Mechanical polishing is one of the most widely used methods in surface preparation. Generally, mechanical polishing consists of several steps. The specimens are initially abraded with silicon carbide paper of various grades, from 400 to 1000 grit. After that, successive additional fine mechanical polishing on silk disks with diamond powders and sprays (up to 1/10 μm grain size) is practiced to yield a mirror finish. This results in a bright and smooth surface suitable for optical measurements. But, it is well known that mechanical treatments change the structure of surface layers to varying depths depending on the material and the treatment. Mechanically polished surfaces do not have the same structural and optical properties as the bulk material. As a result of mechanical polishing, surface crystallinity is impaired. In addition, there exists a thin deformed layer extending from the surface to the interior due to the friction and heating caused by mechanical polishing. Such changes are revealed by the deviations in the optical properties of the surface from those of the bulk. Hence mechanical polishing is utilized as a sole preparation method, primarily if the specimen will be used as a substrate for ellipsometric study of some other surface reactions, e.g., adsorption, thermal, or electrochemical formation of oxide films and polymer electrodeposition.

Chemical Polishing

This method of surface preparation is generally used after mechanical polishing in order to remove the damaged layer produced by the mechanical action. A specimen is immersed in a bath for a controlled time and subsequently ultrasonically washed in an alcohol solution. The final cleaning is extremely important to remove bath components that may otherwise be trapped on the surface.

Various baths of different chemical compositions and immersion conditions (temperature of bath and time of treatment depending on the nature of the metal specimen) are described in the literature (Tegart, 1960). During chemical polishing, oxygen evolution is possible along with the chemical dissolution of the metal substrate. In such cases, the polished surfaces may lose their reflectivity, becoming less suitable for optical measurements. A major problem associated with chemical polishing is the possible formation of surface viscous layers that result in impurities on the surface. Care must be taken to identify and remove impurities like S, Cl, N, O, and C that might be formed by the use of chemicals.

Electrochemical Polishing

Electrochemical polishing is a better way to prepare metal surfaces than mechanical and chemical polishing. The metal is placed in an electrochemical cell as an anode, while a Pt or carbon electrode with a large surface area is used as the cathode. Passage of current causes the dissolution of parts of the metal surface, the peaks dissolving at a greater rate than the valleys, which leads to planarization and a subsequently reflecting surface.

Electrochemical Dissolution of Natural Oxide Films

Dissolution of the naturally formed oxide films can be carried out by cathodic polarization. It is very important to determine an optimum value of the cathodic potential for each metal in order to minimize the thickness of the oxide layer. For potentials more anodic than the optimum value, the dissolution is very slow and the natural oxide film is not dissolved completely. Potentials higher than this optimum increase the risk for hydrogen contamination at the surface, its penetration in the substrate, and its inclusion in the metal lattice. The formation of thin hydrated layers is also possible.

PROBLEMS

There are various sources, some from the equipment and others from the measuring system or the measurement process itself, that can introduce errors and uncertainties during an ellipsometric measurement. Most of these errors are correctable with certain precautions and corrections during or after the experiment.

A frequent source of error is the presence of a residual oxide layer on the surface of the film under study. The presence of even a very thin film (50 Å) can cause the refractive index to be markedly different than the actual substrate value (Archer, 1962). Hence, in the case of an absorbing substrate and a nonabsorbing thin film, four optical parameters need to be determined: the refractive index and the thickness of the film, n_2 and d_2, and the complex refractive index coefficients of the substrate, n_3 and k_3. Since only two parameters are determined, Δ and ψ, it is not possible to determine all four parameters using a single measurement. To estimate the optical properties of the substrate, multiple measurements are made (So and Vedam, 1972) using (1) various film thickness values, (2) various angles of incidence, or (3) various incident media. One set of substrate optical properties consistent with all the multiple readings can then be found.

Errors in measurement also occur due to surface roughness in the substrate (or the film). Predictions of the optical parameters for surfaces with very minor surface roughness (50 Å) have shown large errors in the determined refractive indices (Festenmaker and McCrackin, 1969). Hence, it is imperative that one has a good knowledge of the degree of impurities or abnormalities that a sample might have. Sample preparation is crucial to the accuracy of the results, and care must be taken to determine a method most suited for the particular application.

The polarizer, compensator, and analyzer are all subject to possibly incorrect settings and hence azimuth errors. The analysis can be freed from azimuth errors by performing the analysis and averaging the results with components set at angles that are 90° apart, described as zone averaging by McCrackin et al. (1963).

The magnitudes of Δ and ψ vary as a function of the angle of incidence. There are several types of systematic errors encountered during the angle-of-incidence measurements that produce errors in Δ and ψ. Many studies suggest that the derived constants are not true constants, but are dependent on the incidence angle (Vasicek, 1960; Martens et al., 1963). The beam area divided by the cosine of the angle of incidence gives the area of the surface under examination. Hence, there is a significant increase in the area under examination for a small change in the incident angle. A change in the angle of incidence simultaneously changes the area of the surface under examination. As a matter of convenience, it is suggested that the ellipsometric measurements be made with an angle of incidence near the principal angle, i.e., the angle at which the relative phase shift between the parallel and perpendicular components of reflected light, Δ, is 90°. The value of this principal angle depends mainly on the refractive index of the substrate, and is between 60° and 80° for typical metal substrates.

Other sources of error include those arising from the deflection of the incident light beam due to an imperfection in the polarizer, multiply reflected beams, and incompletely polarized incident light. The importance of reliable and accurate optical components should therefore be stressed, since most of these errors are connected to the quality of the equipment one procures.

It should also be noted that the steps after the experimental determination of Δ and ψ are also susceptible to error. One typically has to input the values of Δ and ψ into a numerical algorithm to compute the optical properties. One should have an idea of the precision of the computation accuracy of the input data. There are also cases in which the approximations in the relations used to compute the physical parameters are more extensive than necessary and introduce more uncertainty than a conservative approach would cause.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

A	Analyzer settings with respect to the plane of incidence, deg
C	Compensator settings with respect to the plane of incidence, deg
E_i	Amplitude of the incident electric wave
E_r	Amplititude of the reflected electric wave
d	Film thickness, cm
E_x	Amplitude of the electric wave in the x axis
i	$\sqrt{-1}$
k	Absorption index (imaginary part of the refractive index)
n	Real part of the refractive index
$\hat{n}$	Complex refractive index
P	Polarizer settings with respect to the plane of incidence, deg
Q	Compensator settings with respect to the plane of incidence, deg
R	Reflectivity
r_p	Fresnel reflection coefficient for light polarized parallel to the plane of incidence
r_s	Fresnel reflection coefficient for light polarized perpendicular to the plane of incidence
Δ	Relative phase change, deg
δ	Change of phase of the beam crossing the film
$\hat{\varepsilon}$	Complex dielectric function
λ	Wavelength, cm
ν	Frequency, s^{-1}
ρ	Ratio of complex reflection coefficients
$\hat{\sigma}$	Complex optical conductivity
φ	Angle of incidence, deg
$\tan\psi$	Relative amplitude attenuation, deg
ω	Angular velocity, rad

IMPULSIVE STIMULATED THERMAL SCATTERING

INTRODUCTION

Impulsive stimulated thermal scattering (ISTS) is a purely optical, non-contacting method for characterizing the acoustic behavior of surfaces, thin membranes, coatings, and multilayer assemblies (Rogers et al., 2000a), as well as bulk materials (Nelson and Fayer, 1980). The method has emerged as a useful tool for materials research in part because: (1) it enables accurate, fast, and nondestructive measurement of important acoustic (direct) and elastic (derived) properties that can be difficult or impossible to evaluate in thin films using other techniques; (2) it can be applied to a wide range of materials that occur in microelectronics, biotechnology, optics, and other areas of technology; and (3) it does not require specialized test structures or impedance-matching fluids which are commonly needed for conventional mechanical and acoustic tests. Further, recent advances in experimental design have simplified the ISTS measurement dramatically, resulting in straightforward, low-cost setups, and even in the development of a commercial ISTS photoacoustic instrument that requires no user adjustments of lasers or optics. With this tool, automated single-point measurements, as well as scanning-mode acquisition of images of acoustic and other physical properties, are routine.

ISTS, which is based on transient grating (TG) methods (Nelson and Fayer, 1980; Eichler et al., 1986), is a spectroscopic technique that measures the acoustic properties of thin films over a range of acoustic wavelengths. It uses mild heating produced by crossed picosecond laser pulses to launch coherent, wavelength-tunable acoustic modes and thermal disturbances. The time-dependent surface ripple produced by these motions diffracts a continuous-wave probing laser beam that is overlapped with the excited region of the sample. Measuring the temporal variation of the intensity of the diffracted light yields the frequencies and damping rates of acoustic waves that propagate in the plane of the film. It also determines the arrival times of acoustic echoes generated by subsurface reflections of longitudinal acoustic wavepackets that are launched at the surface of the film. The wavelength dependence of the acoustic phase velocities (i.e., product of the frequency and the wavelength) of in-plane modes, which is known as the acoustic dispersion, is determined either from a single measurement that involves the excitation of acoustic waves with a well defined set of wavelengths, or from the combined results of a series of measurements that each determine the acoustic response at a single wavelength. Interpreting this dispersion with suitable models of the acoustic waveguide physics yields viscoelastic (e.g., Young's modulus, Poisson's ratio, acoustic damping rates, stress, etc.) and/or other physical properties (e.g., density, thickness, presence or absence of adhesion, etc.) of the films. The acoustic echoes, which are recorded in the same measurements, provide additional information that can simplify this modeling. The ISTS data also generally contain information from nonacoustic (e.g., thermal, electronic, etc.) responses. This unit, however, focuses only on ISTS measurement of acoustic motions in thin films. It begins with an overview of other related measurement techniques. It then describes the ISTS acoustic data and demonstrates how it can be used to determine: (1) the stress and flexural rigidity in thin membranes (Rogers and Bogart, 2000; Rogers et al., 2000b; Rogers and Nelson, 1995); (2) the elastic constants of membranes and supported films (Rogers and Nelson, 1995; Duggal et al., 1992; Shen et al., 1996; Rogers and Nelson, 1994; Rogers et al., 1994a); and (3) the thicknesses of single or multiple films in multilayer stacks (Banet et al., 1998; Gostein et al., 2000).

Competitive and Related Techniques

Acoustic properties of thin films are most commonly evaluated with conventional ultrasonic tests, which involve a

source of ultrasound (e.g., a transducer), a propagation path, and a detector. The ability to excite and detect acoustic waves with wavelengths that are short enough for thin film evaluation (i.e., wavelengths comparable to or smaller than the film thickness) requires high-frequency transducers/detectors fabricated directly on the sample, or coupled efficiently to it with impedance-matching liquids or gels. Both of these approaches restrict the range of structures that can be examined; they limit the usefulness of conventional acoustic tests for thin film measurement. Photoacoustic methods overcome the challenge of acoustic coupling by using laser light to excite and probe acoustic disturbances without contacting the sample. In addition to ISTS, there are two other general classes of photoacoustic techniques for measuring acoustics in thin films. In the first, a single excitation pulse arrives at the surface of the sample and launches, through mild heating, a longitudinal (i.e., compressional) acoustic wavepacket that propagates into the depth of the structure (Thomsen et al., 1986; Eesley et al., 1987; Wright and Kawashima, 1991). Parts of this acoustic disturbance reflect at buried interfaces, such as the one between the film and its support or between films in a complex multilayer stack. A variably delayed probe pulse measures the time dependence of the optical reflectivity or the slope of the front surface of the sample in order to determine the time of arrival of the various acoustic echoes. Data from this type of measurement are similar in information content to the acoustic echo component of the ISTS signal. In both cases, the data reveal the out-of-plane longitudinal acoustic velocities when the thicknesses of the films are known. The measured acoustic reflectivity can also be used to determine properties (e.g., density) that are related to the change in acoustic impedance that occurs at the interface. This technique has the disadvantage that it requires the excitation pulses to be strongly absorbed by the sample. It also typically relies on expensive and complex femtosec laser sources and relatively slow detection schemes that use probe pulses. Although it can be used to measure thicknesses accurately, it does not yield information on transversely polarized (i.e., shear) acoustic waves or on modes that propagate in the plane of the film. As a result, the only elastic property that can be evaluated easily is the out-of-plane compressional modulus.

Another method uses a cylindrically-focused excitation pulse as a broadband line source for surface propagating waves (Neubrand and Hess, 1992; Hess, 1996). Examining the changes in position, intensity, or phase of at least one other laser beam that strikes the sample at a location spatially separated from the excitation region provides a means for probing these waves. The data enable reliable measurement of surface acoustic wave velocities over a continuous range of acoustic wavelengths (i.e., the dispersion) when the separation between the excitation and probing beams (or between the probing beams themselves) is known precisely. The measured dispersion can be used, with suitable models for the acoustic physics, to extract other properties (e.g., density, thickness, elastic properties) of the samples. This technique has the disadvantage that out-of-plane acoustic properties are not probed directly. Also, data that include multiple acoustic velocities at a single wavelength (e.g., multiple modes in an acoustic waveguide) can be difficult to interpret. We note that this method and the one described in the previous paragraph share the "source–propagation path–receiver" approach of conventional acoustic testing techniques. They are similar also in their generation of an essentially single-cycle acoustic pulse or "wavepacket" that includes a wide range of wavevectors and corresponding frequencies. The combined information from these two techniques is present in the ISTS data, in a separable and more easily analyzed form.

Although it is not strictly a photoacoustic method, surface Brillouin scattering (SBS; Nizzoli and Sandercock, 1990) is perhaps more closely related to ISTS than the techniques described above. An SBS experiment measures the spectral properties of light scattered at a well-defined angle from the sample. The spectrum reveals the frequencies of incoherent, thermally populated acoustic modes with wavelengths that satisfy the associated phase-matching condition for scattering into the chosen angle. The information obtained from SBS and ISTS measurements is similar. An important difference is that the ISTS technique uses coherent, laser-excited phonons rather than incoherent, thermally populated ones. ISTS signals are therefore much stronger than those in SBS and they can be detected rapidly in the time domain. This form of detection enables acoustic damping rates, for example, to be evaluated accurately without the deconvolution procedures that are necessary to interpret spectra collected with the sensitive Fabry-Perot filters that are commonly used in SBS. Also, with ISTS it is possible simultaneously to excite and monitor acoustic modes with more than one wavelength, to determine their phases, and to measure them in real-time as they propagate across the sample. These and other capabilities, which are useful for accurately evaluating films or other structures with dimensions comparable to the acoustic wavelength, are absent from traditional forms of SBS.

Finally, in some cases, certain properties that can be derived from ISTS measurements (e.g., elastic constants, density, thickness, stress, etc.) can be determined with other, nonacoustic methods. Although complete descriptions of all of the possible techniques is beyond the scope of this unit, we list a few of the more established methods.

1. Elastic constants can be determined with uniaxial pull-testers, nanoindenters (Pharr and Oliver, 1992), and specialized micromechanical test structures (Allen et al., 1987).
2. Stress, and sometimes elastic constants, are typically measured with tests that use deflections or vibrations of drumhead membranes (Maden et al., 1994; Vlassak and Nix, 1992) or cantilevered beams (Mizubayashi et al., 1992), or these are inferred from strain evaluated using X-ray diffraction (Clemens and Bain, 1992; also see X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS).
3. Thicknesses of transparent films are often determined with reflectometers or ellipsometers (See ELLIPSOMETRY). For opaque films, thickness is evaluated

using stylus profilometry or grazing incidence x-ray reflection; in the case of conducting films, it is determined indirectly from measurements of sheet resistance. Vinci and Vlassak (1996) present a review of techniques for measuring the mechanical properties of thin films and membranes.

PRINCIPLES OF THE METHOD

As mentioned above (see Introduction), ISTS uses short (relative to the time-scale of the material response of interest) pulses of light from an excitation laser to stimulate acoustic motions in a sample. The responses are measured with a separate probing laser. Figure 1 schematically illustrates the mechanisms for excitation and detection in the simplest case. Here, a single pair of excitation pulses crosses at an angle θ at the surface of a thin film on a substrate. The optical interference of these pulses produces a sinusoidal variation in intensity with a period Λ, given by

$$\Lambda = \frac{\lambda_e}{2\sin(\theta/2)} \tag{1}$$

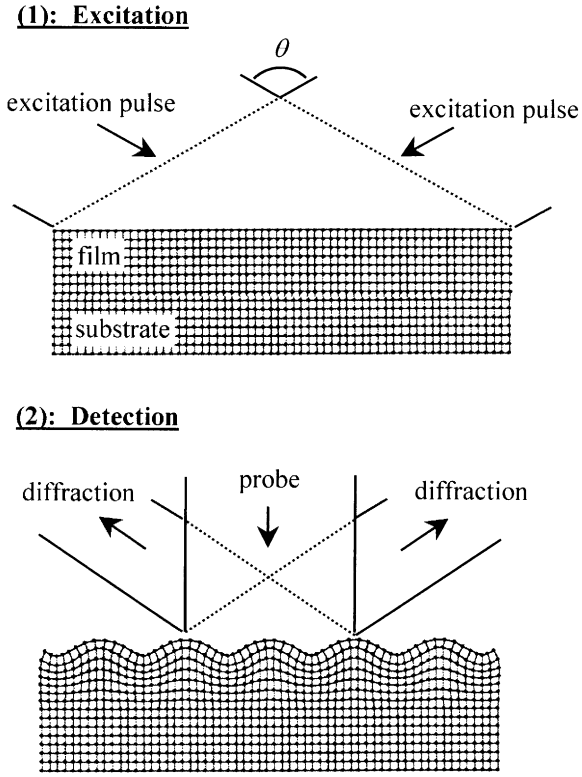

Figure 1. Schematic illustration of the ISTS measurement. Crossed laser pulses form an optical interference pattern and induce coherent, monochromatic acoustic and thermal motions with wavelengths that match this pattern. The angle between the pulses determines the wavelength of the response. A continuous wave probing laser diffracts from the ripple on the surface of the sample. Measuring the intensity of the diffracted light with a fast detector and transient recorder reveals the time dependence of the motions.

The wavelength of the excitation light (λ_e) is chosen so that it is partly absorbed by the sample; this absorption induces heating in the geometry of the interference pattern. The resulting spatially periodic thermal expansion launches coherent, monochromatic counter-propagating surface acoustic modes with wavelength Λ. It also simultaneously generates acoustic waves that propagate into the bulk of the sample and produce the acoustic echoes mentioned previously (Shen et al., 1996; Crimmins et al., 1998). In thin films, the former and latter responses typically occur on nanosecond and picosecond time scales, respectively. On microsecond time scales, the thermally induced strain slowly relaxes via thermal diffusion. The temporal nature of the surface motions that result from these responses can be determined in real time with each shot of the excitation laser by measuring the intensity of diffraction of a continuous wave probe laser with a fast detector and transient recorder. For motions that exceed the bandwidth of conventional detection electronics (typically ~1 to 2 GHz), it is possible to use either variably delayed picosecond probing pulses to map out the response in a point-by-point fashion (Shen et al., 1996; Crimmins et al., 1998) or a continuous wave probe with a streak camera for ultrafast real-time detection. It is also possible to use, instead of the streak camera, a scanning spectral filter to resolve the motions in the frequency domain (Maznev et al., 1996). This unit focuses primarily on the in-plane acoustic modes, partly because they can be excited and detected rapidly in real-time using commercially available, low-cost laser sources and electronics. Also, these modes provide a route to measuring a wide range of thin film elastic constants and other physical properties.

The following functional form describes the response, *R(t)*, when the thermal and the in-plane acoustic motions both contribute

$$R(t) \propto A_{\text{therm}} e^{-\Gamma_t} + \sum_i B_i e^{-\gamma_i t} \cos\omega_i t \tag{2}$$

where A_{therm} and B_i are the amplitudes of the thermal and acoustic responses, respectively, and the ω_i are the frequencies of the acoustic modes. The summation extends over the excited acoustic modes, i, of the system. The thermal and acoustic decay rates are, respectively, Γ_t and γ_i. In the simplest diffraction-based detection scheme, the measured signal is proportional to the diffraction efficiency, which is determined by the square of the *R(t)*. These responses, as well as the acoustic echoes, are all recorded in a single measurement of the area of the sample that is illuminated by the excitation and probing lasers. The ISTS measurement provides spatial resolution that is comparable to this area, which is typically a circular or elliptical region with a characteristic dimension (e.g., diameter or major axis) of 50 to 500 μm. In certain situations, the effective resolution can be significantly better than this length scale (Gostein et al., 2000).

Figure 2 shows data from a polymer film on a silicon substrate. The onset of diffraction coincides with the arrival of the excitation pulses at $t = 0$. The slow decay of signal is associated with thermal diffusion (Fig. 2B); the oscillations in Fig. 2A are due to acoustic modes that propagate

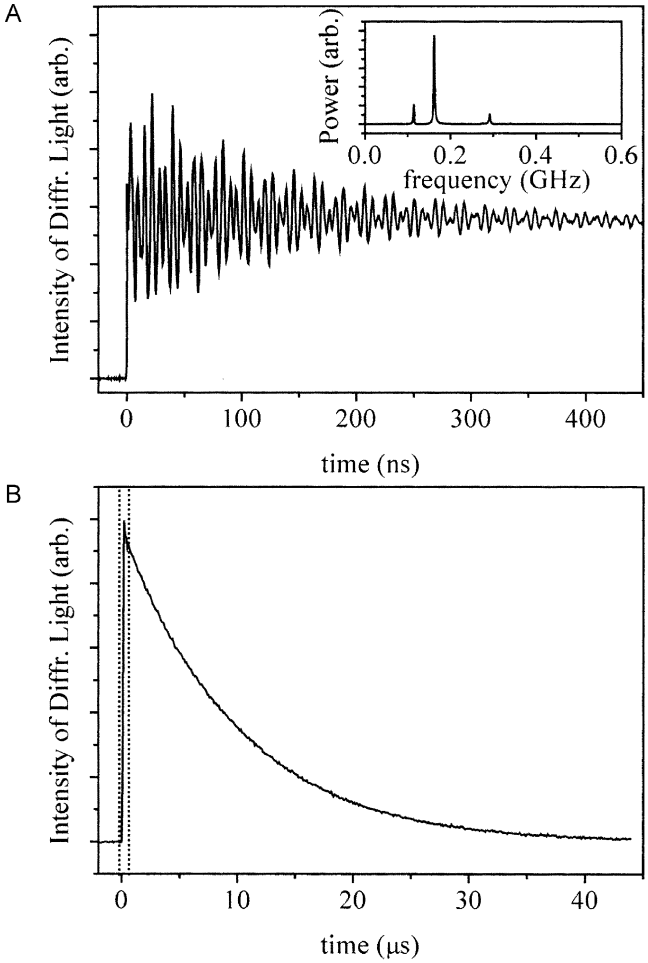

Figure 2. Typical ISTS data from a thin polymer film (thickness ~4 μm) on a silicon substrate. Part (**A**) shows the in-plane acoustic response, which occurs on a nanosec time scale and has a single well defined wavelength (8.32 μm) determined by the color and crossing angle of the excitation pulses. The oscillations in the signal reveal the frequencies of the different acoustic waveguide modes that are excited in this measurement. The inset shows the power spectrum. The frequencies are determined by the acoustic wavelength and the mechanical properties of the film, the substrate, and the nature of the interface between them. The acoustic waves eventually damp out and leave a nonoscillatory component of signal that decays on a microsec time scale (**B**). This slow response is associated with the thermal grating. Its decay rate is determined by the wavelength of the response and the thermal diffusivity of the structure. The dashed lines in (B) indicate the temporal range displayed in (A).

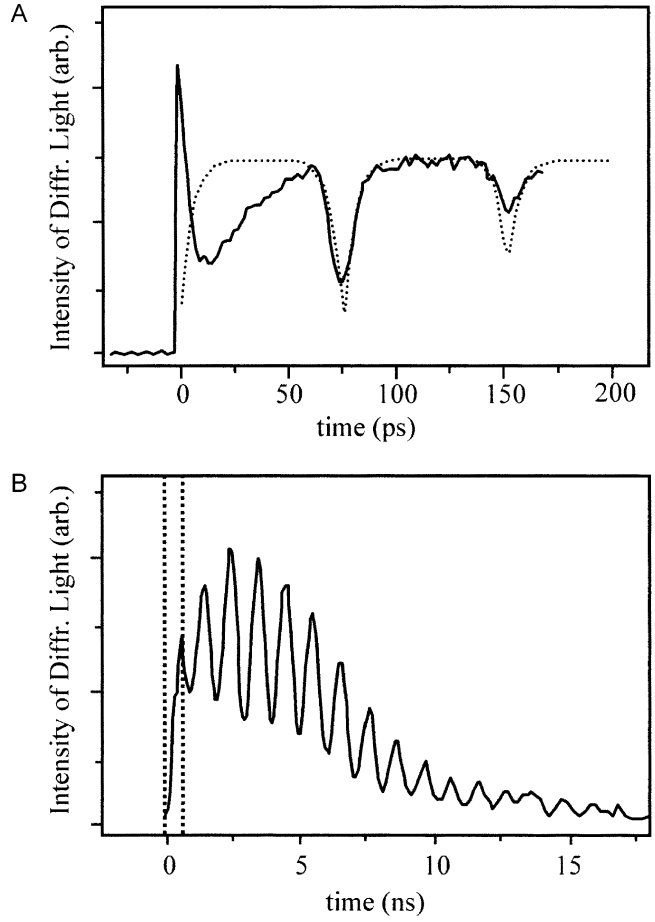

Figure 3. Typical ISTS data from an ultrathin metal film (thickness ~200 nm) on a silicon substrate. Part (**A**) shows the arrival of two acoustic echoes produced by longitudinal acoustic wavepackets that are launched at the surface of the film and reflect at the interface between the film and the substrate and at the interface between the film and the surrounding air. Propagation of acoustic modes in the plane of the film causes oscillations in the signal on a nanosec time scale (**B**). Thermal diffusion produces the overall decay in signal that occurs on a nanosec time scale. The dashed lines in (B) indicate the temporal range displayed in (A).

in the plane of the film. The frequencies and damping rates of the acoustic modes, along with the acoustic wavelength determined from Equation 1, define the real and imaginary parts of the phase velocities. On a typically faster (picosecond) time scale it is also possible to resolve responses due to longitudinal waves that reflect from the film/substrate interface. Figure 3 shows both types of acoustic responses evaluated in a single measurement on a thin metal film on a silicon substrate.

Although the measured acoustic frequencies and echoes themselves can be important (e.g., for filters that use surface acoustic waves or thin film acoustic resonances, respectively), the intrinsic elastic properties of the films are often of interest. The acoustic echoes yield, in a simple way, the out-of-plane compressional modulus, c_o, when the density, ρ, and thickness, h, are known. The measured roundtrip time in this case defines, with the thickness, the out-of-plane longitudinal acoustic velocity, v_o; the modulus is $c_0 = \rho v_0^2$.

Extracting moduli from the in-plane acoustic responses is more difficult because thin films form planar acoustic waveguides that couple in- and out-of-plane compressional and shearing motions (Farnell and Adler, 1972; Viktorov, 1976). An advantage of this characteristic is that, in principle, the dispersion of the waveguide modes can be used to determine a set of anisotropic elastic constants as well as film thicknesses and densities. Determining these properties requires an accurate measurement of the dispersion of the waveguide and a detailed understanding of how

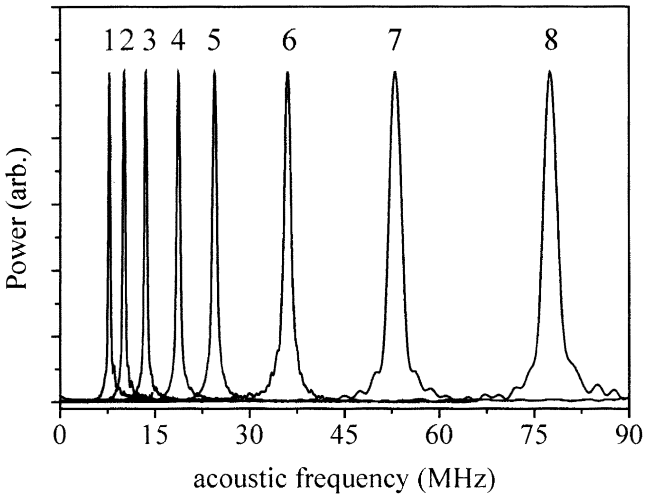

Figure 4. Power spectra from data collected in ISTS measurements on a thin membrane at several different acoustic wavelengths between ~30 μm and ~6 μm and labeled 1 to 8. The variation of the frequency with wavelength defines the acoustic dispersion. Analyzing this dispersion with physical models of the waveguide acoustics of the membrane yields the elastic constants and other properties.

acoustic waves propagate in layered systems. There are two approaches for determining the dispersion. One involves a series of measurements with different angles between the excitation pulses to determine the acoustic response as a function of wavelength. Figure 4 shows the results of measurements that determine the dispersion of a thin unsuppported membrane using this method (Rogers and Bogart, 2000). The other approach uses a single measurement performed with specialized beam-shaping optics that generate more than two excitation pulses (Rogers, 1998). Figure 5 shows data that were collected in an

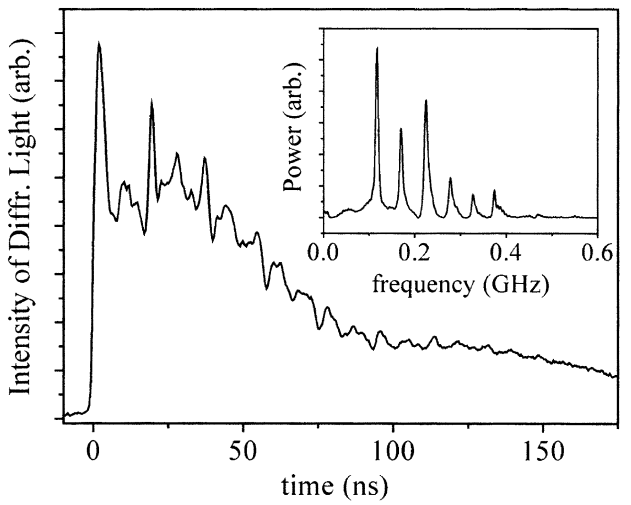

Figure 5. ISTS data from a thin film of platinum on a silicon wafer. This measurement used a system of optics to generate and cross six excitation pulses at the surface of the sample. The complex acoustic disturbance launched by these pulses is characterized by six different wavelengths. The power spectrum reveals the frequency components of the signal. A single measurement of this type defines the acoustic dispersion.

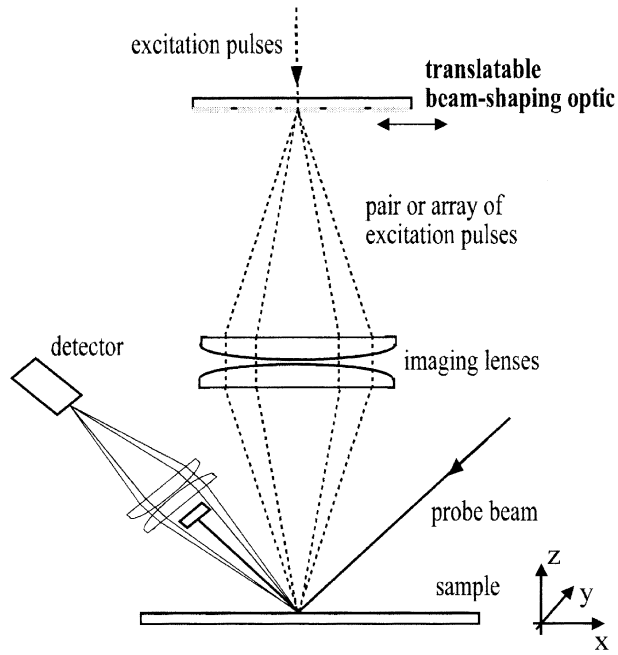

Figure 6. Optical system for ISTS measurements. Pulses from an excitation laser pass through a beam-shaping optic that splits the incident pulse into an array of diverging pulses. This optic contains a set of patterns, each of which produces a different number and distribution of pulses. A pair of imaging lenses crosses some of the pulses at the surface of a sample. The optical interference pattern produced in this way defines the wavelengths of acoustic motions stimulated in the sample. Diffraction of a probe laser is used to monitor the time dependence of these motions. A pair of lenses collects the diffracted signal light and directs it to a fast photodetector. The wavelengths of the acoustic waves can be changed simply by translating the beam-shaping optic.

ISTS measurement with six crossed excitation pulses. The response in this case contains contributions from acoustic modes with six different wavelengths, which are defined by the geometry of the six-pulse interference pattern. In both cases, the size of the excitation region is chosen, through selection of appropriate lenses, to be at least several times larger than the longest acoustic wavelength. This geometry ensures precise definition of the spatial periods of the interference patterns and, therefore, of the acoustic wavelengths.

The simplicity and general utility of the modern form of ISTS derives from engineering advances in optical systems that enable rapid measurement of acoustic dispersion with the two approaches described above (Rogers et al., 1997; Maznev et al., 1998; Rogers and Nelson, 1996; Rogers, 1998). Figure 6 schematically illustrates one version of the optical setup. Specially designed, phase-only beam shaping optics produce, through diffraction, a pair or an array of excitation pulses from a single incident pulse. A selected set of the diffracted pulses pass through a pair of imaging lenses and cross at the sample surface. Their interference produces simple or complex intensity patterns with geometries defined by the beam shaping optic and the imaging lenses. For the simple two-beam interference described by Equation 1, this optic typically

consists of a binary phase grating optimized for diffraction at the excitation wavelength. Roughly 80% of the light that passes through this type of grating diffracts into the $+1$ and -1 orders. The imaging lenses cross these two orders at the sample to produce a sinusoidal intensity pattern with periodicity Λ when the magnification of the lenses is unity and the period of the grating is 2Λ. More complex beam-shaping optics produce more than two excitation pulses, and, therefore, interference patterns that are characterized by more than one period. In either case, a useful beam-shaping optic contains many (20 to 50) different spatially separated diffracting patterns. The excitation geometry can then be adjusted simply by translating this optic so that the incident excitation pulses pass through different patterns. With this approach, the response of the sample at many different wavelengths can be determined rapidly, without moving any of the other elements in the optical system.

Detection is accomplished by imaging one or more diffracted probe laser beams onto the active area of a fast detector. When the intensity of these beams is measured directly, the signal is proportional to the product of the square of the amplitude of the out-of-plane acoustic displacements (i.e., the square of Equation 2) and the intensity of the probing light. Heterodyne detection approaches, which measure the intensity of the coherent optical interference of the signal beams with collinear reference beams generated from the same probe laser, provide enhanced sensitivity. They also simplify data interpretation since the heterodyne signal, *S(t)*, is linear in the material response. In particular, in the limit that the intensity of the reference beam, I_r, is large compared to the diffracted signal

$$S(t) \propto |\sqrt{I_p}R(t) + \sqrt{I_r}e^{i\varphi}| \approx I_r + 2\sqrt{I_p I_r}R(t)\cos\varphi \qquad (3)$$

where φ is the phase difference between the reference and diffracted beams and I_p is the intensity of the probing beam. A general scheme for heterodyne detection that uses the beam-shaping optic to produce the excitation pulses, as well as to generate the reference beam, is a relatively new and remarkably simple approach that makes this sensitive detection method suitable for routine use (Maznev et al., 1998; Rogers and Nelson, 1996). Figure 7 schematically illustrates the optics for measurements on transparent samples; a similar setup can be used in reflection mode. With heterodyne and nonheterodyne detection, peaks in the power spectrum of the signal define frequencies of the acoustic responses. In the case of nonheterodyne signals, sums and differences and twice these frequencies (i.e., cross terms that result from squaring Equation 2) also appear. Figure 8 compares responses measured with and without heterodyne detection.

The measured dispersion can be combined with models of the waveguide acoustics to determine intrinsic material properties. The general equation of motion for a nonpiezoelectric material is given by

$$\frac{\partial^2 \mathbf{u}_j}{\partial t^2} = \frac{\mathbf{c}_{ijkl}}{\rho}\frac{\partial^2 \mathbf{u}_k}{\partial x_i \partial x_l} + \frac{\partial}{\partial x_i}\left(\boldsymbol{\sigma}_{ik}^{(r)}\frac{\partial \mathbf{u}_j}{\partial x_k}\right) \qquad (4)$$

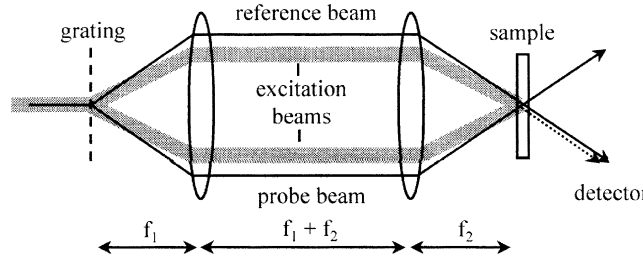

Figure 7. Optical system for ISTS measurements with heterodyne detection. Both the probe and the excitation laser beams pass through the same beam-shaping optic. The excitation pulses are split and recombined at the surface of the sample to launch the acoustic waves. The probe light is also split by this optic into more than one beam. For this illustration, the beam shaping optic produces a single pair of probing and excitation pulses. One of the probe beams is used to monitor the material response. The other emerges collinear with the signal light and acts as a reference beam for heterodyne amplification of signal generated by diffraction of the beam used for probing. The beam-shaping optic and imaging lenses ensure overlap of the signal and reference light. An optical setup similar to the one illustrated here can be used for measurements in reflection mode.

where $\mathbf{c}$ is the elastic stiffness tensor, $\mathbf{u}$ is the displacement vector, ρ is the density of the material and $\boldsymbol{\sigma}$ is the residual stress tensor. Solutions to this equation, with suitable boundary conditions at all material interfaces, define the dispersion of the velocities of waveguide modes in arbitrary systems (Farnell and Adler, 1972;Viktorov, 1976). Inversion algorithms based on these solutions can be used to determine the elastic constants, densities, and/or film thicknesses from the measured dispersion. For thickness determination, the elastic constants and densities are typically assumed to be known; they are treated as fixed parameters in the inversion. Similarly, for elastic constant evaluation, the thicknesses and densities are treated as fixed parameters. It is important to note, however, that only the elastic constants that determine the velocities of modes with displacement components in the vertical (i.e., sagittal) plane can be determined, because ISTS probes only these modes. Elastic constants that govern the propagation of in-plane shear acoustic waves polarized in the plane of the film, for example, cannot be evaluated. Figure 9 illustrates calculated distributions of displacements in the lowest six sagittal modes for a polymer film that is strongly bonded to a silicon substrate. As this figure illustrates, the modes involve coupled in- and out-of-plane shearing and compressional motions in the film and the substrate. The elastic constants and densities of the film and substrate materials and the thickness of the film determine the spatial characters and velocities of the modes. Their relative contributions to the ISTS signal are determined by their excitation efficiency and by their diffraction efficiency; the latter is dictated by the amount of surface ripple that is associated with their motion.

PRACTICAL ASPECTS OF THE METHOD

The setup illustrated in Figure 6 represents the core of the experimental apparatus. The entire system can either

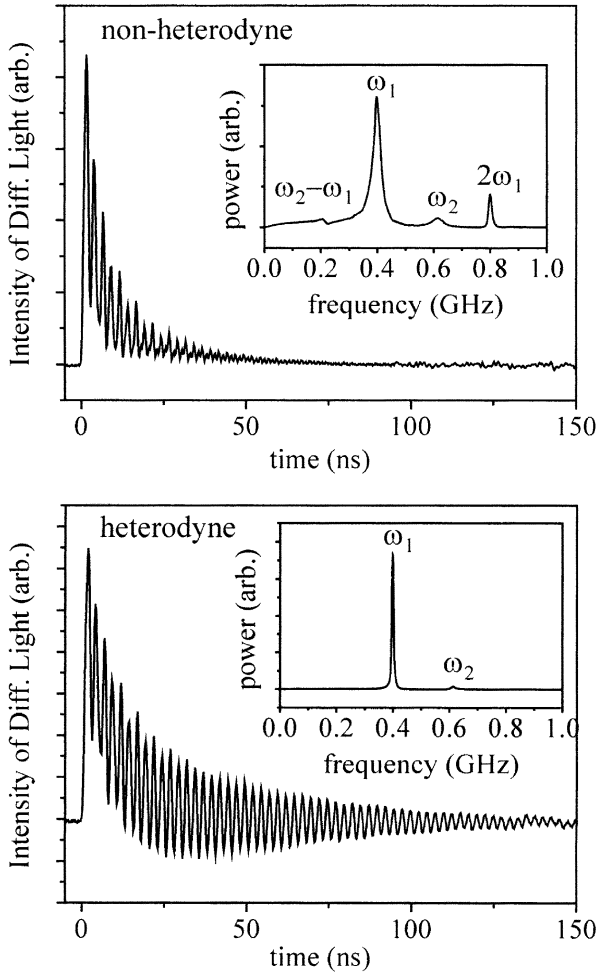

Figure 8. ISTS signal and power spectrum of the signal from an electroplated copper film (thickness ~1.8 μm) on a layer of silicon dioxide (thickness ~0.1 μm) on a silicon substrate at an acoustic wavelength ~7 μm. Part (**A**) shows the signal obtained without heterodyne amplification. The fact that the signal is quadratic with respect to the material displacement results in what appears as a fast decay of the acoustic oscillations. This effect is caused by the decay of the background thermal response rather than a decay in the acoustic component of the signal itself. Part (**B**) shows the heterodyne signal; the spectrum contains two peaks corresponding to Rayleigh and Sezawa waves, i.e., the two lowest-order modes of the layered structure. The signal without heterodyning shows these frequencies and combinations of them, due to the quadratic dependence of the signal on the response. The peak width in the spectrum of the signal in (**A**) is considerably larger than that in (**B**). This effect is due to the contribution of the thermal decay to the peak width in the nonheterodyne case. Note also that the heterodyne signal appears to drop below the baseline signal measured before the excitation pulses arrive. This artifact results from the insensitivity of the detector to DC levels of light.

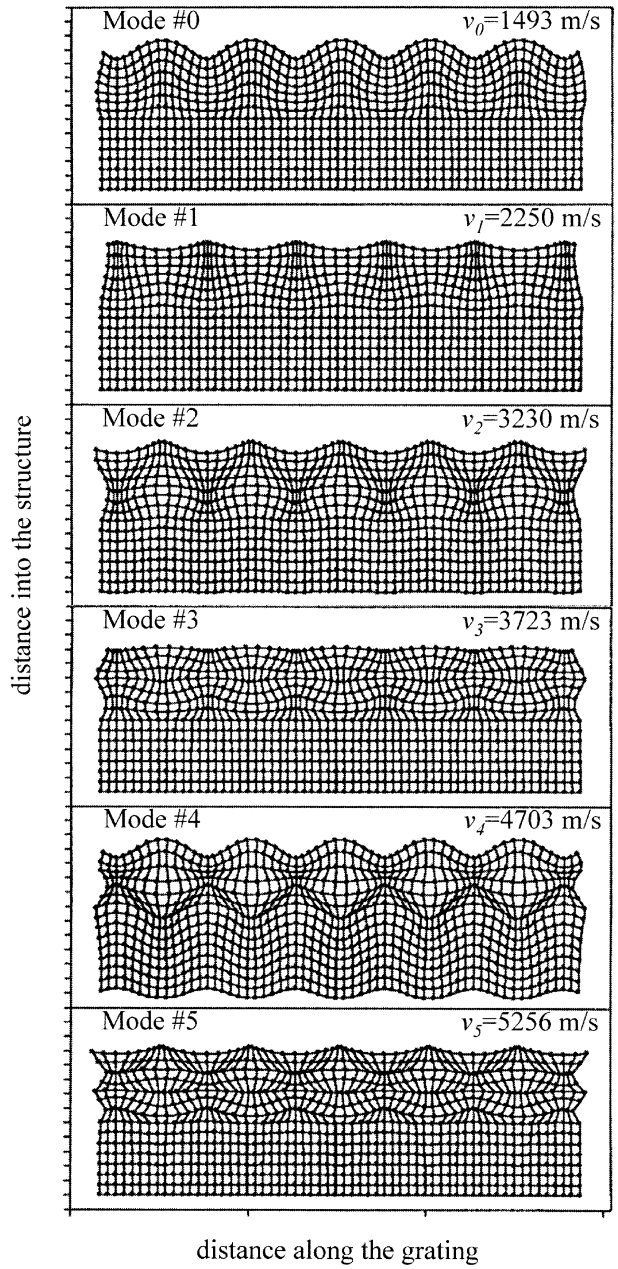

Figure 9. Computed displacement distributions for the lowest six waveguide modes in a polymer film supported by a silicon substrate. These modes are known as Rayleigh or Sezawa modes. They are excited and probed efficiently in ISTS measurements because they involve sagittal displacements that couple strongly both to the thermal expansion induced by the excitation pulses and to surface ripple, which is commonly responsible for diffracting the probe laser. The spatial nature of these modes and their velocities are defined by the mechanical properties of the film and the substrate, the nature of the interface between them, and the ratio of the acoustic wavelength to the film thickness.

be obtained commercially or most of it can be assembled from conventional, off-the-shelf components (lenses, lasers, etc.). The beam-shaping optics can be obtained as special order parts from commercial digital optics vendors. Alternatively, they can be custom built using relatively simple techniques for microfabrication (Rogers, 1998).

The excitation pulses are typically derived from a flash lamp or diode-pumped Nd:YAG laser, although any source of laser pulses with good coherence and mode properties can be used. The pulse duration must be short compared to the temporal period of the excited acoustic wave. In many instances, pulses shorter than ~300 psec

are suitable. Pulse energies in the range of one or a few μJ provide adequate excitation for most samples. Nonlinear crystals can be used to double, triple, quadruple, or even quintuple the output of the Nd:YAG (wavelength ~1064 nm) to produce 532, 355, 266, or 213 nm light. The color is selected so that a sufficient fraction of the incident light is absorbed by the sample. Ultraviolet (UV) light is a generally useful wavelength in this regard, although the expense and experimental complexity of using multiple nonlinear crystals represent a disadvantage of UV light when a Nd:YAG laser is used. Nonlinear frequency conversion can be avoided by depositing thin absorbing films onto samples that are otherwise too transparent or reflective to examine directly at the fundamental wavelength of the laser. The probe laser can be pulsed or continuous wave. For most of the data presented in this unit, we used a continuous-wave infrared (850 nm) diode laser with a power of ~200 mW. Its output is electronically gated so that it emits only during the material response, which typically lasts no longer than 100 μsec after the excitation pulses strike the sample.

Alignment of the optics (which is performed at the factory for commercial instruments) ensures that the probing beam overlaps the crossed excitation beams and that signal light reaches the detector. The size of the beams at the crossing point is typically in the range of one or several hundred microns. The alignment of the probe laser can be aided by the use of a pinhole aperture to locate the crossing point of the excitation beams. Routine measurement is accomplished by placing the surface of the sample at the intersection of the excitation and probing laser beams, moving the beam-shaping optic to the desired pattern(s), recording data, and interpreting the data. The sample placement is most easily achieved by moving the sample along the *z* direction (Fig. 6) to maximize the measured signal, which can be visualized in real time on a digitizing oscilloscope. The surface normal of the sample is adjusted to be parallel to the bisector of the excitation beams.

Recorded data typically consist of an average of responses measured for a specified number of excitation-probing events. The strength of the signal, the required precision, and the necessary measurement time determine the number of averages: between one hundred and one thousand is typical. This averaging requires <1 sec with common excitation lasers (repetition rates ~1 kHz). Translating this optic so that the excitation laser beam passes through different diffracting patterns changes the acoustic wavelength(s). Single or multiple measurements of this type define acoustic response frequencies as a function of wavelength, which, in most cases, varies from 2 to 200 μm. The optics and the wavelengths of the lasers determine the range that is practical.

The measurement procedures described above apply to a wide variety of samples. Figures 10 to 13 show, respectively, data from a film of lead zirconium titanate (PZT) on silicon, a thin layer of nanoporous silica glass on silicon, a layer of paint on a plastic automobile bumper part, and a film of cellulose. In the last example, the data were collected with a single shot of the laser. In each case, the oscillations in the signal are produced by surface acoustic waveguide modes that involve coupled displacements in the outer film, and, in general, in all material layers beneath it. Their frequencies are therefore functions of the material properties of each component of the structure and the nature of the boundary conditions between them. These and other waveguide properties can be calculated

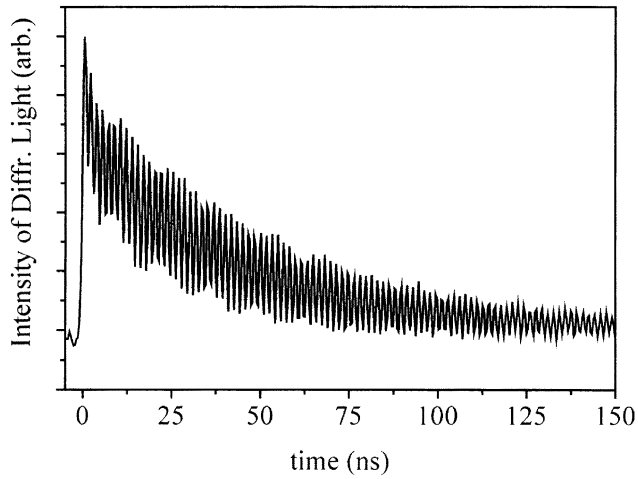

Figure 10. ISTS data from a thin film of lead zirconium titanate on a layer of platinum on a silicon wafer. Crossed laser pulses coherently stimulate the lowest-order Rayleigh waveguide acoustic mode, with a wavelength defined by the optical interference pattern. The motions induce ripple on the surface of the structure; this ripple diffracts a probing laser beam that is overlapped with the excited region of the sample. The acoustic waveguide motions involve coupled displacements in the film and underlying substrate. In this case, the overall decay of the signal caused by thermal diffusion occurs on a time scale comparable to the acoustic decay time.

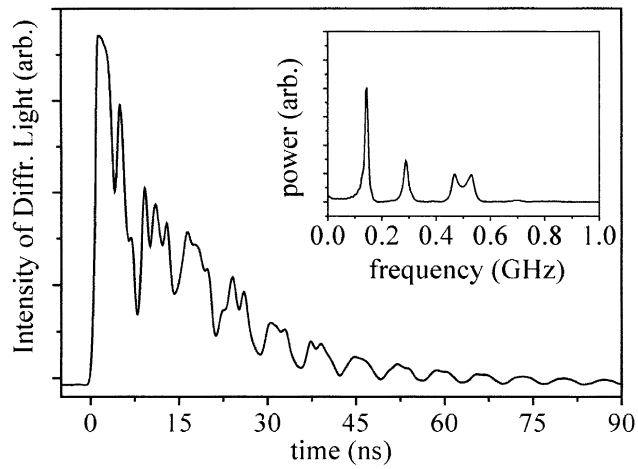

Figure 11. ISTS data from a thin film of a nanoporous glass on a silicon substrate. A thin overlayer of aluminum was added in this case to induce optical absorption at the wavelength of the excitation laser (1064 nm). The measurement stimulates numerous acoustic waveguide modes, each with a wavelength equal to the period of the optical interference pattern formed by the crossed laser pulses. The power spectrum in the inset shows the various frequency components of the signal. In this case, the overall decay of the signal caused by thermal diffusion occurs on a time scale comparable to the decay time of the lowest order acoustic waveguide mode.

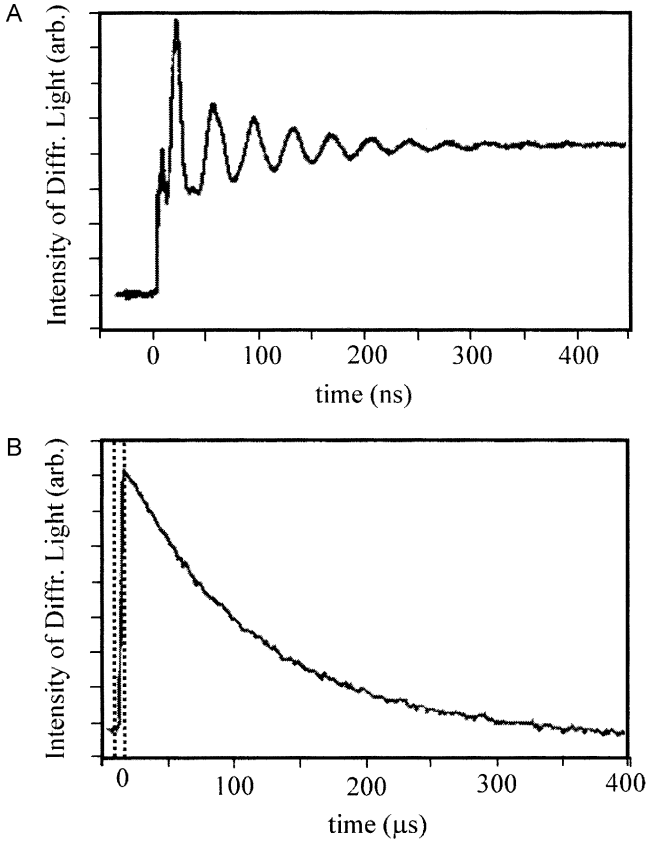

Figure 12. ISTS data from a layer of paint on a plastic automobile bumper part. Part (**A**) shows the acoustic component of the signal. Part (**B**) shows the thermal decay, which occurs on a microsec time scale. The vertical dashed lines in the bottom frame indicate the temporal window of the signal shown in the upper frame. The acoustic and thermal properties of paint can be relevant to developing materials that resist delamination and maintain their mechanical flexibility even after exposure to harsh environmental conditions. The dashed lines in (B) indicate the temporal range illustrated in (A).

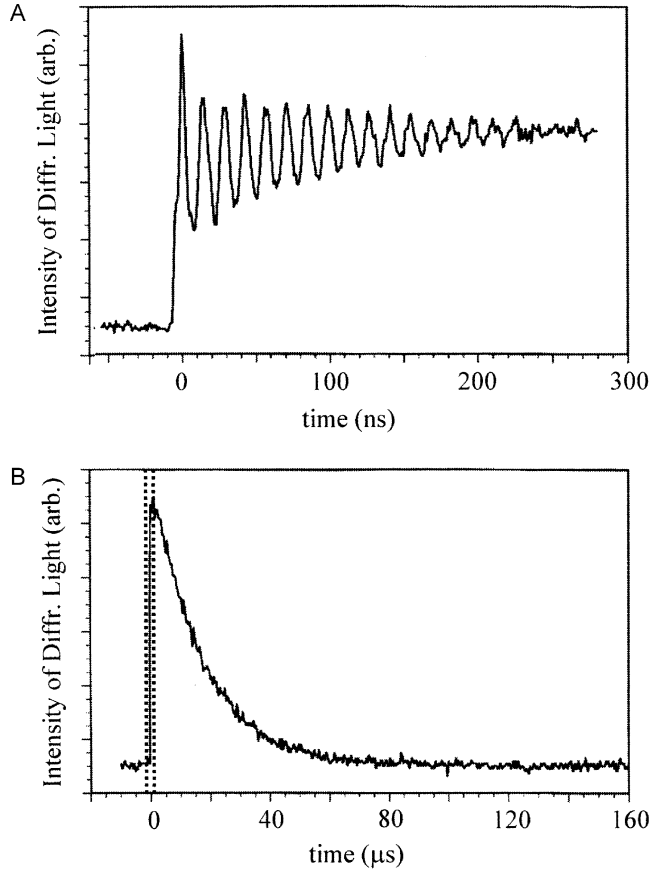

Figure 13. ISTS data collected in a single shot of the laser from a film of cellulose. Parts (**A**) and (**B**) show the acoustic and thermal components of the signal that was recorded in this measurement. The dashed lines in (B) indicate the temporal range illustrated in (A).

from first principles using standard procedures (Farnell and Adler, 1972; Viktorov, 1976).

The results in Figures 10 to 13 are representative of the range of acoustic responses that are typically encountered. The PZT film on silicon (Fig. 10) only supports a single waveguide mode at this acoustic wavelength, because its thickness is small compared to the wavelength. The response consists, therefore, of a single frequency whose value is determined primarily by the density and thickness of the film and by the mechanical properties of the silicon. In contrast, the nanoporous glass on silicon (Fig. 11) supports many acoustic waveguide modes because the acoustic wavelength is comparable to the film thickness. The data, as a result, contain many frequency components. Several of these modes involve motions confined largely to the film; their characteristics are determined primarily by the film mechanical properties and its film thickness. The layer of paint on the plastic bumper part (Fig. 12) is thick compared to the acoustic wavelength and it therefore supports many waveguide modes, like the nanoporous glass. The excitation in this case, however, is localized to the very top surface of the sample. Only the lowest waveguide mode, which is known as the Rayleigh mode, is stimulated and detected efficiently. The frequency of this mode is determined entirely by the mechanical properties of the film. It is independent of the film thickness and of the mechanical properties of the substrate. Finally, the cellulose sample (Fig. 13) is a thick free-standing film. The excited mode, in this case, is similar, in its physical characteristics and in its sensitivity to film properties, to the Rayleigh mode observed in the paint sample.

The precision (i.e., repeatability) of the frequencies measured from data like those shown in Figs. 10 to 13 can be better than 0.01% to 0.001%. The acoustic wavelengths are determined by the experimental apparatus: the geometry of the beam-shaping optic, its position relative to the imaging lenses, and the magnification of these lenses. This information, or a direct measurement of the excitation beam crossing angles, can be used to evaluate the wavelengths. Measurements with high accuracy are typically achieved by measuring response frequencies from standard samples or by using a microscope to view the interference pattern directly. With these latter two techniques the wavelengths can be determined to an accuracy of better than 0.1%.

METHOD AUTOMATION

Many aspects of the measurement can be automated. The beam-shaping optic in a commercial machine, for example, is mounted on a computer-controlled motorized translation stage. This motor, along with the transient recorder (i.e., digitizing oscilloscope), a variable neutral density filter for adjusting the intensity of the excitation light, and a precision stage that supports the sample, are all controlled by a single computer interface. Robotic handlers are also available to load and unload samples into and from the machine. An automated focusing operation positions the sample along the z direction to maximize the signal. The computer controls data collection at user-defined acoustic wavelengths and also computes the power spectrum from the time domain data. It fits peaks in this spectrum to define the acoustic frequencies, and, in the case of film thickness, uses these frequencies (and the known acoustic wavelength, elastic constants, and densities) to evaluate the unknown layer(s). This fully automated procedure can be coordinated with motion of the sample stage to yield high-resolution (better than 10-μm in certain cases) images of the acoustic frequency, other aspects of the ISTS signal (e.g., amplitude, acoustic damping rate, thermal decay time, etc.), and/or computed material characteristics (e.g., film thickness). In a noncommercial ISTS apparatus for general laboratory use, the stages for the sample, the beam-shaping optic, the neutral density filter, etc., are manually controlled. Data downloaded from an oscillosope in such a setup are analyzed using a separate computer equipped with software for the fitting and modeling procedures.

DATA ANALYSIS AND INITIAL INTERPRETATION

As discussed in the previous sections, the ISTS measurements provide information on the acoustic properties of the sample. The acoustic frequencies can be obtained directly by fitting the time domain ISTS data to expressions given in Equation 2 or Equation 3. They can also be determined by Fourier transformation. In the latter case, the positions of the peaks in the power spectrum are typically defined by fitting them to Lorentzian or Gaussian line shapes. The experimental apparatus defines the crossing angles of the excitation pulses and, therefore, the acoustic wavelength(s).

Inverse modeling with the acoustic frequencies and wavelengths determines elastic and other properties. In this procedure, the elastic constants, densities and thicknesses of the "unknown" layer(s) are first set to some approximate initial values. The dispersion is then calculated with Equation 4 and the known properties of the other layers. The sum of squared differences, χ^2, between the computed and measured modal phase velocities provides a metric for how well the modeling reproduces the observed dispersion. In a generally nonlinear iterative search routine, the properties of the unknown layers are adjusted and χ^2 is calculated for each case. The properties that minimize χ^2 represent best fit estimates for the intrinsic characteristics of the "unknown" layers. For the simple case of determining the thickness of a single layer in a film stack whose other properties are known, this procedure reduces to a straightforward non-iterative calculation that yields the thickness from a single measured phase velocity. Clearly, for these types of fitting procedures to be successful, the number of parameters to be determined cannot exceed the number of measured velocities. The uncertainties in the fitted parameters will typically decrease as the number of measured velocities, and the range of wavelengths increase. These uncertainties can be quantitatively estimated using established statistical analysis such as the F test (Beale, 1960). Below we examine this inverse modeling in some detail, with illustrations for rigidity and stress determination in thin membranes, elastic moduli determination in supported and unsupported films, and thickness evaluation of films in multilayer stacks.

We begin with the simple case of a thin unsupported membrane. When the thickness (h) of the membrane is much smaller than the acoustic wavelength, then it is possible to model the dispersion of the drumhead mode (i.e., the lowest-order waveguide mode, which is typically easy to observe in an ISTS measurement) with small-deflection plate theory. We also assume that the ISTS excitation region is large enough to ignore the dimension perpendicular to the interference fringes (i.e., the y axis is Fig. 6). In these limits, Equation 4 reduces to (Rogers and Bogart, 2000)

$$\frac{Eh^2}{12(1-\upsilon^2)}\frac{\partial^4 \mathbf{u}}{\partial x^4} + \rho\frac{\partial^2 \mathbf{u}}{\partial t^2} = \sigma\frac{\partial^2 \mathbf{u}}{\partial x^2} \tag{5}$$

where E is Young's modulus, ν is the Poisson ratio, ρ is the density of the film, and σ is the residual stress. The coordinate x lies along the interference fringes. The dispersion of the phase velocity (ν_φ) determined with Equation 5 can be written

$$\nu_\varphi = \sqrt{\frac{E}{12\rho(1-\nu^2)}(kh)^2 + \frac{\sigma}{\rho}} = \sqrt{\frac{D}{\rho h}k^2 + \frac{\sigma}{\rho}} \tag{6}$$

where D is the flexural rigidity. This simple equation can be used with ISTS measurements of the dispersion of the lowest-order Lamb mode to determine, for example, the flexural rigidity and stress when the thickness and density of the membrane are known. Figure 14 shows ISTS data from an unsupported bilayer membrane of tungsten (W; ~25 nm)/silicon nitride (SiN; ~150 nm) and best fit curves that use Equation 6. The results confirm the validity of the plate mode approximations for this sample. The stress and rigidity measured for this sample are 241 ± 1 MPa and 253 ± 1 GPa respectively. The uncertainties in this case are dominated by uncertainties in the density of the membrane. We note that the ISTS results agree with independent evaluation of these quantities by the resonant frequency (RF) method and the bulge test, respectively (Rogers and Bogart, 2000; Rogers et al., 2000b). Unlike ISTS, however, both of these methods require specialized test structures. Also, they do not offer spatial resolution

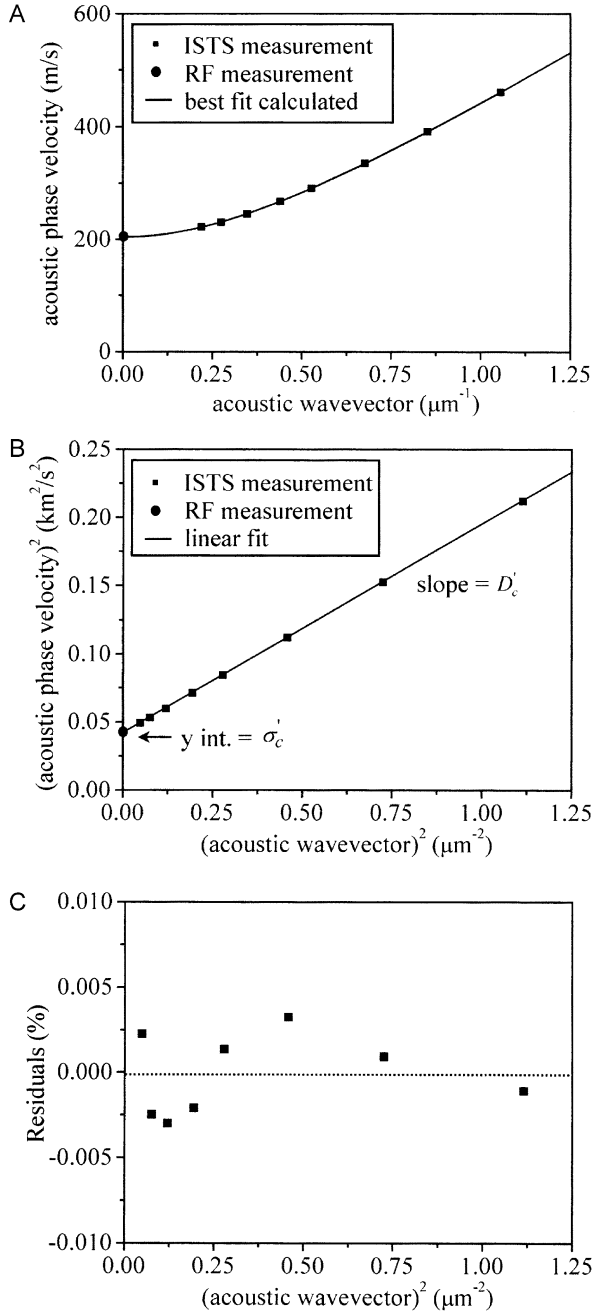

Figure 14. Dispersion in a bilayer membrane of tungsten (25 nm) and silicon nitride (150 nm) measured by ISTS. Part (**A**) shows the measured (symbols) and best fit calculated (line) variation of the acoustic phase velocity with wavevector. Part (**B**) shows the expected linear behavior of the square of the velocity with the square of the wavevector. The slope of the line that passes through these data points defines the ratio of the composite flexural rigidity to the product of the composite density and the membrane thickness. Its intercept determines the ratio of the composite residual stress (tensile) to the composite density. Part (**C**) illustrates the percent deviation of the data shown in part (**B**) from the best fit line. The small size of these residuals provides some indication of (1) the accuracy of the acoustic frequency measured by ISTS, (2) the accuracy of the measured wavelengths, and (3) the validity of the plate theory approximations. The large circular symbols in parts (**A**) and (**B**) are data from independent resonant frequency measurements on this sample.

and they cannot easily evaluate in-plane anisotropies in the stress or rigidity.

As the acoustic wavelength approaches the thickness of the membrane, the plate theory ceases to be valid, and a complete waveguide description based on Equation 4 is required. In this regime, multiple dispersive modes known as Lamb modes are possible (Farnell and Adler, 1972; Viktorov, 1976). Their velocities, v_i, at an acoustic wavelength, Λ, are defined by positions of zeroes in the determinant of a matrix defined by the boundary conditions appropriate for the system. If this determinant is denoted by the function G, then for a mechanically isotropic, stress-free membrane we can write

$$G(v_i, \Lambda, h, v_{tr}^{(f)}, v_{lg}^{(f)}) = 0 \tag{7}$$

where $v_{tr}^{(f)}$ and $v_{lg}^{(f)}$ are the intrinsic transverse and longitudinal velocities of the film (i.e., the velocities that would characterize acoustic propagation in a bulk sample of the film material). Simple equations relate these intrinsic velocities to the Young's modulus and Poisson ratio (Fetter and Walecka, 1980). Figure 15 shows the measured dispersion of a set of Lamb modes in an unstressed polymer membrane and calculations based on Equation 7 with best fit estimates for the intrinsic velocities: $v_{tr}^{(f)} = 1126 \pm 4$ m/sec, and $v_{lg}^{(f)} = 2570 \pm 40$ m/sec (Rogers et al., 1994b). A general feature of the dispersion is that the mode velocities scale with the product of the acoustic wavevector, $k = 2\pi/\Lambda$, and the thickness, h, as expected based on the plate mode result of Equation 6. Plate-like behavior of the lowest-order mode results when the acoustic wavelength is long compared to the film thickness (i.e., kh is small). In this limit, the second-lowest-order mode acquires a velocity slightly smaller than the intrinsic longitudinal velocity of the film, $v_{lg}^{(f)}$. When kh is large, the velocities of the two lowest modes approach the Rayleigh wave velocity of the film (i.e., the Rayleigh mode is a surface localized wave that propagates on a semi-infinite substrate). All

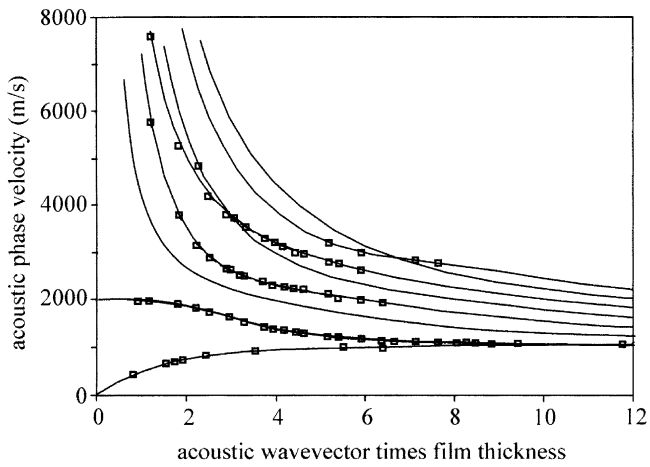

Figure 15. Dispersion in a thin unsupported polymer film measured by ISTS (symbols). The lines represent best fit calculations that allowed the intrinsic longitudinal and transverse acoustic velocities of the film to vary. With the density, simple expressions can be used to relate these velocities to the elastic moduli.

other mode velocities approach the intrinsic transverse velocity of the film, $v_{tr}^{(f)}$. These and other characteristic features of the dispersion illustrate how the elastic properties (i.e., intrinsic velocities) of a thin film can be determined from the measured variation of waveguide mode velocities with wavelength. Iterative fitting routines achieve this determination in an automated fashion that also allows for statistical estimation of uncertainties. Similar procedures can be used to evaluate membranes with anisotropic elastic constants (Rogers et al., 1994a).

When the film is supported by a substrate or when it is part of a multilayer stack, the associated boundary conditions are functions of the elastic properties, densities, and thicknesses of all constituent layers and the supporting substrate. In the general case, the boundary condition determinant can be written

$$G(v_i, \Lambda, h^{(f1)}, v_{tr}^{(fl)}, v_{lg}^{(f1)}, \rho^{(f1)}, h^{(f2)}, v_{tr}^{(f2)}, v_{lg}^{(f2)}, \rho^{(f2)}, \ldots, v_{tr}^{(s)}, v_{lg}^{(s)}, \rho^{(s)}) = 0 \quad (8)$$

where $v_{tr}^{(fi)}$ and $v_{lg}^{(fi)}$ are the intrinsic transverse and longitudinal velocities of the films, $h^{(i)}$ are their thicknesses, and $\rho^{(fi)}$ are their densities. The corresponding quantities for the substrate (assumed to be semi-infinite) are $v_{tr}^{(s)}$, $v_{lg}^{(s)}$ and $\rho^{(s)}$. Figure 16 shows the best fit computed and measured dispersion for a thin film of nanoporous silica on a silicon wafer (Rogers and Case, 1999). The intrinsic velocities determined from this fitting are $v_{lg} = 610 \pm 50$ m/sec and $v_{tr} = 400 \pm 30$ m/sec. The uncertainties in this case are dominated by uncertainties in the thickness and density of a thin overlayer of aluminum that was used to induce slight absorption at 1064 nm, the wavelength of the excitation pulses in these measurements. Note that the overall behavior of the dispersion in this case is much different from that for an unsupported film (Fig. 15). The velocity of the lowest mode approaches the Rayleigh velocities of the film and substrate at large and small values of kh, respectively. All other modes approach $v_{tr}^{(f)}$ at large kh. As kh decreases, each of these modes is, at a certain value of kh, "cut off" at $v_{tr}^{(s)}$. Above this velocity they are no longer strictly guided modes. In this regime, some of their energy "leaks" into bulk transverse waves in the semi-infinite substrate.

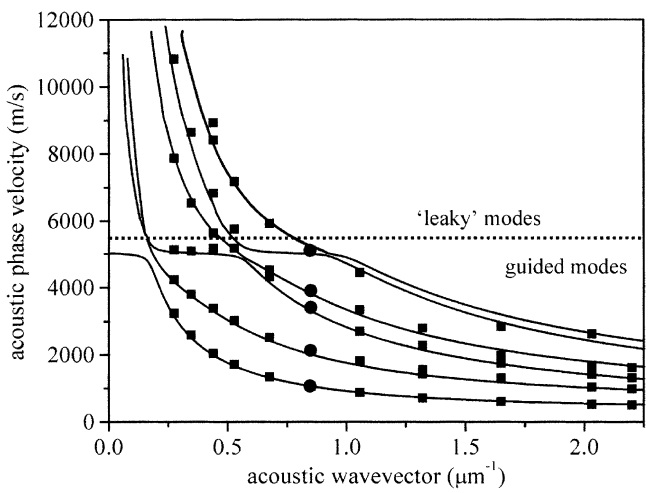

Figure 16. Dispersion in a thin film of nanoporous glass on a silicon substrate measured by ISTS (symbols). In this case, a thin film of aluminum (thickness ~75 nm) was deposited on top of the nanoporous glass in order to induce absorption at the wavelength (1064 nm) of the excitation laser used for these measurements. The lines represent best fit calculations that allowed the intrinsic longitudinal and transverse acoustic velocities of the nanoporous glass to vary. The fitting used literature values for the densities and elastic properties of the aluminum and the silicon. The thickness of the aluminum film was fixed to its nominal value. The circular symbols represent data illustrated in Figure 8b.6.11.

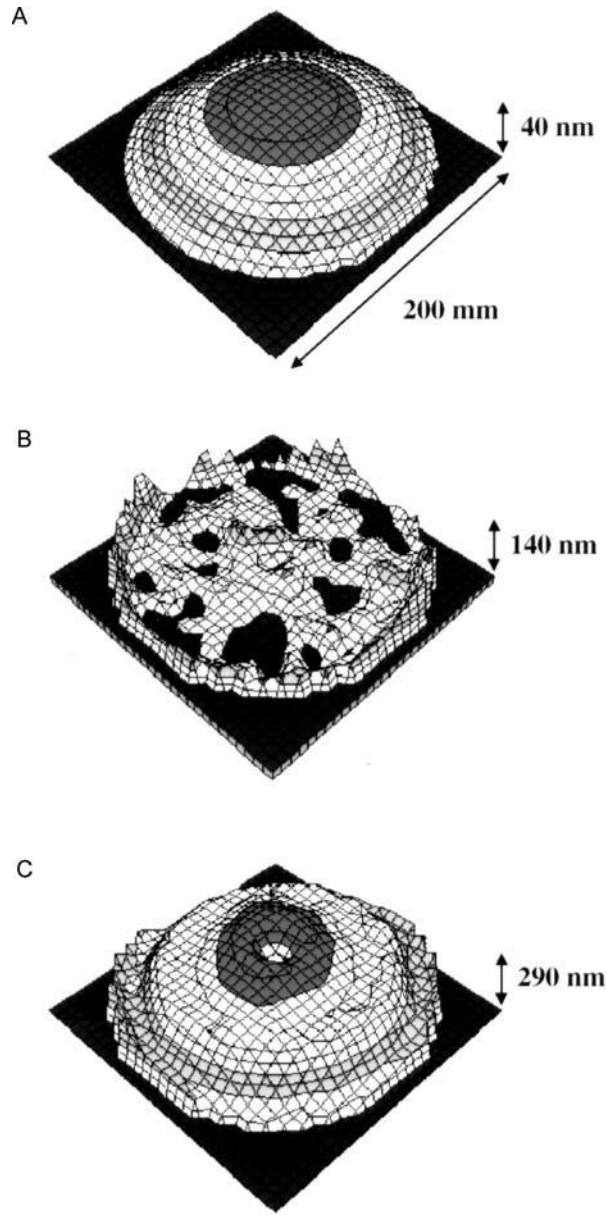

Figure 17. ISTS measured maps of thickness in thin films of copper on silicon wafers with 200 mm diameters. Parts (**A**), (**B**), and (**C**) show, respectively, copper deposited by sputter deposition (average thickness ~180 nm), electroplating (average thickness ~1.6 μm), and an electroplated copper film after chemical-mechanical polishing (average thickness ~500 nm).

The dependence of the waveguide mode velocities on film thickness provides the basis for thickness determination with ISTS (Banet et al., 1998). Often, in practice a single measurement of a mode velocity coupled with the properties of the other components of the structure determines the thickness. The accuracy of the measurement is, of course, highest when the velocity of the waveguide mode depends strongly on the thickness and when the properties of the other components of the structure are known accurately. In a silicon supported system, the velocity of the lowest-order mode (typically excited and probed efficiently in an ISTS measurement) in most cases exhibits sufficient variation with thickness when kh is not large. For films with thicknesses less than ~100 μm, and with properties that are reasonably dissimilar to those of the substrate, it is possible to tune k into a range that allows good sensitivity. Figures 17 and 18 show several examples of thickness evaluation in thin metal films used in microelectronics. Note that the accuracy of the measured thickness depends on the assumed elastic properties, densities, and thicknesses of the substrate and other films in the stack. For many systems, literature values for the physical properties yield acceptable accuracy. In other cases, procedures that calibrate these properties through ISTS analysis of samples with known thicknesses are necessary. For complex structures, such as copper damascene features in microelectronics (i.e., lines of copper embedded in layers of oxide), effective medium models are often preferred to the complex calculations that are required to simulate these systems using first-principles physics based on Equation 4. Figure 19 shows the results of line scans across copper damascene structures that use these types of models for computing thicknesses. With calibrated tools for measuring these and other systems for microelectronics, thickness

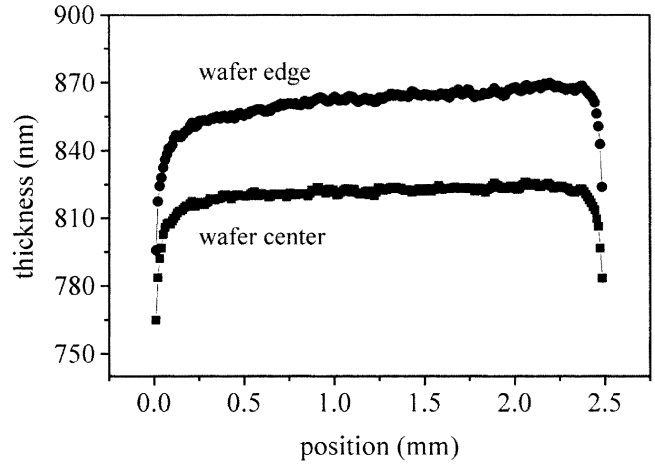

Figure 19. Thickness profiles of copper damascene arrays consisting of copper lines (width 0.5 μm, length ~1 mm and average thickness ~800 nm) separated by 0.5 μm and embedded in a layer of silicon dioxide. Acoustic wave propagation direction is along the trenches (i.e., fringes of the excitation interference pattern lie perpendicular to the long dimension of the copper lines). In this case, effective elastic properties of the copper damascene structure needed for the thickness calculation can be determined by averaging elastic constants of copper and silicon dioxide using a parallel spring model. Thickness values determined using these effective properties were in agreement with SEM measurements. The data illustrate a major problem in the copper interconnect technology, i.e., nonuniformities in the chemical-mechanical polishing process used to form these structures.

