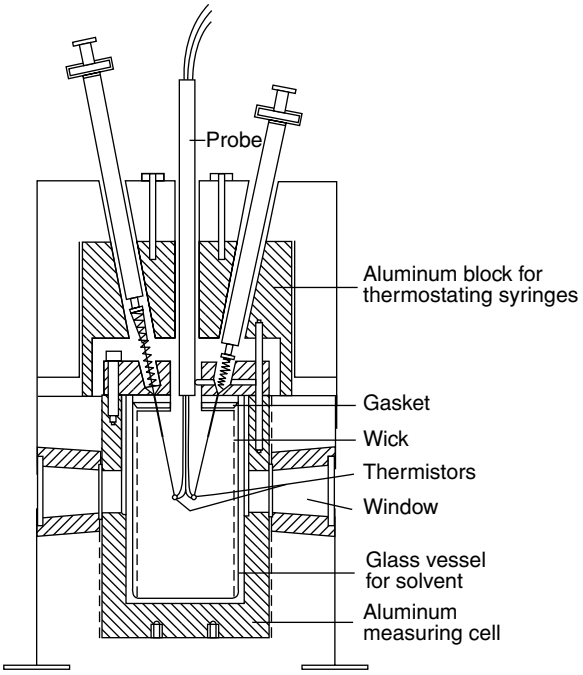

Fig. 2. Vapor-pressure osmometer apparatus (H. Knauer, Berlin, unpublished data, 1987). Courtesy of Dr. -Ing. Herbert Knauer GmbH.

where c is the concentration of solute in g/1000 g of solvent. In older osmometers the calibration curve depended on the material used to perform the calibration. For the Wescan instrument and another research vapor-pressure osmometer (69), both based on the same design (70), the calibration constant was independent of the material. These instruments have determined polystyrene $\bar{M}_n$ values of 400,000 (71), 100,000 (72), and 100,000 (69); polyolefins have been characterized at 140°C (73) and styrene/methylmethacrylate copolymers (32). For higher molecular weight solutes, the virial coefficients become important. In this case $\Delta R/c$ must be plotted against c in order to extrapolate the $\Delta R/c$ value to infinite dilution. When the plot is not linear, it is necessary to plot $(\Delta R/c)^{1/2}$ vs c to obtain a linear extrapolation to infinite dilution.

Membrane Osmometry. Membrane osmometry is a well-established technique (68,74–81). Commercial instrumentation is available (Gonotec GmbH, Knauer). A standardized method is available (GB/T 6596-86). The main problem is membrane permeation by lower molecular weight species (82). Improvements in membranes with well-defined, low molecular weight cutoffs can be expected as a consequence of the renewed interest in membrane-separation techniques (83,84) (see MEMBRANE TECHNOLOGY). Membrane osmometry has been applied to a wide variety of polymers, including operation at high temperatures for polymers difficult to dissolve. Comb-like polymers have been characterized and the results compared with those from gel permeation chromatography (GPC) (85). Preliminary results of an online osmometer for GPC detection have been described (86,87). The upper limit for molecular weight determination is ca 1×10^6. The lower limit

depends on the molecular weight distribution, ie, the details of the composition of the low molecular weight tail. In most cases the concentration dependence of osmotic pressure Π must be determined and Π/c extrapolated to zero concentration by plotting Π/c vs c, or $(\Pi/c)^{1/2}$ vs c.

Viscosity-Average Molecular Weight. The viscosity of dilute polymer solutions may be related to the molecular weight of the polymer by the appropriate calibration (see Viscometry). The polymer is usually separated into narrow molecular weight distribution fractions, which are characterized by absolute molecular weight methods. The molecular weight is related to the intrinsic viscosity $[\eta]$ by the Mark–Houwink relationship (eq. 6).

The intrinsic viscosity is obtained using viscometer types of viscometer tubes and plotting the reduced or inherent viscosity of a series of polymer solutions with various concentrations against the solution concentration. Extrapolation to zero concentration yields the intrinsic viscosity. The technique has found widespread application (88–92), and compilations of Mark–Houwink constants are available (93). A novel method to determine intrinsic viscosity using a flow piezoelectric quartz crystal has been developed (94). Static and continuous measurements of intrinsic viscosity using a differential viscometer (Viscotek) have been reviewed (95). If the Mark–Houwink constants are determined using narrow molecular weight distribution materials, the average molecular weight obtained from equation 6 is the viscosity-average molecular weight $\bar{M}_v$. The range of molecular weights that may be characterized is very large. Special precautions are required for extremely high molecular weight samples to avoid degradation during the solution process or the measurement (96). Dilute solution viscometry for measurement of molecular weight, branching, and other physical parameters have been reviewed (97). A method to calculate the viscosity average molecular weight from GPC for a polymer with unknown Mark–Houwink constants has been reported (98).

Weight-Average Molecular Weight.

Light Scattering. Laser Light Scattering (qv) is a technique (99–106) widely used to characterize polymeric materials. Standardized methods are available (ASTD D4001 and GB/T 6598-86). Commercial instrumentation is available to measure the light-scattering properties of polymer solutions and the refractive index increment (107). Older instrumentation includes the Brice Phoenix Photometer, the Sofica Light Scattering Photometer, as well as the Chromatix product. Wyatt Technology and Malvern Instruments currently produce instruments. Lasers are used as light sources to measure scattering at small angles to the beam. This is important since the data obtained must be extrapolated to zero concentration and zero scattering angle using Zimm plots (108). The weight-average molecular weight is determined by this technique, and the molecular weights accessible range from a few hundred to several million. The solutions employed must be free of dust and are usually subjected to filtration or centrifugation. Solutions of high molecular weight degradable polymers are the most difficult to clarify. The solvent is selected to give a reasonable difference in refractive index with the solute. The technique has been applied to determine the molecular weight of difficultly soluble polymers such as polyethylene (109,110) and of polytetrafluoroethylene and its copolymers with ethylene (111–113). Copolymers with homogeneous distribution of monomer units in the polymer chain may be analyzed by the same methods as homopolymers. If the composition varies as a function of molecular weight, the analysis is more complicated (114). Terpolymers have also been considered (115).

True molecular weights and heterogeneity of styrene-butyl acrylate copolymers have been determined using static low angle laser light scattering (LALLS) and GPC/LALLS (116) and styrene–polydimethylsiloxane block copolymers (117) using GPC/LALLS. Multi-angle laser light scattering (MALLS) has been used as a GPC detector to characterize molecular weight, molecular size, and branching of organic and water soluble polymers (118).

Dynamic light scattering (119) has been used to determine the number average molecular weight (120) and molecular weight distribution of polymers in solution (121–123). There are several mathematical approaches to determine the molecular weight distribution from PCS data. Comparisons with GPC and numerical simulation have been made (124). The resolution of bimodal distributions has been demonstrated (125).

Pulse-induced critical scattering (126,127), although not utilized as a method for molecular weight characterization, may be a sensitive procedure for detecting small differences in molecular weight distribution.

X-ray (128) and neutron scattering (qv) (129,130) may also be used to determine weight-average molecular weights. The main drawback is the greater expense and the lack of suitable facilities.

Ultracentrifuge. The ultracentrifuge is used to determine molecular weights (131–133). Sedimentation velocity employs a sufficiently high centrifugal field so that the sedimentation rate may be measured. The sedimentation coefficient S is empirically corrected for concentration and pressure effects to give S_0, the sedimentation coefficient at zero concentration. The method also requires the measurement of the diffusion coefficient at infinite dilution D_0. The molecular weight is calculated from the Svedberg equation

$$\frac{S_0}{D_0} = \frac{M(1 - \nu\rho)}{RT}$$

where ν is the partial specific volume of the solute and ρ the density of the solution. For a polydisperse solute the correct averages for S and D are combined in the Svedberg equation to yield a well-defined average molecular weight. If D is obtained from intensity-fluctuation spectroscopy (134) and combined with the weight average S value, the weight-average molecular weight is obtained. The application of the sedimentation velocity method to calculate molecular weight distribution is extremely complex, but has been successful in special studies (135).

In the sedimentation equilibrium method, a lower centrifugal field is maintained for a period of time in such a way that sedimentation is balanced by diffusion and an equilibrium distribution of polymer is established in the cell. Although $\bar{M}_w$ and $\bar{M}_z$ are easily determined, the length of time of the experiment is a disadvantage. In contrast to light scattering, this method is not affected by dust particles, and no calibration is needed. The molecular weight distribution may be obtained from the sedimentation velocity data, but not without mathematical difficulties (136) or requiring additional data at other rotor speeds (137,138). An improved detection system for the analytical ultracentrifuge has been reported (139,140). A new 8-cell rotor that allows increased throughput of samples has been described (141).

Improved data analysis has led to the simultaneous determination of the sedimentation coefficient and diffusion coefficient, and a calculation of the molecular weight from the Svedberg equation (142). The Svedberg method is capable of determining molecular weights of up to 40×10^6 (96) on an absolute basis. Sedimentation equilibrium in a density gradient has been used to determine the compositional analysis of copolymers, eg, butadiene-styrene (143).

Munk (144) has recently reviewed the use of sedimentation velocity and sedimentation equilibrium to characterize molecular weight. A new absolute method for the determination of molecular weight distribution based on band sedimentation and LALLS has been applied to water-soluble polymers (145).

Higher Molecular Weight Averages. Classical techniques often cannot be used for higher molecular weight averages ($\bar{M}_z$, $\bar{M}_{z+1}$, etc). These are usually measured by determining the molecular weight distribution by fractionation (qv) or affinity chromatography (qv) and back-calculating the averages from the distribution.

Determination of Molecular Weight Distribution

Fractionation. Polymers may be separated on the basis of molecular weight by precipitation or phase-separation techniques (146–149). The polymer that is originally in solution separates on the basis of molecular weight when the thermodynamic quality of the solvents is changed, ie, by changing the solvent composition or temperature. The principal techniques are *fractional precipitation* and *coacervate extraction*, both solution-based (Fig. 3). The former is based on the removal of material from the polymer-rich precipitated phase and the latter on the removal of fractions from the polymer-lean solution phase. Computer simulations and experimental results have shown the coacervate extraction technique (150) to yield narrower molecular weight distribution fractions than the fractional precipitation method (151–153).

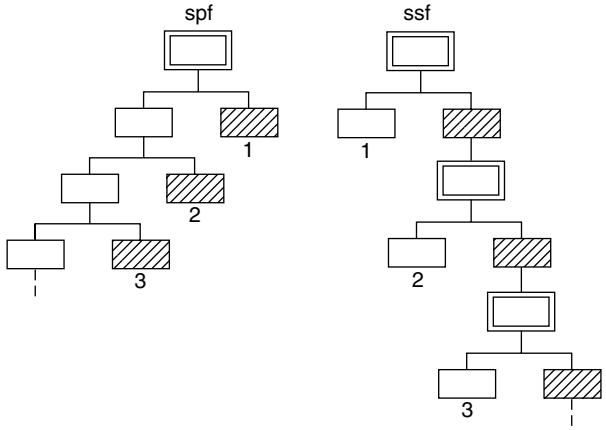

Fig. 3. Successive precipitation (SPF) and solution fractionation (SSF) (coacervate extraction): ▭, mother solution; ▭, polymer rich phase; and ▨, polymer-lean phase. Numbers denote fraction numbers (148). Courtesy of Society of Chemical Industry.

To obtain the molecular weight distribution, the fractions of known mass must be characterized by a molecular weight technique. The integral and differential molecular weight distribution may be evaluated using a method (154) that assumes no particular molecular weight distribution function for the fraction or treatments that assume a particular model for the molecular weight distribution of the fractions (155). Fractionation may also be achieved by crystallization from dilute solution (156).

In column fractionation (157,158) the polymer is precipitated onto an inert support, which is placed at the top of a packed column (159). A solvent mixture of increasing solvent power is pumped through the column; a temperature gradient is often maintained. This is known as *Baker–Williams fractionation* (160). This technique is applicable to all amorphous homopolymers and crystalline homopolymers above the melting point. For copolymers and more complex compositions, the same technique may be employed, but the analysis is considerably more difficult.

Temperature rising elution fractionation (TREF) (161,162) is a useful fractionation technique which gives information on the compositional distribution.

Chromatography. The determination of molecular weight distribution and chemical composition by chromatographic techniques has been discussed (163).

Gel Permeation (Size-Exclusion) Chromatography. GPC has been in use since the 1960s and has been a most important development in molecular weight determination (164–169). For this technique the polymer must be soluble, and calibration with suitable standards is required. The method is extremely efficient; it requires 0.5–2 h per sample and only a few milligrams of material. Standardized methods are available (GB/T 6599-86, ASTM D5296-97, and A83 ASTM D6747-99). Commercial instrumentation capable of operating up to 150°C is available from Waters and Polymer Laboratories. Detection is normally accomplished by differential refractometry, although uv and ir (170) absorption spectrometry have also been employed. The chromatographic columns are packed with spherical- or irregular-shaped porous beads. The packing may be a crosslinked polymer, a porous glass, or a silica material. The pore size distribution determines the separation range of the columns. Calibration is normally performed using well-characterized narrow MWD standards. Calibration can be performed using broad MWD materials (171). Typical calibration curves (172) are shown in Figure 4. By combining columns in series, a separation range may be achieved covering the molecular weight distribution of the sample. Mathematical treatments of the chromatogram and calibration curve to calculate the molecular weight distribution are given (173). Broadening by the chromatographic process must be calibrated for and corrections applied to produce true molecular weight distributions. *Chemimetrics* has been applied to GPC calibration equations (174) and helped to establish the best equations. Data reduction in GPC (175) has been described. A new solvent system which allows polyesters and polyamides to be characterized by GPC at room temperature has been developed (176). High speed GPC of low molecular weight polymers has been described (177).

The design and use of a continuous, viscometric detector (178,179) has further advanced the application of the GPC technique, and a commercial viscometric detector is on the market from Viscotek Corp (180,181).

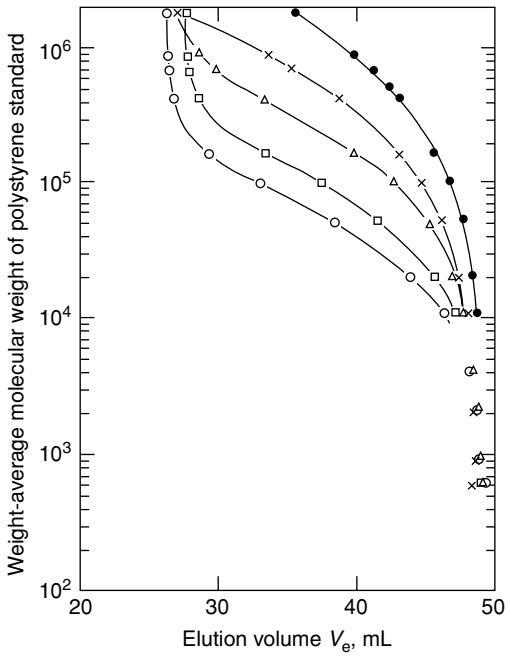

Fig. 4. GPC calibration curve for Corning porous glasses with various pore sizes: ○, CPG 10–240; □, CPG 10–370; ×, CPG 10–1250; and ●, CPG 10–2000 (172). Courtesy of John Wiley & Sons, Inc.

Direct determination of the polymer molecular weight in the detector cell after separation by GPC is possible by LALLS. The technique (182–184) is applicable to the dilute polymer solutions emerging from the chromatographic column; commercial equipment is available, older models (Chromatix KMX6 and LSD100 from LDC/Milton Roy) and newer instruments (Wyatt and Polymer Labs). A review of prior development and a description of a methodology for correcting for dispersion in the concentration detector and the light scattering detector has been published (185). A review of GPC and the application of molecular weight detectors and related separation techniques has been published (186). The characterization of complex polymers by GPC and high performance liquid chromatography (HPLC) has been discussed (187). Quantitative high temperature GPC of polyolefins using refractive index and differential viscometer detection (188) and differential viscometer and light scattering detectors (189) has been reported. This method has been used for on-line molecular weight measurement and branching characterization of water-soluble polymers (185,190). Shear degradation during the chromatographic process may be a problem (191), but can be detected by viscometry and LALLS. A triple detector employing a concentration detector, a viscometer, and a light scattering detector is available (Viscotek). Three detectors, an evaporative light scattering detector to measure concentration, a refractometer, and LALLS, have been used to determine MWD of copolymers (EPM and EPDM) (192). LALLS has proven useful in detecting and eliminating aggregates in dilute polymer solutions which would affect the GPC results (193). Nuclear magnetic resonance,

NMR, has been employed as an on-line detector for GPC (194). Goldwasser (195) developed an analysis which allows the calculation of absolute values for $\bar{M}_n$ from the combined results from GPC and differential viscometry. Mass spectrometry has been coupled with GPC to characterize a variety of polymers (196–198). A comparison of the most probably peak value of polymer distributions has been evaluated between MALDI MS and GPC (199).

Analyses by GPC of block and statistical copolymers (200,201) and copolymers (202) and polymer mixtures (203) have been reported. Full copolymer characterization by combining GPC-NMR with GPC-MALDI has been demonstrated (204).

Other detectors that are capable of determining the polymer concentration in the effluent are based on dielectric constant (205) and density (206–213). Mass can be determined directly with a piezoelectric quartz sensor having a sensitivity of 10^{-10} g (214). A universal mass detector, evaporative light scattering Detector (ELSD) based on the formation of droplets in a nebulizer gas and detection by light scattering using a laser, has been developed and applied to GPC (215). Commercial ELSD units are available from Alltech, Varex Corp., and Polymer Laboratories.

A direct molecular weight method (216) employs the LALLS detector, but uses sedimentation velocity instead of GPC to separate the polymers.

Round robin tests for reproducibility of GPC results have been reported (217). Twenty-four laboratories used calibration standards from two different sources and three test polymers. The results for the three samples varied from 3 to 14% depending on which calibration was used. Similar results for number-average molecular weights have been documented (218). Round robin characterization of polyethylene by high temperature GPC in 15 laboratories has been documented (219).

High Performance Liquid Chromatography and Supercritical Fluid Chromatography. For lower molecular weights, HPLC and supercritical fluid chromatography (SFC) (220) offer higher resolution than GPC. Higher molecular weights may produce multiple peaks from monodisperse standards (221). The oligomers are resolved into individual peaks, and molecular weight averages are calculated (222). HPLC is more common and has been applied to phenol-formaldehyde resins (223), polyurethanes (224), polyesters (225), and polycarbonates (226). Since solvent gradients are often used in HPLC the refractometer detector cannot be used, and ultraviolet/visible spectrometers and/or ELSDs must be used. The ELSD may also be used in SFC. SFC can resolve higher oligomers than HPLC. Polystyrene oligomers of up to $n = 50$ may be resolved by SFC; the process requires 18 h (227). Several commercial SFC units are available and their availability should rapidly increase the application of this technique to characterize oligomeric species. A review of supercritical fractionation of polymers and copolymers has been published (228). Mass spectrometry has been used in conjunction with SFC and capillary GPC to characterize polypropylene glycol (229).

Liquid adsorption chromatography (LAV) and GPC have been used to determine chemical composition distribution (CCD) and MWD of styrene–methyacrylate copolymers (230).

Thin-Layer Chromatography. Thin-layer chromatography (TLC) is widely applicable to polymer characterization and has been used to characterize

molecular weight distribution and compositional distribution (231–233). Cellulose nitrate has been fractionated by this method on the basis of molecular weight or nitrogen content (234).

Mass Spectrometry. Advances in soft ionization techniques and developments in high resolution mass spectrometers has led to the possibility of determining intact molecular ions up to 1×10^6 Da and the measurement of the entire MWD (235,236). The application of mass spectrometry techniques to characterize polymer molecular weight distribution has evaluated (237–243). The MWD of polystyrene SRM 1487 and a narrow MND polymethylmethacrylate (MW 6300) determined by MALDI TOF mass spectrometry have been compared with results from the ultracentrifuge and GPC (244).

Phase-Distribution Chromatography. A chromatographic fractionation is achieved in this method (245,246), by partitioning a solute between a solvent flowing through a column, packed with a support coated with a thin layer of high molecular weight, non-cross-linked polymer. The temperature of operation is below the Θ-temperature of the solute, and separation efficiency increases sharply with decreasing temperature. A fully automated chromatograph has been designed (247), and applications have been reported (248–250).

Field–Flow Fractionation. Field-flow fractionation (FFF) employs a one-phase chromatographic system (251,252). Commercial instrumentation is available from Postnova Analytics and Tecan. Separation occurs in a thin channel containing a single moving fluid. The field applied across the channel may be selected on the basis of the solute. Possible fields include sedimentation, cross-flow, concentration, dielectric, thermal, and magnetic. A book (253) and a review (254) of this technique and its comparison with GPC for the characterization of polymer molecular weights have been published.

Thermal fields have been used for the separation of polymers in organic solvents (255). Methods for calculation of MWD from thermal FFF have been published (256). For aqueous systems a cross-flow of solvent has been used to separate polyelectrolytes (257) and high molecular weight polyacrylamides (258). Water-soluble polymers have also been characterized by this technique (259,260), in conjunction with LALLS detector (261) and MALLS (262). Extremely high molecular weights of up to 10^{12} can be determined (263); because no abrupt changes occur in the forces imposed on the polymer molecules, no degradation takes place. Sedimentation fields were investigated (264), and small samples were quickly fractionated. Compositional heterogeneity has been determined by sequential GPC and FFF (265).

Electrophoresis. Electrophoresis is widely practiced on biopolymers (266–268) for the determination of molecular weights of proteins and their subunits. Typically, a polyacrylamide bed is used to separate or characterize these solutes under the influence of an electric field, on the basis of charge and molecular size. The proteins are frequently denatured with sodium dodecyl sulfonate (SDS), and these subunit-SDS complexes are separated on the basis of molecular size. A densitometer employing a soft laser scanning device is commercially available to automate the data-reduction process (269).

Rheological Measurements. Some polymers are difficult to dissolve. Mechanical spectroscopy or rheological measurements (qv) offer a way to determine the molecular weight distribution of these materials. Mechanical spectroscopy has

been applied to characterize the MWD of polyolefins (270) Rheological data has been used to determine the MWD of polybutadiene and polypropylene (271). Measurements of ethylene–tetrafluorethylene copolymers using dynamic mechanical analysis of the melts showed broader distributions than those determined by high temperature laser light scattering (272).

Other Techniques. Atomization of polymer solutions to form single molecules deposited in a solvent-free state on a surface has been demonstrated for a wide variety of polymers (273). The electron microscope is used at 20,000–30,000 × after platinum shadowing to determine size and size distribution (274). The scanning transmission electron microscope is employed for biological macromolecules (275). For extremely high molecular weight polymers hydrodynamic chromatography (HDC) may be a viable technique. Columns are packed with solid spheres and the diameter determines the separation range. Solid particles between 5 and 300 nm may be separated. Columns are available from Polymer Laboratories, and using a high temperature infrared detector cell the composition of polyolefin copolymers can be characterized. A mathematical model for HDC and GPC for porous column packings has been published (276). Methods to characterize insoluble polymers have been discussed (277,278).

NANOCOMPOSITES, LAYER-BY-LAYER ASSEMBLY

Introduction

Advanced materials from inorganic nanoparticles (NPs) and other nanocolloids such as single wall carbon nanotubes (SWNT) are currently one of the most dynamic areas of today's science. They represent significant fundamental and commercial interest with a wide range of applications including the next generation optics, electronics, and sensors (1–6). Synthetic methods of colloidal chemistry afford manipulation of their size, surface structure, and hence, their properties (7). In optical, electrical, and magnetic devices, nanocolloids will be mostly used as thin films. Currently, such films are typically made by spin coating, spraying, or sometimes by simple painting of nanoparticle–matrix mixtures. The layer-by-layer assembly (LBL) is one of the most promising new methods of thin film deposition, which is often used for oppositely charged polyelectrolytes (PE) (8,9). It has also been successfully applied to thin films of nanocolloids (10–33). One of the major advantages of LBL is simplicity: the process requires neither sophisticated hardware nor high purity of the components. At the same time under optimal conditions, the method produces high quality of coatings with thickness controllable at the nanometer level (26). This deposition technique is also quite universal: for virtually any aqueous dispersion of NPs, one can find a matching polyelectrolyte and deposition conditions yielding a steady film buildup (34). The lateral packing of the NPs and SWNTs in individual adsorption layers can also be controlled by different means producing densely packed coatings (15,27,34). The LBL coatings are also highly homogeneous unlike the composite polymer/NP coatings obtained by other means (35), where phase separation may occur (36). Last but not the least, LBL affords combining NPs with other functional materials often used by

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

this technique such as dyes, proteins, and DNAs, leading to a palette of multifunctional nanostructured materials (37). In essence, LBL can be a convenient method for processing NPs in thin films, which opens broad perspectives for this technique, both in research and in industry. This article attempts to summarize the current status of understanding of the LBL deposition of NPs, the structure of produced films and the future applications for these materials.

Layer-By-Layer Assembly

Layer-by-layer assembly can be described as the sequential adsorption of positively and negatively charged species, say A and B, by dipping a substrate alternatively into their solutions. Rinsing with water between adsorption steps removes the excess of the previous solution and leaves a thin layer of charged species on the surface, thereby preparing the surface for the next adsorption step. The dynamic development of LBL that has been seen recently was sparked mainly by its great success with assembly of polyelectrolytes (9,30,38–40); However, similar ideas were previously used (41) for the assembly of colloids, for production of semiconductor films (42,43), and for the assembly of NP/PE magnetic films (10). The description of experimental details of the technique can be found in the original publications of the respected authors (see also COLLOIDS; POLYELECTROLYTES; LANGMUIR-BLODGETT FILMS).

From the analysis of the abundant literature on LBL, one can say that A and B are preferentially chosen to be of relatively high molecular weight. The experimental work on polymers with different chain lengths indicates that the increase of the molecular mass of species promotes stable LBL growth (15,44–46), which is related to the diverse nature of intermolecular interactions involved in the process (see SWNT/Polyelectrolyte Composites). Although for relatively low molecular weight species such as multicharged metal ions (47–51) and molecular dyes (52–54), the LBL assembly was also reported, and their tendency to leach out should be accentuated (55). Heavy mass and the multiple points of attachment of A and B render the absorption sufficiently irreversible to allow for the deposition of the next layer. Either A or B is almost always a PE, while the other LBL partner can be a dispersion of NPs, clay sheets, proteins, dyes, vesicles, DNA, viruses or other species. The omnipresence of PEs in LBL assemblies acquired popularity in the 1990s is explained by their ability to cover irregularities owing to the rod-like conformation of the charged macromolecules in aqueous solutions (9,56).

Ultrastrong Materials

The mass–strength ratio of materials is of exceptional importance for many different applications. The critical parts of different vehicles and crafts depend on strength and toughness of the materials they are made of, while strict limitations on the weight of the different components are placed by the modern air and spacecraft technology. SWNT presents significant potential as a basic material for space applications. Exceptional mechanical properties of SWNT (57–62) have prompted

intensive studies of SWNT composites. These qualities can also be used in a variety of other technologies from automotive to military and medical. However, the present composites have shown only a moderate strength enhancement when compared to other hybrid materials (53–65). Although substantial advances have been made (66), mechanical characteristics of SWNT-doped polymers are noticeably below their highly anticipated potential. Pristine SWNTs are well known for poor solubilization, which leads to phase segregation of composites. Severe structural inhomogeneities result in the premature failure of the hybrid SWNT/polymer materials. Connectivity with and uniform distribution within the matrix are essential structural requirements for strong SWNT composites (67–69). A new processing approach based on sequential layering of chemically-modified nanotubes and polyelectrolytes can greatly diminish the phase segregation and render SWNT composites highly homogeneous. Combined with chemical cross-linking, this processing leads to drastically improved mechanical properties. Tensile strength of the composites is several times higher than that of SWNT composites made via mixing; it approaches values seen for hard ceramics. The universality of the layering approach applicable to a wide range of functional materials makes possible successful incorporation of SWNT into a variety of composites imparting to them required mechanical properties.

The thin film membranes that are obtained as a result of the layer-by-layer process can be used as an intermediate or as a component of ultrastrong laminates. At the same time, the prepared membranes can also be utilized in the as-prepared form for space and biomedical technologies because they combine the strength and multiple functionality of the SWNT membranes.

SWNT composites are typically prepared by blending, *in situ* polymerization, and extrusion. After extensive surface modification, such as grafting or polymer wrapping (68–70), the phase segregation from a macromolecular matrix is smaller than for pristine SWNT, but still remains high owing to the high affinity of SWNTs to each other. Vastly different molecular mobilities of both components also contribute to widespread phase separation. Very intense research on appropriate surface modification of SWNT is currently under way in many groups around the world. Nevertheless, most common loadings of nanotubes in the polymer matrix are within the 1–15 wt% range, whereas more than 50% of the SWNT content is needed for materials with special mechanical performance without compromising the homogeneity of the composite at the nanometer level. This high loading of the nanotubes is particularly important when both electrical and mechanical qualities of the nanotubes are going to be utilized.

The phase segregation between dissimilar materials can be circumvented by applying a layer-by-layer assembly (LBL) (71). The immobilization of the macromolecular compounds and strong interdigitation of the nanometer-thick film allows for the close-to-perfect molecular blending of the components (72,73).

SWNT/Polyelectrolyte Composites. The SWNT/polyelectrolyte composites produced in this study were assembled onto a solid support via alternate dipping of a solid substrate (glass slides, Si wafers) into dispersions of SWNT and polyelectrolyte solutions (74–76). The individual assembly steps, ie adsorption of SWNT and polyelectrolyte monolayers, were interlaced by rinsing steps to remove the excess of assembling materials. When the LBL procedure

was complete, the multilayer films were lifted off the substrate to obtain uniform free-standing membranes, which can be handled as regular composites (77). Such films make possible straightforward testing of their mechanical properties.

SWNT were produced by laser ablation and subsequently purified via acid treatment. Single-wall nanotubes were manufactured by laser vaporization of carbon rods doped with Co, Ni and FeS in an atmosphere of $Ar:H_2$. Standard SWNT products made by HiPCO and other methods contain significant amount of sooth, graphite flakes, and remnants of the catalyst, which need to be removed prior to the assembly. The quality of the dispersion directly affects the mechanical performance of the resulting composite.

A suspension of SWNT raw material was refluxed in 65% HNO_3 and subsequently purified by centrifugation. Supplemented by sonication, this treatment results in the partial oxidation of ca 5% of the total number of carbon atoms both in caps and walls of SWNT (78). A similar type of dispersion can also be made following other recipes such as polymer wrapping the nanotubes, and chemical derivatization. Optimization of the aqueous nanotube dispersions should be considered as one of the most critical direction of the optimization of the carbon nanotube composites and speed and quality of their processing in the composites. Dispersions made by other methods are expected to be also applicable for the preparation of LBL films. The strength and other mechanical properties will depend though on energy of attractive interactions between the coating agent and the matrix as well as between SWNT and the coating agent.

In slightly oxidized nanotubes, the presence of carboxylic acid groups affords the preparation of metastable SWNT dispersions after 1 min sonication in deionized water without any additional surfactant. Thus prepared negatively charged SWNT with zetapotential of -0.08 V can be layer-by-layer assembled with positively charged polyelectrolyte, such as branched poly(ethyleneimine), $M_w = 70{,}000$ (PEI) (Fig. 1). Since the overall negative charge of the SWNT used here was fairly small, after every 5th deposition cycle, a layer of SWNT was replaced with a layer of poly(acrylic acid), $M_w = 450{,}000$ (PAA) (Fig. 1). These additional layers improve

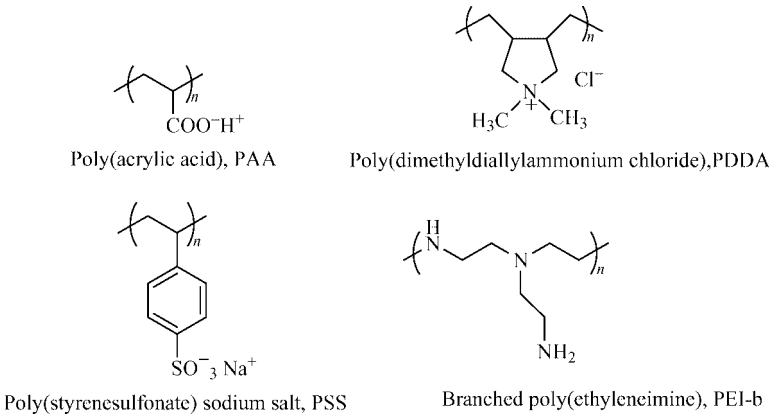

Fig. 1. Common polyelectrolytes, used for LBL process.

the linearity of the deposition process and present a convenient chemical anchor for subsequent chemical modification. For the same reasons, a single PEI/PAA bilayer was deposited on a bare glass or Si substrate prior to the SWNT assembly. The assembly conditions of the entire procedure (pH, ionic strength, concentrations, etc) were optimized so that the dipping cycles can be repeated as many times as needed with linear growth of the multilayers (Fig. 2**a**). This enables the preparation of films with any desirable thickness and architecture tailored to different applications. The ionic conditions of LBL assembly were the following: 1% solution of PEI at pH 8.5; 1% PAA at pH 6 (pH 3 for wafer coating); SWNT at pH 6.8. All solutions were made in 18 MΩ deionized (DI) water without addition of any extra salt or other low molecular weigh electrolyte. DI water was also used for rinsing at pH 8.5 adjusted by NaOH. Wafers/glass slides were cleaned in piranha solution, rinsed with DI water, sonicated for 15 min and again thoroughly rinsed with DI water. After that, they were coated with a precursor layer: PEI (10 min) + PAA (15 min, pH 3), followed by the deposition of $(PEI/SWNT)_5$. The layer sequence of $(PEI/PAA)(PEI/SWNT)_5$ was repeated until the desirable thickness is obtained. Exposure times of 10 and 60 min was used for polylectrolytes and SWNT baths, respectively.

Multilayer stacks with a cumulative structure of $((PEI/PAA)(PEI/SWNT)_5)_6$ and $((PEI/PAA)(PEI/SWNT)_5)_8$ containing 30 and 40 (PEI/SWNT) bilayers, respectively, were typically used in this study.

Currently, other methods are being investigated for dispersing SWNT in water to avoid excessive damage to the SWNT wall such as wrapping of the nanotubes with copolymers, which can equally well work on the SWNT and multiwall carbon nanotubes (MWNT). For some applications, MWNTs can be a preferred materials due to lower cost.

Similarly to other polyelectrolyte LBL systems (71), a submonolayer of SWNT is deposited in each deposition cycle. The final morphology of the multilayers can be described as a mixture of individual carbon nanotubes and their 4–9 nm bundles intricately interwoven together in a fine fabric (Fig. 2**c**) (74,75). Two important structural characteristics should be pointed out. SWNT uniformly cover the entire surface of the substrate without any evidence of phase separation. Also, the presence of oxidized flat graphite sheets and other forms of carbon colloids in the experiments was very small. Both these factors contributed to the mechanical properties of the composites. The quality of the nanotube material was also assessed by Raman spectroscopy. (Raman measurements were performed in a backscattering configuration with a 50 mW of 514.5 nm laser light was incident on the samples.) The characteristic Raman peaks for SWNTs, eg the radial breathing mode at $\sim$182 cm^{-1} and the tangential C–C stretching modes located at $\sim$1560 cm^{-1} (G1 mode) and $\sim$1583 cm^{-1} (G2 mode), were very sharp and narrow indicating the high uniformity of the SWNT and low level of impurities present in the films. A barely visible peak at $\sim$1340 cm^{-1} (D mode) revealed the presence of residual amounts of disordered carbon structures. Using the correlation between the frequency of the radial breathing mode, ν, and the SWNT diameter, d, expressed as $d = 223.75/\nu$ (79), a value of $d = 1.2$ nm is obtained, which is in a good agreement with the SWNT diameters obtained from AFM images of many individual nanotubes. From these images, the length of the nanotubes was estimated to be 2–7 μm.

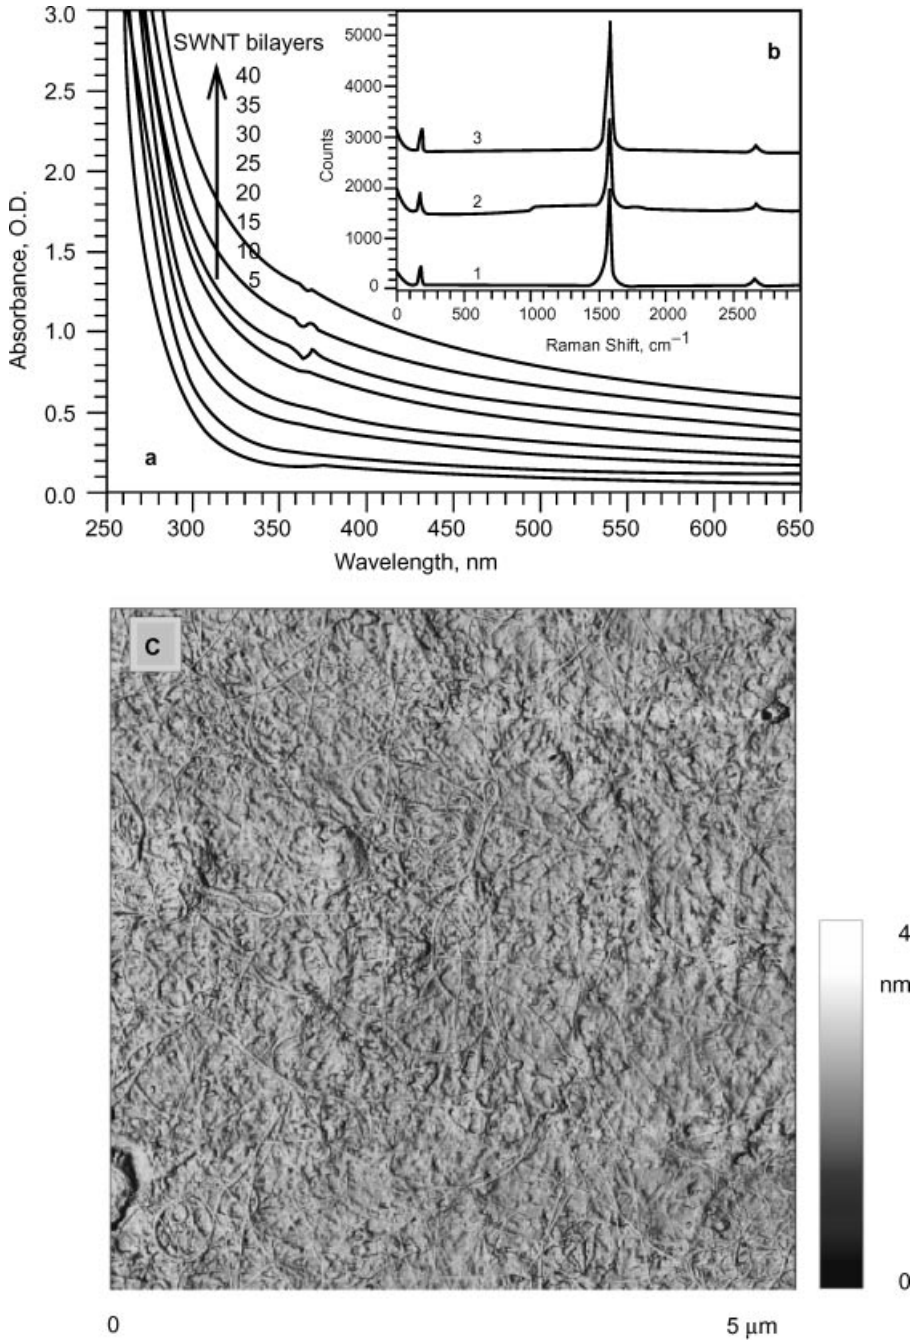

Fig. 2. Structural characterization of SWNT multilayers. (**a**) Sequential UV–vis spectra of a glass substrate in the course of the LBL deposition of SWNT. The spectra were taken for a total number of (PEI/SWNT) bilayers indicated in the graph. (**b**) Raman scattering spectra of SWNT dispersion (*1*), LBL film on a glass substrate (*2*) and free-standing film (*3*). (**c**) Tapping mode AFM image (DI, multimode IIIA) of a Si wafer bearing (PEI/PAA)(PEI/SWNT)$_5$. See Refs. 74,75.

PEI was utilized as the LBL partner of SWNT because of terminal $-NH_2$ and backbone —NH— groups in the main chain and branches suitable for the subsequent chemical modification of the composite (80). The PEI chains can be cross-linked (*1*) with each other and (*2*) with carboxyl groups on SWNT and PAA. Chemical stitching increases the connectivity of the polyelectrolyte matrix with SWNT, and therefore, load transfer in the composite (80). The combination of both modification pathways was used. SWNT/PEI/PAA composite was heated to 130°C after the deposition of each layer. According to the study by Sullivan and co-workers (81), this treatment should result in amide bonds between a variety of protonated and nonprotonated functional groups of PEI, PAA, and SWNT complementing the intrinsic ionic cross-linking of the LBL films (81). Subsequently, the film was exposed to glutaraldehyde at room temperature. This treatment is well known to produce covalent bonds with primary amine groups present in the polyelectrolyte. Samples were cross-linked in 0.5% glutardialdehyde solution in phosphonate buffer (0.054 *M* Na_2HPO_4, 0.013 *M* NaH_2PO_4, pH 7.4) for 1 h at room temperature. To remove unreacted glutaraldidehyde, the film was rinsed with tap water for 3 × 10 min and then with DI water the same number of times. This reaction produces a tight network of polymeric chains and nanotubes connected by dialdehyde linkages. It was found that if only 1% of all carbon atoms of SWNT are chemically bonded to the polymer matrix, such as cross-linking drastically increases the shear between them by an order of magnitude (80). Therefore, a 5% density of —COOH groups on the SWNT surface cited above should be sufficient to obtain good connectivity with the polyelectrolyte matrix. Note these groups are not completely utilized at the moment, because of the relatively low temperature of amide bond cross-linking step.

Mechanical Properties and Testing

The mechanical properties of the LBL-assembled SWNT thin films were studied in their free-standing form prepared by the chemical delamination from the substrate (77). SWNT multilayers were separated from the silicon wafers by immersion into 0.5% aqueous HF for 3 min. The Raman scattering spectrum of the separated film is almost identical to that of the supported film and original nanotubes (Fig. 2**b**), demonstrating that the structure of SWNT remains mostly unaltered during the cross-linking and delamination. The breathing mode frequency shifts from 185 cm^{-1} in the assembled film to 182 cm^{-1} in the cross-linked self-standing films indicating a small expansion of the tube diameters.

The delaminated thin films (Fig. 3**a**), can be easily handled in a variety of ways. They can be made of any desirable size or shape determined only by the dimensions of the substrate. The films that we routinely prepare in this study were ca 1 × 3 cm. Assemblies with a structure of $((PEI/PAA)(PEI/SWNT)_5)_6$ and $((PEI/PAA)(PEI/SWNT)_5)_8$ displayed an SWNT content of 50 ± 5 wt% as calculated from carbon and nitrogen EDAX peak integrals. Previously reported composites made with modified SWNT revealed strong inhomogeneities even at SWNT loadings as low as 6–8% (64,65). The cross-sectional image of the free-standing film (Figs. 4**a** and 4**b**) clearly demonstrates the absence of micrometer-scale inhomogeneities although the occasional inclusion of a round 30–60 nm particles can be

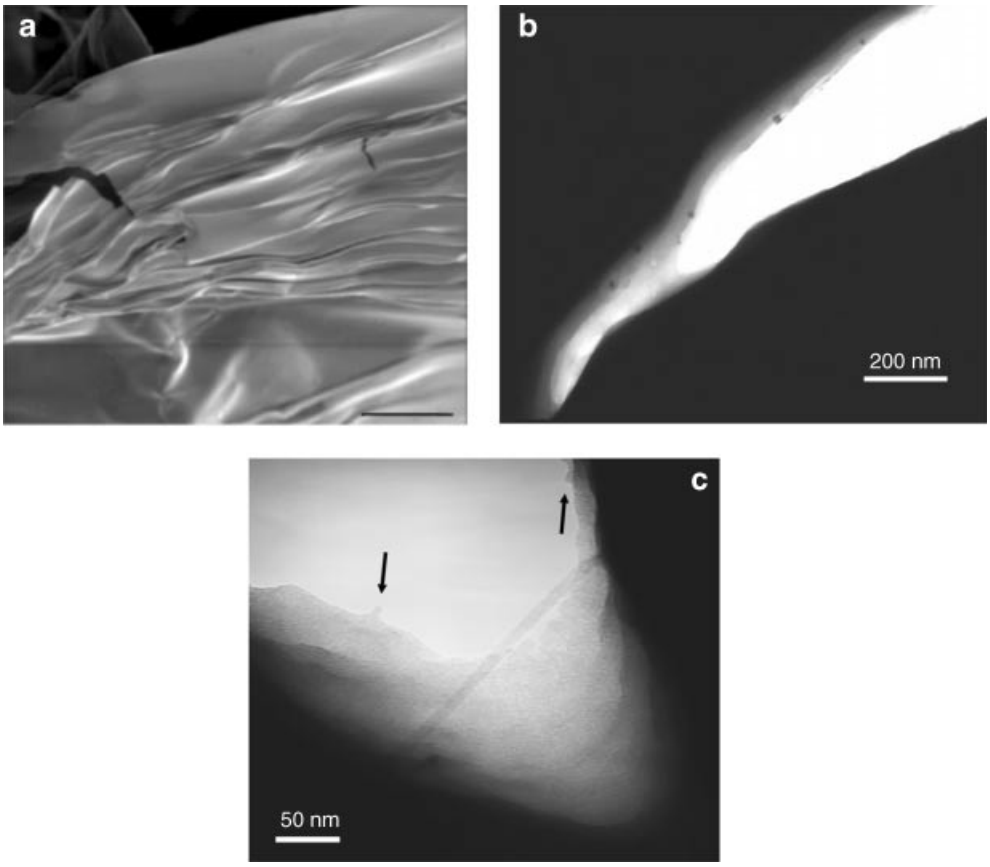

Fig. 3. Electron microscopy of the rupture region in SWNT multilayers. (**a**) SEM image of the surface and broken edges of $((PEI/PAA)(PEI/SWNT)_5)_8$. (**b**) and (**c**) TEM images of ruptured areas of the freestanding films. The arrows indicate the likely stubs of the broken nanotubes bundles. They were identified as such because (*1*) the diameter of both of them is equal to theat of the actual SWNT bundle bridging the gap and (*2*) their mutual positioning presents a virtually perfect match with the expected location of the ends of a bundle broken during gap opening.

seen (possibly dust). The slight variations in the gray scale contrast between different strata show the actual variations in SWNT distribution within the sample. They originate from small deviations in SWNT adsorption conditions, such as dispersion concentration and pH, during the buildup procedure. In SEM microscopy (Fig. 3**a**), the surface of the sample also appears smooth and continuous. Typically, the separation of single/multiwall carbon nanotubes and their bundles in mixed polymer composites can be observed as whiskers clearly visible in TEM and SEM images (60,82). The TEM examination of the initial stages of rupturing showed that virtually no fiber pullout occurs in the LBL multilayers (Fig. 3**b**). This can be contrasted by extensive nanotube pullout reported before by several groups (60,82). For many TEM images obtained in different areas of the self-standing films, we were able to observe only one SWNT bundle bridging the break region

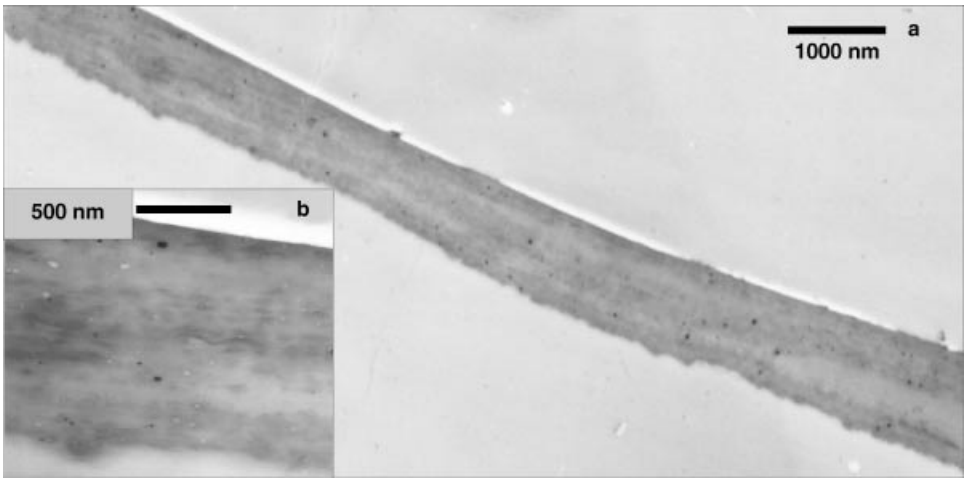

Fig. 4. TEM examination of the homogeneity of the SWNT LBL film. Survey (**a**) and closeup (**b**) TEM images of SWNT film cross sections. The top and botom sides of the film are slightly different in roughness: the one that was adjacent to the flat substrate is smoother than the "growth" surface of the film. See Refs. 74,75.

(Fig. 3**c**). The same image also shows two broken carbon fiber stubs imbedded in the walls of the crack (marked by arrows in Fig. 3**c**). In total, the microscopy results indicate efficient load transfer in the LBL composite. Currently, similar films are prepared from multiwall carbon nanotubes utilizing polymer wrapping (Fig. 5).

The mechanical properties of the layered composites were tested on a custom-made thin film tensile strength tester (McAllister Inc.) recording the displacement and applied force by using pieces cut from $((PEI/PAA)(PEI/SWNT)_5)_6$ and $((PEI/PAA)(PEI/SWNT)_5)_8$ free-standing films. The tester was calibrated on similar pieces made from cellulose acetate membranes and Nylon threads. $((PEI/PAA)(PEI/SWNT)_5)_6$ and $((PEI/PAA)(PEI/SWNT)_5)_8$ samples had an average TEM thickness of 0.75 and 1.0 μm, respectively. Their typical stress (σ) vs strain (ε) curves differed quite markedly from stretching curves seen previously

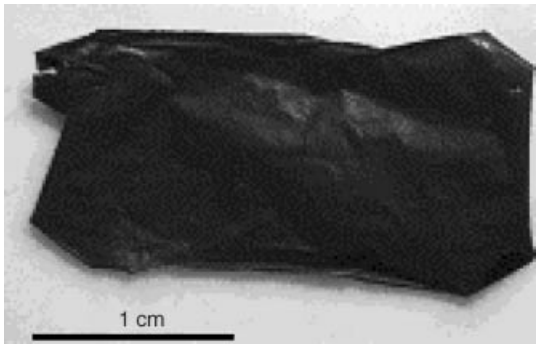

Fig. 5. Optical photograph of the freestanding LBL films made from multiwall carbon nanotubes.

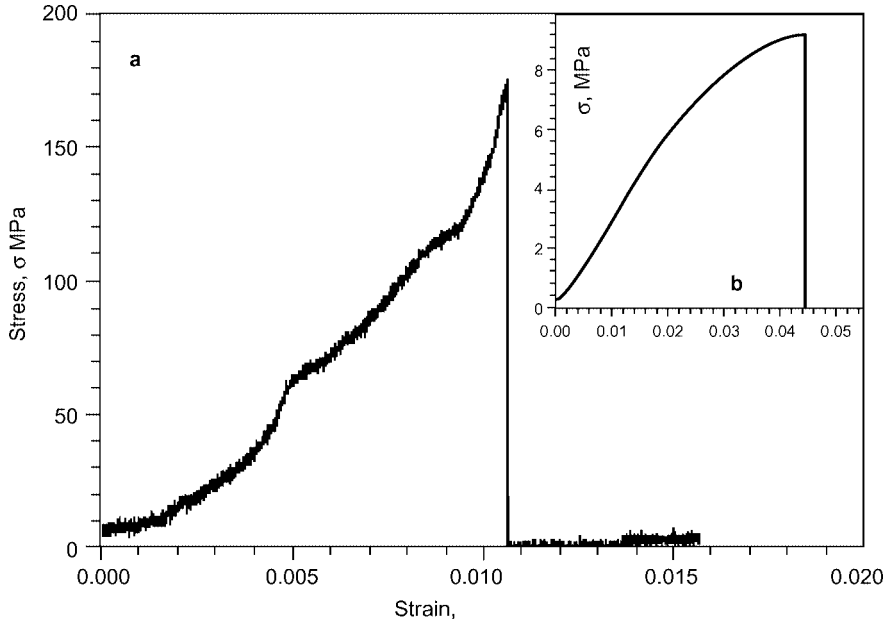

Fig. 6. Typical tensile strength curves of the SWNT LBL films. Stress–strain dependence for (**a**) $((PEI/PAA)(PEI/SWNT)_5)_8$ and (**b**) a similar free-standing multilayer film made solely from polyelectrolytes. The dependence of the mechanical properties of the cross-linked LBL composites on humidity was tested in the range of relative humidity of 30–100%, $T = 298^{\circ}C$, and was found to be negligible See Refs. 74,75.

for SWNT composites (66) and for LBL films made solely from polyelectrolytes, $(PEI/PAA)_{40}$, obtained by the same assembly procedure (Fig. 6**b**). They displayed a characteristic wave-like pattern, gradual increase of $d\sigma/d\varepsilon$ derivative, and the complete absence of the plateau region for high strains corresponding to plastic deformations (Fig. 6**a**). The latter correlates well with the enhanced connectivity of SWNT with the polymer matrix (Fig. 3). Other mentioned stretching features indicate the reorganization of the layered composite under stress. A process similar to the sequential breakage of cross-linked parts of coiled molecules (see AFM image in Figure 2) observed in natural nanocomposites, such as seashells and bones (83,84), is likely to be responsible for the wave-like pattern and the increase of the stretching curve slope.

Considering the complexity of the deformation process, the assessment of elastic and inelastic behavior in each part of the curve will be done upon detailed microscopy investigation. Meanwhile, the values of $d\sigma/d\varepsilon$ exceeding 50 GPa should be noted.

The comparison with stretching curves for polyelectrolytes (Fig. 6**b**) shows that the incorporation of nanotubes in the LBL structure resulted in the transfer of the SWNT strength to the entire assembly. The stretching curves of the SWNT multilayers display a clear break point. The ultimate tensile strength, T, was found to be 220 ± 40 MPa with some readings being as high as 325 MPa. This is several times to an order of magnitude greater than the tensile strength of

strong industrial plastics with $T = 20$–66 MPa (85). It is also substantially higher than the tensile strength of carbon fiber composites made by mixing: polypropylene filled with 50 vol% Carbon Fibers (qv) has $T = 53$ MPa (86). A recent study on SWNT/poly(vinyl alcohol) ribbons with axially aligned nanotubes reported a tensile strength of 150 MPa (66). The T values obtained for SWNT LBL films are, in fact, close to those of ultrahard ceramics and cermets such as tungsten monocarbide, $T = 340$ MPa, silicon monocarbide, $T = 300$ MPa, and tantalum monocarbide, $T = 290$ MPa (85). Such strength and failure strain greater than in cermets (ca >1% in SWNT LBL vs. 0.2–0.6% in carbides) displayed by an organic composite is quite remarkable.

The tensile strength of single carbon nanotubes was experimentally determined to be between 13 and 50 GPa (82,87). The lower values obtained for the SWNT multilayers should be mainly attributed to the contribution of polyelectrolytes and some uncertainty in the actual cross-sectional area at the break point and a degree of cross-linking. The mixing law predicts that a polyelectrolyte matrix with $T = 9$ MPa makes a negligible contribution to the strength of the composite while taking about 50% of its volume fraction (SWNT is $d = 1.14$ g/cm^3). Since the density of the polyelectrolytes used for the preparation of the multilaters, ie PDDA $d = 1.04$ g/cm^3, PAA $d = 1.14$ g/cm^3 is almost the same, the volume fraction of SWNT in the composite can be considered to be equal to the mass fraction). Additionally, the decrease of the mechanical strength of the nanotubes in the process of ionic functionalization (estimate 15%) (88) should also be considered as a factor affecting the strength of these composites. These issues are pointed out as means of further optimization of the multilayers. Tuning of their molecular structure and composition should lead to vast improvement of their mechanical properties that could possibly approach those of pristine carbon nanotubes.

It is also interesting to compare the T values for SWNT composite films to those obtained for other LBL films made with other inorganic components such as montmorillonite platelets, M, and nanoparticles, NP, for instance 8–10 nm magnetite nanoparticles. The free-standing films $(PDDA/NP)_{40}$ and $(PDDA/NP/PDDA/M)_{40}$ made according to Reference (77) revealed T equal to 40 and 72 MPa, respectively. In conjunction with the tensile strength data (see above), it can be concluded that inorganic or SWNT components act as a molecular armor in the layered composites significantly reinforcing them. The molecular organization of the material made possible the transfer of a part of their strength to the entire assembly.

The high structural homogeneity and interconnectivity of the structural components of the LBL films combined with high SWNT loading leads to significant increase of the strength of SWNT composites, being somewhat weaker than some other organic and carbon fiber materials but at the same time being far beyond their potential as ultrastrong composites. The described technique minimizes the structural defects originating from phase segregation and opens a possibility for the molecular design of layered hybrid structural materials from different polymers and other nanoscale building blocks. The prepared free-standing membranes can serve as a unique component for a variety of technologies. One of the great advantages of it in respect to other technologies is the ability to prepare ultrathin, ultrastrong membranes with minimal heterogeneity.

NANOCOMPOSITES, METAL-FILLED

Introduction

Atomic clusters of transition metals embedded into polymeric matrices represent a very attractive class of materials which combine properties belonging to the nanometer-sized metal phase (such as certain magnetic, electronic, optical, or catalytic properties) and the polymer phase (such as processability and film-forming properties) (1). By the careful selection and combination of both components, tailor-made functional materials exhibiting unique characteristics (2) can be obtained, with the advantage of using the well-established, low cost technologies available for polymer processing, such as printing, spraying, or spin-coating.

Polymeric dispersions of nanometer-sized metal particles offer the possibility of functionalizing the polymer by properties coming from the large number of surface atoms (3) and the quantum-size effects (4). Nanometric metals show properties that differ significantly from that of bulk metals, which makes these nanocomposite systems intriguing for scientific study and potentially useful for a number of technological applications (5–12). The control of nanoparticle morphology becomes a very important aspect, since morphology profoundly influences the material performance. As a long-term goal the ability to control and vary particle size, distributions, shapes, and composition independently from one another is very desierable, in order to allow the tuning of nanocomposite properties. A broad area of nanoparticle features, ranging from nanosized single crystals to somewhat larger (in the range of about 100–200 nm) yet well-stabilized nonagglomerates, gain significant technological importance.

Polymer-embedded nanostructures are potentially useful for a number of technological applications, especially as advanced functional materials (eg, high energy radiation shielding materials, microwave absorbers, optical limiters, polarizers, sensors, hydrogen storage systems) (5–12). In addition to the intrinsic nanoscopic material properties, the presence of a very large interface area in these polymer-based nanocomposites can affect significantly polymer characteristics (eg, glass-transition temperature, crystallinity, free volume content, ignition temperature), allowing the appearance of further technologically exploitable mechanical and physical properties (eg, fire-resistance, low gas diffusivity).

Historical Background

The fundamental knowledge on the preparation and nature of metal/polymer nanocomposites looks back at a long history which is connected to the names of many illustrious scientists (2).

The oldest technique for the preparation of metal/polymer nanocomposites that can be found in the literature was described in detail in an abstract in 1835 (13). The original article appeared in 1833 (*J. Erdmann, p. 22*). In an aqueous solution, a gold salt was reduced in the presence of gum-arabic, and subsequently a nanocomposite material was obtained in the form of a purple solid simply by coprecipitation with ethanol.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Around 1900, widely forgotten reports indicated the preparation of polymer nanocomposites with uniaxially oriented inorganic particles, and their remarkable optical properties (14,15). Dichroic plants and animal fibrils (eg, linen, cotton, spruce, or chitin, amongst others) were prepared by impregnation with solutions of silver nitrate, silver acetate, or gold chloride, followed by reduction of the corresponding metal ions under the action of light (16).

Dichroic films were also obtained using gold chloride treated gelatin which was subsequently drawn, dried, and finally exposed to light (17). Similar results were obtained when gelatin was mixed with colloidal gold before drying and drawing (18). The gold or silver content in such systems amounted typically to ca 1% by weight (19).

In 1904, Kirchner and Zsigmondy (Nobel Laureate in Chemistry, 1925) reported that nanocomposites of colloidal gold and gelatin reversibly changed color from blue to red upon swelling with water (20). In order to explain the mechanism of nanocomposite color change, they suggested that the material absorption must also be influenced by the distance between the embedded particles. In addition, around the same time, the color of gold particles embedded in dielectric matrices was subject of detailed theoretical analyses by Maxwell Garnett who explained the color shifts upon variation of particle size and volume fraction in a medium (21,22).

During the following three decades, dichroic fibers were prepared with many different elements (ie, Os, Rh, Pd, Pt, Cu, Ag, Au, Hg, P, As, Sb, Bi, S, Se, Te, Br, I) (23–27). The dichroism was found to depend strongly on the employed element, and optical spectra of dichroic nanocomposites, made of stretched poly(vinyl alcohol) films containing gold, silver, or mercury, were presented in 1946 (however, the preparative scheme used is not really clear) (28). It was assumed already in the early reports that dichroism was originated by the linear arrangement of small particles (29) or by polycrystalline rod-like particles (30) located in the uniaxially oriented spaces present in the fibers. An electron micrograph depicted in 1951 showed that tellurium needles with typical dimensions of ca 5×50 nm were present inside a dichroic film made of stretched poly(vinyl alcohol), however also in this case, just a limited number of details were given about the technique used for sample preparation (31).

In 1910, Kolbe was the first to prove that dichroic nanocomposite samples based on gold contained the metal indeed in its zero-valence state. Such affirmation was confirmed a few years later by X-ray scattering. In particular, it was shown that zero-valence silver and gold were present in the respective nanocomposites made with oriented ramie fibers, and the ring-like interference patterns of the metal crystallites showed that the individual primary crystallites were not oriented (32). Based on Scherrer's equation, which was developed just in this period, the average particle diameter of silver and gold crystallites was determined in fibers of ramie, hemp, bamboo, silk, wool, viscose, and cellulose acetate to be between 5 and 14 nm (33).

Basic Concepts

A nanocomposite is a material made of two or more phases one of which has at least one dimension in a nanometric size range. Metal/polymer nanocomposites

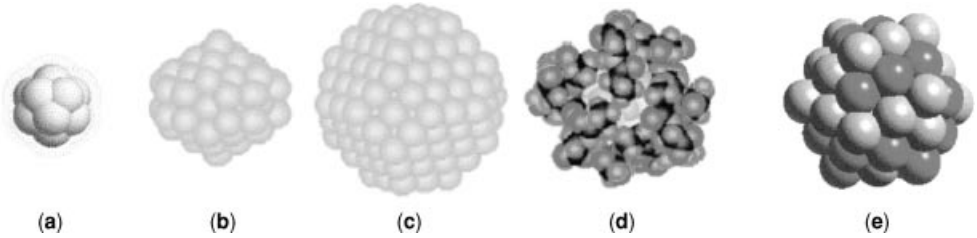

Fig. 1. Structure of atomic clusters of metals: (**a**) elemental cluster, (**b**) small cluster, (**c**) large cluster, (**d**) thiol-derivatized cluster, and (**e**) alloyed cluster.

are made of a continuous polymeric matrix embedding nanosized metal domains. Thermoplastic polymers, elastomers, and thermosetting resins can be potentially used as matrix, but amorphous linear polymers, like optical plastics (eg, polystyrene, poly(methyl methacrylate)) and conductive polymers are the most frequently used. About the metallic filler, very small clusters and nanoparticles with a pseudospherical shape are frequently employed (see Fig. 1). The use of nanorods and nanowires has also been described (2).

In these materials, the polymer has the function of protecting the nanostructures and allowing their manipulation, whereas the nanosized filler provides the polymeric matrix with unique properties coming from "small-size" effects (ie, *mesoscopic properties*). To allow the appearance of mesoscopic properties, the nanoparticle size is required to be very small; usually a dimension less than 30 nm is necessary for most metallic materials. In particular, the metal domain size, where electrons move, needs to be comparable to the critical lengths of physical phenomena (eg, wavelength of the electrons at the Fermi edge, mean free paths of electrons or phonons, coherency length, screening length). Such phenomenon is named *electron confinement* (4). In addition, on this size scale, also phenomena related to the high percentage of surface atoms appear in the material (3).

Different topologies can result in the preparation of polymer-embedded metal clusters. To prepare materials characterized by the properties of surface atoms or with characteristics coming from the confinement effect, a contact-free dispersion of clusters must result in the polymer matrix, since only in this case the large amount of surface atoms present allows the surface properties of matter to prevail on that of bulk. Both regular (eg, uniaxially oriented pearl-necklace type of arrays of nanoparticles) and irregular metal cluster distributions are used in technological applications.

The properties of nanometric particles strictly depend on their microscopical structure (ie, chemical composition, shape, size, percentage of defects, microstrain concentration, etc). For example, the characteristic surface plasmon absorption of a system of metal nanoparticles dispersed into a dielectric matrix is related to the particle shape and size (34). To prepare a color filter, identical particles should be used, otherwise the material will appear black. The presence of a single type of microscopic structure allows each particle to provide the same contribution to the composite properties. From a theoretical point of view, an ideal nanostructured composite should be made of identical metal domains uniformly dispersed into the polymeric matrix. However, since it is very difficult to prepare a sample of

identical metal grains, the only practically possible situation is a system of single crystals with a narrow size distribution.

Because of the high surface chemical reactivity, metal clusters can be easily oxidized or contaminated by nucleophilic molecules. The surface reactivity of small clusters is so high that even noble metals (eg, Pt, Pd, Ag) can be oxidized by air. Since small molecules present in the air (eg, oxygen, water, sulfur dioxide) are dissolved in polymers and can diffuse through it, the polymeric matrix cannot prevent metal from surface reactions. Finally, the polymer matrix has only the function to freeze particles, avoiding their diffusion and aggregation by sintering. For such a reason the nanoparticles need to be passivated before their embedding in polymers. The surface treatment (eg, thiol-derivatization, see Fig. 1d) prevents particle aggregation by short-range steric repulsion and stabilizes the metal core principally by electronic effects. Surface passivation offers also the possibility to disperse filler into most of liquid monomers and organic solvents where polymers are soluble.

Classification

Nanocomposites are biphasic materials that can be classified on the basis of their microstructure by the self-connectivity concept, that is the number of space directions (X, Y, Z) in which each phase inside the composite physically contacts itself. Composite classification based on self-connectivity has been proposed for the first time by Newnham in 1978 (35). Because of the discontinuous nature of most nanocomposite materials, the self-connectivity concept needs to be applied to a limited but representative composite portion (ie, a local self-connectivity definition should be used). In particular, like in macro- and microcomposite systems, each phase in a nano-composite material can be locally self-connected in zero, one, two, or three dimensions. It is natural to confine the attention to three perpendicular axes since all property tensors are generally referred to such a system. In general, for a n-phase system the number of possible self-connectivity patterns is given by $(n + 3)!/3!n!$. Therefore, inside a biphasic system ($n = 2$) there are 10 different self-connectivity patterns: $(0–0)^*$, $(1–0)^*$, $(2–0)^*$, $(3–0)^*$, $(1–1)^*$, $(2–1)^*$, $(3–1)^*$, $(2–2)^*$, $(3–2)^*$, and $(3–3)^*$. The first number in the notation represents the physical connectivity of one of the two phases and the second number refers to connectivity of the other one. A schematic representation of these 10 types of self-connectivities is given in Figure 2, using a cube as the basic building block. Arrows are used in Figure 2 to indicate the connected directions, and an asterisk has been introduced in the symbol to indicate the local connectivity.

Properties of Nanosized Metals

Nanosized metals are characterized by novel thermodynamic, chemical, catalytic, optical, magnetic, and transport properties which are much different from those of corresponding massive metals. For this reason a 3-D periodic table of elements has been frequently proposed by chemists working in this material science field (36).

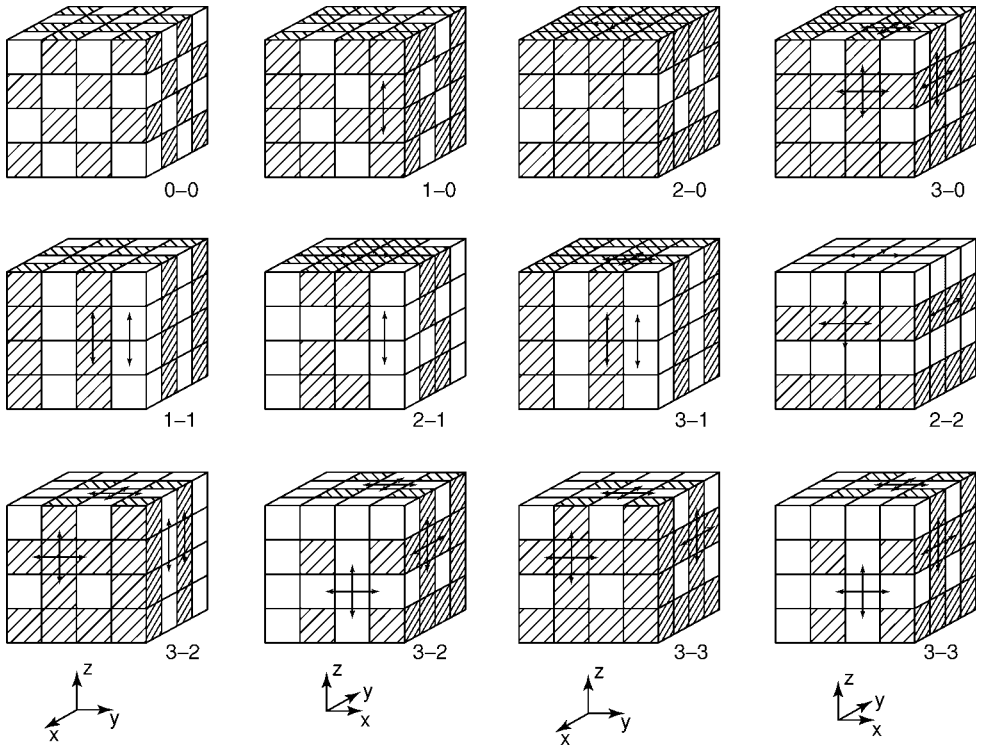

Fig. 2. The connectivity patterns of a biphasic solid (35).

The thermodynamic properties of matter are classically described as natural constants; however, they change significantly when the dimension approaches a few nanometers (37). The first small-size effect which has been observed for metals is the change in the melting point (38–43). When a solid is heated, it melts, and the melting temperature is normally considered one of the most important characteristics of a material. Nanometer-size crystals melt at much lower temperatures than extended ones. This can be understood in two ways. First, the cohesive energy of a crystal arises by the sum of all pairwise interactions between the atoms. In a very small crystal the number of surface atoms is large, and therefore the cohesive energy per atom has not yet converged on the bulk value. A second picture is more thermodynamic: as a solid is heated, melting takes place at the temperature where the chemical potentials of solid and liquid are equal. In addition to the usual term in the chemical potential, a very small crystal also has a term in it for the surface energy. In general, the surface energy of liquids is less than that of solids, because a liquid can readily assume the lowest surface area shape, a sphere. As a consequence, the smaller the crystal the lower is the melting temperature, and the reduction in the melting temperature is proportional to the surface to volume ratio, or inversely proportional to the nanocrystal radius. This scaling law for melting temperature reduction has been verified in many metals (37).

Several interesting chemical properties arise as the grain size of a metal is decreased to a nanometer-size range (eg, enhanced reactivity, stoichiometric behavior of heterogeneous reactions, new reaction routes). Theoretical computations

(37) showed that the fraction of metal atoms residing on the surface of a 100-nm grain increases from 1–2% up to 85–95% for grain sizes in the range of 1–2 nm. The importance of this observation is that the chemistry of such surfaces is much different from that of the same atoms contained within larger grains. If the size of a cubic crystal is decreased from 100 nm down to the 3–5 nm range, the fraction of atoms contained in edge sites as compared to those contained in basal planes increases to 70%. The consequence of this observation is that as the crystal size decreases, the fraction of atoms located in low coordination sites increases sharply, which inherently imparts a higher chemical reactivity to such materials (activated metals). High surface areas and intrinsically high surface reactivities of hyperfine reactants allow surface reactions to approach stoichiometric conversion. With the development of hyperfine powders, the heterogeneous phase reaction can be carried out much faster and at lower temperatures (44,45). Finally, gas–solid reactions and liquid–solid reactions take on a new dimension, and hyperfine solids enter now in the chemist's arsenal as novel chemical reagents.

The properties of nanosized metals in heterogeneous catalysis are well established, since heterogeneous catalysts represent one of the pioneering fields of nanotechnology (3). The increasing portion of surface atoms with decreasing particle size, compared with bulk metals, makes small metal particles as highly reactive catalysts, since surface atoms are the active centers for catalytic elementary processes. Among the surface atoms, those sitting on the crystal edges and corners (see Fig. 3) are more reactive than those on basal planes. The percentage of edge

Fig. 3. SEM micrograph of 3-D self-organized poly(methyl methacrylate) particles. If beads are considered as atoms, the picture can be used to visualize the different catalytic sites on the surface of a metal crystal.

and corner atoms also increases with decreasing size and this is the reason for the enhanced catalytic activity (ie, supercatalytic effect) and different selectivity of very small metal catalysts.

If metal particles become very small, reaching the nanometer-size scale, a color may occur. This is a typical phenomenon of nanometric metals. Actually, optical absorption may result in the ultraviolet or visible part of the spectrum, and this arises from a surface plasmon resonance. This is due to a collective electron plasma oscillation (plasmon) that is coupled to an external transverse electromagnetic field through the particle surface. It is possible to quantitatively relate the absorption coefficient to the wavelength of the exciting radiation by the Mie theory for spherical inclusions in a dielectric matrix (34). Far-IR luminescence is another optical phenomenon frequently observed with nanosized metals (46).

New magnetic properties appear in metals when the size approaches the nanometric regime (47). The so-called odd–even effect is a phenomenon observed when diamagnetic metals are reduced to a nanometric-size regime. In particular, diamagnetic materials have only spin-paired electrons. However, in practice it cannot be assumed that a macroscopic piece of a diamagnetic metal does not have one or more unpaired electrons. This cannot be measured because of the effectively infinite number of atoms and electrons. However, if the particle size is small enough to make one unpaired electron measurable, the odd–even effect should become visible. Among small diamagnetic metal particles there should be an equal percentage of odd and even numbers of electrons.

For magnetic materials such as Fe, Co, and Ni, the magnetic properties are size-dependent (47). In particular, the coercivity force H_c needed to reverse an internal magnetic field within the particle changes with particle size and it is maximum for single-domain particles. Further, the strength of the internal magnetic field of a single particle can be size-dependent.

Giant magnetostriction, magnetoresistivity, and magnetocaloric effects represent further examples of new properties arising from the small size of magnetic domains (48).

Also transport properties, which are strictly related to the electronic structure of a metal particle, critically depend on size (37). For small particles, the electronic states are not continuous, but discrete, because of the confinement of electron wave function. Consequently, also properties like electrical and thermal conductivity may exhibit quantum-size effects.

Most of these unique chemical and physical characteristics of nanosized metals can be used for the functionalization of plastic materials.

Preparation Methods

A limited number of methods have been developed for the preparation of metal/polymer nanocomposites. Usually, such techniques consist of highly specific approaches, which can be classified as *in situ* and *ex situ* methods. In the *in situ* methods two steps are needed: firstly, the monomer is polymerized in solution, with metal ions introduced before or after polymerization. Secondly, metal ions in the polymer matrix are reduced chemically, thermally, or by UV/γ- irradiation. In the *ex situ* processes, the metal nanoparticles are chemically synthesized,

and their surface is organically passivated. The derivatized nanoparticles are dispersed into a liquid monomer which is then polymerized.

***In situ* Methods.** A simple, direct, and versatile *in situ* method was proposed by Watkins and McCarthy (49). In this method, an organometallic precursor is dissolved in supercritical fluid (SCF) carbon dioxide and infused into a solid polymer as SCF solution. Chemical or thermal reduction of the precursor to the zero-valence metal either in presence of SCF or subsequent to its removal produces metal domains within the solid polymer matrix. Such technique has been used in the synthesis of nanoscale platinum clusters embedded into poly(4-methyl-1-pentene) and poly(tetrafluoroethylene), using dimethyl(cyclooctadiene)Pt(II) as metal precursor. There are multiple advantages associated with this approach: first, the high permeation of CO_2 in virtually all polymers and the wide range of organic and organometallic reagents which are soluble in CO_2 render this technique a generally useful scheme for the synthesis of polymer composites. Neither the polymer substrate nor the reaction product needs to be soluble in CO_2. Second, the sorption of CO_2 is a very fast process which significantly enhances the kinetics of the penetrant absorption. The degree of polymer swelling, diffusion rates within the substrate, and the partitioning of penetrates between the SCF and the swollen polymer can be controlled by density mediated adjustments of solvent strength via changes in temperature and pressure. Coupled with manipulation of reaction rates, SCFs offer unprecedented control over composite composition and morphology. In addition, SCFs such as CO_2 are gases at ambient conditions and the solvent dissipates rapidly upon the release of pressure. In the case of metalation using dimethyl(cyclooctadiene)Pt(II), the process effluent consists of CO_2 and light hydrocarbons (methane and cyclooctane) derived from the precursor ligands.

Bronstein and co-workers (50) reported an *in situ* method for the preparation of polymer-cobalt nanocomposites by mixing $CO_2(CO)_8$ with a polyacrylonitrile copolymer or an aromatic polyamide in dimethylformamide (DMF). The cobalt carbonyl interacts with DMF giving the complex $[Co(DMF)_6]^{2+}[Co(CO)_4]^{2-}$, which is then converted to nanodispersed Co particles by thermolysis.

Analogously, silver/polyimide nanocomposites have been prepared by Fragalà and co-workers (51) by thermolysis of a mixture of a metallorganic silver complex and polyamidic acid (PPA). The PAA precursor transforms in polyimide (PI) at a curing temperature compatible with the metallorganic precursor reduction temperature, so that at the same time the precursor decomposes, giving metallic silver particles, and the PAA transforms itself in PI, allowing the silver particles to remain trapped in the polymeric cage.

Copper/polymer nanocomposites have been prepared in the solid state by Lyons and co-workers (52). A soluble precursor was synthesized by complexing poly(2-vinylpyridine) with copper formate (ie, $Cu(HCO_2)_2$) in methanol. The thermal decomposition of the complex results in a redox reaction whereby Cu(II) is reduced to copper metal and the formate anion is oxidized to CO_2 and H_2. By incorporating a reducing agent into the complex, the thermal decomposition reaction is not diffusion-limited, and nanocrystalline copper particles can be prepared in the solid state.

Chen and co-workers (53) describe the synthesis of iron nanoparticles dispersed in poly(4-vinylpyridine) homopolymer and vinylstyrene-4-vinylpyridine copolymers by chemical reduction of thin films of iron chloride/polymer

nanocomposite precursors swollen by DMF. Idrazine was used as reducing agent. Such approach can be used because the metal ions have a high tendency to form ionic clusters in a polymeric matrix. The produced microscopic phases, which are separated by the hydrophobic portions of the polymer, have a diameter ranging from 2 to 10 nm. The chemical reduction of the dispersed ionic metal domains produces ultrafine metal particles.

Huang and co-workers (54) prepared copper/poly(itaconic acid-*co*-acrylic acid) nanocomposites via *in situ* chemical reduction of the Cu^{2+}–polymer complex by hydrazine hydrate aqueous solution.

Metal/polymer nanocomposites were prepared by Chen and co-workers (55) using dispersion of metal chlorides in polyurethane. Both polyurethane and metal salts were dissolved in *N*,*N*′-dimethylacetamide, followed by film casting and reduction of the metal salts by sodium borohydrate. The metal particle size depended on the type of metal salt used and on its concentration.

Zhu and co-workers (56) developed a method for the preparation of metal/polymer nanocomposites based on γ-irradiation. In this method, the metal salt was dissolved in the organic monomer, and the formation of nanocrystalline metal particles and monomer polymerization was obtained simultaneously in solution by irradiation with a ^{60}Co γ-ray source, leading to a homogeneous dispersion of nanocrystalline metal particles in the polymer matrix. Also UV-irradiation has been used for the reduction of metal ions dispersed in polymer matrices (57).

Wizel and co-workers (58) have described the use of ultrasounds in the *in situ* synthesis of composite materials made of polystyrene and iron. The propagation of ultrasound waves through a fluid causes the formation of cavitation bubbles. The collapse of these bubbles, described as an implosion in the hot-spot theory, is the origin of extreme local conditions: high temperatures (5000–25,000 K) and high pressures (1000 atm). The cooling rates obtained during the bubble collapse are greater than $10^7\ K \cdot s^{-1}$. These high cooling rates have been utilized in the sonication of $Fe(CO)_5$ as a neat liquid or in solution, to produce amorphous iron nanoparticles. In addition, ultrasound radiation has been widely used for the preparation of polymers without the use of initiators (59). These two chemical processes have been combined for the fabrication of metal/polymer nanocomposites by sonication of styrene solution of iron carbonyl.

***Ex Situ* Methods.** Because of the high optical purity that can be achieved in the final product, the *ex situ* synthesis of metal/polymer nanocomposites is a very attractive technique, especially in the preparation of materials for optical applications. The particulate material of the required size, as obtained by a solution chemistry route, is stabilized by legand chemisorption (eg, thiols) in order to reduce their surface reactivity and tendency to agglomeration, and then it is incorporated into a castable polymeric matrix. Usually, the passivated nanoparticles are dispersed into a liquid monomer–initiator mixture (eg, styrene or methyl methacrylate activated by benzoyl peroxide), which is then thermally polymerized. Because a little amount of filler is required, the polymerization behavior of the monomer is not significantly influenced by the presence of passivated nanoparticles (the reaction rate is only slightly decreased (60)). Gonsalves and co-workers (60,61) have prepared surface-derivatized gold particles by phase-transfer reaction of gold ions with dodecanthiol and used these particles for the synthesis of poly(methyl methacrylate) based nanocomposites. Carotenuto (62) has developed

a new technique for the preparation of bulk quantities of atomic clusters of gold, derivatized by thiols by a modification of the well-known *Polyol Process* technique (63). The *ex situ* approach has been used also in the synthesis of silver/polyethylene nanocomposites (64,65). A variety of high nuclearity metal cluster compounds which can be used for the polymeric nanocomposite preparation have been recently synthesized and studied (66–76).

Clusters of noble and easily reducible metals (eg, Ag, Au, Pd) can be obtained by alcoholic reduction of metal ions in presence of polymeric stabilizers. Poly(vinylpyrrolidinone), poly(vinyl alcohol), poly(methylvinyl ether), etc are usually utilized. High quality polymer-protected metal clusters can be obtained at the end of reaction simply by addition of a nonsolvent liquid which causes the nanocomposite separation from the reactive mixture (coprecipitation) (77–79). However, the use of such nanocomposites is limited because of their excessive moisture sensitivity.

Characterization Techniques

For the comprehension of mechanisms involved in the appearance of novel properties in polymer-embedded metal nanostructures, their characterization represents the fundamental starting point. The microstructural characterization of nanofillers and nanocomposite materials is performed mainly by transmission electron microscopy (TEM), large-angle X-ray diffraction (XRD), and optical spectroscopy (UV–vis). These three techniques are very effective to determine particle morphology, crystal structure, composition, and grain size (48).

Of the many techniques which have been used to study the structure of metal/polymer nanocomposites, TEM has undoubtedly been the most useful. This technique is currently used to probe the internal morphology of nanocomposites. As visible in Figure 4, high quality images can be obtained because of the presence, in the sample, of regions that do not allow the high voltage electron beam passage (ie, the metallic domains) and region perfectly transparent to the electron beam (ie, the polymeric matrix). High resolution TEM (HRTEM) allows morphological investigations with a resolution of 0.1nm, and thus this technique makes possible to accurately image nanoparticle sizes, shapes, and in some cases even inner atoms (80) (see Fig. 5).

Large-angle X-ray powder diffraction (XRD) has been one of the most versatile techniques utilized for the structural characterization of nanocrystalline metal powders. The modern improvements in electronics, computers, and X-ray sources have allowed it to become an indispensable tool for identifying nanocrystalline phases as well as crystal size and crystal strain (see Fig. 6). The comparison of the crystallite size obtained by the XRD diffractogram using the Scherrer formula with the grain size obtained from the TEM image allows to establish if the nanoparticles have a mono- or polycrystalline nature (11).

Metal clusters are characterized by the surface plasmon resonance, which is an oscillation of the surface plasma electrons induced by the electromagnetic field, and consequently their microstructure can be indirectly investigated by optical spectroscopy (UV–vis spectroscopy). The characteristics of this absorption (shape, intensity, position, etc) are strictly related to the nature, structure, topology, etc

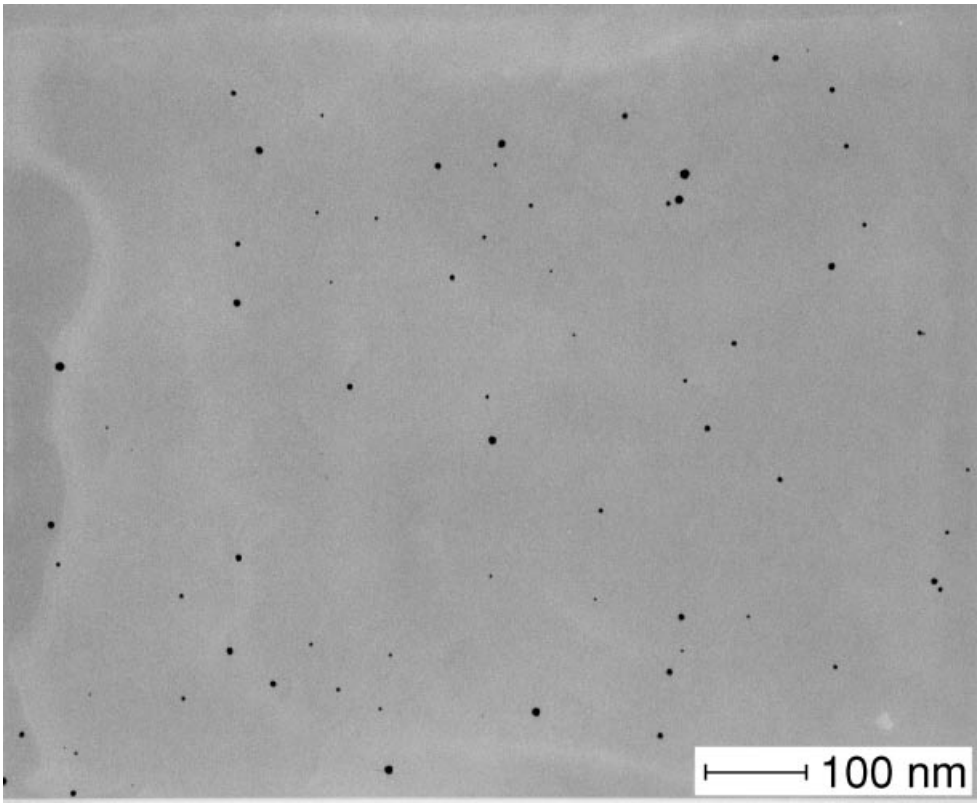

Fig. 4. TEM micrograph of metal gold clusters embedded in poly(vinylpyrrolidinone).

of the cluster system. In fact, the absorption frequency is a fingerprint of the particular metal, the eventual peak splitting reflects aggregation phenomena, the intensity of the peak is related to the particle size, the absorption wavelength is related to the particle shape, the shift of the absorption with increasing of temperature is indicative of a cluster melting, and so on. For bimetallic particles information about inner structure (intermetallic or core/shell) and composition can be obtained from the maximum absorption frequency (81). Differently from *out-line* techniques (eg, TEM, XRD) this method allows *on-line* and *in situ* cluster sizing and monitoring of morphological evolution of the system (see Fig. 7). This method has been used also in the study of cluster nucleation and growth mechanisms (82,83). In addition to multielectron transition (ie, plasmon absorption) also single-electron transition (interband transition) can be detected and studied by optical spectroscopy in order to obtain important microstructural information.

This outline of the principal characterization techniques for nanocomposite materials and nanosized metal fillers is far from being complete. Advances in Raman spectroscopy, energy dispersive spectroscopy, infrared spectroscopy, and many other techniques are of considerable importance as well. In fact, the success that nanostructured materials are having in the last few years is strictly related to the advanced characterization techniques which are available today.

Applications

Applications of metal/polymer nanocomposites have already been made in different technological fields. However the use of a much larger number of devices based on these materials is predicted for the near future.

Because of the plasmon surface absorption band, atomic clusters of metals can be used as pigments for optical plastics. The color of the resulting nanocomposites is light-fast and intensive, and these materials are perfectly transparent, since the cluster size is much lower than light wavelength. Gold, silver, and copper can be used for color filter application. Also UV absorbers can be made for example by using Pd clusters. The plasmon surface absorption frequency is modulated by making intermetallic particles (eg, Pd/Ag, Au/Ag) of adequate composition.

As shown in Figure 8, polymeric films containing uniaxially oriented pearl-necklace type of arrays of nanoparticles exhibit a polarization-dependent and tunable color (64,65,84–86). The color of these systems is very bright and can change strongly, modifying the light polarization direction. These materials are obtained by dispersing metal nanoparticles in polymeric thin films and subsequently reorganizing the dispersed phase into pearl-necklace arrays by solid-state drawing at temperature below the polymer melting point. The formation of these arrays in the films is the cause of a strong polarization-direction-dependent color which can

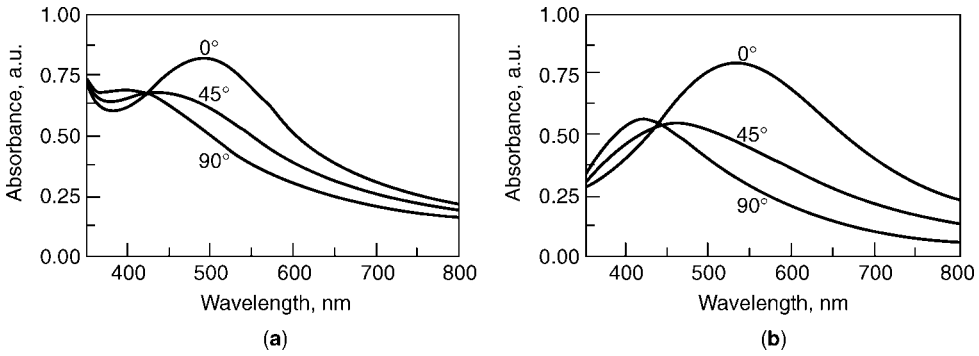

Fig. 8. (**a**) UV–vis spectra of drawn polyethylene/silver nanocomposites containing 4 wt% dodecanethiol coated silver nanoparticles in linearly polarized light. (**b**) Absorption spectra of drawn polyethylene/silver nanocomposite film annealed for 15 h at 180°C. The angle between the polarization direction of the light and the drawing direction of the film is given (64).

be used in the fabrication of liquid-crystal color display (see Fig. 9) and special electrooptical devices (see Fig. 10).

Surface plasmon resonance has been used to produce a wide variety of optical sensors, eg, systems which are able to change their color in presence of specific analytes. These devices can be used as sensors for immunoassay, gas, and liquid (see Fig. 11) (48).

Metals are characterized by ultrahigh/low refractive indices and therefore they can be used to modify the refractive index of optical plastics (87–89). Ultrahigh/low refractive index optical plastics can be used in the waveguide technology (eg, planar waveguides and optical fibers).

Plastics doped by atomic clusters of ferromagnetic metals show magnetooptical properties (ie, when subject to a strong magnetic field, they can rotate the vibration plane of a plane-polarized light) and therefore they can be used

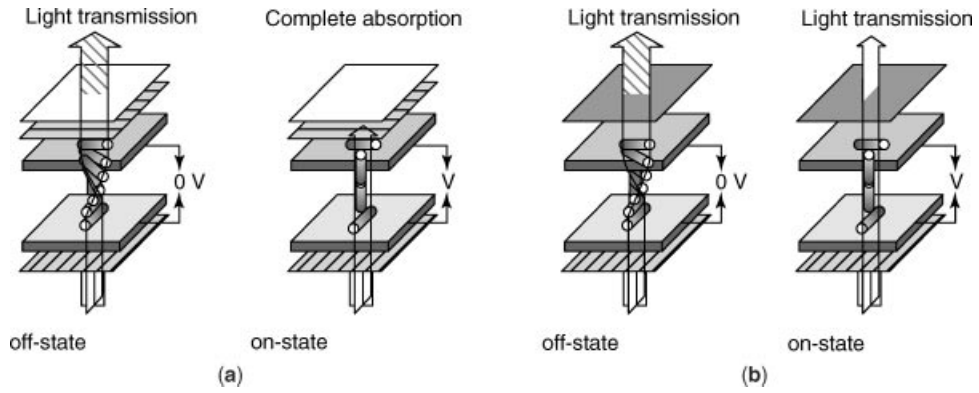

Fig. 9. Schematic representation of (**a**) a conventional color twisted nematic liquid-crystal display; and (**b**) display set-up containing a color polarizing filter (64).

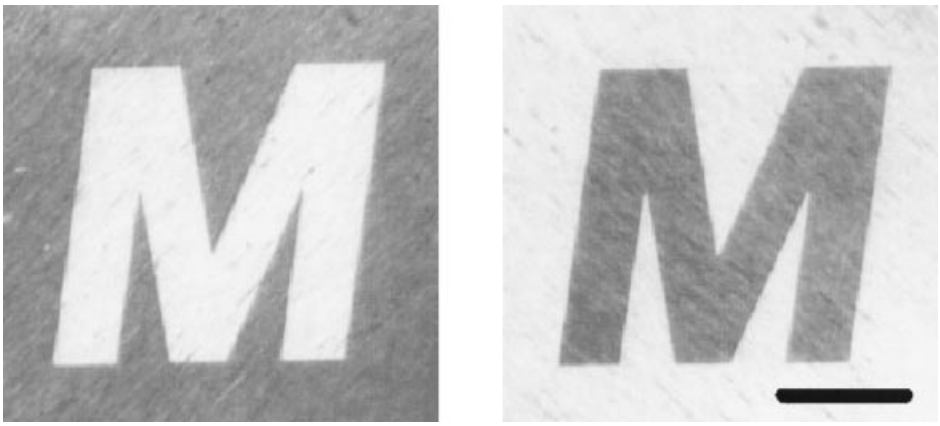

Fig. 10. Twisted nematic liquid-crystal cell equipped with a polyethylene/silver nanocomposite filter (65).

as Faraday rotators (90,91). These devices have a number of important optical applications (eg, magneto-optic modulators, optical isolators, optical shutters).

Nanosized metals (eg, gold, silver) have attracted much interest because of the nonlinear optical polarizability, which is caused by the quantum confinement of the metal's electron cloud (92) (see NONLINEAR OPTICAL PROPERTIES). When irradiated with light above a certain threshold power, the optical polarizability deviates from the usual linear dependence on that power. By incorporating these particles into a clear polymeric matrix, nonlinear optical devices can be made in a readily processable form (61). These materials are used to prepare a number of devices for photonics and electrooptics (see ELECTROOPTICAL APPLICATIONS).

Contact-free dispersion of noble metal clusters in polymer can be also used as nonporous catalytic membranes (93–95). Traditionally, nonporous catalytic separation layers are composed of palladium or palladium alloy foils. Reduction in

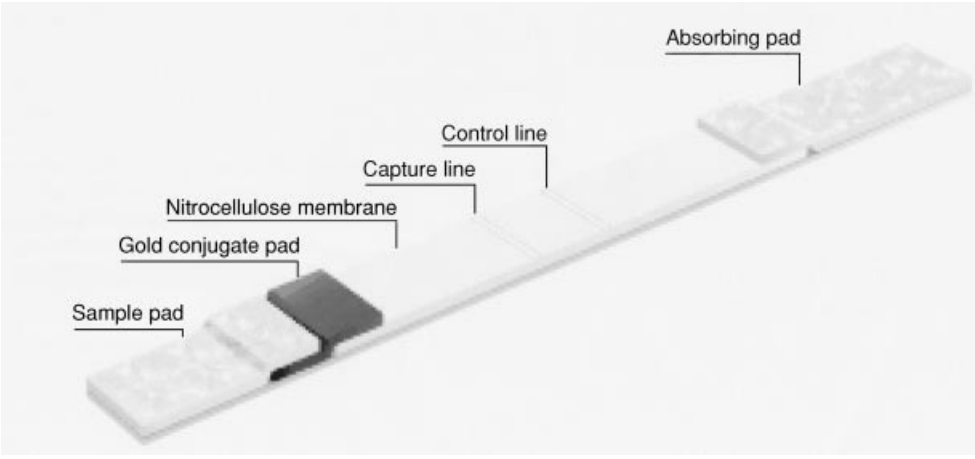

Fig. 11. Nanosized gold-based optical sensor for biological assay.

thickness by metal film deposition on special supports increases the hydrogen permeability and reduces the costs for the precious metal. Polymeric matrix filled by a catalytic nanosized metal offers in addition to the above advantages, the possibility of using the catalytic properties of nanoscale metal catalysts.

One of the most important characteristics of polymers filled by metal microclusters is their ability to absorb microwave radiation, producing heat (96). These plastic materials can be processed by using new technologies based on the microwave heating and can be used for food packaging, microwave shielding, RADAR camouflage, plastic welding by microwaves, etc.

Metal/polymer nanocomposites can have many other important applications. For example, nanoparticles embedded into poly(vinylpyrrolidinone) can be used for the electroless plating of polymeric, ceramic, and semiconductor substrates (93–98). These materials have also been used for the preparation of "smart" systems that experience a reversible alteration of their properties upon exposure to light. They are used as infrared barriers against exposures to intense solar light or fires (99).

Summary

Metal cluster–polymer systems are receiving increased attention because of the interesting properties and large potentialities for technological applications. In particular, these nanocomposite systems can provide simple, low cost options for obtaining tailored materials with high promise for various catalytic, optical, magnetic, and electronic applications. Usually, the control of the nanoparticle morphology, ie, particle size, size distribution, shape, and composition, is of main interest. Nanoparticle features can be varied by selection of preparation method and variation of experimental conditions. In addition to the versatility of the nanoparticle features and the polymer morphologies, options can be provided to tailor the topology of the metal–polymer systems. This includes for example the uniaxially oriented pearl-necklace type distribution of metal nanoparticles within the polymer matrix. For a variety of applications special topologies are important and determining factors for tuning the composite material performance.

In conclusion, further research activity in this field is extremely important for the development of advanced devices for functional applications based on these materials.

NEUTRON SCATTERING

Introduction

"Scattering" to most polymer scientists means light scattering, and the extent of their experience with the experiment is often the description in a course of how light scattering can be used to determine the molecular weight and radius of gyration of a polymer in solution, as well as the second virial coefficient of the solution, by measuring the scattered light intensity from a series of dilute solutions for multiple angles. (1–4) This data is then plotted as a Zimm plot to obtain the desired characteristics of the polymer chain and solution. Or maybe the polymer scientist is interested in the crystal structure of a commercial polymer and uses X-ray diffraction to provide details of the local ordering of the pertinent long-chain molecule. (5–7) The X-ray scatterer may not see the correlation between the diffraction peaks and the information in the Zimm plot, but there is one. The

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

angular dependence of scattered radiation provides direct information on the spatial distribution and microscopic structure of the scattering particles, whether in light scattering, X-ray diffraction, or neutron scattering experiments. For X-ray diffraction this information is on the order of angstroms and provides the arrangement of atoms on an ordered lattice, while (small-angle) light scattering provides data on the average size of a complete polymer chain on a length scale of a few to tens of nanometers.

In fact, scattering is a powerful analytical method that can be utilized to determine the structure and dynamics of a range of "soft" materials (colloids, polymers, proteins, etc) using X-rays, light, and neutrons. Moreover, the fundamental physics of the correlation between the angular dependence of the scattered intensity to the microscopic structure of the scattering particle is identical for all types of radiation; it is only the manner in which the data is treated and analyzed to provide information on the structure that makes them appear different. A given analysis can be used with any type of radiation; the same analyses that are used in X-ray diffraction are used in neutron diffraction, and can be used in light-diffraction experiments, if it will provide important data on the ordering of the particles that are diffracting (scattering) the incoming radiation. Small-angle X-ray, neutron, and light-scattering experiments are commonly reported in journals, with similar analyses and types of results. The primary difference is the type of radiation that shines on the sample and its interaction with the scattering particle.

The Scattering Experiment

Differences among radiation types can best be explained through a discussion of the scattering experiment itself. A scattering experiment can be depicted as in Figure 1, where the radiation shines on the sample, interacts with the sample, and is scattered in all directions. The intensity of the scattered radiation (I) is then measured at a detector for multiple angles (θ) and can be plotted as shown in the I vs θ plot in Figure 1. For most geometries and samples, the scattering intensity is a maximum at zero angle and drops with increasing angle. In this diagram the wavelength of the incident radiation (λ_i) and the wavelength of the scattered radiation (λ_s) are equal, and thus this is an elastic scattering event. The angular dependence of the scattering intensity can then be analyzed to provide information on the size, shape, and orientation of the scattering particle in the sample. This type of experiment is often termed a *static* scattering experiment as the information garnered is related to the static structure of the scattering particle, not its dynamics.

However, in order to obtain a useful I vs θ curve, a number of specific criteria must be met. Two of the most important criteria are that the measurement be taken in the correct angular range and that there be sufficient contrast in the sample for scattering to occur.

The correct angular range and sufficient contrast in the sample depends intimately on the type of radiation that is used in the scattering experiment, and a more detailed discussion of the scattering process is necessary to clarify this point.

Consider two vials, one that contains pure solvent and another that contains a solution with particles that may scatter light. Figure 2 shows a beam of light

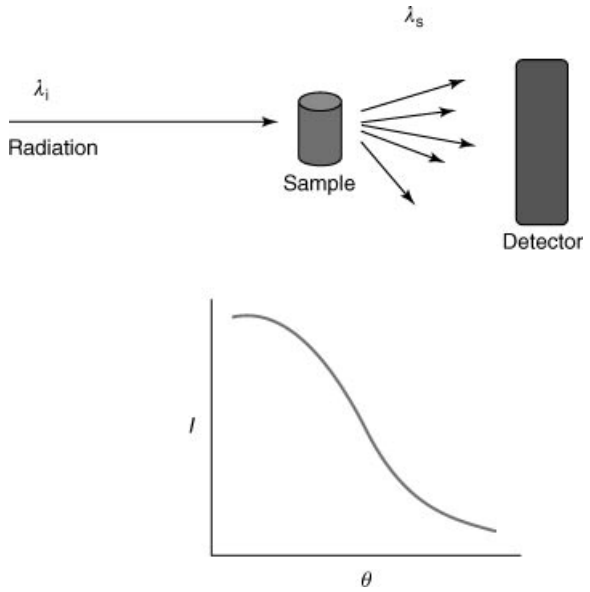

Fig. 1. (**a**) Schematic of an experiment to determine the angular dependence of the scattering of an incident radiation by a sample; (**b**) Typical intensity of scattered radiation vs scattering angle plot.

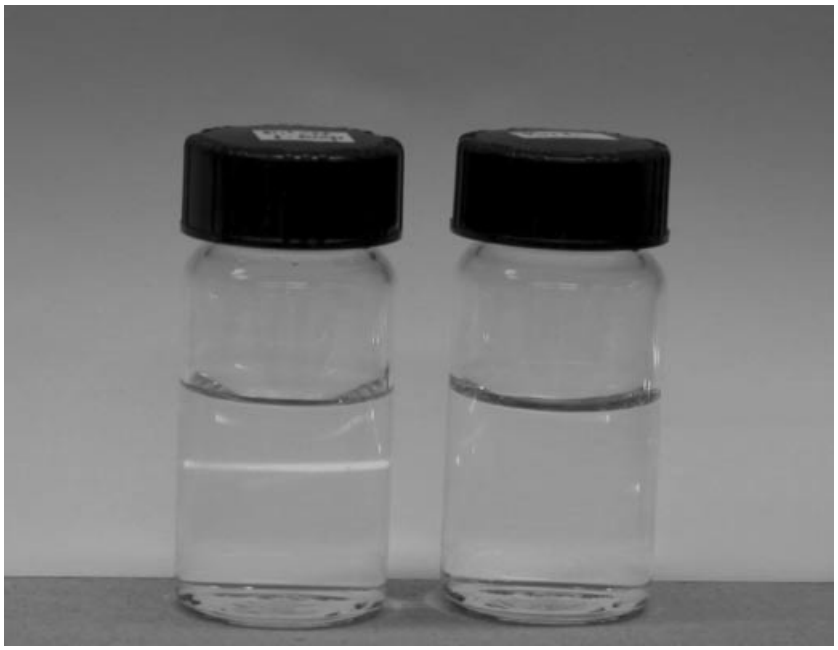

Fig. 2. Illustration of scattering power. The left vial contains polystyrene spheres that have a different refractive index than water, which provides contrast that results in scattering of the laser that is observable by the human eye.

from a laser pointer shining through two vials, where the right-hand one is pure water and the left is a 0.0002% solution of polystyrene (PS) microspheres (0.4 μm) in water. Notice how the laser light is strongly scattered by the solution, but not the pure solvent. That is because the solution contains PS particles that have a different refractive index than the water solvent that it is immersed in. This difference in the refractive index of the solute (PS, $n = 1.59$) and the solvent (water, $n = 1.33$) provides the contrast that is needed to observe scattering. Notice that in the pure water, there is no portion of the sample that has a different refractive index than the rest of the sample, and thus there is no observable scattering because there is no contrast. It is important to emphasize that it is possible to have a solution, but still not have sufficient contrast between the solvent and solute to observe scattering. For instance, if you have a solution where the solute and solvent have refractive indices that are identical, there will be no portion of the sample that has a different refractive index than the rest of the sample, and therefore there is no significant scattering. This phenomenon is termed *contrast matching* and is utilized in some scattering experiments to extract the scattering from a single component in a multicomponent sample.