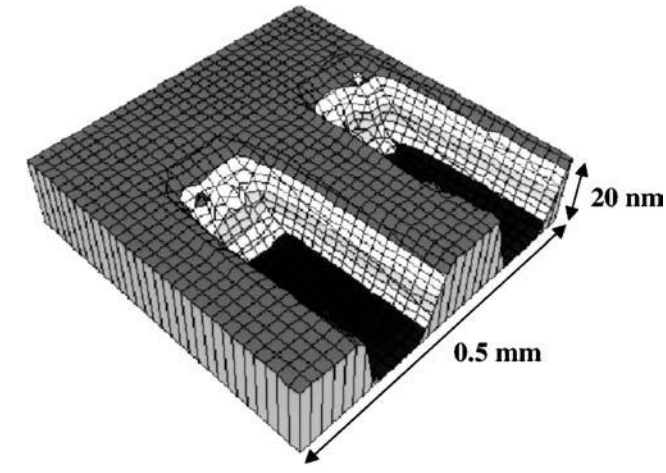

Figure 18. Detailed contour map of an 0.8 × 0.8−mm region showing variations in the thickness of a layer of tantalum in a stack structure of 200 nm copper/Ta (patterned)/300 nm silicon dioxide/silicon. The measurements clearly resolve the regions of the structure where there is no tantalum. The thickness of tantalum in the other areas is ~25 nm. In order to measure the thickness of this buried layer, thicknesses and properties of the other layers, and the mechanical properties and density of the tantalum, were assumed to be known.

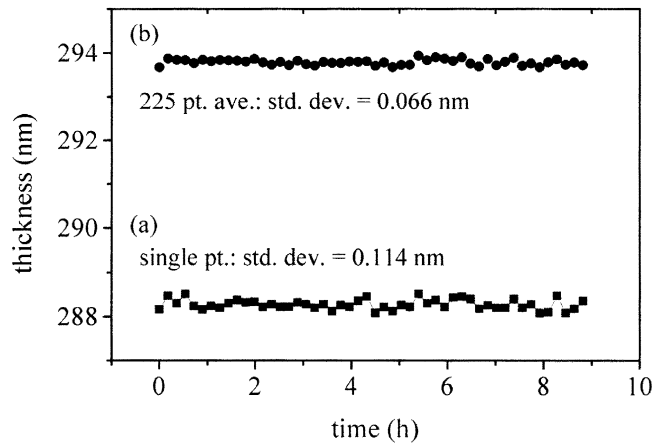

Figure 20. Reproducibility data of ISTS metal film thickness measurement obtained on a commercially available system (Philips Analytical's PQ Emerald). The sample (a silicon wafer with 200 mm diameter and coated with 300 nm tantalum on 300 nm silicon dioxide) was loaded and unloaded from the system for each measurement. The signal was averaged over 300 laser shots (measurement time ~1 sec per point). (**A**) Single-point data. (**B**) Average of a 225-point wafer map. In both cases, the reproducibility is on the order or less than 0.1 nm, roughly a single atomic diameter.

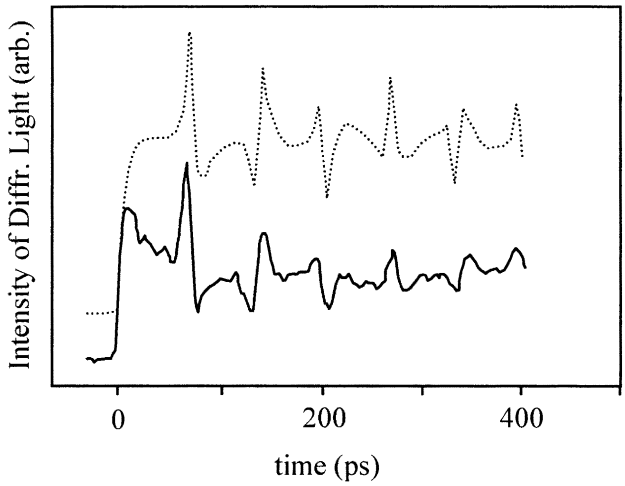

Figure 21. ISTS data on a picosec time scale from a multilayer stack of aluminum (thickness ~100 nm) on titanium-tungsten (thickness ~75 nm) on a silicon wafer. The dashed line shows a simulated response. The features in the data correspond to reflections of longitudinal acoustic wavepackets generated at the surface of the sample by the crossed excitation pulses. The timing of these echoes, with the out-of-plane longitudinal acoustic velocities of the materials, yields the thicknesses of both of the films.

precision and accuracy are both in the range of a few angstroms. Figure 20 illustrates the repeatability for a typical film.

When the thicknesses of more than one film in a multilayer stack are required, additional data, such as (1) velocities of more than one waveguide mode, (2) the velocity of a single mode at more than one k, (3) information other than the acoustic frequency (e.g., acoustic damping, thermal or electronic response, etc.), or (4) the out-of-plane acoustic echo component of the ISTS signal can be employed. Figure 21 illustrates the last approach. The precision and accuracy (again, with proper calibration) are both in the angstrom range with this method. Commercial ISTS tools use a combination of the thermal and acoustic components of the data to determine thicknesses of two films in a stack (Gostein et al., 2000). Here, the precision and accuracy are in the range of 0.05 to 0.15 nm. The particular technique that is most convenient for a given measurement application depends on the sample.

SAMPLE PREPARATION AND SPECIMEN MODIFICATION

The primary constraints on the sample are that (1) it be sufficiently smooth that it does not scatter enough light to interfere with measurement of the diffracted signal, and (2) it absorb a sufficient fraction of the excitation light to yield a measurable response. From a practical standpoint, the intensity of scattered light that is spatially close to or overlapping the signal should not be large compared to the intensity of the signal itself. Typical diffraction efficiencies from acoustic motions in an ISTS experiment are in the range of 10^{-6}. Heterodyne detection schemes significantly amplify the signal levels, thereby reducing the effects of parasitic scatter. Spatial filtering can also help to reduce the amount of scatter that reaches the detector. From a sample-preparation point of view, scatter can be reduced in many cases by adding an index-matching fluid, or by mechanical polishing.

As mentioned above (see Practical Aspects of the Method), in order to ensure adequate ISTS signals, excitation light must produce some mild amount of heating in the sample. This heating can be achieved by using an excitation wavelength that is absorbed directly by the sample, or by adding a thin absorbing overlayer. Generally, the materials used for these overlayer films and their thicknesses are chosen to minimize their effects on the acoustic response of the sample under test. Alternatively, the acoustic influence of these films can be accounted for directly through calculation. Thin aluminum coatings are useful because they provide sufficient absorption to allow high quality ISTS measurements with excitation pulse energies in the range of a few μJ and wavelengths in the infrared (e.g., 1064 nm). Aluminum also has the advantage that it is a low-density material (small acoustic loading for thin films) that can be easily deposited in thin film form by thermal evaporation. Coatings with ~50 to 75 nm thickness provide sufficient absorption, and they also only minimally affect the acoustic response of most samples.

PROBLEMS

Problems that can arise with ISTS evaluation fall into two classes, those associated with acquiring data and those related to interpreting it. For interpretation, multilayer samples can provide the biggest challenge, because uncertainties in the properties of any layer in the stack can significantly affect the accuracy for evaluating the "unknown" layer(s). Accurate measurements of the dispersion of multiple modes over a wide range of k reduces the significance of this problem because it decreases the number of assumptions necessary for the properties of the other layers in the stack.

For data collection, the sample must absorb some reasonable fraction of the excitation light. Convenient laser sources for excitation (e.g., pulsed Nd:YAG lasers) provide direct output in the near-IR range (e.g., 1064 nm). Because of the relatively high peak power, nonlinear optical crystals can be used to generate harmonics of this fundamental frequency. Gold, for example, reflects too efficiently at 1064 nm to allow for ISTS measurement with the fundamental output of a Nd:YAG laser. It absorbs, however, enough frequency-doubled light at 532 nm to allow for easy measurement. Generally, the fourth harmonic of these types of lasers (266 nm) provides a useful wavelength for measurements on a wide range of samples.

With a suitable wavelength for excitation, high-quality signals can be obtained for most samples that do not scatter strongly at the wavelength of the probing laser. Scattered light that reaches the detector can interfere with data collection either by simply adding noise or, when it coherently interferes with diffracted signal light, by distorting the shape of the measured waveform. The former problem can, in most cases, be eliminated by carefully

blocking the scattered light so that it does not reach the detector. The latter problem cannot be handled in the same way because these effects are produced by scattered light that spatially overlaps the signal light. This interference essentially causes uncontrolled heterodyne amplification. It is often difficult to simulate accurately this interference and its subtle effects on the accuracy of procedures for extracting the response frequency (e.g., Fourier transformation followed by peak fitting), because the phase and intensity of the scattered light are not generally known. These effects can be minimized, however, by employing heterodyne detection and adjusting the intensity of the reference beam so that its interference with the signal dominates the measured response. In any case, the precision of the measurement can be easily evaluated by repeated measurement of a single spot on a sample. The standard deviation of a set of frequencies measured in this fashion should be less than ~0.1% for most samples.

APPENDIX: VENDOR INFORMATION

Currently there is a single vendor that sells complete ISTS instruments for metrology of thin metal films found in microelectronics:

Philips Analytical
Worldwide headquarters:
Lelyweg 1, 7602 EA Almelo,
The Netherlands
Tel.: +31 546 534 444
Fax: +31 546 534 598

In the U.S.:
Philips Analytical
12 Michigan Dr.
Natick, Mass. 01760
Tel.: (508) 647–1100
Fax: (508) 647–1111
http://www.analytical.philips.com

The names of the two free-standing tools are Impulse 300 and PQ Emerald.

There are also integrated metrology solutions for Cu interconnect process tools (e.g.: Paragon electroplating system from Semitool).

Semitool
655 West Reserve Dr.
Kalispell, Montana 59901
Tel.: (406) 752-2107
Fax: (406) 752-5522

Philips Analytical's Impulse 300 and PQ Emerald are fully automated all-optical metal thin film metrology systems for metal interconnect process control in semiconductor integrated circuit manufacturing. Impulse 300 is a versatile system for wafers up to 300 mm in size. PQ Emerald is a small-footprint (1.2 $\times$ 1.53−m) system for wafer size up to 200 mm. Both systems have measurement spot size 25 $\times$ 90 microns and pattern-recognition capabilities enabling measurements on product wafers. Measurements can be done on test pads as well as on high-density arrays of submicron structures, e.g., damascene line arrays.

Typical reproducibility: 1 to 2 Å (plasma vapor deposited Cu, Ta), 10 to 50 Å (thick electroplated Cu). Measurement time 1 sec /site, throughput up to 70 wafers per hr.

Key applications are copper interconnect process control, including seed deposition, electroplating and chemical-mechanical polishing.

Philips Analytical also offers integrated metrology solutions for Cu PVD, electroplating and polishing process tools.

RESONANCE METHODS

INTRODUCTION

This chapter shows how nuclear and electron resonance spectroscopies can help solve problems in materials science. The concept of a probe, located centrally within a material, is common to all resonance spectroscopy techniques. For example, the nucleus serves as the probe in nuclear magnetic resonance (NMR), nuclear quadrupole resonance (NQR), and Mössbauer spectrometry, while a paramagnetic atom (i.e., one containing unpaired electrons) often serves as a probe in electron spin resonance (ESR). Sometimes the interest is in measuring the total numbers of probes within a material, or the concentration profiles of probe nuclei as in the case for basic NMR imaging. More typically, details of the measured energy spectra are of interest. The spectra provide the energies of photons that are absorbed by the probe, and these are affected by the electronic and/or nuclear environment in the neighborhood of the probe. It is often a challenge to relate this local electronic information to larger features of the structure of materials.

The units in this chapter describe how local electronic and magnetic structure can be studied with resonance techniques. The energy levels of the probe originate with fundamental electrostatic and magnetic interactions. These are the interaction of the nuclear charge with the local electron density, the electric quadrupole moment of the nucleus with the local electric field gradient, and the spin of the nucleus or spin of the electrons with the local magnetic field. For magnetic interactions in NMR, for example, the experimental spectra depend on how the energy of the probe differs for different orientations of the nuclear spin in the local magnetic field. In general these interactions involve some constant factors of the probe itself, such as its spin and gyromagnetic ratio. The energy level of the probe is the product of these constant factors and a local field. The resonance condition is such that a photon is absorbed, which causes the probe to undergo a transition to a state that differs in energy from its initial state by the energy of the absorbed photon. Since the parameters intrinsic to the probe are known for both states, the experimental spectrum provides the spectrum of the local field quantity characteristic of the material. Continuous wave methods excite probes with specific local fields. Pulse techniques excite all available probes, and differentiate them later by the phases of their precession in their local fields.

The energy differences of the probe levels are small. Radio transmitters provide the excitation photons in the case of NMR and NQR, and microwave generators provide the photons in ESR. The energy from these excitations is eventually converted into heat in the material. For Mössbauer spectrometry and other nuclear methods such as perturbed angular correlation spectroscopy (PACS), the photon, a γ ray, is provided by a radioisotope source. The photon energy is absorbed by exciting internal nuclear transitions. The subsequent decay occurs through the emission of ionizing radiation.

The ultimate energy resolution of these resonance spectroscopies is the energy precision, ΔE, that is set by the uncertainty principle

$$\Delta E \cong \frac{\hbar}{\Delta t} \tag{1}$$

where Δt is the lifetime of the excited state. [The Δt can also be imposed experimentally by exposing the sample to an additional radiofrequency pulse(s).] It is fortunate for the nuclear techniques of NMR, NQR, and Mössbauer spectrometry that Δt is relatively long, so the energy resolution, ΔE, is high. This makes nuclear spectra useful for studies of materials, because the weak hyperfine interactions between the nucleus and the surrounding electrons provide information about the electrons in the solid. The sampling of the local field is modified when the probe atom undergoes diffusive motions during the time Δt. Local probe methods provide unique information on the jumping frequencies of the probe atoms, and sometimes on the jump directions.

In spite of the high energy resolution of resonance spectroscopies, they are not typically known for their spatial resolution. Microscopies, as those for electrons or light, have not been developed for resonance spectroscopies because their photons cannot be focused. Especially for NMR and NQR, however, control over magnetic fields and the imposed pulse sequences can be used to make images of the concentrations of resonant probes within the material. These methods are under rapid development, driven largely by market forces outside materials science.

The units in this chapter enumerate some requirements for samples, but an obvious requirement is that the material must contain the probe itself. A set of allowed nuclei is listed in the units of NMR, NQR, and Mössbauer spectrometry, and the unit on ESR discusses unpaired electrons in materials. It is rare for the sample to have too high a concentration of probes; usually the difficulty is that the sample is too dilute in the nuclear or electron probe. Sensitivity is often a weakness of resonance spectroscopies, and measurements may require modest sample sizes and long data acquisition times to achieve statistically reliable spectra. An increased data acquisition rate is possible if the resonance frequencies are known in advance, and data need be acquired at only one point of the spectrum. Such specialized methods can be useful for routine characterizations of materials, but are usually not the main mode of operation for laboratory spectrometers.

Sometimes the probe is peripheral to the item of interest, which may be an adjacent atom, for example. Useful data can sometimes be obtained from measurements where the probe is a nearby spectator. As a rule of thumb, however, resonant probe experiments tend to be most informative when the probe is itself at the center of the

action, or at least is located at the atom of interest in the material.

Nuclear and electron resonance spectroscopies are specialized techniques. They are not methods that will be used by many groups in materials science. Especially when capital investment is high, as in the case of NMR imaging, it makes sense to contact an expert in the field to assess feasibility and reliability of measurements. Even when the capital investment in equipment is low, as for Mössbauer spectrometry, novices can be misled in several aspects of data interpretation. Collaborations are fairly commonplace for practitioners of resonance spectroscopies. The viewpoint of a material from a resonant probe is a small one, so resonance spectroscopists are accustomed to obtaining complementary experimental information when solving problems in materials science. Nevertheless, the viewpoint of a material from a resonant probe is unique, and can provide information unavailable by other means.

NUCLEAR MAGNETIC RESONANCE IMAGING

INTRODUCTION

Nuclear magnetic resonance imaging is a tomographic imaging technique that produces maps of the nuclear magnetic resonance signal in a sample. The signal from a volume element (voxel) in the sample is represented as an intensity of a picture element (pixel) in an image of the object. Nuclear magnetic resonance imaging has developed as an excellent noninvasive medical imaging technique, providing images of anatomy, pathology, circulation, and functionality that are unmatched by other medical imaging techniques. Nuclear magnetic resonance imaging is also an excellent nondestructive analytical tool for studying materials. Applications of nuclear magnetic resonance imaging in the field of materials science have also been developed, but to a lesser extent. The most probable reason why the development of materials applications of nuclear magnetic resonance imaging has lagged behind that of clinical applications is the cost-to-information ratio. The 1998 price of a clinical magnetic resonance imager is between one and two million U.S. dollars.

Before beginning a discussion of nuclear magnetic resonance imaging, it is useful to review the field of magnetic resonance (MR). Magnetic resonance is the general term that encompasses resonance processes associated with magnetic moments of matter. Please refer to Figure 1 throughout this introductory discussion. The two major branches of magnetic resonance are electron paramagnetic resonance (EPR), or electron spin resonance (ESR), as it is sometimes called (see ELECTRON PARAMAGNETIC RESONANCE SPECTROSCOPY), and nuclear magnetic resonance (NMR). A much smaller third component of magnetic resonance is muon spin resonance (μSR). EPR and ESR measure properties of the magnetic moment of the electrons or electron orbitals, while NMR is concerned with the magnetic moment of nuclei with unpaired protons and neutrons. Electron nuclear double resonance (ENDOR) examines the interactions between the nuclear and electron moments. All of the above techniques are used to measure properties of atoms and molecules in materials.

Within the fields of EPR and NMR are imaging disciplines. The term magnetic resonance imaging (MRI) should be used to describe imaging techniques based on both NMR and EPR or ESR. For historical reasons, MRI has been used for nuclear magnetic resonance imaging, the mapping of the spatial distribution of the NMR signals in matter. EPR imaging (EPRI) and ESR imaging (ESRI) have been used to describe imaging of the spatial distribution of electron and electron orbital magnetic moments in matter. This unit will concentrate on MRI, as previously defined, of materials.

MRI is used to image both large- and small-diameter objects. When imaging small objects, <1 cm in diameter, the imaging process is typically called NMR microscopy. When imaging larger objects, the procedure is generally called MRI. In reality, the imaging procedures are the same. The distinction arises from the type of instrument used, rather than the dimensions of the material. NMR microscopy is performed on an NMR spectrometer equipped with imaging hardware. Samples that do not fit into the microscope are imaged on a small-bore imager or clinical whole-body imager. No distinction will be made in this unit between MRI and NMR microscopy of materials.

MRI has been applied in many disciplines to study materials. MRI, as a nondestructive analytical technique, has very few competing techniques. X-ray and ultrasound imaging techniques come close to providing similar information in a nondestructive manner, but do not have the sensitivity to many of the fundamental properties of matter that MRI has. MRI may be used to measure distance, flow, diffusion coefficients, concentration, microscopic viscosity, partial pressure, pH (Metz et al., 1998), temperature (Aime et al., 1996; Zuo et al., 1996), magnetic susceptibility, and the dielectric constant. A few good MRI reviews are (Komoroski, 1993; Callaghan, 1991; Blumich et al., 1994; Hall et al., 1990; Gibbs and Hall, 1996; and Attard et al., 1991).

In food science, MRI has been used to study the consistency (Duce et al., 1990), baking (Duce and Ablett, 1995), cooking, curing (Guiheneuf et al., 1996; Guiheneuf, Gibbs, and Hall, 1997), storage, spoilage (Guiheneuf et al., 1997), hydration (Duce and Hall, 1995), and gelling (Holme and Hall, 1991) of food. MRI can be used to examine the ripening of fruits and vegetables, as well as damage by disease, insects, and bruising. MRI can determine the moisture and oil content, distribution, and transport in harvested grains and seeds (Duce et al., 1994). Lumber grading, or the mapping of knots, defects, and disease in lumber (Pearce et al., 1997), can be achieved by MRI. MRI has been used in botany to study disease and the flow and diffusion of water in plants.

In soil science, MRI can be used to map the water content and transport in soil. Soil (Amin et al., 1994, 1996), rock cores (Horsfield et al., 1990; Fordham et al., 1993a; Fordham et al., 1995), and oil well cores have been imaged to determine hydrocarbon and water content, as well as porosity, diffusion (Fordham et al., 1994; Horsfield, 1994), capillary migration (Carpenter et al., 1993), and flow characteristics.

In civil engineering, MRI has been used to study the curing and porosity of cement as well as water transport in concrete (Link et al., 1994) and other building materials (Pel et al., 1996). MRI can determine the effectiveness of paints and sealers in keeping out moisture.

In chemistry, MRI has been used to image chemical waves associated with certain chemical reactions (Armstrong et al., 1992), hydrogen adsorption into palladium metal (McFarland et al., 1993), processes in chromatographic columns (Ilg et al., 1992), as well as in reactions and crystals (Komoroski, 1993). MRI has been used to characterize ceramics (Wang et al., 1995)—flaws (Karunanithy and Mooibrook, 1989), cracks, voids (Wallner and Ritchey, 1993), and binder distribution (Wang et al., 1993) in ceramics have been imaged. MRI has been used to noninvasively study the homogeneity of solid rocket propellants (Maas et al., 1997; Sinton et al., 1991).

Polymers have been the subject of many MRI investigations (Blumich and Blumler, 1993). MRI has been used to study the uptake of water into the polymer coating used on silicon chips (Hafner and Kuhn, 1994) and polyurethane dispersion coating (Nieminen and Koenig, 1990). MRI has been used to study curing (Jackson, 1992), vulcanization (Mori and Koenig, 1995), solvent ingress (Webb and Hall, 1991), inhomogeneities (Webb et al., 1989), diffusion (Webb and Hall, 1990), multicomponent diffusion (Grinsted and Koenig, 1992), cyclic sorption-desorption (Grinsted et al., 1992), aging (Knorgen et al., 1997), filler inhomogeneities (Sarkar and Komoroski, 1992), adhesion (Nieminen and Koenig, 1989), and water uptake (Fyfe et al., 1992) in polymers.

MRI is also used to image flow (Amin et al., 1997; Seymour and Callaghan, 1997), diffusion (Callaghan and Xia, 1991), and drainage (Fordham et al., 1993b) in materials, and hence gain a better understanding of the internal microscopic structure of the materials.

There have been two ways in which MRI has been used to study materials. One approach images the material, and the other images the absence of material. The first approach is to directly image the NMR signal from a signal-bearing substance in the sample. The second is to introduce a signal-bearing substance into voids within the material and image the signal from the signal-bearing substance. The latter procedure is good for porous samples that do not have a measurable NMR signal of their own. The latter approach is more common because it can be performed on clinical magnetic resonance imagers with routinely available clinical imaging sequences. The former approach typically requires either faster imaging sequences, or different hardware and imaging sequences capable of looking at a solid-state NMR signal.

PRINCIPLES OF THE METHOD

Nuclear magnetic resonance imaging is based on the principles of nuclear magnetic resonance. The choice of imaging parameters necessary to produce a high quality MR image requires knowledge of many of the microscopic properties of the system of spins being imaged. It is therefore necessary to understand the principles of NMR before those of MRI can be introduced.

Theory of NMR

NMR is based on a property of the nucleus of an atom called spin. The material presented in this unit pertains to spin 1/2 nuclei. Spin can be thought of as a simple magnetic moment. When a spin 1/2 nucleus is placed in an external magnetic field, the magnetic moment can take one of two possible orientations, one low-energy orientation aligned with the field and one high-energy orientation opposing the field. A photon with an amount of energy equal to the energy difference between the two orientations or states will cause a transition between the states. The greater the magnetic field, the greater the energy difference, and hence the greater the frequency of the absorbed photon. The relationship between the applied magnetic field B and the frequency of the absorbed photon ν is linear.

$$\nu = \gamma B \tag{1}$$

The proportionality constant γ is called the gyromagnetic ratio. The gyromagnetic ratio is a function of the magnitude of the nuclear magnetic moment. Therefore, each isotope with a net nuclear spin possesses a unique γ. The γ value of some of the more commonly imaged nuclei are listed in Table 1. In NMR, B fields are typically 1 to 10 tesla (T); therefore ν is in the MHz range.

Table 1. Gyromagnetic Ratio of Some Commonly Imaged Nuclei

Nucleus	Gyromagnetic Ratio (MHz/T)
^{1}H	42.58
^{13}C	10.71
^{17}O	5.77
^{19}F	40.05
^{23}Na	11.26
^{31}P	17.24

NMR has the ability to distinguish between nuclei in different chemical environments. For example, the resonance frequency of hydrogen in water is different than that for the hydrogen nuclei in benzene. This difference is called the chemical shift of the nucleus, and is usually reported in ppm relative to a reference. In hydrogen NMR this reference is tetramethylsilane (TMS). The chemical shift for a freely tumbling nucleus i in a nonviscous solution is

$$\delta_i = \frac{(\nu_{TMS} - \nu_i)}{\nu_{TMS}} \times 10^6 \qquad (2)$$

In solids and some viscous liquids, δ may be anisotropic due to the fixed distribution of orientations of the nuclei in the molecule.

Molecules with interacting spins will display spin-spin coupling, or a splitting of the energy levels due to interactions between the nuclei. The spin-spin interaction is orientation-dependent. Once again, in nonviscous liquids, this orientation-dependence is averaged out and seen as one average interaction. In liquids, multiple resonance lines may be observed in an NMR spectrum, depending on the magnitude of the spin-spin coupling. In solids and viscous liquids, the distribution of orientations results in broad spectral absorption peaks. Imaging solids will require different and less routine techniques than are used in imaging nonviscous liquids.

The remainder of this description of NMR will adopt a more macroscopic perspective of the spin system in which a static magnetic field, B_0, is applied along the z axis. Groups of nuclei experiencing the exact same B_0 are called spin packets. When placed in a B_0 field, spin packets precess about the direction of B_0 just as a spinning top precesses about the direction of the gravitational field on earth. The precessional frequency, also called the Larmor frequency, ω, is equal to $2\pi\nu$. Adapting the conventional magnetic resonance coordinate system, the direction of the precession is clockwise about B_0, and the symbol ν_0 is reserved for spin packets experiencing exactly B_0 (Fig. 2). It is often helpful in NMR and MRI to adopt a rotating frame of reference to describe the motion of magnetization vectors. This frame of reference rotates about the z axis at ν_0. The coordinates in the rotating frame of reference are referred to as z, x', and y'. An excellent animated depiction of the motion of a magnetization vector in a magnetic field can be found in the Web-based hypertext book, *The Basics of MRI*, by J. P. Hornak (*http://www.cis.rit.edu/htbooks/mri/*).

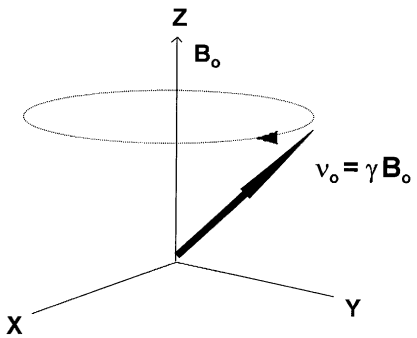

Figure 2. Clockwise precession of the net magnetization vector in an *xyz* coordinate system.

An NMR sample contains millions of spin packets, each with a slightly different Larmor frequency. The magnetization vectors from all these spin packets form a cone of magnetization around the z axis. At equilibrium, the net magnetization vector **M** from all the spins in a sample lies in the center of the cone along the z axis. Therefore, the longitudinal magnetization M_z equals M and the transverse magnetization M_{xy} equals zero at equilibrium. Net magnetization perturbed from its equilibrium position will want to return to its equilibrium position. This process is called spin relaxation.

The return of the z component of magnetization to its equilibrium value is called spin-lattice relaxation. The time constant that describes the exponential rate at which M_z returns to its equilibrium value M_{z0} is called the spin-lattice relaxation time, T_1. Spin-lattice relaxation is caused by time-varying magnetic fields at the Larmor frequency. These variations in the magnetic field at the Larmor frequency cause transitions between the spin states and hence change M_z. Time-varying fields are caused by the random rotational and translational motions of the molecules in the sample possessing nuclei with magnetic moments. The frequency distribution of random motions in a liquid varies with temperature and viscosity. In general, relaxation times tend to get longer as B_0 increases. T_1 lengthens because there are fewer relaxation-causing frequency components present in the random motions of the molecules as ν increases.

At equilibrium, the transverse magnetization, M_{xy}, equals zero. A net magnetization vector rotated off of the z axis creates transverse magnetization. This transverse magnetization decays exponentially with a time constant called the spin-spin relaxation time T_2. Spin-spin relaxation is caused by fluctuating magnetic fields that perturb the energy levels of the spin states and dephase the transverse magnetization. T_2 is inversely proportional to the number of molecular motions less than and equal to the Larmor frequency. Specialists in NMR break down T_2 further into a pure T_2 due to molecular interactions and one due to inhomogeneities in the B_o field. The overall T_2^* is referred to as "T_2 star."

$$\frac{1}{T_2^*} = \frac{1}{T_{2\,\text{molec}}} + \frac{1}{T_{2\,\text{inhomogeneous}}} \qquad (3)$$

In pulsed NMR and MRI, radiofrequency (RF) energy is put into a spin system by sending RF into a resonant LC circuit, the inductor of which is placed around the sample. The inductor must be oriented with respect to the B_0 magnetic field so that the oscillating RF field created by the RF flowing through the inductor is perpendicular to B_0. The RF magnetic field is called the B_1 magnetic field. When the RF inductor, or coil as it more often called, is placed around the x axis, the B_1 field will oscillate back and forth along the x axis.

In pulsed NMR spectroscopy, it is the B_1 field that is pulsed. Turning on a B_1 field for a period of time, τ, will

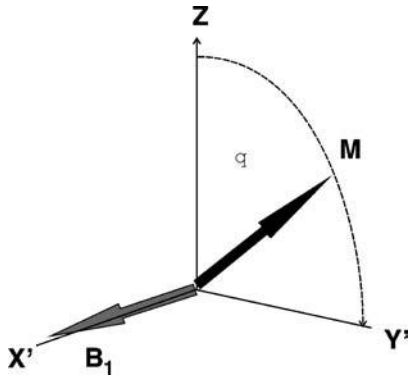

Figure 3. Rotation of net magnetization vector M by B_1 field in a rotating frame of reference.

cause the net magnetization vector to precess in ever widening circles around the z axis. Eventually the vector will reach the xy plane. If B_1 is left on longer, the net magnetization vector will reach the negative z axis. In the rotating frame of reference this vector appears to rotate away from the z axis, as depicted in Figure 3. The rotation angle θ, which is measured clockwise about the direction of B_1 in radians, is proportional to γ, B_1, and τ

$$\theta = 2\pi\gamma B_1 \tau \tag{4}$$

Any transverse magnetization, M_{xy}, will precess about the direction of B_0. An NMR signal is generated from transverse magnetization rotating about the z axis. This magnetization will induce a current in a coil of wire placed around the x or y axis. As long as there is transverse magnetization that is changing with respect to time, there will be an induced current in the coil. For a group of nuclei with one identical chemical shift, the signal will be an exponentially decaying sine wave. The sine wave decays with time constant T_2^*. It is predominantly the inhomogeneities in B_0 that cause the spin packets to dephase.

Net magnetization, which has been rotated away from its equilibrium position along the z axis by exactly 180°, will not create transverse magnetization and hence not give a signal. The time-domain signal from a net magnetization vector in the xy plane is called a free induction decay (FID). This time-domain signal must be converted to a frequency-domain spectrum to be interpreted for chemical information. The conversion is performed using a Fourier transform. The hardware in most NMR spectrometers and magnetic resonance imagers detects both M_x and M_y simultaneously. This detection scheme is called quadrature detection. These two signals are equivalent to the real and imaginary signals; therefore the input to the Fourier transform will be complex. Sampling theory tells us that one need only digitize the FID at a frequency of f complex points per second in order to obtain a spectrum of frequency width f, in Hz.

In pulsed Fourier transform NMR spectroscopy, short bursts of RF energy are applied to a spin system to induce a particular signal from the spins within a sample. A pulse sequence is a description of the types of RF pulses used and the response of the magnetization to the pulses. The simplest and most widely used pulse sequence for routine NMR spectroscopy is the 90-FID pulse sequence. As the name implies, the pulse sequence is a 90° pulse followed by the acquisition of the time-domain signal called an FID. The net magnetization vector, which at equilibrium is along the positive z axis, is rotated by 90° down into the xy plane. The rotation is accomplished by choosing an RF pulse width and amplitude so that the rotation equation for a 90° pulse is satisfied. At this time the net magnetization begins to precess about the direction of the applied magnetic field B_0. Assuming that the spin-spin relaxation time is much shorter than the spin-lattice relaxation time ($T_2 \ll T_1$), the net magnetization vector begins to dephase as the vectors from the individual spin packets in the sample precess at their own Larmor frequencies. Eventually, M_{xy} will equal zero and the net magnetization will return to its equilibrium value along z. The signal that is detected by the spectrometer is the decay of the transverse magnetization as a function of time. The FID or time-domain signal is Fourier transformed to yield the frequency domain NMR spectrum.

Theory of MRI

The basis of MRI is Equation 1, which states that the resonance frequency of a nucleus is proportional to the magnetic field it is experiencing. The application of a spatially varying magnetic field across a sample will cause the nuclei within the sample to resonate at a frequency related to their position.

For example, assume that a one-dimensional linear magnetic field gradient G_z is set up in the B_0 field along the z axis. The resonant frequency, ν, will be equal to

$$\nu = \gamma(B_0 + zG_z) \tag{5}$$

The origin of the xyz coordinate system is taken to be the point in the magnet where the field is exactly equal to B_0 and spins resonate at ν_0. This point is referred to as the isocenter of the magnet. Equation 6 explains how a simple one-dimensional imaging experiment can be performed. The sample to be imaged is placed in a magnetic field B_0. A 90° pulse of RF energy is applied to rotate magnetization into the xy plane. A one-dimensional linear magnetic field gradient G_z is turned on after the RF pulse and the FID is immediately recorded. The Fourier transform of the FID yields a frequency spectrum that can be converted to a spatial, z, spectrum as a function

$$z = \frac{(\nu - \nu_0)}{\gamma G_z} \tag{6}$$

This simple concept of a one-dimensional image can be expanded to a two-dimensional image by employing the concept of back-projection imaging similar to that used in computed tomography (CT) imaging. (Hornak, 1995). If a series of one-dimensional images, or projections of the signal in a sample, are recorded for linear one-dimensional magnetic field gradients applied along several different trajectories in a plane, the spectra can be transformed into a two-dimensional image using an inverse

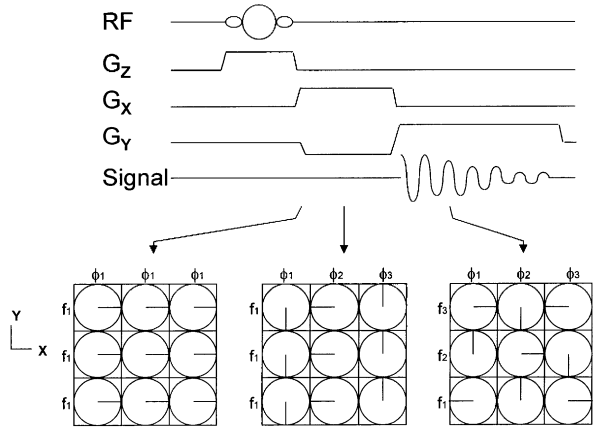

Figure 4. Timing diagram for a 90-FID imaging sequence and the behavior of nine spin vectors in the imaged plane at three times in the imaging sequence.

radon transform (Sanz, 1988) or back projection algorithm (Lauterbur, 1973). This procedure is often used in materials imaging where short T_2 values prevent the use of the more popular Fourier-based method (Kumar and Ernst, 1975; Smith, 1985). A Fourier-based imaging technique collects data from the k space of the imaged object. This k space is the two-dimensional Fourier transform of the image. Figure 4 depicts a timing diagram for a Fourier imaging sequence using simple 90-FID sequence. The timing diagram describes the application of RF and three magnetic-field gradients called the slice selection (G_s), phase encoding (G_p), and frequency encoding (G_f) gradients. The first step in the Fourier imaging procedure is slice selection of those spins in the object for which the image is to be generated.

Slice selection is accomplished by the application of a magnetic field gradient at the same time as the RF pulse is applied. An RF pulse, with frequency width $\Delta\nu$ centered at ν, will excite, when applied in conjunction with a field gradient G_z, spins centered at $z = (\nu - \nu_0)/\gamma G_z$ with a spread of spins at z values $\Delta z = \Delta\nu/\gamma G_z$. Spins experiencing a magnetic field strength not satisfying the resonance condition will not be rotated by the RF pulses, and hence slice selection is accomplished. The image slice thickness (Thk) is given by Δz. For a clean slice, i.e., where all spins along the slice thickness are rotated by the prescribed rotations, the frequency content of the pulse must be equal to a rectangular-shaped function. Therefore, the RF pulse must be shaped as a sinc function ($\sin x/x$) in the time domain.

The next step in the Fourier imaging procedure is to encode some property of the spins as to the location in the selected plane. One could easily encode spins as to their x position by applying a gradient G_x after the RF pulse and during the acquisition of the FID. The difficulty is in encoding the spins with information as to their y location. This is accomplished by encoding the phase of the precessing spin packets with y position (Fig. 4). Phase encoding is accomplished by turning on a gradient in the y direction immediately after the slice-selection gradient is turned off and before the frequency-encoding gradient is turned on. The spins in the excited plane now precess at a frequency dependent on their y position. After a period of time, the gradient is turned off and the spins have acquired a phase equal to

$$\phi = 2\pi\gamma\tau y G_y \tag{7}$$

Figure 4 describes, for nine magnetization vectors, the effect of the application of a phase-encoding gradient, G_y, and a frequency-encoding gradient, G_x. The phase-encoding gradient assigns each y position a unique phase. The frequency-encoding gradient assigns each x position a unique frequency. If one had the capability of independently assessing the phase and frequency of a spin packet, one could assign its position in the xy plane. Unfortunately, this cannot be accomplished with a single pulse and signal. The amplitude of the phase-encoding gradient must be varied so a 2π radian phase variation between the isocenter and the first resolvable point in the y direction can be achieved, as well as a $256\,\pi$ radian variation from center to edge of the imaged space for 256-pixel resolution in the phase-encoding direction. The result is to traverse, line by line, the k space of the image. The negative lobe on the frequency-encoding gradient (Fig. 4.), which was not previously described, shifts the center of k space to the center of the signal acquisition window.

The B_0 field is created by a large-diameter, solenoidal-shaped, superconducting magnet. The gradient fields are created by room temperature gradient coils located within the bore of the magnet. These coils are driven by high-current audiofrequency amplifiers. The B_1 field is introduced into the sample by means of a large LC circuit that surrounds the object to be imaged. The same or a separate LC circuit is used to detect the signals from the precessing spins in the body.

The field of view (FOV) is dependent on the quadrature sampling rate, R_s during the G_f and on the magnitude of G_f.

$$\mathrm{FOV} = R_s/G_f \tag{8}$$

The two-dimensional k space data set is Fourier transformed and the magnitude image generated from the real and imaginary outputs of the Fourier transform.

The number of pixels across the field of view, N, is typically 256 in both directions of the image. Assuming a 20-cm FOV and 3-mm slice thickness, the in-plane resolution is $\sim$0.8 mm. The volume of a voxel is therefore $\sim$2 mm^2. When imaging features occupying fractions of a voxel, each voxel comprises more than one substance. As a consequence, the NMR signal from a voxel is a sum of the NMR signals from the substances found in the voxel. Variations in the signal from a voxel, due to the relative amounts of the components found in a voxel, is referred to as a partial volume effect.

A magnetic resonance image can be thought of as a convolution of a two-dimensional NMR spectrum of the spin-bearing substance with the spin-concentration map from the imaged object. This is better visualized in one dimension, where x is the imaged dimension. If $f_i(\nu G_x/\gamma)$ is the NMR spectrum of the spin type converted to distance units, and $g_i(x)$ is the distribution of the spins,

the one-dimensional image is the convolution of these two functions. Since there may be more than one component in a voxel, the one-dimensional image, $h(x)$, becomes

$$h(x) = \sum_i g_i(x) \otimes f_i(\nu G_x/\gamma) \tag{9}$$

Defining Γ_i as the full line width at half height of component i in Hz, $\Gamma_i G_x/\gamma$ for the largest Γ_i must be less than FOV/N for optimum resolution in $h(x)$.

The most commonly imaged spin-bearing nucleus is hydrogen. The two most commonly imaged molecules containing hydrogen are hydrocarbons and water. These hydrogens yield one signal in the image, as chemical shift and spin-spin splitting information is generally not utilized. Occasionally the different chemical shifts for water and hydrocarbon hydrogens can lead to an artifact in an image called a chemical-shift artifact. Other hydrogens associated with many samples have very short T_2 values and do not contribute directly to the signal.

In the example of Figure 4, the slice-selection gradient was applied along the z axis and the phase and frequency-encoding gradients along the y and x axes, respectively. In practice, the gradients can be applied along any three orthogonal directions, with the only restrictions being that the slice selection gradient be perpendicular to the imaged plane.

The most routinely used imaging sequence is the spin-echo. Its popularity is attributable to its ability to produce images that display variations in T_1, T_2, and spin concentration of samples. This sequence consists of 90° and 180° RF pulses repeated every TR seconds (Fig. 5). These pulses are applied in conjunction with the slice selection gradients.

The phase-encoding gradient is applied between the 90° and 180° pulses. The frequency-encoding gradient is turned on during the acquisition of the signal. The signal is referred to as an echo because it comes about from the refocusing of the transverse magnetization at time TE after the application of the 90° pulse. The signal, when TE $\ll$ TR, from a voxel will be equal to a sum over all the different types of spins, i, in the voxel.

$$S(\mathrm{TE}, \mathrm{TR}) = k \sum_i \rho_i (1 - e^{-\mathrm{TR}/T_{1i}}) e^{-\mathrm{TE}/T_{2i}} \tag{10}$$

Spin density, ρ, is the number of spins per voxel, and k is a proportionality constant.

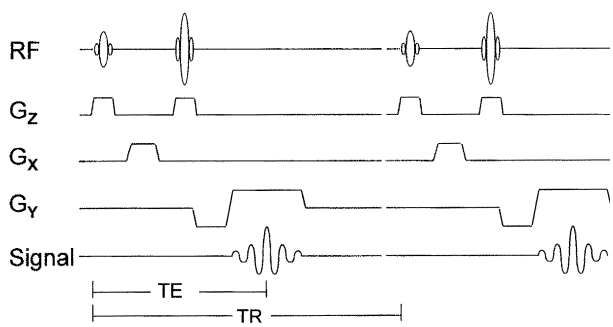

Figure 5. Timing diagram for a spin-echo imaging sequence.

PRACTICAL ASPECTS OF THE METHOD

The signal in a magnetic resonance image is a function of T_1, T_2, T_2^*, ρ, the diffusion coefficient (D), the velocity (V), and chemical shift (δ) of the spins. The various imaging sequences are designed to produce a signal that is proportional to one of these parameters. A weighted image is one in which the signal intensity is dependent on one of these properties. For example, a T_1-weighted image is one in which the image intensity displays differences in T_1 of the sample.

All images are generated with the aid of an imaging pulse sequence similar to those presented in Figures 4 and 5. There are hundreds of imaging sequences, but only a fraction of these are routinely used. A few are mentioned here, and others can be found in the literature. Because the implementation of these is imager-dependent, readers are encouraged to refer to their instrument manuals for specific details. When searching the scientific literature for information on pulse sequences, the reader is reminded that much MRI development work has been published by scientists in the clinical literature.

There are two goals in MRI of materials. One is to visualize structure, texture, or morphology in samples. The second is to visualize spatial or temporal variations in some property of the sample. In the former, the MRI researcher needs to maximize the contrast-to-noise ratio between features in the sample. The imaging parameters are chosen to maximize the difference in signal intensity of two adjacent regions in the image of the sample. For example, Figures 6 and 7 indicate how contrast can be achieved based on the choice of TE and differences in T_2, and the choice of TR and variations in T_1. If the visualization of spatial or temporal variations is the goal, the absolute intensity of a pixel is important and the choice of imaging parameters is generally chosen to maximize the signal-to-noise ratio.

Before any of the following imaging sequences may be implemented, T_1 and T_2 of the sample at the field strength of the imager must be known. These values are needed to determine the optimum values of TR, TE, FOV, Thk, and so on.

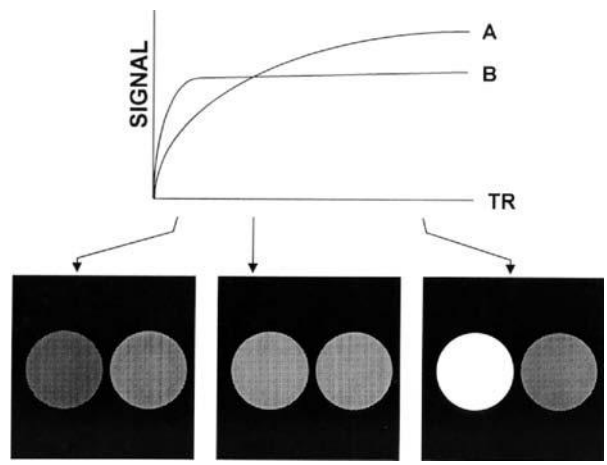

Figure 6. Signal of two substances, A and B, as a function of TR, and their corresponding simulated images at the indicated TR values.

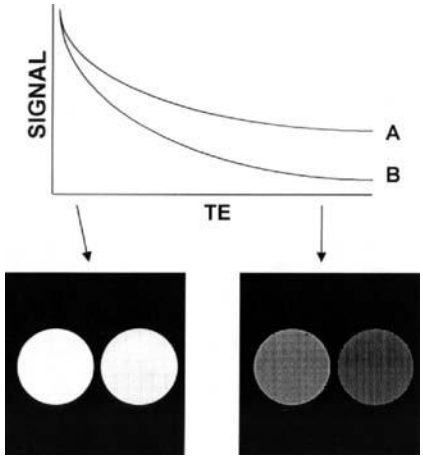

Figure 7. Signal of two substances, A and B, as a function of TE, and their corresponding simulated images at the indicated TE values.

Spin-Echo Sequence

The spin-echo sequence is one of the most common imaging sequences. This sequence was described earlier (see discussion of Theory of MRI), and its timing diagram can be found in Figure 5. This sequence is used to produce images whose signal intensity is a function of the T_1, T_2, and ρ of the sample as described by Equation 10.

A spin-echo sequence will produce a T_1 weighted image when TR $< T_1$ and TE $\ll T_2$. A T_2-weighted image can be produced by a spin-echo sequence when TR $\gg T_1$ and TE $> T_2$. A spin-echo sequence will produce a ρ-weighted image when TR $\gg T_1$ and TE $\ll T_2$. Due to time constraints, these conditions are rarely precisely met, so weighted images will have some dependence on the remaining two properties.

Gradient Recalled Echo Sequence

A gradient recalled echo sequence is essentially the 90-FID sequence described earlier in the theory section. The signal from the gradient-recalled echo sequence is given by the following equation, where θ is the rotation angle of the RF pulse

$$S(\mathrm{TE},\mathrm{TR}) = k\sum_i \rho_i \frac{(1-e^{\mathrm{TR}/T_{1i}})\sin\theta\, e^{-\mathrm{TE}/T^*_{2i}}}{(1-\cos\theta\, e^{-\mathrm{TR}/T_{1i}})} \qquad (11)$$

The repetition time, TR, has the same definition as in the spin-echo sequence. A maximum in the signal is produced because the frequency-encoding gradient is first turned on negative so as to position the start of the signal at the edge of k space. Therefore, the echo time, TE, is the time between the RF pulse and the maximum signal. The signal has a T_2^* dependence instead of a T_2 dependence. The rotation angle θ is often set to a value less than 90° so that equilibrium is reached more quickly in the period TR. T_1-, T_2^*-, and ρ-weighted images can be made with a gradient-recalled sequence.

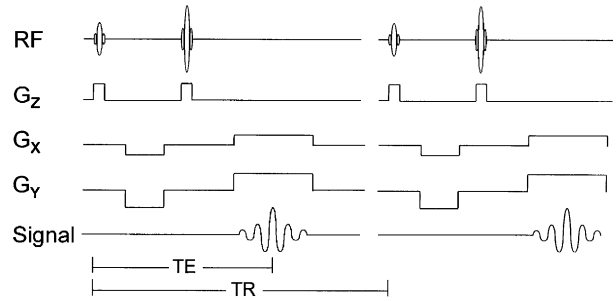

Figure 8. Timing diagram for a back-projection imaging sequence.

Back-Projection Imaging Sequence

The back-projection imaging sequence is useful when T_2 values are shorter than 10 ms. The principle is based on the acquisition of several one-dimensional images of the sample (Lauterbur, 1973). The direction of the one-dimensional image is varied by 360° around the imaged object. Figure 8 depicts the timing diagram for a spin-echo back-projection sequence. A slice selection gradient is applied in conjunction with the RF pulses so as to select the desired image plane. In this example an xy plane is imaged.

A readout gradient, G_R, is applied during the acquisition of the signal such that the angle (α) subtended by its direction relative to the x-axis varies between 1° and 360° as given by the following equations

$$G_x = G_R\cos(\alpha) \qquad (12)$$
$$G_y = G_R\sin(\alpha) \qquad (13)$$

Each of these one-dimensional images represents the projection of the NMR signal across the image perpendicular to G_R. G_R is also applied between the 90° and 180° pulses so as to position the echo properly in k space. This set of projection images is back-projected through space using an inverse radon transform to produce an image (Sanz et al., 1988). The advantage of this sequence is that TE can be made less than the corresponding TE in a conventional spin-echo sequence. Therefore samples with shorter T_2 values can be imaged. Since this back-projection sequence utilizes a spin-echo pulse sequence, S(TR,TE) is given by Equation 10. Since

$$\Gamma_i = \frac{1}{\pi T_{2i}} \qquad (14)$$

and being mindful of Equation 9, gradient strengths must be greater for samples with shorter T_2 values.

Echo-Planar Imaging Sequence

Echo-planar imaging is a rapid magnetic resonance imaging technique, capable of producing images at video rates. The technique records an entire image in a single TR period. Echo-planar imaging therefore measures all lines of k space in a single TR period. A timing diagram for an echo-planar imaging sequence is depicted in Figure 9.

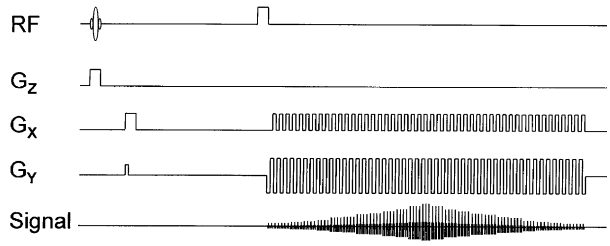

Figure 9. Timing diagram for an echo-planar imaging sequence.

A 90° slice-selective RF pulse is applied in conjunction with a slice-selection gradient. Initial phase-encoding gradient and frequency-encoding gradient pulses position the spins at the corner of k space. A 180° pulse follows, which is not slice selective. Next, the phase- and frequency-encoding gradients are cycled so as to raster through k space. This is equivalent to putting 256 phase- and frequency-encoding gradients in the usual period when the echo is recorded.

The rate at which k space is traversed is so rapid that it is possible to obtain 30 images per second. This implies that echo-planar imaging is suitable for studying dynamic processes in materials such as reaction kinetics. Echo-planar images require large and faster-than-normal gradients. As a consequence, echo-planar images are prone to severe magnetic susceptibility artifacts.

Diffusion Imaging Sequence

Diffusion imaging is used to produce images whose intensity is related to the diffusion coefficient, D, of the spins being imaged. The pulsed-gradient spin-echo imaging sequence is used to produce diffusion-weighted images. The timing diagram for this sequence is presented in Figure 10. The signal from a pulsed-gradient spin-echo imaging sequence, S, as a function of TR, TE, diffusion encoding gradient (G_j) in the j direction, width of the diffusion gradient (δ), and separation of the diffusion gradients (Δ) is given by Equation 15.

$$S(\mathrm{TR}, \mathrm{TE}, G_j, \delta, \Delta) = k \sum_i \rho_i (1 - e^{-\mathrm{TR}/T_{1i}}) \times e^{-\mathrm{TE}/T_{2i}^{-(G_j \gamma \delta)^2 D_{j,i}(\Delta - \delta/3)}} \quad (15)$$

The summation is over the i components in the voxel. The function of the diffusion gradient pulses is to dephase magnetization from spins that have diffused to a new location in the period Δ. These pulses have no effect on stationary spins, as can be seen by Equation 15 reducing to Equation 10 when the diffusion coefficient is zero.

An image map of the diffusion in one dimension (j) may be calculated from diffusion images recorded at different G_j values. Data of $S(G_\mathrm{j})$ as a function of G_j^2 is fit on a pixel-by-pixel basis to obtain D_j for each pixel in the image space. Diffusion coefficient images can be measured for $10^{-9} < D_\mathrm{j} < 10^{-4}$ cm^2/s.

Flow Imaging Sequence

A flow imaging sequence is similar to that used for diffusion imaging, except that the motion-encoding gradients are tuned to pick up very fast motion. Figure 11 depicts the timing diagram for a phase-contrast imaging sequence implemented with a spin-echo sequence for imaging flow in the z direction. The basis of the phase-contrast sequence is a bipolar magnetic field gradient (G_BP) pulse. A bipolar gradient pulse is one in which the gradient is turned on and off in one direction for a period of time, and then turned on and off in the opposite direction for an equivalent amount of time. A positive bipolar gradient pulse has the positive lobe first and a negative bipolar gradient pulse has the negative lobe first. The area under the first lobe of the gradient pulse must equal that of the second. A bipolar gradient pulse has no net effect on stationary spins. The bipolar gradient pulse will affect spins that have a velocity component in the direction of the gradient.

If a bipolar gradient pulse is placed in an imaging sequence, it will not affect the image since all we have done is impart a phase shift to the moving spins. Since an image is a magnitude representation of the transverse magnetization, there is no effect. However, if two imaging sequences are performed in which the first has a positive bipolar gradient pulse and the second a negative bipolar gradient pulse, and the raw data from the two are subtracted, the signals from the stationary spins will cancel and the flowing spins will add. The vectors from the stationary spins cancel and those from the moving spins have a net magnitude. The net effect is an image of the flowing spins.

The direction of the bipolar gradient yields signal only from those spins with a flow component in that direction. The timing diagram in Figure 11 will measure flow in the z

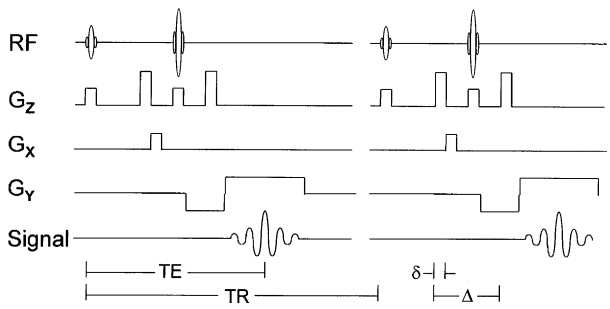

Figure 10. Timing diagram for a diffusion imaging sequence.

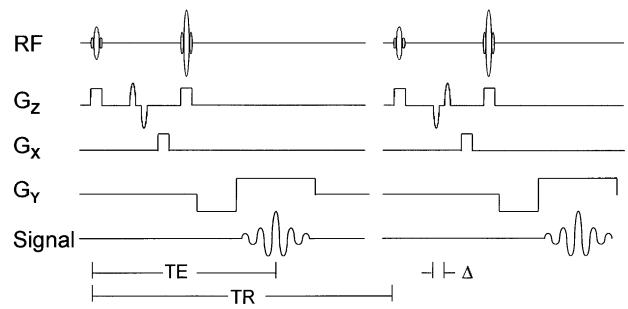

Figure 11. Timing diagram for a flow imaging sequence.

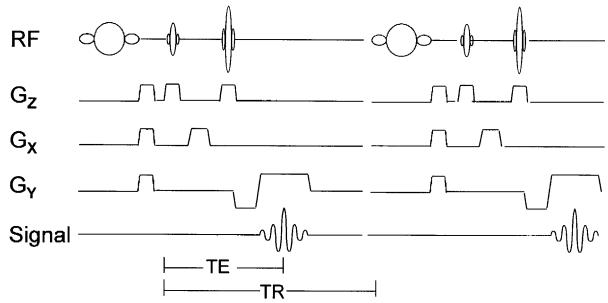

Figure 12. Timing diagram for a chemical shift imaging sequence that saturates the spins at a specific chemical shift.

direction because the bipolar gradient pulses are applied by G_z. Images of the flow rate between 5 and 400 cm/s may be recorded.

Chemical Shift Imaging Sequence

A chemical shift imaging (CSI) sequence is one that can map the spatial distribution of a narrow band of chemical shift components found in a sample. There are several possible CSI sequences. The one presented here consists of the modified spin-echo sequence in Figure 12. This sequence has the usual slice-selective 90° and 180° pulses, and gradients. It has an additional one or more saturation pulses before the normal spin-echo sequence designed to saturate the spins at specific chemical shift values. The frequency of the 90° and 180° pulses are tuned to the resonance frequency of the desired chemical shift component. The frequency of the saturation pulse is tuned to the resonance frequency of the chemical shift component that is to be eliminated. The frequency, bandwidth, and amplitude of the saturation pulse must be set to effectively saturate the undesired chemical shift components. This technique works best when the T_1 of the saturated component is long, thus preventing the generation of transverse magnetization before the application of the spin-echo sequence. Magnetic field gradients are occasionally applied between the saturation pulse and the spin echo sequence to dephase any residual transverse magnetization after the saturation pulse. Images of chemical shift differences as low as 1 ppm are attainable.

Three-Dimensional Imaging

With the development of fast desktop computers with high-resolution video or holographic monitors, three-dimensional images are readily viewed and manipulated. MRI can readily produce three-dimensional images by acquiring contiguous tomographic slices through an object. To minimize the time necessary to acquire this amount of data, a fast imaging sequence, such as a gradient-recalled echo or echo-planar is typically used. Alternatively, a multislice sequence, which utilizes the dead time between repetitions to acquire data from other slices, can be utilized.

Solid-State Imaging

The NMR spectra of solids typically consist of very broad absorption lines due to anisotropic chemical shifts and spin-spin (or dipole-dipole) interactions. Recalling the limitations imposed by Equation 14 and Equation 9, this would require extremely large and fast gradients, as well as fast digitizers. Solid-state magic-angle spinning NMR techniques can be used to decrease the line width (Fukushima, 1981). This task is accomplished by spinning the sample about an axis oriented at 54.7° to the applied B_0 field. This angle is referred to as the magic angle because at this angle the dipole interaction contribution to the line width equals zero. Unfortunately, two-dimensional imaging becomes difficult due to the need to spin the sample at the magic angle. A one-dimensional image may be recorded of a sample spinning at the magic angle by applying a frequency-encoding gradient along the direction of the magic-angle spinning axis.

The dipolar interaction may also be minimized using line-narrowing pulse sequences. The specifics of these sequences are beyond the scope of this unit. The reader is directed to the relevant literature (Chingas et al., 1986; McDonald et al., 1987; Rommel et al., 1990) and instrument manuals for specifics.

Instrument Setup and Tuning

Certain aspects of the imager should be tuned for each sample. These aspects include the sample probe or imaging coil, the power required to produce a 90° pulse, the receiver gain, and the homogeneity of the B_0 magnetic field. The reader is directed to a more detailed work (Fukushima and Roeder, 1981) for more information than is presented here.

The imaging coil sends an RF magnetic field into the sample and detects an RF response from the sample. The homogeneity of the transmitted RF field as well as that of the sensitivity will directly influence image quality. A coil with maximal field homogeneity, or a technique for correcting the inhomogeneity in the measured property (Li, 1994), is needed.

The imaging coil is an LC circuit which is designed to resonate at the operating frequency of the imager. This resonance frequency changes when the sample is placed inside the imaging coil. A tuning capacitor on many imaging coils allows the user to change the resonance frequency of the coil. A second capacitor allows the user to adjust the impedance of the coil to that of the imager, typically 50 Ω.

The amount of power necessary to produce a 90° pulse, P_{90}, will vary from sample to sample and from sample coil to sample coil. P_{90} is proportional to the coil volume, V_c, and the bandwidth, BW, of the imaging coil. Therefore the more closely matched the coil is to the size of the sample, the less power is required to produce a 90° pulse. The BW of the imaging coil will depend on the electrical quality of the coil and the dielectric constant and conductivity of the sample. A salt water solution sample will cause the imaging coil to have a larger BW than a hydrocarbon sample, and hence require more transmitter power to produce a 90° pulse. The amount of power necessary to produce a 90° pulse is determined by observing the signal from the sample as the transmitter power is increased from zero. The first maximum in the signal corresponds to the

amount of power necessary to produce a 90° pulse. Optimizing V_c and BW is also important because the signal is proportional to the fraction of the imaging coil occupied by the imaged object, and inversely proportional to the BW of the coil.

The receiver gain of the imager must be adjusted such that the amplitude of the greatest signal is less than that of the dynamic range of the digitizer. Each imager has a slightly different procedure for achieving this step. In general, the amplitude of the time-domain signal from the center of k space must be less than the dynamic range. To set this, the image acquisition parameters, such as TR, TE, FOV, and Thk, are first set and a time-domain signal is recorded from the imaging sequence with the phase-encoding gradient turned off. Amplifier gains are adjusted to keep this signal from saturating the amplifier.

The quality of the images produced by an MR imaging device is directly related to the homogeneity of the B_0 magnetic field across the sample. The B_0 field from the imaging magnet may be extremely homogeneous in the absence of a sample. When a sample is placed in the magnetic field, it distorts the fields around and within the sample due to its magnetic susceptibility and geometry. The homogeneity of the B_0 field in the sample is optimized using a set of shim coils found on the imager. The coils are set up to superimpose small, temporally static, spatial magnetic field gradients on the B_0 field. There are often ten or twenty different functional gradient forms (i.e., z, z^2, x, x^2, y, y^2, xy, etc.) which can be superimposed on B_0. These fields can be adjusted to cancel out spatial variations in the B_0 field across the sample. The FID from a 90-FID pulse is monitored as the gradients are varied. Maximizing the height and length of the FID optimizes the B_0 field.

Safety

Imaging magnets are typically 1 to 5 tesla (T). These magnets, especially those with a large-diameter bore, tend to have large magnetic fields that extend out around the magnet. These magnetic fields can cause pacemakers to malfunction, erase magnetic storage media, and attract ferromagnetic objects into the bore of the magnet. Persons with pacemakers must not be allowed to stray into a magnetic field of greater than 5×10^{-4} T. A magnetic field of approximately 5×10^{-3} T will erase the magnetically encoded material on credit cards and floppy disks. Ferromagnetic materials should be kept clear of the magnet, for these objects can be attracted to the magnet and damage experimental apparatus or injure persons in their path. They will also cause damage to the internal support structure of the superconducting magnet and could cause the magnet to quench.

DATA ANALYSIS AND INITIAL INTERPRETATION

The raw data from a magnetic resonance imager is the k space data of the image. These data are converted to the image with the use of a two-dimensional Fourier transform. The raw k space data are occasionally multiplied by an exponential with a time constant less than T_2^* to reduce noise in the image. This is equivalent to convolving the image with a Lorentzian function, but less time-consuming. This procedure for reducing the noise in an image will also reduce resolution if the time constant for the exponential multiplier is less than T_2^*.

Most magnetic resonance imaging data are 16-bit unsigned integer numbers and many images have signals that span this range. Displaying these data in the form of a pixel in an image for interpretation by the human eye necessitates the windowing and leveling of the data. This process takes the useable portion of the 16-bit data and converts it to 8-bit data for interpretation by the human eye-brain system. All imagers have software to perform this conversion. The level is translated to a brightness, and the window to the contrast, on a monitor.

Often the goal is to determine the concentration of a signal-bearing substance in the sample as a function of distance. When TE is much less than the minimum T_2 value and TR is much greater than the maximum T_1 in the sample, the image intensity from a spin-echo sequence is approximately equal to the concentration. Often it is not possible or practical to record an image under these conditions. In these cases, the spatial variation in T_1 and T_2 must be measured before the spin density can be determined.

There are several MR imagers on the market ranging in price from one to two million U.S. dollars. As with any instrument, there is a range of available sophistication. An expensive unit may be purchased that has much of the hardware and software necessary to image any material. Less expensive instruments are available that require the user to write some specific pulse sequence computer code or build specific application imaging coils. Details on imaging coil construction can be found in the literature (Hornak et al., 1986, 1987, 1988; Marshall et al., 1998; Szeglowski and Hornak, 1993).

When imaging a pure substance, T_1, T_2, and ρ images may be calculated from spin-echo data. T_1 is best calculated from S(TR) at constant TE using a fast least-squares technique (Gong, 1992). T_2 is calculated from S(TE) at constant TR using a nonlinear least-squares approach (Li and Hornak, 1993). The spin density may then be calculated from S(TR,TE), T_1, T_2, and Equation 10. Samples with multiple components require multiexponential techniques for calculating T_{1i}, T_{2i}, and ρ_i (Windig et al., 1998).

The concentration of some substances may be imaged indirectly through their effect on T_1 and T_2. For example, paramagnetic substances will shorten T_1 and T_2 of water. The relaxation rates ($1/T_1$ and $1/T_2$) of water are inversely proportional to the concentration of the paramagnetic species. Therefore, if images of T_1 or T_2 can be generated, the concentration of the paramagnetic substance can be determined. The concentration profiles of paramagnetic substances that have been studied by this technique include oxygen and transition metal ions, such as Ni, Cu, and Mn (Antalek, 1991). Other properties of materials, such as pH and temperature, may be measured if they cause a change in resonant frequency of the imaged nucleus. A change in the frequency will cause a change in the phase in the image. Phase information is typically discarded when a magnitude image is taken, so this information must be extracted before the magnitude calculation.

SAMPLE PREPARATION

In nuclear MRI, sample preparation is minimal, as the goal is to image samples in their natural state. Samples must be of a size that will fit inside of the RF sample coil of the imager. Sample containers must be made of materials that are transparent to RF. The dielectric constant of the sample container must be between that of air and that of the sample, so as to minimize reflection of RF. Polyvinyl chloride or polyethylene work well for most aqueous and hydrocarbon-based signals. The magnetic susceptibility of the sample container, and the sample, must be approximately equal to that of air to minimize susceptibility distortions. Glass containers produce large susceptibility distortions.

MRI of materials under extreme conditions of pressure and temperature are possible, but sample containers and hardware for containing the extreme pressures and temperatures are not commercially available and must be made by the researcher.

PROBLEMS

The major reason for not seeing a magnetic resonance image or for seeing one with a poor signal-to-noise ratio (SNR) is insufficient signal intensity. Occasionally, other hardware problems may be the cause. Both of these causes are discussed in this section.

Recall from Equation 8 that the signal intensity in an imaging sequence is proportional to the spin density. If the number of spins in a voxel is insufficient to produce a measurable signal, a poor SNR will result. The spin density may be increased by increasing the concentration of the signal-bearing nuclei or by increasing the voxel size. The voxel size may be increased by increasing the Thk, decreasing the number of pixels across the image, or by increasing the FOV. Increasing the voxel size will, however, result in a loss of image resolution.

Equation 10 also tells us that if T_2 is small compared to TE, or if T_1 is long compared to TR, we will see a small signal. These conditions are often the case in many solids. A short T_2 will cause the transverse magnetization to decay before a signal can be detected. A long T_1 will not allow the net magnetization to recover to its equilibrium value along the positive z axis before the next set of RF pulses.

Occasionally, a sample may contain ferromagnetic particles that destroy the homogeneity of the B_0 field in the sample and either distort the image or destroy the signal entirely. Certain concrete samples contain iron filings, which prevent one from seeing an image of free water in concrete. Some samples contain high concentrations of paramagnetic substances that shorten the T_2 of water to value less than TE, thus destroying the signal.

Two additional properties that may perturb the NMR signal are conductivity and dielectric constant (Roe et al., 1996). A high conductivity will cause a skin effect artifact in the image. A high conductivity causes the RF magnetic fields to diminish with depth into the sample. Therefore, the outside of the object appears brighter than the inside of the object. A sample with a high dielectric constant causes the opposite artifact. Standing waves are set up within the imaged object when the dimension of the object approaches a half wavelength of the RF in the object. If concentration maps are desired, it may be possible to compensate for the effects of the spatially inhomogeneous B_1 field (Li, 1994).

The magnetic resonance imager is a multicomponent, complex imaging system consisting of RF, gradient, magnet, computer, etc. subsystems. All of these subsystems must be operating properly for optimal signal. As with any complex instrument, it is recommended that test standards be imaged before each run to test the operation of the subsystem components individually and as a whole, integrated system. The subcomponent that the user has the most control over is the imaging coil. The imaging coil sends out the oscillating B_1 field into the sample and detects the oscillating field from the magnetization in the sample. The imaging coil is an electrical LC circuit that must be tuned to the resonant frequency of the spins in the sample at the magnetic field strength of the imager, and impedance matched to that of the transmission line from the imager. The conductivity and dielectric constant of the sample affect the resonant frequency of the imaging coil and the matching. When high-Q imaging coils are used, the resonant frequency of the coil must be tuned for and the impedance matched for each sample. Failure to tune and match the coil for each sample may result in large amounts of reflected power from the imaging coil, which will diminish signal and possibly damage the RF transmission and detection circuitry. Tuning and matching the coil is typically accomplished with tuning and matching variable capacitors located on the imaging coil.

Differences in the magnetic susceptibility of the sample may distort the image. Adjusting the shim settings may minimize the susceptibility artifact.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

α	angle between readout gradient and x axis
B_0	static magnetic field
B_1	magnitude of the RF magnetic field
BW	bandwidth
C	capacitance
CSI	chemical shift imaging
D_i	diffusion coefficient of component i
δ	width of the diffusion encoding gradient in a pulse sequence
Δ	separation of the diffusion encoding gradients in a pulse sequence
δ_i	chemical shift of component i
ESR	electron spin resonance
EPR	electron paramagnetic resonance
FOV	field of view
f	frequency width of an NMR spectrum
ϕ	phase angle
γ	gyromagnetic ratio
G_BP	bipolar magnetic field gradient pulse
G_i	magnetic field gradient in the i direction
G_R	readout gradient
G_s	slice selection gradient
G_p	phase encoding gradient
G_f	frequency encoding gradient

Γ_i	full width at half height of a spectral absorption line for component i
k	proportionality constant used in NMR signal equations to include amplifier gains
L	inductance
MRI	magnetic resonance imaging
$\mathbf{M}$	net magnetization vector
$\mathbf{M}_{xy}$	transverse component of magnetization
$\mathbf{M}_z$	longitudinal component of magnetization
μSR	muon spin resonance
NMR	nuclear magnetic resonance
ν_i	frequency of i
P_{90}	RF power necessary to produce a 90° pulse
ρ_i	spin density of i
RF	radio frequency
S	signal
T_{1i}	spin-lattice relaxation time or component i
T_{2i}	spin-spin relaxation time of component i
T_{2i}	$^*T_2$ star of component i
Thk	slice thickness
TR	repetition time
TE	echo time
τ	width of an RF or phase encoding gradient pulse
TMS	the NMR standard tetramethylsilane
θ	rotation angle of magnetization by the RF pulse
V	velocity
V_c	imaging coil volume
$\otimes$	convolution symbol

Rochester, New York

NUCLEAR QUADRUPOLE RESONANCE

INTRODUCTION

Nuclear quadrupole resonance (NQR) was once written off as a "dead" field, but has recently had a modest rebirth, and has been applied with success to several areas of materials science, most notably the high-T_c superconductors. The name itself is a misnomer—NQR is really (NMR) at zero field. For that reason, it has many of the same disadvantages as the more familiar NMR spectroscopy (NUCLEAR MAGNETIC RESONANCE IMAGING)—e.g., poor sensitivity and complications arising from molecular dynamics, but because it does not require a superconducting magnet, NQR is generally cheaper and can be applied to a far greater number of nuclei. It is inherently noninvasive and nondestructive, and can be applied both to pure substances and to materials in situ. It is currently, for example, being used as an antiterrorist technique to screen persons and baggage for the presence of explosives, using receiver coils that are of the order of 1 m in radius. The principal disadvantage of NQR, other than sensitivity, is that, as a radiofrequency (RF) technique, it is incompatible with conducting or ferromagnetic materials; however, for the somewhat narrow range of materials to which it can be applied, NQR gives information which is otherwise unavailable.

The NQR properties of a material are primarily defined by a transition frequency or set of transition frequencies, which can be used to determine two parameters—the quadrupole coupling constant or q.c.c., and the asymmetry parameter, or η. These quantities are often quite characteristic of particular materials—as when they are used to detect drugs or explosives—but are also sensitive to temperature and pressure, and can therefore be used as a noninvasive probe of these properties. Moreover, by applying external spatially varying magnetic or radiofrequency fields, the NQR signal can be made position-dependent, allowing the distribution of the NQR-active species in the material to be imaged. Finally, the relaxation times of NQR nuclei are highly sensitive to dynamics, and so can be used as a local probe of molecular mobility.

In general, NQR imaging gives the same information about the distribution of NMR active species as NMR imaging, but applies to nuclei with spin $>1/2$ rather than spin 1/2 nuclei.

The internal structure of materials can also be imaged by x-ray tomography and ultrasonic methods, which depend on the existence of inhomogeneities in the distribution of x-ray absorbers, or acoustic properties, respectively. The stress and pressure dependences of the NQR frequency are generally much stronger than those of NMR imaging, and therefore NQR is a superior method for mapping the temperature or stress distribution across a sample. Such stress distributions can be determined for optically transparent material by using polarized light; for opaque material, there may be no alternative methods.

This unit aims to be a general and somewhat cursory review of the theory and practice of modern one-dimensional (1D) and two-dimensional (2D) NQR and NQR imaging. It will certainly not be comprehensive. For a more general grounding in the theory of the method, one may best go back to the classic works of Abragam (1961) and Das and Hahn (1958); more modern reviews are referenced elsewhere in the text.

PRINCIPLES OF THE METHOD

Nuclear Moments

Elementary electrostatics teaches us that the nucleus, like any electromagnetic distribution, can be physically treated from the outside as a series of electric and magnetic moments. The moments of the nucleus follow a peculiar alternating pattern; nuclei in general have an electric monopole (the nuclear charge), a magnetic dipole moment, electric quadrupole moment, magnetic octopole moment, and electric hexadecapole moment. The last two, while they have been observed (Liao and Harbison, 1994) have little practical significance, and will not be examined further. The magnetic dipole moment of the nucleus enables NMR, which is treated elsewhere (NUCLEAR MAGNETIC RESONANCE IMAGING). It is the electric quadrupole moment of the nucleus that enables NQR.

Whether or not a nucleus has an electric quadrupole moment depends on its total spin angular momentum, $\mathbf{I}$, a property that is quantized in half-integer multiples of the quantum of action, h (Planck's constant), and often

referred to in shorthand form as the nuclear spin. Nuclei with spin zero, such as ^{12}C, have neither a magnetic dipole nor an electric quadrupole moment. Nuclei with spin 1/2 have magnetic dipole moments but not electric quadrupole moments, while nuclei with spin 1 or higher have both magnetic dipole moments and electric quadrupole moments. For reasons connected with the details of nuclear structure and particularly the paucity of odd-odd nuclei (those with odd numbers of both protons and neutrons) there are few nuclei with integer spin: the naturally occurring spin 1 nuclei are ^{2}H, ^{6}Li, and ^{14}N, while ^{10}B, ^{40}K, and ^{50}V are the single examples of spin 3, 4, and 6 respectively. The quadrupole moments of ^{2}H and ^{6}Li are extremely small, making direct nuclear quadrupole resonance impossible except through the use of SQUIDs (superconducting quantum interference devices, see Practical Aspects of the Method and (TECHNIQUES TO MEASURE MAGNETIC DOMAIN STRUCTURES). The higher integer spin nuclei are of no experimental importance, and therefore the only integer spin nucleus that has been studied much by NQR is ^{14}N.

In contrast, half-integer spin nuclei are liberally spread across the periodic table, and they have therefore been the subject of most NQR work. They range from the very common spin 3/2, for which there are scores of different stable isotopes, through the comparatively rare spin 9/2, which is present in a few, such as ^{87}Sr and ^{209}Bi.

Nuclear electric quadrupole moments are typically about eight orders of magnitude smaller than molecular electric quadrupole moments. In Figure 1, they are listed in SI units of $C \cdot m^2$, though it is common to divide out the charge of the electron and give them in units of area. They vary from the tiny moment of -1.6×10^{-50} $C \cdot m^2$ for ^{6}Li to the comparatively huge value of 6.1×10^{-47} $C \cdot m^2$ in ^{179}Hf. They can be directly measured by atomic beam methods, but are frequently known only with very rough precision; for example, recent measurements of the moment of ^{137}Ba have varied from $Q = 0.228$ barns (1 barn $= 10^{-28}$ m^2)to $Q = 0.35$ barns (to convert Q in barns to eQ in $C \cdot m^2$ multiply by 1.602×10^{-47}). An extensive tabulation of measurements of nuclear moments is available in Raghavan (1989). As will be discussed below, such moments cannot easily be independently determined by NQR.

Nuclear Couplings

The Electric Field Gradient. Group theory dictates that nuclear moments couple only with the derivative of the local electric or magnetic field that possesses the same symmetry. This means that the nuclear magnetic dipole couples only with the magnetic field, and the electric quadrupole couples with the electric field gradient. In NMR, the magnetic field is usually externally applied and in most cases dwarfs the local field from the paramagnetism of the sample. However, in NQR, the local electric field gradient dwarfs any experimentally feasible external field gradient. As a ball park estimate of the local field gradient ($\nabla \mathbf{E}$) in an ionic crystal, we can compute the magnitude of the field gradient at a distance of $r = 0.2$ nm from a unipositive ion (q_r), using

$$\nabla \mathbf{E} = -\frac{(3\hat{\mathbf{r}}\hat{\mathbf{r}} - 1)q_r}{4\pi\varepsilon_0 r^3} \tag{1}$$

where ε_0 is the permitivity of the vacuum and $\hat{\mathbf{r}}$ is a unit vector. This yields a gradient of 3.6×10^{20} $V \cdot m^{-2}$, or between 8 and 9 orders of magnitude greater than the external field gradients that can currently be produced in the laboratory. NQR is therefore carried out using only the local field gradient of the sample.