This concept of "contrast" also holds true for the scattering of X-rays and neutrons by a polymer solution. However, when X-rays are being scattered by a particle, the X-rays interact with electrons of an atom and thus the intensity of scattering from a given atom depends on the electron density of that atom, not the refractive index. The electron density increases with atomic number on the periodic chart. Thus, for a polymer solution to strongly scatter X-rays, the electron density of the polymer and solvent must be significantly different. Finally, when neutrons are scattered, the neutrons interact with the nucleus of the atom and thus the intensity of the scattered radiation depends on the structure of the nucleus. This scattering power is quantified by the scattering length density b of a given atom and can vary by isotope. Therefore, to observe significant scattering from a polymer in solution, the scattering length density of the polymer must differ from that of the solvent. This has dramatic consequences for studying polymers and other soft matter by neutron scattering, as the scattering length densities of hydrogen and deuterium are significantly different. Thus, by changing the level of deuteration of a polymer (or solvent), the contrast (and thus amount of scattering) of a polymer in solution can be tuned without dramatically altering the thermodynamics of the mixture. (8–10)

This control of contrast in polymer mixtures by selective deuteration results is a unique and powerful aspect of neutron scattering in studying polymer systems; by the dispersion of a deuterated polymer chain in a matrix of identical hydrogenated chains, neutron scattering can be used to examine the structure and dynamics of a polymer in the melt or concentrated solution. This ability to "highlight" a single molecule in a matrix of identical polymer chains is illustrated in Figure 3. In Figure 3**a**, groups of polymer chains are shown, all drawn the same color. Because there is no contrast between the various chains, it is difficult to pick out one single chain. In Figure 3**b**, the color of one of the chains has been changed slightly, modeling the system where the scattering length density of one chain is slightly different than that of the matrix. Although this chain may now be observable, it is still difficult to examine. Finally in Figure 3**c**, a single chain is much darker than the remainder and is easy to pick out from the matrix and examine

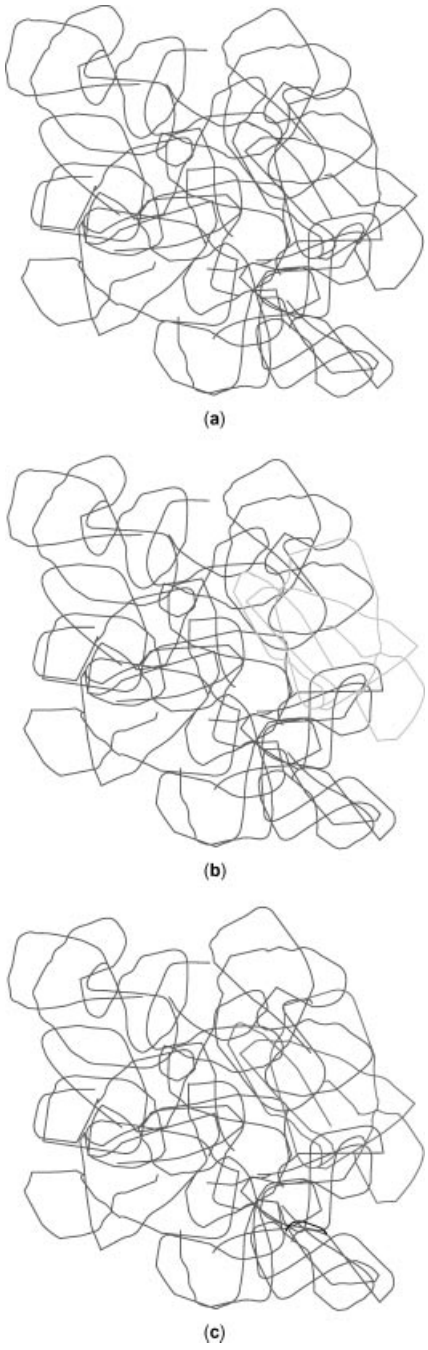

Fig. 3. Illustration of contrast. Figure **a** contains 10 polymer chains, where each chain is the same color, and thus there is no contrast between chains and it is difficult to differentiate one chain from the rest. Figure **b** contains the same 10 chains, but one has a slightly different color than the remaining chains, and thus this chain may be examined with difficulty. Figure **c** contains the same 10 chains, where one is now much darker than the remaining chains, providing a mechanism to clearly study this chain.

precisely. This picture illustrates the system where that chain is deuterated while the matrix of chains remains protonated with respect to neutron scattering. This one chains stands out as different from the matrix and can be selectively studied by neutron scattering.

The other criterion that is required to successfully utilize scattering to study polymer systems involves completing a scattering experiment in the correct angular range to extract useful information concerning the structure of the scattering particle from the angular dependence of the scattering intensity. This can best be exemplified in Figure 4, which shows the resultant I vs θ plots for scattering experiments that are completed in the wrong angular range. The I vs θ plot shown in Figure 4**a** shows a quick drop in intensity at low angle and very little scattering at higher angles. This type of curve is the result of measuring over too wide of an angular range so that the important information in the small-angle region is not resolved. Alternatively, Figure 4**b** shows a modest drop in intensity with angle, but no significant change in scattering intensity over the angular range of the scattering. In this case, the angular range is too small and there is insufficient data to quantify the drop in intensity with angle that can provide information on the structure and size of the scattering particle.

The quantification of this "correct" angular range requirement provides a correlation of the length scales that can be studied by radiation of a given wavelength. At small angles, the length scale that is measured, d, is approximately λ/θ, where λ is the wavelength of the radiation and θ is the scattering angle. This approximation demonstrates that neutrons are indeed ideal to examine the structure of proteins and polymers; for cold neutrons, $\lambda = 0.5 - 1.5$ nm, and small-angle scattering instruments provide a range of θ that allows the observation of the structure of soft matter over length scales ranging from 1 to 100 nm, perfect to determine the structure of a macromolecule from the local to global length scales.

Scattering with Neutrons. Thus, observing the scattering of neutrons by a polymeric system is a very powerful tool to determine the structure and dynamics of polymers over the correct length scales, primarily because of the ability to tune the contrast between components by selectively deuterating the particles (or portions of particles) that are of interest. Additionally, neutrons offer further benefits, including their ability to penetrate matter. Because the neutrons interact with the nucleus of an atom, a large portion of the neutrons that impact a sample will be transmitted through it without absorption or scattering. One useful result of this is that the sample holder can be quite large and complex as the neutrons are then able to penetrate a large sample holder and scatter from the sample. Thus, it is possible to complete neutron-scattering experiments from a broad range of sample environments including *in situ* steady shear (11–13), high pressure (14,15), oscillatory shear (16), and even when the sample is an aerosol (17,18).

However, there are some drawbacks to using neutron scattering. Most notably, the production of neutrons is a very costly process, as the neutrons are most often produced for scattering experiments by nuclear fission in a nuclear reactor or by spallation. *Spallation* is the process where energetic subatomic particles, such as protons, strike a target and eject particles, including many neutrons from the nuclei of the atoms in the target. These neutrons then serve as the source of the radiation for the neutron-scattering experiments. In either case, the cost of a

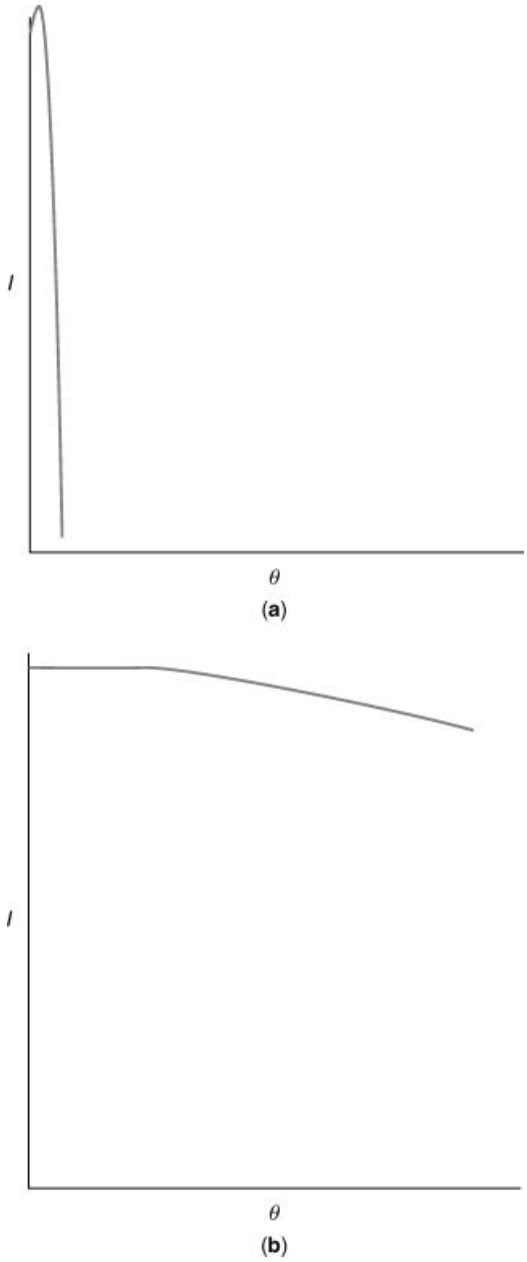

Fig. 4. Examples of the measured angular dependence of the scattering intensity for poorly designed experiments. The angular range in (**a**) is too broad, while the experiment shown in (**b**) is the result of an experiment where the angular range is too narrow.

nuclear reactor or spallation source is beyond most companies or laboratories and thus is in the domain of government agencies. Thus, there exist a handful of facilities in the United States, with more spread out around the world, where a polymer scientist can complete neutron-scattering experiments, and their completion

requires the time and expense of travel. Additionally, the current flux of neutrons requires significant sample size (usually, ~0.1–1.0 g), with larger sizes needed for exotic sample environments, such as a shear cell. This may be a particular problem for biological and exotic samples, where it is difficult to create more than a few milligrams of a given material. However, the Spallation Neutron source that is currently being built in Oak Ridge, Tennessee, will provide much greater intensity of neutrons on the sample, and thus allow faster measurements on smaller samples.

Even given these limitations, neutron scattering is a unique and very powerful technique that can provide information on the microscopic structure and dynamics of a polymeric material that is not obtainable by any other method. For instance, no other method provides a direct measure of the size of a polymer chain in the melt that is available by measuring the scattered intensity of neutrons from a blend of deuterated and protonated versions of the same polymer. Similarly, the shape and thermodynamic interactions of polymers in concentrated mixtures are most effectively monitored by carefully designed neutron-scattering experiments, some of which will be described in detail later in the article.

Structure from the Scattering Curve

There are a number of excellent reviews that detail the relationship between the angular dependence of the scattering intensity to the density distribution of the scattering system, and that will not be duplicated here (19,20). Rather, the methods to extract the structural information of the scattering system from the scattering pattern will be emphasized.

Classical scattering theory shows that the coherent scattering from a one-component system is proportional to the Fourier transform of the density correlation function, $C(\mathbf{r})$, of the particles in the system (19,21,22):

$$\left(\frac{\partial\sigma}{\partial\Omega}\right) \propto \int_V \exp(-i\mathbf{q}\cdot\mathbf{r})\, C(\mathbf{r})\mathrm{d}\mathbf{r} \tag{1}$$

where $(\frac{\partial\sigma}{\partial\Omega})$ is the number of scattered neutrons per second per solid angle $\partial\Omega$ in the neutron-scattering experiment. For simplicity, this quantity will be replaced by $I(q)$ in the remainder of this article. In equation 1, $\mathbf{q}$ is the scattering or momentum transfer vector, and has a magnitude $|\mathbf{q}| = q = 4\pi/\lambda \sin(\theta/2)$, where λ is the wavelength of the scattered radiation and θ is the scattering angle.

In a multicomponent system, such as a mixture of two constituents (component 1 and component 2), the scattering intensity now has contributions from correlations among particles of type 1, correlations among particles of type 2, and correlations between type 1 and type 2 particles, resulting in a scattering intensity $I(q)$ that can be described as

$$I(q) = b_1^2 S_{11}(q) + b_2^2 S_{22}(q) + 2b_1 b_2\, S_{12}(q) \tag{2}$$

Where b_i is the scattering length of component i and S_{ij} is the partial structure factor that describes the contribution to the scattering of the correlations between components i and j and is

$$S_{ij} = \int_{V,} \int_{V'} \langle n_i(\mathbf{r}) n_j(\mathbf{r}') \rangle \exp[-i\mathbf{q} \cdot (\mathbf{r}' - \mathbf{r})] d\mathbf{r}\ d\mathbf{r}' \tag{3}$$

where n_i ($\mathbf{r}$) is the local density of component i at point $\mathbf{r}$ and $\langle \ldots \rangle$ denotes an average over the scattering volume. Note that comparing equation 1 and equation 3, the density distribution function of the scattering particles $C(\mathbf{r}'') = \langle n_i(\mathbf{r}) n_j(\mathbf{r}') \rangle$ where $\mathbf{r}'' = \mathbf{r} - \mathbf{r}'$. Thus, the partial structure factor is the Fourier transform of the density distribution of the scattering particles, and if it can be extracted from the measured scattering intensity, it will provide information on the structure of the scattering particles; ie, $S_{11}(q)$ will provide information on the spatial distribution of the particles of type 1.

At first glance, the sum of three partial structure factors appears to add significant complexity to analyzing the $I(q)$ to determine the correlation between measured scattering patterns and structure of the scattering sample. However, it is relatively straightforward to show that, for two scattering particles of equal volumes, $S_{11}(q) = S_{22}(q) = -\frac{1}{2} S_{12}(q)$, which simplifies equation 2 to (23,24)

$$I(q) = (b_1 - b_2)^2 S_{11}(q) = (b_1 - b_2)^2 S_{22}(q) = -(b_1 - b_2)^2 S_{12}(q) \tag{4}$$

Thus, the angular dependence of the scattering intensity of a binary mixture can be analyzed as the Fourier transform of the density correlation function of any of the scattering particles scaled by the square of the difference in scattering lengths of the two components.

Let us assume that component 1 is a polymer and component 2 is a solvent. The requirement that the scattering particles (1 and 2) have equal volume for equation 4 to be valid requires that "particle 1" be equivalent to a section of the polymer chain that is the same volume as the solvent. Approximating this as a monomer segment of the polymer chain leads to an interesting result. Equation 4 tells us that $I(q) = (b_1 – b_2)^2 S_{11}(q)$; therefore the scattering pattern from a polymer/solvent mixture will provide a direct measure of the spatial distribution of the monomers (as they have been defined as the scattering particles of type 1). Moreover, if the polymer molecules are sufficiently dilute to be independent of each other, the q dependence of the scattering pattern is the Fourier transform of the spatial distribution of the monomers in a single-particle chain. This quantity is known as the *Particle Form Factor* of the polymer chain, $P(q)$, and Debye has shown that the Fourier transform of a Gaussian segment distribution, known as the *Debye Function*, is (25)

$$P(q) = 2\frac{[\upsilon^2 - 1 + \exp(-\upsilon)^2]}{\upsilon^4} \tag{5}$$

where $\upsilon = qR_g$, and R_g is the radius of gyration of the polymer molecule. Thus, by fitting the experimentally determined scattering pattern to equation 5, the radius of gyration and random coil nature of the polymer chain can be determined.

If the polymer molecules are not dilute, then a term for the *intermolecular* correlation between monomer segments [$Q(q)$] also contributes to the scattering pattern and must be accounted for in any subsequent data analysis. Fortuitously, when analyzing the scattering pattern of a mixture of two identical polymers, where one is deuterated and the other is not, $Q(q)$ can be related to the single particle form factor $P(q)$, and thus the scattering intensity pattern, $I(q)$, from this type of mixture can be directly correlated to the single-particle form factor, $P(q)$. Therefore the scattering from a mixture of deuterated and protonated identical polymers *at any concentration* can be readily analyzed to provide information on the structure of a polymer chain in the melt (23,24)

$$I(q) = (b_d - b_h)^2 x(1-x) N z^2 P(q) \tag{6}$$

where b_d is the scattering length of the deuterated polymer, b_h is the scattering length of the protonated polymer, x is the volume fraction of deuterated polymer, N is the total number of polymer molecules, and z is the number of monomer segments in the polymers.

Thus, from a practical standpoint, the scattering intensity of neutrons from a polymeric system as a function of angle can be measured. This scattering pattern is the Fourier transform of the density distribution of the scattering particles and, therefore, can be analyzed to provide information on the spatial distribution of the scattering particles. More specifically, in dilute mixtures or when a deuterated polymer is dispersed in its protonated counterpart, the size (R_g) and structure (does it obey the Gaussian distribution and is thus a random coil?) of the polymer chain can be readily determined from this scattering intensity pattern. Other single-particle form factors can also be used to model scattering data, such as that for a rigid rod, hollow sphere, or cylinder (26,27), which can provide size and structural information on other objects beyond random coils. For instance, the packing of a thermotropic, semiflexible liquid crystalline polymer has been shown to pack into a cylindrical conformation by fitting the resultant neutron scattering to the single particle form factor of a cylinder, where the radius and length of the cylinder are readily obtained from the fit (28).

Moreover, it is not difficult to design other experiments and apply broader analysis techniques to the measured $I(q)$ to provide information on the structure and thermodynamics of polymeric systems beyond the conformation of a polymer chain in the melt. Rather than describe the exact conditions and analyses for each of these opportunities, the remainder of this article will detail specific examples that describe efforts to examine particular structural aspects of polymeric systems with small-angle neutron scattering.

The Conformation of a Polymer Chain in the Melt

The most well-known examples of neutron-scattering experiments were completed in the early 1970s to unequivocally determine the conformation of a polymer chain

in the melt. Over 20 years earlier, Flory had predicted that a polymer chain that is dispersed in a matrix of identical polymer chains would follow random walk statistics (29) rather than the more obvious self-avoiding walk statistics that polymers are known to adopt in a good solvent. Unfortunately, there were no available techniques at the time to determine the conformational statistics of a single chain in the melt to test this prediction. However, the advent of neutron scattering provided a mechanism to determine the structure of a single polymer chain in the melt by selectively deuterating one molecule, dispersing it in a matrix of nearly identical protonated polymers, and examining it.

The design of these experiments was straightforward; the researchers dispersed protonated poly(methyl methacrylate) in deuterated poly(methyl methacrylate) at a level of a few percent and analyzed the resulting neutron-scattering intensity patterns to determine the radius of gyration of the polymer as well as the second virial coefficient of this solution. These results show that the polymer attains the same radius of gyration as that measured in a theta solvent and that the second virial coefficient of this mixture is zero (30–32). Similar experiments on mixtures of protonated polystyrene and deuterated polystyrene were completed that provided information on the scaling relationship between the radius of gyration and molecular weight for this polymer (33,34). All of these experiments demonstrated that the R_g scales as $M^{0.5}$ in the melt and obeys the Debye function down to a length scale of 1 nm, as would be expected from random walk statistics and was predicted by Flory.

In fact, further experiments over the years have shown that the R_g scales as $M_w^{0.5}$ for a range of polymers in the melt or glassy state with the proportionality constant equal to that which is observed in a theta solvent, verifying that flexible polymer chains in the melt attain a configuration that is accurately modeled as random coil. These results are tabulated in Table 1, where the data are taken from Reference 19 (see also CONFORMATIONS AND CONFIGURATION).

Table 1. Conformation of Polymer Chain in the Melt and in a θ Solvent

		Bulk	In θ solvent
Polymer	State	$R_g{}^a/M_w^{0.5}$,Å/(g/mol)$^{0.5}$	$R_g{}^a/M_w^{0.5}$,Å/(g/mol)$^{0.5}$
Atactic poly(methyl methacrylate)	Glass	0.25–0.27	0.25
Isotactic poly(methyl methacrylate)	Glass	0.30	0.28
Syndiotactic poly(methyl methacrylate)	Glass	0.29	0.24

The Location of End Groups in Dendrimers

Dendrimers are highly branched polymers that can be synthesized by the consecutive addition of multifunctional monomers to a multifunctional core to form a tree-like structure (35,36), where an illustration of a dendrimer formed from trifunctional monomers is presented in Figure 5 (see DENDRONIZED POLYMERS). These macromolecules have recently attracted significant attention as possible sensors, drug carriers, lubricants, and surface-active agents. As the molecule is synthesized and becomes larger, more active sites remain at the outer edge of the molecules with each successive generation. As the number of active growth sites increases with size, the mass of the molecule increases exponentially with the number of generations. Clearly, the packing of each new generation becomes more dense, until the density saturates and the size of the molecule reaches a maximum.

The density profile of these unique structures has been the subject of much investigation. DeGennes first predicted that the dendrimer will have a density minimum at the center of the molecule, increase with radius, and reach a maximum at the outer edge of the spherical molecule (37). This structure provides a cavity in the center of the molecule that would provide an ideal structure for its use as a carrier. However, further theoretical and simulation studies have suggested that the molecule is not hollow, but has a density maximum at the center that decreases with radius (38–40).

Small-angle X-ray scattering and other studies have not clarified the radial structure of these intriguing molecules (41,42); however, a recent study of the radial density profile by small-angle neutron scattering has provided a clearer picture of its structure (43). Lindner and co-workers have used contrast variation small angle neutron scattering to unequivocally show that these molecules have a density maximum at the center, and a density profile that decreases with radius.

The specifics of this set of experiments take advantage of the ability to control the contrast between the dendrimer and the solvent by varying the extent of deuteration of the solvent, which is accomplished by mixing deuterated dimethyl acetamide (DMA-D_9) and protonated dimethyl acetamide (DMA-H_9). These

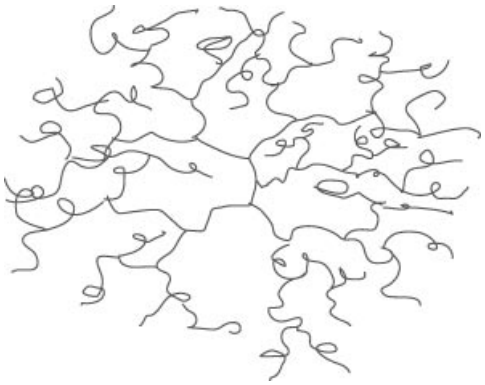

Fig. 5. Illustration of a dendrimer that is formed from trifunctional monomers, grown to the fourth generation.

researchers determined the scattering pattern of a fifth-generation dendrimer dissolved in DMA at various concentrations and varying ratios of DMA-D_9 to DMA-H_9. The authors analyze this data to extract the portion of the scattering that is due solely to the shape of the dendrimer [I_s (q)] from the measured scattering intensity which also contains contributions due to inhomogeneities of the dendritic structure, which may result from imperfections in the structure and the fact that the building blocks of the dendrimer may not all have the same structure (and thus scattering length). This careful analysis provides a measure of the average scattering length density of the dendrimer, which provides an exact measure of the molecular weight of the dendrimer. A comparison of this value to the ideal fifth-generation dendrimer indicates that the structure is not perfect.

Finally, the authors extract the radial density profile of the dendrimer from I_s (q) by its Fourier inversion to show that the density of the dendrimer is a maximum at the center that decreases smoothly to the outer edge. Moreover, the results demonstrate that the dendrimer radius extends to 6 nm and is thus a fluctuating, not a dense, structure. This analysis is further verified by comparing the scattering intensity [I_s (q)] to the Fourier transform of this density distribution and to the Fourier transform of the homogeneous sphere, where this comparison shows a clear coincidence to the experimentally determined density profile and clear deviations from that of the homogeneous sphere.

Thus the ability to systematically vary the contrast between the solute and solvent by mixing deuterated and protonated solvents provides a mechanism to unequivocally extract the scattering from the solute, and thus determine the structure of that solute. These results show that the end groups of this dendrimer are not confined to the outer layer of this centrosymmetric structure, which would result in a core-shell density profile. Rather, the end groups are distributed throughout the volume of the macromolecule. This information will have significant impact on the utilization of these novel macromolecules and their use in the design of molecular scale sensors, drug carriers, and lubricants.

The Radius of Gyration of Polymers in Ultrathin Films

It is well known that confining a polymer molecule to a thin film or near a surface lowers its configurational entropy. This confinement may also alter the configuration of the polymer, which may impact its adhesive and thermal properties, among others. One can easily imagine that a polymer chain that is confined to a thin film that is on the order of (or less than) its radius of gyration may be flattened. Moreover, as devices become smaller, polymers are often utilized in applications where the confinement of the polymer chain is significant. Thus, the alteration of the configuration of a polymer chain by confinement is of importance to their use in micro- and nanoscale devices. It is, therefore, important to understand how confinement alters the size and shape of a polymer chain, with the expectation that this data can provide fundamental information to predict, understand, and control the properties of polymers in these environments.

As polymers in miniature devices are mostly melts, neutron scattering becomes an ideal experimental technique to provide this information. Clearly, by

dispersing a fraction of deuterated polymer in a protonated thin film of the polymer, SANS can be used to determine the radius of gyration of a polymer confined to the film, as a function of film thickness, in a similar way to the bulk measurements in the 1970s that verified the random coil nature of the polymer chain in the melt (30,32,33). However, the relatively low intensity of neutrons that strike the sample in a scattering experiment introduces a complication into this planned experiment. In a scattering experiment, the intensity of scattered radiation is proportional to the amount of sample in the beam. In a bulk SANS experiment, a sample usually contains on the order of 0.1–0.5 g to optimize the signal to noise. However, with a radius of a neutron beam that is on the order of a centimeter, a thin film of polymer that is only as thick as the radius of gyration of a polymer will only provide 0.000785 mg of sample in the beam, clearly an amount that is insufficient to provide adequate signal-to-noise ratio to accurately determine the radius of gyration of a polymer. Researchers who have completed such a study overcame this obstacle by simultaneously scattering from multiple, identical thin films, thus effectively increasing the sample size (44,45).

The authors of this study measured the neutron-scattering intensity of isotopic blends that contain 25 wt% deuterated polystyrene and 75 wt% protonated polystyrene in thin films that vary in thickness (D) from 1 μm down to 10 nm. These thicknesses correspond to $D/R_{g,bulk}$ that range from 50 to 0.5. The samples were annealed at high temperature and quenched to ensure that the samples were at equilibrium. The data were analyzed by accounting for scattering from interfacial roughness in the form of capillary waves and incoherent scattering to extract the scattering due to the dispersion of the deuterated polymers in the protonated matrix $I_s(q)$. This scattering, $I_s(q)$, was then analyzed using the RPA model and the Kratky approach (q^2I vs q^2) to determine the radius of gyration of the deuterated polymers and test the Gaussian nature of the confined chains, respectively. The R_g results are shown in Figure 6, which shows that the size of

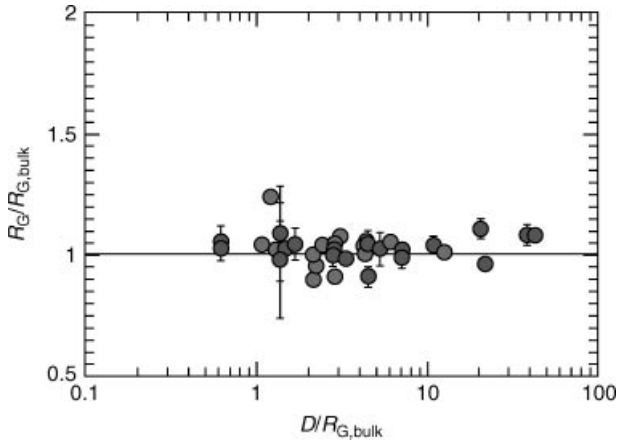

Fig. 6. The radius of gyration of deuterated polystyrene in a thin film normalized to its radius of gyration in the bulk as a function of film thickness that is also normalized to the radius of gyration of the polymer in the bulk. ● $M_w = 270$ K, ● $M_w = 650$ K. Fig. 7. Representative phase diagram of a binary mixture of two molecules that have similar sizes.

the polymer chain in the plane of the surface does not change from that of the chain in the bulk, even when the thickness of the film is less than the R_g of the bulk chain. The data also verify that the chains do retain their Gaussian character for all film thicknesses studied. This result agrees with recent simulation and theoretical studies and will have implications on the properties and dynamics of a polymer chain in confined geometries.

Polymer Blends

The Spinodal Decomposition Process in Polymer Blends. For many mixtures, there exists a temperature range where the system will remain miscible for all compositions, while a change in temperature will alter the balance of the enthalpy and entropy of mixing to create a thermodynamic state where the most stable system is one where two phases coexist and the mixture, therefore, phase separates. This situation is illustrated in Figure 7, which shows the phase diagram of a regular solution (46). When below the critical temperature, the outer line of this phase diagram denotes the compositions of the two phases that coexist at a given temperature. Therefore, for this system, it is possible to design a temperature program where the system is brought from the one-phase state at high temperature to a phase-separated system at low temperature.

In fact, the kinetics of the process by which the system goes from a homogeneous, one-phase system to the final equilibrium state of two coexisting phases is extremely important to both industrial and academic researchers. From an industrial standpoint, understanding and control of the morphology of the

phase-separated system can provide a mechanism to create new materials with novel properties. From an academic point of view, the self-assembling process of the phase separation and resultant morphologies provide insight into nonequilibrium thermodynamics. Of particular interest, a more complete understanding of the kinetics of spinodal decomposition as a phase separation process has been an area of intense study (47–51).

It is known from thermodynamics that in the region of the phase diagram below the spinodal line (dotted line in Figure 7) that a one-phase system is absolutely unstable and the system will phase separate spontaneously via the spinodal decomposition mechanism (SD). Moreover, the time evolution of the change in concentration is well described in the early stages of SD by the theory first presented by Cahn for small molecules (52,53). This theory predicts that there exists a dominant length scale for the phase separation process that does not change with time in this early stage and that the amplitude of the concentration fluctuations [$\Delta\phi$ (**r**,t)] that occur on this length scale grows exponentially with time. Unfortunately, these predictions were difficult to observe in small molecular mixtures, as the time scale of the early stage is too brief (ie $<$1 s) for experimental measurements. However, because polymers are larger and slower, the time scale over which this early stage lasts is minutes, providing sufficient time to monitor the time dependence of the growth of the concentration fluctuations to test this theory. Moreover, small-angle neutron scattering is an ideal tool to monitor these changes, as the scattering intensity [$I(q)$] of the mixture provides direct information on the distribution of the scattering particles, and thus can be used to observe the variation of the spatial distribution of the concentration fluctuations as a function of time.

Time-resolved small-angle neutron scattering has, thus, been used to determine the coarsening kinetics of spinodal decomposition in polymer blends. Blends systems that have been investigated include mixtures of hydrogenated and deuterated polybutadiene as well as deuterated polystyrene and poly(vinyl methyl ether) (49–51) where the deuteration of one component in the blend provides the necessary contrast to complete the experiments. In these experiments, the researchers create a polymer blend that is initially in the one phase-region (* in Fig. 7). This mixture is then quickly brought to a temperature in the phase-separated regime, below the spinodal decomposition line ($\circ$ in Fig. 7), and subsequently the scattering intensity [$I(q)$] for the system as a function of time is measured. The resultant scattering patterns can then be fit to the Fourier transform of the theoretically predicted concentration fluctuation distribution (47), which provides a direct mechanism to test the theories of the kinetics of spinodal decomposition.

These results confirm that $\Delta\phi$ (**r**,t) grows exponentially with time while the characteristic length scale **r** remains constant in the early stage (54). Further experiments have documented that at later times, in the intermediate stage of SD, the phase-separated morphology coarsens with time, resulting in a nonexponential growth of $\Delta\phi$ (**r**,t) and an increase in **r** with time. At even later times, in the late stage of the SD process, the interface between the separate domains narrows and $\Delta\phi$ (**r**,t) reaches an equilibrium value, which is defined by the specifics of the phase diagram. These domains can coarsen further (though more slowly than earlier stages) and thus, the length scale of the domains, **r**, continues to grow slowly.

Thus, the ability of small-angle neutron scattering to tune the contrast of the phase separating blends combined with its ability to examine the correct length

scales of this phase separation process make SANS an ideal technique to determine the kinetics of the concentration fluctuation growth during spinodal decomposition. Moreover, the results show that the linearized Cahn–Hilliard–Cook theory of SD (52,53,55) accurately describes the early stage of spinodal decomposition, and that the intermediate and late stage kinetics obey universal kinetics.

The Crossover from Mean-Field to Ising Behavior in Critical Polymer Blends. Polymer systems have long been known to follow mean-field behavior at most temperatures, as long-range fluctuations are readily damped because of their slow relaxation processes and intimate mixing of chains (56,57). However, it is expected from critical theory that as a mean field system approaches a critical point, fluctuations will become more prevalent and impact the structure of the system. The increased importance of the fluctuations results in a polymer mixture transitioning to behave as a non-mean-field (Ising) system (58). The point where this transition occurs is known as the *Ginzburg criterion* (59). This transition from mean-field to non-mean-field behavior can be determined by monitoring the temperature dependence of concentration fluctuation size (ξ), where it is expected that $\xi \sim (T - T_c)^{-\nu}$ and $\nu = 0.5$ for a system that obeys mean-field behavior and $\nu = 0.63$ for an Ising type system.

As neutron scattering measures the fluctuation in the scattering length density of a system, it is an ideal tool to monitor the presence and growth of concentration fluctuations in a polymer/polymer mixture. In fact, the inverse of the zero-angle scattering, $I^{-1}(q{=}0)$, is proportional to the second derivative of the free energy of the mixture with respect to the blend concentration, which is the osmotic compressibility of a mixture. Theories of cooperative phenomena show that $I^{-1}(q{=}0) \sim (T - T_c)^{-2\nu}$ (60) and thus the determination of $I^{-1}(q)$ extrapolated to $q{=}0$ for a polymer blend at a series of temperatures near T_c will provide a method to verify the existence of this crossover and its influence on the mixing behavior of two polymers (61,62).

To test this prediction of the crossover from mean-field to Ising-type behavior, very precise small-angle neutron scattering measurements were completed on blends of deuterated polystyrene (d-PS) and poly(vinyl methyl ether) (PVME) at the critical concentration for a series of temperatures as the one-phase mixture approaches the temperature of phase separation (ie, the critical point T_c in Fig. 7) (61). The data were analyzed by fitting the measured $I\ (q)$ to the random phase approximation to estimate $I(q{=}0)$ for each temperature, where the temperature is controlled to ± 0.01 K.

Far away from the critical temperature, Schwahn and co-workers found that the inverse of the scattering intensity at zero angle, $I^{-1}(q{=}0)$, scales with $(T_c - T)$ where T is the temperature at which the scattering is measured, as would be expected from a mean-field system. However, as the temperature approached the critical temperature, $I^{-1}\ (q{=}0)$ diverges from a linear relationship with $(T_c\text{-}T)$ within 3 K of T_c. Moreover, in this narrow region near the critical point, $I^{-1}(0)$ scales as $(T_c\text{-}T)^{1.26}$ as one would expect from a system that obeys Ising-type behavior. This transition is shown in Figure 8, taken from Reference 61.

This result emphasizes that mean-field theory is a very accurate model to describe the behavior of polymer systems for most of the phase diagram, except in a narrow window near the critical temperature and concentration. This implies that concentration fluctuations do not significantly influence the phase behavior

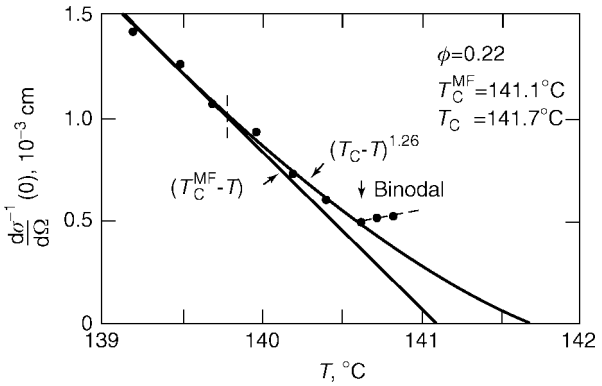

Fig. 8. The inverse of the zero-angle scattering of a polymer blend (d-PS/PVME) as it approaches the phase separation temperature. Note the deviation from mean-field behavior just below 140 °C. Reprinted with permission from Ref. 61. Copyright (1987) by the American Physical Society.

of polymers, whereas for small molecule mixtures, it is known that composition fluctuations can influence the system throughout the phase diagram of the mixture and neutron scattering is an instrumental technique in defining these differences.

Flow-Induced Structure in Polymers

In order to create a useful polymeric product, the material will have to undergo some level of processing where a shear flow is applied to a polymer melt or solution to create the desired shape. However, it is well known that the application of a shear field onto a polymer melt or solution can modify its structure (63). One interesting phenomenon that has been observed is the enhancement of concentration fluctuations by the application of a shear field. In other words, a polymer solution that is miscible at rest appears to phase separate when it is sheared. This phenomenon has been well studied, but is not completely understood (64–67).

As neutron scattering provides information on the spatial distribution of concentration fluctuations by virtue of its ability to provide direct evidence of the spatial distribution of the scattering particles, it is an ideal technique to examine the changes that occur during this phenomenon on length scales ranging from the monomeric level to that of many chains. Moreover, if combined with light scattering, which provides information on larger length scales than that of neutrons, an understanding of the development and deformation of the concentration fluctuations as a function of parameters such as shear rate and temperature over length scales ranging from submolecular to micrometers can be found. There exist a number of articles describing the monitoring of the structures that are induced in polymer blends, phase-separated block copolymer, liquid crystalline polymer solutions and melts, and polymer solutions by an applied shear field; but to exemplify the utility of this technique, the work of Hashimoto and Lindner on the impact of temperature and shear rate on the enhancement and deformation of concentration fluctuations in polystyrene/dioctyl phthalate solutions (PS/DOP) using neutron- and light-scattering experiments will be discussed (68).

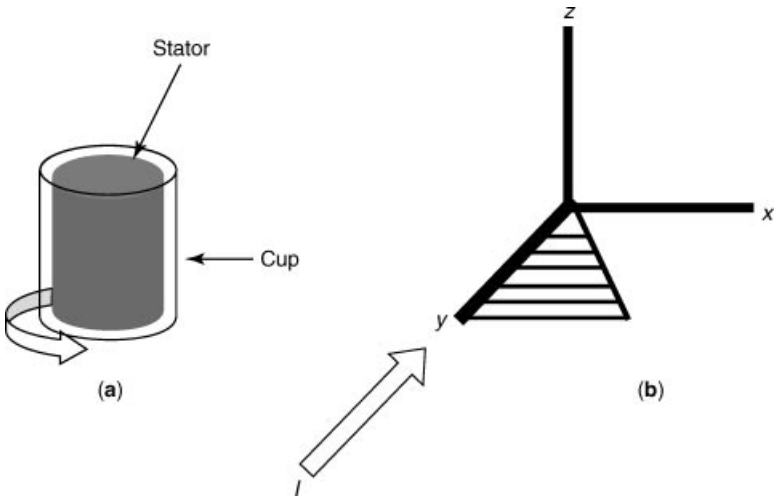

Fig. 9. (**a**) Diagrammatic representation of a couette shear cell. (**b**) The resultant geometry of the shear field, where the x-axis is the flow direction, the y-axis is the shear gradient and the z-axis is the vorticity direction. Note that the incident radiation is also along the y-axis, and the measured scattering intensity is in the flow–vorticity plane.

In this work, the investigators measured the scattering patterns of PS/DOP while they were being sheared. This requires that a sample holder be designed whereby the material can be constantly sheared during the time that the scattering pattern is collected. A geometry that has provided significant success at collecting the scattering of polymer systems *in situ*, during shear flow, is a couette cell as shown in Figure 9. In this cell, an outer cup is made out of a material that is relatively transparent to neutrons, such as quartz. This cup then contains a stator that fits symmetrically into the cup, but leaves a thin annulus between the cup and the stator into which the polymer melt or solution can be filled (11). It is important that the stator also be manufactured from a material that allows large transmission of neutrons. Stators have been successfully made from quartz and oxygen free copper, where the copper provides better heat transport and higher use temperatures, and thus provides the ability to measure shear effects on bulk polymer materials as well as solutions.

The SALS and SANS data were combined to provide information on the structure of the concentration fluctuations on length scales ranging from tens of angstroms to 10 microns. The authors were able to fit the data to model the scattering from the structure of the thermal concentration fluctuations as well as the contributions from the demixed phases. The scattering pattern was, thus, fit to the sum of an Ornstein–Zernike function (to model thermal fluctuations) and a modified squared Lorentzian function (to model the demixed phases). From these fits, the authors were able to provide quantitative information regarding the size and shape of the demixing domains as a function of temperature, shear rate, and polymer molecular weight. Moreover, the results provide a data set that can be used to test current and pioneering theoretical models of this phenomenon and find that earlier theoretical treatments do not agree well with this broad set of results.

The results, however, do appear to agree with more recent theoretical models and thus provide critical insight into the physics of this unique phenomenon.

Thus, the combination of neutron scattering and light scattering is a valuable tool set that allows these researchers to monitor the structures that exist in the phase-separating mixture on a broad range of length scales. It is only with the information of the structure of this polymer solution over these length scales that allows the researchers to critically evaluate theoretical models of shear-induced phase separation in polymer mixtures.

Structure of Proteins by Contrast Variation

The mechanism by which biological enzymes become active, bind with substrates, and affect a catalytic reaction is of broad interest. Specific details on how the enzymes coordinate and interact with regulators are of particular importance in understanding enzymatic activity. For instance, calmodulin is a receptor for calcium that is responsible for binding of Ca^{2+} in calcium-dependent regulation of cellular processes via interactions with enzymes (69). A model system for this regulation of enzymatic activity is the calcium/calmodulin activation of myosin light chain kinase (MLCK) (70,71). MLCK contains a catalytic cleft that is normally inhibited by a regulatory sequence within the MLCK. The binding of the Ca^{2+}/calmodulin (CaM) to the MLCK activates the catalytic cleft, and enables target enzyme recognition and substrate binding. However, the specific structural mechanism by which the CaM complex activates the catalytic cleft was not verified until Trewhella and co-workers utilized small-angle neutron scattering experiments with contrast variation to elucidate the change in structure of the CaM complex and MLCK upon binding that results in the activation of the catalytic cleft. (72,73)

In these experiments (73), the authors determined the scattering patterns for CaM–MLCK (in which the CaM is deuterated) complexes in H_2O/D_2O mixtures that were 0, 20, 75, 82, and 85% D_2O. This range of mixtures provided the needed information to extract the individual shape functions of the MLCK and CaM structures at various stages of the binding process. This is accomplished by analyzing the measured scattering function $I\,(q, \Delta b_c, \Delta b_K)$ with the following equation

$$I\,(q, \Delta b_c, \Delta b_K) = \Delta b_c^2\, I_c\,(q) + \Delta b_c\, \Delta b_K\, I_{CK}\,(q) + \Delta b_K^2\, I_K\,(q) \qquad (7)$$

where subscripts c and K denote deuterated CaM and MLCK, respectively, Δb_i is the contrast between the scattering length density of component i and solvent ($b_i - b_s$) and $I_c\,(q)$, $I_K\,(q)$, and $I_{CK}(q)$ denote the contribution to the total scattering from the structure of the CaM, the structure of the MLCK, and the correlation between the structures of CaM and MLCK, respectively. Note that by completing the experiments for a series of D_2O/H_2O mixtures, a series of equations that fit equation 7 are created, and the scattering from each individual structure [$I_c\,(q)$ and $I_K\,(q)$] can be extracted and analyzed.

The authors do precisely that: they fit the resulting individual form factors to those of two ellipsoids that provide information on the size, shape, and relative

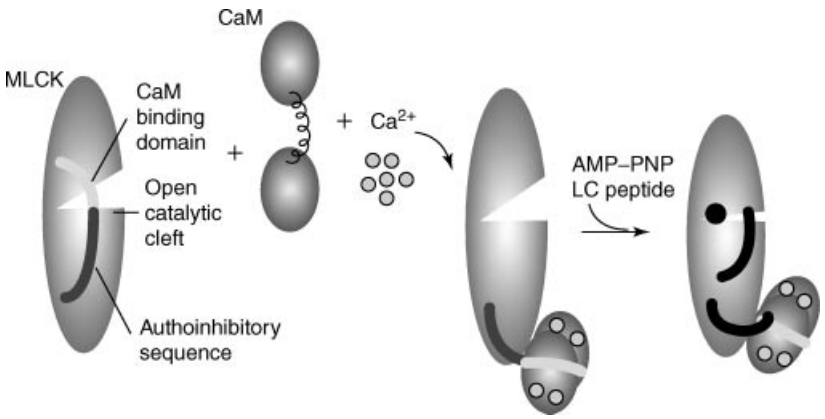

Fig. 10. Diagram that depicts the interaction of CaM to MLCK that results in the activation of the catalytic cleft of MLCK to enzymatic activity. Reprinted with permission from Ref. 73. Copyright (1998) American Chemical Society.

dispositions of the CaM and MLCK. This information provides a very precise picture of how the two molecular components come together, interact, and activate the catalytic cleft of the MLCK, which is illustrated in Figure 10 (from Reference 73). The scattering results indicate that a regulatory sequence within the MLCK keeps its catalytic cleft open. The binding of Ca^{2+} to CaM opens hydrophobic clefts in the CaM. Upon binding of the CaM with MLCK, the hydrophobic clefts on the CaM interact with hydrophobic residues of the MLCK sequence, which induces movement of the MLCK regulatory sequence away from its catalytic cleft, relieving the MLCK auto-inhibition and providing an activated structure that can now bind with substrates and thus enable enzymatic activity.

This example further demonstrates the power of neutron scattering to extract structural information of individual components in a complex system by use of the contrast variation method. Contrast variation provides an additional sample preparation technique that allows the extraction of the scattering of a single component in a multicomponent mixture and broadens the utility of neutron scattering into fields such as the study of biological complexes and the structure of diblock copolymers (74).

NONLINEAR OPTICAL PROPERTIES

Introduction

This article introduces the field of nonlinear optics and the electronic nonlinear optical (NLO) response of polymers and polymer composites. Both second- and third-order NLO phenomena are included, with primary emphasis on harmonic generation, the intensity-dependent refractive index, and nonlinear (multiphoton) absorption effects. The beginning sections introduce the phenomena and explain how the order of the nonlinearity can be understood from a series expansion of the polarization in powers of the electric-field. In addition to listing the variety of nonlinear optical phenomena and some applications, some of the advantages of polymeric materials for NLO applications are also surveyed.

Structure-property relationships that are important to the NLO response are explored in later sections. The approach taken in this article is to work backwards from the bulk effects, described first, to their origin at the molecular level. Thus, Section 5 describes the connection between the constituent molecular NLO hyperpolarizabilities and the macroscopic NLO response. Topics include local field effects, orientation of molecules and polymers, methods of incorporating NLO chromophores into polymers, and limitations on the application of simple summative models. Particular molecular properties that determine the microscopic NLO response are discussed and a few distinct models and parameters useful for optimizing second-order and third-order material properties are provided. The emphasis is on understanding the influence of π-electrons and electron delocalization, as well as on the nature and scaling of polymer repeat units for third-order materials. Also briefly reviewed are several categories of polymer structures that have been studied, and their advantages and disadvantages for NLO applications. Finally, major test methods for measuring the NLO properties of materials are surveyed.

The research literature on nonlinear optics and NLO polymers is vast, whereas this article is, of necessity, intended to serve primarily as a starting point for further investigation. Major topics of related NLO research are left to other articles in this Encyclopedia and to the reading list and bibliography. The reading list at the end of this article recommends books, proceedings, and special journal issues devoted to nonlinear optics and the NLO properties of molecular organic materials and polymers. (See, especially, References 1–7). The article is also focused primarily on all-optical nonlinearities. See article ELECTROOPTICAL APPLICATIONS for a discussion of the changes in the optical response of polymers due to an applied AC or DC electric-field from the so-called Pockels or Kerr effects. Nonlinearities arising primarily from vibrational or rotational/orientational motion (8) are not considered here. Also omitted are the unique NLO properties of many specialized classes of polymers, such as liquid crystalline polymers (see LIQUID CRYSTALLINE POLYMERS, MAIN-CHAIN), organometallic polymers (see METAL-CONTAINING POLYMERS), chiral and biological polymers, and magneto-optical polymers. Similarly, promising studies of polymer-based nanoscale structures, the optical properties of conducting polymers (9) and their application to the development of electroluminescent polymers for organic light-emitting diodes (LEDs) and lasers are outside the scope of this article (see LIGHT-EMITTING DIODES).

Overview of Nonlinear Susceptibilities

Linear and Nonlinear Optics Compared. A simple comparison with the characteristics of linear optics illustrates some of the unique phenomena associated with nonlinear optics. Light bends (refracts) at an optical interface between two media because of the change in speed of propagation of light, as described by each media's refractive index. In linear optics, the refractive index n of the material does not change with the intensity of the light at ordinary light levels. (Otherwise one would need different power eyeglasses for low levels of light and for bright sunshine.) Also, the light transmitted by a linear transparent material does not change frequency upon passing through it. An incident red light emerges red. For both linear and nonlinear optics, media are dispersive, so that the index of refraction changes with the frequency of the light, and a medium may absorb visible light at some frequencies, giving the material a distinctive color. If the optical properties are linear, however, both the dispersion and the relative fraction of power absorbed are independent of the intensity of the light.

If the incident light is sufficiently intense, as in a laser, these simple linear relationships are no longer sufficient to describe the optical response of so-called nonlinear media (or any media, for that matter, if the measurement is precise enough or the intensity is high enough and the material is not destroyed in the process). When the optical properties of the material become nonlinear, the refractive index may change with the intensity of the incident light, thereby changing the optical path length and the focusing properties of an optical element made from that material. In addition, the presence of one beam may amplify another or change its polarization when the beams overlap in the medium, as in an optical switch. Also, the material's absorption (the imaginary part of the index of refraction) may vary with incident intensity. For example, in an optical limiter, the material may appear to be transparent to low levels of light, but a sufficiently intense beam will trigger significant absorption. Conversely, the absorption of a so-called saturable absorber decreases as the intensity of the light increases. Finally, the frequency response of the medium may also be altered when nonlinear effects become apparent. For example, an intense infrared laser may produce a significant visible frequency component upon passing through a material, through harmonic generation, or through another frequency conversion process.

Anharmonic Oscillator Model. At the microscopic level, materials respond to light (or more specifically to the oscillations of the electric-field of the light) through the back-and-forth movement of charges. As an example of how the nonlinear displacement of the charge affects the detected response, it is helpful to view the effects of the oscillating optical electric-field on a material using an anharmonic oscillator model (10). Ignoring the vector nature of the field for the present, the force on the electron in an electric-field E is simply $F_e = eE$, where e is the electron charge. For linear media, the restoring force on the electrons in the presence of the optical field is directly proportional to the electron displacement x from equilibrium, just like the restoring force for a simple spring, $F_{\text{restore}} = -kx = -m\omega_0{}^2x$, where k is the spring constant, ω_0 the resonant frequency, and m the mass. The resulting equation of motion for the electron, ignoring damping of the oscillations, is then simply $eE - m\omega_0^2 x = m\frac{d^2x}{dt^2}$. The solution to this equation in

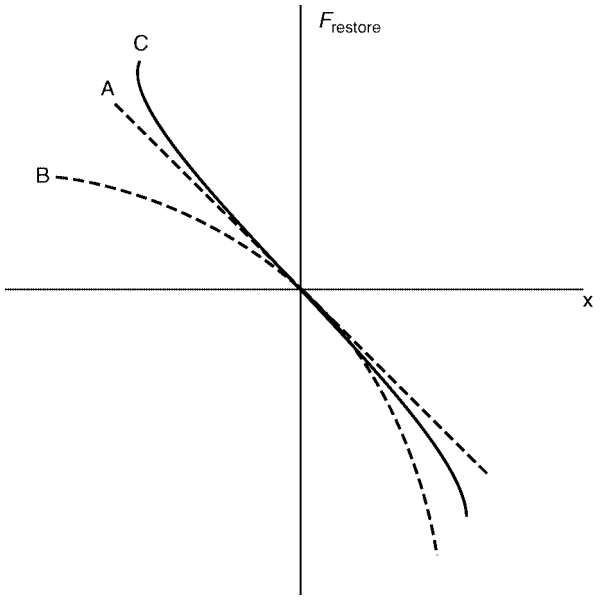

Fig. 1. Examples of restoring forces $F_{restore}$ as functions of x for (A) a linear restoring force, (B) a restoring force with a quadratic nonlinear term, and (C) a restoring force with a cubic nonlinear term.

the case of a monochromatic optical field oscillating at ω ($E = E_0 \cos\omega t$) is

$$x = -\frac{e}{m}\frac{E}{\left(\omega_0^2 - \omega^2\right)} \tag{1}$$

As the pull of the applied field becomes stronger, however, the electron's spring-like response becomes distorted. The restoring force must include additional, nonlinear terms proportional to the square of the displacement for second-order processes ($F_{restore} = -kx - ax^2$) or the cube of the displacement for third-order processes ($F_{restore} = -kx - bx^3$). (Coefficients a and b may be positive or negative. Figure 1 shows examples of quadratic and cubic nonlinear restoring forces for positive coefficients.) The solution to the equation of motion in the case of an anharmonic restoring force is not possible in closed form, but the solution can be expressed as a series expansion, $x = x_1 + x_2 + x_3 + \cdots$, where x_1 is the solution without any anharmonic term in the restoring force (given by equation 1). Given a single monochromatic incident optical field as a driving force for the oscillator, again expressed as $E = E_0 \cos \omega t$, the simplest nonlinear contributions turn out to be proportional to the square $x_2 \sim {E_0}^2 \cos^2\omega t$ and the cube $x_3 \sim {E_0}^3 \cos^3\omega t$ of the incident field (11). Application of simple trigonometric identities to the expressions for x_2 and x_3 reveals typical resulting phenomena. Using the identity $\cos^2 \omega t = \frac{1}{2} + \frac{1}{2} \cos 2\omega t$, the $\cos^2\omega t$ term may be expressed as a combination of a second-harmonic response ($2\omega = \omega + \omega$) and a constant DC field response called optical rectification ($0 = \omega - \omega$). The expansion $\cos^3\omega t = \frac{3}{4} \cos\omega t + \frac{1}{4} \cos 3\omega t$ similarly leads to a third harmonic response ($3\omega = \omega + \omega + \omega$) and a response at the incident

frequency ($\omega = \omega + \omega - \omega$). The latter is responsible for the intensity-dependent refractive index change in the material (12).

Nonlinear Susceptibilities. Nonlinear optical effects are formally understood through the series expansion of the ith component of the polarization (average dipole moment per unit volume) $\boldsymbol{P}$ of a material in powers of the electric-field in the medium $\boldsymbol{E}$ (typically on the order of 10^6 V/m or greater for nonlinear effects to appear), as in (13)

$$P_i^{\omega} = P_i + \varepsilon_0\left[\chi_{ij}^{(1)}(-\omega;\omega)E_j^{\omega} + \chi_{ijk}^{(2)}(-\omega;\omega_1,\omega_2)E_j^{\omega_1}E_k^{\omega_2} + \chi_{ijkl}^{(3)}(-\omega;\omega_1,\omega_2,\omega_3)E_j^{\omega_1}E_k^{\omega_2}E_l^{\omega_3} + \cdots\right] \tag{2}$$

where summation over repeated coordinate indices (i, j, k) is assumed, ε_0 is the permittivity of free space, and the frequency dependence will vary with the NLO process under investigation. [Equation 2 expresses the components of the polarization in the frequency domain, which is the customary approach appropriate for monochromatic or nearly monochromatic fields. In some cases, such as recent research using ultrashort pulses, an analogous and more general time-domain expansion may be preferable (14).] The resultant response frequency ω is a combination (sum and/or difference) of the incident frequencies ω_n. The negative sign is included as a reminder that photon energy (and momentum) is conserved in these parametric processes. Thus, the sum of the frequencies given within each of the parentheses equals zero. The first term on the right, P_i, represents the permanent dipole moment per unit volume in the material. The second term provides the linear contribution to the refractive index (and, if $\chi^{(1)}$ is complex, the absorption coefficient) through the usual second-rank tensor for the linear susceptibility $\chi^{(1)}$. (Recall, in the case of linear homogeneous, isotropic, transparent media, the index of refraction is related to $\chi^{(1)}$ by $n = \sqrt{1+\chi^{(1)}}$.) The remaining terms are responsible for the NLO properties of the material, primarily through the second- and third-order susceptibility tensors, $\chi^{(2)}$ and $\chi^{(3)}$. Although including an arbitrarily large number of terms in the expansion of the polarization in equation 2 is possible, categorizing nonlinear phenomena as either second-order or third-order, using just the terms explicitly shown in equation 2, is practically sufficient. Higher order terms are usually of greatly diminished strength (15).

Centrosymmetric vs Noncentrosymmetric Bulk Media. The distinction between second- and third-order nonlinearities is particularly important for the design of NLO materials for different applications. The terms with even powers in the series expansion of the polarization (eq. 2) are identically zero for centrosymmetric materials. Only noncentrosymmetric materials can exhibit second-order ($\chi^{(2)}$) NLO properties, such as second harmonic generation. [All materials, however, are noncentrosymmetric at their surfaces, and researchers have used surface techniques, such as surface second-harmonic generation, to study centrosymmetric materials (16). For recent reviews, see Reference 17.] The presence of second-order effects depends on the asymmetry both of the individual molecules and on the arrangement of those molecules. The requisite asymmetry is not found naturally in bulk amorphous polymers. The amorphous nature of most polymers requires special preparation to produce the requisite asymmetry, such as

electric-field poling (18), a liquid crystalline phase (19), self-assembly (20), or film formation techniques, as in a Langmuir–Blodgett film (21,22). Most of these techniques are used to align dipolar donor–acceptor groups that are either dissolved in a guest–host system or attached to a polymer to produce macroscopic asymmetry, as discussed in Section 5.4 on incorporating chromophores into polymers. These film preparation techniques and the material properties based on them are beyond the scope of this article, but the references above provide starting points for further investigation (see also LANGMUIR-BLODGETT FILMS; LIQUID CRYSTALLINE POLYMERS, MAIN-CHAIN). Polymer orientation is also discussed at length in the article Electrooptical Applications (qv) because the second-order susceptibility is critical to linear electrooptic devices.

Nonlinear Susceptibility Tensor Elements. In general, the nonlinear susceptibilities, $\chi^{(2)}$ and $\chi^{(3)}$, are complex third- and fourth- rank tensors and, therefore, are comprised of 3^3 and 3^4 different complex numbers, respectively. Fortunately, various symmetries significantly restrict the number of independent tensor elements. Kleinman showed that in certain circumstances, the susceptibility tensor elements are identical for rearrangements of the tensor indices (23). For second-harmonic generation in lossless media, for example, Kleinman's symmetry reduces the number of elements of $\chi^{(2)}$ to 10. In this case, an abbreviated notation has been introduced, $d_{il} = \frac{1}{2}\chi^{(2)}_{ijk,}$, where l represents the six permuted combinations of the jk indices ($l = 1, 2, 3, 4, 5$, and 6, corresponding to the respective index combinations $11, 22, 33, 23 = 32, 13 = 31$, and $12 = 21$), and the ijk indices can be freely permuted (10). Thus, for example, $2d_{13} = \chi^{(2)}_{133} = \chi^{(2)}_{313} = \chi^{(2)}_{331} = 2d_{35}$ and $2d_{33} = \chi^{(2)}_{333}$. For cylindrically symmetric materials (a poled polymer, for example) only two tensor elements are important: the element d_{33}, which describes interactions parallel to the dipolar axis, and the element d_{31}, which describes interactions perpendicular to the dipolar axis (24).

For centrosymmetric materials, such as amorphous polymers, the lowest order nonzero nonlinear susceptibility is $\chi^{(3)}$. For an isotropic polymer, the number of independent $\chi^{(3)}_{ijkl}$ elements is only three, generally, because no direction can be preferred over any other and each direction must appear at least twice (leading to $\chi^{(3)}_{1111} = \chi^{(3)}_{1122} + \chi^{(3)}_{1212} + \chi^{(3)}_{1221}$) [It should be noted that an isotropic solution of chiral molecules will exhibit second-order nonlinearities, but not second-harmonic generation (25)]. For third-harmonic generation, the susceptibility elements simplify to only one ($\chi^{(3)}_{1122} = \chi^{(3)}_{1212} = \chi^{(3)}_{1221}$), and for the nonlinear refractive index, the number of elements needed is only two ($\chi^{(3)}_{1122} = \chi^{(3)}_{1212}$). Furthermore, the nature of the physical mechanism leading to the nonlinear refractive index can sometimes be determined from the ratio of the elements. For example, the relation $\chi^{(3)}_{1122} = \chi^{(3)}_{1221}$ applies if the refractive index change is only due to the nonresonant electronic response of the charges, but $\chi^{(3)}_{1221} = 6\chi^{(3)}_{1122}$ applies if the refractive index change is due to molecular reorientation (26). Fortunately, in many cases it is not necessary to specify individual tensor elements. Unless otherwise stated, the effective nonlinear susceptibility appropriate for the geometry of the material and configuration of the experiment should be assumed.

Problems With Conventions, Reference Standards, and Units. The expression for the relationship between the response and the input fields given by equation 2 is not the only expression commonly used in the literature. Variations

include expanding the polarization in a Taylor series instead of a power series (27), and defining the relationship between the field and the polarization differently (28). Differences between conventions often make it difficult to compare bulk nonlinear susceptibilities and the related molecular susceptibilities (or hyperpolarizabilities) obtained by different experimental methods and by different researchers (29). A more complete theoretical discussion of the problem of comparing conventions as well as the inconsistent use of reference standards for NLO process can be found in Reference 28. For purposes of this article, trends in structure-property relationships will be emphasized, rather than precise values of the NLO coefficients measured. Nonetheless, typical SI values for $\chi^{(2)}$ are $10^{-12} - 10^{-9}$ m/V and for $\chi^{(3)}$ are $10^{-22} - 10^{-18}$ m^2/V^2. Dramatic variations in these values are possible, particularly near a resonance where thermal effects and saturated absorption also contribute to the NLO response. Slower, nonelectronic effects, such as reorientation and electrostriction, also can increase the effective nonlinear susceptibility by orders of magnitude (30). The permittivity factor ε_0 in equation 2 is appropriate for SI units. Most researchers publish results in electrostatic units (esu), however, sometimes without even specifying the fundamental dimensions to which these units refer. Conversion to SI is a straightforward, though not always obvious process. For example, a typical polymer $\chi^{(3)}$ value of 10^{-12} esu $= 10^{-12}$ cm^2/statvolt^2 converts to $4\pi/9 \times 10^{-20}$ m^2/V^2 in SI units, whereas a typical poled polymer $\chi^{(2)}$ value of 10^{-8} esu $= 10^{-8}$ cm/statvolt becomes $4\pi/3$ pm/V in SI. A detailed discussion of the unit conversion process can be found in Reference 31, with the caveat that different conversions are required between SI and esu depending upon the choice of convention for the series expansion of the polarization (28). For example, many authors choose to omit the factor of 4π in the conversion (32).

Nonlinear Phenomena

This section surveys the most widely studied phenomena included among NLO effects that arise due to the electronic contributions to the real and imaginary parts of $\chi^{(2)}$ and $\chi^{(3)}$. This review will be primarily concerned with phenomena related to harmonic generation, the intensity-dependent refractive index, and multiphoton absorption.

Parametric Processes. Parametric processes are those in which photon energy is conserved while the light propagates through the medium. Parametric phenomena of particular interest for devices due to the real part of the nonlinear susceptibility tensors include

(1) second-harmonic generation (SHG) given by

$$P_i^{2\omega} = \frac{1}{2}\varepsilon_0 \chi_{ijk}^{(2)}(-2\omega; \omega, \omega) E_j^{\omega} E_k^{\omega} \tag{3}$$

(2) third-harmonic generation (THG) given by

$$P_i^{3\omega} = \frac{1}{4}\varepsilon_0 \chi_{ijkl}^{(3)}(-3\omega;\, \omega,\, \omega,\, \omega) E_j^{\omega} E_k^{\omega} E_l^{\omega}, \tag{4}$$

(3) degenerate four-wave mixing, (DFWM or the all-optical Kerr effect, OKE) given by

$$P_i^{\omega} = \frac{3}{4}\varepsilon_0 \chi_{ijkl}^{(3)}(-\omega;\, \omega,\, \omega,\, -\omega) E_j^{\omega} E_k^{\omega} E_l^{-\omega} \tag{5}$$

In each case above, the fractional prefactor accounts for the indistinguishability (degeneracy) of the frequencies of the incident fields so that different expressions yield the same susceptibilities in the zero-frequency limit. This convention is common, but not universally adopted (33).

Harmonic Generation. Nonlinear frequency conversion, especially harmonic generation, is important for the development of sources of coherent light at frequencies not otherwise accessible by efficient lasers, in particular the blue, violet, and UV frequencies needed for dense data storage. Harmonic generation is also useful for nonlinear spectroscopic studies, which probe excited states in materials (34).

For harmonic conversion, the conversion efficiency (the ratio of harmonic to fundamental power, η) is largely determined by the size of the effective nonlinearity, the input power P_ω, the interaction length l, and the ability to phase-match the spatial frequencies of the second harmonic and the fundamental light (35). For purposes of illustration, in the limit where only a small fraction of the power is converted and the index of refraction, n_ω, in the material is assumed to be real (lossless) and isotropic, the conversion efficiency can be expressed as (36)

$$\eta = \frac{128\pi^5 \left(\chi_{\text{eff}}^{(2)}\right)^2 l^2 P_\omega}{n_{2\omega} n_\omega^2 \lambda^2 c} \left(\frac{\sin\Delta\varphi/2}{\Delta\varphi/2}\right)^2 \tag{6}$$

Here, $\Delta\varphi = \pi l/\lambda\,(n_{2\omega} - n_\omega)$ is the phase shift between the propagating fundamental and the generated harmonic light, λ is the wavelength in free space, and c is the speed of light. If $\Delta\varphi = 0$, then the factor $(\sin(\Delta\varphi/2)/\Delta\varphi/2)$ in equation 6 takes on its maximum value 1. If the indices of refraction at the second harmonic ($n_{2\omega}$) and the fundamental (n_ω) are not equal, however, the resulting efficiency oscillates with rapidly diminishing peaks as the interaction length increases. The process of minimizing $\Delta\phi$ by making the *effective* refractive indices the same for the fundamental and harmonic light is called *phase-matching*. Techniques for phase-matching are discussed in later in connection with the discussion of using harmonic generation as a technique for characterizing the NLO properties of a polymeric material and for device applications. Poled polymers, have been studied extensively for use in second harmonic generation and other frequency conversion devices.

Degenerate Four-Wave Mixing. DFWM involves input and output light all at the same frequency. When applied to a single input beam, this effect is responsible for applications such as self-focusing and defocusing due to differences

in intensity across the beam profile. When two distinct input beams overlap in a sample, another effect of DFWM may be the transfer of energy between the beams, which is useful for many applications such as single-frequency, all-optical switching (37).

DFWM is best understood in terms of an intensity-dependent refractive index. The two lowest order terms in the refractive index expansion for isotropic media may be written simply as

$$n = n_0 + n_2 I \tag{7}$$

where I is the incident intensity, n_0 is the usual linear index (as seen for lower light levels), and

$$n_2 = \frac{3}{4\varepsilon_0 c n_0^2} \mathrm{Re}\left[\chi^{(3)}\right] \tag{8}$$

The key parameter in optical switching is the intensity-dependent phase-shift (as might appear between the arms of a Mach–Zehnder interferometer (38) or in a directional coupler (39), for example) given by

$$\Delta\varphi(\lambda, L) = \frac{2\pi L n_2 I}{\lambda} \tag{9}$$

where L is the interaction length, and n_2 also depends upon the wavelength λ (40). Phase shifts of π or greater are required for most devices, though some applications require only a shift of $\pi/2$ (41).

Sum and Difference Frequencies; Nondegenerate Four-Wave Mixing. In addition to the phenomena described above, interesting NLO phenomena may also result from a combination of monochromatic fields of different frequencies, as in sum ($\omega = \omega_1 + \omega_2$) and difference ($\omega = \omega_1 - \omega_2$) frequency generation in second-order processes, or nondegenerate four-wave mixing, a third-order process in which the detected frequency may be any combination of the input frequencies (for example, $\omega = 2\omega_1 - \omega_2$ or $\omega = \omega_1 + 2\omega_2$). These phenomena have historically been of less importance for polymer device applications, though commercial applications for optical parametric generation using inorganic crystals, such as β-barium borate are well developed. Finally, third-order, nondegenerate, four-wave mixing may also involve the use of light of one frequency to cause a change in the refractive index of the medium that is experienced by a second beam at a different frequency ($\omega = \omega_1 - \omega_1 + \omega_2$) (42,43).

Resonant Nonlinear Phenomena. The susceptibility tensors $\chi^{(2)}$ and $\chi^{(3)}$ may be complex, indicating the presence of multiphoton resonances and nonlinear absorption effects. The effects of nonlinear absorption are of significant interest in polymer device applications and are typically expressed in a power series in the incident intensity with the transmitted intensity I_1 given by (44)

$$\frac{\mathrm{d}I_1}{\mathrm{d}z} = -\alpha^{(1)} I_1 - \alpha^{(2)} I_1 I_2 - \alpha^{(3)} I_1 I_2 I_3 - \cdots \tag{10}$$

where the light propagates in the z-direction and the different subscripts 1, 2, 3 allow for light of different wavelengths to impact the transmission at wavelength 1. The two-photon absorption coefficient $\alpha^{(2)}$ is related to the imaginary part of the complex third-order susceptibility for an isotropic medium by

$$\alpha^{(2)} = \frac{3\omega}{2\varepsilon_0 c^2 n_0^2} \operatorname{Im}\left[\chi^{(3)}\right] \tag{11}$$

One figure of merit for all-optical switching is the relative two-photon absorption that accompanies an intensity-dependent change in refractive index. The quantity $2\alpha^{(2)}\lambda/n_2$ must be less than unity for switching to be possible (45).

In some resonant phenomena, such as saturated absorption, the use of a power series as shown in equation 10 may be inappropriate because of the contributions from higher order processes. For a dye in a solid polymer matrix, the intensity-dependent absorption coefficient, based on inhomogeneous broadening of the absorption, is often expressed in terms of the saturation intensity I_s at which the population of excited states in the dye from decay processes matches the decay rate from the excited states (46):

$$\alpha(I) = \frac{\alpha^{(1)}}{(I + I_s)^{\frac{1}{2}}} \tag{12}$$

Multiphoton absorption is already widely used for spectroscopic analysis. As discussed later in this article, linear absorption spectra of centrosymmetric molecules only give transitions between states of opposite parity. Two-photon absorption is capable of providing information about transitions between states of the same parity, or so-called two-photon states. In addition, even in noncentrosymmetric materials, two-photon absorption can probe the bulk properties of the medium at frequencies near the linear absorption band where a linear probe may be absorbed at the material surface (44). Two-photon absorption promises to be useful for ultrafast optical limiters, which protect against damage due to high power laser pulses. Polymers containing metal centers or carbon-60 (fullerene) have been especially interesting for this application (47–49). Multiphoton absorption effects are also being investigated currently for their application to laser mode locking, optical pulse shaping, and other beam processing applications (50).

Other Effects.

Combination with Static Fields. A common technique, useful for optoelectronic devices, is to combine a monochromatic optical field with a DC or quasi-static field. This combination can lead to refractive index and absorption changes (linear or quadratic electrooptic effects and electroabsorption), or to electric-field induced second-harmonic generation (EFISH or DC-SHG, $2\omega = \omega + \omega + 0$) in a quasi-third-order process. In EFISH, the DC field orients the molecular dipole moments to enable or enhance the second-harmonic response of the material to the applied laser frequency. The combination of a DC field component with a single optical field is referred to as the linear electrooptic (Pockels) effect ($\omega = \omega + 0$), or the quadratic electrooptic (Kerr) effect ($\omega = \omega + 0 + 0$). These electrooptic effects are discussed extensively in the article Electrooptical Applications (qv). EFISH is

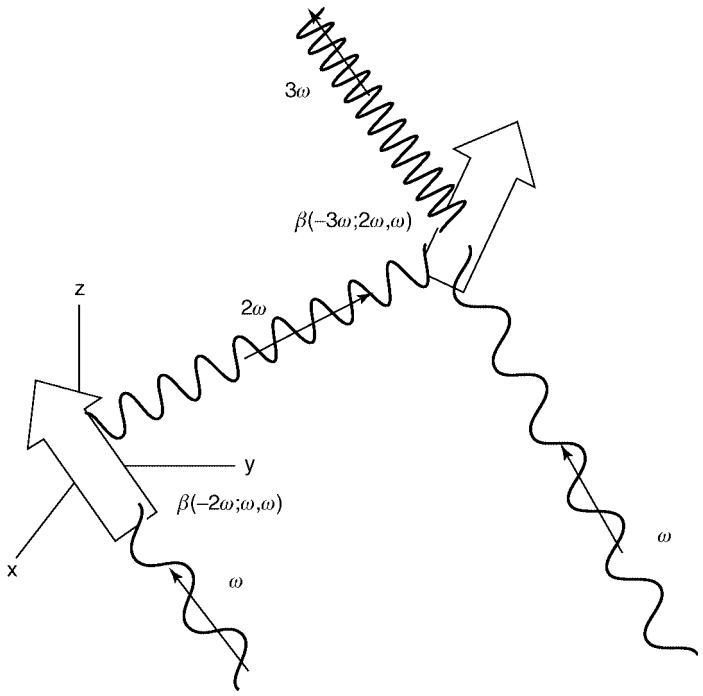

Fig. 2. Schematic showing a cascaded optical nonlinearity in which the second harmonic generated at one molecule combines with the fundamental by sum frequency generation at a nearby molecule to result in a third harmonic generated through a cascade of second-order processes.

discussed in this article, however, for the important role that it has played in the characterization of nonlinear optical materials for other applications.

Cascading. In most cases, the distinction between second- and third-order nonlinearities is evident from the different phenomena each produce. That distinction blurs, however, when one considers the cascading of second-order effects to produce third-order nonlinear phenomena (51). In a cascaded process, the nonlinear optical field generated as a second-order response at one place combines anew with the incident field in a subsequent second-order process. Figure 2 shows a schematic of this effect at the molecular level where second-order effects in noncentrosymmetric molecules combine to yield a third-order response that may be difficult to separate from a pure third-order process. This form of cascading is complicated by the near-field relationships that appear in the interaction between molecules, but analysis of cascaded phenomena is of interest, because it provides a way to explore local fields and the correlations between orientations of dipoles in a centrosymmetric material (52).

Another form of cascading takes advantage of nonlocal, phase-matched cascading of successive $\chi^{(2)}$ processes to produce third-order nonlinear phase shifts (53). These cascading effects have been investigated for their ability to lead to large intensity-dependent refractive indices in poled waveguide materials (54). For example, two successive second-order effects, such as second-harmonic generation, followed by down conversion ($\omega = 2\omega - \omega$), or optical rectification, followed by the

linear electrooptic effect, lead to an intensity-dependent refractive index based on successive $\chi^{(2)}$:$\chi^{(2)}$ interactions (55). The interested reader is referred to the references for a more complete discussion of the enhancements that have been achieved through cascaded nonlinearities.

Nonlinear Light Scattering. Other forms of frequency conversion processes and nonlinear spectral broadening are possible through nonlinear light scattering. When the scattering is due to fluctuations in the molecular susceptibility, the result provides yet another method for investigating NLO properties referred to as hyper-Rayleigh scattering (HRS) (56,57). A brief description of HRS is included later because of its growing use in measuring optical nonlinearities of organic chromophores incorporated into NLO polymers, especially octupolar molecules and conducting solutions, not amenable to investigation through EFISH. Other nonlinear optical scattering processes are generally beyond the scope of this article, but are mentioned here for completeness. Stimulated Raman scattering and coherent anti-Stokes Raman spectroscopy (CARS), for example, involve light scattering from optical phonons and are widely used to convert available laser output frequencies to a variety of infrared, visible or even ultra-violet wavelengths, via so-called Stokes and anti-Stokes shifts (58,59). Stimulated Brillouin scattering involves light scattering from sound waves, a photon/acoustic phonon interaction through electrostriction (60). Rayleigh scattering leads to frequency shifts from inhomogeneities in the material and is called Rayleigh wing-scattering if due to fluctuations in the orientation of anisotropic molecules (61).

Advantages of NLO Polymers

Optical second-harmonic generation (SHG) in an organic material was first reported in 1964 (62). The first measurements of the third-order NLO response of a polymer were performed on polydiacetylene crystalline polymers by Sauteret and co-workers in 1976 (63). Interest in polymeric second-order materials increased dramatically in the early 1980s when Meredith and co-workers performed the first studies on dye-doped glass-forming systems (64) and Singer and co-workers developed the process of electric-field poling to lock in the orientation of the chromophores in a guest–host system (65).

Why Polymers?. Though most current commercial NLO applications use inorganic crystals and semiconductors, polymeric materials have been found to offer many advantages over their inorganic counterparts. These advantages include fast (subpicosecond) response times for nonresonant electronic effects, high optical damage thresholds, large susceptibilities combined with low dielectric constants, ease of processability as thin films or as fibers, ability to be integrated into silicon-based semiconductor structures or onto almost any substrate through spin-coating or other film deposition techniques, and, most importantly, compositional flexibility, which allows their physical and chemical properties to be tailored for specific end use applications through custom-functional design. These advantages, in turn, lead to large figures of merit for device applications. Disadvantages to be overcome, however, include lower thermal stability at high and low temperatures, lower mechanical strength, and, in some cases, higher linear optical absorption and scattering.

Generally, the suitability of a material for device applications requires a balance between optical nonlinearity, thermal and chemical stability, optical losses, and processability. Tradeoffs are to be expected as higher nonlinearities near resonance, for example, lead to increased absorption losses. For third-order materials, the all-optical device applications are especially diverse and promising. These devices include all-optical switches (66), logic gates, optical memories, optical limiters, light modulators, ultrafast shutters, directional couplers (67), nonlinear amplifiers (68), and phase conjugators (69). The application of polymers to waveguide devices is a very important area of applied research, though the details are beyond the scope of this article. Polymer fibers have also been studied for their ability to provide high quality long-length interaction for nonlinear effects with low losses and large bandwidth (70–72). Though no devices have yet been put into mass production (41), the basic figures of merit for switching device applications have been met by several materials and methods, including polydiacetylene waveguides (38) and poly(methyl methacrylate) fibers (73), and through the use of cascaded nonlinearities (74).

Connecting Macroscopic Properties to Microscopic Unit Properties

The foregoing sections described how various NLO phenomena can be understood in terms of the nonlinear susceptibilities. In this section, those susceptibilities are described in terms of the polarizabilities and hyperpolarizabilities, which characterize the separation of charge due to the electric-field at the molecular level. Major factors considered in bridging between the microscopic and the macroscopic properties include (*1*) local field effects, (*2*) orientation effects, (*3*) methods for incorporating NLO chromophores into a polymer to optimize the bulk properties, and (*4*) limits to the optimization of bulk properties through additive effects of the microscopic response.

Relating Macroscopic and Molecular Properties. For many organic/polymeric materials, the bulk polarization is best understood through averaging of the molecular polarizabilities of the weakly-interacting constituent materials. The molecular polarizability is expressed in a series expansion, similar to equation 2 for the polarization, (28)

$$p_I^{\omega} = \mu_I + \alpha_{IJ}(-\omega;\omega)F_J^{\omega} + \beta_{IJK}(-\omega;\omega_1,\omega_2)F_J^{\omega_1}F_K^{\omega_2} + \gamma_{IJKL}(-\omega;\omega_1,\omega_2,\omega_3)F_J^{\omega_1}F_K^{\omega_2}F_L^{\omega_3} + \cdots \tag{13}$$

where $\boldsymbol{F}$ represents the *local* electric-field at the molecule. It is helpful to note the terminology differences between the macroscopic and molecular levels. Upper case subscripts are used to distinguish the molecular coordinate system from the laboratory coordinate system in which the macroscopic properties are measured. μ is the permanent dipole moment of the molecule. α is the linear polarizability tensor (not the absorption coefficient found in equation 10). The $\chi^{(2)}$ and $\chi^{(3)}$ tensors are referred to as *second*- and *third*-order susceptibilities; the corresponding molecular level tensors, β and γ, are called the *first* and *second* hyperpolarizabilities. Values for β and γ are usually given in esu, where a typical chromophore

value for β of 10^{-30} esu $= 10^{-30}$ cm^4/statvolt becomes 4.2×10^{-40} m^4/V in SI units and a value for γ of 10^{-33} esu $= 10^{-33}$ cm^5/statvolt^2 becomes 1.4×10^{-47} m^5/V^2 in SI (28). The reader is warned, however, that different unit conventions, and different conversion factors, are also used (75).

Local Fields. Relating the macroscopic nonlinear susceptibilities to the hyperpolarizabilities requires (*1*) incorporating the effects of the local fields at the molecules, and (*2*) averaging over the arrangement of molecules in the bulk. In general, finding the relationship between the local field in equation 13 and the macroscopic field found in equation 2 is a highly nonlinear and difficult problem (the "local field problem") (49). (Analysis in the case of monomolecular films is simpler because local field corrections are less important and the materials are highly oriented (76)). The local field $\boldsymbol{F}$ acting on the molecule is the vector sum of the applied field and the polarization field. The polarization field is the difference between the field due to nearest neighbor molecules and the collective field of a large number of molecules in a carefully defined volume around the molecule. The local field problem is solved satisfactorily for homogeneous materials by approximating the polarization by the linear term in the series expansion of equation 2 and assuming that the molecule exists in a spherical cavity in a homogenous media (77). This method of analysis, first described by Lorentz, leads to the so-called Lorentz local field factors, $f_\omega = (n_\omega^2 + 2)/3$, where n_ω is the linear index of refraction of the medium at frequency ω. (If static fields are involved, an Onsager local field treatment provides a first approximation to a more detailed treatment. In this case, the relevant local field factor becomes $f_0 = [\varepsilon(n^2 + 3)]/(n^2 + 2\varepsilon)$ where ε represents the relative permittivity (78)). Thus, for homogeneous isotropic media and optical fields only,

$$\chi^{(2)}(-\omega; \omega_1, \omega_2) = N/\varepsilon_0 \times f_\omega f_{\omega_2} f_{\omega_1} \times \langle \beta(-\omega; \omega_1, \omega_2) \rangle \tag{14}$$

$$\chi^{(3)}(-\omega; \omega_1, \omega_2, \omega_3) = N/\varepsilon_0 \times f_\omega f_{\omega_3} f_{\omega_2} f_{\omega_1} \times \langle \gamma(-\omega; \omega_1, \omega_2, \omega_3) \rangle \tag{15}$$

with N being the number density of the molecules and $\langle\ \rangle$ representing orientational averaging, which is discussed in the following section.

The local field effects for *composite* materials require more detailed analysis and can lead to a significant enhancement of the NLO response. For example, a promising method for enhancing the nonlinearity by several orders of magnitude through local field effects is to embed either finely distributed or fractal clusters of metal particles (79) in a polymer matrix.

Orientational Averaging. In general, orientational averaging requires careful consideration of the tensor nature of the hyperpolarizabilities and susceptibilities, and an appropriate choice of distribution functions for the geometries of the molecules involved and their arrangement in the bulk. The orientational averaging of γ (or β) is given formally by the integration of γ (or β), weighted by an appropriate distribution function for the range of orientations, over the appropriate range of angular orientations (79)

$$\langle \gamma \rangle = \frac{\int G(\Omega)\gamma(\Omega)\, \mathrm{d}\Omega}{\int G(\Omega)\, \mathrm{d}\Omega} \tag{16}$$

In the case of an isotropic polymer, the weighting function $G(\Omega)$ is a constant for all orientations. See also Reference 80 for a discussion of theoretical models used to calculate the appropriate order parameters used to perform the orientational averaging for β.

Electric-Field Poling for Second-Order NLO Polymers. As previously discussed, only noncentrosymmetric media have nonzero $\chi^{(2)}$ values. Similarly, the molecular constituents of the media must have nonzero β. Moreover, in amorphous polymers, the bulk is centrosymmetric with $\chi^{(2)} = 0$, even if β is nonzero, due to the random orientation of the molecules. Thus, it is necessary to align the polar constituents in the polymer in order to generate second-harmonic or produce other $\chi^{(2)}$ effects (though second-harmonic generation through hyper-Rayleigh scattering is still possible). Alignment is usually accomplished through electric-field poling, as illustrated in Figure 3. Poling involves heating the polymer, with the NLO chromophore incorporated into it, to a temperature above the temperature at which the polymer becomes rubbery, called the glass-transition temperature, T_g. (See GLASS TRANSITION) At and above T_g, the dipoles can be aligned simply by the

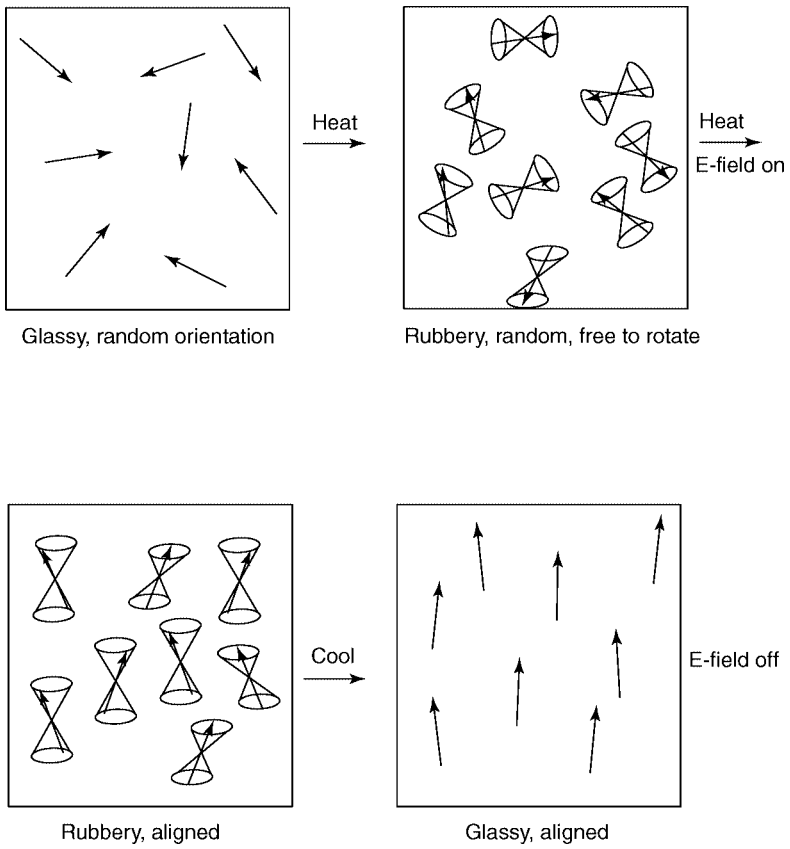

Fig. 3. Illustration of the electric-field poling process where the arrows represent the dipole moment orientation for NLO chromophores dissolved in a polymer matrix. (First appearing in Reference 81. Reprinted with permission.)

application of an external electric (poling) field, typically on the order of 100 MV/m. With the poling field maintained, the polymer is cooled back to room temperature, locking in the polar alignment (at least temporarily). See Reference (78) for a more complete description of the poling process and its implications for orientational averaging and long-term thermal stability. The foregoing section assumes that T_g is lower than the chromophore decomposition temperature. Hybrid pressure poling and all-optical poling methods are also in use. These utilize other optical effects such as photoisomerization to assist the poling process (82).

For an isotropic, poled polymer film of essentially one-dimensional NLO molecules, the orientational average is expressed in terms of the average angle between the ground-state dipole moments of the chromophores and the direction in the film they would be pointing if perfectly aligned (83). For a polymer film in which the nonlinear component or moiety is rotationally symmetric about the film normal (z-axis), the only two nonzero susceptibility components can be determined from the angle (θ) between the film normal and the molecular Z-axis, (84)

$$\chi^{(2)}_{zzz} = N\beta^*_{ZZZ}\langle\cos^3\theta\rangle \qquad \chi^{(2)}_{xxz} = \frac{1}{2}N\beta^*_{XXZ}\langle\cos\theta\,\sin^2\theta\rangle \tag{17}$$

where * indicates that appropriate local field corrections are already incorporated into the hyperpolarizabilities. For poled polymer materials, the orientational averages shown in equation 17 are determined thermodynamically by the coupling between the poling field E_p and the nonzero molecular dipole moment μ. (The ground state dipole moment can be determined from measurements of the permittivity and refractive index as a function of concentration (85)). The only two tensor components of χ^2 can then be expressed simply as

$$\chi^{(2)}_{zzz} = N\beta^*\frac{\mu^* E_p}{5\varepsilon_0 kT} \qquad \chi^{(2)}_{xxz} = N\beta^*\frac{\mu^* E_p}{15\varepsilon_0 kT} \tag{18}$$

where kT is the Boltzman energy. When poling is needed to induce polar order, the molecular figure of merit is the $\mu\beta$ product. Nonresonant values of $\mu\beta$ as great as 10×10^{-45} esu have been reported for 3-phenyl-5-isoxazolone, for example (86). In the absence of dipolar interactions, such as assemblies of octupolar multidimensional molecules, a more complicated analysis is required. In these cases, the desired alignment may be a highly ordered octupolar state without dipolar interactions (87). A later section briefly discusses polymeric materials with multidimensional constituents.

Maintaining polar order in a poled polymer is of great importance for second-order applications (88,89). The dielectric relaxation process leading to decay in the orientation of ordered polymers has been studied extensively and is the subject of another article (see DIELECTRIC RELAXATION). Several models that describe the chromophore reorientation for NLO materials have been proposed, including the Kohlrausch–Williams–Watts (KWW) model (90,91), biexponential and triexponential decay models (92), time-dependent Debye relaxation time models (93), and the Liu–Ramkrishna–Lackritz (LRL) model (94). For further information on

these and other issues relating to dielectric relaxation in poled polymers, see also Reference 95.

One more example of the difficulties that can arise in comparing the hyperpolarizabilities and bulk susceptibilities is seen in the case of EFISH. Although EFISH is a macroscopic third-order process, the microscopic–macroscopic transition for EFISH is expressed as

$$\chi^{(3)}_{ijkl}(-2\omega;\omega,\omega,0) = N[\langle\gamma^{*}_{\mathrm{IJKL}}(-2\omega;\omega,\omega,0)\rangle_{ijkl} + \langle\mu^{*}_{I}(-0;0)\beta^{*}_{JKL}(-2\omega;\omega,\omega)\rangle_{ijkl}] \quad (19)$$

The second term on the right side of equation 19 ultimately determines the usefulness of the molecule when incorporated into a polymer for second-order applications (96). A DC field aligns the dipole moment μ so that the first hyperpolarizability, β, can contribute to the bulk response. A similar expression is applied to poled polymers (24). The assumption that γ is negligible compared to β is usually valid for nonlinear chromophores, but not for extended π-electron donor–acceptor systems because γ increases with conjugation length faster than β (97).

Orientational Effects in Third-Order Polymers. Bulk asymmetry is not required for a third-order NLO response, but orientation of polymer chains remains an important factor even if $\beta = 0$. For one-dimensional, π-electron conjugated polymers, the largest contribution to the NLO response occurs for light polarized parallel to the direction of the conjugated chain. Therefore, alignment of polymer chains, which restricts electron delocalization to one-dimension, enhances the magnitude of the NLO response of the polymer. Polymers with high levels of anisotropy exhibit significantly larger NLO response when the applied electric-field is polarized in a direction parallel to the chain orientation. The NLO response of an unoriented film of linear chain molecules has been shown to be one-fifth the NLO response of oriented film when the electric-field is applied parallel to the molecules (98). The implication is that processing polymers on a microscopic level is one method of enhancing the third order response of the polymer. A common method used to align polymer chains is stretch orientation of thin films (99). See also Reference 79 for an example of the application of the orientational averaging process to third-order materials.

Incorporating Chromophores into Polymers. The dominant approach used to enhance the second-order NLO response of organic materials is to incorporate optimized chromophores into a polymer matrix. The method used for incorporating the chromophore varies. The choice of polymer depends upon linear optical and other properties that make the polymer suitable for devices (81).

Guest–Host Polymers. The simplest, but not optimal, approach to incorporating NLO chromophores into a polymer is to dissolve the dye molecules into the polymer in a guest–host solid solution system (see Fig. 4**a**). (Poly (methyl methacrylate) has been one of the most commonly used polymers for this purpose for its ease of processability.) There are several significant drawbacks, however, to using a guest–host system. (*1*) The amount of dye that can be dissolved is usually very limited. (*2*) The glass transition temperature drops with increased doping due to plasticization. (*3*) The chromophore tends to leave the polymer at elevated temperatures. (*4*) Finally, the alignment of the molecular dipoles is less stable, so that a poled guest–host system is unlikely to retain its orientation for long periods

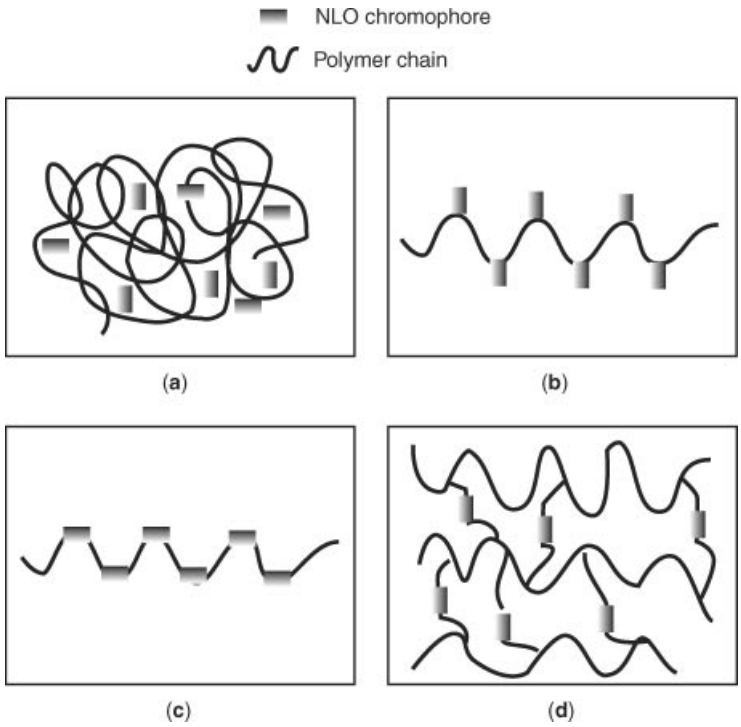

Fig. 4. Schematic of methods for incorporating NLO chromophores into a polymer, including (**a**) guest–host system, (**b**) side-chain functionalized system, (**c**) main-chain functionalized system, and (**d**) cross-linking system.

(24). Methods to overcome these limitations include using high glass-transition temperature polymers, such as polyimides or polyetherketones, doped with relatively miscible chromophores (100,101).

Side-Chain Polymers. Though more challenging to produce than a guest–host system, a side-chain functionalized system in which at least one end of each of the chromophores is attached as a side chain to the polymer backbone, avoids some of the limitations of the guest–host system (see Fig. 4**b**). The resultant polymer retains the nonlinearity of the dopant molecules and permits greater chromophore concentration for a larger NLO response. Still, packing problems may appear if the chromophore concentration becomes too high. Attaching the chromophore as a side chain causes the orientational stability and other thermal properties of the system to depend more on the thermal properties of the polymer. For example, a polyimide with a high T_g is better able to preserve the polar order of the chromophore if the chromophore is incorporated as a side chain, rather than a simple solute (102).

Main-Chain Polymers. Main-chain polymers incorporate the chromophore directly into the chain by linking both ends of the chromophore, in either head-to-tail (isoregic) or head-to-head (syndioregic) configuration or some combination. Though a main chain configuration should add stability, establishing polar order in these polymers is not always obvious. The syndioregic configuration offers the possibility of folding the polymer like an accordion so that the chromophores will align (103) (see Figure 4**c**).

Cross-Linked Polymers. Perhaps the greatest promise for long-term stability in molecular materials comes from cross-linked polymers (see Fig. 4**d**). Cross-linking must be performed during poling, but can be accomplished with guest–host (104), side-chain, or main-chain systems. The cross-linking must be done carefully to avoid the introduction of defects. One promising approach is the use of interpenetrating polymer networks (105).

Limitations to Relating the Polymer Response to Molecular and Oligomeric Properties. In many cases, the NLO response of the polymer can be derived entirely from the response of the molecular NLO chromophore units and their concentration in the polymer as a medium. The assumption that the system is weakly interacting is justified if the nonlinearity is a linear function of molecular concentration (106,107). For large concentrations of molecules in a polymer matrix, the assumption of a weakly interacting system may break down, however, as dimerization or aggregation become important (108).

Oligomers. Similarly, the third-order NLO properties of π-conjugated polymers are often extrapolated from oligomeric structure studies. Effective conjugation length scaling laws and band gap narrowing are examples of properties that have been investigated in terms of the oligomeric unit (109,110). Unfortunately, some aspects of a polymeric system cannot be modeled by smaller molecules, and extending oligomeric structure–property relationships to polymeric materials can be problematic. For instance, saturation effects in electron delocalization become apparent as conjugated chains become very long. Also, it is known that the excited state structure of a polymer may differ from its corresponding oligomer (111), and the effect that substitution may have on a polymer is not reflected by substitution on its related oligomeric or polyeneic structure (112). Many other issues that surround the extension of oligomer structure–property relationships to polymer relationships have been considered and much literature is available on the topic (113). With these caveats in mind, the next section discusses the electronic character of constituent NLO materials for the purpose of understanding the origin of the hyperpolarizabilities.

Structure–Property Relationships: Understanding Constituent NLO Properties

How macroscopic NLO properties of a material are determined from the response of its microscopic constituents was shown in the previous section. The origin of the NLO properties of these constituents is discussed here. A fundamental theoretical problem is to calculate the NLO response directly from the electronic configuration of the molecules. This section explores the molecular parameters that contribute to large hyperpolarizabilities. Particular emphasis is on sum rule calculations and essential states models as guides to obtaining the optimal NLO response.

The discussion necessarily divides into separate consideration of the structure–property relationships for the molecular constituents, which particularly impact the $\chi^{(2)}$ response, and the nature of the supramolecular and polymeric effects, especially relevant to $\chi^{(3)}$ materials. Fundamental factors affecting each are discussed, including symmetry, donor–acceptor groups and

charge transfer, conjugation or π-electron delocalization length, the nature of the π-electron bonding sequence, bond length alternation (or bond order alternation), aromaticity, multidimensionality, and the substitution of alternate atoms into the conjugated structure.

Brief Overview of Quantum Calculations. Most organic and polymeric systems, unlike inorganic systems, owe their nonlinear response to virtual electron excitations occurring in the individual molecular or monomeric units. A complete theoretical understanding of the NLO response requires extensive quantum mechanical calculations, which encompass every structural aspect of the system. These aspects include the positions and electron configuration of each atom, the nature of the bonds between atoms, and the full electronic energy band structure, including all interactions. The linear and nonlinear properties can be deduced from the wavefunction of the system, which is the solution to the Schroedinger equation $H\Psi = E\Psi$, where H is the suitably chosen Hamiltonian operator including interactions among all the charges and E is the energy of the system. The molecular orbital (MO) approach expands the wavefunction in a self-consistent set of basis functions with appropriate configuration interactions (CI), using a linear combination of atomic orbitals (114). The number of CI integrals to be calculated increases as the fourth power or higher of the number of basis functions in the molecule, so that calculations even for small molecules can be time-consuming (115).

At least three different approaches are used to calculate the nonlinear response from quantum chemical considerations (40,116). In so-called "derivative" techniques, the polarizability and hyperpolarizabilities are found by taking derivatives of the dipole moment components with respect to the various electric-field components.

$$\alpha_{ij} = \frac{\partial \mu_i}{\partial E_j}$$
$$\beta_{ijk} = \frac{\partial^2 \mu_i}{\partial E_j \partial E_k} \tag{20}$$
$$\gamma_{ijkl} = \frac{\partial^3 \mu_i}{\partial E_j \partial E_k \partial E}$$

These derivatives are evaluated using so-called coupled Hartree–Fock techniques and either static or oscillating fields (117). A second approach is to model the nonlinear media as a set of coupled anharmonic oscillators, with resonant frequencies corresponding to excited state transition frequencies. The strength of the coupling is a function of the proximity of the external field frequency to the resonant frequency of the oscillator.

A third approach, the one most important for the current discussions, is to treat the electric-field as a source of perturbation of the total molecular energy using real and virtual excited state transitions. This approach uses electronic wave functions either for all of the electrons of the molecule (ab initio calculations) or for only the valence electrons (so-called semiempirical theories). Semiempirical Hamiltonians may ignore electron interactions completely (Huckel theory). They may assume one π-orbital per carbon and assume no overlap between adjacent electron orbitals (Pariser–Parr–Pople or PPP). Or, they may include both the σ and

π electrons and either no overlap (so-called complete neglect of differential overlap or CNDO), or only include overlap between orbitals on the same atom (intermediate neglect of differential overlap or INDO). The goal of each of these techniques is to compute the energy levels, transition moments, and dipole moment differences for essential energy states of a molecule (118). These parameters are used in a sum-over-states perturbation approach to determine the hyperpolarizabilities. See, for example, References (40,119–121). An advantage of the perturbation approach is the explicit appearance of the frequency response and the role that different excited states play in the frequency response.

Sum-Over-Essential States Models for Molecular Materials.

The Two-Level Model for β. For NLO organic chromophores (dyes) used to provide a large second-order nonlinear response, the sum-over-states approach has proven to be a particularly valuable predictor of β and its spectral dispersion. In the sum-over-states approach, hyperpolarizabilities may be calculated in theory by including contributions from virtual and real transitions to and from *all* of the excited states or energy levels of the molecules. In practice, however, only a few states are expected to contribute measurably. The key to using this approach for optimizing β (or γ) is to identify and characterize the contributions of the most important excited states of the molecule in the spectral region of interest. In fact, β is often well understood by truncating the sum to include only the ground state and *one* excited state, a so-called two-level model. The energy difference between these two states is sometimes called the optical gap, and the nature and location of the transition (gap) between the two states is particularly important for its dominant role in the linear absorption spectrum. The two-level model yields a simple formula for β in the case of second-harmonic generation (122):

$$\beta_{\text{two-level}} = \frac{3}{2\hbar^2} \frac{\omega^2 \left|\mu_{01}^2\right| \Delta\mu_{10}}{\left[\omega_{10}^2 - \omega^2\right]\left[\omega_{10}^2 - 4\omega^2\right]} \tag{21}$$

where $\hbar\omega_{10}$ is the energy difference between the ground and excited state, μ_{01} is the transition dipole moment between the two states, "0" (the ground state) and "1" (the excited state), and $\Delta\mu_{10} = \mu_{11} - \mu_{00}$ is the difference between dipole moments of these two states. The transition dipole moment μ_{01} can be determined by numerical integration of the absorption spectra. The ground state dipole moment μ_{00} is determined through concentration-dependent measurements of the relative permittivity and refractive index. The excited state dipole moment μ_{11} is typically found by analysis of spectral shifts in the absorption band due to changes in the local electric-field (electrochromism or solvatochromism) (85).

The two-level model justifies the dominant approach for optimization of the second-order NLO response, which is to couple the largest transition moment with the largest dipole moment difference. This combination of a large transition moment and large dipole moment difference is usually accompanied by a sharp absorption peak. A general rule-of-thumb, which has been adopted by many researchers into second-order molecular materials is summed up by the adage, "Redder is better." In effect, the lower the energy of the dominant absorption peak of the chromophore, the greater is the nonlinear response. (Interestingly, some highly nonlinear organic chromophores such as Foron brilliant blue and squaraine dyes

(123,124) have sharp absorption peaks shifted so far into the visible so as to absorb the red wavelengths, yet transmit higher energy blue wavelengths, prompting the enigmatic description that such chromophores "are so red, they're blue!")

The two-level model has guided researchers in finding optimal chromophores for nonlinear polymers ever since the original work by Oudar and Chemla in the early 1970's (125). More recent theoretical analysis by Kuzyk of sum-rule-restricted off-resonance contributions to the optical nonlinearity shows that a full quantum sum-rule analysis provides a physical limit to the maximum diagonal tensor component, *off resonance*, for *both* β (126), and γ (127). This study indicates that the key to increasing β and γ is to design molecules that have *one* dominant excited state at an energy close to the ground state with as many double (or triple) bonds (delocalized electrons) as possible. Molecules with a single dominant excited state are, therefore, particularly well-suited to a two-level model analysis. Kuzyk has also extended this work to off-diagonal tensor components to show that the maximum off-diagonal components can be no larger than the largest possible diagonal component (128). (The off-diagonal components for a particular molecule, however, may be larger than the available diagonal components for that molecule (25)).

Donor–Acceptor Groups. The difference between the ground state and excited state dipole moments, $\Delta\mu_{01}$, is important in designing optimal second-order NLO chromophores because $\Delta\mu_{01}$ quantifies the ability of the electrons in the molecule to shift preferentially in one direction along the molecule with the application of an oscillating electric-field. To impart such a bias, initial studies used aromatic and long-chain π-electron systems with an electron donating group at one end and an accepting group at the other. A prototypical dye molecule with these features, dimethylaminonitrostilbene (DANS), is shown in Figure 5. Recall that the dipole moment is simply a measure of the separation of a unit charge along the length of the molecule. The effect of substitution of different electron donor and acceptor groups has been the subject of extensive study, and tables of values for different groups can be found in References 129 and 130.

Nature of π-Electron Bonding, Aromaticity, and Bond Length Alternation. A comparison between the ground and excited state structures in Figure 5 introduces another line of inquiry for optimizing β. In the charge-transfer (CT) excited state,

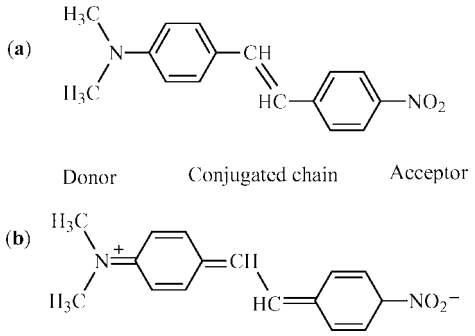

Fig. 5. Typical linear donor–acceptor chromophore (DANS) (**a**) ground state and (**b**) first excited state structures.

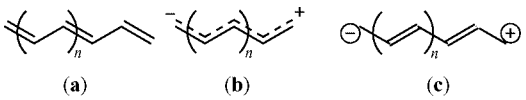

Fig. 6. The nature of π-electron bonding varies between the (**a**) polyene, (**b**) cyanine, and (**c**) zwitterionic limits.

the charge configuration will change from the aromatic structure of Figure 5**a** to the more quinonal (and zwitterionic) structure represented in Figure 5**b**. In this case, the CT state has lost "aromaticity," as can be seen by the loss of conjugation in the rings. Marder and co-workers have studied CT processes and found that a larger effective donor–acceptor strength will often result from a degenerate ground state in which the π-electrons are optimally delocalized along the chain. In this case, the CT state gains aromaticity and the $\Delta\mu_{01}$ factor will be negative, leading to a negative β off-resonance (131).

The relative contributions to the ground-state energy of different electron configurations (as those shown in Figs. 5**a** and 5**b** can be described by the tendency of the ground state to exhibit pronounced bond length alternation (BLA). In general, BLA refers to the difference in the bond lengths between adjacent carbon atoms within the backbone chain of the molecule. (Similarly, bond order alternation refers to the extent of alternating single, double, or triple bonds along the backbone, where single bonds are longest and triple shortest.) The nature of the π-electron bonding can be seen also in Figure 6, which illustrates the difference between polyene, cyanine, and zwitterionic forms for the conjugated chain. The polyene and zwitterionic structures show significant bond length alternation, while the cyanine shows none (131). Tuning between these forms is possible through changing solvent polarity and the strength of the donor and acceptor end groups (118).