The electric field gradient $\nabla \mathbf{E}$ is a traceless symmetric second-rank tensor with five independent elements that can be expressed in terms of two magnitudes and three

Figure 1. Spin and quadrupolar moments (in $C \cdot m^2$ \times 10^{50}) of quadrupolar nuclei.

Euler angles defining its directionality. The magnitude of the field gradient tensor along its *zz* direction in its principal axis system $(\nabla E)_{zz}$ is often given the shorthand notation *eq*, with *e*, the electric charge, factored out. The asymmetry parameter η is defined by

$$\eta = \frac{(\nabla E)_{yy} - (\nabla E)_{xx}}{(\nabla E)_{zz}} \tag{2}$$

Electric field gradients can be computed for nuclear sites in ionic lattices and in covalently bound molecules. For lattice calculations, point-charge models are rarely adequate, and in fact often give results that are entirely wrong. In most cases, we find that fixed and induced dipole and quadrupole moments need to be introduced for each atom or residue in order to get accurate values. For example, in calculations of the field gradient at the ^{14}N and cationic sites in $Ba(NO_3)_2$ and $Sr(NO_3)_2$ (Kye, 1998), we include the charges, the quadrupole moment of the nitrate ion (treated as a single entity and calculated by *ab initio* methods), the anisotropic electric polarizability of the nitrate ion (obtained from the refractive indices of a series of nitrates via the Clausius-Mosotti equation), and the quadrupole polarizability of the cations (calculated by other authors *ab initio*). We omit the electric polarizability of the cations only because they sit at a center of crystal symmetry and the net dipole moment must inevitably be zero; otherwise, this would be an important contribution. Briefly, after calculating the field and field gradient for each site using point charges, we compute the induced dipole at the nitrate as a vector using the nitrate polarizability tensor, and recalculate the field iteratively until convergence is obtained. We repeat this procedure again after introducing the quadrupole moment of the nitrate and quadrupole polarizabilities of the cations. Convergence of the lattice sums may be facilitated by an intelligent choice of the unit cells. The contributions of the various terms to the total field gradient at the nitrate in $Ba(NO_3)_2$ and $Pb(NO_3)_2$ are shown in Figure 2.

In covalent molecules, field gradients at the nucleus may be adequately obtained using computational modeling methods.

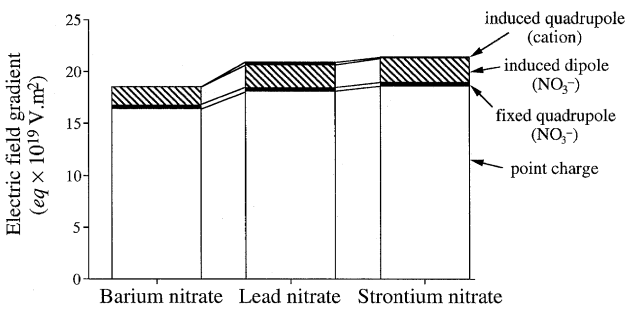

Figure 2. Contributions of the point charges, induced dipole moments, fixed quadrupolar and induced quadrupole moments to the total electric field gradient in ionic nitrates (from Kye and Harbison, 1998).

The Electric Quadrupole Hamiltonian. The coupling between the electric quadrupole moment and the ambient electric field gradient is expressed mathematically by the electric quadrupole coupling Hamiltonian.

$$H = \frac{e^2qQ}{4hI(2I-1)}\left[3I_z^2 - I(I+1) + \frac{\eta}{2}(I_+^2 + I_-^2)\right] \tag{3}$$

The quantity e^2qQ/h is the so-called electric quadrupole coupling constant, and is a measure of the strength of the coupling, dimensioned, as is usual in radiofrequency spectroscopy, in frequency units. I_z, I_+, and I_- are nuclear spin operators defined in the eigenbasis of the field gradient tensor.

The Sternheimer Effect and Electron Deformation Densities. One major complication of lattice calculations of electric field gradients is the Sternheimer antishielding phenomenon. Briefly, an atom or ion in the presence of a field gradient deforms into an induced quadrupole. The induced quadrupole does not merely perturb other atoms in the lattice; it also changes the field gradient within the electron distribution, usually increasing it, and often by a large amount. The field experienced by the nucleus is related to the external field by

$$\nabla \mathbf{E}_{\text{nuclear}} = (1 - \gamma_\infty)\nabla \mathbf{E}_{\text{external}} \tag{4}$$

where γ_∞ is the Sternheimer antishielding factor. Antishielding factors can be calculated by *ab initio* methods, and are widely available in the literature. They vary from small negative values for ions isoelectronic with helium, to positive values of several hundred for heavy ions. A representative selection of such factors for common ions is given in Table 1.

Energy Levels at Zero Field

Spin 1. At zero field, the electric quadrupole coupling is generally the only important component of the spin Hamiltonian. If the asymmetry parameter is zero, the Hamiltonian is already diagonal in the Cartesian (field gradient) representation, and yields nuclear energy levels of

$$E_{\pm 1} = \frac{e^2qQ}{4h}; \qquad E_0 = -\frac{e^2qQ}{2h} \tag{5}$$

There are two degenerate transitions, between $m = -1 \rightarrow m = 0$ and $m = 0 \rightarrow m = +1$, appearing at a frequency

$$\omega_Q = E_{\pm 1} - E_0 = \frac{3e^2qQ}{4h} \tag{6}$$

If $\eta \neq 0$, the degeneracy is lifted and the Hamiltonian is no longer diagonal in any Cartesian representation, meaning that the nuclear spin states are no longer pure eigenstates of the angular momentum along any direction, but rather are linear combinations of such eigenstates. The three energies are given by the equation

$$E_\pm = \frac{e^2qQ}{4h}(1 \pm \eta); \qquad E_0 = -\frac{e^2qQ}{2h} \tag{7}$$

And there are now three observable transitions, two of which correspond to the degenerate transitions for $\eta = 0$, and one which generally falls at very low frequency.

$$\omega_{\pm} = \frac{3e^2qQ}{4h}\left(1 \pm \frac{\eta}{3}\right); \qquad \omega_0 = \frac{e^2qQ\eta}{2h} \tag{8}$$

Observation of a single NQR transition at zero field for ^{14}N is an indication that the asymmetry parameter is zero (or that one transition has been missed). Observation of a pair of transitions for any species permits the q.c.c. and η to be extracted, and thence all of the magnitude information for the tensor to be obtained. The low-frequency transition is seldom observed, and in any case contains redundant information.

Spin 3/2. The energy levels of spin 3/2 nuclei are given by

$$E_{\pm 1/2} = -\frac{e^2qQ}{4h}\left(1 + \frac{\eta^2}{3}\right)^{1/2} : E_{\pm 3/2} = \frac{e^2qQ}{4h}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{9}$$

As can be seen, the 1/2 and −1/2 states are degenerate, as are the 3/2 and −3/2 states. This degeneracy is not lifted by a nonzero asymmetry parameter, which mixes the degenerate states without splitting them. The single quadrupolar frequency is

$$\omega_Q = \frac{e^2qQ}{2h}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{10}$$

Since this frequency is a function of both $e^{2qQ/h}$ and η, those quantities cannot be separately measured by simple NQR, though they can be obtained by a variety of two-dimensional methods (see Practical Aspects of the Method).

Spin 5/2. At $\eta = 0$, the energy levels of the spin 5/2 nucleus are given by

$$E_{\pm 1/2} = \frac{e^2qQ}{5h}; \quad E_{\pm 3/2} = -\frac{e^2qQ}{20h}; \quad e_{\pm 5/2} = \frac{e^2qQ}{4h} \tag{11}$$

Transitions between the $m = \pm 1/2$ and $\pm 3/2$ states, and between the $\pm 3/2$ and $\pm 5/2$ states are allowed. These appear at

$$\omega_1 = \frac{3e^2qQ}{20h}; \qquad \omega_2 = \frac{3e^2qQ}{10h} \tag{12}$$

and obviously lead to a 2:1 ratio of frequencies.

If the asymmetry parameter is nonzero, there are still two transition frequencies, but these deviate from a 2:1 ratio. Solving for them requires finding the roots of a cubic secular equation. The algebraic solutions have been published (Creel et al., 1980; Yu, 1991); more useful are the q.c.c. and η in terms of the measured frequencies

$$\begin{aligned} \frac{e^2qQ}{h} &= \frac{20}{3}\sqrt{\frac{(\nu_2^2 + \nu_2\nu_1 + \nu_1^2)}{7}}\cos(\phi/3) \\ \eta &= \sqrt{3}\tan(\phi/3) \\ \cos\phi &= \left(\frac{7}{(\nu_2^2 + \nu_2\nu_1 + \nu_1^2)}\right)^{3/2}\frac{(\nu_2 + 2\nu_1)(\nu_2 - \nu_1)(2\nu_2 + \nu_1)}{20} \end{aligned} \tag{13}$$

with $\nu_{1,2} = \omega_{1,2}/2\pi$. Thus, measurement of both frequencies for a spin 5/2 nucleus such as ^{127}I gives a complete set of magnitude information about the quadrupolar tensor.

In addition to these two transitions, for $\eta \neq 0$ the $\pm 1/2 \rightarrow \pm 5/2$ transition becomes weakly allowed, and can occasionally be observed. However, if the two single-quantum frequencies are already known, this nearly forbidden transition gives only redundant information.

Higher-Spin Nuclei. Spin 7/2 nuclei have three, and spin 9/2 four observable transitions at zero field. At $\eta = 0$, these frequencies are in simple algebraic ratio, and can be easily obtained from the Hamiltonian given in Abragam (1961). If $\eta \neq 0$, the situation is more complicated, although analytical expressions for the spin 7/2 frequencies are still available by solution of a quartic secular equation (Creel, 1983). Any pair of frequencies (if assigned) is sufficient to give e^2qQ/h and η.

First-Order Zeeman Perturbation and Zeeman Line Shapes

Most NQR spectra are collected not at zero field, but in the earth's field. In practice, in most cases, the effect of this small field is unobservable, save for certain systems with extremely narrow NQR lines. In these cases, most frequently highly ordered ionic crystals, Zeeman effects may be observed.

An external field introduces a preferential external reference from of the system, and for a single crystal (the simplest case) it therefore makes the spectrum dependent on the relative orientation of magnetic field and $\nabla\mathbf{E}$. For spin 3/2 systems (which are most frequently studied) the effect is to split the single transition into a pair of doublets whose splittings depend on the size of the magnetic field and its orientation with respect to the field-gradient tensor. Analytical expressions for the positions of these lines have been determined (Creel, 1983); in addition, certain preferred orientations of the tensor relative to field give no splitting, and the loci of these cones of zero splitting can be used to get the field-gradient tensor orientation, which is not directly available from NQR at zero field (Markworth et al., 1987).

In powders, Zeeman-perturbed spectra of spin 3/2 nuclei have a characteristic lineshape with four maxima; these line shapes can be used to determine the asymmetry parameter (Morino and Toyama, 1961).

Figure 3 shows the Zeeman-perturbed spectra of potassium chlorate ($KClO_3$), an excellent test sample for NQR, which has a ^{35}Cl resonance at 28.08 MHz. The spectra were obtained in a probe with an external field coil oriented parallel to the Earth's field, and shown for a series of coil currents. As can be seen, the minimum linewidth is obtained with a current of 0.2 A, where the external field presumably nulls out the Earth's field precisely. At higher or lower values of the current, characteristic Zeeman-perturbed line shapes are obtained.

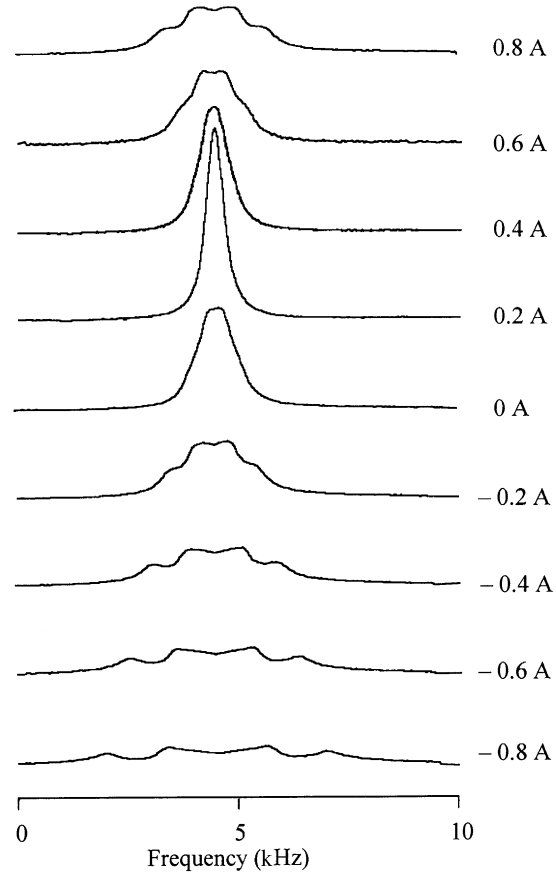

Figure 3. Effect of small external magnetic fields (expressed in terms of external coil current) on the lineshape of potassium chlorate resonance recorded at 28.85 MHz. A negative current corresponds to an applied field in the direction of the terrestrial magnetic field.

Spin Relaxation in NQR

As in NMR, NQR relaxation is generally parameterized in terms of two relaxation times: T_1, the longitudinal relaxation time, which is the time constant for relaxation of the populations of the diagonal elements of the electric quadrupole coupling tensor in its eigenbasis, and T_2, the transverse relaxation time, which governs the relaxation of off-diagonal elements. Except in the case of spin 3/2, more than one T_1 and T_2 are generally observed.

The longitudinal relaxation time is probably in most cases dominated by relaxation via very high-frequency motions of the crystal, typically librations of bonds or groups. Phenomenologically, it is generally observed to have an Arrhenius-like dependence on temperature, even in the absence of a well defined thermally activated motional mechanism.

The transverse relaxation time, T_2, must be distinguished from T_2^*, the reciprocal of the NQR line width. The latter is generally dominated by inhomogeneous broadening, which is a significant factor in all but the most perfectly crystalline systems. The processes giving rise to T_2 in NQR have, to our knowledge, not been systematically investigated, but it has been our observation that, in many cases, T_2 is similar in value to T_1, and is therefore likely a result of the same high-frequency motions.

T_1 and T_2 may be measured by the same pulse sequences used in high-field NMR; T_1 by an inversion recovery pulse sequence ($\pi - t - \pi/2 -$ acquire); T_2 using a single spin echo or train of spin echoes. T_1 values at room

temperature range from hundreds of microseconds to tens of milliseconds for half-integer spin nuclei with appreciable quadrupole coupling constants, such as ^{35}Cl, ^{63}Cu, ^{79}Br, or ^{127}I; for nuclei with smaller quadrupole moments, such as ^{14}N, they can range from a few milliseconds to (in rare cases) hundreds of seconds. T_1 values generally increase by one or two orders of magnitude on cooling to 77 K.

One phenomenon in which spin-relaxation times in NQR can be used to get detailed dynamical information is the "bleach-out" effect seen for trichloromethyl groups in the solid state. At low temperatures, three chlorine resonances are usually seen for such groups; however, as the temperature is raised, the resonances broaden and weaken, eventually disappearing, as a result of reorientation of the group about its three-fold axis. Depending on the environment of the grouping, "bleach-out temperatures" can be as low as $-100°C$ or as high at $70°C$, as is observed in the compound *p*-chloroaniline trichloroacetate (Markworth et al., 1987). Such exchange effects are quantum-mechanically very different from exchange effects in NMR, since reorientation of the group dramatically reorients the axis of quantization of the nuclear spin Hamiltonian, and is therefore in the limit of the "strong collision" regime. Under these circumstances, the relaxation time T_1 is to a very good approximation equal to the correlation time for the reorientation, making extraction of that correlation time trivial.

Similar phenomena are expected for other large-angle, low-frequency motions, but have otherwise been reported only for ^{14}N.

PRACTICAL ASPECTS OF THE METHOD

Spectrometers for Direct Detection of NQR Transitions

Frequency-Swept Continuous Wave Detection. For its first 30 years, the bulk of NQR spectroscopy was done using superregenerative spectrometers, either home-built or commercial (Decca Radar). The superregenerative oscillator was a solution to the constraint that an NMR spectrometer must be capable of sweeping over a wide range of frequencies, while in the 1950s and 1960s most radiofrequency devices (e.g., amplifiers, phase modulators and detectors, and receivers) were narrow-band and tunable. Briefly, the superregenerative circuit is one where the sample coil forms the inductive element in the tank circuit of the primary oscillator, which is frequency-swept using a motor-driven variable capacitor. Absorption of radiofrequency by the NQR spins causes a damping of the oscillator, which can be detected by a bridge circuit. The result is a frequency-swept spectrum in which NQR transitions are detected as the second derivative of their lineshape. The superregenerative circuit has the virtues of cheapness and robustness; however it has all the disadvantages of continuous wave detection—it does not lend itself easily to signal averaging, or to the more sophisticated 2D approaches discussed below. It is probably useful only for pure samples of molecular weights < 1000 Da.

Frequency-swept Fourier-transform Spectrometers. Most modern NQR spectroscopy likely is done on commercial solid-state NMR instruments, as the equipment requirements (save for the magnet) are very similar to those of NMR. Critical elements are a fast digitizer (<2 μs/point) and high-power amplification (preferably capable of 2 kW over a range of 5 to 200 MHz, although this depends on the sample).

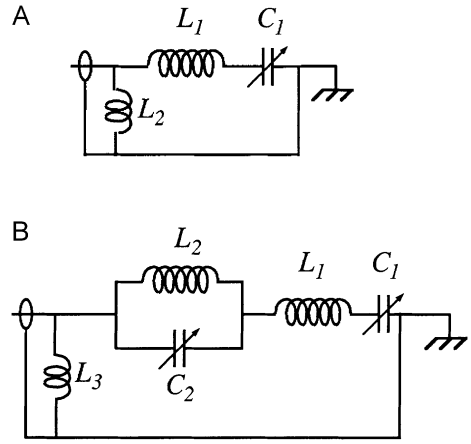

Figure 4. Probes for Fourier transform NQR. (**A**) Inductively matched series tank single-resonance probe; (**B**) inductively matched series/parallel tank double-resonance probe.

Standard static single-resonance solid-state NMR probes can be used for NQR; however, since there is no necessity that the probe be inserted in a magnet bore, some efficiencies can be achieved by building a dedicated probe. The circuit in Figure 4, panel A, has been successfully used for 10 years in the authors' laboratory. L_1, the sample coil, is typically a 20-turn solenoid wound from 26 AWG (American Wire Gauge) magnet wire, with dimensions of 4 cm long by 1.2 cm diameter; it holds a sample volume of ~4 ml. It is tuned by a series capacitance C_1; we generally employ a 1.5 to 30 pF Jennings vacuum capacitor rated at 15 kV. Matching to 50 Ω is accomplished by a 3 turn, 1 cm diameter inductor L_2. In general, inductive matches, while somewhat more cumbersome to adjust, are much more broad-banded than capacitive matches.

The probe gives a 1 to 2 μs $\pi/2$ pulse for most nuclei over a frequency range of ~20 to 45 MHz at a pulse power level of 500 W; additional series capacitance can be used to lower the frequency range, while going higher requires a smaller sample coil. The probe can simply be built inside an aluminum box, though somewhat better ringdown times are achieved with stainless steel. Acoustic ringing is however much less of a problem than in solid-state NMR, since the magnetoacoustic contribution is not present. If low temperatures are desired, the sample coil can be immersed in a coolant such as liquid nitrogen.

For double-resonance experiments, such as are required to correlate connected NQR transitions, we use the probe design in Figure 4, panel B. These double-resonance techniques involve irradiation of a spin $>3/2$ at two frequencies corresponding to distinct but connected NQR resonances. Double-resonance methods have not yet found significant application in materials research, and so are not described at length here; the interested reader is referred to Liao and

Harbison (1994). The circuit consists of a series and a parallel tank in series. In principle, either coil could contain the sample; in practice we use the series inductor L_1. A typical probe configuration uses coil inductances of $L_1 = 2.3$ μH and $L_2 = 1.2$ μH, with a small two- or three-turn matching inductor L_3. The circuit is essentially a pair of tank circuits, whose coupling varies with the separation of their resonance frequencies. Again, high-voltage 1.5 to 30 pF variable capacitors are used for C_1 and C_2. The two-fold difference between L_1 and L_2 ensures that the coupling between the two tanks is only moderate, so that resonance ν_1 primarily resides in tank circuit L_1C_1 and ν_2 in L_2C_2. With this configuration, ν_1 tunes between 17 MHz and 44 MHz and ν_2 between 47 and 101 MHz, although the two ranges are not entirely independent.

L_3 acts as a matching inductor for both resonances; differential adjustment of the matching inductance can be achieved by adjusting the coupling between the two inductors, either by partially screening the two coils by an intervening aluminum plate, or even by adjusting their relative orientation with a pair of pliers.

One notable feature that the probe lacks is any isolation between the two resonances; in fact, it has but a single port. This is because, unlike high-field NMR, it is seldom necessary to pulse one resonance while observing a second. We can therefore combine the output of both radio frequency channels before the final amplifier (which is broad-band and linear) and send the single amplifier output to a standard quarter-wave duplexer, which in practice is broad-band enough to handle the typical 2 : 1 frequency ratio used in NQR double-resonance experiments. Using single output state amplification and omitting isolation makes it far easier to design a probe to tune both channels over a wide frequency range.

SQUID Detectors. To overcome the sensitivity problems of NQR at low frequency, a DC superconducting quantum interference device (SQUID)—based amplifier can be used (Clarke, 1994; TonThat and Clarke, 1996). Using this device allows one to detect magnetic flux directly rather than differentially. This makes the intensity of the signal a linear function of the frequency instead of a quadratic function, greatly improving sensitivity at low frequencies compared to conventional amplification. SQUID NMR spectrometers can operate in both the continuous wave (Connor et al., 1990) or pulsed (TonThat and Clarke, 1996) modes. The latest spectrometers can attain a bandwidth up to 5 MHz (TonThat and Clarke, 1996). One of the drawbacks of the technique is cost, a result of the more complex design of the probe and spectrometer. SQUID spectrometers are not yet commercially available.

Experiments are performed at 4.2 K in liquid helium. Examples of nuclei observed using this technique are ^{27}Al in $Al_2O_3[Cr^{3+}]$ at 714 kHz (TonThat and Clarke, 1996), ^{129}Xe in laser-polarized solid xenon (Ton That et al., 1997), and ^{14}N in materials such as amino acids (Werner-Zwanzinger et al., 1994), cocaine hydrochloride (Yesinowski et al., 1995), and ammonium perchlorate (Clarke, 1994). Note that the detection of nitrogen transitions can be performed by cross-relaxation to protons coupled to nitrogen by the dipole-dipole interaction (Werner-Zwanzinger et al., 1994; Yesinowski et al., 1995).

Indirect Detection of NQR Transitions by Field Cycling Methods

Where relaxation properties of a material are favorable (long intrinsic proton relaxation time, short quadrupole relaxation time), indirect detection methods give a significant improvement in signal-to-noise ratio, since detection is via the proton spins, which have a large gyromagnetic ratio and relatively narrow linewidth. Such methods are therefore often favored over direct detection methods for spins with low NQR frequencies and low magnetic moments, e.g., ^{14}N or ^{35}Cl.

The term "field cycling" comes from the fact that the sample experiences different magnetic fields during the course of the experiment. The field intensity is therefore cycled between transients. Field cycling techniques were first developed during the 1950s (Pound, 1951). During a simple cycle, the sample is first magnetized at a high field, B_0, then rapidly brought adiabatically to a low field or to zero field. During the evolution period, the magnetization is allowed to oscillate under local interactions. The sample is finally brought back to high field, where the signal is detected. The field strength during the detection period can be identical to that for the preparation period, which is convenient but it can also be lower, as in "soak field" techniques (Koening and Schillinger, 1969). Also, other cycles involving more than two different field strengths have been developed, such as the "zero-field technique" (Bielecki et al., 1983). Field switching can be implemented either by electronic switches or by mechanically moving the sample. The latter is more simple and can be easily implemented on any spectrometer, but is limited for experiments necessitating very rapid field switching. Electronic switches are limited by Faraday's induction law, which dictates the maximum value of (dB_0/dt) for a given static B_0 field.

Field cycling can be applied in the solution state and in liquid crystals as well as in the solid state. As a competitive technique to NQR, quadrupolar nuclei can be observed directly; some examples are, but are not limited to, deuterium (Thayer and Pines, 1987) and nitrogen-14 (Selinger et al., 1994). Indirect detection ("level crossing") is also feasible by observing the signal of the abundant nucleus (typically protons) dipolar-coupled to the quadrupolar nucleus (Millar et al., 1985). An example of level crossing is given in a latter section to record the nutation spectrum of *tris*-sarcosine calcium chloride at 600 kHz (Blinc and Selinger, 1992). The large number of applications of field cycling NMR is outside the scope of this unit, and more detailed information can be found in reviews by Kimmich (1980) and Noack (1986); see Literature Cited for additional information.

One-Dimensional Fourier Transform NQR: Implementation

The hardest task in Fourier transform NQR is to find the resonance. While the chemistry of the species being studied sometimes gives one insight about where the resonances might lie—e.g., an organochlorine can be expected

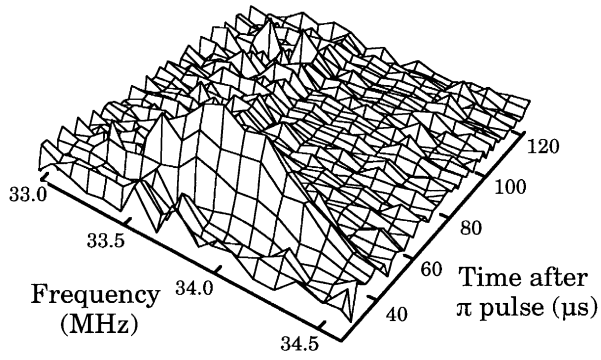

Figure 5. Frequency-swept spin-echo NQR. Each slice in the time dimension is a spin echo, recorded at a particular frequency; a slice in the frequency dimension parallel to the frequency axis gives the NQR spectrum.

to fall between 30 and 40 MHz—in general, this range will be far wider than the bandwidth of an NQR probe or the effective bandwidth of a high-power pulse. Some frequency sweeping will therefore have to be done. In a modern solid-state NMR spectrometer, the output power will usually be fairly constant over a range of 10 to 20 MHz, and the other components will generally be broad-band. Sweeping frequency, therefore, involves incrementing the spectrometer frequency by some fairly large fraction of the probe bandwidth, retuning the probe to that frequency, and acquiring a free-induction decay or preferably a spin echo at that frequency. Spectrometer frequencies are generally under computer control; the task of retuning the probe can be accomplished manually, or preferably automatically, by controlling the probe's tuning capacitor from the spectrometer via a stepper motor, and using this motor to minimize reflected power. The result of such a sweep is a series of spin echoes collected as a function of spectrometer bandwidth; these echoes, either phased or in magnitude mode, can be stacked in an array such as shown in Figure 5, which is a set of spin echoes collected for the ^{35}Cl signal of the polymer poly-4-chlorostyrene. A slice along the spine of the spin echo is the NQR spectrum collected at the resolution of the frequency sweep. If the line is narrower than this step frequency, the individual spin-echo slice in which the line appears may be Fourier transformed; if it is broad, the slice through the spin echoes suffices.

Two-dimensional Zero-Field NQR

Zeeman-Perturbed Nuclear Resonance Spectroscopy ZNQRS. For 3/2 spins, the $\pm 3/2 \rightarrow \pm 1/2$ transition depends on both the quadrupolar coupling constant, e^2qQ/h, and the asymmetry parameter η. The resonance frequency of the single line is given by

$$\nu_Q = \frac{1}{2}\left[\frac{e^2qQ}{h}\right]\left(1+\frac{\eta^2}{3}\right)^{1/2} \qquad (14)$$

That single-resonance frequency is insufficient to determine these two parameters separately. To overcome the problem, Ramachandran and Oldfield (1984) applied a small static Zeeman field, H_0, parallel to H_1, the radiofrequency field, as a perturbation to remove the degeneracy of the quadrupolar levels. The resulting splitting creates singularities, first described by Morino and Toyama (1961), at

$$\nu_Q \pm (1+\eta)\nu_0 \qquad (15)$$

and

$$\nu_Q \pm (1-\eta)\nu_0 \qquad (16)$$

where ν_0 is the Larmor frequency.

Note that applying the static field H_0 perpendicular to H_1 does not change the position of the singularities but affects the intensity distribution. By measuring the splitting, the asymmetry parameter can be determined.

Ramachandran and Oldfield's two-dimensional version of this experiment was implemented using both one pulse and spin echo (see Fig. 6, panels A and B). The field is turned on during the preparation period, during which the spins evolve under both the Zeeman and quadrupole interactions. The field is turned off during acquisition. The 2D spectrum is obtained by incrementing t_1 in regular intervals followed by 2D Fourier transform. The projection

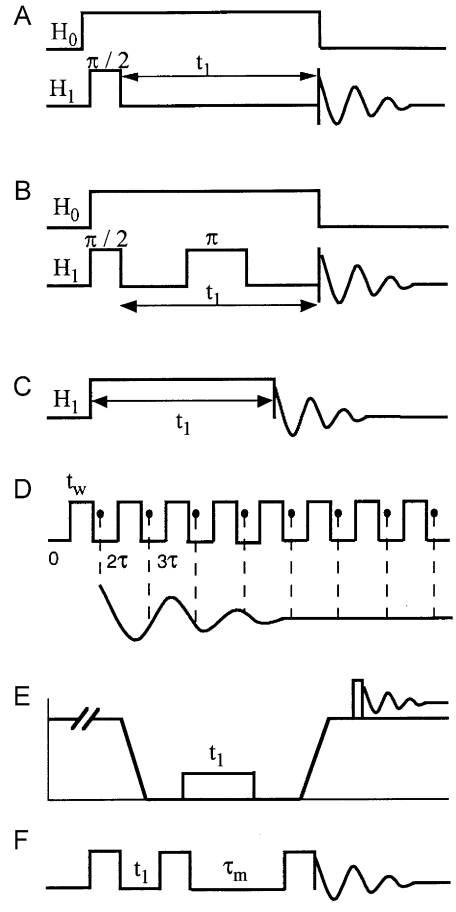

Figure 6. 2D NQR pulse sequences: (**A**) Zeeman-perturbed NQR one-pulse; (**B**) Zeeman-perturbed NQR spin echo; (**C**) zero-field nutation; (**D**) RF pulse train method; (**E**) level-crossing double resonance NQR nutation; (**F**) 2D exchange NQR.

on the ω_2 axis shows the zero-field NQR spectrum. The Zeeman NQR powder pattern is observed by projection along the ω_1 axis, which allows the determination of the asymmetry parameter η. The limitation of the method is that it requires a rapidly switchable homogeneous Zeeman field.

Zero-Field Nutation Nuclear Resonance Spectroscopy. Another method to determine the asymmetry parameter has been described (Harbison et al., 1989; Harbison and Slokenbergs, 1990) in which no Zeeman field is applied. The absence of a static field makes the frequency spectrum orientation independent. To determine η, it is necessary to obtain an orientation-dependent spectrum, but to do so, it is unnecessary to introduce an extra perturbation such as the Zeeman field. The sample radio frequency coil itself introduces an external preferential axis and thus an orientation dependence.

During an RF pulse in a zero-field NQR experiment, a 3/2 spin undergoes nutation about the unique axis of the EFG (Bloom et al., 1955). The strength of the effective H_1 field depends on the relative orientation of the coil and quadrupolar axes and goes to zero when the two axes are parallel. The nutation frequency is given by

$$\omega_N = (\sqrt{3}\omega_R \sin\theta)/2 \tag{17}$$

where $\omega_R = \gamma H_1$, θ is the angle between the coil axis and the unique axis of the electric field gradient tensor, and γ is the gyromagnetic ratio of the nucleus.

The voltage induced in the coil by the precessing magnetization after the pulse is proportional to $\sin\theta$. Figure 6, panel C, shows the 2D nutation NQR pulse sequence. For a single crystal, the NQR free precession signal is

$$F(t_1, t_2, \theta) \propto \sin\theta \sin(\sqrt{3}\omega_R t_1 \sin\theta/2) \sin(\omega_Q t_2) \tag{18}$$

where ω_Q is the quadrupolar frequency, t_1 is the time the RF pulse is applied and t_2 is the acquisition time.

For an isotropic powder, the nutation spectrum is obtained by powder integration over θ, followed by complex Fourier transformation in the second dimension and an imaginary Fourier transform in the first

$$G(\omega_1, \omega_2) \propto \int_0^{\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \sin^2\theta \sin(\sqrt{3}\omega_R t_1 \sin\theta/2) \times \sin(\omega_Q t_2) e^{i\omega_1 t_1} e^{i\omega_2 t_2}\, dt_2\, dt_1 d\theta \tag{19}$$

The angular factor $\sin\theta$ must be replaced by a factor $R(\theta, \phi)$ where θ and ϕ are the polar angles relating the coil axis and the quadrupolar tensor (Pratt et al., 1975). For an axially asymmetric tensor

$$R(\theta, \phi) = \sqrt{4\eta^2 \cos^2\theta + [9 + \eta^2 + 6\eta\cos(2\phi)]\sin^2\theta} \tag{20}$$

The 2D frequency-domain spectrum becomes

$$G(\omega_1, \omega_2) \propto \int_0^{\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \sin\theta R(\theta, \phi) \sin(\omega_R t_1 R(\theta, \phi)/2\sqrt{3}\rho) \times \sin(\omega_Q t_2) e^{i\omega_1 t_1} e^{i\omega_2 t_2} dt_2\, dt_1\, d\theta\, d\phi \tag{21}$$

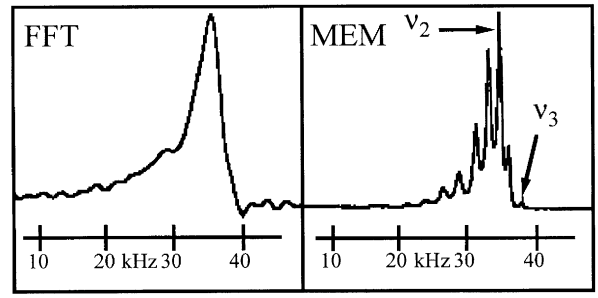

Figure 7. Fourier transform of the on-resonance nutation spectrum and corresponding MEM spectrum (the slices through the 2D spectrum parallel to the F_1 axis at $F_2 = \nu_{NQR}$) obtained at 77 K for $\nu_{NQR} = 36.772$ in $C_3N_3Cl_3$. The linear prediction filter used to obtain the MEM spectrum from $N = 162$ time-domain data points was $m = 0.95$ N (from Mackowiak and Katowski, 1996).

The on-resonance nutation spectrum in the ω_1 dimension (see Fig. 7) shows three singularities, ν_1, ν_2, and ν_3, whose frequencies are given by

$$2\pi\nu_1 = \frac{\eta\omega_R}{\sqrt{3}\sqrt{1 + \frac{1}{3}\eta^2}}, \quad 2\pi\nu_2 = \frac{(3 - \eta)\omega_R}{2\sqrt{3}\sqrt{1 + \frac{1}{3}\eta^2}},$$
$$\text{and} \quad 2\pi\nu_3 = \frac{(3 + \eta)\omega_R}{2\sqrt{3}\sqrt{1 + \frac{1}{3}\eta^2}} \tag{22}$$

The asymmetry parameter can be determined from the position of ν_2 and ν_3 alone (Harbison et al., 1989)

$$\eta = \frac{3(\nu_3 - \nu_2)}{\nu_3 + \nu_2} \tag{23}$$

Off-resonance effects can be calculated using a similar procedure (Mackowiak and Katowski, 1996). The nutation frequency is given by

$$\nu_N^{off} = \xi/\pi = \sqrt{(\nu_N^{on})^2 + (\Delta\nu)^2} \tag{24}$$

where ν_N^{on} is the on-resonance nutation frequency and $\Delta\nu$ is the resonance offset.

The asymmetry parameter is determined from the relation

$$\eta = \frac{3\left[\sqrt{(\nu_3^{off})^2 - (\Delta\nu)^2} - \sqrt{(\nu_2^{off})^2 - (\Delta\nu)^2}\right]}{\sqrt{(\nu_3^{off})^2 - (\Delta\nu)^2} + \sqrt{(\nu_2^{off})^2 - (\Delta\nu)^2}} \tag{25}$$

Another way to do an off-resonance nutation experiment is to start acquisition at some constant delay, t_o, after the RF pulse procedure (Sinyavski, 1991; Mackowiak and Katowski, 1996). The nutation spectrum consists of three lines. The line at $\Delta\nu$ is independent of the EFG parameters

and the asymmetry parameter can be calculated from any of the two other lines using

$$\eta = \frac{3\left[\sqrt{(\nu_3^{off})^2 \pm 2(\Delta\nu)^2} - \sqrt{(\nu_2^{off})^2 \pm 2(\Delta\nu)^2}\right]}{\sqrt{(\nu_3^{off})^2 \pm 2(\Delta\nu)^2} + \sqrt{(\nu_2^{off})^2 \pm 2(\Delta\nu)^2}} \quad (26)$$

The spectral resolution for an off-resonance experiment decreases with the frequency offset up to ~80% for a 100 kHz offset.

For experimental nutation spectra, the data are occasionally truncated and noisy. Therefore the position of the singularities is often poorly resolved, which makes an accurate determination of η difficult. As an alternative to the 2D Fourier transform, the maximum entropy method (MEM) can be used for processing the time-domain data (Sinjavski, 1991; Mackowiak and Katowski, 1993, 1996). The basis of the maximum entropy method is to maximize the entropy of the spectrum while maintaining correlation between the inverse Fourier transform of the spectrum and the free induction decay (FID). The process works by successive iterations in calculating the χ^2 correlation between the inverse Fourier transform of the trial spectrum and the FID. The spectrum is modified so its entropy increases without drastically increasing χ^2, until convergence is reached. One of the inherent advantages to this method is that the MEM spectrum is virtually noiseless and free of artifacts. Mackowiak and Katowski used the Burg algorithm to determine the lineshape that maximizes the entropy for the nutation experiment (Stephenson, 1988; Mackowiak and Katowski, 1993, 1996). In this unit we do not intend to discuss the mathematics involved in MEM, but we can point readers to a review by D.S. Stephenson about linear prediction and maximum entropy methods used in NMR spectroscopy (Stephenson, 1988; also see references therein). MEM has been very successfully applied in high-field NMR for both1D and 2D data reconstruction.

Figure 7 shows on-resonance simulated and experimental 2D Fourier transform (FT) and MEM spectra. The noise and resolution improvements for the MEM method are clearly visible. The singularities ν_2 and ν_3 can be easily measured from the MEM spectrum. The asymmetry parameter is determined as previously using Equation 23.

The quadrupolar frequency is very temperature sensitive. Rapid recycling can cause significant sample heating and introduce unwanted frequency shifts during the nutation experiment. Thus, recycle delays much longer than necessary for spin relaxation are used (Harbison et al., 1989; Harbison and Slokenbergs, 1990; Mackowiak and Katowski, 1996), together with active gas cooling. Changes in the RF excitation pulse length between slices can cause undesirable effects. Also, for weak NQR lines, acquiring the 2D NQR nutation experiment can take a long time. To reduce the experiment time, Sinyavski et al. (1996) reported a sequence of identical short RF pulses separated by time intervals τ.

The NQR signal induced in the RF coil just after turnoff of the nth pulse is

$$G(nt_w) = \langle I_x\rangle_n \sin\theta\cos\phi + \langle I_y\rangle_n \sin\theta\sin\phi + \langle I_z\rangle_n \cos\theta \quad (27)$$

where $\langle I_{x,y,z}\rangle_n$ are the expectation values of the magnetization along the coordinate axis and are calculated using a wave function approach (Pratt et al., 1975; Sinyavski et al., 1996).

In the general case, the expression in Equation 27 is a sum of signals with various phases. For the case when

$$-\omega_0\tau + \Delta\omega t_w = 2\pi k \quad \text{with} \quad k = 0, \pm1, \pm2\ldots \quad (28)$$

that is, when the phase accumulated due to resonance offset is an integer multiple of 2π, the free induction decay obtained is identical to that found in the two-dimensional nutation experiment. Here, t_w is the time delay between pulses in the nutation pulse train.

In addition, if the NQR signal is measured at some constant delay, t_d, after each pulse in the sequence, then the signal after synchronous detection is

$$G(nt_w) = \alpha R^2(\theta,\phi) \times \begin{bmatrix}\sin(2n\xi t_w)\cos(\Delta\omega t_d + \Psi) \\ +\Delta\omega[1-\cos(2n\xi t_w)]\sin(\Delta\omega t_d + \Psi)/2\xi\end{bmatrix} \Big/ 2\xi \quad (29)$$

$R(\theta,\phi)$ is defined in Equation 20, $\Delta\omega$ is the frequency offset, Ψ is a constant phase shift of the reference signal for the synchronous detector, and

$$2\xi = \sqrt{(\Delta\omega)^2 + 4m^2} \quad \text{with} \quad m = (\gamma H_1/4)R(\theta,\phi)/\sqrt{3+\eta^2} \quad (30)$$

Equation 29 describes the "discrete interferogram" of a single nutation line at the frequency 2ξ (Sinyavski et al., 1996). The pulse sequence for the train-pulse method is shown in Figure 6, panel D.

For the on-resonance condition ($\Delta\omega = 0$), t_w and τ can easily be chosen so that condition in Equation 28 is satisfied. For $\Delta\omega \neq 0$, Equation 28 can also be satisfied. If the sum of the intervals $t_w + \tau$ in the pulse train is an integer multiple of the data sampling period, the nutation interferogram $D(i)$ can be reconstructed from the raw data by the simple algorithm

$$D(i) = D[c + (i-1)(p\backslash n)] \quad (31)$$

where $i = 1, 2, \ldots, n, n$ is the number of pulses, p the number of data points, the backslash denotes an integer division (e.g., $a\backslash b$ is the largest integer less than a/b), and c is a constant that can be determined by trial (Sinyavski et al., 1996).

If the NQR line is broad, dead-time problems occur and a spin echo signal can be used. The equivalent of the expression in Equation 29 for the echo signal is

$$G(nt_w) = \alpha R^2(\theta,\phi)(1-[\Delta\omega/2\xi]^2)[1-\cos(2\xi t'_w)]\times [-\sin(2n\xi t_w)\cos\Psi + \Delta\omega[1-\cos(2n\xi t_w)]\sin\Psi/(4\xi)]/4\xi \quad (32)$$

where t'_w is the delay between nutation pulses.

The maximum time-saving factor can be roughly estimated as equal to the number of pulses contained in a pulse train (Sinyavski et al., 1996).

Level-Crossing Double Resonance NQR Nutation Spectroscopy. When the NQR signal of the 3/2 spin nuclei is weak (low natural abundance) or if the quadrupolar frequency is too low to be observable, a double-resonance technique known as level-crossing double resonance NQR nutation (Blinc and Selinger, 1992) can be used to retrieve the nutation spectrum. In this experiment, the quadrupolar nuclei are observed via their effect on signals from the other nuclei (typically protons). Dipolar coupling must be present between the two nuclei and spin-lattice relaxation times have to be relatively long. Figure 6, panel E, shows the field cycling and pulse sequence used for the experiment. The sample is first polarized in a strong magnetic field, H_0. The system is then adiabatically brought to zero magnetic field (either by decreasing H_0 or by moving the sample out of the magnet). At a specific field strength, level crossing occurs between the Zeeman levels of the 1/2 spin (protons) and the Zeeman-perturbed quadrupolar levels (Blinc et al., 1972; Edmonds and Speight, 1972; Blinc and Selinger, 1992). The level crossing polarizes the quadrupolar nuclei (decreasing the population difference $N_{\pm 1/2} - N_{\pm 3/2}$) and decreases the magnetization of the protons. An RF pulse of length t_1 is applied at zero field with frequency of $\Omega = \omega_Q + \delta$, where ω_Q is the pure quadrupolar frequency. The proton system is remagnetized and the proton FID acquired after a 90° pulse. The 2D spectrum is acquired by varying t_1 and Ω. The proton signal $S_H(t_1)$ is proportional to the population difference (Blinc and Selinger, 1992).

$$S_H(t_1) \propto (N_{\pm 1/2} - N_{\pm 3/2}) = A \cos[\omega(\theta, \varphi, \delta) t_1] \qquad (33)$$

where A is a constant and $\omega(\theta, \varphi, \delta) = \gamma_Q H_1 R(\theta, \varphi)/(2\sqrt{3} + \eta)$ is the nutation frequency of the quadrupolar nuclei. For a powder, Equation 33 is integrated over the solid angle Ω

$$S_H(t_1) = \frac{S_H(0)}{4\pi} \int \cos[\omega(\theta, \varphi, \delta) t_1] d\Omega \qquad (34)$$

The Fourier transform of $S_H(t_1)$ gives the nutation spectrum with singularities given in Equation 22. The ω_2 dimension shows the zero-field NQR spectra. This technique has been successfully applied to determine e^2qQ/h and η for NQR frequencies as low as 600 kHz (Blinc and Selinger, 1992) for *tris*-sarcosine calcium chloride.

2D Exchange NQR Spectroscopy. 2D exchange NMR spectroscopy was first suggested by Jeener et al. (1979) The technique has been widely used in high field. Rommel et al. (1992a) reported the first NQR application of the 2D exchange experiment.

The 2D exchange experiment (Rommel et al., 1992a; Nickel and Kimmich, 1995) consists of three identical RF pulses separated by interval t_1 and τ_m (Fig. 6, panel F). The first pulse produces spin coherence evolving during t_1; the second pulse partially transfers the magnetization components orthogonal to the rotating frame RF field into components along the local direction of the EFG. The mixing time, τ_m, is set to be much longer than t_1, so most of the exchange occurs during this interval. The last pulse generates the FID. The NQR signal oscillates along the axis of the RF coil. By incrementing t_1, and after double Fourier transform, the 2D spectrum $S(\nu_1, \nu_2, \tau_m)$ shows diagonal and cross-peaks, the latter corresponding to nuclei undergoing exchange.

The theoretical treatment is based on the fictitious spin 1/2 formalism (Abragam, 1961; Goldman, 1990; Nickel and Kimmich, 1995). The matrix treatment of the high field 2D exchange NMR (Ernst et al., 1987) has to be modified for the specifics of the NQR experiment. During the exchange process, in contrast to its high-field equivalent (where only the resonance frequency changes), the direction of quantization (given by the direction of the EFG) can also change. This reduces the cross-peak intensities by projection losses from the initial to the final direction of quantization of the exchange process (Nickel and Kimmich, 1995).

It is important for the 2D exchange that all resonances participating in the exchange be excited simultaneously. Phase-alternating pulses producing tunable sidebands can overcome this problem (Rommel et al., 1992a). If the exchanging resonances fall outside the feasable single resonance bandwidth, a double-resonance configuration could be used instead.

Spatially Resolved NQR and NQR Imaging

A logical step following 2D NQR experiments is to perform spatially resolved NQR and NQR imaging. This would be of particular value for the characterization of solid materials. Imaging is a very recent technique in NQR spectroscopy that only a handful of research groups are developing. The main restriction to performing NQR imaging is that even if the quadrupole resonances are narrow, it is practically impossible to shift the NQR frequency, since it only depends on the interaction between the quadrupole moment and the electric field gradient at the nuclei.

Magnetic Field Gradient Method. The first NQR experiment that allowed retrieval of spatial information was performed recently by Matsui et al. (1990). If the NQR resonance is relatively sharp, the half-width of a Zeeman-perturbed spectrum is proportional to the strength of the small static Zeeman field applied (Das and Hahn, 1958). Thus, the height of the pattern at the resonance frequency is reduced proportionally to the Zeeman field strength (Matsui et al., 1990). Figure 3 shows the changes in the spectrum lineshape of potassium chlorate due to different Zeeman field strengths. The sample coil is placed between two Helmholtz coils oriented perpendicular to the terrestrial magnetic field. Changing the current applied through the coil changes the field strength. Note that because the Zeeman field is parallel to the terrestrial field, a shimming effect appears for a current of 0.2 A, reducing the half-width by approximately a factor of two (unpublished results). This effect was not observed in the work of Matsui et al. (1990).

If a magnetic field gradient is applied, the reduction effect can be used for imaging since it depends on spatial location (Matsui et al., 1990). Given N discrete quadrupolar spin densities $\rho(X_n)$, the observed signal for the one-dimensional experiment will be the sum of all the powder

patterns affected by the field gradient. The spectral height of the spectrum at the resonance frequency ω_0 becomes

$$H(X_{n_0}) = \sum_{n=1}^{N} W(X_n - X_{n_0})\rho(X_n) \quad (35)$$

The function $W(X_n - X_{n_0})$represents the spectral height reduction at X_n. The reduction function can be measured by applying uniform Zeeman fields of known strength. The N discrete spin densities can be determined by solving the system of N linear equations given by Equation 21 at the resonance frequency (Matsui et al., 1990).

As the field gradient increases, the plot becomes similar to the projection of the sample. This is because the signal contribution of the neighboring locations decreases with increasing gradients. Determining the spin densities is a deconvolution, and small experimental errors (e.g., amplitude and location) are enhanced by the conversion.

Rotating Frame NQR Imaging. Rotating frame NQR imaging (ρ NQRI) is similar to the rotating frame zeugmatography proposed by Hoult (1979). This technique has the advantage of using pure NQR without any magnetic field or magnetic-field gradient, in contrast to the previous method. The rotating frame zeugmatography is a flip-angle encoding technique used in NMR imaging. Nonuniform radiofrequency fields are applied so that the flip angle of an RF pulse depends on the position with respect to the RF field gradient. The RF coils are designed to produce constant field gradients. For NQR, only the amplitude-encoding form of the method is applicable. In NQR, the transverse magnetization oscillates rather than precesses, making the phase encoding (Hoult, 1979) variant of the method inapplicable.

The first application of ρ NQRI was developed by Rommel et al. (1991b) in order to determine the one-dimensional profile of solid samples. In this experiment, an anti-Helmholtz coil (transmitter coil) produces the RF whose distribution is given by

$$B_1(z) = \frac{\mu_0 I}{2}\left[\frac{R^2}{(R^2 + (z+z_0)^2)^{3/2}} - \frac{R^2}{(R^2 + (z-z_0)^2)^{3/2}}\right] \quad (36)$$

where R is the coil radius, $z_0 = R\sqrt{3}/2$ is half the distance between the coils and $2I$ is the current amplitude through the coils. The receiver coil is placed coaxial to the transmitter coil (Rommel et al., 1991b). With this arrangement, transmitter and receiver coils are electrically decoupled. Later coil designs (Nickel et al., 1991) prefer the use of a surface coil acting as both a transmitter and a receiver coil. The sample is placed in only one-half of the transmitter coil.

The pulse sequence for the experiment is very similar to the 2D-nutation experiment (Harbison et al., 1989) described earlier in this unit. Free induction decay signals are excited with increasing RF pulse length.

Since ρ NQRI is restricted to solid samples, a simple way to access the second dimension is to rotate the sample by small angle increments, the rotation axis being perpendicular to the RF field gradient (Nickel et al., 1991; Kimmich et al., 1992; Rommel et al., 1992b). Using a surface coil, where the sample is placed outside the coil, creates the RF field gradient and allows two-dimensional spatial encoding. The 2D image is reconstructed using the projection/reconstruction procedure proposed by Lauterbur (1973). A stepping motor allows the sample to rotate, producing the 2D image. The surface coil is placed perpendicular to the rotation axis. The spatial information is amplitude encoded in the FID signals by the gradient of the RF pulse B_1. The RF gradient (G_1) is aligned along the coil z axis and considered as constant (Nickel et al., 1991).

$$G_1(z) = \frac{\partial B_1(z)}{\partial z} \quad (37)$$

The excitation pulse is characterized by the effective pulse length: $t_p = t_w\alpha$, where α is the transmitter attenuation factor and t_w is the proper pulse length. t_p can be varied by varying either t_w or α.

For 3/2 spins, the "pseudo" FID given in Equation 21 for the nutation experiment (Harbison et al., 1989) can be rewritten as

$$S(t_p) = \int_0^\infty \frac{1}{\pi}\tilde{\rho}(z)dz \int_0^\pi d\theta \int_0^{2\pi} \frac{\sqrt{3}}{2} R(\theta,\phi)\,\sin\theta \times \sin(\sqrt{3}t_p\omega_1(z)R(\theta,\phi)/2\sqrt{1+\eta^2/3}) \quad (38)$$

or

$$S(t_p) = c\int_0^\infty \frac{1}{\pi}\tilde{\rho}(z) f(z,t_p)dz \quad (39)$$

The proper distribution is $\tilde{\rho}(z) = g(\omega,z)\rho(z)$, where $g(\omega,z)$ is the local line shape acting as a weighting factor. $\omega_1(z) = \gamma B_1(z)$ and $R(\theta,\phi)$ are defined by Equation 6. For constant gradient, $\omega_1(z). = G_1$.

Introducing $t_p = t_d e^u, z = z_0 e^{-v}$ and $\xi = u - \nu$ leads to

$$\tilde{S}(u) \equiv S(t_d e^u) = c\int_0^\infty f_a(\nu) f_b(u-\nu)d\nu \quad (40)$$

The deconvolution can be performed using the following expression

$$f_a(\nu) = F_u^{-1}\left\{\frac{F_u\{S(t_d e^u)\}}{F_\xi\{f_b(\xi)\}}\right\} \quad (41)$$

$f_a(\nu)$ can be derived numerically, since both $f_b(\xi)$ and $S(t_d e^u)$ are known. The profile is given by $\tilde{\rho}\,(z) = f_a(v)/z$ and $v = \ln(z_o/z)$.

The 2D image is reconstructed from the profiles of all the orientations using the following steps (Nickel et al., 1991; Kimmich et al., 1992; Rommel et al., 1992b). The pseudo FIDs are baseline- and phase-corrected so that the imaginary part can be zeroed with no loss of information, and the profiles are determined. The profiles are

centered with respect to the rotation axis. If $G_1(z)$ is not constant, the profiles must be stretched or compressed by a coordinate transformation so that the abscissae are linearly related to the space coordinate. The profile ordinates must be corrected by a factor $G_1(z)/B_1(z)$ because the RF pickup sensitivity of the coil depends on z in the same way as B_1 and because the signal intensity is weighted by a factor $1/G_1(z)$. Finally, the image is reconstructed by the back-projection method (Lauterbur, 1973).

Robert et al. (1994) used the maximum entropy method (MEM) as an alternative to the Fourier transform to process the pseudo FIDs. The MEM procedure shows better resolution and avoids the noise and artifacts of the Fourier method. The drawback is the much longer time required for the MEM method to process the data (~30 s per FID compare to the millisecond scale of the fast Fourier transform or FFT). A Hankel transform can also be applied instead of FFT or MEM (Robert et al., 1994).

To reduce the acquisition time, a procedure similar to the 2D nutation NQR train pulse method (Sinyavski et al., 1996), discussed previously, can be used (Robert et al., 1996). Theoretical calculations show that the pseudo-FIDs recorded using this single experiment (SEXI) method (Robert et al., 1996) are identical to those obtained using the multiple-experiment procedure. Data processing and image reconstruction are performed as described previously using MEM processing and the back-projection algorithm. The SEXI method reduces acquisition time by a factor of ~50. So far, theoretical treatments and experiments using the SEXI method are only applied for 3/2 spins, while the multiple-experiment method also can be applied for 5/2 spins (Robert et al., 1996).

The combination of ρ NQRI and Matsui's Zeeman perturbed NQR technique, described earlier, allows adding the third dimension to the imaging process by adding slice selection (Robert and Pusiol, 1996a,b). The width of the Zeeman-perturbed NQR spectrum is proportional to the local Zeeman field (Matsui et al., 1990). In a zero-crossing magnetic field gradient, the nuclei in the zero-field region show sharp resonance while nuclei experiencing a field show weak and broad resonances. Therefore, the sample slice localized within the $B = 0$ plane will show an unchanged spectrum, while the other slices away from the zero-field plane show broad or even vanishing spectra. If the field gradient is large enough, signals outside the zero-field slice virtually disappear. Two Helmholtz coils of similar diameter, separated by a distance L and carrying current in opposite directions, produce the magnetic field gradient. Obviously, other coil designs can be used to produce the magnetic field gradient. Varying the electric current ratio between the Helmholtz coils shifts the zero-field plane. Each slice can be obtained as described previously using the SEXI method.

Robert and Pusiol (1996a,b) applied the ρ NQRI with slice-selection method on a test object filled with *p*-dichlorobenzene. Results are shown in Figure 8 for two different orientations of the test object. In both cases, the geometry of the test objects is well resolved and slice-selection appears to be a nice improvement of the ρ NQRI method.

Recently, a new imaging technique developed by Robert and Pusiol (1997) was reported. This method, instead of

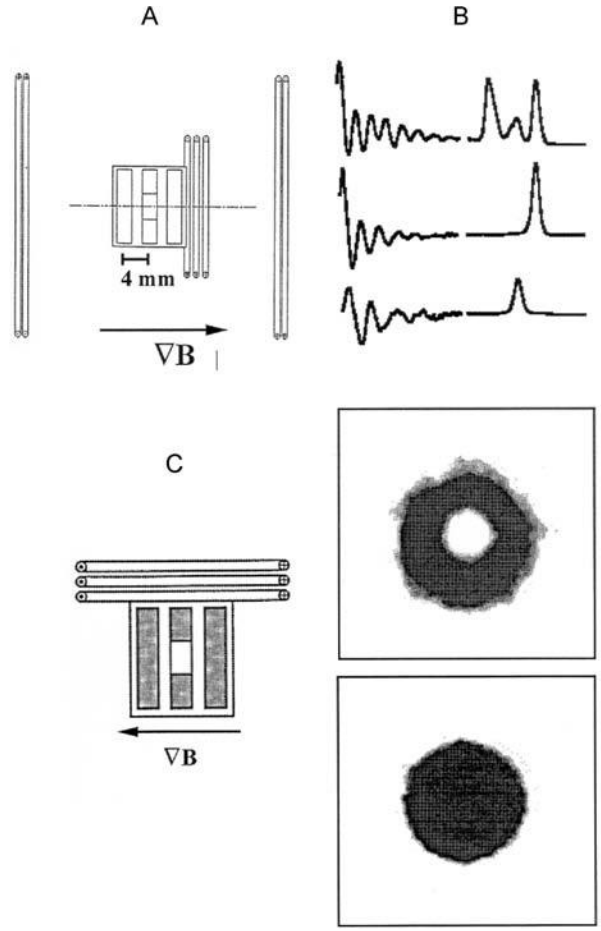

Figure 8. (**A**) Schematic arrangement of the surface RF and the selective magnetic gradient coils together with the cross-section of the object used for the test experiment. The selective static field gradient (∇B) is applied in a direction normal to the desired image plane. (**B**) Top: Pseudo-FID and profile along the cylindrical symmetry axis of the object imaged without external magnetic field. Middle: Magnetic gradient selecting the right hand cylinder. Bottom: After shifting the $B = 0$ plane towards the central cylinder. (**C**) Coil and test object arrangement for the 2D imaging experiment and cross image for the selection of the central cylinder (top) and of the external paradichlorobenzene disks (bottom) From Robert and Pusiol (1996a).

retrieving the second spatial dimension by rotating the sample, used a second surface RF coil perpendicular to the first one. In the "bidimensional rotating frame imaging technique 2D ρ NQRI," orthogonal RF gradients along the x and y axis are applied. A constant time interval T is introduced between the two pulses t_x and t_y. This is necessary to remove the transverse coherence created by the first pulse (Robert and Pusiol, 1997). The 2D experiment is carried out by incrementing t_x and t_y. Alternatively, the second pulse can be replaced by the SEXI train pulse described previously (Robert et al., 1996), and the complete 2D signal is obtained by incrementing only t_x. The resulting FIDs depend on both the x and y coordinates

$$F(t_x, t_y) \approx \int_0^\infty dx \int_0^\infty H_d \rho(x,y) S_1(t_x) S_2(t_y)\, dy \qquad (42)$$

where

$$S_1(t_x) = \int_0^{2\pi} d\phi_1 \int_0^{\pi} \sin\theta_1 \cos[\omega_1 \lambda(\theta_1, \phi_1) t_x]\, d\theta_1 \qquad (43)$$

and

$$S_2(t_y) = \int_0^{2\pi} d\phi_2 \int_0^{\pi} \sin\theta_2 \lambda(\theta_2, \phi_2) \sin[\omega_2 \lambda(\theta_2, \phi_2) t_y]\, d\theta_2 \qquad (44)$$

$\lambda(\theta, \phi)$ is proportional to $R(\theta, \phi)$ from Equation 20.

The corresponding 2D image is produced by determining the two-dimensional spin density function $\rho(t_x, t_y)$ The 2D image reconstruction is performed by a "true" 2D version of maximum entropy method and after RF field correction (Robert and Pusiol, 1997).

Temperature, Stress, and Pressure Imaging. As mentioned earlier, temperature strongly affects the quadrupolar frequency. Although this is an inconvenience for the spatially resolved imaging techniques, where the temperature must remain constant during acquisition to avoid undesired artifacts or loss in resolution, the temperature shift, as well as the effect of applying pressure or stress to the sample, can in fact be useful to detect temperature and pressure gradients, giving spectroscopic resolution in the second dimension. The spatial resolution in the first dimension can be performed using the initial ρ NQRI technique (Rommel et al., 1991a; Nickel et al., 1994) with no rotation of the sample and with a surface coil to produce the RF field gradient.

To study the effect of the temperature (Rommel et al., 1991b), a temperature gradient can be applied by two water baths at different temperature on each side of the sample. Data are collected in the usual way and are processed by 2D fast Fourier transform (FFT; Brigham, 1974). Figure 9, panel A, represents the ρ NQRI image of the test object and clearly shows the temperature gradients on the three sample layers through their corresponding frequency shifts. Using this technique, temperature gradients can be resolved to ~1°C/mm. Using MEM and deconvolution methods can highly improve the resolution, and experimental times can be greatly reduced by using the pulse-train method (Robert et al., 1996) instead of the multiple-experiment method.

To study pressure and stress, a similar procedure can be applied (Nickel et al., 1994). The probe contains two sample compartments, the first one serving as a reference while pressure is exerted on the second. Images are recorded for different applied pressures. If the sample is "partially embedded" in soft rubber or other soft matrices, broadening due to localized distribution of stress does not appear and only frequency shifts are observed in the image. If the pressure coefficient (in kHz/MPa) is known, pressures can be calculated from the corresponding frequency shifts. Figure 9, panel B, shows the shifting effect of applied pressure on the test sample. In the case of harder matrices or pure crystals, the frequency shift is accompanied by a line broadening caused by the local

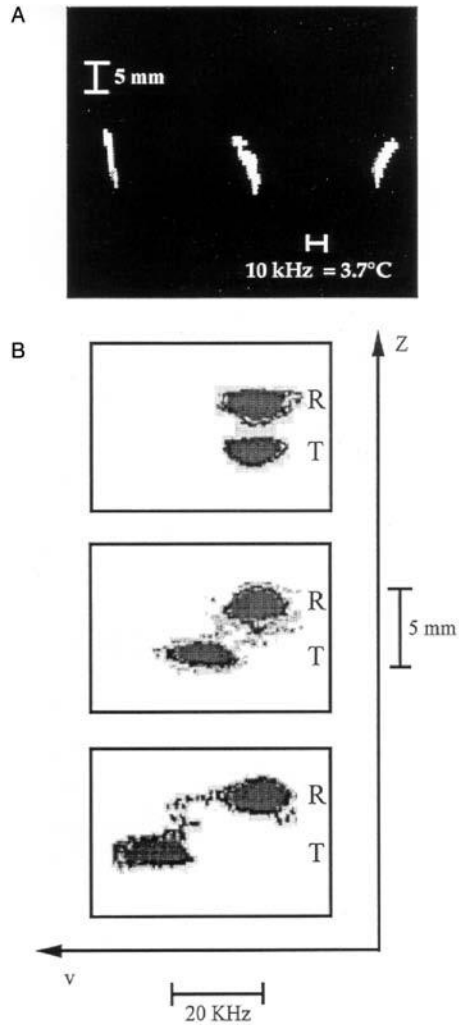

Figure 9. (**A**) Two-dimensional representation of temperature imaging experiments. The vertical axis represents the spacial distribution of the (cylindrical) sample, whereas the horizontal axis is the line shift corresponding to the local temperature (from Rommel et al., 1991a). (**B**) Spatial distribution of the ^{127}I NQR spectra of lithium iodate embedded in rubber in a two-compartment sample arrangement. Top: no applied pressure. Middle and bottom: applied pressure of 7 MPa and 14 MPa, respectively (from Nickel et al.,1994).

stress distribution within the sample. This broadening can even hide the shifting effect of the stress or pressure applied and the image only shows a decrease in intensity (Nickel et al., 1994).

Field Cycling Methods. Field cycling techniques are of potential interest for the imaging of materials containing quadrupolar nuclei dipolar-coupled to an abundant 1/2 nucleus (i.e., protons), and for detecting signals in the case where the quadrupolar frequency is too low or the signal too weak to be directly observed by pure NQR spectroscopy. Recently, Lee et al. (1993) applied field cycling to the one-dimensional ^{11}B imaging of a phantom of boric acid. The experiment consisted of a period at high field, during which the proton magnetization is built up, followed by a

rapid passage to zero field, during which the magnetization is transferred to the quadrupolar nuclei. RF irradiation at the quadrupolar frequency is applied and the remaining magnetization is transferred back to the proton by rapidly bringing the sample back to high field. Finally, the proton FID is obtained after solid echo. Spatial resolution is obtained by translating along the sample the small irradiation RF coil that produced the field gradient (Lee et al., 1993). The percentage of "recovered magnetization" is obtained from two reference experiments—maximum and minimum values of the "recovered magnetization" corresponding to "normal" and long residence times at zero field with no irradiation. Despite the low resolution, the image accurately represents the object and the experiment demonstrated the applicability of the technique. Using more elaborate coil designs, the same research group (Lee and Butler, 1995) produced ^{14}N 2D images spatially resolved in one dimension and frequency-resolved in the other. The image was produced by swapping both the RF coil position and the irradiation frequency at zero field.

It may be worth noting that field cycling imaging can possibly be achieved by performing the "level crossing double resonance NQR nutation spectroscopy" experiment (Blinc and Selinger, 1992) as described earlier, with a surface RF coil arrangement to access the spatial information as in the ρ NQRI techniques. If applicable, this would lead to improved image resolution.

So far, in contrast to its high field equivalent, and especially compared to medical imaging, the spatial resolution of the NQR imaging techniques is still fairly poor ($\sim$1 mm). Nevertheless, the recent advances are very convincing for the future importance of NQR imaging in materials science. Resolution improvements can be achieved by new coil arrangement designs and deconvolution algorithms. The limiting factor in resolution is ultimately the intrinsic linewidth of the signal. The future of NQR imaging may reside in the development of line-narrowing techniques.

DATA ANALYSIS AND INITIAL INTERPRETATION

Most modern NMR spectrometers contain a full package of one and two-dimensional data processing routines, and the interested reader is referred to the spectrometer documentation. Very briefly, processing time domain NMR data (free induction decays or FIDs) is done in five steps.

1. Baseline correction is applied to remove the DC offset in the FID.
2. Usually, the first few points of the free-induction decays are contaminated by pulse ringdown and give rise to artifacts. They must be removed by shifting the all data sets by several points.
3. Exponential multiplication is usually performed to increase the signal-to-noise ratio. This is performed by multiplying the real and imaginary part by the function $(-Ct)$, where t is the time in seconds and C is a constant in Hz. The larger the C, the faster the decay and the larger will be the broadening in the spectrum after the Fourier transform. This is equivalent to convolving the frequency domain spectrum with a Lorentzian function. Other apodization functions, such as sinebell and Gaussian multiplication, can also be used.
4. Spectral resolution can also be improved by doubling the size of the data set. This is done by filling the second half of the time-domain data with zeros.
5. Fourier transform allows transformation from the time to the frequency domain where the spectrum is analyzed. The theory of the fast Fourier transform (FFT) has been described in detail elsewhere and will not be discussed here. We refer the reader instead to Brigham (1974).

Two-dimensional data processing in general repeats this procedure in a second dimension, although there are some mathematical niceties involved. Any modern handbook of NMR spectroscopy, such as Ernst et al. (1987), deals with the details.

PROBLEMS

Sensitivity

As with most radiofrequency spectroscopy methods, the overriding problem is sensitivity. Boltzmann populations and magnetic moments of quadrupolar nuclei are small, and their direct detection either by nuclear induction or by SQUID methods often stretches spectrometers to the limit. Offsetting these sensitivity difficulties is the fact that longitudinal relaxation times are often short, and so very rapid signal averaging is often possible; in fact, typical data acquisition rates are limited not by relaxation but by thermal heating of the sample by the RF pulses.

Sensitivity depends on a host of factors—linewidth, relaxation times, the quadrupole constant and gyromagnetic ratio of the nucleus, the amount of sample, and, of course, the quality of the spectrometer. As an order-of-magnitude estimate, a "typical" NMR nucleus (^{63}Cu) with a quadrupole coupling constant in the range 20 to 25 MHz, can probably be detected in amounts of 1 to 10 μM.

Spurious Signals

As in any form of spectroscopy, it is essential to distinguish between signals arising from the sample and artifactual resonances from the sample container, probe, or elsewhere in the experimental apparatus. Artifacts extraneous to the sample can, generally, easily be detected by adequate controls, and with experience can be recognized and discounted; our probes, for example, have an impressive-looking NQR signal at 32.0 MHz, apparently due to a ceramic in the capacitors! A harder problem to deal with is identifying and assigning multiple NQR resonances in the same material; in contrast to NMR, at zero field the identity of a resonance cannot simply be determined from its frequency. The particular nucleus giving rise to an NQR signal can be identified with certainty if there exists another isotope of that nucleus. For example, natural-abundance copper has two isotopes—^{63}Cu and ^{65}Cu—with

a well-known ratio of quadrupole moments. Similar pairs are ^{35}Cl and ^{37}Cl, ^{79}Br and ^{81}Br, ^{121}Sb and ^{123}Sb, etc. Where a second isotope does not exist, or where additional confirmation is required, the gyromagnetic ratio of the nucleus can be measured with a nutation experiment (see Practical Aspects of the Method).

Two signals from the same nucleus and arising from different chemical species are the most difficult problem to deal with. Such signals generally cannot be assigned by independent means, but must be inferred from the composition and chemistry of the sample. This is an area where much more work needs to be done.

Dynamics

The broadening and disappearance of NQR lines caused by dynamical processes on a time scale comparable to the NQR frequency is a useful means of quantifying dynamics, if such processes are recognized; however, they may also cause expected NQR signals to be very weak or absent. We suspect the tendency of NQR signals to be very idiosyncratic in intensity to be largely due to this effect. If NQR lines are missing, or unaccountably weak, and dynamics is suspected to be the culprit, cooling the sample will often alleviate the problem.

Heterogeneous Broadening

Finally, another limitation on the detectability of NQR samples is heterogeneous broadening. In pure samples of perfect crystals, NQR lines can often be very narrow, but such systems are seldom of interest to the materials scientist; more often the material contains considerable physical or chemical heterogeneity. The spectrum of poly-4-chlorostyrene in Figure 5 is an example of chemically heterogeneous broadening; the coupling constants of the chlorine are distributed over $\sim$1 MHz due to local variations in the chemical environment of the aromatic chlorines. Similar broadening is observed, for example, in the copper NQR signals of high T_c superconductors. Physical heterogeneous broadening is induced by variations in temperature or strain over the sample. Simply acquiring NQR data too fast will generally induce inhomogenous RF heating of the sample, and since NQR resonances are exquisitely temperature dependent, the result is a highly broadened and shifted line. Strain broadening can be demonstrated simply by grinding a crystalline NQR sample in a mortar and pestle; the strain induced by grinding will often broaden the lines by tens or hundreds of kilohertz. Obviously, the former effect can be avoided by limiting the rate of data acquisition, and the latter by careful sample handling. When working with crystalline solids, we avoid even pressing the material into the sample tube, but pack it instead by agitation.

ACKNOWLEDGMENTS

We thank Young-Sik Kye for permission to include unpublished results. The data in Figure 5 were collected by Solomon Arhunmwunde, who died under tragic circumstances in 1996. This project was funded by NSF under grant number MCB 9604521.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

eq	the most distinct principal value of the electric field gradient at the nucleus
eQ	electric quadrupole moment of the nucleus
h	Planck's constant
H_1	applied radiofrequency field in tesla
I	nuclear spin
T_1, T_2	longitudinal and transverse relaxation times
γ	gyromagnetic ratio of the nucleus
γ_∞	Sternheimer antishielding factor of the atom or ion
η	asymmetry parameter of the electric field gradient at the nucleus
ν_Q	NQR resonance frequency in Hz
ω_Q	NQR resonance frequency in rad s^{-1}
ω_R	intrinsic precession frequency in rad s^{-1}; $\omega_R = \gamma H_1$

ELECTRON PARAMAGNETIC RESONANCE SPECTROSCOPY

INTRODUCTION

Electron paramagnetic resonance (EPR) spectroscopy, also called electron spin resonance (ESR) or electron magnetic resonance (EMR), measures the absorption of electromagnetic energy by a paramagnetic center with one or more unpaired electrons (Atherton, 1993; Weil et al., 1994). In the presence of a magnetic field, the degeneracy of the electron spin energy levels is removed and transitions between the energy levels can be caused to occur by supplying energy. When the energy of the microwave photons equals the separation between the energy levels of the unpaired electrons, there is absorption of energy by the sample and the system is said to be at "resonance" (Fig. 1). The fundamental equation that describes the experiment for a paramagnetic center with one unpaired electron is $h\nu = g\beta B$, where h is Planck's constant, ν is the frequency of the microwaves, g is a characteristic of the sample, β is the Bohr magneton, and B is the strength of the magnetic field in which the sample is placed. Typically the experiment is performed with magnetic fields such that the energies are in the microwave region. If the paramagnetic center is tumbling rapidly in solution, g is a scalar quantity. When the paramagnetic center is immobilized, as in solid samples, most samples exhibit g anisotropy and g is then represented by a matrix. Hyperfine splitting of the signal occurs due to interaction with nuclear spins and can therefore be used to identify the number and types of nuclear spins in proximity to the paramagnetic center.

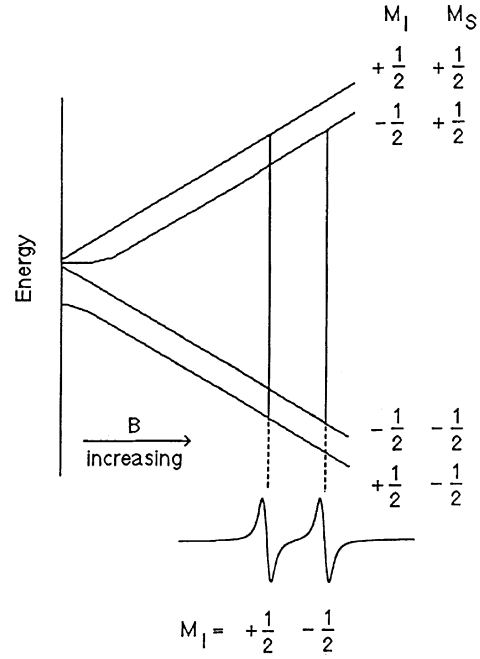

Figure 1. Energy-level splitting diagram for an unpaired electron in the presence of a magnetic field, interacting with one nucleus with $I = 1/2$. The energy separation between the two levels for the unpaired electron is linearly proportional to the magnetic field strength, B. Coupling to the nuclear spin splits each electron spin energy level into two. Transitions between the two electron energy levels are stimulated by microwave radiation when $h\nu = g\beta B$, where β is the electron Bohr magneton. Only transitions with $\Delta m_S = \pm 1, \Delta m_I = 0$ are allowed, so interaction with nuclear spins causes the signal to split into $2nI + 1$ lines, where n is the number of equivalent nuclei with spin I. The microwave magnetic field, B_1 is perpendicular to B. If the line shape is determined by relaxation, it is Lorentzian. The customary display in EPR spectroscopy is the first derivative of the absorption line shape. Sometimes the dispersion signal is detected instead of the absorption because the dispersion signal saturates less readily than the absorption. The dispersion signal is related to the absorption signal by the Kramers-Kronig transform.

The information content of EPR arises from the ability to detect a signal and from characteristics of the signal, including integrated intensity, hyperfine splitting by nuclear spins, *g* value, line shape, and electron spin relaxation time. The characteristics of the signal may depend on environmental factors, including temperature, pressure, solvent, and other chemical species. Various types of EPR experiments can optimize information concerning these observables. The following list includes some commonly asked materials science questions that one might seek to answer based on these observables and some corresponding experimental design considerations. Detailed background information on the physical significance and theoretical basis for the observable parameters is provided in the standard texts cited (Poole, 1967, 1983; Pake and Estle, 1973; Eaton and Eaton, 1990a, 1997a; Weil et al., 1994). Some general information and practical considerations are given in this unit.

Whenever unpaired electrons are involved, EPR is potentially the best physical technique for studying the system. Historically, the majority of applications of EPR have been to the study of organic free radicals and transition metal complexes (Abragam and Bleaney, 1970; Swartz et al., 1972; Dalton, 1985; Pilbrow, 1990). Today, these applications continue, but in the context of biological systems, where the organic radicals are naturally occurring radicals, spin labels, and spin-trapped radicals, and the transition metals are in metalloproteins (Berliner, 1976, 1979; Eaton et al., 1998). Applications to the study of materials are extensive, but deserve more attention than they have had in the past. Recent studies include the use of EPR to monitor the age of archeological artifacts (Ikeya, 1993), characterize semiconductors and superconductors, measure the spatial distribution of radicals in processed polymers, monitor photochemical degradation of paints, and characterize the molecular structure of glasses (Rudowicz et al., 1998).

One might seek to answer the following types of questions.

1. Are there paramagnetic species in the sample?

The signal could be due to organic radicals, paramagnetic metal ions, defects in materials (Lancaster, 1967) such as dangling bonds or radiation damage, or paramagnetic species intentionally added as probes. The primary concern in this case would be the presence or absence of a signal. The search for a signal might include obtaining data over a range of temperatures, because some signals can only be detected at low temperatures and others are best detected near room temperature.

2. What is the concentration of paramagnetic species? Does the concentration of paramagnetic species change as a function of procedure used to prepare the material or of sample handling?

Spectra would need to be recorded in a quantitative fashion (Eaton and Eaton, 1980, 1990a, 1992, 1997a).

3. What is the nature of the paramagnetic species? If it is due to a paramagnetic metal, what metal? If it is due to an organic radical, what is the nature of the radical? Is more than one paramagnetic species present in the sample?

One would seek to obtain spectra that are as well resolved as possible. To examine weak interactions with nuclear spins that are too small compared with line widths to be resolved in the typical EPR spectrum, but which might help to identify the species that gives rise to the EPR signal, one might use techniques such as ENDOR (electron nuclear double resonance; Atherton, 1993) or ESEEM (electron spin echo envelope modulation; Dikanov and Tsvetkov, 1992).