Studies by Meyers and co-workers have shown that the NLO response of many strong donor-acceptor molecules suffer from too much bond length alternation (on the order of 0.01 nm), which inhibits charge transfer in the excited state (132). β is zero in the cyanine limit, however, when there is no bond length alternation. Interestingly, β peaks with opposite sign when the BLA is either intermediate between the polyene/cyanine structure or intermediate between a cyanine/zwitterionic structure (BLA $\sim \pm 0.004$ nm) (133). One important result from these studies is that the relative amount of charge separation is a function not only of the end groups involved, but also of the molecular environment due to solvatochromic effects (118). For a more extensive discussion of the balance of factors represented in the two-level model and techniques for optimizing β, see also Reference 134. A discussion of methods for determining the dependence of β on other parameters may also be found in Reference 135.

Conjugation Length. The dominant characteristics for second-order materials are π-electron delocalization and strong acceptor–donor dipolar charge transfer. Thus, the distance and magnitude of the charge transfer of the π-electrons in the excited state determines the magnitude of β. β increases with charge separation (electron delocalization) only if strong coupling through the conjugated bridge unit between the donor and the acceptor ends is preserved. Studies of the conjugation length dependence of β have shown an initial increase as the third

power in that length, at least for the first 12 π-electrons or more (136). However, studies have demonstrated that the donor–acceptor interaction stops increasing after a certain chain length, limiting the electron delocalization, and the result is an observable saturation effect (137,138). Unfortunately, increased conjugation length correlates with increased absorption, leading to reduced linear optical transparency. The significance of conjugation length is also explored further below in connection with third-order materials.

The Two-Level Model for γ and Its Limitations. Generally, essential-states-model calculations have been very successful in explaining and predicting the second-order response of noncentrosymmetric materials, but considerable work remains for understanding third-order materials. As a starting point, consider again the two-level model, which can be expressed for third-harmonic generation as (139)

$$\gamma_{\text{two-level}} = \frac{\mu_{01}^2}{4\hbar^3}\left[\Delta\mu_{10}^2 D_{111} - \mu_{01}^2 D_{11}\right] \tag{22}$$

The dependence on the energy difference between the ground state and excited state and the incident photon energy is given by the denominator "D" factors (omitting resonance damping effects near the excited state transition energies)

$$\begin{aligned} D_{111} = {} & [(\omega_{10} - 3\omega)(\omega_{10} - 2\omega)(\omega_{10} - \omega)]^{-1} + [(\omega_{10} + \omega)(\omega_{10} - 2\omega)(\omega_{10} - \omega)]^{-1} \\ & + [(\omega_{10} + \omega)(\omega_{10} + 2\omega)(\omega_{10} - \omega)]^{-1} + [(\omega_{10} + \omega)(\omega_{10} + 2\omega)(\omega_{10} + 3\omega)]^{-1} \end{aligned}$$

and

$$\begin{aligned} D_{11} = {} & \left[(\omega_{10} - \omega)^2(\omega_{10} - 3\omega)\right]^{-1} + \left[(\omega_{10} + \omega)(\omega_{10} - \omega)^2\right]^{-1} \\ & + \left[(\omega_{10} + \omega)^2(\omega_{10} - \omega)\right]^{-1} + \left[(\omega_{10} + \omega)^2(\omega_{10} + 3\omega)\right]^{-1} \end{aligned} \tag{23}$$

A major difference between $\beta_{\text{two-level}}$ and $\gamma_{\text{two-level}}$ is the presence of two competing terms in equation 22. (Only the second term will contribute, however, with a centrosymmetric material, yielding a negative γ if D_{111} and D_{11} are positive, as they must be below resonance.) Competition between the two terms of the model results for noncentrosymmetric molecules. Fundamental calculations by Kuzyk show that the maximum theoretical result for noncentrosymmetric molecules is positive and four times the value in the centrosymmetric case (127).

Two-Photon Resonant Enhancement. The frequency dependence of the essential states models is also important as indicated by the potential for resonant enhancement in the denominators "D" of the sum-over-states (with appropriate damping effects not indicated in eq. 23). Generally, it is undesirable to operate near a resonance with either the fundamental input frequency ω or the desired harmonic output. When 2ω approaches ω_{10}, however, an important intermediate two-photon resonance is evident from the second D_{111} term. In this case, resonant enhancement appears without undesirable absorption effects. The $(\omega_{10}-2\omega)$ denominator term also appears in expressions for other types of frequency conversion and even the nonlinear refractive index. Intermediate resonant enhancement applies not only to the two-level model. Absorption and/or resonant enhancement

are possible whenever there are real energy levels close to the one, two, or three photon transitions (140).

Bond Length Alternation Revisited. Meyers and co-workers have also theoretically examined simple donor–acceptor polyenes by applying an external, static homogeneous electric-field to tune to different degrees of bond length alternation and mimic the effects of varying solvent polarity. Their studies indicate that for highly bond-length alternated molecules, such as polyenes, the off-resonant γ is positive, but, as the bond alternation is decreased, γ changes sign and peaks negatively in the cyanine limit (133).

Extension to Multilevel Models for Constituent Materials.

Symmetry and Excited States. It should be emphasized that Kuzyk's sum-rule calculations, which highlight the importance of the energy difference between the ground and the first excited states, only provide upper bounds on the values of β and γ. Predicting actual values require more complex relationships. Similarly, the two-level model has been shown to be inadequate even as a starting point for many materials, (139,141) failing to account even for the sign of γ. For example, measurements, as well as full quantum chemical calculations, show that centrosymmetric polyene-like molecular materials show a positive off-resonant nonlinearity. The two-level model predicts only negative γ off-resonance for centrosymmetric systems (142). In contrast, linear cyanines have been modeled theoretically in detail by Pierce, who found that, below resonance, $\gamma < 0$ for all-trans linear centrosymmetric cyanines. His calculations, as well as several experimental studies, however, show that the two-level model is still inadequate for these molecules and higher lying two-photon states must be included (143,144).

To understand the effects of additional states beyond the two-level model in centrosymmetric molecular materials, it is helpful to analyze symmetry conditions that dictate allowable transitions between states. Because the ground state (also called the 1Ag state) is of Ag symmetry, the lowest optically allowed one-photon transition is to the 1Bu state (of opposite symmetry), which is the lowest lying one-photon excited state in the linear absorption spectrum. The 1Bu state is not necessarily the lowest lying excited state, however. One fundamental difference between centrosymmetric polyenes and cyanines is the location of another excited state, the lowest lying two-photon state or 2Ag state. Studies show that the 2Ag state lies energetically below the linear absorption peak (1Bu state) for polyenes, but above the peak for cyanines. Electron correlations that lower the 2Ag state below the 1Bu state create a nonradiative decay pathway for the 1Bu state and can significantly detract from the nonlinear response (145).

Excited-State Enhancements. Several studies also consider further enhancements that may be possible if starting *from* an excited state (146). By optically pumping to increase the population of an excited state, Heflin and co-workers observed a two-order magnitude enhancement (147). The reasons for this increase can be seen again from the terms of the two-level model in equations 21 and 22. By starting from an excited state, one can take advantage of larger optical transition moments μ_{nm}, where n and m are both excited states, and smaller energy differences, $\hbar\omega_{nm}$, between the populated excited state n and the excited state m.

Some Structure–Property Relationships for Third-Order Polymers and Macromolecules. The preferred approach for developing dipolar second-order materials has been to find optimized chromophores and incorporate these

into a polymer with appropriate functionalization. For third-order applications chromophore doping is sometimes used, but is not necessary as the conjugated polymer itself contributes significantly to the NLO response. Third-order materials more often focus on the polymer matrix itself as a system for maximizing extended π-electron conjugation, though researchers have probed third-order phenomena through the use of smaller, simpler monomers and oligomers. Polymers systems are more difficult to probe because of their size and complexity. Optimization parameters include conjugation length (limited by significant saturation effects, and optimizing interaction among the electrons through chain conformation) and the introduction of spacers and donor–acceptor groups, sometimes leading to increased dimensionality of the polymer system.

Conjugation Length and Saturation Effects. The effective conjugation length of a polymer heavily influences the size of the third-order NLO response (148). The free-electron model of Rustagi and Ducuing showed that γ increases exponentially with the number of repeat units in the chain (L) by, $\gamma \sim L^n$, where $n = 5$ for short chains (149). Experimental studies agree (150), in general, with this relationship, though the scaling exponent varies in the range of $n \sim 3$–5.4 (151). The scaling exponent n is dependant upon factors such as the chemical structure of the material and substituent groups. For instance, ($n \sim 2.5$) was reported by Samuel and co-workers for unsubstituted polyacetylene (152), and various substituted polyacetylenes values of n between 2.3 and 4.6 were reported by Neher and co-workers (153). The effect of electron correlations on the scaling has also been investigated, but is beyond the scope of this article. See, for example, Reference 154.

Oligomeric studies have also shown, however, that the NLO response of a conjugated polymer can become quickly saturated as the quantity of repeat units in the chain is increased beyond a certain, critical value. For example, very long chain polyene oligomers showed a saturation of γ at 60 double bonds (155), and poly(triacetylene) oligomers showed saturation of NLO values at 10 repeat units (110). Another study by Yang and co-workers provided evidence that suggested that the exponential scaling factor n in longer conjugated chains actually becomes dependant upon the number of repeat units (L) in the chain (156). This function, $n(L)$, can be used to gain a more detailed understanding of the phenomena that occurs during the transition from a very short chain oligomer to a very long chain oligomer and ultimately a polymer.

Donor–Acceptor Groups, Spacers, and Planar Structure for Third-Order Polymers. A rigid planar structure in a polymeric material increases the third-order nonlinear optical response by maximizing the overlap area of the π-electron orbitals, thereby enhancing electron delocalization (157). Electron donor–acceptor groups are sometimes incorporated in conjugated, third-order polymer systems to enhance electron delocalization. As with second-order NLO chromophores, these "push–pull" groups can be added as end groups, or can be inserted directly into the conjugated backbone structure. A recent study by Gubler and co-workers showed that inserting various spacer groups in the conjugated pathway of a polyene molecule increased γ for the molecule due to increased electron delocalization (158). The relationship between the presence of spacers and the maintenance of a rigid planar structure can be complicated. In the Gubler study, when the polyene to which spacers were added was polymerized, the third-order response of related polymeric materials did not maintain the increased NLO response of the polyenes.

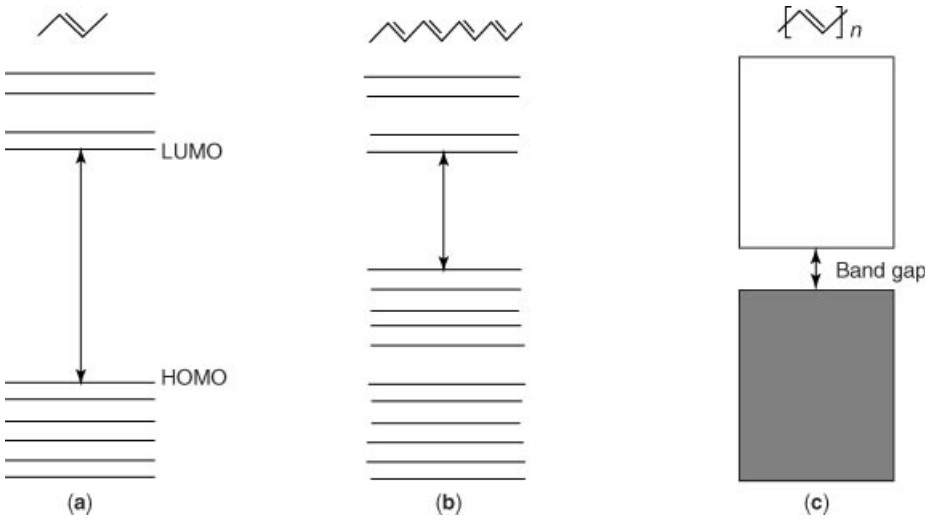

Fig. 7. Electronic effects upon increasing the number of repeat units in a conjugated chain. In a very long chain, discrete energy levels are replaced by valence and conduction bands, and as the conjugation length is increased, the band gap is typically reduced. (**a**) π-conjugated chain with few repeat units, (**b**) π-conjugated chain with increased number of repeat units, and (**c**) π-conjugated polymer chain.

This loss in scaling was attributed to a decrease in electron delocalization due to a loss of planar structure that occurred in the polymer sample as a result of the interchain spacers. Other studies have also indicated that the planarity of the polymer is a dominating factor in deciding the third-order nonlinear response of the polymer (159). Further investigation of the effect of the spacers and the effect of the substitution on third-order materials is needed.

Band Gap. A common model for characterizing the effects of excited states for extended polymer systems is to consider the so-called band gap in the polymer. π-Conjugated polymers are sometimes considered organic semiconductors because the energies of their electrons exist in energy bands rather than discrete energy levels. The transition of the electronic structure (of a growing π-conjugated chain), from energy levels to energy bands, occurs as monomer units are added to a growing chain (see Fig. 7). As units are added, the number of valance and conduction energy bands increases as does the amount of electron delocalization. When the chain is sufficiently long, the energy levels are forced together so closely that energy bands are formed and discrete energy levels no longer exist.

The band gap is considered to be the energy difference that exists between the highest occupied molecular orbital (HOMO) in the ground state and the lowest unoccupied molecular orbital (LUMO) in the excited state. Theoretically, the *band gap* is defined as the amount of energy required for an electron to transition from the ground state to the first dipole-allowed (one-photon) excited state. Experimentally, the band gap of a π-conjugated material is quantified by measuring by the longest wavelength electronic absorption maximum (λ_{max}) (160). In general, reducing the band gap causes an increase in electron delocalization along a conjugated chain and therefore an increase in the third-order NLO response.

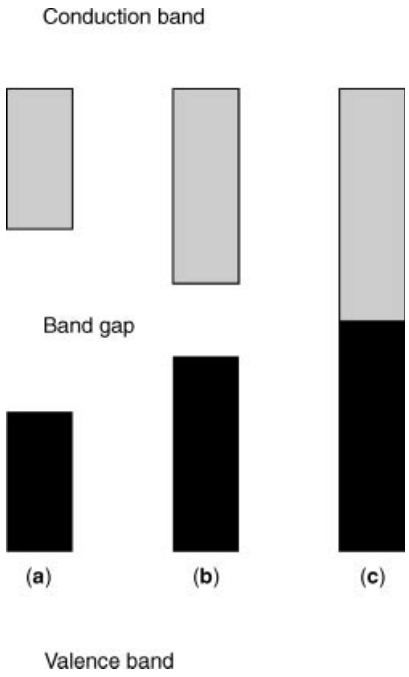

Fig. 8. Band gaps in (**a**) an insulator, where the gap is large and electrons are unable to pass from valence band to conduction band; (**b**) a semiconductor, where electrons with sufficient energy are able to pass from the valence to the conduction band; and (**c**) a conductor, where no band gap exists.

Much research in third-order π-conjugated materials is driven towards reducing the band gap to a semiconductor (161) or even intrinsically conducting status, as illustrated in Figure 8 (162). Two important approaches to minimizing the band gap of π-conjugated materials are minimizing BLA and incorporating donor–acceptor groups (163). Polyacetylene, for instance, would have a zero band gap (and be a intrinsically conducting polymer) if the adjacent carbons atoms along the chain were all equidistant; in other words, if the BLA value were zero. This is not the case, however, due to the alternating single and double bonds along the PA chain. Therefore PA has a finite band gap. Consider a thiophene monomer, which can have either an aromatic or quinoid structure. The structure that is exclusively quinoid has a relatively large band gap because the bonds between the thiophene repeat units are completely double bond in nature. Similarly, the linkages between the aromatic repeat units are fully single bond in character. The ideal strategy in reducing the band gap of a polythiophene is synthesizing a structure in which the quinoid and aromatic structures balance in such a way that the BLA is effectively zero.

The excited states in semiconducting materials can be viewed as containing electrons and "holes" (vacancies left by the absence of an electron), which are formed from the ground state by promoting electrons from filled (valence band) orbitals to the empty (conduction band) orbitals. In the free charge continuum, these electrons and holes are uncorrelated, meaning that the knowledge of the

position of either an electron or a hole does not yield any information about the location of the other. Any state that lies below the band edge of the continuum is known as an excitonic state. In these states, the motion of the electron and hole are correlated, and the combination is referred to as an "exciton." At energies close to a one-photon resonance, double-excited states or "biexcitons" can play a major role in the two-photon absorption spectrum (164).

Multidimensional Molecular Materials. Current trends in the field have shifted away from quasi-one-dimensional or dipolar intermolecular charge transfer materials, and towards inherently two- or three-dimensional and octupolar molecules (165). The hyperpolarizabilities of these molecules do not follow the rules of Kleinman symmetry referred to earlier. The electrons move in at least two dimensions, allowing for polarization-independent applications (25). A main advantage of pushing beyond traditional one-dimensional materials is that alignment of nondipolar materials enables high density packing arrangements not feasible in the presence of dipolar interactions (166). The scope of materials that can be utilized is also much increased. Materials studied include tight-packing donor–acceptor–donor Λ-shaped molecules, stretchable chains to induce axial nonpolar alignment (87), and a variety of chiral shapes, including chiral bulk materials made from achiral molecules arranged in a chiral fashion, such as a threefold propeller-like arrangement (167).

Second-order studies have also begun to focus on large-scale dendritic structures for which large β are seen in HRS measurements without the need for bulk alignment (168,169). Functionalized dendrimers have been also investigated recently for second- and third-order applications. In these large structures, the nonlinear chromophore is placed in the core, along a branch, or at the ends of the dendrimeric structure depending on the application (170). Phthalocyanines and organometallics are interesting second- and third-order nonlinear materials, in part due to their generally high chemical and thermal stability. The π-electron behavior in the molecule is altered by the presence of a metal in the conjugated structure. Ligand-metal bonding leads to transfer of electron density between the metal atom and the ligand systems, causing the electron orbitals of the metal and the ligands to overlap, leading to large hyperpolarizabilities. This class of materials includes polysilanes, metalloporphyrin complexes and metallophthallocyanines (171).

Polymer Structures for NLO Applications. Polymers with π-electron conjugated backbones are favored and widely researched candidates for third-order NLO studies (172–176). The broad categories of π-electron conjugated polymers considered for third-order include linearly conjugated polymers such as polyacetylene (PA), polydiacetylene (PDA), polyazines (PAZ), and linear polyimides (PI); polyheterocyclic polymers such as polypyrrole (Ppy) (177), heterocyclic polyimides, polyquinoline (PQ) (178) polythiophene (PT), polyvinylenes (PV), and polyanilines (PANI) (179); Rigid-Rod Polymers (qv) such as poly(*p*-phenylene benzobisoxazole) (PBZO) and poly(*p*-phenylene benzobisthiazole) (PBZT); and benzimidaxobenzophenanthroline-type (BBB or BBL) ladder polymers. Though localized σ-bonds in carbon chains generally contribute little to the nonlinear response, silicon-based polymers, polysilianes (180), have been studied for their advantages as a third-order material. These polymers are σ-electron conjugated, and therefore maintain the fundamental electron delocalization required for large

third-order NLO response. A short survey of some of the more widely studied of these basic polymeric structures, follows; see also Table 1.

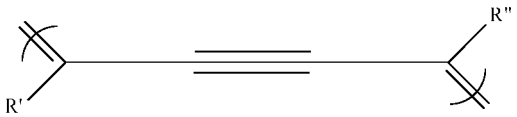
Polydiacetylene—First NLO Polymer Research. Polydiacetylene (**1**) was the first polymer to be investigated for third-order NLO properties. In the late 1970s, Sauteret and co-workers published the first documentation of a large third-order NLO response in a single *p*-toluene sulfate crystal of polydiacetylene (63). The crystal displayed a fast response time (10^{-14} s), a high NLO response (on the order of 10^{-11} esu), and a high laser damage threshold (50 Gw/cm^2 with picosecond response times for a single crystal). Subsequent reports have given third-order susceptibility values ranging over several orders of magnitude (201–203). Influencing factors are chemical structure, resonance enhancement, and measurement techniques.

Polydiacetylenes are linear polymers with highly conjugated π-electron backbones (see DIACETYLENE AND TRIACETYLENE POLYMERS). They can be synthesized via a solid-state polymerization reaction, namely a 1,4-topochemical polymerization of diacetylene monomeric units (204–206). This synthesis mechanism is unique because the polymer product retains the crystalline structure of its monomeric precursors, whereas most polymers have a predominately amorphous structure and limited regions of crystallinity. This type of polymerization has been achieved for polydiacetylene thin films (207,208), Langmuir–Blodgett films (209–211) monolayers (212), single crystals (62), and solutions (213,214). The crystalline structure offers enhanced third-order NLO properties due to high levels of anisotropy (215), but preparation of crystals with high optical quality can be difficult.

One of the most promising of all materials studied for third-order applications is the polydiacetylene, poly(diacetylene *para*-toluene-sulfonate), commonly

referred to as PTS. PTS is thermally stable to ∼180°C, and so less prone to optically induced thermal effects. It can be processed into waveguide structures for device applications and is one of the very few materials that have been shown to meet the standard figures of merit for optical switching devices (38).

Polydiacetylene has been useful in probing third-order phenomena for several reasons. Its centrosymmetric structure excludes second-order NLO effects. Also, polydiacetylenes exhibit chromism in response to such external influences as temperature and solvents (216). Thermochromic and solvatochromic properties have been used to probe third-order effects as a function of conjugation (217). The high degree of structural control that is possible through side-chain substitution allows a wide variety of polydiacetylene polymers to be synthesized (216). It is common to substitute a long alkyl chain as one side group and a carboxylic group as the second. Undergoing this type of substitution allows the polymer to be processed as a Langmuir–Blodgett film. Butoxycarbonylmethylurathane (BCMU)-type polydiacetylenes (**1**) have side groups $R_1 = R_2 =$ $-(CH_2)_3-O-CO-NH-CH_2-COO-C_nH_{2n+1}$ widely studied due to their high solubility in aqueous and nonaqueous solvents, the planar structure, and alternation of color observable with change in conjugation (218–220). Many other polydiactylene-type polymers have been investigated for their third-order NLO properties (181). Future efforts will likely include methodologies such as engineering diacetylene monomers to obtain polymers with enhanced optical properties and processability, and synthesizing a polydiacetylene with a ladder polymer structure (221).



1

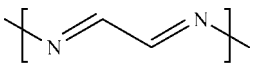
Polyacetylenes. Another widely-studied class of linear conjugated polymer are polyacetylenes, (222) which exist in both the trans and cis isomeric states. The trans isomer (**2**) exhibits cubic susceptibility values an order of magnitude greater than the cis isomer, over the entire range of the optical spectrum (223). This phenomenon has been attributed to the twofold degenerate ground state (224). A ground state is degenerate if the single and double bonds along the chain can be interchanged with no change in corresponding conformational energy. Soliton formation is unique to structures that have degenerate ground states (225). Within the class of NLO π-conjugated polymers, soliton formation is common in *trans*-polyacetylene and some forms of polyaniline (the reduced leucoemeraldine-base or LB (226), and the fully oxidized form, polypernigraniline (227)) In a nondegenerate ground state, exchanging of single and double bonds results in a higher and a lower energy configuration (228,229). Solitons form on a chain when the ground state has twofold degeneracy, which means that two energetically equivalent conformations are possible. A region of degeneracy is formed on the same chain and is separated by a transition region (which is the soliton) in which the BLA decreases and ultimately becomes zero at the center. One energy level is formed directly in the center of the band gap. Soliton movement is not analogous to that of polaron

(discussed below under Polyazines) in that a soliton is a topological defect that cannot pass from chain to chain or through another soliton on the same chain.

Polyacetylenes have very good mechanical properties and high electrical conductivity values, as compared to other conducting polymers. (Although electrical conductivity is not directly linked to NLO activity, a polymer with high electrical conductivity and large NLO response could be a promising candidate for device applications.) Polyacetylene is an air-sensitive and insoluble polymer (230). Attempts have been made to alter the polymer to afford increased solubility and environmental stability (222). A graft copolymer of polyacetylene and poly (methyl methacrylate), for example, has displayed enhanced solubility and stability (231). Substituting a phenyl ring onto polyacetylene offers increased stability. This polymer, poly(phenyl acetylene), has a lesser NLO response as compared to polyacetylene. One method used to increase the NLO response of poly(phenyl acetylene) is further substitution on the phenyl ring itself (232) (see ACETYLENIC POLYMERS, SUBSTITUTED).

2

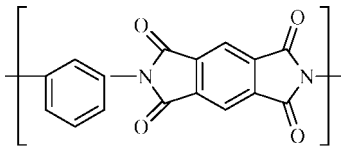
Polyazines. Polyazines (**3**) are one-dimensional π-conjugated, arylene-type polymers that are isoelectric to polyacetylene. The differentiating factor is that polyazines have nitrogen atoms substituted into the backbone structure, whereas polyacetylene backbone contains carbon atoms exclusively. Polyazine, like most conjugated polymers, has a nondegenerate ground state, which means that, unlike *trans*-polyacetylene, no solitons will be present in the polymer. It is thought, however, that polyazines contain polaron and bipolaron defects. Polaron-type excitations are common to π-conjugated chains and can be formed by adding an electron (or an electron hole) to a conjugated chain, leading to changes in chain conformation, energy levels, and electron delocalization. (See Reference 233 for a comprehensive discussion of excited states in conjugated polymers.) Incorporating nitrogen increases the environmental stability and optical transparency of polyazine polymers. The chief advantages of polyazines are extreme architectural flexibility, environmental stability, and solubility; and the characteristic disadvantage is the high optical absorption. Compensation for absorption is possible, however, through chemical modification.



3

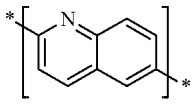
Polyimides. Polyimides (**4**) contain carbon–nitrogen double bonds. Linearly conjugated polyimides exist as both thermoplastics and thermosets. High mechanical strength, good insulating properties, processability from a soluble precursor, long-term chemical and orientational stability, and high thermal stability are among the characteristics that make polyimides a useful contender for optical applications (234). Heterocyclic polyimides have also been investigated due to increase in electron delocalization inherent to the ring structure. Polyimides (qv) are

commonly synthesized under severe reaction conditions which limits the ability to chemically modify the polymer (by either NLO chromophore addition or other NLO enhancing substituents) (235).



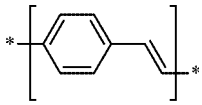
4

Polyquinolines. The high mechanical strength, solubility in organic solvents, ability to be easily processed into thin films with desirable optical properties (such as low optical loss), and thermal stability (at temperatures as high as 600°C) make polyquinolines good candidates for device application studies. Polyquinolines (**5**) are commonly used as the host in guest host polymer systems, and are therefore the subject of much second-order poling research (236). They have also been studied as NLO chromophore functionalized polymers (235). In addition to good end use and processability properties, polyquinolines also have large third-order susceptibilities because of the electron delocalization occurring between carbon–nitrogen double bonds. One recent study reported off-resonant $\chi^{(3)}$ values as large as 1.1×10^{-10} esu for a polyquinoline copolymer with flourene chromophores [the chromophores were incorporated to increase planarity and rigidity of the polymer which enhances the third-order NLO response (237)].



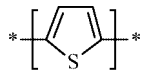
5

Polyvinylenes. Polyvinylenes, particularly poly(*p*-phenylenevinylene) (qv) (238,239), have been studied for their large $\chi^{(3)}$ values on the order of magnitude of 10^{-11}esu (but varying over several orders of magnitude) (240). Polyvinylenes (**6**) can be prepared via a soluble precursor, which is of interest for device applications because the polymer solution can be easily processed and then converted, via thermal polymerization, to its finalized solid-state form (241). Good optical quality thin films have been achieved, which exhibit high mechanical strength, large optical damage thresholds, high electrical conductivity values upon doping, and a high degree of orientational anisotropy (242). For dipolar polymers, a high degree of anisotropy increases the third-order NLO response under conditions where the incident polarization is directed parallel to the polymer backbone (243).



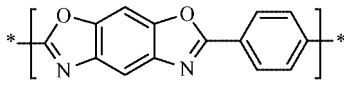
6

Polythiophenes. Polythiophenes (**7**) are polyheterocylic polymers that have a thiophene ring as a repeating backbone unit. Polythiophenes exhibit high electrical conductivity values, yet offer increased environmental stability (244) as compared to polyacetylenes (see ELECTRICALLY ACTIVE POLYMERS). Doping polythiophenes changes their electrical conductivity, but the third-order response of the polymer has been reported to be the same in doped and undoped samples, suggesting that electrical conductivity and NLO response originate from dissimilar origins (245). They are intensely colored materials due to high optical absorptions, and have large resonant third-order responses (246). Polythiophenes are not soluble in organic solvents. Successful efforts to countermand this disadvantage include incorporating methyl methacrylate units in the main chain via copolymerization (247), and substitution of an alkyl chain at the 3-position on the thiophene ring of the polymer (248).

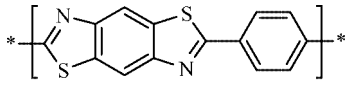


7

Rigid Rod Polymers. One class of rigid polymers that has been commonly studied for its optical, as well as electrical, properties is poly(*p*-phenylenebenzazoles) (PBX). The rigid rod structure of these polymers provides excellent mechanical strength and thermal and thermo-oxidative stability, and they are classed as high performance polymers (249). Two PBX-type polymers that have been of particular interest to NLO applications are poly(*p*-phenylenebenzobisoxazole) (**8**) (PBZO or PBO) and poly(*p*-phenylenebenzobisthiazole) (**9**) (PBZT or PBT) (251). The backbones of these polymers are uniquely conjugated, collinear, and coplanar, which makes intramolecular charge mobility possible, and allows for a large third-order NLO response (see RIGID-ROD POLYMERS).



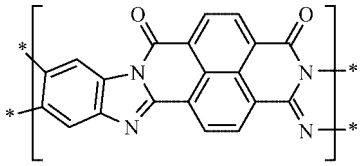
8



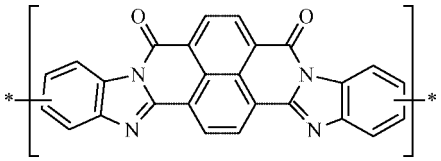
9

Heteroaromatic Ladder Polymers. BBB and BBL are benzimidazophenanthroline ladder polymers which lend themselves to third-order NLOs through their planar conformation, quasi-two-dimensional structure, and to end use applications through their mechanical and thermal stability and electrical properties (252). BBL and BBB are very similar in their repeat unit structure; the manner in which the monomer units are linked together, however, is different. BBL (**10**) has a full-ladder structure, which means that the monomeric units are linked by two covalent bonds, whereas BBB (**11**) has a semi ladder structure because its

monomer units are linked by a single covalent bond. As a result, the $\chi^{(3)}$ of BBL is about three times larger than that of BBB. BBL has a larger NLO response due to the increased planarity of the full-ladder structure of the polymer.



10



11

Measurement Techniques and Devices

For every nonlinear optical effect, one would expect that there is a measurement technique to characterize it. Not all of NLO effects, however, are subject to measurements that are convenient or informative for comparative purposes or device applications. This section highlights a few of the more common test methods for NLO organic molecules and polymers, and provides references for more detailed explanations of these techniques. Significant omissions here are techniques based on the linear and quadratic electrooptic effect, which are discussed in the article ELECTROOPTICAL APPLICATIONS.

Just as there are two broad categories of nonlinear effects, (*1*) changes in the frequency of the output, and (*2*) changes in the refractive index or absorption, so also there are two types of measurements that are typically performed to quantify these effects. The first type includes measurements based on frequency mixing where the input and detected frequencies differ, as in harmonic generation, nondegenerate four-wave mixing, and hyper-Rayleigh scattering. The second type measures changes in the refractive index through birefringence, diffraction, or other methods, as in the optical Kerr effect and degenerate four-wave mixing. Both types of measurements can be adapted to spectral studies and determination of the real and the imaginary parts of the nonlinear susceptibilities, and, in turn, the related hyperpolarizabilities.

The nonlinear susceptibility can be determined either through absolute or relative methods (253). Absolute measurements are very difficult to implement, however, because they require an accurate determination of the incident and harmonic powers. Even for standard reference materials with relatively large nonlinearities, inconsistent reporting and disagreement over the appropriate values has complicated comparisons (28). Whether the standard values can be agreed upon or

not, determination of the susceptibilities relative to common accepted standards is the favored approach for reporting nonlinearities of new materials.

Frequency Mixing Techniques: Harmonic Generation, Hyper-Rayleigh Scattering, and Nondegenerate Four-Wave Mixing. A major advantage of frequency mixing techniques is their ability to distinguish electronic contributions to the nonlinear susceptibility from contributions due to vibrational, orientational, and thermal effects, and to distinguish resonant and nonresonant electronic motions. The price paid for this advantage is the requirement of very high powered lasers, especially for third harmonic and other third-order effects, and the need for careful filtering and weak-signal detection of non-phase-matched outputs.

Harmonic Generation. In a typical relative measurement involving harmonic generation, the input laser radiation is split into two beams, one incident upon the sample to be measured and the second on a suitable reference standard, such as quartz glass for second-harmonic generation or BK-7 glass for third-harmonic generation, or carbon disulfide for other third-order processes. By simultaneously measuring the harmonic response of both the sample and the reference, the effects of laser fluctuations in power are greatly diminished. After suitable spectral filtering of the output beams to detect only the harmonic (typically using photomultiplier tubes or avalanche photodiodes), the harmonics from the previously characterized reference and the sample are compared.

Simply placing the source and reference in the laser's path is not sufficient, however, to ensure a useful relative measurement. The magnitude of the harmonic response is a function of the path length in the material, and harmonic intensity generated fluctuates through the mismatch in propagation phase between the fundamental and the harmonic wave. The typical sample is not "phase-matched" in that the harmonic and fundamental do not propagate at the same speed through the sample. In second-harmonic generation, the coherence length is the spatial period of the oscillation in the output and, thus, a measure of the effective length in the material for efficiently generating second harmonic. The coherence length of the output in this case is defined as

$$\ell_{\text{coh}} = \frac{\pi}{\Delta k} \qquad \Delta k = \frac{2\omega(n_{2\omega} - n_{\omega})}{c} \tag{24}$$

where n_{ω} is the refractive index at ω. The coherence length for a polymer is typically on the order of 20 μm (254). For samples approaching that thickness or greater, the optical path length through the material must be systematically altered during measurement either by translating a wedge-shaped sample and reference through the beam during measurement, or by rotating the sample and reference each about an axis through and perpendicular to the beam path. The resulting interference patterns (sometimes called Maker fringes (255)) are then analyzed in terms of both their magnitudes and their periodicity to determine the nonlinear susceptibility (256). The second harmonic output, for example, is given

by

$$I_{2\omega} \propto \frac{\left|\chi^{(2)}(-2\omega;\omega,\omega)\right|^2 (I_\omega)^2 L^2}{\lambda_{2\omega}^2 n_\omega^2 n_{2\omega} \varepsilon_0^2} \frac{\sin^2(2\pi L/\ell_{\text{coh}})}{2\pi L/\ell_{\text{coh}}} \tag{25}$$

where I_ω is the incident intensity and L is the interaction length (thickness) in the sample. The accuracy and interpretation of these measurements depends also on careful measurements of the linear optical properties and geometries of the samples and setup, including the effects of multiple reflections at the interfaces (257). Significant birefringence and/or absorption further complicate the analysis, (258) but also provide information about the imaginary parts of the nonlinear susceptibilities.

Phase-Matching. As indicated previously, due to spectral dispersion, $n_{2\omega}$ and n_ω are generally not equal in an isotropic material. In regions of ordinary dispersion, for example, the refractive index at the second harmonic is always greater than the refractive index of the fundamental for two beams of the same polarization propagating in the same direction. Second-order materials are *not* isotropic, however, so that the natural birefringence of these materials (that is, the different refractive indices for different light polarizations) can be used to achieve a reasonable degree of phase matching. The nature of the birefringence of a material depends upon its crystal class. Poled polymers, being cylindrically symmetric about the polar axis, are classed as ∞mm materials because they have a unique axis "3" in the poling direction about which there is an infinite-fold rotation, and an infinity of mirror planes (259,260). In a positive uniaxial crystal, for example, as well as some poled polymers (261), the index of refraction, n_0, for light polarized perpendicular to the plane of incidence and so also perpendicular to poling direction (a so-called ordinary ray) is smaller than that for light having a component parallel to the optic axis or poling direction (an extraordinary ray with index n_e). For a negative uniaxial crystal, the relative values of the extraordinary indices are smaller than the ordinary index.

For poled polymers, if light is polarized along the poling axis, it will couple more strongly to the charge-transfer axis, which should have a larger polarizability and hence larger refractive index. So n_e should be greater than n_0 leading to a positive uniaxial material. For polymers like polyimides, however, it is possible that the index for the polymer dominates, and polyimides molecules tend to lie in the plane of the film. So in general, the birefringence of the polymer would tend to give a larger index in the plane, and the molecule would tend to give a larger index perpendicular to the plane of the film. Depending on the concentrations and polarizabilities, the overall birefringence could have either sign (K. D. Singer, private communication).

Because both the extraordinary ray and the optic axis are in the plane of incidence, the index of refraction seen by the extraordinary ray depends upon the angle of incidence. Thus, a common method for achieving phase-matching, called "Type I" phase-matching as shown in Figure 9, is to find the angle at which the index of refraction of the fundamental extraordinary ray, $n_e(\theta)$, at ω equals that of the harmonic ordinary ray, n_0, at 2ω. Another common method, called "Type II," is for the fundamental to consist of two orthogonal polarizations that average to

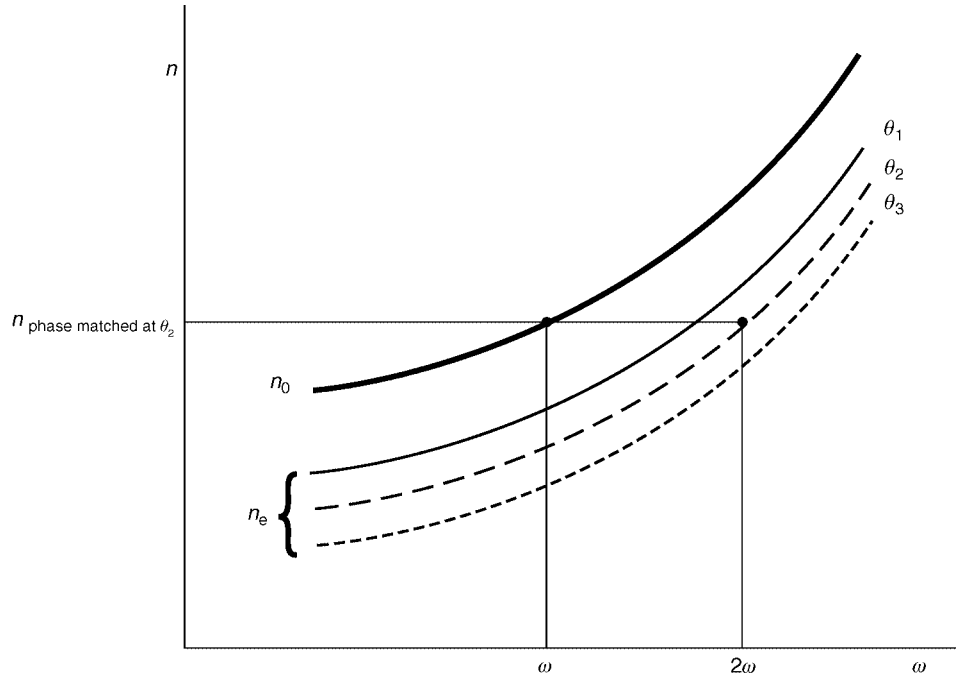


Fig. 9. Sample ordinary and extraordinary dispersion curves in the normal dispersion regime for a negative birefringent material for which the possible extraordinary indices are smaller than the ordinary indices. For the frequencies shown, the phase-matching condition is met for the second harmonic when the light propagates at θ_2 with respect to the optic axis.

the same index of refraction as that experienced by the harmonic. For further details, See Reference 262. A significant drawback of these methods is that the different indices of refraction for the orthogonal polarizations also lead to different angles of refraction for the fundamental and harmonic rays. Thus, the interaction length is further constrained by the walk-off of the rays from one another due to birefringence. If can arrange that the angle for optimal phase-matching is 90° (as might be seen in a single-mode guided wave), then there will be no walk-off.

Another method for phase-matching, which does not require that the rays have different polarization directions and so avoids the problem of walk-off, is to arrange the harmonic conversion frequencies and material properties so that the device operates in a spectral region where there is an absorption peak at frequencies between the fundamental and the harmonic. In this case, a region of anomalous dispersion where the index of refraction is a decreasing function of frequency, accompanies the presence of the intermediate absorption. By carefully combining materials, so that the resulting composite has the same index of refraction at both the fundamental and harmonic, phase-matching results for that pair of frequencies (263) (see Fig. 10).

In integrated optics devices, phase matching must occur in a waveguide structure. The quantized effective indices of refraction vary for different modes of propagation in the waveguide, and the dispersion in the effective mode

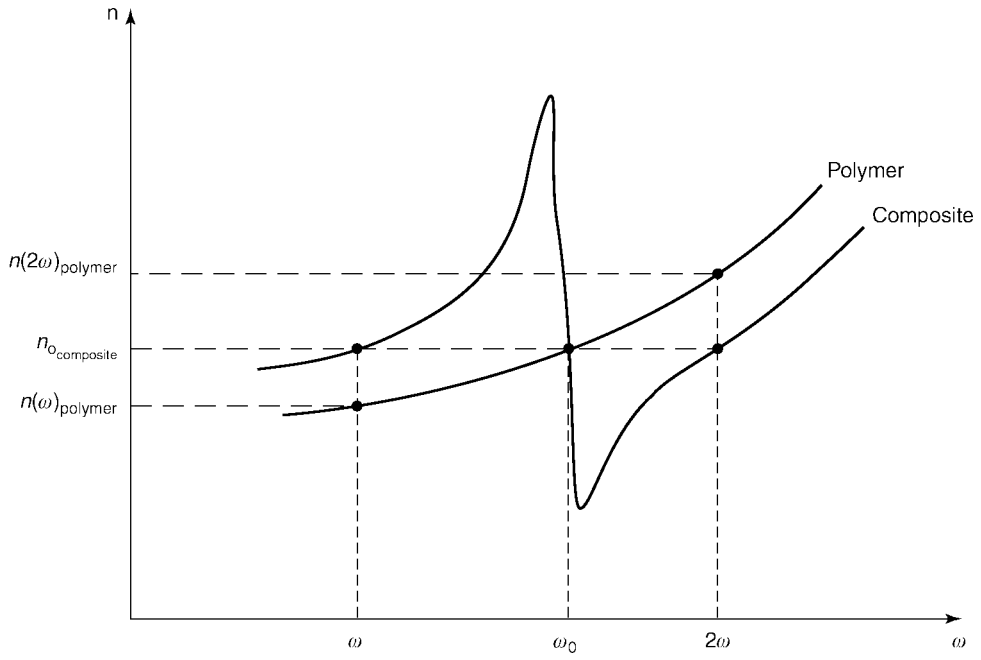

Fig. 10. An example of anomalous dispersion phase-matching in which the dopant molecule exhibits a strong absorption at frequency ω_0 between the fundamental (ω) and harmonic (2ω), leading to a lower index of refraction at the harmonic. The dopant is added to a polymer exhibiting normal dispersion resulting in a composite with equal refractive indices at the fundamental and harmonic, n_0.

index of refraction is generally greater than that of the bulk index of refraction. Phase-matching may be achieved by propagating the fundamental in one mode and polarization and the harmonic in a different mode or different polarization. The details of this procedure can be found in Reference 264. A major drawback of phase-matching in different modes in a waveguide is that light rays propagating in different modes do not necessarily overlap well in the waveguide, limiting their interaction.

Phase-matching in a waveguide is also accomplished by spatial periodic poling (so-called quasi-phase-matching), where the direction of poling is either reversed or polar order is inhibited in the waveguide at regular intervals so that the length of each interaction region is at or shorter than the coherence length (the length over which the phase-mismatch begins to decrease the harmonic output.) Figure 11 illustrates this process by showing the growth in second-harmonic intensity as a function of interaction length. This method has also been applied to cascaded nonlinearities where it induces effective cubic nonlinearities (265).

Electric-Field-Induced Second Harmonic Generation. As previously discussed, in almost all cases the bulk NLO second-order response can be understood through summation over molecular nonlinearities of the constituents. Thus, the key measurements for optimizing polymeric NLO materials are aimed at characterizing their molecular constituents. The wedged cell technique described above has been applied to liquids containing dissolved organic chromophores, through

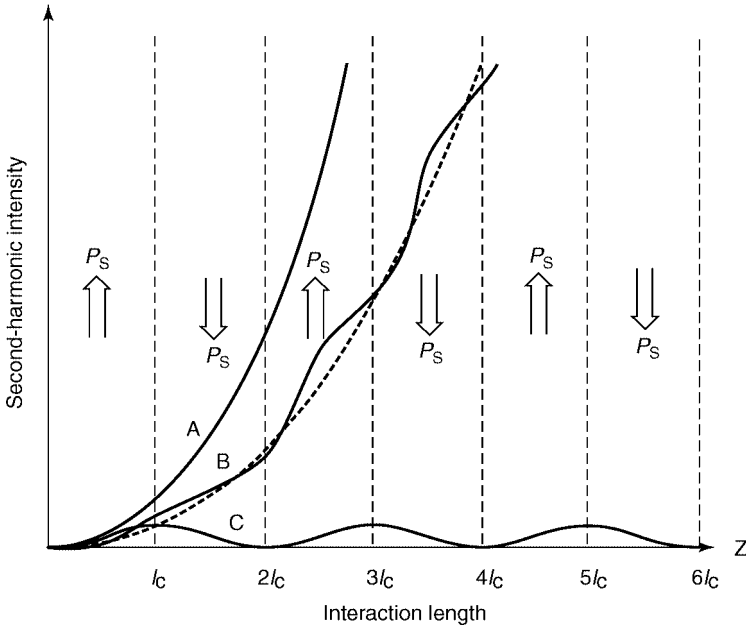

Fig. 11. Variation of second-harmonic intensity as a function of interaction length represented for (A) a phase-matched system, (B) a periodically poled system for which the poling field, and therefore the nonlinearity, changes direction every coherence length, and (C) a non-phase-matched process for which the power flows back from the harmonic completely back to the fundamental during every other coherence length of interaction. (From Reference 6, p. 262. Reprinted with permission.)

electric-field-induced second harmonic generation. The major additional factor in this case is that solutions of polar molecules lack the requisite bulk asymmetry needed for second harmonic generation. To align the dipoles and break the symmetry, a large, but usually very short, DC voltage is applied across the solution just as the beam passes through it (266). (The relationship between the $\chi^{(3)}$ value obtained through this measurement and the molecular properties of the dipoles is given by equation 19).

Hyper-Rayleigh Scattering. EFISH cannot be used, however, on ionic or conductive solutions, due to the need for a large DC field, or on molecules that have no dipole moment, but only have an octupolar moment. Instead, researchers often prefer to use hyper-Rayleigh scattering (HRS) to make measurements, which can be used for all types of molecules, including multidimensional structures, chiral molecules, and stretched polymers (56,267). In the HRS technique, the nonlinear response of the sample is measured from the *scattered* second harmonic, rather than second harmonic transmitted through the sample, again by comparison to a known reference. Careful comparisons between the EFISH and HRS response, including spectral dispersion of each, have shown the consistency of these two methods (268). Ostroverkhova and co-workers have shown that with measurements based on just two different polarizations, the full hyper-Rayleigh scattering tensor can be expressed in terms of its rotationally invariant components for

β, and that figures of merit corresponding to each of the rotationally invariant tensors can be determined (269). The range of information that can be obtained by HRS is expanded by varying the polarization of the detected light, including circular and elliptical polarizations, (270) and by varying the angle at which the scattered light is measured to determine the relative tensor components to the susceptibility. HRS measurements are complicated by the need to account for solvent effects and background fluorescence. The β values obtained are combinations of β-tensor components.

Measuring Nonlinear Refractive Index Changes.

Z-Scan. Z-scan is one of the simpler methods to implement and rapidly measure both the nonlinear refractive index and the nonlinear absorption in a solid, liquid, or solution (271). Many different variations on the basic idea behind z-scan exist and interpretation of the results of a z-scan measurement can be complicated. The most common z-scan technique, illustrated in Figure 12, involves focusing a laser beam on a point in space and translating the sample through the focal point for a distance a few times greater than the diffraction length, $Z_0 = \pi {w_0}^2/\lambda$ (where w_0 is the focal spot half-width at $1/e^2$ of the maximum irradiance and λ is the laser wavelength). The detector is placed behind a fixed aperture on the other side of the sample for measuring the transmitted light in the far-field. As the location of the sample changes, so does the amount of transmission through the aperture according to the placement of the sample in the path, the thickness of the sample and its index of refraction, and, most importantly, the changes in the sample's refractive index with intensity. As the sample approaches the focal point from the far side of the aperture, the light through the aperture is diminished by a self-focusing nonlinearity ($\Delta n > 0$). The sample acts so as to enhance the focusing power of the lens, thus taking the focal point away from the aperture and reducing transmission through the aperture to the detector. As the sample passes through the focal point, the situation is reversed and the same positive Δn in the

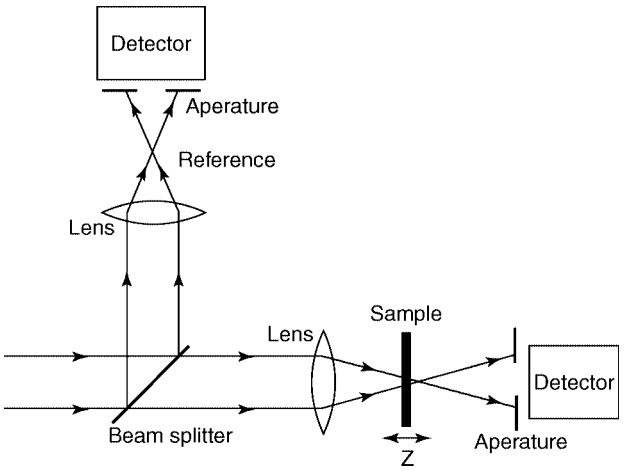

Fig. 12. Schematic for z-scan technique. By varying the placement of the sample along the optic axis, the amount of light being detected through the aperture changes due to the intensity-dependent refractive index of the sample.

sample will tend to reduce the divergence of the light, increasing the transmission through the aperture. For $\Delta n < 0$ and self-defocusing, the result is reversed in that the transmission through the aperture is increased when the sample is on the far side of focal point and decreased on the near side from the aperture (272).

Interpretation of the resulting normalized transmittance can yield both the nonlinear refractive index (based on the change in optical path length) and the nonlinear absorption coefficient (based on the change in absorption by the sample). The results depend upon knowing the laser beams spatial and temporal profile, power content, and stability. One disadvantage of the technique is that it cannot be used to identify the origin of the nonlinearity, as it treats nonlinearities arising from electronic processes the same as orientational and other processes by giving only time-averaged results. Thus, the results must be interpreted based on the theoretical origin of the nonlinearity. Furthermore, the z-scan technique is more difficult to apply with thick samples where the nonlinearity may cause changes in the beam profile through diffraction or self-focusing inside the sample.

Many parameters for and variations on z-scan must be omitted here, but some of the variations include (*1*) open aperture z-scans, (273) where all the transmitted light is collected in order to determine two-photon absorption effects, (*2*) eclipsing z-scan (EZ-scan), (274) which replaces the aperture with a block and collects the light at the outer edges, (*3*) excite-probe and two-color z-scans, (275) which use two collinear beams that differ in either polarization or wavelength and can be time-resolved, and (*4*) non-Gaussian beam or top-hat beam z-scans, (276) which use a beam with a steeper curvature gradient spatial profile to increase the z-scan's sensitivity.

Optical Kerr Effect. Another important method used to characterize polymers is the optical Kerr effect (OKE). The optical Kerr effect differs from the quadratic electrooptic effect in that the birefringence effects are induced solely by an optical field (37). In this measurement, an intense linearly polarized pump pulse induces birefringence in the nonlinear sample through an intensity-dependent refractive index change. The sample is placed between crossed polarizers and a weak, typically tunable, continuous wave (cw) probe laser (usually at a different wavelength and polarized at 45° to the pump pulse) overlaps the pumped region. The increased transmission of the probe beam when the pump pulse arrives is proportional to $(\chi_{\text{eff}}^{(3)})^2$, a combination of elements of the $\chi^{(1)}$ tensor. Many variations on this technique have been used including (*1*) use of a pulsed probe beam to reduce the effects of stray probe light, (277) (*2*) use of a nonlinear mixing crystal, after the analyzer in which a portion of the pump beam is frequency mixed with the probe to enhance the signal to noise ratio by creating an optical gate for the probe coincident with the pump pulse, (278) (*3*) use of an optical heterodyne technique in which a slightly uncrossed analyzer polarization allows for interference between the optical Kerr effect signal and the unaltered probe beam, (279) and (*4*) use of circularly and elliptically polarized pump beams tuned near a Raman active vibration in the sample to determine the Raman spectrum and $\chi_{\text{eff}}^{(3)}$ simultaneously (called the Raman-induced optical Kerr effect) (280). OKE measurements using pulsed probes and time-domain studies are especially helpful for characterizing molecular mechanisms contributing to the effect (281). The optical Kerr effect is especially significant in characterizing polymers for applications such as ultrafast light gates or optical shutters.

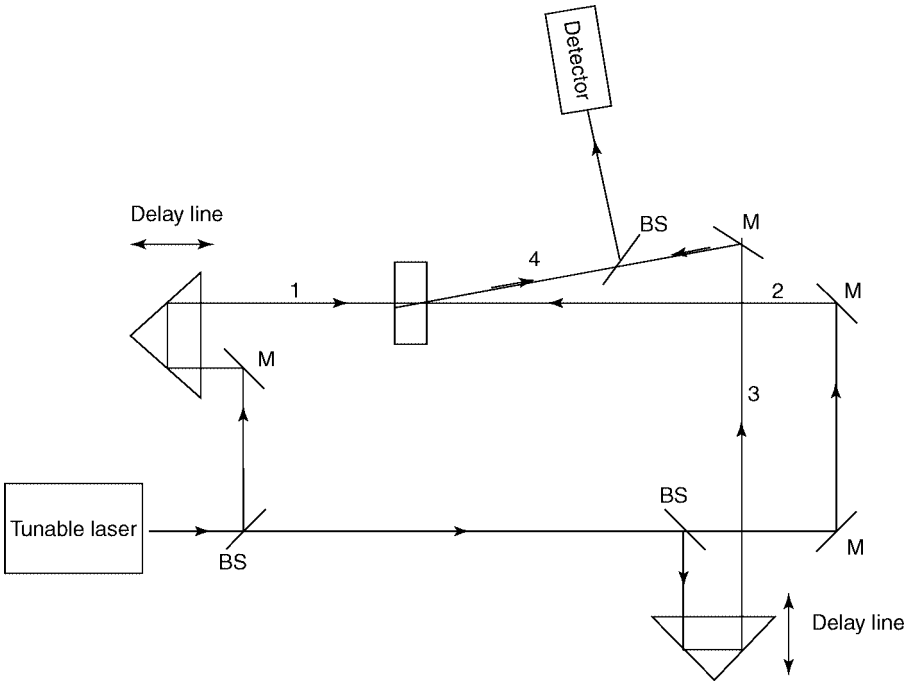

Fig. 13. Schematic for backward scattered (phase conjugate) degenerate four-wave mixing. (BS = beam splitter, M = mirror.) The pump beams (1) and (2) are collinear and counterpropagating. The probe beam (3) when incident on the sample leads to the creation of the phase conjugate beam (4), which is detected and compared to a suitable reference. The delay lines are included so that the timing of pulsed light arriving at the sample via paths (1), (2), and (3) can be varied.

Degenerate Four-Wave Mixing. A slightly more complex configuration for studying real third-order nonlinearities is one in which a single laser beam is split into two or more beams, which are then crossed at the sample, leading to intensity-dependent diffraction. There are two common geometries of this so-called degenerate four-wave mixing (DFWM) (*1*) backward or phase conjugate scattering and (*2*) forward scattering. In the former case, shown in Figure 13, two counter propagating pump beams will be incident on the sample with approximately equal intensities, and a third, probe beam, will cross these at the sample. The result of the nonlinear interaction is a backward scattering of the probe beam. The backward scattered beam is the phase conjugate of the probe and the ratio of the phase conjugate reflectivity to the incident probe intensity yields $\chi^{(3)}_{\text{eff}}$, as a function of the sample length, absorption, and field amplitudes on both sides of the sample (37).

In the forward scattering, or two-wave mixing geometry, two strong pump beams with wave vectors $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ cross to generate a diffracted beam that conserves momentum with the wave vector direction $2\boldsymbol{k}_1 + \boldsymbol{k}_2$. By varying the delay between the two beams arrival, real-time studies of grating dynamics can be used to distinguish nonresonant electronic nonlinearities. DFWM is a favored technique for studying photorefraction in NLO polymers and other materials.

Nonlinear Absorption. In theory, any of the above measurement techniques could be applied to materials in the presence of nonlinear absorption and interpreted to provide the two-photon absorption coefficient $\alpha^{(2)}$ or the two-photon cross-section $\sigma^{(2)}$. The study of multiphoton absorption is, of course, inherently spectroscopic, probing the multiphoton resonances that impact various nonlinear phenomena. Third-harmonic generation in thin films has been used to characterize the phase of the complex $\chi^{(3)}$ and thus $\alpha^{(2)}$, but the experimental technique requires additional steps and interpretation may be complicated by excited state absorption and three-photon resonances (282). The presence of an imaginary component of $\chi^{(3)}$ significantly complicates DFWM measurements by adding additional phase grating components to the phase conjugate beam, including thermal gratings. Separation of the different contributions to the imaginary part of $\chi^{(3)}$ has been accomplished by time-resolved (283) and picosecond time-scale (284) measurements.

If the primary aim is to characterize the nonlinear absorption, several direct techniques are more easily implemented or interpreted. Conceptually, the simplest technique is to measure the transmitted intensity as a function of the incident intensity on the sample. Separating the linear and nonlinear contributions depends upon the spatial and temporal characteristics of the laser, however, as well as the thickness L and reflectivity R of the sample surfaces. For example, if the laser provides a CW beam of uniform spatial intensity, normally incident on a sample, the transmission T may be expressed as a product $T = T_L T_{NL}$ of the linear transmission $T_L = (1-R^2) \quad e^{-\alpha^{(1)}L}$ and a nonlinear factor $T_{NL} = 1/(1+f)$ where

$$f = \frac{\alpha^{(2)}(1-R)I_1\left(1-e^{-\alpha^{(1)}L}\right)}{\alpha^{(1)}} \tag{26}$$

Of course, the illumination is more commonly of nonuniform spatial and temporal quality, leading to more complicated expressions for T_{NL} (44). Instead, it may be easier to use relative measures of nonlinear absorption by splitting the beam between the sample and a reference, such as ZnSe (285).

Another technique is to use a z-scan setup with an open aperture so that the change in collected light as the sample is translated through the focal point is determined solely by the relative absorption in the sample rather than the focusing or defocusing effects of the sample. This technique includes both two-photon effects and excited-state absorption. Van Stryland and co-workers have shown that the two effects can be separated by comparing the absorption for equal incident energies, but different powers, by adjusting the pulse duration. The two-photon absorption depends upon the intensity, whereas the excited-state absorption depends upon the fluence of the pulse (286).

Many other techniques have been used in addition to those discussed. For example, additional absorption techniques, generally beyond the scope of this article include two-photon luminescence (287), thermal lensing (288), photoacoustic techniques (289), and white-light continuum spectroscopy (290). For further information, the reader is referred particularly to Reference 1.

READING LIST

With respect to polymeric and organic molecular materials, there are several monographs and numerous collections of research works to consider. Annual proceedings presenting current research were published through 1997 by the Society of Photo-optical Instrumentation Engineers (SPIE) under the title *Nonlinear Optical Properties of Organic Materials*, Vols. I–X. Since 2001, this series has been superceded by the annual series *Linear and Nonlinear Optics of Organic Materials*, Vols. I–III, currently edited by M. Kuzyk. Additional recent relevant proceedings from SPIE include:

M. G. Kuzyk, *Third Order Nonlinear Optical Materials*, 3473 SPIE, Bellingham, Wash., 1998.

M. Eich, *Organic Nonlinear Optical Materials*, 3796 SPIE, Bellingham, Wash., 1999.

The proceedings of the October 2003 annual meeting, entitled *Organic Materials and Nanotechnology*, CDS 100 SPIE, Bellingham, Wash., 2004, promise to provide an up-to-date account of research in that field.

Noteworthy collections and monographs include:

K.-S. Lee, ed., *Polymers for Photonics Applications, Vol. 1: Advances in Polymer Science*, Vol. 158, Springer, Berlin, 2002.

H. S. Nalwa, ed., *Supramolecular Photosensitive and Electroactive Materials*, Academic Press, San Diego, Calif., 2001.

NONWOVEN FABRICS, SPUNBONDED

Introduction

In 2001, the global production of spunbonded fabrics reached a record 1,400,000 t with an annual growth rate of between 6 and 8% (1). There are approximately 260 individual production lines in operation throughout the world. Spunbonded fabrics are distinguished from other nonwoven fabrics in their one-step manufacturing process which provides either a complete chemical-to-fabric or polymer-to-fabric process. Although the use of monomers as part of the in-line process is no longer in commercial use, in either instance the manufacturing process integrates the spinning, laydown, consolidation, and bonding of continuous filaments to form a

fabric. Commercialization of this process dates to the early 1960s in the United States and Western Europe (2,3) and in the early 1970s in Japan (4). Many of the first plants constructed are still in operation attesting to the usefulness of the method. New production plants continue to be built (1,5) to supply the growing demand (Table 1).

The large investment required for a turnkey spunbonded plant ($15–50 million, 2002 U.S. dollars) is offset by their high productivity. Spunbonded production was originally limited to western Europe, the United States, and Japan, but has since spread to virtually all areas of the world. Production lines, mainly nonproprietary, have been installed throughout Asia, South America, and the Middle East, areas and countries that previously did not participate in the technology. Considerable ownership changes occurred in the United States and Europe as the strategies of companies committed to the technology evolved (6).

Early marketing efforts for spunbonded fabrics centered on their substitution for existing (ie, woven) textile fabrics. Generally, success was achieved in areas where only functionality was important. Extremely slow progress has occurred in areas where textile-like aesthetics are required. Only in the area of disposable protective clothing has success been achieved for the garment market. Nevertheless, spunbonded fabrics are recognized as a unique class of materials within the general category of nonwoven fabrics (see NONWOVEN FABRICS, STAPLE FIBERS).

The area of largest growth for spunbonded fabrics continues to be disposable diaper coverstock, that accounts for approximately 70% of the U.S. coverstock market. Forecasts for the future growth of spunbonded fabrics continue to be favorable as consumption in both durable and disposable areas continues to grow. Growth is forecast to generally exceed the growth of all nonwovens, which itself is expected to grow at 3–6% per annum (1,6). In addition to diaper coverstock and hygiene, growth is anticipated in geotextiles, roofing, carpet backing, medical wrap, and durable paper applications such as envelopes (6).

New plant construction will bring increased capacity to levels of regional overcapacity, which will force producers to export large quantities of product to keep supply and demand in balance. Considerable consolidation of ownership has occurred during the last five years and the investment and output for each new line has grown enormously. New production lines can produce up to 1 billion m^2 of coverstock per year more than doubling the annual output of lines built only 5 years ago. Environmental issues have had relatively little effect on either production or products. Consumers prefer the convenience of disposable diapers, and studies have shown that diapers are still a relatively small contributor to landfill space.

Although producers have benefited from the generally stable prices for crude oil, a sudden increase in these prices or decrease in availability of resin feedstocks would adversely impact both profitability and growth. Producers who have not upgraded to newer, faster, and more efficient lines have experienced low or negative profitability. There appear to be no new fiber technologies that would radically change the manner in which spunbonded structures are produced. Any serious challenges to existing markets will likely come from film, airlay, or advances in alternative technologies within a specific market segment.

Table 1. Spunbond Producers by Region

Company	Polymer base[a]	Technology base

[h] Cerex process.

General Characteristics

Spunbonded fabrics are filament sheets made through an integrated process of spinning, attenuation, deposition, bonding, and winding into roll goods. The fabrics are made up to 5.2 m wide and usually not $>$ 3.0 m in order to facilitate productivity. Fiber sizes range from 0.1 to 50 dtex although a range of 2–20 dtex is most common. A combination of thickness, fiber fineness (denier), and number of fibers per unit area determines the fabric basis weight which ranges from 8–800 g/m^2; 13–180 g/m^2 is typical. Average basis weights in hygiene have fallen by 20% or more because of improvements in process technology.

Most spunbonded processes yield a sheet having planar–isotropic properties owing to the random laydown of the fibers (Table 2). Unlike woven fabrics, spunbonded sheets are generally nondirectional and can be cut and used without concern for higher stretching in the bias direction or unraveling at the edges.

Table 2. Physical Properties of Spunbonded Products

Product	Basis weight, g/m^2	Thickness, mm	Tensile strength,[a] N[b]	Tear strength,[a] N[b]	Mullen burst, kPa[c]	Bonding method
Accord	69		144 MD 175 XD	36 MD 40 XD	323	Point thermal

Typar	103	0.305	540 MD 495 XD	207 MD 235 XD	825	Undrawn segments Area thermal
Tyvek	54	0.15	4.6[e] MD 5.1[e] XD	4.5 MD 4.5 XD		Area and point thermal

[a]MD = Machine direction; XD = cross-direction.
[b]Unless otherwise noted. To convert N to pound-force, divide by 4.448.
[c]To convert kPa to psi, multiply by 0.145.
[d]300 N/5 cm = 34.5 ppi.
[e]N/mm; to convert N/mm to ppi, divide by 0.175.

It is possible to produce nonisotropic properties by controlling the orientation of the fibers in the web during laydown. Although it is not readily apparent, most sheets are layered or shingled structures with the number of layers increasing with higher basis weights for a given product. Fabric thickness varies from 0.1 to 4.0 mm; the range 0.15–1.5 mm represents the majority of fabrics in demand. The method of bonding greatly affects the thickness of the sheets, as well as other characteristics. Fiber webs bonded by thermal calendering are thinner than the same web that has been needle-punched, because calendering compresses the structure through pressure, whereas needle-punching moves fibers from the x–y plane of the fabric into the z (thickness) direction.

The structure of traditional woven and knit fabrics permits the fibers to readily move within the fabric when in-plane shear forces are applied, resulting in a fabric that readily conforms in three dimensions. Because calender bonding of a spun web causes some of the fibers to fuse together, thus giving the sheet integrity, the structure has a relatively stiff hand or drape compared to traditional textile fabrics. This is a result of the immobilization of fibers in the areas of fiber-to-fiber fusion. The immobilization may be moderated by limiting the bonds to very small areas (points) or by entangling the fibers mechanically or hydraulically. Saturation bonding of spun webs with chemical binders such as acrylic emulsions can bond the structure throughout and result in very stiff sheets. This technique is used to provide thermal and mechanical dimensional stability to certain structures whereby the emulsion binder functions as a nonthermoplastic component within the thermoplastic matrix.

Other approaches include powder bonding, although this method may be more suitable for bonding nonwoven fabrics made from staple fibers (7,8) (see NONWOVEN FABRICS, STAPLE FIBERS).

The method of fabric manufacture dictates many of the characteristics of the sheet, but intrinsic properties are firmly established by the base polymer selected. Properties such as fiber density, temperature resistance, chemical and light stability, ease of coloration, surface energies, and others are a function of the base polymer. Thus, because nylon absorbs more moisture than polypropylene, spunbonded fabrics made from nylon are more water-absorbent than fabrics of polypropylene.

The majority of spunbonded fabrics are based on either isotactic polypropylene or polyester (Table 1). Small quantities are made from nylon-6,6 and an increasing tonnage from (flashspun) high density polyethylene. Table 3 illustrates the basic characteristics of fibers made from different base polymers. Although

Table 3. Fibers for Spunbonded Nonwoven Fabrics

Fiber type	Breaking tenacity, N/tex[a]	Elongation, %	Specific gravity	Moisture regain,[b] %	Approximate melt point, °C
Polyester	0.17–0.84	12–150	1.38	0.4	248–260
Nylon-6,6	0.26–0.88	12–70	1.14	4.0	248–260
Polypropylene	0.22–0.48	20–100	0.91	~0.0	162–171

[a] To convert N/tex to gf/den, multiply by 11.3.
[b] At 21°C and 65% rh.

some interest has been seen in the use of linear low density polyethylene (LLDPE) as a base polymer, largely because of potential increases in the softness of the final fabric (9), economic factors continue to favor polypropylene (see PROPYLENE POLYMERS (PP)). Bicomponent technology will allow polyethylene to be used in a more economical way by directing it only to the surfaces where it brings a useful property.

Isotactic polypropylene is the most widely used polymer in spunbonded production because it is the least expensive fiber-forming polymer that provides the highest yield (fiber per weight) and covering power owing to its low density. Isotactic polypropylene is only ca 70% the density of most types of polyesters, and thus equivalent yields of fiber require a greater weight of more expensive polyester. Large advances have been made in the manufacture of polypropylene resins and additives since the first spunbonded polypropylene fabrics were commercialized in the 1960s. Unstabilized polypropylene fibers are readily degraded by ultraviolet UV light, but dramatic improvements in additives permit years of outdoor exposure to occur before fiber properties are significantly affected. Metallocene polypropylene resins are the latest major resin improvement available for spun bonding.

Polypropylene fibers are neither dyeable by conventional methods nor readily stained because dye receptor sites do not naturally exist along the molecular backbone. However, some spunbonded polypropylene fabrics are colored by the addition of a pigment to the polymer melt, wherein the pigment becomes encased within the fiber interior. Advantages to this method include higher resistance to fading and bleeding and ease of reproducibility of color shades from lot to lot. A key disadvantage is the generation of small to large quantities of off-quality production during the transitions into and out of a particular color, and coloration normally occurs only on low output lines. A delustering pigment, eg TiO_2, is often added to polypropylene as it almost always is with the manufacture of nylon fibers.

Most off-quality or scrap polypropylene fibers may be repelletized and blended in small percentages with virgin polymer to produce first-grade spunbonded fabrics. The economics are of great importance in a process where high yields are required in order to be competitive. Some manufacturing equipment directly recycles edge-trim back into an extruder, where it is blended back into the polymer melt (see OLEFIN FIBERS).

Polyester fiber has several performance advantages versus polypropylene, although it is less economical. Polyester can produce higher tensile strength and modulus fabrics that are dimensionally stable at higher temperatures than polypropylene. This is of importance in selected applications such as roofing, automotive carpet backing, and dryer sheets. Polyester fabrics are easily dyed and printed with conventional equipment which is of extreme importance in apparel and face fabrics, although of lesser importance in most spunbonded applications (see POLYESTERS, FIBERS).

Spunbonded fabrics have been made from both nylon-6 and nylon-6,6 polymers. Because nylon is more costly and highly energy-intensive, it is less economical than either polyethylene or polypropylene. Although a considerable body of knowledge exists in the preparation of nylon polymers, such as end group control, it has been of little advantage in spunbonded fabric production. Historically, nylon-6,6 spunbonded fabrics have been commercially produced at weights as low

as 10 g/m^2 with excellent cover and strength, but recently this has been achieved with polypropylene as well. Unlike the olefins and polyesters, fabrics made from nylon absorb water quite readily through hydrogen bonding between the amide group and water molecules (see POLYAMIDES, FIBERS).

Traditional melt spun methods have not utilized polyethylene as the base polymer because the resin is more expensive and the physical properties obtained have been lower compared to those obtained with polypropylene. Advances in polyethylene technology have resulted in the commercialization of new spunbonded structures having characteristics, such as softness, not attainable with polypropylene. Although fiber-grade polyethylene resin was announced in late 1986, it has seen limited acceptance because of higher costs and continuing improvements in polypropylene resin technology (see ETHYLENE POLYMERS).

Flashspun high density polyethylene fabrics have been commercial since the early 1960s; however, this is a proprietary and radically different process of manufacturing a spunbonded fabric, more technically challenging to produce, and highly capital-intensive. Today, there is only one manufacturer of flashspun fabrics, although they are produced in both Europe and the United States.

Some fabrics are composed of combinations of polymers where a lower melting polymer functions as the binder element. The binder element may be a separate fiber interspersed with higher melting fibers (10), or the two polymers may be combined in one fiber type (11). In the latter case, the so-called bicomponent fiber may have the lower melting portion as a sheath covering a core of the higher melting polymer (Fig. 1). Bicomponent fibers can also be spun, whereby the two polymers are extruded side by side. The polymer composition of the binder element in such structures may be either polyethylene, nylon-6, and polyester copolymers typically modified by lowering the terephthalic acid content by substitution with isophthalic acid. Great advances have been made in bicomponent spinning and a large variety of intrafiber structures can be easily produced from turnkey spinbeams (Fig. 2) (12). Bicomponent webs can be subjected to mechanical stresses such as water jet impact which causes the individual filament to fracture into its components yielding a new number of filaments equal to the number of components or segments created in the filament during spinning. Thus, a single filament containing 16 pie segments will fracture into 16 smaller wedge-shaped filaments.

Spunbonded fabrics with elastomeric properties are now commercial. One type of structure has been commercialized in Japan on the basis of thermoplastic polyurethanes, but the process is more similar to melt blowing than spun bonding (13). This represented the first commercial production of such fabrics, although spunbonded urethane fabrics have been previously discussed (14). A more economical approach using polypropylene has recently become commercial and is used in medical and hygienic applications (15). High costs and inferior performance versus woven fabrics continue to exclude these fabrics from the huge apparel markets. Elastomeric fabrics may also be created using the meltblown process for specialty applications.

There is an almost unlimited number of ways to characterize spunbonded fabrics. Many tests in use were originally developed for the characterization of textiles and paper products. When taken together, properties such as tensile, tear, and burst strength; toughness; elongation to break; basis weight; thickness; air porosity; dimensional stability; and resistance to heat and chemicals are often

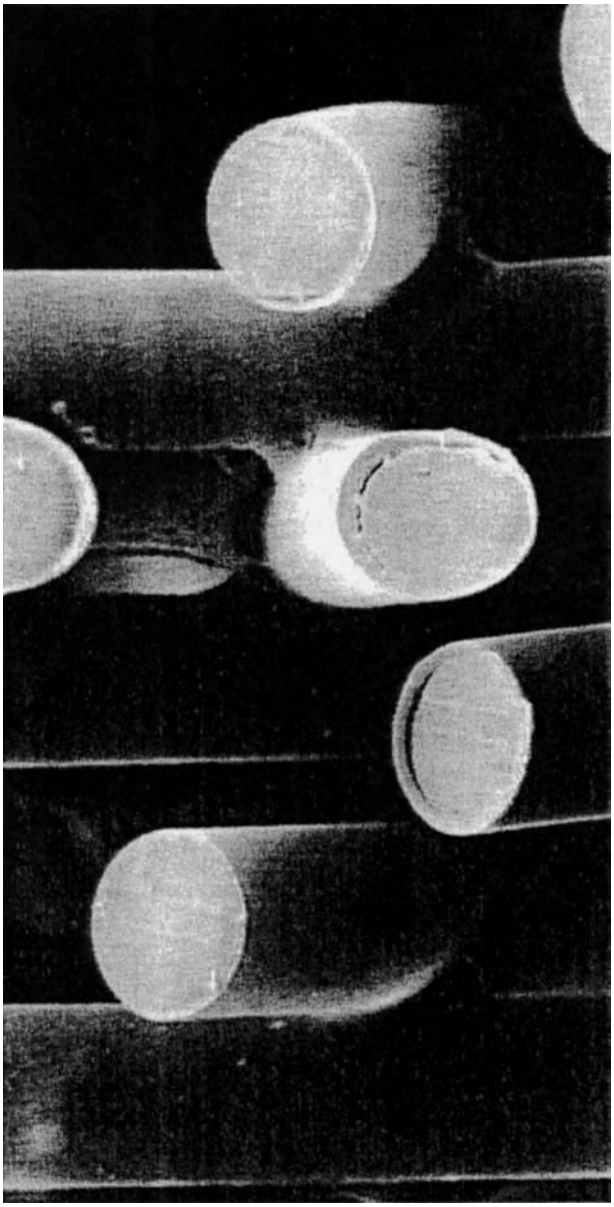

Fig. 1. Microstereo view of the cross-section of skin core filaments.

sufficient to uniquely describe one product. The reason is that these properties reflect both the fabric composition and its structure, the latter being defined by a manufacturing process unique to that fabric. Compare, eg, the differing shapes of the generic stress–strain curves of thermally bonded and needle-punch bonded fabrics (Fig. 3). The shape of each curve is largely a function of the freedom of the filaments to move when the fabric is placed under stress, and is thus a function of fabric structure.

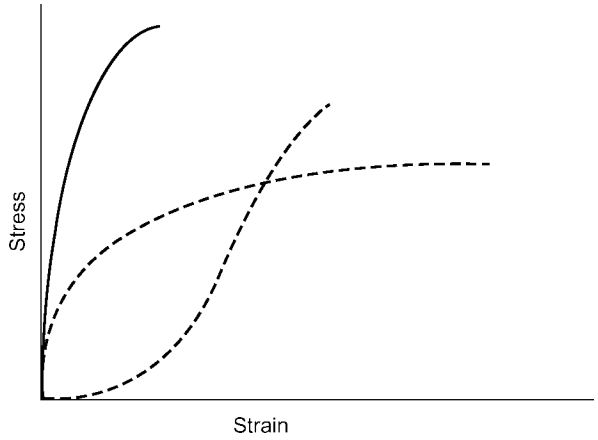

Fig. 3. Typical stress–strain curves of nonwoven fabrics, where (——) is woven; (– – –), thermally bonded nonwoven; and (- - -), needle-punched nonwoven.

Diverse applications for the fabric sometimes demand specialized tests, such as for moisture vapor, liquid transport barrier to fluids, coefficient of friction, seam strength, resistance to sunlight, oxidation and burning, and/or comparative aesthetic properties. Most properties can be determined using standardized test procedures that have been published as nonwoven standards. Test methods adopted in the USA are published by INDA, while those adopted in Europe are published by EDANA. A comparison of typical physical properties for selected spunbonded products is shown in Table (2).

Spinning and Web Formation

Spunbonded fabric production couples the fiber spinning operation with the formation and consolidation of the web in order to maximize productivity. It is the coupling of these processes that distinguishes the spunbonded process from traditional methods of fabric formation where fiber is first spun and collected, then formed into a fabric by a separate process such as weaving or carded into a web. If the bonding device is placed in line with spinning and web formation, the web is converted into bonded fabric in one step (Fig. 4). In some arrangements, the web is bonded off-line in a separate step which appears at first to be less efficient; however, this offers the advantage of being more flexible if more than one type of bonding is to be performed on the web being produced. Some specialty processes also separate the spinning and the laydown steps which adds cost but provides high control on the fiber properties and ensures few breaks in laydown.

The basic spinning process is similar to the production of continuous filament yarns and utilizes similar extruder conditions for a given polymer (16). Fibers are formed as the molten polymer exits the 500 or more tiny holes (ca 0.2 mm) of each spinnerette, where it is immediately quenched by chilled air. Since a key objective of the process is to produce a relatively wide (eg, 3–4 m) web, individual spinnerettes are placed side by side in order that sufficient fibers be generated

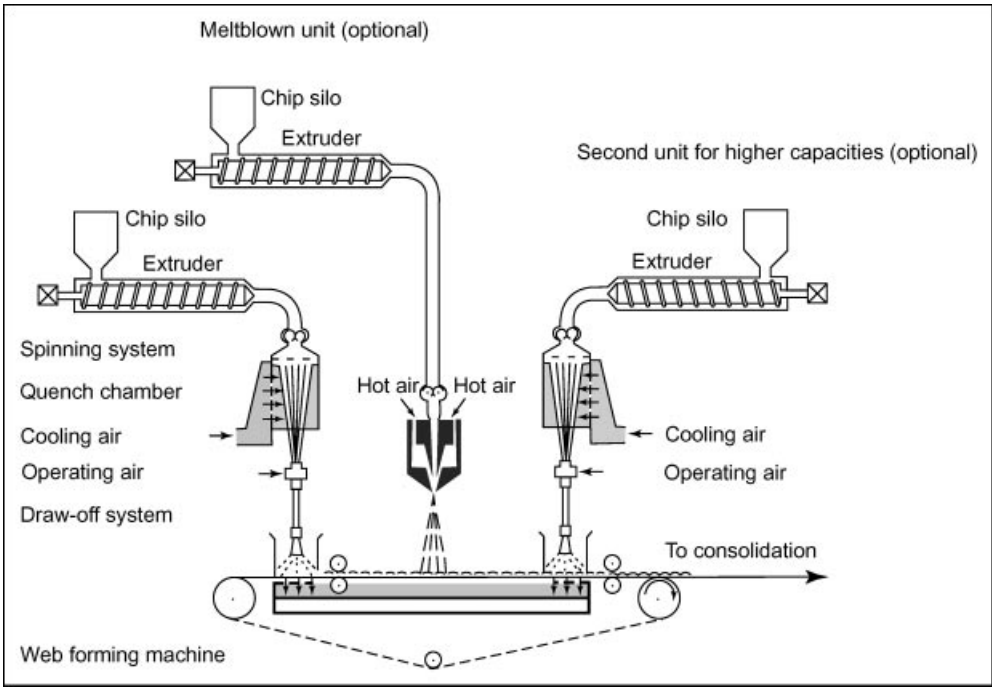

Fig. 4. Typical multibeam spunbonded process (3).

across the width. This entire grouping of spinnerettes is often called a block or bank, and in commercial production it is common for between two and four blocks, but as many as eight, to be used in tandem in order to increase the coverage and uniformity of laydown of the fibers in the web.

Most spunbond machinery producers now utilize large rectilinear spinplates in lieu of multiple small individual spinnerettes. In effect, the spinning plate is slightly wider than the desired web, and a continuous curtain of filaments is formed providing uniformity from point to point relative to multiple side by-side-spinnerettes in a block. Each spinbeam can contain up to 30,000 holes and it is common for multiple spinbeams to be used in tandem to further improve uniformity and increase throughput.

Prior to deposition on a moving belt or screen, the molten polymer threads from a spinnerette must be attenuated to orient the molecular chains of the fibers in order to increase fiber strength and decrease extendibility. This is accomplished by hauling the plastic fibers off immediately after they have exited the spinnerette. In practice, this is done by accelerating the fibers either mechanically (17) or pneumatically (17–19). In older processes, the fibers are pneumatically accelerated in multiple filament bundles; however, most new installations accelerate an entire beam or curtain of filaments (20–22).

In traditional textile spinning, some orientation of fibers is achieved by winding up the filaments at a rate of 3000–5000 m/min to produce the so-called partially oriented yarns (POYs) (23). The POYs can then be mechanically drawn in a separate step to achieve maximum strength. In spunbonded production, filament

bundles are partially oriented by being pneumatically accelerated at speeds of 6000 m/min or greater (19,24). Accelerating the filaments at such great speeds not only achieves a partial orientation but results in extremely high rates for web formation, particularly for lightweight structures (eg, 15 g/m^2). The formation of wide webs at high speeds results in a high efficiency of manufacture. Newer processes have been commercialized, that can accelerate filaments at speeds up to 8000 m/min and simultaneously create very small fiber deniers with high throughput (25).

For many applications this partial degree of orientation imparts a sufficient increase in strength and decrease in extendibility to make the final bonded fabric perfectly functional; eg, diaper coverstock. However, some applications, such as geotextiles and primary carpet backing, demand that the filaments achieve a very high tensile strength and low degree of extension. This requires subsequent additional attenuation, such as the mechanical drawing of filaments, a process usually accomplished over heated rolls with a typical draw ratio of ca 3.5:1 (17). After drawing, the filaments are pneumatically deposited onto a moving belt or screen. Because drawing rolls cannot normally dispatch filaments as fast as pneumatic jets, the web-forming process is usually less rapid, although the resulting web has greater physical strength.

The pneumatic deposition of the filament bundles onto the moving belt results in formation of the web. A pneumatic gun uses high pressure air to move the filaments through a constricted area of lower pressure but higher velocity, as in a venturi tube. Pneumatic jets used in spunbonded production have been described (17,24). Unfortunately, the excellent filament uniformity coming out of the spinnerette is lost when the filaments are consolidated going through a gun.

In order for the web to achieve maximum uniformity and cover, it is imperative that the individual filaments be separate from each other prior to reaching the belt. Failure to sufficiently separate individual filaments results in the appearance of "ropes" in the web. One method used to effect this state of separation is to induce an electrostatic charge onto the bundle while still under tension and prior to pneumatic deposition. The charge may be induced either triboelectrically or more typically by applying a high voltage charge to the filaments (26). The level of electrostatic charge on the filaments must be at least 30,000 esu/m^2 of filament surface area (16) to be effective. After deposition onto the moving belt, it is necessary to discharge the filaments; this is usually accomplished by bringing the filaments in contact with a conductive grounded surface. In some cases, the deposition belt is made of conductive wire and connected to ground. The electrostatic repulsion method has the advantage of being relatively simple and reliable. Producing webs by spinning rectilinearly arranged filaments through a so-called slot jet reduces or eliminates the need for such bundle-separating devices (20,21), because the filament bundles are not collapsed en route to the belt as they are in a pneumatic gun.

Other routes to reachieving filament separation have been described and rely on mechanical or aerodynamic forces to affect separation. Figure 5 illustrates one method that utilizes a rotating deflector plane to force the filaments apart while depositing the opened filaments in overlapping loops (27). After the splayed filaments fall to the deposition surface or forming screen, a suction from below the disposition surface holds the fiber mass in place.

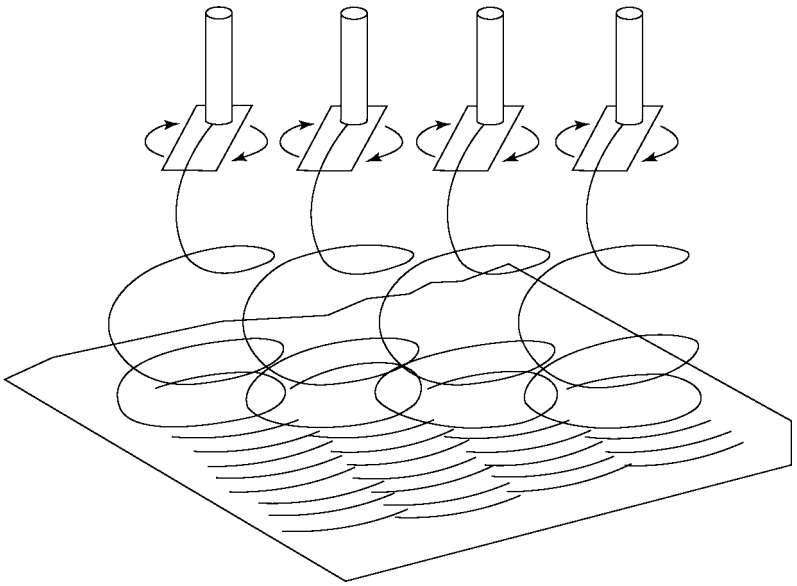

Fig. 5. Deflector plane for separation of filaments.

For many applications, it is acceptable or desirable to lay down the filaments in a random fashion without orienting the filament bundles with respect to the direction of the laydown belt (24). However, it is sometimes desirable to control the directionality of the splayed filaments on the laydown belt in order to achieve a particular characteristic in the final fabric. Directionality can be controlled by traversing the filament bundles either mechanically (19,27) or aerodynamically (17,28) as they travel downward toward the collecting belt. The aerodynamic method consists of supplying alternating pulses of air on either side of the filaments as they emerge from the pneumatic jet. By properly arranging the spinnerette blocks and the directing jets, laydown can be achieved predominately in the desired direction. Figure 6 illustrates the production of a web with predominately machine and cross-machine direction filament laydown (17). It is possible to generate highly ordered laydown patterns by oscillating filament bundles between closely spaced plates to achieve a high degree of parallelism.

If the laydown belt is moving and filaments are rapidly traversed across this direction of motion, the filaments are deposited in a zigzag or sine wave pattern on the surface of the moving belt. The effect of the traverse motion on the coverage and uniformity of the web have been described mathematically (29). The relationships between the collecting belt speed, period of traverse, and the width of filament curtain being traversed determine the appearance of the formed web upon the laydown belt. Figure 7 illustrates the laydown for a process where the collecting belt travels a distance equal to the width of the filament curtain, x, during one complete period of traverse across a belt width y. If the belt speed is v_b and the traverse speed is v_t, the number of layers deposited, z, is calculated by the formula, $z = (x \cdot v_t)(y \cdot v_b)$. It can be seen that if the traverse speed is twice the belt speed and if x and y are equal, then a double coverage will occur over all areas of the belt.

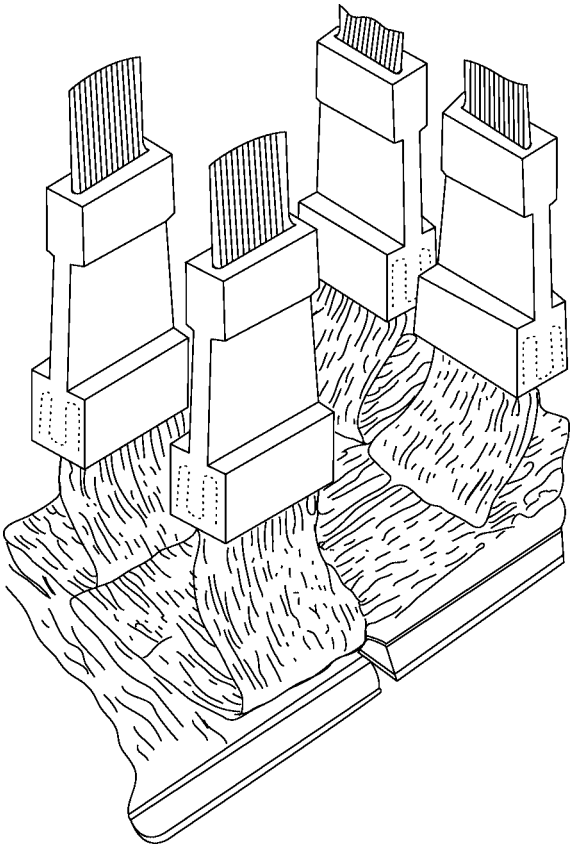

Fig. 6. Web production with predominantly machine and cross-machine direction.

The alternative to the use of multiple spinnerettes per bank, and now the most widely utilized process, is the so-called curtain spin process, which utilizes a single plate of the width of the desired web which has been drilled with holes for fiber formation. The advantage to this approach is that it results in a uniform distribution of filaments within the curtain of continuous fibers produced from the

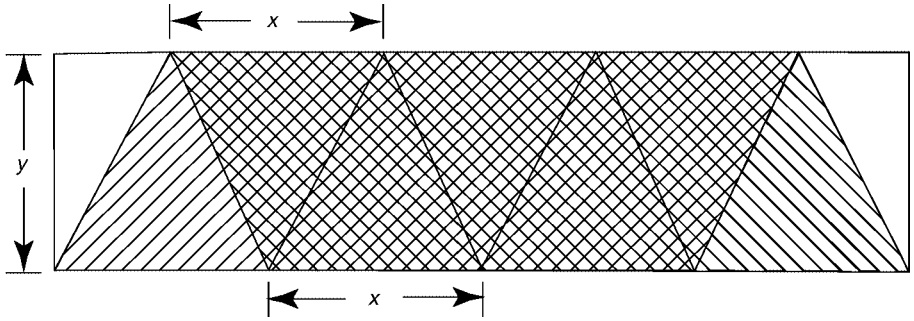

Fig. 7. Laydown pattern diagram.

spinning plate. The use of the single uniform distribution of filaments within the curtain of continuous fibers is produced from the spinning plate. The use of the single spinning plate automatically places the fibers in a uniformly distributed array and thereby presents a curtain of high uniformity filaments to the fiber attenuation mechanism. Care must be taken to keep individual filaments from sticking while they are still plastic, which is normally in the quench or cooling area between the spin plate and the laydown jet.

By comparison, the multiple spinnerette per bank process requires additional effort prior to laydown in order to compensate for the gaps between the individual spinnerettes. Failure to present a uniformly distributed filament array to the laydown screen will result in spot-to-spot variations in fiber density and a web that has the appearance of blotch.

In general, once the curtain of filaments has been produced, it is necessary to attenuate the filaments in order to provide strength and resistance to deformation. The most commonly practiced approach is to utilize a single slot, which is at least the width of the curtain, at a point below the spinning plate and above the laydown screen. There are three practical approaches taken. The first utilizes the injection of low pressure air at a point above the slot so that the fibers attain sufficient acceleration in the slot to provide adequate draw (21) (Fig. 8). The second utilizes a low pressure vacuum below a venturi to provide the pressure differential required for sufficient acceleration and resulting attenuation (30). The third utilizes an acceleration slot immediately below the spin plate with little or no quench or cooling of the filaments (25).

One of the limitations of the curtain–slot draw process has been that the amount of fiber attenuation is constrained because of the short distance generally allowed between the spinnerette and the venturi slot, and the use of relatively low pressure air for drawing so as not to induce high turbulence in the area of the laydown. In order to adapt this concept for the production of polyester fabrics that inherently require much higher fiber acceleration to attain the desired polyester fiber properties, a new process has been commercialized (25).

Bonding

Many methods can be used to bind the fibers in the spun web. Although most procedures were originally developed for use with nonwoven staple fibers, three were adapted for use with continuous filaments: mechanical needling, thermal, and chemical/binder. Thermal and chemical–binder methods may bond the web by fusion or adhesion of fibers using either large or small regions, generally referred to as area bonding and point bonding, respectively. Point bonding results in the fusion of fibers at discrete points with fibers remaining relatively free in between the point bonds. Other methods that are used with staple fiber webs, but which are not routinely used with continuous filament webs, are stitchbonding (29,31), ultrasonic fusing (8,32), and hydraulic entanglement (33). Hydraulic entanglement is currently being developed as a high speed bonding process for spunlaid webs as a way to achieve superior softness. It has the potential to produce the most radically different continuous filament structures; however, it has the disadvantage of being a more costly and complex bonding process.

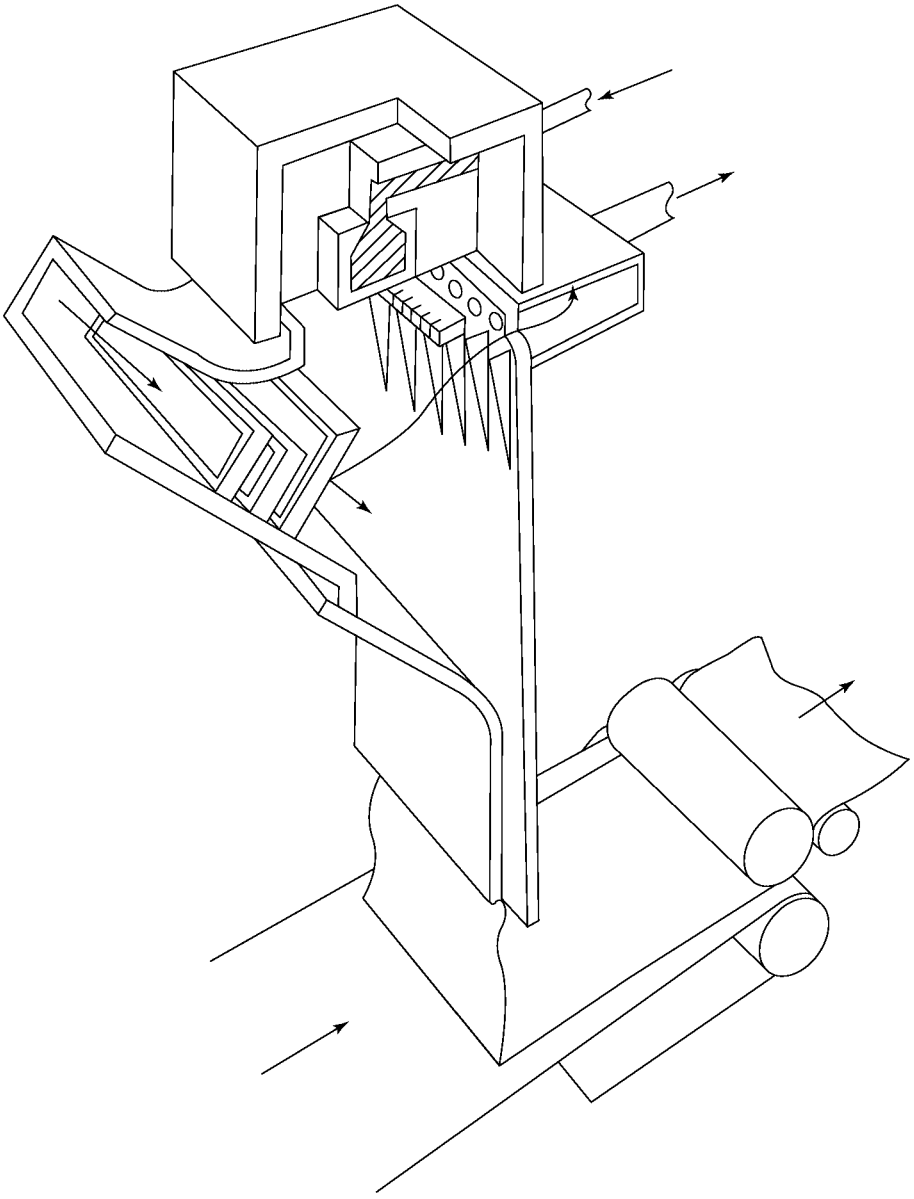

Fig. 8. Curtain spinning process (22).

Of the three standard bonding methods used in spunbonded manufacturing, mechanical needling, also called needle punching or needle bonding, is the simplest and least expensive. Although it is the oldest process, it continues to be widely used. Significant improvements in throughput and flexibility have resulted in the sales growth of needle-bonded fabrics, particularly for geotextiles (qv) and roofing. An excellent review of mechanical needling technology has been published (29).

In the needle-punching process, a continuous filament web is subjected to barbed needles which are rapidly passed through the plane of the moving spun web (see NONWOVEN FABRICS, STAPLE FIBERS). The needles pass in and out of the web at frequencies exceeding 3,000 strokes/min that can result in as many as 500 penetrations/cm^2 depending on the needle density and the line speed, which can be as high as 150 m/min (34). The effect of this operation is to interlace the fibers and thus bond the structure together, relying only on the mechanical entanglement and fiber-to-fiber friction. The fabric produced tends to be more conformable and bulky than fabrics bonded by thermal or chemical/binder methods. Because the fibers have freedom to move over each other, the fabric is easily deformed and exhibits a low initial modulus (Fig. 2).

The principal variables in needle-punching are the needle design, punch density, and depth of punch. Considerable research has been conducted on the shape and design of the needles and how this affects the interlacing of the fibers (29). Needling produces a fabric that is 100% fiber with no points or areas of fusion or melting, thus it is easily adapted to most fiber webs and requires less precise control than thermal bonding. In addition it is the only bonding method suitable for the production of spunbonded fabrics of very high basis weights, eg, 800 g/m^2. It is, however, only suitable for the production of uniform fabrics greater than ca 80 g/m^2 because needling tends to concentrate fibers in areas resulting in loss of visual uniformity at lower weights.

Unlike mechanical needling, both thermal and chemical/binder bonding depend on fiber-to-fiber attachment as the means of establishing fabric integrity. It is the degree and extent of attachment that determines many of the fabric qualities, most notably the hand or softness. Because point bonding can be accomplished using as little as 10% bonding area, (ie, 90% unbonded area), such fabrics are considerably softer than area-bonded structures. Fiber mobility is retained, in part or in total, outside the areas of the point bonds. Thermal bonding is far more common than chemical–binder bonding and is generally more economical because the latter method adds the cost of resin and still requires a thermal curing treatment as the final step. Both area and point thermal bonding are rapid processes having line speeds in excess of 300 m/min and up to 800 m/min during production of lightweight fabrics.

Area thermal bonding can be accomplished by passing the spun web through a source of heat, usually steam or hot air. Prior to entering the bonding area, the spun web may be consolidated by passing it under compressional restraint through a heated prebonding area which adds integrity to the web (10). While in the bonder, the consolidated web is exposed to hot air or pressurized steam that causes fusion to occur between some, but not all, of the fiber crossover points. Complete fusion leads to a paper-like structure with low resistance to tearing. The spun web may contain small percentages, typically 5–30%, of a lower melting fiber (10), or the filaments may contain undrawn segments that are lower melting than the drawn or matrix segment (28). Heterofilament structures utilize a lower melting covering (sheath) on the outside of the filaments to effect fusion. Both polyethylene and nylon-6 have been used as the lower melting sheath in commercial spunbonded products.

The use of steam is generally limited to polypropylene and polyethylene fusion because impractical pressures are required to reach the temperature levels

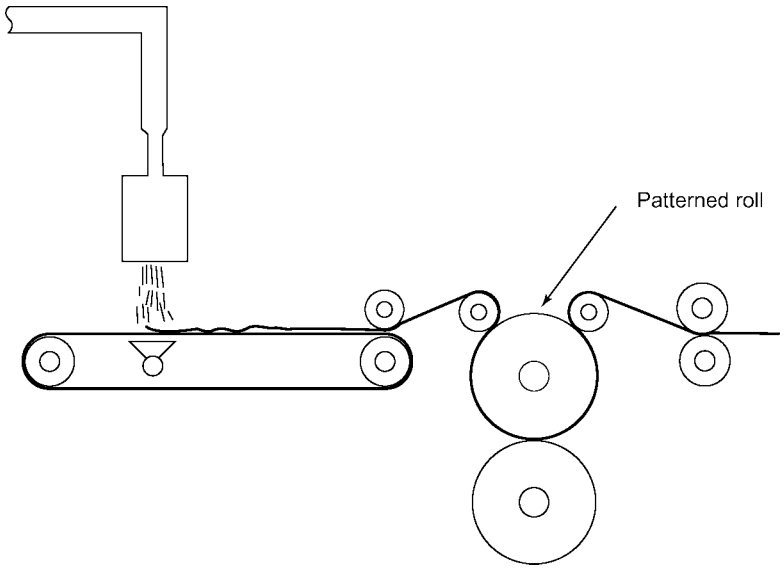

Fig. 9. Pattern bonding roll at the end of a spun bonding line.

(eg, >200°C) required for bonding polyesters. In general, greater temperature control is required for area bonding polypropylene than for other polymers because the temperature difference between the matrix and binder fibers can be only 3°C (28).

Whereas thermal area bonding uses temperature as the variable to a great degree and relies on sophisticated web structures containing binder fibers, thermal point bonding utilizes both temperature and pressure to affect fiber-to-fiber fusion. Thus it is a simpler approach to bonding because it does not require the web to contain lower melting fibers or segments and is less demanding of the technology required to produce the web. Point bonding is usually accomplished by passing a web, previously consolidated or compacted with either heated or unheated press rolls, through heated nip rolls, one of which contains a raised pattern on its surface (Fig. 9). When bonding, polypropylene roll temperatures generally do not exceed 170°C; however, pressures on the raised points are quite high, preferably 138–310 MPa (20,000–45,000 psi) (35). The degree of bonding between the points can be controlled by varying the ratio of heights of the raised points to the depth of the web (36). Typically only 10–25% of the surface available for bonding is converted to fused, compacted areas of bonding.

Optimum conditions of pressure and temperature are dependent on many variables including, but not limited to, the nature of the web, line speed, and engraved pattern. Optimized conditions are best obtained through detailed investigations and much experience. Even subtle changes in any of these variables can result in significant changes in the properties of the finished fabric (7,8). New designs for bonding calenders continue to refine the process (37).

Because engraved point bonding rolls can be as wide as 5 m, the problem of maintaining uniform pressure across the width must be addressed. Small differences in pressure across the width can produce an unacceptably variable product.

Hydraulic pressure is applied at the ends to the roll causing a slight deflection that results in less pressure being applied in the center compared to the ends. A number of solutions to this problem have been devised (37), including cambering wherein the roll diameter decreases slightly from the center to the ends and mechanical means such as pressurizing the external shell of one of the two nip rollers.

Chemical–binder bonding is used less frequently than thermal bonding in the production of spunbonded fabrics, and in a shift over the past decade the same is also true for staple fiber nonwovens. Resin binders are occasionally used with spunbonded webs to achieve special characteristics that are unattainable thermally (38). In a typical case, acrylic resin(s) are applied to saturate the web, excess resin is removed by nip rolls, and the wet web is passed through a drying oven to remove excess water and cure the resin which tends to concentrate at fiber–fiber junctions. By curing the resin, a thermoset binder conveys high thermal dimensional stability to the web for applications such as roofing.

Resin binders may alternatively be applied in discreet points in a pattern so as to immobilize fewer fibers and produce a softer fabric; however, it is difficult to accurately control the diffusion of the resin, and the drying step requirements make it less attractive than thermal bonding.

Chemical bonding with hydrogen chloride gas has been used with spun webs of nylon-6,6 to commercially produce spunbonded nylon fabrics (39). In this bonding process, the activating hydrogen chloride gas is passed over web fibers held in close contact by tension. The hydrogen chloride disrupts hydrogen bonds between the polymer chains and forms a complex with the amide group. When the gas is desorbed the process reverses, this time with new hydrogen bonds formed between polymer chains in different fibers. This basic method has been further refined to permit only the formation of pattern bonds, whereby fiber mobility is retained between the bonded areas yielding a softer hand to the bonded fabric (40).

Bonding a web by any means allows for certain generalizations. If the web is highly bonded, most of the fibers are bonded to another fiber. The resulting structure is relatively stiff, paper-like, and has higher tensile and modulus but lower resistance to tear propagation. On the other hand, if the web is only slightly bonded fewer fiber-to-fiber bonds are present and the structure is more conformable with lower tensile and modulus but higher resistance to tear propagation due to bunching of filaments. Additionally, webs that are only slightly bonded exhibit low surface abrasion resistance. In comparing area to point bonding, greater varieties of structures are achievable through point bonding because of the various bonding roll patterns available. The expense associated with the manufacture of the pattern roll generally dictates the careful selection of the pattern, however.

Meltblown Fabrics

Meltblown fabrics differ from the traditional spunbonded fabrics by having lower fiber denier (fineness) and by usually being composed of discontinuous filaments. Although meltblown fabrics are not generally referred to as spunbonded, the integration of spinning, attenuation (although slight), laydown, and bonding during the production of meltblown webs describes a process traditionally defined as spun

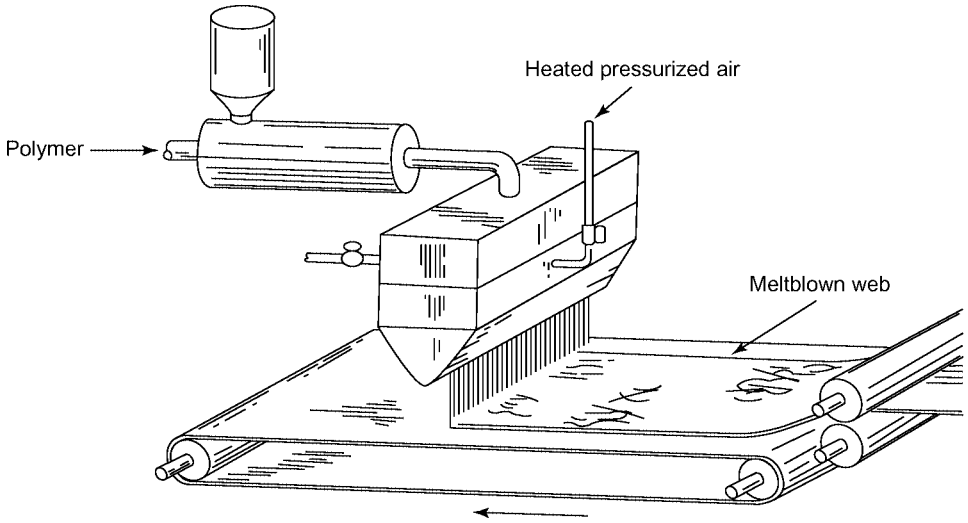

Fig. 10. Schematic of the meltdown process.

bonding. The inherent fiber entanglement often makes additional bonding unnecessary, however. Fibers produced by melt blowing are very fine, having typical diameters of 3 μm (41,42), smaller by nearly an order of magnitude than traditional spunbonded fibers. The fibers are extremely fine and largely unoriented, causing the webs to be quite weak and easily distorted. Most thermoplastic polymers have been meltblown, but the majority of commercial products are produced from high melt flow grade polypropylene.

In the manufacture of meltblown fabrics, a special die is used in which heated, pressurized air attenuates the molten polymer filament as it exits the orifice of the dye or nozzle (Fig. 10). Air temperatures range from 260 to 480°C with sonic velocity flow rates (43).

The rapidly moving hot air greatly attenuates the fibers as they exit from the orifices to create their small diameters. The fibers are relatively weak and deposited on the forming screen as a random entangled web that may be thermally point bonded to improve strength and appearance. The web may also be deposited onto a conventional spun web, then thermally bonded. Sandwich structures, called SMS, are routinely created with the meltblown web in the middle between two conventional spunbonded webs (44). Other materials, eg, cellulosics, have been blended into the meltblown filament stream to yield a meltblown structure with a unique combination of properties (45). Mixtures of meltblown and crimped bulking fibers have been sold as thin thermal insulation for use in outdoor clothing and gear (46). Meltblown technology has also been adapted to produce nontraditional spunbonded fabrics, such as elastomeric webs (47).

The great quantity of very fine fibers in a meltblown web creates several unique properties such as large surface areas and small (<1 μm) pore sizes. These have been used in creating new structures for hospital gowns, sterile wrap, incontinence devices, oil spill absorbers, battery separators, and special requirement filters. During the last decade, meltblown technology has experienced large growth mainly in the form of SMS or SMMS sandwich structures in hygiene (6).

Flashspun Fabrics

The process of producing spunbonded webs by flash spinning is a radical departure from the conventional melt spinning approach. In melt spinning, a molten polymer is typically extruded through a spin plate containing ~20,000 tiny holes. This produces a fiber curtain containing ~20,000 fibers, each typically 15–50 μm in diameter. The fibers are kept separate from each other until the bonding operation connects some or all of them.

By contrast, flash spinning begins with a 10–15% polymer solution prepared by dissolving a solid polymer, such as high density polyethylene, with a suitable solvent, such as pentane, trichlorofluoromethane, or methylene chloride (48). The solution is heated to approximately 200°C, pressurized to ~4.5 MPa (653 psi), and the pressurized vessel is connected to a spinnerette containing a single hole. When the pressurized solution is permitted to expand rapidly through the hole, the low boiling solvent is instantaneously flashed off leaving behind a three-dimensional film–fibril network referred to as a plexifilament. The three-dimensionality results from the cross-linking interconnection of the fine fibers which produces a film thickness of 4 μm or less (48). Thus many individual but interconnected fibers are created from a single-hole spinnerette.

It is believed that bubbles form rapidly as the pressurized solution undergoes depressurization during spinning and the bubbles may grow and rupture, thus forming the plexifilamental network (48). Gases that are effectively insoluble in the solvent may be added to the pressurized solution in order to facilitate high rates of bubble nucleation.

When a multiplicity of single-hole spinnerettes are assembled across a width, the plexifilaments produced can form a wide web that can be thermally bonded to produce a flat sheet structure (49). The web-forming procedure is ameliorated by use of a baffle that deflects the stream of plexifilaments after exiting the spinnerette.

Unlike fine fibers prepared by melt blowing, the plexifilaments from flash spinning are substantially oriented and possess relatively high tenacities [0.08 N/tex ($>$1g $\cdot$ f/den)]. The plexifilaments scatter light effectively as a result of high surface areas (ca 2 m^2/g) and thus form opaque webs. In addition, the fineness of the plexifilament fibrils also results in a web structure of exceptional softness. Webs are either area or point bonded to yield paper- or cloth-like aesthetics, respectively. The paper-like sheets are used as durable papers and may be printed using conventional inks (qv) and printing equipment, whereas the point-bonded structures are very soft and find use in disposable protective clothing.

Flash spinning is the most complex and sophisticated method for manufacturing spunbonded fabrics. A single production line can require an investment of nearly $200 million, and serious safety issues must be addressed in the plant's design and operation. Although the process has been in use since 1962, the need to spin heated and pressurized solutions under precise conditions has resulted in only one company (DuPont) practicing the technology as a route to these unique spunbonded products. A second producer (Asahi) stopped producing in Japan some years ago after forming a marketing joint venture with Du Pont. Hydrocarbon solvents are now being used for the process since chlorofluorocarbons, the traditional solvents, are restricted because of environmental regulations (50).

The physical properties of flashspun fabrics are unique and not attainable via the melt-spun spunbond process. Even bicomponent melt spinning cannot produce similar structures. As a result the profitability of a flashspun operation is very high when the capacity of a line is fully utilized.

Test Methods

Spunbonded fabrics are characterized by standardized test procedures originally developed for textile fabrics and paper products. The Association of the Nonwoven Fabrics Industry (INDA) has published a list of test procedures (Table 4) (51) which are routinely used in determining specific physical characteristics of spunbonded and other nonwoven fabrics. Analogous test methods are published in Europe by EDANA, the European Association of Nonwoven Fabrics. INDA and EDANA are working together to develop and publish harmonized international test procedures. Many tests are established for the evaluation of nonstrength-related properties such as washability, stiffness, and softness. Great strides have been made in the test methodology used to evaluate the hand of materials for textile applications such as clothing. A methodology and equipment, permitting quantitative evaluation of fabric hand, have been developed (52).

As applications are developed, the need for new end use specific test methods grows. Geotextile uses are a good example of how a large new application requires the design of new test methods (54). In addition to break, stretch, tear, and burst resistances described in Table 4, geotextile fabrics are tested for puncture, maximum opening size, permittivity, and asphalt retention, according to IST 180.1–9. The puncture test notes the resistance to being punctured by a probe with either a flat or spherical tip. Maximum opening measures the largest size glass beads that can pass through a fabric, thereby reflecting the size of soil particles that can be stopped by a geotextile. Permittivity is how fast water, at a given pressure, passes through a geotextile. Asphalt retention is judged by how much asphalt cement is left in a geotextile after it is dipped in the cement and allowed to drain, and what change in area the geotextile undergoes.

Long-term applications also demand test methodology on the aging characteristics of spunbonded fabrics. Roofing applications, for example, require that the saturated fabrics retain their strength for many years despite a hostile environment. By heating the fabric at several different temperatures higher than the expected nominal conditions, and measuring the time it takes to observe a significant property change, for instance loss of 50% tensile strength, effects can be plotted to permit some extrapolation back to expected nominal conditions (55). The importance of aging tests will increase as more long-term applications are developed for synthetic fabrics. The Swedish Building Institute has developed heat aging tests and standards for films and fabrics used in building construction. Canada has established a number of longevity and performance test procedures for construction fabrics, such as housewrap.

In medical applications, many test procedures have been developed for screening the efficiency of fabrics to block the passage of viruses, blood-borne pathogens, etc. Spunbonded SMS sandwich fabrics are widely used as protective

Table 4. INDA Test Methods[a]

Property	Description	IST number
Absorbency	Amtount of liquid absorbed and speed of absorption	10.1–3
Abrasion	Resistance of nonwovens to being worn away	20.1–5
Bursting strength	Force to rupture nonwoven under water pressure	30.1
Electrostatic properties	Amt of charge that can build up on a sample	40.1–2
Optical properties	Opacity: resistance to light being passed brightness: whiteness	60.1–2
Permeability	Ease of air or water vapor passage under pressure	70.1–2
Repellency	Resistance of nonwovens to wetting and penetration after exposure to water, salt solutions, alcohol, and hydrocarbon solvents and oils	80.1–9
Bacterial	Resistance of a nonwoven to penetratration by bacteria in a salt solution under water pressure	
Stiffness		
Cantilever	Tendency for a nonlimp nonwoven to droop as it is pushed over the edge of a surface	90.1
Curly	Ability of a heavy, stiff nonwoven to push a pendulum aside as it is moved past it	90.2
Handle-O-Meter	ability of a soft, lightweight nonwoven to flex and not drag as it is pushed through an opening	90.3
Tear	Resistance of a nonwoven to continue to tear after being cut and pulled from both sides	100.1–3
Breaking load and elongation	Force to break a nonwoven when it is pulled from both ends; extent of stretching before breaking	110.1–4
Seam breaking	Force needed to break a seam holding two pieces of nonwoven together when the sample is pulled from both ends	
Bond strength of laminates	Force to separate a nonwoven from another material after they have been laminated together	
Internal bond strength	Force to pull a nonwoven fabric into two plies	
Thickness	How thick a nonwoven is when it is held between a weight and a surface	120.1–2
Coefficient of friction	Drag when a nonwoven is slid over itself or over a polished surface	140.1
Dry cleaning and laundering	Shrinkage, loss of strength, ability to be peeled apart experienced by a single fabric or laminate	150.1
Linting	Extent of particles loosened from nonwoven as it is bent and flexed in air stream	160.1
Extraction	Amt of material leached out of nonwoven after exposure to hot solvents	190.1

[a] Ref. 53.

gowns in hospital operating rooms because of their combination of barrier and comfort.

Overall, the test methods published by INDA (Table (4)) continue to be the general tests used to characterize fabrics; however, specific market applications often generate special test procedures to fulfill unique needs.

Applications for Spunbonded Fabrics

Uses for spunbonded fabrics have traditionally been segmented into durable and disposable categories. In the early 1970s, consumption of spunbondeds was predominately for durable uses such as carpet backing, furniture, bedding, and geotextiles. By 1980, however, disposable applications accounted for an increasingly large percentage because of the acceptance of lightweight (eg, 17 g/m^2) spunbonded polypropylene fabrics as a coverstock for diapers and incontinence devices (6). In the 1990s, the use of new diaper and training pants designs have increased the demand for lightweight fabrics far beyond earlier predictions.

Both the durable and disposable markets for spunbondeds have experienced dramatic growth (~6% per year). Disposable applications utilize the vast majority of the yardage produced although only ~50% on a tonnage basis (56). Significant areas of durable growth have been in the building and construction industries where spunbondeds are used in geotextiles, roofing membranes, and Housewrap. Growth has also been achieved in primary carpet backing in automotive carpets and carpet tiles, where moldability and high dimensional stability, respectively, were achieved through the use of polyester spunbonds.

With the possible exception of Housewrap, however, there have been virtually no new markets established as a result of the special characteristics of spunbonded fabrics. Growth has come about in an evolutionary fashion where spunbonded fabrics were substituted for woven fabrics, other nonwoven fabrics (including knits), paper or film in previously existing applications, or where the cost–property relationship has permitted an extension of an existing application, such as the redesign of diapers. The principal contributions that spunbondeds have made in these markets generally have been attractive economics, or improved processibility and performance in the final product. This combination has greatly accelerated the use of the products within an application and consequently contributed to the growth of specific markets. General market opportunities for nonwovens have been reviewed (6,7,56).

Of the four basic polymer types available in spunbonded form (ie, polypropylene, polyethylene, polyester, and nylon), both polyester and nylon are more costly polymer forms than either of the olefins. It is possible for this cost advantage to be offset by other factors, such as production of the fabric in lighter unit weight, but in general olefin-based products have an economic advantage for an equivalent weight fabric. In addition, the lower density of olefinic polymers provides a greater "yield" of more fibers per unit area, which provides better cover and performance. In some applications, however, this advantage is moot if the olefin-based product cannot perform properly. An example of this is in roofing membranes where a key requirement is dimensional stability to hot bitumen at temperatures approaching 200°C, which is above the melting point of both polypropylene and polyethylene

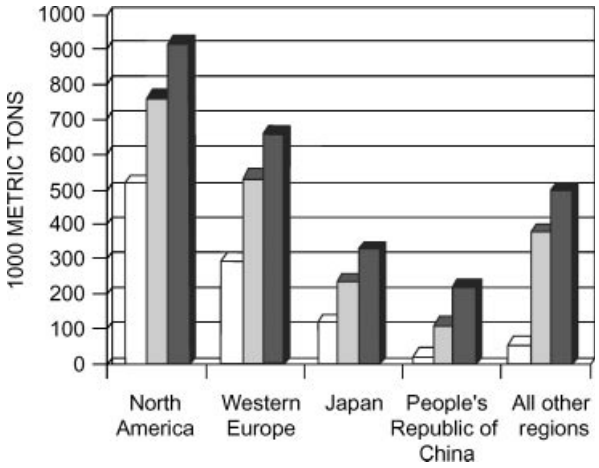

Fig. 11. Global demand forcost for nonwoven fabrics. □ 1988; ■ 1996; ■ 2001 (57).

but well within the performance limits of polyester. To a great extent this one property, ie, higher temperature resistance, largely differentiates the opportunities for polyester spunbondeds versus olefinic counterparts. Although polyester fibers exhibit higher modulus and more flexible dyeing, these properties seem to be of little advantage in the markets for spunbonded fabrics.

Spunbonded Markets: Durable Applications. A summary of late 1990s markets for nonwoven fabrics in the United States and western Europe is shown in Figures 11, 12, and 13. Approximately 37% of total global nonwoven production for 2001 was estimated as being spunbonded (1). In North America this represents 550,000 t of spunbonded production with volume growth of 8.5% per year for the period 1996–2001 (1). The principal durable applications center around construction and automotive applications although there are other smaller areas.

One of the first durable applications was the use of spunbonded polypropylene in primary carpet backing. First introduced in the mid-1960s as a replacement for woven jute, it is still used in specialty carpets and holds a unique position in applications that require isotropic planar properties for dimensional stability such as printed or patterned carpets. The finer fiber versus woven ribbons or jute also allows tufting needles to penetrate with little deflection where fine-gauge tufting is desired. Finally, because the spunbonded backing is bonded at many fiber junctions, it offers the advantage of maintaining clean edges after cutting or trimming, making it attractive for use in small rugs where the unraveling feature of woven ribbon backings can be a concern. Although the first spunbonded primary carpet backing was made from polypropylene, other spunbonded products based on polyester and polyester–nylon were later commercialized as tuftable carpet backing products, mainly for automotive uses.

An extremely successful application for spunbonded fabrics is in the area of furniture, bedding, and home furnishings. In furniture construction the use of lower cost spunbonded fabrics has become routine, whereas in the 1970s woven sheeting dominated the market. Spunbondeds are used in hidden areas requiring

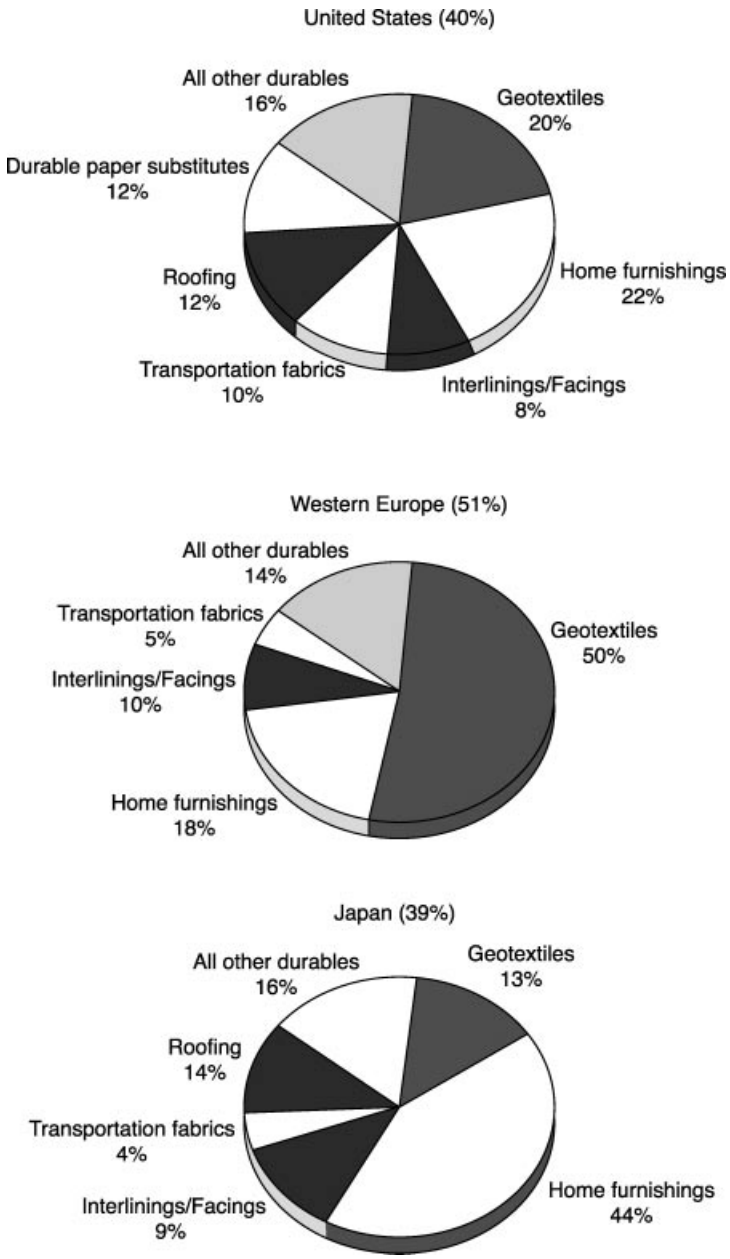

Fig. 12. Durable nonwovens market demand by applications and region (58).

high strength and support in chairs, sofas, and other seating. The bottoms of chairs are often covered with dust covers made of spunbonded fabrics because of the nonfraying characteristics, high porosity, excellent cover, and low cost. An inherent resistance to rot and mildew versus natural fabrics also adds to the popularity of spunbonded fabrics in home uses.

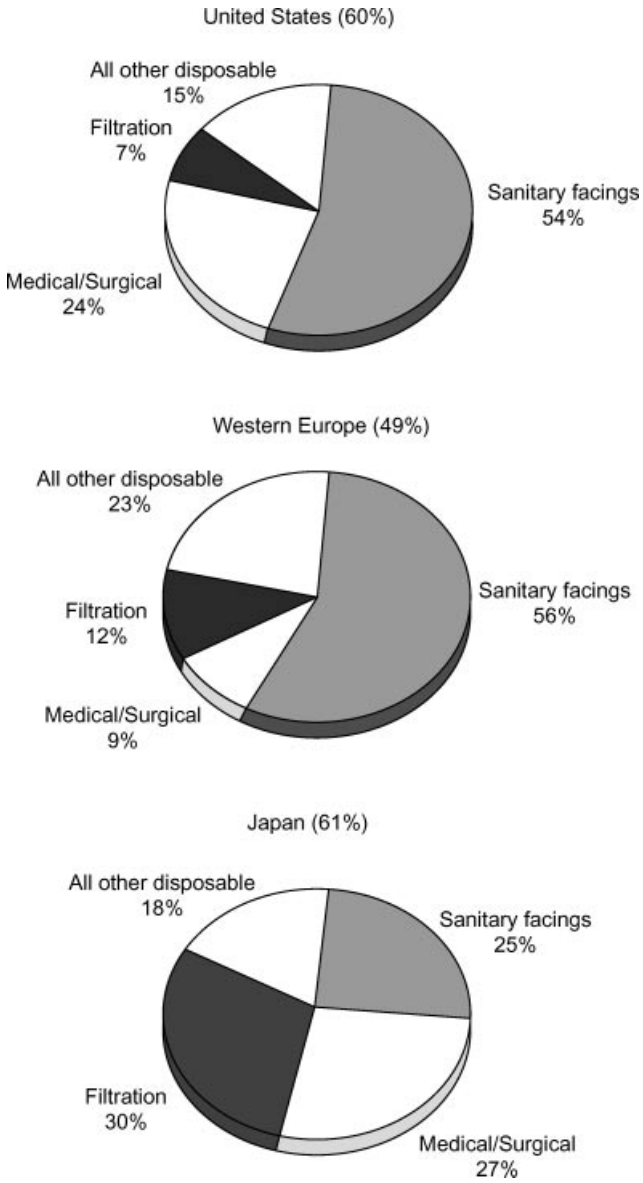

Fig. 13. Disposable nonwovens market demand by applications and region (59).

In bedding, spunbondeds are used as spring insulators, spring wrapping in mattress construction, dust covers under box springs, and facing cloth for quilting. Home furnishing uses include mattress pad covers where the spunbonded fabric serves as the top and bottom of a sandwich structure with a middle layer of fiberfill and fastened by ultrasonic quilting. Draperies also have used spunbonded fabrics wherein the lightweight fabric serves as a stitching medium for use with stitch-bonding equipment. Spunbonded fabrics are also used in blinds, both vertical and

horizontal, wherein the fabric, which must be extremely uniform, may be saturated with colored resins to form opaque and optionally pleatable blinds.

A high growth application for spunbonded fabrics is the air infiltration barrier whereby the penultimate vertical surfaces of old or newly constructed houses are covered with a layer of spunbonded fabric followed by the application of the ultimate external sheathing such as siding or masonry. The objective is to construct a barrier to the infiltration of air into the wall cavity and to the insides of homes, thus lowering the cost of heating and cooling. Tests conducted by the National Bureau of Standards and the National Association of Homebuilders confirmed the effectiveness of the air infiltration barrier concept as a means of lowering the cost of heating a home (60). Certain spunbonded fabrics are well suited for this application because they possess a unique combination of properties required for functionality. These include resistance to the penetration of liquid water and low porosity to air currents, but with a simultaneously high transport of moisture vapor. In a winter climate, warm moist air from inside the house can penetrate through the wall cavity and to the outside. If the air barrier material is not sufficiently permeable to moisture vapor, condensation can occur inside the wall cavity where damage from moisture can occur. In addition, the effective R-value of the insulation (eg, fiber glass) inside the wall cavity is diminished by the presence of liquid and solid water. Trapped moisture in wall cavities provides an opportunity for the growth of molds, a growing concern in warm moist climates. The combination of water and air current resistance combined with breathability to moisture vapor and high tensile and tear strength is a difficult combination of properties to assemble. Spunbonded technology can provide these characteristics in economical form.

Uses for nonwovens in automobiles have grown from a rather modest beginning in the 1970s to a position of significance (58). Although needle-punched nonwoven fabrics have been used in large-area applications, such as backing for vinyl seats and landau tops, spunbonded fabrics have, historically, been utilized in lower volume applications such as labels for seat belts, spring insulators, listings in seats, and as coated fabrics for ducting. Spunbonded polyester has become accepted as a tuftable backing in molded carpets where the use of spunbonded backing allows for greater molding precision, improved dimensional stability, and resistance to puncture. Newer applications include headliners, which are often complex composites that can be molded into sophisticated shapes. Lightweight spunbonds are used as sound insulators in between dashboard components, and as the base fabric in interior door panels and sun visors.

Material acceptance in roofing applications has changed significantly since the mid-1970s, particularly for spunbonded fabrics. The market opportunity is extremely large and is thought to exceed 1.86×10^8 m^2 for commercial buildings (flat roofing) in the United States alone. Much of the development for roofing applications was done in Europe and slowly became accepted in the United States. Although fiber glass fabrics have been the largest volume nonwoven consumed in roofing, spunbonded polyester and polypropylene have made considerable penetration (61). A significant difference between glass and polyester is the ability of polyester to flex and stretch without damage to the filaments. Because rooftops are known to expand and contract with seasonal changes, fabrics of polyester are less susceptible to damage from sudden temperature fluctuations which induce rapid dimensional changes.

Spunbonded polyester is basically a carrier for bituminous waterproofing membrane. Here spunbonded fabric is saturated with bitumen and serves to provide integrity and dimensional stability to the bitumen. As bitumen coatings modified with elastomeric polymers, such as atatic polypropylene (APP) or sequenced butadiene–styrene (SBS), became accepted as improvements over unmodified bitumen, changes occurred in the installation and manufacture of membranes. Historically, built-up roofs were made *in situ* by mopping hot bitumen into organic felts that had been placed on the roof decking. In the 1990s, the roof membrane was manufactured under tightly controlled conditions in a factory distant from the site of application. The spunbonded fabric is typically saturated with modified bitumen by dipping into tanks of hot bitumen which are heated up to 200°C. Excess bitumen is metered off and the cooled surfaces are coated with a release material such as talc to prevent blocking together on the roll. The composite is packaged into rolls approximately 1 m wide and 50 m long. The rolls are then shipped to the job site and applied to the flat roof surface by slowly unrolling while heating the underside to tackiness with a propane torch to enable it to adhere to the roof deck. Adjacent rolls are lap seamed to provide for watertightness across the roll width of the roof. Spunbonded polyester is also used in the so-called cold roof method, typically used for roof maintenance. In this method, a cold mastic is applied over a fiber glass base sheet, followed by more mastic, another layer of polyester, more mastic, and a final topcoat.

In Europe, particularly France and Germany, bitumen-coated spunbonded polypropylene fabrics are widely accepted as rooflinings under concrete, clay, or ceramic tiles for pitched-roof construction. In this use, the spunbonded fabric is a critical element of the membrane because the rooflining is draped between roof rafters and depends on the strength of the spunbonded for self-support during the life of the roof. The bitumen coating renders the spunbonded waterproof and allows it to shed any water that might leak between the tiles during snow and rainstorms. Spunbonded fabrics coated with nonbituminous materials such as acrylics have also been used in Europe. Rooflinings represent a considerable opportunity for spunbonded fabrics in Europe and in the sunbelt areas of the United States.

Nonwoven fabrics have played an important part in the development of geotextile applications. Needle-punch fabrics manufactured from either staple fibers or spunbonded continuous filaments have found worldwide acceptance on the basis of field performance. In 2000, it is estimated that North America consumed approximately 300 million m^2 of geotextiles (62).

Many fabric manufacturers have dedicated considerable effort to the marketing of their products in order to participate in this growth area. Geotextile fabrics function by being porous to water but not to the fines of the soil, thereby permitting them to effectively separate or partition soil fines from other elements. The net effect is keeping the soil from eroding or moving position. For example, in the construction of a new road the geotextile can separate the subsoil from the gravel or aggregate. By maintaining this separation, the aggregate is not driven into the subsoil base by the weight of vehicles nor are soil fines pumped up into the aggregate since the geotextile filters out their passage. However, water is freely transported through the fabric, enabling proper drainage without buildup of hydrostatic pressures. Thus the road resists rutting and sustains the weight of traffic more effectively while permitting proper drainage of water through the fabric. In

drainage ditches, perforated drainage pipes are often wrapped with a geotextile prior to installation to prevent them from becoming clogged.

Spunbonded fabrics are effective filters in that they are layered structures of relatively fine fibers, the three-dimensional structure of which creates a torturous path. Even relatively thin spunbonded fabrics (eg, 0.2–0.25 mm) present a significant challenge to the passage of soil fines and are suitable for use in some filtration applications. The porosity of geotextile fabrics is classified by means of several procedures such as flux (volume flow/area per time) and equivalent opening size (EOS), which is a measure of the apparent pore size of the openings in the fabric. The flux measures the porosity to liquid water, and the EOS measures the porosity to solid particles of a known diameter. Literature is available on limitations of particular styles of fabrics within an application.

Growing university research ensures that users and specifiers will continue to become more sophisticated in their methodology and more demanding of manufacturers. Excellent textbooks are available for both students and practicing engineers (53,63).

A growing use for spunbond fabrics is in landscaping where lightweight (eg, 70–100 gsm) fabrics are sold as landscape fabrics for weed control. Typically these fabrics are placed in landscape beds over the soil and covered with stones or mulch where they resist the emergence of weeds from the soil while allowing water to drain through into the soil. They will not, however, prevent seed germination in the mulch, and they should be viewed as only a partial solution for weed control.

Other durable applications such as interlinings and coating/laminating substrates do not appear to offer much near-term opportunity for growth for spunbonded fabrics. In interlinings, however, spunlaced nonwovens have received wider acceptance because of the outstanding drape and softness, previously unavailable from any other fabric.

Spunbonded fabrics have a relatively small percentage of the coated fabric market which is dominated by other nonwovens. Needle-punched nonwovens offer more of the bulk and resiliency required for functionality in automotive and furniture seating.

Many filtration requirements are fulfilled by spunbonded structures, and a growing but technically complex market has developed since the 1970s (64). Applications include pool and spa, air particulate, coolant, milk, and sediment for household water.

A recent development is the automatic shaping of heavyweight spunbonded and needlepunched fabrics into three-dimensional honeycomb-shaped structures that allows, for the first time, the use of spunbonded fabrics as a three-dimensional solid object (65). This platform process opens up vast new applications previously unreachable by the two dimensional nature of these fabrics. Spunbond fabrics can be automatically converted into products as diverse as matresses, sandwich panels, air-flow straighteners, sand walls for temporary dikes, and drainage containment blocks. There is high interest in third world areas for the very inexpensive mattresses that can be produced from spunbond lines already in place in these areas. This process holds promise to open up large new markets for existing spunbonded fabrics.

Spunbonded Markets: Disposable Applications. The outlook for spunbonded disposable applications indicates a 5–7% compounded annual growth

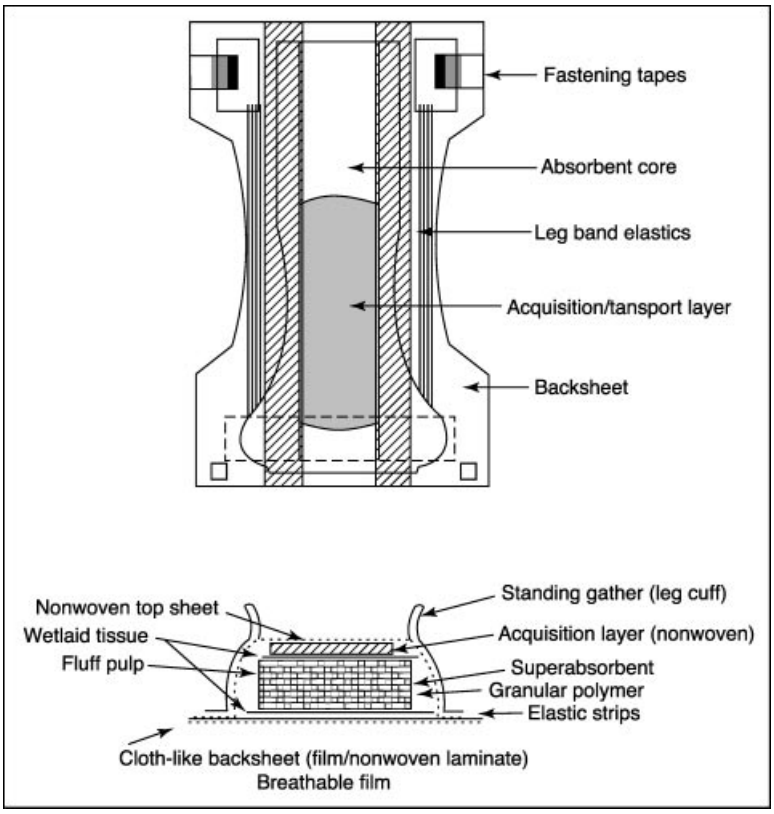

Fig. 14. Components of a modern disposable diaper (56).

forecast (1,6). Spunbonded plant capacity installed or announced since the 1980s has been aimed at satisfying increased demand largely for disposable applications. Key markets are components for baby diapers, training pants, incontinence devices, surgical gowns and drapes, medical sterilization wrap, protective clothing, and envelopes (see Fig 13, Ref. 69).

The use of spunbonded fabrics as coverstock for diapers and incontinence devices has grown dramatically since 1980, and by 1995 consumption exceeded 2 billion m^2 in the United States and is forecast to reach 3.5 billion within five years (67). A coverstock functions as a one-way medium through which urine is transported into the absorbent core. The laminar structural feature of the coverstock helps keep the skin of the user dry and comfortable. Figure 14 shows the uses of nonwovens in a premium price diaper (68). Although 17 g/m^2 spunbonded polyester was originally used in diaper coverstock, it has been supplanted entirely by 15–17 gsm weight spunbonded polypropylene.

Changes in diaper design have made disposable diapers among the most highly engineered disposable products in the world, and involve not only coverstock but the nature of the absorbent layer and design of the diaper itself. The use of form-fitting legs with leg cuffs for leak protection, as well as refastenable closures, has accelerated the acceptance of disposable diapers for both infants and

adults. Spunbonded fabrics are used in several major components of the diaper, including coverstock, leg cuffs, and backsheet (68). Spunbonded coverstock is also widely used in feminine napkins and, to a limited extent, in tampons. The conversion of eastern European countries to market economies has created increasing demand for disposable diapers and consequently spunbonded polypropylene coverstock. Other areas of the world showing higher penetration of disposable diapers are South America and China.

The uses of spunbonded fabrics as fabrics in diapers and other personal absorbent devices will most likely remain unchallenged for the near term. Virtually any other nonwoven production method appears to be at a cost disadvantage opposite spunbonded polypropylene. Perforated films lack tactile feel and are largely limited to use in femine napkins. There have been composite products developed from meltblown and spunbonded combinations, generally where improved hydrophobicity is desired. These products can be produced on-line at relatively low additional cost and offer high value to diaper manufacturers.

In medical applications, great progress has been made in the substitution of traditional reuseable woven materials with higher performing spunbondeds (69). Historically, flashspunbonded polyethylene was the first 100% spunbonded to find limited acceptance in medical uses such as disposable operating room gowns, shoe covers, and sterilizable packaging. Other spunbonded fabrics of polypropylene or nylon found some acceptance as cellulosic composites with the lightweight spunbonded serving to add physical strength to the composite. Over the last decade, composite structures of spunbond-meltblown-spunbond polypropylene (SMS) have gained wide acceptance in operating room gowns and sterilizable (CSR) wrap. Structures made of spunlaced polyester–cellulose are also widely used but have lost market share to SMS because of the higher barrier of SMS.

Operating room gowns worn by members of the surgical team place very high demands on fabric properties. Key requirements include breathability for comfort, low noise, absolute barrier to fluid penetration, low particle generation (linting), sterilizability, and impermeability to bacteria and viral particles. Woven cotton fabric gowns were worn for many years but had to be reused because of high cost. This required the added expense of laundering the garments and the need to decide when each garment was no longer suitable for use in the operating room. Several studies comparing disposable and reusable fabrics have been conducted in an attempt to correlate the effect of fabric linting with post-operative infections. Although no correlation has yet been established, some studies have demonstrated that single-use fabrics generate significantly fewer particles than cotton fabrics (70). Other studies have indicated that the rate of postoperative wound infection is reduced with the use of high barrier spunbonded olefin gowns and drapes. Concern for viral transmission (eg, AIDS) has increased the demand for disposable, higher barrier fabrics without loss of comfort.

Medical devices or trays of devices are often sterilized after the nonsterile device is sealed in a package. A part of this package, such as the lid, is made from flashspun or spunbonded/meltblown fabric because it possesses the unique property of permitting the sterilizing gas of ethylene oxide to pass through while remaining impenetrable to bacteria. These fabrics are manufactured to tightly controlled standards to ensure the highest resistance to bacterial/viral

penetration. The superiority of a spunbonded fabric to the alternative coated papers has been reviewed (71).

Spunbonded fabrics have been utilized as shoe covers in the operating room. The covers are usually sewn with an elastic band at the top to allow them to be held snugly in place. The fabric requirements are toughness, some porosity for comfort, nonlinting, resistance to slippage, and a nonstatic characteristic. In order to achieve the last property, the fabric is usually treated with an antistatic coating. Failure to use a nonstatic fabric may cause sparks to be generated in the operating room environment, which could damage sensitive electronic devices or lead to fire. Other medical applications for spunbonded fabrics include head covers, face masks, drapes, and other uses requiring breathable/barrier properties.

A large-volume area for spunbonded fabrics is the disposable protective clothing market (72). To a great extent the demand for high performance disposable protective clothing has tracked high technology manufacturing, environmental demands, and more recently the concern from biological or chemical terrorism. The manufacture of particulate sensitive electronic components, such as silicon chip integrated circuits, resulted in the construction of clean rooms where the generation of any particulate was in part controlled through the use of nonlinting yet comfortable clothing made from spunbonded fabrics. Because the spunbonded fabrics are made of continuous filaments, practically no linting results. At the same time the structure allows the passage of moisture and air, thus helping the wearer to remain comfortable. The spunbonded garment is worn over other clothing; therefore the maximum pore size must be sufficiently small to prevent the passage of lint and other particles through the garment and into the clean room.

The 1980s saw the beginning of the removal of large quantities of asbestos (qv) from schools and buildings, creating the need for clothing which could not be penetrated by small asbestos fibrils, yet inexpensive enough to permit daily disposal. Certain spunbonded and spunbond/meltblown laminate fabrics demonstrate excellent resistance to asbestos penetration from particles as small as 0.5 μm.

Similarly the handling of hazardous materials has prompted the need for affordable, disposable protective clothing. Once exposed to toxic waste, pesticides, or radioactive materials, the clothing itself is transformed into a hazardous material and must be disposed of to prevent spreading of contamination. Garments that demand the utmost in protection at the lowest price are often made by extrusion coating, laminating spunbonded fabrics with polyethylene, or laminating the fabric to poly(vinylidene chloride) film.

Packaging applications for spunbonded fabrics are for the most part a specialty area in which paper products or plastic films do not adequately perform. One of the largest packaging applications for spunbonded fabric is high performance envelopes. Although lightweight tear- and puncture-resistant envelopes are not in demand by individual consumers, both large and small businesses have found spunbonded envelopes to outperform those made from conventional paper products. The lighter weight of the spunbonded envelope allows for postal savings, and some corporations specializing in overnight delivery have successfully used spunbonded envelopes with excellent results. Coated spunbonded fabrics are used as the outerwrap of coils of steel and aluminum where they outperform alternative materials such as films and papers.

A significant percentage of U.S. synthetic staple fiber production is packaged in bales of extrusion coated spunbonded fabrics, so treated to render the fabric impervious. Synthetic fibers have been shipped worldwide in this manner with great success.

Although other nonwoven processes such as spunlacing have experienced large growth in disposable wipes, spunbonded fabrics have not participated in this segment generally because some cellulosic fibers are required in the wipe and spun bonding cannot readily utilize such fibers.

A reverse-wipe application is seen in the clothes dryer fabric softener sheet wherein the spunbonded fabric is coated with a complex combination of wax, surfactants, and perfumes which are released into the environment of a hot clothes dryer to soften and perfume the clothes, as well as provide an antistatic quality. The spunbonded sheet, which must be made of polyester or nylon for temperature resistance, provides a simple and cost-effective medium to store the chemical compounds prior to release in the dryer.

There are many other smaller specialty disposable applications for spunbonded fabrics which vary widely from country to country. These applications include candy wrapping, agricultural coverings, wall covering, and packaging.

NONWOVEN FABRICS, STAPLE FIBERS

Introduction

A nonwoven fabric is a textile structure made from fibers, without a yarn being first made; knitted and woven fabrics, require yarns. A nonwoven fabric normally comprises a network of fibers or continuous filament yarns strengthened by mechanical, chemical, or thermally interlocking processes. Examples are bonding with binders such as latex polymers, needling, hydroentanglement, and stitchbonding.

History. Johnson and Johnson became involved in nonwovens in the 1930s (1). After 10 years of experimentation its nonwovens department became part of Chicopee Manufacturing Corp. Viscose rayon was used to make a wide range of products including bedpads, surgical towels, disposable diapers, sanitary napkins, and wiping cloths. In the 1970s water jets were being used to bond fibers together to make surgical gauze.

Other companies with an early involvement in developing nonwovens to replace textiles include Avondale Mills, Kimberly-Clark, The Kendall Co., and the West Point Manufacturing Co. Freudenberg started trying to make a leather substitute in the 1930s (2).

The spunbond process transforms polymer directly to fabric by extruding filaments, orienting them as bundles or groupings, layering them on a conveying screen, and interlocking them by thermal fusion, mechanical entanglement, chemical binders, or combinations of these. The technology was developed by Freudenberg and DuPont in the 1950s (see NONWOVEN FABRICS, SPUNBONDED).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Meltblown fabrics are also made directly from thermoplastic resins. Polymer granules are melted and extruded. As soon as the melt passes through the extrusion orifice, it is blown with air at high temperature. The airstreams attenuate the molten polymer and solidify it into a random array of very fine fibers. The fibers are then separated from the air stream as a randomly entangled web and compressed between heated rolls. The combination of fine-diameter fibers, random entanglement, and close packing results in a fabric structure with a large surface area and many small pores.

After the development of spunbonded and meltblown processes, combined systems such as SMS (spunbonded/meltblown/spunbonded) were developed to combine the benefits of each fabric type. In the late 1990s bicomponent spunbonded technology was introduced.

Definitions. The Textile Institute defines nonwovens as "textile structures made directly from fibre rather than yarn. These fabrics are normally made from continuous filaments or from fibre webs or batts strengthened by bonding using various techniques: these include adhesive bonding, mechanical interlocking by needling or fluid jet entanglement, thermal bonding and stitch bonding."

The ISO 9092 definition is as follows: "A manufactured sheet, web or batt of directionally or randomly orientated fibres, bonded by friction, and/or cohesion and/or adhesion, excluding paper and products which are woven, knitted, tufted, stitch-bonded incorporating binding yarns or filaments, or felted by wet-milling, whether or not additionally needled. The fibres may be of natural or manufactured origin. They may be staple or continuous filaments or be formed in situ." Various notes are included in this definition including clarification on the difference between a wet-laid nonwoven and a wet-laid paper—in essence, the difference depends on the presence of a substantial proportion of fibers.

Nonwoven structures need not be considered as substitutes for knitted or woven fabrics—they are a class in their own, enabling a unique range of engineered properties and aesthetics to be achieved.

Nonwoven Processes

The basic concept employed in making a nonwoven fabric is to transform fiber-based materials into two-dimensional sheet structures with fabric-like properties. These are flexibility, porosity, and mechanical integrity. Their manufacturing processes can be split into four groups: dry-laid webs, extrusion-formed webs, wet-laid webs, and web-bonding.

Dry-Laid Processes. These include mechanical, eg carded, and aerodynamic, eg air-laid routes. Dry-laid nonwovens are made with staple fiber processing machinery such as cards and garnetts, which are designed to manipulate staple fibers in the dry state. Also included in this category are nonwovens made from filaments in the form of tow, and fabrics composed of staple fibers and stitching filaments or yarns, ie, stitchbonded nonwovens.

Extrusion-Formed Webs. Examples include spunbonded and meltblown. Extrusion technology is used to produce spunbond, meltblown and porous-film nonwovens. These fabrics are made with machinery associated with polymer

extrusion methods such as melt-spinning, film casting and extrusion coating (see EXTRUSION).

Wet-Laid Processes. Papermaking technology is used to process wood pulp fibers, synthetic fibers longer than wood pulp, and other fibers that differ in other ways from pulps. Included in this category are methods for producing dry-laid pulp and wet-laid nonwovens. These fabrics are made with machinery associated with pulp fiberizing, such as hammer mills, and paperforming, ie slurry pumping onto continuous screens which are designed to manipulate short fibers in a fluid.

Web-Bonding Processes. These can be split into chemical and physical. Chemical bonding refers to the use of water-based and solvent-based polymers to bind together the fibrous webs. These binders can be applied by saturation (impregnation), spraying, printing, or application as a foam. Physical bonding processes include thermal processes such as calendering and hot air bonding, and mechanical processes such as needling and hydroentangling.

The various nonwoven processes and the fabrics made from each have a number of common characteristics. In general, textile technology-based processes provide maximum product versatility, because most textile fibers and bonding systems can be utilized and conventional textile web processing equipment can be readily adapted at minimal cost. Extrusion technology-based processes provide somewhat less versatility in product properties, but yield fabric structures with exceptional strength-to-weight ratios, as is the case with spunbonds; high surface area-to-weight characteristics, a benefit of using meltblown technology; or high property uniformity per unit weight, as is the case with textured films, at modest cost.

Paper technology-based nonwoven processes provide the least product versatility and require a high investment at the outset, but yield outstandingly uniform products at exceptional speeds. Hybrid processes provide combined technological advantages for specific applications.

Fibers for Nonwovens

Nonwoven fabrics made directly from polymers are discussed elsewhere. The properties of nonwoven fabrics are highly influenced by the properties of their constituent fibers.

Technically, a fiber is a material characterized by fineness, flexibility, and by having a high ratio of length to thickness. Textile fibers also exhibit sufficient strength and extensibility, elasticity, flexibility, and temperature stability to endure the environments in which they are to be used. They can be divided into continuous filaments or staple forms. Staple fibers range in length from about 2 to 20 mm. Fibers with thicknesses greater than about 100 μm are generally considered coarse bristles; fibers with lengths less than a centimeter are generally not processed on textile-based processing machinery.

Typical textile fibers used, for example, in a needle-punched filter fabric, are a blend of 3.3 and 6.6 dtex polyester staple fibers. These are about 5 cm long, have diameters ranging from 18 to 25 μm, linear density of 350–650 mg per 1000 m and length-to-width ratios in the order of 1000 to 1.

Table 1. Properties of Some Commercially Available Textile Fibers

Fiber	Density, g/mL	Modulus, N/tex[a]	Tenacity, N/tex[a]	Elongation, %	Regain, %	T_m, °C
Cotton	1.52	4.85	0.26–0.44	7	7	
Jute	1.52	17.2	044–052	2	12	
Wool	1.31	2.38	0.08–0.17	40	13	
Rayon	1.54	4.85–7.5	0.8–0.44	8–20	11	177
Acetate	1.32	3.53	0.11	25–45	6.5	260
Nylon	1.14	2.65	0.44–0.79	15–50	3–5	260
Polyester	1.38	4.41–8.38	0.35–0.71	15–50	0.4	254
Acrylic	1.16	6.44	0.17–0.26	20–30	1–1.5	
Polypropylene	0.91	7.76	0.26–2.64	20	0.01–0.1	177
Nomex[b]	1.38	8.83	0.35–0.44	20–30	4	371
Kevlar[b]	1.44	42.34	0.79–1.14	1.5–4	5	482
Sulfur	1.37	2.65–3.53	0.26–0.35	25–35	0.6	285
Glass	2.56	30.89	0.79–1.76	2–5	0	1482

[b] Polyamides.

Virtually all fibers (an important exception is glass fibers) are composed of long-chain molecules or polymers arranged along the fiber axis. Essential requirements for fiber formation include long-chain molecules with no bulky side groups, strong main-chain bonding, parallel arrangement of polymer chains, and chain-to-chain attraction or bonding. Basic phases in the fiber formation process are obtaining a suitable polymeric material, converting the material to liquid form, solidifying the material into fiber dimensions, and treating the fiber to bring about desired properties. These four phases are present in the formation of natural as well as manufactured synthetic fibers, the principal differences being the amount of time and energy required.

A selection of fiber properties is given in Table 1. In general, fiber diameters range from 5 to over 40 μm for natural fibers, and from less than 10 μm (microfibers) upwards for manufactured fibers.

Almost all the fibers used in nonwovens are synthetic. The split is approximately as follows: Polypropylene 63%; polyester 23%; viscose rayon 7%; acrylic 2%; polyamide 2%; other 3%; (see PROPYLENE POLYMERS (PP); OLEFIN FIBERS; POLYESTERS, FIBERS; CELLULOSE FIBERS, REGENERATED; ACRYLIC FIBERS; POLYAMIDES, FIBERS).

With the increasing need to reduce cost and achieve sustainability, there has been a growth in interest in using recycled fibers, eg, from polyester bottles.

Web Formation

Web formation, the second phase in manufacturing nonwoven fabrics, transforms fibers or filaments from linear elements into planar arrays in the form of preferentially arranged layers of lofty and loosely held fiber networks termed webs, batts, or sheets. Mechanical and fluid means are used to achieve the fiber arrangement. Basic fabric parameters established at web formation, in addition to fiber orientation, are the unfinished product weight per unit area and the manufactured

width. In all nonwoven manufacturing systems, the fiber material is deposited or laid on a forming or conveying surface. The physical environment at this phase is dry when textile technology is used, wet when papermaking technology is used, and molten when extrusion technology is used.

Webs are prepared by opening, blending, and carding.

Opening and Blending. A bale of fibers needs to be broken apart and the closely packed fibers in the tufts need separating before further processing can be carried out. This is an important first stage to forming a web—once the web has been formed it cannot be made more even by further processing, and any irregularities will adversely affect product performance. So it is important to open the fiber tufts, remove any contamination, and even out bale-to-bale variation before further processing.

Textile Carding. Carding is the process of disentangling, cleaning, and intermixing fibers to make a web for further processing into a nonwoven. The aim is to take a mass of fiber tufts and produce a uniform, clean web. The process predominantly aligns the fibers which are held together as a web by slight mechanical entanglement and fiber–fiber friction. The main type of card is a roller card. The carding action is the combing or working of fibers between the points of saw-tooth wire clothing on a series of interworking card rollers. Short fibers and foreign bodies are removed, the fiber tufts are opened, and the fibers are arranged more or less parallel. The carding or parallelization of fibers occurs when one of the surfaces moves at a speed greater than the other. Fibers are removed, or "stripped," when the points are arranged in the same direction and the more quickly moving surface removes or transfers the fibers from the more slowly moving surface.

Woollen cards, for example, were designed to process a rather wide range of fiber lengths ($<$1–20 cm) and diameters ($<$20–50 μm) with additional objectives of removing contaminants, mixing fibers, preserving fiber length, extracting as few fibers as possible, and delivering as many as 100 slivers. Conventional woollen cards, consequently, consist of a series of relatively wide and large cylinders to achieve productivity and accommodate fiber length requirements; multiple rolls to work and mix fibers on the large cylinders; and smaller cylinders and rolls to take fibers to and transfer them from each working area.

Cotton cards, on the other hand, were designed to process shorter fibers (15–30 mm) and a more narrow range of fiber diameters (15–30 μms). Additional requirements include eliminating very short fiber segments and extracting nonfibrous material such as seed coat particles and leaf fragments. A traditional cotton card consists of a roll-to-plate mat feeding assembly, a fiber-from-mat separating roll (lickerin), one large cylinder and several curvilinear surfaces (revolving flats) between which the carding action takes place, a smaller cylinder which removes fibers (doffs) from the carding cylinder, and a web-condensing and sliver-coiling assembly.

When short (35–50 mm) synthetic fibers are processed on cotton cards, the flats are often replaced with stationary granular surfaces in order to minimize the fiber extraction and damage. Fibers up to 150 mm in length are processed on cotton cards with workers and strippers (Fig. 1).

Garnetts were designed to thoroughly disentangle textile fibers which were reclaimed from various fiber or textile manufacturing operations or regenerated from threads and rags. Garnetts are compact, versatile, and highly productive. Most have a feeding section, a gentle opening section, a working section consisting

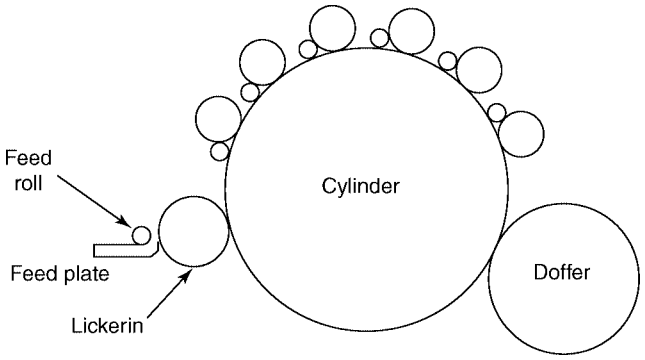

Fig. 1. Cotton card with workers and strippers (doffers).

of one to four cylinders with or without a worker and stripper rolls, and one to four doffers.

The choice between using a cotton card, a woollen card, or a garnett depended on fiber dimensions. Woollen cards were used for long, coarse fibers, cotton cards for finer, shorter fibers, and garnetts for fibers having a wide range of dimensions.

Nonwoven Cards. Modern, high speed cards designed to produce nonwoven webs show evidence of either a cotton or wool fiber-processing heritage and have processing rate capabilities comparable to those of garnetts. Contemporary nonwoven cards are available up to 5 m and are configured with one or more main cylinders, roller or stationary tops, one or two doffers, or various combinations of these principal components.

Single-cylinder cards are usually used for products requiring machine-direction or parallel-fiber orientation. Double-cylinder cards, frequently called tandem cards, are basically two single-cylinder cards linked together by a section of stripper and feed rolls to transport and feed the web from the first working area to the second. The coupling of two carding units in tandem distributes the working area and permits greater fiber throughput at web quality levels comparable to slower single-cylinder machines.

Roller-top cards have five to seven sets of workers and strippers to mix and card the fibers carried on the cylinder. The multiple transferring action and reintroduction of new groupings of fibers to the carding zones provides a doubling effect which enhances web uniformity. Stationary-top cards have strips of metallic clothing mounted on plates positioned concavely around the upper periphery of the cylinder. The additional carding surfaces thus established provide expanded fiber alignment with minimum fiber extraction.

Double-doffer cards are generally used to conserve manufacturing space or optimize throughput while maintaining web quality. The double-doffer configuration splits the web, which essentially doubles the output of lightweight structures or yields an additional doubling action for heavier ones (Fig. 2).

Web Layering

Forming fibers into a web on a carding or garnetting machine takes place at the doffer. The web forms as the doffer strips and accumulates fibers from the cylinder. The number of fibers accumulated and the mass of each fiber determine the weight

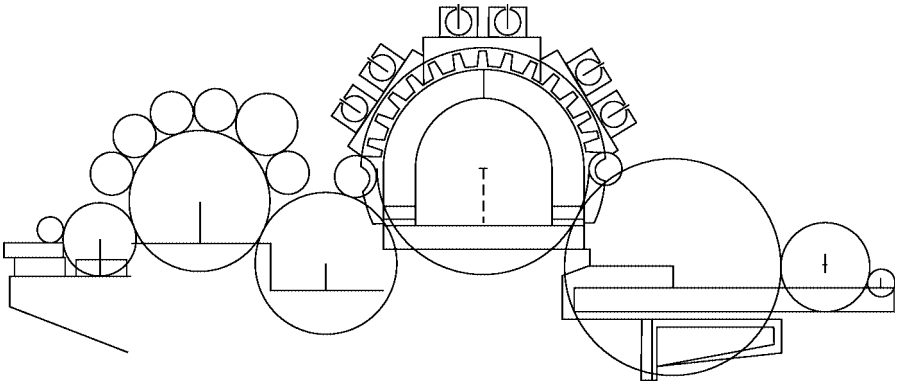

Fig. 2. Contemporary nonwoven card configuration.

of the web. For a given fiber orientation, web weight per unit area is limited by the ratio of the surface speed of the cylinder to the surface speed of the doffer. This is typically 10–15. The result is that cotton cards give up to 10 g/m^2 per doffer, woollen cards up to 25 g/m^2, and garnetts up to 50 g/m^2.

Nonwoven fabrics are made in weights ranging from less than 10 to several hundred grams per square meter, and fiber orientations ranging from parallel to random. Webs can be built up or layered to achieve the desired weight. This can be done by folding from one machine, collection from multiple forming machines, or cross-lapping.

Web folders or straight plaiters are used with cotton cards to produce surgical waddings, and with woollen cards and garnetts to produce padding and cushion filler. The resulting batt is limited in width to the width of the forming machine. Delivery is in the form of individual stacks of parallel fiber layers. Layering of webs from two or more cards or garnetts arranged in tandem onto a conveying apron or screen provides continuous delivery. Tandemly arranged, roller-top cotton carding lines are used to form webs for diaper and feminine pad facings, interlinings, and wipes. In this instance, web weight is controlled by the number of cards included and finite adjustment of cylinder or doffer speed ratios. Density gradient and multifiber laminate webs can be formed by processing fibers of different sizes and chemical types on individual cards in the line. Web characteristics include a high degree of fiber parallelization and increased uniformity due to the doubling effect of layering.

Parallel laid webs can only be the width of the card web and they remain anisotropic; cross-laid webs can be wider and more uniform.

Cross-lapping is essentially the plaiting or folding of a fiber web onto a conveying device placed at an angle of 90° to the forming unit. Delivery is continuous and fiber orientation is biaxial. In addition to being a means of determining a range of product weights, cross-lapping is also a means of determining a range of product widths. Additives, such as binder and particulate matter, can also be deposited onto individual web layers at the lapping stage.

Cross-lapping can be achieved by doffing webs onto reciprocating floor aprons, inclined aprons (camel back) reciprocating onto stationary floor aprons or conveyors, or runout (horizontal) apron folders reciprocating onto stationary floor

aprons or conveyors. Cross-lapped web widths may range from several centimeters to several meters. Cross-lapped webs are used in the production of highloft and needled structures.

Web Spreading and Web Drafting. Spreading layers of parallel fiber webs is a means of simultaneously increasing web width, decreasing web weight, and altering fiber orientation. Controlled stretching or drafting web layers is a means of simultaneously increasing web throughput, decreasing web weight, and altering fiber orientation.

Spreading devices typically consist of modules of bowed rolls of increasingly wider widths operating at speeds slightly greater than the conveying speed of the input web. Fibers move longitudinally but mostly horizontally past one another, resulting in a lateral stretching or drafting of the web and overall repositioning of individual fibers. Width increases of 50–250% are common. Web-drafting devices consist of a series of top-and-bottom roll sets of the same width operating at successively increasing speeds. When heavy cross-lapped layers are drafted, a more isotropic arrangement of fibers is achieved. Draft ratios of six and higher are practiced in some nonwoven operations. Web drafters are also used as a means for in-line weight control.

Random Cards. Fiber orientation ratios as low as 3:1 can be achieved on cards by expanding the condensing action at doffing through the addition of scrambling or randomizing rolls operating at successively slower surface speeds. Proper selection of clothing wire and speed ratios can yield webs with increased *z*-direction fiber orientation, resulting in increased thickness and loft; throughput speed, however, is decreased. Cards specifically designed to produce random webs at contemporary throughputs are configured with several small cylinders that hurl the fibers onto adjacent doffers or cylinders, which in turn transfer the fibers centrifugally onto subsequent cylinders. Figure 3**a** shows the roll arrangement for lightweight nonwovens and Figure 3**b** for heavier weight nonwovens.

Aerodynamic Web Formation. Heavy webs, especially of coarse fibers, cannot easily be made on a mechanical system such as carding. Air-laying is the preferred manufacturing route. By this means it is possible to make a heavy fabric as a single layer, unlike carding or folding for which the layers can split. The principle is that the fibers are well-opened before being directed by air currents onto a collector which can be a flat conveyor or a drum. In principle a better balance of properties in the CD and MD directions should be possible, with a significant proportion of fiber elements in the thickness direction.

Air-laid nonwovens can be grouped into two categories: those formed from natural or synthetic textile fibers and those formed from natural or synthetic pulps. The basic elements are a preformed feed mat, a feeding arrangement, a fiber separation device, an air-generating means, an air-regulation means, and a fiber collection or condensing means.

As fibers in the feed mat pass between the feed roll and feed plate, they are separated by metallic wire teeth on the lickerin roll and carried to an air venturi where they are stripped and tumbled until they strike a moving, perforated collection surface (Fig. 4). At the collection surface, the airborne fibers follow paths of least resistance and accumulate in a self-levelling manner while the air passes through perforations. Fiber orientation in the web is isotropic in layers corresponding to the number of fibers transferred from the wire teeth to

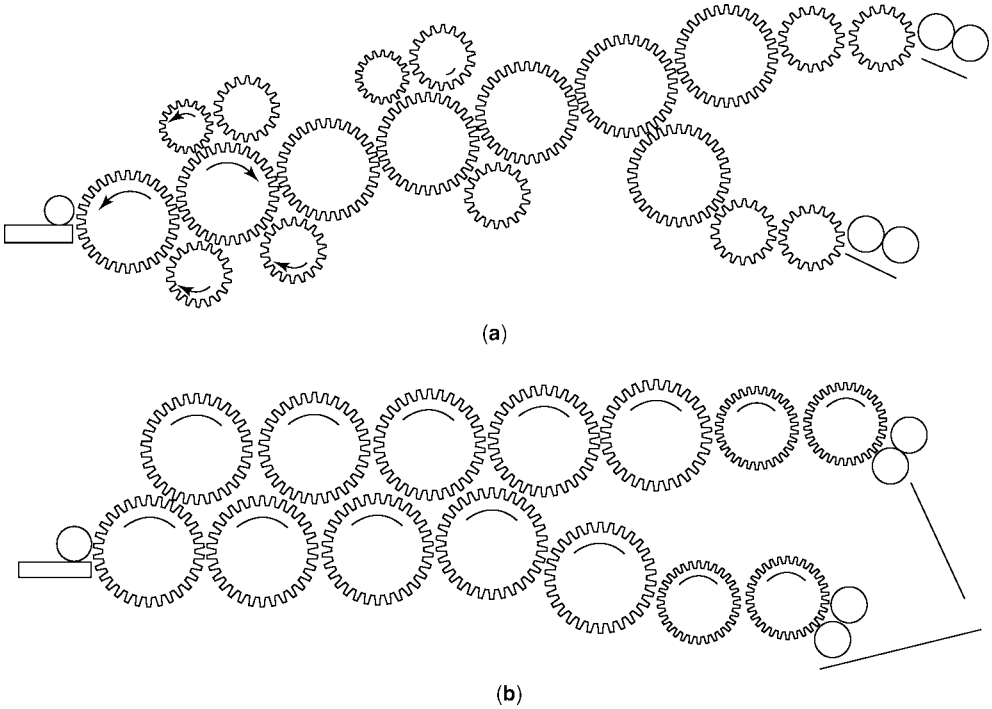

Fig. 3. Random card roll arrangements designed for (a) lightweight nonwovens and (b) highloft nonwovens.

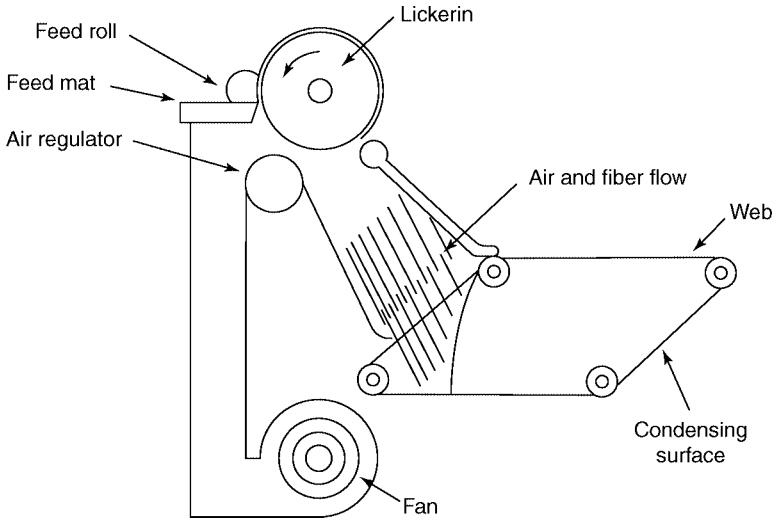

Fig. 4. Aerodynamic web formation.

the air-transportation zone, the intensity of the air, and the speed of the collection surface.

Other configurations include a standard roller card with a series of workers and clearers to open the fiber, with various arrangements of air distribution, eg overpressure or under pressure to direct the fibers and lay them on the perforated collector.

Three-dimensional webs can be made on air-forming machines, provided the fibers used are relatively short and stiff and the webs made are of relatively low density. Air-forming machines allow for production of web thicknesses up to several centimeters, and weights ranging from 30 to 3000 g/m^2 at widths from one to several meters.

Textile fibers can be air-formed directly into end-use configuration by including a shaped condensing surface or, as in the production of pillows, an air-permeable screen drum or belt. Aerodynamic web formation is a suitable means of processing brittle fibers such as glass and ceramics.

Fibers of different diameters, lengths, shapes, and densities break up when processed together in air streams. This fractionation results in the formation of webs with different top and bottom surface characteristics, as well as varying density and porosity gradients. Such structures have been used in filtration.

Short Fiber Systems. The web formation phase of the papermaking process occurs between the headbox and the forming wire. In this area, the fibers, suspended in a dilute water slurry, are deposited on a moving screen which permits the water to pass and the fibers to collect. Traditional papers use a variety of wood pulps or other short cellulosic fibers which pack together to form relatively dense, nonporous, self-adhered sheets. The use of textile fibers, instead of cellulose-based materials, with papermaking machinery distinguishes wet-laid nonwoven manufacturing from traditional paper manufacturing. Both manufacturing methods, however, transport the fibers in a water slurry. The use of papermaking fibers on air-laid nonwoven machinery bridges a gap between textile and paper systems. In both technologies, the transport medium is a fluid: water in wet-laid nonwovens and air in dry-laid pulps.

Dry-Laid Pulp. A principal objective of using air to form webs from natural and synthetic fiber pulps is to produce relatively lofty, porous structures from short fibers, without using water. Air or dry-laid pulp machinery can be imagined as a series of forming-unit modules. Each module consists of two to four perforated drums through which airborne fibers are circulated and further agitated by mechanical beaters placed in close proximity to the inner drum surfaces. As the fibers circulate and separate by the force of the air and the sweeping action of the beaters, they are pulled through the drum perforations by a vacuum onto a condensing conveyor.

Air-laid pulp-forming lines generally consist of three or more forming heads in tandem. Web weights range 70–2000 g/m^2 at throughputs of about 1000 kg/h.

Wet-Laid Web Formation. In the wet-lay or wet-forming process, fibers are suspended in water, brought to a forming unit where the water is drained off through a forming screen, and the fibers are deposited on the screen wire. A principal objective of wet-laid nonwoven manufacture is to produce structures with textile characteristics, primarily flexibility and strength, at papermaking speeds. This can be done by incorporating textile fibers at web formation.

In general, however, it is difficult to incorporate textile fibers because they do not readily wet out, are difficult to disperse, and tend to tangle with one another. Consequently, large amounts of water are needed to keep the fibers in suspension. Also, if the slurry is not handled properly, the fibers tangle and cause poor sheet formation. This can be overcome by increasing the slurry dilution and controlling fiber orientation.

Forming machine designs that have been commercially successful include the inclined-wire fourdrinier and the cylinder former. Inclining the forming wire and suction boxes on a fourdrinier machine to an angle of 5°–30° expands the forming area, which in turn decreases the flow requirements for web formation, increases drainage, and aligns fibers along the machine direction. The cylinder former configuration also provides an expanded forming area. Another benefit of this design is that higher vacuum pressures can be used, which results in the ability to produce both heavy and dense as well as light and relatively impermeable structures.

Web Consolidation

Nonwoven bonding processes interlock webs or layers of fibers, filaments, or yarns by mechanical, chemical, or thermal means. The extent of bonding is a significant factor in determining fabric strength, flexibility, porosity, density, loft, and thickness. Bonding is normally a sequential operation performed in tandem with web formation but it is also carried out as a separate and distinct operation.

In some fabric constructions, more than one bonding process is used, for example, sometimes a needled fabric is thermally bonded and then chemically bonded with the aim of achieving high stiffness.

Needle-Punching. In this method, fiber webs are mechanically interlocked by physically moving some of the fibers or elements of the length of some fibers from a near-horizontal to a near-vertical position. This is achieved by intermittently passing an array of barbed needles into the web to move groups of fibers, and then withdrawing the needles without significantly disturbing the newly-positioned fibers. The degree of interlocking depends on the extent to which the needles penetrate the web (depth of penetration), the needling density (penetrations per unit area of fabric), and the number of groups of fibers or fiber elements which are repositioned per penetration. The latter depends on the design of the needles used.

The basic parts of a needleloom are the web-feeding mechanism, the needle beam which comprises a needleboard which holds the needles, a stripper plate, a bed plate, and a fabric take-up mechanism. (Fig. 5).

The fiber web, sometimes carried or reinforced by a scrim or other fabric, is guided between bed and stripper plates, which have openings corresponding to the arrangement of needles in the needle board. During the downstroke of the needle beam, each barb carries groups of fibers, corresponding in number to the number of needles and number of barbs per needle, into subsequent web layers to a distance corresponding to the penetration depth. During the upstroke of the needle beam, the fibers are released from the barbs, and interlocking is accomplished. At the end of the upstroke, the fabric is advanced by the take-up, and the cycle is repeated.

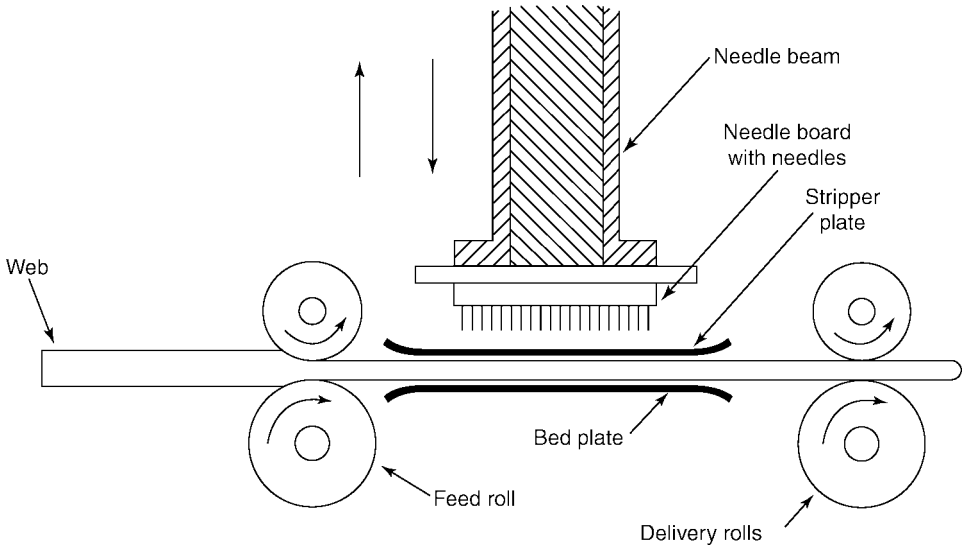

Fig. 5. Basic elements of a needle-punch machine.

Needling density is determined by both the distance advanced and the number of penetrations per stroke.

The development of a mechanical process for producing felt is dated to 1820 and has been attributed to J.R. Williams (3). The transition from interlocking fibers by working the scales on adjacent fiber surfaces against one another to working the fibers by a scaled external member in the form of a barbed penetrating device took place during the last quarter of the nineteenth century. This transition was made possible by the development of the mechanisms and machinery to produce needled nonwovens in a factory environment.

Needle looms are produced in widths ranging from several centimeters to several meters. Virtually all needle looms employ reciprocating motion to provide the penetration action. The most common needle loom configuration is the single upper-board, downstroke arrangement. Other arrangements include double upper-board, single upper- and lower-board, and double upper- and lower-board. To achieve high penetration densities on both sides of a fabric, needle looms of differing configurations are often placed in tandem.

Needle looms with low density boards are used to lightly consolidate webs and are termed pre-needlers or tackers. Machines with multiple or high density needle capabilities are referred to as consolidation or finishing needle looms. Machines designed to produce patterned or raised surfaces are termed structuring looms and are used as a mechanical finishing process.

Fabric weights range from 50 to 5000 g/m^2, and needling densities range from fewer than a hundred to several thousand penetrations per square centimeter.

Most needled fabric is made in flat form; however, tubular fabric, ranging in diameter from a few millimeters to papermakers' felt dimensions, can be made on some machines.

Needled nonwovens are sometimes mistaken for fabrics which have been felted or fabrics made directly from fibers which have been interlocked by a

combination of mechanical work, chemical action, moisture, and heat. Fabrics which have been felted are generally composed of yarns spun from wool fibers and have undergone a controlled shrinkage by subjection to the fulling process, a mechanical beating in the presence of lubricating agents. Fabrics made directly from fibers which have been interlocked by a combination of mechanical work, chemical action, moisture, and heat are felts. Felts are generally composed of wool or fur fibers and are physically held together by the interlocking of scales on individual fibers. Fiber interlocking in a felt is achieved by a process called *hardening*, which consists of passing fiber webs between oscillating and vibrating plates in the presence of steam. Following hardening, the felt is subjected to a fulling process. Felt density, stiffness, and tenacity are dependent on web weight and extent of hardening and fulling.

On the other hand, a needled felt is a fabric composed of natural, synthetic, or a combination of natural and synthetic fibers physically interlocked by the action of a needle loom with or without combination of other textile fabrics and with or without suitable combination of mechanical work, chemical action, moisture, and heat, but without weaving, knitting, stitching, thermal bonding, or adhesives (4).

Early needle-punched nonwovens were made from coarse animal hair and vegetable fibers and were used as carpet underlays and padding for mattresses and furniture. By the late 1950s needled synthetic products were being introduced for home furnishings and apparel. Several attempts were made to make synthetic leather in the 1960s, with the needled fabric as a substrate.

The main applications of needle-punched fabrics are automotive, geotextiles, footwear components, insulation, and roofing substrates.

Stitchbonding. This is a mechanical bonding method that uses knitting elements, with or without yarn, to interlock fiber webs. Sometimes called stitchthrough or web knitting, this technology was developed in eastern Europe in the late 1940s. Maliwatt and Arachne machines use yarn; Malivlies and Arabeva machines use modified knitting needles to interlock the fibers. Both families of machines operate essentially on the same principle, but differ in the positioning of the knitting elements, direction of web passage, and type of needles used.

The sequence of operations for a web-consolidation cycle on an Arachne machine is as follows. The web is guided upward and positioned between the web-holder table and knock-over table and penetrated by the needle. After passing through the web, the hook of the needle is provided with a yarn properly placed by the closing motion of the yarn guide. When the needle reaches the end of the upward stroke, the yarn is pulled through the previously formed loop, the loop is cast off, the fabric is advanced, and the cycle is repeated. Similar functions are served by the Arachne web-holder table and the needle loom bed plate, the Arachne knock-over table and the needle loom stripper plate, and the Arachne knitting needle and the needle loom needle. Thus, when yarn is eliminated, stitchbonding and needle-felting methods interlock fibers similarly.

Stitchbonded fabrics are used in home furnishings, footwear, filtration, and coating.

Hydroentanglement. This is a generic term for a nonwoven process that can be used for web consolidation, fabric surface-texturing purposes, or both. The mechanism is one of fiber rearrangement within a preformed web by means of fluid forces. When used for bonding, hydroentanglement repositions individual fibers

into configurations that result in frictional interlocking. When used as a surface-texturing means, hydroentanglement repositions fibers into open-patterned arrangements.

Also termed spunlaced or jet-laced nonwovens, fabrics of this type have been sold commercially since the early 1970s and have been successfully used in applications such as interlinings, wipes, wound dressings, and surgical gowns. The earliest hydroentangled fabrics were lightweight but now weights of up to 400 g/m^2 are possible.

The hydroentanglement process, as illustrated by DuPont patent drawings (5), involves subjecting the web and its conveying device to increasingly higher pressure jets of water. When the water jet strikes the web, it moves individual fibers away from the high points of the conveying means and is deflected by the conveying surface. As a result, voids are created in the web, and fibers intermingle. Whether the fabric surface is visibly smooth or openly patterned depends on the wire design or surface geometry. When highly interlocked, mechanically bonded (spunlace) structures are desired, high water pressure and plain mesh wire are used. The resulting fabric surface is comparatively smooth and the overall structure is relatively strong because of a large amount of individual fiber entanglement. When open-surface (apertured) structures are desired, lower water pressure and conveying wire combinations or surfaces with preferred patterning configurations and depths are used, and a fabric surface with an overall aperture geometry reflective of wire or surface contour is established. A wide variety of aperture shapes and lines are possible. Individual aperture shape or hole clarity is a function of fiber dimensions, jetting pressure, and wire interlacing or embossment shape and height.

Chemical Bonding. Sometimes called resin bonding, chemical bonding is a general term describing the technologies employed to interlock fibers by the application and curing of a chemical binder. The chemical binder most frequently used to bond nonwovens is waterborne latex. Most latex binders are made from vinyl polymers, such as vinyl acetate, vinyl chloride, styrene, butadiene, acrylic, or combinations thereof. The monomer is polymerized in water, and the polymeric material takes the form of suspended (emulsified) particles. Thus the emulsion polymerization of vinyl acetate yields a vinyl acetate polymer binder and the copolymerization of styrene and butadiene yields styrene–butadiene copolymer (qv) or styrene-butadiene rubber (SBR) binder.

Latexes (or latices) are widely used as nonwoven binders because they are versatile, can be easily applied, and are effective adhesives. The chemical composition of the monomer determines stiffness and softness properties, strength, water affinity, elasticity, and durability. The type and nature of functional side groups determine solvent resistance, adhesive characteristics, and cross-linking nature. The type and quantity of surfactant used influence the polymerization process and application method. The ability to incorporate additives such as colorants, water repellents, bacteriastats, flame retardants, wetting agents, and lubricants expands this versatility even further (see LATEX TECHNOLOGY).

Chemical binders are applied to webs in amounts ranging from about 5 to 60 wt%. In some instances when clays or other weight additives are included, add-on levels can approach or even exceed the weight of the web. Waterborne binders are applied by spray, saturation, print, and foam methods. A general objective of

each method is to apply the binder material in a manner sufficient to interlock the fibers and provide chemical and mechanical properties sufficient for the intended use of the fabric.

Spray bonding is used for fabric applications which require the maintenance of high loft or bulk, such as fiberfill. The binder is atomized by air pressure, hydraulic pressure, or centrifugal force, and is applied to the upper surfaces of the web in droplet form using a system of nozzles. To apply binder to the lower surface, the web direction is reversed on a second conveyor and the web passes under a second spray station. After each spraying, the web is passed through a heating zone to remove water. The binder is cured, or cross-linked, upon passage through a third heating zone. Drying and curing is frequently done in a three-pass oven. Binder addition levels commonly range from 30 to 60% of the fiber weight.

Saturation bonding (sometimes simply called "impregnation") is used in conjunction with processes that require rapid binder addition, such as card-bond systems, and for fabric applications that require strength and maximum fiber encapsulation, such as carrier fabrics or some shoe stiffeners. Fiber encapsulation is achieved by totally immersing the web in a binder bath or by flooding the web as it enters the nip point of a set of pressure rolls. Excess binder is removed by vacuum or roll pressure. There are three variations of saturation bonding: screen, dip-squeeze, and size-press. Screen saturation is used for medium weight nonwovens, such as interlinings. Dip-squeeze saturation is used for web structures with sufficient strength to withstand immersion without support. Size-press saturation is used in high speed processes, such as wet-laid nonwovens. Through-air ovens or perforated drum dryers are used to remove water and cure the resin. Binder addition levels range from 20 to 60% of fiber weight.

In print bonding, binder is applied in predetermined areas or patterns. This method is used for fabric applications that require some areas of the fabric to be binder-free, such as wipes and coverstocks. Many lightweight nonwovens are print-bonded. Printing patterns are designed to enhance strength, fluid transport, softness, hand, and drape. Print bonding is most often carried out with gravure rolls arranged as shown in Figure 6**a**. Binder addition levels are dependent on both engraved area and depth, and the binder-solids level. Increased pattern versatility can be achieved by using rotary-screen rolls arranged as shown in Figure 6**b**. Drying and curing are carried out on heated drums or steam-heated cans.

Foam bonding is used when low water and high binder-solids concentration levels are desired. The basic concept involves using air as well as water as the binder carrier medium. Foam-bonded nonwovens generally require less drying and curing energy because less water is used. The foam is generated by concurrently aerating and mechanically agitating the binder compound. Air/binder dilutions (blow ratios) range from 5 to 25. The addition of a stabilizing agent to the binder solution causes the foam to resist collapse during application and curing, and yields a fabric with enhanced loft, hand, and resilience.

Nonstabilized foams are referred to as froths; froth-bonded fabrics are similar in properties to some saturation-bonded nonwovens. Typical foams used as nonwoven binder solutions have a consistency similar to shaving cream. Application methods include knife-edge layering onto a horizontal web surface followed by vacuum penetration, and saturation and penetration of a vertical web surface

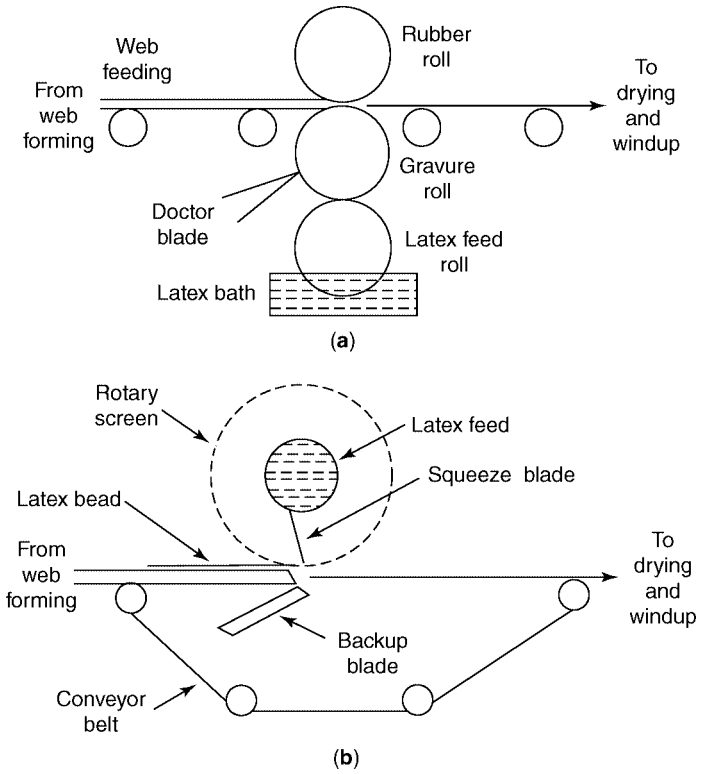

Fig. 6. Print bonding methods where (a) is gravure and (b) is rotary-screen printing.

using a horizontal-nip pad. Drying and curing are carried out in ovens, drum dryers, or steam cans.

Thermal Bonding. In thermal bonding, heat energy is used to activate an adhesive, which in turn flows to fiber intersections and interlocks the fibers upon cooling. The adhesive may be individual fibers, portions of individual fibers, or powders. Advantages of thermal bonding include low cost and the wide availability of binder materials and machines. The use of thermal bonding is increasing and replacing chemical bonding in medium weight nonwovens.

Thermal bonding is achieved as the result of a sequence of three events: heating, flowing, and cooling. The adhesive component, distributed in a nonwoven web in the form of a unicomponent fiber, bicomponent fiber, or powder particle, is subjected to heat. For binder fibers and powders, initial heat softens the binder surface and expands its contact area with other fibers; additional heat induces binder flow, resulting in molten binder–fiber wetting and broader binder-to-fiber contact. As the adhesive approaches its melting point, its surface softens, and contact areas with more stable fibers expand further to form potential bonding sites. Upon melting, the adhesive, now in liquid form, becomes attached to a network fiber. It then flows along the network fiber into a crossing of two or more fibers, or forms an adhesive bead. Upon cooling, the adhesive solidifies and forms a bond at each fiber contact.

In addition to the melt-flow properties of the adhesive, bond strength is a function of the percentage of fiber surface area joined or shared at fiber intersections, the heating and cooling times, and bonding temperature. Bond effectiveness is also dependent on binder distribution and binder concentration. Fabric strength, resilience, softness, and drape are affected by bond strength, bond position, and total bonded area. A properly produced thermal-bonded nonwoven can approach the idealized nonwoven structure, namely, one in which individual fibers are connected at crossings with each other.

Three basic methods of heating are used for thermal bonding: conduction, radiation, and convection. Conduction technologies include fixed contact with a heated surface and ultrasonic welding. Direct contact heating is done with heated calender rolls. For area or surface glazing, smooth rolls are used. For point bonding, patterned or embossed rolls are used. Thermal calendering is most efficient in terms of heat loss, but heavy roll pressures tend to destroy fabric loft.

For fabrics containing a significant proportion of thermoplastic material which is usually thermoplastic fibers but could be powder, bonding, including in patterns, can be done ultrasonically. An illustration of the basic elements of an ultrasonic bonding unit is given in Figure 7. In this bonding method, a web is placed between a high frequency oscillator or horn, and a patterned roll. As the waves pass through the web and are concentrated on the raised points of the patterned roll, sound energy heats the fibers. If they are thermoplastic, they will soften and start to melt, bonding the fabric together in patterns corresponding to those on the surface of the roll.

Radiation heating concentrates fiber bonding on the surface. For lofty or thick structures, this effect yields a bond intensity gradient throughout the fabric thickness. Radiant heating systems are used mostly for applications which require

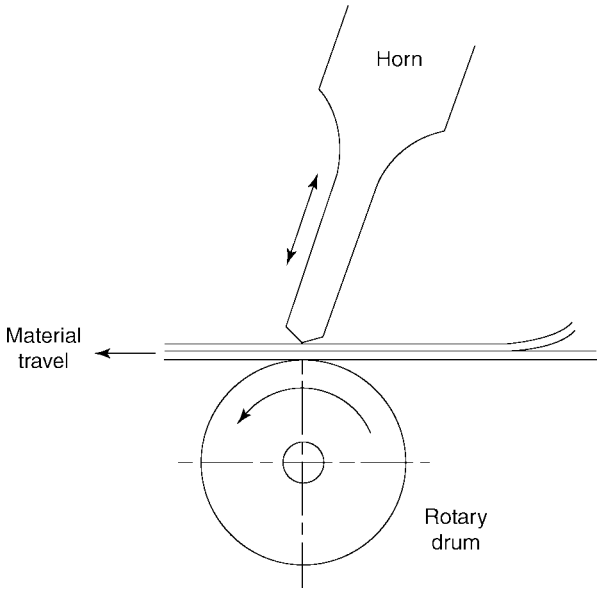

Fig. 7. Basic elements of ultrasonic bonding.

instant heating and concentrated heating zones. Convection heating methods pass heated air through the nonwoven web and are used to bond many medium and heavy weight nonwovens. Two common commercial configurations are multizone through-air ovens and compact through-air ovens. Multizone ovens transport the nonwoven web through heating and cooling zones on a flat conveyor, with production speed and dwell time requirements being accommodated by increasing oven length. Compact through-air ovens use felt or perforated belts to guide the webs around perforated drums. In these systems, hot air is recirculated through the fabric, drum, and heat exchanger by low speed radial fans. The belt guide conveyor serves to stabilize the nonwoven batt during heating, and also controls fabric loft and shrinkage.

From an energy standpoint, modern thermal bonding, ie web consolidation with no heat requirement for water removal, is very efficient. Manufacturing lines for thermal-bonded nonwovens also require less floor space and operate at higher production rates. Thermal-bonded nonwovens are generally softer and drier, have greater strength per unit weight, and are absorbent and porous because of smaller bonding points.

Thermal bonding also provides the opportunity to design fabrics which are more easily recyclable than chemically bonded fabrics.

Finishing

Commercial nonwoven fabrics are transported from the manufacturing plant to the customer in the form of rolls of varying dimensions to accommodate the fabric end-use application or subsequent conversion processes. Slitting and winding are finishing processes common to all nonwoven manufacturing methods. Roll width is determined at the slitting operation, and roll length is determined at the winding operation.

The fabric may also be given one or more of a number of other finishing treatments, either in tandem with web formation and bonding or off-line as a separate operation, as a means of enhancing fabric performance or aesthetic properties. Performance properties include functional characteristics such as moisture transport, absorbency, or repellency, flame retardancy, electrical conductivity, abrasion resistance, and frictional behavior. Aesthetic properties include appearance, surface texture, and smell.

Generally, nonwoven finishing processes can be categorized as either chemical, mechanical, or thermomechanical. Chemical finishing involves the application of chemical coatings to fabric surfaces or the impregnation of fabrics with chemical additives or fillers. Mechanical finishing involves altering the texture of fabric surfaces by physically reorienting or shaping fibers on or near the fabric surface. Thermomechanical finishing involves altering fabric dimensions or physical properties through the use of heat and pressure.

Finishing may also be viewed as another means for providing nonwovens with additional application-dependent chemical and/or physical properties. Finishing processes bring about value-added fabrics with technically sophisticated properties for specific end-use applications.

Chemical Finishing. For many nonwovens, chemical finishing is an extension of the binder application process through the use of technology associated with fabric coating. In most instances, the coating process is applied to enhance the properties of the nonwoven; however, in some applications, the nonwoven is used as a carrier to transmit the properties of the coating material. The coating may be applied as a continuous covering or as a pattern; it is most frequently applied in aqueous solution form. With many nonwoven substrates, special care must be taken because of the delicate nature of the structure itself or the arrangement of fibers on or near the fabric surface.

A number of different methods are used to coat nonwovens depending on the viscosity requirements of the coating material and the amount and location of coating desired. Knife-over-roll (blade coating), reverse-roll, air-knife, wire-wound rod, transfer-roll, rotary screen, and slot-die methods are used to apply continuous coatings to single surfaces. Double-surface coating of relatively nonporous nonwovens with high viscosity materials can be achieved by using dip saturators or size presses with gapped or low pressure squeeze rolls. Impregnation of substantially porous nonwovens can be achieved by using the same equipment at higher roll pressures. Patterned coatings or decorative printing can be achieved with the use of gravure rolls or rotary screens. Likewise, fabrics can be impregnated with different impregnants either side, using rotary screens followed by a pair of nip rolls.

Transfer roll, rotary screen, saturation, size press, and gravure apparatus are similar to those used for resin bonding. Reverse-roll coaters are similar in configuration to gravure print-bonding apparatus, but differ in the surface patterning and direction of rotation of the applicator roll. The amount of material applied when using this method is controlled by adjusting the relative speeds of the applicator roll and the rate of fabric passage through the coating system.

In knife-over-roll or blade coating, the coating material is placed on the fabric surface behind a knife, or doctor blade, and metered according to the gap set between the blade and the fabric surface. This method is used to apply thick coatings of highly viscous materials such as pastes, plastisols, or foams.

Air-knife coating is a high speed process used to apply continuous coatings of relatively low viscosity materials onto nonwovens with irregular surfaces. The principal components of this system are illustrated in Figure 8. Following an initial application, the coating material is metered by air impingement.

Wire-bar (Mayer) coating is used to uniformly coat lightweight material applications. As in air-knife coating, the material is applied initially at a first station, but in this system, the coating material is metered and levelled by a wire-wound rod. Coating weight and uniformity are controlled by changing wire thickness and pitch on the metering rod.

Transfer-roll or flexographic coating is used to apply continuous coatings of low or medium viscosity materials at high speeds. This system is particularly suitable for coating stiff or irregularly surfaced nonwovens and for applying abrasives. With high viscosity materials and appropriately designed gravure rolls, flexographic coaters can be used as pattern applicators for decorative prints.

Rotary-screen coating is also used to apply either continuous or discontinuous coatings to nonwovens. The screen is a sleeve, perforated according to a mesh size which corresponds to the size and number of hole per unit area of surface. A

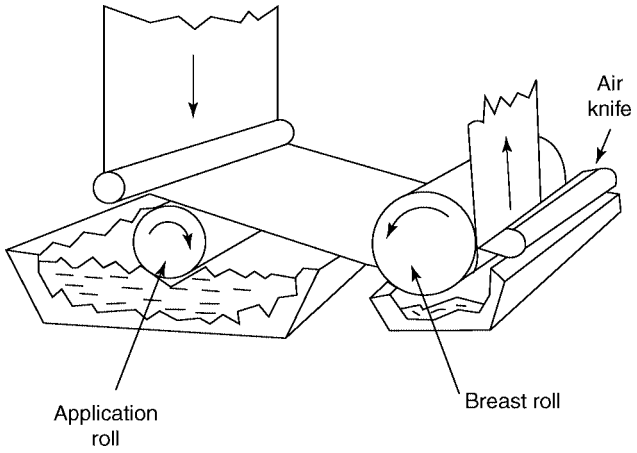

Fig. 8. Components of an air-knife coating apparatus.

material supply tube and squeegee blade are fitted inside the screen. The coating material, in the form of a paste or foam, is forced by the blade through the perforations of the rotating screen onto the nonwoven. For a given coating material, coating weight and penetration are controlled by varying mesh size and squeegee pressure. Patterned coatings or printed designs can be achieved by blocking out selected perforations.

Slot-die or extrusion coating involves the application of molten polymer resin through a slot die directly onto the surface of a nonwoven. Upon extrusion, the resin is smoothed and quenched by a cooling roll. Coating weight is controlled by slot size and extrusion rate. In a variant of this method, nonwoven fabrics are combined with an extruded film just after the die and before the roll-stack. The fabrics can be subsequently chemically bonded to give a sandwich structure. Such products are used as waterproof insales in shoes.

Various chemical finishes can be applied by impregnation, spraying, etc. These include softeners, flame retardants, and antistatic, antisoil, water-repellent, and antibacteria finishes.

Finally dyeing and printing can be included as examples of chemical finishing of nonwovens.

Mechanical and Thermomechanical Methods. These methods provide nonwovens with patterned surface structures, enhance the surface texture of nonwovens, or both. Patterned surfaces may be established by embossing, by compressive shrinkage, and for needle-felted nonwovens, by creating loops or pile. Surface textures, ranging from flat and smooth to raised and levelled, may be created or altered by calendering, sueding, napping, polishing, brushing, or shearing. In general, mechanical finishing processes operate at speeds slower than web-consolidation processes and, consequently, are carried out off-line or as a separate batch process.

Smooth surfaces are normally established by calendering, a process which subjects the fabric at the nip point(s) of two or more rolls to the influence of controlled time, temperature and pressure. When calendering is used as a

thermal-bonding process, the rolls are of the same dimension and composition and are independently driven. However, when calendering is used as a fabric finishing operation, the rolls are frequently of different dimensions and composition and are not always independently driven.

Specific terms have been designated according to the function and composition of various rolls. Steel rolls that impose pressure, transmit heat, and emboss a pattern onto the fabric are known as pattern rolls. Flexible surface rolls that transport the fabric and permit pressure transmission to the fabric are termed bowl rolls or bowls. Bowl rolls are usually larger in diameter than pattern rolls. The material used to make these types of rolls is chosen according to the depth of surface smoothness to be placed on the fabric being calendered, and must be compatible with the pattern roll.

Calender designations include embossing calenders, friction calenders, and compaction calenders. Most embossing calenders are fitted with a main pattern roll and either one or two bowl rolls which are positively driven by the pattern roll through interconnecting gearing. In friction calendering, the rubbing action is accomplished by operating the pattern rolls at higher rates than their bowl counterparts. Compaction calendering establishes desired fabric thicknesses or calliper through adjustable gapping or roll spacing.

Sueding is a mechanical finishing process in which fibers on the surface of a fabric are cut by the abrasive action of a sanding roll operating at relatively high speed. The cut fibers are oriented in the direction of the sand roll rotation and protrude about a millimeter from the surface. The primary components of a sueding machine are the guiding system, sanding roll, support roll, and roll spacing structure and control. Sueding is sometimes used to reduce the gauge and raise the surface of synthetic leather materials.

The napping process mechanically raises fibers to the surface of a lubricated fabric by withdrawing the fibers from the interior of the fabric. A planetary napping machine configuration is shown in Figure 9; basic components include a series of working rolls wound with hooked wire and a fabric guiding system. The working rolls are operated in a direction opposite the fabric and at surface speeds greater than the fabric passage speed. The napping action takes place as

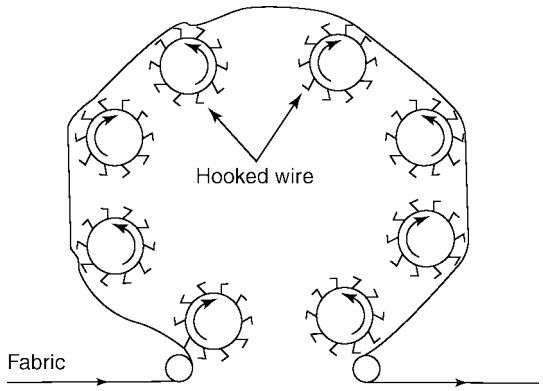

Fig. 9. Planetary napping machine configuration.

the wires of the working rolls penetrate the fabric, withdraw fibers, and form a nap of raised fibers on the surface of the fabric. Depending on wire design, wire wrapping pattern, roll arrangement, number of rolls, and relative roll rotation and direction, nappers can be used to produce a wide range of either loop or velour surface effects.

Polishing is a thermomechanical process that aligns the pile of a raised fabric surface. Polishing machine components include a guiding system consisting of a tension blanket and a spirally grooved heated cylinder. The mechanical action of the rotating edge of the roll groove against the tensioned fabric surface results in a static charging of the pile fibers, which in turn aligns the fibers in a parallel orientation. Rotation of the spiral roll in the direction that momentarily entraps fibers in the grooves results in a raised, parallel pile surface. Rotation of the spiral roll in the opposite direction results in a flat, parallel pile surface.

Brushing is a mechanical finishing process that lifts fibers to the fabric surface and aligns the raised fibers along the machine direction of the fabric. Brushing machinery is similar in configuration to both sueding and napping machinery, but the composition of the working roll is different. Straight-wire clothing is used in brushing machine rolls. As the working roll rotates against the fabric surface, the straight wire withdraws and orients the fibers along the direction of fabric passage through the machine. The length of fiber withdrawn is determined by the gap adjustment between the working and support rolls.

Shearing cuts raised fibers to uniform heights. Fabric shearing generally follows a brushing operation and consists of subjecting the fabric surface to a series of spirally wound shearing blades rotating over a stationary ledger blade. The working elements of a shearing machine are similar in configuration to a reel-type lawn mower. In operation, the fabric is guided under the shear blades while the pile is held in a raised position by vacuum. As the fabric passes a shearing point, the raised fibers strike the ledger blade and are cut by the rotating shear blades. Cut pile height is controlled by adjustment of the distance between the fabric guide and the rotating blades.

Tumbling can be used to soften chemically bonded fabrics—this technology was developed for leather and involves breaking of internal bonds in the structure to provide increased softness and suppleness.

The addition of some shrinkage fibers enables the fabric to be shrunk by heating to an appropriate temperature. This technique is often used to increase the density of a needled fabric and is employed in the manufacture of synthetic leather—after needling, the fabric is shrunk and then chemically bonded.

Another process commonly used in synthetic leather manufacture is splitting. A thick and dense, chemically bonded needlefelt is split up to six times to provide material for shoe-linings, handbags, etc.

Production

Total consumption of nonwovens in 2001 was around 3 million tons and was thought to be growing to about 4 million tons by 2005. Ninetynine percent of all nonwovens are made from synthetic fibers. Polypropylene predominates (63%), with polyester being second (23%) and viscose rayon third (7%).

The United States continues to be the major nonwoven producer (37%), then Western Europe (29%), followed by Japan (8%) and China (6%). Production in China is growing quickly—especially in spunbonded and spunlace fabrics.

Production according to manufacturing technology is approximately as follows: highloft 26%, spunbonded 17%, needlepunched 10%, bonded pulp 8%, thermal-bonded carded webs 7%, hybrids 7%, resin-bonded carded webs 6%, spunlace 5%, wet-laid 5%, meltblown 4%, and the rest 5%.

The majority of card-resin-bonded and card-thermal-bonded fabrics are used as coverstock; interlinings, wipes, and carrier sheets account for most of the remainder. More than half the highloft volume is used in furniture and sleeping applications; filtration, apparel, insulation, healthcare, with geotextiles accounting for most of the remainder. Stitchbonded fabrics are used in bedding, shoe linings, and a variety of coated products. Needlepunch fabrics are used in automotive, geotextiles, filtration, bedding, and home furnishing applications.

The major use for spunlace fabrics is in medical products; other applications include wipes, industrial apparel, interlinings, absorbent components, filtration, and coating. Medical applications account for about a third of all wet-laid nonwovens. Most bonded pulp fabrics are used as wipes or as absorbent components.

Spunbondeds are commonly used for coverstock, geotextiles, roofing substrates, carpet-backing, medical products, filtration, furniture, and packaging. Meltblown fabrics, because of their relatively fine fiber structure, is commonly used in filtration, sorbents, wipes, and sanitary products.

Applications

Nonwoven goods applications split into disposables and durables, with disposables being the major share.

Coverstock is the nonwoven fabric placed on the user's side of sanitary absorbent products such as baby diapers, nappy liners, adult diapers, incontinence products, and feminine hygiene products. Medical and surgical products include protective wrap for hospital items which are distributed through the central supply room; surgical drapes, packs, and gowns; other protective products such as face masks, caps, aprons, bibs, and shoe covers; absorbent products such as surgical dressings and sponges; and other hospital products such as isolation gowns, examination gowns, sheets, shrouds, underpads, and bedding.

Nonwoven wipes includes products for babies and adults, the food service and electronics industries, medical and clean room applications, dusters, shoe cleaning cloths and hand towels. Nonwoven fabrics are used to filter air, water, petroleum, food, and beverages. Nonwovens loaded with abrasives, cleansers, or finishes are used in a wide range of products for cleaning and scouring. Also, many protective garments are made from nonwoven fabrics.

Durable products include geotextiles, for example, to stabilize earth works, roads, landscaping, etc. In agriculture, nonwovens are used as protective or capillary mats, shading, and windbreaks.

In aircraft, nonwovens are used as reinforcement media in composites and lightweight insulation. In electronic components, nonwovens are used as battery separators, and in cable insulation—nonwovens of superabsorbent fiber have been

used as cablewrap to protect the core from the ingress of water. Vehicle applications include moldable carpet backings, headlinings, and interior trim. In building construction, nonwovens are used for roofing, insulation, and water-impermeable wrappings. In furniture and bedding, nonwovens are used as decking and ticking, quilt backings, carpet backings, underlays, wallcoverings, and padding. In shoes, chemically bonded nonwovens are used as shoe stiffeners and insoles. Uppers and linings are made from synthetic leather which comprises chemically bonded nonwovens made from microfibers.

NUCLEAR MAGNETIC RESONANCE

Introduction

An important objective in materials science is the establishment of relationships between the microscopic structure or molecular dynamics and the resulting macroscopic properties. Once established, this knowledge then allows the design of improved materials. Thus, the availability of powerful analytical tools such as NMR spectroscopy (1–13) is one of the key issues in polymer science. Its unique chemical selectivity and high flexibility allows one to study structure, chain conformation and molecular dynamics in much detail and depth. NMR in its different variants provides information from the molecular to the macroscopic length scale and on molecular motions from 1 to 10^{10} Hz. It can be applied to crystalline as well as to amorphous samples which is of particular importance for the study of polymers.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Moreover, NMR can be conveniently applied to polymers since they contain predominantly nuclei that are NMR sensitive such as ^{1}H and ^{13}C.

Although well established for liquid-like samples such as macromolecules in solutions (14,15), the applications of NMR to solid or solid-like polymers is more demanding because of the presence of anisotropic interactions that complicate the analysis of the results. Several techniques for the removal of these interactions have thus been developed and are nowadays in a state where they could be routinely applied. Nonaveraged anisotropic interactions on the other hand provide valuable information that is lost in the solution state. Thus, while it is often necessary to remove the anisotropic interactions, in many cases one would simultaneously like to preserve them in order to exploit their information content.

This is where two-dimensional (2D) spectroscopy comes into play (1), for instance, by correlating one-dimension where the anisotropic interactions are preserved with a (high resolution) dimension where they are removed. Multidimensional NMR spectroscopy proves to be a powerful method to reveal structural and dynamical information at the molecular level in elastomers (16). Residual dipolar couplings can be measured site-selectively and correlated with the cross-link density and mechanical stress. The local segmental order and information on local molecular motions can also be obtained with newly developed 2D NMR methods (16). The information at the molecular level can be correlated with macroscopic properties of elastomers and provides the basis for a better design of material properties for specific applications.

From the viewpoint of NMR, elastomers, and other viscoelastic polymers above their glass-transition temperature exhibit both, solid-like and liquid-like features (12). Whereas the segmental motions give rise to the liquid-like behavior, the presence of permanent or nonpermanent cross-links leads to residual dipolar couplings, that is responsible for the solid-like properties. This promises that both properties can be exploited, but the application of 2D techniques to viscoelastic materials has to deal with the difficulties related to both, rigid and mobile samples (16). Compared with the wealth of applications in solution and in the solid state, NMR has not been widely applied to viscoelastic polymers, although it can provide information on such important areas as the chain dynamics in elastomers, the local structure, residual couplings (induced by chemical cross-links and topological constraints), dynamic order parameters, internuclear distances, intermolecular interactions (which are important for instance for the miscibility), the effects of fillers on molecular motions, and segmental orientation under mechanical stress and others.

NMR imaging finds most of its applications in medical diagnostics of humans and pathology studies of animal models (17–22). The success of the method is based on noninvasiveness of the nuclear magnetic resonance and the unsurpassed soft-matter contrast, which is hard to achieve with competitive methods like X-ray or computer tomography. The same advantages can be exploited in imaging studies related to materials science (19,22). Here, an important class of soft-matter materials is given by synthetic polymers above the glass transition temperature. Apart from Semicrystalline Polymers (qv) like polyethylene, polypropylene, some polyamides, and polymer melts, elastomers constitute the most striking class of synthetic soft matter with a modulus similar to many biological tissues. Applications of imaging for which nondestructiveness or contrast are essential, are

competitive with other imaging techniques in the information gained and the cost of the experiment. Such applications to elastomers concern distributions in temperature, stress, cross-link density, modulus, and the dynamics of fluid absorption and swelling.

The nucleus imaged most often is the proton. The reason is not only sensitivity but also the weak dipolar couplings between protons in a chemical group and between different chemical groups which dominate the signal decay by relaxation. These dipolar couplings are motionally averaged by the often fast but nearly always anisotropic motion of intercross-link chains. This motion and consequently the value of the residual dipolar couplings are affected by chain stiffness, cross-link density, chain orientation, temperature, and additives, etc. Given that the residual dipolar interactions are too strong to obtain chemical-shift resolution without sample spinning or multipulse techniques, relaxation techniques that probe different time regimes of molecular motion provide the primary access to contrast in imaging of elastomers.