4. Does the sample undergo phase transitions that change the environment of the paramagnetic center?

Experiments could be run as a function of temperature, pressure, or other parameters that cause the phase transition.

5. Are the paramagnetic centers isolated from each other or present in pairs, clusters, or higher aggregates?

EPR spectra are very sensitive to interactions between paramagnetic centers (Bencini and Gatteschi, 1990). Strong interactions are reflected in line shapes. Weaker interactions are reflected in relaxation times.

6. What is the mobility of the paramagnetic centers?

EPR spectra are sensitive to motion on the time scale of anisotropies in resonance energies that arise from anisotropies in g values and/or electron-nuclear hyperfine interactions. This time scale typically is microseconds to nanoseconds, depending on the experiment. Thus, EPR spectra can be used as probes of local mobility and microviscosity (Berliner and Reuben, 1989).

7. Are the paramagnetic centers uniformly distributed through the sample or spatially localized?

This issue would be best addressed with an EPR imaging experiment (Eaton and Eaton, 1988a, 1990b, 1991, 1993a, 1995a, 1996b, 1999a; Eaton et al., 1991; Sueki et al., 1990).

Bulk magnetic susceptibility (GENERATION AND MEASUREMENT OF MAGNETIC FIELDS & MAGNETIC MOMENT AND MAGNETIZATION) also can be used to study systems with unpaired electrons, and can be used to determine the nature of the interactions between spins in concentrated spin systems. Rather large samples are required for bulk magnetic susceptibility measurements, whereas EPR typically is limited to rather small samples. Bulk susceptibility and EPR are complementary techniques. EPR has the great advantage that it uniquely measures unpaired electrons in low concentrations, and in fact is most informative for systems that are magnetically dilute. It is particularly powerful for identification of paramagnetic species present in the sample and characterization of the environment of the paramagnetic species.

In this unit, we seek to provide enough information so that a potential user can determine whether EPR is likely to be informative for a particular type of sample, and which type of EPR experiment would most likely be useful.

PRINCIPLES OF EPR

The fundamental principles of EPR are similar to those of nuclear magnetic resonance (NMR; Carrington and

McLachlan, 1967) and magnetic resonance imaging (MRI), which are described elsewhere in this volume (NUCLEAR MAGNETIC RESONANCE IMAGING). However, several major differences between the properties of unpaired electron spins and of nuclear spins result in substantial differences between NMR and EPR spectroscopy. First, the magnetogyric ratio of the electron is 658 times that of the proton, so for the same magnetic field the frequency for electron spin resonance is 658 times the frequency for proton resonance. Many EPR spectrometers operate in the 9 to 9.5 GHz frequency range (called "X-band"), which corresponds to resonance for an organic radical ($g \sim 2$) at a magnetic field of 3200 to 3400 gauss [G; 1 G=10^{-4} tesla (T)]. Second, electron spins couple to the electron orbital angular momentum, resulting in shorter relaxation times than are observed in NMR. Electron spin relaxation times are strongly dependent on the type of paramagnetic centers. For example, typical room temperature electron spin relaxation times range from $\sim 10^{-6}$ s for organic radicals to as short as 10^{-12} s for low-spin Fe(III). Third, short relaxation times can result in very broad lines. Even for organic radicals with relatively long relaxation times, EPR lines frequently are relatively broad due to unresolved coupling to neighboring nuclear spins. Line widths for detectable EPR signals range from fractions of a gauss to tens or hundreds of gauss. Since 1 G corresponds to about 2.8 MHz, these EPR line widths correspond to 10^6 to 10^8 Hz, which is much greater than NMR line widths. Fourth, coupling to the electron orbital angular momentum also results in larger spectral dispersion for EPR than for NMR. A room temperature spectrum of an organic radical might extend over 10 to 100 G. However, the spectrum for a transition metal ion might extend over one hundred to several thousand gauss. Finally, the larger magnetic moment of the unpaired electron also results in larger spin–spin interactions, so high-resolution spectra require lower concentrations for EPR than for NMR. These differences make the EPR measurement much more technically challenging than the NMR measurement. For example, pulsed Fourier transform NMR provides major advances in sensitivity; however pulsed Fourier transform spectroscopy has more restricted applicability in EPR because a pulse of finite width cannot excite the full spectrum for many types of paramagnetic samples (Kevan and Schwartz, 1979; Kevan and Bowman, 1990).

In a typical EPR experiment the sample tube is placed in a structure that is called a resonator. The most common type of resonator is a rectangular cavity. This name is used because microwaves from a source are used to set up a standing wave pattern. In order to set up the standing wave pattern, the resonator must have dimensions appropriate for a relatively narrow range of microwave frequencies. Although the use of a resonator enhances the signal-to-noise (S/N) ratio for the experiment, it requires that the microwave frequency be held approximately constant and that the magnetic field be swept to achieve resonance. The spectrometer detects the microwave energy reflected from the resonator. When spins are at resonance, energy is absorbed from the standing wave pattern, the reflected energy decreases, and a signal is detected. In a typical continuous wave (CW) EPR experiment, the magnetic field is swept and the change in reflected energy (the EPR signal) is recorded. To further improve S/N, the magnetic field is usually modulated (100 kHz modulation is commonly used), and the EPR signal is detected using a phase-sensitive detector at this modulation frequency. This detection scheme produces a first derivative of the EPR absorption signal. A sketch of how magnetic-field modulation results in a derivative display is found in Eaton and Eaton, (1990a, 1997a). Because taking a derivative is a form of resolution enhancement and EPR signals frequently are broad, it is advantageous for many types of samples to work directly with the first-derivative display. Thus, the traditional EPR spectrum is a plot of the first derivative of the EPR absorption as a function of magnetic field. A block diagram for a CW EPR spectrometer is given in Figure 2.

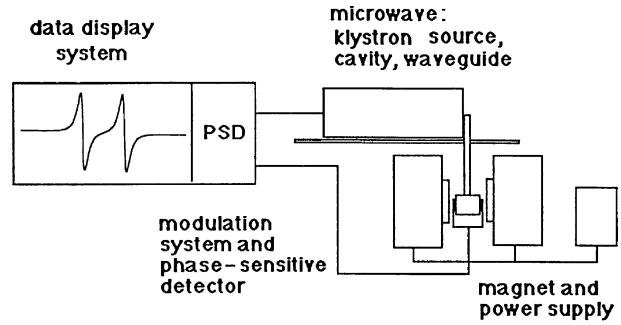

Figure 2. Block diagram of an EPR spectrometer. The fundamental modules of a CW EPR spectrometer include: the microwave system comprising source, resonator, and detector; the magnet system comprising power supply and field controller; the magnetic field modulation and phase-sensitive detection system; and the data display and manipulation system. Each of these subsystems can be largely independent of the others. In modern spectrometers there is a trend toward increasing integration of these units via interfaces to a computer. The computer is then the controller of the spectrometer and also provides the data display and manipulation. In a pulse system a pulse timing unit is added and magnetic field modulation is not used.

Types of EPR Experiments

One can list over 100 separate types of EPR spectra. One such list is in an issue of the *EPR Newsletter* (Eaton and Eaton, 1997b). For this unit we focus primarily on experiments that can be done with commercial spectrometers. For the near future, those are the experiments that are most likely to be routinely available to materials scientists. In the following paragraphs we outline some of the more common types of experiments and indicate what characteristics of the sample might indicate the desirability of a particular type of experiment. Experimental details are reserved for a later section.

1. CW Experiments at X-band with a Rectangular Resonator

This category represents the vast majority of experiments currently performed, whether for routine analysis or for research, in materials or in biomedical areas. In this experiment the microwaves are on continuously and the magnetic field is scanned to achieve resonance. This is the experiment that was described in the introductory

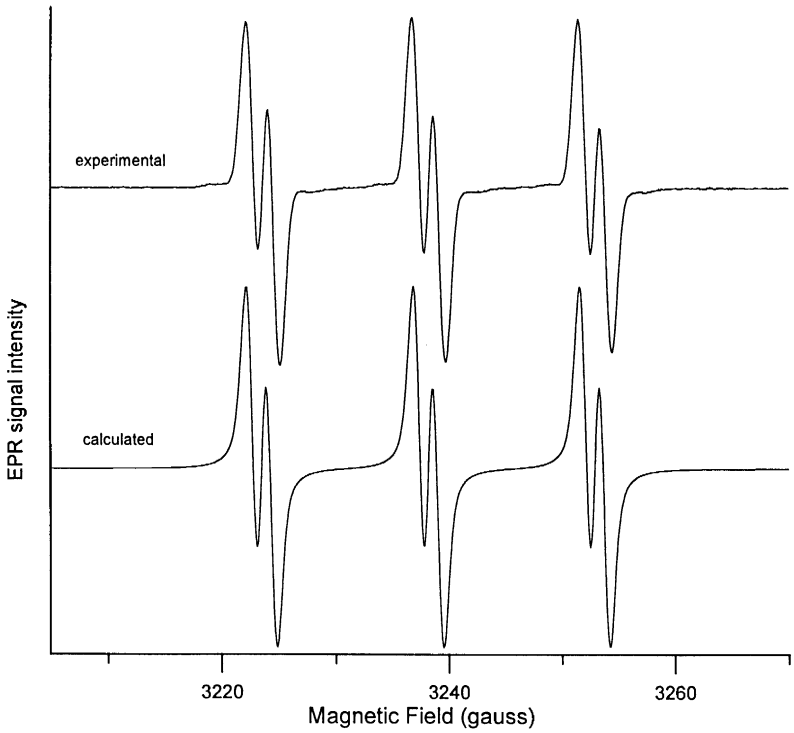

Figure 3. Room temperature CW spectrum of a nitroxyl radical obtained with a microwave frequency of 9.09 GHz. The major three-line splitting is due to coupling to the nitroxyl nitrogen ($I = 1$) and the small doublet splitting is due to interaction with a unique proton ($I = 1/2$). The calculated spectrum was obtained with hyperfine coupling to the nitrogen of 14.7 G, coupling to the proton of 1.6 G, and a Gaussian line width of 1.1 G due to additional unresolved proton hyperfine coupling. The g value (2.0056) is shifted from 2.0023 because of spin-orbit coupling involving the nitrogen heteroatom.

paragraphs and which will be the focus of much of this unit. Examples of spectra obtained at X-band in fluid solution and for an immobilized sample are shown in Figures 3 and 4. The parameters obtained by simulation of these spectra are indicated in the figure captions.

2. CW Experiments at Frequencies Other than X-band

Until relatively recently, almost all EPR was performed at approximately 9 GHz (X-band). However, experiments at lower frequencies can be advantageous in dealing with larger samples and samples composed of materials that absorb microwaves strongly at X-band, as well as for resolving nitrogen hyperfine splitting in certain Cu(II) complexes (Hyde and Froncisz, 1982).

Experiments at higher microwave frequencies are advantageous in resolving signals from species with small g-value differences (Krinichnyi, 1995; Eaton and Eaton, 1993c, 1999b), in obtaining signals from

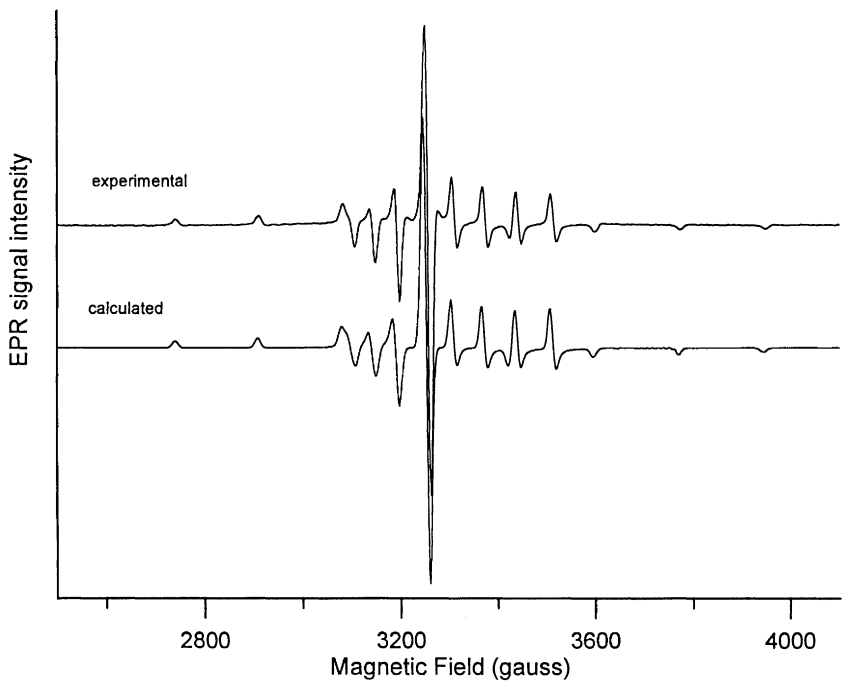

Figure 4. Room temperature CW spectrum of a vanadyl porphyrin in a 2:1 toluene:chloroform glass at 100 K, obtained with a microwave frequency of 9.200 GHz. The anisotropy of the g and hyperfine values results in different resonant conditions for the molecules as a function of orientation with respect to the external field. For this random distribution of orientations, the EPR absorption signal extends from about 2750 to 3950 G. The first derivative display emphasizes regions of the spectrum where there are more rapid changes in slope, so "peaks" in the first derivative curve occur at extrema in the powder distribution. These extrema define the values of g and A along the principal axes of the magnetic tensors. The hyperfine splitting into eight approximately equally spaced lines is due to the nuclear spin ($I = 3.5$) of the vanadium nucleus. The hyperfine splitting is greater along the normal to the porphyrin plane (z axis) than in the perpendicular plane. The calculated spectrum was obtained with $g_x = 1.984$, $g_y = 1.981$, $g_z = 1.965$, $A_x = 55 \times 10^{-4}$ cm^{-1}, $A_y = 53 \times 10^{-4}$ cm^{-1}, and $A_z = 158 \times 10^{-4}$ cm^{-1}.

paramagnetic centers with more than one unpaired electron, and in analyzing magnetic interactions in magnetically concentrated samples (Date, 1983). In principle, experiments at higher microwave frequency should have higher sensitivity than experiments at X-band, due to the larger difference in the Boltzmann populations of the electron spin states. Sensitivity varies with $(\text{frequency})^{11/4}$ if the microwave magnetic field at the sample is kept constant and the size of the resonator is scaled inversely with frequency (Rinard et al., 1999). This is a realistic projection for very small samples, as might occur in some materials research applications. To achieve the expected increase in sensitivity (Rinard et al., 1999) will require substantial engineering improvements in the sources, resonators and detectors used at higher frequency.

Computer simulations of complicated spectra as a function of microwave frequency provide a much more stringent test of the parameters than can be obtained at a single frequency.

3. Electron-Nuclear Double Resonance (ENDOR)

Due to the large line widths of many EPR signals, it is difficult to resolve couplings to nuclear spins. However, these couplings often are key to identifying the paramagnetic center that gives rise to the EPR signal. By simultaneously applying radio frequency (RF) and microwave frequency energies, one can achieve double resonance of both the electron and nuclear spins. The line widths of the signals in this experiment are much narrower than typical EPR line widths and the total number of lines in the spectrum is smaller, so it is easier to identify the nuclear spins that are interacting with the electron spin in an ENDOR spectrum (Box, 1977; Schweiger, 1982; Atherton, 1993; Piekara-Sady and Kispert, 1994; Goslar et al., 1994) than in an experiment without the RF frequency—i.e., a "normal" CW spectrum.

4. Pulsed/Fourier Transform EPR

Measurements of relaxation times via pulsed or time-domain techniques typically are much more accurate than continuous wave measurements. Pulse sequences also can be tailored to obtain detailed information about the spins. However, the much shorter relaxation times for electron spins than for nuclear spins limit pulse sequences to shorter times than can be used in pulsed NMR (Kevan and Schwartz, 1979). A technique referred to as electron spin echo envelope modulation (ESEEM) is particularly useful in characterizing interacting nuclear spins, including applications in materials (Kevan and Bowman, 1990). Interaction between inequivalent unpaired electrons can cause changes in relaxation times that depend on distance between the spins (Eaton and Eaton, 1996a).

5. Experiments with Resonators Other than the Rectangular Resonator

New lumped-circuit resonators, such as the loop-gap resonator (LGR) and others designed on this principle (Hyde and Froncisz, 1986) can be adapted to a specific experiment to optimize aspects of the measurement (Rinard et al., 1993, 1994, 1996a, 1996b). These structures are particularly important for pulsed experiments and for experiments at frequencies lower than X-band.

PRACTICAL ASPECTS OF THE CW METHOD

The selection of the microwave power and modulation amplitude for recording CW EPR signals is very important in obtaining reliable results. We therefore give a brief discussion of issues related to the selection of these parameters. Greater detail concerning the selection of parameters can be found in Eaton and Eaton (1990a, 1997a).

Microwave Power

If microwave power is absorbed by the sample at a rate that is faster than the sample can dissipate energy to the lattice (i.e., faster than the electron spin relaxation rate), the EPR signal will not be proportional to the number of spins in the sample. This condition is called saturation. The power that can be used without saturating the sample depends on the relaxation rate. To avoid saturation of spectra, much lower powers must be used for samples that have long relaxation times, such as organic radicals, than for samples with much shorter relaxation times, such as transition metals. Relaxation times can range over more than 18 orders of magnitude, from hours to 10^{-14} s, with a wide range of temperature dependence, from T^9 to temperature-independent, and a wide variety of magnetic field dependence and/or dependence on position in the EPR spectrum (Du et al., 1995). One can test for saturation by recording signal amplitude at a series of microwave powers, P, and plotting signal amplitude as a function of $\sqrt{P}$. This plot is called a power-saturation curve. The point where the signal dependence on $\sqrt{P}$ begins to deviate from linearity is called the onset of saturation. Data must be recorded at a power level below the onset of saturation in order to use integrated data to determine the spin concentration in the sample. Higher powers also cause line broadening, so powers should be kept below the onset of saturation if data analysis is based on line shape information. Above the onset of saturation, the signal intensity typically increases with increasing power and goes through a maximum. If the primary goal is to get maximum S/N at the expense of line shape or quantitation, then one can operate at the power level that gives maximum signal amplitude, but under such conditions quantitation of spins can be erroneous.

Modulation Amplitude

Provided that the modulation amplitude is less than 1/10 of the peak-to-peak line width of the first-derivative EPR signal to be recorded, increasing modulation amplitude improves S/N without distorting line shape. However, as the modulation amplitude is increased further, it causes broadening and distortion (Poole, 1967). If the key information to be obtained from the spectrum is based on the line shape, care must be taken in selecting the modulation

amplitude. Unlike the problems that occur when too high a microwave power is used to record the spectrum, increasing the modulation amplitude does not change the linear relationship between integrated signal intensity and modulation amplitude. Thus, if the primary information to be obtained from a spectrum is the integrated signal intensity (to determine spin concentration), it can be useful to increase modulation amplitude, and thereby improve S/N, at the expense of some line shape distortion. The maximum spectral amplitude, and therefore the best S/N, occurs at a peak-to-peak modulation amplitude ~2 times the peak-to-peak width of the derivative EPR spectrum.

Sensitivity

The most important issue concerning practical applications of EPR is sensitivity (Eaton and Eaton 1980, 1992; Rinard et al., 1999). In many analytical methods, one can describe sensitivity simply in terms of minimum detectable concentrations. The problem is more complicated for EPR because of the wide range of line widths and large differences in power saturation among species of interest. Vendor literature cites sensitivity as about $0.8 \times 10^{10}/\Delta B$ spins/G, where ΔB is the line width of the EPR signal. This is a statement of the minimum number of detectable spins with a S/N of 1. It is based on the assumption that spectra can be recorded at a power of 200 mW, with a modulation amplitude of 8 G, and that there is no hyperfine splitting that divides intensity of the signal into multiple resolved lines. To apply this statement to estimate sensitivity for another sample requires taking account of the actual conditions appropriate for a particular sample. Those conditions depend upon the information that one requires from the spectra. One can consider two types of conditions as described below.

Case 1. Selection of microwave power, modulation amplitude, and time constant of the signal detection system that provide undistorted line shapes. This mode of operation is crucial if one wishes to obtain information concerning mobility of the paramagnetic center or partially resolved hyperfine interactions. Typically this would also require a S/N significantly greater than 1. This case might be called "minimum number of detectable spins with desired spectral information." It would require the use of a microwave power that did not cause saturation and a modulation amplitude that did not cause line broadening.

Case 2. Selection of microwave power, modulation amplitude, and time constant of the signal detection system that provide the maximum signal amplitude, at the expense of line shape information. This mode of operation might be selected, for example, in some spin trapping experiments, where one seeks to determine whether an EPR signal is present and one can obtain adequate information for identification of the species from observed hyperfine couplings even in the presence of line shape distortions that come from power broadening or overmodulation. This case might be called "minimum number of detectable spins."

To correct the minimum number of detectable spins for microwave power, multiply $0.8 \times 10^{10}/\Delta B$ by

$$\sqrt{\frac{P_{sample}}{200}} \tag{1}$$

where P_{sample} is the power incident on the critically coupled resonator, in mW. To correct for changes in modulation amplitude (MA), multiply by MA_{sample} (in gauss)/8 (G). For samples with narrow lines and long relaxation times, the minimum number of detectable spins may be higher than $0.8 \times 10^{10}/\Delta B$ by several orders of magnitude.

Calibration

Quality assurance requires a major effort in EPR (Eaton and Eaton 1980, 1992). Because the properties of the sample affect the characteristics of the resonator, and because the microwave magnetic field varies over the sample, selecting a standard for quantitation of the number of spins requires understanding of the spin system and of the spectrometer [Poole, 1967, 1983; Wilmshurst, 1968 (see especially THERMAL ANALYSIS); Alger 1968; Czoch and Francik, 1989]. In general, the standard should be as similar as possible to the sample to be measured, in the same solvent or solid host, and in a tube that is as close as possible to the same size. The EPR tube has to be treated as a volumetric flask, and calibrated accordingly. Determining the number of spins in the sample requires subtraction of any background signal, and then integrating twice (derivative → absorption → area). If there is background slope, the double integration may not be very accurate. All of this requires that the EPR spectrum be in digital form. If the line shape is the same for the sample and the reference, then peak heights can be used instead of integrated areas. This is sometimes difficult to ensure, especially in the wings of the spectrum, which may constitute a lot of the area under the spectrum. However, for fairly widespread applications, such as spin trapping and spin labeling, reasonable estimates of spin concentration can be obtained by peak-height comparison with gravimetrically prepared standard solutions. Very noisy spectra with well defined peak positions might best be quantitated using simulated spectra that best fit the experimental spectra.

Another important calibration is of magnetic field scan. The best standard is an NMR gaussmeter, but note that the magnetic field varies across the pole face, and the gaussmeter probe has to be as close to the sample as possible—ideally inside the resonator. A few carefully-measured samples that can be prepared reproducibly have been reported in the literature (Eaton and Eaton 1980, 1992) and are good secondary standards for magnetic field calibrations.

The magnetic field control device on electromagnet-based EPR spectrometers is a Hall probe. These are inherently not very accurate devices, but EPR field control units contain circuitry to correct for their inaccuracies. Recent Bruker field controllers, for example, use a ROM containing the characteristics of the specific Hall probe with which it is matched. Such systems provide sufficient accuracy for most EPR measurements.

METHOD AUTOMATION

Early EPR spectrometers did not include computers. Many, but not all of those systems, have been retrofitted with computers for data acquisition. Historically, the operator spent full time at the EPR spectrometer console while the spectrometer was being operated. In the next generation, a computer was attached to the EPR spectrometer for data acquisition, but the spectrometer was still substantially manually operated. Even when computers were built into the spectrometer, there was a control console at which the operator sat. The newer spectrometers are operated from the computer, and have a console of electronic modules that control various functions of the magnet, microwave system, and data acquisition. The latest pulsed EPR spectrometers are able to execute long (including overnight) multipulse experiments without operator intervention. The most recent cryogenic temperature-control systems also can be programmed and can control the cryogen valve in addition to the heater. There is one research lab that has highly automated ENDOR spectrometers (Corradi et al, 1991). Except for these examples, EPR has not been automated to a significant degree.

For many samples, the sample positioning is sufficiently critical, as is the resonator tuning and coupling, that automation of sample changing for unattended operation is less feasible than for many other forms of spectroscopy, including NMR. Automation would be feasible for multiple samples that shared the same geometry, dielectric constant, and microwave loss factor, if they could be run near room temperature. The only currently available spectrometer with an automatic sample changer is one designed by Bruker for dosimetry. This system is customized to handle a particular style of alanine dosimeter and includes software to quantitate the radical signal and to prepare reports. References to computer use for acquisition and interpretation are given by Vancamp and Heiss (1981) and Kirste (1994).

DATA ANALYSIS AND INITIAL INTERPRETATION

The wide range of queries one may make of the spin system, listed elsewhere in this unit, makes the data analysis and interpretation diverse. An example of a spectrum of an organic radical in fluid solution is shown in Figure 3. Computer simulation of the spectrum gives the g value for the radical and the nuclear hyperfine splittings which can be used to identify the nuclear spins with the largest couplings to the unpaired electrons. An example of a spectrum of a vanadyl complex immobilized in 1:1 toluene:chloroform at 100 K is shown in Figure 4. The characteristic 8-line splitting patterns permit unambiguous assignment as a vanadium species ($I = 3.5$). Computer simulation of the spectrum gives the anisotropic components of the g and A values, which permits a more detailed characterization of the electronic structure of the paramagnetic center than could be obtained from the isotropic averages of these parameters observed in fluid solution.

As discussed above, under instrument calibration, a first stage in data analysis and interpretation is to determine how many spins are present, as well as the magnitude of line widths and hyperfine splittings. The importance of quantitation should not be underestimated. There are many reports in the literature of detailed analysis of a signal that accounts for only a very small fraction of the spins in the sample, the others having been overlooked. The problem is particularly acute in samples that contain both sharp and broad signals. The first-derivative display tends to emphasize the sharp signals, and it is easy to overlook broad signals unless spectra are recorded under a wide range of experimental conditions.

The software available as part of the spectrometer systems is increasingly powerful and versatile. Additional software is available, some commercially and some from individual labs (easily locatable via the EPR Society software exchange; *http://www.ierc.scs.uiuc.edu*), for simulation of more specialized spin systems. The understanding of many spin systems is now at the stage where a full simulation of the experimental line shape is a necessary step in interpreting an EPR spectrum. For $S = 1/2$ organic radicals in fluid solution, one should be able to fit spectra within experimental error if the radical has been correctly identified. However, there will always remain important problems for which the key is to understand the spin system, and for these systems simulation may push the state of the art. For example, for many high-spin Fe(III) systems, there is little information about zero-field splitting (ZFS) terms, so one does not even know which transitions should be included in the simulation.

In pulsed EPR measurements, the first step after quantitation is to determine the relaxation times, and, if relevant, the ESEEM frequencies in the echo decay by Fourier transformation of the time-domain signal. Software for these analyses and for interpretation of the results is still largely resident within individual research groups, especially for newly evolved experiments.

SAMPLE PREPARATION

Samples for study by EPR can be solid, dissolved solid, liquid, or, less frequently, gas. In the gas phase the electron spin couples to the rotational angular momentum, so EPR spectroscopy has been used primarily for very small molecules. Thus, the focus of this unit is on samples in solid or liquid phases. For most EPR resonators at X-band or lower frequency, the sample is placed in a 4-mm outside diameter (o.d.) quartz tube. Usually, synthetic fused silica is used to avoid paramagnetic metal impurities. The weaker the sample signal, the higher the quality of quartz required. Pyrex or Kimax (trade names of Corning and Kimble) have very strong EPR signals.

Often, oxygen must be removed from the sample because the sample reacts with oxygen, or because the paramagnetic O_2 broadens EPR signals by Heisenberg exchange during collisions. The oxygen broadening is a problem for high-resolution spectra of organic radicals in solution and for the study of carbonaceous materials. This problem is so severe that one can turn this around and use oxygen broadening as a measure of oxygen concentration. EPR oximetry is a powerful analytical tool (Hyde and Subczynski, 1989).

For some problems one would want to study the concentrated solid, which may not exist in any other form. Maybe one wants to examine the spin-spin interaction as a function of temperature. In this case, one would put the solid directly into the EPR tube, either as a powder or as a single crystal, which might be oriented. There are a number of caveats for these types of samples. First, one must avoid overloading the resonator. More sample is not always better. With a "standard" TE_{102} (transverse electric 102 mode cavity) rectangular resonator (which until recently was the most common EPR resonator), one cannot use more than $\sim 10^{17}$ spins (Goldberg and Crowe, 1977). If the number of spins is too high, one violates the criterion that the energy absorption on resonance is a small perturbation to the energy reflected from the resonator. This is not an uncommon problem, especially with "unknown" samples, which might contain, for example, large quantities of iron oxide.

A similar problem occurs with samples that are lossy—i.e., that absorb microwaves other than by magnetic resonance (Dalal et al., 1981). Water is a prime example. For aqueous samples, and especially biological samples, there are special flat cells to keep the lossy material in a nodal plane of the microwave field in the resonator. There are special resonators to optimize the S/N for lossy samples. Usually, these operate with a TM (transverse magnetic) mode rather than a TE mode. Lower frequency can also be advantageous for lossy samples. There are many examples of lossy materials commonly encountered in the study of materials. Carbonaceous materials often have highly conducting regions. Some semiconductors are sufficiently conducting that only small amounts of sample can be put in the resonator without reducing the Q (the resonator quality factor) so much that the spectrometer cannot operate.

These problems are obvious to the experienced operator, because general-purpose commercial EPR spectrometers provide a readout of the microwave power as a function of frequency during the "tune" mode of setting up the measurement. The power absorbed by the resonator appears as a "dip" in the power versus frequency display. The broader the dip, the lower the resonator Q. One useful definition of Q is the resonant frequency divided by the half-power bandwidth of the resonator, $Q = \nu/\Delta\nu$. A lossy or conducting sample lowers Q, which is evident to the operator as a broadening of the dip. If the sample has much effect on Q, care must be taken in quantitation of the EPR signal, since the signal amplitude is proportional to Q. Ideally, one would measure the Q for every sample if spin quantitation is a goal. No commercial spectrometer gives an accurate readout of Q, so the best approach is to make the Q effect of the samples under comparison as precisely the same as possible.

Magnetically concentrated solids can exhibit the full range of magnetic interactions, including antiferromagnetism, ferromagnetism, and ferrimagnetism, in addition to paramagnetism, many of which are amenable to study by EPR (Bencini and Gatteschi, 1990; Stevens, 1997). Because of the strength of magnetic interactions in magnetically concentrated solids, ferrimagnetic resonance and ferromagnetic resonance have become separate subfields of magnetic resonance. High-field EPR is especially valuable to studies of magnetically concentrated solids, because it is possible in some cases to achieve external magnetic fields on the order of or greater than the internal magnetic fields.

If the goal is the study of isolated spins, they need to be magnetically dilute. In practice, this means that the spin concentration in a doped solid or liquid or solid solution should be less than $\sim$1 mM ($\sim 6 \times 10^{17}$ spins per cm^3). For narrow-line spectra, such as defect centers in solids or organic radicals, either in liquid or solid solution, concentrations less than 1 mM are required to achieve minimum line width. For accurate measurement of relaxation times, concentrations have to be lower than those required for accurate measurement of line widths in CW spectra. For some materials, it is convenient to prepare a solution and cool it to obtain an immobilized sample. If this is done, it is important to select a solvent or solvent mixture that forms a glass, not crystals, when it is cooled. Crystallization excludes solute from the lattice and thereby generates regions of locally high concentrations, which can result in poor resolution of the spectra.

The discussion of lossy samples hints at part of the problem of preparing fluid solution samples. The solvent has to be nonlossy, or the sample has to be very small and carefully located. Some solvents are more lossy at given temperatures than others. Most solvents are nonlossy when frozen. Broadening by oxygen is usually not detectable in frozen solution line widths, but there still can be an impact on relaxation times. Furthermore, the paramagnetic O_2 also can yield an EPR signal in frozen solution (it is detectable in the gas phase and in the solid, but not in fluid solution), and can be mistaken for signals in the sample under study.

Care must be taken when examining powdered crystalline solids to get a true powder (random orientation) line shape. If the particles are not small enough they may preferentially orient when placed in the sample tube. At high magnetic fields, magnetically anisotropic solids can align in the magnetic field. Either of these effects can yield spectra that are representative of special crystal orientations, rather than a powder (spherical) average. The combination of these effects can dominate attempts to obtain spectra at high magnetic fields, such as at 95 GHz and above, where very small samples are needed and magnetic fields are strong enough to macroscopically align microcrystals.

Although experiments are more time consuming, very detailed information concerning the electronic structure of the paramagnetic center can be obtained by examining single crystals. In these samples, data are obtained as a function of the orientation of the crystal, which then provides a full mapping of the orientation dependence of the g-matrix and of the electron-nuclear hyperfine interaction (Byrn and Strouse, 1983; Weil et al., 1994).

SPECIMEN MODIFICATION

The issue of specimen modification is inherent in the discussion of sample preparation. EPR is appropriately described as a nondestructive technique. If the sample fits the EPR resonator, it can be recovered unchanged.

However, some of the detailed sample preparations discussed above do result in modification of the sample. Grinding to achieve a true powder average spectrum destroys the original crystal. Sometimes grinding itself introduces defects that yield EPR signals, and this could be a study in itself. Sometimes grinding exposes surfaces to reactants that convert the sample to something different. Similarly, dissolving a sample may irreversibly change it, due to reactivity or association or dissociation equilibria. Cooling or heating a single crystal sometimes causes phase transitions that shatter the crystal. Unfortunately freezing a solvent may shatter the quartz EPR tube, due to differences in coefficient of expansion, causing loss of the sample.

These potential problems notwithstanding, EPR is a nondestructive and noninvasive methodology for study of materials. Consider the alternatives to EPR imaging to determine spatial distribution of paramagnetic centers. Even using EPR to monitor the radical concentration, one would grind or etch away the surface of the sample, monitoring changes in the signal after each step of surface removal. The sample is destroyed in the process. With EPR imaging, the sample is still intact and can be used for a further study, e.g., additional irradiation or heat treatment (Sueki et al., 1995).

PROBLEMS

How to Decide Whether and How EPR Should be Used

What do you want to learn about the sample? Is EPR the right tool for the task? This section attempts to guide thinking about these questions.

Is there an EPR signal? The first thing we learn via EPR is whether the sample in a particular environment exhibits resonance at the selected frequency, magnetic field, temperature, microwave power, and time after a pulse. This is a nontrivial observation, and by itself may provide almost the full answer to a question about the material. One should be careful, however, about jumping to conclusions based on only qualitative EPR results. With care it is possible to find an EPR signal in almost any sample, but that signal may not even be relevant to the information desired about the sample. There are spins everywhere. Dirt and dust in the environment, even indoors, will yield an EPR signal, often with strong Mn(II) signals and large broad signals due to iron oxides. Quartz sample tubes and Dewars contain impurities that yield EPR signal close to $g = 2$ and slightly higher. Most often, these are "background" interferences that have to be subtracted for quantitative work.

What if the sample does not exhibit a nonbackground EPR signal? Does this mean that there are no unpaired spins in the sample? Definitely not! The experienced spectroscopist is more likely to find a signal than the novice, because of the extensive number of tradeoffs needed to optimize an EPR spectrum (sample positioning, microwave frequency, resonator coupling, magnetic field sweep, microwave power, modulation frequency and amplitude, and time constant). The sample might have relaxation times such that the EPR signal is not observable at the temperature selected (Eaton and Eaton 1990a). In general, relaxation times increase with decreasing temperature, and there will be some optimum temperature at which the relaxation time is sufficiently long that the lines are not immeasurably broad, but not so long that the line is saturated at all available microwave power levels.

Furthermore, the failure to observe an EPR signal could be a fundamental property of the spin system. If the electron spin, S, for the paramagnetic center of interest is half-integer, usually at least the transition between the $m_s = \pm 1/2$ levels will be observable at some temperature. However, for integer spin systems ($S = 1, 2, 3$) the transition may not be observable at all in the usual spectrometer configuration, even if the right frequency, field, temperature, and so forth are chosen (Abragam and Bleaney, 1970; Pilbrow, 1990). This is because such spin transitions are forbidden when the microwave magnetic field, B_1, is perpendicular to the external magnetic field, B_0, i.e., in the usual arrangement. For integer spin systems one needs B_1 parallel to B_0, and a special cavity is required. Fortunately, these are commercially available at X-band. Thus, if the question is "does this sample contain paramagnetic Ni(II)," a special parallel mode resonator is needed. An overview of EPR-detectable paramagnetic centers and corresponding parameters can be found in Eaton and Eaton (1990a).

Another reason for not observing an EPR signal, or at least the signal from the species of interest, is that spin-spin interaction resulted in a singlet-triplet separation such that only one of these states is significantly populated under the conditions of measurement. A classic example is dimeric Cu(II) complexes, which have singlet ground states, so the signal disappears as the sample is cooled to He temperatures. Similarly, in fullerene chemistry it was found that the EPR signal from C_{60}^{2-} is due to a thermally excited triplet state and could only be seen in a restricted temperature range (Trulove et al., 1995).

Even if the goal is to measure relaxation times with pulsed EPR, one would usually start with CW survey spectra to ensure the integrity of the sample. Usually, pulsed EPR is less sensitive on a molar spin basis than CW EPR when both are optimized, because of the better noise filtering that can be done in CW EPR. However, if the relaxation time is long, it may not be possible to obtain a valid slow-passage CW EPR spectrum, and alternative techniques will be superior. Sometimes rapid-passage CW EPR, or dispersion spectra instead of absorption spectra, could be the EPR methodology of choice, especially for broad signals. However, for EPR signals that are narrow relative to the bandwidth of the resonator, pulsed FT EPR may provide both better S/N and more fidelity in line shape than CW EPR. This is the case for the signal of the E' center in the γ-irradiated fused quartz sample that has been proposed as a standard sample for time-domain EPR (Eaton and Eaton, 1993b; available from Wilmad Glass).

How many species are there? In many forms of spectroscopy one can monitor isosbestic points to determine limits on the number of species present. Note that, since the common CW EPR spectrum is a derivative display, one should in general not interpret spectral positions that

are constant as a function of some variable as isosbestic points. Because of the derivative display they are isoclinic points—points of the same slope, not points of the same absorption. Integrated spectra need to be used to judge relative behavior of multiple species in the way that has become common in UV-visible electronic spectroscopy.

Relatively few paramagnetic species yield single-line EPR spectra, due to electron-nuclear coupling and electron-electron coupling. If the nuclear coupling is well resolved in a CW spectrum, it is a straightforward exercise to figure out the number of nuclear spins of each nuclear moment. However, unresolved coupling is common, and more powerful (and expensive) techniques have to be used. Electron-nuclear double resonance (ENDOR), which uses RF at the nuclear resonant frequency simultaneous with microwaves resonant at particular EPR transition, is a powerful tool for identifying nuclear couplings not resolved in CW EPR spectra (Kevan and Kispert, 1976; Box, 1977; Dorio and Freed, 1979; Schweiger, 1982; Piekara-Sady and Kispert, 1994; Goslar et al., 1994). A good introduction is given in (Atherton, 1993). Nuclear couplings too small to be observed in ENDOR commonly can be observed with spin echo EPR, where they result in electron spin echo envelope modulation (ESEEM, also abbreviated ESEM; Dikanov and Tsvetkov, 1992). This technique requires a pulsed EPR spectrometer. ESEEM is especially powerful for determining the nuclei in the environment of an electron spin, and is extensively used in metalloprotein studies.

Where are the species that yield the EPR signals? The ENDOR and ESEEM techniques provide answers about the immediate environments of the paramagnetic centers, but there may be a larger-scale question: are the paramagnetic species on the surface of the sample (Sueki et al., 1995), in the center, uniformly distributed, or localized in high-concentration regions throughout the sample? These questions also are answerable via various EPR techniques. EPR imaging can tell where in the sample the spins are located (Eaton et al., 1991). EPR imaging is analogous to NMR imaging, but is most often performed with slowly stepped magnetic field gradients and CW spectra, whereas most NMR imaging is done with pulsed-field gradients and time-domain (usually spin echo) spectra (see NUCLEAR MAGNETIC RESONANCE IMAGING). The differences in technique are due to the differences in spectral width and relaxation times. Low-frequency (L-band) spectrometers are available from JEOL and Bruker.

Uniform versus nonuniform distributions of paramagnetic centers can be ascertained by several observations. Nonuniformity is a more common problem than is recognized. Dopants (impurities) in solids usually distort the geometry of the lattice and sometimes the charge balance, so they are often not distributed in a truly random fashion. Frozen solutions (at whatever temperature) often exhibit partial precipitation and/or aggregation of the paramagnetic centers. The use of pure solvents rarely gives a good glass. For example, even flash freezing does not yield glassy water under normal laboratory conditions. A cosolvent such as glycerol is needed to form a glass. If there is even partial devitrification, it is likely that the paramagnetic species (an impurity in the solvent) will be localized at grain boundaries. Local high concentrations sometimes can be recognized by broadening of the spectra (if one knows what the "normal" spectrum should look like), or even exchange narrowing of the spectra when concentrations are very high. Time-domain (pulse) spectra are more sensitive than CW spectra to these effects, and provide a convenient measure through a phenomenon called instantaneous diffusion (Eaton and Eaton, 1991), which is revealed when the two-pulse echo decay rate depends on the pulse power. The observation of instantaneous diffusion is an indication that the spin concentration is high. If the bulk concentration is known to be low enough that instantaneous diffusion is not likely to be observed (e.g., less than $\sim$1 mM for broad spectra and less than $\sim$0.1 mM for narrow spectra), then the observation of instantaneous diffusion indicates that there are locally high concentrations of spins—i.e., that the spin distribution is microscopically nonuniform.

Multiple species can show up as multiple time constants in pulsed EPR, but there may be reasons other than multiple species for the multiple time constants. Many checks are needed, and the literature of time-domain EPR should be consulted (Standley and Vaughan, 1969; Muus and Atkins, 1972; Kevan and Schwartz, 1979; Dikanov and Tsvetkov, 1992; Kevan and Bowman, 1990).

One of the most common questions is "how long will it take to run an EPR spectrum?" The answer depends strongly on what one wants to learn from the sample, and can range from a few minutes to many weeks. Even the simple question as to whether there are any unpaired electrons present may take quite a bit of effort to answer, unless one already knows a lot about the sample. The spins may have relaxation times so long that they are difficult to observe without saturation (e.g., defect centers in solids) or so short that they cannot be observed except at very low temperature, where the relaxation times become longer [e.g., high-spin Co(II) in many environments]. At the other extreme, column fractions of a nitroxyl-spin-labeled protein can be monitored for radicals about as fast as the samples can be put in the spectrometer. This is an example of an application that could be automated. Similarly, alanine-based radiation dosimeters, if of a standard geometry, can be loaded automatically into a Bruker spectrometer designed for this application, and the spectra can be run in a few minutes. If, on the other hand, one wants to know the concentration of high-spin Co(II) in a sample, the need for quantitative sample preparation, accurate cryogenic temperature control, careful background subtraction, and skillful setting of instrument parameters leads to a rather time-consuming measurement.

Current research on EPR is usually reported in the *Journal of Magnetic Resonance*, *Applied Magnetic Resonance*, *Chemical Physics Letters*, *Journal of Chemical Physics*, and journals focusing on application areas, such as *Macromolecules*, *Journal of Non-Crystalline Solids*, *Inorganic Chemistry*, and numerous biochemical journals. Examination of the current literature will suggest applications of EPR to materials science beyond those briefly mentioned in this unit. The *Specialist Periodical Report* on ESR of the Royal Society of Chemistry is the best source of annual updates on progress in EPR.

Reports of two workshops on the future of EPR (in 1987 and 1992) and a volume celebrating the first 50 years of EPR (Eaton et al., 1998) provide a vision of the future directions of the field (Eaton and Eaton, 1988b, 1995b).

Finally, it should be pointed out that merely obtaining an EPR spectrum properly, and characterizing its dependence on the factors discussed above, is just the first step. Its interpretation in terms of the physical properties of the material of interest is the real intellectual challenge and payoff.

Web page for the authors' lab. The above Centers and the authors' lab attempt to link to each other and collectively provide many references to recent papers, notices of meetings, and background on magnetic resonance. There now exist many electronic data bases that one can search to find recent papers on EPR. However, only a small portion of the relevant papers will be found by using just "EPR" as the search term. Our experience is that at least the following set of keywords have to be used to retrieve the bulk of the papers: ESR, EPR, electron spin, electron paramag, ESEEM, ENDOR, and echo modulation. Other relevant papers will be found using keywords for the application field, since words relating to EPR may not occur in the title or abstract of the paper even if EPR is a primary tool of the study.*

APPENDIX: INSTRUMENTATION

EPR measurements require a significant investment in instrumentation. There are three fundamental parts to an EPR spectrometer: the microwave system, the magnet system, and the data acquisition and analysis system (Figure 2). Brief discussions of spectrometer design are in introductory texts (Weil et al., 1994, Eaton and Eaton, 1990, 1997). Extensive discussions of microwaves relevant to EPR are available (Poole, 1967, 1983; Baden-Fuller, 1990). Some recent papers give details on pulsed EPR design (Quine et al., 1987, 1992, 1996). The magnets used in EPR range from ~3-in. to 12-in. diameter pole faces, the larger magnets providing better magnetic field homogeneity for larger gaps. Larger magnet gaps permit a wider range of accessory instrumentation for various measurements, such as controlling the sample temperature. A 3-in. magnet weighs roughly 300 pounds, and a 12-in. magnet weighs roughly 4000 pounds. Power supplies for the magnet, and cooling water systems, which optimally are temperature-controlled-recirculating deionized water systems, also require an investment in floor space. The microwave system usually sits on a table supported on the magnet for stability.

EPR spectrometers are expensive to purchase and to operate. They require a well trained operator, and except for a few tabletop models, they take up a lot of floor space and use substantial electrical power and cooling water for the electromagnet. Newer EPR spectrometer systems are operated via a computer, so the new operator who is familiar with use of computers can learn operation much faster than in the older equipment where remembering a critical sequence of manual valves and knobs was part of doing spectroscopy. Even so, the use of a high-Q resonator results in much stronger interaction between the sample and the spectrometer than in most other analytical techniques, and a lot of judgment is needed to get useful, especially quantitatively meaningful results.

Commercial Instruments

Most materials science needs will be satisfied by commercial spectrometers. Some references are provided below to recent spectrometers built by various research labs. These provide some details about design that may be helpful to the reader who wants to go beyond the level of this article. The following brief outline of commercial instruments is intended to guide the reader to the range of spectrometers available. The largest manufacturers—Bruker Instruments EPR Division, and JEOL—market general-purpose spectrometers intended to fulfill most analytical needs. The focus is on X-band (~9 to 10 GHz) CW spectrometers, with a wide variety of resonators to provide for many types of samples. Accessories facilitate control of the sample temperature from <4 to ~700 K. Magnets commonly range from 6- to 12-in. pole face diameters. Smaller tabletop spectrometers are available from Bruker, JEOL, and Resonance Instruments. Some of these have permanent magnets and sweep coils for applications that focus on spectra near $g = 2$, but some have electromagnets permitting wide field sweeps. Bruker makes one small system optimized for quantitation of organic radicals and defect centers, such as for dosimetry.

Bruker and JEOL market pulsed, time-domain spectrometers as well as CW spectrometers. These suppliers also market spectrometers for frequencies lower than X-band, which are useful for study of lossy samples. Bruker and Resonance Technologies market high-frequency, high-field EPR spectrometers, which require superconducting magnets, not resistive electromagnets.

There are numerous vendors of accessories and supplies essential for various aspects of EPR measurements, including Oxford Instruments (cryostats), Cryo Industries (cryostats), Wilmad (sample tubes, quartz Dewars, standard samples), Oxis (spin traps), Medical Advances (loop gap resonators), Research Specialties (accessories and service), Summit Technology (small spectrometers, accessories), Scientific Software Services (data acquisition), Cambridge Isotope Labs (labeled compounds), and CPI (klystrons). Addresses and up-to-date information can be accessed via the EPR Newsletter.

CYCLOTRON RESONANCE

INTRODUCTION

Cyclotron resonance (CR) is a method for measuring the effective masses of charge carriers in solids. It is by far the most direct and accurate method for providing such information. In the simplest description, the principle of the method can be stated as follows. A particle of effective mass m^* and charge e in a DC magnetic field B executes a helical motion around B with the cyclotron frequency $\omega_c = eB/m^*$. If, at the same time, an AC electric field of frequency $\omega = \omega_c$ is applied to the system, perpendicular to B, the particle will resonantly absorb energy from the AC field. Since B and/or ω can be continuously swept through the resonance and known to a very high degree of accuracy, m^* can be directly determined with high accuracy by $m^* = eB/\omega$.

In crystalline solids, the dynamics of charge carriers (or Bloch electrons) can be most conveniently described by the use of the effective mass tensor, defined for simple nondegenerate bands as

$$(\bar{m})_{\mu\nu} = \left(\frac{1}{\hbar^2}\frac{\partial^2 E(\vec{k})}{\partial k_\mu \partial k_\nu}\right)^{-1}, \qquad (\mu, \nu = 1, 2, 3) \qquad (1)$$

where $E = E(\vec{k})$ is the energy dispersion relation near the band edge ($\vec{p} = \hbar\vec{k}$ is the crystal momentum). Hence, the primary purpose of CR in solids is to determine the components of the effective mass tensor, or the curvature of the energy surface, at the extrema of the conduction and valence bands (or at the Fermi surface in the case of a metal). In the 1950s, the first CR studies were carried out in germanium and silicon crystals (Dresselhaus et al., 1953, 1955; Lax et al., 1953), which, in conjunction with the effective-mass theory (e.g., Luttinger and Kohn, 1955; Luttinger, 1956), successfully determined the band-edge parameters for these materials with unprecedented accuracy. Since then CR has been investigated in a large number of elementary and compound materials and their alloys and heterostructures.

Quantum mechanically, the energy of a free electron in a magnetic field is quantized as $E_N = (N + 1/2)\hbar\omega_c$, where $N = 0, 1, 2, \ldots \infty$ and $\hbar\omega_c$ is called the cyclotron energy. These equally-spaced energy levels, or an infinite ladder, are the well-known Landau levels (see, e.g., Kittel, 1987). At high magnetic fields and low temperatures (T), where $k_B T < \hbar\omega_c$ (k_B is the Boltzmann constant), this magnetic quantization becomes important, and CR may then be viewed as a quantum transition between adjacent Landau levels ($\Delta N = \pm 1$).

In real solids, Landau levels are generally not equally-spaced since the energy dispersion relation, E versus $\vec{k}$, is not generally given by a simple parabolic dispersion relation $E(\vec{k}) = \hbar^2|\vec{k}|^2/2m^*$. The degree of nonparabolicity and anisotropy depends on the material, but, in general, the effective mass is energy-dependent as well as direction-dependent. Landau levels for free carriers in solids cannot be obtained analytically, but several useful approximation models exist (e.g., Luttinger, 1956; Bowers and Yafet, 1959; Pidgeon and Brown, 1966). These calculations could be complex, especially when one is concerned with degenerate bands such as the valence bands of group IV, III-V and II-VI semiconductors. However, a detailed comparison between theory and experiment on quantum CR can provide a critical test of the band theory of solids (e.g., Suzuki and Hensel, 1974; Hensel and Suzuki, 1974).

As a secondary purpose, one can also use CR to study carrier scattering phenomena in solids by examining the scattering lifetime τ (the time between collisions, also known as the collision time or the transport/momentum relaxation time), which can be found from the linewidth of CR peaks. In the classical regime, where most electrons reside in states with high Landau indices, τ is directly related to the static (or DC) conductivity in the absence of the magnetic field. The temperature dependence of τ then shows markedly different characteristics for phonon scattering, impurity scattering, and scattering from various imperfections. However, in the quantum regime, where most electrons are in the first few Landau levels, the effect of the magnetic field on scattering mechanisms is no longer negligible and τ loses its direct relationship with the DC mobility (for theory, see, e.g., Kawabata, 1967).

As the frequency of scattering events (or the density of scatterers) increases, CR linewidth increases, and, eventually, CR becomes unobservable when scattering occurs too frequently. More quantitatively, in order to observe CR, τ must be long enough to allow the electron to travel at least $1/2\pi$ of a revolution between two scattering events, i.e.,

$$\tau > \frac{T_c}{2\pi} = \frac{1}{\omega_c}$$

or

$$\omega_c\tau = \frac{eB}{m^*}\tau = \frac{e\tau}{m^*}B = \mu B > 1 \qquad (2)$$

where T_c is the period of cyclotron motion and $\mu = e\tau/m^*$ is the DC mobility of the electron. Let us examine this CR observability condition for a realistic set of parameters. If $m^* = 0.1m_0$ (where $m_0 = 9.1 \times 10^{-31}$ kg) and $B = 1$ Tesla, then $\omega_c = eB/m^* \approx 2 \times 10^{12}$ sec^{-1}. Thus one needs a microwave field with a frequency of $f_c = \omega_c/2\pi \approx 3 \times 10^{11}$ Hz $= 300$ GHz (or a wavelength of $\lambda_c = c/f_c \approx 1$ mm). Then, in order to satisfy Equation 2, one needs a minimum mobility of $\mu = 1$ m^2/V-sec $= 1 \times 10^4$ cm^2/V-sec. This value of mobility can be achieved only in a limited number of high-purity semiconductors at low temperatures, thereby posing a severe limit on the observations of microwave CR.

From the resonance condition $\omega = \omega_c$, it is obvious that if a higher magnetic field is available (see GENERATION AND MEASUREMENT OF MAGNETIC FIELDS) one can use a higher frequency (or a shorter wavelength), which should make Equation 2 easier to satisfy. Hence modern CR methods almost invariably use far-infrared (FIR) [or Terahertz (THz)] radiation instead of microwaves. Strong magnetic

fields are available either in pulsed form (up to $\sim 10^3$ T) or in steady form by superconducting magnets (up to ~20 T), water-cooled magnets (up to ~30 T), or hybrid magnets (up to ~45 T). In these cases, even at room temperature, Equation 2 may be fulfilled. Here we are only concerned with the methods of FIR-CR. The reader particularly interested in microwave CR is referred to Lax and Mavroides (1960).

Although this unit is mainly concerned with the simplest case of free carrier CR in bulk semiconductors, one can also study a wide variety of FIR magneto-optical phenomena with essentially the same techniques as CR. These phenomena ("derivatives" of CR) include: (a) spin-flip resonances, i.e., electron spin resonance and combined resonance, (b) resonances of bound carriers, i.e., internal transitions of shallow impurities and excitons, (c) polaronic coupling, i.e., resonant interactions of carriers with phonons and plasmons, and (d) 1-D and 2-D magnetoplasmon excitations. It should be also mentioned that in 2-D systems in the magnetic quantum limit, there are still unresolved issues concerning the effects of disorder and electron-electron interactions on CR (for a review, see, e.g., Petrou and McCombe, 1991; Nicholas, 1994).

It is important to note that all the early CR studies were carried out on semiconductors, not on metals. This is because of the high carrier concentrations present in metals, which preclude direct transmission spectroscopy except in the case of very thin films where thickness is less than the depth of penetration (skin depth) of the electromagnetic fields. In bulk metals, special geometries are thus required to detect CR, the most important of which is the Azbel-Kaner geometry (Azbel and Kaner, 1958). In this geometry, both the DC magnetic field $\vec{B}$ and the AC electric field $\vec{E}$ are applied parallel to the sample surface, either $\vec{B}//\vec{E}$ or $\vec{B} \perp \vec{E}$. The electrons then execute a spiral motion along $\vec{B}$, moving in and out of the skin depth, where $\vec{E}$ is present. Thus, whenever the electron enters the skin depth, it is accelerated by $\vec{E}$ and if the phase of $\vec{E}$ is the same every time the electron enters the skin depth, then the electron can resonantly absorb energy from the AC field. The condition for resonance here is $n\omega_c = \omega (n = 1, 2, 3, \ldots)$. For more details on CR in metals, see, e.g., Mavroides (1972).

Many techniques can provide information on effective masses, but none can rival CR for directness and accuracy. Effective masses can be estimated from the temperature dependence of the amplitude of the galvanomagnetic effects, i.e., the Shubnikov–de Haas and de Haas–van Alphen effects. Interband magneto-optical absorption can determine the reduced mass $\mu = (1/m_e + 1/m_h)^{-1}$ of photo-created electrons and holes. Measurements of the infrared Faraday rotation effect due to free carriers can provide information on the anisotropy of elliptical equienergy surfaces. The temperature dependence of electronic specific heat provides a good measure of the density of levels at the Fermi level, which in turn is proportional to the effective mass. Nonresonant free carrier absorption (see CARRIER LIFETIME: FREE CARRIER ABSORPTION, PHOTOCONDUCTIVITY, AND PHOTOLUMINESCENCE) can be used to estimate effective masses, but, of course, this simply represents a tail or shoulder of a CR absorption curve.

It is worth pointing out here that several different definitions of effective masses exist in the literature and care must be taken when one discusses masses. The band-edge mass, defined as in Equation 1 at band extrema (e.g., $\vec{k} = 0$ in most semiconductors), is the most important band parameter to characterize a material. The specific heat mass is directly related to the density of states at the Fermi level, and is thus also called the density-of-states mass. The cyclotron mass is defined as $m_c^* = (\hbar^2/2\pi)\partial A/\partial E$, where A is the momentum-space area enclosed by the cyclotron orbit; this definition follows naturally from calculation of ω_c in momentum space. The spectroscopic mass can be defined for any resonance peak, and is identical to the cyclotron mass when the resonance is due to free-carrier CR (also see Data Analysis and Initial Interpretation).

The basic theory and experimental methods of cyclotron resonance is presented in this unit. Basic theoretical back ground will first be presented (see Principles of the Method). A detailed description will be given of the actual experimentation procedures (see Practical Aspects of the Method). Finally, typical data analysis procedures are presented (see Data Analysis and Initial Interpretation).

PRINCIPLES OF THE METHOD

As described in the Introduction, the basic physics of CR is the interaction of electromagnetic (EM) radiation with charge carriers in a magnetic field. Here, more quantitative descriptions of this physical phenomenon will be presented, based on (1) a semiclassical model and (2) a quantum-mechanical model. In analyzing CR data, judicious combination, modification, and refinement of these basic models are necessary, depending upon the experimental conditions and the material under study, in order to obtain the maximum amount of information from a given set of data.

The most commonly used method for describing the motion of charge carriers in solids perturbed by external fields is the effective-mass approximation (EMA), developed by many workers in the early history of the quantum theory of solids. The beauty of this method lies in the ability to replace the effect of the lattice periodic potential on electron motion by a mass tensor, the elements of which are determined by the unperturbed band structure. In other words, instead of considering electrons in a lattice we may consider the motion of effective-mass particles, which obey simple equations of motion in the presence of external fields. Rigorous treatments and full justification of the EMA can be found in the early original papers (e.g., Wannier, 1937; Slater, 1949; Luttinger, 1951; Luttinger and Kohn, 1955).

Semiclassical Drude Description of CR

In many cases it is satisfactory to use the semiclassical Drude model (e.g., Aschcroft and Mermin, 1976) to describe the conductivity tensor of free carriers in a magnetic field (see MAGNETOTRANSPORT IN METALS AND ALLOYS). In this

model each electron is assumed to independently obey the equation of motion

$$\overleftrightarrow{m}^* \cdot \frac{d\vec{v}}{dt} + \overleftrightarrow{m}^* \cdot \frac{\vec{v}}{\tau} = e(\vec{E} + \vec{v} \times \vec{B}) \tag{3}$$

where $\overleftrightarrow{m}^*$ is the effective-mass tensor (see, e.g., Equation 1 for nondegenerate bands), $\vec{v}$ is the drift velocity of the electrons, τ is the scattering lifetime (which is assumed to be a constant), $\vec{E}$ is the AC electric field, and $\vec{B}$ is the DC magnetic field. The complex conductivity tensor $\overleftrightarrow{\sigma}$ is then defined by $\vec{J} = ne\vec{v} = \overleftrightarrow{\sigma} \cdot \vec{E}$, where $\vec{J}$ is the current density and n is the carrier density. Assuming that the AC field and the drift velocity have the harmonically varying form, i.e., $\vec{E}(t) = \vec{E}_0 \exp(-i\omega t)$, $\vec{v}(t) = \vec{v}_0 \exp(-i\omega t)$, one can easily solve Equation 3. In particular, for cubic materials and for $\vec{B} \parallel \hat{z}$, $\overleftrightarrow{\sigma}$ is given by

$$\overleftrightarrow{\sigma} = \begin{pmatrix} \sigma_{xx} & \sigma_{xy} & 0 \\ \sigma_{yx} & \sigma_{yy} & 0 \\ 0 & 0 & \sigma_{zz} \end{pmatrix} \tag{4a}$$

$$\sigma_{xx} = \sigma_{yy} = \sigma_0 \frac{i\omega\tau + 1}{(i\omega\tau + 1)^2 + \omega_c^2\tau^2} \tag{4b}$$

$$\sigma_{xy} = -\sigma_{yx} = \sigma_0 \frac{\omega_c\tau}{(i\omega\tau + 1)^2 + \omega_c^2\tau^2} \tag{4c}$$

$$\sigma_{zz} = \sigma_0 \frac{1}{i\omega\tau + 1} \tag{4d}$$

$$\sigma_0 = ne\mu = \frac{ne^2\tau}{m^*} \tag{4e}$$

where μ is the carrier mobility and σ_0 is the DC conductivity.

Once we know the conductivity tensor, we can evaluate the power P absorbed by the carriers from the AC field as

$$P = \langle \vec{J}(t) \cdot \vec{E}(t) \rangle = \frac{1}{2} Re(\vec{j} \cdot \vec{E}^*) \tag{5}$$

where $\langle \ldots \rangle$ represents the time average and $\vec{E}^*$ is the complex conjugate of $\vec{E}$. For an EM wave linearly polarized in the x-direction, i.e., $\vec{E} = (E_x, 0, 0)$, Equation 5 simplifies to

$$P = \frac{1}{2} Re(J_x E_x^*) = \frac{1}{2} |E_0|^2 Re(\sigma_{xx}) \tag{6}$$

Substituting part b of Equation 4 into Equation 6, we obtain

$$\begin{aligned} P(\omega) &= \frac{1}{2} |E_0|^2 \sigma_0 Re\left\{ \frac{i\omega\tau + 1}{(i\omega\tau + 1)^2 + \omega_c^2\tau^2} \right\} \\ &= \frac{1}{4} |E_0|^2 \sigma_0 \left[\frac{1}{(\omega - \omega_c)^2\tau^2 + 1} + \frac{1}{(\omega + \omega_c)^2\tau^2 + 1} \right] \end{aligned} \tag{7}$$

This is plotted in Fig. 1 for different values of the parameter $\omega_c\tau$. It is evident from this figure that the absorption peak occurs when $\omega = \omega_c$ and $\omega_c\tau > 1$.

Note that Equation 7 contains two resonances—one at $\omega = \omega_c$ and the other at $\omega = -\omega_c$. These two resonances correspond to the two opposite senses of circular polarization. It can be shown (see, e.g., Palik and Furdyna, 1970) that in the Faraday geometry $\vec{q} \parallel \vec{B} \parallel \hat{z}$, where $\vec{q}$ is the wavevector of the EM wave) a 3-D magneto-plasma can support only two propagating EM modes represented by

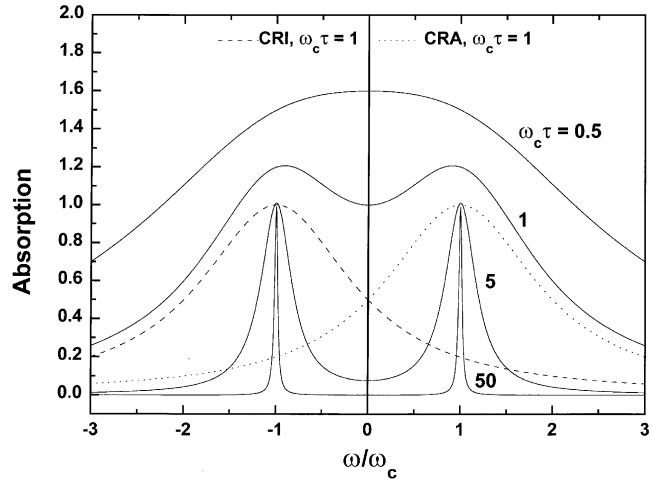

Figure 1. The CR absorption power versus ω for different values of $\omega_c\tau$. The traces are obtained from Equation 7. CR occurs at $\omega = \omega_c$ when $\omega_c\tau > 1$. The absorption is expressed in units of $|E_0|^2\sigma_0/4$.

$$\vec{E}_\pm = E_0 \frac{1}{\sqrt{2}} (\vec{e}_x \pm i\vec{e}_y) \exp[i(q_\pm z - \omega t)] \tag{8}$$

where $\vec{e}_x$ and $\vec{e}_y$ are the unit vectors in the x and y directions, respectively. The dispersion relations, $q_\pm$ versus ω, for the two modes are obtained from

$$q_\pm = \frac{\omega N_\pm}{c} \tag{9a}$$

$$\begin{cases} N_\pm^2 = \kappa_\pm = \kappa_{xx} \pm ik_{xy} & (9b) \\ \kappa_{xx} = \kappa_l + \dfrac{i}{\omega\varepsilon_0}\sigma_{xx} = \kappa_l + \dfrac{i\sigma_0}{\omega\varepsilon_0} \dfrac{i\omega\tau + 1}{(i\omega\tau + 1)^2 + \omega_c^2\tau^2} & (9c) \\ \kappa_{xy} = \dfrac{i}{\omega\varepsilon_0}\sigma_{xy} = \dfrac{i\sigma_0}{\omega\varepsilon_0} \dfrac{\omega_c\tau}{(i\omega\tau + 1)^2 + \omega_c^2\tau^2} & (9d) \end{cases}$$

where $N_\pm$ is the complex refractive index, κ_l is the relative dielectric constant of the lattice (assumed to be constant in the FIR), and κ_{xx} and κ_{xy} are components of the generalized dielectric tensor $\overleftrightarrow{\kappa} = \kappa_l \overleftrightarrow{I} + (i/\omega\varepsilon_0)\overleftrightarrow{\sigma}$, where $\overleftrightarrow{I}$ is the unit tensor and $\overleftrightarrow{\sigma}$ is the conductivity tensor (Equation 4). The positive sign corresponds to a circularly-polarized FIR field, rotating in the same sense as a negatively-charged particle, and is traditionally referred to as cyclotron-resonance-active (CRA) for electrons. Similarly, the negative sign represents the opposite sense of circular polarization, cyclotron-resonance-inactive (CRI) for electrons. The CRA mode for electrons is the CRI mode for holes, and vice versa. For linearly-polarized FIR radiation, which is an equal-weight mixture of the two modes, both terms in Equation 7 contribute to the absorption curve, as represented in Figure 1.

Quantum Mechanical Description of CR

According to the EMA, if the unperturbed energy-momentum relation for the band n, $E_n(\vec{p})$, is known, then the allowed energies E of a crystalline system perturbed by a uniform DC magnetic field $\vec{B} = \vec{\nabla} \times \vec{A}$ (where $\vec{A}$ is the vector potential) are given approximately by solving the effective Schrödinger equation

$$\hat{H}F_n(\vec{r}) = \hat{E}_n(-i\hbar\vec{\nabla} + e\vec{A})F_n(\vec{r}) = EF_n(\vec{r}) \tag{10}$$

Here the operator $\hat{E}_n(-i\hbar\vec{\nabla} + e\vec{A})$ means that we first replace the momentum $\vec{p}$ in the function $E_n(\vec{p})$ with the kinematic (or mechanical) momentum $\vec{\pi} = \vec{p} + e\vec{A}$ (see, e.g., Sakurai, 1985) and then transform it into an operator by $\vec{p} \rightarrow -i\hbar\vec{\nabla}$. The function $F_n(\vec{r})$ is a slowly varying "envelope" wavefunction; the total wavefunction $\Psi(\vec{r})$ is given by a linear combination of the Bloch functions at $\vec{p} = 0$ (or the cell-periodic function) $\psi_{n0}(\vec{r})$

$$\Psi(\vec{r}) = \sum_n F_n(\vec{r})\psi_{n0}(\vec{r}) \tag{11}$$

For simplicity let us consider a 2-D electron in a conduction-band with a parabolic and isotropic dispersion $E_n(\vec{p}) = |\vec{p}|^2/2m^* = (P_x^2 + P_y^2)/2m^*$. The Hamiltonian in Equation 10 is then simply expressed as

$$\hat{H}_0 = \frac{|\vec{\pi}|^2}{2m^*} = \frac{1}{2m^*}(\pi_x^2 + \pi_y^2) \tag{12}$$

These kinematic momentum operators obey the following commutation relations

$$[x, \pi_x] = [y, \pi_y] = i\hbar \tag{13a}$$
$$[x, \pi_y] = [y, \pi_x] = [x, y] = 0 \tag{13b}$$
$$[\pi_x, \pi_y] = -i\hbar^2/\ell^2 \tag{13c}$$

where $\ell = (\hbar/eB)^{1/2}$ is the magnetic length, which measures the spatial extent of electronic (envelope) wavefunctions in magnetic fields—the quantum mechanical counterpart of the cyclotron radius r_c. Note the non-commutability between π_x and π_y (Equation 13, line c), in contrast to p_x and p_y in the zero magnetic-field case.

We now introduce the Landau level raising and lowering operators

$$\hat{a}_\pm = \frac{\ell}{\sqrt{2}\hbar}(\pi_x \pm i\pi_y) \tag{14}$$

for which we can show that

$$[\hat{a}_-, \hat{a}_+] = 1 \tag{15a}$$
$$[\hat{H}_0, \hat{a}_\pm] = \pm\hbar\omega_c\hat{a}_\pm \tag{15b}$$

Combining Equations 13 to 15, we can see that $\hat{a}_\pm$ connects the state $|N\rangle$ and the states $|N \pm 1\rangle$ and that $\hat{H}_0 = \hbar\omega_c(\hat{a}_+\hat{a}_- + 1/2)$, and hence the eigenenergies are

$$E = \left(N + \frac{1}{2}\right)\hbar\omega_c, \quad (N = 0, 1, \ldots) \tag{16}$$

These discrete energy levels are well-known as Landau levels.

If we now apply a FIR field with CRA (CRI) polarization (Equation 8) to the system, then, in the electric dipole approximation, the Hamiltonian becomes

$$\hat{H} = \frac{1}{2m^*}|\vec{p} + e\hat{A} + e\hat{A}'_\pm|^2 \approx \frac{1}{2m^*}|\vec{\pi}|^2 + \frac{e}{m^*}\vec{\pi}\cdot\vec{A}'_\pm = \hat{H}_0 + \hat{H}' \tag{17}$$

where, from Equation 8, the vector potential for the FIR field $\vec{A}'_\pm$ is given by

$$\vec{A}'_\pm = -\frac{E_0}{\sqrt{2}i\omega}(\vec{e}_x \pm i\vec{e}_y)\exp(-i\omega t) \tag{18}$$

Thus the perturbation Hamiltonian $\hat{H}'$ is given by

$$\begin{aligned}\hat{H}' &= \frac{e}{m^*}(\pi_x A'_{\pm,x} + \pi_y A_{\pm,y}) \\ &= -\frac{eE_0}{\sqrt{2}i\omega m^*}(\pi_x \pm i\pi_y)\exp(-i\omega t) \\ &= -\frac{e\hbar E_0}{i\omega m^*\ell}\hat{a}_\pm\exp(-i\omega t)\end{aligned} \tag{19}$$

We can immediately see that this perturbation, containing $\vec{a}_\pm$, connects the state $|N\rangle$ with the states $|N \pm 1\rangle$, so that a sharp absorption occurs at $\omega = \omega_c$.

PRACTICAL ASPECTS OF THE METHOD

CR spectroscopy, or the more general FIR magneto-spectroscopy, is performed in two distinct ways—Fourier-transform magneto-spectroscopy (FTMS) and laser magneto-spectroscopy (LMS). The former is wavelength-dependent spectroscopy and the latter is magnetic-field-dependent spectroscopy. Generally speaking, these two methods are complimentary.

Narrow spectral widths and high output powers are two of the main advantages of lasers. The former makes LMS suitable for investigating spectral features that cannot be resolved by using FTMS, and the latter makes it suitable for studying absorption features in the presence of strong background absorption or reflection. It is also much easier to conduct polarization-dependent measurements by LMS than by FTMS. Moreover, LMS can be easily combined with strong pulsed magnets. Finally, with intense and short-pulse lasers such as the free-electron laser (FEL; see e.g., Brau, 1990), LMS can be extended to nonlinear and time-resolved FIR magneto-spectroscopy.

On the other hand, FTMS has some significant advantages with respect to LMS. First, currently available FIR laser sources (except for FELs) can produce only discrete wavelengths, whereas FTMS uses light sources that produce continuous spectra. Second, it is needless to say that LMS can only detect spectral features that are magnetic-field-dependent, so that it is unable to generate zero-field spectra. Third, LMS often overlooks or distorts features that have a very weak field dependence, in which case only FTMS can give unambiguous results, the

$1s \rightarrow 2p_-$ transition of shallow neutral donors being a good example (e.g., McCombe and Wagner, 1975). Finally, for studying 2-D electron systems, spectroscopy at fixed filling factors, namely at fixed magnetic fields, is sometimes crucial. In this section, after briefly reviewing FIR sources, these two modes of operation—FTMS and LMS—will be described in detail. In addition, short descriptions of two other unconventional methods—cross-modulation (or photoconductivity), in which the sample itself is used as a detector, and optically detected resonance (ODR) spectroscopy, which is a recently developed, highly sensitive method—will be provided. For the reader interested in a detailed description of FIR detectors and other FIR techniques, see, e.g., Kimmitt (1970), Stewart (1970), and Chantry (1971).

Far-Infrared Sources

The two "classic" sources of FIR radiation commonly used in FTMS are the globar and the Hg arc lamp. The globar consists of a rod of silicon carbide usually ~2 cm long and 0.5 cm in diameter. It is heated by electrical conduction; normally 5 A are passed through it, which raises its temperature to ~1500 K. The globar is bright at wavelengths between 2 and 40 μm, but beyond 40 μm its emissivity falls slowly, although it is still sufficient for spectroscopy up to ~100 μm. The mercury lamp has higher emissivity than the globar at wavelengths longer than 100 μm. It is normally termed a "high-pressure" arc, although the actual pressure is only 1 to 2 atm. (Low-pressure gaseous discharges are not useful here because they emit discrete line spectra.) It is contained in a fused quartz inner envelope. At the shorter wavelengths of the FIR, quartz is opaque, but it becomes very hot and emits thermal radiation. At the longer wavelengths, radiation from the mercury plasma is transmitted by the quartz and replaces the thermal radiation. Originally used by Rubens and von Baeyer (1911), the mercury arc lamp is still the most widely employed source in the FIR.

Three types of laser sources currently available to FIR spectroscopists are molecular-gas lasers, the FEL, and the *p*-type germanium laser. The most frequently used among these are the hundreds of laser lines available from a large number of molecular gases. The low-pressure gas consisting of HCN, H_2O, D_2O, CH_3OH, CH_3CN, etc., flows through a glass or metal tube, where population inversion is achieved either through a high-voltage discharge or by optical excitation with a CO_2 laser. Output powers range from a few μW to several hundred mW, depending on the line, gas pressure, pumping power, and whether continuous or pulsed excitation is used. The FEL, first operated in 1977, is an unusual laser source which converts the kinetic energy of free electrons to EM radiation. It is tunable in a wide range of frequencies, from millimeter to ultraviolet. An FEL consists of an electron gun, an accelerator, an optical cavity, and a periodic array of magnets called an undulator or wiggler. The wavelength of the output optical beam is determined by (1) the kinetic energy of the incident electrons, (2) the spatial period of the wiggler, and (3) the strength of the wiggler magnets, all of which are continuously tunable. With FEL's enormously high peak powers (up to ~1 GW) and short pulse widths (down to ~200 fsec), a new class of nonequilibrium phenomena is currently being explored in the FIR. The *p*-Ge laser is a new type of tunable solid-state FIR laser (for a review, see Gornik, 1991; Pidgeon, 1994). Its operation relies on the fact that streaming holes in the valence band in crossed strong electric and magnetic fields can result in an inverted hot-carrier distribution. Two different lasing processes, employing light hole–light hole and light hole–heavy hole transitions, respectively, have been identified (the former is the first realization of a CR laser). The lasing wavelength is continuously tunable, by adjusting the electric and magnetic fields. Lasing in a wide spectral range (75 to 500 μm) with powers up to almost 1 W has been reported.

Nonlinear optical effects provide tunable sources in the FIR. Various schemes exist, but the most thoroughly studied method has been Difference Frequency Mixing using the 9.6 and 10.6 μm lines from two CO_2 lasers (for a review, see, Aggarwal and Lax, 1977). InSb is usually used as the mixing crystal. Phase matching is achieved either through the use of temperature dependence of the anomalous dispersion or by using the free-carrier contribution to the refractive index in a magnetic field. As the CO_2 laser produces a large number of closely spaced lines at 9.6 and 10.6 μm, thousands of lines covering the FIR region from ~70 μm to mm can be produced. However, the efficiency of this method is very low: considerable input laser powers are necessary to obtain output powers only in the μW range. Another important method for generating FIR radiation is Optical Parametric Oscillation (OPO; see, e.g., Byer and Herbst, 1977). In this method, a birefringent crystal in an optical cavity is used to split the pump beam at frequency ω_3 into simultaneous oscillations at two other frequencies ω_1 (idler) and ω_2 (signal), where $\omega_1 + \omega_2 = \omega_3$. This is achieved either spontaneously (through vacuum fluctuation) or by feeding a beam at frequency ω_1. The advantages of OPO are high efficiency, wide tuning range, and an all solid-state system. The longest wavelength currently available from OPO is ~25 μm. More recently, the remarkable advances in high-speed opto-electronic and NIR/visible femtosecond laser technology have enabled generation and detection of ultrashort pulses of broadband FIR radiation (more frequently referred to as THz radiation or "T Rays" in this context). The technique has proven to be extremely useful for FIR spectroscopic measurements in the time domain. Many experiments have shown that ultrafast photoexcitation of semiconductors and semiconductor heterostructures can be used to generate coherent charge oscillations, which emit transient THz EM radiation. This is currently an active topic of research, and the interested reader is referred to, e.g., Nuss and Orenstein (1998) and references therein.

Fourier Transform FIR Magneto-Spectroscopy

A Fourier-transform spectrometer is essentially a Michelson type two-beam interferometer, the basic components of which are collimating optics, a fixed mirror, a beam splitter, and a movable mirror. The basic operation principle can be stated as follows. IR radiation emitted from the

light source is divided by the beam splitter into two beams with approximately the same intensity. One of the beams reaches the fixed mirror, and the other reaches the movable mirror. The two beams bounce back from the two mirrors and recombine at the beam splitter. When the movable mirror is at the zero-path-difference (ZPD) position, the output of the light intensity becomes maximum, since the two beams constructively interfere at all wavelengths. When the path difference, x, measured from the ZPD position is varied, an interference pattern as a function of x, called an interferogram, is obtained that is the FT of the spectrum of the light passing through the interferometer. Hence, by taking the inverse Fourier transform of the interferogram using a computer, one obtains the spectrum.

Two different types of FT spectrometers exist: (1) "slow-scan" (or step-scan) and (2) "fast-scan" spectrometers. In a slow-scan FT spectrometer, a stepping motor drives the movable mirror. A computer controls the step size in multiples of the fundamental step size, the dwell time at each mirror position, and the total number of steps. The product of the step size and the number of steps determines the total path difference, and hence the spectral resolution. A mechanical chopper (see Fig. 2) usually chops the FIR beam. The AC signal at this frequency from the detector is fed into a lock-in amplifier and the reference signal from the chopper into the reference input of the lock-in amplifier. The data acquisition occurs at each movable-mirror position, and thus an interferogram is constructed as the magnitude of the output versus the position of the movable mirror. Computer Fourier analysis with a Fast Fourier Transform algorithm converts the interferogram into an intensity versus frequency distribution—the spectrum. Rapid-scan FT spectrometers operate quite differently, although the basic principles are the same. The movable mirror of a rapid-scan FT machine is driven at a constant velocity. Instead of using a mechanical chopper, the constant velocity of the mirror produces a sinusoidal intensity variation with a unique frequency for each spectral element ω. The modulation frequency is given by $\vartheta = 2V\omega$, where V is the velocity of the mirror. High precision of parallel alignment between the two mirrors and the constant velocity of the moving mirror is provided *in situ* by a dynamic feedback controlling system. The signal sampling takes place at equally spaced mirror displacements, and is determined by the fringes of a He-Ne laser reference.

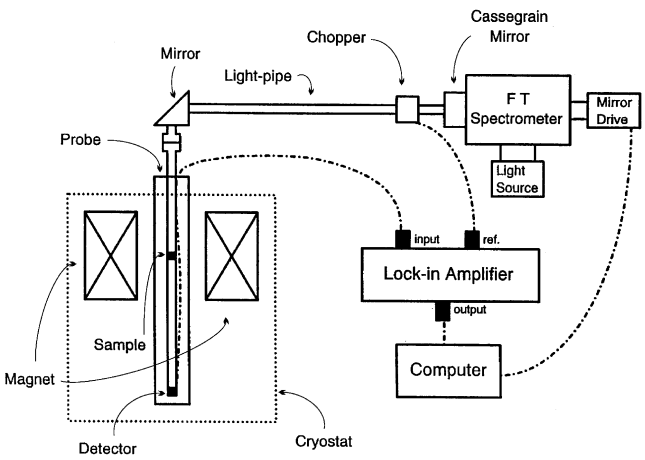

Figure 2. Schematic diagram of an experimental setup for CR studies with a (step-scan) Fourier transform spectrometer.

A slow-scan FTMS system for transmission CR studies is schematically shown in Fig. 2. FIR radiation generated by a Hg-arc lamp inside the spectrometer is coupled out by a Cassegrain output mirror and guided through a 3/4 -inch ("oversized") brass light-pipe to a 45° mirror. The beam reflected by the mirror is then directed down and passes through a white polyethylene window into a sample probe, which consists of a stainless-steel light pipe, a sample-holder/heater/temperature-sensor complex, metallic light cones, and a detector. The probe is sealed by the white polyethylene window and a stainless steel vacuum jacket, and inserted into a superconducting-magnet cryostat. The beam is focused by a condensing cone onto the sample located at the end of the light-cone at the center of the field. A black polyethylene filter is placed in front of the sample in order to filter out the high frequency part ($\geq$500 cm^{-1}) of the radiation from the light source. The FIR light transmitted through the sample is further guided by light-pipe/light-cone optics into a detector, which is placed at the bottom of the light-pipe system, far away from the center of the magnet. If a cancellation coil is available, the detector is placed at the center of the cancellation coil where $B = 0$. The sample and detector are cooled by helium exchange gas contained in the vacuum jacket of the probe.

Figures 3A and 3B show a typical interferogram and spectrum, respectively. The spectrum obtained contains not only the spectral response (transmittance in this case) of the sample but also the spectral response of combined effects of any absorption, filtering, and reflection when the light travels from the source to the detector, in addition to the output intensity spectrum of the radiation source. Therefore, in most experimental situations, spectra such as those obtained Fig. 3B are ratioed to an appropriate background spectrum taken under a different condition such as a different magnetic field, temperature, optical pumping intensity, or some other parameter that would only change the transmittance of the sample. In CR studies, spectra are usually ratioed to a zero-magnetic-field spectrum. In this way all the unwanted field-insensitive spectral structures are canceled out.

Laser FIR Magneto-Spectroscopy

LMS is generally easier to carry out than FTMS, although the experimental setup is almost identical to that of FTMS (the only difference is that the FT spectrometer is replaced by a laser in Fig. 2). This is partly because of the high power available from lasers compared with conventional radiation sources employed in FTMS, and also because mathematical treatments of the recorded data are not required. The data acquisition simply consists of monitoring an output signal from the detector that is proportional to the amount of FIR light transmitted by the sample while

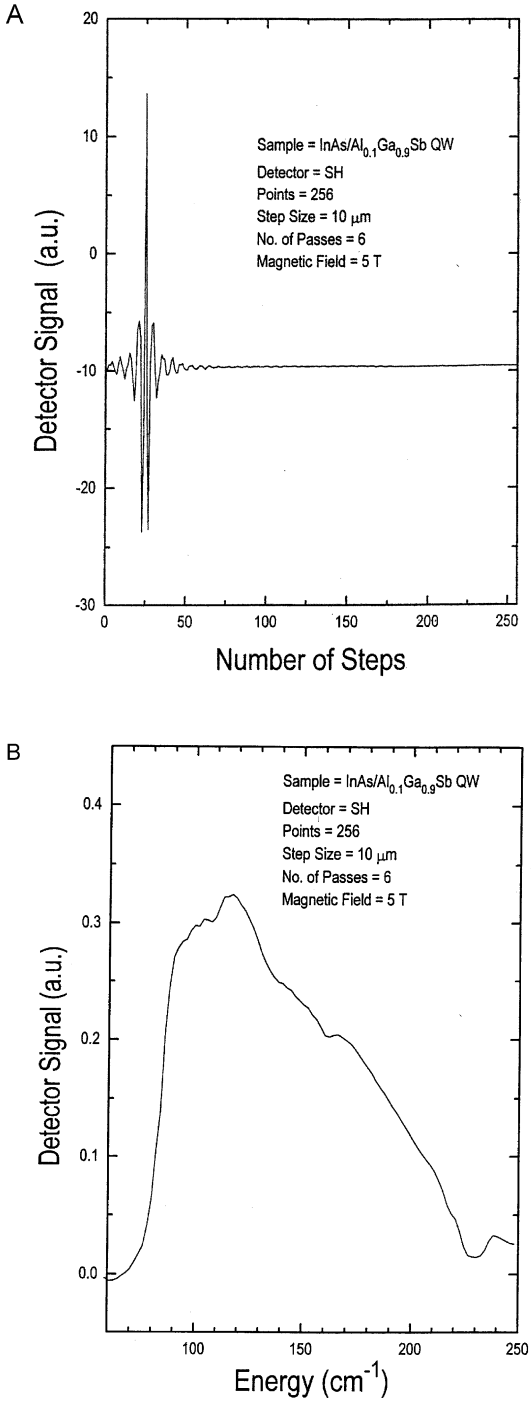

Figure 3. (**A**) An interferogram obtained with the FTMS setup shown in Fig. 2. (**B**) Spectrum obtained after Fourier transforming the interferogram in (A). This spectrum contains the output intensity spectrum of the Hg arc lamp, the spectral response of all the components between the source and the detector (filters, light-pipes, light cones, etc.), the responsivity spectrum of the detector (Ge:Ge extrinsic photoconductor), as well as the transmission spectrum of the sample.

the magnetic field is swept. The signal changes with magnetic field, decreasing resonantly and showing minima at resonant magnetic fields (see Fig. 4). Only magnetic-field-dependent features can thus be observed. If the laser output is stable while the field is being swept, no ratioing is necessary.

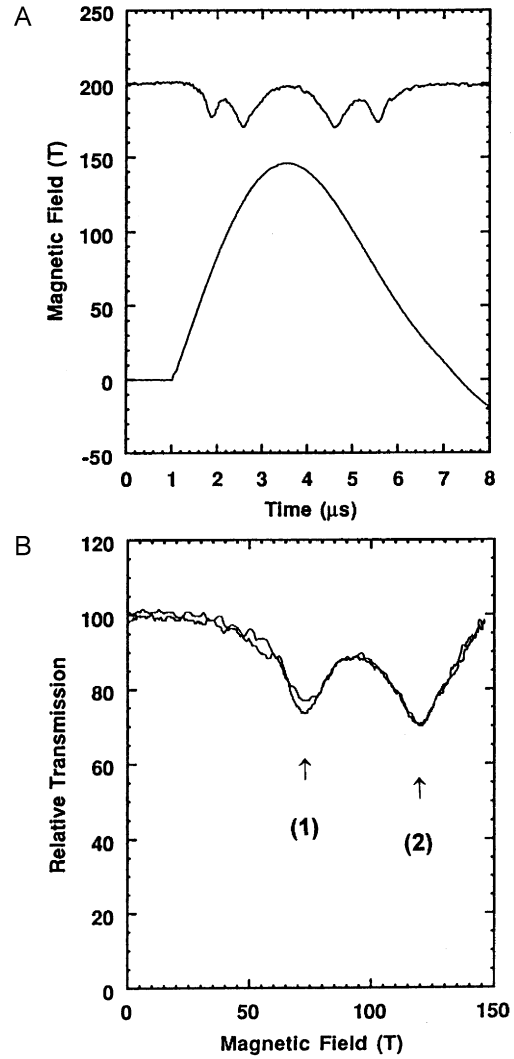

Figure 4. Example of CR with a laser in very high pulsed magnetic fields. (**A**) FIR transmission and magnetic field as functions of time. (**B**) Replot of the transmission signal as a function of magnetic field where the two traces arise from the rising and falling portions of the field strength shown in (A). Data obtained for *n*-type 3C-SiC.

A very important feature of LMS is that it can easily incorporate pulsed magnets, thus allowing observations of CR at very high magnetic fields (see Miura, 1984). Pulsed magnetic fields up to 40 to 60 Tesla with millisecond pulse durations can be routinely produced at various laboratories. Stronger magnetic fields in the megagauss (1 megagauss = 100 Tesla) range can be also generated by special destructive methods (see, e.g., Herlach, 1984) at some institutes. These strong fields have been used to explore new physics in the ultra-quantum limit (see, e.g., Herlach, 1984; Miura, 1984) as well as to observe CR in wide-gap, heavy-mass, and low-mobility materials unmeasurable by other techniques (see, e.g., Kono et al., 1993). The cyclotron energy of electrons in megagauss fields can

exceed other characteristic energies in solids such as binding energies of impurities and excitons, optical phonon energies, plasma energies, and even the fundamental band-gap in some materials, causing strong modifications in CR spectra.

An example of megagauss CR is shown in Fig. 4. Here, the recorded traces of the magnetic field pulse and the transmitted radiation from an *n*-type silicon carbide sample are plotted in Fig. 4A. The transmitted signal is then plotted as a function of magnetic field in Fig. 4B. The 36-μm line from a water-cooled H_2O vapor pulse laser and a Ge:Cu impurity photoconductive detector are used. The magnetic field is generated by a destructive single-turn coil method (see, e.g., Herlach, 1984), in which one shot of large current (~2.5 MA) from a fast capacitor bank (100 kJ, 40 kV) is passed through a thin single-turn copper coil. Although the coil is destroyed during the shot due to the EM force and the Joule heat, the sample can survive a number of such shots, so that repeated measurements can be made on the same sample. The resonance absorption is observed twice in one pulse, in the rising and falling slopes of the magnetic field, as seen in Fig. 4. It should be noted that the coincidence of the two traces (Fig. 4B) confirms a sufficiently fast response of the detector system.

Cross-Modulation (or Photoconductivity)

It is well known that the energy transferred from EM radiation to an electron system due to CR absorption induces significant heating in the system (free-carrier or Drude heating). This type of heating in turn induces a change in the conductivity tensor (e.g., an increase in $1/\tau$ or m^*), which causes (third-order) optical nonlinearity and modulation at other frequencies, allowing an observation of CR at a second frequency. Most conveniently, the DC conductivity $\sigma(\omega = 0)$ shows a pronounced change at a resonant magnetic field. This effect is known as Cross-Modulation or CR-induced photoconductivity, and has been described as a very sensitive technique to detect CR (Zeiger et al., 1959; Lax and Mavroides, 1960). The beauty of this method is that the sample acts as its own detector, so that there is no detector-related noise. The disadvantage is that the detection mechanism(s) is not well understood, so that quantitative lineshape analysis is difficult, unlike direct absorption. Either a decrease or increase in conductivity is observed, depending on a number of experimental conditions. Although many suggestions concerning the underlying mechanism(s) have been proposed, a complete understanding has been elusive.

Contrary to the situation of CR, which is a free carrier resonance, the mechanism of photoconductivity due to bound carrier resonances is much more clearly understood (see CARRIER LIFETIME: FREE CARRIER ABSORPTION, PHOTOCONDUCTIVITY, AND PHOTOLUMINESCENCE). For example, a resonant absorption occurs due to the 1*s* to 2*p* hydrogenic impurity transition in zero magnetic field in GaAs. Although the 2*p* state is below the continuum, an electron in the 2*p* state can be thermally excited into the conduction band, increasing conductivity (photo-thermal ionization). Other *p*-like excited states also can be studied in this manner, and these states evolve with increasing magnetic fields. As a result, one can map out the hydrogenic spectrum of the GaAs impurities simply by studying the photoconductivity of the sample. Since this is a null technique (i.e., there is photoresponse only at resonances), it is much more sensitive than transmission studies.

Optically-Detected Resonance Spectroscopy

Recently, a great deal of development work has centered on a new type of detection scheme, Optically-Detected Resonance (ODR) spectroscopy in the FIR. This novel technique possesses several significant advantages over conventional CR methods, stimulating considerable interest among workers in the community. With this technique, FIR resonances are detected through the change in the intensity of photoluminescence (PL; see CARRIER LIFETIME: FREE CARRIER ABSORPTION, PHOTOCONDUCTIVITY, AND PHOTOLUMINESCENCE) while the magnetic field is swept, rather than measuring FIR absorption directly. This technique, originally developed for the microwave region, was extended to the FIR by Wright et al. (1990) in studies of epitaxial GaAs, and subsequently by others. Remarkable sensitivity in comparison with conventional FIR methods has been demonstrated in studies of CR (e.g., Ahmed et al., 1992), impurity transitions (Michels et al., 1994; Kono et al., 1995), and internal transitions in excitons (Cerne et al., 1996; Salib et al., 1996). Since carriers are optically created, ODR enables detection of CR in "clean" systems with no intentional doping, with increased scattering time, and in materials for which doping is difficult. Furthermore, with ODR it is possible to select a specific PL feature in the spectrum, among various band-edge features, as the detection "channel." It is then possible to use the specificity of the FIR spectrum to obtain information about recombination mechanisms and the interactions that give rise to the various lines.

Figure 5A is a schematic of the experimental apparatus used for an ODR study (Kono et al., 1995). The sample is mounted in the Faraday geometry in a FIR lightpipe at the center of a 9-T superconducting magnet cooled to 4.2 K. PL is excited with the 632.8 nm line of a He-Ne laser via a 600-μm-diameter optical fiber. The signals are collected with a second 600-μm fiber, and analyzed with 0.25-m single-grating spectrometer/Si diode detector combination. A CO_2-pumped FIR laser is used to generate FIR radiation. The FIR laser power supply is chopped with the lock-in amplifier referenced to this chopped signal. A computer is used to simultaneously record the magnetic field values and the detected changes in the PL, and to step the monochromator to follow the center of the desired PL peak as it shifts with magnetic field. Two scans of the change in PL intensity as a function of magnetic field (ODR signal) for a FIR laser line of 118.8 μm are presented in Fig. 6. The upper trace shows a positive change (i.e., increase) in the intensity of the free exciton PL from a well-center-doped GaAs quantum well, whereas the lower trace shows a negative change (i.e., decrease) in the intensity of the bound exciton luminescence, demonstrating spectral specificity. For both scans, four different FIR resonances are clearly seen with an excellent signal-to-noise ratio (the sharp feature near 6T is the electron CR, and the other features are donor-related features).

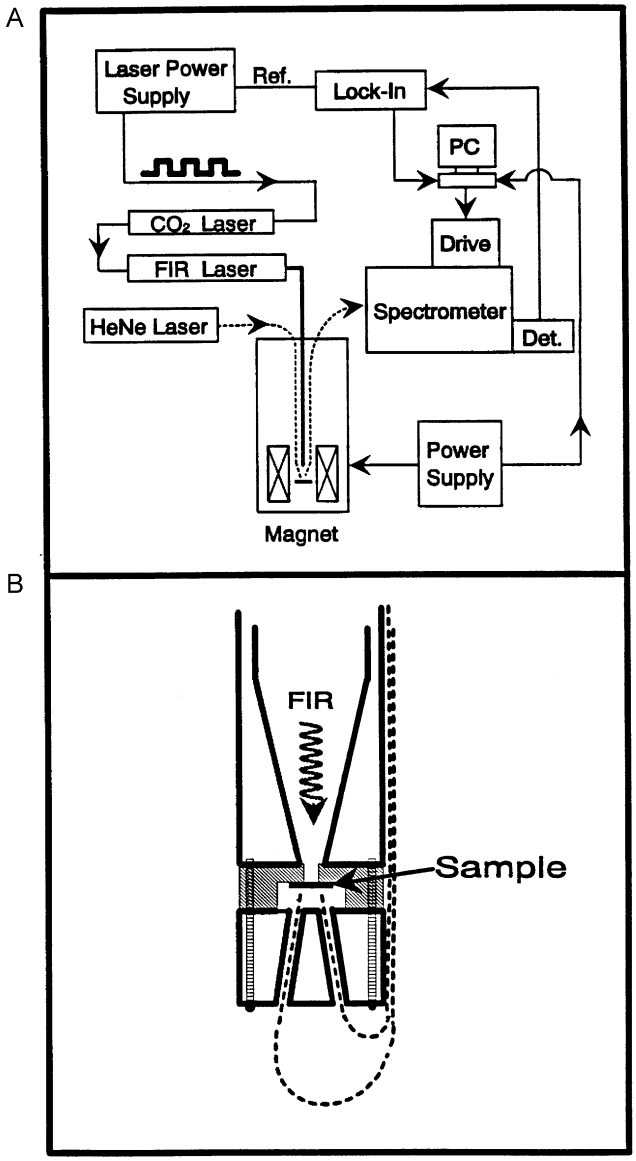

Figure 5. (**A**) Schematic diagram of an experimental setup for ODR spectroscopy. (**B**) Diagram of the FIR light cone, sample, and optical fiber arrangement used.

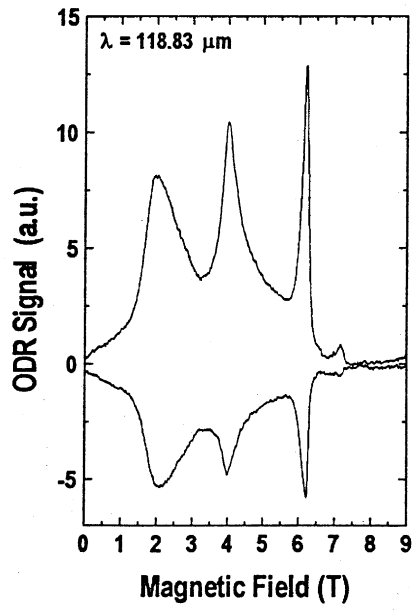

Figure 6. Two ODR spectra for a well-center-doped GaAs quantum well at a FIR wavelength of 118.8 μm. The upper trace shows a positive change in the intensity of the free exciton PL, whereas the lower trace shows a negative change in the intensity of the bound exciton luminescence, demonstrating the spectral specificity of ODR signals.

DATA ANALYSIS AND INITIAL INTERPRETATION

After minimizing noise to get as clean a spectrum as possible, and making sure that the spectrum is free from any artifacts and multiple-reflection interference effects, one can analyze resonance "positions" (i.e., magnetic fields in LMS and frequencies in FTMS). For each resonance feature, an effective mass m^* in units of m_0 (free electron mass in vacuum) can be obtained in different unit systems as follows

$$\frac{m^*}{m_0} = \frac{eB}{m_0\omega} = \frac{0.1158 \cdot B[\mathrm{T}]}{\hbar\omega[\mathrm{meV}]} = \frac{0.9337 \cdot B[\mathrm{T}]}{\tilde{\nu}[\mathrm{cm}^{-1}]} = \frac{27.99 \cdot B[\mathrm{T}]}{f[\mathrm{GHz}]} = 93.37 \cdot B[\mathrm{T}] \cdot \lambda[\mathrm{m}] \qquad (20)$$

Note that one can obtain an effective mass (a spectroscopic mass) for any resonance. For example, for the resonances (1) and (2) for SiC in Fig. 4B one can obtain $m_1 = 0.247m_0$ and $m_2 = 0.406m_0$, and for the resonances (a) – (d) for doped GaAs quantum wells in Fig. 5C one can obtain $m_a = 0.023m_0$, $m_b = 0.044m_0$, $m_c = 0.069m_0$, and $m_d = 0.079m_0$, irrespective of their origins. However, the spectroscopic mass is identical to the cyclotron mass only when the feature is due to free carrier CR; bound-carrier resonances such as the donor-related features in Fig. 6, have different spectroscopic masses at different frequencies/fields. Hence one needs to know which spectroscopic feature(s) arises from free-carrier CR. This can be found by two methods: temperature dependence and magnetic field (or frequency) dependence.

Examining the temperature dependence of a spectral feature is the easiest way to check the origin of the feature. As a rule of thumb, features associated with bound carriers increase in intensity with decreasing temperature at the expense of free carrier resonances. This is because in bulk semiconductors with doping level below the Mott condition, free carriers freeze out onto impurities, leaving no electrical conductivity at the lowest temperature. Thus, free-carrier CR grows with increasing temperature, but it broadens with the resulting increase of carrier scattering.

A more stringent test of whether a particular feature originates from CR is the response of its frequency versus magnetic field. In the case of LMS, one can take data only at discrete frequencies, but in the case of FTMS one can generate a continuous relationship between frequency and magnetic field. This is one of the advantages of FTMS over LMS as discussed earlier. Therefore, LMS is

usually performed to study, at a fixed wavelength with a higher resolution than FTMS and with circular polarizers if necessary, those spectral features whose magnetic-field-dependence is already known by FTMS. The resonance frequency versus magnetic field thus obtained for CR should show a straight line passing through the origin, if the nonparabolicity of the material is negligible and there are no localization effects (e.g., Nicholas, 1994). The slope of this straight line then provides the spectroscopic mass, which is constant and identical to the cyclotron mass and is also equal to the band-edge mass in this idealized situation. In the case of a nonparabolic band, the cyclotron mass gradually increases with magnetic field. This means that the slope versus B for CR becomes smaller (i.e., the line bends down) with increasing B.

Impurity-related lines, on the other hand, extrapolate to *finite* frequencies at zero magnetic field, corresponding to the zero-field binding energies of impurities. Different transitions have different slopes versus B, but all transitions originating from the same impurity atoms converge to an approximately common intersect at zero field. The most dominant donor-related line, the $1s$ to $2p_+$ transition, is sometimes called impurity-shifted CR (ICR). This is because its slope versus B becomes nearly equal to that of free electron CR in the high-field limit, i.e., $\hbar\omega_c \gg R_y^*$, where R_y^* is the binding energy of the impurity at zero field (McCombe and Wagner, 1975).

In many cases, multiple CR lines are observed in one spectrum (see, e.g., Dresselhaus et al., 1955; Otsuka, 1991; Petrou and McCombe, 1991; Nicolas, 1994). This generally indicates the existence of multiple types of carriers with different masses. Possible origins include: multi-valley splitting in the conduction band, light holes and heavy holes in the valence band, splitting due to resonant electron-phonon coupling, nonparabolicity-induced spin splitting, Landau-level splitting (see THEORY OF MAGNETIC PHASE TRANSITIONS), and population of two sub-bands in a quantum well. Explanation of each of these phenomena would be beyond the scope of this unit.

As discussed in the Introduction, CR linewidth is a sensitive probe for studying carrier scattering phenomena. In general, the linewidth of a CR line is related to the scattering lifetime, and the integrated absorption intensity of a CR line is related to the density of carriers participating in CR. Thus, if carrier density is constant, the product of absorption linewidth and depth is constant, even though the width and depth are not individually constant. More quantitatively, if the observed lineshape is well fitted by a Lorentzian, in the small absorption and reflection approximation it may be compared with

$$\frac{T(\omega,B)}{T(\omega,0)} = 1 - A(\omega,B) = 1 - \frac{1}{2}\frac{dne^2\tau}{c\varepsilon_0\kappa_l^{1/2}m^*}\frac{1}{1+(\omega-\omega_c)^2\tau^2} \tag{21}$$

where T is transmission, A is absorption, d is the sample thickness, c is the speed of light, and the other symbols have been defined earlier. The half-width at half maximum (HWHM) is thus equal to $1/\tau$. The peak absorption depth gives an estimate of the carrier density. For a more detailed and complete description on carrier transport studies using CR, see Otsuka (1991).

SAMPLE PREPARATION

Cyclotron resonance does not require any complicated sample preparation unless it is combined with other experimental techniques. The minimum sample size required depends on the design of the FIR optics used, i.e., how tightly the FIR beam can be focused onto the sample. Highly absorptive samples and samples with high carrier concentrations need to be polished down so that they are thin enough for transmission studies. In any case, wedging the sample substrates 2° to 3° is necessary to avoid multiple-reflection interference effects. Choosing the right sample is crucial for the success of a CR study. Samples with the highest possible carrier mobility are always preferable, if available. The DC mobility and density (see CONDUCTIVITY MEASUREMENT) can provide a rough estimate for the CR lineshape expected.

PROBLEMS

Generally speaking, the FIR (or THz) frequency regime, where CR is usually observed, is a difficult spectral range in which to carry out sophisticated spectroscopy. This range lies in the so-called "technology-gap" existing between electronics ($\leq$100 GHz) and optics ($\geq$10 THz) frequencies. The well-developed NIR/visible technology does not extend to this range; sources are dimmer and detectors are less sensitive. In addition, because of the lack of efficient non-linear crystals, there exist no amplitude or phase modulators in the FIR, except for simple mechanical choppers. Therefore, in many experiments, one deals with small signals having large background noise. In steady-state experiments with a step-scan FT spectrometer, lock-in techniques are always preferable. Modulating a property of the sample that only changes the size of the signal of interest—e.g., modulating the carrier density with tunable gate electrodes—has proven to be a very efficient way to detect small signals. The cross-modulation (or photoconductivity) technique is also frequently used to detect small signals since it is a very sensitive method, as discussed earlier.

Aside from this signal-to-noise problem inherent in the FIR, there are some additional problems that CR spectroscopists might encounter. A problem particularly important in bulk semiconductors is the carrier freeze-out effect mentioned earlier. In most semiconductors, low-temperature FIR magneto-spectra are dominated by impurity transitions. At high temperatures, free carriers are liberated from the impurities, but at the same time CR often becomes too broad to be observed because of the increased scattering rate. So one has to be careful in choosing the right temperature range to study CR. In very pure semiconductors, the only way to get any CR signal is by optical pumping. In Si and Ge, whose carrier lifetimes are very long ($\sim$msec in high-quality samples), one can create a large number of carriers sufficient for steady-state

FIR absorption spectroscopy. In direct-gap semiconductors such as GaAs, carrier lifetimes are very short ($\leq$1 nsec), so that it is nearly impossible to create enough carriers for steady-state FIR experiments, although short-pulse NIR-FIR two-color spectroscopy with an FEL is able to capture transient FIR absorption by photo-created nonequilibrium carriers. In low-dimensional semiconductor systems, so-called modulation doping is possible, where carriers can be spatially separated from their parent impurities so that they do not freeze out even at the lowest temperature.

The use of a strong magnet introduces a new class of problems. As we have seen above, in all CR studies, either in the form of FTMS or LMS, the transmission through the sample at finite magnetic field is compared with the transmission at zero magnetic field. The success of this ratioing relies on the assumption that it is only the sample that changes transmissivity with magnetic field. If anything else in the system changes some property with magnetic field, this method fails. Therefore, great care must be taken in order to make sure that no optical components have magnetic-field-dependent characteristics, that the FIR source and detector are not affected by the magnetic field, and that no component moves with magnetic field.

ACKNOWLEDGMENTS

The author would like to thank Prof. B. D. McCombe for useful discussions, comments, and suggestions. He is also grateful to Prof. N. Miura for critically reading the article, Prof. R. A. Stradling and Prof. C. R. Pidgeon for useful comments, and G. Vacca and D. C. Larrabee for proofreading the manuscript. This work was supported in part by NSF DMR-0049024 and ONR N00014-94-1-1024.

MÖSSBAUER SPECTROMETRY

INTRODUCTION

Mössbauer spectrometry is based on the quantum-mechanical "Mössbauer effect," which provides a nonintuitive link between nuclear and solid-state physics. Mössbauer spectrometry measures the spectrum of energies at which specific nuclei absorb γ rays. Curiously, for one nucleus to emit a γ ray and a second nucleus to absorb it with efficiency, the atoms containing the two nuclei must be bonded chemically in solids. A young R. L. Mössbauer observed this efficient γ-ray emission and absorption process in ^{191}Ir, and explained why the nuclei must be embedded in solids. Mössbauer spectrometry is now performed primarily with the nuclei ^{57}Fe, ^{119}Sn, ^{151}Eu, ^{121}Sb, and ^{161}Dy. Mössbauer spectrometry can be performed with other nuclei, but only if the experimenter can accept short radioisotope half-lives, cryogenic temperatures, and the preparation of radiation sources in hot cells.

Most applications of Mössbauer spectrometry in materials science utilize "hyperfine interactions," in which the electrons around a nucleus perturb the energies of nuclear states. Hyperfine interactions cause very small perturbations of 10^{-9} to 10^{-7} eV in the energies of Mössbauer γ rays. For comparison, the γ rays themselves have energies of 10^4 to 10^5 eV. Surprisingly, these small hyperfine perturbations of γ-ray energies can be measured easily, and with high accuracy, using a low-cost Mössbauer spectrometer.

Interpretations of Mössbauer spectra have few parallels with other methods of materials characterization. A Mössbauer spectrum looks at a material from the "inside out," where "inside" means the Mössbauer nucleus. Hyperfine interactions are sensitive to the electronic structure at the Mössbauer atom, or at its nearest neighbors. The important hyperfine interactions originate with the electron density at the nucleus, the gradient of the electric field at the nucleus, or the unpaired electron spins at the nucleus. These three hyperfine interactions are called the "isomer shift," "electric quadrupole splitting," and "hyperfine magnetic field," respectively.

The viewpoint from the nucleus is sometimes too small to address problems in the microstructure of materials.

Over the past four decades, however, there has been considerable effort to learn how the three hyperfine interactions respond to the environment around the nucleus. In general, it is found that Mössbauer spectrometry is best for identifying the electronic or magnetic structure at the Mössbauer atom itself, such as its valence, spin state, or magnetic moment. The Mössbauer effect is sensitive to the arrangements of surrounding atoms, however, because the local crystal structure will affect the electronic or magnetic structure at the nucleus. Different chemical and structural environments around the nucleus can often be assigned to specific hyperfine interactions. In such cases, measuring the fractions of nuclei with different hyperfine interactions is equivalent to measuring the fractions of the various chemical and structural environments in a material. Phase fractions and solute distributions, for example, can be determined in this way.

Other applications of the Mössbauer effect utilize its sensitivity to vibrations in solids, its timescale for scattering, or its coherence. To date these phenomena have seen little use outside the international community of a few hundred Mössbauer spectroscopists. Nevertheless, some new applications for them have recently become possible with the advent of synchrotron sources for Mössbauer spectrometry.

There have been a number of books written about the Mössbauer effect and its spectroscopies (see Key References). Most include reviews of materials research. These reviews typically demonstrate applications of the measurable quantities in Mössbauer spectrometry, and provide copious references. This unit is not a review of the field, but an instructional reference that gives the working materials scientist a basis for evaluating whether or not Mössbauer spectrometry may be useful for a research problem.

Recent research publications on Mössbauer spectrometry of materials have involved, in descending order in terms of numbers of papers: oxides, metals and alloys, organometallics, glasses, and minerals. For some problems, materials characterization by Mössbauer spectrometry is now "routine." A few representative applications to materials studies are presented. These applications were chosen in part according to the taste of the author, who makes no claim to have reviewed the literature of approximately 40,000 publications utilizing the Mössbauer effect (see Internet Resources for Mössbauer Effect Data Center Web site).

PRINCIPLES OF THE METHOD

Nuclear Excitations

Many properties of atomic nuclei and nuclear matter are well established, but these properties are generally not of importance to materials scientists. Since Mössbauer spectrometry measures transitions between states of nuclei, however, some knowledge of nuclear properties is necessary to understand the measurements.

A nucleus can undergo transitions between quantum states, much like the electrons of an atom, and doing so involves large changes in energy. For example, the first excited state of ^{57}Fe is 14.41 keV above its ground state. The Mössbauer effect is sometimes called "nuclear resonant γ-ray scattering" because it involves the emission of a γ ray from an excited nucleus, followed by the absorption of this γ ray by a second nucleus, which becomes excited. The scattering is called "resonant" because the phase and energy relationships for the γ-ray emission and absorption processes are much the same as for two coupled harmonic oscillators.

The state of a nucleus is described in part by the quantum numbers E, I, and I_z, where E is energy and I is the nuclear spin with orientation I_z along a z axis. In addition to these three internal nuclear coordinates, to understand the Mössbauer effect we also need spatial coordinates, X, for the nuclear center of mass as the nucleus moves through space or vibrates in a crystal lattice. These center-of-mass coordinates are decoupled from the internal excitations of the nucleus.

The internal coordinates of the nucleus are mutually coupled. For example, the first excited state of the nucleus ^{57}Fe has spin $I = 3/2$. For $I = 3/2$, there are four possible values of I_z, namely, $-3/2$, $-1/2$, $+1/2$, and $+3/2$. The ground state of ^{57}Fe has $I = 1/2$ and two allowed values of I_z. In the absence of hyperfine interactions to lift the energy degeneracies of spin levels, all allowed transitions between these spin levels will occur at the same energy, giving a total cross-section for nuclear absorption, σ_0, of 2.57×10^{-18} cm^2. Although σ_0 is smaller by a factor of 100 than a typical projected area of an atomic electron cloud, σ_0 is much larger than the characteristic size of the nucleus. It is also hundreds of times larger than the cross-section for scattering a 14.41-keV photon by the atomic electrons at ^{57}Fe.

The characteristic lifetime of the excited state of the ^{57}Fe nucleus, τ, is 141 ns, which is relatively long. An ensemble of independent ^{57}Fe nuclei that are excited simultaneously, by a flash of synchrotron light, for example, will decay at various times, t, with the probability per unit time of $\frac{1}{\tau}\exp(-1/\tau)$. The time uncertainty of the nuclear excited state, τ, is related to the energy uncertainty of the excited state, ΔE, through the uncertainty relationship, $\hbar \sim \Delta E\tau$. For $\tau = 141$ ns, the uncertainty relationship provides $\Delta E = 4.7 \times 10^{-9}$ eV. This is remarkably small—the energy of the nuclear excited state is extremely precise in energy. A nuclear resonant γ-ray emission or absorption has an oscillator quality factor, Q, of 3×10^{12}. The purity of phase of the γ ray is equally impressive. In terms of information technology, it is possible in principle to transmit high-quality audio recordings of all the Beethoven symphonies on a single Mössbauer γ-ray photon. The technology for modulating and demodulating this information remains problematic, however.

In the absence of significant hyperfine interactions, the energy dependence of the cross-section for Mössbauer scattering is of Lorentzian form, with a width determined by the small lifetime broadening of the excited state energy

$$\sigma_j(E) = \frac{\sigma_0 p_j}{1 + \left(\frac{E - E_j}{\Gamma/2}\right)^2} \quad (1)$$

where for ^{57}Fe, $\Gamma = \Delta E = 4.7 \times 10^{-9}$ eV, and E_j is the mean energy of the nuclear level transition ($\sim$14.41 keV). Here p_j is the fraction of nuclear absorptions that will occur with energy E_j. In the usual case where the energy levels of the different Mössbauer nuclei are inequivalent and the nuclei scatter independently, the total cross section is

$$\sigma(E) = \sum_j \sigma_j(E) \tag{2}$$

A Mössbauer spectrometry measurement is usually designed to measure the energy dependence of the total cross-section, $\sigma(E)$, which is often a sum of Lorentzian functions of natural line width Γ.

A highly monochromatic γ ray from a first nucleus is required to excite a second Mössbauer nucleus. The subsequent decay of the nuclear excitation need not occur by the reemission of a γ ray, however, and for ^{57}Fe only 10.9% of the decays occur in this way. Most of the decays occur by "internal conversion" processes, where the energy of the nuclear excited state is transferred to the atomic electrons. These electrons typically leave the atom, or rearrange their atomic states to emit an x ray. These conversion electrons or conversion x rays can themselves be used for measuring a Mössbauer spectrum. The conversion electrons offer the capability for surface analysis of a material. The surface sensitivity of conversion electron Mössbauer spectrometry can be as small as a monolayer (Faldum et al., 1994; Stahl and Kankeleit, 1997; Kruijer et al., 1997). More typically, electrons of a wide range of energies are detected, providing a depth sensitivity for conversion electron Mössbauer spectrometry of $\sim$100 nm (Gancedo et al., 1991; Williamson, 1993).

It is sometimes possible to measure coherent Mössbauer scattering. Here the total intensity, $I(E)$, from a sample is not the sum of independent intensity contributions from individual nuclei. One considers instead the total wave, $\Psi(\mathbf{r},E)$, at a detector located at $\mathbf{r}$. The total wave, $\Psi(\mathbf{r},E)$, is the sum of the scattered waves from individual nuclei, j

$$\Psi(\mathbf{r},E) = \sum_j \Psi_j(\mathbf{r},E) \tag{3}$$

Equation 3 is fundamentally different from Equation 2, since wave amplitudes rather than intensities are added. Since we add the individual Ψ_j, it is necessary to account precisely for the phases of the waves scattered by the different nuclei.

The Mössbauer Effect

Up to this point, we have assumed it possible for a second nucleus to become excited by absorbing the energy of a γ ray emitted by a first nucleus. There were a few such experiments performed before Mössbauer's discovery, but they suffered from a well recognized difficulty. As mentioned above, the energy precision of a nuclear excited state can be on the order of 10^{-8} eV. This is an extremely small energy target to hit with an incident γ ray. At room temperature, for example, vibrations of the nuclear center of mass have energies of 2.5×10^{-2} eV/atom. If there were any change in the vibrational energy of the nucleus caused by γ-ray emission, the γ ray would be far too imprecise in energy to be absorbed by the sharp resonance of a second nucleus. Such a change seems likely, since the emission of a γ ray of momentum $p_\gamma = E_\gamma/c$ requires the recoil of the emitting system with an opposite momentum (where E_γ is the γ-ray energy and c is the speed of light). A mass, m, will recoil after such a momentum transfer, and the kinetic energy in the recoil, E_{recoil}, will detract from the γ-ray energy

$$E_{\text{recoil}} = \frac{p_\gamma^2}{2m} = \left(\frac{E_\gamma^2}{2mc^2}\right) \tag{4}$$

For the recoil of a single nucleus, we use the mass of a ^{57}Fe nucleus for m in Equation 4, and find that $E_{\text{recoil}} = 1.86 \times 10^{-3}$ eV. This is again many orders of magnitude larger than the energy precision required for the γ ray to be absorbed by a second nucleus.

Rudolf Mössbauer's doctoral thesis project was to measure nuclear resonant scattering in ^{191}Ir. His approach was to use thermal Doppler broadening of the emission line to compensate for the recoil energy. A few resonant nuclear absorptions could be expected this way. To his surprise, the number of resonant absorptions was large, and was even larger when his radiation source and absorber were cooled to liquid nitrogen temperature (where the thermal Doppler broadening is smaller). Adapting a theory developed by W. E. Lamb for neutron resonant scattering (Lamb, 1939), Mössbauer interpreted his observed effect and obtained the equivalent of Equation 9, below. Mössbauer further realized that by using small mechanical motions, he could provide Doppler shifts to the γ-ray energies and tune through the nuclear resonance. He did so, and observed a spectrum without thermal Doppler broadening. In 1961, R. L. Mössbauer won the Nobel prize in physics. He was 32.

Mössbauer discovered (Mössbauer, 1958) that under appropriate conditions, the mass, m, in Equation 4 could be equal to the mass of the crystal. In such a case, the recoil energy is trivially small, the energy of the outgoing γ ray is precise to better than 10^{-9} eV, and the γ ray can be absorbed by exciting a second nucleus. The question is now how the mass, m, could be so large. The idea is that the nuclear mass is attached rigidly to the mass of the crystal. This sounds rather unrealistic, of course, and a better model is that the ^{57}Fe nucleus is attached to the crystal mass by a spring. This is the problem of a simple harmonic oscillator, or equivalently the Einstein model of a solid with Einstein frequency ω_E. The solution to this quantum mechanical problem shows that some of the nuclear recoils occur as if the nucleus is indeed attached rigidly to the crystal, but other γ-ray emissions occur by changing the state of the Einstein oscillator.

Nearly all of the energy of the emitted γ ray comes from changes in the internal coordinates of the nucleus, independently of the motion of the nuclear center of mass. The concern about the change in the nuclear center of mass coordinates arises from the conservation of the

momentum during the emission of a γ ray with momentum $p_\gamma = E_\gamma/c$. Eventually, the momentum of the γ-ray emission will be taken up by the recoil of the crystal as a whole. However, it is possible that the energy levels of a simple harmonic oscillator (comprising the Mössbauer nucleus bound to the other atoms of the crystal lattice) could be changed by the γ-ray emission. An excitation of this oscillator would depreciate the γ-ray energy by $n\hbar$ if n phonons are excited during the γ-ray emission. Since $\hbar\omega_E$ is on the order of 10^{-2} eV, any change in oscillator energy would spoil the possibility for a subsequent resonant absorption. In essence, changes in the oscillator excitation (or phonons in a periodic solid) replace the classical recoil energy of Equation 4 for spoiling the energy precision of the emitted γ ray. We need to calculate the probability that phonon excitation will not occur during γ-ray emission.

Before γ-ray emission, the wavefunction of the nuclear center of mass is $\psi_i(X)$, which can also be represented in momentum space through the Fourier transformation

$$\phi_i(p) = \frac{1}{\sqrt{2\pi\hbar}} \int_{-\infty}^{\infty} \exp\left(\frac{-ipX}{\hbar}\right) \psi_i(X')\, dX' \tag{5}$$

or

$$\psi_i(X) = \frac{1}{\sqrt{2\pi\hbar}} \int_{-\infty}^{\infty} \exp\left(\frac{ipX}{\hbar}\right) \phi_i(p)\, dp \tag{6}$$

The momentum space representation can handily accommodate the impulse of the γ-ray emission, to provide the final state of the nuclear center of mass, $\psi_f(X)$. Recall that the impulse is the time integral of the force, $F = dp/dt$, which equals the change in momentum. The analog to impulse in momentum space is a translation in real-space, such as $X \rightarrow X - X_0$. This corresponds to obtaining a final state by a shift in origin of an initial eigenstate. With the emission of a γ ray having momentum p_γ, we obtain the final state wave function from the initial eigenstate through a shift of origin in momentum space, $\phi_i(p) \rightarrow \phi_i(p - p_\gamma)$. We interpret the final state in real-space, $\psi_f(X)$, with Equation 6

$$\psi_f(X) = \frac{1}{\sqrt{2\pi\hbar}} \int_{-\infty}^{\infty} \exp\left(\frac{i(p + p_\gamma)X}{\hbar}\right) \phi_i(p) dp \tag{7}$$

Now, substituting Equation 5 into Equation 7

$$\psi_f(X) = \frac{1}{2\pi\hbar} \int_{-\infty}^{\infty} \exp\left(\frac{i(p + p_\gamma)X}{\hbar}\right) \times \int_{-\infty}^{\infty} \exp\left(\frac{-ipX'}{\hbar}\right) \psi_i(X') dX' dp \tag{8}$$

Isolating the integration over momentum, p

$$\psi_f(X) = \frac{1}{2\pi\hbar} \int_{-\infty}^{\infty} \exp\left(\frac{ip_\gamma X}{\hbar}\right) \psi_i(X') \left[\int_{-\infty}^{\infty} \exp\left(\frac{ip(X - X')}{\hbar}\right) dp \right] dX' \tag{9}$$

because this integration over p gives a Dirac delta function (times $2\pi\hbar$)

$$\psi_f(X) = \int_{-\infty}^{\infty} \exp\left(\frac{ip_\gamma X}{\hbar}\right) \psi_i(X') \delta(X - X')\, dX' \tag{10}$$

$$\psi_f(X) = \exp\left(\frac{ip_\gamma X}{\hbar}\right) \psi_i(X) \tag{11}$$

The exponential in Equation 11 is a translation of the eigenstate, $\Psi_i(X)$, in position for a fixed momentum transfer, $-p_\gamma$. It is similar to the translation in time, t, of an eigenstate with fixed energy, E, which is $\exp(-iEt/\hbar)$ or a translation in momentum for a fixed spatial translation, X_0, which is $\exp(-ipX_0/\hbar)$. (If the initial state is not an eigenstate, p_γ in Equation 11 must be replaced by an operator.)

For the nuclear center-of-mass wavefunction after γ-ray emission, we seek the amplitude of the initial state wavefunction that remains in the final state wavefunction. In Dirac notation

$$\langle i|f\rangle = \int_{-\infty}^{\infty} \psi_i^*(X) \psi_f(X)\, dX \tag{12}$$

Substituting Equation 11 into Equation 12, and using Dirac notation

$$\langle i|f\rangle = \langle i| \exp\left(\frac{ip_\gamma X}{\hbar}\right) |i\rangle \tag{13}$$

Using the convention for the γ-ray wavevector, $k_\gamma \equiv 2\pi\nu/c = E_\gamma/\hbar c$

$$\langle i|f\rangle = \langle i| \exp(ik_\gamma X) |i\rangle \tag{14}$$

The inner product $\langle i|f\rangle$ is the projection of the initial state of the nuclear center of mass on the final state after emission of the γ ray. It provides the probability that there is no change in the state of the nuclear center of mass caused by γ-ray emission. The probability of this recoilless emission, f, is the square of the matrix element of Equation 14, normalized by all possible changes of the center-of-mass eigenfunctions

$$f = \frac{|\langle i| \exp(ik_\gamma X) |i\rangle|^2}{\sum_j |\langle j| \exp(ik_\gamma X) |i\rangle|^2} \tag{15}$$

$$f = \frac{|\langle i| \exp(ik_\gamma X) |i\rangle|^2}{\sum_j \langle i| \exp(-ik_\gamma X) j\rangle \langle j| \exp(+ik_\gamma X) |i\rangle} \tag{16}$$

Using the closure relation $\Sigma_j |j\rangle\langle j| = 1$ and the normalization $\langle i|i\rangle = 1$, Equation 16 becomes

$$f = |\langle i| \exp(ik_\gamma X) |i\rangle|^2 \tag{17}$$

The quantity f is the "recoil-free-fraction." It is the probability that, after the γ ray removes momentum p_γ from the nuclear center of mass, there will be no change in the lattice state function involving the nuclear center of mass. In other words, f is the probability that a γ ray will be emitted with no energy loss to phonons. A similar factor is required for the absorption of a γ ray by a nucleus in a second crystal (e.g., the sample). The evaluation of f is straightforward for the ground state of the Einstein solid. The ground state wavefunction is

$$\psi^0_{\mathrm{CM}}(\mathrm{X}) = \left(\frac{m\omega_\mathrm{E}}{\pi\hbar}\right)^{1/4} \exp\left(-\frac{m\omega_\mathrm{E}\mathrm{X}^2}{2\hbar}\right) \qquad (18)$$

Inserting Equation 18 into Equation 17, and evaluating the integral (which is the Fourier transform of a Gaussian function)

$$f = \exp\left(-\frac{\hbar^2 k_\gamma^2}{2m\hbar\omega_\mathrm{E}}\right) = \exp\left(-\frac{E_\mathrm{R}}{\hbar\omega_\mathrm{E}}\right) = \exp\left(-k_\gamma^2\langle \mathrm{X}^2\rangle\right) \qquad (19)$$

where E_R is the recoil energy of a free ^{57}Fe nucleus, and $\langle \mathrm{X}^2\rangle$ is the mean-squared displacement of the nucleus when bound in an oscillator. It is somewhat more complicated to use a Debye model for calculating f with a distribution of phonon energies (Mössbauer, 1958). When the lattice dynamics are known, computer calculations can be used to obtain f from the full phonon spectrum of the solid, including the phonon polarizations. These more detailed calculations essentially confirm the result of Equation 19. The only nontrivial point is that low-energy phonons do not alter the result significantly. The recoil of a single nucleus does not couple effectively to long wavelength phonons, and there are few of them, so their excitation is not a problem for recoilless emission.

The condition for obtaining a significant number of "recoilless" γ-ray emissions is that the characteristic recoil energy of a free nucleus, E_R, is smaller than, or on the order of, the energy of the short wavelength phonons in the solid. These phonon energies are typically estimated from the Debye or Einstein temperatures of the solid to be a few tens of meV. Since $E_\mathrm{R} = 1.86 \times 10^{-3}$ eV for ^{57}Fe, this condition is satisfied nicely. It is not uncommon for most of the γ-ray emissions or absorptions from ^{57}Fe to be recoil-free. It is helpful that the energy of the γ ray, 14.41 keV, is relatively low. Higher-energy γ rays cause E_R to be large, as seen by the quadratic relation in Equation 4. Energies of most γ rays are far greater than 14 keV, so Mössbauer spectrometry is not practical for most nuclear transitions.

Overview of Hyperfine Interactions

Given the existence of the Mössbauer effect, the question remains as to what it can do. The answer is given in two parts: what are the phenomena that can be measured, and then what do these measurables tell us about materials? The four standard measurable quantities are the recoil-free fraction and the three hyperfine interactions: the isomer shift, the electric quadrupole splitting, and the hyperfine magnetic field. To date, the three hyperfine interactions have proved the most useful measurable quantities for the characterization of materials by Mössbauer spectrometry. This overview provides a few rules of thumb as to the types of information that can be obtained from hyperfine interactions. The section below (see More Exotic Measurable Quantities) describes quantities that are measurable, but which have seen fewer applications so far. For specific applications of hyperfine interactions for studies of materials, see Practical Aspects of the Method.

The isomer shift is the easiest hyperfine interaction to understand. It is a direct measure of electron density, albeit at the nucleus and away from the electron density responsible for chemical bonding between the Mössbauer atom and its neighbors. The isomer shift changes considerably with the valence of the Mössbauer atom in the cases of ^{57}Fe and ^{119}Sn. It is possible to use the isomer shift to estimate the fraction of Mössbauer isotope in different valence states, which may originate from different crystallographic site occupancies or from the presence of multiple phases in a sample. Valence analysis is often straightforward, and is probably the most common type of service work that Mössbauer spectroscopists provide for other materials scientists. The isomer shift has proven most useful for studies of ionic or covalently bonded materials such as oxides and minerals. Unfortunately, although the isomer shift is in principle sensitive to local atomic coordinations, it has usually not proven useful for structural characterization of materials, except when changes in valence are involved. The isomer shifts caused by most local structural distortions are generally too small to be useful.

Electric field gradients (EFG) are often correlated to isomer shifts. The existence of an EFG requires an asymmetric (i.e., noncubic) electronic environment around the nucleus, however, and this usually correlates with the local atomic structure. Again, like the isomer shift, the EFG has proven most useful for studies of oxides and minerals. Although interpretations of the EFG are not so straightforward as the isomer shift, the EFG is more capable of providing information about the local atomic coordination of the Mössbauer isotope. For ^{57}Fe, the shifts in peak positions caused by the EFG tend to be comparable to, or larger than, those caused by the isomer shift.

While isomer shifts are universal, hyperfine magnetic fields are confined to ferro-, ferri-, or antiferromagnetic materials. However, while isomer shifts tend to be small, hyperfine magnetic fields usually provide large and distinct shifts of Mössbauer peaks. Because their effects are so large and varied, hyperfine magnetic fields often permit detailed materials characterizations by Mössbauer spectrometry. For body-centered cubic (bcc) Fe alloys, it is known how most solutes in the periodic table alter the magnetic moments and hyperfine magnetic fields at neighboring Fe atoms, so it is often possible to measure the distribution of hyperfine magnetic fields and determine solute distributions about ^{57}Fe atoms. In magnetically ordered Fe oxides, the distinct hyperfine magnetic fields allow for ready identification of phase, sometimes more readily than by x-ray diffractometry.

Even in cases where fundamental interpretations of Mössbauer spectra are impossible, the identification of the local chemistry around the Mössbauer isotope is often possible by "fingerprint" comparisons with known standards. Mössbauer spectrometers tend to have similar instrument characteristics, so quantitative comparisons with published spectra are often possible. A literature search for related Mössbauer publications is usually enough to locate standard spectra for comparison. The Mössbauer Effect Data Center (see Internet Resources) is another resource that can provide this information.

Recoil-Free Fraction

An obvious quantity to measure with the Mössbauer effect is its intensity, given by Equation 19 as the recoil-free fraction, f. The recoil-free fraction is reminiscent of the Debye-Waller factor for x-ray diffraction. It is large when the lattice is stiff and ω_E is large. Like the Debye-Waller factor, f is a weighted average over all phonons in the solid. Unlike the Debye-Waller factor, however, f must be determined from measurements with only one value of wavevector k, which is of course k_γ.

It is difficult to obtain f from a single absolute measurement, since details about the sample thickness and absorption characteristics must be known accurately. Comparative studies may be possible with in situ experiments where a material undergoes a phase transition from one state to another while the macroscopic shape of the specimen is unchanged.

The usual way to determine f for a single-phase material is by measuring Mössbauer spectral areas as a function of temperature, T. Equation 19 shows that the intensity of the Mössbauer effect will decrease with $\langle X^2 \rangle$, the mean-squared displacement of the nuclear motion. The $\langle X^2 \rangle$ increases with T, so measurements of spectral intensity versus T can provide the means for determining f, and hence the Debye or Einstein temperature of the solid.

Another effect that occurs with temperature provides a measure of $\langle v^2 \rangle$, where v is the velocity of the nuclear center of mass. This effect is sometimes called the "second order Doppler shift," but it originates with special relativity. When a nucleus emits a γ ray and loses energy, its mass is reduced slightly. The phonon occupation numbers do not change, but the phonon energy is increased slightly owing to the diminished mass. This reduces the energy available to the γ-ray photon. This effect is usually of greater concern for absorption by the specimen, for which the energy shift is

$$E_{\text{therm}} = -\frac{1\langle V^2 \rangle}{2\, c^2} E_0 \qquad (20)$$

The thermal shift scales with the thermal kinetic energy in the sample, which is essentially a measure of temperature. For ^{57}Fe, $E_{\text{therm}} = -7.3 \times 10^{-4}$ mm/s K.

Isomer Shift

The peaks in a Mössbauer spectrum undergo observable shifts in energy when the Mössbauer atom is in different materials. These shifts originate from a hyperfine interaction involving the nucleus and the inner electrons of the atom. These "isomer shifts" are in proportion to the electron density at the nucleus. Two possibly unfamiliar concepts underlie the origin of the isomer shift. First, some atomic electron wavefunctions are actually present inside the nucleus. Second, the nuclear radius is different in the nuclear ground and excited states.

In solving the Schrödinger equation for radial wavefunctions of electrons around a point nucleus, it is found that for $r \to 0$ (i.e., toward the nucleus) the electron wavefunctions go as r^l, where l is the angular momentum quantum number of the electron. For s electrons (1s, 2s, 3s, 4s, etc.) with $l = 0$, the electron wavefunction is quite large at $r = 0$. It might be guessed that the wavefunctions of s electrons could make some sort of sharp wiggle so they go to zero inside the nucleus, but this would cost too much kinetic energy. The s electrons (and some relativistic p electrons) are actually present inside the nucleus. Furthermore, the electron density is essentially constant over the size of the nucleus.

The overlap of the s-electron wavefunction with the finite nucleus provides a Coulomb perturbation which lowers the nuclear energy levels. If the excited state and ground-state energy levels were lowered equally, however, the energy of the nuclear transition would be unaffected, and the emitted (or absorbed) γ ray would have the same energy. It is well known that the radius of an atom changes when an electron enters an excited state. The same type of effect occurs for nuclei—the nuclear radius is different for the nuclear ground and excited states. For ^{57}Fe, the effective radius of the nuclear excited state, R_{ex}, is smaller than the radius of the ground state, R_g, but for ^{119}Sn it is the other way around. For the overlap of a finite nucleus with a constant charge density, the total electrostatic attraction is stronger when the nucleus is smaller. This leads to a difference in energy between the nuclear excited state and ground state in the presence of a constant electron density $|\psi(0)|^2$. This shift in transition energy will usually be different for nuclei in the radiation source and nuclei in the sample, giving the following shift in position of the absorption peak in the measured spectrum

$$\Delta E_{\text{IS}} = \left[CZe^2(R_{\text{ex}}^2 - R_g^2)\right]\left[|\psi_{\text{sample}}(0)|^2 - |\psi_{\text{source}}(0)|^2\right] \qquad (21)$$

The factor C depends on the shape of the nuclear charge distribution, which need not be uniform or spherical. The sign of Equation 21 for ^{57}Fe is such that with an increasing s-electron density at the nucleus, the Mössbauer peaks will be shifted to more negative velocity. For ^{119}Sn, the difference in nuclear radii has the opposite sign. With increasing s-electron density at a ^{119}Sn nucleus, the Mössbauer peaks shift to more positive velocity.

There remains another issue in interpreting isomer shifts, however. In the case of Fe, the 3d electrons are expected to partly screen the nuclear charge from the 4s electrons. An increase in the number of 3d electrons at an ^{57}Fe atom will therefore increase this screening, reducing the s-electron density at the ^{57}Fe nucleus and causing a more positive isomer shift. The s-electron density at the

nucleus is therefore not simply proportional to the number of valence *s* electrons at the ion. The effect of this 3*d* electron screening is large for ionic compounds (Gütlich, 1975). In these compounds there is a series of trend lines for how the isomer shift depends on the 4*s* electron density, where the different trends correspond to the different number of 3*d* electrons at the ^{57}Fe atom (Walker et al., 1961). With more 3*d* electrons, the isomer shift is more positive, but also the isomer shift becomes less sensitive to the number of 4*s* electrons at the atom. Determining the valence state of Fe atoms from isomer shifts is generally a realistic type of experiment, however (see Practical Aspects of the Method).

For metals it has been more recently learned that the isomer shifts do not depend on the 3*d* electron density (Akai et al., 1986). In Fe alloys, the isomer shift corresponds nicely to the 4*s* charge transfer, in spite of changes in the 3*d* electrons at the Fe atoms. For the first factor in Equation 21, a proposed choice for ^{57}Fe is $\left[CZe^2(R_{ex}^2 - R_g^2)\right] = -0.24\ a_0^3$ mm/s (Akai et al., 1986), where a_0 is the Bohr radius of 0.529 Å.

Electric Quadrupole Splitting

The isomer shift, described in the previous section, is an electric monopole interaction. There is no static dipole moment of the nucleus. The nucleus does have an electric quadrupole moment that originates with its asymmetrical shape. The asymmetry of the nucleus depends on its spin, which differs for the ground and excited states of the nucleus. In a uniform electric field, the shape of the nuclear charge distribution has no effect on the Coulomb energy. An EFG, however, will have different interaction energies for different alignments of the electric quadrupole moment of the nucleus. An EFG generally involves a variation with position of the *x*, *y*, and *z* components of the electric field vector. In specifying an EFG, it is necessary to know, for example, how the *x* component of the electric field, $V_x \equiv \partial V/\partial x$ varies along the *y* direction, $V_y \equiv \partial^2 V/\partial y \partial x$ [here $V(x,y,z)$ is the electric potential]. The EFG involves all such partial derivatives, and is a tensor quantity. In the absence of competing hyperfine interactions, it is possible to choose freely a set of principal axes so that the off-diagonal elements of the EFG tensor are zero. By convention, we label the principal axes such that $|V_{zz}| > |V_{yy}| > |V_{xx}|$. Furthermore, because the Laplacian of the potential vanishes, $V_{xx} + V_{yy} + V_{zz} = 0$, there are only two parameters required to specify the EFG. These are chosen to be V_{zz} and an asymmetry parameter, $\eta \equiv (V_{xx} - V_{yy})/V_{zz}$.

The isotopes ^{57}Fe and ^{119}Sn have an excited-state spin of $I = 3/2$ and a ground-state spin of 1/2. The shape of the excited nucleus is that of a prolate spheroid. This prolate spheroid will be oriented with its long axis pointing along the *z* axis of the EFG when $I_z = \pm 3/2$. There is no effect from the sign of I_z, since inverting a prolate spheroid does not change its charge distribution. The $I_z = \pm 3/2$ states have a low energy compared to the $I_z = 1/2$ orientation of the excited state. In the presence of an EFG, the excited-state energy is split into two levels. Since $I_z = \pm 1/2$ for the ground state, however, the ground state

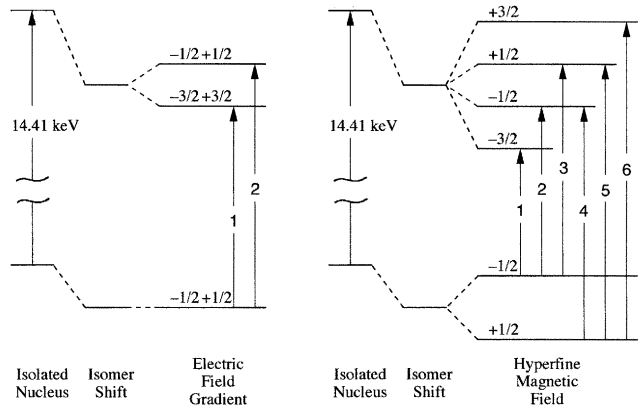

Figure 1. Energy level diagrams for ^{57}Fe in an electric field gradient (EFG; left) or hyperfine magnetic field (HMF; right). For an HMF at the sample, the numbers 1 to 6 indicate progressively more energetic transitions, which give experimental peaks at progressively more positive velocities. Sign convention is that an applied magnetic field along the direction of lattice magnetization will reduce the HMF and the magnetic splitting. The case where the nucleus is exposed simultaneously to an EFG and HMF of approximately the same energies is much more complicated than can be presented on a simple energy level diagram.

energy is not split by the EFG. With an electric quadrupole moment for the excited state defined as *Q*, for ^{57}Fe and ^{119}Sn the quadrupole splitting of energy levels is

$$\Delta E_q = \frac{\pm 1}{4} eQV_{zz}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \qquad (22)$$

where often there is the additional definition $eq \equiv V_{zz}$. The energy level diagram is shown in Figure 1. By definition, $\eta < 1$, so the asymmetry factor can vary only from 1 to 1.155. For ^{57}Fe and ^{119}Sn, for which Equation 22 is valid, the asymmetry can usually be neglected, and the electric quadrupole interaction can be assumed to be a measure of V_{zz}. Unfortunately, it is not possible to determine the sign of V_{zz} easily (although this has been done by applying high magnetic fields to the sample).

The EFG is zero when the electronic environment of the Mössbauer isotope has cubic symmetry. When the electronic symmetry is reduced, a single line in the Mössbauer spectrum appears as two lines separated in energy as described by Equation 22 (as shown in Fig. 1). When the ^{57}Fe atom has a 3*d* electron structure with orbital angular momentum, V_{zz} is large. High- and low-spin Fe complexes can be identified by differences in their electric quadrupole splitting. The electric quadrupole splitting is also sensitive to the local atomic arrangements, such as ligand charge and coordination, but this sensitivity is not possible to interpret by simple calculations. The ligand field gives an enhanced effect on the EFG at the nucleus because the electronic structure at the Mössbauer atom is itself distorted by the ligand. This effect is termed "Sternheimer antishielding," and enhances the EFG from the ligands by a factor of about 7 for ^{57}Fe (Watson and Freeman, 1967).

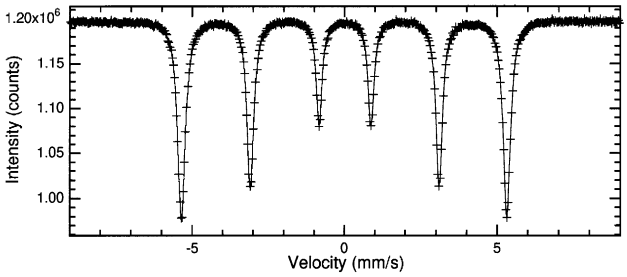

Figure 2. Mössbauer spectrum from bcc Fe. Data were acquired at 300 K in transmission geometry with a constant acceleration spectrometer (Ranger MS900). The points are the experimental data. The solid line is a fit to the data for six independent Lorentzian functions with unconstrained centers, widths, and depths. Also in the fit was a parabolic background function, which accounts for the fact that the radiation source was somewhat closer to the specimen at zero velocity than at the large positive or negative velocities. A ^{57}Co source in Rh was used, but the zero of the velocity scale is the centroid of the Fe spectrum itself. Separation between peaks 1 and 6 is 10.62 mm/s.

Hyperfine Magnetic Field Splitting

The nuclear states have spin, and therefore associated magnetic dipole moments. The spins can be oriented with different projections along a magnetic field. The energies of nuclear transitions are therefore modified when the nucleus is in a magnetic field. The energy perturbations caused by this HMF are sometimes termed the "nuclear Zeeman effect," in analogy with the more familiar splitting of energy levels of atomic electrons when there is a magnetic field at the atom.

A hyperfine magnetic field lifts all degeneracies of the spin states of the nucleus, resulting in separate transitions identifiable in a Mössbauer spectrum (see, e.g., Fig. 2). The I_z range from $-I$ to $+I$ in increments of 1, being $\{-3/2, -1/2, +1/2, +3/2\}$ for the excited state of ^{57}Fe and $\{-1/2, +1/2\}$ for the ground state. The allowed transitions between ground and excited states are set by selection rules. For the M1 magnetic dipole radiation for ^{57}Fe, six transitions are allowed: $\{(-1/2\rightarrow-3/2)\ (-1/2\rightarrow-1/2)\ (-1/2\rightarrow+1/2)\ (+1/2\rightarrow-1/2)\ (+1/2\rightarrow+1/2)\ (+1/2\rightarrow+3/2)\}$. The allowed transitions are shown in Figure 1. Notice the inversion in energy levels of the nuclear ground state.

In ferromagnetic iron metal, the magnetic field at the ^{57}Fe nucleus, the HMF, is 33.0 T at 300 K. The enormity of this HMF suggests immediately that it does not originate from the traditional mechanisms of solid-state magnetism. Furthermore, when an external magnetic field is applied to a sample of Fe metal, there is a decrease in magnetic splitting of the measured Mössbauer peaks. This latter observation shows that the HMF at the ^{57}Fe nucleus has a sign opposite to that of the lattice magnetization of Fe metal, so the HMF is given as -33.0 T.

It is easiest to understand the classical contributions to the HMF, denoted H_{mag}, H_{dip} and H_{orb}. The contribution H_{mag} is the magnetic field from the lattice magnetization, M, which is $4\pi M/3$. To this contribution we add any magnetic fields applied by the experimenter, and we subtract the demagnetization caused by the return flux. Typically, $H_{\mathrm{mag}} < +0.7$ T. The contribution H_{dip} is the classical dipole magnetic field caused by magnetic moments at atoms near the Mössbauer nucleus. In Fe metal, H_{dip} vanishes owing to cubic symmetry, but contributions of $+0.1$ T are possible when neighboring Fe atoms are replaced with nonmagnetic solutes. Finally, H_{orb} originates with any residual orbital magnetic moment from the Mössbauer atom that is not quenched when the atom is a crystal lattice. This contribution is about $+2$ T (Akai, 1986), and it may not change significantly when Fe metal is alloyed with solute atoms, for example. These classical mechanisms make only minor contributions to the HMF.

The big contribution to the HMF at a Mössbauer nucleus originates with the "Fermi contact interaction." Using the Dirac equation, Fermi and Segre discovered a new term in the Hamiltonian for the interaction of a nucleus and an atomic electron

$$\hbar_{\mathrm{FC}} = -\frac{8\pi}{3} g_{\mathrm{e}} g_{\mathrm{N}} \mu_{\mathrm{e}} \mu_{\mathrm{N}} \mathbf{I} \cdot \mathbf{S}\, \delta(\mathbf{r}) \qquad (23)$$

Here $\mathbf{I}$ and $\mathbf{S}$ are spin operators that act on the nuclear and electron wavefunctions, respectively, μ_{e} and μ_{N} are the electron and nuclear magnetons, and $(\mathbf{r})$ ensures that the electron wavefunction is sampled at the nucleus. Much like the electron gyromagnetic ratio, g_e, the nuclear gyromagnetic ratio, g_{N}, is a proportionality between the nuclear spin and the nuclear magnetic moment. Unlike the case for an electron, the nuclear ground and excited states do not have the same value of g_{N}; that of the ground state of ^{57}Fe is larger by a factor of -1.7145. The nuclear magnetic moment is $g_{\mathrm{N}}\ \mu_{\mathrm{N}} I$, so we can express the Fermi contact energy by considering this nuclear magnetic moment in an effective magnetic field, H_{eff}, defined as

$$H_{\mathrm{eff}} = \frac{8\pi}{3} g_{\mathrm{e}} \mu_{\mathrm{e}} S |\psi(0)|^2 \qquad (24)$$

where the electron spin is $\pm 1/2$, and $|\psi(0)|^2$ is the electron density at the nucleus. If two electrons of opposite spin have the same density at the nucleus, their contributions will cancel and H_{eff} will be zero. A large HMF requires an unpaired electron density at the nucleus, expressed as $|S| > 0$.

The Fermi contact interaction explains why the HMF is negative in ^{57}Fe. As described above (see Isomer Shift), only s electrons of Fe have a substantial presence at the nucleus. The largest contribution to the ^{57}Fe HMF is from $2s$ electrons, however, which are spin-paired core electrons. The reason that spin-paired core electrons can make a large contribution to the HMF is that the $2s\uparrow$ and $2s\downarrow$ wavefunctions have slightly different shapes when the Fe atom is magnetic. The magnetic moment of Fe atoms originates primarily with unpaired $3d$ electrons, so the imbalance in numbers of $3d\uparrow$ and $3d\downarrow$ electrons must affect the shapes of the paired $2s\uparrow$ and $2s\downarrow$ electrons.

These shapes of the $2s\uparrow$ and $2s\downarrow$ electron wavefunctions are altered by exchange interactions with the $3d\uparrow$ and $3d\downarrow$ electrons. The exchange interaction originates with the Pauli exclusion principle, which requires that a multielectron wavefunction be antisymmetric under the exchange

of electron coordinates. The process of antisymmetrization of a multielectron wavefunction produces an energy contribution from the Coulomb interaction between electrons called the "exchange energy," since it is the expectation value of the Coulomb energy for all pairs of electrons of like spin exchanged between their wavefunctions.

The net effect of the exchange interaction is to decrease the repulsive energy between electrons of like spin. In particular, the exchange interaction reduces the Coulomb repulsion between the $2s\uparrow$ and $3d\uparrow$ electrons, allowing the more centralized $2s\uparrow$ electrons to expand outward away from the nucleus. The same effect occurs for the $2s\downarrow$ and $3d\downarrow$ electrons, but to a lesser extent because there are fewer $3d\downarrow$ electrons than $3d\uparrow$ electrons in ferromagnetic Fe. The result is a higher density of $2s\downarrow$ than $2s\uparrow$ electrons at the ^{57}Fe nucleus. The same effect occurs for the $1s$ shell, and the net result is that the HMF at the ^{57}Fe nucleus is opposite in sign to the lattice magnetization (which is dominated by the $3d\uparrow$ electrons). The $3s$ electrons contribute to the HMF, but are at about the same mean radius as the $3d$ electrons, so their spin unbalance at the ^{57}Fe nucleus is smaller. The $4s$ electrons, on the other hand, lie outside the $3d$ shell, and exchange interactions bring a higher density of $4s\uparrow$ electrons into the ^{57}Fe nucleus, although not enough to overcome the effects of the $1s\downarrow$ and $2s\downarrow$ electrons. These $4s$ spin polarizations are sensitive to the magnetic moments at nearest neighbor atoms, however, and provide a mechanism for the ^{57}Fe atom to sense the presence of neighboring solute atoms. This is described below (see Solutes in bcc Fe Alloys).

More Exotic Measurable Quantities

Relaxation Phenomena. Hyperfine interactions have natural time windows for sampling electric or magnetic fields. This time window is the characteristic time, τ_{hf}, associated with the energy of a hyperfine splitting, $\tau_{hf} = \hbar/E_{hf}$. When a hyperfine electric or magnetic field undergoes fluctuations on the order of τ_{hf} or faster, observable distortions appear in the measured Mössbauer spectrum. The lifetime of the nuclear excited state does not play a direct role in setting the timescale for observing such relaxation phenomena. However, the lifetime of the nuclear excited state does provide a reasonable estimate of the longest characteristic time for fluctuations that can be measured by Mössbauer spectrometry.

Sensitivity to changes in valence of the Mössbauer atom between Fe(II) and Fe(III) has been used in studies of the Verwey transition in Fe_3O_4, which occurs at $\sim$120 K. Above the Verwey transition temperature the Mössbauer spectrum comprises two sextets, but when Fe_3O_4 is cooled below the Verwey transition temperature the spectrum becomes complex (Degrave et al., 1993).

Atomic diffusion is another phenomenon that can be studied by Mössbauer spectrometry (Ruebenbauer et al., 1994). As an atom jumps to a new site on a crystal lattice, the coherence of its γ-ray emission is disturbed. The shortening of the time for coherent γ-ray emission causes a broadening of the linewidths in the Mössbauer spectrum. In single crystals this broadening can be shown to occur by different amounts along different crystallographic directions, and has been used to identify the atom jump directions and mechanisms of diffusion in Fe alloys (Feldwisch et al., 1994; Vogl et al., 1994; Sepiol et al., 1996).

Perhaps the most familiar example of a relaxation effect in Mössbauer spectrometry is the superparamagnetic behavior of small particles. This phenomenon is described below (see Crystal Defects and Small Particles).

Phonons. The phonon partial density of states (DOS) has recently become measurable by Mössbauer spectrometry. Technically, nuclear resonant scattering that occurs with the creation or annihilation of a phonon is inelastic scattering, and therefore not the Mössbauer effect. However, techniques for measuring the phonon partial DOS have been developed as a capability of synchrotron radiation sources for Mössbauer scattering. The experiments are performed by detuning the incident photon energies above and below the nuclear resonance by 100 meV or so. This range of energy is far beyond the energy width of the Mössbauer resonance or any of its hyperfine interactions. However, it is in the range of typical phonon energies. The inelastic spectra so obtained are called "partial" phonon densities of states because they involve the motions of only the Mössbauer nucleus. The recent experiments (Seto et al., 1995; Sturhahn et al., 1995; Fultz et al., 1997) are performed with incoherent scattering (a Mössbauer γ ray into the sample, a conversion x ray out), and are interpreted in the same way as incoherent inelastic neutron scattering spectra (Squires, 1978). Compared to this latter, more established technique, the inelastic nuclear resonant scattering experiments have the capability of working with much smaller samples, owing to the large cross-section for nuclear resonant scattering. The vibrational spectra of monolayers of ^{57}Fe atoms at interfaces of thin films have been measured in preliminary experiments.

Coherence and Diffraction. Mössbauer scattering can be coherent, meaning that the phase of the incident wave is in a precise relationship to the phase of the scattered wave. For coherent scattering, wave amplitudes are added (Equation 3) instead of independent photon intensities (Equation 2). For the isotope ^{57}Fe, coherency occurs only in experiments where a 14.41 keV γ ray is absorbed and a 14.41 keV γ ray is reemitted through the reverse nuclear transition. The waves scattered by different coherent processes interfere with each other, either constructively or destructively. The interference between Mössbauer scattering and x-ray Rayleigh scattering undergoes a change from constructive in-phase interference above the Mössbauer resonance to destructive out-of-phase interference below. This gives rise to an asymmetry in the peaks measured in an energy spectrum, first observed by measuring a Mössbauer energy spectrum in scattering geometry (Black and Moon, 1960).

Diffraction is a specialized type of interference phenomenon. Of particular interest to the physics of Mössbauer diffraction is a suppression of internal conversion processes when diffraction is strong. With multiple transfers of energy between forward and diffracted beams, there is a nonintuitive enhancement in the rate of decay of the

nuclear excited state (Hannon and Trammell, 1969; van Bürck et al., 1978; Shvyd'ko and Smirnov, 1989), and a broadening of the characteristic linewidth. A fortunate consequence for highly perfect crystals is that with strong Bragg diffraction, a much larger fraction of the reemissions from ^{57}Fe nuclei occur by coherent 14.41 keV emission. The intensities of Mössbauer diffraction peaks therefore become stronger and easier to observe. For solving unknown structures in materials or condensed matter, however, it is difficult to interpret the intensities of diffraction peaks when there are multiple scatterings. Quantification of diffraction intensities with kinematical theory is an advantage of performing Mössbauer diffraction experiments on polycrystalline samples. Such samples also avoid the broadening of features in the Mössbauer energy spectrum that accompanies the speedup of the nuclear decay. Unfortunately, without the dynamical enhancement of coherent decay channels, kinematical diffraction experiments on small crystals suffer a serious penalty in diffraction intensity. Powder diffraction patterns have not been obtained until recently (Stephens et al., 1994), owing to the low intensities of the diffraction peaks. Mössbauer diffraction from polycrystalline alloys does offer a new capability, however, of combining the spectroscopic capabilities of hyperfine interactions to extract a diffraction pattern from a particular chemical environment of the Mössbauer isotope (Stephens and Fultz, 1997).