After a brief introduction of the basic principles of NMR, the one-dimensional (1D) and two-dimensional (2D) methods that have been applied to viscoelastic materials will be reviewed. NMR imaging which can be considered as a special form of multidimensional NMR will be introduced by discussing principles and image contrast. Illustrative examples of NMR imaging to elastomer materials are given.

Basic Principles of NMR

Magnetic Resonance Phenomenon. Magnetic resonance is a branch of spectroscopy that detects the quantum-mechanical transitions induced by electromagnetic radiation in a system of discrete energy levels of electron or nuclei placed in a static magnetic field. Nuclear magnetic resonance (NMR) employs electromagnetic waves in the radio-frequency range between 900 MHz and 2 kHz.

Nuclear magnetic resonance is one of the most powerful method for structural and dynamics investigation on matter in different states of aggregation. This is due to the following features: (*1*) The interaction of nuclear magnetic moments are very weak compared with the thermal energy, therefore, we deal with nuclear paramagnetism. Moreover, the energy delivered by the radio-frequency generator are much larger compared with the strength of these internuclear couplings. That leads to the possibility to manipulate these interactions in a specific way and to simplify the spectral response. (*2*) The radio-frequency photons have much lower energy compared with the energy of chemical bonds. Therefore, the interaction of electromagnetic radiation with the matter, especially, biomolecules is nonionising. (*3*) The number of radio-frequency photons with a specific frequency is very large. Hence, the phase of the associated electromagnetic wave is very well defined. The high degree of coherence of radio-frequency radiation is essential for implementation of NMR experiments including magnetic resonance imaging (MRI).

The appearance of NMR spectra, and consequently the molecular structure they are able to provide, arises from the discrete nature of the energy levels pertaining to a nuclear spin system. The energy levels are mainly a result of the

Zeeman interaction $-\vec{\mu}\cdot\vec{B}_0$ between the static magnetic field of induction $\vec{B}_0$ and nuclear magnetic moment $\vec{\mu}$. The quantum-mechanical quantity called spin momentum $\vec{I}$ is related to magnetic moment by $\vec{\mu}=\gamma\hbar\vec{I}$, where γ is the magnetogyric ratio and $\hbar$ is the Planck constant divided by 2π.

In the absence of the magnetic field the nuclear spin states are degenerated (see Fig. 1**a**). The application of a static magnetic field $\vec{B}_0$ induces a magnetic interaction described by the Zeeman Hamiltonian $H=-\vec{\mu}\cdot\vec{B}_0$. Taking the magnetic field orientation to be along the z-direction we get

$$H=-\gamma\hbar B_0 I_z \tag{1}$$

The eigenvalues E_m of this Hamiltonian can be evaluated from the Schrödinger equation

$$H|m\rangle=-\gamma\hbar B_0 m|m\rangle \tag{2}$$

where $|m\rangle$ is the eigenstate corresponding to the eigenvalue $E_m=-\gamma\hbar B_0 m$. The magnetic quantum number is m where $m=I, I-1,\ldots, -I$. Therefore, the equidistant energy differences are for the single-quantum transitions $\Delta m=\pm 1$ given by

$$\Delta E=\hbar\omega_0 \tag{3}$$

where the Larmor frequency is $\nu_0=\nu_{\mathrm{L}}=\omega_0/2\pi$. Energy level diagrams of a spin $I=1/2$ and $I=1$ are shown in Figure 1.

Another important ingredient for a magnetic resonance experiment is represented by the presence of the radio-frequency (rf) field. Only the magnetic component of the electromagnetic field, ie, $\vec{B}_1(t)=\vec{B}_{10}\cos(2\pi\nu t)$ interacts with the magnetic moment of the nuclei. The amplitude of the rf field is $\vec{B}_{10}$ and ν is the carrier frequency. This field is produced by a rf coil and leads to a perturbation Hamiltonian

$$H_{\mathrm{p}}=-\gamma\hbar\vec{B}_{10}\cdot\vec{I}\cos(2\pi\nu t) \tag{4}$$

From time-dependent perturbation theory of quantum-mechanics, it can be stated that a transition between two states $|\psi\rangle$ and $|\phi\rangle$ is allowed provided that $\langle\psi|H_{\mathrm{p}}|\phi\rangle\neq 0$. This takes place if $\nu\approx\nu_0$ (ie, the resonance condition) and the alternative magnetic field $\vec{B}_1(t)$ is polarized perpendicularly to the static magnetic field $\vec{B}_0$. Concerning a spin $I=1$ (Fig. 1**b**), similar calculations show that only the single-quantum transitions $|0\rangle\rightarrow|1\rangle$ and $|-1\rangle\rightarrow|0\rangle$ (and those in the opposite directions) are allowed in the first approximation and occur at the same frequency, given by equation 3.

Quantitative spin system evolution in the presence of the interspin couplings has to be described in the language of quantum-mechanics. This is a reflection of the quantum-mechanical nature of the spins and the fact that the spin couplings via propagator operators encode NMR observables. Nevertheless, the description of nuclear magnetization relaxation processes is done by a semiclassical approach

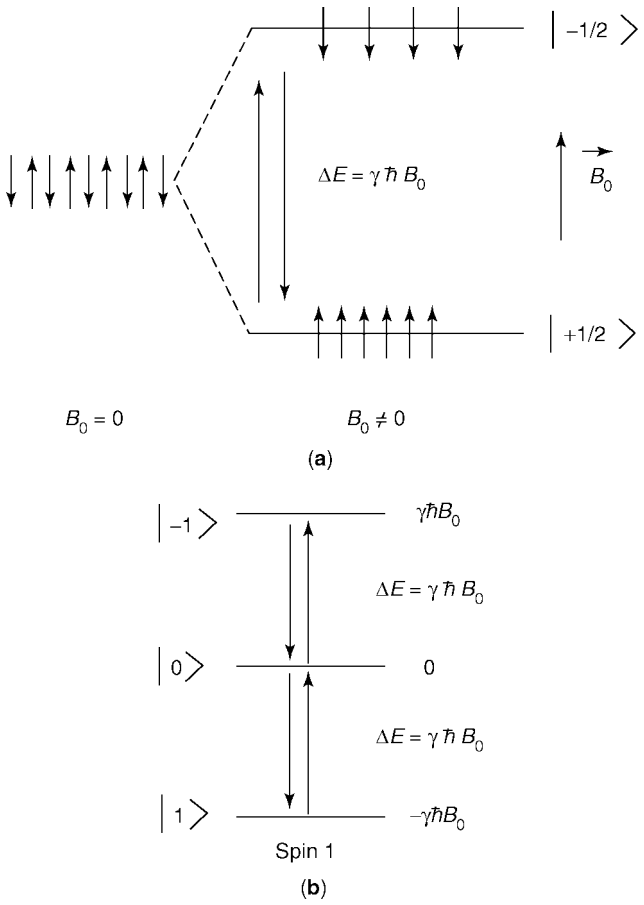

Fig. 1. (**a**) Energy levels diagram and allowed transitions of an ensemble of spins with $I = 1/2$ in the absence and the presence of $\vec{B}_0$. The small arrows indicate the orientation of nuclear spins relative to $\vec{B}_0$. (**b**) Energy diagram and allowed single-quantum transitions for spins with $I = 1$.

where the thermal bath is described classically and the spin system by a quantum-mechanical formalism.

In general, the NMR experiments are performed at high temperatures employing a large number of spins. These features lead to the possibility to treat classically some aspects of the experiments. The excess of spins oriented along the static magnetic field $\vec{B}_0$ with respect of those oriented in the opposite direction (cf Fig. 1**a**) results in a macroscopic nuclear magnetization $\vec{M}$ aligned along the static magnetic field, which is called equilibrium magnetization (cf Fig. 2**a**). It can be displaced from this equilibrium by an appropriate perturbation, for instance, by a rf excitation. It is then subject to a precessional motion around $\vec{B}_0$ with the Larmor frequency ν_L (Fig. 2**b**). The electromagnetic perturbation which brings $\vec{M}$ into a plane perpendicular to $\vec{B}_0$ allows the observation of the Larmor precession through an electromotive force which occurs in a coil whose axis is

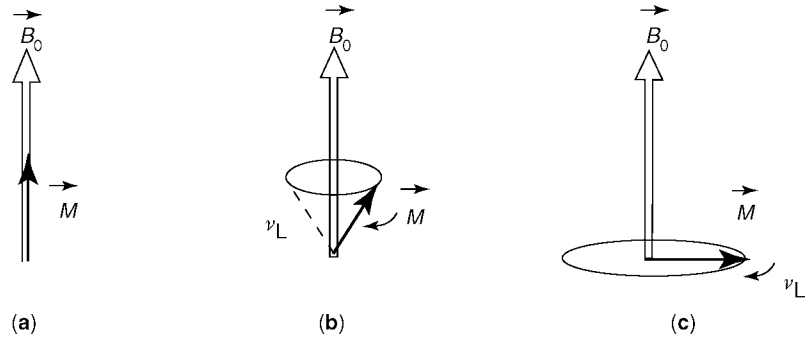

Fig. 2. (**a**) At thermal equilibrium, the nuclear magnetization $\vec{M}$ is collinear with $\vec{B}_0$. (**b**) Under the action of an electromagnetic perturbation $\vec{M}$ is displaced from equilibrium position. It starts undergoes precessional motion around $\vec{B}_0$ at the Larmor frequency $\nu_L = \nu_0$. (**c**) After the action of a 90° rf pulse the magnetization $\vec{M}$ is brought in a transverse plane to $\vec{B}_0$.

contained in that plane (Fig. 2**c**). This can be done by rotation of the nuclear magnetization using a resonant 90° rf pulse. The nuclear magnetization M can be oriented antiparallel to $\vec{B}_0$ by the action of 180° pulse. The majority of NMR experiments used pulse sequences composed of 90° and 180° rf pulses.

Magnetic and Electric Spin Interactions. The nuclear spins can experience various external and internal interactions. These interactions can have magnetic or electric origin. The external interactions are, in general, represented by the Zeeman interactions with static and rf magnetic fields and the gradients of these fields.

The chemical shielding, dipole–dipole, spin–spin indirect coupling or J-coupling, spin-rotation, and hyperfine couplings represent the major internal magnetic interactions. The quadrupolar interaction has an electrostatic character. All these interactions have a tensorial character, ie, are function on the orientation of the principal axes of the tensor relative to the direction of $\vec{B}_0$. They are relevant for solid polymers below and around the glass transition temperatures. For polymer in solution or for soft polymers fast molecular motions average these anisotropic interactions to isotropic or residual values which can be zero. Detailed description of the properties of these spin interactions can be found in References 1–9.

In the studies of elastomers by NMR experiments dipolar and quadrupolar interactions have been mainly used. The presence of the high magnetic field already imposes a manipulation of the spin system which separates certain parts of the spin interaction Hamiltonian. This process is called truncation and the secular dipolar Hamiltonian of two spins I and S has the general form

$$H_{\mathrm{d}}^{(0)} = -\left(\frac{\mu_0}{4\pi}\right)\frac{\gamma_I\gamma_S}{r^3}\frac{1}{2}(3\cos^2\theta_{IS} - 1)(3I_zS_z - \vec{I}\cdot\vec{S}) \qquad (5)$$

The factor $\mu_0/4\pi$, where μ_0 is the magnetic susceptibility of vacuum has been introduced in conformity with MKSA units. The magnetogyric ratios are γ_I and

γ_S. The spin operators are denoted by $\vec{I}$ and $\vec{S}$. The space encoded part of the dipolar Hamiltonian depends on the distance r of spins I and S and the angle θ_{IS} between $\vec{r}$ and $\vec{B}_0$. The anisotropic segmental motions average the space part of $H_{\mathrm{d}}^{(0)}$ to a residual value.

Finally, the truncated form of the axially symmetric quadrupolar Hamiltonian for nuclei with spin I larger than 1/2 can be expressed as

$$H_{\mathrm{Q}}^{(0)} = C_{\mathrm{Q}}\left[3I_z^2 - \vec{I}^{\,2}\right] \tag{6}$$

The quadrupolar coupling C_{Q} is defined by

$$C_Q = \frac{eQV_{\mathrm{ZZ}}}{4hI\,(2I-1)} \tag{7}$$

where eQ is the quadrupolar moment of a specific isotope and V_{ZZ} is the Z component of the electric field tensor at the position of the nucleus. In the presence of anisotropic molecular motions, the electric field gradient tensor is averaged to a residual value.

The spin interactions can be classified as inhomogeneous and homogeneous (4). The NMR spectrum generated by the inhomogeneous spin interaction which is linear in the spin operator I_z, is a sum of independent individual lines. A selective rf irradiation can saturate only a group of spins producing a hole in the spectrum. For homogeneous lines the NMR spectrum is a sum of individual lines with no shift with respect to each other. The spin interactions bilinear in the spin operators generate these spectra. The excitation of the spectrum with a selective pulse will affect all the spectral frequencies.

Magnetization Relaxation. One of the important sources of information about molecular motions is related to the relaxation of the longitudinal (M_z) and transverse (M_x and M_y) components of the macroscopic nuclear magnetization. The molecular motions modulate the spin interactions that lead to the exchange of energy between the nuclear energy levels and the lattice or thermal bath represented by the molecular degree of freedom. This process is described by a time constant T_1 the so-called longitudinal relaxation time. The dephasing of the transverse magnetization components M_x and M_y, which is related to the increase of the entropy of the spin system is described by the transverse relaxation time T_2.

The molecular motions responsible for the relaxation include: (*1*) overall translational or rotational motions, (*2*) local motions such as internal rotations around C—C bonds or molecular axis of symmetry or segmental motions of polymer chains, and (*3*) exchange between two different distinct chemical sites within the same molecule or different molecules.

In the simplest assumption, the time evolution of the nuclear magnetization under relaxation processes can be described by the Bloch equations (see (19), and

references therein)

$$\frac{dM_{x,y}(t)}{dt} = \frac{M_{x,y}(t)}{T_2}$$
$$\frac{dM_z(t)}{dt} = -\frac{M_z(t) - M_0}{T_1} \tag{8}$$

where M_0 is the magnetization of the spin system in the thermodynamic equilibrium. The time evolution of $\vec{M}(t)$ vector under relaxation processes described by equation 8 is given by exponential functions. This approximation is not valid in many cases for polymer or other macromolecular systems where complex relaxation mechanisms are present (23,24). In such cases, a complete treatment requires additional relaxation parameters such as cross-relaxation or cross-correlation rates (1,23–25). Such a situation occurs whenever two spins A and X interact by a random fluctuating spin interactions. For this cross-relaxation process A spins magnetizations induces a modification of X magnetization which add up to the specific evolution of X magnetization. More formally, this coupling can be expressed via the Solomon equations (see for instance, Reference 25) which contain besides the longitudinal relaxation rates of spins A and X also cross-relaxation rate which reflects the coupling between the A and X spin magnetizations. Several two-dimensional NMR experiments (see below) can measure cross-relaxation rates that enhance our knowledge about molecular motions in complex systems (1,25).

The longitudinal magnetization relaxation can be measured using different methods (5,18,19,25) based on the scheme:

$$\text{Initial perturbation} - \text{Evolution}\ (\tau) - \text{Detection}$$

The initial perturbation brings the spin system in a state on nonequilibrium and can be represented by an inversion pulse of 180° (ie, $M_z(0) \rightarrow -M_0$) or a saturation train of 90° pulses (ie, $M_z(0) = 0$). The detection is performed by a standard 90° pulse under low or high resolution conditions.

The transverse relaxation measurements are performed using a Hahn echo (see below) or Carr–Purcell–Meiboom–Gill (CPMG) pulse sequences (18,19). The first method uses the pulse scheme: $90^\circ_x - \tau - 180^\circ_{x,y} - \tau -$ Hahn echo and measure the time evolution of the amplitude of the Hahn echo as a function of echo time 2τ. CPMG scheme, $90^\circ_x - [\tau - 180^\circ_y - \tau -$ Hahn echo$]_N$ allows measuring the transverse magnetization decay in a single scan using a train of N Hahn echoes.

The mechanisms of relaxation are produced by local magnetic fields originating from randomly fluctuating spin interactions like homonuclear or heteronuclear dipolar, quadrupolar or chemical shielding interactions. They would induce quantum-mechanical transitions in the Zeeman energy levels manifold whose effect would be to take the nuclear magnetization back to the equilibrium configuration. When performing a spectra decomposition of these fluctuating local fields $\vec{h}(t)$ (which are in general, tensorial quantities), we can find a nonzero component frequencies equal to those of the various transitions which can exist within the Zeeman energy level diagram. Efficiency of the local magnetic fields to induce

transitions can be appreciated by the quantities named spectral densities of the form

$$J_i(\omega) = \int_0^\infty \overline{h_i(t)h_i(0)}\, \exp(-i\omega t)\, dt \tag{9}$$

where $h_i(t)$ is the random fluctuating i component of local fields. The bar denotes an average over the ensemble of spin systems. On the other hand, a quantum-mechanical transition can be induced by a fluctuating local field at the condition that a certain degree of coherence is present. The autocorrelation function $C(t) = \overline{h_i(t)h_i(0)}$ is indicative of this coherence that essentially persists for a time equal with the correlation time τ_c. A more general correlation function is represented by space–time autocorrelation function $C(\vec{x}, t)$, where $\vec{x}$ is a general spatial coordinate meant to represent translational or rotational coordinates. These correlation functions will turn out to be necessary in the context of characterization of two-dimensional (2D) exchange spectra (2). Moreover, a three-dimensional (3D) spectrum, being a three-time distribution, contains information that cannot be directly retrieved from the 2D spectrum. The detailed information on the nature of the nonexponential loss of correlation in polymers obtained from reduced four-dimensional (4D) exchange spectrum is also not accessible in the corresponding one-dimensional relaxation measurements and the 2D exchange spectrum (2).

Molecular processes with a single correlation time are rarely found in partially or strongly disordered solids like semicrystalline or amorphous polymers. A distribution of the correlation times $g(\tau)$ has to be introduced in order to evaluate the correlation function (2), ie,

$$C(t) = \int_0^\infty \exp\left\{-\frac{t}{\tau}\right\} g(\tau)\, d\tau \tag{10}$$

Such distribution has been shown to span several orders of magnitude for instance in the case of local motions in the glassy state. Instead of the distribution function, other fitting functions for correlation function $C(t)$ are considered. One of these functions is the stretched exponential Kohlraush–Williams–Watts function $\exp\{-(t/\tau_{\mathrm{kww}})^\beta\}$ that has been found to fit the data quite universally (2).

Spin Coherences. In all NMR experiments the spin system evolves under internal and external spin interactions. For isolated spins, the spin dynamics can be described in terms of the motion of classical magnetization vectors. Many structural and molecular dynamics problems in NMR involve couples spins. In this case, it is necessary to recourse to a quantum—mechanical formalism where a density operator describes the state of the system (1).

The density operator $\rho(t)$ is a generalized wave function which describes a so-called mixed state. This state corresponds to a statistical ensemble of quantum-mechanical objects, which in our case is a collection of nuclei with magnetic moments. Therefore, the statistics specific of these objects and the statistics of an ensemble are simultaneously present.

The equation of motion for the density operator is given by Liouville–von-Neumann equation

$$i\frac{\partial\rho(t)}{\partial t} = [H(t), \rho(t)] \tag{11}$$

where $H(t)$ is the Hamiltonian or total energy operator of the system expressed in angular frequency units, which may itself be time dependent. In general, equation 11 does not have an exact solution. Several mathematical methods have been applied to obtain an approximate solution for $\rho(t)$ one of the most efficient and accurate being the Floquet technique (1). The dynamics of the spin system detected via an observable $\langle O(t)\rangle$ described by a quantum-mechanical operator O can be evaluated by

$$\langle O(t)\rangle = \mathrm{Tr}\{O\rho(t)\} \tag{12}$$

Thus, the expectation value is found by evaluating the trace of the product of the observable operator and the density operator.

A particularly simple interpretation of the density matrix is possible in the eigenbase of the Hamiltonian H. The diagonal element ρ_{rr} is equal to the probability that the spin system is found in the eingenstate $|r\rangle$. The population of state $|r\rangle$ is P_r and therefore, $\rho_{rr} = P_r$. The off-diagonal element is defined by

$$\rho_{rs} = \langle r|\rho(t)|s\rangle = \overline{c_r(t)c_s^*(t)} \tag{13}$$

where the bar indicates an ensemble average. These elements describe a "coherent superposition" of eigenstates $c_r(t)|r\rangle + c_s(t)|s\rangle$ in the sense that the time dependence and the phase of the various members of the ensemble are correlated with respect to $|r\rangle$ and $|s\rangle$. Such a coherent superposition is simply called "coherences". A spin coherence can be associated with a transition between two eigenvalues specified by the eigenstates $|r\rangle$ and $|s\rangle$. If the two states span an allowed transitions with a difference in magnetic quantum numbers $\Delta M_{rs} = M_r - M_s = \pm 1$, the coherences ρ_{rs} is related to the NMR observables represented by the transverse magnetization components $M_x^{(rs)} \pm iM_y^{(rs)}$. In general, a matrix element of the density operator ρ_{rs} represents p-quantum coherence for which $p = M_r - M_s$, which, for $p \neq \pm 1$, does not lead to observable magnetization and can only be detected indirectly by two-dimensional spectroscopy (1,26).

The density operator $\rho(t)$ has been formulated for the entire quantum-mechanical system. For magnetic resonance applications, it is usually sufficient to calculate expectation values of a restricted set of operators which act exclusively on nuclear variables. The remaining degrees of freedom are referred to as "lattice". The reduced spin density operator is defined by $\sigma(t) = \mathrm{Tr}_1\{\rho(t)\}$, where Tr_1 denotes a partial trace over the lattice variables. The reduced density operator can be represented as a vector in a Liouville space of dimension

n^2, ie,

$$\sigma(t) = \sum_{r}^{1,n^2} b_r(t) B_r \tag{14}$$

where n is the dimension of the Hilbert space of all admissible state functions and $\{B_r\}$ is a complete set of orthogonal base operators. A proper selection of this base is often essential to ease the solution of a particular spin dynamics problem. For instance, for systems with spins $I_k = 1/2$ the product of the Cartesian spin operators is a convenient base operators (1,27). As an example, the complete set of product operators $\{B_r\}$ for two J or dipolar coupled nuclei with spin $I = 1/2$ consists of $2^{2\times 2} = 16$ operators, ie,

$$\frac{1}{2}E \text{ (E is the unity operator)}, I_{ix}, I_{iy}, I_{iz}$$

$$2I_{ix}I_{jx}, 2I_{iy}I_{jy}, 2I_{iz}I_{jz}, 2I_{ix}I_{jy}, 2I_{ix}I_{jz}, \text{ for } i,j = 1,2 \tag{15}$$

The spin modes described by the product operators of equation 15 are the matrix elements of the density operator

$$\rho = \begin{pmatrix} P_1 & \text{SQ} & \text{SQ} & \text{DQ} \\ \text{SQ} & P_2 & \text{ZQ} & \text{SQ} \\ \text{SQ} & \text{ZQ} & P_3 & \text{SQ} \\ \text{DQ} & \text{SQ} & \text{SQ} & P_4 \end{pmatrix} \tag{16}$$

The above product operators can be detected by a proper design NMR experiment (1,26) and reflect different features of the spin systems related to the structure, spin interaction topology, and molecular dynamics. The most popular spin modes are represented by single-quantum coherences (SQ) of spin i, I_{ix} and I_{iy} that are related to x- and y-magnetizations, respectively. Two-spin coherences of spin i and j consist of superposition of $p = 0$ (zero-quantum (ZQ)) and $p = \pm 2$ (double-quantum (DQ)) quantum coherences. The former is insensitive to the inhomogeneity of the magnetic field and the latter is reflecting the existence of spin couplings. Not only the existence of J- or dipolar couplings can be detected by editing DQ coherences but also the strength of these couplings can be measured including internuclear distances and dihedral angles (27–29).

Spin-Echoes. The evolution of spin coherences under nonfluctuating spin interactions is a reversible process. The strength and sign of the spin Hamiltonians can be manipulated by rf pulses and/or sample rotation such that the evolution of the spin system during a period of time is refocused during the spin system evolution at a latter time.

The spin interactions described by inhomogeneous or homogeneous spin Hamiltonians lead to inhomogeneous and homogeneous spin-echoes. If a linear superposition of both types of spin Hamiltonians is present, a mixed spin-echo can be generated. The most common used inhomogeneous echoes are: Hahn (30),

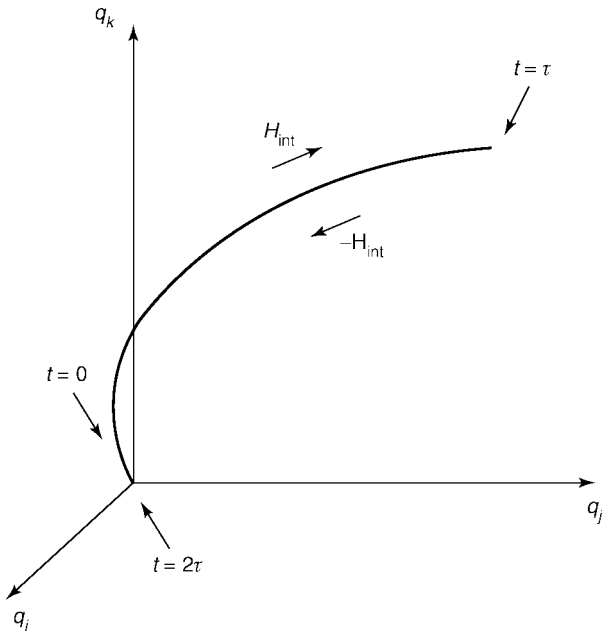

Fig. 3. Evolution of the quantum-mechanical state of a spin system in a Liouville space. The evolution from the initial time $t = 0$ to an intermediate time $t = \tau$ takes place under a Hamiltonian H_{int} which describes internal and external spin interactions. At this time, a pulse sequence change the sign of the spin Hamiltonian. The spin system evolves on the same generalized trajectory and after total evolution time $t = 2\tau$ the initial state is refocused under a spin echo.

stimulated (30), and gradient echoes (5,18). Solid (31) and magic (32–34) echoes are the most familiar types of homogeneous echoes.

In order to understand how a spin echo can be produced, we shall consider a spin system composed of N nuclei, which interact, or not between themselves. The quantum-mechanical state of such a system can be described by a linear superposition of spin coherences represented by a vector evolving in a Liouville space of dimension 2^{2N} (cf Fig. 3). In this abstract space, the state of the spin system at time $t = 0$ is represented by a configurational point. This state corresponds in many cases to the single-quantum coherences excited after a 90° rf pulse. The spin system evolves in laboratory or rotating reference frames for a time τ, evolution described by the propagator operator $E_{\text{evolution}} = \exp\{-\text{i}H_{\text{int}}\tau\}$, where H_{int} is the spin-interaction Hamiltonian. At the end of this evolution period, a pulse or a complex pulse sequence is applied which change the sign of the Hamiltonian H_{int}. During the refocusing period of duration τ the evolution operator is now $E_{\text{refocusing}} = \exp\{-\text{i}(-H_{\text{int}})\tau\}$. This is formally equivalent with a time reversal, ie, $\tau \rightarrow -\tau$. For the full evolution period 2τ, the propagator is $E_{\text{evolution}}\, E_{\text{refocusing}} = E$, where E is the unity operator and the spin system is reaching the initial state. Hence, a spin echo was generated with an amplitude identical with the free induction decay as long as the magnetization relaxation processes are neglected.

The pulse sequence used for generation of inhomogeneous spin-echo of the Hahn type is shown in Fig. 4**a**. The spin systems for which this echo can be

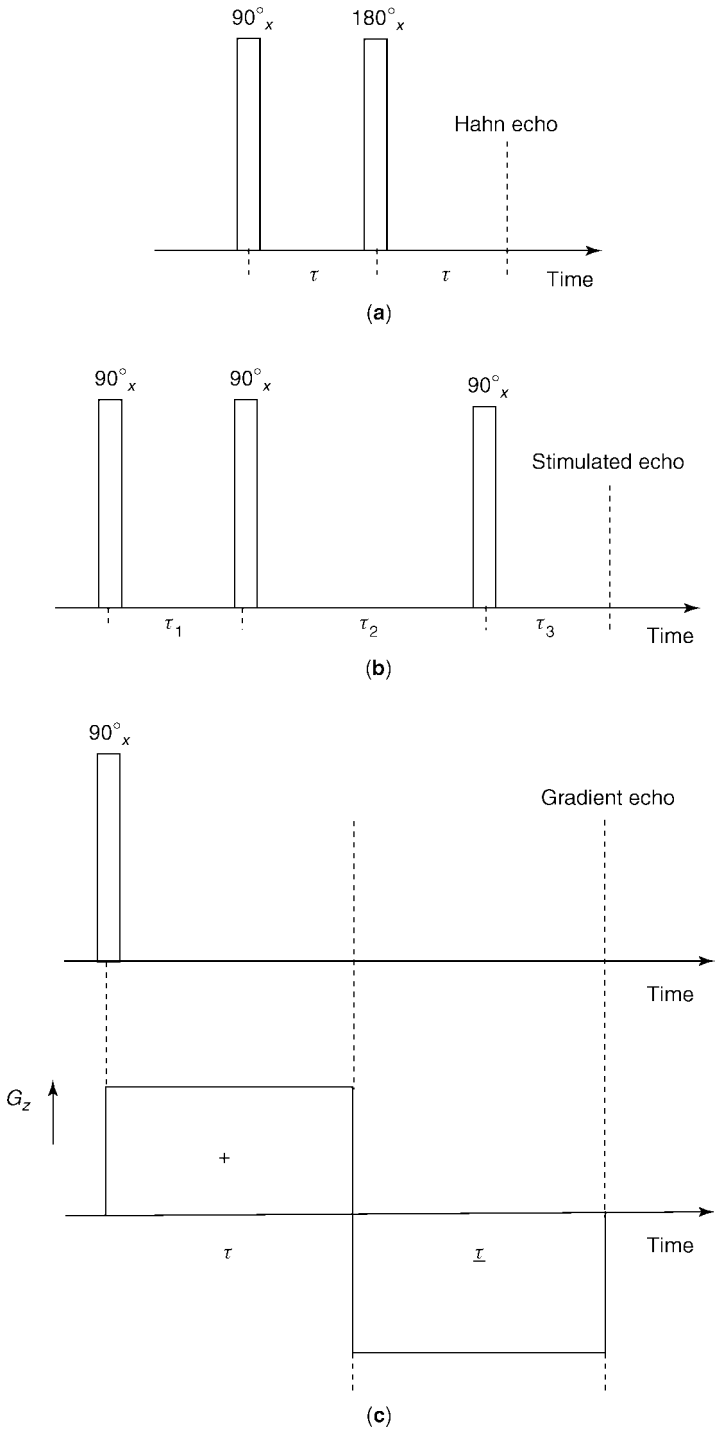

Fig. 4. Pulse sequences used for Hahn echo (**a**), stimulated echo (**b**), and gradient echo (**c**) are shown.

produced are characterized by the Hamiltonian $H_{\text{int}} = -\delta I_z$, where δ describes the inhomogeneity of the magnetic fields or chemical shift distributions. By the action of refocusing 180°_y pulses, the spin operator I_z becomes $-I_z$ and the spin Hamiltonian changes the sign, ie, $H_{\text{int}} = -H_{\text{int}}$. If the transverse magnetization relaxation is neglected, the amplitude of the Hahn echo is equal with the amplitude of the free induction decay generated after 90°_x preparation pulse (cf Fig. 4**a**). The relaxation encoding is given by the factor $\exp\{-2\tau/T_2\}$, where T_2 is the transverse relaxation time. The Hahn echo represents an important tool for measuring residual dipolar couplings, correlation function of molecular motions, and encoding of spatial information and mass transport. If the 180°_x pulse is split in two 90°_x pulses separated by a time τ_2 (cf Fig. 4**b**), a stimulated echo is produced at time τ_1 after the action of the last pulse. This spin-echo has under ideal conditions the amplitude half of the amplitude of FID and the lifetime is much longer compared with that of the Hahn echo. Therefore, it is an ideal instrument for measuring self-diffusion coefficients.

The scheme used for gradient echo is presented in Figure 4**c**. The evolution of the single-quantum excited by a preparation 90°_x pulse under a field gradient G_z is refocused by the filed gradient with the opposite direction $-G_z$. The amplitude of the echo is affected by the presence of the magnetic field gradients inside the sample. This effect is exploited for enhancement of the contrast in MRI.

In many rigid or soft polymers, the protons are dipolar coupled in a complex network. The dipolar Hamiltonian is bilinear in spin operators representing a homogenous interaction. Pulse sequences can be designed that change the sign of the dipolar Hamiltonian H_{d}, ie, $H_{\text{d}} \rightarrow -kH_{\text{d}}$, where k is a scaling factor. An example of such a homogeneous spin-echo is given by magic echo for which $k = 1/2$ (cf Fig. 5**b**). The most simple homogeneous spin echo is represented by solid echo

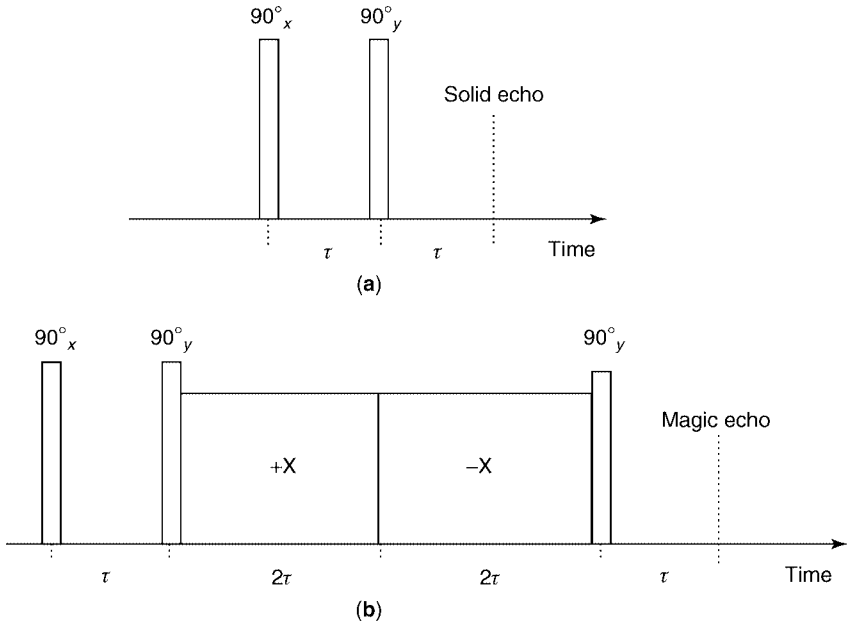

Fig. 5. Pulse sequences used for solid echo (**a**) and magic echo (**b**) are shown.

(Fig. 5**a**). For a spin system composed of spin-1/2 pairs the spin evolution is fully refocused by the solid echo. This is not the case for a multispin dipolar network. These echoes can be used for high resolution NMR spectroscopy of solids, measurement of residual spin interactions, and NMR imaging of rigid polymers.

Two-dimensional Fourier Spectroscopy. Two-dimensional (2D) spectroscopy is a general concept that can be applied to different brunches of spectroscopy which make it possible to acquire more detailed information about the molecular system under investigation. Since the first proposal in the 1971 (35) and the first experimental realization in the 1974 (36–38) a large number of 2D NMR methods have been invented and applied (1) to solve structural and dynamical problems in physics, chemistry, biology, and medicine.

Several strategies can be employed for obtaining a 2D spectrum, which is a signal function $S(\omega_1, \omega_2)$ of two independent frequency variables (ω_1, ω_2) (1). The most popular one is based on the 2D time-domain experiments. In this approach, a time-domain signal $s(t_1, t_2)$ is obtained by incrementing the time interval t_1 parametrically from experiment to experiment, and recording the free induction signal as a function of t_2. In a general case, for a 2D experiment, we distinguish four intervals:

$$[\text{Preparation } (t_p)]-[\text{Evolution } (t_1)]-[\text{Mixing } (t_m)]-[\text{Detection } (t_2)]$$

The four basic intervals have the following qualitative features: (*1*) *Preparation period*: In the course of this period of fixed length the spin system is prepared in a coherent nonequilibrium state. In the simplest experiments, the preparation periods consists of a single rf pulse. However, this period can involve more sophisticated procedures like cross-polarization (39,40) and excitation of multiple-quantum coherences (1,41). (*2*) *Evolution period*: During this period, in general, the spin system evolves under a spin Hamiltonian, which may be modified by heteronuclear decoupling (42), sample spinning (43,44), or homonuclear decoupling pulse sequences (45,46). The evolution during this indirect dimension of the 2D experiment determines the frequencies in the ω_1-domain. (*3*) *Mixing period*: This period may consists of one or more rf pulses, separated by intervals with fixed or variable durations. During the mixing period, transfer of coherences or polarization can take place. For instance, mixing process transforms single (SQ)-, multiple (MQ)- or zero-quantum (ZQ) coherences into observable transverse magnetization. In many cases, the 2D spectrum may be regarded as a visual representation of the pathways of the mixing process. (*4*) *Detection period*: In the course of the detection period, the SQ coherences evolution is measured as a function of time-domain variable t_2. The spin system can be manipulated by the action of coherent averaging pulse sequences and/or sample spinning, or by polarization transfer to nuclei with higher sensitivity. Finally, a complex 2D spectrum is obtain for the time-domain data by a complex 2D Fourier transformation defined by

$$S(\omega_1, \omega_2) = \int_{-\infty}^{\infty} \mathrm{d}t_1 \exp\{-\mathrm{i}\omega_1 t_1\} \int_{-\infty}^{\infty} \mathrm{d}t_2 \exp\{-\mathrm{i}\omega_2 t_2\} s(t_1, t_2) \tag{17}$$

The major advantages of 2D NMR spectroscopy are related to the assignment of complex spectra, of revealing the correlated transitions to establish J- or dipolar

coupling topologies or for studying complex dynamic processes. These features lead to a classification of 2D spectroscopic experiments in three groups (1).

The interpretation of NMR spectra is often impeded by the complexity of overlapping resonances. When the interactions responsible for the multiplet structure are different such as chemical shielding, dipolar, or scalar couplings, it is often possible to render spectra more intelligible by *separating* various interactions in orthogonal frequency domains. In the course of *2D separation* experiments the number of peaks is conserved.

The second group of 2D experiments is represented by *2D correlation* methods based on coherence transfer. These experiments allow interpretation of NMR spectra of networks of coupled spins by establishing the connectivities of nuclear spins coupled by J or dipolar interactions. The appearance of cross-peaks in 2D correlation spectra constitutes a proof of the existence of resolved scalar or dipolar couplings, and allows one to correlate the chemical shifts of coupled partners. These experiments are designed to correlate transitions of coupled spins by transferring magnetization of MQ coherences from one transition to another in the course of a suitable designed mixing process.

A third class of 2D time-domain experiments is concerned with studying *dynamic processes* such as cross-relaxation, nuclear Overhauser effects, chemical exchange, and magnetization exchange including spin diffusion (1,2). These methods have a number of advantages particularly when the system comprises an extended network of exchange processes that occur simultaneously. Moreover, the 2D methods are most useful for studying slow dynamic processes with rates that are two low to affect the lineshapes. The basic idea of 2D exchange spectroscopy is the "frequency labeling" of the longitudinal magnetization of various chemical sites before chemical or magnetization exchange takes place, such that after exchange the pathways of the magnetization can be traced back to their origins.

The magnetic resonance imaging (MRI) techniques used most frequently for applications to soft polymers are directly related to the multidimensional Fourier transform (5,18,19,47). Just like in 2D spectroscopy, the phase of the signal acquired during the detection period (time domain t_2) is modulated by the coherence phases present in the evolution period (t_1). The idea is that the accumulated signal phase is primarily a result of the applied gradient which induces a position encoding. A 2D Fourier transformation then produces a 2D image of the object.

One-Dimensional NMR Studies of Molecular Motions and Dynamic Order

NMR methods can probe molecular dynamics in polymers on various time scales from relatively fast segmental motions (with correlation times of the order of 10^{-10} s) down to slow motions in the 10^{-3} s range or even slower (2–6,48). Dynamics in the range of around 10^{-10} s can be investigated by T_1 measurements that are sensitive to motions around the Larmor frequency. Particularly useful for such investigations is the field cycling technique, where the magnetic field and thus also the Larmor frequency ω can be varied over several orders of magnitudes

down to the 10 kHz regime. By acquiring $T_1(\omega)$, molecular dynamics can be probed over the corresponding range ((5), and references therein).

Slow motions can be studied using so-called longitudinal relaxation in the rotating frame ($T_{1\rho}$) (5). In these experiments, a radio-frequency field ("spin-lock pulse") with field strength of around 10–100 kHz plays the same role as the main magnetic field does for T_1. For instance, the changes in the phase structure under mechanical deformation of thermoplastic elastomers have been investigated by $T_{1\rho}$ measurements of ^{13}C nuclei under MAS (49).

Transverse relaxation (T_2) and lineshape analysis has also been the topic of many studies of molecular dynamics in viscoelastic media ((12,13,50,51), and references therein). It was found to be indicative of heterogeneities of molecular motions (12,13). Transverse relaxation curves therefore often turn out to be composed of a superposition of multiexponential and the Gaussian decays. Measurement of residual dipolar couplings, molecular motions, and other parameters have been performed by this relaxation technique on different nuclei like ^{1}H, ^{13}C, ^{15}N, ^{31}P, and ^{29}Si and could be related to material properties such as the cross-link density (12,13). In order to separate the liquid-like and solid-like contributions of the T_2 decay, a linear combination of Hahn echoes and solid echoes have been used (52,53). While Hahn spin-echo amplitudes are encoded by irreversible dephasing due to molecular motions and by reversible residual dipolar couplings, only the first effect encodes the amplitudes of solid echo (actually mixed echo) to first approximation. The appropriate combination of these spin-echoes thus gives access to residual dipolar couplings and the fluctuation rate (52,53). The method was applied to measure the degree of segmental order induced in natural rubber upon stretching (53).

A powerful technique for the study of orientation and dynamics in viscoelastic media is lineshape analysis in deuteron NMR spectroscopy (2,50,51,53). Recent reviews on this topic were published (50,51). For instance, the average orientation of chain segments in elastomer networks upon macroscopic strain can be determined by this technique (54–60). For a nondeformed rubber, a single resonance line in the deuterium NMR spectrum is observed (57) while the spectrum splits into a well-defined doublet structure under uniaxial deformation. It was shown that the usual network constraint on the end-to-end vector determines the deuterium lineshape under deformation, while the interchain (excluded volume) interactions lead to splitting (57–60). Deuterium NMR is thus able to monitor the average segmental orientation due to the cross-links and mean field separately (60).

The network structure of unfilled and filled elastomers was probed by the analysis of the quadrupolar splitting in ^{2}H solid echo spectra of uniaxially strained samples (55) (see Fig. 6). The local chain order at a given elongation is larger by a factor of 1.5–2 in the filled system. A decrease of local chain mobility in the absorption layer is observed under stress. The same method was applied to investigate molecular dynamic in thermoplastic elastomer based on hydrogen bonding complexes (61,62).

The 1D NMR techniques described above already allow a detailed investigation of polymer dynamics but they are mostly not selective in the sense that they do not provide information on the averaging of particular couplings. For the interpretation of some of the above results therefore a representative spin pair

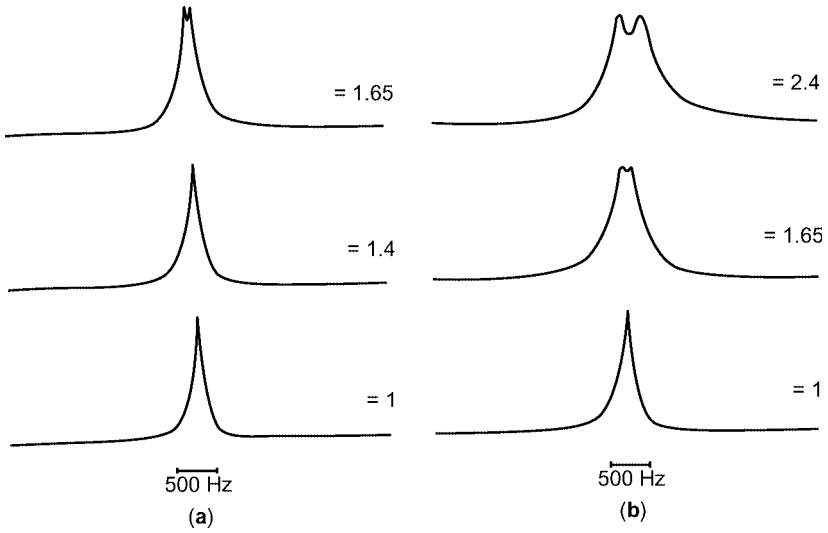

Fig. 6. Deuterium solid echo spectra of unfilled (**a**) and filled (**b**) poly[dimethylsiloxane] networks at 305 K with and without mechanical stress as given by the parameter λ. Reproduced from Ref. 55, with permission from Wiley-VCH.

along the chain was assumed, thus neglecting local site-specific motions as well as the geometry of the bonds. This is where multidimensional NMR techniques come into play.

Residual van Vleck Moments. The difficulties related to these measurements are due to the small values of the residual spin couplings compared to those of other spin interactions, the many-body character of the dipolar couplings and the presence of molecular motions which produce a supplementary encoding of the spin system response.

One-dimensional (1D) NMR methods based on the dipolar correlation effect in combination with the Hahn and solid echoes (52,63), the stimulated echo (5), the magic echo (64), magnetization-exchange (65), and cross-relaxation dynamics (66) provide access only to the second van Vleck moment via a model which takes into account the solid-like and liquid-like contributions to the spin system response (67). Model free access is given by the analysis of multiple-quantum builtup (68) and decay (69) curves recorded in the initial regime of the excitation/reconversion periods.

In the following, we discuss a method to measure model free the residual dipolar van Vleck moments without contributions from inhomogeneous spin interactions originating from static magnetic field inhomogeneities, local susceptibility effects, and heteronuclear dipolar interactions (70). Moreover, in the first approximation this method is insensitive to the transverse relaxation produced by the fluctuating dipolar interactions.

Principles of the Method. The method is based on the mixed echo composed of the Hahn and the magic echo (33,71,72). The Hahn echo explores the magic echo shape generated by an accordion magic sandwich (cf Fig. 7).

One possibility to have the amplitude of the Hahn echo encoded by the homonuclear dipolar interactions is to employ a mismatched magic sandwich

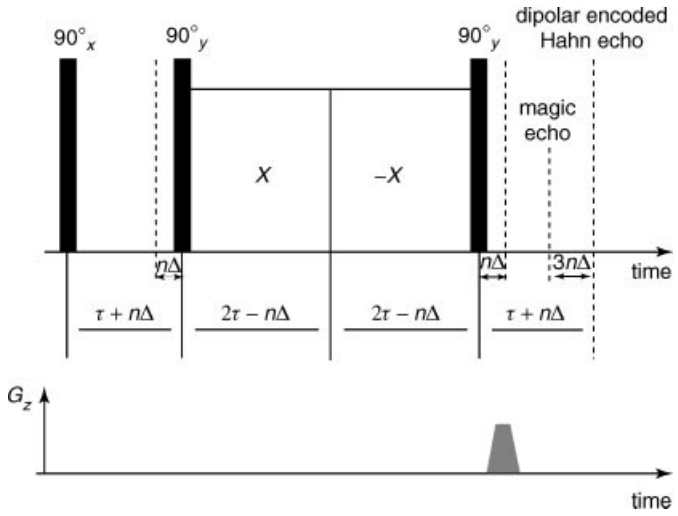

Fig. 7. AIMS pulse sequence used for generation of a mixed echo composed of a magic and a Hahn echo. A dephasing gradient pulse is applied at the end of the sequence. Reproduced from Ref. 70, with permission from Elsevier.

(MS), ie, $90^{\circ}_{x} - (\tau + n\Delta) - 90^{\circ}_{y}$ – Burst Pulse$_{x}$ $(2\tau - n\Delta)$ – Burst Pulse$_{\overline{x}}$ $(2\tau - n\Delta)$ – $90^{\circ}_{y} - (\tau + n\Delta)$ – Mixed Echo (see Fig. 7), where n is a positive and negative integer number and Δ is the time decrement and increment, respectively. We call this mismatched MS composite pulse with variable n the *accordion magic sandwich* (hereafter the method will be called AIMS).

The spin system response to the AIMS sequence was evaluated in Reference 70 for a multispin dipolar network characteristic to elastomers and other soft polymers. It was shown that the normalized amplitude of the Hahn echo measured at time $t = 6\ \tau$ is encoded only by the homonuclear dipolar couplings and relaxation, ie,

$$\frac{S(3n\Delta)}{S(0)} = \frac{\mathrm{Tr}\left\{I_y \exp\left\{-\mathrm{i}\hat{\bar{H}}_d^{(0)}(3|n|\Delta)\right\}I_y\right\}}{\mathrm{Tr}\{I_y^2\}} \exp\left\{-2n\Delta\left(\frac{1}{T_2^*} - \frac{1}{T_{2\rho}^*}\right)\right\} \tag{18}$$

where T_2^* and $T_{2\rho}^*$ are the effective transverse relaxation times in the laboratory and rotating frames, respectively. It is easy to see from the above equation that a combination of signals taken with $+|n|$ and $-|n|$ is given by

$$\frac{S(3|n|\Delta)S(-3|n|\Delta)}{S(0)^2} = G(3|n|\Delta)^2 \tag{19}$$

This composite NMR signal is not encoded by the transverse relaxation. The function $G(t)$ describes the magic echo shape and is given by (4)

$$G(t) = \frac{\mathrm{Tr}\left\{I_y \exp\left\{-\mathrm{i}\hat{\bar{H}}_d^{(0)} t\right\}I_y\right\}}{\mathrm{Tr}\{I_y^2\}} \tag{20}$$

In the short-time limit, ie, for $3|n|\Delta\omega_d \ll 1$, we obtain from the above equations,

$$\frac{S(3|n|\Delta)S(-3|n|\Delta)}{S(0)^2} \cong 1 - \bar{M}_2(3|n|\Delta)^2 + \frac{1}{12}\bar{M}_4(3|n|\Delta)^4 - \cdots \quad (21)$$

where $\bar{M}_2$ and $\bar{M}_4$ are the residual second and forth van Vleck moments, respectively (4).

In conclusion, the AIMS pulse sequence produces a disentanglement of the magic and Hahn echoes in time. The dipolar encoding of the signal occurs because the Hahn echo samples the magic echo shape.

^1H Residual van Vleck Second Moments of Cross-Linked Series of Natural Rubber. Proton residual second and fourth van Vleck moments were measured by AIMS for the samples of cross-linked series of natural rubber (NR). The residual van Vleck moments $\bar{M}_2$ and $\bar{M}_4$ can be evaluated by the best fits of the composite signals with equation 21 and these results are shown in Figures 8**a** and 8**b**, respectively, for the whole NR series.

The measured values of $\bar{M}_2$ are in good agreement with the values measured on the same series using the model dependent dipolar correlation function (64). The best fit of the dependence of $\bar{M}_2$ and $\bar{M}_4$ on shear modulus G is given by continuous lines in figures 9**a** and 9**b**. These are described, in general, by a polynomial $\sum_1^m (-1)^p a_p G^p$ up to the powers four and eight in G, respectively. This polynomial dependence can be justified by considering high order corrections to a Gaussian distribution of the end-to-end vectors (68). The classical Gaussian distribution will lead only to dependences of powers two and four in G which are shown by the dashed lines in these figures. Nevertheless, in the case of samples with low values of the cross-link density the Gaussian approximation is able to describe the experimental data sufficiently well (see the insets of figures 8**a** and 8**b**). These results also show that high order van Vleck moments are more sensitive to cross-link density compared to the second van Vleck moment which is usually used.

The value of the ratio $\bar{M}_4/\bar{M}_2{}^2$ on shear modulus is shown in figure 8**c**. The ^{1}H NMR absorption lineshape is quasi-Lorentzian for all samples but starts to deviate towards a Gaussian lineshape for higher values of the cross-link density.

Residual Dipolar Couplings by ^{1}H Multiple-Quantum NMR. The measurements of residual dipolar couplings in elastomer system is desirable, because they reflect the hindrance to molecular motions by the cross-linking, topological constraints, and the external factors like mechanical stress. Dipolar-encoded longitudinal magnetization (DELM) NMR decay curves, double-quantum (DQ) and triple-quantum (TQ) NMR buildup intensities for measuring the residual dipolar couplings and the associated dynamic order parameters were discussed in Reference 68. These methods allow measuring residual dipolar couplings model free and in the limit of short excitation time regime the effective dipolar network is simplified.

Principles of the Method. One of the important features of the MQ spectroscopy is the possibility to edit the strongest dipolar couplings. This feature is based on the fact that the efficiency of MQ pumping is a nonlinear function of the dipolar coupling strength. For instance, the pumping efficiencies of DQ and TQ coherences in the initial excitation time regime are proportional to $(D^{ij})^2$

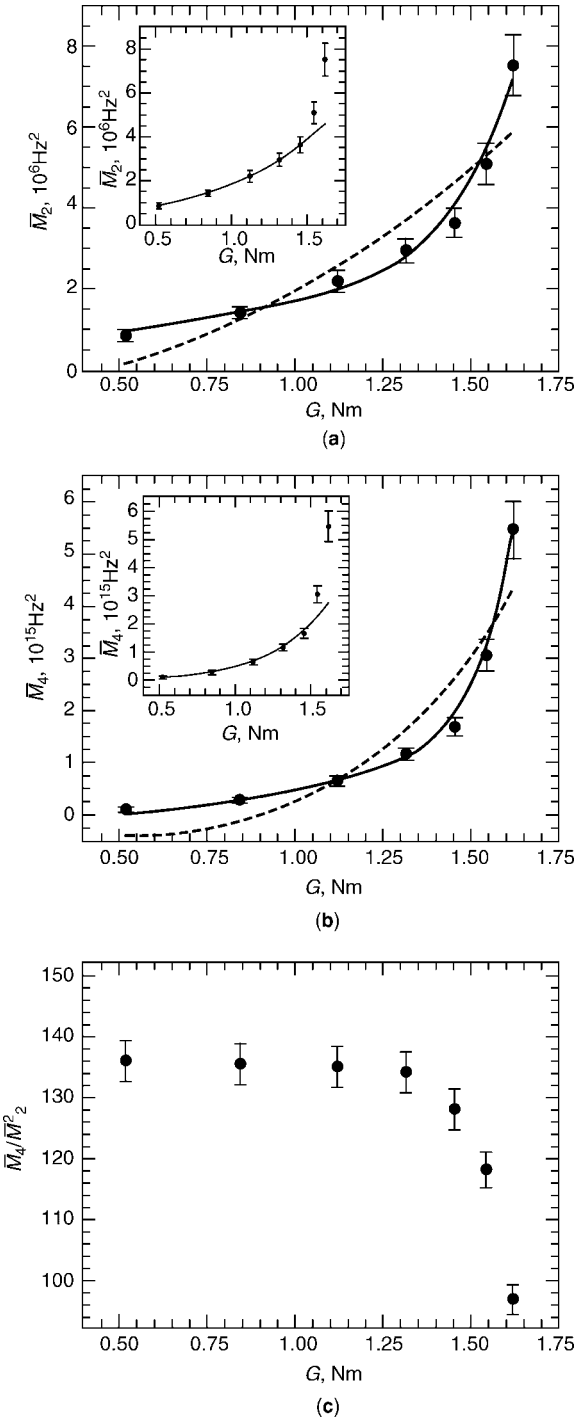

Fig. 8. Proton residual van Vleck moments $\bar{M}_2$ (**a**), $\bar{M}_4$ (**b**), and the ratio $\bar{M}_4/\bar{M}_2{}^2$ (**c**) measured by AIMS for the samples of a series of cross-linked natural rubber versus the shear modulus G. Reproduced from Ref. 70, with permission from Elsevier.

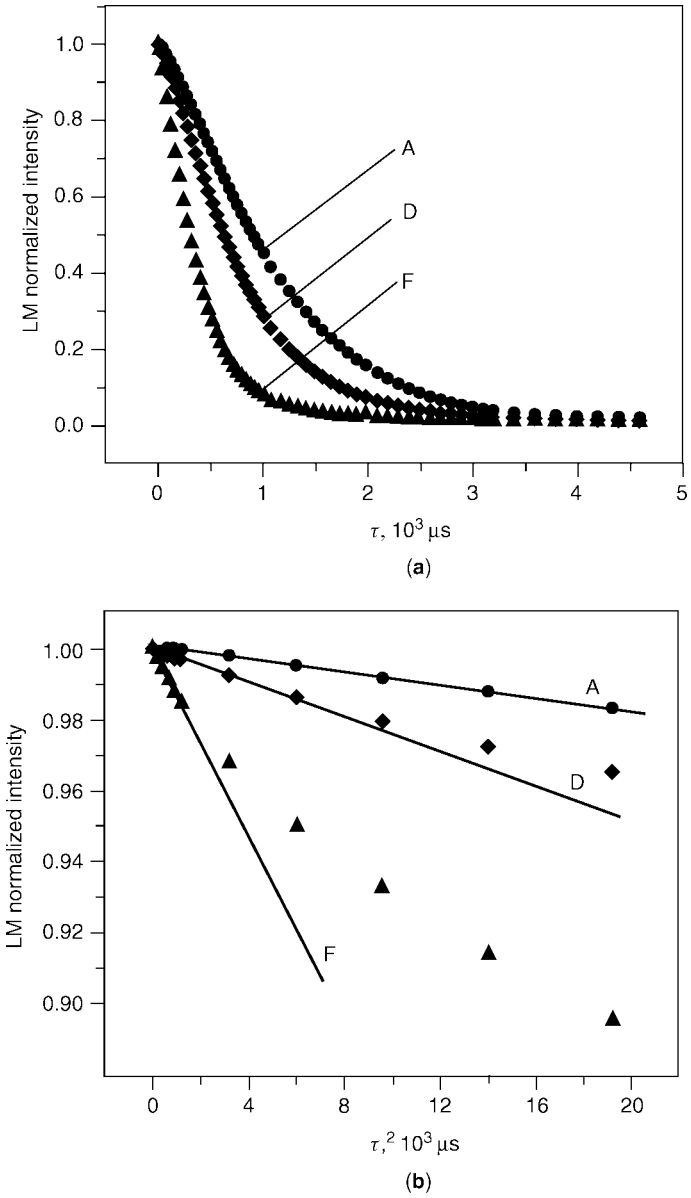

Fig. 9. (**a**) Proton dipolar-encoded longitudinal magnetization decay curves for a series of synthetic polyisoprene samples with different cross-link densities. (**b**) The initial time behavior of DELM decays exhibits a linear dependence in τ^2 (solid lines). Reproduced from Ref. 68, with permission from American Institute of Physics.

and $(D^{ij})^4$, respectively, where D^{ij} is the dipolar strength between protons i and j (73–75). Therefore, we can estimate that the pumping efficiency of DQ coherences for methylene protons is about six times higher compared to that of methyl protons. The editing capabilities are expected to be even better for the intergroup

dipolar interactions. In the case of TQ coherences, the maximum pumping efficiency is expected for the methyl group.

The possibility to implement a MQ dipolar filter has already been demonstrated. For instance, by use of a ^{13}C–^{13}C DQ dipolar filter working in the initial excitation time regime the signal of the crystalline domains in polyethylene could be enhanced (74). The possibility of functional group editing by MQ NMR methods is also supported by DQ experiments performed on static and rotating elastomers. The 2D ^{1}H DQ MAS spectrum of polyisoprene (68) shows that for short excitation times the response of the methylene protons can be approximated well by an isolated spin pair. Moreover, the experiment shows that the DQ coherences at which methyl protons participate are mainly originating from the CH_3 group. This also leads to the conclusion that TQ coherences excited in the initial time regime can be attributed mainly to the methyl groups. Weak dipolar coupling of CH_2 and CH_3 protons with CH protons is demonstrated (68). But, the contribution of the methine protons to the overall NMR signal is only about 12% so that these couplings are negligible in a good approximation.

The spin system response to the pulse sequence used for excitation of different multipolar spin states can be evaluated in the limit of short dipolar encoding time. For DELM, it is possible to write (68)

$$\begin{aligned} S_{\mathrm{DELM}}(\tau) \approx 1 - \left\{ l_2 \left[D^{(2)} S_s^{(2)} \right]^2 + l_3 \left[D^{(3)} S_s^{(3)} \right]^2 + \text{intergroup} \right\} \tau^2 - \cdots \\ \equiv 1 - [D_{\mathrm{eff}}]^2 \tau^2 - \cdots \end{aligned} \tag{22}$$

where the numerical coefficients are $l_2 = 21/80$, and $l_3 = 63/190$ and correspond to the CH_2 and CH_3 groups. D_{eff} is the effective residual dipolar coupling describing contributions from both CH_2 and CH_3 groups as well as intergroup residual dipolar couplings. Nevertheless, the residual dipolar couplings of methylene and methyl protons dominate the intergroup couplings and the slope of the LM decay curve versus the square of the excitation time τ is given by a weighted sum of the squares of dynamic order parameters of CH_2 and CH_3 groups.

The DQ signal can be evaluated in a similar manner, and finally one can write

$$\begin{aligned} S_{\mathrm{DQ}}(\tau) \approx \left(d_2 \left[D^{(2)} S_s^{(2)} \right]^2 + d_3 \left[D^{(3)} S_s^{(3)} \right]^2 + \text{intergroup} \right) \tau^2 + \cdots \\ \equiv [D'_{\mathrm{eff}}]^2 \tau^2 + \cdots \end{aligned} \tag{23}$$

where the numerical coefficients are $d_2 = 21/40$ and $d_3 = 9/200$. An effective residual dipolar coupling D'_{eff} similar (but not identical) to D_{eff} for dipolar encoded longitudinal magnetization can be introduced describing DQ-edited residual dipolar couplings.

In the regime of short excitation times the TQ coherences are derived mainly from the methyl protons. The spin system response to the pulse sequence (68) for a proton triad rotating rapidly around the C_3 axis in a static sample can be evaluated similar to the procedure used for DQ coherences. In the limit of short excitation

times, the normalized TQ-filtered signal is given by

$$S_{TQ}(\tau) \approx \left(r_3\left[D^{(3)}S_s^{(3)}\right]^4 + \text{intergroup}\right)\tau^4 + \cdots \equiv [D''_{\text{eff}}]^4\tau^4 + \cdots \quad (24)$$

where $r_3 = 39/4$. Again as above, an effective residual dipolar coupling D''_{eff} can be introduced for the full dipolar network. These effective residual dipolar couplings, introduced by the above equations, depend on the dipolar network edited by the experiments and it is therefore not easy to express them in terms of site-specific dynamic order parameters. Nevertheless, D''_{eff} is expected to be dominated by the methyl protons.

Dynamic Order Parameters. Dipolar-encoded longitudinal magnetization decay curves were measured for ^{1}H in a series of cross-linked synthetic polyisoprene samples (68). The decays for three samples (A, D, and F with the cross-link density of 0.75, 5.0, and 15.0, respectively) are shown in Figure 9.

The decay curves show a dependence on the cross-link density. In the short-time regime, the dipolar-encoded LM decays display a linear dependence in τ^2, in accordance with equation 22, (cf Fig. 9**b**). DQ buildup curves for the same samples are shown in figure 10 for the full range of excitation time τ. Systematic dependence of the DQ-filtered signal intensity on the cross-link density is evidenced in Figure 10**a**. Based on equation 23, an initial dependence of the signal amplitude on τ^2 will be shown by the DQ signals with a slope related to the scaled dynamic order parameters of methylene and methyl protons (cf Fig. 10**b**). TQ buildup curves for protons in polyisoprene also show a clear dependence on the cross-link density similar to the case of the DQ buildup curves.

Within the limit of experimental errors scaled dynamic order parameters measured from the MQ experiments show a linear dependence on cross-link density (cf Fig. 11).

This is expected because the dynamic order parameters $S_s^{(2)}$ and $S_s^{(3)}$ are inversely proportional to the number N of statistical segments. The same dependence on N is expected for cross-link density as measured in parts per hundred of rubber (phr) of cross-linking agent. For the whole series, the dynamic order parameters of methyl protons are slightly larger than those of the methylene protons. This reflects the hindrance imposed to the motion of methyl groups attributed to backbone chain by the short-range interactions between segments belonging to different chains in comparison with the case of the methylene proton located along the polymer chain.

The values of the effective ^{1}H residual dipolar couplings $D_{\text{eff}}/2\pi$ measured from the initial decays of the LM are shown as a function of cross-link density in Figure 11**b**. In the good approximation, the dipolar couplings are linearly proportional to cross-link density. These quantities can also be evaluated from equations 23 and 24 by using the dynamic-order parameters measured site-selectively from DQ and TQ buildup curves. These $D_{\text{eff}}/2\pi$ are plotted versus cross-linked density in Figure 11**b**, again showing a linear dependence on cross-linked density. They are systematically lower than the values measured from the LM

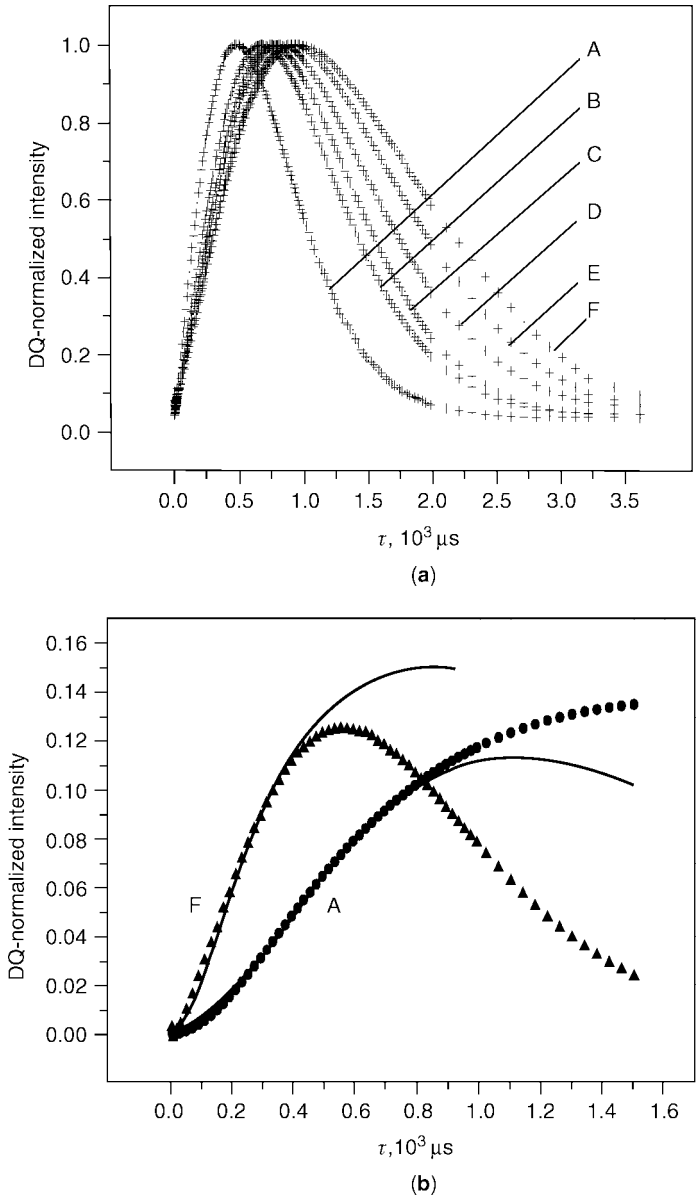

Fig. 10. Proton DQ buildup curves for a series of synthetic polyisoprene samples with different cross-link densities increasing from samples A to F. (**a**) The signal dependence on excitation and reconversion times τ for the full time domain. decays. This fact can be due to the shorter time scale used for extraction of $D_{\text{eff}}/2\pi$ from LM decays compared to that used in DQ and TQ buildup curves.

The dynamic order parameters determined by the above methods can be compared to those measured by other NMR techniques if the specific dynamic

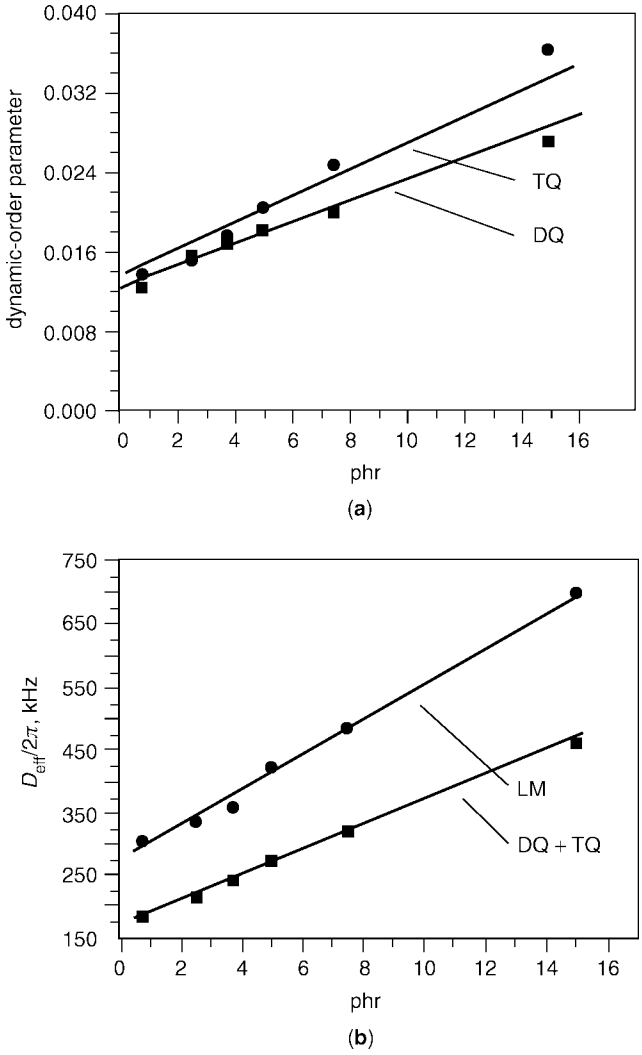

Fig. 11. (**a**) The dependence of dynamic-order parameters measured from DQ (squares) and TQ (circles) buildup curves on the cross-link density for synthetic polyisoprene. (**b**) The effective residual dipolar coupling D_{eff} (circles) measured from dipolar encoded longitudinal magnetization decays together with the D_{eff} values (squares) computed from dynamic-order parameters. A linear dependence on the cross-link density is evidenced in all cases (solid lines). Reproduced from Ref. 68, with permission from American Institute of Physics.

time scale is considered. It was shown that residual dipolar couplings measured in the initial time regime of the LM decays, DQ, and TQ buildup curves are more sensitive to cross-link density as compared to, for instance, transverse relaxation rates (68).

The proposed methods are generally applicable to partially averaged proton dipolar interactions and can be applied for studying segmental order and its associated dynamics in a variety of polymer networks or entangled melts and solutions

(transient networks) without the need for isotopic labeling, sample rotation, or the use of cross-polarization.

Heterogeneity in Segmental Chain Order of Grafted Polymers. Proton multiple-quantum NMR was also used for investigation of heterogeneity in segmental chain order of grafted polymers. The measurements were performed on a series of samples of poly(dimethylsiloxane) (PDMS) layers chemically attached to the surface of hydrophilic silica (76). These grafted PDMS layers consists of partially immobilized chain segments at the PDMS–silica interface and mobile chain portions outside the interface which is probed by measurements of homonuclear double- and triple-quantum buildup curves. These curves reveal a bimodal distribution of the residual dipolar couplings along the PDMS chain (see Fig. 12).

The segmental orientation detected in the interface and mobile regions are related to the average chain length and reflects the competing effects of the surface-induced orientation and chain conformations.

The ^{1}H DQ (and TQ) buildup curves were measured at two temperatures $T = 298$ K and $T = 227$ K for the three grafted PDMS samples with different chain lengths (N_t) and the results are shown in Figure 12. The buildup curves display two maxima. The first maximum shows a relatively sharply defined value of the excitation and reconversion time τ. The second maximum at longer τ values are more difficult to identify in sample PDMS3 ($N_t = 4.5$) and less pronounced in sample PDMS2 ($N_t = 6.2$) due to the small amount of the mobile fraction and the broadness of the signal. Nevertheless, the second maximum is enhanced at lower temperature (cf Fig. 12**b**) due to reduced mobility and therefore increasing residual dipolar coupling. The maximum at short τ values are due to the segments at the interface, and those present at longer τ correspond to the mobile fractions of the grafted PDMS chains. The first maximum occurs at the same τ value for the three samples indicating the same chain immobilization in the interface of all three samples. The immobilizations are caused by a loss of conformation entropy due to chain anchoring to the silica surface and by excluded volume effects from the silica surface and neighboring chains. Thus, the averaged residual dipolar couplings of the interface have the same values independent of N_t. These results are both reflected in the ^{1}H DQ as well as in the ^{1}H TQ buildup curves (76).

The positions of the second maximum of the three samples are also indicative of the anisotropy of chain motions outside the interface. Assuming the same thickness of the interface in all three samples, we deduce that the fraction of the mobile chain fragments decreases from sample PDMS1 ($N_t = 7.7$) to PDMS3 ($N_t = 4.5$). This results in a shorter τ value for the position of the second maximum for sample PDMS3 versus samples PDMS2 and PDMS1 that can be detected in the DQ as well as the TQ buildup curves (76).

A bimodal distribution of the segmental-chain orientation corresponding to the interface and the mobile regions of PDMS chains grafted onto silica was detected by ^{1}H multiple-quantum NMR spectroscopy. The size of the interface is found to be independent of the total length of the PDMS chains. A broad distribution of segmental orientation prevails in the mobile region, and the segmental mobility is proportional to its fraction and therefore to the chain length. At lower temperatures, the mobility decreases until at $T = 198$ K the whole chain appears to be immobile at the time scale of the NMR experiment of about 10^{-5} s.

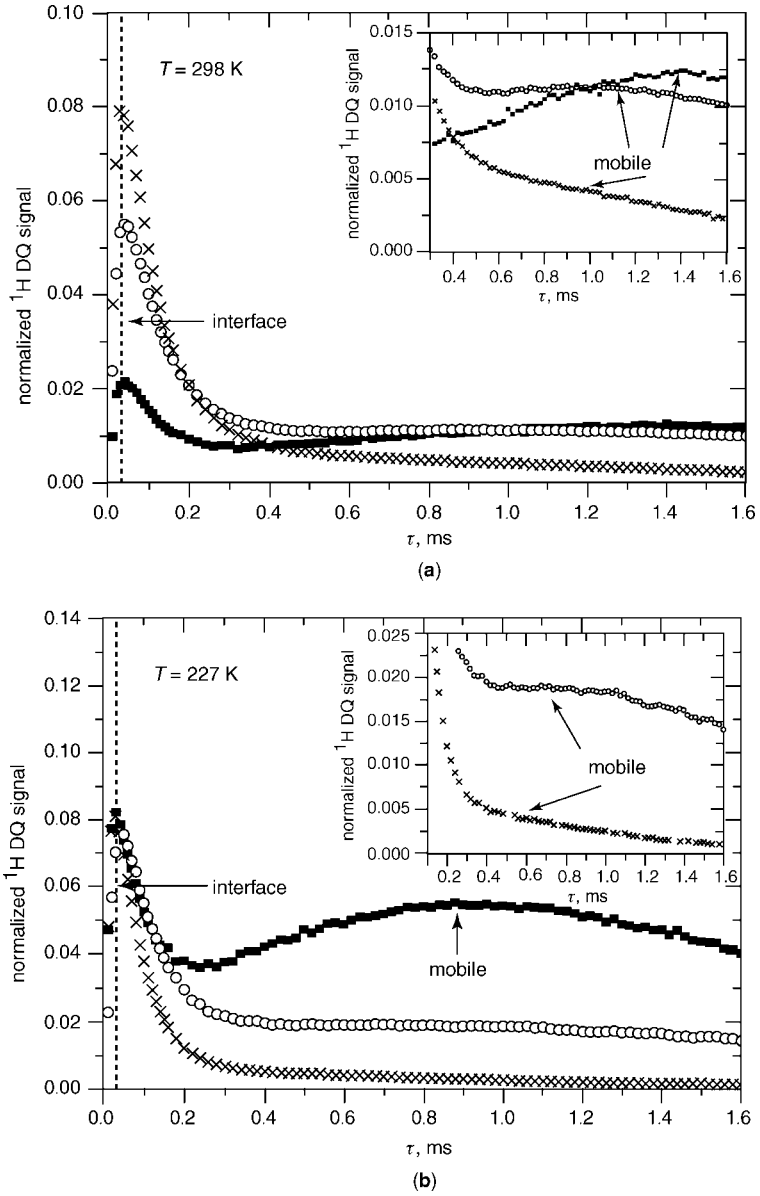

Fig. 12. Proton DQ buildup curves of grafted PDMS samples recorded at $T = 298$ K (**a**) and $T = 227$ K (**b**). (■) PDMS1, (○) PDMS2, and (×) PDMS3. The region of the DQ buildup curves after the first maximum is enlarged in the insets. Reproduced from Ref. 76, with permission from American Chemical Society.

The measurements using transverse ^{1}H relaxation shown that this quantity is also highly sensitive to the heterogeneous mobility of PDMS chains grafted onto a silica surface (77). This method allowed the distinction between a dense brush-like structure of the grafted layer containing chains of a fairly uniform

length and a layer containing a significant fraction of long-chain loops outside the grafted layer. The mobility of the chain outside the interface was found to increase with increasing average length of the grafted chains in agreement with the measurements performed by MQ NMR (76).

Local Segmental Anisotropy Induced by Mechanical Deformation. A well-known consequence of the theory of rubber elasticity is bond orientation (78,79). Deformation of an elastomer induces anisotropy of the backbone bonds of the polymer coil. In recent NMR studies of rubber elasticity, the mechanism of deformation and the orientation of network chains have received increasing attention (50,51). The local segmental anisotropy induced by a uniaxial applied force in elastomers was also investigated by NMR in terms of ^{1}H dipolar encoded longitudinal magnetization decays and double-quantum coherences buildup curves (80). These multipolar nuclear spin states were measured as a function of the angle θ between the static magnetic field and the direction of the applied force. The experimentally determined angular dependence of the effective residual dipolar couplings shows a minimum around the magic angle. These NMR methods offer the possibility to investigate in great detail the mechanisms responsible for the induced local anisotropy in strained polymer networks without contributions from the dipolar correlation effect (*vide infra*) and without need for chain deuteration.

Network Properties by Transverse Magnetization Relaxation. The transverse relaxation reflects mainly the loss of quantum phase coherence of spins. The axial symmetry induced by the presence of static magnetic field is of particular interest for observing the broad spectrum of relaxation rates related to the hierarchy of fluctuations, which affect any polymer chain in a melt or network (from about 10^9 s^{-1} down to less than 1 s^{-1}). For protons attached to polymer chains, the irreversible dynamics of the longitudinal magnetization is sensitive to properties generated by the local viscosity, which governs the random rotations of monomeric units. With regard to the transverse magnetization, the relaxation process cannot by analyzed without considering the time interval allotted for the full random rotations of chemical units that is close to the time interval (about 1 s or more) required for the full renewal of the chain configurations. However, this is to long a process for inducing any magnetic relaxation mechanism; consequently, the transverse magnetization is sensitive to a part of the hierarchy of chain fluctuations, only. In other words, random motions of units are detected as nonisotropic rotations generated by the topological constraints and the irreversible dynamics of the transverse magnetization is thus governed by the nonzero average of the dipolar interactions. A solid-like behavior of the transverse relaxation is expected to be associated with the property of elasticity, provided the time scale of the renewal of configurations is longer than the NMR scale of observation. This effect is considerably enhanced when permanent networks are observed.

Models for Transverse Relaxation. The simplest model to describe chain statistics from the NMR point of view is a chain of freely jointed segments of fixed length (12). Such a chain may be rescaled in several hierarchical steps according to the time scale of the motions which takes place at different space scales, compared to the time scale defined by the NMR spin interactions. All intrachain motions are assumed to be fast enough to average elementary interactions, whereas junction average positions are static.

Let us consider a linear chain of N statistical segments, fixed at its extremities. An average orientation is induced along the chain by these constrains. To estimate the effect of this average orientation on NMR parameters, the simplest picture is to consider that each segment carries an isolated pairs of spins, usually protons (two-spin approximation). Within this framework, the time evolution of the transverse magnetization $M_{\vec{R}}(t)$ for a spin pair attached to a chain may be written in the very simple form

$$M_{\vec{R}}(t) = \mathrm{Re}\left[M_0 \exp\left\{-\frac{t}{T_2}\right\} \exp\{\mathrm{i}\omega_{\vec{R}}\,\mathrm{t}\}\right] \tag{25}$$

where $M_{\vec{R}}(t)$ is the initial polarization, T_2 is the transverse relaxation time related to the fluctuating part of the dipolar Hamiltonian, and $\omega_{\vec{R}}$ is the residual dipolar interaction in angular frequency units. Other theories of transverse relaxation ((13), and references therein) are more complex that this simple approach. A polymer network is considerably disordered. To model this disorder, the end-to-end vector components $\vec{R}(x, y, z)$ may be supposed to obey ideal, the Gaussian statistics, ie,

$$P(\vec{R}) = \left(\frac{3}{2\pi N a^2}\right)^{3/2} \exp\left\{-\frac{3}{2}\frac{\vec{R}^2}{Na^2}\right\} \tag{26}$$

where a is the length of the statistical segment. The overall evolution of the complex transverse magnetization is then obtained by averaging equation 25 over end-to-end vector distribution. This yields (67)

$$M(t) = \mathrm{Re}\left[M_0\left(1 - \frac{2}{3}\mathrm{i}D_{ij}N_{\mathrm{e}}^{-1}t\right)^{-1/2}\left(1 + \frac{1}{3}\mathrm{i}D_{ij}N_e^{-1}t\right)^{-1}\exp\left\{-\frac{t}{T_2}\right\}\right] \tag{27}$$

where D_{ij} is the dipolar coupling constant for a spin pair and N_{e} is the effective number of statistical segments. At short times, ie, for $\Delta^2 N_{\mathrm{e}}{}^{-1}t^2 \ll 1$ the transverse relaxation decay has a Gaussian behavior corresponding to the presence of the residual dipolar couplings.

Experimental transverse relaxation decays cannot be usually described from exponential time functions but integral treatments of these curves yield standard parameters equivalent to relaxation rates (81). Without entering into too many details, it may be worth noting that the integral treatment amount to calculating several moments of the function $P(\vec{R})$. The first and the third moments of the distribution function are obtained from the two following integral treatments of the experimental relaxation curves

$$A_1 = \int_0^\infty \frac{M(t)}{\sqrt{t}}\,\mathrm{d}t, \text{ and } A_3 = \int_0^\infty \frac{\mathrm{d}M(t)/\mathrm{d}t}{\sqrt{t}}\,\mathrm{d}t \tag{28}$$

A NMR structural parameter χ_{c} was introduced which is defined as $\chi_{\mathrm{c}} = A_3/A_1$. The quantity $1/\chi_{\mathrm{c}}$ is proportional to the correlation length of segments between two consecutive nodes. Thermal behavior, swelling effects,

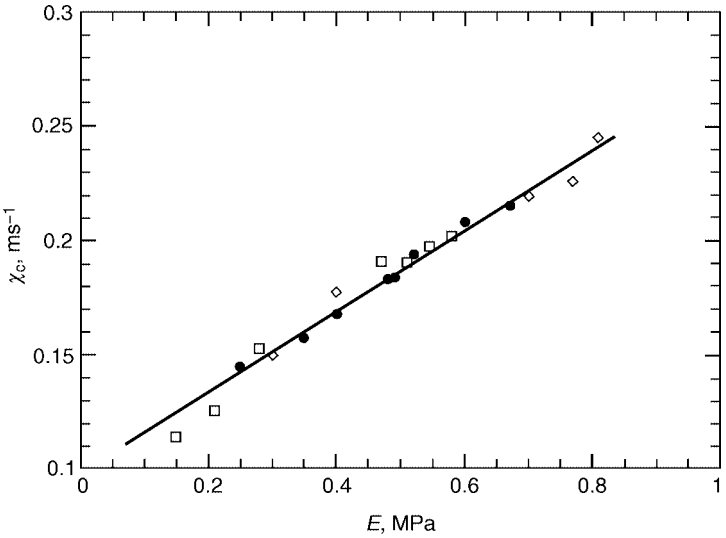

Fig. 13. Relaxation rate parameter χ_c as a function of the Young modulus E for randomly cross-link PDMS chains. NMR measurements were performed without any sample deformation. Reproduced from Ref. 82, with permission from American Chemical Society.

NMR-vulcanization, and NMR-elasticity relationships can be derived using the χ_c parameter ((81), and references therein). For instance, linear dependence of the NMR relaxation rate χ_c on the modulus of elasticity E measured on randomly PDMS chains (82) are shown in Figure 13.

Segmental fluctuations involved in the linear mechanical response to a small strain are directly observed from the transverse magnetization relaxation, in the absence of any strain.

Characterization of Polymer Networks by Transverse Relaxation. The NMR transverse magnetisation relaxation experiments were extensively used for quantitative analysis of the density of chemical cross-links, temporary and trapped chain entanglements and physical network junctions which are formed in filled rubbers, semicrystalline and ionic containing elastomers, and for determination of the molecular-scale heterogeneity of polymer networks ((83), and reference therein).

Several types of heterogeneity may occur in rubbery materials: (*1*) molecular-scale heterogeneity, which is caused by the chemical heterogeneity of uncured elastomers, network defects, and heterogeneous distribution of network junctions on a molecular level; (*2*) morphological heterogeneity of rubbery compounds due to a spatially heterogeneous distribution of components and filler in the compound; (*3*) spatial heterogeneity due to a difference in curing conditions such as temperature and concentration of vulcanisation agents throughout the sample volume.

A significant difference between the large spatial-scale mobility of network chains and that of network defects allows us to determine the degree of network heterogeneity. The most reliable data are obtained for swollen samples, because an increasing solvent content results in the disentanglement of network defects from network chains (84–86). The molecular mobility of network chains is consequently

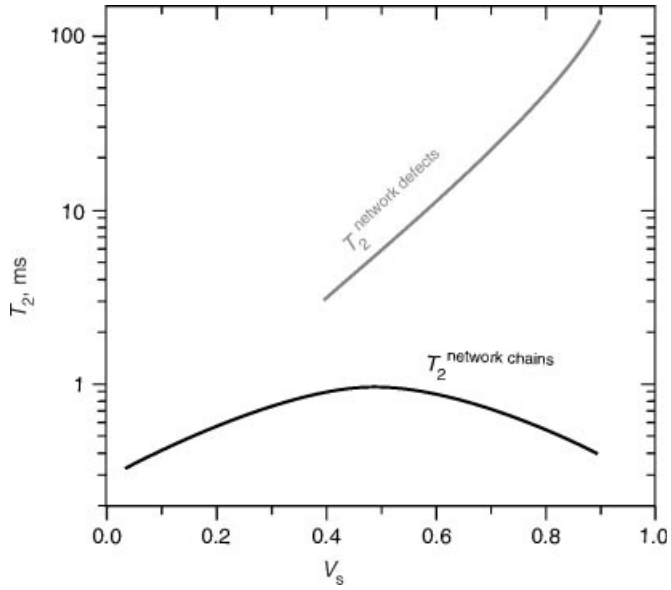

Fig. 14. The transverse relaxation time for a polymer network with defects against the volume fraction of a good solvent. Reproduced from Ref. 84, with permission from American Chemical Society.

decoupled from that of network defects, resulting in a major distinction in the relaxation behavior.

One example is given by the monoexponential T_2 decay of a cured acrylate that is splitted into two components upon swelling. This behavior is most clearly observable at high solvent concentrations (84,85). One component has short decay time (T_2^s), which is comparable with that of the original sample. This component apparently derives from network chains. Starting at a low volume solvent content (see Fig. 14), V_s, T_2^s shows an increase, which may be attributable to the following phenomena: (*1*) the disentanglement of network chains, (*2*) an increase in the frequency of the large spatial-scale chain motion, and (*3*) a slight decrease in the strength of the interchain proton dipole–dipole interactions. At $V_s \approx 40$–50 vol%, T_2^s reaches a maximum value. A value of T_2^s at the maximum, $(T_2^s)^{max}$, is related to the molecular mass of the network chains between chemical cross-links and trapped chain entanglements. At higher values of V_s, T_2^s decreases until the state of equilibrium swelling is reached. This decrease in T_2^s is thought to reflect the increase in the interchain proton dipole–dipole interactions as a result of the network chain elongation following a progressive increase in the solvent fraction in a swollen gel (12).

The long decay time (T_2^l) of the other component is typical of semidiluted polymer solutions. A T_2^l value continuously increases with an increasing solvent content. This component is apparently originated from the relaxation of network defects which are disentangled from network chains in a swollen state. At the equilibrium swelling degree, the relative fraction of the T_2^l relaxation component could be used as a measure of the fraction of highly mobile network defects. The

described behavior of T_2 relaxation decay following a progressive increase in the solvent fraction is typical of networks containing a significant fraction of network defects.

Distinct T_2 relaxation components with widely differing mean decay times suggest molecular or macroscopic heterogeneity of the material. In such cases, the submolecules concept can be used to describe the relaxation behavior (12). In a simplified interpretation, the overall T_2 relaxation decay of a heterogeneous elastomer is the weighted sum of the decays originating from the submolecules, which are defined as the network chains that are formed by the chemical and physical junctions, and network defects, ie, chains that are not attached to the network, chain loops and dangling chain ends. The large spatial-scale mobility of these submolecules differs substantially, and so does their relaxation behavior. The relative contribution of the submolecules to the overall decay is proportional to the number of protons attached to these chain fragments.

A quantitative analysis of the shape of the decay curve is not always straightforward due to the complex origin of the relaxation function itself (12,81,87–89) and the structural heterogeneity of the long-chain molecules. Nevertheless, several examples of the detection of structural heterogeneity by T_2 experiments have been published, for example the analysis of the gel/sol content in cured (90,91) and filled elastomers (85,86), the estimation of the fraction of chain-end blocks in linear and network elastomers (91,92), and the determination of a distribution function for the molecular mass of network chains in cross-linked elastomers (93,94).

Chain Orientation and Slow Dynamics by Dipolar Correlation Effect. An important 1D NMR method used for investigating anisotropy of chain dynamics and segmental order in polymer networks is given by the decay of the solid echo (12,63), a combination of Hahn and solid echoes (52), and a normalized stimulated echo (95–97). For all these cases, the echo amplitude decays can be described by a residual dipolar or quadrupolar correlation function (DCF) (for an introduction, see Reference 5). This function describes the autocorrelation of dipolar or quadrupolar randomly fluctuating interactions around the residual nuclear spin interactions that have been preaveraged by the fast dynamics of the chains and functional groups. Measurement of the DCF together with a corresponding theoretical model reveals important information about local segmental order and slow-chain dynamics under various experimental conditions. The possibility to measure the DCF using a combination of a solid echo, a Hahn echo and the free induction decay of protons, and deuterons has been discussed in Reference 63. An improved method was introduced later by Callaghan and Samulski (52) which exploits the fact that Hahn echo refocuses chemical shielding interactions and magnetic field inhomogeneities. Moreover, the Hahn echo amplitude is encoded by the molecular motions and residual dipolar couplings. The fluctuation of the dipolar interactions encodes the amplitude of the solid echo (actually a mixed echo) to a first approximation. The appropriate combination of these echoes, thus, gives access to residual dipolar couplings and the fluctuation rates. From the viewpoint of the spin system response, the solid echo completely refocuses the evolution of coherences of quadrupolar nuclei of spin $I = 1$ like ^{2}H and of a pair of 1/2 spins other than the ^{1}H multispin dipolar interactions. Therefore, the solid echo is strongly affected by the residual multispin interaction which makes the measurements of

DCF inaccurate. Moreover, the time scale of the dipolar or quadrupolar interaction fluctuations is limited to the time of the solid echo decay which is shorter than the transverse magnetization relaxation time. A considerably longer NMR time-window is offered by the DCF recorded with a stimulated echo (95–97). However, the amplitude of the stimulated echo is smaller than that of the solid echo and is affected by the multispin residual dipolar couplings as well as by the fluctuating dipolar fields. Furthermore, the evolution of the chemical shift Hamiltonian before storage of the z-magnetization encodes the stimulated echo evolution. Moreover, magnetization exchange competes with the dipolar correlation effect.

In all the cases discussed above, only the response of the spin system composed of dipolar coupled spin-1/2 pairs was considered. Proton DQ-NMR spectroscopy on elastomers—static and spinning at the magic angle—proved that the consideration of isolated spin-1/2 pairs is a crude approximation (68). The dipolar couplings between the protons belonging to various functional groups are shown to be active in two-dimensional DQ-MAS spectra for high excitation/reconversion times (68,73).

Dipolar correlation function can be measured for a multispin dipolar coupled network, for example, for the protons in functional groups attached to polymer chains in elastomers by a mixed echo given by the combination of the magic and the Hahn echo. The magic echo refocuses the residual multispin dipolar Hamiltonian with high efficiency (71–73,98). In a good approximation, the amplitude of the mixed echo is independent of residual (quasistatic) multispin couplings and inhomogeneous spin interactions including chemical shielding interaction. The following gives an evaluation of the dipolar correlation function describing slow chain motions within the limits of an exponential correlation function and a distribution of correlation times.

Mixed Echo Decay. The mixed echo amplitude decay can be expressed in terms of the autocorrelation function of the dipolar Hamiltonian (64). Transverse relaxation processes described by a single correlation time are rarely found in amorphous polymers including elastomers. If a normalized distribution of correlation times $g(\tau_c)$ is introduced, than the mixed echo decay is given by (64)

$$S_{ME}(6\tau) \cong 1 - \bar{M}_2 \int_0^\infty {\tau_c}^2 \left\{ e^{-\frac{6\tau}{\tau_c}} - 3\, e^{-\frac{5\tau}{\tau_c}} + \frac{9}{4}\, e^{-\frac{4\tau}{\tau_c}} + 3\, e^{-\frac{\tau}{\tau_c}} + \frac{3\tau}{\tau_c} - \frac{13}{4} \right\} g(\tau_c)\, d\tau_c \tag{29}$$

where τ_c is the correlation time. It is obvious form equation 29 that the measurement of DCF leads to a mixture of contributions from residual van Vlevk second moment and the distribution function of correlation times that is model dependent.

A particularly simple form for the function $g(\tau_c)$ is related to the log-Gaussian distribution (see for instance Reference 2), ie,

$$g(\tau_c) \equiv \frac{1}{\tau_c} F_G(\ln \tau_c) \tag{30}$$

where

$$F_{\mathrm{G}}(\ln\tau_c) \equiv \frac{1}{\sigma_{\ln}\sqrt{2\pi}} \exp\left\{ - \frac{[\ln(\tau_{\mathrm{c}}/\tau_{\mathrm{c0}})]}{2\sigma_{\ln}^2} \right\} \tag{31}$$

The center of gravity of the correlation time distribution is given by $\ln(\tau_{\mathrm{c0}})$ and the width of the distribution is $\Delta_{1/2} = 1.02\,\sigma_{\ln}$.

Parameters of the Dipolar Correlation Function for a Cross-Linked Elastomer Series. The mixed echo decays were measured for a series of cross-linked natural rubber (64). The model involving the distribution of correlation times (see eq. 29) was used to fit the mixed echo decay. The residual second van Vleck moments obtained from fits as a function of shear modulus G.

For ideal polymer coils, the most significant and distinctive property is the Gaussian distribution of the end-to-end distances. By considering the different segments of the freely jointed chain which are statistically independent and can be represented by a Markov chain, one can derive the correction to the Gaussian distribution of the end-to end distances (see Reference 99).

Using the corrected Gaussian distribution function one than gets (64)

$$\langle M_2 \rangle \propto \frac{5}{3}\frac{1}{N^2} - \frac{2}{3}\frac{1}{N^3} \tag{32}$$

Within the limit of the approximation used, it is concluded that the residual second van Vleck moment scales with $1/N^2$ for high numbers of statistical segments, ie, for $N \gg 1$, which means for low cross-link densities. However, this regime is invalid for the series of cross-linked natural rubber investigated using DCF (64). The effective number of statistical segments N is defined by the number of segments $N^{(0)}$ between physical cross-links or topological constraints and the number $N^{(\mathrm{C})}$ of segments between chemical cross-links. If we assume that the contributions to the residual dipolar coupling are additive and topological constraints are independent of the degree of chemical cross-linking, we can write $(N)^{-1} \approx (N^{(0)})^{-1} + (N^{(\mathrm{C})})^{-1}$. In this case, one expects (cf equation 32) that $\langle M_2 \rangle$ has a polynomial dependence on cross-link density or shear modulus.

Based on the dependence of the residual second moment on $1/N$ given by equation 32, the measured $\langle M_2 \rangle$ values can be fitted by a polynomial up to the forth power in the shear modulus G, ie,

$$\langle M_2 \rangle = a_0 - a_1 G + a_2 G^2 - a_3 G^3 + a_4 G^4 \tag{33}$$

This dependence is similar with that shown in Figure 8**a** measured using AIMS method (70). If only the first four values of $\langle M_2 \rangle$ corresponding to an intermediate regime of cross-linking are considered, the G^2 term dominates the dependence as it is expected from a Gaussian distribution of end-to-end vectors. The DCF measurements also reveal that the centre of gravity, as well as the logarithmic width of the distribution function of correlation time—which describes the slow motion of the network chains—scale with the cross-link density in a complex manner (64).

The development of NMR methods that allow accurate measurements of residual second van Vleck moments and the distribution of correlation times yields new tools to test polymer network theories that are more sophisticated than the theory of the freely jointed chain corresponding to a Markov chain.

Viscoelastic Polymers by Two-Dimensional NMR Spectroscopy

The investigation of molecular dynamics and local segmental orientation by two-dimensional (2D) NMR spectroscopy has a number of advantages (1,2) particularly when dealing with complicated spin systems such as viscoelastic polymers. Below, we will discuss examples of such investigations, concentrating on techniques that are particularly sensitive to the viscoelastic regime that is, NMR techniques for measuring residual dipolar couplings and dynamic order parameters. Readers interested in a more general overview of multidimensional NMR of polymers are referred to references (2,3,6).

Chain Orientation from 2D ^{1}H Magnetization Exchange Spectroscopy. Two-dimensional ^{1}H magnetization-exchange spectroscopy and its reduced one-dimensional (1D) variant have been used to probe residual dipole–dipole couplings between different functional groups of a SBR sample, namely between the CH and CH_2 groups of the butadiene units (65,100). The intergroup residual dipolar couplings can then be correlated with the shear modulus that is an independent measure of the cross-link density (65). Hence, the dynamic local-order parameter associated with the partially averaged dipolar coupling can be evaluated taking the average over the relevant dynamic processes.

Principle of the Method. Following the general scheme of 2D NMR spectroscopy, an evolution period of duration t_1 follows the excitation pulse. This interval ends with a flip-back pulse and the system is allowed to exchange during the mixing period t_m. After a third pulse the remaining signal is acquired during the detection interval t_2 (1). The intensity of the cross-peaks in the resulting 2D spectra then reflects the degree of exchange between the corresponding groups. Since full 2D NMR spectroscopy is time-consuming, for quantitative evaluations also a reduced 1D form has been used. In this case, the time t_1 is fixed and adjusted such that it acts as a chemical-shift filter (2) for one of the two butadiene lines in the static SBR spectrum. The reappearance of the filtered line with increasing mixing time is then a measure of the magnetization exchange between the protons of the CH and CH_2 groups. Note, that unlike the 500 MHz spectrum the styrene line and the CH line could not be distinguished in these experiments so that only the CH and CH_2 lines of the butadiene units are resolved. They are separated by about 3.35 ppm, corresponding to 1 kHz at the Larmor frequency of 300 MHz.

The theory needed for the evaluation of the exchange process was also developed (65,100). The model of the spin system used is depicted in Figure 15.

For short mixing times, the measurable exchange of ^{1}H longitudinal magnetization is predominantly determined by the protons belonging to nearest-neighbor CH and CH_2 groups. At longer mixing times on the other hand, a much larger spin system along the polymer chain must be considered, in principle. In Reference 100, however, it was shown that even in this case the intergroup residual dipolar

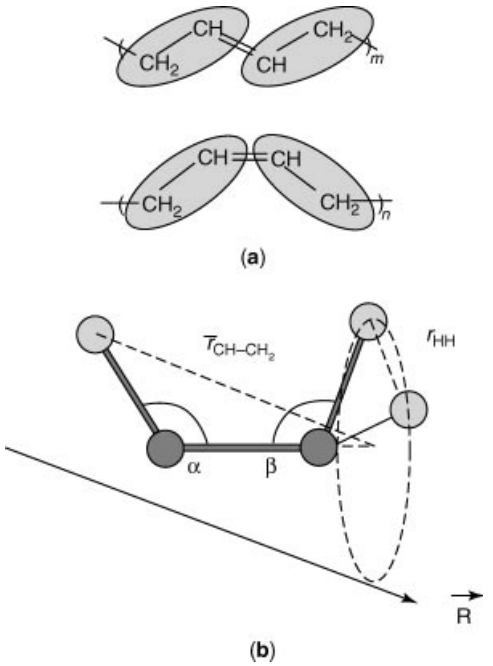

Fig. 15. (**a**) The monomer unit of *trans*- and *cis*-1,4-butadiene. The alternating sequence of CH—CH_2 groups, for which the magnetization-exchange process is treated. (**b**) The geometry of the CH—CH_2 spin system. The shaded circles represent protons and the black circles carbon atoms. The conformational jumps of the methylene protons lead to an average CH—CH_2 proton distance $\bar{r}_{CH—CH_2}$. Reproduced from Ref. 65, with permission from American Institute of Physics.

coupling can be measured from the initial-time regime of the magnetization-exchange decay curve.

In the limit of short mixing times t_m, the initial decay rates for the CH line were found (65,100) to depend only on the intergroup residual dipolar coupling $\bar{D}^{CH—CH_2}$ according to

$$\langle\langle I_z(t_m)\rangle\rangle = 1 - \frac{1}{2}\langle(\bar{D}^{CH—CH_2})^2\rangle t_m^2 \tag{34}$$

where $\langle\langle I_2(t_m)\rangle\rangle$ is the observable for the CH protons (for the CH_2 protons the factor 1/2 must be substituted by 1/4 in equation 34). The symbol $\langle\ \rangle$ represents the statistical ensemble average of the space part of the dipolar coupling in a disordered elastomer. Note, that from such measurements, the intergroup dipolar coupling $\bar{D}^{CH—CH_2}$ can be determined which is largely parallel to the segment axis. That is, it is much more informative with respect to the detection of chain order and chain motion than intragroup couplings would be.

Two-Dimensional ^1H Magnetization-Exchange Processes in Cross-Linked SBR. From the point of view of molecular motion, cross-linked elastomers are highly heterogeneous systems and a solid-like behavior is present together with slow and fast motions of both chains segments and functional

groups. Hence, the magnetization-exchange process is expected to be also heterogeneous, that is, driven by different mechanisms.

In order to investigate this heterogeneity, a series of static 2D NMR experiments was performed on SBR for increasing mixing time (100). As already discussed above, the aromatic and the olefinic protons are not resolved under the applied experimental conditions as can be seen in the 2D spectra shown in Figure 16.

A remarkable feature of the diagonal 2D spectrum for short mixing times is that the width of the diagonal peaks perpendicular to the (ω_1, ω_2) diagonal is much smaller than the widths along the diagonal. This indicates that the ^{1}H NMR spectrum is heterogeneously broadened (65). The width of each line along the diagonal reflects both the solid- and the liquid-like contributions, whereas the width perpendicular to the diagonal reflects selectively the liquid-like line width only. This feature is very pronounced for the CH diagonal peak and less for the CH_2 diagonal peak because of the strong proton–proton coupling within the methylene group. A similar result was already found in a ^{13}C magnetization-exchange experiment on natural rubber aimed to detect chain diffusion (101). While no chain diffusion was detected, the lines were also found to be spread out along the diagonal.

In the ^{1}H magnetization-exchange experiment on SBR not much cross-peak signal is found for mixing times shorter than 2.5 ms (see Fig. 16**a**). This indicates that within this time scale the CH and CH_2 functional groups can be considered in reasonable approximation to be isolated. The intergroup residual dipolar coupling leads to magnetization exchange for longer mixing times. Intense positive cross-peaks are thus present for $t_m = 30$ ms (see Figs. 16**d** and 16**e**). Such positive cross-peaks can arise for two reasons: from the exchange process mediated by residual dipolar couplings and from cross-relaxation induced by segmental motions with correlation times τ_c longer than ${\omega_0}^{-1}$ (1).

Proton Intergroup Residual Dipolar Couplings. The residual dipolar couplings between the protons of the CH and the CH_2 groups were determined from the t_m dependence of the peak intensities. The decay of the longitudinal magnetization $M(t_m)$ of the diagonal signals (normalized to the value M_0 that corresponds to zero mixing time) is recorded for short mixing times for the CH group. According to equation 34, the magnetization-exchange dynamics should show an initial quadratic dependence on t_m. This dependence is indeed found in the experiments and is shown in Figure 17**a** for SBR as an example.