PRACTICAL ASPECTS OF THE METHOD

Radioisotope Sources

The vast majority of Mössbauer spectra have been measured with instrumentation as shown in Figure 3. The spectrum is obtained by counting the number of γ-ray photons that pass through a thin specimen as a function of the γ-ray energy. At energies where the Mössbauer effect is strong, a dip is observed in the γ-ray transmission. The γ-ray energy is tuned with a drive that imparts a Doppler shift, ΔE, to the γ ray in the reference frame of the sample:

$$\Delta E = \frac{v}{c} E_\gamma \qquad (25)$$

where v is the velocity of the drive. A velocity of 10 mm/s will provide an energy shift, ΔE, of 4.8×10^{-7} eV to a 14.41 keV γ ray of ^{57}Fe. Recall that the energy width of the Mössbauer resonance is 4.7×10^{-9} eV, which corresponds to 0.097 mm/s. An energy range of 10 mm/s is usually more than sufficient to tune through the full Mössbauer energy spectrum of ^{57}Fe or ^{119}Sn. It is conventional to present the energy axis of a Mössbauer spectrum in units of mm/s.

The equipment required for Mössbauer spectrometry is simple, and adequate instrumentation is often found in instructional laboratories for undergraduate physics students. In a typical coursework laboratory exercise, students learn the operation of the detector electronics and the spectrometer drive system in a few hours, and complete a measurement or two in about a week. (The understanding of the measured spectrum typically takes much longer.) Most components for the Mössbauer spectrometer in Figure 3 are standard items for x-ray detection and data acquisition. The items specialized for Mössbauer spectrometry are the electromagnetic drive and the radiation source. Abandoned electromagnetic drives and controllers are often found in university and industrial laboratories, and hardware manufactured since about 1970 by Austin Science Associates, Ranger Scientific, Wissel/Oxford Instruments, and Elscint, Ltd. are all capable of providing excellent results. Half-lives for radiation sources are: ^{57}Co, 271 days, ^{119m}Sn, 245 days, ^{151}Sm, 93 years, and ^{125}Te, 2.7 years. A new laboratory setup for ^{57}Fe or ^{119}Sn work may require the purchase of a radiation source. Suppliers include Amersham International, Dupont/NEN, and Isotope Products. It is also possible to obtain high-quality radiation sources from the former Soviet Union. Specifications for the purchase of a new Mössbauer source, besides activity level (typically 20 to 50 mCi for ^{57}Co), should include linewidth and sometimes levels of impurity radioisotopes.

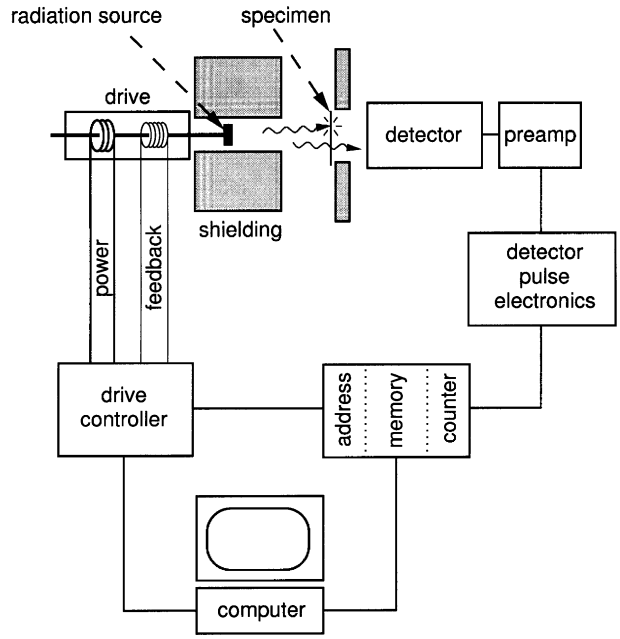

Figure 3. Transmission Mössbauer spectrometer. The radiation source sends γ rays to the right through a thin specimen into a detector. The electromagnetic drive is operated with feedback control by comparing a measured velocity signal with a desired reference waveform. The drive is cycled repetitively, usually so the velocity of the source varies linearly with time (constant acceleration mode). Counts from the detector are accumulated repetitively in short time intervals associated with memory addresses of a multichannel scaler. Each time interval corresponds to a particular velocity of the radiation source. Typical numbers are 1024 data points of 50-μs time duration and a period of 20 Hz.

The measured energy spectrum from the sample is convoluted with the energy spectrum of the radiation source. For a spectrum with sharp Lorentzian lines of natural linewidth, Γ (see Equation 1), the convolution of the source and sample Lorentzian functions provides a measured

Lorentzian function of full width at half-maximum of 0.198 mm/s. An excellent ^{57}Fe spectrum from pure Fe metal over an energy range of 10 mm/s may have linewidths of 0.23 mm/s, although instrumental linewidths of somewhat less than 0.3 mm/s are not uncommon owing to technical problems with the purity of the radiation source and vibrations of the specimen or source.

Radiation sources for ^{57}Fe Mössbauer spectrometry use the ^{57}Co radioisotope. The unstable ^{57}Co nucleus absorbs an inner-shell electron, transmuting to ^{57}Fe and emitting a 122-keV γ ray. The ^{57}Fe nucleus thus formed is in its first excited state, and decays about 141 ns later by the emission of a 14.41-keV γ ray. This second γ ray is the useful photon for Mössbauer spectrometry. While the 122-keV γ ray can be used as a clock to mark the formation of the ^{57}Fe excited state, it is generally considered a nuisance in Mössbauer spectrometry, along with emissions from other contamination radioisotopes in the radiation source. A Mössbauer radiation source is prepared by diffusing the ^{57}Co isotope into a matrix material such as Rh, so that atoms of ^{57}Co reside as dilute substitutional solutes on the fcc Rh crystal lattice. Being dilute, the ^{57}Co atoms have a neighborhood of pure Rh, and therefore all ^{57}Co atoms have the same local environment and the same nuclear energy levels. They will therefore emit γ rays of the same energy. Although radiation precautions are required for handling the source, the samples (absorbers) are not radioactive either before or after measurement in the spectrometer.

Enrichment of the Mössbauer isotope is sometimes needed when, for example, the 2.2% natural abundance of ^{57}Fe is insufficient to provide a strong spectrum. Although ^{57}Fe is not radioactive, material enriched to 95% ^{57}Fe costs approximately $15 to $30 per mg, so specimen preparation usually involves only small quantities of isotope. Biochemical experiments often require growing organisms in the presence of ^{57}Fe. This is common practice for studies on heme proteins, for example. For inorganic materials, it is sometimes possible to study dilute concentrations of Fe by isotopic enrichment. It is also common practice to use ^{57}Fe as an impurity, even when Fe is not part of the structure. Sometimes it is clear that the ^{57}Fe atom will substitute on the site of another transition metal, for example, and the local chemistry of this site can be studied with ^{57}Fe dopants. The same approach can be used with the ^{57}Co radioisotope, but this is not a common practice because it involves the preparation of radioactive materials. With ^{57}Co doping, the sample material itself serves as the radiation source, and the sample is moved with respect to a single-line absorber to acquire the Mössbauer spectrum. These "source experiments" can be performed with concentrations of ^{57}Co in the ppm range, providing a potent local probe in the material. Another advantage of source experiments is that the samples are usually so dilute in the Mössbauer isotope that there is no thickness distortion of the measured spectrum. The single-line absorber, typically sodium ferrocyanide containing 0.2 mg/cm^2 of ^{57}Fe, may itself have thickness distortion, but it is the same for all Doppler velocities. The net effect of absorber thickness is a broadening of spectral features without a distortion of intensities.

Synchrotron Sources

Since 1985 (Gerdau et al., 1985), it has become increasingly practical to perform Mössbauer spectrometry measurements with a synchrotron source of radiation, rather than a radioisotope source. This work has become more routine with the advent of Mössbauer beamlines at the European Synchrotron Radiation Facility at Grenoble, France, the Advanced Photon Source at Argonne National Laboratory, Argonne, Illinois, and the SPring-8 facility in Harima, Japan. Work at these facilities first requires success in an experiment approval process. Successful beamtime proposals will not involve experiments that can be done with radioisotope sources. Special capabilities that are offered by synchrotron radiation sources are the time structure of the incident radiation, its brightness and collimation, and the prospect of measuring energy spectra off-resonance to study phonons and other excitations in solids.

Synchrotron radiation for Mössbauer spectrometry is provided by an undulator magnet device inserted in the synchrotron storage ring. The undulator has tens of magnetic poles, positioned precisely so that the electron accelerations in each pole are arranged to add in phase. This provides a high concentration of radiation within a narrow range of angle, somewhat like Bragg diffraction from a crystal. This highly parallel radiation can be used to advantage in measurements through narrow windows, such as in diamond anvil cells. The highly parallel synchrotron radiation should permit a number of new diffraction experiments, using the Mössbauer effect for the coherent scattering mechanism.

Measurements of energy spectra are impractical with a synchrotron source, but equivalent spectroscopic information is available in the time domain. The method may be perceived as "Fourier transform Mössbauer spectrometry." A synchrotron photon, with time coherence less than 1 ns, can excite all resonant nuclei in the sample. Over the period of time for nuclear decay, 100 ns or so, the nuclei emit photon waves with energies characteristic of their hyperfine fields. Assume that there are two such hyperfine fields in the solid, providing photons of energy $E_\gamma^0 + \varepsilon_1$ and $E_\gamma^0 + \varepsilon_2$. In the forward scattering direction, the two photon waves can add in phase. The time dependence of the photon at the detector is obtained by the coherent sum as in Equation 3

$$T(t) = \exp[i(E_\gamma^0 + \varepsilon_1)t/\hbar] + \exp[i(E_\gamma^0 + \varepsilon_2)t/\hbar] \qquad (26)$$

The photon intensity at the detector, $I(t)$, has the time dependence

$$I(t) = T^*(t)T(t) = 2\{1 + \cos[\varepsilon_2 - \varepsilon_1)t/\hbar]\} \qquad (27)$$

When the energy difference between levels, $\varepsilon_2 - \varepsilon_1$, is greater than the natural linewidth, Γ, the forward scattered intensity measured at the detector will undergo a number of oscillations during the time of the nuclear decay. These "quantum beats" can be Fourier transformed to provide energy differences between hyperfine levels of the nucleus (Smirnov, 1996). It should be mentioned that forward scattering from thick samples also shows a

phenomenon of "dynamical beats," which involve energy interchanges between scattering processes.

Valence and Spin Determination

The isomer shift, with supplementary information provided by the quadrupole splitting, can be used to determine the valence and spin of ^{57}Fe and ^{119}Sn atoms. The isomer shift is proportional to the electron density at the nucleus, but this is influenced by the different σ- and π-donor acceptance strengths of surrounding ligands, their electronegativities, covalency effects, and other phenomena. It is usually best to have some independent knowledge about the electronic state of Fe or Sn in the material before attempting a valency determination. Even for unknown materials, however, valence and spin can often be determined reliably for the Mössbauer isotope.

The ^{57}Fe isomer shifts shown in Figure 4 are useful for determining the valence and spin state of Fe ions. If the ^{57}Fe isomer shift of an unknown compound is +1.2 mm/s with respect to bcc Fe, for example, it is identified as high-spin Fe(II). Low-spin Fe(II) and Fe(III) compounds show very similar isomer shifts, so it is not possible to distinguish between them on the basis of isomer shift alone. Fortunately, there are distinct differences in the electric quadrupole splittings of these electronic states. For low-spin Fe(II), the quadrupole splittings are rather small, being in the range of 0 to 0.8 mm/s. For low spin Fe(III) the electric quadrupole splittings are larger, being in the range 0.7 to 1.7 mm/s. The other oxidation states shown in Figure 4 are not so common, and tend to be of greater interest to chemists than materials scientists.

The previous analysis of valence and spin state assumed that the material is not magnetically ordered. In cases where a hyperfine magnetic field is present, identification of the chemical state of Fe is sometimes even easier. Table 1 presents a few examples of hyperfine magnetic fields and isomer shifts for common magnetic oxides and oxyhydroxides (Simmons and Leidheiser, 1976). This table is given as a convenient guide, but the hyperfine parameters may depend on crystalline quality and stoichiometry (Bowen et al., 1993).

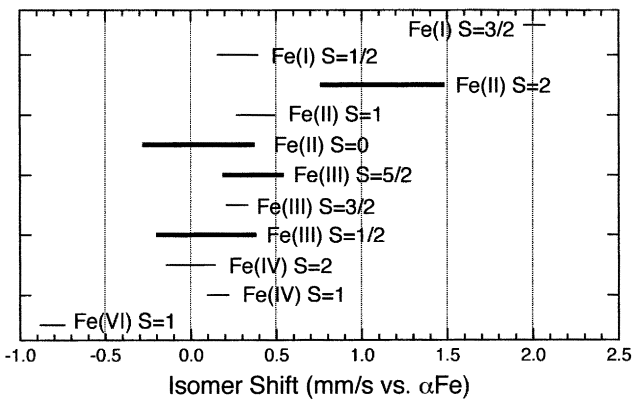

Figure 4. Ranges of isomer shifts in Fe compounds with various valences and spin states, with reference to bcc Fe at 300 K. Thicker lines are more common configurations (Greenwood and Gibb, 1971; Gütlich, 1975).

Table 1. Hyperfine Parameters of Common Oxides and Oxyhydroxides[a]

Compound (Fe Site)	HMF (T)	Q.S.	I.S. (vs. Fe)	Temp. (K)
α-FeOOH	50.0	−0.25		77
α-FeOOH	38.2	−0.25	+0.61	300
β-FeOOH	48.5	0.64	+0.38	80
β-FeOOH	0	0.62	+0.39	300
γ-FeOOH	0	0.60	+0.38	295
δ-FeOOH (large cryst.)	42.0		+0.35	295
FeO		0.8	+0.93	295
Fe_3O_4 (Fe(III), A)	49.3		+0.26	298
Fe_3O_4 (Fe(II, III), B)	46.0		+0.67	298
α-Fe_2O_3	51.8	+0.42	+0.39	296
γ-Fe_2O_3(A)	50.2		+0.18	300
γ-Fe_2O_3(B)	50.3		+0.40	300

[a]Abbreviations: HMF, hyperfine magnetic field; I.S., isomer shift; Q.S., quadrupole splitting; T, tesla.

The isomer shifts for ^{119}Sn compounds have a wider range than for ^{57}Fe compounds. Isomer shifts for compounds with Sn(IV) ions have a range from −0.5 to +1.5 mm/s versus SnO_2. For Sn(II) compounds, the range of isomer shifts is +2.2 to +4.2 versus SnO_2. Within these ranges it is possible to identify other chemical trends. In particular, for Sn compounds there is a strong correlation of isomer shift with the electronegativity of the ligands. This correlation between isomer shift and ligand electronegativity is especially reliable for Sn(IV) ions. Within a family of Sn(IV) compounds of similar coordination, the isomer shift depends on the electronegativity of the surrounding ligands as $-1.27\,\chi$ mm/s, where χ is the Pauling electronegativity. The correlation with Sn(II) is less reliable, in part because of the different coordinations found for this ion.

Finally, it should be mentioned that there have been a number of efforts to correlate the local coordination of ^{57}Fe with the electric quadrupole splitting. These correlations are often reliable within a specific class of compounds, typically showing a semiquantitative relationship between quadrupole splitting and the degree of distortion of the local atomic structure.

Phase Analysis

When more than one crystallographic phase is present in a material containing ^{57}Fe or ^{119}Sn, it is often possible to determine the phase fractions at least semiquantitatively. Usually some supplemental information is required before quantitative information can be derived. For example, most multiphase materials contain several chemical elements. Since Mössbauer spectrometry detects only the Mössbauer isotope, to determine the volume fraction of each phase, it is necessary to know its concentration of Mössbauer isotope. Quantitative phase analysis tends to be most reliable when the material is rich in the Mössbauer atom. Phase fractions in iron alloys, steels, and iron oxides can often be measured routinely by Mössbauer

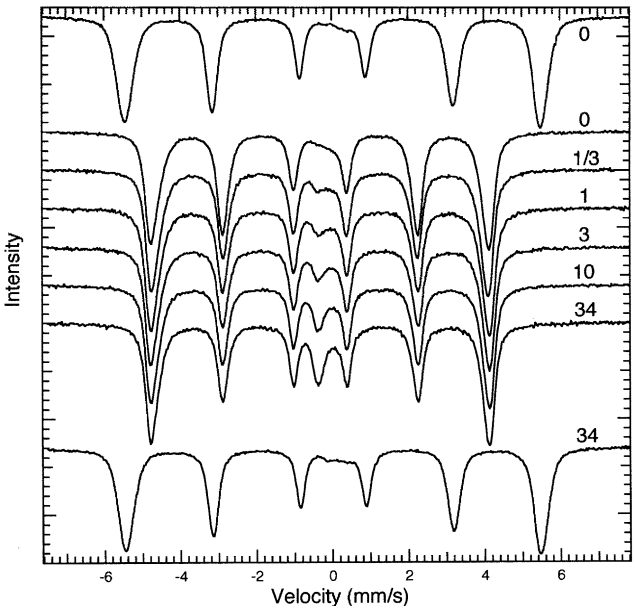

Figure 5. Mössbauer spectra of an alloy of Fe−8.9 atomic % Knee. The initial state of the material was ferromagnetic bcc phase, shown by the six-line spectrum at the top of the figure. This top spectrum was acquired at 23°C. The sample was heated in situ in the Mössbauer spectrometer to 600°C, for the numbers of hours marked on the curves, to form increasing amounts of fcc phase, evident as the single paramagnetic peak near −0.4 mm/s. This fcc phase is stable at 500°C, but not at 23°C, so the middle spectra were acquired at 500°C in interludes between heatings at 600°C for various times. At the end of the high-temperature runs, the sample temperature was again reduced to 23°C, and the final spectrum shown at the bottom of the figure showed that the fcc phase had transformed back into bcc phase. A trace of oxide is evident in all spectra as additional intensity around +0.4 mm/s at 23°C.

spectrometry (Schwartz, 1976; Simmons and Leidheiser, 1976; Cortie and Pollak, 1995; Campbell et al., 1995).

Figure 5 is an example of phase analysis of an Fe-Knee alloy, for which the interest was in determining the kinetics of fcc phase formation at 600°C (Fultz, 1982). The fcc phase, once formed, is stable at 500°C but not at room temperature. To determine the amount of fcc phase formed at 600°C it was necessary to measure Mössbauer spectra at 500°C without an intervening cooling to room temperature for spectrum acquisition. Mössbauer spectrometry is well suited for detecting small amounts of fcc phase in a bcc matrix, since the fcc phase is paramagnetic, and all its intensity appears as a single peak near the center of the spectrum. Amounts of fcc phase ("austenite") of 0.5% can be detected in iron alloys and steels, and quantitative analysis of the fcc phase fraction is straightforward.

The spectra in Figure 5 clearly show the six-line pattern of the bcc phase and the growth of the single peak at −0.4 mm/s from the fcc phase. These spectra show three other features that are common to many Mössbauer spectra. First, the spectrum at the top of Figure 5 shows a broadening of the outer lines of the sextet with respect to the inner lines (also see Fig. 2). This broadening originates with a distribution of hyperfine magnetic fields in alloys. The different numbers of Knee neighbors about the various ^{57}Fe atoms in the bcc phase cause different perturbations of the ^{57}Fe HMF. Second, the Curie temperature of bcc Fe−8.9 atomic % Knee is ∼700°C. At the Curie temperature the average lattice magnetization is zero, and the HMF is also zero. At 500°C the alloy is approaching the Curie temperature, and shows a strong reduction in its HMF as evidenced by the smaller splitting of the six line pattern with respect to the pattern at 23°C. Finally, at 500°C the entire spectrum is shifted to the left towards more negative isomer shift. This is the relativistic thermal shift of Equation 20.

To obtain the phase fractions, the fcc and bcc components of the spectrum were isolated and integrated numerically. Isolating the fcc peak was possible by digital subtraction of the initial spectrum from spectra measured after different annealing times. The fraction of the fcc spectral component then needed two correction factors to convert it into a molar phase fraction. One factor accounted for the different chemical compositions of the fcc and bcc phases (the fcc phase was enriched in Knee to about 25%). A second factor accounted for the differences in recoil-free fraction of the two phases. Fortunately, the Debye temperatures of the two phases were known, and they differed little, so the differences in recoil-free fraction were not significant. The amount of fcc phase in the alloy at 500°C was found to change from 0.5% initially to 7.5% after 34 h of heating at 600°C.

Solutes in bcc Fe Alloys

The HMF in pure bcc Fe is −33.0 T for every Fe atom, since every Fe atom has an identical chemical environment of 8 Fe first-nearest-neighbors (1nn), 6 Fe 2nn, 12 Fe 3nn, etc. In ferromagnetic alloys, however, the ^{57}Fe HMF is perturbed significantly by the presence of neighboring solute atoms. In many cases, this perturbation is about +2.5 T (a reduction in the magnitude of the HMF) for each 1nn solute atom. A compilation of some HMF perturbations for 1nn solutes and 2nn solutes is presented in Figure 6. These data were obtained by analysis of Mössbauer spectra from dilute bcc Fe-X alloys (Vincze and Campbell, 1973; Vincze and Aldred, 1974; Fultz, 1993).

In general, the HMF perturbations at ^{57}Fe nuclei from nearest-neighbor solute atoms originate from several sources, but for nonmagnetic solutes such as Si, the effects are fairly simple to understand. When the Si atom substitutes for an Fe atom in the bcc lattice, a magnetic moment of 2.2 μ_B is removed (the Fe) and replaced with a magnetic hole (the Si). The 4*s* conduction electrons redistribute their spin density around the Si atom, and this redistribution is significant at 1nn and 2nn distances. The Fermi contact interaction and H_{eff} (Equation 24) are sensitive to the 4*s* electron spin density, which has finite probability at the ^{57}Fe nucleus. Another important feature of 3*p*, 4*p*, and 5*p* solutes is that their presence does not significantly affect the magnetic moments at neighboring Fe atoms. Bulk magnetization measurements on Fe-Si and Fe-Al alloys, for example, show that the magnetic moment of the material decreases approximately in proportion to the fraction of Al or Si in the alloy. The core electron

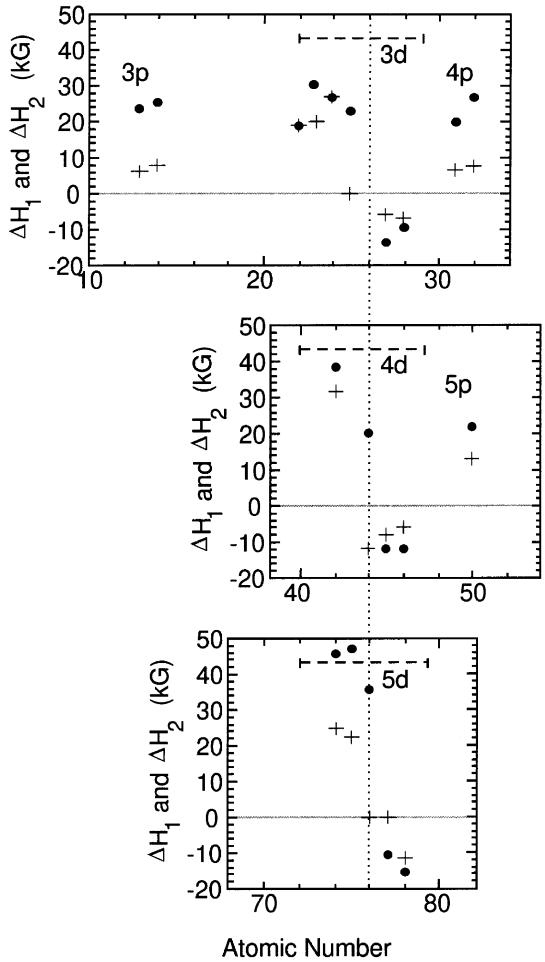

Figure 6. The hyperfine magnetic field perturbation, ΔH_1^X, at a Fe atom caused by one 1nn solute of type X, and the 2nn perturbation, ΔH_2^X, versus the atomic number of the solute. The vertical line denotes the column of Fe in the periodic table.

polarization, which involves exchange interactions between the unpaired 3*d* electrons at the ^{57}Fe atom and its inner-shell *s* electrons, is therefore not much affected by the presence of Si neighbors. The dominant effect comes from the magnetic hole at the solute atom, which causes the redistribution of 4*s* spin density. Figure 6 shows that the nonmagnetic 3*p*, 4*p*, and 5*p* elements all cause about the same HMF perturbation at neighboring ^{57}Fe atoms, as do the nonmagnetic early 3*d* transition metals.

For solutes that perturb significantly the magnetic moments at neighboring Fe atoms, especially the late transition metals, the core polarization at the ^{57}Fe atom is altered. There is an additional complicating effect from the matrix Fe atoms near the ^{57}Fe atom, whose magnetic moments are altered enough to affect the 4*s* conduction electron polarization at the ^{57}Fe (Fultz, 1993).

The HMF distribution can sometimes provide detailed information on the arrangements of solutes in nondilute bcc Fe alloys. For most solutes (that do not perturb significantly the magnetic moments at Fe atoms), the HMF at a ^{57}Fe atom depends monotonically on the number of solute atoms in its 1nn and 2nn shells. Hyperfine magnetic field perturbations can therefore be used to measure the chemical composition or the chemical short-range order in an alloy containing up to 10 atomic % solute or even more. In many cases, it is possible to distinguish among Fe atoms having different numbers of solute atoms as first neighbors, and then determine the fractions of these different first neighbor environments. This is considerably more information on chemical short-range order (SRO) than just the average number of solute neighbors, as provided by a 1nn Warren-Cowley SRO parameter, for example.

An example of chemical short range order in an Fe–26 atomic % Al alloy is presented in Figure 7. The material was cooled at a rate of 10^6 K/s from the melt by piston-anvil quenching, producing a polycrystalline ferromagnetic alloy with a nearly random distribution of Al atoms on the bcc lattice. With low-temperature annealing, the material evolved toward its equilibrium state of $D0_3$ chemical order. The Mössbauer spectra in Figure 7A change significantly as the alloy evolves chemical order. The overlap of several sets of six line patterns does confuse the physical picture, however, and further analysis requires the extraction of an HMF distribution from the experimental data. Software packages available for such work are described below (see Data Analysis). Figure 7B shows HMF distributions extracted from the three spectra of Figure 7A. At the top of Figure 7B are markers indicating the numbers of Al atoms in the 1nn shell of the ^{57}Fe nucleus associated with the HMF. With low-temperature annealing, there is a clear increase in the numbers of ^{57}Fe atoms with 0 and 4 Al neighbors, as expected when $D0_3$ order is evolving in the material. The perfectly ordered $D0_3$ structure has two chemical sites for Fe atoms, one with 0 Al neighbors and the other with 4 Al neighbors, in a 1:2 ratio. The HMF distributions were fit to a set of Gaussian functions to provide data on the chemical short range order in the alloys. These

data on chemical short-range order are presented in Figure 7C.

Crystal Defects and Small Particles

Since Mössbauer spectrometry probes local environments around a nucleus, it has often been proposed that Mössbauer spectra should be sensitive to the local atomic structures at grain boundaries and defects such as dislocations and vacancies. This is in fact true, but the measured spectra are an average over all Mössbauer atoms in a sample. Unless the material is chosen carefully so that the Mössbauer atom is segregated to the defect of interest, the spectral contribution from the defects is usually overwhelmed by the contribution from Mössbauer atoms in regions of perfect crystal. The recent interest in nanocrystalline materials, however, has provided a number of new opportunities for Mössbauer spectrometry (Herr et al., 1987; Fultz et al., 1995). The number of atoms at and near grain boundaries in nanocrystals is typically 35% for bcc Fe alloys with crystallite sizes of 7 nm or so. Such a large fraction of grain boundary atoms makes it possible to identify distinct contributions from Mössbauer atoms at grain boundaries, and to identify their local electronic environment.

Mössbauer spectrometry can provide detailed information on some features of small-particle magnetism (Mørup, 1990). When a magnetically ordered material is in the form of a very small particle, it is easier for thermal energy to realign its direction of magnetization. The particle retains its magnetic order, but the change in axis of magnetization will disturb the shape of the Mössbauer spectrum if the magnetic realignment occurs on the time scale t_s, which is $\hbar$ divided by the hyperfine magnetic field energy (see Relaxation Phenomena for discussion of the time window for measuring hyperfine interactions). An activation energy is associated with this "superparamagnetic" behavior, which is the magnetocrystalline anisotropy energy times the volume of the crystallite, κV. The probability of activating a spin rotation in a small particle is the Boltzmann factor for overcoming the anisotropy energy, so the condition for observing a strong relaxation effect in the Mössbauer spectrum is

$$t_s = A \exp(-\kappa V / k_B T_b) \qquad (28)$$

The temperature, T_b, satisfying Equation 28 is known as the "blocking temperature." The prefactor of Equation 28, the attempt frequency, is not so well understood, so studies of superparamagnetic behavior often study the blocking temperature versus the volume of the particles. In practice, most clusters of small particles have a distribution of blocking temperatures, and there are often interactions between the magnetic moments at adjacent particles. These effects can produce Mössbauer spectra with a wide variety of shapes, including very broad Lorentzian lines.

At temperatures below T_b, the magnetic moments of small particles undergo small fluctuations in their alignment. These small-amplitude fluctuations can be considered as vibrations of the particle magnetization about an average orientation, which serve to reduce the HMF by a modest amount. At increasing temperatures around T_b, however, large fluctuations occur in the magnetic alignment. The result is first a severe uncertainty of the HMF distribution, leading to a very broad background in the spectrum, followed by the growth of a paramagnetic peak near zero velocity. All of these effects can be observed in the spectra shown in Figure 8. Here, the biomaterial samples

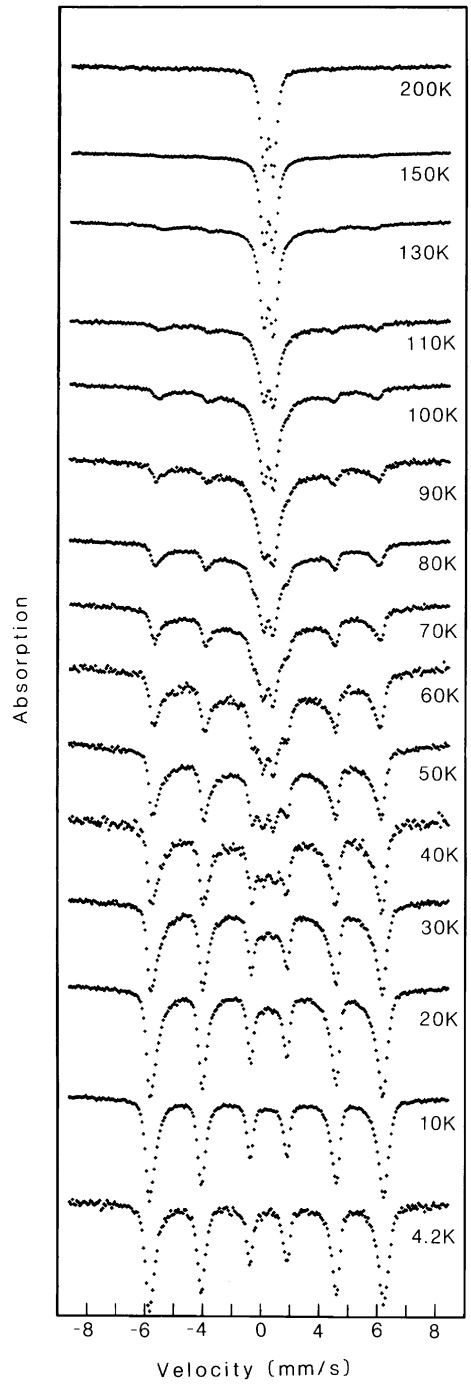

Figure 8. Mössbauer spectra from a specimen of haemosiderin, showing the effects of superparamagnetism with increasing temperature (Bell et al., 1984; Dickson, 1987).

comprised a core of haemosiderin, an iron storage compound, encapsulated within a protein shell. A clear six-line pattern is observed at 4.2 K, but the splitting of these six lines is found to decrease with temperature owing to small amplitude fluctuations in magnetic alignment. At temperatures around 40 to 70 K, a broad background appears under the measured spectrum, and a paramagnetic doublet begins to grow in intensity with increasing temperature. These effects are caused by large thermal reorientations of the magnetization. Finally, by 200 K, the thermally induced magnetic fluctuations are all of large amplitude and of characteristic times too short to permit a HMF to be detected by Mössbauer spectrometry.

DATA ANALYSIS AND INITIAL INTERPRETATION

Mössbauer spectra are often presented for publication with little or no processing. An obvious correction that can be applied to most transmission spectra is a correction for thickness distortion (see Sample Preparation). This correction is rarely performed, however, in large part because the thickness of the specimen is usually not known or is not uniform. The specimen is typically prepared to be thin, or at least this is assumed, and the spectrum is assumed to be representative of the Mössbauer absorption cross-section.

A typical goal of data analysis is to find individual hyperfine parameters, or more typically a distribution of hyperfine parameters, that characterize a measured spectrum. For example, the HMF distribution of Figure 2 should resemble a delta function centered at 330 kG. On the other hand, the HMF distribution of Figure 7B shows a number of peaks that are characteristic of different local chemical environments. Distributions of electric quadrupole splittings and isomer shifts are also useful for understanding heterogeneities in the local atomic arrangements in materials.

Several software packages are available to extract distributions of hyperfine parameters from Mössbauer spectra (Hesse and Rutbartsch, 1974; Le Car and DuBoise, 1979; Brand and Le Caër, 1988; Lagarec and Rancourt, 1997). These programs are often distributed by their authors who may be located with the Mössbauer Information eXchange (see Internet Resources). The different programs extract hyperfine distributions from experimental spectra with different numerical approaches, but all will show how successfully the hyperfine distribution can be used to regenerate the experimental spectrum.

In the presence of statistical noise, the reliability of these derived hyperfine distributions must be considered carefully. In particular, over small ranges of hyperfine parameters, the hyperfine distributions are not unique. For example, it may be unrealistic to distinguish one Lorentzian-shaped peak centered at a particular velocity from the sum of several peaks distributed within a quarter of a linewidth around this same velocity. This nonuniqueness can lead to numerical problems in extracting hyperfine distributions from experimental data. Some software packages use smoothing parameters to penalize the algorithm when it picks a candidate HMF distribution with sharp curvature. When differences in hyperfine distributions are small, there is always an issue of their uniqueness. Sometimes the data analysis cannot distinguish between different types of hyperfine distributions. For example, a spectrum that has been broadened by an EFG distribution, or even an HMF distribution, can be fit perfectly with an IS distribution. The physical origin of hyperfine distributions may not be obvious, especially when the spectrum shows little structure. Application of an external magnetic field may be helpful in identifying a weak HMF, however.

In general, distributions of all three hyperfine parameters (IS, EFG, HMF) will be present simultaneously in a measured spectrum. These parameters may be correlated; for example nuclei having the largest HMF may have the largest (or smallest) IS. Sorting out these correlations is often a research topic in itself, although the software for calculating hyperfine distributions typically allows for simple linear correlations between the distributions.

Both the EFG and the HMF use an axis of quantization for the nuclear spin. However, the direction of magnetization (for the HMF axis) generally does not coincide with the directions of the chemical bonds responsible for the EFG. The general case with comparable hyperfine interaction energies of HMFs and EFGs is quite complicated, and is well beyond the scope of this unit. Some software packages using model spin Hamiltonians are available to calculate spectra acquired under these conditions, however. In the common case when the HMF causes much larger spectral splittings than the EFG, with polycrystalline samples the usual effect of the EFG is a simple broadening of the peaks in the magnetic sextet, with no shifts in their positions.

With even modest experimental care, Mössbauer spectra can be highly reproducible from run to run. For example, the Mössbauer spectrum in Figure 2 was repeated many times over a time period of several years. Almost all of these bcc Fe spectra had data points that overlaid on top of each other, point by point, within the accuracy of the counting statistics. Because of this reproducibility, it is tempting and often appropriate to try to identify spectral features with energy width smaller than the characteristic linewidth. An underexploited technique for data analysis is "partial deconvolution" or "thinning." Since the lineshape of each nuclear transition is close to a Lorentzian function, and can be quite reproducible, it is appropriate to deconvolute a Lorentzian function from the experimental spectrum. This is formally the same as obtaining an IS distribution, but no assumptions about the origin of the hyperfine distributions are implied by this process. The net effect is to sharpen the peaks from the experimental Mössbauer spectrum, and this improvement in effective resolution can be advantageous when overlapping peaks are present in the spectra. The method does require excellent counting statistics to be reliable, however.

Finally, in spite of all the ready availability of computing resources, it is always important to look at differences in the experimental spectra themselves. Sometimes a digital subtraction of one normalized spectrum from another is an excellent way to identify changes in a material. In any

event, if no differences are detected by direct inspection of the data, changes in the hyperfine distributions obtained by computer software should not be believed. For this reason it is still necessary to show actual experimental spectra in research papers that use Mössbauer spectrometry.

SAMPLE PREPARATION

A central concern for transmission Mössbauer spectrometry is the choice and control of specimen thickness. The natural thickness of a specimen is t

$$t \equiv (f_a n_a \sigma_a)^{-1} \tag{29}$$

where f_a is the recoil-free fraction of the Mössbauer isotope in the specimen, n_a is the number of Mössbauer nuclei per cm^3, and σ_a is the cross-section in units of cm^2. The f_a can be estimated from Equation 19, for which it is useful to know that the γ-ray energies are 14.41 keV for ^{57}Fe, 23.875 keV for ^{119}Sn, and 21.64 keV for ^{151}Eu. To obtain n_a it is important to know that the natural isotopic abundance is 2.2% for ^{57}Fe, 8.6% for ^{119}Sn, and 48% for ^{151}Eu. The cross-sections for these isotopes are, in units of 10^{-19} cm^2, 25.7 for ^{57}Fe, 14.0 for ^{119}Sn, and 1.14 for ^{151}Eu. Finally, natural linewidths, Γ, of Equation 1, are 0.097 mm/s for ^{57}Fe, 0.323 mm/s for ^{119}Sn, and 0.652 mm/s for ^{151}Eu.

The observed intensity in a Mössbauer transmission spectrum appears as a dip in count rate as the Mössbauer effect removes γ rays from the transmitted beam. Since this dip in transmission increases with sample thickness, thicker samples provide better signal-to-noise ratios and shorter data acquisition times. For quantitative work, however, it is poor practice to work with samples that are the natural thickness, t, or thicker owing to an effect called "thickness distortion." In a typical constant-acceleration spectrometer, the incident beam will have uniform intensity at all velocities of the source, and the top layer of sample will absorb γ rays in proportion to its cross-section (Equation 2). On the other hand, layers deeper within the sample will be exposed to a γ-ray intensity diminished at velocities where the top layers have absorbed strongly. The effect of this "thickness distortion" is to reduce the overall sample absorption at velocities where the Mössbauer effect is strong. Broadening of the Mössbauer peaks therefore occurs as the samples become thicker. This broadening can be modeled approximately as increasing the effective linewidth of Equation 1 from the natural Γ to $\Gamma(1 + 0.135t/t)$. However, it is important to note that in the tails of the Mössbauer peaks, where the absorption is weak, there is less thickness distortion. The peak shape in the presence of thickness distortion is therefore not a true Lorentzian function. Numerical corrections for the effects of thickness distortion are sometimes possible, but are rarely performed owing to difficulties in knowing the precise sample thickness and thickness uniformity. For quantitative work the standard practice is to use samples of thickness/2 or so.

We calculate an effective thickness, t, for the case of natural Fe metal, which is widely used as a calibration standard for Mössbauer spectrometers. If there are no impurities in the Fe metal, its Mössbauer spectrum has sharp lines as shown in Figure 2. The recoil-free-fraction of bcc Fe is 0.80 at 300 K, and other quantities follow Equation 29

$$= \left(0.80 \times 0.022 \times \frac{7.86\,\mathrm{g}}{\mathrm{cm}^3} \times \frac{1\,\mathrm{mol}}{55.85\,\mathrm{g}} \times \frac{6.023 \times 10^{23}\ \mathrm{atoms}}{\mathrm{mole}} \times 25 \times 10^{-19}\,\mathrm{cm}^2 \frac{1}{4}\right)^{-1} \tag{30}$$

$$= 11 \times 10^{-4}\,\mathrm{cm} = 11\,\mu\mathrm{m} \tag{31}$$

The factor of 1/4 in Equation 30 accounts for the fact that the absorption cross-section is split into six different peaks owing to the hyperfine magnetic field in bcc Fe. The strongest of these comprises 1/4 of the total absorption. Figure 2 was acquired with a sample of natural bcc Fe 25 μm in thickness. The linewidths of the inner two peaks are 0.235 mm/s whereas the outer two are 0.291 mm/s. Although the outer two peaks are broadened by thickness distortion, effects of impurity atoms in the Fe are equally important. The widths of the inner two lines are probably a better measure of the spectrometer resolution.

X-RAY TECHNIQUES

INTRODUCTION

X-ray scattering and spectroscopy methods can provide a wealth of information concerning the physical and electronic structure of crystalline and noncrystalline materials in a variety of external conditions and environments. X-ray powder diffraction, for example, is generally the first, and perhaps the most widely used, probe of crystal structure. Over the last nine decades, especially with the introduction of x-ray synchrotron sources during the last 25 years, x-ray techniques have expanded well beyond their initial role in structure determination.

This chapter explores the wide variety of applications of x-ray scattering and spectroscopy techniques to the study of materials. Materials, in this sense, include not only bulk condensed matter systems, but liquids and surfaces as well. The term "scattering," is generally used to include x-ray measurements on noncrystalline systems, such as glasses and liquids, or poorly crystallized materials, such as polymers, as well as x-ray diffraction from crystalline solids. Information concerning long-range, short-range, and chemical ordering as well as the existence, distribution and characterization of various defects is accessible through these kinds of measurements. Spectroscopy techniques generally make use of the energy dependence of the scattering or absorption cross-section to study chemical short-range order, identify the presence and location of chemical species, and probe the electronic structure through inelastic excitations.

X-ray scattering and spectroscopy provide information complementary to several other techniques found in this volume. Perhaps most closely related are electron and neutron scattering methods described in Chapters 11 and 13, respectively. The utility of all three methods in investigations of atomic scale structure arises from the close match of the wavelength of these probes to typical interatomic distances (a few Ångstroms). Of the three methods, the electron scattering interaction with matter is the strongest, so this technique is most appropriate to the study of surfaces or very thin samples. In addition, samples must be studied in an ultrahigh-vacuum environment. The relatively weak absorption of neutrons by most isotopes allows investigations of bulk samples. The principal neutron scattering interaction involves the nuclei of constituent elements and the magnetic moment of the outer electrons. Indeed, the cross-section for scattering from magnetic electrons is of the same order as scattering from the nuclei, so that this technique is of great utility in studying magnetic structures of magnetic materials. Neutron energies are typically on the order of a few meV to tens of meV, the same energy scale as many important elementary excitations in solids. Therefore inelastic neutron scattering has become a critical probe of elementary excitations including phonon and magnon dispersion in solids. The principal x-ray scattering interaction in materials involves the atomic electrons, but is significantly weaker than the electron-electron scattering cross-section. X-ray absorption by solids is relatively strong at typical energies found in laboratory apparatus (8 keV), penetrating a few tens of microns into a sample. At x-ray synchrotron sources, x-ray beams of energies above 100 keV are available. At these high energies, the absorption of x-rays approaches small values comparable to neutron scattering. The energy dependence of the x-ray absorption cross-section is punctuated by absorption edges or resonances that are associated with interatomic processes of constituent elements. These resonances can be used to great advantage to investigate element-specific properties of the material and are the basis of many of the spectroscopic techniques described in this chapter.

Facilities for x-ray scattering and spectroscopy range from turn-key powder diffraction instruments for laboratory use to very sophisticated beam lines at x-ray synchrotron sources around the world. The growth of these synchrotron facilities in recent years, with corresponding increases in energy and scattering angle resolution, energy tunability, polarization tunability, and raw intensity has spurred tremendous advances in this field. For example, the technique of x-ray absorption spectroscopy (XAS) requires a source of continuous radiation that can be tuned over approximately 1 keV through the absorption edge of interest. Although possible using the bremstrahlung radiation from conventional x-ray tubes, full exploitation of this technique requires the high intensity, collimated beam of synchrotron radiation. As another example, the x-ray magnetic scattering cross-section is quite small (but finite) compared to the charge scattering cross-section. The high flux of x-rays available at synchrotron sources compared to neutron fluxes from reactors, however, allows x-ray magnetic scattering to effectively complement neutron magnetic scattering in several instances. Again, largely due to high x-ray fluxes and strong collimation, energy resolution in the meV range are achievable at current third generation x-ray sources, paving the way for new x-ray inelastic scattering studies of elementary excitations. Third generation sources include the Advanced Photon Source (APS) at the Argonne National Laboratory and the Advanced Light Source (ALS) at the Lawrence Berkeley National Laboratory in the United States, the European Synchrotron Radiation Facility (ESRF) in Europe, and Spring-8 in Japan.

ALAN I. GOLDMAN

X-RAY POWDER DIFFRACTION

INTRODUCTION

X-ray powder diffraction is used to determine the atomic structure of crystalline materials without the need for large ($\sim$100-μm) single crystals. "Powder" can be a misnomer; the technique is applicable to polycrystalline phases

such as cast solids or films grown on a substrate. X-ray powder diffraction can be useful in a wide variety of situations. Below we list a number of questions that can be effectively addressed by this technique. This is an attempt to illustrate the versatility of x-ray powder diffraction and not, by any means, a complete list. Six experiments (corresponding to numbers 1 through 6 below), described later as concrete examples (see Practical Aspects of the Model), constitute an assortment of problems of varying difficulty and involvement that we have come across over the course of several years.

1. The positions and integrated intensities of a set of peaks in an x-ray powder diffraction pattern can be compared to a database of known materials in order to identify the contents of the sample and to determine the presence or absence of any particular phase.
2. A mixture of two or more crystalline phases can be easily and accurately analyzed in terms of its phase fractions, whether or not the crystal structures of all phases are known. This is called quantitative phase analysis, and it is particularly valuable if some or all of the phases are chemically identical and hence cannot be distinguished while in solution.
3. The crystal structure of a new or unknown material can be determined when a similar material with a known structure exists. Depending on the degree of similarity between the new and the old structure, this can be fairly straightforward.
4. The crystal structure of a new or unknown material can be solved *ab initio* even if no information about the material other than its stoichiometry is known. This case is significantly more difficult than the previous one, and it requires both high-resolution data and a significant investment of time and effort on the part of the investigator.
5. Phase transitions and solid-state reactions can be investigated in near real time by recording x-ray powder diffraction patterns as a function of time, pressure, and/or temperature.
6. Subtle structural details such as lattice vacancies of an otherwise known structure can be extracted. This also usually requires high-resolution data and a very high sample quality.

The variation of peak positions with sample orientation can be used to deduce information about the internal strain of a sample. This technique is not covered in this unit, and the interested reader is directed to references such as Noyan and Cohen (1987). Another related technique, not covered here, is texture analysis, the determination of the distribution of orientations in a polycrystalline sample.

X-ray powder diffraction is an old technique, in use for most of this century. The capabilities of the technique have recently grown for two main reasons: (1) development of x-ray sources and optics (e.g., synchrotron radiation, Göbel mirrors) and (2) the increasing power of computers and software for analysis of powder data. This unit discusses the fundamental principles of the technique, including the expression for the intensity of each diffraction peak, gives a brief overview of experimental techniques, describes several illustrative examples, gives a description of the procedures to interpret and analyze diffraction data, and discusses weaknesses and sources of possible errors.

Competitive and Related Techniques

Alternative Methods

1. Single-crystal x-ray diffraction requires single crystals of appropriate size (10 to 100 μm). Solution of single-crystal structures is usually more automated with appropriate software than powder structures. Single-crystal techniques can generally solve more complicated structures than powder techniques, whereas powder diffraction can determine the constituents of a mixture of crystalline solid phases.
2. Neutron powder diffraction generally requires larger samples than x rays. It is more sensitive to light atoms (especially hydrogen) than x rays are. Deuterated samples are often required if the specimen has a significant amount of hydrogen (see NEUTRON POWDER DIFFRACTION). Neutrons are sensitive to the magnetic structure (see MAGNETIC NEUTRON SCATTERING). Measurements must be performed at a special facility (reactor or spallation source).
3. Single-crystal neutron diffraction requires single-crystal samples of millimeter size, is more sensitive to light atoms (especially hydrogen) than are x rays, and often requires deuterated samples if the specimen has a significant amount of hydrogen. As in the powder case, it is sensitive to the magnetic structure and must be performed at a special facility (reactor or spallation source).
4. Electron diffraction can give lattice information for samples that have a strain distribution too great to be indexed by the x-ray powder technique. It provides spatial resolution for inhomogeneous samples and can view individual grains but requires relatively sophisticated equipment (electron microscope; see LOW-ENERGY ELECTRON DIFFRACTION).

PRINCIPLES OF THE METHOD

If an x ray strikes an atom, it will be weakly scattered in all directions. If it encounters a periodic array of atoms, the waves scattered by each atom will reinforce in certain directions and cancel in others. Geometrically, one may imagine that a crystal is made up of families of lattice planes and that the scattering from a given family of planes will only be strong if the x rays reflected by each plane arrive at the detector in phase. This leads to a relationship between the x-ray wavelength λ, the spacing d between lattice planes, and the angle of incidence θ known as Bragg's law, $\lambda = 2d\sin\theta$. Note that the angle of deviation of the x ray is 2θ from its initial direction. This is fairly restrictive for a single crystal: for a given λ, even

if the detector is set at the correct 2θ for a given d spacing within the crystal, there will be no diffracted intensity unless the crystal is properly aligned to both the incident beam and the detector. The essence of the powder diffraction technique is to illuminate a large number of crystallites, so that a substantial number of them are in the correct orientation to diffract x rays into the detector.

The geometry of diffraction in a single grain is described through the reciprocal lattice. The fundamental concepts are in any of the Key References or in introductory solid-state physics texts such as Kittel (1996) or Ashcroft and Mermin (1976); also see SYMMETRY IN CRYSTALLOGRAPHY. If the crystal lattice is defined by three vectors **a**, **b**, and **c**, there are three reciprocal lattice vectors defined as

$$\mathbf{a}^* = \frac{2\pi \mathbf{b} \times \mathbf{c}}{\mathbf{a} \cdot \mathbf{b} \times \mathbf{c}} \tag{1}$$

and cyclic permutations thereof for $\mathbf{b}^*$ and $\mathbf{c}^*$ (in the chemistry literature the factor 2π is usually eliminated in this definition). These vectors define the reciprocal lattice, with the significance that any three integers (hkl) define a family of lattice planes with spacing $d = 2\pi/|h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*|$, so that the diffraction vector $\mathbf{K} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$ satisfies $|\mathbf{K}| = 2\pi/d = 4\pi\sin\theta/\lambda$ (caution: most chemists and some physicists define $|\mathbf{K}| = 1/d = 2\sin\theta/\lambda$).

The intensity of the diffracted beam is governed by the unit cell structure factor, defined as

$$F_{hkl} = \sum_j e^{i\mathbf{K}\cdot\mathbf{R}_j} f_j e^{-2W} \tag{2}$$

where R_j is the position of the jth atom in the unit cell, the summation is taken over all atoms in the unit cell, and f_j is the atomic scattering factor, tabulated in, e.g., the International Tables for Crystallography (Brown et al., 1992), and is equal to the number of atomic electrons at $2\theta = 0$, decreasing as a smooth function of $\sin\theta/\lambda$ (there are "anomalous" corrections to this amplitude if the x-ray energy is close to a transition in a target atom). The Debye-Waller factor $2W$ is given by $2W = K^2 u_{\mathrm{rms}}^2/3$, where u_{rms} is the (three-dimensional) root-mean-square deviation of the atom from its lattice position due to thermal and zero-point fluctuations. Experimental results are often quoted as the thermal parameter B, defined as $8\pi^2 u_{\mathrm{rms}}^2/3$, so that the Debye-Waller factor is given by $2W = 2B\sin^2\theta/\lambda^2$. Note that thermal fluctuations of the atoms about their average position weaken the diffraction lines but do not broaden them. As long as the diffraction is sufficiently weak (kinematic limit, assumed valid for most powders), the diffracted intensity is proportional to the square of the structure factor. In powder diffraction, it is always useful to bear in mind that the positions of the observed peaks indicate the geometry of the lattice, both its dimensions and any internal symmetries, whereas the intensities are governed by the arrangement of atoms within the unit cell.

In a powder experiment, various factors act to spread the intensity over a finite range of the diffraction angle, and so it is useful to consider the integrated intensity (power) of a given peak over the diffraction angle,

$$P_{hkl} = \left[\frac{P_0 \lambda^3 R_e^2 l}{16\pi R}\frac{V_s}{V^2}\right] M_{hkl} F_{hkl}^2 \left(\frac{1+\cos^2 2\theta}{\sin 2\theta \, \sin\theta}\right) \tag{3}$$

where P_0 is the power density of the incident beam, $R_e = 2.82$ fm is the classical electron radius, l and R are the width of the receiving slit and the distance between it and the sample, and V_s and V are the effective illuminated volume of the sample and the volume of one unit cell. The term M_{hkl} is the multiplicity of the hkl peak, e.g., 8 for a cubic hhh and 6 for a cubic $h00$, and $(1+\cos^2 2\theta)/(\sin\theta \sin 2\theta)$ is called the Lorentz polarization factor. The numerator takes the given form only for unpolarized incident radiation and in the absence of any other polarization-sensitive optical elements; it must be adapted, e.g., for a synchrotron-radiation source or a diffracted-beam monochromator. There are considerable experimental difficulties with measuring the absolute intensity either of the incident or the diffracted beam, and so the terms in the square brackets are usually lumped into a normalization factor, and one considers the relative intensity of different diffraction peaks, or more generally, the spectrum of intensity vs. scattering angle.

An inherent limitation on the amount of information that can be derived from a powder diffraction spectrum arises from possible overlap of Bragg peaks with different (hkl), so that their intensities cannot be determined independently. This overlap may be exact, as in the coincidence of cubic (511) and (333) reflections, or it may allow a partial degree of separation, as in the case of two peaks whose positions differ by a fraction of their widths. Because powder diffraction peaks generally become broader and more closely spaced at higher angles, peak overlap is a factor in almost every powder diffraction experiment. Perhaps the most important advance in powder diffraction during the last 30 years is the development of whole-pattern (Rietveld) fitting techniques for dealing with partially overlapped peaks, as discussed below.

Diffraction peaks acquire a nonzero width from three main factors: instrumental resolution (not discussed here), finite grain size, and random strains. If the grains have a linear dimension L, then the full-width at half-maximum (FWHM) in 2θ, expressed in radians, of the diffraction line is estimated by the well-known Scherrer equation, $\mathrm{FWHM}_{2\theta} = 0.89\lambda/L\cos\theta$. This is a reflection of the fact that the length L of a crystal made up of atoms with period d can only be determined to within d. One should not take the numerical value too seriously, as it depends on the precise shape of the crystallites and dispersion of the crystallite size distribution. If the crystallites have a needle or plate morphology, the size can be different for different families of lattice planes. On the other hand, if the crystallites are subject to a random distribution of lattice fractional strains having a FWHM of e_{FWHM}, the FWHM of the diffraction line will be $2\tan\theta e_{\mathrm{FWHM}}$. It is sometimes asserted that size broadening produces a Lorentzian and strain a Gaussian lineshape, but there is no fundamental reason for this to be true, and counterexamples are frequently observed. If the sample peak width

exceeds the instrumental resolution, or can be corrected for that effect, it can be informative to make a plot (called a Williamson-Hall plot) of FWHM$\cos\theta$ vs. $\sin\theta$. If the data points fall on a smooth curve, the intercept will give the particle size and the limiting slope the strain distribution. Indeed, the curve will be a straight line if both effects give a Lorentzian lineshape, because the shape of any peak would be the convolution of the size and strain contributions. If the points in a Williamson-Hall plot are scattered, it may give useful information (or at least a warning) of anisotropic size or strain broadening. More elaborate techniques for the deconvolution of size and strain effects from experimental data are described in the literature (Klug and Alexander, 1974; Balzar and Ledbetter, 1993).

There are two major problems in using powder diffraction measurements to determine the atomic structure of a material. First, as noted above, peaks overlap, so that the measured intensity cannot be uniquely assigned to the correct Miller indices (hkl). Second, even if the intensities were perfectly separated so that the magnitudes of the structure factors were known, one could not Fourier transform the measured structure factors to learn the atomic positions because their phases are not known.

PRACTICAL ASPECTS OF THE METHOD

The requirements to obtain a useful powder diffraction data set are conceptually straightforward: allow a beam of x rays to impinge on the sample and record the diffracted intensity as a function of angle. Practical realizations are governed by the desire to optimize various aspects of the measurement, such as the intensity, resolution, and discrimination against undesired effects (e.g., background from sample fluorescence).

Most laboratory powder x-ray diffractometers use a sealed x-ray tube with a target of copper, molybdenum, or some other metal. About half of the x rays from such a tube are in the characteristic K_α line ($\lambda = 1.54$Å for Cu, $\lambda = 0.70$Å for Mo), and the remainder are in other lines and in a continuous bremsstrahlung spectrum. Rotating-anode x-ray sources can be approximately ten times brighter than fixed targets, with an attendant cost in complexity and reliability. In either case, one can either use the x rays emitted by the anode directly (so that diffraction of the continuous component of the spectrum contributes a smooth background under the diffraction peaks) or select the line radiation by a crystal monochromator (using diffraction to pass only the correct wavelength) or by an energy-sensitive detector. The K_α line is actually a doublet (1.54051 and 1.54433 Å for Cu), which can create the added complication of split peaks unless one uses a monochromator of sufficient resolving power to pass only one component. Synchrotron radiation sources are finding increasing application for powder diffraction, due to their high intensity, intrinsically good collimation ($\sim 0.01^\circ$ in the vertical direction) of x-ray beams, and tunability over a continuous spectrum and the proliferation of user facilities throughout the world.

There are a large number of detectors suitable for powder x-ray diffraction. Perhaps the simplest is photographic film, which allows the collection of an entire diffractogram at one time and, with proper procedures, can be used to obtain quantitative intensities with a dynamic range up to 100:1 (Klug and Alexander, 1974). An updated form of photographic film is the x-ray imaging plate, developed for medical radiography, which is read out electronically (Miyahara et al., 1986; Ito and Amemiya, 1991). The simplest electronic detector, the Geiger counter, is no longer widely used because of its rather long dead time, which limits the maximum count rate. The gas-filled proportional counter offers higher count rates and some degree of x-ray energy resolution. The most widely used x-ray detector today is the scintillation counter, in which x rays are converted into visible light, typically in a thallium-doped NaI crystal, and then into electronic pulses by a photomultiplier tube. Various semiconductor detectors [Si:Li, positive-intrinsic-negative (PIN)] offer energy resolutions of 100 to 300 eV, sufficient to distinguish fluorescence from different elements and from the diffracted x rays, although their count rate capability is generally lower than that of scintillation counters. There are various forms of electronic position-sensitive detectors. Gas-filled proportional detectors can have a spatial resolution of a small fraction of a millimeter and are available as straight-line detectors, limited to several degrees of 2θ by parallax, or as curved detectors covering an angular range as large as 120°. They can operate at a count rate up to 10^5 Hz over the entire detector, but one must bear in mind that the count rate in one individual peak would be significantly less. Also, not all position-sensitive detectors are able to discriminate against x-ray fluorescence from the sample, although there is one elegant design using Kr gas and x rays just exceeding the Kr K edge that addresses this problem (Smith, 1991). Charge-coupled devices (CCDs) are two-dimensional detectors that integrate the total energy deposited into each pixel and therefore may have a larger dynamic range and/or a faster time response (Clarke and Rowe, 1991).

Some of the most important configurations for x-ray powder diffraction instruments are illustrated in Figure 1. The simple Debye-Scherrer camera in (A) records a wide range of angles on curved photographic film but suffers from limited resolution. Modern incarnations include instruments using curved position-sensitive detectors and imaging plates and are in use at several synchrotron sources. It generally requires a thin rod-shaped sample either poured as a powder into a capillary or mixed with an appropriate binder and rolled into the desired shape. The Bragg-Brentano diffractometer illustrated in (B) utilizes parafocusing from a flat sample to increase the resolution available from a diverging x-ray beam; in this exaggerated sketch, the distribution of Bragg angles is 3°, despite the fact that the sample subtends an angle of 15° from source or detector. The addition of a diffracted-beam monochromator illustrated in (C) produces a marked improvement in performance by eliminating x-ray fluorescence from the sample. For high-pressure cells, with limited access for the x-ray beam, the energy-dispersive diffraction approach illustrated in (D) can be an attractive

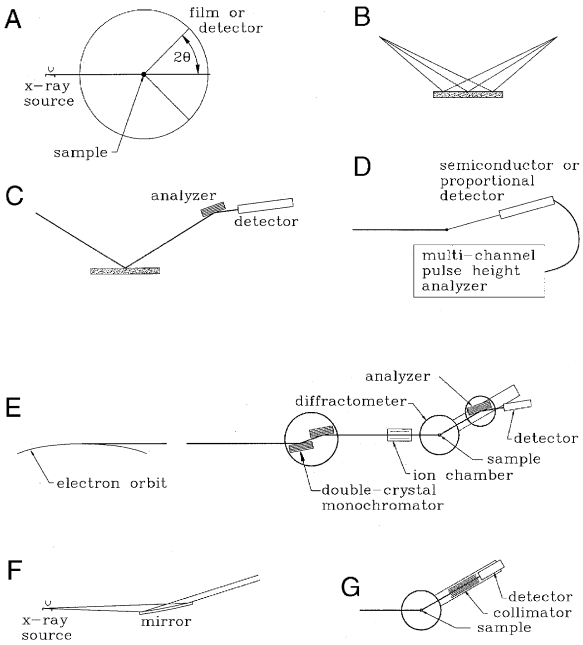

Figure 1. Schematic illustration of experimental setups for powder diffraction measurements.

solution. A polychromatic beam is scattered through a fixed angle, and the energy spectrum of the diffracted x rays is converted to d spacings for interpretation.

A typical synchrotron powder beamline such as X7A or X3B1 at the National Synchrotron Light Source (Brookhaven National Laboratory) is illustrated in (E). One particular wavelength is selected by the dual-crystal monochromator, and the x rays are diffracted again from an analyzer crystal mounted on the 2θ arm. Monochromator and analyzer are typically semiconductor crystals with rocking-curve widths of a few thousandths of a degree. Besides its intrinsically high resolution, this configuration offers the strong advantage that it truly measures the angle through which a parallel beam of radiation is scattered and so is relatively insensitive to parallax or sample transparency errors. The advantage of a parallel incident beam is available on laboratory sources by the use of a curved multilayer (Göbel) mirror (F), currently commercialized by Bruker Analytical X-ray Systems. One can also measure the diffracted angle, free from parallax, by use of a parallel-blade collimator as shown in (G). This generally gives higher intensity than an analyzer crystal at the cost of coarser angular resolution (0.1° to 0.03°), but this is often not a disadvantage because diffraction peaks from real samples are almost always broader than the analyzer rocking curve. However, the analyzer crystal also discriminates against fluorescence.

There are a number of sources of background in a powder diffraction experiment. X rays can be scattered from the sample by a number of mechanisms other than Bragg diffraction: Compton scattering, thermal diffuse scattering, scattering by defects in the crystal lattice, multiple scattering in the sample, and scattering by noncrystalline components of the sample, by the sample holder, or even by air in the x-ray beam path. The x rays scattered by all of these mechanisms will have an energy that is identical to or generally indistinguishable from the primary beam, and so it is not possible to eliminate these effects by using energy-sensitive detectors. Another important source of background is x-ray fluorescence, the emission of x rays by atoms in the target that have been ionized by the primary x-ray beam. X-ray fluorescence is always of a longer wavelength (lower energy) than the primary beam and so can be eliminated by the use of a diffracting crystal between sample and detector or an energy-sensitive detector (with the precaution that the fluorescence radiation does not saturate it) or controlled by appropriate choice of the incident wavelength.

It is not usually possible to predict the shape of this background, and so, once appropriate measures are taken to reduce it as much as practical, it is empirically separated from the relatively sharp powder diffraction peaks of interest. In data analysis such as the Rietveld method, one may take it as a piecewise linear or spline function between specified points or parameterize and adjust it to produce the best fit. There is some controversy about how to treat the statistical errors in a refinement with an adjustable background.

DATA ANALYSIS AND INTERPRETATION

A very important technique for analysis of powder diffraction data is the whole-pattern fitting method proposed by Rietveld (1969). It is based on the following properties of x-ray (and neutron) powder diffraction data: a powder diffraction pattern usually comprises a large number of peaks, many of which overlap, often very seriously, making the separate direct measurement of their integrated intensities difficult or impossible. However, it is possible to describe the shape of all Bragg peaks in the pattern by a small (compared to the number of peaks) number of profile parameters. This allows the least-squares refinement of an atomic model combined with an appropriate peak shape function, i.e., a simulated powder pattern, directly against the measured powder pattern. This may be contrasted to the single-crystal case, where the atomic structure is refined against a list of extracted integrated intensities. The Rietveld method is an extremely powerful tool for the structural analysis of virtually all types of crystalline materials not available as single crystals.

The parameters refined in the Rietveld method fall into two classes: those that describe the shape and position of the Bragg peaks in the pattern (profile parameters) and those that describe the underlying atomic model (atomic or structural parameters). The former include the lattice parameters and those describing the shape and width of the Bragg peaks. In x-ray powder diffraction, a widely used peak shape function is the pseudo-Voigt function (Thompson et al., 1987), a fast-computing approximation to a convolution of a Gaussian and a Lorentzian (Voigt function). It uses only five parameters (usually called U, V, W, X, and Y) to describe the shape of all peaks in the powder pattern. In particular, the peak widths are a smooth function of the scattering angle 2θ. Additional profile parameters are often used to describe the peak

asymmetry at low angles due to the intersection of the curved Debye-Scherrer cone of radiation with a straight receiving slit and corrections for preferred orientation. The structural parameters include the positions, types, and occupancies of the atoms in the structural model and isotropic or anisotropic thermal parameters (Debye-Waller factors). The power of the Rietveld method lies in simultaneous refinement of both profile and atomic parameters, thereby maximizing the amount of information obtained from the powder data.

The analysis of x-ray powder diffraction data can be divided into a number of separate steps. While some of these steps rely on the correct completion of the previous one(s), they generally constitute independent tasks to be completed by the experimenter. Depending on the issues to be addressed by any particular experiment, one, several, or all of these tasks will be encountered, usually in the order in which they are described here.

Crystal Lattice and Space Group Determination from X-Ray Powder Data

Obtaining the lattice parameters (unit cell) of an unknown material is always the first step on the path to a structure solution. While predicting the scattering angles of a set of diffraction peaks given the unit cell is trivial, the inverse task is not, because the powder method reduces the three-dimensional atomic distribution in real space to a one-dimensional diffraction pattern in momentum space. In all but the simplest cases, a computer is required and a variety of programs are available for the task. They generally fall into two categories: those that attempt to find a suitable unit cell by trial and error (also often called the "semiexhaustive" method) and those that use an analytical approach based on the geometry of the reciprocal lattice. Descriptions of these approaches can be found below [see Key References, particularly Bish and Post (1989, pp. 188–196) and Klug and Alexander (1974, Section 6)]. Some widely used auto-indexing programs are TREOR (Werner et al., 1985), ITO (Visser, 1969), and DICVOL (Boultif and Louër, 1991). All of these programs take either a series of peak positions or corresponding d spacings as input, and their accuracy is crucial for this step to succeed. The programs may tolerate reasonably small random errors in the peak position; however, even a small systematic error will prevent them from finding the correct (or any) solution. Hence, the data set used to extract peak positions must be checked carefully for systematic errors such as the diffractometer zero point, for example, by looking at pairs of Bragg peaks whose values of $\sin\theta$ are related by integer multiples.

Once the unit cell is known, the space group can be determined from systematic absences of Bragg peaks, i.e., Bragg peaks allowed by the unit cell but not observed in the actual spectrum. For example, the observed spectrum of a face-centered-cubic (fcc) material contains only Bragg peaks (hkl) for which h, k, and l are either all odd or all even. Tables listing possible systematic absences for each crystal symmetry class and correlating them with space groups can be found in the International Tables for Crystallography (Vos and Buerger, 1996).

Extracting Integrated Intensities of Bragg Peaks

The extraction of accurate integrated intensities of Bragg peaks is a prerequisite for several other steps in x-ray powder diffraction data analysis. However, the fraction of peaks in the observed spectrum that can be individually fitted is usually very small. The problem of peak overlap is partially overcome in the Rietveld method by describing the shapes of all Bragg peaks observed in the x-ray powder pattern by a small number of profile parameters. It is then possible to perform a refinement of the powder pattern without any atomic model using (and refining) only the lattice and profile parameters to describe the position and shape of all Bragg peaks and letting the intensity of each peak vary freely; two variations are referred to as the Pawley (1981) and LeBail (1988) methods. While this does not solve the problem of exact peak overlap [e.g., of the cubic (511) and (333) peaks], it is very powerful in separately determining the intensities of clustered, partially overlapping peaks. The integrated intensities of individual peaks that can be determined in this manner usually constitute a significant fraction of the total number of allowed Bragg peaks, and they can then be used as input to search for candidate atom positions. Many Rietveld programs (see The Final Rietveld Refinement, below) feature an intensity extraction mode that can be used for this task. The resulting fit can also serve as an upper bound for the achievable goodness of fit in the final Rietveld refinement. EXTRA (Altomare et al., 1995) is another intensity extraction routine that interfaces directly with SIRPOW.92 (see Search for Candidate Atom Positions, below), a program that utilizes direct methods. The program EXPO consists of both the EXTRA and SIRPOW.92 modules.

Search for Candidate Atom Positions

When a suitable starting model for a crystal structure is not known and cannot easily be guessed, it must be determined from the x-ray powder data before any Rietveld refinements can be performed. The Fourier transform of the distribution of electrons in a crystal is the x-ray scattering amplitude. However, only the scattering intensity can be measured, and hence all phase information is lost. Nevertheless, the Fourier transform of the intensities can be useful in finding some of the atoms in the unit cell. A plot of the Fourier transform of the measured scattering intensities is called a Patterson map, and its peaks correspond to translation vectors between pairs of atoms in the unit cell. Obviously, the strongest peak will be at the origin, and depending on the crystal structure, it may be anywhere from simple to impossible to deduce atom positions from a Patterson map. Cases where there is one (or few) relatively heavy atom(s) in the unit cell are most favorable for this approach. Similarly, if the positions of most of the atoms in the unit cell (or at least of the heavy atoms) are already known, it may be reasonable to guess that the phases are dominated by the known part of the atomic structure. Then the differences between the measured intensities and those calculated from the known atoms together with the phase information calculated from the known atoms can be used to obtain a difference Fourier map that, if successful, will indicate the positions of the

remaining atoms. The ability to calculate and plot Patterson and Fourier maps is included in common Rietveld packages (see below).

Another approach to finding atom candidate positions is the use of direct methods originally developed (and widely used) for the solution of crystal structures from single-crystal x-ray data. A mathematical description is beyond the scope of this unit; the reader is referred to the literature (e.g., Giacovazzo, 1992, pp. 335–365). In direct methods, an attempt is made to derive the phase of the structure factor directly from the observed amplitudes through mathematical relationships. This is feasible because the electron density function is positive everywhere and consists of discrete atoms. These two properties, "positivity" and "atomicity," are then used to establish likely relationships between the phases of certain groups of Bragg peaks. If the intensities of enough such groups of Bragg peaks have been measured accurately, this method yields the positions of some or all the atoms in the unit cell. The program SIRPOW.92 (Altomare et al., 1994) is an adaptation of direct methods to x-ray powder diffraction data and has been used to solve a number of organic and organometallic crystal structures from such data.

We emphasize that these procedures are not straightforward, and even for experienced researchers, success is far from guaranteed. However, the chance of success increases appreciably with the quality of the data, in particular with the resolution of the x-ray powder pattern.

The Final Rietveld Refinement

Once a suitable starting model is found, the Rietveld method allows the simultaneous refinement of structural parameters such as atomic positions, site occupancies, isotropic or anisotropic Debye-Waller factors, along with lattice and profile parameters, against the observed x-ray powder diffraction pattern. Since the refinement is usually performed using a least-squares algorithm [chi-square (χ^2) minimization], the result will be a local minimum close to the set of starting parameters. It is the responsibility of the experimenter to confirm that this is the global minimum, i.e., that the model is in fact correct. There are criteria based on the goodness-of-fit of the final refinement that, if they are not fulfilled, almost certainly indicate a wrong solution. However, such criteria are not sufficient in establishing the correctness of a model. For example, if an inspection of the final fit shows that a relatively small amount of total residual error is noticeably concentrated in a few peaks rather than being distributed evenly over the entire spectrum, that may be an indication that the model is incorrect. More details on this subject are given in the International Tables for Crystallography (Prince and Spiegelmann, 1992) and in Young (1993) and Bish and Post (1989).

A number of frequently updated Rietveld refinement program packages are available that can be run on various platforms, most of which are distant descendants of the original program by Rietveld (1969). Packages commonly in use today and freely distributed for noncommercial use by their authors include—among several—GSAS (Larson and Von Dreele, 1994) and FULLPROF (Rodriguez-Carvajal, 1990). Notably, both include the latest descriptions of the x-ray powder diffraction peak shape functions (Thompson et al., 1987), analytical descriptions of the peak shape asymmetry at low angles (Finger et al., 1994), and an elementary description for anisotropic strain broadening for different crystal symmetries (Stephens, 1999). Both programs contain comprehensive documentation, which is no substitute for the key references discussing the Rietveld method (Young, 1993; Bish and Post, 1989).

Estimated Standard Deviations in Rietveld Refinements

The assignment of estimated standard deviations (ESDs) of the atomic parameters obtained from Rietveld refinements is a delicate matter. In general, the ESDs calculated by the Rietveld program are measures of the precision (statistical variation between equivalent experiments) rather than the accuracy (discrepancy from the correct value) of any given parameter. The latter cannot, in principle, be determined experimentally, since the "truly" correct model describing experimental data remains unknown. However, it is the accuracy that the experimenter is interested in, and it is desired to make the best possible estimate of it, based both on statistical considerations and the experience and judgment of the experimenter.

The Rietveld program considers each data point of the measured powder pattern to be an independent measurement of the Bragg peak(s) contributing to it. This implicit assumption holds only if the difference between the refined profile and the experimental data is from counting statistics alone (i.e., if $\chi^2 = 1$ and the points of the difference curve form a random, uncorrelated distribution with center 0 and variance N). However, this is not true for real experiments in which the dominant contributions to the difference curve are an imperfect description of the peak shapes and/or an imperfect atomic model. Consequently, accepting the precision of any refined parameter as a measure of its accuracy cannot be justified and would usually be unreasonably optimistic.

A number of corrections to the Rietveld ESDs have been proposed, and even though all are empirical in nature and there is no statistical justification for these procedures, they can be very valuable in order to obtain estimates. If one or more extra parameters are introduced into a model, the fit to the data will invariably improve. The F statistic can be used to determine the likelihood that this improvement represents additional information (i.e., is statistically significant) and is not purely by chance (Prince and Spiegelmann, 1992). This can also be used to determine how far any given parameter must be shifted away from its ideal value in order to make a statistically significant difference in the goodness of fit. This can be used as an estimate of the accuracy of that parameter that is independent of its precision as calculated by the Rietveld program. There exists no rigid rule on whether precision or accuracy should be quoted when presenting results obtained from x-ray powder diffraction; it certainly depends on the motivation and outcome of the experiment. However, it is very important to distinguish between the two. We note that

the International Union of Crystallography has sponsored a Rietveld refinement round robin, during which identical samples of ZrO_2 were measured and Rietveld refined by 51 participants (Hill and Cranswick, 1994), giving an empirical indication of the achievable accuracy from the technique.

Quantitative Phase Analysis

Quantitative phase analysis refers to the important technique of determining the amount of various crystalline phases in a mixture. It can be performed in two ways, based on the intensities of selected peaks or on a multiphase Rietveld refinement.

In the first case, suppose that the sample is a flat plate that is optically thick to x rays. In a mixture of two phases with mass absorption coefficients μ_1^* and μ_2^* (cm^2/g), the intensity of a given peak from phase 1 will be reduced from its value for a pure sample of phase 1 by the ratio

$$\frac{I_1(x_1)}{I_1(\text{pure})} = \frac{x_1\mu_1^*}{x_1\mu_1^* + (1-x_1)\mu_2^*} \tag{4}$$

where x_1 is the weight fraction of phase 1. Note that the intensity is affected both by dilution and by the change of the sample's absorption constant. When the absorption coefficients are not known, they can be determined from experimental measurements, such as by "spiking" the mixture with an additional amount of one of its constituents. Details are given in Klug and Alexander (1974) and Bish and Post (1989).

If the atomic structures of the constituents are known, a multiphase Rietveld refinement (see above) directly yields scale factors s_j for each phase. The weight fraction w_j of the jth phase can then be calculated by

$$w_j = \frac{s_j Z_j m_j V_j}{\sum_i s_i Z_i m_i V_i} \tag{5}$$

where Z_j is the number of formula units per unit cell, m_j is the mass of a formula unit, and V_j is the unit cell volume.

In either case, the expressions above are given under the assumption that the powders are sufficiently fine, i.e., the product of the linear absorption coefficient μ (cm^{-1}, equal to $\mu^*\rho$) and the linear particle (not sample) size D is small ($\mu D < 0.01$). If not, one must make allowance for microabsorption, as described by Brindley (1945).

It is worth noting that the sensitivity of an x-ray powder diffraction experiment to weak peaks originating from trace phases is governed by the signal-to-background ratio. Hence, in order to obtain maximum sensitivity, it is desirable to reduce the relative background as much as possible.

SAMPLE PREPARATION

The preparation of samples to avoid unwanted artifacts is an important consideration in powder diffraction experiments. One issue is that preferred orientation (texture) should be avoided or controlled. The grains of a sample may tend to align, especially if they have a needle or platelike morphology, so that reflections in certain directions are enhanced relative to others. Various measures such as mixing the powder with a binder or an inert material chosen to randomize the grains or pouring the sample sideways into the flat plate sample holder are in common use. [More details are given in, e.g., Klug and Alexander (1974), Bish and Post (1989), and Jenkins and Snyder (1996).] It is also possible to correct experimental data if one can model the distribution of crystallite orientations; this option is available in most common Rietveld programs (see The Final Rietveld Refinement, above).

A related issue is that there must be a sufficient number of individual grains participating in the diffraction measurement to ensure a valid statistical sample. It may be necessary to grind and sieve the sample, especially in the case of strongly absorbing materials. However, grinding can introduce strain broadening into the pattern, and some experimentation is usually necessary to find the optimum means of preparing a sample. A useful test of whether a specimen in a diffractometer is sufficiently powdered is to scan the sample angle θ over several degrees while leaving 2θ fixed at the value of a strong Bragg peak, in steps of perhaps 0.01°; fluctuations of more than a few percent indicate trouble. It is good practice to rock (flat plate) or twirl (capillary) the sample during data collection to increase the number of observed grains.

PROBLEMS

X rays are absorbed by any material through which they pass, and so the effective volume is generally not equal to the actual volume of the sample. Absorption constants are typically tabulated as the mass absorption coefficient μ/ρ (cm^2/g), which makes it easy to work out the attenuation length in a sample as a function of its composition. A plot of the absorption lengths (in micrometers) of some "typical" samples vs. x-ray energy/wavelength is given in Figure 2. To determine the relative intensities of different

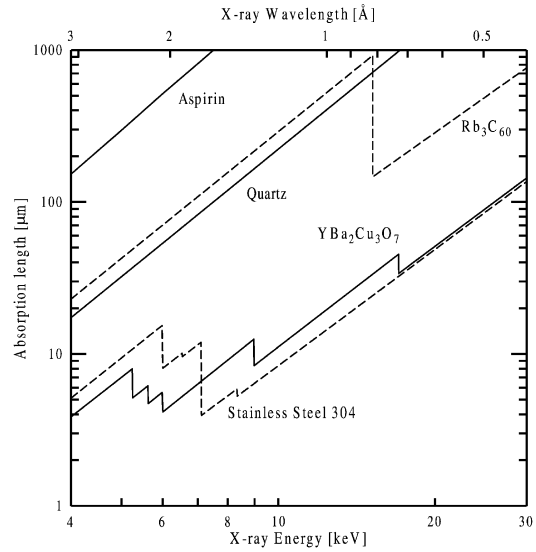

Figure 2. Calculated absorption lengths for several materials as a function of x-ray wavelength or energy.

peaks, it is important to either arrange for the effective volume to be constant or be able to make a quantitative correction. If the sample is a flat plate in symmetrical geometry, as illustrated in Figure 1B, the effective volume is independent of diffraction angle as long as the beam does not spill over the edge of the sample. If the sample is a cylinder and the absorption constant is known, the angle-dependent attenuation constant is tabulated, e.g., in the International Tables for Crystallography (Maslen, 1992). It is also important to ensure that the slits and other optical components of the diffractometer are properly aligned so that the variation of illuminated sample volume with 2θ is well controlled and understood by the experimenter.

Inasmuch as a powder diffraction experiment consists of "simply" measuring the diffracted intensity as a function of angle, one can classify sources of systematic error as arising from measurement of the intensity or the angle or from the underlying assumptions. Errors of intensity can arise from detector saturation, drift or fluctuations of the strength of the x-ray source, and the statistical fluctuations intrinsic to counting the random arrival of photons.

Error of the angle can arise from mechanical faults or instability of the instrument or from displacement of the sample from the axis of the diffractometer (parallax). A subtle form of parallax can occur for flat-plate samples that are moderately transparent to x rays, because the origin of the diffracted radiation is located below the surface of the sample by a distance that depends on the diffraction angle. Another effect that can give rise to an apparent shift of diffraction peaks is the asymmetry caused by the intersection of the curved Debye-Scherrer cone of radiation with a straight receiving slit. This geometric effect has been discussed by several authors (Finger et al., 1994, and references therein), and it can produce a significant shift in the apparent position of low-angle peaks if fitted with a model lineshape that does not properly account for it. A potential source of angle errors in very high precision work is the refraction of x rays; to an x ray, most of the electrons of a solid appear free, and if their number density is n, the index of refraction is given by

$$1 - \left(\frac{e^2}{mc^2}\right)\frac{n\lambda^2}{2\pi} \qquad (6)$$

so that the observed Bragg angle is slightly shifted from its value inside the sample.

The interpretation of powder intensities is based on a number of assumptions that may or may not correspond to experimental reality in any given case.

The integrated intensity is proportional to the square of the structure factor only if the diffracted radiation is sufficiently weak that it does not remove a significant fraction of the incident beam. If the individual grains of the powder sample are too large, strong reflections will be effectively weakened by this "extinction" effect. The basic phenomenon is described in any standard crystallography text, and a treatment specific to powder diffraction is given by Sabine (1993). This can be an issue for grains larger than $\sim$1 μm, which is well below the size that can be easily guaranteed by passing the sample through a sieve. Consequently, it is not easy to assure *a priori* that extinction is not a problem. One might be suspicious of an extinction effect if a refinement shows that the strongest peaks are weaker than predicted by a model that is otherwise satisfactory.

To satisfy the basic premise of powder diffraction, there must be enough grains in the effective volume to produce a statistical sample. This may be a particularly serious issue in highly absorbing materials, for which only a small number of grains at the surface of the sample participate. One can test for this possibility by measuring the intensity of a strong reflection at constant 2θ as a function of sample rotation; if the intensity fluctuates by more than a few percent, it is likely that there is an insufficient number of grains in the sample. One can partly overcome this problem by moving the sample during the measurement to increase the number of grains sampled. A capillary sample can be spun around its axis, while a flat plate can be rocked by a few degrees about the dividing position or rotated about its normal (or both) to achieve this aim.

If the grains of a powder sample are not randomly oriented, it will distort the powder diffraction pattern by making the peaks in certain directions stronger or weaker than they would be in the ideal case. This arises most frequently if the crystallites have a needle- or platelike morphology. [Sample preparation procedures to control this effect are described in, e.g., Klug and Alexander (1974), Bish and Post (1989), and Jenkins and Snyder (1996).] It is also possible to correct experimental data if one can model the distribution of crystallite orientations.

There are a number of standard samples that are useful for verifying and monitoring instrument performance and as internal standards. The National Institute of Standards and Technology sells several materials, such as SRM 640 (Silicon Powder), SRM 660 (LaB_6, which has exceedingly sharp lines), SRM 674a (a set of five metal oxides of various absorption lengths, useful for quantitative analysis standards), and SRM 1976 (corundum Al_2O_3 plate, with somewhat sharper peaks than the same compound in SRM 674a and certified relative intensities). Silver behenate powder has been proposed as a useful standard with a very large lattice spacing of $c = 58.4$ Å (Blanton et al., 1995).

EXAMPLES

Comparison Against a Database of Known Materials

An ongoing investigation of novel carbon materials yielded a series of samples with new and potentially interesting properties: (1) the strongest signal in a mass spectrometer was shown to correspond to the equivalent of an integer number of carbon atoms, (2) electron diffraction indicated that the samples were at least partially crystalline, and (3) while the material was predicted to consist entirely of carbon, the procedures for synthesis and purification had involved an organic Li compound. The top half of Figure 3 shows an x-ray powder diffraction pattern of one such sample recorded at $\lambda = 0.7$ Å at beamline X3B1 of the National Synchrotron Light Source. The peak positions can be indexed (Werner et al., 1985) to a monoclinic unit cell: $a = 8.36$ Å, $b = 4.97$ Å, $c = 6.19$ Å, and $\beta = 114.7°$.

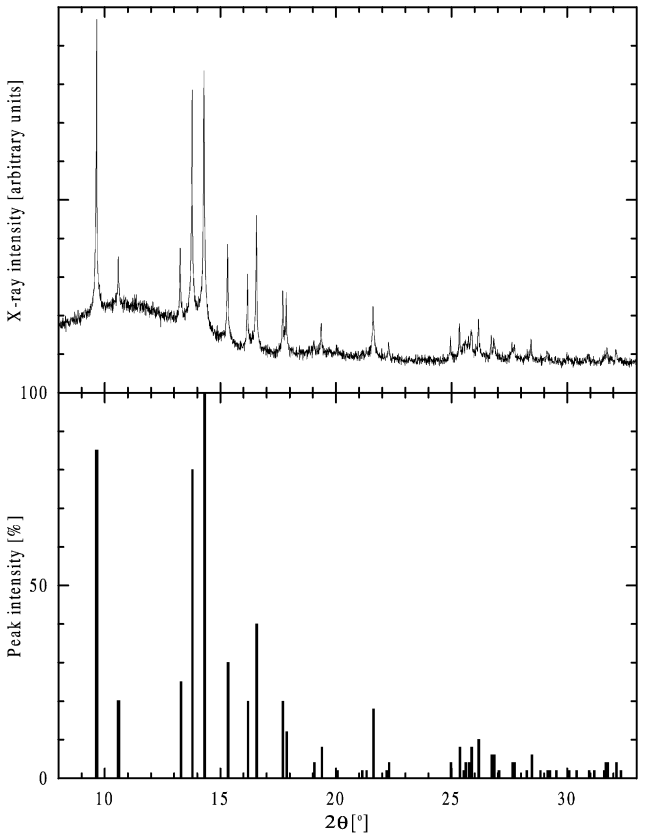

Figure 3. X-ray powder diffraction pattern of "unknown" sample (top) and relative peak intensities of Li_2O_3 as listed in the PDF database (bottom), both at $\lambda = 0.7$ Å.

The Powder Diffraction File (PDF) database provided by the International Center for Diffraction Data (ICDD, 1998) allows for searching based on several search criteria, including types of atoms, positions of Bragg peaks, or unit cell parameters. Note that it is not necessary to know the unit cell of a compound to search the database against its diffraction pattern, nor is it necessary to know the crystal structures (or even the unit cells) of all the compounds included in the database.

Searches for materials with an appropriate position of their strong diffraction peaks containing C only, or containing some or all of C, N, O, or H, did not result in any candidate materials. However, including Li in the list of possible atoms matched the measured pattern with the one in the database for synthetic Li_2CO_3 (zabuyelite). The peak intensities listed in the database, converted to 2θ for the appropriate wavelength, are shown in the bottom half of Figure 3, leading to the conclusion that the only crystalline fraction of the candidate sample is Li_2CO_3, not a new carbon material.

This type of experiment is fairly simple, and both data collection and analysis can be performed quickly. Average sample quality is sufficient, and usually so are relatively low-resolution data from an x-ray tube. In fact, this test is routinely performed before any attempt to solve the structure of an unknown and presumably new material.

Quantitative Phase Analysis

The qualitative and quantitative detection of small traces of polymorphs plays a major role in pharmacology, since many relevant molecules form two or more different crystal structures, and phase purity rather than chemical purity is required for scientific, regulatory, and patent-related legal reasons. Mixtures of the α and γ phases of the anti-inflammatory drug indomethacin ($C_{19}H_{16}ClNO_4$) provide a good example for the detection limit of x-ray powder diffraction experiments in this case (Dinnebier et al., 1996).

Mixtures of 10, 1, 0.1, 0.01, and 0 wt% α phase (with the balance γ phase) were investigated. Using its five strongest Bragg peaks, 0.1% α phase can easily be detected, and the fact that the "pure" γ phase from which the mixtures were prepared contains traces of α became evident, making the quantification of the detection limits below 0.1% difficult. Figure 4 shows the strong (120) peak of the α phase and the weak (010) peak (0.15% intensity of its strongest peak) of the γ phase for three different concentrations of the α phase.

While these experiments and the accompanying data analysis are not difficult to perform per se, it is probably necessary to have access to a synchrotron radiation source with its high resolution to obtain detection limits comparable to or even close to the values mentioned. The data of this example were collected on beamline X3B1 of the National Synchrotron Light Source.

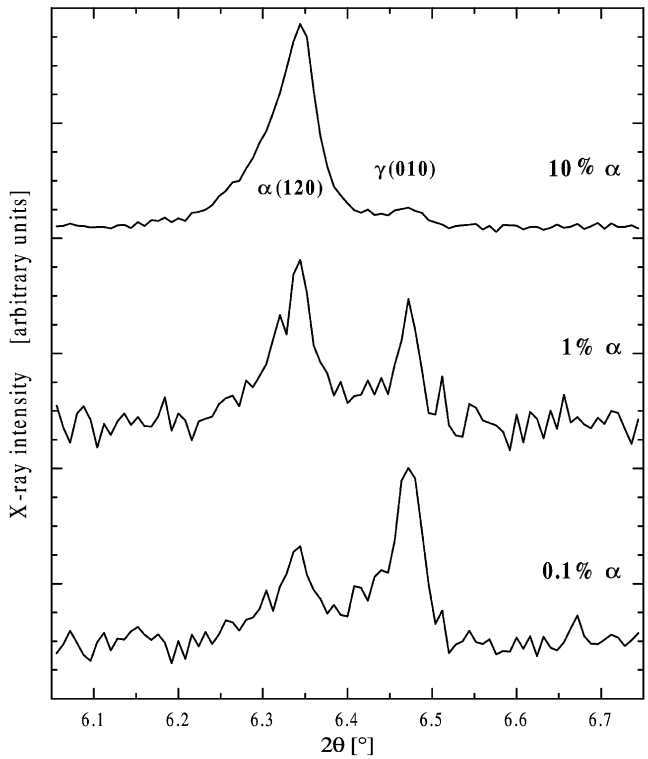

Figure 4. Strong (120) peak of the α phase and weak (010) peak of the γ phase of the drug indomethacin for different concentrations of α phase.

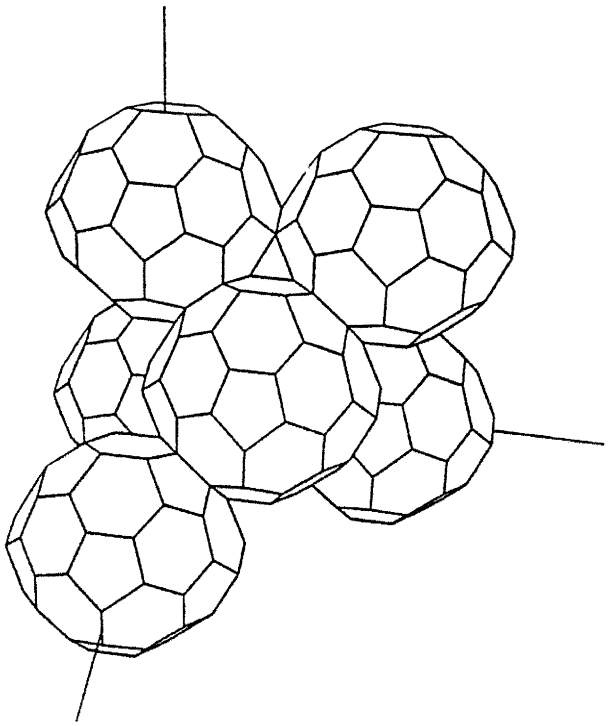

Figure 5 Atomic clusters R(Al-Li-Cu) exhibiting nearly icosahedral symmetry.

Structure Determination in a Known Analog

The icosahedral quasicrystal phase *i*(Al-Li-Cu) is close to a crystalline phase, *R*(Al-Li-Cu), which has a very similar local structure, making the crystal structure of the latter an interesting possible basis for the structure of the former. The crystal symmetry [body-centered-cubic (bcc)], lattice parameter ($a = 13.89$ Å), space group ($Im\bar{3}$), and composition ($Al_{5.6}Li_{2.9}Cu$) suggest that the crystal structure of *R*(Al-Li-Cu) is similar to that of $Mg_{32}(Zn, Al)_{49}$ (Bergman et al., 1952, 1957). However, using the atomic parameters of the latter compound does not give a satisfactory fit to the data of the former. On the other hand, a Rietveld analysis (see Data Analysis and Interpretation, above) using those parameters as starting values converges and gives a stable refinement of occupancies and atom positions (Guryan et al., 1988).

Such an experiment can be done with a standard laboratory x-ray source. This example was solved using Mo K_α radiation from a rotating-anode x-ray generator. Figure 5 shows the nearly icosahedral symmetry of the atomic clusters of which this material is comprised.

Ab Initio Structure Determination

The Kolbe-Schmitt reaction, which proceeds from sodium phenolate, C_6H_5ONa, is the starting point for the synthesis of many pigments, fertilizers, and pharmaceuticals such as aspirin. However, replacing Na with heavier alkalis thwarts the reaction, a fact known since 1874 yet not understood to date. This provides motivation for the solution of the crystal structure of potassium phenolate, C_6H_5OK (Dinnebier et al., 1997).

A high-resolution x-ray powder diffraction pattern of a sample of C_6H_5OK was measured at room temperature, $\lambda = 1.15$ Å, and $2\theta = 5°-65°$ with step size 0.005° for a total counting time of 20 hr on beamline X3B1 of the National Synchrotron Light Source. Low-angle diffraction peaks had a FWHM of 0.013°. Following are the steps that were necessary to obtain the structure solution of this compound.

The powder pattern was indexed (Visser, 1969) to an orthorhombic unit cell, $a = 14.10$ Å, $b = 17.91$ Å, and $c = 7.16$ Å. Observed systematic absences of Bragg peaks, e.g., of all ($h0l$) peaks with h odd, were used to determine the space group, $Pna2_1$ (Vos and Buerger, 1996), and the number of formula units per unit cell ($Z = 12$) was determined from geometrical considerations.

Next, using the LeBail technique (Le Bail et al., 1988), i.e., fitting the powder pattern to lattice and profile parameters without any structural model, ~300 Bragg peak intensities were extracted. Using these as input for the direct-methods program SIRPOW.92 (Altomare et al., 1994), it was possible to deduce the positions of potassium and some candidate oxygen atoms but none of the carbon atoms. In the next stage, the positions of the centers of the phenyl rings were searched by replacing them with diffuse pseudoatoms having the same number of electrons but a high temperature factor. After Rietveld refining this model (see Data Analysis and Interpretation, above) one pseudoatom at a time was back substituted for the corresponding phenyl ring, and the orientation of each phenyl ring was found via a grid search of all of its possible orientations. Upon completion of this procedure, the coordinates of all nonhydrogen atoms had been obtained.

The final Rietveld refinement (see Data Analysis and Interpretation) was performed using the program GSAS (Larson and Von Dreele, 1994), the hydrogen atoms were included, and the model remained stable when all structural parameters were refined simultaneously. Figure 6 shows a plot of the final refinement of C_6H_5OK, and Figure 7 shows the crystal structure obtained.

This example illustrates the power of high-resolution x-ray powder diffraction for the solution of rather complicated crystal structures. There are 24 nonhydrogen atoms in the asymmetric unit, which until recently would have been impossible to solve without the availability of a single crystal. At the same time, it is worth emphasizing that such an *ab initio* structure solution from x-ray powder diffraction requires both a sample of extremely high quality and an instrument with very high resolution. By comparison, it was not possible to obtain the crystal structure of C_6H_5OLi from a data set with approximately 3 times fewer independently observed peaks due to poorer crystallinity of the sample. Even with a sample and data of sufficient quality, solving a structure *ab initio* from a powder sample (unlike the single-crystal case) requires experience and a significant investment of time and effort on the part of the researcher.

Time-Resolved X-Ray Powder Diffraction

Zeolites are widely used in a number of applications, for example, as catalysts and for gas separations. Their

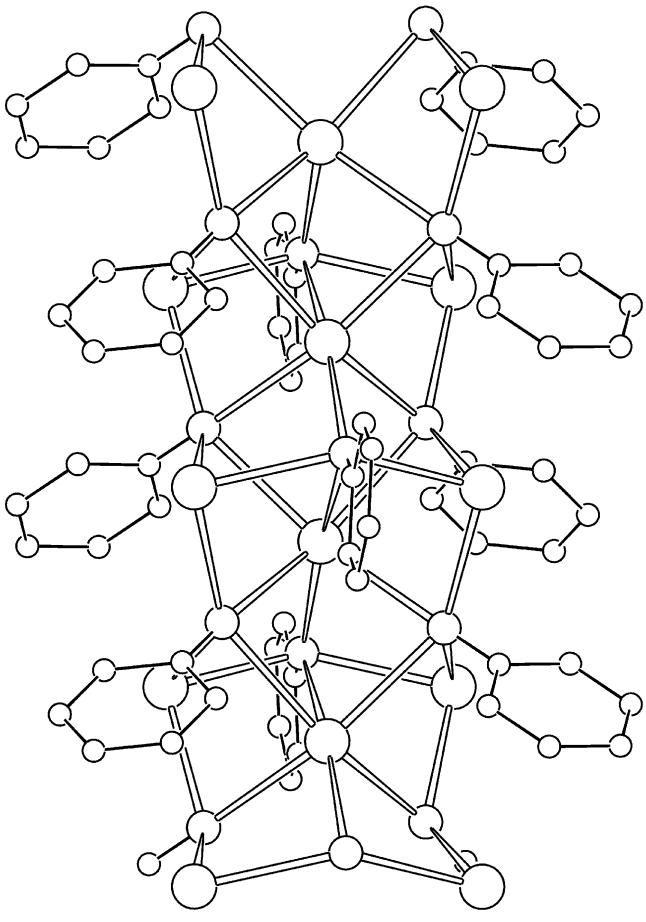

Figure 7. Crystal structure of potassium phenolate, C_6H_5OK, solved *ab initio* from x-ray powder diffraction data.

structural properties, particularly the location of the extra-framework cations, are important in understanding their role in these processes.

Samples of CsY zeolite dehydrated at 300° and at 500°C show differences in their diffraction patterns (Fig. 8). Rietveld analysis (see Data Analysis and Interpretation, above) shows that the changes occur in the extra-framework cations. The basic framework contains large so-called supercages and smaller sodalite cages, and in dehydration at 300°C, almost all of the Cs cations occupy the supercages while the Na cations occupy the sodalite cages. However, after dehydration at 500°C, a fraction of both Cs and Na ions will populate each other's cage position, resulting in mixed occupancy for both sites (Poshni et al., 1997; Norby et al., 1998).

To observe this transition while it occurs, the subtle changes in the CsY zeolite structure were followed by *in situ* dehydration under vacuum. The sample, loosely packed in a 0.7-mm quartz capillary, was ramped to a final temperature of 500°C over a period of 8 hr. Figure 9 shows the evolution of the diffraction pattern as a function of time during the dehydration process (Poshni et al., 1997). The data were collected at beamline X7B of the National Synchrotron Light Source with a translating image plate data collection stage.

To investigate phase transitions and solid-state reactions in near real time by recording x-ray powder diffraction patterns as a function of time, pressure, and/or temperature, a number of conditions must be met. For data collection, a position-sensitive detector or a translating image plate stage is required. Also, since there can be no collimator slits or analyzer crystal between the sample and the detector/image plate, such an experiment is optimally carried out at a synchrotron radiation source. These have an extremely low vertical divergence, allowing for a reasonably good angular resolution in this detector

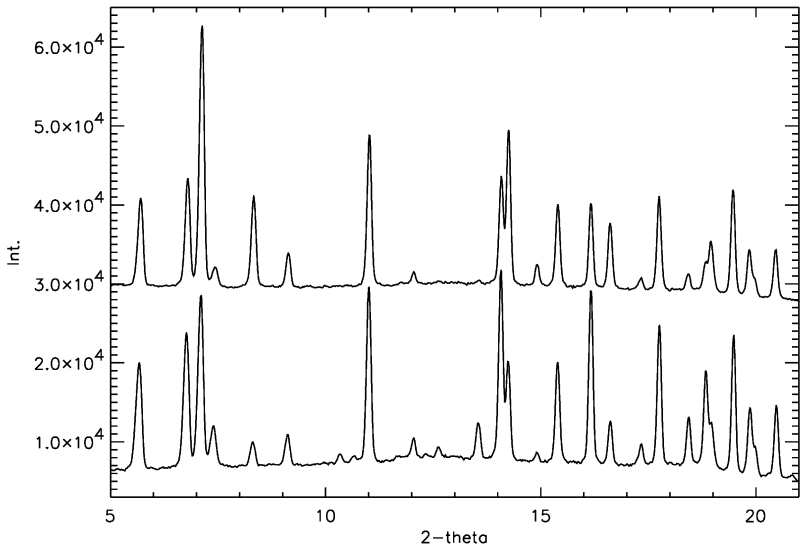

Figure 8. X-ray powder diffraction patterns of CsY zeolite dehydrated at 500°C (top) and 300°C (bottom).

geometry. The sample environment must be designed with care in order to provide, e.g., the desired control of pressure, temperature, and chemical environment compatible with appropriate x-ray access and low background. Examples include a cryostat with a Be can, a sample heater, a diamond-anvil pressure apparatus, and a setup that allows a chemical reaction to take place inside the capillary.

Determination of Subtle Structural Details

The superconductor Rb_3C_{60} has $T_c \approx 30$ K. The fullerenes form an fcc lattice, and of the three Rb^+ cations, one occupies the large octahedral (O) site at ($\frac{1}{2}$, 0, 0) and the remaining two occupy the small tetrahedral (T) sites at ($\frac{1}{4}$, $\frac{1}{4}$, $\frac{1}{4}$). The size mismatch between the smaller Rb^+ ions and the larger octahedral site led to the suggestion that the Rb^+ cations in the large octahedral site could be displaced from the site center, supported by some nuclear magnetic resonance (NMR) and extended x-ray absorption fine structure (EXAFS) experiments (see XAFS Spectroscopy). If true, such a displacement would have a significant impact on the electronic and superconductin properties. By comparison, the Rb−C distances of the Rb^+ cation in the tetrahedral site are consistent with ionic radii.

In principle, a single x-ray pattern cannot distinguish between static displacement of an atom from its site center (as proposed for this system) and dynamic thermal fluctuation about a site (as described by a Debye-Waller factor). Hence, to address this issue, an x-ray powder diffraction study of Rb_3C_{60} at various temperatures was carried out at beamline X3B1 of the National Synchrotron Light Source (Bendele et al., 1998).

At each temperature the data were Rietveld refined (see Data Analysis and Interpretation, above) against two competing (and otherwise identical) structural models: (1) The octahedral Rb^+ cation is fixed at ($\frac{1}{2}$, 0, 0) and its isotropic

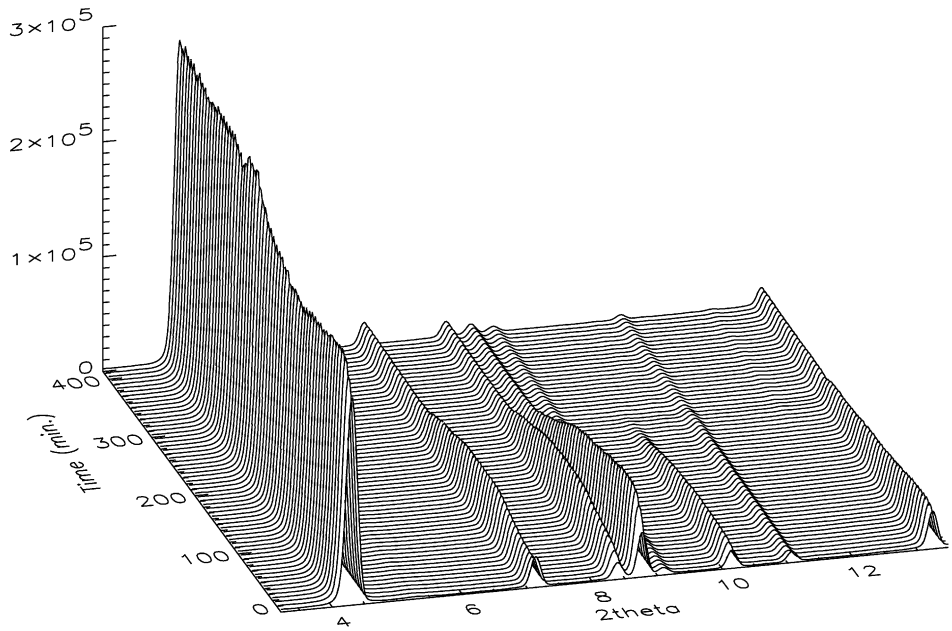

Figure 9. Evolution of the diffraction pattern during the *in situ* dehydration of CsY zeolite.

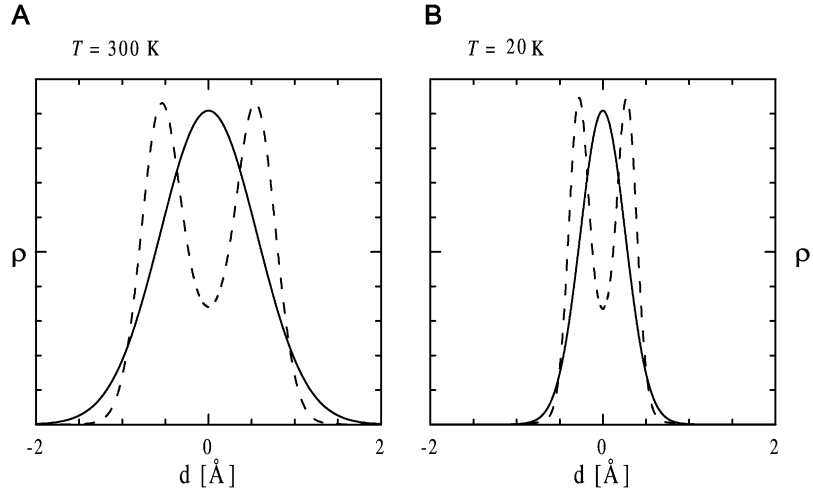

Figure 10. Electron distributions obtained from x-ray powder diffraction data in the octahedral site of Rb_3C_{60} for $T = 300$ K (**A**) and $T = 20$ K (**B**).

Debye-Waller factor B_o is refined and (2) the octahedral Rb^+ cation is shifted an increasing distance ε away from ($\frac{1}{2}$, 0, 0) until the refined B_o becomes comparable to the temperature factor of the tetrahedral ion, B_t. In each case, both models result in an identical goodness of fit, and the direction of the assumed displacement ε has no effect whatsoever. Figure 10 shows the electron distributions in the octahedral site for both models (in each case convoluted with the appropriate Debye-Waller factor). While the width of this distribution (static or dynamic) is 1.32 Å at room temperature, it has decreased to 0.56 Å upon cooling the sample to $T = 20$ K.

If the octahedral Rb^+ cations were truly displaced away from their site center (either at all temperatures or below some transition temperature T_{tr}), the amount of that displacement would act as an order parameter, i.e., increase or saturate with lower temperature and not decrease monotonically to zero as the data show it does. Hence, any off-center displacement of the octahedral Rb^+ cations can be excluded from this x-ray powder diffraction experiment. Consequently, other possible causes for the features seen in NMR and EXAFS experiments that had given rise to this suggestion must be researched. For such an experiment to be valid and successful, it must be possible to put very tight limits on the accuracy of the measured structural parameters. This requires that two conditions are met. First, the sample must have the highest possible quality, in terms of both purity and crystallinity, and the data must have both high resolution and very good counting statistic. Second, the accuracy for each measured parameter must be judged carefully, which is not trivial in x-ray powder diffraction. Note, in particular, the discussion under Estimated Standard Deviations in Rietveld Refinements, above.

SINGLE-CRYSTAL X-RAY STRUCTURE DETERMINATION

INTRODUCTION

X-ray techniques provide one of the most powerful, if not the most powerful, methods for deducing the crystal and molecular structure of a crystalline solid. In general, it is a technique that provides a large number of observations for every parameter to be determined and results obtained thereby can usually be considered very reliable. Significant advances have taken place, especially over the last twenty years, to make the collection of data and the subsequent steps to carry out the rest of the structure determination amenable to the relative novice in the field. This has led to the adoption of single-crystal diffraction methods as a standard analytical tool. It is no accident that this has paralleled the development of the digital computer—modern crystallography is strongly dependent on the use of the digital computer. Typically, a small single crystal (a few tenths of a millimeter in dimension) of the material to be investigated is placed on a diffractometer and data are collected under computer-controlled operation. A moderate-sized unit cell (10 to 20 Å on edge) can yield 5000 or so diffraction maxima, which might require a few day's data collection time on a scintillation counter diffractometer or only hours of data collection time on the newer charge-coupled device (CCD) area detectors.

From these data the fractional coordinates describing the positions of the atoms within the cell, some characteristics of their thermal motion, the cell dimensions, the crystal system, the space group symmetry, the number of formula units per cell, and a calculated density can be obtained. This "solving of the structure" may only take a few additional hours or a day or two if no undue complications occur.

We will concentrate here on the use of X-ray diffraction techniques as would be necessary for the normal crystal structure investigation. A discussion of the basic principles of single-crystal X-ray diffraction will be presented first, followed by a discussion of the practical applications of these techniques. In the course of this discussion, a few of the more widely used methods of overcoming the lack of measured phases, i.e., the "phase problem" in crystallography, will be presented. These methods are usually sufficient to handle most routine crystal structure determinations. Space will not permit discussion of other more specialized techniques that are available and can be used when standard methods fail. The reader may wish to refer to other books devoted to this subject (e.g., Ladd and Palmer, 1985; Stout and Jensen, 1989; Lipscomb and Jacobson, 1990) for further information on these other techniques and for a more in-depth discussion of diffraction methods.

Competitive and Related Techniques

Single-crystal X-ray diffraction is certainly not the only technique available to the investigator for the determination of the structure of materials. Many other techniques can provide information that is often complementary to that obtained from single-crystal X-ray experiments. Some of these other techniques are briefly described below.

Crystalline powders also diffract X rays. In fact, it is convenient to view powder diffraction as single-crystal diffraction integrated over angular coordinates, thus retaining only sin θ dependence (assuming the powder contains crystallites in random orientation). Diffraction maxima with essentially the same sin θ values combine in the powder diffraction pattern. This results in fewer discrete observations and makes the unit cell determination and structure solution more difficult; this is especially true in lower symmetry cases. The fewer number of data points above background translates into larger standard deviations for the determined atomic parameters. Since the angular information is lost, obtaining an initial model is often quite difficult if nothing is known about the structure. Therefore, the majority of quantitative powder diffraction investigations are done in situations where an initial model can be obtained from a related structure; the calculated powder pattern is then fit to the observed one by adjusting the atomic parameters, the unit cell parameters, and the parameters that describe the peak shape of a single diffraction maximum. (This is usually termed Rietveld refinement; see X-RAY POWDER DIFFRACTION and NEUTRON POWDER DIFFRACTION) If an appropriate single crystal of the material could be obtained, single-crystal diffraction would be the preferred approach. Powder diffraction sometimes provides an alternate approach when only very small crystals can be obtained.

Neutrons also undergo diffraction when they pass through crystalline materials. In fact, the theoretical descriptions of X-ray and neutron diffraction are very similar, primarily differing in the atomic scattering factor used (see NEUTRON POWDER DIFFRACTION and SINGLE-CRYSTAL

NEUTRON DIFFRACTION). The principal interaction of X rays with matter is electronic, whereas with neutrons two interactions predominate—one is nuclear and the other is magnetic (Majkrzak et al., 1990). The interaction of the neutron with the nucleus varies with the isotope and typically does not show the larger variation seen with X rays, where the scattering is proportional to the atomic number. Therefore neutrons can be useful in distinguishing between atoms of neighboring atomic number or light atoms, especially hydrogen in the presence of heavy atoms. The neutron scattering factors for hydrogen and deuterium are also markedly different, which opens up a number of interesting possible structural studies, especially of organic and biological compounds. As noted above, neutrons are also sensitive to magnetic structure (see MAGNETIC NEUTRON SCATTERING). In fact, neutron scattering data constitute the most significant body of experimental evidence regarding long-range magnetic ordering in solids. In practice, with the neutron sources that are presently available, it is necessary to use a considerably larger sample for a neutron diffraction investigation than is necessary for an X-ray investigation. Single-crystal X-ray studies are usually carried out initially, followed by the single-crystal neutron investigation to obtain complementary information where sample preparation is not a problem. (It might be noted that for powder studies neutron diffraction can have some advantages over X-ray diffraction in terms of profile pattern fitting due to the Gaussian character of the neutron diffraction peaks and the enhanced intensities that can be obtained at higher sin θ values; see NEUTRON POWDER DIFFRACTION).

Electron diffraction can also provide useful structural information on materials. The mathematical description appropriate for the scattering of an electron by the potential of an atom has many similarities to the description used in discussing X-ray diffraction. Electrons, however, are scattered much more efficiently than either X rays or neutrons, so much so that electrons can penetrate only a few atomic layers in a solid and are likely to undergo multiple scattering events in the process. Hence, electron diffraction is most often applied to the study of surfaces (low-energy electron diffraction; LEED), in electron-microscopic studies of microcrystals, or in gas-phase diffraction studies.

X-ray absorption spectroscopy (EXAFS) (Heald and Tranquada, 1990) provides an additional technique that can be used to obtain structural information (see XAFS SPECTROSCOPY). At typical X-ray energies, absorption is a much more likely event than the scattering process that we associate with single-crystal diffraction. When an X-ray photon is absorbed by an electron in an atom, the electron is emitted with an energy of the X-ray photon minus the electron-binding energy. Thus some minimum photon energy is necessary, and the X-ray absorption spectrum shows sharp increases in absorption as the various electron-binding energies are crossed. These sharp steps are usually termed X-ray edges and have characteristic values for each element. Accurate measurements have revealed that there is structure near the edge. This fine structure is explained by modulations in the final state of the photoelectron that are caused by backscattering from the surrounding atoms. The advent of synchrotron X-ray sources has accelerated the use of EXAFS since they provide the higher intensities that are necessary to observe the fine structure. The local nature of EXAFS makes it particularly sensitive to small perturbations within the unit cell and can thus complement the information obtained in diffraction experiments. With EXAFS it is possible to focus in on a particular atom type, and changes can be monitored without determining the entire structure. It can be routinely performed on a wide variety of heavier elements. When long-range order does not exist, diffraction methods such as X-ray diffraction have less utility. EXAFS yields an averaged radial distribution function pertinent to the particular atom and can be applied to amorphous as well as crystalline materials. EXAFS can be considered as being complementary to single-crystal diffraction.

Solid-state nuclear magnetic resonance (Hendrichs and Hewitt, 1980) and Mössbauer spectroscopy (Berry, 1990; see MOSSBAUER SPECTROMETRY) can sometimes provide additional useful structural information, especially for non-single-crystal materials.

PRINCIPLES OF X-RAY CRYSTALLOGRAPHY

When a material is placed in an X-ray beam, the periodically varying electric field of the X-ray accelerates the electrons into periodic motion; each in turn emits an electromagnetic wave with a frequency essentially identical to that of the incident wave and with a definite phase relation to the source that we will take as identical to that of the incident wave. To the approximation usually employed, all electrons are assumed to scatter with the same amplitude and phase and to do so independently of all other electrons. (The energy of the X ray, approximately 20 keV for Mo Kα, is usually large in comparison with the binding energy of the electron, except for the inner electrons of the heavier atoms. It should be noted, however, that the anomalous behavior of first shell, or first- and second-shell electrons in heavy elements, can provide a useful technique for phase determination in some cases and has proven to be especially valuable in protein crystallography.)

Interference can occur from electrons occupying different spatial positions, providing the spatial difference is comparable to the wavelength being employed. Interference effects can occur within an atom, as is shown in Figure 1, where the variation of scattering with angle for

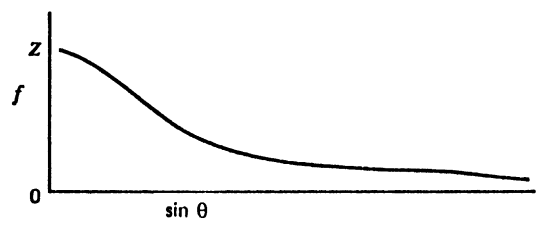

Figure 1. Decrease of amplitude of scattering from an atom of atomic number Z as a function of scattering angle θ. The function f is the atomic scattering factor. All atoms show similar shaped functions, the rate of decrease being somewhat less for atoms of larger Z; their inner electrons are closer to the nucleus.

a typical atom is plotted. These interference effects cause f, the atom's amplitude of scattering, to decrease as the scattering angle increases. Interference effects can also occur between atoms, and it is the latter that permits one to deduce the positions of the atoms in the unit cell, i.e., the crystal structure.

It is mathematically convenient to use a complex exponential description for the X-ray wave,

$$E = E_0 \exp[2\pi i(\nu t - x/\lambda + \delta)] \tag{1}$$

where x is the distance, λ is the wavelength, ν is the frequency, t is the time, and δ is a phase factor for the wave at $x = 0$ and $t = 0$. Anticipating that we will be referring to intensities (i.e., EE^*, E^* being the complex conjugate of E) and only be concerned with effects due to different spatial positions, we will use the simpler form

$$E = E_0 \exp(-2\pi i x/\lambda) \tag{2}$$

For two electrons displaced in one dimension the intensity of scattering would be given by

$$\begin{aligned} I &= EE^* = |E_1 + E_2|^2 \\ &= |E_{0_1} \exp(-2\pi i x_1/\lambda) + E_{0_2} \exp(-2\pi i x_2/\lambda)|^2 \end{aligned} \tag{3}$$

Furthermore, since E_{0_1} would be expected to equal E_{0_2},

$$\begin{aligned} I &= |E_0[\exp(-2\pi i x_1/\lambda) + \exp(-2\pi i x_2/\lambda]|^2 \\ &= E_0^2|[\{1 + \exp[-2\pi i(x_2 - x_1)/\lambda]\}\exp(-2\pi i x_1/\lambda)]|^2 \\ &= E_0^2|\{1 + \exp[-2\pi i(x_2 - x_1)/\lambda]\}|^2 \end{aligned} \tag{4}$$

Generalizing to three dimensions, consider a wave (Fig. 2) incident upon an electron at the origin and a second electron at $\mathbf{r}$. Then the difference in distance would be given by $\mathbf{r} \cdot (\mathbf{s}_0 - \mathbf{s})$, where $\mathbf{s}_0$ and $\mathbf{s}$ represent directions of the incident and scattered rays and $\mathbf{r}$ is the distance between electrons

$$I = E_0^2|1 + \exp[2\pi i \mathbf{r} \bullet (\mathbf{s} - \mathbf{s}_0)/\lambda]|^2 \tag{5}$$

or for n electrons

$$I = E_0^2\left|\sum_{j=0}^{n-1} \exp[2\pi i \mathbf{r}_j \bullet (\mathbf{s} - \mathbf{s}_0)/\lambda]\right|^2 \tag{6}$$

Since we will only require relative intensities, we define

$$F = \sum_{j=0}^{n-1} \exp[2\pi i \mathbf{r}_j \bullet (\mathbf{s} - \mathbf{s}_0)/\lambda] \tag{7}$$

where F is termed the structure factor and

$$I \propto |F|^2 \tag{8}$$

The structure factor expression can be further simplified by replacing the summation by an integral,

$$F = \int_V \rho(\mathbf{r}) \exp[2\pi i \mathbf{r} \bullet (\mathbf{s} - \mathbf{s}_0)/\lambda] dV \tag{9}$$

where $\rho(\mathbf{r})$ is the electron density. If the assumption is made that the electron density is approximated by the sum of atom electron densities, then

$$F = \sum_{j=0}^{N} f_j \exp[2\pi i \mathbf{r}_j \bullet (\mathbf{s} - \mathbf{s}_0)/\lambda)] \tag{10}$$

where f_j is the atomic scattering factor, i.e., the scattering that would be produced by an isolated atom of that atomic number, convoluted with effects due to thermal motion.

To simplify this equation further, we now specify that the sample is a single crystal, and $\mathbf{r}_j = (x_j + p)\mathbf{a}_1 + (y_j + m)\mathbf{a}_2 + (z_j + n)\mathbf{a}_3$. The vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ describe the repeating unit (the unit cell), x_j, y_j, z_j are the fractional coordinates of atom j in the cell, and p, m, and n are integers. Since $\mathbf{r}_j \bullet (\mathbf{s} - \mathbf{s}_0)/\lambda$ must be dimensionless, the $(\mathbf{s} - \mathbf{s}_0)/\lambda$ quantity must be of dimension reciprocal length and can be represented by

$$(\mathbf{s} - \mathbf{s}_0)/\lambda = h\mathbf{b}_1 + k\mathbf{b}_2 + l\mathbf{b}_3 \tag{11}$$

where $\mathbf{b}_1$, $\mathbf{b}_2$, and $\mathbf{b}_3$ are termed the reciprocal cell vectors. They are defined such that $\mathbf{a}_i \cdot \mathbf{b}_i = 1$ and $\mathbf{a}_i \cdot \mathbf{b}_j = 0$. (It should be noted that another common convention is to use $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ to represent unit dimensions in direct space and $\mathbf{a}^*$, $\mathbf{b}^*$, $\mathbf{c}^*$ to represent the reciprocal space quantities.)

By substituting into the structure factor expression and assuming at least a few hundred cells in each direction, it can be shown (Lipscomb and Jacobson, 1990) that the restriction of p, m, and n to integer values yields nonzero diffraction maxima only when h, k, and l are integer. Hence the structure factor for single-crystal diffraction is usually written as

$$F_{hkl} = s\sum_{j=1}^{N} f_j \exp[2\pi i(hx_j + ky_j + lz_j)] \tag{12}$$

where the sum is now over only the atoms in the repeating unit and the other terms (those involving p, m, and n) contribute to a constant multiplying factor, s.

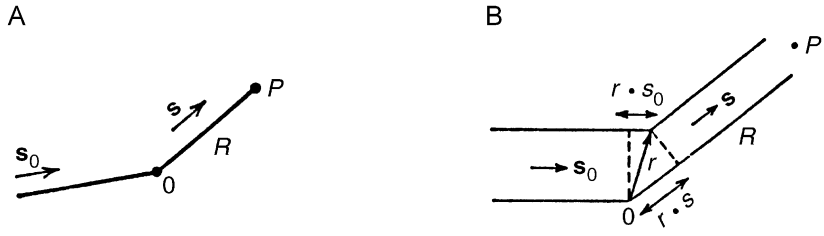

Figure 2. (**A**) Unit vectors $\mathbf{s}_0$ and $\mathbf{s}$ represent directions of the incident and scattered waves, respectively. (**B**) Scattering from a point at the origin and a second point at $\mathbf{r}$. The point of observation P is very far away compared with the distance $\mathbf{r}$.

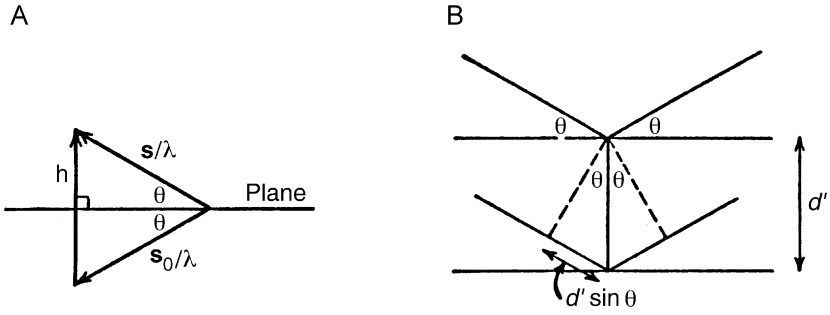

Figure 3. (**A**) Graphical representation of $\mathbf{s}/\lambda - \mathbf{s}_0/\lambda = \mathbf{h}$. (**B**) Path difference between successive planes a distance d' apart is $2d''$ sin θ, which yields a maximum when equal to $n\lambda$.

We now define a reciprocal lattice vector $\mathbf{h}$ as $\mathbf{h} = h\mathbf{b}_1 + k\mathbf{b}_2 + l\mathbf{b}_3$.
Also from Equation 11,

$$\mathbf{h}\lambda = \mathbf{s} - \mathbf{s}_0 \tag{13}$$

and this is termed the Laue equation.

The diffraction pattern from a single crystal therefore can be viewed as yielding a reciprocal lattice pattern (h, k, l all integer) that is weighted by $|F_{hkl}|^2$.

It can be readily shown that $\mathbf{h}$ is a vector normal to a plane passing through the unit cell with intercepts $\mathbf{a}_1/h$, $\mathbf{a}_2/k$, and $\mathbf{a}_3/l$. The integers h, k, and l are termed crystallographic indices (Miller indices if they are relatively prime numbers; see SYMMETRY IN CRYSTALLOGRAPHY). If 2θ is defined as the angle between $\mathbf{s}$ and $\mathbf{s}_0$, then the scalar equivalent of the Laue equation is

$$\lambda = 2d\sin\theta \tag{14}$$

i.e., Bragg's law, where $|\mathbf{h}| = 1/d$, the distance between planes. (If Miller indices are used, a factor of n, the order of the diffraction, is included on the left side of Equation 14.) A convenient graphical representation of the Laue equation is given in Figure 3 and alternately in what is termed the Ewald construction in Figure 4. These are

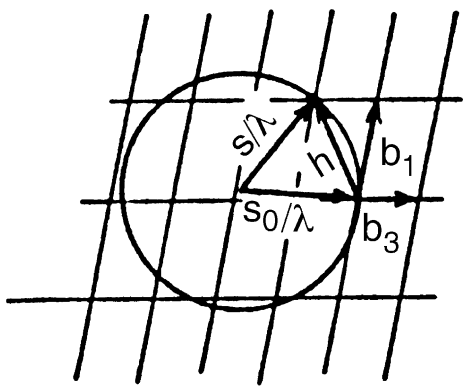

Figure 4. Ewald construction. Assume the reciprocal lattice net represents the $h0l$ zone of a monoclinic crystal. Then the $\mathbf{a}_2$ axis [010] is perpendicular to the plane of the paper. As the crystal is rotated about this axis, various points of the reciprocal lattice cross the circle of reflection; as they do so, the equation $\mathbf{s}/\lambda - \mathbf{s}_0/\lambda = \mathbf{h}$ is satisfied, and a diffracted beam occurs. Diffraction by the [10 1] plane is illustrated.

especially useful when discussing diffractometers and other devices for the collection of X-ray data. Diffraction maxima will only occur when a reciprocal lattice point intersects the sphere of diffraction.

The scattering from an isolated atom represents a combination of the scattering of an atom at rest convoluted with the effects due to thermal motion. These can be separated, and for an atom undergoing isotropic motion, a thermal factor expression

$$T_j = \exp(-B_j \sin^2\theta/\lambda^2) \tag{15}$$

can be used, where $B_j = 8\pi^2\mu^2$, μ^2 being the mean-square amplitude of vibration.

For anisotropic motion, we use

$$T_j = \exp[-2\pi^2(U_{11}h^2\mathbf{b}_1^2 + U_{22}k^2\mathbf{b}_2^2 + U_{33}l^2\mathbf{b}_3^2 + 2U_{12}hk\mathbf{b}_1 \bullet \mathbf{b}_2 + 2U_{13}hl\mathbf{b}_1 \bullet \mathbf{b}_3 + 2U_{23}kl\mathbf{b}_2 \bullet \mathbf{b}_3)] \tag{16a}$$

or the analogous expression

$$T_j = \exp[-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{12}hk + 2\beta_{13}hl + 2\beta_{23}kl)] \tag{16b}$$

The U's are thermal parameters expressed in terms of mean-square amplitudes in angstroms, while the β's are the associated quantities without units.
The structure factor is then written as

$$F_{\mathrm{hkl}} = s\sum_{j=1}^{N} f_j \exp[2\pi i(hx_j + ky_j + lz_j)]T_j \tag{17}$$

As we have seen, one form of the structure factor expression (Equation 9) involves $\rho(\mathbf{r})$, the electron density function, in a Fourier series. Therefore, it would be expected that there exists an inverse Fourier series in which the electron density is expressed in terms of structure factor quantities. Indeed, the electron density function for the cell can be written as

$$\rho(\mathbf{r}) = \frac{1}{V}\sum_{h=-\infty}^{\infty}\sum_{k=-\infty}^{\infty}\sum_{l=-\infty}^{\infty} F_{hkl}\exp[-2\pi i(hx + ky + lz)] \tag{18}$$

In this expression V is the volume of the cell and the triple summation is in theory from $-\infty$ to ∞ and in practice over all the structure factors.

This series can be written in a number of equivalent ways. The structure factor can be expressed in terms of the real and imaginary components A and B as

$$F_{hkl} = A_{hkl} + iB_{hkl} \tag{19}$$

$$= s\sum_j f_j \cos 2\pi(hx_j + ky_j + lz_j)T_j + is\sum_j f_j \sin 2\pi(hx_j + ky_j + lz_j)T_j \tag{20}$$

and

$$\rho(xyz) = \frac{1}{V}\sum_{h=-\infty}^{\infty}\sum_{k=-\infty}^{\infty}\sum_{l=-\infty}^{\infty}[A_{hkl}\cos 2\pi(hx + ky + lz) + B_{hkl}\sin 2\pi(hx + ky + lz)] \tag{21}$$

Another form for the structure factor is

$$F_{hkl} = |F_{hkl}|\exp(2\pi i\alpha_{hkl}) \tag{22}$$

Then

$$\alpha_{hkl} = \tan^{-1}(B_{hkl}/A_{hkl}) \tag{23}$$

and

$$|F_{hkl}| = (A_{hkl}^2 + B_{hkl}^2)^{1/2} \tag{24}$$

The quantity α_{hkl} is termed the crystallographic phase angle. It could also be noted that, using $\bar{h}$ to designate $-h$

$$A_{\bar{h}\bar{k}\bar{l}} = A_{hkl} \tag{25}$$

and

$$B_{\bar{h}\bar{k}\bar{l}} = -B_{hkl} \tag{26}$$

if the atomic scattering factor f_j is real. Also,

$$|F_{hkl}|^2 = |F_{\bar{h}\bar{k}\bar{l}}|^2 \tag{27}$$

Equation 27 is termed Friedel's law and as noted holds as long as f_j is real.

Equation 18 implies that the electron density for the cell can be obtained from the structure factors; a knowledge of the electron density would enable us to deduce the location and types of atoms making up the cell. The magnitude of the structure factor can be obtained from the intensities (Equation 8); however, the phase is not measured, and this gives rise to what is termed the phase problem in crystallography. Considerable effort has been devoted over the last half century to developing reliable methods to deduce these phases. One of the most widely used of the current methods is that developed in large part by J. Karle and H. Hauptman (Hauptman and Karle, 1953; Karle and Hauptman, 1956; Karle and Karle, 1966), which uses a statistical and probability approach to extract phases directly from the magnitudes of the structure factors. We will give a brief discussion of the background of such "direct methods" as well as a discussion of the heavy-atom method, another commonly employed approach. It should be noted, however, that a number of other techniques could be used if these methods fail to yield a good trial model; these will not be discussed here due to space limitations.

Symmetry in Crystals

Symmetry plays an important role in the determination of crystal structures; only those atomic positional and thermal parameters that are symmetry independent need to be determined. In fact, if the proper symmetry is not recognized and attempts are made to refine parameters that are symmetry related, correlation effects occur and unreliable refinement and even divergence can result.

What restrictions are there on the symmetry elements and their combinations that can be present in a crystal? (We will confine our discussion to crystals as generated by a single tiling pattern and exclude cases such as the quasi-crystal.) Consider a lattice vector **a** operated on by a rotation axis perpendicular to the plane of the paper, as shown in Figure 5. Rotation by α or $-\alpha$ will move the head of the vector to two other lattice points, and these can be connected by a vector **b**. Since **b** must be parallel to **a**, one can relate their lengths by $b{=}ma$, where m is an integer, or by $b = 2a\cos\alpha$. Thus $m = 2\cos\alpha$ and

$$\alpha = \cos^{-1}(m/2) \tag{28}$$

Obviously the only allowed values for m are $0, \pm 1, \pm 2$, which yield 0, 60°, 90°, 120°, 180°, 240°, 270°, and 300° as possible values for the rotation angle α. This in turn implies rotation axes of order 1, 2, 3, 4, or 6. No other orders are compatible with the repeating character of the lattice. A lattice can also have inversion symmetry, as would be implied by Friedel's law (Equation 27). Coupling the inversion operation with a rotation axis produces the rotatory inversion axes: 1, 2, 3, 4, and 6. (These operations can be viewed as a rotation followed by an inversion. The 1 is just the inversion operation and 2 the mirror operation.)

Various combinations of these symmetry elements can now be made. In doing so, 32 different point groups are produced (see SYMMETRY IN CRYSTALLOGRAPHY). Since in a lattice description the repeating unit is represented by a point and the lattice has inversion symmetry, those point

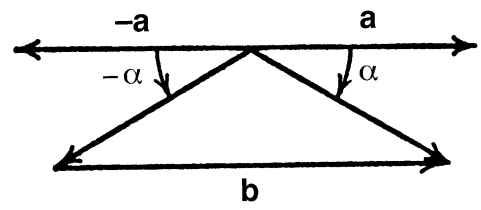

Figure 5. Rotation axis $A(\alpha)$ at a lattice point. Note that the vector **b** is parallel to **a**.

Table 1. Fourteen Bravais Lattices

Symmetry at a Lattice Point	Name	Lattice Points Per Unit Cell	Elementary Cell Relations
$C_i - 1$	Triclinic	1	
$C_{2h} - 2/2m$	Primitive monoclinic	1	$\alpha_1 = \alpha_3 = 90^\circ$
	End-centered monoclinic C	2	
D_{2h}	Primitive orthorhombic	1	$\alpha_1 = \alpha_2 = \alpha_3 = 90^\circ$
	End-centered C, A, B	2	
	Face-centered F	4	
	Body-centered I	2	
$D_{4h} - 4/m\,mm$	Primitive tetragonal (equivalent to end-centered)	1	$\alpha_1 = \alpha_2 = \alpha_3 = 90^\circ$ $a_1 = a_2$
	Body-centered (equivalent to face-centered) I	2	
$D_{3d} - 3m$	Trigonal	1	$\alpha_1 = \alpha_2 = \alpha_3$ $a_1 = a_2 = a_3$ (rhombohedral axes, for hexagonal description, see below)
$D_{6h} - 6/m\,mm$	Heagonal	1	$\alpha_1 = \alpha_2 = 90^\circ$ $\alpha_3 = 120^\circ$ $a_1 = a_2$
$O_h - m3m$	Primitive cubic	1	$\alpha_1 = \alpha_2 = \alpha_3 = 90^\circ$
	Face-centered cubic F	4	$a_1 = a_2 = a_3$
	Body-centered cubic I	2	

groups that differ only by an inversion center can be grouped together. This produces the seven crystal systems given in Table 1. For a number of crystal systems, in addition to the primitive cell (one lattice point per cell), there are also centered cell possibilities. (Such cells are not allowed if redrawing the centered cell to obtain a primitive one can be done without loss of symmetry consistent with the crystal system. Also, if redrawing or renaming axes converts one type to another, only one of these is included.) The notation used to describe centered cells is as follows: A—centered on the $\mathbf{a}_2$, $\mathbf{a}_3$ face; B—centered on the $\mathbf{a}_1$, $\mathbf{a}_3$ face; C—centered on the $\mathbf{a}_1$, $\mathbf{a}_2$ face; I—body centered; and F—face centered.

As noted in the table, trigonal cells can be reported using a primitive rhombohedral cell or as a hexagonal cell. If the latter, then a triply primitive R-centered cell is used. R centering has lattice points at (1/3, 2/3, 2/3) and (2/3, 1/3, 1/3) as well as at (0, 0, 0).

The next task is to convert these 32 point groups into the related space groups. This can be accomplished by generating not only space groups having these point group symmetries but also groups in which the point group operation is replaced by an "isomorphous" operation that has a translational element associated with it. However, this must be done in such a way as to preserve the multiplicative properties of the group.

The symmetry operation isomorphous to the rotation axis is the screw axis. They are designated by N_m, where the rotation is through an angle $2\pi/N$ and the translation is m/N, in terms of fractions of the cell, and is parallel to the rotation axis. Thus 2_1 is a 180° rotation coupled with a 1/2 cell translation, 4_1 is a 90° rotation coupled with 1/4 cell translation, and 6_2 represents a 60° rotation coupled with a 1/3 cell translation. Note that $2_1 \cdot 2_1$ yields a cell translation along the rotation axis direction and hence produces a result isomorphous to the identity operation; performing a 6_2 six times yields a translation of two cell lengths.

Mirror planes can be coupled with a translation and converted to glide planes. The following notation is used: a glide, translates 1/2 in $\mathbf{a}_1$; b glide, translates 1/2 in $\mathbf{a}_2$; c glide, translates 1/2 in $\mathbf{a}_3$; n glide, translates 1/2 along the face diagonal; and d glide, translates 1/4 along the face or body diagonal.

Let us digress for a moment to continue to discuss notation in general. When referring to space groups, the Hermann-Mauguin notation is the one most commonly used (see SYMMETRY IN CRYSTALLOGRAPHY). The symbol given first indicates the cell type, followed by the symmetry in one or more directions as dictated by the crystal system.

For the triclinic system, the only possible space groups are $P1$ and $P\bar{1}$.

For the monoclinic system, the cell type, P or C, is followed by the symmetry in the b direction. (The b direction is typically taken as the unique direction for the monoclinic system, although one can occasionally encounter c-unique monoclinic descriptions in the older literature.) If a rotation axis and the normal to a mirror plane are in the same direction, then a slash (/) is used to designate that the two operations are in the same direction. For the point group C_{2h}, the isomorphous space groups in the monoclinic system include $P2/m$, $P2_1/m$, $P2/c$, $P2_1/c$, $C2/m$ and $C2/c$.

In the orthorhombic system, the lattice type is followed by the symmetry along the **a**, **b**, and **c** directions. The space groups $P222$, $Pca2$, $P2_12_12_1$, $Pmmm$, $Pbca$, $Ama2$,

*Fdd*2, and *Cmcm* are all examples of orthorhombic space groups.

The notation for the higher symmetry crystal systems follows in the same manner. The symmetry along the symmetry axis of order greater than 2 is given first followed by symmetry in the other directions as dictated by the point group. For tetragonal and hexagonal systems, the symmetry along the **c** direction is given, followed by that for **a** and then for the **ab** diagonal, when isomorphous with a *D*-type point group. For cubic space groups the order is symmetry along the cell edge, followed by that along the body diagonal, followed by the symmetry along the face diagonal, where appropriate.

A space group operation can be represented by

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \mathbf{R}\begin{pmatrix} x \\ y \\ z \end{pmatrix} + \mathbf{t} \tag{29}$$

where $\mathbf{R}$ is a 3×3 matrix corresponding to the point group operation and $\mathbf{t}$ is a column vector containing the three components of the associated translation. As noted above, group properties require that operations in the space group combine in the same fashion as those in the isomorphous point group; this in turn usually dictates the positions in the cell of the various symmetry elements making up the space group. Consider, for example, the space group $P2_1/c$ in the monoclinic system. This commonly occurring space group is derived from the C_{2h} point group. Since in the point group a twofold rotation followed by the reflection is equivalent to the inversion, in the space group the 2_1 operation followed by the *c* glide must be equivalent to the inversion. The usual convention is to place an inversion at the origin of the cell. For this to be so, the screw axis has to be placed at $z = 1/4$ and the *c* glide at $y = 1/4$. Therefore, in $P2_1/c$, the following relations hold:

$$x,y,z \xrightarrow{i} -x,-y,-z \tag{30a}$$

$$x,y,z \xrightarrow{2_1} -x,1/2+y,1/2-z \tag{30b}$$

$$x,y,z \xrightarrow{c} x,1/2-y,1/2+z \tag{30c}$$

and these four equivalent positions are termed the general positions in the space group. In many space groups it is also possible for atoms to reside in "special positions," locations in the cell where a point group operation leaves the position invariant. Obviously these can only occur for symmetry elements that contain no translational components. In $P2_1/c$, the only special position possible is associated with the inversion. The number of equivalent positions in this case is two, namely, 0, 0, 0 and 0, 1/2, 1/2 or any of the translationally related pairs.

By replacing any point group operation by any allowable isomorphous space operation, the 32 point groups yield 230 space groups. A complete listing of all the space groups with associated cell diagrams showing the placement of the symmetry elements and a listing of the general and special position coordinates can be found in Volume A, International Tables for Crystallography, 1983.

Examination of the symmetry of the diffraction pattern (the Laue symmetry) permits the determination of the crystal system. To further limit the possible space groups within the crystal system, one needs to determine those classes of reflections that are systematically absent (extinct).

Consider the *c*-glide plane as present in $P2_1/c$. For every atom at (x, y, z), there is another at $(x, 1/2-y, 1/2+z)$. The structure factor can then be written as

$$F_{hkl} = \sum_{j=1}^{N/2} f_j \left\{ \exp[2\pi i(hx_j + ky_j + lz_j)] + \exp\left[2\pi i\left(hx_j + k\left(\frac{1}{2} - y_j\right) + l\left(\frac{1}{2} - z_j\right)\right)\right]\right\} \tag{31}$$

For those reflections with $k = 0$,

$$F_{h0l} = \sum_{j=1}^{N/2} f_j \exp[2\pi i(hx_j + lz_j)][1 + (-1)^l] \tag{32}$$

Thus, for $h0l$ reflections, all intensities with l odd would be absent. Different symmetry elements give different patterns of missing reflections as long as the symmetry element has a translational component. Point group elements show no systematic missing reflections.

Table 2 lists the extinction conditions caused by various symmetry elements. In many cases an examination of the extinctions will uniquely determine the space group. In others, two possibilities may remain that differ only by the presence or absence of a center of symmetry. Statistical tests (Wilson, 1944) have been devised to detect the presence of a center of symmetry; one of the most reliable is that developed by Howells et al. (1950). It should be cautioned, however, that while such tests are usually reliable, one should not interpret their results as being 100% certain.

Further discussion of space group symmetry can be found in SYMMETRY IN CRYSTALLOGRAPHY as well as in the literature (International Tables for Crystallography, 1983; Ladd and Palmer, 1985; Stout and Jensen, 1989; Lipscomb and Jacobson, 1990).

Crystal Structure Refinement

After data have been collected and the space group determined, a first approximation to the crystal structure must then be found. (Methods to do so are described in the next section.) Such a model must then be refined to obtain a final model that best agrees with the experimental data. Although a Fourier series approach could be used (using electron density map or difference electron density map calculations), this approach has the disadvantage that the structural model could be affected by systematic errors due to series termination effects, related to truncation of data at the observation limit. Consequently, a least-squares refinement method is employed instead. Changes in the positional and thermal parameters are calculated that minimize the difference between $|\mathbf{F}_{hkl}^{\text{obs}}|$ and $|\mathbf{F}_{hkl}^{\text{calc}}|$, or alternatively $\mathbf{I}_{hkl}^{\text{obs}}$ and $\mathbf{I}_{hkl}^{\text{calc}}$.

Table 2. Extinctions Caused by Symmetry Elements[a]

Class of Reflection	Condition for Nonextinction (n, an integer)	Interpretation of Extinction	Symbol for Symmetry Element
hkl	$h+k+l=2n$	Body-centered lattice	I
	$h+k=2n$	C-centered lattice	C
	$h+l=2n$	B-centered lattice	B
	$k+l=2n$	A-centered lattice	A
	$h+k,h+l$	Face-centered lattice	F
	$h+l=2n$		
	$-h+k+l=3n$	Rhombohedral lattice indexed on hexagonal lattice	R
	$h+k+l=3n$	Hexagonal lattice indexed on rhombohedral lattice	H
Okl	$k=2n$	Glide plane $\perp a$, translation $b/2$	b
	$l=2n$	Glide plane $\perp a$, translation $c/2$	c
	$k+l=2n$	Glide plane $\perp a$, translation $(b+c)/2$	n
	$k+l=4n$	Glide plane $\perp a$, translation $(b+c)/4$	d
$h0l$	$h=2n$	Glide plane $\perp b$, translation $a/2$	a
	$l=2n$	Glide plane $\perp b$, translation $c/2$	c
	$h+l=2n$	Glide plane $\perp b$, translation $(a+c)/2$	n
	$h+k=4n$	Glide plane $\perp a$, translation $(a+b)/4$	d
hhl	$l=2n$	Glide plane $\perp (a-b)$, translation $c/2$	c
	$2h+l=2n$	Glide plane $\perp (a-b)$, translation $(a+b+c)/2$	n
	$2h+l=2n$	Glide plane $\perp (a-b)$, translation $(a+b+c)/4$	d
$h00$[b]	$h=2n$	Screw axis $\parallel a$, translation $a/2$	2_1, 4_2
	$h=4n$	Screw axis $\parallel a$, translation $a/4$	4_1, 4_3
$00l$	$l=2n$	Screw axis $\parallel c$, translation $c/2$	2_1, 4_2, 6_3
	$l=4n$	Screw axis $\parallel c$, translation $c/4$	4_1, 4_3
	$i=3n$	Screw axis $\parallel c$, translation $c/3$	3_1, 3_2, 6_2, 6_4
	$l=6n$	Screw axis $\parallel c$, translation $c/6$	6_1, 6_5
$hh0$	$h=2n$	Screw axis $\parallel (a+b)$, translation $(a+b)/2$	2_1

[a] Adapted from Buerger, 1942.
[b] Similarly for k and b translations.

It is common practice to refer to one portion of the data set as observed data and the other as unobserved. The terminology is a carry-over from the early days of crystallography when the data were measured from photographic film by visual matching to a standard scale. Intensities could be measured only to some lower limit, hence the "observed" and "unobserved" categories. Although measurements are now made with digital counters (scintillation detectors or area detectors), the distinction between these categories is still made; often $I > 3\sigma(I)$ or a similar condition involving $|F|$ is used for designating observed reflections. Such a distinction is still valuable when refining on $|F|$ (see below) and when discussing R factors.

Crystallographers typically refer to a residual index (R factor) as a gauge for assessing the validity of a structure. It is defined as

$$R = \frac{\sum_{\mathbf{h}} \| F_{\mathbf{h}}^{\text{obs}}| - |F_{\mathbf{h}}^{\text{obs}} \|}{\sum_{\mathbf{h}} |F_{\mathbf{h}}^{\text{obs}}|} \tag{33}$$

Atoms placed in incorrect positions usually produce $R > 0.40$. If positional parameters are correct, R's in the 0.20 to 0.30 range are common. Structures with refined isotropic thermal parameters typically give $R \sim 0.15$, and least-squares refinement of the anisotropic thermal parameters will reduce this to $\sim$0.05 or less for a well-behaved structure.

Positional and thermal parameters occur in trigonometric and exponential functions, respectively. To refine such nonlinear functions, a Taylor series expansion is used. If f is a nonlinear function of parameters $p_1, p_2, \ldots, p_n$, then f can be written as a Taylor series

$$f = f^0 + \sum_{i=1}^{n} \left(\frac{\partial f}{\partial p_i}\right)_{p_j} \Delta p_i + \text{higher order terms} \tag{34}$$

where f^0 represents the value of the function evaluated with the initial parameters and the Δp_i's are the shifts in these parameters. In practice, the higher order terms are neglected; if Δ_j for observation j is defined as

$$\Delta_j = f_j - f_j^0 - \sum_{i=1}^{n} \left(\frac{\partial f}{\partial p_i}\right)_{p_j} \Delta p_i \tag{35}$$

then $\sum_j w_j \Delta_j^2$ can be minimized to obtain the set of best shifts of the parameters in a least squares sense. These in turn can be used to obtain a new set of f^0s, and the process repeated until all the shifts are smaller than some prescribed minimum. The weights w_j are chosen such as to be reciprocally related to the square of the standard deviation associated with that observation.

In the X-ray case, as noted above, f can be I_{hkl} or $|F_{hkl}|$. If the latter, then

$$\begin{aligned} |F_{hkl}^c| &= F_{hkl}^c \exp(-2\pi i \alpha_{hkl}) \\ &= A_{hkl}^c \cos\alpha_{hkl} + B_{hkl}^c \sin\alpha_{hkl} \end{aligned} \tag{36}$$

In this case, only observed reflections should be used to calculate parameter shifts since the least-squares method assumes a Gaussian distribution of errors in the observations. (For net intensities that are negative, i.e., where the total intensity is somewhat less than the background measurement, $|F^0_{hkl}|$ is not defined. After refinement, structure factors can still be calculated for these unobserved reflections.)

The set of least-squares equations can be obtained from these Δ_j equations as follows for m observations. Express

$$\begin{pmatrix} \frac{\partial f_1}{\partial p_1} & \frac{\partial f_1}{\partial p_2} & \frac{\partial f_1}{\partial p_3} & \cdots & \frac{\partial f_1}{\partial p_n} \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ \frac{\partial f_m}{\partial p_1} & \frac{\partial f_m}{\partial p_2} & \frac{\partial f_m}{\partial p_3} & \cdots & \frac{\partial f_m}{\partial p_n} \end{pmatrix} \begin{pmatrix} \Delta p_1 \\ \Delta p_2 \\ \vdots \\ \Delta p_n \end{pmatrix} = \begin{pmatrix} f_1 - f_1^0 \\ f_2 - f_2^0 \\ \vdots \\ f_m - f_m^0 \end{pmatrix} \quad (37)$$

It is convenient to represent these matrices by $\mathbf{MP} = \mathbf{Y}$. Then multiplying both sides by the transpose of $\mathbf{M}$, $\mathbf{M^T}$, gives $\mathbf{M^T MP} = \mathbf{M^T Y}$. Let $\mathbf{A} = \mathbf{M^T M}$ and $\mathbf{B} = \mathbf{M^T Y}$. Since $\mathbf{A}$ is now a square matrix, $\mathbf{P} = \mathbf{A}^{-1}\mathbf{B}$. Least-squares methods not only give a final set of parameters but also provide

$$s^2(p_j) = a^{jj}\left(\frac{\sum_i w_i \Delta j^2}{m - n}\right) \quad (38)$$

where s is the standard deviation associated with the parameter p_j, a^{ij} is the jth diagonal matrix element of the inverse matrix, m is the number of observations, and n is the number of parameters. The square root of the quantity in parentheses is sometimes referred to as the standard deviation of an observation of unit weight, or the goodness-of-fit parameter. If the weights are correct, i.e., if the errors in the data are strictly random and correctly estimated, and if the crystal structure is properly being modeled, then the value of this quantity should approximately equal unity.

PRACTICAL ASPECTS OF THE METHOD

In practice, the application of single-crystal X-ray diffraction methods for the determination of crystal and molecular structure can be subdivided into a number of tasks. The investigator must: (i) select and mount a suitable crystal; (ii) collect the diffracted intensities produced by the crystal; (iii) correct the data for various experimental effects; (iv) obtain an initial approximate model of the structure; (v) refine this model to obtain the best fit between the observed intensities and their calculated counterparts; and (vi) calculate derived results (e.g., bond distances and angles and stereographic drawings including thermal ellipsoid plots) from the atomic parameters associated with the final model.

For further discussion of the selection and mounting of a crystal see Sample Preparation, below; for further details on methods of data collection, see Data Collection Techniques.

The fiber or capillary holding the crystal is placed in a pin on a goniometer head that has x, y, z translations. (Preliminary investigation using film techniques—precession or Weissenberg—could be carried out at this stage, if desired, but we will not discuss such investigations here.) The goniometer head is then placed on the diffractometer and adjusted using the instrument's microscope so that the center of the crystal remains fixed during axial rotations.

The next task is to determine the cell dimensions, the orientation of the cell relative to the laboratory coordinate system, and the likely Bravais lattice and crystal system. This process is usually termed indexing.

To accomplish this, an initial survey of the low to mid angle (θ) regions of reciprocal space is carried out. This can be done via a rotation photograph using a Polaroid cassette—the user then inputs the x, y positions of the diffraction maxima and the diffractometer searches in the rotation angle—or by initiating a search procedure that varies a variety of the angles on a four-circle diffractometer. Any peaks found are centered. Peak profiles give an indication of crystal quality—one would expect Gaussian-like peaks from a crystal of good quality. Sometimes successful structure determinations can be carried out on crystals that give split peaks or have a significant side peak, but it is best to work with crystals giving well-shaped peaks if possible. With an area detector, reflections can be collected from a few frames at different rotation angles. An indexing program is then employed that uses this information to determine the most probable cell and crystal system. (Although these indexing programs are usually quite reliable, the user must remember that the information is being obtained from a reasonably small number of reflections and some caution is advisable. The user should verify that all or almost all of the reflections were satisfactorily assigned indices by the program.)

Computer programs (Jacobson, 1976, 1997) typically produce a reduced cell as a result of indexing. The reduced cell is one that minimizes the lengths of $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ that describe the repeating unit (and hence give angles as close to 90° as possible) (Niggli, 1928; Lawton and Jacobson, 1965; Santoro and Mighell, 1970). It also orders the axes according to a convention such as $|\mathbf{a}_1| \leq |\mathbf{a}_2| \leq |\mathbf{a}_3|$. This is followed by a Bravais lattice determination in which characteristic length and angle relationships are used to predict the presence of centered cells and the axes are rearranged to be consistent with the likely crystal system. The next step would then be to measure intensities of some sets of reflections that would be predicted to be equal by the Laue group symmetry (to obtain additional experimental verification as to the actual Laue group of the crystal or a possible subgroup).

Once the likely Laue symmetry has been determined, the data collection can begin. This author usually prefers to collect more than just a unique data set; the subsequent data averaging gives a good estimate of data quality. Data are typically collected to a 2θ maximum from 50 to 60° with Mo K_α radiation, the maximum chosen depending on the crystal quality and the amount of thermal motion associated with the atoms. (Greater thermal motion means weaker average intensities as 2θ increases.)

Once data collection has finished, the data will need to be corrected for geometric effects such as the Lorentz effect (the velocity with which the reciprocal lattice point moves

through the sphere of reflection) and the polarization effect; the X-ray beam becomes partially polarized in the course of the diffraction process. Usually data will also have to be corrected for absorption since as the beam traverses the crystal, absorption occurs, as given by the relation $e^{-\mu t}$, where μ is the absorption coefficient and t is the path length. "Analytical" absorption correction can be made if the orientations of crystal faces and their distances from the center of the crystal are carefully measured. Often empirical absorption corrections are employed instead. For data collected on a four-circle diffractometer, a series of psi scans can be used for this purpose. These are scans at different ϕ angle positions for reflections close to $\chi = 90°$. (For a reflection at $\chi = 90°$, diffraction is ϕ independent and any variation in observed diffraction can be attributable to effects due to absorption.) For data collected on an area detector, computer programs determine the parameters associated with an analytic representation of the absorption surface using the observed differences found between the intensities of symmetry-related reflections. Corrections can also be made for a decrease in scattering caused by crystal decomposition effects, if necessary. This composite set of corrections is often referred to as data reduction.

Following data reduction, the data can be averaged and then the probable space group or groups found by an examination of systematic absences in the data. Statistical tests, such as the Howells, Philips, and Rogers tests for the possible presence of a center of symmetry, can be carried out if more than one space group is indicated.

Next the investigator typically seeks an initial trial model using a direct method program, or if a heavy-atom approach is appropriate, the analysis of peaks between symmetry-related atoms found in the Patterson calculation might be used as discussed below. An initial electron density map would then be calculated. The bond distances and bond angles that are associated with these atom position possibilities and the residual index often indicate whether a valid solution has been found. If so, the inclusion of additional atoms found on electron density or difference electron density maps and subsequent refinement usually leads to a final structural model. Final bond distances, angles, and their standard deviations can be produced along with a plot of the atom positions (e.g., an ORTEP drawing); see Data Analysis and Initial Interpretations, Derived Results.

If a valid initial model is not obtained, the number of phase set trials might be changed if using a direct method program. Different Patterson peaks could be tried. Other space group or crystal system possibilities could be investigated. Other structure solution methods beyond the scope of this chapter might have to be employed to deduce an appropriate trial model. Fortunately, if the data are of good quality, most structures can be solved using the standard computer software available with commercial systems.