From the slope of the initial magnetization decay, the values of the effective residual dipolar couplings $D_{\mathrm{eff}}^{\mathrm{CH{-}CH_2}} \equiv \langle (\bar{D}_{\mathrm{eff}}^{\mathrm{CH{-}CH_2}})^2 \rangle^{1/2}$ could be evaluated and it could be shown that these couplings scale with the cross-link density (65,100). The correlation of the coupling constant $D_{\mathrm{eff}}^{\mathrm{CH{-}CH_2}}$ with the shear modulus G as an independent measure of the cross-link density demonstrates this behavior (Fig. 17**b**). Note, however, that the line in Figure 17**b** does not cross the origin but provides a significant value for $D_{\mathrm{eff}}^{\mathrm{CH{-}CH_2}}$ at G = 0. This is not in contradiction with the applied model, but reflects the influence of local chain order (physical cross-links). From extrapolating to $G = 0$ in Figure 17**b**, the intergroup residual coupling of an uncross-linked SBR melt was determined to be $\bar{D}_{\mathrm{eff}}^{\mathrm{CH{-}CH_2}} \approx 533$ Hz. Using average internuclear distances and bond angles for SBR, one can extract the value for the dynamic-order parameter $S_{\mathrm{H{-}H_2}}$ of the CH—CH_2 intergroup linkage

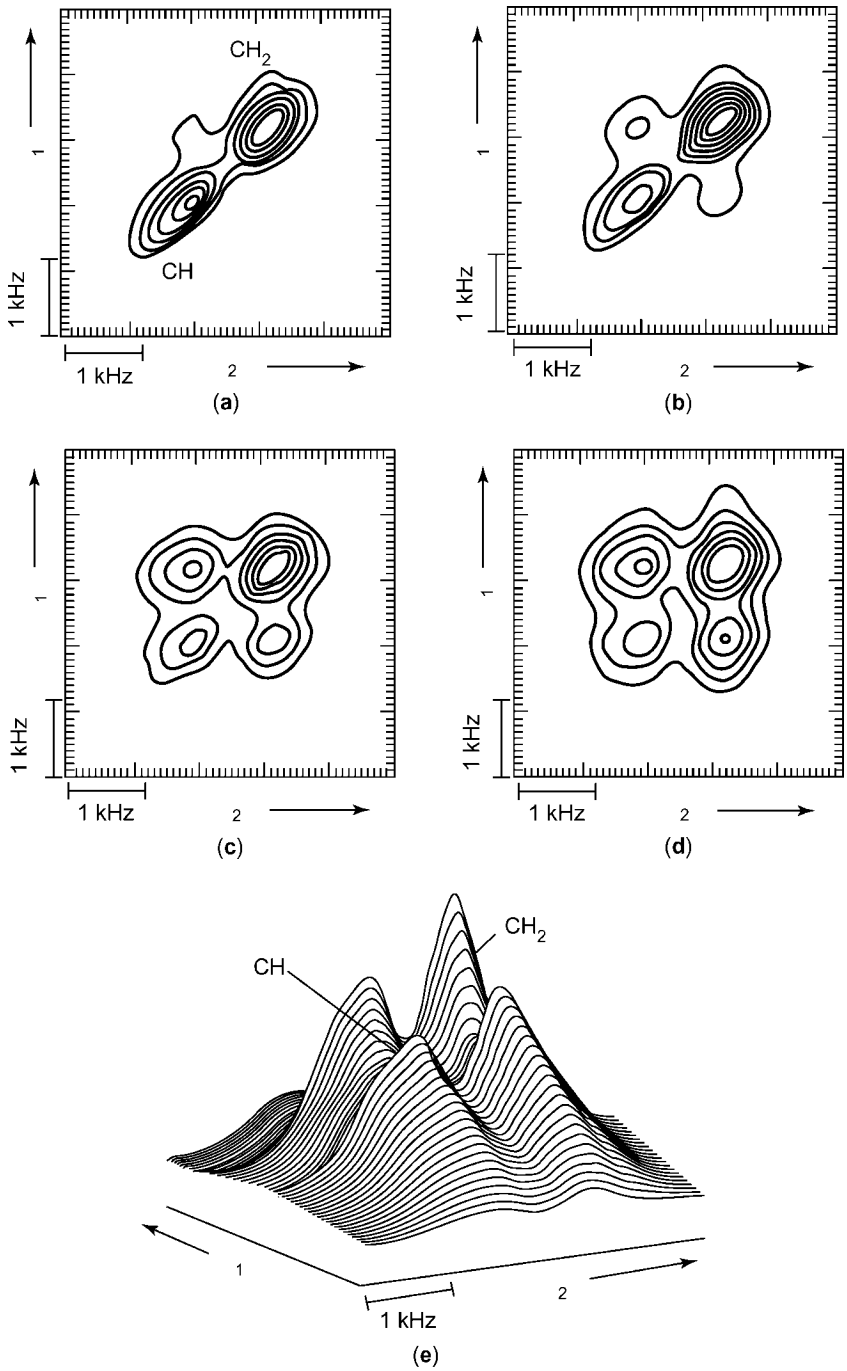

Fig. 16. Two-dimensional ^{1}H magnetization-exchange spectra of a SBR recorded with different mixing times have been used: $t_m = 2.5$ ms (**a**), 5 ms (**b**), 15 ms (**c**), and 30 ms (**d**). The 2D surface representation for $t_m = 30$ ms in (**e**) shows that all cross-peaks are positive. Reproduced from Ref. 65, with permission from American Institute of Physics.

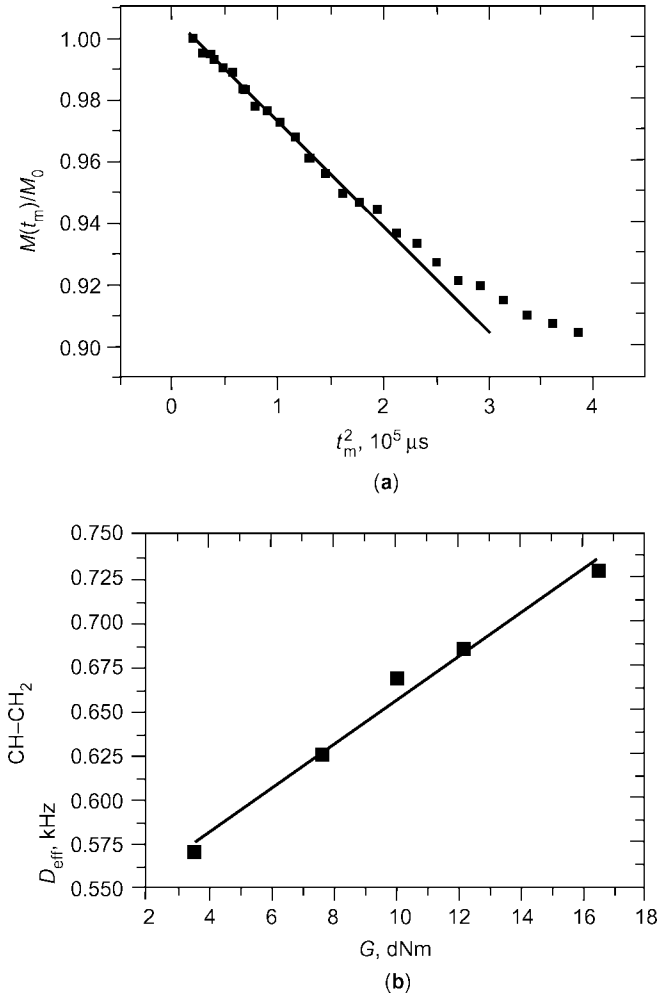

Fig. 17. (**a**) The initial decays of the proton magnetization for the exchange process CH → CH_2. The initial part of the magnetization-exchange data (starting with $t_m = 100\ \mu s$) shows the predicted dependence in t_m^2. The effective CH—CH_2 intergroup dipolar coupling constant $D_{eff}^{CH—CH_2}$ can be evaluated by fitting the theoretical curve. (**b**) $D_{eff}^{CH—CH_2}$ as a function of the shear modulus G for a series of differently cross-linked SBR samples. Reproduced from Ref. 65, with permission from American Institute of Physics.

$\vec{r}_{CH—CH_2}$ according to $\bar{D}_{eff}^{CH—CH_2} = D_{rigid}^{CH—CH_2} S_{H—H_2}$. This yields $S_{H—H_2} \approx 0.1$ and suggests an even higher value for the dynamic-order parameter for the corresponding carbon–carbon bond $S_{C—C} \approx 0.13$, since $\vec{r}_{CH—CH_2}$ and $\vec{r}_{C—C}$ forms an angle of 24°. Thus, even in polymer melts the chain motion can be largely anisotropic, as shown previously for poly(methacrylates) (102).

Magnetization-exchange NMR spectroscopy offers a convenient means for measuring the residual dipolar couplings between functional groups along the polymer chains. The intergroup dipolar coupling is remarkably high even in uncross-linked melts representing relatively high local segmental order. In

cross-linked samples, it scales with the cross-link density as predicted by the scale-invariant model of residual dipolar couplings (12), emphasing its relation to viscoelastic properties of the elastomers.

Segmental Motions by 2D NOESY-MAS Spectroscopy. In the previous paragraph, we have discussed the coherent magnetization-exchange process by ^{1}H non vanishing average dipolar couplings. Under fast MAS conditions, however, the residual couplings responsible for the exchange are largely refocused for full rotor periods and cross-relaxation by the fluctuating part of the dipolar interaction predominates. This so-called nuclear Overhauser effect (NOE) (103) takes place if the spins system is not in internal equilibrium. It corresponds to relaxation between dipolar-coupled nuclei such as ^{13}C and ^{1}H or between different nonequivalent magnetically sites of the same type of nucleus. NOE spectroscopy (NOESY) is well known in liquid-state NMR where it is one of the standard 2D techniques to elucidate and assign structures of macromolecules in solution (1).

Following the success of the technique in solution state, NOESY has been also applied to polymers or viscoelastic materials (104–110). As in solution experiments, one takes advantage of the fluctuating part of the dipolar coupling to extract useful structural and dynamical information. Using this method, nuclear Overhauser enhancement factors have been measured in polyisoprene over a range of temperatures with static ^{13}C NOE spectroscopy (104). A molecular-weight independent change of regime was observed at around 60°C for the backbone motion reflecting a loss of motional cooperativity with increasing temperature. Also the temperature-independent correlation time of the internal rotation of the methyl group could be inferred.

The polymer miscibility in polymer blends (PS/PVME) was probed by ^{13}C NOE spectroscopy under MAS (105). This study takes advantage of the fact that cross-peaks appear only between spins that are neighbors of each other, thus establishing NOE as a probe for the degree of mixture on the molecular level. Additional information on the molecular structure of the blend could be obtained from the NOE growth rates. The results suggest that there exists a specific interaction between the phenyl ring of the PS and the PVME methyl group. In Reference 106 the same technique was applied for investigating methyl groups as a source of cross-relaxation in solid polymers such as polycarbonate or polystyrene.

Static ^{1}H 2D NOE spectroscopy was applied in a first experiment showing that the technique can be used to measure interchain interactions (107). This work was then continued by applying the technique under MAS to investigate the intermolecular interactions responsible for the miscibility in polybutadiene/polyisoprene blends above the glass-transition temperature (108). It could be shown that intermolecular association can be probed by this technique and the results reveal the existence of weak intermolecular interactions between the polyisoprene methyl group and the vinyl side chain of the polybutadiene.

Segmental Motions of Elastomers. NOESY experiment under MAS on protons was used to study molecular motions in technical relevant materials such as rubbers (109,110). For the evaluation of these parameters, it is necessary to understand the cross-relaxation process in the presence of anisotropic motions and under sample spinning. Such a treatment is provided in Reference 110 and the cross-relaxation rates were found to weakly depend on fast motions in the Larmor frequency range and strongly on slow motions of the order of the spinning

frequency ν_R. Explicit expressions for the ν_R dependent cross-relaxation rates were derived for different motional models. Examples explicitly discussed were based on a heterogeneous distribution of correlation times (2,12,111) or on a multistep process in the most simple case assuming a bimodal distribution of correlation times (112–114).

The derived relationships were tested experimentally on a cross-linking series of styrene–butadiene rubbers and the cross-relaxation was studied as a function of the rotor frequency ν_R. As an illustration of such measurements, Figure 18**a** shows a surface representation of the gradient-selected 2D NOESY spectrum of a SBR sample acquired with a mixing time of 2.7 ms at a rotor frequency of 8 kHz. The lines corresponding to the aliphatic, the olefinic, and the aromatic protons are well resolved and can be assigned as indicated. Already at short mixing times pronounced cross-peaks are visible, in particular between the olefinic CH and the CH_2 group.

Figure 18**b** shows the decay curve of the diagonal peaks for mixing times up to 3 ms. Unlike in the magnetization-exchange case (65), the decay is found to be approximately linear in t_m in the short mixing time regime and exponential or biexponential for long times (110). A similar curve can be plotted for the increase of the cross-peaks. In order to investigate the effect of the sample spinning on the cross-relaxation rates, series of 2D NOESY-MAS spectra were acquired as a function of the rotor frequency. The rates evaluated from these series were found to decrease linearly with rotor frequency that is an indication that cross-relaxation in elastomers is dominated by slow motions in the 10 kHz regime rather than by motions in the Larmor frequency range as in case of liquids. The cross-relaxation rates at room temperature were found to depend moderately only on the cross-link density that is another indication that cross-relaxation is dominated by the α process.

The experimental rates were analyzed in terms of the explicit expressions derived by the theoretical treatment (110). As expected for a statistical copolymer, segmental motions in the SBR samples cannot be described by a single correlation time (2). From T_1 data that were also measured the correlation time should be in the range of 10^{-8} s while the rotor frequency ν_R dependence of the cross-relaxation rates requires a correlation time of 10^{-5} s. So it is clear that at least two different correlation times are necessary to account for the experimental findings. The relaxation dispersion data T_1 (ω) (ω being the Larmor frequency) (96), however, show no discontinuity that would indicate the presence of two distinct motional processes. Thus, the data were analyzed in terms of a broad distribution of correlation times for almost isotropic segmental motions (α relaxation). With a simple log-Gaussian distribution function of reasonable parameters (110) it was found that one could account for both the T_1 values and the ν_R-dependent cross-relaxation rates. From the center of gravity of the distribution, the glass-transition temperature could be estimated as $T_g = 230$ K using the well-known Williams–Landel–Ferry (WLF) equation (2). This value compares favorably with the known value of $T_g = 220$ K for uncross-linked SBR-1500.

Selective Residual Dipolar Couplings by ^{1}H Multiple-Quantum NMR Spectroscopy. Multiple-quantum MQ NMR spectroscopy is well established for structural studies of liquids and highly mobile solutes in liquid crystals (1,26).

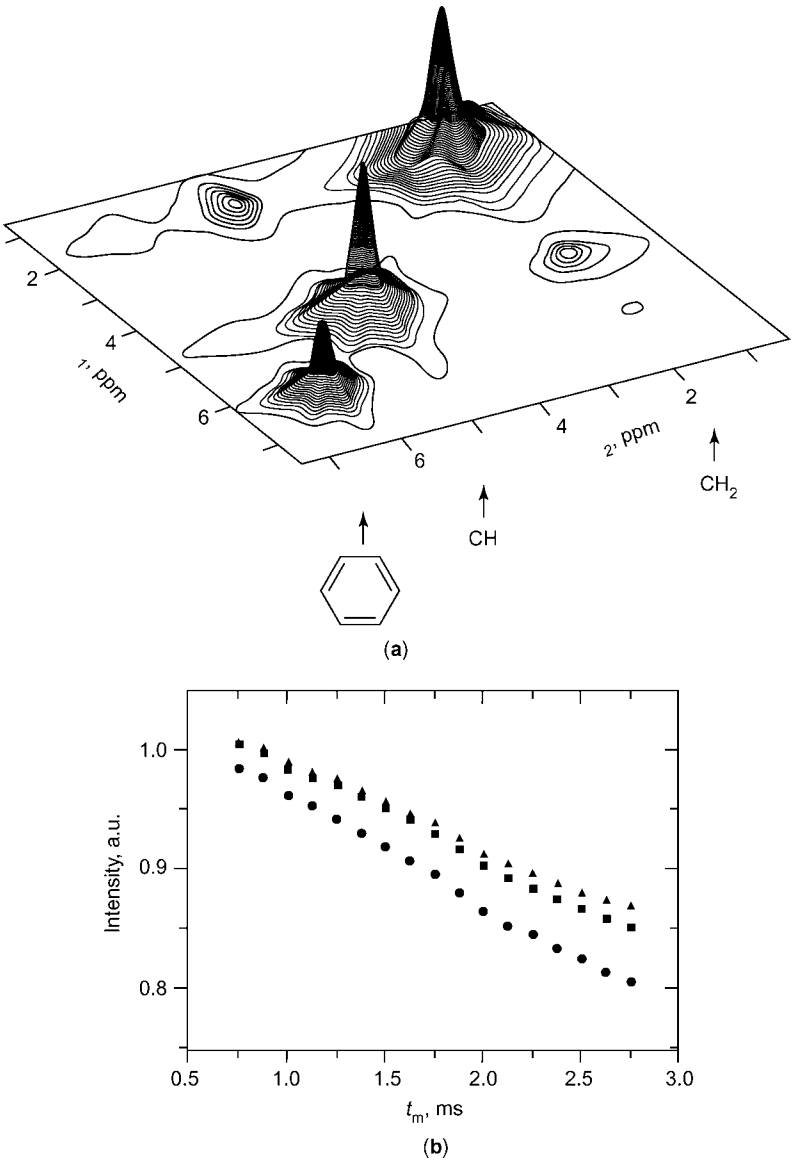

Fig. 18. (**a**) 2D ^{1}H-NOESY surface spectrum of SBR acquired for a mixing time of 2.7 ms and under 8 kHz MAS. Already at this short mixing time pronounced cross-peaks are visible. (**b**) Short-time decay of the cross-peak intensity evaluated from a series of 2D spectra. Such curves can be analyzed providing information on internuclear distances and segmental dynamics (■) aromatic CH, (●) olefinic CH, (▲) CH. Reproduced from Ref. 110, with permission from Taylor & Francis Ltd.

In recent years, there has been a sustained effort to obtain homonuclear (73,115–119) and heteronuclear (120–122) high resolution MQ NMR spectra also for organic solids using fast MAS to increase resolution and sensitivity. Such MQ spectra proved to be valuable tools for determining dipolar connectivities between

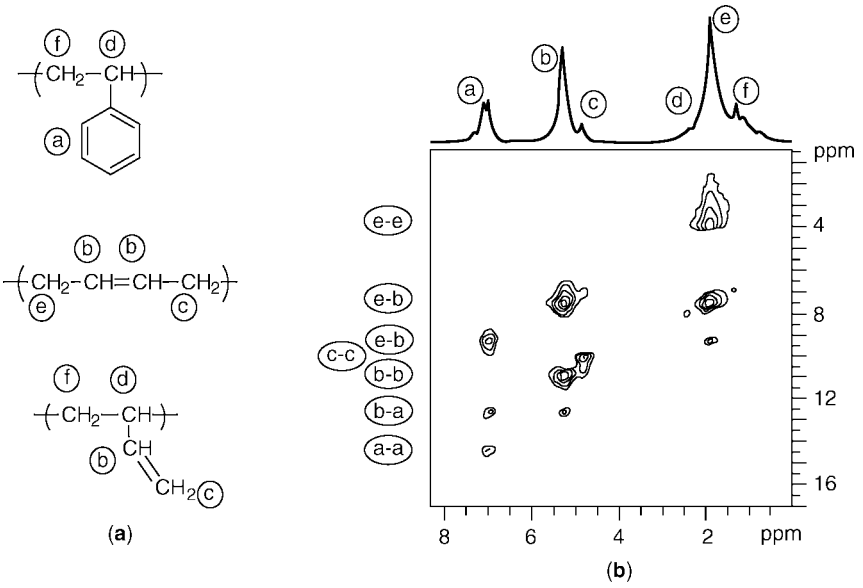

Fig. 19. Proton DQ MAS spectrum of a SBR sample with a low value of cross-link density (0.8–0.8 phr sulfur accelerator). The rotor frequency was 10 kHz and the t_1 increment was 15 μs. The diagonal peaks and the cross-peaks of the functional groups are assigned as indicated (compare (**a**) and (**b**)). Reproduced from Ref. 73, with permission Elsevier.

spin-1/2 nuclei (74,75,116). More quantitatively, dipolar couplings, internuclear distances, and molecular torsion angles can be measured by these techniques (74). For viscoelastic materials, it was recently shown that ^{1}H high resolution MQ NMR spectroscopy offers the possibility to measure site-selective residual dipolar couplings between all resolved protons (73,119). The MQ technique thus is an attractive tool for studying structure and dynamics in polymer melts (119) and elastomers (68,73).

Dipolar Connectivities from the High Resolution ^{1}H DQ MAS Spectroscopy. Figure 19 shows the ^{1}H DQ spectrum of a cross-linked SBR sample that has been acquired at a spinning frequency of 10 kHz (73).

The peaks in the 2D DQ spectrum correspond to double-quantum coherences between two spins which must be relatively close neighbors in space in order to contribute significantly to the peak intensity as follows from the strong distance sensitivity of the dipolar coupling. From the existence of the corresponding peaks therefore through space dipolar connectivities can be easily established.

The assignment of the peaks is shown along the ω_1 dimension by pairs of letters a–f (see Fig. 19**a**) which indicates the functional groups that are involved in the generation of the corresponding DQ peaks. From a simple qualitative inspection of the DQ spectrum, it can be seen that there are dipolar connectivities between practically all functional groups. The strongest DQ signals are found between protons of the polybutadiene groups, but also DQ peaks of considerable intensity are visible between the polybutadiene protons and the aromatic protons of the styrene units. This indicates a good mixture of the different functional

groups on the nanometer length scale as is found for instance in the case of a statistical copolymer.

Another recent example of the use of ^{1}H DQ MAS NMR spectroscopy is given by the study of molecular scale miscibility of poly(butylenes terephtalate)-*block*-poly(tetramethylene oxide) multiblock (PBT-*block*-PTMO) copolymers (123) by looking for correlation peaks between signals from the hard and soft blocks.

Previous ^{13}C NMR MAS relaxation experiments revealed a large, bimodal-like heterogeneity of the PTMO chain mobility, which were explained by microphase separation of the amorphous phase into a highly mobile PTMO-rich phase and a less mobile PBT/PTMO mixed phase (PBT/PTMO interface) (124). However, the motional heterogeneity of the PTMO blocks can also originate from a dynamical interface due to anchoring of PTMO blocks to rigid PBT domains, which can cause apparent "two-phase" behavior. 2D NMR experiments can provide direct information on the molecular scale miscibility in polymeric materials. ^{1}H DQ correlation spectroscopy under fast MAS using the back-to-back (BABA) sequence is used in the present study to determine the proximity of the PBT and PTMO chain units in the block copolymers.

The ^{1}H MAS NMR spectrum of PBT-*block*-PTMO consists of resonances at 8.0, 4.4, 3.4, and 1.6 ppm that originate from the aromatic protons of PBT, OCH_2 protons of PBT, OCH_2 protons of PTMO, and the $(CH_2)_2$ protons of PBT and PTMO, respectively. It is noted that the OCH_2 protons of PBT and PTMO at the transition from PBT to PTMO blocks along the chain have slightly different chemical shifts, as measured by ^{1}H solution NMR spectra, ie, 4.35 and 3.45 ppm for PBT and PTMO, respectively. However, these resonances are not resolved in the solid state NMR spectra. Figure 20 shows the phase-sensitive 2D spectrum of sample A1000/35 measured using the BABA sequence (123). The single-quantum (SQ) and double-quantum (DQ) dimensions are shown on the horizontal and vertical axes, respectively. The signals in the DQ dimension are situated at the sum of the frequencies of the two-coupled protons. Therefore, a DQ signal between two protons with identical chemical shifts will be on the diagonal, and signals between two protons with different chemical shifts will be off-diagonal giving rise to two signals equally spaced from the diagonal. One should note the different positions of off-diagonal signals are compared to COSY/NOESY spectra.

As expected, all resonances of PBT and PTMO blocks are present in the 2D spectrum, ie, all diagonal peaks and off-diagonal correlation peaks between the aromatic and the OCH_2 protons of PBT as well as a correlation peak between the CH_2 and OCH_2 peaks of PTMO. Additionally, there is a correlation peak between the aromatic protons from PBT and the OCH_2 groups from PTMO, suggesting a close proximity of these two chain fragments. The signal is in fact much more intense than one would expect (*1*) from a small fraction (only 14%) of PTMO chain units that are located at the transition from PBT to PTMO blocks in a single chain and (*2*) from the rather long intrachain distance between aromatic PBT and the OCH_2 protons of PTMO at the transition from the hard to the soft blocks along the chain. The correlation peak cannot be explained by spin diffusion during the 1ms *z*-magnetization delay after the reconversion period. Therefore, the DQ BABA MAS experiment is not affected essentially by the spin diffusion process and gives information about the molecular scale mixing. This correlation peak has to come primarily from intermolecular couplings between the PBT and PTMO protons

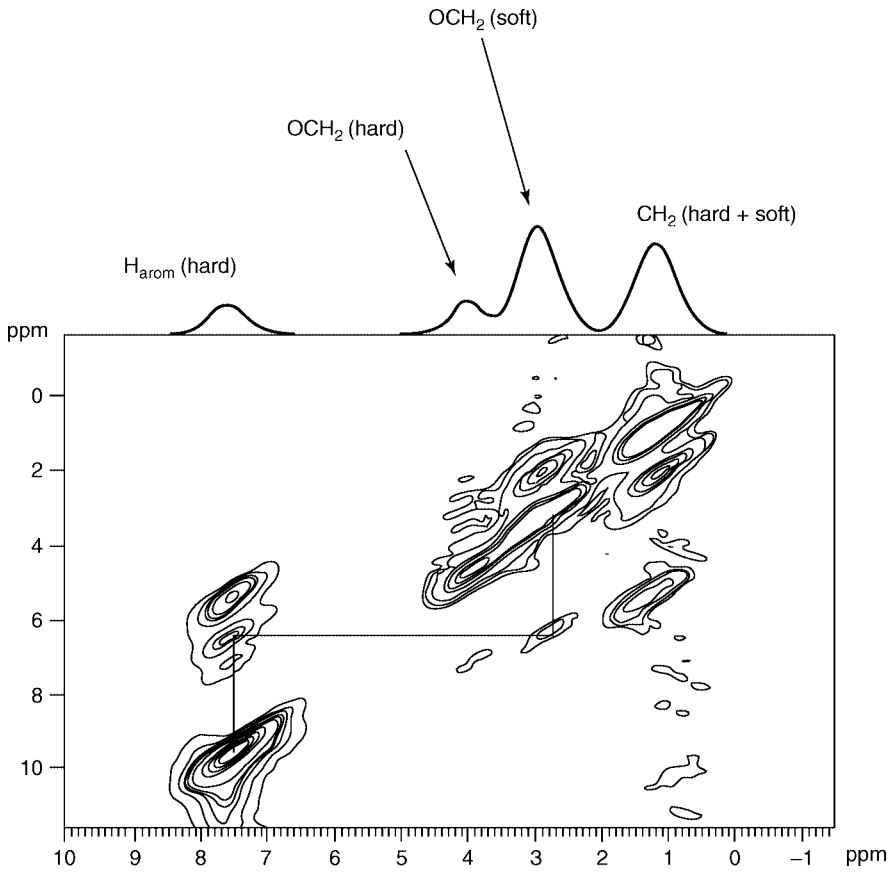

Fig. 20. Two-dimensional ^{1}H DQ MAS spectrum for thermoplastic elastomers PBT-*block*-PTMO with a length of PTMO block of 1000 g/mol and amount of PTMO block of 35% in weight (sample A1000/35) showing the dipolar correlation between the resonances of PBT and PTMO chain units, as indicated by the lines connecting the peak positions. Reproduced from Ref. 123, with permission from American Chemical Society.

of adjacent chains. In fact, it was shown that a DQ correlation signal arises at short recoupling times, which in our case, marks an interproton distance below 0.5 nm. Therefore, this correlation peak can be unambiguously attributed to PBT and PTMO units in a mixed PBT/PTMO phase.

Site-Selective Double-Quantum Buildup Curves and Correlation with Cross-Link Density. A more quantitative evaluation of the DQ peak intensities is possible by acquiring the experimental DQ buildup curves for each of the peaks performing a series of DQ experiments with increasing excitation time. As an example, the buildup curves for the three main contributions are shown in Figure 21 for two SBR samples with different cross-link densities (73).

A fit of the experimental DQ builtup curves using a relationship derived in the spin-pair approximation allows the ratio of the corresponding residual dipolar couplings to be determined, ie, $(\bar{D}^{CH_2} S_s^{CH_2}) : (\bar{D}^{CH_2-CH} S_s^{CH_2-CH}) : (\bar{D}^{CH-CH} S_s^{CH-CH})$, where $\bar{D}^{ij}$ represents a preaveraged dipolar coupling constant and S_s^{ij} the

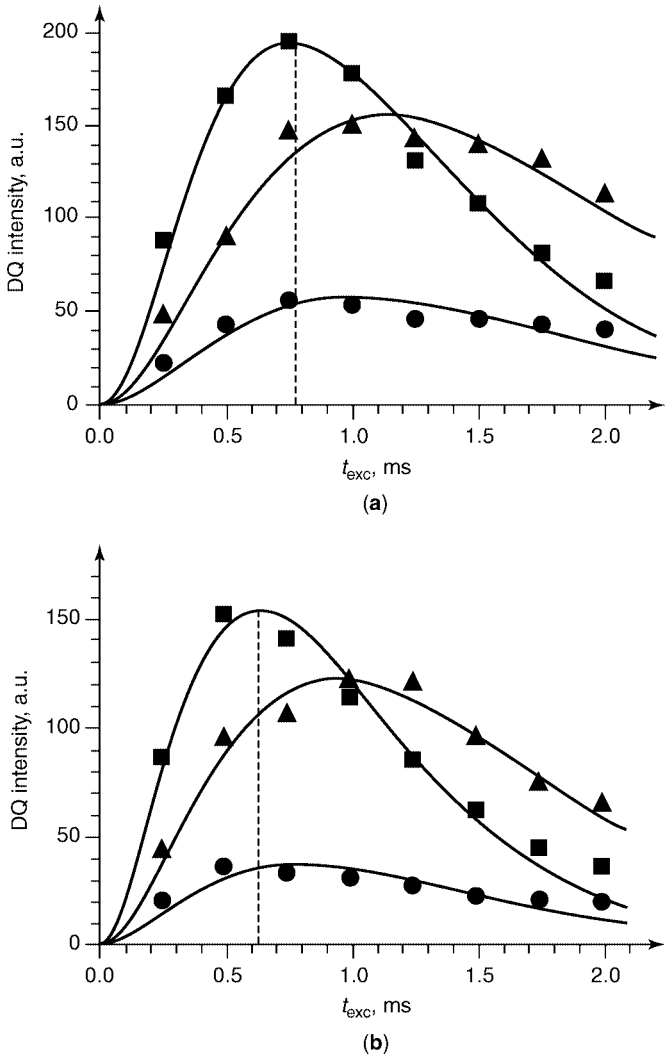

Fig. 21. Site-selective ^{1}H DQ buildup curves for low (**a**) and high (**b**) cross-linked SBR samples. The DQ signals correspond to the —CH_2— (■), CH_2—CH— (▲) and CH═CH coherences (●). The vertical dashed lines mark the excitation times for the maximum signal for the methylene protons, which differs for the two cases. Reproduced from Ref. 123, with permission from Elsevier.

corresponding scaled dynamic-order parameter (73,119). The order parameter $S_s^{CH_2—CH}$ (calibrated using a 1D MAS sideband pattern) is found to be close to the value $S_s^{CH_2—CH} = 0.1$ that has been estimated for SBR samples by the magnetization-exchange experiments described above (65). The order parameter corresponding to the CH—CH coupling is even higher (73). This coupling provides the best measure for the chain dynamics since it is predominantly aligned along the segmental axis.

For investigating a series of samples with different cross-link densities, however, the procedure described above is very time-consuming. In this case, a somewhat less detailed 1D measurement of the integral DQ-filtered signal can be used to establish the relationship between the total DQ intensity and the cross-link density. The square root of the DQ intensity is found to be an approximately linear function of the cross-link density but, more important, the topological constraints that are already present in the melt are found to dominate the residual couplings (see also Reference 119). Hence, the technique is not so much a sensitive measure of the cross-link density but is a rather sensitive and selective probe for local dynamic chain order.

The strongest residual dipolar couplings were also edited in a nonrotating cross-linked polyisoprene series by exciting double- and triple-quantum coherences in the short time regime (68). From this, the dynamic order parameters of the methylene and methyl groups were estimated and correlated with the cross-link density. Essentially, the same behavior was found as for SBR.

Residual Local Dipolar Fields by Heteronuclear Correlation Experiments. The NMR spectrum of rare spins (e.g. ^{13}C) contains extremely useful information because of the usually high chemical-shift dispersion and the possibility to easily eliminate undesired spin interactions. It would thus be advantageous to combine this high resolution dimension with ^{1}H spectroscopy in form of a heteronuclear correlation experiment (1). In the following, we will concentrate on the so-called wide-line separation (WISE) experiment (2,125–128), in which ^{1}H broadline information is correlated with the ^{13}C spectroscopic information. There are however also other possibilities for including heteronuclear information in a 2D experiment, for instance, 2D heteronuclear *J*-resolved spectroscopy which was applied for the investigation of filled natural rubber in Reference 101. It was concluded that there must be a high degree of motion in order to allow the scalar ^{13}C—^{1}H couplings to be revealed by magic-angle spinning alone. The ^{13}C line width was found to be determined by susceptibility effects due to the presence of the filler.

While the (heteronuclear and homonuclear) residual dipolar couplings have to be eliminated in such *J*-resolved experiments, they are the main source of information in the WISE experiment described below. For the investigation of viscoelastic materials the experiment thus must be performed under static conditions or under slow magic-angle spinning. The method is discussed in the previous section.

^{13}C–^{1}H Local Residual Dipolar Couplings by WISE-MAS Experiments. For elastomers and rubbery-like materials well above the glass-transition temperature T_g, the high molecular mobility reduces the dipolar couplings dramatically. The WISE experiment allows one to investigate site-selectively residual dipolar interactions and thus molecular dynamics by editing the corresponding proton slices of the 2D data set.

In References 129 and 130 ^{13}C-edited ^{1}H transverse relaxation was investigated in a nonrotating SBR cross-linking series. A short contact time was used to avoid ^{1}H spin diffusion. As a consequence of this, only ^{1}H atoms directly bonded to ^{13}C atoms are observed and the ^{1}H transverse relaxation is thus found to be mainly governed by ^{1}H—^{13}C heteronuclear couplings which makes analysis simple. The ^{13}C-edited ^{1}H transverse relaxation could be fitted with only one adjustable

parameter, the effective number of statistical segments (129). This was invoked as a justification for the heterogeneous model used to describe transverse relaxation. Moreover, the effect of cross-linking could be investigated and it was shown that it affects the dynamics of all functional groups to the same extend (125).

A similar experiment has been performed in (125) but under MAS conditions. For a series of cross-linked natural rubber samples (A-F1), ^{13}C-edited ^{1}H spinning sidebands have been extracted from the 2D spectrum. These sideband patterns are encoded by the residual dipolar couplings of the corresponding functional groups and are presented in Figure 22.

For the experimental conditions given, the spectra are found to be dominated by heteronuclear dipolar interactions which leads to relatively narrow, well-separated dipolar spinning sidebands. The heteronuclear dipolar couplings could be evaluated by simulating the spectra on this basis (see right column in Figure 22). They where found to be between 0.9 and 1.5 kHz for the samples of the series (the intercross-link masses M_c were between 6700 and 11,000 g/mol). A practically identical envelope of the spinning-sidebands intensities in the indirect dimension is found for all functional groups. This indicates that the effective ^{1}H—^{13}C vectors of different segments are affected in approximately the same way by internal motions.

Spin diffusion as an alternative explanation of this effect could be excluded by a similar experiment with additional ^{13}C decoupling during the evolution period t_1 which eliminates the encoding by the heteronuclear dipolar couplings (125). Distinct features are then visible for the spinning sideband patterns of the CH_3, CH_2 and CH groups (see Reference 125) proving that different functional groups are relatively isolated from each other on the time scale of the experiment as a consequence of the reduction of homonuclear dipolar interactions by high segmental mobility and magic-angle sample spinning. Therefore, the indirect detection of the spinning sideband patterns via cross-polarization ^{13}C spectroscopy allows for selective measurements of residual dipolar interactions on different functional groups (125).

Deuterium NMR Studies on Thermoplastic Elastomers. For the investigation of the molecular dynamics in polymers, deuteron solid-state nuclear magnetic resonance (^{2}D-NMR) spectroscopy has been shown to be a powerful method (2). In the field of viscoelastic polymers, segmental dynamics of poly(urethanes) has been studied intensively by ^{2}D-NMR (131,132). In addition to 1D NMR Spectoscopy, 2D NMR exchange spectroscopy was used to extend the time scale of molecular dynamics up to the order of milliseconds or even seconds. In combination with line-shape simulation, this technique allows one to obtain correlation times and correlation-time distributions of the molecular mobility as well as detailed information about the geometry of the motional process (2).

Principles of the Method. The scheme typically used for such 2D-exchange NMR experiments corresponds to that given in References 1 and 2, however, in case of deuterons often a solid echo sequence is used for detection instead of the last pulse. During the mixing time t_m of the experiment, molecular reorientations are allowed to take place. If the molecular orientation of a C—^{2}H bond has changed due to slow molecular motions, the signal continues to evolve with a new frequency. For reorientation about a well-defined angle θ, the 2D exchange spectrum exhibits

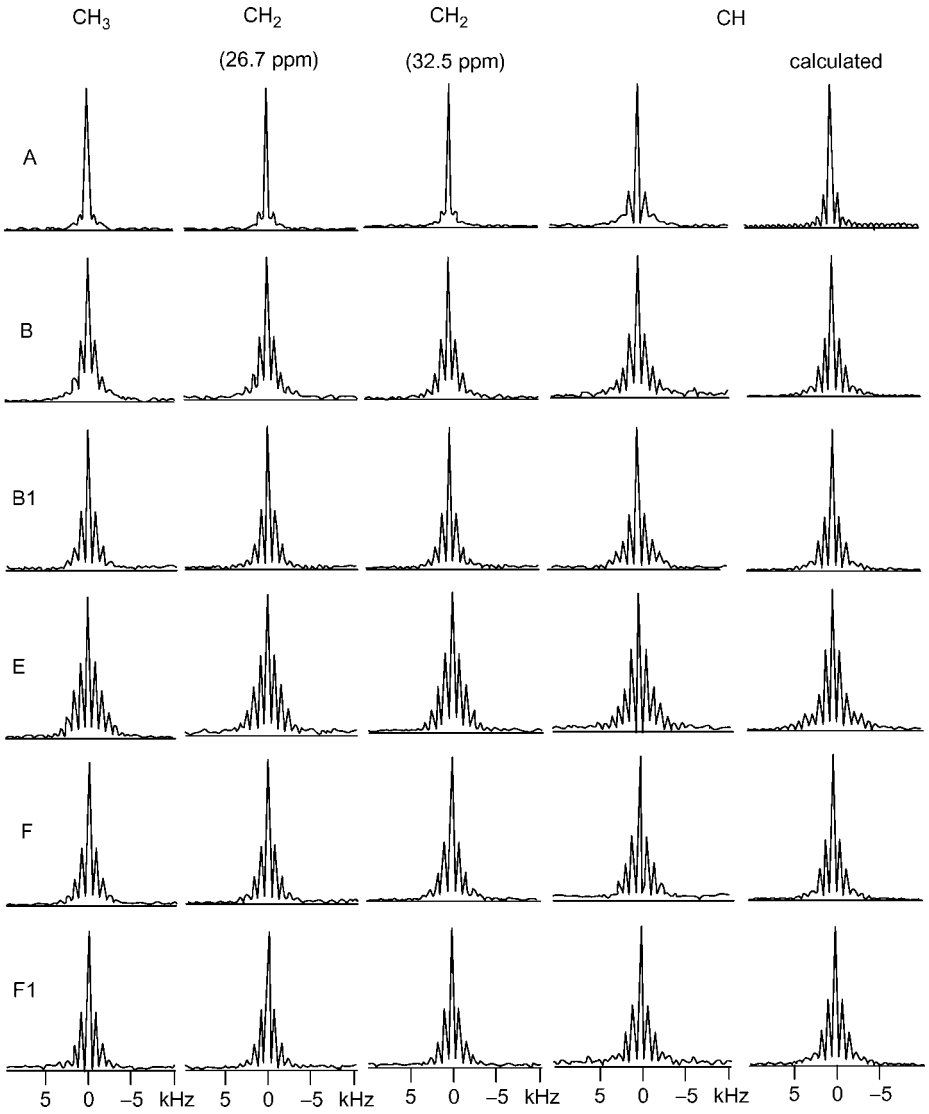

Fig. 22. Slices from a 2D experiment corresponding to $^{13}C—^{1}H$ WISE experiment performed on a series of cross-linked natural rubber samples A—F1 under magic-angle spinning. The slices reflecting proton sideband pattern for the different functional groups that are encoded by the ^{1}H residual dipolar couplings. The distinct features of dipolar slices prove that the different functional groups may be considered as relatively isolated groups of spins on the time scale of the evolution and cross-polarization. characteristic ridges in the form of ellipses that can be analyzed with respect to motions (for details about the analysis we refer to literature (2)).

Local Motions and Segmental Orientation in Supramolecular Hydrogen Bond Assemblies. In the field of viscoelastic materials, the technique has been mainly applied to thermoplastic elastomers. One interesting elastomer belonging

to this class consists of polybutadiene chains functionalised by 4-(3,5-dioxo-1,2,4-triazolidin-4-yl) benzoic acid (U4A) units which act as effective junctions zones. The molecular dynamics of the phenyl rings of the U4A units has been probed by 1D and 2D ^{2}H-NMR (see Reference 133, and references therein). In this system, there are three spatially separated environments that are reflected in the mobility of the polar units. Phenyl rings which are incorporated in the structure are either rigid or undergo 180° phenyl flips. The small fraction of free functional groups move isotropically and their mobility is coupled to the dynamics of the polymer matrix. The 1D ^{2}H-NMR spectra can be described quantitatively assuming a distribution of correlation times over 2–3 decades and the geometry of the motional processes is defined by the environment in the clusters up to the order–disorder transition temperature. 2D spectra of the model compounds show an elliptical exchange patterns, indicating well-defined slow 180° phenyl flips on a time scale of 100 ms up to 3 s.

Principles of NMR Imaging Methods

In polymers, the spatial distribution of the nuclei and the spin interactions as well as motions can be probed by NMR at different length scales using different strategies. The NMR techniques suitable for investigation of spatial structures are identified in Figure 23 together with the appropriate spatial resolution scale. In the nanoscale range, spectroscopic methods based on manipulation of spin interactions can measure internuclear distances and bond angles ((27), and references therein).

The field gradients are used for selection of the coherence pathways and encoding of molecular diffusion but many methods perform without the demand for field gradients. In the mesoscopic range, spin diffusion ((2), and references therein) can be used for measuring domain sizes and morphology. The domain of NMR imaging of polymers (134–138), which uses space encoding by field gradients can probe today only the macroscopically distributed heterogeneities, ie, in the order of 10–100 μm.

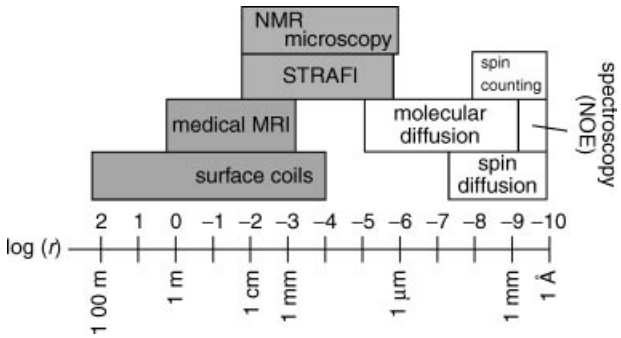

Fig. 23. Range of spatial resolution available from different NMR experiments that covers over teen orders of magnitude. The methods using direct space encoding by gradient are shaded, but all other spatial information can be included for creation of image contrast. Reproduced from Ref. 136, with permission from Wiley.

In recent years, the field of spatially resolved magnetic resonance which includes imaging, microscopy, and volume localized spectroscopy of materials (5,18) has been advanced by the introduction of several new techniques and improvement of the existing ones designed to overcome, mainly, the dipolar interactions of abundant proton spins in rigid polymers that contribute to broadening of the NMR resonance lines. The well-known condition $\Delta x = 2\pi\,\Delta\nu_{1/2}/(\gamma G_x)$ (see for instance, Reference 47) for the spatial resolution Δx^{-1} by frequency encoding, where γ is the magnetogiric ratio, $\Delta\nu_{1/2}$ is the full width at half height of NMR spectrum and G_x is the field gradient strength in the x-direction, can define the strategies for improving the quality of NMR images. There are, in principle, two possibilities: either the gradient strength can be increased or the line width be reduced (47,139–141). This can be achieved by manipulation of the spin or the space part of the interaction Hamiltonian or both, or by dilution manipulations (4). Increasing the gradient, strength might seem the simpler approach. However, the difficulty of using a large gradient is that the receiver bandwidth must be increased to accommodate the spread in resonance frequencies and therefore more noise is introduced into the resultant image. The noise content is proportional to the square root of the receiver bandwidth, and hence the time to acquire a given quality image, in both resolution and sensitivity, depends on the line width.

Many solid-state imaging techniques use spin coherences refocused by *echoes* for different purposes: (*1*) To record very short free induction decays present, in general, for solids and/or in the presence of strong field gradients. (*2*) For space encoding during the echo time. (*3*) For line narrowing by homonuclear or heteronuclear dipolar decoupling. (*4*) Reconversion of multiple-quantum (MQ) coherences into detectable single-quantum coherences. The properties of the spin echoes that refocus inhomogeneous and homogeneopus spin interactions have been discussed in the previous section. Also mixed echoes can be produced which eliminate all internal and external spin interactions. In the maximum of a mixed echo, each individual spin is fully isolated in the rotating reference frame in the absence of relaxation processes; a "time-suspension" process is taking place.

Methods of liquid-state imaging which can be applied, for instance, for analysis of elastomers or polymer swelling have been reviewed on several occasions (see for instance, References 19,47,135, and 139–141). Many of the methods used to record NMR images of solids can be combined with spectroscopic information. This unique feature and the richness in parameter contrast compensate for the relatively modest spatial resolution in many applications. If the spatial information is phase encoded, ie, indirectly detected, then the spectroscopic dimension is scanned directly, in many cases, by means of spin-echoes and in the absence of gradients. This approach is referred to as spectral frequency encoding. On the other hand, the spectroscopic information can be phase encoded or detected indirectly in the same way as in conventional two-dimensional spectroscopy. This approach is referred to as spectral phase encoding.

Spin System Response for a Heterogeneous Sample. In the following, a heterogeneous sample having magnetically equivalent nuclei with magnetogiric ratio γ and the local spin density $\rho(\vec{r})$ is considered. The space localized thermodynamic equilibrium magnetization corresponding to a voxel with coordinates (x, y, z) of the position vector $\vec{r}$ is given by $m_0\,(x, y, z) = C\rho(x, y, z)$, where C is the Curie constant. In the rotating reference frame at the resonance frequency,

the single-pulse NMR spin system response $s(\vec{r},t)$ can be expressed by the local free induction decay (FID) $f(\vec{r}, t)$,

$$s(\vec{r},t) = C\rho(\vec{r})f(\vec{r},t) \tag{35}$$

Spatially resolved NMR is concerned with unraveling the spatial distribution of $\rho(x, y, z)$ and measuring associated NMR parameters at individual "volume cells", or voxels at space point specified by the vector $\vec{r}$. If many contiguous voxels are investigated on a plane, or if a projection is investigated, one refers to NMR *imaging*, if individual voxels are investigated one refers to volume-selective NMR.

The spin density distribution can be resolved by different techniques. The standard approach exploits the possibility of introducing space dependence to the resonance frequency ω in each voxel by superposing a magnetic field gradient to a homogeneous magnetic field $\vec{B}_0(0,0,B_0)$ by the use of additional coils. In general, the field gradient is a Cartesian tensor with nine components related by the Maxwell equations. In the limit of large static magnetic field and small gradient, the gradient tensor can be reduced to a gradient vector $\vec{G}$ for an approximate description of the imaging experiments with good accuracy. Then the resonance frequency becomes dependent on the space vector $\vec{r}$, ie, $\omega(\vec{r}) = \gamma(B_0 + \vec{G}\cdot\vec{r}) = \omega_0 + \gamma\vec{G}\cdot\vec{r}$, where the field gradient vector collects the derivatives of the magnetic field in the z-direction with respect to the space coordinates defined by the component of the field gradient: $\vec{G}(\partial B_0/\partial x, \partial B_0/\partial y, \partial B_0/\partial z)$.

The total time-dependent signal of an inhomogeneous object of volume V measured in a magnetic field gradient and in rotating frame at the angular frequency ω_0 is given by

$$S(t) \propto C\iiint_V \rho(x,y,z)f(x,y,z,t)\exp\{\mathrm{i}\gamma\vec{G}\cdot\vec{r}t\}\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z \tag{36}$$

In high magnetic field the spatial dependence of the Curie constant can be neglected in a good approximation.

In order to illustrate the basic concepts of space encoding time-dependent gradients $\vec{G}(t)$ shall be admitted. The wave vector $\vec{k}$ can be introduced which is the Fourier conjugate to the space variable $\vec{r}$,

$$\vec{k}(t) = \gamma\int_0^t \vec{G}(t')\,\mathrm{d}t'. \tag{37}$$

In this notation, the single-pulse response signal in time-dependent main field gradients becomes

$$S(t) \propto C\iiint_V \rho(x,y,z)f(x,y,z,t)\exp\{\mathrm{i}\vec{k}(t)\cdot\vec{r}\}\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z. \tag{38}$$

This equation is the starting point for the discussion of spatial resolved NMR basic procedures.

Spatial Resolution by Frequency Encoding. The principle of the spatial resolution of NMR imaging by frequency encoding is discussed in the following in the presence of a pulsed uniform gradient, say $G_x = \partial B_0/\partial x$. After the radio-frequency excitation pulse the quantity $k_x(t)$ grows linearly with time according to equation 37, ie, $k_x(t) = \gamma G_x t$. Thus, $\vec{k}$ space is sampled in the direction of k_x, and time t and k_x are equivalent variables. If t is replaced by $k_x/(\gamma G_x)$ the spin system response given by equation 38 becomes

$$S(k_x/(\gamma G_x)) \propto C \iiint_V \rho(x, y, z) f(x, y, z, k_x/(\gamma G_x)) \exp\{i\gamma k_x \cdot x\} \, dx \, dy \, dz \tag{39}$$

The complex FID signal acquired in this way is composed of contributions evolving according to the local offset resonance frequency $\gamma G_x x$ labeling the nuclei responsible for this local transverse magnetization, hence, the term frequency encoding. Note that this is the conventional way of encoding in the Fourier transform spectroscopy. However, in context with NMR imaging, signals are processed in terms of the wave numbers k_x rather than of offset frequencies. The Fourier transform over k_x produces the convolution of the Fourier transform of the functions $\rho(x, y, z)$ and $f(x, y, z, k_x/(\gamma G_x))$. If $f(x, y, z, k_x/(\gamma G_x)) \approx f(k_x/(\gamma G_x))$, the Fourier transform of the FID is the space-dependent spectral response $F(x)$ and the Fourier transform of the triple integral is a projection $P(x) = \int\int \rho(x, y, z) \, dy \, dz$ of the spin density on the x-axis. Then, the Fourier transform of equation 39, can be written as

$$S(x) \propto C \int_{x_{\text{sample}}} F(x - x') P(x') \, dx' \tag{40}$$

where x_{sample} represents the sample size in the x-direction. A faithful representation of the spin-density projection $P(x)$ would be obtained by this method of frequency encoding only if the spectrum $F(x - x')$ is a Dirac function $\delta(x - x')$, or a narrow NMR absorption line like for liquid samples.

The above discussion is illustrated in Figure 24. If the samples are liquid, a narrow NMR absorption line is observed for both samples in a homogeneous magnetic field and a projection of the object along the x-axis is measured in the presence of the field gradient G_x. The signal amplitude at each resonance frequency or space coordinate is determined by the number of spins that experience the same magnetic field strength. If the spectrum in a homogeneous field is broad like in the solid samples (bottom traces) then the convolution (cf eq. 40) of the projection of the spin density by the line shape becomes noticeable, and the spatial features are smeared out. Thus, the minimum distance Δx which can be resolved is defined by the ratio of the full width at half spectral intensity $\Delta\omega_{1/2}$ of spectral features to the spread of the resonances introduced by the field gradient, ie,

$$\Delta x = \frac{\Delta\omega_{1/2}}{\gamma G_x} \tag{41}$$

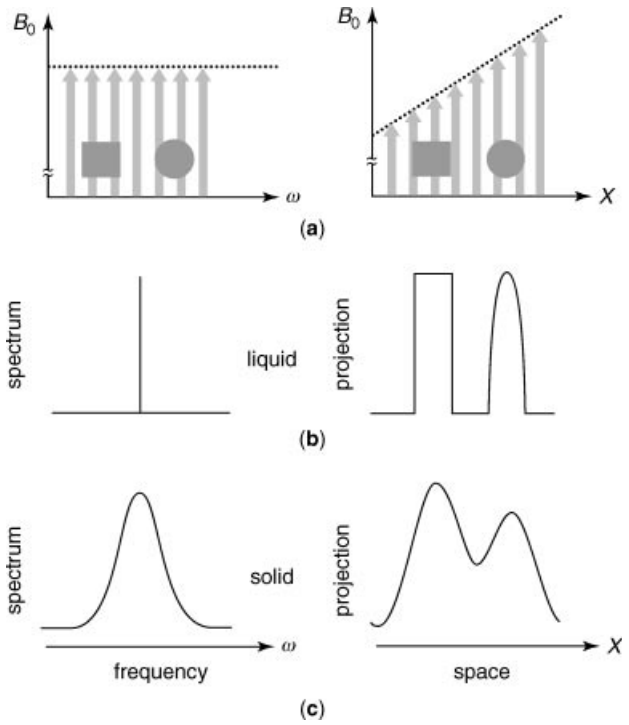

Fig. 24. Effect of field gradient on the NMR signal. The samples consists of a rectangular and a circular object. (**a**) Homogeneous magnetic field (left) and magnetic field with a linear space dependence (right). (**b**) Spectroscopic response for a liquid sample with a single, narrow line in the NMR spectrum. (**c**) Spectroscopic response for a solid sample with a single, broad line in the NMR spectrum. Reproduced from Ref. 136, with permission from Wiley.

Clearly, equation 41 indicates that when the line width increases, the gradient strength G_x also has to be increased, at least when the resolution Δx is to be kept constant.

Spatial Resolution by Phase Encoding. Broadening of the projection by the NMR spectrum (cf eq. 40 can be avoided if the spatial information is detected indirectly in the fashion of the multidimensional Fourier NMR spectroscopy (1). For instance, a magnetic-field gradient G_y is switched on for an evolution time t_1 following a radio-frequency excitation pulse, and the signal is acquired in a detection time t_2 after the gradient has been switched off. For this 2D scheme, the NMR signal can be written as

$$S(t_1, t_2) \propto Cf(t_1) f(t_2) \int_{y_{\text{sample}}} P(y) \exp\{i\gamma k_y y\} \, dy \tag{42}$$

where k_y- $\gamma G_y t_1$ and $P(y) = \int\int \rho(x, y, z) \, dx \, dz$. It becomes clear that there are two ways to perform the experiment: either t_1 is varied in the custom of 2D NMR spectroscopy, or t_1 is kept constant and G_y is stepped in increments ΔG_y. The first

case bears no advantage compared to direct frequency encoding discussed above. As time t_1 proceeds, not only does k_y increase, but also the free induction decay $f(t_1)$ evolve and deteriorate the signal intensity and finally the spatial resolution. But, if t_1 is kept constant $f(t_1)$ has a fixed value, and the phase change of the signal in the evolution period depends only on the wave vector k_y. Thus, the spatial resolution achievable for phase encoding depends on the maximum gradient strength available and on the signal-to-noise ratio, because the signal strength decreases with increasing $\vec{k}$.

The digital resolution or the pixel resolution of an NMR image can be much higher than the actual space resolution. The digital resolution $1/\Delta y$ of the NMR imaging in y-direction is determined by the maximum value of k_y or equivalently by the number n_y of complex signal values and the $\vec{k}$ space sampling intervals Δk_y, ie, $1/\Delta y = n_y\ \Delta k_y/(2\pi)$. To avoid signal aliasing, k_y has to be stepped in small enough intervals so that the signal-phase increment $y_{\max}\ \Delta k_y$ for the maximum object coordinate $y_{\max}$ never exceeds 2π.

Sampling $\vec{k}$ Space. Different imaging schemes are often discriminated against the way $\vec{k}$ space is sampled (for more details see Reference 19).

Two elementary 2D NMR imaging methods are illustrated in Figure 25: 2D Fourier imaging (2DFI, Fig. 25**a**) and back-projection imaging (BPI, Fig. 25**b**). Orthogonal gradients are switched subsequently in 2DFI and simultaneously in BPI. As a consequence, $\vec{k}$ space is sampled in orthogonal coordinates for 2DFI.

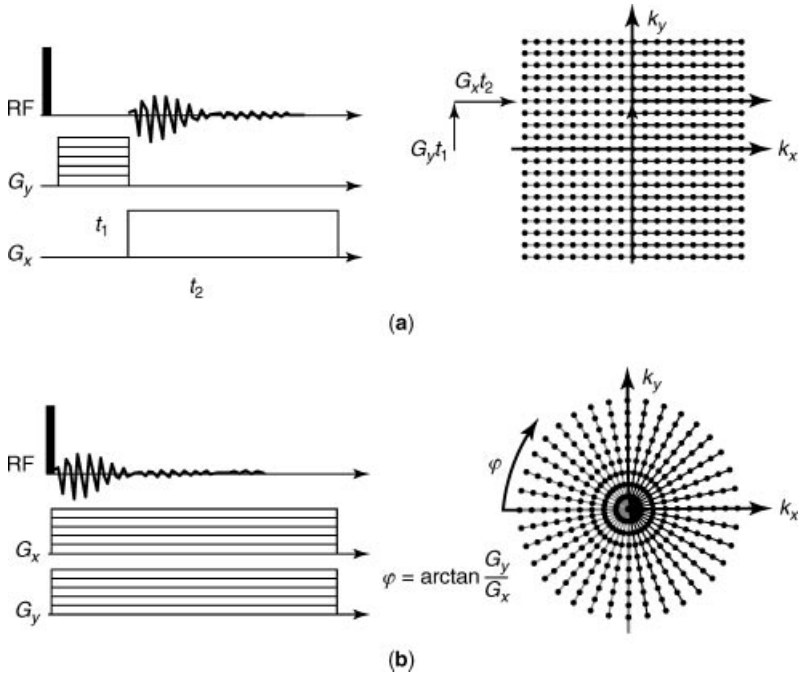

Fig. 25. Schemes for acquisition of 2D NMR images. Excitation and detection schemes (left) and maps in $\vec{k}$ space, where NMR signals is acquired (right). Reproduced from Ref. 136, with permission from Wiley.

When applied simultaneously, the direction of the resulting gradient changes depending on the relative strengths of G_x and G_y gradients. In this way, $\vec{k}$ space can be sampled in cylindrical coordinates in BPI. In either case, the image is obtained by the Fourier transformation of the $\vec{k}$-space data.

Often phase and frequency encoding are combined for acquisition of two-dimensional (2D) images (cf Fig. 25**a**, left). Then the gradient G_y is called the phase encoding gradient, and G_x is the frequency encoding gradient. This is one of the most used methods for recording images in elastomers materials that are soft solids with NMR line widths $\Delta\nu_{1/2} \approx 100$ Hz/1 kHz.

Contrast in NMR Imaging. Compared with other image-forming methods, the NMR imaging is characterized by the abundance of parameters that can be exploited for producing contrast (142,143). Many features invisible to other image-forming techniques can thus be visualized with NMR. To exploit the diversity of contrast features, it is useful to optimize the imaging experiment for generation of maximum contrast. The local contrast C is defined as the relative difference in image intensities M of neighboring structures i and j (17)

$$C = \frac{|M(\vec{r}_i) - M(\vec{r}_j)|}{|M_{\max}|} \tag{43}$$

where $|M_{\max}|$ is the absolute maximum of $M(\vec{r}_i)$ and $M(\vec{r}_j)$, where $\vec{r}_i$ and $\vec{r}_j$ are the space coordinates of voxels i and j under consideration.

Contrast Parameters and Material Properties. The contrast parameters relevant for polymer characterization by NMR imaging are directly related to the spin density, static and fluctuating nuclear spin interactions, and to the mass transport parameters. Even if the above quantities can change on molecular or mesoscopic scale only the variation of them on the space domains larger than the resolution of image can be detected in NMR imaging. The residual dipolar and quadrupolar interactions are related to the NMR parameters like van Vleck moments (4) and relaxation times (144). The fluctuating part of spin interactions leads to a variety of contrast parameters of magnetization relaxation type like spin-lattice relaxation in the laboratory reference frame (T_1), rotating frame (T_{1r}), transverse relaxation (T_2), solid echo or coherent averaging pulse sequences decay time (T_{2e}) (4), and dipolar correlation decays (5). The relaxation NMR parameters are also related to the manipulation of sample by contrast agents like paramagnetic relaxation agents, ferromagnetic particles (17), and hyperpolarized xenon (145,146).

The chemical shielding interaction leads to chemical contrast parameters related to the chemical composition as well as molecular orientation. Differences in magnetic susceptibility and the distribution of magnetic fields produced by electrical currents can be also detected via chemical shift (19).

The NMR quantities defining the contrast of NMR images depend on various macroscopic and microscopic physical and chemical parameters of the investigated samples that affect the nuclear spin interactions or molecular transport parameters. They can be classified as internal and external. Moreover, they can be state parameters that are stationary quantities like stress, strain, moduli of shear and compression, cross-link density, distribution and agglomeration of filler particles, molecular orientation, fibril orientation and domain size distribution,

distribution of voids, and the temperature distribution. Transition parameters or kinetic parameters characterize the time evolution of the polymer system. They are determined in *in situ* NMR experiments or in stop-and-go experiments. Examples are characteristic times of chemical and physical aging (147,148) of vulcanization (149) and curing (150) processes of heat dissipation and fluid permeation (151,152).

Transition parameters can be determined directly from the analysis of the time evolution of changes in NMR images, but state parameters must be related to NMR parameters either by theory or calibration. Theories have been published that relate the cross-link density of unfilled and filled elastomers to the parameters of transverse relaxation parameters (153) and others relating dynamic storage modulus of polymers to the cross-polarization rate (154).

A simpler approach is based on empirical correlations between NMR parameters and sample properties, which often can be established by calibration of an NMR parameter against a material parameter (155,156). An example of stress–strain calibration is given in Figure 26 by calibration of T_2 of filled poly(dimethyl siloxane) rubber against strain (153), (cf Fig. 26**a**). By use of the stress–strain curve (Fig. 26**b**) from mechanical measurements, T_2 can be calibrated against stress (see Fig. 26**c**).

The procedure can be used to translate the spatially resolved NMR parameters T_2 into values related to the strength of local stress.

Another possibility is given by the observation of the quadrupole splitting in deuteron NMR (155,157). For small strain, the splitting Δ_Q is linearly proportional to $\Lambda^2 - \Lambda^{-1}$ where $\Lambda = \frac{L}{L_0}$ is the elongation ratio, L and L_0 are the length of polymer band after stretching and in the relaxed state, respectively (see Fig. 27).

The rubber samples are prepared by swelling in a solution of deuterated spy molecules, these molecules follow the polymer network alignment under strain and the residual quadrupolar coupling that results from their anisotropic motion is observed either by spectroscopic imaging or by double-quantum imaging (158,159). The above deuteration procedure leads to the modification of the network and to potential modulation of the NMR signal encoding by the self-diffusion of the incorporated oligomers.

The above adverse effects can be avoided if ^{1}H residual dipolar couplings of elastomer chains (68) were used to generate contrast in NMR imaging of stretched samples. Dipolar contrast filters can be implemented based on dipolar encoded longitudinal magnetization as well as double- and triple-quantum coherences (160,161). The associated contrast filter parameters were investigated by measurements of the line width in ^{1}H multiple-quantum filtered spectra, the dipolar encoded longitudinal magnetization decay curves, and the double- and triple-quantum buildup curves as a function of the extension ratio for a natural rubber band. Together with stress–strain measurements, these results allow for correlation of ^{1}H residual dipolar couplings with stress values in stretched natural rubber.

Magnetization Filters. The contrast generation in NMR imaging is directly related to the concept of magnetization or coherences filters. Various molecular (internal) or external parameter weights are introduced by the use of magnetization or coherences filters (Fig. 28), which block part of the incoming signal originating from the thermodynamic equilibrium magnetization.

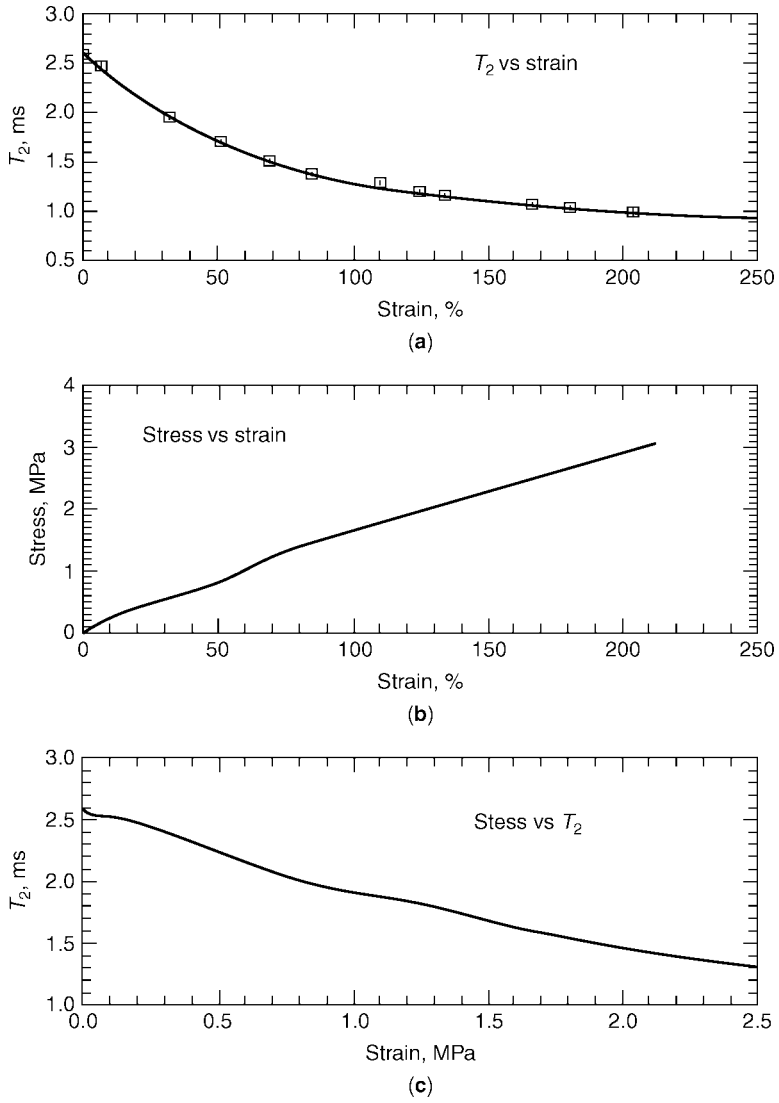

Fig. 26. Calibration of T_2 values measured for different strain (**a**) of filled poly(dimethyl siloxane) against stress (**c**) by use of the mechanical stress–strain curve (**b**). Reproduced from Ref. 142, with permission from Wiley.

As a result, there is a gain in selectivity of the output signal at the expense of a deterioration of signal-to-noise ratio.

A generic scheme for contrast optimisation in the Fourier NMR imaging is illustrated in Figure 28**b**, (142). In general, three periods are distinguished: a filter period, a space-encoding period, and a spectroscopy period. For image contrast other than the often-uninformative spin density, the space-encoding period must be combined either with a magnetization filter or with spectroscopic data acquisition or both. The signal detected after the action of the general pulse sequence

Initial nuclear magnetization is filtered by the radio-frequency irradiation of resonant nuclei (TX) before or also during space encoding period by magnetic-field gradients ($\vec{G}$). In the absence of gradients, the NMR signal is detected (RX) for the extraction of spectroscopic information. Reproduced from Ref. 143, with permission from Wiley.

designed to introduce image contrast can be written as (162)

$$S(\vec{k}) = \int \rho(\vec{r}) F_c(\{p\}, \vec{r}) \exp[-i\,2\pi \vec{k} \cdot \vec{r}]\, d\vec{r} \tag{44}$$

where the contrast parameter manifold is denoted by $\{p\}$ and $F_c(\{p\}, \vec{r})$ is the combined local contrast function. This function could be a product of several parameter contrast functions, such as

$$F_c(\{p\}, \vec{r}) \equiv F_c(T_1, \vec{r}) F_c(T_{1\rho}, \vec{r}) F_c(T_2, \vec{r}) F_c(\delta_i, \vec{r}) F_c(\vec{q}, \vec{r}) \cdots \tag{45}$$

where for instance, the contrast factors in the right-hand side of equation 45 representing the effects of longitudinal (T_1 and $T_{1\rho}$) and transverse (T_2) relaxation times, chemical shift (δ), and the effect of coherent and incoherent molecular translation motions described in the $\vec{q}$ space (18).

There are two basic approaches by which the image contrast can be studied. The first makes the pulse sequence sensitive to a particular contrast parameter p so that the image intensity bears or is weighted by the influence of that contrast. This approach offers the advantage of time efficiency but is only qualitative. The quantitative information can be obtained by the second approach that include inter alia two-image scheme (162). This method requires two imaging experiments under two contrast conditions. The final parameter map is computed from the two images, voxel by voxel, by means of some mathematical calculation, such as division.

The first approach is illustrated in Figure 29 for the simple case of spin-lock-filtered projections of a composite piece of rubber cut from the tread of a car tire. Such a filter imposes a $T_{1\rho}$ weight on the spin density (cf Fig. 29**a**). From the space distributed magnetization decays, the parameter map of $T_{1\rho}$ can be obtained (cf Fig. 29**b**) independent of spin densities.

An important class of magnetization filters are mobility filters which select magnetization based on the time scale of segmental motions ((19), and references therein). The parameters for discrimination are the amplitude and characteristic frequency or the correlation time τ_c of molecular motions. The effect a filter exerts on a NMR signal can be represented by the filter transfer function. Examples are given in Figure 30 (163,164) with transfer function for filters, which select magnetization based on the time scale of molecular motion.

Depending on the time scale, different pulse sequences can be used. In the fast motion regime, T_1 filters are applicable. Both saturation recovery and the stimulated echo can be used for this, but the transfer function of both filters is complementary. The spin-echo or Hahn echo filter has a transfer function similar to that of the saturation recovery filter, but because T_2 processes are efficient at slower molecular motions, the filter cut off is shifted to longer correlation times. The dipolar filter exploits the strength of the dipolar couplings averaged by the molecular motions. The residual dipolar filters can use ^{1}H double- and triple-quantum coherences (160,161) as well as ^{1}H–^{1}H magnetization exchange (165). Dipolar correlation effect detected via stimulated echo can be used for a mixed residual dipolar coupling/slow motion filter (166). Resolved splitting of the residual quadrupolar coupling of ^{2}H of spy molecules has been used as quadrupolar

coupling filter (158,159). The spin-lattice relaxation in the rotating frame or $T_{1\rho}$ filter is efficient at slow motions with correlation times of the order of the inverse of the angular frequency of the spin-look radio-frequency pulse. The transverse magnetization decay for a train of solid echoes or magic echoes is characterized

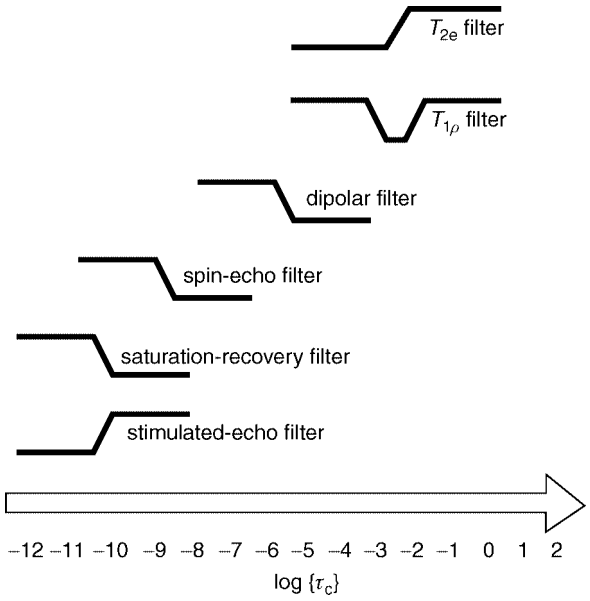

Fig. 30. Time scale of molecular motion and filter transfer functions of pulse sequences, which can be used for selecting magnetization according to the time scale of the molecular motion. Reproduced from Ref. 143, with permission from Wiley.

by the effective transverse relaxation time T_{2e} (68) a parameter sensitive to the slow segmental motion like $T_{1\rho}$.

The identification of material heterogeneities based on differences in molecular motion is an important feature of NMR imaging. The importance of slow molecular motion for image contrast is demonstrated in Figure 31 with relaxation time parameter images through a partially aged sheet of carbon-black-filled styrene-*co*-butadiene rubber (SBR) (147).

The one-dimensional space scale starts at the unaged center of the rubber sheet at $\Delta r = 0$ and ends at the aged surface at $\Delta r = 700$ μm. Two curves are shown for each relaxation parameters as a function of space. The top curve is for unaged material and it varies little with space. The bottom curve is for the aged material. Both curves overlap in the center of the sheet and split toward the surface. The splitting is a direct measure of image contrast. The contrast is largest for those relaxation times that are sensitive to slow molecular motions. the contrast is largest for T_{2e} and $T_{1\rho}$ images and almost zero for T_1.

NMR Imaging of Elastomers

Potentially rather useful applications of NMR imaging are in elastomer industry. This section features some selected examples that illustrate the type of information obtained by imaging of elastomers. Such applications to elastomers concern distribution in temperature stress, cross-link density, modulus, and the dynamics of fluid absorption and swelling.

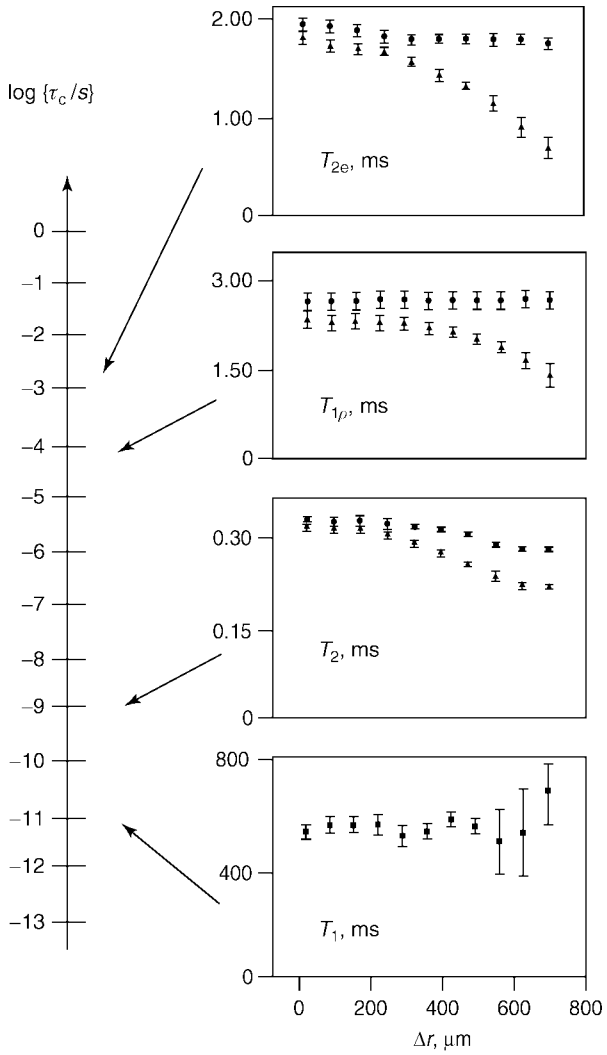

Fig. 31. Relaxation parameters T_1, T_2, $T_{1\rho}$, and T_{2e} for contrast in thermal oxidative aging of SBR. The insets depict the space distribution of relaxation times for a partially aged (lower curve) and an unaged (upper curve) rubber sheet. Reproduced from Ref. 147, with permission from Wiley.

Heterogeneities in Elastomers. Heterogeneities in elastomers materials are related to the defects induced in the process of preparation. The processes that lead to the defects are as follows.

Mixing Processes. Technical elastomers are blends of up to about 30 different compounds like natural rubber, styrene–butadiene rubber, silicate and carbon-black fillers, and mobile components like oils and waxes. Improper mixing leads to inhomogeneities with corresponding variation in mechanical and thermal properties. An important source of heterogeneities of this type is represented by filler

clusters. Even the variance of the distribution statistics of active filler may lead to heterogeneities detected as an average over a volume cell or voxel with the spatial resolution of NMR imaging.

Vulcanization. Heterogeneous structures arise from effects of thermal conductivity, which lead to space-dependent temperature profile during the vulcanization process depending on the position of the heat source and on heat dissipation. As a result, inhomogeneous cross-link densities may be established (167). If the process of cross-linking is incomplete the defects represents by the free chains are also presents. The changes in segmental mobility from progress of the vulcanization reaction and from the associated sample temperature distribution can be monitored directly by the NMR imaging *in situ* (149). In the covulcanization of blends and sheets from different formulations, inhomogeneities in cross-link density max arise from differences in solubility and diffusion of curatives (168).

Aging. Aging processes are often induced by ultraviolet (UV) irradiation or other ionization radiations (169), exposure to heat and oxygen, and by biological mechanisms. Depending on the load applied, different aging processes are observed (170). The action of electromagnetic radiation with high energy of the associated photons as well as nuclear irradiation will produce chain scission with decrease in the cross-link density and associated increase in chain mobility. Thermal oxidative aging usually leads to the formation of hardened surface layers in natural rubber (NR) as well as synthetic rubber (styrene-*co*-butadiene rubber (SBR) (147,148,171–174). Typically, these layers approach a thickness of 200–300 μm and inhibit progress of the aging process further into the bulk of thin sample. The material hardening is explained by an increase in cross-link density. In the absence of oxygen, chain scission may dominate at elevated temperatures with an associated increase in the segmental mobility. Other types of aging involve aggressive fluids and gases. In this context, a sample of degraded rubber hose gas been investigated (175), but also the degradation of polyethylene pipes and the enzymatic degradation of biologically synthesized polymers (176) have been studied through NMR imaging. Related investigations have been carried out on asphalts (177). Aging associated with swelling of the rubber particles has been observed in crumb-rubber modified asphalts (178).

Mechanical Load. Static mechanical load by strain leads to stretching of random-coil polymer chains in the direction of sample elongation and chain compression in the orthogonal directions. The value of the residual dipolar and quadrupolar couplings is increased by the mechanical load, and moreover, the distribution of the correlation times is also modified. Therefore, many NMR parameters sensitive to the residual dipolar couplings and slow motions can be used for characterization of the local strain–stress effects in heterogeneous elastomers (158,160,161,179). Dynamics mechanical load leads to sample heating where the temperature distribution in dynamic equilibrium is determined by the temperature-dependent loss-modulus and the thermal conductivity of the sample. Because transverse relaxation rate (approximated by the T_2 relaxation) scales with the temperature for carbon filled SBR, a T_2 map provides a temperature map of the sample. Such temperature maps have been measured for carbon-black filled SBR cylinders for different filler contents and mechanical load (180).

NMR Images and Parameter Maps in Elastomers. NMR of elastomers including NMR imaging appears to address one of the industrially most relevant applications of NMR. Applications of the one- (1D) and two-dimensional (2D) NMR images and parameter maps for characterization of elastomer materials with heterogeneous mesoscopic and macroscopic structure will be reviewed in the following.

Vulcanization and Covulcanization. The main effect taking place during the vulcanization process is the space distribution in the cross-link density. One source of this variation is the spatial distribution of the rubber formulation, although short-scale variations are often smoothed by component diffusion during the vulcanization process. Differences on the millimeter scale can lead to interfacial structures.

Another source of variations in cross-link density on the millimeter scale is the curing process in combination with the sample geometry. Heat is supplied to the sample for a certain time and after vulcanization is removed from the sample in certain time. Near the heat source the cross-linking process induced by vulcanization is set in first and near the heat sink is sets in last. Depending on the time dependence of the heat from the source and sink, surface and the thermal properties of the sample, complicated time-dependent temperature profiles are established in the sample.

The vulcanization process has been followed across a thick disk from unfilled SBR by NMR imaging of the effective transverse signal decay (149). The measurements were carried out in a magnetic field slightly inhomogeneous from the construction of a special vulcanization probe and the effective transverse relaxation time T_2^* was measured (see Fig 32). Despite accelerated signal decay from the field inhomogeneities, T_2^* still turned out to be sensitive to chain mobility because of a sufficiently strong contribution from T_2.

A nonlinear relationship between the effective transverse relaxation rate $1/T_2^*$ and the reduced shear modulus was found. Nevertheless, the relationship that low modulus corresponds to high T_2^* and high modulus to low T_2^* can be used to interpret the imaging data across the SBR sheet measured during the vulcanization process (see Fig. 32). Immediately after sample heating, chain mobility is high and so is T_2^*. With the formation of the cross-links chain mobility decreases and so does T_2^*. The vulcanization front is defined by the center of change in T_2^*. It can be seen to migrate through the thin sample on a time scale of about half an hour with the temperature in the range between 140 and 170°C across the sample. With increasing time the slope of the T_2^* curve flattens indicating a broadening of the reactive vulcanization zone.

Another example of spatial determination of the local cross-link density in inhomogeneous vulcanized elastomers by means of the spatially dependent T_2^* decay times was discussed on poly(isobutylene-*p*-methylstyrene-*p*-bromon-ethylstryrene) (PIB-PMS/BrPMS) (181). It was shown that by swelling the elastomers in the aprotic solvent CCl_4, the proton signal in the magnetic resonance images originates almost exclusively from the rubber methyl protons (182). This makes it possible to acquire selective images of the rubbery phase, which were demonstrated to be superior toward the visualization of the network homogeneity. Moreover, swelling of these elastomers in an appropriate solvent enhances the molecular chain mobility and reduces the

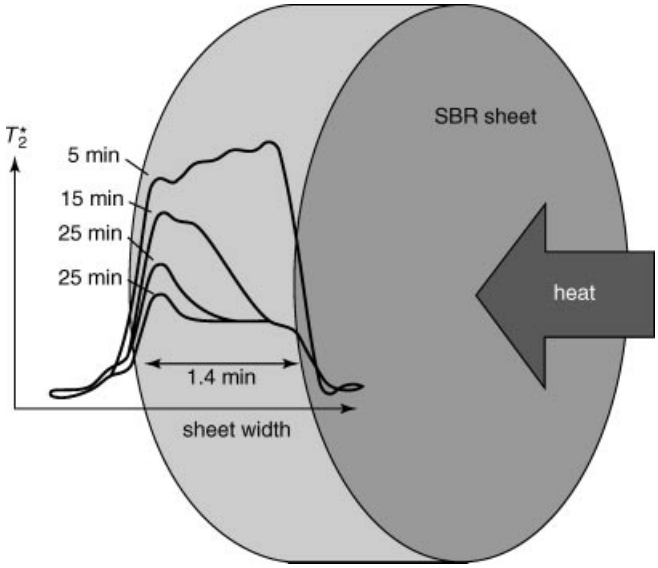

Fig. 32. Time-resolved T_2^* parameter one-dimensional images across a 1.4 mm thick sheet of SBR following the vulcanisation process. Reproduced from Ref. 149, with permission from Rapra Technology.

proton line width to an extent acceptable for recording magnetic resonance images.

The gravimetric Flory–Rehner (183) experiments are combined with NMR imaging to study spatially dependent degree of cross-linking, in unfilled, 1,6-hexamethylenediamine-cured PIB-PMS/BrPMS therpolymers (181). Localized relaxometry reveals two proton T_2^* relaxation decay times in CCl_4 swollen specimens: a fast decaying component reflecting the constrained chain segments near the cross-links and topological constraints (T_{2s}^*) and a slow decaying component originating from less constrained, remote chains (T_{2l}^*). On the basis of a linear relation between the bulk number-average molecular weight between effective cross-link ($M_{n,\mathrm{eff}}^{\mathrm{bulk}}$) and the volume average T_2^*, magnetic resonance images allow the determination of the local cross-link density in inhomogeneous cross-link PIB terpolymer samples by means of the spatially-dependent effective transverse relaxation. The measurements of the localized T_{2s}^*, and T_{2l}^* allow to deduce the localized molecular weight between the effective cross-links $M_{n,\mathrm{eff}}(\vec{r})$ for each region of interest labeled 1–10 in Fig. 33. This method reveals that the sample 1 exposes a very heterogeneous network structure as is illustrated by a large variation in the localized $M_{n,\mathrm{eff}}(\vec{r})$. This indicates an unfavourable mixing. This in strong contrast to specimen 2, having a rather homogeneous network structure as is demonstrated by the small variation in $M_{\mathrm{n,eff}}(\vec{r})$ as a result of a uniform curing. The homogeneity of mixing and curing of the specimens 3 and 4 (cf Fig. 33) is somewhere in between. These results clearly demonstrate that NMR image is a useful technique to investigate the homogeneity of mixing and curing of elastomers.

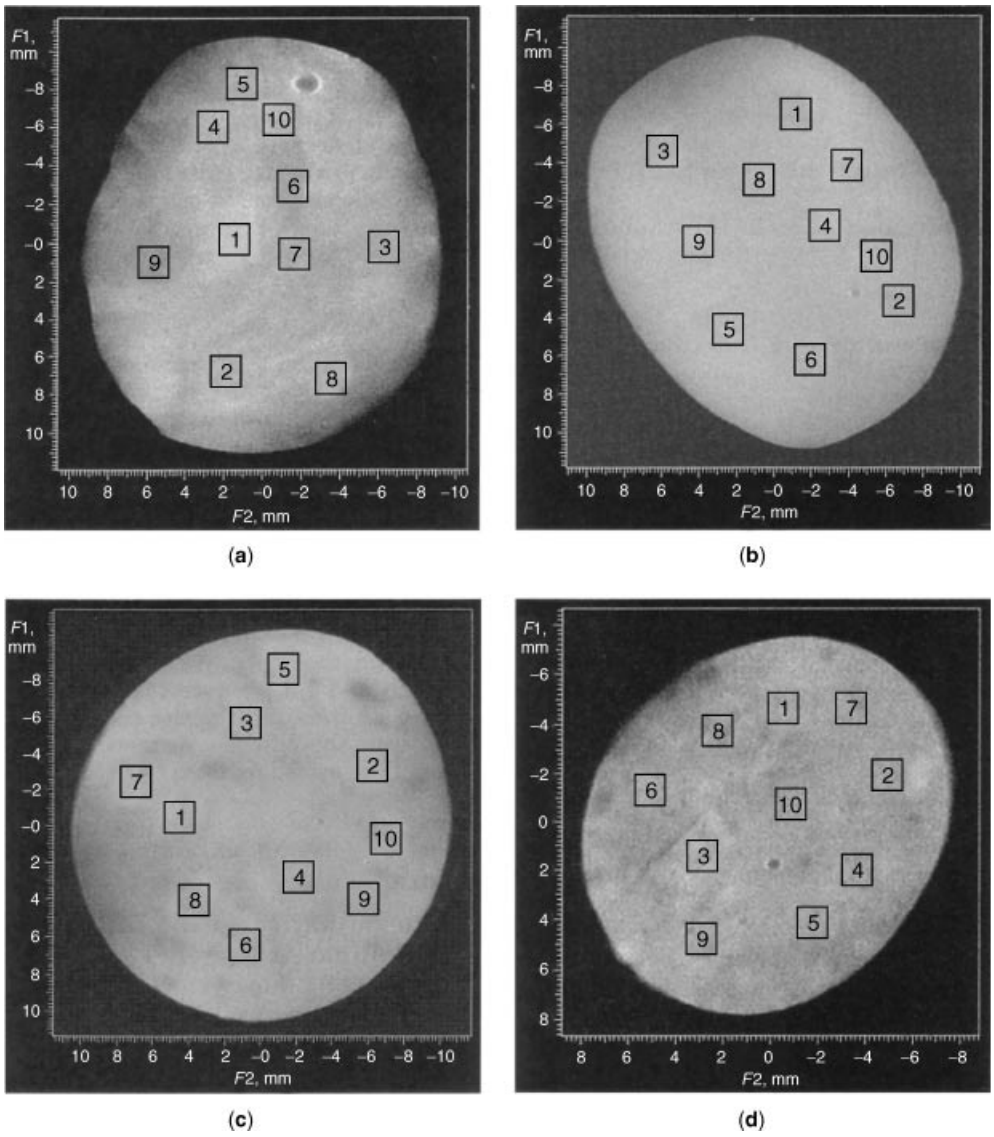

Fig. 33. Proton NMR images of unfilled polyisobutilene-based elastomers, cured with 1,6-hexamethylenediamine, after equilibrium swelling in CCl_4. The degree of cross-linking increases from samples 1 to 4. The regions of interest indicate the locations used to determine the local relaxation decay times. Reproduced from Ref. 181, with permission from American Chemical Society.

During fabrication of elastomer products like car tires different elastomer formulations often need to be covulcanizes. At the interface between an SBR and an NR layer, an interfacial layer with a modulus higher than either SBR and NR had been detected (145,171). In images detected using Hahn-echo method

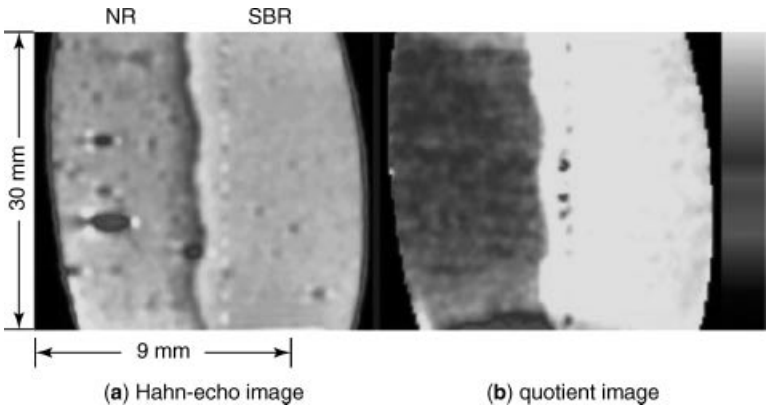

Fig. 34. Proton T_2^*-weighted Hahn-echo image (**a**) of an unfilled SBR/NR covulcanisate with dimensions 9 mm × 30 mm. The image has been acquired with an echo time of $t_E = 3.3$ ms. A quotient image (**b**) computed as the quotient of two Hahn-echo images acquired with different echo times of 4.2 and 3.4 ms. Reproduced from Ref. 145, with permission from Rapra Technology.

the interface is identified by a dark line paralleled to a slightly brighter line (see Fig. 34).

A mixture of spin density and relaxation forms contrast in the Hahn-echo image. Contrast in the quotient image is determined only by transverse relaxation. In this image, the interface appears abrupt and well defined. The image of the interface shows a transition from the hard SBR component to the soft NR component with a width of the order of 0–5 mm (184,185). This is the space scale on which the modulus changes. The shape and dimension of the interface are defined by the concentration differences in the vulcanizing agents, which diffuse at elevated temperatures across the interface until their diffusion is hampered by their role in the vulcanization reaction. Thus, the interface arises from a delicate balance between diffusion, reaction, heat supply, and removal.

Blending. Interfaces similar to those encountered during covulcanization may arise in blends with incomplete mixing. In unvulcanized samples, heterogeneities from blending can be deduced by gradient echo imaging, where the contrast is enhanced by differences in magnetic susceptibility of the components (186). However, fine structures are usually homogenized during the vulcanization process. Larger structures survive, in particular, when one component had already been vulcanized.

An example of such a case is illustrated in Figure 35 by two orthogonal slices through a block of a vulcanised blend from a soft (bright) and a previously vulcanised hard (dark) component (141). In slice (a), the structures invoked by mixing of components appear course but random, but slice (b) reveals stream lines of material flow in the rolling mill.

The presence of carbon-black filler usually does not affect the NMR data in contrast to functionalized silicate filler. This is attributed to rapid transverse relaxation of network chain segments near carbon-black filler particles caused by paramagnetic centers in the filler. Thus, for the technologically important

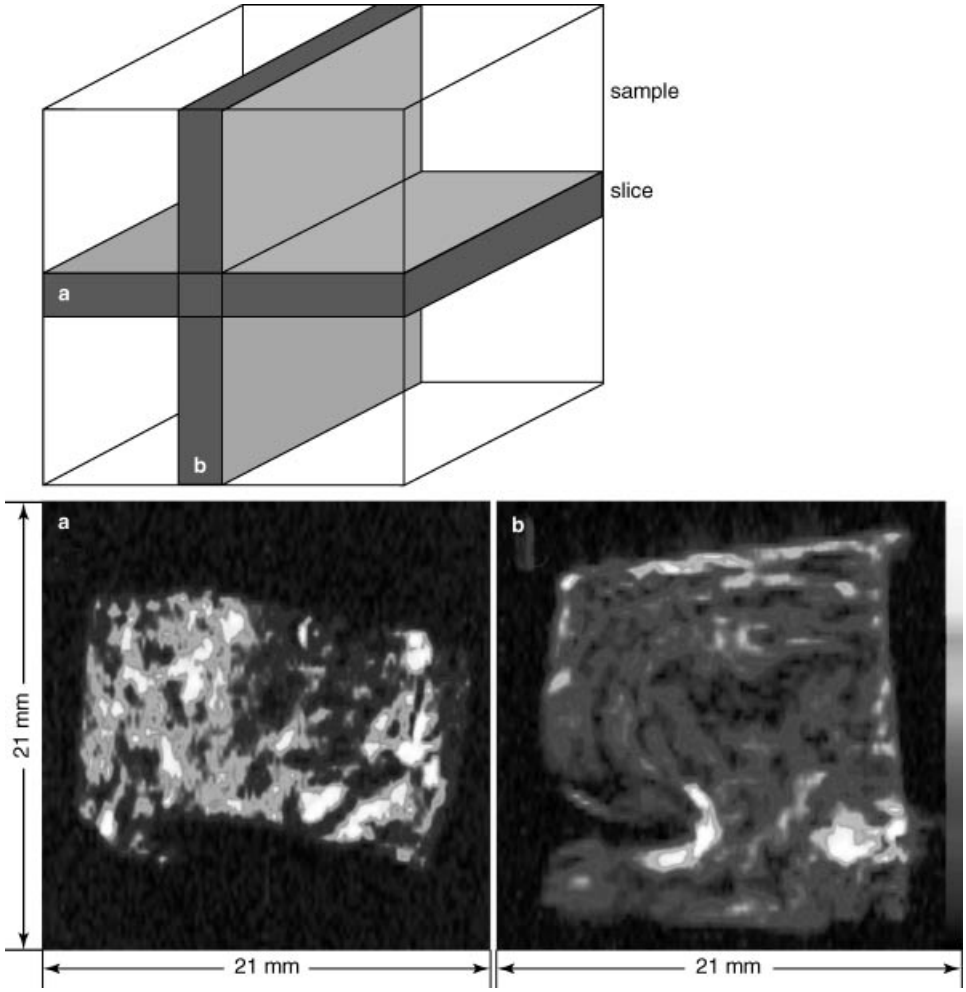

Fig. 35. (**a**) Proton T_2^*-weighted orthogonal slices of a carbon-black filled blend with a soft (bright) and a hard (dark) component. Insufficient blending in a rolling mill is visualized by the stream lines in slice (**b**). Reproduced from Ref. 145, with permission from Rapra Technology.

class of carbon-filled elastomers, NMR can provide the chemical cross-link density.

Aging. Aging of elastomers is a process that affects the mobility of intercross-link chains by packing, chain scission, and formation of new cross-links. Thermooxidative aging of many elastomers including SBR and NR leads to the formation of a brittle surface layer with reduced mobility that appears dark in ^{1}H Hahn-echo images. Often this region is followed by a zone of brighter image intensity, which can be attributed to chain scission or the accumulation of low molecular-weight additives (148).

The time evolution of the thermooxidative aging in SBR has been studied by NMR imaging (see Ref. 145). In order to detect the aged surface layer with reduced

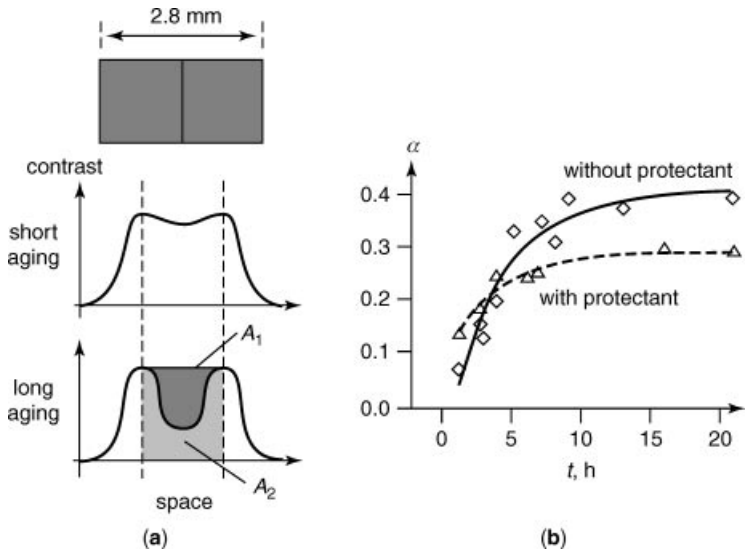

Fig. 36. Analysis of thermal oxidative aging by T_2^*-weighted Hahn-echo imaging. (**a**) Two SBR layers stacked after aging. The aged layer suffers a signal loss marked by the area A_1. The relative signal decrease defines the aging parameter α. (**b**) The progress in aging can be followed by evaluating the aging parameter α as a function of aging time t. signal intensity in Hahn-echo images, two aged sheets were stacked and the stack was imaged along its axis. In this way, the signal from the soft core delineated the hardened surface layers (cf Fig. 36).

Sample Deformation. Sample deformations modify the number of accessible conformations of intercross-link chains, so that they can be detected by analysis of relaxation and residual dipolar and quadrupolar couplings. For instance, dynamic mechanical load on elastomers is often exerted at small deformations and low deformation rates but over extended time periods. Then part of the mechanical energy is dissipated into heat depending on the value of the loss modulus. As a consequence, a temperature profile is established within the sample. Then the modulus varies across the sample depending on the temperature profile and properties determined for thick samples under dynamic load are average quantities.

The temperature profile associated with sample heating during weak dynamic shear deformation of carbon-black filled SBR cylinders of 10 mm diameter and 10 mm in height has been imaged by NMR by use of a specially designed probe (180).

The transverse relaxation time strongly depends on temperature (cf Fig. 37**a**), so that the temperature can be mapped by parameter imaging of T_2. Axial parameter projections have been acquired in dynamic equilibrium at a shear rate of 10 Hz and for carbon-black contents ranging from 10 to 70 phr. One-dimensional cross sections through those projections are depicted in Figure 37**b**. An increase of the temperature in the center of the sample is observed with increasing carbon-black contents which scales with the increasing loss modulus of

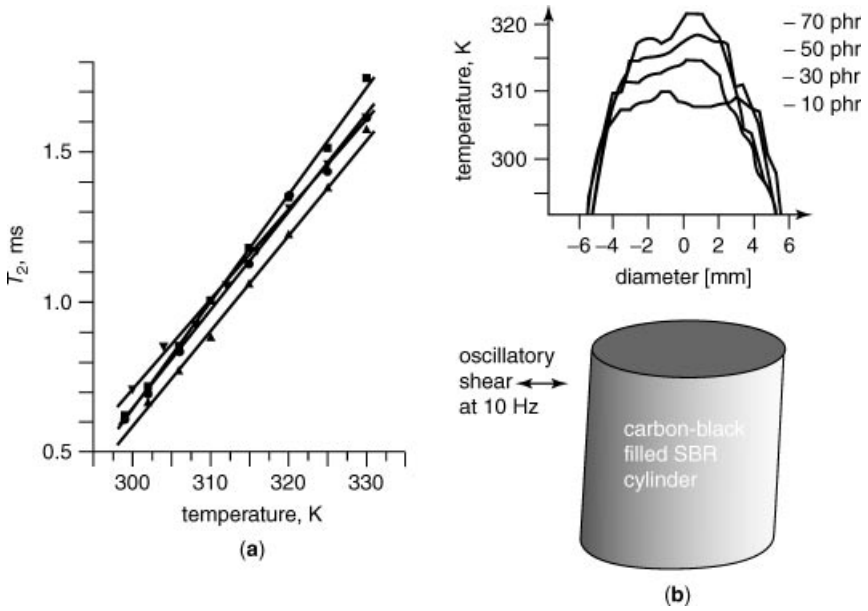

Fig. 37. Temperature profiles from T_2 parameter images of SBR cylinders with different carbon-black filler contents undergoing oscillatory shear deformations. the sample. The 70 phr sample is warmer by over 10°C in the center of the sample than the 10 phr sample.

NMR Mobile Sensor for Quality Control of Elastomers. Over the last few years, a mobile NMR surface scanner called NMR-MOUSE has been developed for the nondestructive investigation of arbitrarily large objects (187,188). The NMR-MOUSE is a palm-size NMR device which is built up from two permanent magnets. The magnets are mounted on an iron yoke with antiparallel polarization to form the classical horseshoe geometry. The main direction of the polarization magnetic field $\boldsymbol{B}_0$ is across the gap and the field strength decreases rapidly with increasing distance from the surface. The radio-frequency (rf) field $\boldsymbol{B}_1$ is generated by a surface coil which is mounted in the gap. The NMR-MOUSE is characterized by strong inhomogeneities in the static and radio-frequency magnetic fields. Due to these fields inhomogeneities, NMR spectroscopy of the chemical shift is not possible, but magnetization relaxation times and parameters of translational motion can be measured by echo techniques (189–192). Moreover, the orientation dependence of NMR parameters can be easily investigated with the mobile NMR sensor for large samples on stretching devices (191).

Some selected applications of the NMR-MOUSE to elastomers are summarized in Figure 38 (193). In Figure 38**a**, transverse relaxation times have been measured for a series of carbon-filled NR samples with different curing times. Normalized values measured at high and homogeneous magnetic field (7 T, DMX 300) are compared to those measured with the NMR-MOUSE (0.5 T). Although

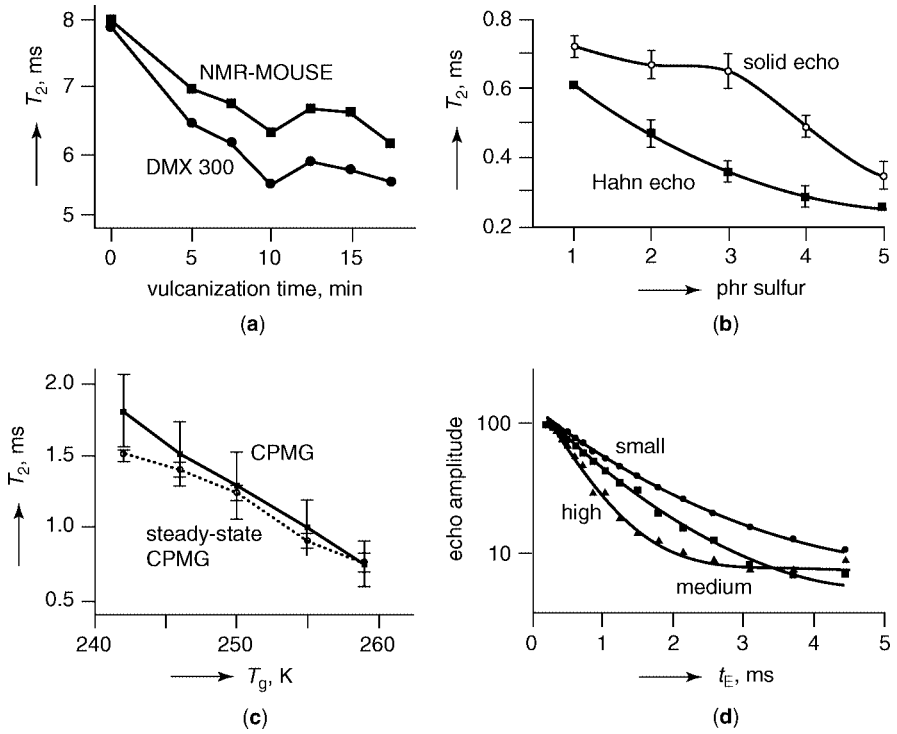

Fig. 38. Applications of the NMR-MOUSE to elastomer materials. (**a**) Values of ^{1}H T_2 for a curing series of carbon-black filled NR. The measurements made with NMR-MOUSE are compared with the values obtained at 300 MHz in high homogeneous field. (**b**) T_2 of a cross-link series of unfilled SBR with different sulfur contents. (**c**) T_2 versus glass-transition temperature T_g of unfilled SBR by the CPMG and steady-state CPMG methods. (**d**) Normalized Hahn-echo decays for polybutadiene latex samples for small, medium, and large cross-link densities. Reproduced from Refs. 189 and 190, with permission from Rapra Technology.

the values differ because of different $\boldsymbol{B}_0$ field strengths, they closely follow the same trend. This confirms that relaxation measurements by the NMR-MOUSE are a valid alternative to relaxation measurements at homogeneous magnetic fields.

In Figure 38**b**, relaxation times are shown for a series unfilled SBR samples with variations in sulfur content. With increasing sulfur content the chemical cross-link density increases. Relaxation times are given for measurements with Hahn echoes and with solid echoes. The change in relaxation times and thus the sensitivity of the method is larger for the Hahn-echo measurements at small cross-link density and for the solid echo measurements at high cross-link density. Solid echoes reduce the signal attenuation from the dipole–dipole interaction between two spins in addition to producing a Hahn echo. At high cross-link density multi-center dipolar couplings become effective and the solid echo becomes less effective in reducing signal attenuation from dipolar interactions. The Hahn echo does not

affect the dipole–dipole interaction at all. This explains the difference in contrast obtained with both methods.

A reduction in measurement time is gained when the measurements are performed in dynamic equilibrium between radio-frequency excitation and longitudinal relaxation (1). NMR methods which operate in this regime are referred to as steady-state methods. They deliver equivalent information compared to methods which demand complete relaxation to thermodynamic equilibrium between scans. T_2 measurements performed with the CPMG and the steady-state CPMG method are depicted in Figure 38**c** and correlated with the glass-transition temperature T_g of unfilled SBR laboratory samples of different cross-link densities. The NMR measurements were done at room temperature, whereas T_g had been determined by temperature-dependent measurements of the dynamic-mechanical loss modulus (189,190). The correlation between both measurements is not surprizing, because both probe the network dynamics. These data demonstrate that in certain cases T_g can be determined locally and nondestructively on large samples at room temperature by the NMR-MOUSE.

The large magnetic-field gradients give rise to rapid signal loss from molecules with translational motion, so that signal from low molecular-weight fluids is suppressed at echo times t_E of the order of 1 ms and more. The signal detected at larger echo times is from larger molecules or particles. This effect of solvent suppression is exploited in the characterization of cross-link density in polybutadiene latex samples (see Fig. 38**d**). The signal decay for weak cross-link density is slow compared to that for large cross-link density. In summary, Figure 38 demonstrates that the NMR-MOUSE is a suitable device for determination of relative cross-link density in a number of different soft materials.