Data Collection Techniques

Film has long been used to record X-ray diffraction intensities. However, film has a number of disadvantages; it is relatively insensitive, especially for the shorter X-ray wavelengths, and does not have a large dynamic range. Gas-filled proportional counters can be used to detect X rays. These detectors can attain high efficiencies for longer wavelength radiations; with the use of a center wire of high resistance, they can be used to obtain positional information as well. The curved one-dimensional versions are used for powder diffraction studies, and the two-dimensional counterparts form the basis for some of the area detectors used in biochemical applications. They operate at reasonably high voltages (800 to 1700 V), and the passage of an X-ray photon causes ionization and an avalanche of electrons to occur that migrate to the anode. The number of electrons is proportional to the number of ion pairs, which is approximately proportional to the energy of the incident X-ray photon.

The scintillation counter is composed of a NaI crystal that has been activated by the addition of some Tl. An absorbed X-ray produces a photoelectron and one or more Auger electrons; the latter energize the Tl sites, which in turn emit visible photons. The crystal is placed against a photomultiplier tube that converts the light into a pulse of electrons. The number of color centers energized are approximately dependent on the initial X-ray energy.

Scintillation detectors are typically used on four-circle diffractometers. The four-circle diffractometer is one of the most popular of the counter diffractometers. As the name suggests, this diffractometer has four shafts that can be moved usually in an independent fashion. Such a diffractometer is shown schematically in Figure 6. The 2θ axis is used to move the detector parallel to the basal plane, while the remaining three axes position the crystal (Hamilton, 1974). The ω axis rotates around an axis that is perpendicular to the basal plane, the χ axis rotates around an axis that is perpendicular to the face of the circle, and the ϕ axis rotates around the goniometer head mount. To collect data with such an instrument, these angles must be positioned such that the Laue equation, or its scalar equivalent, Bragg's law, is satisfied (see DYNAMICAL DIFFRACTION).

Electronic area detectors have become more routinely available in the last few years and represent a major new advance in detector technology. Two such new detectors are the CCD detector and the imaging plate detector. In a typical CCD system, the X-ray photons impinge on a phosphor such as gadolinium oxysulfide. The light

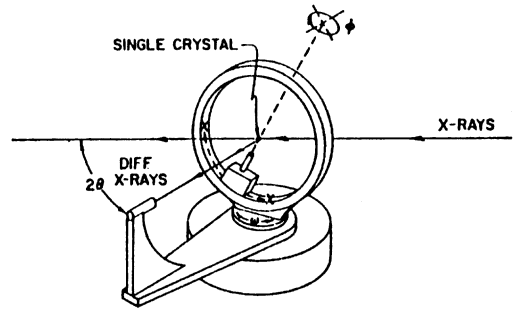

Figure 6. Four-circle diffractometer.

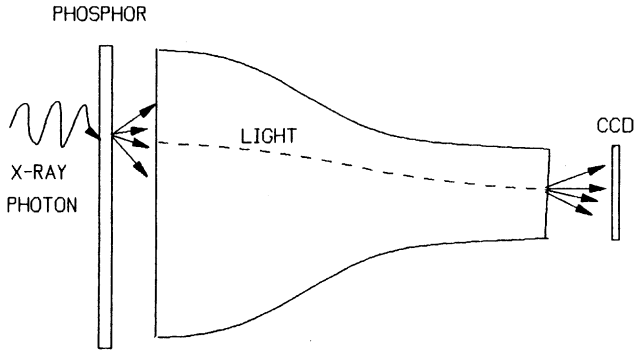

Figure 7. A CCD area detector. An X-ray photon arriving from the left is converted to light photons at the phosphor. Fiber optics conduct these to the CCD chip on the right.

produced is conducted to a CCD chip via fiber optics, as shown in Figure 7, yielding about eight electrons per X-ray photon. The typical system is maintained at $-50°C$ and has a dynamic range of 1 to $> 10^5$ photons per pixel. Readout times are typically 2 to 9 s depending on the noise suppression desired.

In a typical imaging plate system, the X-ray photons impinge on a phosphor (e.g., europium-doped barium halide) and produce color centers in the imaging plate. Following the exposure, these color centers are read by a laser and the light emitted is converted to an electronic signal using a photomultiplier. The laser action also erases the image so that the plate can be reused. In practice, usually one plate is being exposed while another is being read. The readout time is somewhat longer than with a CCD, typically 4 min or so per frame. However, the imaging plate has excellent dynamic range, 1 to $>10^6$ photons per pixel, and a considerably larger active area. It operates at room temperature.

As noted above, imaging plate systems usually provide a larger detector surface and slightly greater dynamic range than does the CCD detector, but frames from the latter system can be read much more rapidly than with imaging plate systems. Crystallographers doing small-molecule studies often tend to prefer CCD detectors, while imaging plate systems tend to be found in those laboratories doing structural studies of large biological molecules. Both types of area detectors permit the crystallographer to collect data in a manner almost independent of cell size. With the older scintillation counter system, a doubling of the cell size translates into a doubling of the time needed to collect the data set (since the number of reflections would be doubled). On the other hand, with an area detector, as long as the detector does not have to be moved further away from the source to increase the separation between reflections, the time for a data collection is essentially independent of cell size. Furthermore, if the crystal is rotated around one axis (e.g., the vertical axis) via a series of small oscillations and the associated frame data are stored to memory, most of the accessible data within a theta sphere would be collected. The remaining "blind region" could be collected by offsetting the crystal and performing a second limited rotation. Many commercial instruments use a four-circle diffractometer to provide maximum rotational capability. Due to the high sensitivity of the detector, a full data collection can be readily carried out with one of these systems in a fraction of a day for moderate-size unit cells.

METHOD AUTOMATION

Single-crystal X-ray methods involve the collection and processing of thousands to tens of thousands of X-ray intensities. Therefore, modern instrumentation comes with appropriate automation and related computer software to carry out this process in an efficient manner. Often, user input is confined to the selection of one of a few options at various stages in the data-collection process. The same is true of subsequent data processing, structure solution, and refinement.

DATA ANALYSIS AND INITIAL INTERPRETATION

Obtaining the Initial Model

There are a number of approaches that can be utilized to obtain an initial model of the structure appropriate for input into the refinement process. Many are specialized and tend to be used to "solve" particular kinds of structures, e.g., the use of isomorphous replacement methods for protein structure determination. Here we will primarily confine ourselves to two approaches: direct methods and the heavy-atom method.

Direct methods employ probability relations relying on the magnitudes of the structure factors and a few known signs or phases to determine enough other phases to reveal the structure from an electron density map calculation. The possibility that phase information could be extracted from the structure factor magnitudes has intrigued investigators throughout the history of crystallography. Karle and Hauptman (1956), building on the earlier work of Harker and Kasper (1948) and Sayre (1952), developed equations that have made these methods practical. A much more complete discussion of direct methods can be found in the Appendix.

One of the most important of the equations developed for the direct methods approach is the sigma-two equation:

$$E_{\mathbf{h}} \approx \langle E_{\mathbf{h}} E_{\mathbf{h}-\mathbf{k}} \rangle_{\mathbf{k}} \tag{39}$$

where E_{h} is derived from F_{h} and $\langle\rangle_{\mathbf{k}}$ represents the average over the $\mathbf{k}$ contributors. In practice, only those E's whose sign or phase has been determined are used in the average on the right. Since $|E_{\mathbf{h}}|$ is known, the equation is used to predict the most probable sign or place of the reflection.

The probability of $|E_{\mathbf{h}}|$ being positive is given by

$$P_+(\mathbf{h}) = \frac{1}{2} + \frac{1}{2}\tanh \sigma_3 \sigma_2^{-3/2} |E_{\mathbf{h}}| \sum_{\mathbf{k}} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}} \tag{40}$$

For the non-centrosymmetric case

$$\tan\alpha_{\mathbf{h}} = \frac{\sum_{\mathbf{k}} |E_{\mathbf{h}}\| E_{\mathbf{h}-\mathbf{h}}| \sin(\alpha_{\mathbf{k}} + \alpha_{\mathbf{h}-\mathbf{k}})}{\sum_{\mathbf{k}} |E_{\mathbf{k}}\| E_{\mathbf{h}-\mathbf{k}}| \cos(\alpha_{\mathbf{k}} + \alpha_{\mathbf{h}-\mathbf{k}})} \tag{41}$$

Direct method computer programs use these equations and other related ones as described in the Appendix to attempt to obtain an approximate set of signs (or phases) directly from the magnitudes of the structure factors. These are then used to calculate an electron density map, which could reveal the approximate positions of most of the atoms in the structure. Further details on two of the more commonly used direct methods programs can be found in the Appendix.

Direct methods can be expected to be the most reliable when applied to structures in which most of the atoms are approximately equal in atomic number. In structures where one or a few atoms are present that have appreciably larger atomic numbers than the rest, the heavy-atom method is typically the approach of choice.

The basic assumption of the heavy-atom method is that these atoms alone provide good enough initial phasing of an electron density map that other atoms can be found and included, and the process repeated, until all atoms are located. See the Appendix for a more complete theoretical treatment of the heavy-atom method. The initial positions for the heavy atoms can come from direct methods or from an analysis of the Patterson function (see Appendix).

Derived Results

As a result of a crystal structure determination, one usually wishes to obtain, e.g., bond distances, bond angles, and least-squares planes, along with associated standard deviations. These can be determined from the least-squares results in a straightforward fashion.

Consider the bond distance between two atoms A and B. In vector notation, using $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ to represent the unit cell vectors.

$$\begin{aligned} d_{AB} &= |\mathbf{r}_B - \mathbf{r}_A| = [(\mathbf{r}_B - \mathbf{r}_A) \bullet (\mathbf{r}_B - \mathbf{r}_A)]^{1/2} \\ &= [(x_B - x_A)^2 a_1^2 + (y_B - y_A)^2 a_2^2 \\ &\quad + (z_B - z_A)^2 a_3^2 + 2(x_B - x_A)(y_B - y_A)\mathbf{a}_1 \bullet \mathbf{a}_2 \\ &\quad + 2(y_B - y_A)(z_B - z_A)\mathbf{a}_2 \bullet \mathbf{a}_3 \\ &\quad + 2(x_B - x_A)(z_B - z_A)\mathbf{a}_1 \bullet \mathbf{a}^3]^{1/2} \end{aligned} \tag{42}$$

For atoms *A*, *B*, and *C*, the bond angle A–B–C can be obtained from

$$\text{Angle} = \cos^{-1}\left\{\frac{(\mathbf{r}_A - \mathbf{r}_B) \bullet (\mathbf{r}_C - \mathbf{r}_B)}{d_{AB} \bullet d_{BC}}\right\} \tag{43}$$

Furthermore, the standard deviation in the bond distances can be obtained from

$$\sigma^2(d) = \sum_j \left(\frac{\partial d}{\partial p_j}\right)\sigma^2(p_j) \tag{44}$$

if the parameters are uncorrelated. The parameters in this case are the fractional coordinates (x_A, y_A, z_A, x_B, y_B, z_B) and their standard deviations ($\sigma(x_A)$, $\sigma(y_A)$, $\sigma(z_A)$, $\sigma(x_B)$, $\sigma(y_B)$, $\sigma(z_B)$) and the cell dimensions and their standard deviations. [Usually the major contributors to $\sigma(d)$ are from the errors in the fractional coordinates.] A similar expression can be written for the standard deviation in the bond angle. One can also extend these arguments to e.g., torsion angles and least-squares planes.

As noted above, anisotropic thermal parameters are usually obtained as part of a crystal structure refinement. One should keep in mind that *R* factors will tend to be lower on introduction of anisotropic temperature factors, but this could merely be an artifact due to the introduction of more parameters (five for each atom). One of the most popular ways of viewing the structure, including the thermal ellipsoids, is via plots using ORTEP [a Fortran thermal ellipsoid plot program for crystal structure illustration (Johnson, 1965)]. ORTEP plots provide a visual way of helping the investigator decide if these parameters are physically meaningful. Atoms would be expected to show less thermal motion along bonds and more motion perpendicular to them. Atoms, especially those in similar environments, would be expected to exhibit similar thermal ellipsoids. Very long or very short principal moments in the thermal ellipsoids could be due to disordering effects, poor corrections for effects such as absorption, or an incorrect choice of space groups, to mention just some of the more common causes.

Once data collection has finished, the data will need to be corrected for geometric effects such as the Lorentz effect (the velocity with which the reciprocal lattice point moves through the sphere of reflection) and the polarization effect; the X-ray beam becomes partially polarized in the course of the diffraction process. Usually data will also have to be corrected for absorption since as the beam traverses the crystal, absorption occurs, as given by the relation $e^{-\mu t}$, where μ is the absorption coefficient and t is the path length. "Analytical" absorption correction can be made if the orientations of crystal faces and their distances from the center of the crystal are carefully measured. Often empirical absorption corrections are employed instead. For data collected on a four-circle diffractometer, a series of psi scans can be used for this purpose. These are scans at different ϕ angle positions for reflections close to $\chi = 90^\circ$. (For a reflection at $\chi = 90^\circ$, diffraction is ϕ independent and any variation in observed diffraction can be attributable to effects due to absorption.) For data collected on an area detector, computer programs determine the parameters associated with an analytic representation of the absorption surface using the observed differences found between symmetry-related reflections. Corrections can also be made for a decrease in scattering caused by crystal decomposition effects, if necessary. This composite set of corrections is often referred to as data reduction.

Following data reduction, the data can be averaged, if desired, and then the probable space group or groups found by an examination of systematic absences in the data. Statistical tests such as the Howells, Philips, and Rogers tests can be carried out to check for the possible presence of a center of symmetry; if more than one space group is indicated.

Next the investigator typically seeks an initial trial model using a direct method program, or if a heavy-atom approach is appropriate, the analysis of peaks between symmetry-related atoms found in the Patterson approach might be used. An initial electron density map would then be calculated. The bond distances and bond angles that are associated with these atom position possibilities and sometimes the residual index often indicate whether a valid solution has been found. If so, the inclusion of additional atoms found on electron density or difference electron density maps and subsequent refinement usually leads to a final structural model. Final bond distances, angles, and their standard deviations can be produced along with a plot of the atom positions (e.g., an ORTEP drawing).

If a valid initial model is not obtained, the number of phase set trials might be changed if using a direct method program. Different Patterson peaks could be tried. Other space group or crystal system possibilities could be investigated. Other structure solution methods beyond the scope of this chapter might have to be employed to deduce an appropriate trial model. Fortunately, if the data are of good quality, most structures can be solved using the standard computer software available with commercial systems.

Example

The compound $(C_5H_5)(CO)_2$MnDBT, where DBT is dibenzothiophene, was synthesized in R. J. Angelici's group as part of their study of prototype hydrodesulfurization catalysts (Reynolds et al., 1999). It readily formed large, brown, parallelepiped-shaped crystals. A crystal of approximate dimensions $0.6 \times 0.6 \times 0.5$ mm was selected and mounted on a glass fiber. (This crystal was larger than what would normally be used, but it did not cleave readily and the absorption coefficient for this material is quite small, $\mu = 9.34\,\text{cm}^{-1}$. A larger than normal collimator was used.) It was then placed on a Bruker P4 diffractometer, a four-circle diffractometer equipped with a scintillation counter. Molybdenum K_α radiation was used as a source from a sealed tube target and a graphite monochromator ($\lambda = 0.71069$ Å).

A set of 42 reflections was found by a random-search procedure in the range $10 \leq 2\theta \leq 25°$. These were carefully centered, indexed, and found to fit a monoclinic cell with dimensions $a = 13.076(2)$, $b = 10.309(1)$, $c = 23.484(3)$ Å, and $\beta = 92.93(1)°$. Based on atomic volume estimates and a formula weight of 360.31 g/mol, a calculated density of 1.514 g/cm^3 was obtained with eight molecules per cell. Systematic absences of $h0l$: $h + l \neq 2n$ and $0k0$: $k \neq 2n$ indicated space group $P2_1/n$, with two molecules per asymmetric unit, which was later confirmed by successful refinement.

Data were collected at room temperature (23°C) using an ω-scan technique for reflections with $2\theta \leq 50°$. A hemisphere of data was collected ($+h, \pm k, \pm l$), yielding 12,361 reflections. Symmetry-related reflections were averaged (5556 reflections) and 4141 had $F > 3\sigma(F)$ and were considered observed. The data were corrected for Lorentz and polarization effects and were corrected for absorption using an empirical method based on psi scans. The transmission factors ranged from 0.44 to 0.57.

[a] $B_{eq} = (8\pi^2/3)\sum_{i=1}^{3}\sum_{j=1}^{3} u_{ij} a_i^* a_j^* a_i \bullet a_j$.

The SHELX direct method procedure was used and yielded positions for the heavier atoms and possible positions for many of the carbon atoms. An electron density map was calculated using the phases from the heavier atoms; this map yielded further information on the lighter atom positions, which were then added. Hydrogen atoms were placed in calculated positions and all nonhydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement converged with an unweighted residual $R = \sum \| F_0| - |F_c \| / \sum |F_0|$ of 3.3% and a weighted residual $R_w = [\sum w \ (|F_0| - |F_c|)^2 / \sum w F_0^2]^{1/2}$, where $w = 1/\sigma^2(F)$, of 3.9%. The maximum peak in the final electron density difference map was 0.26 e/Å^3. Atomic scattering factors were taken from Cromer and Weber (1974), including corrections for anomalous dispersion. Fractional atomic coordinates for one of the molecules in the asymmetric unit are given in Table 3, and their anisotropic temperature factors in Table 4.

The two independent molecules in the asymmetric unit have essentially identical geometries within standard deviations. A few selected bond distances and angles are given in Table 5 and Table 6, respectively. A thermal ellipsoid plot of one of the molecules is shown in Figure 8.

SAMPLE PREPARATION

The typical investigation starts obviously with the selection of a crystal. This is done by examining the material under a low- or moderate-power microscope. Samples that display sharp, well-defined faces are more likely to be single crystals. Crystals with average dimensions of a

few tenths of a millimeter are often appropriate—somewhat larger for an organic material. (An approximately spherical crystal with diameter $2/\mu$, where μ is the absorption coefficient, would be optimum.) The longest dimension should not exceed the diameter of the X-ray beam, i.e., it is important that the crystal be completely bathed by the beam if observed intensities are to be compared to their calculated counterparts.

The crystal can be mounted on the end of a thin glass fiber or glass capillary if stable to the atmosphere using any of a variety of glues, epoxy, or even fingernail polish. If unstable, it can be sealed inside a thin-walled glass capillary. If the investigation is to be carried out at low temperature and the sample is unstable in air, it can be immersed in an oil drop and then quickly frozen; the oil should contain light elements and be selected such as to form a glassy solid when cooled.

SPECIMEN MODIFICATION

In most instances, little if any specimen modification occurs, especially when area detectors are employed for data collection, thereby reducing exposure times. In some cases, the X-ray beam can cause some decomposition of the crystal. Decomposition can often be reduced by collecting data at low temperatures.

PROBLEMS

Single-crystal X-ray diffraction has an advantage over many other methods of structure determination in that there are many more observations (the X-ray intensities) than parameters (atomic coordinates and thermal parameters). The residual index (R-value) therefore usually serves as a good guide to the general reliability of the solution. Thermal ellipsoids from ORTEP should also be examined, as well as the agreement between distances involving similar atoms, taking into account their standard deviations. Ideally, such distance differences should be less than 3 sigma, but may be somewhat greater if packing or

systematic error effects are present. If thermal ellipsoids are abnormal, this can be an indication of a problem with some aspect of the structure determination. This might be due to a poor correction for absorption of X rays as they pass through the crystal, a disordering of atoms in the structure, an extinction coefficient, or an incorrect choice of space group.

Approximations are inherent in any absorption correction, and therefore it is best to limit such effects by choosing a smaller crystal or using a different wavelength where the linear absorption coefficient would be less. The optimum thickness for a crystal is discussed above (see Sample Preparation).

If an atom is disordered over a couple of sites in the unit cell, an appropriate average of the electron density is observed and an elongation of the thermal ellipsoid may be observed if these sites are only slightly displaced. Sometimes it is possible to include multiple occupancies in the refinement to reasonably model such behavior with a constraint on the sum of the occupancies.

If a crystal is very perfect, extinction effects may occur, i.e., a scattered X-ray photon is scattered a second time. If this occurs in the same "mosaic block," it is termed primary extinction; if it occurs in another "mosaic block," it is termed secondary extinction. The effect is most noticeable in the largest intensities and usually manifests itself in a situation in which ten or so of the largest intensities are found to have calculated values that exceed the observed ones. Mathematical techniques exist to approximately correct for such extinction effects, and most crystallographic programs include such options.

Problems can be encountered if some dimension of the crystal exceeds the beam diameter. The crystal must be completely bathed in a uniform beam of X rays for all orientations of the crystal, if accurate intensities are to be predicted for any model.

The crystal should not decompose significantly (less than about 10%) in the X-ray beam. Some decomposition effects can be accounted for as long as they are limited.

Provides a much more detailed description of the kinematic theory of X-ray scattering and its application to single-crystal structure determination.

Ladd and Palmer, 1985. See above.

Another good text that introduces the methods of crystallography, yet does so without being too mathematical; also provides a number of problems following each chapter to facilitate subject comprehension.

Stout and Jensen, 1989. See above.

A good general text on X-ray diffraction and one that emphasizes many of the practical aspects of the technique.

APPENDIX

Direct Methods

There were a number of early attempts to use statistical approaches to develop relations that could yield the phases (or signs for the centrosymmetric case) of some of the reflections. Harker and Kasper (1948), for example, developed a set of inequalities based on the use of Cauchy's inequality. A different approach was suggested by Sayre (1952). Although later superceded by the work of Karle and Hauptman (1956), this work is still of some interest since it affords some physical insight into these methods.

Sayre (1952) noted that ρ^2 would be expected to look much like ρ, especially if the structure contains atoms that are all comparable in size. (Ideally, ρ should be nonnegative; it should contain peaks where atoms are and should equal zero elsewhere, and hence its square should

have the same characteristics with modified peak shape.) One can express ρ^2 as a Fourier series,

$$\rho^2(xyz) = \frac{1}{V}\sum_h \sum_k \sum_l G_{hkl} \exp[-2\pi i(hx + ky + lz)] \quad (45)$$

where the G's are the Fourier transform coefficients.

Since ρ^2 would be made up of "squared" atoms, G_{hkl} can be expressed as

$$G_{hkl} = \sum_{j=1}^{n} g_j \exp[2\pi i(hx_j + ky_j + lz_j)] \quad (46)$$

or

$$G_{hkl} \approx \frac{g}{f} F_{hkl} \quad (47)$$

if all atoms are assumed to be approximately equal. Therefore

$$\rho^2(xyz) = \frac{1}{V}\sum_h \sum_k \sum_l \frac{g}{f} F_{hkl} \exp[2\pi i(hx + ky + lz)] \quad (48)$$

but also

$$\begin{aligned}\rho^2(xyz) &= \frac{1}{V^2}\left(\sum_h \sum_k \sum_l F_{hkl} \exp[2\pi i(hx + ky + lz)]\right) \\ &\quad \times \left(\sum_H \sum_K \sum_L \frac{g}{f} F_{HKL} \exp[2\pi i(Hx + Ky + Lz)]\right) \\ &= \frac{1}{V^2}\sum_h \sum_k \sum_l \sum_H \sum_K \sum_L F_{hkl} \exp\{2\pi i[(h + H)x \\ &\quad + (k + K)y + (l + L)z]\} \end{aligned} \quad (49)$$

Comparing the two expressions for ρ^2 and letting $\mathbf{h} = \mathbf{k} + \mathbf{H}$ yield

$$\frac{g}{f} F_{\mathbf{h}} = \frac{1}{V}\sum_k F_{\mathbf{h}-\mathbf{k}} F_{\mathbf{k}} \quad (50)$$

Sayre's relation therefore implies that the structure factors are interrelated. The above relation would suggest that in a centrosymmetric structure, if $F_{\mathbf{k}}$ and $F_{\mathbf{h}-\mathbf{k}}$ are both large in magnitude and of known sign, the sign of $F_{\mathbf{h}}$ would likely be given by the product $F_{\mathbf{k}}F_{\mathbf{h}-\mathbf{k}}$ since this term will tend to predominate in the sum. Sayre's relation was primarily of academic interest since in practice few F's with known signs have large magnitudes, and the possibilities for obtaining new phases or signs are limited.

Karle and Hauptman (1956), using a different statistical approach, developed a similar equation along with a number of other useful statistical-based relations. They did so using E_{hkl}'s that are related to the structure factor by defining

$$|E_{hkl}|^2 = |F_{hkl}|^2/\varepsilon \sum f_j^2 \quad (51)$$

where f_j is the atomic scattering factor corrected for thermal effects and ε is a factor to account for degeneracy and is usually unity except for special projections.

For the equal atom case, a simple derivation can be given (Karle and Karle, 1966). Then

$$|E_{\mathbf{h}}|^2 = f^2 \left| \sum_j \exp(2\pi i \mathbf{h} \bullet \mathbf{r}_j) \right|^2 / Nf^2 \quad (52)$$

or

$$E_{\mathbf{h}} = \frac{1}{N^{1/2}} \sum_{j=1}^{N} \exp(2\pi i \mathbf{h} \bullet \mathbf{r}_j) \quad (53)$$

Now consider

$$\begin{aligned} E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}} &= \frac{1}{N}\left[\sum_j \exp(2\pi i \mathbf{k} \bullet \mathbf{r}_j)\right] \\ &\quad \times \left[\sum_j \exp(2\pi i(\mathbf{h} - \mathbf{k}) \bullet \mathbf{r}_j)\right] \\ &= \frac{1}{N}\left\{\sum_j \exp(2\pi i \mathbf{h} \bullet \mathbf{r}_j)\right. \\ &\quad \left. + \sum_i \sum_j \exp[2\pi i \mathbf{k} \bullet (\mathbf{r}_j - \mathbf{r}_i)][\exp(2\pi i \mathbf{h} \bullet \mathbf{r}_i)]\right\} \end{aligned} \quad (54)$$

If an average is now taken over a reasonably large number of such pairs, keeping h constant, then

$$\begin{aligned} \langle E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}\rangle &\approx \frac{1}{N}\sum \exp(2\pi i \mathbf{h} \bullet \mathbf{r}_i) \\ &\approx \frac{1}{N^{1/2}} E_{\mathbf{h}} \end{aligned} \quad (55)$$

(The second term in Equation 54 will tend to average to zero.) Since the magnitudes are measured and our concern is with the phase, we write

$$E_{\mathbf{h}} \propto \langle E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}\rangle_{\mathbf{k}} \quad (56)$$

Karle and Hauptman showed, using a more sophisticated mathematical approach, that for the unequal atom ease, a similar relation will hold. Equation 56 is often referred to as the sigma-two ($\sum_2$) relation.

For the non-centrosymmetric case, this is more conveniently written (Karle and Hauptman, 1956) as

$$\tan\alpha_{\mathbf{h}} = \frac{\sum_{\mathbf{k}} |E_{\mathbf{h}}\| E_{\mathbf{h}-\mathbf{h}}| \sin(\alpha_{\mathbf{k}} + \alpha_{\mathbf{h}-\mathbf{k}})}{\sum_{\mathbf{k}} |E_{\mathbf{k}}\| E_{\mathbf{h}-\mathbf{k}}| \cos(\alpha_{\mathbf{k}} + \alpha_{\mathbf{h}-\mathbf{k}})} \quad (57)$$

Karle and Hauptman argued that the relation should hold for an average using a limited set of data if the $|E|$'s are large, and Cochran and Woolfson (1955) obtained an approximate expression for $|E_{\mathrm{h}}|$ being positive from the $\sum_2$ relation,

$$P_+(\mathbf{h}) = \frac{1}{2} + \frac{1}{2}\tanh \sigma_3 \sigma_2^{-3/2} |E_{\mathbf{h}}| \sum_{\mathbf{k}} E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}} \quad (58)$$

where, Z_j being the atomic number of atom j

$$\sigma_n = \sum_j Z_j^n \tag{59}$$

The strategy then is to start with a few reflections whose phases are known and extend these using the $\sum_2$ relation accepting only those indications that have high probability (typically >95%) of being correct. The process is then repeated until no significant further changes in phases occur.

However, to employ the above strategy, phases of a few of the largest $|E|$'s must be known. How does one obtain an appropriate starting set? If working in a crystal system of orthorhombic symmetry or lower, three reflections can be used to specify the origin. Consider a centrosymmetric space group. The unit cell has centers of symmetry not only at (0, 0, 0) but also halfway along the cell in any direction. Therefore the cell can be displaced by 1/2 in any direction and an equally valid structural solution obtained (same set of intensities) using the tabulated equivalent positions of the space group. If in the structure factor expression all x_j were replaced by $1/2+x_j$, then

$$E_{hkl}^{\text{new}} = (-1)^h E_{hkl}^{\text{old}} \tag{60}$$

Therefore the signs of the structure factors for h odd would change while the signs for the even would not. Thus specifying a sign for an h odd reflection amounts to specifying an origin in the x direction. A similar argument can be made for the y and z directions as long as the reflection choices are independent. Such choices will be independent if they obey

$$\mathbf{h}_1 + \mathbf{h}_2 + \mathbf{h}_3 \neq (e,e,e) \tag{61a}$$

$$\mathbf{h}_1 + \mathbf{h}_2 \neq (e,e,e), \cdots \tag{61b}$$

$$\mathbf{h}_1 \neq (e,e,e), \cdots \tag{61c}$$

where e indicates an even value of the index.

Another useful approach to the derivation of direct method equations is through the use of what are termed structure semivariants and structure invariants.

Structure semivariants are those reflections or linear combination of reflections that are independent of the choice of permissible origins, such as has just been described above.

Structure invariants are certain linear combinations of the phases whose values are determined by the structure alone and are independent of the choice of origin. We will consider here two subgroups, the three-phase (triplet) structure invariant and the four-phase (quartet) structure invariant.

A three-phase structure invariant is a set of three reciprocal vectors $\mathbf{h}_1$, $\mathbf{h}_2$, and $\mathbf{h}_3$ that satisfy the relation

$$\mathbf{h}_1 + \mathbf{h}_2 + \mathbf{h}_3 = 0 \tag{62}$$

Let

$$A = \frac{\sigma_3}{\sigma_2^{3/2}} (|E_{\mathbf{h}_1} \parallel E_{\mathbf{h}_2} \parallel E_{\mathbf{h}_3}|) \tag{63}$$

and, in terms of phases φ

$$\varphi_3 = \varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_2} + \varphi_{\mathbf{h}_3} \tag{64}$$

then φ_3 is found to be distributed about zero with a variance that is dependent on A—the larger its value, the narrower the distribution. It is obviously then another version of the $\sum_2$ relation.

A four-phase structure invariant is similarly four reciprocal vectors $\mathbf{h}_1$, $\mathbf{h}_2$, $\mathbf{h}_3$, and $\mathbf{h}_4$ that satisfy the relation

$$\mathbf{h}_1 + \mathbf{h}_2 + \mathbf{h}_3 + \mathbf{h}_4 = 0 \tag{65}$$

Let

$$B = \frac{\sigma_3}{\sigma_2^{3/2}} (|E_{\mathbf{h}_1} \parallel E_{\mathbf{h}_2} \parallel E_{\mathbf{h}_3} \parallel E_{\mathbf{h}_4}|) \tag{66}$$

and

$$\varphi_4 = \varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_2} + \varphi_{\mathbf{h}_3} + \varphi_{\mathbf{h}_4} \tag{67}$$

If furthermore three additional magnitudes are known, $|E_{\mathbf{h}_1+\mathbf{h}_2}|, |E_{\mathbf{h}_2+\mathbf{h}_3}|$, and $|E_{\mathbf{h}_3+\mathbf{h}_1}|$, then, in favorable cases, a more reliable estimate of φ_4 may be obtained, and furthermore, the estimate may lie anywhere in the interval 0 to π. If all seven of the above $|E|$'s are large, then it is likely that $\varphi_4 = 0$. However, it can also be shown that for the case where $|E_{\mathbf{h}_1}|, |E_{\mathbf{h}_2}|, |E_{\mathbf{h}_3}|$, and $|E_{\mathbf{h}_4}|$ are large but $|E_{\mathbf{h}_1+\mathbf{h}_2}|, |E_{\mathbf{h}_2+\mathbf{h}_3}|$ and $|E_{\mathbf{h}_3+\mathbf{h}_1}|$ are small, the most probable value of φ_4 is π. The latter is sometimes referred to as the negative-quartet relation. (For more details see Ladd and Palmer, 1980.)

Normally additional reflections will be needed to obtain a sufficient starting set. Various computer programs adopt their own specialized procedures to accomplish this end. Some of the more common approaches include random choices for signs or phases for a few hundred reflections followed by refinement and extension; alternately, phases for a smaller set of reflections, chosen to maximize their interaction with other reflections, are systematically varied followed by refinement and extension (for an example of the latter, see Woolfson and Germain, 1970; Germain et al., 1970). Various figures of merit have also been devised by the programmers to test the validity of the phase sets so obtained.

Direct method approaches readily lend themselves to the development of automatic techniques. Over the years, they have been extended and refined to make them generally applicable, and this has led to their widespread use for deducing an initial model.

Computer programs such as the SHELX direct method programs (Sheldrick, 1990) use both the $\sum_2$ (three-phase structure invariant) and the negative four-phase quartet to determine phases. Starting phases are produced by random-number generation techniques and then refined using

$$\text{New } \varphi_h = \text{phase of } [\alpha - \eta] \tag{68}$$

where α is defined by

$$\alpha = 2|E_{\mathbf{h}}|E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}/N^{1/2} \tag{69}$$

and η is defined by

$$\eta = g|E_{\mathbf{h}}|E_{\mathbf{k}}E_{\mathbf{l}}E_{\mathbf{h}-\mathbf{k}-\mathbf{l}}/N \tag{70}$$

N is the number of atoms (for an equal atom case), and g is a constant to compensate for the smaller absolute value of η compared to α. In the calculation of η, only those quartets are used for which all three cross terms have been measured and are weak. An E map is then calculated for the refined phase set giving the best figure of merit.

Heavy-Atom Method

Direct methods can be expected to be the most reliable when applied to structures in which most of the atoms are approximately equal in atomic number. In structures where one or a few atoms are present that have appreciably larger atomic numbers than the rest, the heavy-atom method is typically the approach of choice.

Assume a structure contains one atom in the asymmetric unit that is "heavier" than the rest. Also assume for the moment that the position of this atom (r_{H}) is known. The structure factor can be written as

$$F_{hkl} = f_H \exp(2\pi i\mathbf{h} \bullet \mathbf{r}_H) + \sum_{j=2}^{N} f_j \exp(2i\mathbf{h} \bullet \mathbf{r}_j) \tag{71}$$

Alternately the structure factor can be written as

$$F_{hkl} = F_{hld}^{\mathrm{heavy}} + F_{hkl}^{\mathrm{other}} \tag{72}$$

where "heavy" denotes the contributors to the structure factor from the heavy atom(s) and "other" represents the contribution to the structure factor from the remaining atoms in the structure. The latter contains many small contributions, which can be expected to partially cancel one another in most reflections. Therefore, if the "other" contribution does not contain too large a number of these smaller contributors, one would expect the sign (or the phase) of the observed structure factor to be approximately that calculated from F_{hkl}^{heavy}, although the agreement in terms of magnitudes would likely be poor. Thus the approach is to calculate F_{hkl}^{heavy} and transfer its sign or phase to the $|F_{hkl}^{\mathrm{obs}}|$, unless $|F_{hkl}^{\mathrm{heavy}}|$ is quite small. Use these phased $|F_{hkl}^{\mathrm{obs}}|$ to calculate an electron density map and examine this map to attempt to find additional positions. (As a general rule of thumb, atoms often appear with $\sim 1/3$ of their true height if not included in the structure factor calculation.) Those atoms that appear, especially if they are in chemically reasonable positions, are then added to the structure factor calculation, giving improved phases, and the process is repeated until all the atoms have been found. For this approach to be successful, it is usually necessary for $\sum Z_{\mathrm{H}}^2 \geq \sum Z_{\mathrm{L}}^2$.

How does one go about finding the position of the heavy atom or atoms, assuming the statistics indicate that the heavy-atom approach could be successful? One possibility is to use direct methods as discussed earlier. Although direct methods may not provide the full structure, the largest peaks on the calculated map may well correspond to the positions of the heavier atoms.

An alternate approach is to deduce the position of the heavy atom(s) through the use of a Patterson function (Patterson, 1935). The Patterson function is an autocorrelation function of the electron density function:

$$P(\mathbf{u}) = \int \rho(\mathbf{r}) \bullet \rho(\mathbf{r} + \mathbf{u}) d\tau \tag{73}$$

If the Fourier series expressions for ρ are substituted into this equation, it can be readily shown that

$$P(\mathbf{u}) = \frac{1}{V} \sum_h \sum_k \sum_l |F_{hkl}|^2 \cos 2\pi\mathbf{h} \bullet \mathbf{u} \tag{74}$$

The Patterson function therefore can be directly calculated from the intensities. From a physical point of view, a peak would be expected in the Patterson function anytime two atoms are separated by a vector displacement $\mathbf{u}$. Since a vector could be drawn from A to B or B to A, a centrosymmetric function would be expected, consistent with a cosine function. Moreover, the heights of the peaks in the Patterson function should be proportional to the products of the atomic electron densities, i.e., Z_{iZj}. If a structure contained nickel and oxygen atoms, the heights of the Ni-Ni, Ni-O, and O-O vectors would be expected to be in the ratio 784:224:64 for peaks representing single interactions.

Most materials crystallize in unit cells that have symmetry higher than triclinic. This symmetry can provide an additional very useful tool in the analysis of the Patterson function. All Patterson functions have the same symmetry as the Laue group associated with the related crystal system. Often peaks corresponding to vectors between symmetry-related atoms occur in special planes or lines. This is probably easiest seen with an example. Consider the monoclinic space group $P2_1/c$. The Patterson function would have $2/m$ symmetry—the symmetry of the monoclinic Laue group. Moreover, because of the general equivalent positions in this space group, namely, $(x, y, z)(x, 1/2 - y, 1/2 + z)(\bar{x}, 1/2 + y, 1/2 - z)(\bar{x}, \bar{y}, \bar{z})$, peaks between symmetry-related atoms would be found at $(0, 1/2 - 2y, 1/2)(0, 1/2 + 2y, 1/2)$ $(-2x, 1/2, 1/2 - 2z)$ $(2x, 1/2, 1/2 + 2z)$ $(-2x, 2y, -2z)$ $(2x, 2y, 2z)$ $(-2x, 2y, -2z)$ and $(2x, -2y, 2z)$ as deduced by obtaining all the differences between these equivalent positions. Such vectors are often termed Harker vectors (Harker, 1936; Buerger, 1959). In the case of the first four peaks, two differences give the same values and yield a double peak on the Patterson function. This set of Patterson peaks can be used to determine the position of a heavy atom. First we should again note that the peaks corresponding to vectors between heavy atoms should be larger than the other types. For this space group, one can select those peaks with $u = 0$ and $w = 1/2$ and, from their v coordinate, determine y possibilities. In a similar fashion, by selecting those large peaks with $\nu = 1/2$ (remember peaks in both of these categories

must be double), an x and z pair can be determined. These results can be combined together to predict the $2x$, $2y$, $2z$ type peak position, which can then be tested to see if the combination is a valid one. The same process can be carried out if more than one heavy atom is present per asymmetric unit—the analysis just becomes somewhat more complicated. [There is another category of methods termed Patterson superposition methods, which are designed to systematically break down the multiple images of the structure present in the Patterson function to obtain essentially a single image of the structure. Because of space limitations, they will not be discussed here. An interested reader should consult Richardson and Jacobson (1987) and Lipscomb and Jacobson (1990) and references therein for further details.] It may also be appropriate here to remind the reader that the intensities are invariant if the structure is acted upon by any symmetry element in the Laue group or is displaced by half-cell displacements. Two solutions differing only in this fashion are equivalent.

XAFS SPECTROSCOPY

INTRODUCTION

X rays, like other forms of electromagnetic radiation, are both absorbed and scattered when they encounter matter. X-ray scattering and diffraction are widely utilized structural methods employed in thousands of laboratories around the world. X-ray diffraction techniques are undeniably among the most important analysis tools in nearly every physical and biological science. As this unit will show, x-ray absorption measurements are achieving a similar range of application and utility. Absorption methods are often complementary to diffraction methods in terms of the area of application and the information obtained.

The basic utility of x-ray absorption arises from the fact that each element has characteristic absorption energies, usually referred to as absorption edges. These occur when the x rays exceed the energy necessary to ionize a particular atomic level. Since this is a new channel for absorption, the absorption coefficient shows a sharp rise. Some examples are shown in Figure 1A for elements in a high-temperature superconductor. Note that the spectra for each element can be separately obtained and have distinctly different structure. Often the spectra are divided into two regions. The region right at the edge is often called the XANES (x-ray absorption near-edge structure), and the region starting ~20 or 30 eV past its edge is referred to as EXAFS (extended x-ray absorption fine structure). The isolated EXAFS structure is shown in Figure 1B. Recent theories have begun to treat these in a more unified manner, and the trend is to refer to the entire spectrum as the XAFS (x-ray absorption fine structure) and the technique in general as XAS (x-ray absorption spectroscopy). Historically the principal quantum number of the initial state atomic level is labeled by the letters K, L, M, N, ... for $n = 1, 2, 3, 4, \ldots$, and the angular momentum state of the level is denoted as subscripts $1, 2, 3, 4, \ldots$ for the s, $p_{1/2}$, $p_{3/2}$, $d_{3/2}, \ldots$ levels. The most common edges used for XAFS are the K edge or $1s$ initial state (the subscript 1 is omitted since it is the only possibility) and the L_3 edge or $2p_{3/2}$ initial state.

The utility of XAS is demonstrated in Figure 1. The different elements have different fine structure because they have different local atomic environments. In this unit it will be shown how these spectra can be analyzed to obtain detailed information about each atom's environment. This includes the types of neighboring atoms, their distances, the disorder in these distances, and the type of bonding. The near-edge region is more sensitive to chemical effects and can often be used to determine the formal valence of the absorbing atom as well as its site symmetry.

In the simplest picture, the spectra are a result of quantum interference of the photoelectron generated by the absorption process as it is scattered from the neighboring atoms. This interference pattern is, of course, related to the local arrangement of atoms causing the scattering. As the incoming x-ray energy is changed, the energy of the photoelectron also varies along with its corresponding

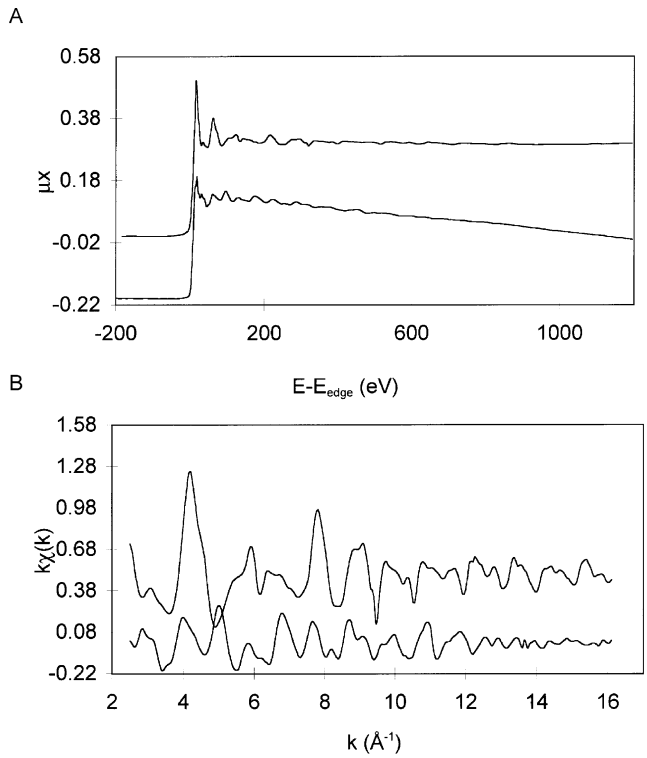

Figure 1. Examples of x-ray absorption data from the high-temperature superconductor material $YBa_2Cu_3O_7$. (**A**) X-ray absorption. (**B**) Normalized extended fine structure vs. wave vector extracted from the spectra in (A). The top spectra in both plots are for the Y K edge at 17,038 eV, and the bottom spectra are for the Cu K edge at 8,980 eV. Both edges were obtained at liquid nitrogen temperature.

wavelength. Therefore, the interference from the different surrounding atoms goes in and out of phase, giving the oscillatory behavior seen in Figure 1B. Each type of atom also has a characteristic backscattering amplitude and phase shift variation with energy. This allows different atom types to be distinguished by the energy dependence of the phase and amplitude of the different oscillatory components of the spectrum. This simple picture will be expanded below (see Principles of the Method) and will form the basis for the detailed analysis procedures used to extract the structural parameters. It is important to emphasize that the oscillations originate from a local process that does not depend on long-range order. XAFS will be observed any time an atom has at least one well-defined neighbor and, in addition to well-ordered crystalline or polycrystalline materials, has been observed in molecular gases, liquids, and amorphous materials.

The widespread use of x-ray absorption methods is intimately connected to the development of synchrotron radiation sources. The measurements require a degree of tunability and intensity that is difficult to obtain with conventional laboratory sources. Because of this need and of advances in the theoretical understanding that came at about the same time as the major synchrotron sources were first developed, the modern application of absorption methods for materials analysis is only ~25 years old. However, it has a long history as a physical phenomenon to be understood, with extensive work beginning in the 1930s. For a review of the early work see Azaroff and Pease (1974) and Stumm von Bordwehr (1989).

This unit will concentrate on the modern application of XAS at synchrotron sources. Conducting experiments at remote facilities is a process with its own style that may not be familiar to new practitioners. Some issues related to working at synchrotrons will be discussed (see Practical Aspects of the Method).

Comparison to Other Techniques

There are a wide variety of structural techniques; they can be broadly classified as direct and indirect methods. Direct methods give signals that directly reflect the structure of the material. Diffraction measurements can, in principle, be directly inverted to give the atomic positions. Of course, the difficulty in measuring both the phase and amplitude of the diffraction signals usually precludes such an inversion. However, the diffraction pattern still directly reflects the underlying symmetry of the crystal lattice, and unit cell symmetry and size can be simply determined. More detailed modeling or determination of phase information is required to place the atoms accurately within the unit cell. Because there is such a direct relation between structure and the diffraction pattern, diffraction techniques can often provide unsurpassed precision in the atomic distances.

Indirect methods are sensitive to structure but typically require modeling or comparison to standards to extract the structural parameters. This does not mean they are not extremely useful structural methods, only that the signal does not have a direct and obvious relation to the structure. Examples of such methods include Mössbauer spectroscopy (MOSSBAUER SPECTROMETRY), nuclear magnetic resonance (NMR; NUCLEAR MAGNETIC RESONANCE IMAGING), electron paramagnetic resonance (EPR; ELECTRON PARAMAGNETIC RESONANCE SPECTROSCOPY), and Raman spectroscopy (RAMAN SPECTROSCOPY OF SOLIDS). The XANES part of the x-ray absorption signal can be fit into this category. As will be shown, strong multiple-scattering and chemical effects make direct extraction of the structural parameters difficult, and analysis usually proceeds by comparison of the spectra with calculated or measured models. On the other hand, as is the case with many of the other indirect methods, the complicating factors can often be used to advantage to learn more about the chemical bonding.

The indirect methods usually share the characteristic that they are atomic probes. That is, they are foremost measures of the state of an individual atom. The structure affects the signal since it affects the atomic environment, but long range order is usually not required. Also, atomic concentration is not important in determining the form of the signal, only its detectability. Therefore, exquisite sensitivity to low concentrations is often possible. This is also true for x-ray absorption. Methods that allow detection of structural information to concentrations for which diffraction techniques would be useless will be described under Detection Methods, below.

In some respects, the EXAFS part of the absorption signal shares the characteristics of both direct and indirect structural methods. The absorbing atom acts as both the source and detector of the propagating photoelectrons. The measured signal contains both phase and amplitude information, and, as in direct methods, can be inverted to obtain structural information. However, the photoelectrons interact strongly with the surrounding atoms, which modifies both their amplitude and phase. Therefore, a direct inversion (Fourier transform) of the spectrum gives only a qualitative view of the local structure. This qualitative view can be informative, but modeling is usually required to extract detailed structural parameters.

PRINCIPLES OF THE METHOD

Single-Scattering Picture

When an x ray is absorbed, most of the time an electron is knocked out of the atom, which results in a photoelectron with energy $E = E_x - E_b$, where E_x is the x-ray energy and E_b is the binding energy of the electron. The x-ray edge occurs when $E_x = E_b$. The photoelectron propagates as a spherical wave with a wave vector given by

$$k = \frac{\sqrt{2m_e E}}{\hbar} \quad (1)$$

As shown in Figure 2, this wave can be scattered back to the central atom and interfere with the original absorption. In a classical picture this can seem like a strange concept, but this process must be treated quantum mechanically, and the absorption cross-section is governed by Fermi's golden rule:

$$\sigma_K = 4\pi^2 \alpha \hbar\omega \sum_j |\langle \Psi_f | \mathbf{e} \cdot \mathbf{r} | \Psi_K \rangle|^2 \times \delta(E_f + E_K - \hbar\omega) \quad (2)$$

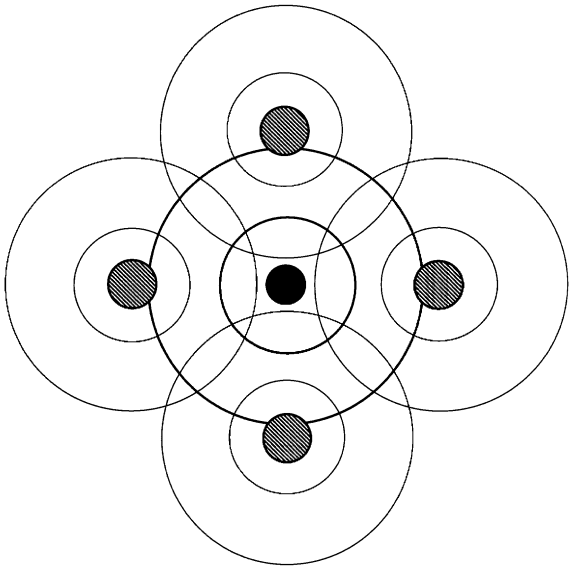

Figure 2. Two-dimensional schematic of the EXAFS scattering process. The photoelectron originates from the central (black) atom and is scattered by the four neighbors. The rings represent the maxima of the photoelectron direct and scattered waves.

where **e** is the electric field vector, **r** is the radial distance vector, α is the fine structure constant, ω is the angular frequency of the photon, and Ψ_K and Ψ_f are the initial state (e.g., the 1*s* state in the *K* shell) and the final state, respectively. The sum is over all possible final states of the photoelectron.

It is necessary to consider the overlap of the initial core state with a final state consisting of the excited atom and the outgoing and backscattered photoelectron. Since the photoelectron has a well-defined wavelength, the backscattered wave will have a well-defined phase relative to the origin (deep core electrons characteristic of x-ray edges are highly localized at the center of the absorbing atom). This phase will vary with energy, resulting in a characteristic oscillation of the absorption probability as the two waves go in and out of phase. Using this simple idea and considering only single scattering events gives the following simple expression (Sayers et al., 1971; Ashley and Doniach, 1975; Lee and Pendry, 1975):

$$\chi(k) = \frac{\mu(k) - \mu_0(k)}{\mu_0(k)} = \sum_j \frac{N_j}{kR_j^2} A_j(k) p_j(\mathbf{e}) \sin[2kR_j + \Psi_j(k)] \qquad (3)$$

where $\chi(k)$ is the normalized oscillatory part of the absorption determined by subtracting the smooth part of the absorption, μ_0, from the total absorption, μ, and normalizing by μ_0. The sum is over the neighboring shells of atoms each of which consists of N_j atoms at a similar distance R_j. The R_j^2 factor accounts for the fall-off of the spherical photoelectron wave with distance.

The sine term accounts for the interference. The total path length of the photoelectron as it travels to a shell and back is $2kR_j$. The factor $p_j(\mathbf{e})$ accounts for the polarization of the incoming x-rays. The remaining factors, $A_j(k)$ and $\Psi_j(k)$, are overall amplitude and phase factors. It is these two factors that must be calibrated by theory or experiment. The amplitude factor $A(k)$ can be further broken down to give

$$A_j(k) = S_0^2 F_j(k) Q_j(k) e^{-2R_j/\lambda} \qquad (4)$$

The amplitude reduction factor S_0^2 results from multielectron excitations in the central atom (the simple picture assumes only a single photoelectron is excited). This factor depends on the central atom type and typically has nearly k independent values from 0.7 to 0.9. The magnitude of the complex backscattering amplitude factor $f_j(k, \pi)$, $F_j(k)$ depends on the type of scattering atom. Often its k -dependence can be used to determine the type of backscattering atom. The factor $Q_j(k)$ accounts for any thermal or structural disorder in the jth shell of atoms. It will be discussed in more detail later. The final exponential factor is a mean free path factor that accounts for inelastic scattering and core hole lifetime effects.

The phase term can be broken down to give

$$\Psi_j(k) = 2\phi_c + \theta_j(k) + \varphi_j(k) \qquad (5)$$

where $\theta_j(k)$ is the phase of the backscattering factor $f_j(k, \pi)$, ϕ_c is the p-wave phase shift caused by the potential of the central atom, and $\varphi_j(k)$ is a phase factor related to the disorder of the jth shell.

In the past, the phase and amplitude terms were generally calibrated using model compounds that had known structures and chemical environments similar to those of the substance being investigated. The problem with this approach is that suitable models were often difficult to come by, since a major justification for applying XAFS is the lack of other structural information. In recent years the theory has advanced to the state where it is often more accurate to make a theoretical determination of the phase and amplitude factors. Using theory also allows for proper consideration of multiple scattering complications to the simple single scattering picture presented so far. This will be discussed below (see Data Analysis and Initial Interpretation). Figures 3, 4, and 5 show some calculated

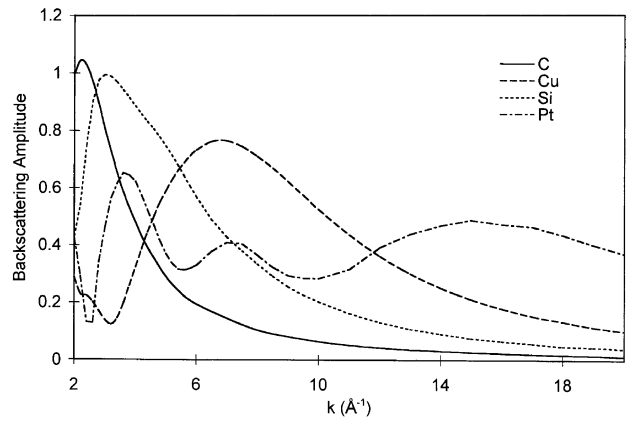

Figure 3. Theoretical backscattering amplitude versus photoelectron wave vector k for some representative backscattering atoms. Calculated using FEFF 5.0 (Zabinsky et al., 1995).

amplitudes and phases, illustrating two main points. First, there are significant differences in the backscattering from different elements. Therefore, it is possible to distinguish between different types of atoms in a shell. For neighboring atoms such as Fe and Co, the differences are generally too small to distinguish them reliably, but if the atomic numbers of atoms in a shell differ by more than ~10%, then their contributions can be separated. The figures nicely illustrate this. Platinum is quite different from the other elements and is easily distinguished. Silicon and carbon have similar backscattering amplitudes that could be difficult to distinguish if the additional amplitude variations from disorder terms are not known. However, the backscattering phase is about a factor of π different, which means their oscillations will be out of phase and easily distinguished. Similarly, copper and carbon have almost the same phase but a distinctly different amplitude.

The second point is that the phase shifts are fairly linear with k. This means that the sinusoidal oscillations in Equation 3 will maintain their periodic character. The additional phase term will primarily result in a constant frequency shift. Each shell of atoms will still have a characteristic frequency, and a Fourier transform of the spectrum can be used to separate them. This is shown in Figure 6, which is a Fourier transform of the Cu data in Figure 1B. The magnitude of the Fourier transform is related to the partial radial distribution function of the absorbing atoms. The peaks are shifted to lower R by the phase shift terms, and the amplitude of the peaks depends on the atomic type, number of atoms in a shell, and disorder of the shell. This is a complex structure and there are no well-defined peaks that are well separated from the others. Methods that can be used to extract the structural information are described below (see Data Analysis and Initial Intepretation). This is high-quality data and all the structure shown is reproducible and real. However, above ~4 Å the structure is a composite of such a large number of single- and multiple-scattering contributions that it is not possible to analyze. This is typical of most structures, which become too complex to analyze at distances above 4 to 5 Å. It is also important to note that because of the additional phase and amplitude terms, the transform does not give the true radial distribution. It should only be used as an intermediate step in the analysis and as a method for making a simple qualitative examination of the data. It is very useful for assessing the noise in the data and for pointing out artifacts that can result in nonphysical peaks.

EXTENSIONS TO THE SIMPLE PICTURE

Disorder

The x-ray absorption process is energetic and takes place in a typical time scale of 10^{-15} sec. This is much faster than the typical vibrational periods of atoms and means that the x-ray absorption takes a snapshot of the atomic configuration. Even for an ideal shell of atoms all at a single distance, thermal vibrations will result in a distribution about the average R_j. In addition, for complex or disordered structures there can be a structural contribution to the distribution in R_j. This results in the disorder factors $Q_j(k)$ and $\varphi_j(k)$ given above. To a good approximation these factors are given by the Fourier transform of the real-space distribution $P_j(r)$:

$$Q_j(k)\exp[i\varphi_j(k)] = \int dr\, P_j(r)\exp[i2k(r-R_j)] \qquad (6)$$

The simplest case is for a well-ordered shell at low temperature where the harmonic approximation for the vibrations applies. Then the distribution is Gaussian, and the transform is also Gaussian. This results in $\varphi_j(k) = 0$ and a Debye-Waller-like term for $Q : Q_j(k) = \exp(-2k^2\sigma_j^2)$, where σ_j^2 is the mean-square width of the distribution. This simple approximation is often valid and provides a good starting point for analysis. However, it is a fairly extreme approximation and can break down. If $\sigma^2 >\sim 0.01^2$, more exact methods should be used that include the contribution to the phase (Boyce et al., 1981; Crozier et al., 1988; Stern et al., 1992). One commonly used method included in many analysis packages is the cumulant expansion (Bunker, 1983).

The changes in the Debye-Waller term with temperature can often be determined relatively accurately. It can be quite sensitive to temperature, and low-temperature measurements will often produce larger signals and higher data quality.

Although the EXAFS disorder term is often called a Debye-Waller factor, this is not strictly correct. The EXAFS Debye-Waller factor is different from that determined by x-ray diffraction or Mössbauer spectroscopy (Beni and Plantzman, 1976). Those techniques measure the mean-square deviation from the ideal lattice position. The EXAFS term is sensitive to the mean-square deviation in the bond length. Long-wavelength vibrational modes in which neighboring atoms move together make relatively little contribution to the EXAFS Debye-Waller term but can dominate the conventional Debye-Waller factor. Thus, the temperature dependence of the EXAFS Debye-Waller term is a sensitive meaure of the bond strength since it directly measures the relative vibrational motion of the bonded atoms.

L Edges

The preceding discussion is limited to the K edge since that has a simple 1s initial state. For an L or higher edge the situation can be more complicated. For the L_2 or L_3 edge, the initial state has 2p symmetry and the final state can have either s or d symmetry. It is also possible to have mixed final states where an outgoing d wave is scattered back as an s state or vice versa. The result is three separate contributions to the function $\chi(k)$ that can be denoted χ_{00}, χ_{22}, and χ_{20}, where the subscripts refer to the angular momentum state of the outgoing and backscattered photoelectron wave. Each of these can have different phase and amplitude functions. The total EXAFS can then be expressed as follows (Lee, 1976; Heald and Stern, 1977):

$$\chi = \frac{M_{21}^2\chi_{22} + M_{01}^2\chi_{00} + 2M_{01}M_{21}\chi_{20}}{M_{21}^2 + M_{01}^2/2} \tag{7}$$

The matrix element terms (e.g., M_{01}) refer to radial dipole matrix elements between the core wave function with $l = 1$ and the final states with $l = 0$ and 2. For the K edge there is only one possibility for M that cancels out. The L_1 edge, which has a 2s initial state, has a similar cancellation and can be treated the same as the K edge.

This would seriously complicate the analysis of $L_{2,3}$ edges, but for two fortuitous simplifications. The most important is that M_{01} is only $\sim$0.2 of M_{21}. Therefore, the M_{01}^2 terms can be ignored. The cross-term can still be $\sim$40% of the main term. Fortunately, for an unoriented polycrystalline sample or a material with at least cubic symmetry, the angular average of this term is zero. The cross-term must be accounted for when the sample has an orientation. This most commonly occurs for surface XAFS experiments, which often employ L edges and which have an intrinsic asymmetry.

Polarization

At synchrotron sources the radiation is highly polarized. The most common form of polarization is linear polarization, which will be considered here (it is also possible to have circular polarization). For linear polarization, the photoelectron is preferentially emitted along the electric field direction. At synchrotrons the electric field is normally oriented horizontally in a direction perpendicular to the beam direction. For K and L_1 shells the polarization factor in Equation 3 is $p_j(\mathbf{e}) = 3\langle\cos^2\theta\rangle$, where

$$\langle\cos^2\theta\rangle = \frac{1}{N_j}\sum_i \cos^2\theta_i \tag{8}$$

The sum is over the i individual atoms in shell j. If the material has cubic or higher symmety or is randomly oriented, then $\langle\cos^2\theta\rangle = \frac{1}{3}$, and $p_j(\mathbf{e}) = 1$. A common situation is a sample with uniaxial symmetry such as a layered material or a surface experiment. If the symmetry in the plane is 3-fold, then the signal does not depend on the orientation of $\mathbf{e}$ within the plane. The signal only depends on the orientation of the electric field vector with respect to the plane, Θ, and $\chi(\Theta) = 2\chi_0\cos^2\Theta/3 + \chi_{90}\sin^2\Theta/3$, where χ_0 and χ_{90} are the signals with the field parallel and perpendicular to the plane, respectively.

For $L_{2,3}$ edges the situation is more complicated (Heald and Stern, 1977). There are separate polarization factors for the three contributions:

$$\begin{aligned} p_{22}^j &= \frac{1}{2}(1 + 3\langle\cos^2\theta\rangle_j) \\ p_{00}^j &= \frac{1}{2} \\ p_{02}^j &= \frac{1}{2}(1 - 3\langle\cos^2\theta\rangle_j) \end{aligned} \tag{9}$$

As mentioned previously, the 00 case can be ignored. For the unoriented case $\langle\cos^2\theta\rangle_j = 1/3$, giving $p_{22} = 1$ and $p_{02} = 0$. This is the reason the cross-term can often be ignored.

Multiple Scattering

The most important extension to the simple single-scattering picture discussed so far is the inclusion of multiple-scattering paths. For example, considering the first shell of atoms, the photoelectron can scatter from one first-shell atom to a second first-shell atom before being scattered back to the origin. Since in an ordered structure there

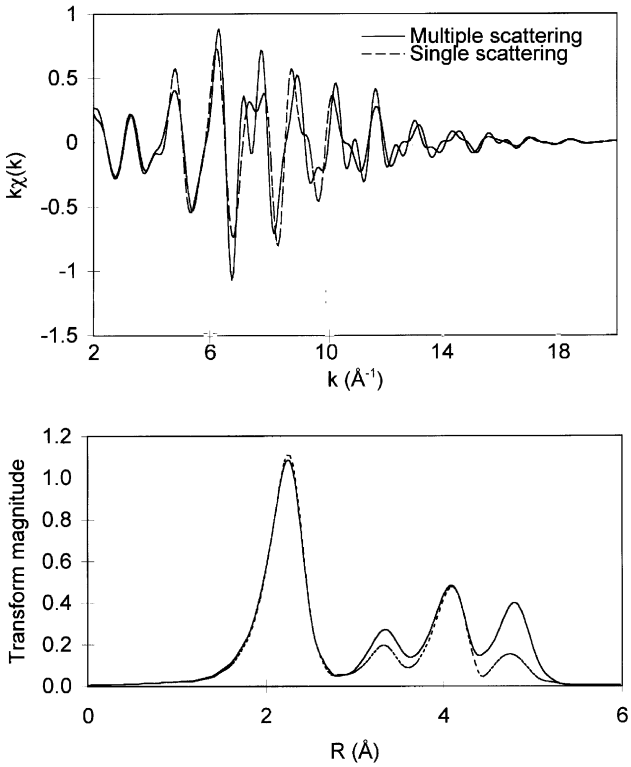

Figure 7. Comparison of the theoretical multiple- and single-scattering spectra for Cu metal at 80 K. The calculation only included the first four shells of atoms, which show up as four distinct peaks in the transform.

are typically 4 to 12 first-shell atoms, there are a large number of equivalent paths of this type, and the contribution can potentially be comparable to the single-scattering signal from the first shell. Two facts rescue the single-scattering picture. First, it is obvious that the multiple-scattering path is longer than the single-scattering path. Therefore, the multiple-scattering contribution would not contaminate the first-shell signal. It can, however, complicate the analysis of the higher shells. The second important point is that the scattering of the photoelectron is maximum when the scattering angle is either 0° (forward scattering) or 180° (backscattering). For the example given, there are two scattering events at intermediate angles and the contribution to the signal is reduced.

The single-scattering picture is still valid for the first shell and provides a reasonably accurate representation of the next one or two shells. For best results, however, modern analysis practice dictates that multiple scattering should be taken into account whenever shells past the first are analyzed, and this will be discussed further in the analysis section.

The enhancement of the photoelectron wave in the forward direction is often referred to as the focusing affect. It results in strong enhancement of shells of atoms that are directly in line with inner shells. An example is a face-centered-cubic (fcc) material such as copper. The fourth-shell atoms are directly in line with the first. This gives a strong enhancement of the fourth-shell signal and significantly changes the phase of the signal relative to a single-scattering calculation. Figure 7 compares the $\chi(k)$ and the Fourier transforms of calculated spectra for copper in the single-scattering and multiple-scattering cases. Sometimes this focusing effect can be used to advantage in the study of lattice distortions. Because the focusing effect is strongly peaked in the forward direction, small deviations from perfect colinearity are amplified in the signal, allowing such distortions to be resolved even when the change in atomic position of the atoms is too small to resolve directly (Rechav et al., 1994). The focusing effect has even allowed the detection of hydrogen atoms, which normally have negligible backscattering (Lengeler, 1986).

XANES

The primary difference in the near-edge region is the dominance of multiple-scattering contributions (Bianconi, 1988). At low energies the scattering is more isotropic, and many more multiple-scattering paths must be accounted for, including paths that have negligible amplitude in the extended region. This complicates both the quantitative analysis and calculation of the near-edge region. However, the same multiple scattering makes the near-edge region much more sensitive to the symmetry of the neighboring atoms. Often near-edge features can be used as indicators of such things as tetrahedral versus octahedral bonding. Since the bond symmetry can be intimately related to formal valence, the near edge can be a sensitive indicator of valence in certain systems. A classic example is the near edge of Cr, where, as shown in Figure 8, the chromate ion has a very strong pre-edge feature that makes it easy to distinguish from other types. This near-edge feature is much larger than any EXAFS signal and can be used to estimate the chromate-to-total-Cr ratio in many cases for which the EXAFS would be too noisy for reliable analysis.

While great strides have been made in the calculation of near-edge spectra, the level of accuracy often is much less than for the extended fine structure. In addition to the multiple scattering approach discussed, attempts have been made to relate the near-edge structure to the projected density of final states obtained from a band-structure-type calculation. In this approach, for the *K* edge,

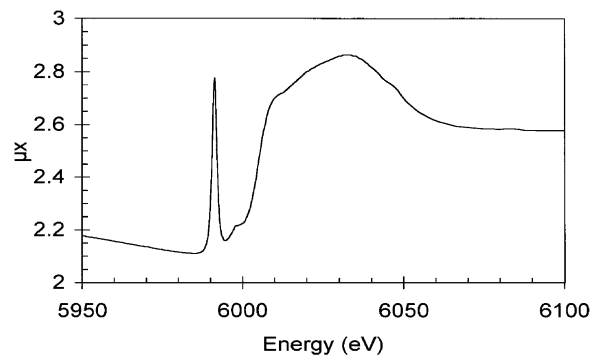

Figure 8. Near-edge region for the Cr *K* edge in a 0.5 M solution of $KCrO_4$.

the p density of states would be calculated. Often there is quite good qualitative agreement with near-edge features that allows them to be correlated to certain electronic states. This approach has some merit since one approach to band structure calculation is to consider all possible scattering paths for an electron in the solid, a quite similar calculation to that for the multiple scattering of the photoelectron. However, the band structure calculations do not account for the ionized core hole created when the photoelectron is excited. If local screening is not strong, the core hole can significantly affect the local potential and the resulting local density of states. While the band structure approach can often be informative, it cannot be taken as a definitive identification of near-edge features without supporting evidence.

It is important to point out that the near edge has the same polarization dependence as the rest of the XAFS. Thus, the polarization dependence of the XANES features can be used to associate them with different bonds. For example, in the K edge of a planar system a feature associated with the in-plane bonding will have a $\cos^2\Theta$ dependence as the polarization vector is rotated out of the plane by Θ. For surface studies this can be a powerful method of determining the orientation of molecules on a surface (Stohr, 1988).

PRACTICAL ASPECTS OF THE METHOD

Detection Methods

The simplest method for determining the absorption coefficient μ is to measure the attenuation of the beam as it passes through the sample:

$$I_t = I_0 e^{-} \quad \text{or} \quad \mu x = \ln(I_0/I_t) \tag{10}$$

Here, I_0 is measured with a partially transmitting detector, typically a gas ionization chamber with the gas chosen to absorb a fraction of the beam. It can be shown statistically that the optimum fraction of absorption for the I_0 detector is $f = 1/(1 + e^{\mu x/2})$, or $\sim 10\%$ to 30% for typical samples (Rose and Shapiro, 1948). The choice of the optimum sample thickness depends on several factors and will be discussed in more detail later. There are two methods for measuring the transmission: the standard scanning method and the dispersive method.

The scanning method uses a monochromatic beam that is scanned in energy as the transmission is monitored. The energy scanning can be either in a step-by-step mode, where the monochromator is halted at each point for a fixed time, or the so-called quick XAFS method, where the monochromator is continuously scanned and data are collected "on the fly" (Frahm, 1988). The step-scanning mode has some overhead in starting and stopping the monochromator but does not require as high a stability of the monochromator during scanning.

The dispersive method uses a bent crystal monochromator to focus a range of energies onto the sample (Matsushita and Phizackerley, 1981; Flank et al., 1982). After the sample, the focused beam is allowed to diverge. The constituent energies have different angles of divergence and eventually separate enough to allow their individual detection on a linear detector. The method has no moving parts, and spectra can be collected in a millisecond time frame. The lack of moving apparatus also means that a very stable energy calibration can be achieved, and the method is very good for looking at the time response of small near-edge changes. With existing dispersive setups, the total energy range is limited, often to a smaller range than would be desired for a full EXAFS measurement. Also, it should be noted that, in principle, the dispersive and quick XAFS methods have the same statistical noise for a given acquisition time, assuming they both use the same beam divergence from the source. For N data points, the dispersive method uses $1/N$ of the flux in each data bin for the full acquisition time, while the quick XAFS method uses the full flux for $1/N$ of the time.

The transmission method is the preferred choice for concentrated samples that can be prepared in a uniform layer of the appropriate thickness. As the element of interest becomes more dilute, the fluorescence technique begins to be preferred. In transmission the signal-to-noise ratio applies to the total signal, and for the XAFS of a dilute component the signal-to-noise ratio will be degraded by a factor related to the diluteness. With the large number of x rays (10^{10} to 10^{13} photons/s) available at synchrotron sources, if the signal-to-noise ratio was dominated by statistical errors, then the transmission method would be possible for very dilute samples. However, systematic errors, beam fluctuation, nonuniform samples, and amplifier noise generally limit the total signal-to-noise ratio to $\sim 10^4$. Therefore, if the contribution of an element to the total absorption is only a few percent, the XAFS signal, which is only a few percent of that element's absorption, will be difficult to extract from the transmission signal.

In the fluorescence method, the fluorescence photons emitted by the element of interest are detected (Jacklevic et al., 1977). The probability of fluorescence is essentially constant with energy, and the fluorescence intensity is, therefore, directly proportional to the absorption of a specific atomic species. The advantage is that each element has a characteristic fluorescence energy, and in principle the fluorescence from the element under study can be measured separately from the total absorption. For an ideal detector the signal-to-noise ratio would then be independent of the concentration, and would depend only on the number of photons collected. Of course, the number of fluorescence photons that can be collected does depend on concentration, and there would be practical limits. In actuality the real limits are determined by the efficiency of the detectors. It is difficult to achieve a high degree of background discrimination along with a high efficiency of collection. Figure 9 shows a schematic of the energy spectrum from a fluorescence sample. The main fluorescence line is $\sim 10\%$ lower than the edge energy. The main background peak is from the elastic scattered incident photons. There are also Compton-scattered photons, which are energy-shifted slightly below the elastic peak. The width and shape of the Compton scattering peak is determined by the acceptance angle of the detector. In multicomponent samples there can also be fluorescence lines from other sample components.

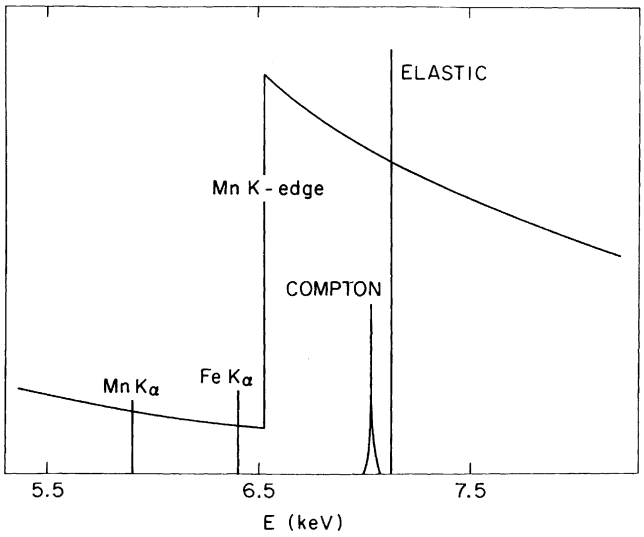

Figure 9. Schematic of the fluorescence spectrum from an Fe-containing sample with the incident energy set at the Fe K edge. The details of the Compton peak depend on the solid angle and location of the detector. This does not include complications such as fluorescence lines from other components in the sample. Also shown is the Mn K-edge absorption as an example of how filters can be used to reduce the Compton and elastic background.

To obtain a reasonable fluorescence spectrum, it is typically necessary to collect at least 10^6 photons in each energy channel. This would give a fractional statistical error of 10^{-3} for the total signal and 1% to 10% in the EXAFS. If the fluorescence signal N_f is accompanied by a background N_b, which cannot be separated by the detector, then the signal-to-noise ratio is equivalent to a signal $N_f/(1+A)$, where $A = N_b/N_f$. Therefore, a detector that is inefficient at separating the background can substantially increase the counts required.

There are three basic approaches to fluorescence detection: solid-state detectors, filters and slits (Stern and Heald, 1979), and crystal spectrometers. High-resolution Ge or Si detectors can provide energy resolution sufficient to separate the fluorescence peak. The problem is that their total counting rate (signal plus all sources of background) is limited to somewhere in the range of 2×10^4 to 5×10^5 counts per second depending on the type of detector and electronics used. Since the fluorescence from a dilute sample can be a small fraction of the total, collecting enough photons for good statistics can be time consuming. One solution has been the development of multichannel detectors with up to 100 individual detector elements (Pullia et al., 1997).

The other two approaches try to get around the count rate limitations of solid-state detectors by using other means of energy resolution. Then a detector such as an ion chamber can be used that has essentially no count rate limitations (saturation occurs at signal levels much greater than from a typical sample). The principle behind filters is shown in Figure 9. It is often possible to find a material whose absorption edge is between the fluorescence line and the elastic background peak. This will selectively attenuate the background. There is one problem with this approach: the filter will reemit the absorbed photons as its own fluorescence. Many of these can be prevented from reaching the detector by using appropriate slits, but no filter slit system can be perfect. The selectivity of a crystal spectrometer is nearly ideal since Bragg reflection is used to select only the fluorescence line. However, the extreme angular selectivity of Bragg reflection means that it is difficult to collect a large solid angle, and many fluorescent photons are wasted. Thus, the filter with a slit detector trades off energy selectivity to collect large solid angles, while the crystal spectrometer achieves excellent resolution at the expense of solid angles.

Which approach is best will depend on the experimental conditions. For samples with moderate diluteness (cases where the background ratio $A <\sim 20$), the filter slit is an excellent choice, providing simple setup and alignment, ease of changing the fluorescence energy, and good collection efficiency. For more dilute samples or samples with multiple fluorescence lines that cannot be filtered out, the standard method is to use a multielement detector. These can often collect a substantial solid angle and with the right control software can be fairly easy to set up. As sources become more intense, the count rate limitations of solid-state detectors become more serious. This has spurred renewed interest in developing either faster detectors or those with more elements (Gauthier et al., 1996; Pullia et al., 1997) and more efficient crystal detectors. The potential user would be advised to discuss with facility managers the performance of the detectors they have available. Since x-ray cross-sections are well known, it is usually possible to estimate the relative merits of the different detection methods for a particular experiment.

The emission of a fluorescence photon is only one possible outcome of an absorption event. Another, which is dominant for light elements, is the emission of Auger electrons (see AUGER ELECTRON SPECTROSCOPY). The electron yield detection method takes advantage of this. There are several schemes for detecting the electron emission (Stohr, 1988), but the total electron yield method is by far the most widely used. This involves measuring the total electron current emitted by the sample, usually by using a positively biased collecting electrode. It is also possible to measure the sample drain current, which in effect uses the sample chamber as the collecting electrode. The electron yield method can be performed in a vacuum, which makes it an attractive choice for surface XAFS experiments carried out in ultra-high-vacuum (UHV) chambers. The yield signal is composed of the excited photoelectron, directly emitted Auger electrons, and numerous secondary electrons excited by the primary Auger or photoelectrons. Since the electron mean free path in solids is very short, all of these electron signals originate from the surface region (typically within 10 to 100 nm of the surface). This effectively discriminates against absorption occurring deep within a sample and allows for monolayer sensitivity in UHV surface experiments.

For samples that do not need UHV conditions, it is also possible to use a gas such as He or H_2 to enhance the electron signal (Kordesch and Hoffman, 1984). In this case, the emitted electrons ionize the gas atoms or molecules, which are then detected as in an ionization chamber. It typically

requires ~30 eV to ionize a gas atom, and the electrons can have energies up to several keV. Thus many gas ions can be produced for each absorption event, giving an effective amplification of the signal current. The total yield method is often applied to concentrated samples that are difficult to prepare in a thin uniform manner. It is especially useful for avoiding thickness effects in samples with strong white lines, as will be discussed below (see Data Analysis and