The possibility to excite and detect proton NMR double-quantum coherences in inhomogeneous static and radio-frequency magnetic fields was also investigated (194,195). For this purpose, specialized pulse sequences which partially refocus the strongly inhomogeneous evolution of the spin system and generate double-quantum buildup and decay curves were implemented on the NMR-MOUSE. It was shown that DQ decay curves have a better signal-to-noise ratio in the initial time regime compared to DQ buildup curves. The double-quantum buildup and decay curves were recorded for a series of cross-linked natural rubber samples. These curves give access to quantitative values of the ratio of proton total residual dipolar couplings that are in good agreement with those measured in homogeneous fields. A linear dependence of these ratios on the sulfur-accelerator content was reported.

The self-diffusion coefficient (D) of swollen liquids in elastomers can be measured using NMR-MOUSE with a bar magnet (192). The method was shown to be particularly useful for measuring D of small penetrant molecules in elastomers without the need for measurements of the transverse relaxation rates. The self-diffusion coefficient of toluene in a series of cross-linked natural rubber samples was measured and correlated with the cross-link density.

The NMR-MOUSE is simple mobile NMR sensor suitable for operation in an industrial environment. Its use for quality control is demonstrated in Figure 39 by the T_2 statistics measured at both sides of a conveyor belt with steel cords (193). The magnetic field $\boldsymbol{B}_0$ distortions from the steel cords were minimized by suitable orientation of the NMR-MOUSE with respect to the direction of the cords.

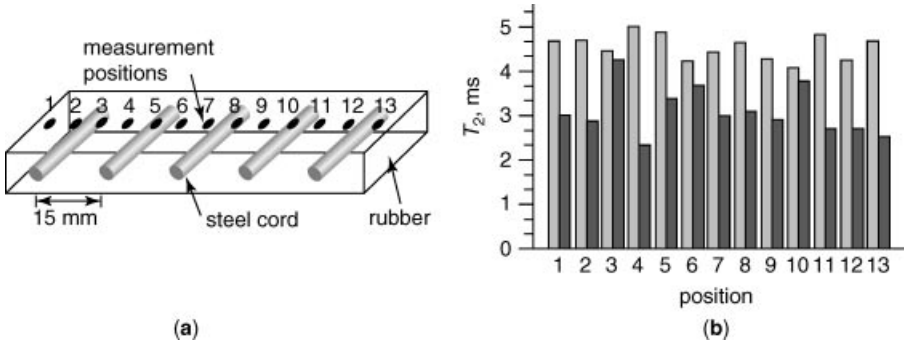

Fig. 39. Quality control of a conveyor-belt section with steel cords. (**a**) Position of measurement points. (**b**) T_2 values for upper and lower sides determined with the CPMG pulse sequence (▒) upper side and (■) lower side. Reproduced from Ref. 193, with permission from Rapra Technology.

The upper side of the belt exhibits a higher average T_2 value than the lower side, which indicates lower cross-link density. In addition to that the variance of the measured values is larger for the lower side indicating a better quality material on the upper side.

Images can be obtained with the NMR-MOUSE by measuring voxels individually by lateral displacement of the device or a change of excitation frequency to shift the sensitive volume in depth (193). On the other hand, also pulsed magnetic field gradients can be employed for phase encoding of the space information. Frequency encoding is hampered by the nonlinear magnetic field profile together with the inaccessibility of the FID.

In direction parallel to the magnetic gap, the magnetic field gradient is weakest, and a sensitive volume of a centimeter and more in width can be excited by a short rf pulse. Solenoidal gradient coils can readily be incorporated into the gap and pulsed to produce antiparallel magnetic fields (196,197). Then a gradient field is established along the gap and spatial resolution can be introduced into the measurement by phase-encoding techniques similar to single-point imaging. The effects of the background field inhomogeneity $B_z - B_0$ and of chemical shift on the magnetization phase are balanced in the peak of the Hahn echo and the only phase evolution from the pulsed field gradient remains. By applying gradient pulses with different amplitudes, $\boldsymbol{k}$ space can be scanned in the direction along the gap, so that the Fourier transformation of the acquired signal produces a one-dimensional image (196). This measurement protocol has been applied in a study of a rubber sheet with parallel textile fibers. The fibers do not contribute to the detected signal, so that their positions can be located by the dips in the 1D profile.

Clearly, the basic imaging scheme can be extended to include relaxation-time contrast for discrimination of variations in cross-link density and strain, and the 1D MRI-MOUSE (magnetic resonance imaging MOUSE) can be extended with further gradient coils to permit imaging in three dimensions. Recently, a two-dimensional imaging with a single-sided NMR probe was reported (197). Numerous applications of the MRI-MOUSE can be envisioned in soft-matter analysis, in

particular in those areas, where imaging with conventional equipment has proven to be successful and where smaller, less expensive, and mobile devices are in need.

OLEFIN FIBERS

Introduction

Olefin fibers, also called polyolefin fibers, are defined as manufactured fibers in which the fiber-forming substance is a synthetic polymer of at least 85 wt% ethylene, propylene, or other olefin units (1). Several olefin polymers are capable of forming fibers, but only polypropylene [9003-07-0] (PP) and, to a much lesser extent, polyethylene [9002-88-4] (PE) are of practical importance. Olefin polymers are hydrophobic and resistant to most solvents. These properties impart resistance to staining but cause the polymers to be essentially undyeable in an unmodified form.

The first commercial application of olefin fibers was for automobile seat covers in the late 1940s. These fibers, made from low density polyethylene (LDPE) by melt extrusion, were not very successful. They lacked dimensional stability, abrasion resistance, resilience, and light stability. The success of olefin fibers began when high density polyethylene (HDPE) was introduced in the late 1950s (see ETHYLENE POLYMERS, HDPE). Yarns made from this highly crystalline, linear polyethylene have higher tenacity than yarns made from the less crystalline, branched form (LDPE) (see ETHYLENE POLYMERS, LDPE). Markets were developed for HDPE fiber in marine rope where water resistance and buoyancy are important. However, the fibers also possess a low melting point, lack resilience, and have poor light stability. These traits caused the polyethylene fibers to have limited applications.

Isotactic polypropylene, based on the stereospecific polymerization catalysts discovered by Ziegler and Natta, was introduced commercially in the United States in 1957. Commercial polypropylene fibers followed in 1961. The first market of significance, contract carpet, was based on a three-ply, crimper-textured yarn. It competed favorably against wool and rayon–wool blends because of its lighter

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

weight, longer wear, and lower cost. In the mid-1960s, the discovery of improved light stabilizers led to the development of outdoor carpeting based on polypropylene. In 1967, woven carpet backing based on a film warp and fine-filament fill was produced. In the early 1970s, a bulked-continuous-filament (BCF) yarn was introduced for woven, texturized upholstery. In the mid-1970s, further improvement in light stabilization of polypropylene led to a staple product for automotive interiors and nonwoven velours for floor and wall carpet tiles. In the early 1980s, polypropylene was introduced as a fine-filament staple for thermal bonded nonwovens.

The growth of polyolefin fibers continues. Advances in olefin polymerization provide a wide range of polymer properties to the fiber producer. Inroads into new markets are being made through improvements in stabilization, and new and improved methods of extrusion and production, including multicomponent extrusion and spunbonded and meltblown nonwovens.

Properties

Physical Properties. Table 1 (2) shows that olefin fibers differ from other synthetic fibers in two important respects: (*1*) olefin fibers have very low moisture absorption and thus excellent stain resistance and almost equal wet and dry properties, and (*2*) the low density of olefin fibers allows a much lighter weight product at a specified size or coverage. Thus 1 kg of polypropylene fiber can produce a fabric, carpet, etc, with much more fiber per unit area than a kilogram of most other fibers.

Tensile Strength. Tensile properties of all polymers are a function of molecular weight, morphology, and testing conditions. The effect of temperature on the tensile properties of a typical polypropylene fiber is shown in Figure 1 (3). Tensile properties are also affected by strain rate, as shown in Figure 2 (3).

Table 1. Physical Properties of Commercial Fibers[a]

Polymer	Standard tenacity, GPa[b]	Breaking elongation, %	Modulus, GPa[b]	Density, kg/m^3	Moisture regain[c]
Olefin	0.16–0.44	20–200	0.24–3.22	910	0.01
Polyester	0.37–0.73	13–40	2.1–3.7	1380	0.4
Carbon	3.1	1	227	1730	
Nylon	0.23–0.60	25–65	0.5–2.4	1130	4–5
Rayon	0.25–0.42	8–30	0.8–5.3	1500	11–13
Acetate	0.14–0.16	25–45	0.41–0.64	1320	6
Acrylic	0.22–0.27	35–55	0.51–1.02	1160	1.5
Glass	4.6	5.3–5.7	89	2490	
Aramid	2.8	2.5–4.0	113	1440	4.5–7
Fluorocarbon	0.18–0.74	5–140	0.18–1.48	2100	
Polybenzimidazole	0.33–0.38	25–30	1.14–1.52	1430	15

Lower temperature and higher strain rate result in higher breaking stresses at lower elongations, consistent with the general viscoelastic behavior of polymeric materials. Similar effects are observed on other fiber tensile properties, such as tenacity or stress at break, energy to rupture, and extension at break (4). Under the same spinning, processing, and testing conditions, higher molecular weight results in higher tensile strength. The effect of molecular weight distribution on tensile properties is complex because of the interaction with spinning conditions (4,5). In general, narrower molecular weight distributions result in higher breaking tenacity and lower elongation (4,6). The variation of tenacity and elongation with draw ratio for a given spun yarn correlates well with amorphous orientation (7,8). However, when different spun yarns are compared, neither average nor amorphous orientation completely explains these variations (9–11). Theory suggests that the number of tie molecules, both from molecules traversing the interlamellar region and especially those resulting from entanglements in the interlamellar region, defines the range of tensile properties achievable using draw-induced orientation (12,13). Increased entanglements (more ties) result in higher tenacity and lower elongation.

Creep, Stress Relaxation, and Elastic Recovery. Olefin fibers exhibit creep, or time-dependent deformation under load, and undergo stress relaxation, or the spontaneous relief of internal stress. Because of the variety of molecular sizes and morphological states present in semicrystalline polymers, the creep and stress relaxation properties for materials such as polypropylene cannot be represented in one curve by using time–temperature superposition principles (14). However, given a spun yarn and thus a given structural state, curves for creep fracture (time to break under variable load) can be developed for different draw ratios, as shown in Figure 3 (15), indicating the importance of spun-yarn structure in a crystallizable polyolefin fiber. The same superposition can be carried out up to 110°C, where substantial reordering of polymer crystalline structure occurs (16).

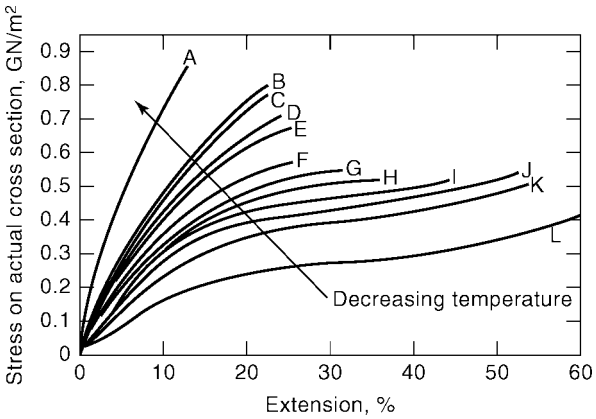

Fig. 1. Effect of temperature on tensile properties of polypropylene (3); strain rate = 6.47×10^{-4} s^{-1}. In degrees Kelvin: A, 90; B, 200; C, 213; D, 227; E, 243; F, 257; G, 266; H, 273; I, 278; J, 283; K, 293; and L, 308 (broken at 74.8% extension, 4.84×10^8 N/m^2). In s^{-1}: A, 4.9×10^2; B, 2.48×10^2; C, 1.26×10^2; D, 6.3×10^1; E, 3.2×10^1; F, 2.87×10^1; G, 2.3×10^{-1}; H, 3.3×10^{-2}; I, 1.33×10^{-2}; J, 4.17×10^{-3}; K, 1.67×10^{-3}; and L, 3.3×10^{-4}. To convert GN/m^2 to $dyne/cm^2$, multiply by 10^{10}.

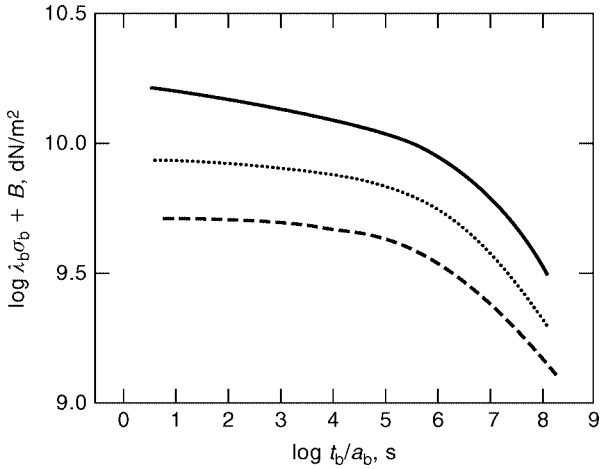

Fig. 3. Composite curve of true stress at break $\lambda_b\sigma_b$ at 40°C vs reduced time to break t_b/a_b for polypropylene fibers of three draw ratios (15): (———), 2.7 × draw, **B** = 0; (·····), 3.5 × draw, $B = 0.2$ (– – –), 4.5 × draw, $B = 0.4$. Values of B are arbitrary.

High molecular weight and high orientation reduce creep. At a fixed molecular weight, the stress-relaxation modulus is higher for a highly crystalline sample prepared by slow cooling than for a smectic sample prepared by rapid quench (14). Annealing the smectic sample raises the relaxation modulus slightly, but not to the degree present in the fiber prepared by slow cooling.

Elastic recovery or resilience is the recovery of length upon release of stress after extension or compression. A fiber, fabric, or carpet must possess this property in order to spring back to its original shape after being crushed or wrinkled. Polyolefin fibers have poorer resilience than nylon; this is thought to be partially

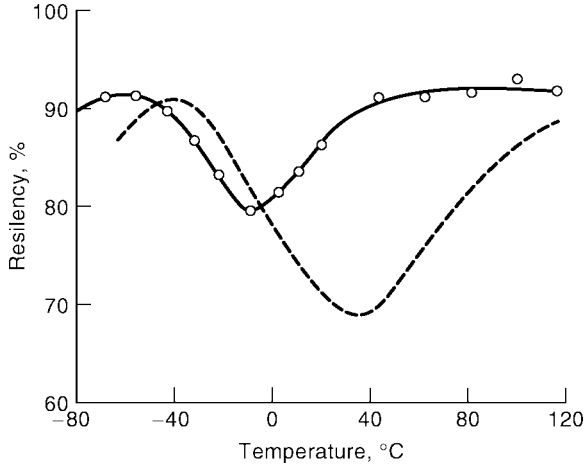

Fig. 4. Resiliency of polypropylene (—○—) and polyethylene (– – –), multifilament yarns as a function of temperature (17).

related to the creep properties of the polyolefins. Recovery from small strain cyclic loading is a function of temperature, as shown in Figure 4, and found to be a minimum for polypropylene at 10°C, near the glass-transition temperature T_g (17). The minimum for polyethylene is at 30°C, higher than the amorphous T_g. This minimum is thought to be associated with motions in the crystalline phase of the highly oriented crystalline structure (17).

Chemical Properties. The hydrocarbon nature of olefin fibers, lacking any polarity, imparts high hydrophobicity and, consequently, resistance to soiling or staining by polar materials, a property important in carpet and upholstery applications. Unlike the condensation polymer fibers, such as polyester and nylon, olefin fibers are resistant to acids and bases. At room temperature, polyolefins are resistant to most organic solvents, except for some swelling in chlorinated hydrocarbon solvents. At higher temperatures, polyolefins dissolve in aromatic or chlorinated aromatic solvents, and show some solubility in high boiling hydrocarbon solvents. At high temperatures, polyolefins are degraded by strong oxidizing acids.

Thermal and Oxidative Stability. The thermal transitions of several polyolefins are compared to other polymers in Table 2. In general, polyolefins undergo thermal transitions at much lower temperatures than condensation polymers, and thus the thermal and oxidative stability of polyolefin fibers are comparatively poor (18). They are highly sensitive to oxygen, which must be carefully controlled in all processing. The tertiary hydrogen in polypropylene imparts sensitivity to oxidative degradation by chain scission resulting in molecular weight degradation. Polyolefins are stabilized by hindered phenols or phosphites. Hindered phenol stabilizers provide moderate melt stability and good long-term heat aging, but undergo gas yellowing, which is a chemical reaction of phenolic compounds and nitrous oxide gases producing yellow-colored compounds. Typical sources of nitrous oxides are gas-fired heaters, dryers, and tenters, and propane-fueled lift trucks used in warehouses. Phosphites are good melt stabilizers and do not gas

Table 2. Thermal Properties of Olefins and Other Fiber-Forming Polymers

yellow, but have poor long-term heat aging. Preferred stabilizers are highly substituted phenols such as Cyanox 1790 and Irganox 1010, or phosphites such as Ultranox 626 and Irgafos 168 (see ANTIOXIDANTS; HEAT STABILIZERS).

Ultraviolet Degradation. Polyolefins are subject to light-induced degradation (19); polyethylene is more resistant than polypropylene. Although the mechanism of UV degradation is different from thermal degradation, the resulting chain scission and molecular weight degradation is similar. In fiber applications, stabilization against light is necessary to prevent loss of properties. The stabilizer must be compatible, have low volatility, be resistant to light and thermal degradation itself, and must last over the lifetime of the fiber. Chemical and physical interactions with other additives must be avoided. Minimal odor and toxicity, colorlessness, resistance to gas yellowing, and low cost are additional requirements (see UV STABILIZERS).

Stabilizers that act as UV screens or energy quenchers are usually ineffective by themselves. Because polyolefins readily form hydroperoxides, the more effective light stabilizers are radical scavengers. Hindered amine light stabilizers (HALS) are favored, especially high molecular weight and polymeric amines that have lower mobility and less tendency to migrate to the surface of the fiber (20,21). This migration is commonly called *bloom*. Test results for some typical stabilizers are given in Table 3 (22).

Table 3. Stabilization of Polypropylene Fiber by Polymeric HALS[a]

HALS	Manufacturer	Carbon arc T50, h[b]	Florida T50, kJ/m^2[c,d]

[c] kJ/m^2 to 50% retention of tensile strength; Florida under glass exposure.
[d] To convert kJ/m^2 to Langley, multiply by 239.

Flammability. Flammability of polymeric materials is measured by many methods, most commonly by the limiting-oxygen-index test (ASTM D2863), which defines the minimum oxygen concentration necessary to support combustion, or the UL 94 vertical-burn test, which measures the burn length of a fabric. Most polyolefins can be made fire retardant using a stabilizer, usually a bromine-containing organic compound, and a synergist such as antimony oxide (23). However, the required loadings are usually too high for fibers to be spun. Fire-retardant polypropylene fibers exhibit reduced light and thermal resistance. Commercial fire-retardant polyolefin fibers have just recently been introduced, but as expected the fibers have limited light stability and poor luster. Where applications require fire retardancy, it is usually conferred by fabric finishes or incorporation of fire retardants in a latex, such as in latex-bonded nonwovens and latex-coated wovens.

Dyeing Properties. Because of their nonionic chemical nature, olefin fibers are difficult to dye. Oil-soluble dispersed dyes diffuse into polypropylene but readily bloom and rub off. In the first commercial dyeing of olefin fibers, nickel dyes such as UV-1084, also a light stabilizer, were used. The dyed fibers were colorfast but dull and hazy. A broad variety of polymeric dye-sites have been blended with polypropylene; nitrogen-containing copolymers are the most favored (24–26). A commercial acid-dyeable polypropylene fiber is prepared by blending the polypropylene with a basic amino-polyamide terpolymer (27). In apparel applications where dyeing is important, dyeable blends are expensive and create problems in spinning fine denier fibers. Hence, olefin fibers are usually colored by pigment blending during manufacture, called *solution dyeing* in the trade.

Manufacture and Processing

Olefin fibers are manufactured commercially by melt spinning, similar to the methods employed for polyester and polyamide fibers (see POLYESTERS, FIBERS; POLYAMIDES, FIBERS). The basic process of melt spinning is illustrated in Figure 5. The polymer resin and ingredients, primarily stabilizers, pigments, and rheological modifiers, are fed into a screw extruder, melted, and extruded through fine diameter holes. The plate containing the holes is commonly called a *spinnerette*. A metering pump and a mixing device are usually installed in front of the spinneret to ensure uniform delivery and mixing to facilitate uniform drawdown at high speeds. In the traditional or long spinning process, the fiber is pulled through a long cooling stack-type quench chamber by a take-up device at speeds in the range of 50–2000 m/min and discontinuously routed to downstream finishing operations. In the short spinning process, filaments are cooled within a few centimeters of the spinneret at speeds of 50–150 m/min. Because of the lower speeds, fiber can be continuously routed to downstream finishing operations in a one-step process (28). Finishing operations include drawing the fiber to as much as six times its original length, heat treatment to relieve internal stresses, and texturizing processes, which are combinations of deformational and heat treatments. These treatments were developed to impart specific characteristics to the olefin fiber dependent on its end use. Commercial olefin fibers are produced in a broad range of linear densities, from 0.1 to 12 tex (1.1–110 den), to fit a variety of applications, as shown in Figure 6 (29).

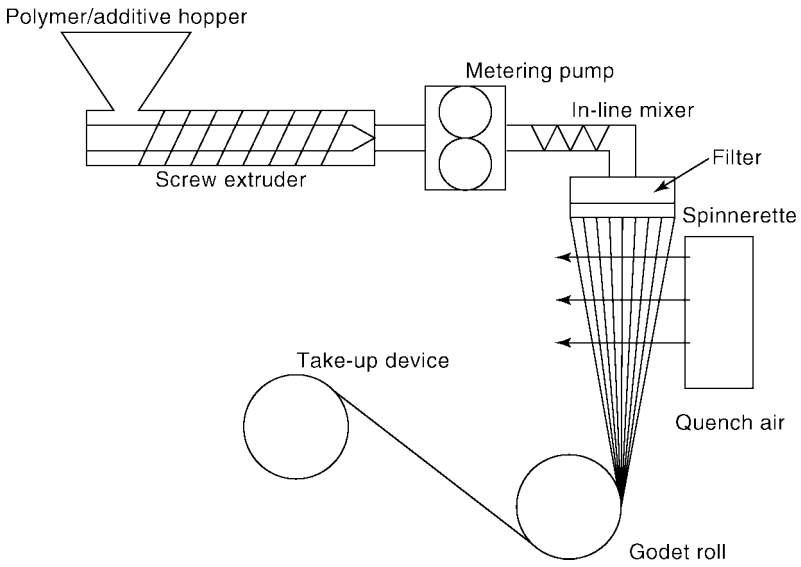

Fig. 5. Melt spinning process.

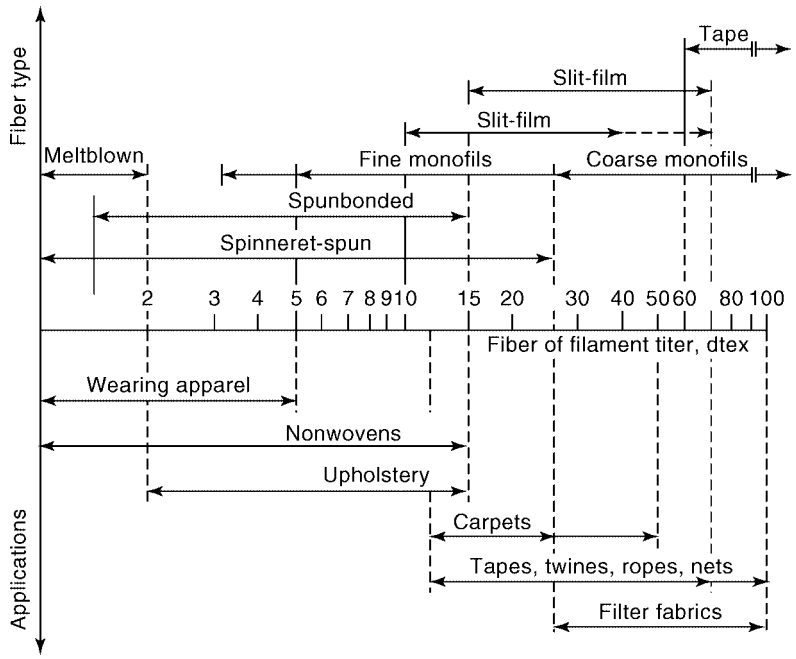

Fig. 6. Linear density of olefin fibers in various applications (29); dtex = 1.1 den.

Extrusion. Polymer resin and additives are melted and pumped through an extruder into a spinning pump. The pump meters the molten polymer through a filter system which removes particles from the molten polymer stream that might clog the capillaries of the spinneret or cause discontinuities in fine diameter fiber. These filters are typically either sand packs or metal screens. The polymer continues to a spinneret, where it is extruded through holes under pressure. These holes or capillaries define the size and shape of the extruded fiber. A spinneret may contain up to several thousand capillaries, typically 0.3–0.5 mm in diameter. The length of the capillary is sized to the melt viscosity of the polymer. Typical length-to-diameter ratios of spinneret capillaries are 2:1 to 8:1. The spinneret holes can be arranged in a variety of hole spacings and patterns, including rectangular, round, and annular. Considerations include throughput rate, heat transfer required to quench the fiber, and fiber diameter.

The extrusion of olefin fibers is largely controlled by the polymer. Polyolefin melts are strongly viscoelastic, and melt extrusion of polyolefin fibers differs from that of polyesters and polyamides. Polyolefins are manufactured in a broad range of molecular weights and ratios of weight-average to number-average molecular weight (M_w/M_n). Unlike the condensation polymers, which typically have molecular weights of 10,000–15,000 and M_w/M_n of approximately 2, polyolefins have weight-average molecular weights ranging from 50,000 to 1,000,000 and, as polymerized, M_w/M_n ranges from 4 to 15. Further control of molecular weight and distribution is obtained by chemical or thermal degradation. The full range of molecular weights used in olefin fiber manufacture is above 20,000, and M_w/M_n varies from 2 to 15. As molecular weight increases and molecular weight distribution broadens, the polymer melt becomes more pseudoplastic as indicated in Table 4 and shown in Figure 7 (30). In the sizing of extrusion equipment for olefin fiber production, the wide range of shear viscosities and thinning effects must be considered because these affect both power requirements and mixing efficiencies.

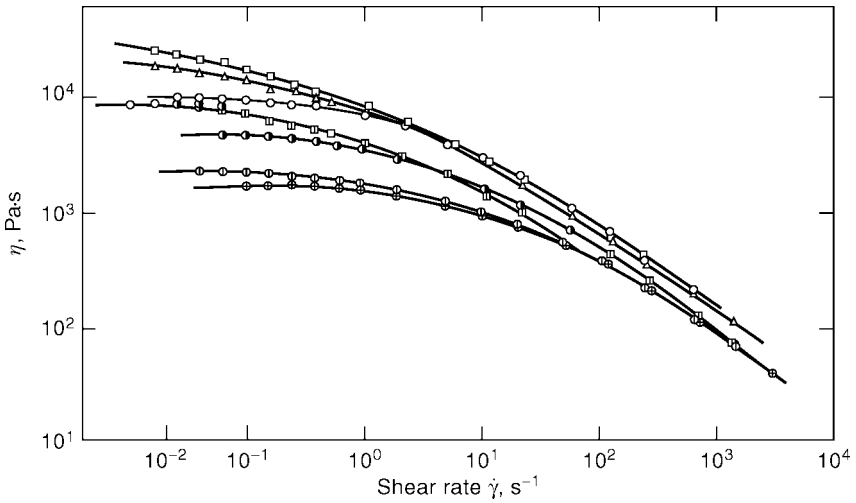

Fig. 7. Shear viscosity at 180°C of polypropylene of different molecular weight and distribution vs shear rate (30); see Table 4 for key. $Pa \cdot s = 0.1$ P.

Fiber spinning is a uniaxial extension process, and the elongational viscosity behavior, which is the stress–strain relationship in uniaxial extension, is more important than the shear viscosity behavior. The narrower molecular weight distributions tend to be less thinning, and as shown in Figure 8 (30), elongational viscosity increases at higher extension rates. This leads to higher melt orientation, which in turn is reflected in higher spun fiber orientation, higher tenacity, and lower extensibility. In contrast, the broad molecular weight distributions tend to be more thinning and hence more prone to necking and fracture at high spinning speeds (30,31), but yield a less oriented, higher elongation spun fiber. The

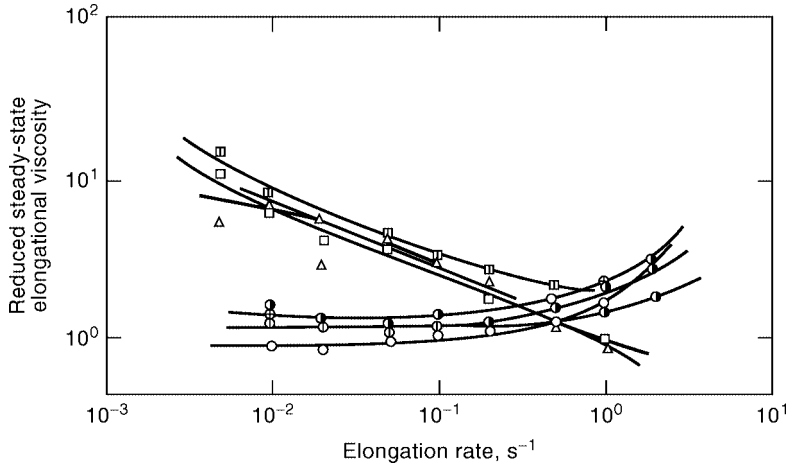

Fig. 8. Elongational viscosity at 180°C of polypropylene of different molecular weight and distribution (30); see Table 4 for key.

choice of an optimum molecular weight and molecular weight distribution is determined by the desired properties of the fiber and the process continuity on available equipment.

Because of the high melt viscosity of polyolefins, normal spinning melt temperatures are 240–310°C, which is 80–150°C above the crystalline melting point. Because of the high melt temperatures used for polyolefin fiber spinning, thermal stabilizers such as substituted hindered phenols are added. In the presence of pigments, the melt temperature must be carefully controlled to prevent color degradation and to obtain uniform color dispersion.

Polyolefin melts have a high degree of viscoelastic memory or elasticity. First normal stress differences of polyolefins, a rheological measure of melt elasticity, are shown in Figure 9 (30). At a fixed molecular weight and shear rate, the first normal stress difference increases as M_w/M_n increases. The high shear rate obtained in fine capillaries, typically on the order of 10^3–10^4 s^{-1}, coupled with the viscoelastic memory, causes the filament to swell (die swell or extrudate swell) upon leaving the capillary. On a molecular scale, the residence time in the region of die swell is sufficient to allow relaxation of any shear-induced orientation. However, high die swell significantly affects the drawdown or extension rate, leading to threadline breaks. Die swell can be reduced by lower molecular weight, narrower molecular weight distribution, or higher melt temperature.

Quench. Attempts have been made to model this nonisothermal process (32–35), but the complexity of the actual system makes quench design an art.

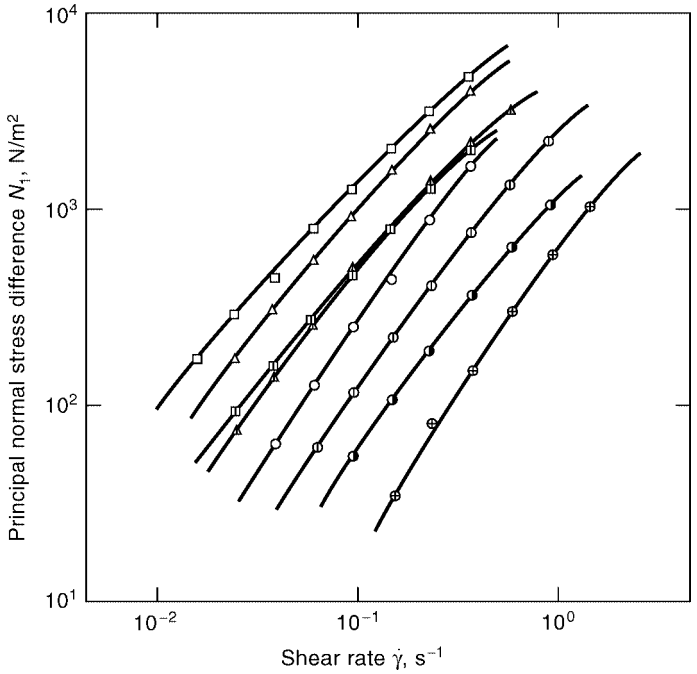

Fig. 9. First normal stress differences of polypropylene of different molecular weight and distribution (30); see Table 4 for key. To convert N/m^2 to dyne/cm^2, multiply by 10.

Arrangements include straight-through, and outside-in and inside-out radial patterns (36). The optimum configuration depends on spinneret size, hole pattern, filament size, quench-chamber dimensions, take-up rate, and desired physical properties. Process continuity and final fiber properties are governed by the temperature profile and extension rate.

Polypropylene and other linear polyolefins crystallize more rapidly than most other crystallizable polymers. Unlike polyester, which is normally amorphous as spun, the fiber morphology of polyolefins is fixed in the spinning process; this limits the range of properties in subsequent drawing and annealing operations. In a low crystallinity state, sometimes called the paracrystalline or smectic form, a large degree of local order still exists. It can be reached by extruding low molecular weight polyolefins, processing at low draw ratio, or by a rapid quench such as by using a cold water bath (37).

Quench is more commonly practiced commercially by a controlled air quench in which the rate of cooling is controlled by the velocity and temperature of the air. During normal cooling, crystallization occurs in the threadline. In-line X-ray scattering studies demonstrate that crystallization is extremely rapid; the full crystalline structure is almost completely developed in fractions of a second (38). Fiber spinning is an extensional process during which significant molecular orientation occurs. Under rapid crystallization, this orientation is fixed during the spinning process. Small-angle neutron-scattering studies of quiescent polypropylene crystallization show that the chain dimensions in both melt and crystallized forms are comparable (39). Although there may be significant relaxation of the amorphous region after spinning, the primary structure of the fiber is fixed during spinning and controls subsequent drawing and texturizing of the fiber. For fixed extrusion and take-up rates, a more rapid quench reduces the average melt-deformation temperature, increases relaxation times, and gives a more entangled melt when crystallization begins. The rapidly quenched fiber usually gives lower elongation and higher tenacity during subsequent draw (40). Using a very rapid quench, the melt may not be able to relax fast enough to sustain drawdown, resulting in melt fracture. Under conditions of a slow quench, the melt may totally relax, leading to ductile failure of the threadline.

A common measurement useful in predicting threadline behavior is fiber tension, frequently misnamed spinline stress. It is normally measured after the crystallization point in the threadline when the steady state is reached and the threadline is no longer deformed. Fiber tension increases as take-up velocity increases (38) and molecular weight increases. Tension decreases as temperature increases (41). Crystallinity increases slightly as fiber tension is increased (38). At low tension, the birefringence increases as tension is increased, leveling off at a spinline tension of 10 MPa (1450 psi) (38).

Take-Up. Take-up devices attenuate the spinline to the desired linear density and collect the spun yarn in a form suitable for further processing. A godet wheel is typically used to control the take-up velocity which varies from 1–2 m/s for heavy monofilaments to 10–33 m/s for fine yarns. The yarn can be stacked in cans, taken up on bobbins, or directly transferred to drawing and texturizing equipment.

In the spunbond process (Fig. 10), an aspiratory is used to draw the fibers in spinning and directly deposit them as a web of continuous, randomly oriented

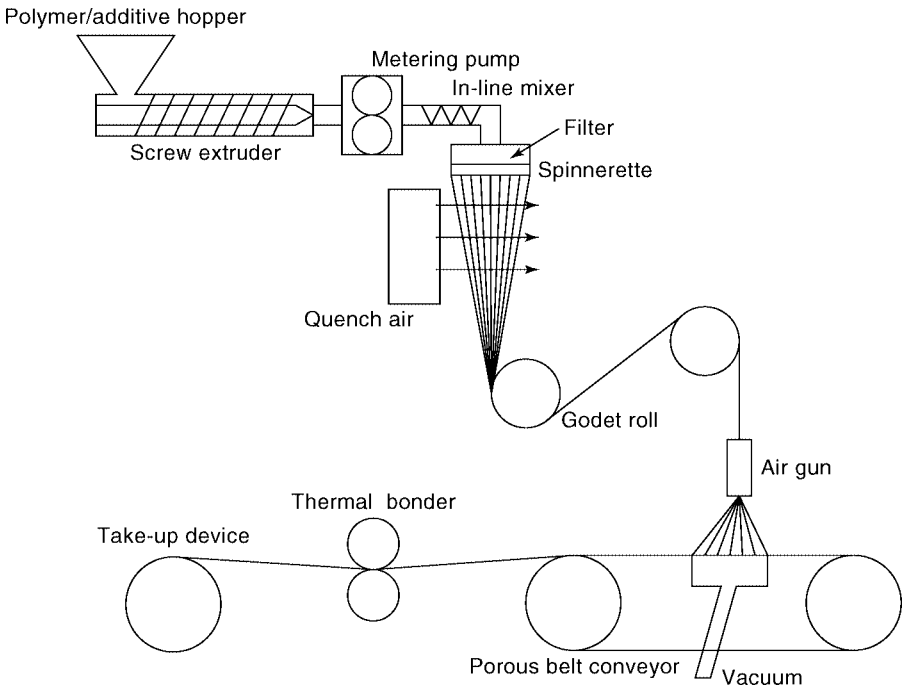

Fig. 10. Flow sheet for typical spunbond fabric manufacture.

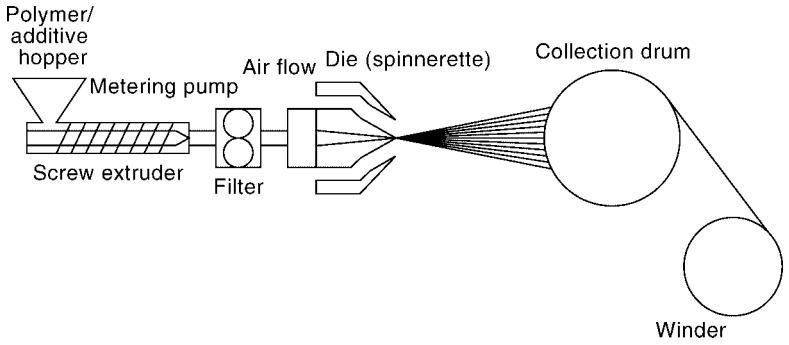

Fig. 11. Flow sheet for typical meltblown fabric manufacture.

filaments onto a moving conveyor belt. In the meltblown process (Fig. 11), high velocity air is used to draw the extruded melt into fine-denier fibers that are laid down in a continuous web on a collector drum.

Draw. Polyolefin fibers are usually drawn to increase orientation and further modify the physical properties of the fiber. Linear density, necessary to control the textile properties, is more easily reduced during drawing than in spinning. The draw step can be accomplished in-line with spinning in a continuous spin–draw–texturing process (36,42) or in a second processing step. This second processing step allows simultaneous mixing of colors in a multi-ply continuous

filament yarn for textiles. For staple fiber production, large bundles or tows consisting of up to a million or more filaments are stretched, texturized (crimped), and cut.

In secondary drawing operations, the aging properties of the spun yarn must be considered. Because polypropylene fibers have a low T_g, the spun yarn is restructured between spinning and drawing; this is more important as the smectic content is increased (43). The aging process depends on whether the yarn is stored on bobbins under tension or coiled in cans with no tension on the fiber. The aging of quick-quenched (smectic) polypropylene films has been studied (43). Stored at room temperature, the increase in yield stress is 5% in 24 hours. Similar data on polypropylene spun fibers have not been published, but aging effects are similar. Drawn fiber properties, such as density, stress relaxation modulus, and heat of fusion, age because of collapse of excess free volume in the noncrystalline fraction (44).

The crystalline structure of the spun yarn affects the draw process. Monoclinic yarns tend to exhibit higher tenacity and lower elongation at low draw ratios than smectic yarns (6). They exhibit lower maximum draw ratios, undergo brittle fracture, and form microvoids (45) at significantly lower draw temperatures, which creates a chalky appearance. Studies of the effect of spun-yarn structure on drawing behavior show that the as-spun orientation and morphology determine fiber properties at a given draw ratio, as shown in Figure 12 (9,45,46). However, final fiber properties can be correlated with birefringence, a measure of the average orientation, as shown in Figure 13 (9,45). Fiber properties and amorphous orientation show good correlation in some studies (Fig. 14) (7,8), but in most studies the range of spun-yarn properties is limited. Such studies suggest that the deformation during draw primarily affects the interlamellar amorphous region

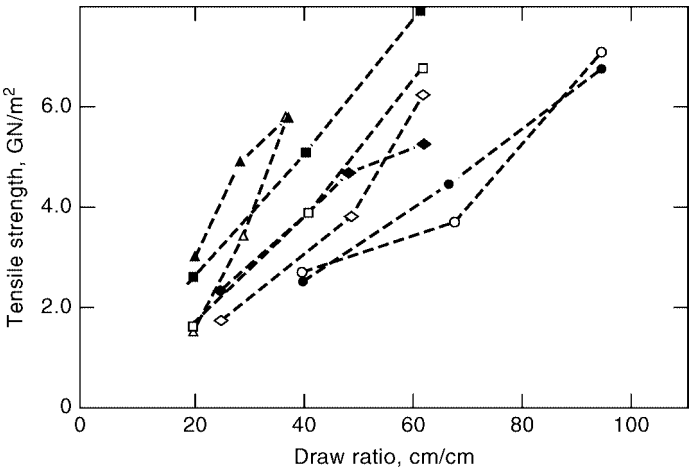

Fig. 12. Tensile strength vs draw ratio (6): 0.42 melt index spun at 50 m/min, ■, □; and 500 m/min, ▲, △; 12.0 melt index spun at 100 m/min, ●, ○; and 500 m/min, ♦ ◇. Open symbols = cold drawn and annealed at 140°C; filled symbols = drawn at 140°C. To convert GN/m^2 to $dyne/cm^2$, multiply by 10^{10}.

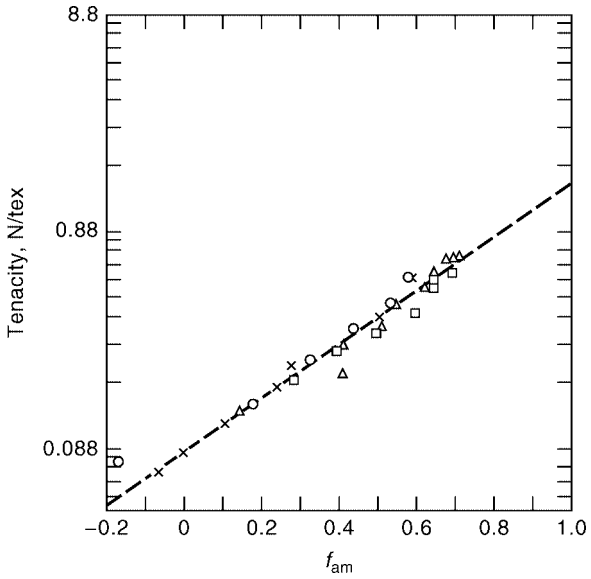

Fig. 14. Tenacity as a function of amorphous orientation (f_{am}) for polypropylene fibers and films (7). Film drawn at 135°C (○), 110°C (×), and 90°C (□). △, Heat-set fiber. To convert N/tex to gf/den, multiply by 11.3. $\text{Tenacity}_{max} = 1.3$ N/tex (15 gf/den).

at low draw ratio. At higher draw ratio, the crystalline structure is substantially disrupted.

Texturing. The final step in olefin fiber production is texturing; the method depends primarily on the application. For carpet and upholstery, the fiber is usually bulked, a procedure in which fiber is deformed by hot air or steam jet turbulence in a nozzle and deposited on a moving screen to cool. The fiber takes

on a three-dimensional crimp that aids in developing bulk and coverage in the final fabric. Stuffer box crimping, a process in which heated tow is overfed into a restricted outlet box, imparts a two-dimensional sawtooth crimp commonly found in olefin staple used in carded nonwovens and upholstery yarns.

Slit-Film Fiber. A substantial volume of olefin fiber is produced by slit-film or film-to-fiber technology (29). For producing filaments with high linear density, above 0.7 tex (6.6 den), the production economics are more favorable than monofilament spinning (29). The fibers are used primarily for carpet backing and rope or cordage applications. The processes used to make slit-film fibers are versatile and economical.

The equipment for the slit-film fiber process is shown in Figure 15 (29). An olefin film is cast, and, as in melt spinning, the morphology and composition of the film determine the processing characteristics. Fibers may be produced by cutting or slitting the film, or by chemomechanical fibrillation. The film is fibrillated mechanically by rubbing or brushing. Immiscible polymers, such as polyethylene or polystyrene (PS), may be added to polypropylene to promote fibrillation. Many common fiber-texturing techniques such as stuffer-box, false-twist, or knife-edge treatments improve the textile characteristics of slit-film fibers.

Several more recent variations of the film-to-fiber approach result in direct conversion of film to fabric. The film may be embossed in a controlled pattern and subsequently drawn uniaxially or biaxially to produce a variety of nonwoven products (47). Addition of chemical blowing agents to the film causes fibrillation upon extrusion. Nonwovens can be formed directly from blown film using a unique radial die and control of the biaxial draw ratio (48) (see NONWOVEN FABRICS, STAPLE FIBERS).

Bicomponent Fibers. Polypropylene fibers have made substantial inroads into nonwoven markets because they are easily thermal bonded. Further enhancement in thermal bonding is obtained using bicomponent fibers (49). In

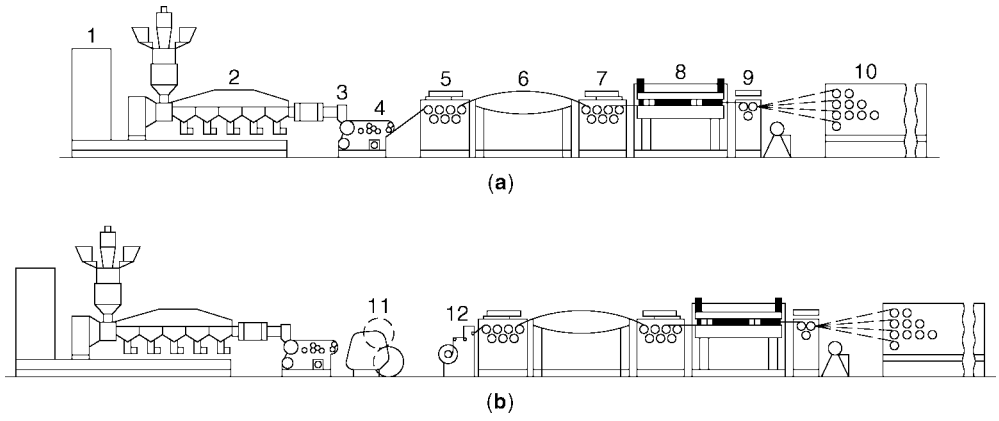

Fig. 15. Production lines for stretched film tape (29): (**a**) continuous production line for film tape; (**b**) discontinuous production lines for film and film tape. 1, Control cabinet; 2, extruder; 3, flat die; 4, chill roll; 5, septet (seven rolls); 6, hot plate; 7, septet (seven rolls); 8, heat-setting oven; 9, trio (three rolls); 10, bobbin winder; 11, film winder; and 12, film-unrolling stand.

these fibers, two incompatible polymers, such as polypropylene and polyethylene, polyester and polyethylene, or polyester and polypropylene, are spun together to give a fiber with a side-by-side or core–sheath arrangement of the two materials. The lower melting polymer can melt and form adhesive bonds to other fibers; the higher melting component causes the fiber to retain some of its textile characteristics.

Bicomponent fibers have also provided a route to self-texturing (self-crimping) fibers. The crimp results from the length differential developed during processing caused by differential shrinkage in the two polymers in side-by-side or eccentric core–sheath configurations (50).

Conventional spinning technology is limited in the production of very fine denier filaments because of spinning and mass uniformity problems as the melt drawdown is increased. Ultrafine filaments (microfibers) can be produced through bicomponent technology by extruding two or more components together as a single fiber and later separating the components through chemical or mechanical processes. Fibers of 0.1–0.001 tex (~1–0.01 den) per filament can be produced (50,51).

Meltblown, Spunbond, and Spurted Fibers. A variety of directly formed nonwovens exhibiting excellent filtration characteristics are made by meltblown processes (52), producing very fine, submicrometer filaments. A simple schematic of the die is shown in Figure 11. A stream of high velocity hot air is directed on the molten polymer filaments as they are extruded from a spinneret. This air attenuates, entangles, and transports the fiber to a collection device. Because the fiber cannot be separated and wound for subsequent processing, a nonwoven web is directly formed. Mechanical integrity of the web is usually obtained by thermal bonding or needling, although other methods, such as latex bonding, can be used. Meltblown fabrics are made commercially from polypropylene and polyethylene. The webs are soft, breathable, and drapable (53–55).

In the spunbond process, the fiber is spun similarly to conventional melt spinning, but the fibers are attenuated by air drag applied at a distance from the spinneret (see NONWOVEN FABRICS). This allows a reasonably high level of filament orientation to be developed. The fibers are directly deposited onto a moving conveyor belt as a web of continuous randomly oriented filaments. As with meltblown webs, the fibers are usually thermal bonded or needled (53).

Pulp-like olefin fibers are produced by a high pressure spurting process developed by Hercules, Inc. and Solvay, Inc. Polypropylene or polyethylene is dissolved in volatile solvents at high temperature and pressure. After the solution is released, the solvent is volatilized, and the polymer expands into a highly fluffed, pulp-like product. Additives are included to modify the surface characteristics of the pulp. Uses include felted fabrics, substitution in whole or in part for wood pulp in papermaking, and replacement of asbestos in reinforcing applications (56).

High Strength Fibers. The properties of commercial olefin fibers are far inferior to those theoretically attainable. Theoretical and actual strengths of common commercial fibers are listed in Table 5 (57). A number of methods, including superdrawing (58), high pressure extrusion (59), spinning of liquid crystalline polymers or solutions (60), gel spinning (61–65), and hot drawing

Table 5. Theoretical and Actual Strengths of Commercial Fibers[a]

Polymer	Density, kg/m^3	Molecular area, nm^2	Theoretical strength, GPa[b]	Strength of commercial fiber, GPa[b]
Polyethylene	960	0.193	31.6	0.76
Polypropylene	910	0.348	17.6	0.72
Nylon-6	1140	0.192	31.9	0.96
Polyoxymethylene	1410	0.185	32.9

(66) produce higher strengths than those given in Table 5 for commercial fibers, but these methods are tedious and uneconomical for olefin fibers. A high modulus commercial polyethylene fiber with properties approaching those of aramid and graphite fibers (Table 6) (67) is prepared by gel spinning (68) (see CARBON FIBERS; POLYAMIDES, AROMATIC). Although most of these techniques produce substantial increases in modulus, higher tensile strengths are currently available only from gel spinning or dilute fibrillar crystal growth. Even using these techniques, the maximum strengths observed to date are only a fraction of the theoretical strengths.

Hard-Elastic Fibers. Hard-elastic fibers are prepared by annealing a moderately oriented spun yarn at high temperature under tension. They are prepared from a variety of olefin polymers, acetal copolymers, and polypivalolactone (69,70). Whereas the strengths observed are comparable to those of highly drawn commercial fiber, in the range 0.52–0.61 N/tex (6–7 gf/den), the recovery from elongation is substantially better. Hard-elastic fibers typically exhibit 90% recovery from 50% elongation, whereas highly drawn, high tenacity commercial fibers exhibit only 50–75% recovery from 5% elongation. The mechanism of elastic recovery

differs from the entropic models normally used to explain plastic properties. The hard elastic fibers are thought to deform through opening of the lamellae stacked structure, resulting in void formations; recovery is controlled by energy considerations. Although there are potential uses in applications involving substantial deformation, products such as stretch fabrics and hard-elastic fibers are not yet used commercially.

Economic Aspects

Polyolefin fiber (from polypropylene or ethylene polymers) has continued to be one of the fastest growing segments of the synthetic fiber industry. Worldwide production has been increasing at an annul rate of 6% since 1996 and reached 5.5 million ton in 1999. Polyolefin fibers account for 18% of the worldwide synthetic fibers market. Polypropylene fibers predominate and account for 89–95% of the polyolefin production in Western Europe and the United State. The remainder is manufactured from polyethylene. Polypropylene fibers account for 80% usage in Japan (71).

The principal use for polyolefin fibers is in consumer products. The primary use is the production of carpets and rugs, and includes backings. Polyolefins in the form of nonwoven fabrics is the second largest use.

Nonwoven fabrics continue to be the largest growing segment in the textile industry. In 2001, worldwide consumption was 3.5 billion ton valued at over $14 billion. Between 1997 and 2001, world consumption grew at a rate of 11.2%/year. For much of the past decade, solid growth has occurred in industrialized nations. Double-digit growth is now seen in developing nations (primarily Aisa). In 2001, developing countries consumed 39% of all nonwovens produced. Consumption is up from 11% in 1988. Use should continue to grow at the rate of 10–12% through 2006 (72).

Demand for nonwoven roll goods currently exceeds local capacity by 50%. Growth, particularly in China, has seen expansion of local manufacturing capabilities. In North America, Western Europe, and Japan, damand for nonwovens is expected to increase at 3–5%/year through 2006.

Industrial applications of polyolefin fibers include woven and nonwoven geotextiles, agriculatural fabrics, construction sheeting, automobile fabrics, filtration media, rope/twine, woven bags, narrow-woven web and tapes, tents, and tarpaulins. Geosynthetic fabrics will continue to be a growing market for polypropylene nonwovens.

Applications

Olefin fibers are used for a variety of purposes from home furnishings to industrial applications. These include carpets, upholstery, drapery, rope, geotextiles, and both disposable and nondisposable nonwovens. Fiber mechanical properties, relative chemical inertness, low moisture absorption, and low density contribute to desirable product properties. Olefin fiber use in apparel has been restricted by low melting temperatures, which make machine drying and ironing of polyethylene

and polypropylene fabrics difficult or impossible. However, this market is increasing as manufacturers take advantage of the wicking properties (moisture transport) as in lightweight sportswear (73).

Polypropylene fibers are used in every aspect of carpet construction from face fiber to primary and secondary backings. Polypropylene's advantages over jute as carpet backing are dimensional stability and minimal moisture absorption. Drawbacks include difficulty in dyeing and higher cost. Bulked-continuous-filament (BCF) carpet yarns provide face fiber with improved crimp and elasticity. BCF carpet yarns are especially important in contract carpets, characterized by low dense loops, where easy cleaning is an advantage.

Olefin fiber is an important material for nonwovens (74). The geotextile market is still small, despite expectations that polypropylene is to be the principal fiber in such applications. Disposable nonwoven applications include hygienic coverstock, sanitary wipes, and medical roll goods. The two competing processes for the coverstock market are thermal-bonded carded staple and spunbond, both of which have displaced latex-bonded polyester because of improved strength, softness, and inertness.

A special use for meltblown olefin fiber is in filtration media such as surgical masks and industrial filters (75). The high surface area of these ultrafine filament fibers permits preparation of nonwoven filters with effective pore sizes as small as 0.5 μm.

Other applications, including rope, cordage, outdoor furniture webbing, bags, and synthetic turf, make up the remaining segments of the olefin fiber market. Spunbond polyethylene is used in packaging applications requiring high strength and low weight. Specialty olefin fibers are employed in asphalt and concrete reinforcement (76–79). Hollow fibers have been tested in several filtration applications (80,81). Ultrafine fibers are used in synthetic leather, silk-like fabrics, and special filters (50,51). These fibers are also used in sports outerwear, where the tight weaves produce fabrics that are windproof and waterproof, but are able to pass vapors from perspiration and thus keep the wearer cool and dry (51). If the economics of the high modulus olefin fibers becomes more favorable, substantial markets could be developed in reinforced composites such as boat hulls (67).

OXIDATIVE POLYMERIZATION

Introduction

Oxidative polymerization is, formally, abstraction of two hydrogen atoms from a monomer to give a polymer, and thus may be classified as polycondensation. The applicable monomers are mainly aromatic compounds. Electrical and chemical oxidation methods are often used, in which catalysis with dioxygen or hydrogen peroxide is the most favorable; the reaction temperature is moderate and the by-product is water only. Oxidative polymerization is one of the cleanest and lowest loading methods in polycondensation. However, the reaction mechanism is unclear in many cases and the coupling selectivity is not generally easy to control.

This article deals with oxidative polymerization of phenols, anilines, thiophenol derivatives, aromatic hydrocarbons, heterocyclic aromatics, and other monomers. The reaction mechanism, the coupling selectivity, and the characteristics of the resulting polymers are discussed.

2,6-Disubstituted Phenols

Until the 1950s, oxidation of 2,6-dimethylphenol (2,6-Me_2P) by an oxidant like benzoyl peroxide (1) or alkaline ferricyanide (2) mainly gave 3,3′,5,5′-tetramethyldiphenoquinone (DPQ) (Fig. 1). In 1959, oxidative polymerization of 2,6-Me_2P catalyzed by CuCl/pyridine (Py) under dioxygen leading to poly(2,6-dimethyl-1,4-phenylene oxide) (Poly-2,6-Me_2P) was discovered (3). Various catalysts such as copper/substituted-ethylenediamine complexes were developed and Poly-2,6-Me_2P was found completely miscible with polystyrene (4) (see POLYETHERS, AROMATIC).

Oxidative Coupling Mechanism. Poly-2,6-Me_2P is a C—O coupling product and DPQ is a product via C—C coupling. Control of the C—O coupling is a most important question (5). Three possible reaction mechanisms for the C—O coupling

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

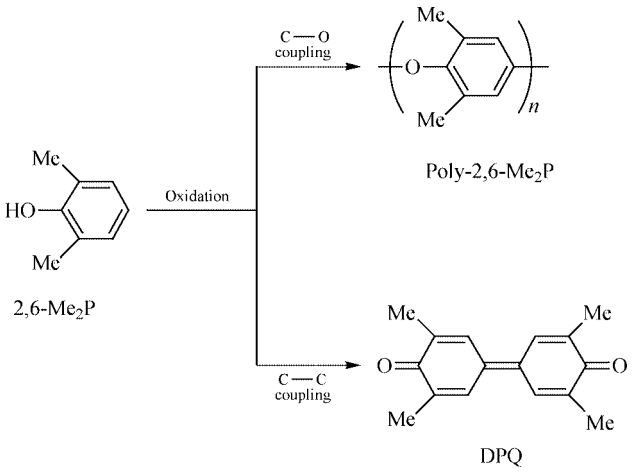

Fig. 1. Oxidation of 2,6-dimethylphenol.

selectivity have been proposed as follows: (*1*) coupling of free phenoxy radicals resulting from one-electron-oxidation of 2,6-Me_2P, (*2*) coupling of phenoxy radicals coordinated to a catalyst complex, and (*3*) coupling through phenoxonium cation formed by two-electron-oxidation of 2,6-Me_2P (Fig. 2).

Coupling of Phenoxy Radicals Coordinated to Catalyst Complex. Because the oxidative coupling of 2,6-Me_2P with benzoyl peroxide or alkaline ferricyanide affords DPQ as the main product (1,2), it seems that the free phenoxy radical leads to C—C coupling. C—O coupling results from the phenoxy radical

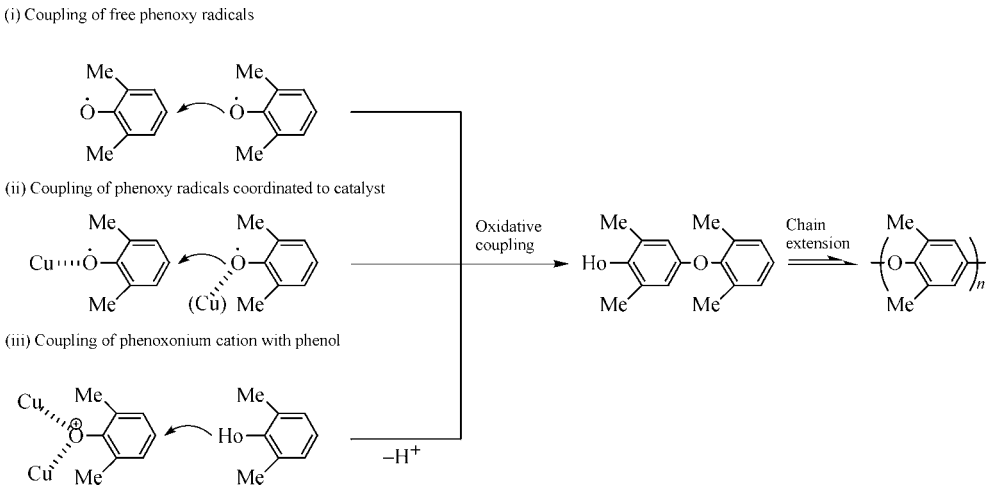

Fig. 2. Three possible mechanisms for C—O coupling in the oxidative polymerization of 2,6-dimethylphenol.

coordinated to the copper complex [(ii) in Fig. 2]. In CuCl/Py catalysis, increasing the amount of Py to copper (6,7) favors the C—O coupling. Substituents at the 2,6-positions of Py (6) or high reaction temperature (8) makes the C—C coupling favorable.

The kinetic study of Cu/Py catalysis showed that the oxidative polymerization proceeded by a Michaelis–Menten-type reaction mechanism and the C—O coupling is preferred when at least one of the radicals is coordinated to copper (9). ESR measurements using a copper(II) acetate/Py complex (10), where Py/Cu = 20, showed two phenoxo-copper(II) complexes, and the oxidative polymerization gave mainly Poly-2,6-Me_2P. For Py/Cu = 2, none of phenoxo-copper(II) complexes was detected and the major product was DPQ. Thus, these data suggest that coupling via the coordinated phenoxy radicals mainly leads to the C—O coupling.

Coupling of Phenoxonium Cation with 2,6-Dimethylphenol. No ESR signals of free phenoxy radicals in the oxidation of 2,6-Me_2P with a [CuCl(OCH_3)Py] complex were detected (11). It was assumed that the phenoxy radical was oxidized by the Cu(II) complex (totally two-electron-oxidation from the phenol) to give the phenoxonium cation, which can couple with the phenol leading to C—O coupling [(iii) in Fig. 2]. For a Cu/*N*-methylimidazole (NMI) catalyst, the reaction order in copper changed from 1.22 at NMI/Cu=10 to 1.70 at NMI/Cu=75, and the selectivity for the C—O coupling reached a maximum at the NMI/Cu ratio of at least 30 (12). From the data, the key intermediate may be a μ-phenoxo dicopper(II) complex, in which two-electron-transfer from phenoxo moiety to two copper atoms can give a phenoxonium cation.

By ab initio calculation, the atomic charges for the phenol, phenolate anion, phenoxy radical, phenoxonium cations of 2,6-Me_2P were determined (13). Since the oxygen atoms in all the species were negative, it was considered that the species susceptible to the C—O coupling has positive charge on the *para*-carbon, and therefore, it should be the phenoxonium cation. The coupling of the phenoxy radicals was excluded, because the treatment of 2,6-Me_2P with benzoyl peroxide yielded DPQ (1). The reaction between the phenoxy radical and phenol was ruled out, because 2,6-dimethylanisole did not react in the oxidative polymerization of 2,6-Me_2P (14).

If the oxidative coupling of 2,6-Me_2P proceeds via the phenoxonium cation, in the presence of a nucleophilic reagent in excess to the phenol, the phenoxo cation should react with the nucleophile, and hence, Poly-2,6-Me_2P cannot be obtained. In fact, it was found that the oxidative polymerization of 2,6-Me_2P catalyzed by a Cu(tmed) (tmed: *N,N,N′,N′*-tetramethylethylenediamine) complex with an excess amount of *n*-pentylamine produced Poly-2,6-Me_2P in 75% yields (5). The nucleophilicity of *n*-pentylamine toward benzyl chloride was confirmed to be much greater than that of 2,6-Me_2P. These facts strongly indicate that such electrophilic intermediates as a phenoxonium cation are not involved in the oxidative polymerization.

Coupling of Free Phenoxy Radicals. The above two mechanisms [(ii) and (iii) in Fig. 2] are based on the assumption that the coupling via free phenoxy radicals of 2,6-Me_2P leads to the C—C coupling mainly. With alkaline ferricyanide (2), DPQ was produced in 45–50% but the other half of the oxidized material was a yellow nonketonic polymer, probably Poly-2,6-Me_2P. On the other hand, the oxidation with benzoyl peroxide afforded the C—C coupling products in total 60% yield (1).

However, detailed analysis for this oxidation reaction showed that the reaction mechanism did not involve radical intermediates but rather a benzoyl perester intermediate (15). It was reported that the thermal decomposition of benzoyl 2,6-dimethylphenyl carbonate, which should generate the phenoxy radical, produced Poly-2,6-Me_2P and DPQ in 35–38% and 10% yield, respectively (16). From these studies, it seems that some complicated experimental results and different understandings were involved in the above assumption of the C—C coupling selectivity in the free-radical coupling, which was pointed out before (17).

In addition, many studies on the oxidative coupling of 2,6-Me_2P with inorganic oxidants were performed, and in some cases the free radical was observed. The oxidation with MnO_2, PbO_2, and Ag_2O produced Poly-2,6-Me_2P in 60–95% yields. For MnO_2 (18) and Ag_2O (19), the free radicals of 2,6-Me_2P and Poly-2,6-Me_2P were detected by ESR measurements. By the addition of increasing amount of triethylamine in oxidative polymerization with PbO_2, the formation of DPQ was suppressed and the yield of Poly-2,6-Me_2P was increased (20). On the other hand, the oxidation by hexachloroiridate(IV) anion in an acidic aqueous solution afforded DPQ in 55–65% (21).

It was considered from the above studies (20,21) that the selectivity for the C—O or C—C coupling of 2,6-Me_2P was much affected by a coexisting base or acid. Recently, oxidative coupling of 2,6-Me_2P with Ag_2CO_3 was examined in the presence of excess *n*-pentylamine (nPA) or acetic acid (AcOH) (5). The ratio of the products Poly-2,6-Me_2P and DPQ was 50/50 without these additives, >99/∼0 with nPA, and 0/100 with AcOH. These data indicate that generally in the oxidative coupling of 2,6-Me_2P the addition of a base would lead to the C—O coupling and that of an acid to the C—C coupling.

The above observations may be explained by the following proposal (22): in basic reaction media, a free phenoxy radical is formed leading to C—O coupling [(i) in Fig. 2], and in acidic reaction media, a phenoxonium cation could be generated to give the C—C coupling. In the electrochemical oxidation of 2,6-Me_2P, the oxidation above pH 5.2 takes place via two monoelectronic steps, the first of which forms the free phenoxy radical; the oxidation below pH 5.2 undergoes one dielectronic step, which might generate the phenoxonium cation (23). It is still unclear whether or not the phenoxonium cation is really involved as the intermediate in the oxidative coupling; however, at least the phenoxonium cation should be easier to form under acidic conditions than under basic conditions.

To summarize on the above observations about the reaction mechanisms, the C—O/C—C coupling selectivity in the oxidative polymerization of 2,6-Me_2P appears to be as follows (5).

(1) The coupling via coordinated phenoxy radicals and the coupling of free phenoxy radicals under basic conditions would mainly lead to the C—O coupling.
(2) The coupling of free phenoxy radicals under acidic conditions or the coupling of phenoxonium cations from the two electron oxidation with phenol would favor the C—C coupling.

Chain Extension Mechanism. The chain extension mechanism in the oxidative polymerization of 2,6-Me_2P has been almost established (Fig. 3). It has

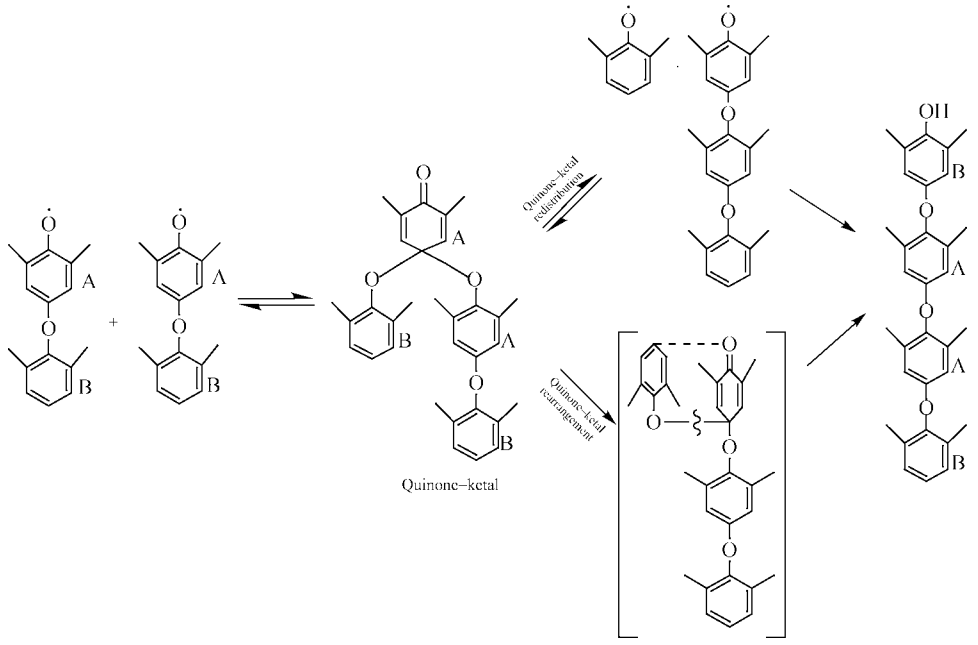

Fig. 3. Chain extension in the oxidative polymerization of 2,6-dimethylphenol.

been widely accepted that two dimeric phenoxy radicals couple with each other to give a quinone-ketal intermediate, which has not been detected. No reactivity of the tail phenoxy group (marked B in Fig. 3) was observed, because the π-conjugation is cut off by the ether bond (25); ie, the head-tail coupling mechanism, in which the oxygen atom of head phenol unit couples at the *para*-carbon atom of tail phenoxy group (24), is excluded. The oxidation of a 4-phenoxyphenol marked with methyl group (let it be A-B as two distinguishable aromatic rings) yielded none of the dimer through a head-tail coupling (A-B-A-B) but the dimer through a quinone-ketal intermediate (B-A-A-B) (26).

Two reaction routes from a quinone-ketal intermediate to a tetramer were proposed; one is a quinone-ketal redistribution to give a monomer radical and a trimer radical (27), and the other is a quinone-ketal intramolecular rearrangement (28). The oxidative polymerization from 2,6-Me_2P dimer produced the oligomers of even numbers such as 2,6-Me_2P itself and the trimer (27,29). From these data, the extension mechanism for the oxidative polymerization of 2,6-Me_2P definitely involves quinone-ketal redistribution and it is unclear whether or not quinone-ketal rearrangement actually occurs. For 2-methyl substituted and 2,6-unsubstituted 4-phenoxyphenols, only quinone-ketal rearrangement took place at a low temperature; however, at higher reaction temperatures, quinone-ketal redistribution also occurred (26). Application of the redistribution mechanism resulted in the modification (30–32) and depolymerization (33) of Poly-2,6-Me_2P.

In general, the oxidative polymerization of phenols undergoes a stepwise growth mechanism, although the electrochemical oxidative polymerization has been suggested to be a chain reaction mechanism (34). However, phenolic dimers

and higher oligomers have electron-donating phenoxy groups at *p*-positions and become easier to oxidize (more reactive) than phenolic monomers. Therefore, until the monomer is almost consumed, the reaction mixture consists mainly of the monomer and polymer, and so it often seems to proceed formally via chain reaction mechanism, but it is actually reactive intermediate polycondensation (35).

Other 2,6-Disubstituted Monomers. Various poly(2,6-substituted-1,4-phenylene oxide)s possessing alkyl, aryl, alkoxyl, and halogen groups have been produced (see POLYETHERS, AROMATIC). Recently, some functional polymers (36–39) were synthesized, one of which was converted to a heterocyclic ladder polymer (39). Poly(2,6-difluoro-1,4-phenylene oxide)s with crystallinity (40) and no crystallinity (41) were synthesized. By enzyme catalysis, oxidative polymerization of 3,5-disubstituted-4-hydroxybenzoic acids, with liberation of carbon dioxide, produced poly(2,6-disubstituted-1,4-phenylene oxide)s (42,43).

2- and/or 6-Unsubstituted Phenols

A phenoxy radical intermediate has four reactive positions: the oxygen and *para*-carbon as well as two *ortho*-carbons. Therefore, for *o*-unsubstituted phenols, it is difficult to regulate the coupling selectivity. Enzyme catalysts and enzyme model catalysts have been studied for the control of the polymerization of 2- and/or 6-unsubstituted phenols.

Enzyme Catalyst. Oxidative coupling of phenols is involved in some biological reactions; for example, formation of lignin (qv) or melanin is catalyzed by oxidoreductase enzymes such as peroxidase, oxidase, or oxygenase (44,45). In 1983, horse radish peroxidase (HRP) catalyst was used to remove phenols from waste water, affording water-insoluble low molecular weight phenolic polymers (46). Since HRP was employed as the polymerization catalyst (47–49), the polymerization of various phenols by using HRP with hydrogen peroxide or laccase (an oxidase) with dioxygen has been extensively investigated (50,51). These enzymes show high catalytic activity for generating free radicals from phenols, but are unable to control the coupling selectivity (52).

In oxidative polymerization of phenol by HRP catalyst (53,54), soluble polyphenol was obtained for the first time by controlling the polymer structure and molecular weight (55). Regio-controlled poly(hydroxyphenylene) was synthesized by using poly(ethylene glycol) (PEG) as template (eq. 1) (56). The enzyme-catalyzed oxidative polymerizations of alkylphenols (57–61), biphenols (62–64), and various functional phenols (65–70) were also performed. For glucose-β-D-hydroquinone, only C—C coupling at *o*-positions was claimed (eq. 2) (65). Chemoselective polymerization of a phenolic monomer having a methacryloyl group (eq. 3) (71) and an ethynyl group (72) was achieved and gave the corresponding polyphenol. "Artificial urushi" was prepared by laccase-catalyzed cross-linking reactions of urushiol analogues (73,74). (see ENZYMATIC POLYMERIZATION).

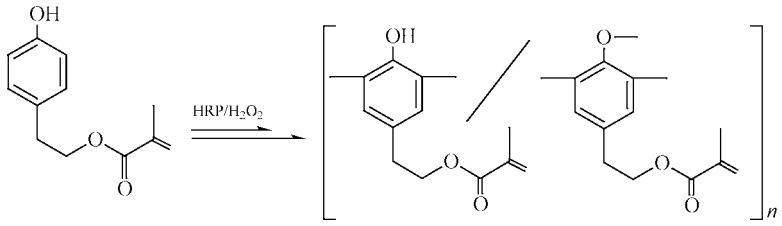
(2)



(3)

Peroxidase Model Catalyst. An *N,N′*-bis(salicylidene)ethylenediamino iron [Fe(salen)] complex was found to be a cheap peroxidase model catalyst for oxidative polymerization of phenols with hydrogen peroxide (75–79). Hematin also polymerized ethylphenol in a reaction mechanism similar to that for HRP (80).

Tyrosinase Model Catalyst ("Radical-Controlled" Oxidative Polymerization Catalyst). Conventional copper catalysts were not able to give useful polymers from phenols having at least one *o*-position unsubstituted (26,81,82). Peroxidase (HRP), oxidase (laccase), and peroxidase-model [Fe(salen)] catalysts also showed a limited ability for controlling the coupling selectivity of such phenols (5,53). New copper catalysts were then studied. Copper(I)/diamine complexes, typical conventional catalysts, reacted with dioxygen to give bis(μ-oxo) dicopper(III) complexes (83). In the reaction of HRP with hydrogen peroxide, Fe(IV)=O intermediates were formed (84). These active oxygen complexes were subjected to the reaction with phenols to afford "free" phenoxy radical species (83,85). These data suggest that the regioselective coupling cannot be achieved by the catalysts generating "electrophilic" or "radical" active oxygen species.

Then, a working hypothesis was made (Fig. 4) (86,87): if a catalyst generates only a "nucleophilic," strictly speaking "basic," μ-η^2:η^2-peroxo dicopper(II)complex **1** (88,89), it will abstract a proton (not a hydrogen atom) from phenol to give phenoxo–copper(II) complex **2**, equivalent to phenoxy radical–copper(I) complex **3**. Intermediate species **2** and/or **3** are not "free" radicals but "controlled" radicals, and therefore regioselectivity of the subsequent coupling will be entirely regulated. The difficulty for conventional catalysts to control the regioselectivity (90,91) is probably due to generation of free radicals. This new concept is characterized by the exclusive formation of controlled phenoxy radicals, and hence the new concept was termed a "radical-controlled" oxidative polymerization (87).

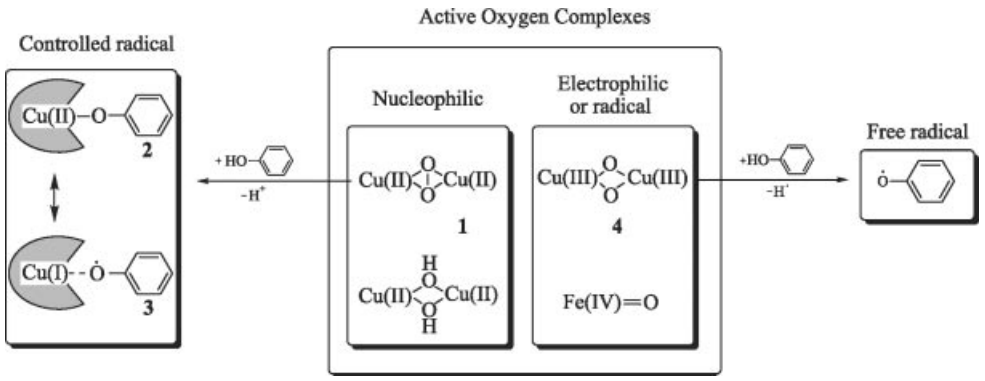


Fig. 4. Nucleophilic vs electrophilic active oxygen complexes.

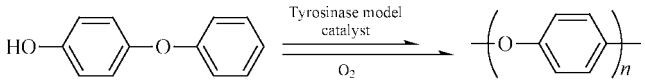
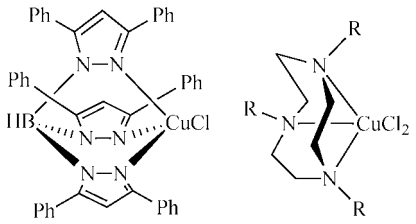
Oxidative Polymerization of 4-Phenoxyphenol by Tyrosinase Model Catalyst. "Radical-controlled" oxidative polymerization of 4-phenoxyphenol (PPL) catalyzed by tyrosinase model complexes has been developed (eq. 4)(86,87,92,93).



PPL PPO (4)

This was the first simple synthesis of crystalline poly(1,4-phenylene oxide) (PPO) having a melting point by the catalytic oxidative polymerization method, although other time-consuming synthesis procedures have been reported (94–96). As the tyrosinase model, (hydrotris(3,5-diphenyl-1-pyrazolyl)borate) copper [Cu(Tpzb)] complex (**5**) and (1,4,7-R_3-1,4,7-triazacyclononane) copper [$Cu(L^R)$: R = isopropyl (iPr), cyclohexyl (cHex), and *n*-butyl (nBu)] complexes (**6**) were employed.



5 **6**

To examine the coupling selectivity, the ratio of oxidative coupling dimers formed at the initial stage of polymerization of PPL was investigated (Table 1) (86,87). CuCl/*N*,*N*,*N*′,*N*′-tetraethylethylenediamine (teed), which was the sole catalyst reported for oxidative coupling of PPL (26), was also employed (entry 7). As a model system of free phenoxy radical coupling, an equimolar amount of 2,2′-azobisisobutyronitrile (AIBN) was used for the oxidation of PPL (entry 8). In the

Table 1. Dimer Ratio at Initial Stage of Oxidative Polymerization of 4-Phenoxyphenol

				Initial dimer ratio, %			
Entry	Catalyst	Oxidant	Solvent	**7**	**8**	**9**	**10**
1	Cu(Tpzb)Cl[a]	O_2	Toluene	91	9	0	0
2	Cu(Tpzb)Cl[a]	O_2	THF	91	9	0	0
3	$Cu(L^{iPr})Cl_2$[a]	O_2	Toluene	93	7	0	0
4	$Cu(L^{iPr})Cl_2$[a]	O_2	THF	89	7	1	3
5	$Cu(L^{cHex})Cl_2$[a]	O_2	Toluene	95	5	0	0
6	$Cu(L^{nBu})Cl_2$[a]	O_2	Toluene	90	9	0	1

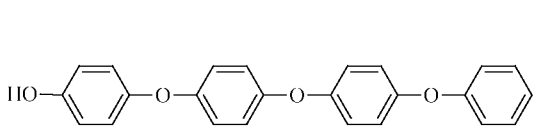
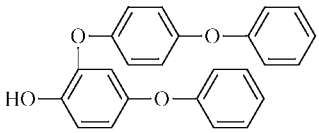
8	[b]	AIBN	Toluene	82	4	2	12

[a] Polymerization of PPL (0.60 mmol) with Cu complex (0.030 mmol) and 2,6-diphenylpyridine (0.30 mmol) in solvent (1.2 g) under dioxygen (101.3 kPa) at 40°C. CuCl (0.030 mmol) and teed (0.015 mmol) was used as the Cu complex in entry 7.
[b] Oxidized by AIBN (0.60 mmol) under nitrogen at 40°C.

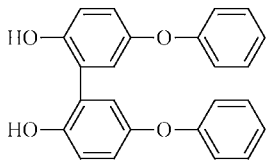
case of CuCl/teed, four dimers were detected and the structures of the dimers were identified as **7**, **8**, **9**, and **10**. Products **7** and **8** are formed by C—O coupling, and formation of **9** and **10** is based on C—C coupling.



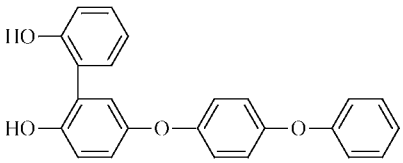
7



8



9



10

For the CuCl/teed catalyst, considerable amounts of the two C—C coupling dimers of **9** and **10** were detected and **7** selectivity was low (79%). The dimer ratio was very similar to that via free-radical coupling by AIBN oxidation, in which considerable amounts of the C—C coupling dimers were observed. However, for Cu(Tpzb) (**5**) in toluene and in THF, and for the $Cu(L^{iPr})$, $Cu(L^{cHex})$, and $Cu(L^{nBu})$ (**6**) in toluene, none or very little of the C—C coupling dimers were detected, showing high regioselectivity of **7**. The order of **7** selectivity was $Cu(L^{nBu})$ (90%) < $Cu(L^{iPr})$ (93%) < $Cu(L^{cHex})$ (95%), in good agreement with that of steric hindrance of the substituents (87). These data show that the regioselectivity of phenoxy radical coupling can be controlled by these catalysts. The dimerization catalyzed by the $Cu(L^{iPr})$ in THF gave C—C coupling dimers to some extent.

The resulting polymer was isolated as a methanol-insoluble part. In the cases with little or no C—C dimer formation (entries 1–3,5,6), white powdery polymers

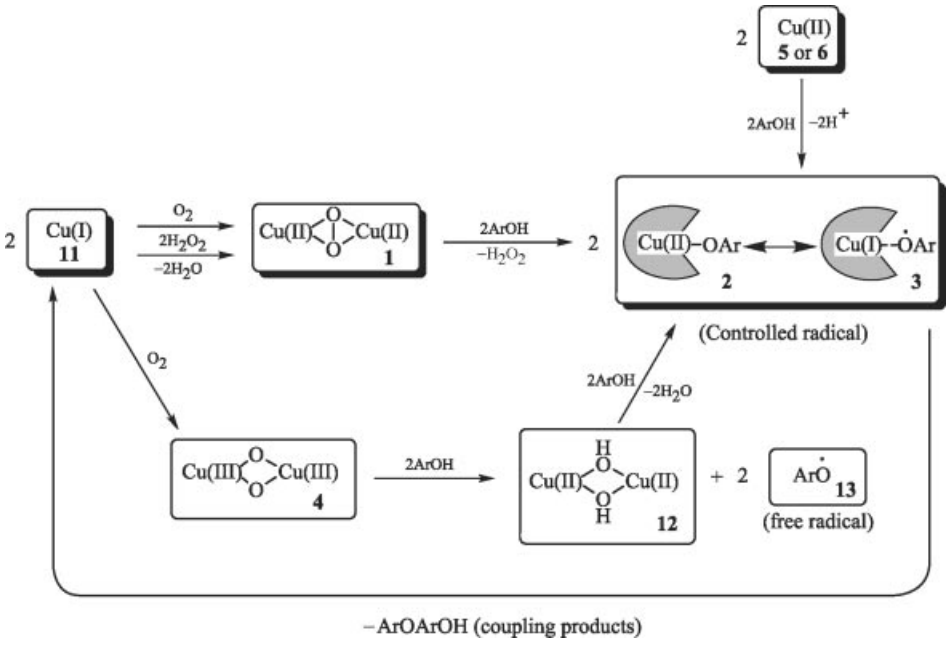


Fig. 5. Reaction mechanism for copper complex catalysis of oxidative polymerization.

with M_w of 700–4700 were obtained. The IR spectrum patterns of the polymers were very similar to that of PPO synthesized by Ullmann condensation (95). From the DSC analysis, the polymers showed melting points (T_m) at 171–194°C. In polymerizations giving considerable amounts of the C—C dimers (entries 4,7,8), the brownish polymers showed no clear melting points in the DSC traces.

Reaction Mechanism of Catalytic Cycle. On the basis of the above data, the reaction mechanism for the copper complex catalysis is postulated as follows (Fig. 5). First, the starting copper(II) chloride complex Cu(Tpzb)Cl (**5**) or $Cu(L^R)Cl_2$ (**6**) reacts with PPL or oligomers of PPL to give phenoxo-copper(II) complex (**2**), equivalent to phenoxy radical-copper(I) complex (**3**). Regioselective coupling takes place between two molecules of **2** and/or 3 to produce copper(I) complexes (**11**) as well as the phenylene oxide products having *p*-linkage selectively, because the steric hindrance of the catalysts blocks the coupling at *o*-positions.

In case of the Cu(Tpzb) complex (**5**), formation of μ-η^2:η^2-peroxo dicopper(II) complex (**1**) from **11** was confirmed under dioxygen (89) in both toluene and THF. For the $Cu(L^{iPr})$ complex as well as the $Cu(L^{cHex})$ and $Cu(L^{nBu})$ complexes (**6**), it was reported that **11** afforded complex **1** in nonpolar solvents such as toluene (97). **1** reacts with phenols to regenerate **2** (98) and hydrogen peroxide (99). Hence, this catalytic system would allow only the regioselective coupling process from **2** and/or **3** and completely exclude free-radical coupling reactions; the present reaction is thus recognized as "radical-controlled" oxidative polymerization.

For the $Cu(L^{iPr})$ complex under dioxygen in THF, **11** gave bis(μ-oxo) dicopper(III) complex (**4**) (97). **4** abstracts hydrogen atoms from phenols to give bis(μ-hydroxo) dicopper(II) complex (**12**) and free phenoxy radical (**13**). Therefore,

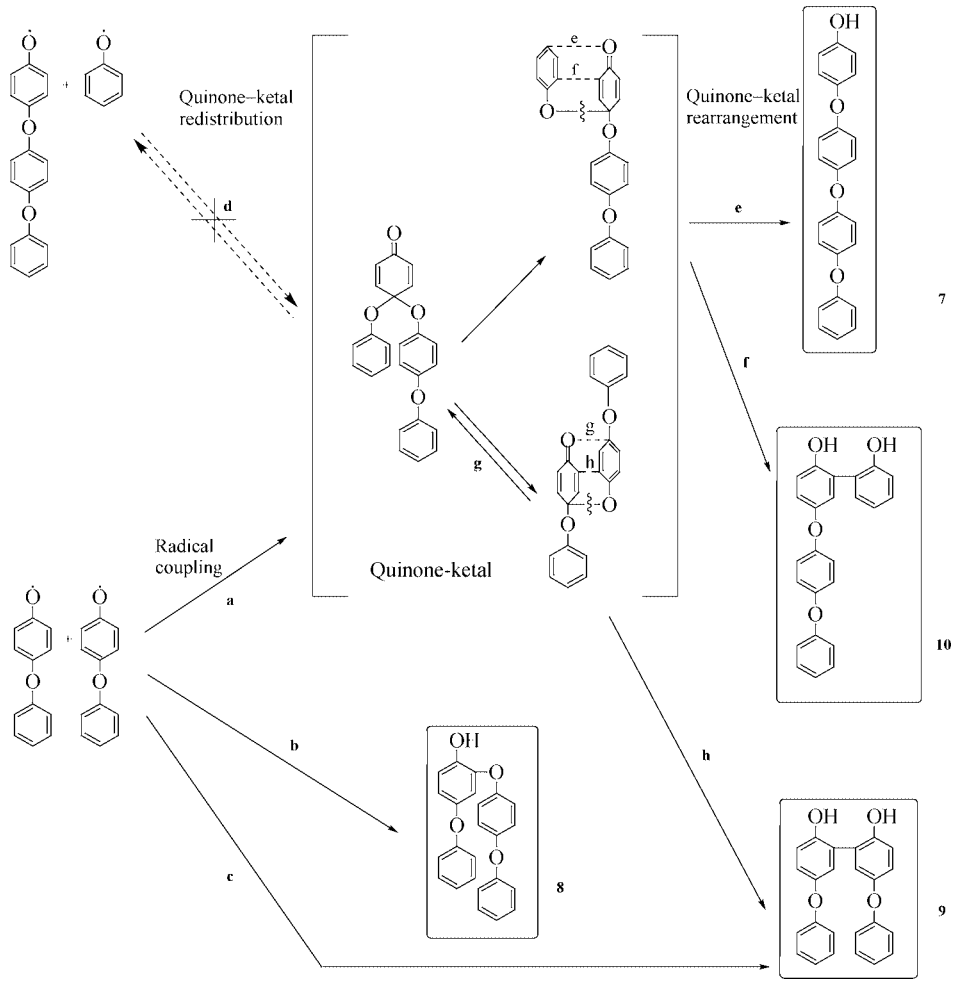

Fig. 6. Reaction mechanism for oxidative coupling and chain extension of 4-phenoxyphenol.

this catalytic cycle involves the free-radical coupling with the formation of C—C linkages, although production of **2** from complex **12** also takes place (100). The CuCl/teed complex also reacts with dioxygen to give **4** (83).

Two computational studies have been performed; one disagreed with the above reaction mechanism (101), but the other was in good agreement (102).

Reaction Mechanism of Oxidative Coupling and Chain Extension. Figure 6 shows a specrulative reaction mechanism for oxidative coupling of PPL to produce dimers (87,92). For simplicity, the mechanism is argued here by expressing intermediate structures in the form of free radical rather than controlled radicals. First, two phenoxy radicals are generated from PPL and couple to each other (radical coupling); then only three reaction routes (**a**, **b**, and **c**) can take place, giving rise to a quinone-ketal intermediate, **8** and **9**, respectively. From the quinone-ketal, the redistribution path (quinone-ketal redistribution, **d**) was

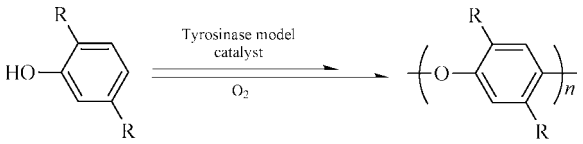
ruled out, and therefore the rearrangement path (quinone-ketal rearrangement) is proposed in the oxidative coupling of PPL. On cleavage of the ketal C—O bond, synchronous bond formation of route **e** to **7**, that of **f** to **10**, and that of **h** to **9** can occur, but that of **g** regenerates the quinone-ketal.

In the "radical-controlled" oxidative coupling of PPL, the radical coupling takes place from controlled phenoxy radical–copper(I) intermediate. Therefore, the steric effect of the catalyst would suppress **8** formation (route **b**) and inhibit **9** formation (route **c**), mainly giving quinone-ketal intermediate (route **a**). Moreover, almost no detection of **10** as well as **9** shows that the catalyst must be kept interacting with the quinone-ketal intermediate during the rearrangement. Probably, the carbonyl group of the quinone-ketal coordinates to the copper(I) atom of the catalyst. Thereby, bond formation at the *o*-position to **10** and **9** via routes **f** and **h**, respectively, would be protected and give **7** predominantly via route **e**. Further chain extension follows in a similar way to that of dimerization.

Oxidative Polymerization of Other Phenols by Tyrosinase Model Catalyst. The substituent effect of phenol monomers on the reaction rates has been investigated (103). For the Cu(tmed) catalyst, the reaction rates were governed by the O—H homolytic bond dissociation energies of the monomers, which are closely related to the electronic effect of substituents. On the other hand, for the Cu(L^{iPr}) catalyst, the steric effect of substituents at the *o*-positions depressed the reaction rates.

In the oxidative polymerization of phenol, the Cu(L^{iPr}) catalyst showed high selectivity for C—O coupling; however, it did not exclude the formation of C—C coupling (104). The resulting polymer consisted mainly of a 1,4-phenylene oxide unit but contained a considerable amount of C—C coupling structures, showing no crystallinity. The oxidative polymerization of 2- and 3-methylphenol regioselectively produced soluble poly(phenylene oxide)s, showing good thermal stability (105,106).

The polymers obtained from 2,5-dialkylphenols [2,5-R_2P: R = methyl (Me), ethyl (Et), *n*-propyl (nPr)] are noteworthy (107) (eq. 5). The oxidative polymerization of 2,5-Me_2P catalyzed by Cu(L^{iPr})Cl_2 in toluene under dioxygen produced a white polymer. The M_w was 19,300 and the structure was composed exclusively of a 2,5-dimethyl-1,4-phenylene oxide unit. The melting temperatures in the first and second scan (T_{m1} and T_{m2}) were detected at 308 and 303°C, respectively. Poly-2,5-Me_2P (eq. 5) showing heat-reversible crystallinity was synthesized for the first time. The isomeric polymer Poly-2,6-Me_2P (Fig. 1) showed a melting point at 237°C (T_{m1}), but once the crystaline part had been totally melted, recrystallization never occurred (T_{m2} not detected) by slow cooling or after annealing (108). Since thermoplastic polymers are mainly used as melt-moldings, Poly-2,6-Me_2P is generally accepted as an amorphous polymer; however, Poly-2,5-Me_2P is considered as a crystalline one.



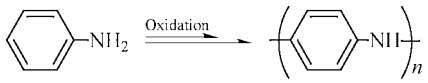
2,5-R_2P P-2,5-R_2P (5)

In the oxidative polymerization of 2,5-Et_2P and 2,5-n-Pr_2P (107), white polymers with M_w of 23,100 and 32,200, respectively, possessed only the 1,4-phenylene oxide units. The latter showed heat-reversible crystallinity with T_{m2} at 276°C, however, the former did not show a detectable T_{m2}. The recrystallization for poly(alkylated phenylene oxide)s after melting seems to be governed by both the position and nature of alkyl substituents.

Oxidative Polymerization of Naphthol Derivatives. Oxidative polymerization of 2-naphtol (109) and 1,5-dihydroxynaphthalene (110) has been done using enzyme catalysts. Solid-state polycondensation of 2,6-dihydroxynaphthalene with $FeCl_3$ catalyst (111) has been accomplished. Asymmetric oxidative coupling polymerization of 2,3-dihydroxynaphthalenes and their derivatives was achieved by chiral copper catalysts (112–115).

Oxidative Polymerization of Anilines

Oxidative polymerization of aniline produces polyaniline (PAN) (eq. 6). This polymer was obtained as aniline black about a century ago (116,117) and has been revived as an electrically conducting polymer (see ELECTRICALLY ACTIVE POLYMERS).



(6)

Polyaniline has been synthesized electrochemically (118,119) and with chemical oxidizing agents (120–123); a typical oxidizing agent is ammonium persulfate (120,121). Catalytic oxidative polymerization of aniline using iron salt catalyst (124) or HRP enzyme catalyst (125–129) with hydrogen peroxide, iron salt catalyst with ozone (130), and copper salt catalyst with dioxygen (131) has been done. A photo-induced catalytic system (132,133) and a gas-phase plasma method (134) have also been reported. Strongly acidic reaction conditions in the polymerization are normally selected, because polymer structure and electrical conductivity of PAN depend on the pH of the polymerization reaction (135,136).

The reaction mechanism of oxidative polymerization of aniline has been a big controversy (Fig. 7). The dimerization step is generally proposed as (i), in which aniline is one-electron-oxidized to a cation radical, followed by coupling of two molecules of the cation radical to a dimer. The subsequent steps of chain extension are under discussion; routes involving coupling of cation radicals such as (ii)–(iv) (137–140) and routes via electrophilic attack of a two-electron-oxidized quinodal diiminium ion (v) or nitrenium ion (vi) (141,142) have been proposed. The addition of electron-rich arenes does not inhibit the polymerization, and therefore the route through the nitrenium ion (vi) seems to be rejected (137).

Protonic doping is necessary to convert PAN from an insulator to a conductor (136), and so various dopants such as acid-substituted polymers (143–146) and chiral sulfonic acids (147–149) have been employed. Emulsion polymerization of aniline-afforded PAN particles (150–156) and PAN–silica particles (157,158). Polyaniline nanofibers have been synthesized by template-guided polymerization

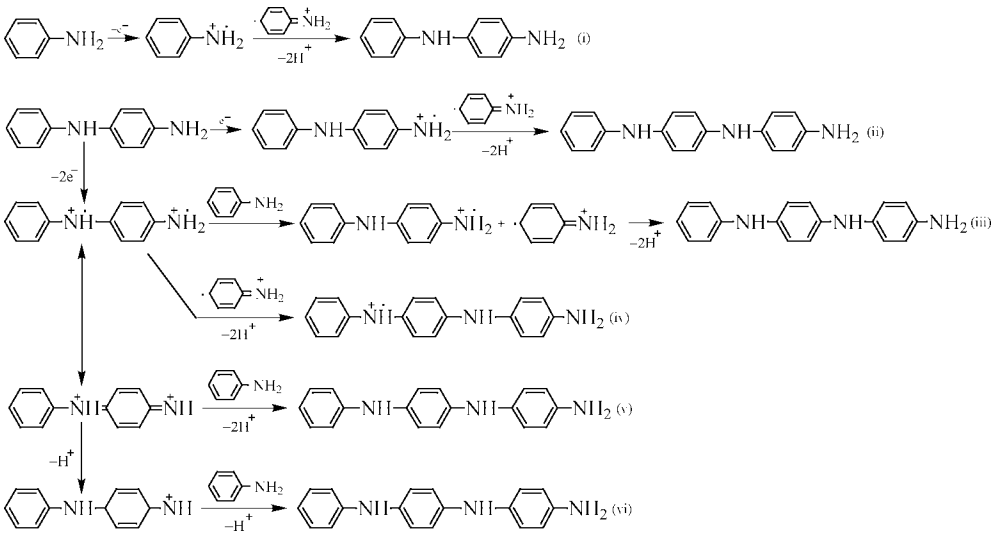


Fig. 7. Reaction mechanism for oxidative polymerization of aniline.

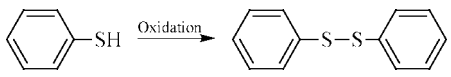
(159,160) and aqueous/organic interfacial polymerization (161–163). Intercalated PANs in V_2O_5 (164), $VOPO_4$ (165), MoO_3 (166), and FeOCl (167) have been obtained, and included PANs in zeolite molecular sieves (168) and mesoporous channel hosts (169).

Many substituted polyanilines were also synthesized (170). Typical examples are self-doping polymers, such as sulfonic acid ring-substituted PANs (171–177), mercaptopropanesulfonic acid substituted PANs (178), *N*-alkylsulfonic acid substituted PANs (179–181), and *N*-phenylsulfonic acid substituted PANs (182,183). Polyanilines having boronic acid for detecting sugar and dopamine (184,185) and for controlling self-doped states (186) have been produced. Long-chain-substituted anilines were polymerized at an air–water interface by the Langmuir–Blodgett technique (138,187,188). (see LANGMUIR-BLODGETT FILMS). Polyanilines with liquid crystalline substituents (189,190) and redox-active disulfide unit (191) were synthesized. Oxidative polymerization of 1-aminonaphthlenes gave PAN-like polymers (192,193).

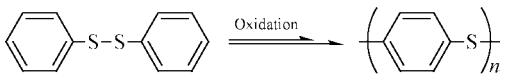
Oxidative Polymerization of Thiophenols and Their Derivatives

Thiophenol is oxidatively coupled to give diphenyldisulfide (eq. 7), because formation of an S—S bond, resulting from the coupling of thiophenoxyl radicals, happens more readily than formation of a C—S bond (194). Oxidative polymerization of 1,3-dimercaptobenzene afforded poly(1,3-phenylenedisulfide) (195–197).



(7)

Poly(phenylene sulfide) (PPS) has been synthesized by oxidative polymerization of diphenyl disulfide, which was obtained via oxidation of thiophenol (eq. 8) (198–208). PPS is an engineering plastic with a high melting point, which is manufactured by condensation polymerization eliminating a salt.



(8)

The oxidative polymerization of diphenyl disulfide was carried out in the presence of a strong acid by electrolysis (198) and by reaction with Lewis acids such as $SbCl_5$ (199–201) or quinones such as 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (202–205). VO catalysts such as vanadyl acetylacetonate with O_2 have also been used for the oxidative polymerization (206–208), and the catalytic reaction mechanism involving four-electron reduction of O_2 has been discussed (209–215).

The chain extension mechanism is shown in Figure 8 (201). Diphenyl disulfide is oxidized to a cation radical, which reacts with diphenyl disulfide to give phenylbis(phenylthio)sulfonium cation, followed by electophilic attack of diphenyl sulfide on the cation.

The use of various diaryl disulfides as the monomer produced PPSs substituted with methyl groups at the 2- or 3-, 2,3-, 2,5-, or 2,6-positions, methoxy at the 2-position, etc. (204,207). Reactive functionalized oligomers (216) and block polymers containing alkylene and perfluoroalkylene groups (217,218) have been obtained. Cyclic hexakis(1,4-phenylene sulfide) was synthesized (219), and ring-opening polymerization of such cyclic oligomers was also found (220).

The synthesis of PPS via poly(sulfonium cation) as a soluble precursor (221) was developed through oxidative polymerization of methyl 4-(phenylthio)phenyl sulfide (222), followed by dealkylation (eq. 9) (223–225).

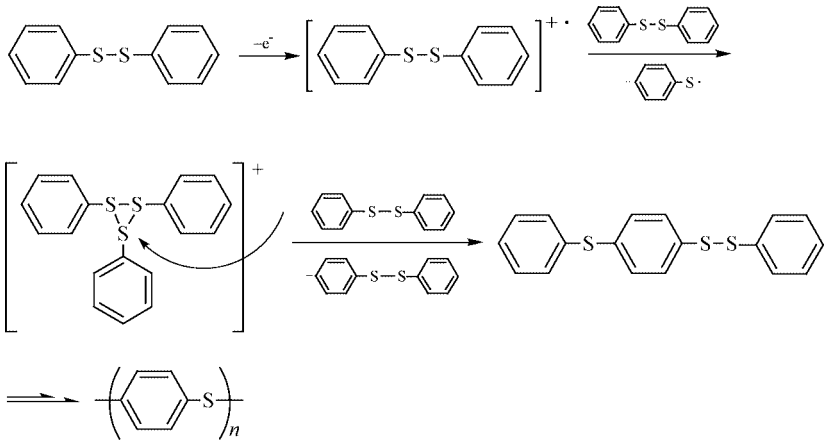


Fig. 8. Reaction mechanism for oxidative polymerization of diphenyl disulfide.

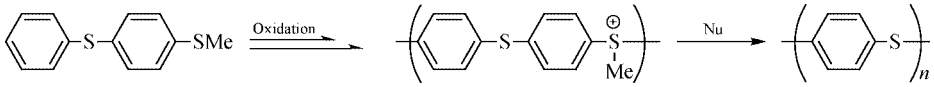
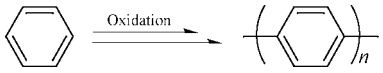


(9)

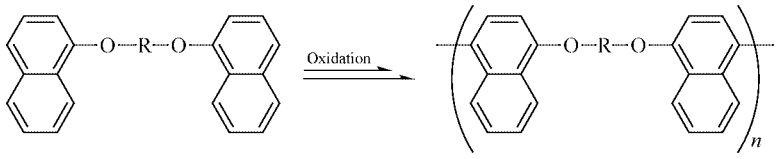
Oxidative Polymerization of Aromatic Hydrocarbons

In the 1960s, oxidative polymerization of benzene by $CuCl_2$-$AlCl_3$ was discovered (eq. 10) (226). Other oxidants such as $AlCl_3$-MnO_2, $FeCl_3$, and $MoCl_5$ were employed. These systems allowed the polymerization of various monomers such as toluene, chlorobenzene, diphenyl, naphthalene, and phenanthrene (227).

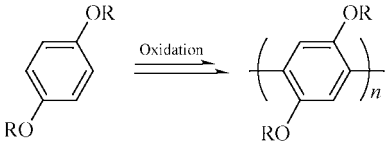


(10)

Oxidative polymerization of bis(1-naphthoxy) monomers is known as the Sholl Reaction (eq. 11) (228). 1,4-Dialkoxybenzenes have been polymerized using $FeCl_3$ (229,230) and oxovanadium catalyst with dioxygen (231) to give poly(2,5-dialkoxy-1,4-phenylene)s (eq. 12). Poly(4,6-di-*n*-butyl-1,3-phenylene) was also obtained (232).



(11)



(12)

Three reaction mechanisms of C—C coupling in oxidative polymerization of benzenes have been reported (Fig. 9). The first step of each mechanism is one electron oxidation of a monomer to give a cation radical. The next step may be (i) coupling of two cation radicals (233,234), (ii) coupling of one cation radical with one neutral molecule (226,228), or (iii) coupling of one cation radical with many neutral molecules (stair-step mechanism) (235).

Oxidative Polymerization of Heterocyclic Aromatics

Oxidative polymerization of pyrrole (236), thiophene (237), furan (238), and selenophene (239) was performed with electrical methods around two decades ago

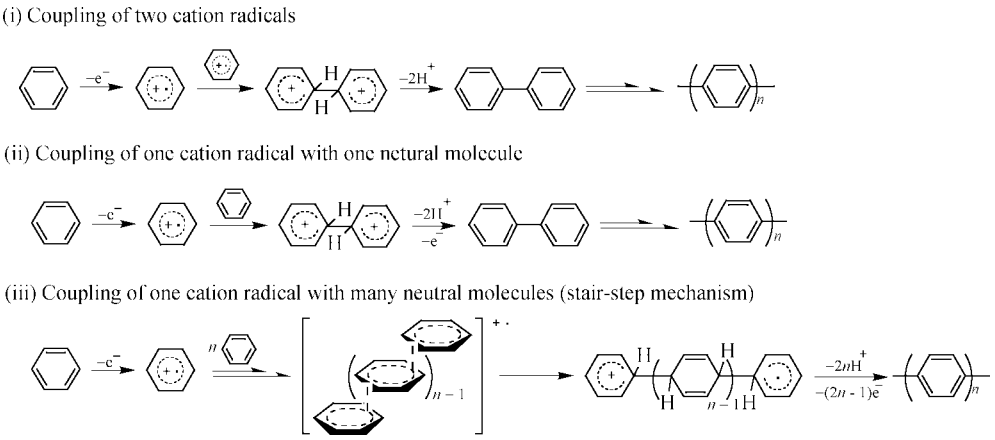


Fig. 9. Reaction mechanism for oxidative polymerization of benzene.

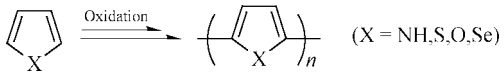
(eq. 13). More recently, numerous studies on the resulting polymers, particularly polypyrroles and polythiophenes, have been performed in terms of electrical conductivity (see ELECTRICALLY ACTIVE POLYMERS).



(13)

For the oxidative polymerization of heterocyclic aromatics, two reaction mechanisms, similar to that of benzenes, have been proposed (Fig. 10). One is coupling of two cation radicals [(i) in Fig. 10] (240,241), and the other is coupling of one cation radical with one neutral molecule [(ii) in Fig. 10] (242,243).

Oxidative Polymerization of Pyrroles. The synthesis of pyrrole blacks was performed by chemical oxidative polymerization with a variety of oxidizing agents such as hydrogen peroxide, lead dioxide, quinines, ferric chloride, and persulfates (244) before the electrical method was employed (236). The catalytic oxidative polymerization under dioxygen to give polypyrrole (PPY) has also been developed (245–247).

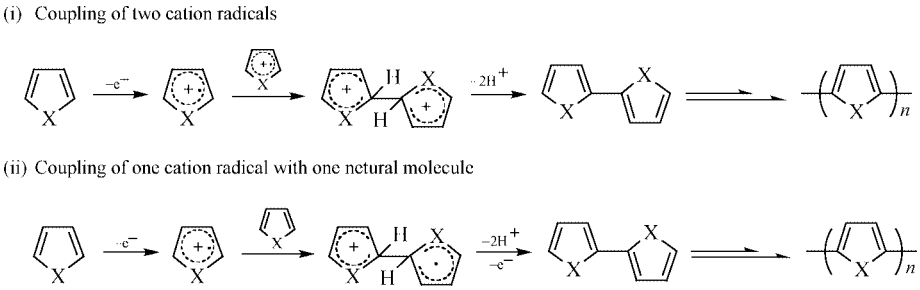


Fig. 10. Reaction mechanism for oxidative polymerization of heterocyclic aromatics.

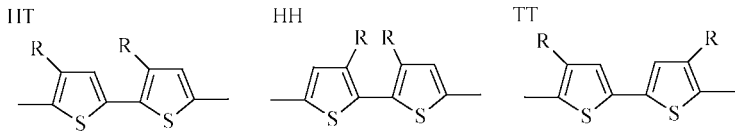

Fig. 11. Regioisomers of 3-substituted polythiophenes.

Various PPYs having 1-substituted (248), 3-substituted (249,250), and 3,4-disubstituted (251–253) groups, and transition metal complex moieties (254–256) have been obtained.

PPY particles were produced by colloidal dispersion method (257–259). Monolayer and multilayer PPYs were obtained by thiol–Au interaction (260,261), by deposition on $YBa_2Cu_3O_{7-\delta}$ (262,263), by intercalation in FeOCl (264), and by monomer amphiphilicity (265). PPY wires (266–268), PPY tubes (269–271), and PPY microcontainers (272,273) have also been synthesized.

Oxidative Polymerization of Thiophenes. Thiophene is oxidatively polymerized to give polythiophene (PTH) by electrochemical oxidation (237); by chemical oxidation with AsF_5 (274), NO salts (275), and $FeCl_3$ (276); and by catalytic oxidation with dioxygen (277).

PTH can be substituted at the 3- and/or 4-positions (278). 3-Substituted PTHs have regioisomers (Fig. 11), and the regioregularity greatly affects conjugation length and electronic properties. For poly(3-alkylthiophene)s, high regioselectivity of 91–98% HT has been obtained by organometalic reaction (279,280); however, a maximum 89% HT (Fig. 11) has been obtained by oxidative polymerization (281,282). In oxidative polymerization of 3-arylthiophenes (283–285) and 3-alkoxy-4-methylthiophenes (286), 94–96% HT contents were achieved. This regioselectivity has been discussed as arising from the spin density of the radical cations (287,288).

Poly(3,4-ethylenedioxythiophene) was developed around 1990, and its combination with poly(styrene sulfonic acid) became practical because of its high film-formability, conductivity, transparency, and stability (289). Many functional PTHs were prepared possessing crown ether (290,291), tetrathiafluvalene-like structures (292,293), C_{60}-attachment (294,295), probes for affinity chromism (296–298), and various metal complexes (299–306).

PTH film obtained by electrochemical deposition was stronger than aluminum film (307). PTH fibers were produced by using capillary flow cell (308) and with electrically independent connections (309). PTHs were included in zeolite (310,311) and such PTH wires (312) were obtained. PTH catenanes and rotaxanes have also been synthesized (313,314).

Oxidative Polymerization of Other Monomers

Treatment of *m*-diethynylbenzene with a copper catalyst and dioxygen gave a poly(phenylene butadiynylene) (315). Use of Cu-incorporated mesoporous materials as the oxidative polymerization catalyst for 1,4-diethynylbenzene produced highly conjugated poly(1,4-phenylene-1,4-butadiynylene) (316).

Bifunctional *p*-tolylcyanoacetic esters (317) and monofunctional phenylcyanoacetic esters (318) were oxidatively polymerized using a copper catalyst with dioxygen.

PHASE TRANSFORMATION

Introduction

Phase transformations of polymeric materials, such as unmixing of a polymer solution or polymer blend, or the crystallization of a polymer melt or its glass transition into an amorphous structure, are very common phenomena and have important applications. This article briefly summarizes some key theoretical concepts about these phenomena, discusses the extent to which they differ from related phenomena in other materials (1) and mentions a few typical experiments to introduce the main techniques used to study such phase transitions.

Some transitions that are only known for macromolecules, however, will not be mentioned at all since they are covered elsewhere in this Encyclopedia (see, eg. GEL POINT). Also we shall not be concerned here with the transformations from the molten state to the solid state of polymeric materials, since this is the subject of separate treatments (see CRYSTALLIZATION KINETICS; GLASS TRANSITION; VISCOELASTICITY). Unlike other materials, polymers in the solid state rarely reach full thermal equilibrium. Of course, all amorphous materials can be considered as frozen fluids (see GLASS TRANSITION) Rather perfect crystals exist for metals, oxides, semiconductors etc, whereas polymers typically are semicrystalline, where amorphous regions alternate with crystalline lamellae, and the detailed structure and properties are history-dependent (see SEMICRYSTALLINE POLYMERS). Such out-of-equilibrium aspects are out of the scope of the present article, which rather emphasizes general facts of the statistical thermodynamics (qv) of phase transitions and their applications to polymers in fluid phases.

Thermodynamics

According to the Gibbs phase rule, a system containing z "components," ie, chemically different constituents, and r phases, has $f = z + 2 - r$ degrees of freedom (such as temperature T, pressure p, or relative concentration c_i of the ith component (2)). When one applies this formula to systems containing polymers, one usually treats one chemical type of polymer as one component, even if it is polydisperse. Strictly speaking, each fraction with a specific molecular weight needs to be treated as a distinct component (see THERMODYNAMIC PROPERTIES OF POLYMERS). For many practical purposes this complication can be neglected. Special effects on phase transitions (3) due to polydispersity will be mentioned when appropriate.

"Phases" in thermodynamic systems are then macroscopic homogeneous parts with distinct physical properties. For example, densities of "extensive thermodynamical variables," such as particle number N_i of the ith species, enthalpy U, volume V, entropy S, and possible order parameters, such as the nematic order parameter for a liquid crystalline polymer etc, differ in such coexisting phases. In equilibrium, "intensive thermodynamic variables," namely T, p, and the chemical potentials μ_i have to be the same in all phases. Coexisting phases are separated by well-defined interfaces (the width and internal structure of such interfaces play an important role in the kinetics of the phase transformation (1) and in other

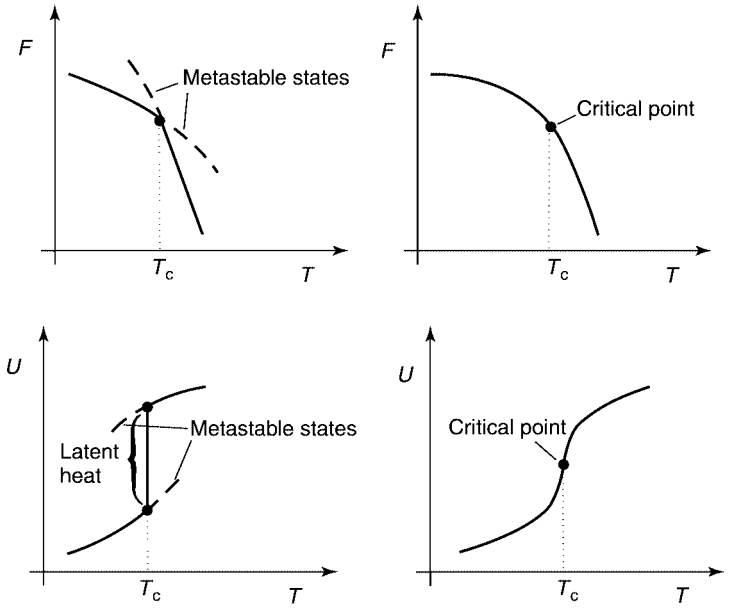

Fig. 1. Schematic variation of the Gibbs free energy F of a single-component system with temperature at constant pressure for a first-order transition (upper part left) and a second-order transition (upper part right). Lower part shows the corresponding behavior of the internal energy U.

material properties, see eg (4,5)). Phase transformations can be brought about eg by varying parameters such as temperature (Fig. 1) or pressure. In magnetic systems and superconductors also the magnetic field H is a suitable control parameter, in dielectric materials the electric field E. These variables will be ignored here throughout, although the switching of block copolymer mesophase structures by electric fields in thin films is of interest (6).

Figure 1 shows that one must distinguish first-order phase transitions [where first derivatives of the appropriate thermodynamic potential F, such as the enthalpy $U = [\partial(\beta F)/\partial\beta]_p$, where $\beta = 1/k_B T$, k_B being Boltzmann's constant, or volume $V \equiv (\partial F/\partial p)_T$ exhibit a jump] and second-order transitions, where U,V are continuous, but second derivatives are singular (1,2,7). The classical example for the latter case is the gas–liquid critical point, where the specific heat $C_p = (\partial U/\partial T)_p$ or the isothermal compressibility $\kappa_T = -(1/V)(\partial V/\partial p)_T$ diverge,

$$\kappa_T = \hat{\kappa}_T (T/T_c - 1)^{-\gamma}, \qquad p = p_c, \qquad T \to T_c^+ \tag{1}$$

where p_c is the critical pressure, T_c the critical temperature, $\hat{\kappa}_T$ is called a "critical amplitude" and γ a "critical exponent," which has the value $\gamma_{MF} = 1$ according to van der Waals theory and related mean-field theories (7,8), while $\gamma_I \approx 1.24$ according to the Ising model "universality class" (7–10). Here we have already invoked the notion that the critical exponents that describe the asymptotic singular behavior as a critical point is approached do not depend upon which specific material is

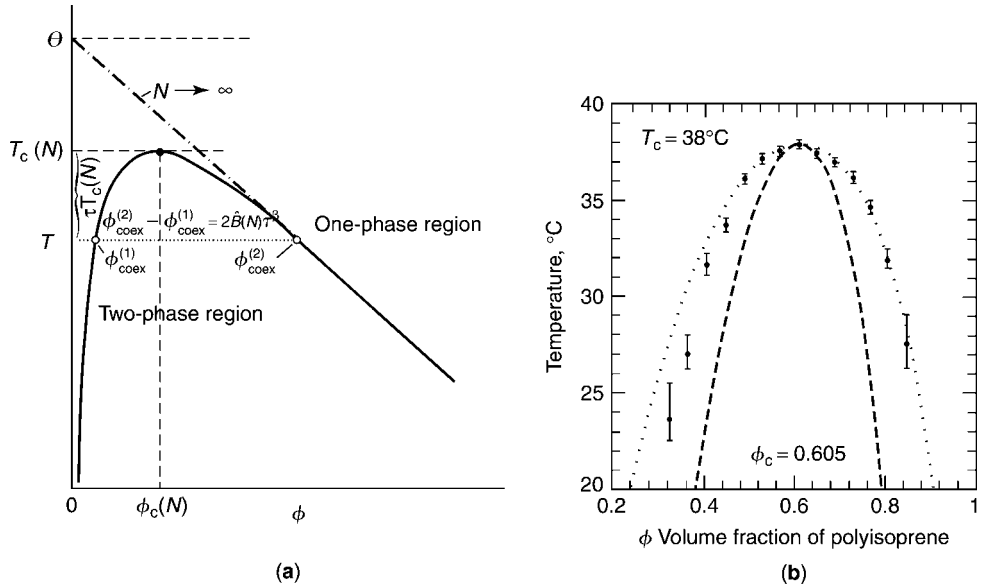

Fig. 2. (**a**) Schematic phase diagram of a polymer solution, at constant pressure, using temperature T and volume fraction ϕ of the polymer as variables. Phase separation into a dilute or semidilute solution (with volume fraction $\phi_{coex}^{(1)}$) and a more concentrated solution (with volume fraction $\phi_{coex}^{(2)})_{occurs}$ for states (T, ϕ) that fall in the two-phase region underneath the coexistence curve (binodal). The binodal ends in the critical point $\phi_c(N)$, $T_c(N)$, where N is the degree of polymerization of the polymer. For $N \to \infty$ the critical point merges with the theta point of the dilute solution, ie, $T = \Theta$, $\phi_c(N \to \infty) = 0$. For further explanations cf text. (**b**) Phase diagram of the partially miscible polymer blend poly(isoprene)–poly(ethylene) with molecular weights of 2000 and 5000, respectively. From Ref. 12. Broken curve inside of the coexistence curve (dotted) is the spinodal as estimated from a Flory–Huggins fit.

investigated, but are the same for all systems belonging to the same class. There are only a few classes, eg all systems in $d = 3$ space dimensions, exhibiting for $T < T_c$ a scalar "order parameter" belong to this same class. Of course, the gas–liquid transition is of little relevance for polymers simply because for high molecular weights T_c is too high, so that the polymer would chemically degrade already at much lower temperatures. Only for short alkanes gas–liquid critical phenomena can be studied (eg $T_c = 723$ K for $C_{16}H_{34}$ (11) while for $C_{24}H_{50}$ T_c is no longer available). However, it turns out that the phase diagram of a polymer in a solvent of variable quality (assuming that the quality is controlled by temperature) is isomorphic to the gas–liquid phase diagram of the polymer, see Figure 2**a**. Also phase diagrams of partially miscible polymer blends (qv) (see also MISCIBILITY) belong to the Ising class. Figure 2**b** presents an experimental example (12).

In Figure 2**a**, it was assumed that the pure solvent critical point is much higher than the Θ temperature of the solution, so the latter can be approximated as incompressible for simplicity. Then the role of the pressure for the gas–liquid transition is now played by the osmotic pressure of the polymer in solution, and the volume fraction ϕ rather than the density is used to distinguish the phases. In terms of $t \equiv 1 - T/T_c(N)$ we can introduce another power law for the "order

parameter" of the transition ψ,

$$\psi = \left(\phi_{\text{coex}}^{(2)} - \phi_{\text{coex}}^{(1)}\right)/2 = \hat{B}(N)t^{\beta} \tag{2}$$

where $\hat{B}(N)$ is another critical amplitude, and the exponent β takes the values $\beta_{\text{MF}} = 1/2$ in the mean-field theories and $\beta_{\text{I}} \approx 0.325$ in the Ising class. Here N denotes the degree of polymerization or "chain length" of the flexible linear polymer, respectively.

In Figure 1 we have already emphasized that at a first-order transition one typically finds metastable states. In principle, statistical thermodynamics describes systems in thermal equilibrium only, ie, only those branches of F that are the lower solid ones in the upper part of Figure 1 (left part) can be described, and nothing is said about the dashed continuations describing the metastable states. However, mean-field theories (such as the van der Waals equation of a fluid, or Flory–Huggins theory (13–15) for a polymer mixture) readily yield approximate descriptions of metastable states up to a "limit of metastability" or "spinodal." Such a "spinodal curve" delineating this boundary between metastable and unstable regions in the (T, ϕ) plane of a binary polymer mixture has been drawn in Figure 2**b**. It is important to realize, however, that such spinodals are mean-field concepts. They are meaningful objects in statistical thermodynamics in very special limiting cases only. One such limit is realized for polymer blends when the chain lengths $N_{\text{A}}, N_{\text{B}}$ of the two flexible linear polymers constituting the mixture both tend to infinity (15–17). Then the mean-field spinodal line adopts a well-defined meaning as a sharp dividing line between two distinct kinetic mechanisms of phase separation: Metastable states in between binodal and spinodal (Fig. 2**b**) decay via nucleation and growth, while "unstable states" underneath the spinodal curve of the binary mixture decay by the spontaneous growth of "concentration waves" with wavelengths exceeding a characteristic critical wavelength λ_{c}, which diverges at the spinodal curve (Fig. 3). This mechanism of phase separation is called "spinodal decomposition" (15–20). Theory predicts (15–17) that in the limit $N_{\text{A}} \to \infty$, $N_{\text{B}} \to \infty$ the lifetime of metastable states becomes infinite right up to the spinodal curve, since homogenous nucleation is suppressed. Although there is ample experimental evidence for the occurrence of (nonlinear) spinodal decomposition as a mechanism of phase separation in polymer blends (19), experimental evidence for the specific singularities associated with spinodal lines in the phase diagrams of mixtures is still lacking. Thus, although spinodal curves are often drawn in phase diagrams of real materials, such as in Figure 2**b**, we caution the reader that these curves are either the result of a mean-field fit or of some extrapolation procedure, and hence of limited validity.

Phase Diagrams

When one approaches the critical point in the phase diagram (Figs. 2 and 3), the distinction between the two coexisting phases and also the difference $\phi_{\text{coex}}^{(2)} - \phi_{\text{coex}}^{(1)}$ (cf eq. 2) vanish. Also the two branches of the spinodal curve meet in the critical point of the phase diagram. In Figures 2 and 3, we have assumed that the phase

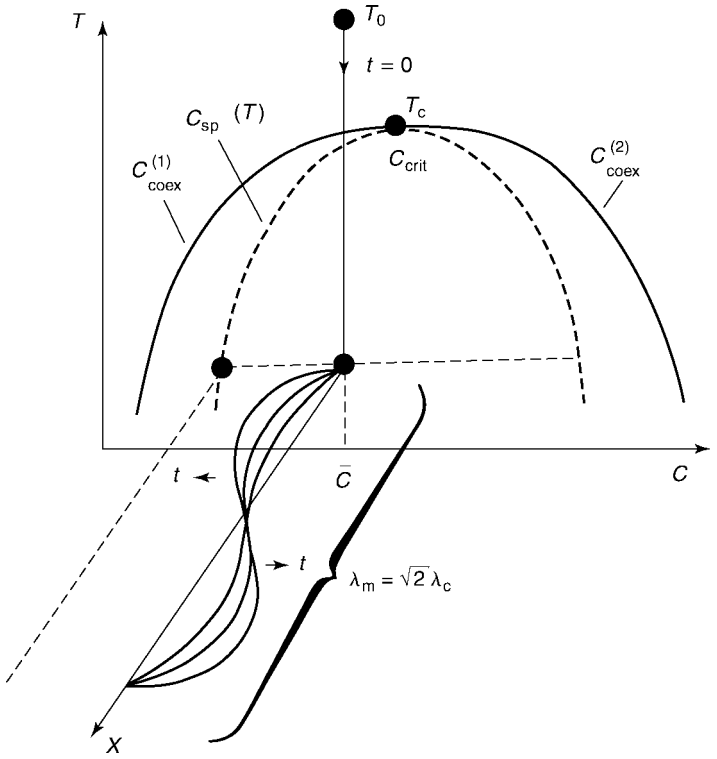

Fig. 3. Schematic illustration of a "quenching experiment" of a binary mixture, where phase separation via "spinodal decomposition" is initiated by a sudden reduction of temperature T from an initial temperature T_0 in the one-phase region to a temperature T in the two-phase region in the temperature concentration (c) plane underneath the spinodal (shown as broken curve) at time $t = 0$. While the average concentration $\bar{c}$ stays constant, of course, in the course of time concentration inhomogeneities spontaneously develop with wavelengths $\lambda_c < \lambda < \infty$. Maximum growth occurs at a wavelength $\lambda_m = \sqrt{2\lambda_c}$, according to the linearized theory of spinodal decomposition (18). This is symbolically indicated by showing growing waves assuming one spatial coordinate x only. In practice there is a band of growing wavelengths, and the phases of the waves and the orientations of the wave vectors are randomly distributed, and hence in real space the concentration pattern is not periodic.

diagram contains a miscibility gap at low temperatures, ie, an "upper critical solution temperature" (UCST) where T_c, ϕ_c is a maximum of both the coexistence curve and the spinodal. In fact, many polymer solutions and polymer blends show the opposite behavior, ie, the phases separate when the temperature is raised, starting at a "lower critical solution temperature" (LCST) (21) and there also are examples of systems that exhibit both LCST and UCST behavior, eg poly(isobutylene) dissolved in benzene (22).

At this point, we mention one important caveat: The assertion that the critical point is at a maximum or minimum of the coexistence curve in the (T, ϕ)-plane is only true if the polymer is strictly monodisperse. One of the characteristic effects of polydispersity is that the critical point no longer coincides with the extremum of the coexistence curve (although it still is an extremum of the spinodal)

(23). An example for this behavior is the LCST mixture of poly(styrene) (PS) and poly(vinylmethylether) (PVME). For example, for molecular weights $\bar{M}_w = 62700$ and $\bar{M}_w = 60000$, obtained from light scattering, one finds the minimum of the binodal at about $\phi_{min} \approx 0.38$ PS while $\phi_c \approx 0.48$ PS (24).

Of course, the concepts of a "limit of metastability" for metastable states at first-order transitions, and the distinction between two mechanisms of phase separation (nucleation and growth of a new phase vs long wavelength instabilities (25,26)) is not only used for solutions or mixtures, but for first-order transitions (Fig. 1) in general. For example, for metallic alloys undergoing order–disorder transitions to ordered superstructures, which in typical cases (such as the Au–Cu system (1)) are of first-order, the concept of "spinodal ordering" was coined (27), and similar phenomena where an order parameter grows spontaneously out of a disordered phase are expected to occur for the order–disorder transition of block copolymers, for instance. As is well known (15,28–36), diblock copolymer melts display an order–disorder transition (ODT; also referred to as "microphase separation transition") from a disordered melt to mesophases with various types of long-ranged order (Fig. 4) when the product of chain length N and Flory–Huggins parameter χ [that characterizes the degree of incompatibility between the partners A and B of the block copolymer, $N = N_A + N_B$, $f = N_A/(N_A + N_B)$] is large enough. Actually, the phase diagrams of Figure 4 are grossly simplified as they assume perfect symmetry between A and B (same size and shape of the monomers, same chain stiffness, etc), and therefore the phase diagrams are perfectly symmetric around $f = 1/2$, which experimentally is known not to be the case (37). Additional phases occur in narrow regions of the phase diagram (such as the gyroid and close-packed spherical phases (33)) which are not displayed in Figure 4. At this point we also mentioned that ordered phases were also observed (37), such as the double diamond and perforated lamellar structure, which are—at least in the idealized mean-field limit—only metastable rather than truly stable phases (33).

While in the mean-field limit the self-assembly of block copolymers into ordered mesophases is only controlled by two parameters, χN and f, this is no longer true when one goes beyond mean-field theory by including the effect of statistical fluctuations (30). Then the chain length N enters as a separate parameter, and the topology of the phase diagram changes (Fig. 4**b**). Only in the limit $N \to \infty$ mean-field theory is recovered, but this limit is hard to achieve since even for an effective chain length $\bar{N} = 10^4 (\bar{N} = [(\sqrt{6}R_g)^3 \rho_c]^2)$, ρ_c being the chain density and R_g the gyration radius) there are appreciable differences between the actual phase diagram (Fig. 4**b**) and the corresponding mean-field limit (Fig. 4**a**). While in the mean-field limit for $f = 1/2$ the ODT is a second-order transition, it is actually weakly of first order. Therefore close to the transition point the ordered phase forms from the disordered one also by nucleation and growth (31). Defining as an order parameter the amplitude A of a concentration wave

$$\phi(\vec{r}) = 2A \cos(q^* \vec{n} \cdot \vec{r} + \varphi), \qquad q^* \approx 1.945/R_g \tag{3}$$

where $\vec{n}$ is a unit vector perpendicular to the lamellas and φ characterizes the phase of the concentration wave, one can derive an effective free-energy functional $f_H(A)$ as shown in Figure 5 (31). When $\chi > \chi_0$, only the disordered phase is stable

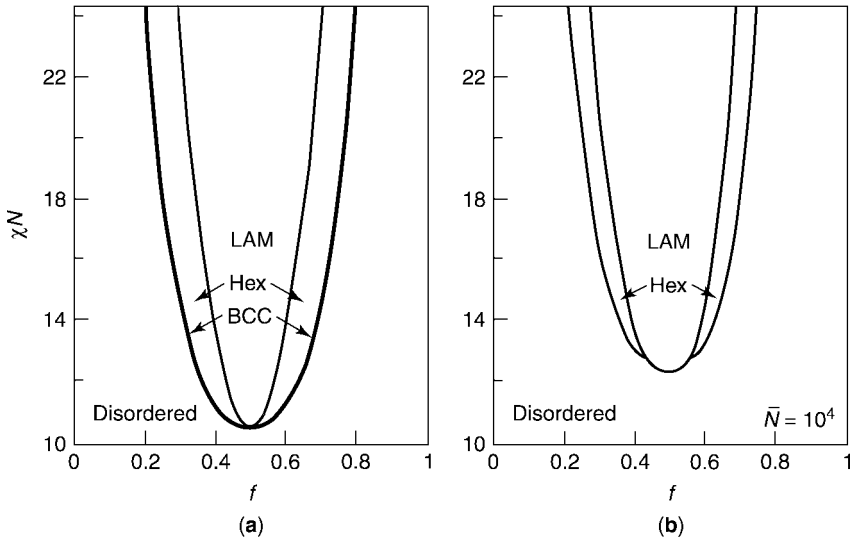

Fig. 4. Theoretically predicted phase diagrams of diblock copolymer $A_f\,B_{1-f}$ melts in the plane of parameters χN (χ = Flory–Huggins parameter, N = chain length) and composition f[where $f = N_A/(N_A + N_B)$], according to the Leibler (29) random phase approximation (**a**) and the Fredrickson-Helfand (30) Hartree approximation (**b**). Mesophases considered are the lamellar (LAM) phase, the hexagonal (HEX) phase where cylinders rich in the minority component are arranged periodically, a cross section perpendicular through the cylinders yielding a triangular lattice, and the body-centered cubic (BCC) lattice of spherical micelles. From Ref. 32.

(single minimum of $f_H(A)$ at $A = 0$, Fig. 5**a**), while at $\chi = \chi_0$ metastable minima with nonzero A appear, which become degenerate in depth with $f_H(A = 0)$ at the transition point, $\chi = \chi_t$, (see Fig. 5**c**). Even for $\chi > \chi_t$ the disordered phase ($A = 0$) is still metastable, since the minimum at $A = 0$ still persists and is separated by barriers from the stable minima. Note that the point $\chi = \chi_0$ is a spinodal point of the ordered phase within the region of the phase diagram where the disordered phase is the stable one. Finally, we recall from equation 3 that the characteristic wavelength $\lambda^* = 2\pi/q^*$ of the ordering is of the same order as the gyration radius of the chains, and hence of a "mesoscopic" scale rather than an atomistic scale. This justifies the name "mesophase" for the ordered structures in Figure 4.

Similar considerations as outlined here for diblock copolymers can be made for other types of orderings (liquid crystals (38,39)) or density functional theory of crystallization (melting transitions (40)). However, we shall not dwell on these topics (rather see LIQUID CRYSTALLINE POLYMERS and CRYSTALLIZATION KINETICS).

Surfaces

The concept of phase transitions can be carried over from bulk systems also to their surfaces (41–47). To be specific, let us consider a binary polymer blend (A,B) in a thin-film geometry (46,47). We suppose the film has a uniform thickness $\mathcal{D}$

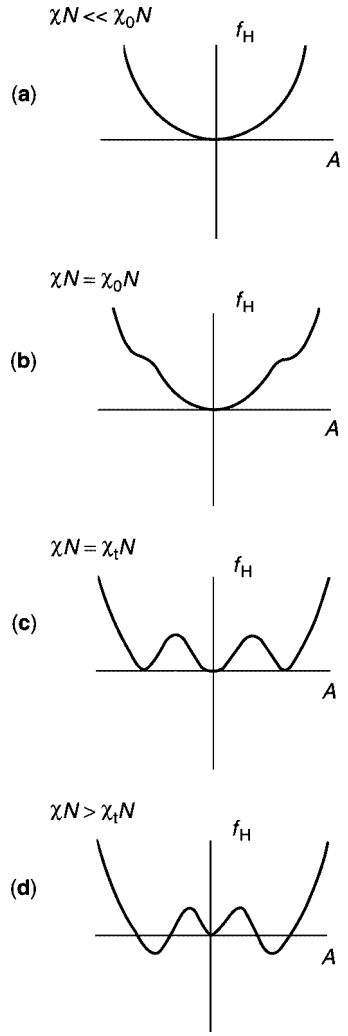

Fig. 5. Schematic free-energy functional $f_H(A)$ of a symmetrical diblock copolymer ($f = 1/2$) plotted vs the amplitude A of the concentration wave characterizing the lamellar ordering in the weak segregation limit. Cases (**a**–**d**) show $f_H(A)$ for regions above (**a**) and at (**b**) the spinodal χ_0 of the ordered phase, at the order–disorder transition (**c**) and below it (**d**). From Ref. 31.

and is bounded by a substrate on its lower surface and by some other material (or gas or vacuum, respectively) on its upper surface, as is the common situation in the application of thin polymer films (4,5). Then the thermodynamic potential F needs to be decomposed into bulk and surface terms (41–47)

$$F = F_{\text{bulk}} + \frac{1}{\mathcal{D}} F_s^{(l)} + \frac{1}{\mathcal{D}} F_s^{(u)}, \qquad \mathcal{D} \to \infty \tag{4}$$

where $F_s^{(l,u)}$ are the surface excess free energies due to the lower (upper) boundary of the thin film. Just as the bulk free energy F may exhibit singularities (Fig. 1) as a function of external control parameters due to phase transitions, also surface excess free energies F_s may exhibit singularities due to surface phase transitions. For example, in a binary polymer blend one expects that one species (eg, B) is preferred by a surface, and hence there is an enrichment layer of B at this surface. A surface phase transition (of first order) then physically corresponds to a jump in thickness of this enrichment layer, caused eg by variation of temperature (if the thickness of the layer jumps from a finite value to infinity, this is called a "wetting transition," while it is called "prewetting transition" if the jump occurs from a smaller to a larger value (48–50). Similar surface-induced ordering can also be considered for block copolymers (46,47,51,52). There is also great interest (both from theory (47,53) and from experiment (54) on surface effects on the kinetics of phase transformations in polymer blends ("surface-directed spinodal decomposition" (55,56). Finally, we mention that related concepts also apply to phase transformations of thin homopolymer films on substrates: If the film is metastable, the dewetting of the substrate starts by the nucleation and growth of holes in the film (57), while for unstable films "spinodal dewetting" (58,59) is predicted. A particular active field is also the study of phase transformations in thin block copolymer films (36,47,60,61).

Critical Phenomena in Polymer Solutions and Blends

In this section we elaborate further on the phenomena that occur in the vicinity of the critical points (cf phase diagrams Figs. 2**a** and 2**b**), since these phenomena were extensively studied in the last decade and a rather definite knowledge about them has been gained.

Of course, a useful starting point of the discussion still is the Flory–Huggins mean-field theory (13–16), where the excess free-energy density of mixing is written as

$$\frac{1}{a^3}\frac{\Delta F_{\mathrm{mix}}}{k_{\mathrm{B}}T} = \frac{\phi_{\mathrm{A}} \ln \phi_{\mathrm{A}}}{N_{\mathrm{A}}} + \frac{\phi_{\mathrm{B}} \ln \phi_{\mathrm{B}}}{N_{\mathrm{B}}} + \chi \phi_{\mathrm{A}} \phi_{\mathrm{B}} \tag{5}$$

where a is the lattice spacing of the underlying lattice model; ϕ_{A}, and $\phi_{\mathrm{B}} = 1 - \phi_{\mathrm{A}}$ are the volume fractions of the two types of (effective) monomers; N_{A}, N_{B} are the chain lengths of the two polymers (formally a polymer solution is obtained putting $N_{\mathrm{A}} = N$, $N_{\mathrm{B}} = 1$); and the Flory–Huggins parameter χ is related to pairwise interaction energies $\varepsilon_{\mathrm{AA}}$, $\varepsilon_{\mathrm{AB}}$, $\varepsilon_{\mathrm{BB}}$ via $\chi = z\,[\varepsilon_{\mathrm{AB}} - (\varepsilon_{\mathrm{AA}} + \varepsilon_{\mathrm{BB}})/2]/k_{\mathrm{B}}T = z(\Delta\varepsilon)/k_{\mathrm{B}}T$, z being the coordination number of the lattice.

Neglecting any possible dependence of χ on ϕ $(= \phi_{\mathrm{A}})$, the condition of the spinodal χ_{s} becomes

$$\left.\frac{\partial^2(\Delta F_{\mathrm{mix}}/k_{\mathrm{B}}T)}{\partial \phi^2}\right|_{\phi=\phi_{\mathrm{s}}(\chi)} = 0 \Rightarrow 2\chi_{\mathrm{s}}(\phi) = \frac{1}{\phi N_{\mathrm{A}}} + \frac{1}{(1-\phi)N_{\mathrm{B}}} \tag{6}$$

For monodisperse polymers, the maximum of the spinodal $\phi_s(\phi)$ yields the critical point

$$\phi_c^{FH} = (\sqrt{N_A/N_B} + 1)^{-1}, \qquad 1/\chi_c^{FH} = 2\left(N_A^{-1/2} + N_B^{-1/2}\right)^{-2} \tag{7}$$

For the special case of a symmetric mixture ($N_A = N_B = N$), we have $\phi_c = 1/2$ and $\chi_c = 2/N$, ie, the critical temperature $k_B T_c = z(\Delta\varepsilon)/\chi_c = z(\Delta\varepsilon)N/2$ scales linearly with N. For the other special case of a polymer solution, $\phi_c \propto 1/\sqrt{N}$ for $N \to \infty$, and $1/\chi_c \to 2$, ie, the theta temperature (Fig. 2**a**) is $\Theta = 2z\,(\Delta\varepsilon)/k_B$. The two branches of the coexistence curve are obtained as

$$\phi_{coex}^{(1,2)} - \phi_c = \pm\hat{B}(\chi/\chi_c - 1)^{1/2} \tag{8}$$

where $\hat{B} = \sqrt{3}/2$ for a symmetric mixture, while $\hat{B} \propto N^{-1/4}$ for a solution. In the latter case equation 8 holds only for $x = \frac{1}{2}\sqrt{N}(\chi/\chi_c - 1) \ll 1$ (62). In the opposite limit $x \gg 1$, one rather finds (62)

$$\phi_{coex}^{(1)} \approx \frac{3}{2}(1 - T/T_c)\exp\left[-\frac{3}{8}(1 - T/T_c)^2 N\right], \qquad \phi_{coex}^{(2)} \approx \frac{3}{2}(1 - T/\Theta) \tag{9}$$

For $N \to \infty$ (keeping $1 - T/\Theta$ fixed) one hence finds $\phi_{coex}^{(2)} - \phi_{coex}^{(2)} \propto (1 - T/\Theta)$, ie, the exponent of the order parameter now is $\beta^t{}_{MF} = 1$, as expected for a tricritical point (62).

Of course, it is of interest to study how the critical properties of a polymer solution scale with $N \to \infty$ (62–68). A standard assumption invokes power laws (66)

$$\hat{B}(N) \propto N^{-x_1}, \qquad \phi_c(N) \propto N^{-x_2}, \qquad \Theta - T_c\ (N) \propto N^{-x_3} \tag{10}$$

which have the mean field values ${x_1}^{MF} = 1/4, {x_2}^{MF} = 1/2, {x_3}^{MF} = 1/2$. Assuming that the mean-field–type scaling behavior $\phi_{coex}^{(2)} - \phi_{coex}^{(1)} \propto N^{-1/2}\tilde{\phi}[N^{1/2}(1 - T/T_c)]$ holds generally but in the vicinity of T_c one must recover equation 2 with the correct Ising universality class exponent $\beta \approx 0.325$ yields instead $x_1 = (1-\beta)/2 \approx 0.34$ (14,62), while the exponents x_1, x_3 would keep their mean-field values. However, the results of many experiments (64,65) and simulations (66,67) agree only with $x_3 = 1/2$ but suggest instead $x_2 \approx 0.38$, if one insists on the simple power laws (eq. 10). The idea involved to explain $x_2 \approx 0.38$, namely that the chains at the critical point are already partially collapsed and no longer ideal Gaussian coils (as they should be at the theta point (14)), is also clearly refuted by the simulations. There are several possibilities to explain the problems with equation 10. For example, one expects logarithmic corrections to the simple power laws near a tricritical point (63)

$$\phi_c(N) \propto (\ln N)^{1/2}/N^{1/2}, \qquad \Theta - T_c(N) \propto N^{-1/2}(\ln N)^{-3/11}, \qquad N \to \infty \tag{11}$$

It is rather likely, however, that neither experiments nor simulations have reached the regime of sufficiently large N yet where equation 11 is observed.

Another possibility is that the crossover between mean field and Ising critical behavior, which is spread out over many decades in $1 - T/T_c$ (68,69), also causes the exponents x_1, x_2, x_3 in equation 10 to be "effective exponents," which show a significant variation when one studies $\hat{B}(N),\phi_c(N)$, etc. over many decades in N. Usually experiments and simulations have only 1 to 2 decades in N at their disposal, and therefore all conclusions on the validity of equations 10 and 11 are still preliminary. However, experiments do allow a study of enough decades in $|1 - T/T_c|$ to confirm the theoretical expectation that the critical exponents β,γ, etc. take the values of the Ising universality class.

While the Flory–Huggins mean-field theory is not a good approximation for the description of critical phenomena in polymer solutions, it works much better for (approximately symmetric) polymer blends. To understand this fact, it is useful to consider the scattering from concentration fluctuation within the framework of the "random phase approximation (RPA)" (14). It is based on the assumption that the chain configurations in the blend are unperturbed Gaussian coils, and it reduces the collective scattering function $S_{coll}(\vec{q})$, q being the scattering wavevector, to the single-chain factors $S_A(\vec{q}),S_B(\vec{q})$ as follows,

$$S_{coll}^{-1}(\vec{q}) = [\phi S_A(\vec{q})]^{-1} + [(1-\phi)S_B(\vec{q})]^{-1} - 2\chi_{eff} \tag{12}$$

where $S_A(q) = Nf_D(R^2_{g,A}q^2)$, $f_D(x)$ being the Debye function $f_D(x) = (2/x^2)[\exp(-x) - 1 + x]$,$R_{g,A} = \sigma_A\sqrt{N_A/6}$ being the gyration radius of the A chains, and σ_A their segment sizes. A similar notation holds for the B component. $\chi_{eff} = \chi$ if χ is strictly independent of χ, otherwise (15,16) $\chi_{eff} = -(1/2)\,\partial^2/\partial\phi^2[\phi(1-\phi)\chi(\phi)]$. The RPA expression is routinely used to extract the Flory–Huggins parameter from small-angle neutron scattering experiments. Unfortunately, the value depends slightly on the system (eg, there are differences between homopolymer blends and block copolymer systems (70)) and on the method (eg, scattering, composition of the coexisting phases and surface enrichment (71)). Expanding equation 12 for small q yields

$$S_{coll}(q) = S_{coll}(0)/(1 + q^2\xi^2) \tag{13}$$

with $S_{coll}^{-1}(0) = (\phi N_A)^{-1} + [(1-\phi)N_B]^{-1} - 2\chi_{eff}$. $1/S_{coll}$ vanishes at the spinodal curves (cf eq. 6, and ξ is the correlation length of the concentration fluctuations. Defining the effective lattice parameter a of the Flory–Huggins lattice by $a^2 = \sigma^2_A(1-\phi) + \sigma^2_B\,\phi$, one finds for $\phi = \phi_c$, $\chi < \chi_c$ that

$$S_{coll}(0) = (2\chi_c)^{-1}(1 - \chi/\chi_c)^{-1}, \qquad \xi = \frac{a}{6}(4N_AN_B)^{1/4}(1 - \chi/\chi_c)^{-1/2} \tag{14}$$

which are special cases of the relations $S_{coll}(0) = \hat{S}(T/T_c - 1)^{-\gamma}$,$\xi = \hat{\xi}(T/T_c - 1)^{-\nu}$ describing the critical singularities of the critical scattering intensity and correlation length, respectively, with $\gamma_{MF} = 1$, $\nu_{MF} = 1/2$, the corresponding mean-field exponents. Equation 14 shows that the critical amplitude $\hat{\xi}$ for a symmetrical polymer mixture is of the same order as the gyration radius R_g (while for a

polymer solution it is much smaller, $\hat{\xi} \propto \sqrt{aR_g}$). This large value of $\hat{\xi}$ is critical for the validity of mean-field theory for $N \to \infty$, as the Ginzburg criterion (72,73) shows. According to this criterion mean-field theory is valid when the fluctuation of the order parameter in a correlation volume is much less than the mean square order parameter itself. This yields (in d dimensions)

$$\hat{S}\hat{\xi}^{-d}/\hat{B}^2 \ll |1 - T/T_c|^{(2-d)/2} \qquad \text{or} \qquad \text{Gi} \ll |1 - T/T_c| \tag{15}$$

where the "Ginzburg number" Gi is proportional to $(\hat{S}\hat{\xi}^{-d}/\hat{B}^2)^{2/(4-d)}$. For a symmetric polymer mixture, $\hat{B}$ is of order unity, while $\hat{S} \propto N$, $\hat{\xi} \propto N^{1/2}$, and hence $\text{Gi} \propto \text{N}^{(2-\text{d})/(4-\text{d})}$ ($= 1/N$ in $d = 3$). Thus for large enough N mean-field theory becomes valid for polymer mixtures in $d = 3$ (but not in $d = 2$, ie, for polymer blends in thin film geometry Gi is of order unity). For polymer solutions, where $\hat{B} \propto N^{-1/4}$, $\hat{S}$ of order unity, $\hat{\xi} \propto N^{1/4}$, one rather finds $\text{Gi} \propto N^{-1/2}$ in $d = 3$. Since equation 8 is only supposed to hold if $\sqrt{N}(1-T/T_c) \ll 1$ but equation 15 requires that $|1 - T/T_c| \gg 1/\sqrt{N}$, we see that Flory–Huggins theory must fail in the critical region of a phase-separating polymer solution, and this is confirmed by experiment (65,69).

For polymer blends in $d = 3$ it then turns out that a crossover scaling description applies (74–76), $t = |1 - T/T_c|$,

$$\phi^{(2)}_{\text{coex}} - \phi^{(1)}_{\text{coex}} \propto \text{t}^{1/2}\tilde{B}(t/\text{Gi}), \qquad S_{\text{coll}}(0) \propto Nt^{-1}\tilde{S}(t/\text{Gi}) \tag{16}$$

where the scaling functions for small values of their arguments behave as $\tilde{B}(x) \propto x^{\beta - 1/2}$,$\tilde{S}(x) \propto x^{1-\gamma}$, to reproduce the critical behavior of the Ising universality class. There exists an analytic approximation (74) for $\tilde{\xi}(x)$ that provides a very good fit to the experimental data (76). However, while the above prediction $\text{Gi} \propto 1/N$ is confirmed by simulations of an idealized lattice model (75) it is not compatible with the experimental data for polymer blends (76,77). This discrepancy is attributed to the compressibility of the blend (which is completely neglected in eqs. 5, 12 and 13, which gives rise to an anomalous pressure dependence of the Ginzburg number (77).

At this point, it is appropriate to critically reexamine to what extent the Flory–Huggins description (Eqs. 5–7) is valid as a phenomenological model. One important qualitative effect that is neglected completely is the "correlation hole effect" (14): For an effective monomer of a chain it is more likely to have other monomers in the neighborhood that belong to the same chain rather than to other chains. Of course, only interchain interactions and no intrachain interaction contribute to macroscopic phase separation, and hence the "effective coordination number" z that enters the Flory–Huggins parameter χ gets reduced. It turns out (78) that this leads to $1/\sqrt{N}$ corrections in $d = 3$, $z = z_\infty + \text{const}/\sqrt{N}$, and similarly $\chi_c = \chi_\infty + \text{const}/\sqrt{N}$, $\phi_c = \phi_c^{\text{FH}} + \text{const}/\sqrt{N}$, etc. In $d = 2$, however, this effect is far more drastic, since the chains can interpenetrate only rather little, and hence $z \propto 1/\sqrt{N} \to 0$ as $\to N \to \infty$, and therefore also (79) $\chi_c \propto 1/\sqrt{N}$ rather than $\chi_c \propto 1/N$ as in the case of $d = 3$. The linear scaling of the critical temperature T_c with N in $d = 3$ has been experimentally verified (80) while no systematic

studies of phase separation of polymer blends in ultrathin films so far have been possible.

Of course, polymer blends are fluids, and a more realistic description of the packing of neighboring atomic groups is needed than can be achieved by Flory–Huggins theory (and its extensions that account for compressibility (81). An approach that attempts to generalize theories of fluid structure and thermodynamics to polymer mixtures is the polymer reference interaction site model (PRISM) (82,83). While this approach is not useful for the critical properties, it clearly is a powerful description of the general interplay between structure and thermodynamics in polymer blends. It shares a disadvantage with the Monte Carlo computer simulation approach (75,78,84,85), namely that extensive numerical computations are mandatory. A complementary approach is the lattice cluster theory of Freed and co-workers (86), which takes better account of asymmetry in size and shape of monomers by using a lattice model with "monomers" occupying several lattice sites. The monomer shape might impart an entropic contribution (87,88) or a composition dependence (88) onto the Flory–Huggins parameter that might result in a significant modification of the phase behavior as a function of temperature and composition. However, there is neither a fully satisfactory approach that could predict the Flory–Huggins parameter (if one uses eq. 5 as an effective description) from atomistic input, nor can one describe the complete phase diagrams of binary and ternary blends and the structure of the coils under the various thermodynamic conditions accurately. Note that the RPA (eq. 12) also is a rough approximation only. In reality, the polymer coils do respond to the conditions of the thermodynamic state in which the system is in; eg, in a polymer blend typically chains of the minority component contract (89,90), while in block copolymer melts pretransitional chain stretching occurs (91,92)—and also is seen in the experiment (93)—because the center of mass of the A block gets separated from that of the B block, so that the polymer coil adopts a dumbbell-like shape. Because of all these limitations, the understanding of more complex phase-separation phenomena—where eg, microphase separation of block copolymers competes with macroscopic phase separation—are much less well understood, and will not be treated here. Such phenomena occur in blends of block copolymers (94) or blends of homopolymers with block copolymers (95).

We only mention, that for homopolymer–block copolymer mixtures RPA predicts that the wavelength λ^* of lamellar ordering may diverge at particular points in the phase diagram, so-called Lifshitz points (96); however, isotropic Lifshitz points are destabilized by statistical fluctuations and hence exist only in the mean field limit, while in reality one expects there a kind of "microemulsion" in the phase diagram. Such microemulsion phases also occur presumably in random copolymer melts (97), interpenetrating polymer networks (98), etc.

Returning now to the phase diagram of polymer solutions, we emphasize also that much more complicated phenomena than envisaged in Figure 2**a** can occur. For example, considering the solution of short alkane chains (eg hexadecane) in carbondioxide, one encounters a competition between gas–liquid transitions of both polymer (C_{16} H_{34}) and solvent (CO_2) and liquid–liquid phase separation (99,100). Thus the phase diagram not only contains (in the space of three variables p,T, and ϕ) various lines of critical points, but special points such as critical end points, triple points, and tricritical points may also occur. Each system then

requires a separate detailed discussion on an atomistic level to understand all the possible phase changes that it can undergo. In this article, we hence have not emphasized these rather specific aspects, but the general feature of the critical-point phenomena involved.

Interfaces between Coexisting Phases

There are two methods to extend equation 5 to the inhomogeneous situation where a domain of the phase rich in polymer coexists with solvent or a domain rich in polymer A coexists with another domain rich in polymer B. The simplest approach (15,16,99,101) amends equation 5 with a $(\nabla\phi)^2$ term; this is appropriate in the "weak segregation limit." In the opposite case ("strong segregation limit") one goes from pure A to pure B in a blend and the method of choice is the self-consistent field theory (102–106), which also is a powerful method for the study of the block copolymer phase diagrams in this strong segregation limit (32–36). These theories predict the "interfacial tension" f_{int} (= excess free energy due to the interface per unit area) and the "intrinsic width" w_0 of the interface. For a polymer solution in the critical region near $T_c(N)$, the mean field theory yields (107)

$$f_{\text{int}} \propto N^{-1/4}[1 - T/T_c(N)]^{3/2}, \qquad w_0 = 2\xi \propto N^{1/4}[1 - T/T_c(N)]^{-1/2} \tag{17}$$

while actually the behavior compatible with Ising universality class is (107), with $\nu \approx 0.63$,

$$f_{\text{int}} \propto \xi^{-2} = N^{\nu-1}[1 - T/T_c(N)]^{2\nu}, \qquad w_0 \propto N^{(1-\nu)/2}[1 - T/T_c(N)]^{-\nu} \tag{18}$$

Conversely, for the symmetrical polymer blend in the mean field critical regime the corresponding results are (15,16)

$$f_{\text{int}} \propto N^{-1/2}(1 - \chi_c/\chi)^{3/2}, \qquad w_0 = 2\xi \propto N^{1/2}(1 - \chi_c/\chi)^{-1/2} \tag{19}$$

while in the Ising critical regime one has

$$f_{\text{int}} \propto \xi^{-2} = N^{2(\nu-1)}(1 - \chi_c/\chi)^{2\nu}, \qquad w_0 = 2\xi \propto N^{1-\nu}(1 - \chi_c/\chi)^{-\nu} \tag{20}$$

Finally, we note the behavior in the strong segregation limit (102), ρ being the monomer density and a the statistical segment length, and a factor $(k_B T)^{-1}$ is absorbed in f_{int}

$$f_{\text{int}} = \rho a \sqrt{\chi/6}, \qquad w_0 = a/\sqrt{6\chi} \tag{21}$$

Equation 20 also holds for a strongly segregated polymer solution (but then χ is of order unity).

Now interfacial widths can be measured by depth-profiling techniques which eg use a nuclear reaction analysis to obtain the concentration profile through a thin polymer film (108,109) or by total reflection of neutrons (110) or X-rays. However, it should be noted that neither in an experiment nor in a simulation can one ever observe the "intrinsic width" of an interface, which is an absolutely hypothetical object (106,111). Rather the observed width always results from a convolution of the intrinsic profile with the capillary wave broadening (106,111,112). On a lateral length scale L, one obtains for the actual mean square width

$$w^2 = w_0^2 + \frac{1}{4f_{\text{int}}}(\ln \mathrm{L} - \ln\lambda_0) \tag{22}$$

where λ_0 is the short wavelength cutoff of the capillary wave spectrum, and it was assumed that the thickness $\mathcal{D}$ of the film is large enough such that the finite size effect due to $\mathcal{D}$ is still negligible. In many circumstances this is not the case (109), and then a much stronger size effect $w^2 \propto (\text{const}\ \mathcal{D})$ may result (113). Now the appropriate choice of λ_0 is still questionable (104–106,114), and while f_{int} can be extracted if one observes the predicted linear variation between w^2 and L, obviously there is no unique separation between $w^2{}_0$ and $\ln \lambda_0/(4 f_{\text{int}})$. In practice, observations of equation 22 are rare, and f_{int} is estimated experimentally by other methods (eg the "capillary rise" method or the "sessile drop" method, see eg Ref. 115).

Since many application properties of amorphous solid polymer blends (which often are phase-separated on a mesoscopic scale) are controlled by the interfaces they contain, a good understanding of the structure and properties of interfaces is very important. Simulations (116) have shown that free volume and chain ends get enriched at the interfaces, and homopolymers become oriented parallel to the interface at strong segregation, while adsorbed block copolymers tend to orient perpendicularly (117). The compatibilizing effect of block copolymers adsorbed to interfaces in unmixed blends is well known.

Once more, we emphasize that our treatment has simplified the topic enormously, and only the most salient features were mentioned. Complications due to the pressure dependence in blends and due to the gas–liquid transitions in polymer solvent-systems may lead to new effects. For example, for the interfaces between gaseous CO_2 bubbles in a $C_{16}H_{34}$ matrix one obtains interfacial wetting of fluid CO_2, which reduces the interfacial tension drastically and hence facilitates nucleation (118). In fact, an understanding of nucleation in polymer blends (119) and solutions (118) is just emerging.

PHOTOPOLYMERIZATION, CATIONIC

Introduction

Light-induced polymerization reactions, commonly known as *photopolymerizations*, are generally chain reactions in which the propagating active centers (free radicals or cations) are produced by a photochemical event. These reactions may be initiated using ultraviolet or visible light, and offer many advantages when compared to the more common thermal polymerizations in which heat is used to produce active centers. For example, photopolymerization uniquely offers spatial control (since the light may be directed to locations of interest in the system) and temporal control (since the light is readily modulated on and off) of the initiation reaction, and the rate of production of active centers is often independent of temperature. In addition, since active centers can be produced rapidly and efficiently using photochemical processes, photocuring offers high production rates, and is highly energy efficient compared to thermal polymerizations in which the entire system must be raised to elevated temperatures. A major application of photopolymerization that exploits these advantages is films and coatings that exhibit high cure rates without the use of volatile solvents, thereby minimizing emissions of organic compounds.

The vast majority of photopolymerizations used in industry are free-radical polymerizations, which have been studied extensively (for reviews, see references 1–5 as well as Photopolymerization, Free Radical (qv)). By far the most widely used classes of monomers for UV-initiated free-radical photopolymerizations are multifunctional acrylates and methacrylates. Several investigations have demonstrated that free-radical polymerizations of these monomers exhibit unusual kinetic behavior, including immediate onset of autoacceleration, the formation of heterogeneous polymers (2,6–11), and the attainment of a maximum conversion

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

significantly less than unity (2,12–15). These monomers polymerize very rapidly, and are easily modified on the ester group, allowing materials with a variety of properties to be obtained (2); and a wide range of acrylates and methacrylates are commercially available. However, free-radical photopolymerizations have a number of problems and drawbacks that have lead scientists to examine other photopolymerization systems. For example, many acrylates are relatively volatile (methacrylates are generally less volatile than acrylates), and have an unpleasant odor. Moreover, there has been a growing concern over potential health hazards associated with the acrylates (3,4,16). Finally, the free-radical photopolymerizations are inhibited by oxygen and must be carried out under an inert atmosphere such as nitrogen or under a protective film or mold to achieve the highest reaction rates and the optimal properties of the film or coating.

UV-initiated cationic photopolymerizations exhibit several advantages when compared with the free-radical photopolymerization discussed above. First of all the cationic photopolymerizations are not inhibited by oxygen. This feature provides a significant practical advantage for industrial processes since it is not necessary to blanket the system with nitrogen to achieve rapid cure rates. Secondly, in contrast to the free-radical photopolymerizations which experience a rapid decrease in polymerization rate when the light source is removed (due to radical–radical termination reactions), the cationic polymerizations proceed long after the irradiation has ceased, consuming nearly all of the monomer. Finally, cationic photopolymerization is a very versatile technique and may be used to polymerize important classes of monomers, including epoxides and vinyl ethers. Although these classes of monomers cannot cure by free-radical photopolymerizations, they exhibit many desirable properties, including low volatility, good rheological properties, and low toxicity (3). Furthermore, the cured polymer films associated with these monomers exhibit excellent clarity, adhesion, abrasion resistance, and chemical resistance. In addition, the cationic ring-opening polymerizations of epoxides exhibit less shrinkage, as low as 1–2% (17), than do polymerizations of unsaturated monomers such as acrylates and methacrylates, which is typically 5–20%. However, the presence of water vapor may impede the cationic curing, notably if thin films are cured at a low light intensity.

The reaction kinetics are an important aspect of any photopolymerization system under consideration for an application. For some applications, such as coatings on optical fibers, photopolymerization is perhaps the only way in which cure can be achieved fast enough to meet the requirements of the system. The reaction kinetics fundamentally follow from the mechanism by which the reaction takes place, and chain photopolymerization processes generally begin with an initiation step in which active centers are produced photochemically; proceed by the propagation step in which the active center reacts successively with a number of monomer molecules to link them covalently into a polymer chain; and may end in a termination step in which the active centers are consumed by a chemical reaction. Photopolymerization is distinguished by the fact that it is the absorption of a photon (by a specially designed photoinitiator molecule) that results in the production of active centers. Therefore, it is important to understand the photochemical processes by which the active centers are generated. The fundamental nature of the propagation and termination steps is the same for photo- and thermal polymerizations.

This article provides an overview of the important features of the kinetics of cationic photopolymerization, and a valuable resource for any scientist or engineer who is considering these reactions for a study or an application. The article begins with a description of the photoinitiation step, including the compounds and mechanisms by which cationic active centers are produced by a unimolecular process (typically a photo-induced fragmentation of the initiator), or a bimolecular process (typically an energy or electron-transfer process between a photosensitizer and the initiator). Commonly used photoinitiators and photosensitizers have been described and compared. The photoinitiation step is especially important because it is the step that distinguishes these reactions from their thermally initiated counterparts. Next, a description of traditional cationically polymerizable monomers as well as recently developed, highly reactive monomers is provided. Representative kinetic rate expressions have been presented to illustrate the link between the reaction mechanism and a quantitative description of the polymerization rate, and to illustrate the important variables that affect the rate.

Photoinitiation

Despite the advantages of UV-initiated cationic photopolymerizations discussed above, this technique has received considerably less attention than the analogous free-radical reactions, and most of the studies in the literature have focused on the photoinitiation step. This fact may be attributed to the lack of suitable UV-sensitive cationic photoinitiators until recent years. In fact, applicable photoinitiators for cationic polymerizations were not developed until the late 1970s, several decades after free-radical photoinitiators had been reported. Until then, photoinitiators developed were specific to particular reaction systems. For example, Asai and co-workers (18–23) investigated the use of numerous metal salts such as sodium chloroaurate, silver salts in aromatic solvents, copper perchlorate, vanadium tetrachloride and titanium tetrachloride, as photoinitiators for cationic polymerization of *N*-vinylcarbazole. Photopolymerizations of isobutylene in the presence of Lewis acids such as vanadium chloride, titanium chloride, and tin chloride have been reported (24) via a radical–cation mechanism. A variety of monoepoxides were polymerized using manganese decacarbonyl (25) and methylcyclopentadienyl manganese tricarbonyl (26). Other examples include photocatalyzed polymerization of epichlorohydrin using bis(cyclopentadienyl) iron complex (27), and polymerization of 2-chloroethyl vinyl ether photosensitized by bis(cyclopentadienyl) titanium chloride (28).

The first more generally applicable cationic photoinitiators that achieved some success were diazonium salts of complex metal halide anions (29–35). These diazonium salts were mainly used for the cationic ring-opening photopolymerization of epoxides. Upon photolysis, these salts produce an aryl halide, molecular nitrogen, and a strong Lewis acid capable of initiating cationic polymerization, as illustrated in Figure 1. The efficiency of the diazonium salt depends on the structure of the phenyl ring, which also affects the spectral sensitivity of the molecule, and the nature of the anion moiety (17,34,36,37).

The use of these diazonium salts, however, was limited because of their poor thermal stability requiring the photoinitiators to be added just before the

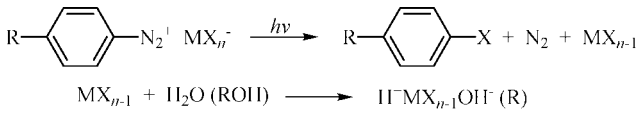

Fig. 1. Reaction mechanism for the photolysis of a diazonium photoinitiator. Here, R denotes substituents on the phenyl ring and MX_n^- represents a metal halide.

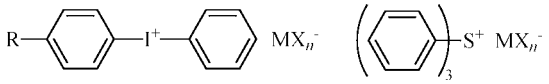
irradiation, and the release of nitrogen gas as a by-product which caused bubbles and pinholes in the coatings, for which they were mainly used, rendering practical constraint on the film thickness to be less than 15 μm (38). Some attempts have been made to stabilize these salts by adding additives such as nitriles (39), amides (40), sulfoxides (41), and poly(vinyl pyrrolidone) (42); however, these approaches achieved limited success and were not widely adopted.

Iodonium and Sulfonium Photoinitiators. A breakthrough in the development of cationic photoinitiators occurred in the late 1970s with the development of the first iodonium salt photoinitiators. These initiators, which were developed independently at the General Electric (43) and 3M (44), avoided the shortcomings of the diazonium photoinitiators. Unlike previous initiators, these salts are remarkably stable in the absence of light, are thermally stable at room temperature, and do not degrade in the presence of moisture. Shortly after the iodonium photoinitiators were introduced, Crivello and Lam (45) reported the development of the triarylsulfonium salts as a second class of highly efficient cationic photoinitiators that offered many of the same advantages. Representative molecular structures of the diaryliodonium salts and triarylsulfonium salts are shown as structures **1** and **2** respectively. R denotes substituents selected to enhance solubility in organic monomers and to alter the absorbance characteristics of the photoinitiator, and MX_n^- represents a metal halide.



1 **2**

The mechanism by which these compounds produce active centers for polymerization is described in detail below; however, at this point it should be noted that in their latent state, the compounds possess a cationic center (situated on the iodine or sulfur atoms), and possess a large anionic counterion. The aromatic rings can generally be functionalized (typically in the ortho and para positions) to enhance solubility in the organic monomers and to alter the absorbance characteristics of the photoinitiator. A number of excellent reviews are available which provide an account of the development of these initiators as well as a comprehensive list of compounds that have been synthesized (36,46,47).

The cation and the anion in the iodonium and sulfonium salts each play an important role in the performance of the photoinitiator. The cation is the light-absorbing component, and adding substituents to the aromatic rings can alter the UV absorption characteristics (for a review of this topic see Ref. 36,47, and 48). Generally, an unsubstituted iodonium salt will exhibit an absorbance maximum in the deep UV region of the spectrum at around 220 nm, and this absorbance maximum can be redshifted to around 270 nm by the addition of substituents such

as ether groups, or additional aromatic rings. Sulfonium salts generally exhibit their absorbance maximum at longer wavelengths than do the iodonium salts, and may exhibit notable absorbance peaks between 300 and 320 nm. The structure of the cation also controls the quantum yield (number of molecules of active centers produced per photon absorbed) and the thermal stability of the photoinitiator (46). The iodonium salt exhibits high quantum yield (between 0.7 and 0.9) and these yields are generally higher than those for the sulfonium salts. In summary, the cation of the photoinitiator plays the determining role in the production of active centers, including the wavelengths of light for which the compound will be active, the efficiency with which the light will be used to create active centers, and, as described in more detail below, the ability of the salt to be photosensitized. The cation has very little effect on any of the processes (such as propagation) that occur after the active centers are produced and, as described below, it is the anion that plays a defining role in the rate of the propagation reaction.

Before the active center is produced, the anion serves as the counterion for the iodonium or sulfonium cation, and plays a relatively unimportant role at this stage since it has little effect on the absorbance characteristics of the salt. After the active center is produced, however, the anion serves as the counterion for the propagating active center, and at this stage plays a critical role in the rate of the propagation reaction and, therefore, ultimately in the performance of the initiator. For the propagation reaction to progress at a high rate the propagating active center must have access to monomer with which it may react; therefore it is important that the active center is not encumbered with a closely associated counterion. This can be achieved if the counterion is large and the negative charge is dispersed over a large volume. This consideration has led to the use of a variety of nonnucleophilic anions such as BF_4^-, PF_6^-, AsF_6^-, SbF_6^-, $FeCl_4^-$, and $SbCl_6^-$. A nucleophilic anion such as Cl^- quickly quenches any cationic species generated during the photolysis by forming a closely associated ion pair, which prevents propagation. Based upon the above consideration, the rate of the propagation reaction is directly controlled by the counterion, and for the four most commonly used counterions, polymerization rate follows the order: $BF_4^- < PF_6^- < AsF_4^- < SbF_6^-$ (36). Although the use of arsenic and antimony leds to the strongest superacids and the highest polymerization rates, they are toxic heavy metals, and may present problems associated with recycling when used on a large scale. For this reason, Castellanos and co-workers (49) reported a new anion, tetrakis pentafluorophenyl borate, which is as effective as SbF_6^-, but does not contain a heavy metal.

The mechanism by which onium photoinitiators produce active centers is very complex and the details are still under investigation by a number of researchers (47,50–56). The generally accepted photoinitiation reaction mechanism for iodonium salts is shown in Figure 2. Upon absorption of a photon the iodonium salt is promoted to an electronic excited state (denoted by an asterisk in the figure),

$$Ar_2I^+MX_n^- \xrightarrow{h\nu} (Ar_2I^+ MX_n^-)^* \longrightarrow ArI^+\cdot + Ar\cdot + MX_n^-$$

$$ArI^+\cdot + R{-}H \longrightarrow ArI^+H + R\cdot$$

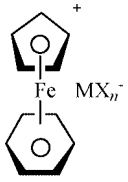
$$ArI^+H + Mx_n^- \longrightarrow ArI + H^+MX_n^-$$

Fig. 2. Reaction mechanism for the photolysis of an iodonium photoinitiator. Here, Ar represents aryl group.

and then undergoes an irreversible photofragmentation in which a carbon–iodine bond is cleaved to produce an aryliodonium radical–cation and an aryl radical. It is unclear that precisely which excited state is involved in the fragmentation reaction, as some investigators (47) have concluded that it is a singlet state, while others (52,53) have concluded that it is a triplet state. In any case, it is generally accepted that the result of the fragmentation reaction is the formation of an iodine radical–cation [this has been observed by transient absorption experiments and is highly reactive with a lifetime of approximately 6 μs (36)]. This highly reactive radical–cation will abstract a hydrogen atom from any convenient source, which can be the monomer, water, alcohol, or other impurities; rate constants for this reaction have been measured to be of the order of $10^6\ M^{-1} \cdot s^{-1}$ (36). This hydrogen abstraction step yields an aryl iodine cation and a neutral organic radical, which can initiate radical polymerizations. The aryl iodine cation will quickly expel a proton to form a neutral aryl iodine molecule and a superacid formed by the proton and the counterion. This superacid initiates the cationic polymerization by addition to the monomer. The mechanism for a sulfonium salt photoinitiator is similar with the cleavage of a carbon–sulfur bond under irradiation.

Other Onium Salts and Organometallic Photoinitiators. The success of the iodonium and sulfonium salts as photoinitiators has led to the investigation of a number of analogous onium salts based on the halides and the Group VIA atoms; however, these alternative initiators have not been widely used for various reasons. For example, chloronium and bromonium salts were prepared (57,58) and they were also found to function as cationic photoinitiators, but these salts are difficult to prepare and they have low thermal stability. Similarly, triarylselenonium salts have also been investigated and found to function as cationic initiators (59); however their preparation has been found to be expensive (60). Other onium salts such as phosphonium and arsonium salts, developed by Abu-Abdoun and co-workers for the photopolymerization of *p*-methylstyrene and styrene, have also been reported (61–63) as successful cationic photoinitiators. Photopolymerization of carbazolyloxiranes with sulfonium and tropylium salts has been reported (64). Dialkylphenacyl sulfonium photoinitiator (65–67) has been reported with excellent solubility in both polar and nonpolar monomers. Pyridinium and isoquinolinium salts have also been reported and they were found useful for polymerizing both the epoxide and vinyl ether monomers (68).

Organometallic compounds which can act as highly efficient photoinitiators for epoxide monomers have been described in the literature (25–27,69–71). The most commonly used organometallic compounds are the photoinitiators based on iron arene complex developed by the investigators at the Ciba-Geigy Corp. (37,69–71). These salts are generally prepared from ferrocene, as reviewed by Lohse and Zweifel (37). The molecular structure of a typical iron–arene complex is shown as (**3**).



3

Upon irradiation with an appropriate light source, the iron–arene complex looses the uncharged tridentate arene ligand and the positive charge moves to iron, which in association with the anion acts as a Lewis acid capable of polymerization (37). One drawback of these photoinitiators is that they are known to polymerize only the ring-opening monomers and may not be suitable for monomers with unsaturated bonds such as vinyl ethers (46).

Bimolecular Photoinitiation and Photosensitization. As mentioned above, the iodonium and sulfonium photoinitiators generally absorb light in the wavelength range of 200–300 nm. The effective initiating wavelength may be expanded by the use of photosensitizers or co-initiators, which shift the effective spectral window to well above 300 nm (into the near-UV and visible regions of the spectrum). The near-UV region of the spectrum is particularly convenient for initiating polymerizations because most monomers and resins absorb negligibly at these wavelengths, yet industrial medium and high pressure mercury lamps exhibit strong emission bands in this region. In addition, use of a large fraction of the available light contributes to an overall more efficient photolysis of the initiator and, as a consequence, acceleration in the polymerization rate. A variety of compounds can be used as photosensitizers, including heterocyclic and fused-ring aromatic hydrocarbons, organic dyes, and aromatic ketones.

In general, photosensitization results from a direct interaction between an excited photosensitizer molecule (the first excited singlet state or the lowest energy triplet state that takes place due to the absorption of photon by these molecules) and the initiator. This interaction can be either an energy transfer or an electron transfer process. In the energy transfer mechanism the excited-state photosensitizer interacts with a ground-state initiator molecule to form an exciplex. In the exciplex, the excited-state energy is transferred to the initiator by vibrational relaxation that fragments the initiator to create active centers. According to this mechanism, the photosensitizer functions essentially as a catalyst and is regenerated in its ground state. For this energy transfer to be thermodynamically feasible, the excited-state energy of the photosensitizer must be greater than that of the initiator (47), a condition which is rarely met for onium salt photoinitiators.

A second possible mechanism for photosensitization involves electron transfer from the excited state of the photosensitizer to the initiator within the exciplex (47,54,72,73). Figure 3 (73) shows the important photochemical and electron transfer steps in the reaction between anthracene (the photosensitizer) and an iodonium salt. As shown in the figure, when an anthracene molecule is exposed to light it absorbs photons and goes into the first excited singlet state. From this excited state a fraction of anthracene molecules undergoes intersystem crossing to go to the lowest triplet state, where they form an excited-state complex with the initiator molecules. There has been some ambiguity as to whether the exciplex is formed in the triplet state of the sensitizer or the singlet state. Recently, on the basis of a series of fluorescence and phosphorescence lifetime studies, combined with the photochemical rate calculations and triplet state quencher studies, Nelson and co-workers (73) reported that electron transfer occurs predominantly from the triplet excited state of anthracene to the initiator. In this exciplex anthracene may undergo electron transfer to the initiator, forming a radical cation which is capable of initiating cationic polymerization.

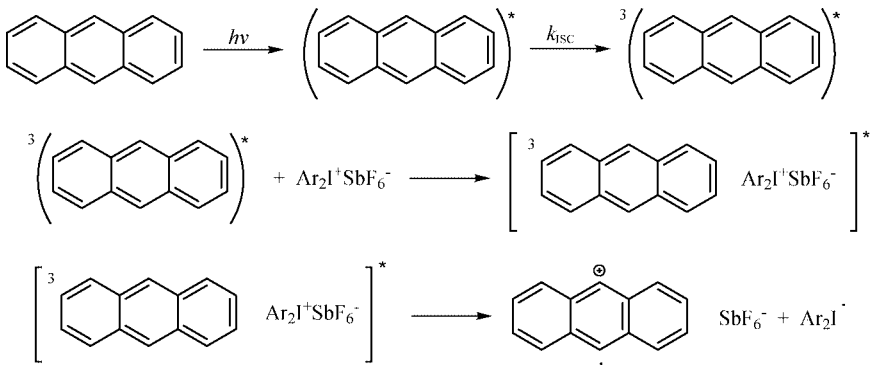


Fig. 3. Photosensitization mechanism based on electron transfer from triplet-state anthracene to the iodonium initiator (see reference 73).

For the electron transfer mechanism, the thermodynamic feasibility is governed by the excited-state energy of the photosensitizer (the state that participates in the electron transfer step), the oxidation potential of the excited-state photosensitizer, and the reduction potential of the initiator. It has generally been accepted that the photosensitization of diaryliodonium initiators most often proceeds by the electron transfer mechanism and a number of researchers have studied these reactions (38,47,54,74–77). Moorjani and co-workers (78) showed that the reaction system viscosity has an important effect on the overall rate of the photosensitization of diaryliodonium salts. As the reaction proceeds and the viscosity of the mixture increases because of polymerization, the rate of photosensitization will decrease substantially. It is therefore expected that the rate of initiation will become extremely low after a certain degree of polymerization, and that any further reaction will be almost exclusively from the propagation of existing active centers. This applies especially to the monomers that form glassy polymers. A number of references are available reporting the use of a variety of sensitizers with iodonium photoinitiators (68,79–85).

Three-Component Photoinitiator Systems. Three-component initiator systems are flexible and versatile photoinitiators that were initially developed for free-radical photopolymerizations, but may, with careful selection of the components, be used for cationic photopolymerizations. These systems generally contain a light absorbing component (often called a dye), an electron donor (typically an amine), and a third component, which is typically an iodonium salt. These initiator systems offer a number of advantages that have been demonstrated in free-radical photopolymerizations, and are also relevant for cationic photopolymerizations. For example, a wide variety of dyes may be used with the same electron donor and iodonium salt, thereby providing tremendous flexibility in selection of the initiating wavelength and therefore the light source. Indeed, effective visible-light-sensitive systems may allow use of very inexpensive light sources such as halogen and tungsten incandescent lamps. In addition, three-component systems have consistently been found to be faster, more efficient, and more sensitive than other photoinitiator systems. A variety of mechanistic investigations of free-radical three-component initiators have been reported, and the results are

generally applicable to the cationic systems as well. For a review of the literature on free radicals literature including a comprehensive list of dyes and electron donors that have been used, as well as a discussion of the mechanisms by which these reaction may proceed, see Reference 86.

Care must be taken to properly design a three-component initiator system for cationic photopolymerizations. Specifically, most of the amine electron donors that are used in free-radical initiator systems are not applicable for cationic polymerizations because they are highly nucleophilic and will terminate the cationic active center. In addition, the iodonium salt must have a nonnucleophilic anion (note that for free-radical initiation, a chloride counterion is commonly used, but is clearly inappropriate for cationic polymerizations). Fewer guidelines have been provided for selection of dyes to initiate cationic photopolymerizations. Bi and Neckers (87) demonstrated cationic photopolymerizations of epoxides initiated using a three-component initiator system containing a variety of xanthene dyes, amines with low basicity, and iodonium salts with a nonnucleophilic anion. Using this system, the polymerization was initiated by a tungsten lamp equipped with filters that eliminated light below 520 nm (where the iodonium salt does not directly absorb light). The authors further reported that presence of all the three components is required for photopolymerization above this wavelength. The authors attributed the reaction to a mechanism with three primary steps: absorption of light by the dye; production of radicals by reaction of the photoexcited dye with the amine; and production of initiating carbocations by oxidation of the radicals by the iodonium salt.

Detailed guidelines for the design of three-component initiator systems for cationic photopolymerizations were provided by Oxman and co-workers (88–91). These investigators studied a variety of electron donors, including a series of amines with systematically varying basicity (characterized by the pK_b), and varying oxidation potential (characterized by the oxidation potential relative to a saturated calomel electrode). They found that to achieve appreciable conversion of epoxide monomer the electron donor should have an oxidation potential less than 1.34 V (to achieve desired photo-induced electron transfer between the electron donor and the onium salt to produce both the cations and the radicals) and a pK_b value greater than 8 (so that the basicity of the reaction system is low enough for the Lewis acid to proceed with the cationic polymerization without getting completely consumed). These authors used the blue-light absorbing dye camphorquinone in their studies. In addition, since these photoinitiator systems produce both radicals and cations, Oxman and co-workers demonstrated their utility for controlled sequential free-radical/cationic photopolymerization of hybrid systems consisting of methacrylates and epoxides.

Monomers for Cationic Photopolymerization

A variety of classes of monomers undergo cationic chain polymerization, including epoxides, vinyl ethers, propenyl ethers, siloxanes, oxetanes, cyclic acetals and formals, cyclic sulfides, lactones, and lactams. Any monomer that undergoes cationic polymerization is a candidate for cationic photopolymerization, and a suitable monomer may be selected based upon the specific requirements of the application.

Note that these cationically polymerizable monomers include both unsaturated monomers that undergo a chain polymerization through the carbon–carbon double bond, and cyclic ethers that undergo ring-opening polymerizations. An unsaturated monomer is capable of cationic polymerization only if a carbon atom that participates in the double bond also has an electron-releasing substituent such as an alkoxy, phenyl, vinyl, or 1,1-dialkyl group (92). Presence of any of these substituents produces an electron-rich double bond susceptible to electrophilic attack by the propagating cation. Cyclic ethers undergo cationic polymerization because of the presence of the accessible ether electron lone pairs, which are also susceptible to electrophilic attack by the propagating cation, as described in more detail below.

Cationic Ring-Opening Photopolymerization. A number of cyclic monomers can be polymerized by the ring-opening process, including ethers (oxiranes, oxetanes, etc), acetals, amides (lactams), esters (lactones), siloxanes, and sulfides (92). Thermodynamically, ring-opening polymerization of cyclic ethers is favored for all except the six-membered ring (the Gibbs free energy is positive for opening a six-membered ring), and the three- and four-membered rings (oxiranes and oxetanes, respectively) exhibit the most strain and therefore the most rapid polymerizations. Copolymerization of oxirane and oxetane has also been studied (93,94) and presence of oxetane has been reported to increase the overall polymerization rate. Figure 4 shows representative molecular structures of some prominent classes of monomers which undergo ring-opening polymerization. By far the most widely used and thoroughly studied monomers are the oxiranes or epoxides and therefore these monomers provide the basis for most of our discussion. Historically, the epoxide monomers were developed for condensation polymerization with other nucleophilic species such as amines and anhydrides, but they were found to be suitable for cationic ring-opening polymerization as well.

The generally accepted propagation mechanism for cationic ring-opening polymerization for ethylene oxide is shown in Figure 5. According to this mechanism, the proton of the superacid (produced from the initiation step as explained in

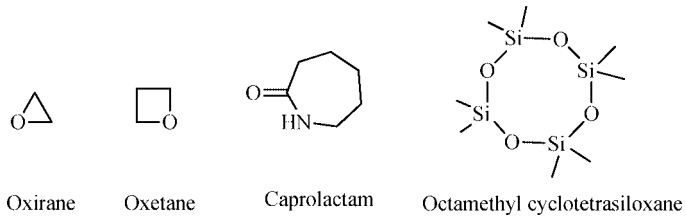

Fig. 4. Molecular structures of representative monomers which undergo cationic ring-opening polymerization.

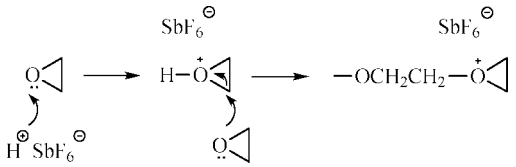

Fig. 5. Propagation step for cationic polymerization of an ethylene oxide monomer.

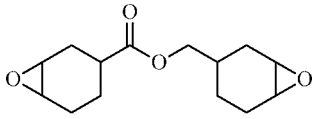
an earlier section) undergoes an electrophilic addition to the oxygen atom present in the epoxide ring, resulting in the formation of an oxonium ion, which is the propagating species. The α-carbon of the oxonium ion is electron deficient because of its proximity to the positively charged oxygen, and is therefore subject to nucleophilic attack by a monomer unit. This nucleophilic attack opens the epoxide ring (by breaking the carbon–oxygen bond) and produces a new oxonium ion, thereby propagating the active center to the new monomer unit. This process is repeated a number of times to make a polymer chain, and the polymer chain length is determined by the number of propagation steps that occur before the active center undergoes chain transfer or termination. The kinetics of the propagation reaction and the reaction parameters affecting it are examined in more detail in the next section.

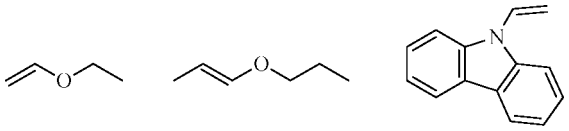
Commercial epoxide monomers can be generally categorized into two classes: glycidyl ether resins and cycloaliphatic epoxides. An industry standard cycloaliphatic epoxide is 3,4-epoxycyclohexylmethyl-3,4-epoxycyclohexane carboxylate (**4**).



4

The structure of an epoxide plays an important role in the polymerization reactivity, as characterized in a number of papers including References 95 and 96. In general, cycloaliphatic epoxides exhibit shorter cure times than do the glycidyl ether resins because of the enhanced epoxy ring strain, which promotes the ring opening of the oxonium ion during the propagation step (17). In addition, viscosity of the cycloaliphatic epoxides is generally lower than that of the glycidyl ethers and hence they may be used as reactive diluents with the latter.

Cationic Photopolymerization of Unsaturated Monomers. Prominent classes of cationically polymerizable unsaturated monomers include vinyl ethers (**5**), propenyl ethers (**6**), and *N*-vinylcarbazole (**7**).



5 **6** **7**

Although a number of unsaturated monomers theoretically may undergo cationic photopolymerizations, there have been few studies of these photopolymerization systems reported in the literature. In the last decade some systematic studies of the cationic photopolymerization of vinyl ethers have been reported; therefore these systems are the focus of our discussion. Vinyl ether and propenyl ether monomers are among the most reactive monomers (which polymerize by a cationic mechanism) and they exhibit low vapor pressure, low toxicity, and relatively low viscosity. Hence, these monomers may be used as reactive diluents to enhance the effective cure rates of epoxide photopolymerizations.

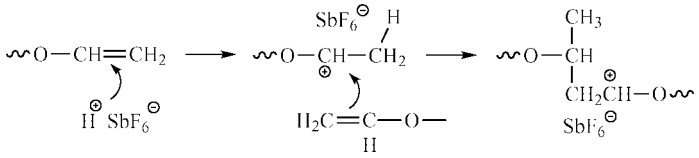


Fig. 6. Propagation step for cationic polymerization of a vinyl ether monomer.

The propagation mechanism for cationic polymerization of a vinyl ether monomer is shown in Figure 6. According to this mechanism, proton of the superacid (produced from the initiation step as explained in an earlier section) breaks the carbon–carbon double bond by attaching itself to one carbon atom, making the other carbon atom electron deficient. This carbocation is subjected to a nucleophilic attack by another monomer molecule which results in the formation of a carbon–carbon bond and transfer of the positive charge to the other carbon atom. This process is repeated a number of times to produce the polymer chain (again, the polymer chain length is determined by the number of propagation steps that occur before the active center undergoes chain transfer or termination).

Development of New Monomers. In the past decade, several new cationically polymerizable monomers exhibiting enhanced reaction rates and desirable film properties have been reported, most notably by Crivello and collaborators. These monomers may not be commercially available; however, a synthetic scheme for preparation of such monomers is usually provided. A detailed account of the utility of each monomer is beyond the scope of this article; however, a list of references that may be useful to the interested reader is provided here. Examples of novel cationically polymerizable monomers include epoxide monomers based on benzyl, allyl, propargyl acetal, and propargyl ether groups (97); epoxide monomers based on α-terpineol (98); difunctional epoxide monomers (99); epoxide monomers based on bisvinyl ethers or propenyl ethers (16,100); monomers based on 1-butenyl ethers (101,102) or 1-butenyl glycidyl ether (103); 1-propenyl ethers (104–107) or 1-propenyl glycidyl ethers (108); aromatic monomers bearing two, three, four, and six cationically polymerizable vinyl, isopropenyl, or propenyl functional groups (109); novel silicon-containing epoxy resins (110–113), oxetanes (114), and 1-propenyl ethers (115,116); novel cycloaliphatic epoxide monomers (117); multifunctional monomers bearing a combination of either epoxy, vinyl ether, cycloaliphatic epoxy, or 1-propenyl ether groups (118,119); ketene acetals (120); epoxy norbornane monomers (121,122); mono-, bi-, and trifunctional oxetanes (123); alkoxy allene monomers (124); monomers based on nopol (125); and dicyclopentadiene (126,127); monomers bearing two, four, and six aryl 2-propenyl groups prepared by isomerization of corresponding allyl groups (128); monomers based on isopropylphenoxy groups (129,130); carbazolyl containing epoxy monomers (131); and novel cycloaliphatic epoxide monomers bearing benzyl ether groups (132). Finally, it should be noted that a wide variety of cationically polymerizable epoxide monomers have been prepared from inexpensive and biorenewable sources such as linseed oil and soybean oil (133–135). In addition, epoxidized soybean oil has also been studied as a reactive diluent with other monomers and the polymerization rate of the reaction system has been characterized (135–137).

Kinetics of Cationic Photopolymerization

Cationic polymerizations, like other chain polymerizations, begin with the initiation step (which results in the production of active centers); then proceed by the propagation step in which the active center reacts successively with a number of monomer molecules to link them covalently into a polymer chain; and finally may end in a termination step in which the active centers are consumed by a chemical reaction. The photoinitiation step, as described in detail in the preceding section, is the only step that is dependent on light. Once the active centers are produced the propagation and termination steps generally proceed by the normal cationic polymerization processes and are subject to the usual reaction variables and kinetic considerations, although the typical counterions for cationic photopolymerization may be different than those used in thermal cationic polymerizations. This may be important since the counterions generally have a marked effect on both the propagation and termination reactions. Finally, in the presence of a Lewis base such as water or alcohols, a growing cationic polymer chain may undergo a chain transfer reaction, which results in the termination of one growing chain and the generation of a proton capable of initiating a new chain. This reaction can have a significant effect on the structure of the polymer, especially in crosslinked systems. In thin coatings exposed to humid air, polymerization may even be suppressed.

The polymer chain length (the number of repeat units per chain, or degree of polymerization) is determined by the number of propagation steps that occur before the active center undergoes chain transfer or termination. In contrast, the kinetic chain length corresponds to the total number of propagation steps that occur during the lifetime of the active center, and therefore corresponds to the number of propagation steps that occur before termination. If no chain transfer occurs the polymer chain length is equal to the kinetic chain length, however, trace amounts of nucleophiles such as water or alcohol are typically present and active center chain transfer is common in cationic polymerization. For this reason the degree of polymerization in cationic photopolymerization is typically significantly lower than the kinetic chain length.

The kinetics of cationic polymerizations are considerably more complex than those of the free-radical polymerizations, and kinetic data is difficult to interpret because of several reasons (92,138–140). For example, in cationic polymerizations the identity and proximity of the counterion has a marked effect on the reactivity of the active center. An active center that is encumbered by a closely associated counterion has a dramatically lower reactivity (typically an order of magnitude lower) than an active center that is separated from the counterion. As described in the section on photoinitiation, this consideration has lead to the development of large, nonnucleophilic counterions; however the reactivity of a cationic active center still depends on the proximity of the counterion. Therefore, at any given time, a variety of propagating species may exist, ranging from ion pairs to separated ions. For this reason, an effective propagation rate constant which includes contributions from all propagating species is usually adopted, as described below. Secondly, unlike free-radical polymerizations, the steady-state approximation for active center concentration is not valid since the cationic active centers are not reactive toward one another, and the rate of active center

generation through initiation is typically much higher than the rate of consumption of active centers through termination. Therefore, the active center concentration generally increases continuously until the photoinitiator is completely consumed, and must be either measured experimentally (which is extremely difficult) or calculated using unsteady-state species balances. Photosensitized polymerizations are further complicated by the fact that the rate of generation of active centers depends upon the system viscosity (which changes appreciably during the course of the reaction). With these general considerations in mind, in this section we provide an overview of the propagation and termination reactions in cationic photopolymerization, focusing on the aspects that will be of greatest value to scientists and engineers considering these systems for studies or applications.

***In Situ* Characterization of the Rate of Cationic Photopolymerization.** Before an examination of the propagation and termination reactions individually, a brief overview of the methods that have been used to obtain profiles of the polymerization rate as a function of time is provided. The photopolymerization rate can be monitored by any technique that measures a physical quantity which changes as the reaction progresses. In theory, a wide variety of analytical techniques could be used for this purpose (139–148), and new methods are continuously being developed (149). The commonly used methods for obtaining complete polymerization rate profiles are differential scanning calorimetry, fluorescence spectroscopy, and vibrational spectroscopies such as Raman and infrared.

Differential scanning calorimeter (DSC) has, perhaps, become the most widely used instrument for studying the kinetics of polymerization reactions (139,141,142). In this calorimetric technique, the reaction rate is monitored by measuring the heat released during the exothermic polymerization. For homopolymerizations, the rate at which heat is released is directly proportional to the polymerization rate, and conversion profiles can be obtained by integrating the reaction rate profiles. The DSC response time is relatively slow (of the order of 2–3 s); therefore this technique cannot be used for rapid photopolymerization systems. Real-time infrared (RTIR) spectroscopy was developed by Decker and Moussa in the early 1990s (143) to investigate the polymerization of acrylates. This technique has also been used to investigate the polymerization of epoxides (144) by simultaneously monitoring the monomer consumption and the polymer formation by using two IR detectors at the wavelengths of 790 and 1100 cm^{-1}, respectively. Infrared spectroscopy (both FTIR and RTIR) has sufficient time resolution to monitor rapid polymerizations. For example, FTIR instruments generally allow spectra to be collected every 40 or 50 ms. Raman spectroscopy has also been used for *in situ* monitoring of photopolymerizations of vinyl ether, acrylates, etc. Raman spectroscopy involves the inelastic scattering of photons rather than their direct absorption or emission by a material; therefore the intrinsic time scale of this method is extremely fast (of the order of femtoseconds). The practical time resolution is determined by the signal intensity, and generally several usable spectra can be acquired in a second (140,145). Fluorescence spectroscopy has been used for real-time monitoring of polymerizations and generally the monitoring schemes are based upon fluorescence probes which exhibit enhanced fluorescence intensity with change in variables such as system viscosity with the progress of polymerization due to decreased nonradiative energy transfer (72,146–148).

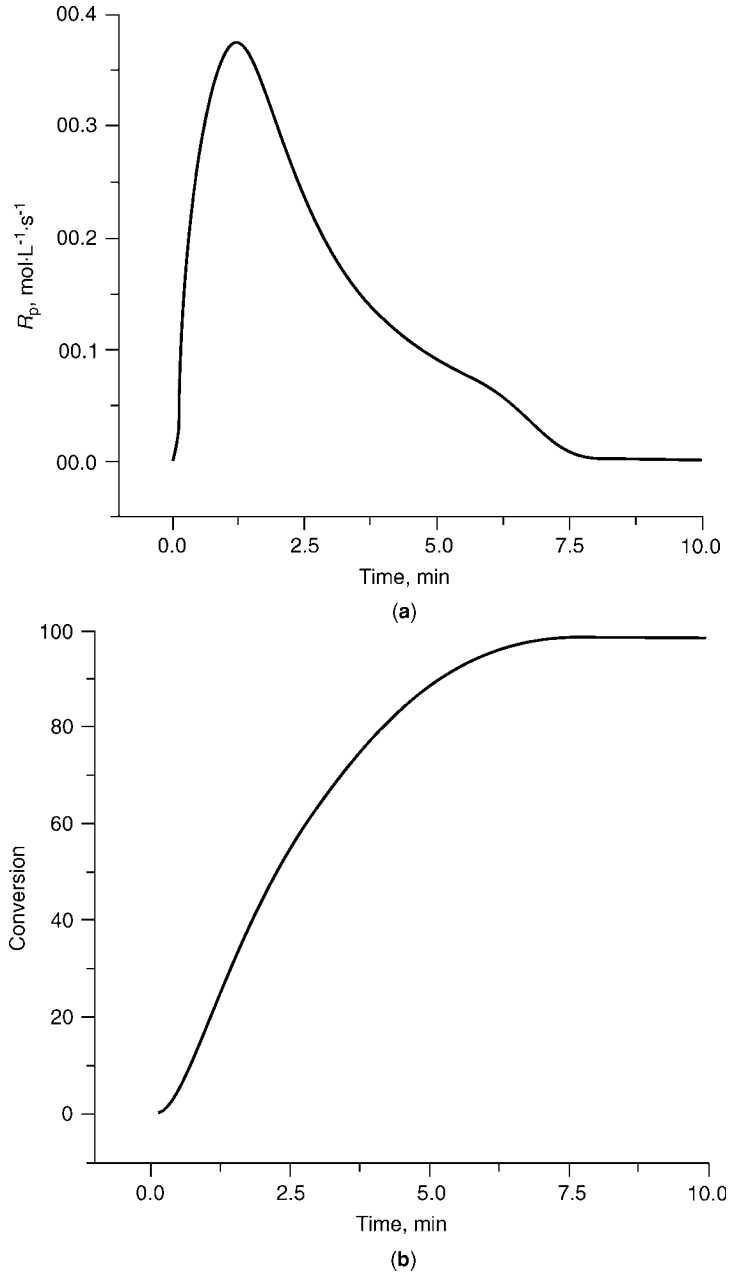

Fig. 7. Polymerization rate and percentage conversion vs time profiles for photopolymerization of phenyl glycidyl ether initiated using 8.86 mM of iodonium tetrakis pentafluorophenyl borate salt at 50°C and light intensity of 25 mW·cm^{-2} (see reference 150).

Figure 7 (150) contains profiles of the polymerization rate and conversion as function of time for cationic photopolymerization of an epoxide monomer obtained using a photo-DSC. As shown in the figure, the reaction rate profile has a general shape that is characteristic of cationic photopolymerizations. Immediately

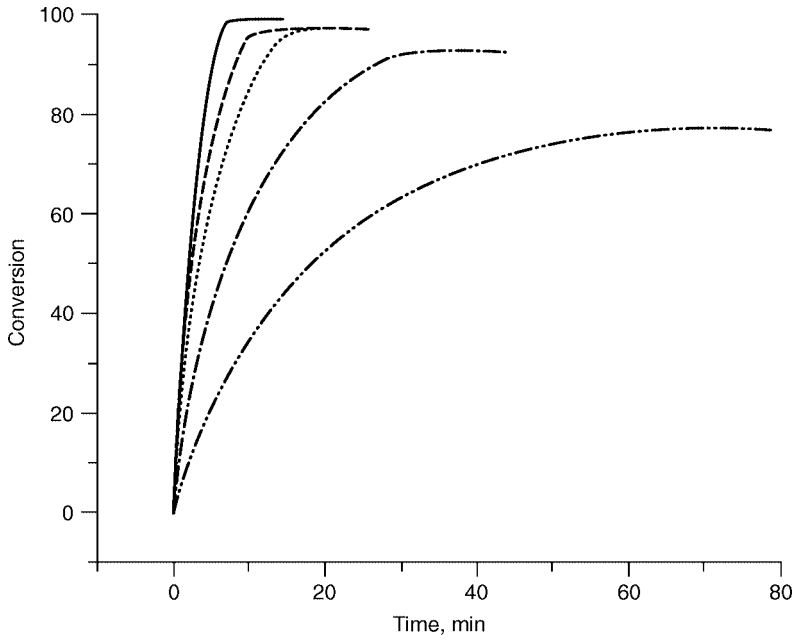

Fig. 8. Profiles of percentage conversion vs time for various illumination times for photopolymerizations of phenyl glycidyl ether initiated using 8.86 m*M* of iodonium tetrakis pentafluorophenyl borate salt at 50°C and light intensity of 25 mW·cm^{-2} (see reference 150). ——; Full illumination; – – 90-s illumination; - - - 60-s illumination; – - – 30-s illumination; – - - – 15-s illumination.

upon illumination, cationic active centers are produced and they react with the surrounding monomer molecules to form a growing polymer chain. The reaction rate increases monotonically because of the increase in the concentration of active centers, reaches a peak, and then decreases, primarily because of the decrease in the concentration of monomer. Typically, as the conversion reaches a high value, the polymerization rate will slow because of diffusional limitations and may ultimately stop at a limiting conversion below 100% if the system turns glassy and vitrification occurs.

One important characteristic of cationic photopolymerization is that the reaction continues for a long time even after the light has been shuttered off. This is strikingly different from free-radical photopolymerization where the reaction stops in a very short time in dark. Figure 8 (150) shows the reaction rate as a function of time for photopolymerization of an epoxide monomer for various illumination times. The figure contains profiles of the conversion as a function of time for five identical reaction systems illuminated for different periods of time ranging from 15 s to the duration of the experiment (full illumination) and it shows that the polymerization reaction proceeds long after the illumination has ceased, often consuming all of the monomer. For example, the sample that was illuminated for only 15 s continues to react for more than an hour in the dark.

Rate Constants for Propagation and Termination. For cationic chain polymerizations, the rate of polymerization is generally accepted to be proportional

to the product of the monomer concentration and the active center concentration, with the proportionality constant being the effective propagation rate constant k_p, as shown in equation 1:

$$R_p = k_p[M][M^+] \quad (1)$$

The propagation rate constant k_p includes contributions from a variety of propagating species ranging from ion pairs to separated ions. The value of k_p depends, of course, on the monomer being polymerized (the previous section contained a description of attempts to create new, highly reactive monomers), and for a given monomer the value of k_p also depends upon the temperature, the photoinitiator anion, and the proximity of the counterion to the active center, as described below. The propagation rate constants for vinyl ether and epoxide monomers have been studied extensively using techniques such as differential scanning calorimetry and Raman spectroscopy (139,140,150,151).

An interesting hypothesis that has been reported in the literature (139,140) is that the value of k_p can change appreciably during the course of the reaction because of a change in the proximity of the counterion and the active center. According to this hypothesis, k_p initially increases sharply, then levels off at a plateau value, and finally as the limiting conversion is reached the value of k_p decreases. At the beginning of the polymerization reaction, it is hypothesized that the active center and the counterion are relatively close to one another since the viscosity is relatively low, and the diffusional mobility of the counterion allows it to move with the cation. As the polymerization progresses there is an increase in the system viscosity, which reduces diffusional mobility of all the species present in the reaction system. The active center retains considerable mobility through propagation since the cation effectively moves through the reaction mixture by reacting with the monomer units (which is termed *reaction diffusion*). The counterion, however, experiences a decrease in mobility as the system viscosity increases, since it has to physically diffuse through the reaction mixture. During this process, the counterion and the active center separate, and since the separated ions are much more reactive than the ion pairs, it leads to a large increase in the value of k_p. Finally, the value of k_p decreases because of the trapping of the active centers. Therefore, a limiting conversion at which the reaction ceases is observed despite the presence of active centers and unreacted monomer.

The rate of termination and, consequently, the active center lifetime for the cationic and radical polymerizations are notably different. Free radicals, which are highly reactive toward one another, have very high termination rate constants (of the order of 10^5 $L \cdot mol^{-1} \cdot s^{-1}$) and have correspondingly short active centers lifetimes (typically less than a second). In contrast, for cationic polymerizations the rate of consumption of active centers is very slow, and generally takes place by some type of nucleophilic attack on the propagating cation. The precise nature of this chemical termination may be system specific, and is generally not well understood. In some cases, termination may occur by combination of the propagating active center with the anion. For example an active center may combine with the metal halide ion such as PF_6^- (the photoinitiator anion), abstract a fluorine atom, and expel a proton, thus regenerating a Lewis acid. Although it has been relatively unstudied, the average cationic active center lifetime has been found to be of the order of tens of minutes (139,140,150).

In addition to this termination by a chemical reaction, the active center may stop propagating owing to trapping. In this case, although the active centers are still present (they have not terminated per se), they are no longer propagating because the surrounding monomer molecules have polymerized and the active centers are unable to access the unreacted monomer. If the "termination" reaction is studied by investigating the reduction of the polymerization rate in the dark, then trapping cannot be distinguished from chemical termination. The termination/trapping of the active centers is commonly modeled as first order, which results in the following equation:

$$\frac{d[M^+]}{dt} = -k_{t/t}[M^+] \tag{2}$$

Here, $[M^+]$ corresponds to the concentration of propagating (untrapped) active centers, while $k_{t/t}$ represents the first-order kinetic rate constant for termination/trapping of active centers.

Effect of Light Intensity. The rate of a cationic photopolymerization depends upon the incident light intensity (radiant flux or photon flux) since an increasing light intensity increases the rate of production of active centers. The rate constants for propagation and termination are independent of light intensity. Therefore, in equation 1, the effect of light intensity is contained within the active center concentration $[M^+]$. The relationship between the light intensity and the active center concentration can be captured within a rate constant for absorbance, k_{abs}, defined as the product of the incident photon flux and the photoinitiator absorption cross section summed over all incident wavelengths (150). The concentration of cationic active centers produced by the photolysis of a photoinitiator (unimolecular initiation) is given by equation 3:

$$[M^+] = \phi I_0(1 - e^{-k_{abs}t}) \tag{3}$$

Here, ϕ is the quantum yield of the photoinitiator cleavage (the number of active centers formed per photon absorbed), and I_0 is the photoinitiator concentration at time $t = 0$. This equation illustrates that the active center concentration is not at steady state, but rather grows with time until the photoinitiator is consumed. Note that this equation accounts only for production of active centers by photolysis. To completely describe the active center concentration, equations 2 and 3 should be combined to account for both the production and the consumption of active centers. It is important to note that while the incident light intensity does affect the rate of polymerization, it generally has no impact on the final limiting conversion (if the temperature is held constant).

Effect of Temperature and Photoinitiator Anion. The polymerization temperature has a significant effect on both the rate of polymerization and the final limiting conversion. For example, Figure 9 contains a series of plots of reaction rate as a function of time for photopolymerization of an epoxide monomer. This figure illustrates that as the temperature is increased, the peak reaction rate increases and the reaction time decreases. The increase in reaction rate with increasing temperature ultimately arises from the effect of temperature on the propagation rate constant (which increases with increasing temperature as described by the Arrhenius equation for the rate constants). The rate of photoinitiation is

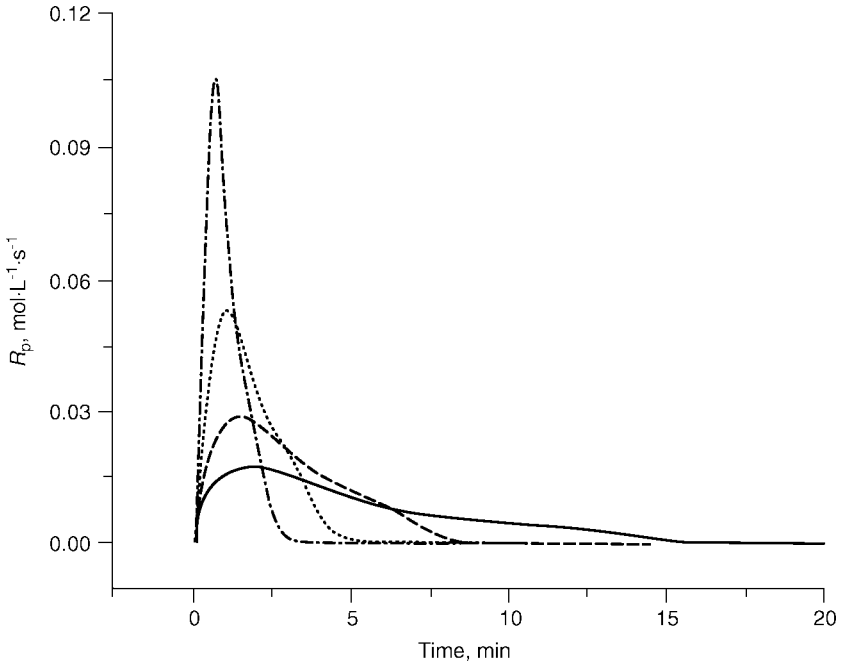

Fig. 9. Effect of temperature on the reaction rate as a function of time for photopolymerizations of phenyl glycidyl ether initiated using 8.86 m*M* of iodonium tetrakis pentafluorophenyl borate salt at light intensity of 25 mW·cm^{-2}. ——— 40°C; - - - - 40°C; ····· 60°C; -·-·- 70°C.

generally independent of temperature (for unimolecular photoinitiation the activation energy is zero since the initiating energy comes from light rather than heat). In addition, as the temperature is increased the final limiting conversion invariably increases because of enhanced mobility of the active centers and diminishing effect of vitrification. The effect of temperature on the propagation and termination rate constants for cationic photopolymerizations of a few vinyl ether and epoxide monomers have been reported (140,150). For example, propagation and termination rate constants for photopolymerization of an epoxide monomer are shown in Table 1 (150).

Table 1. Effect of the Temperature and the Photoinitiator Counterion on the Termination and Propagation Rate Constants[a]

	Iodonium tetrakis pentafluorophenyl borate salt		Iodonium hexafluoroantimonate salt	
Temperature, °C	k_t, s^{-1}	k_p, L·mol^{-1}·s^{-1}	k_t, s^{-1}	k_p, L·mol^{-1}·s^{-1}
50	4.5×10^{-4}	0.6	6.8×10^{-4}	0.4
60	5.5×10^{-4}	1.4	11.3×10^{-4}	0.8

[a] For photopolymerizations of phenyl glycidyl ether monomer at 50°C and 25 mW·cm^{-2} light intensity and at 8.86 m*M* concentration of photoinitiators (see reference 150).

The data in Table 1 also illustrate the effect of the size of the counterion on the values of the propagation and termination rate constant (150,151). This table illustrates that the tetrakis pentafluorophenyl borate anion, which is 14 times more voluminous than the hexafluoroantimonate anion, results in a higher propagation rate constant and lower termination rate constant for the photopolymerization. These are the expected trends since the larger counterion will result in a more weakly associated ion pair.
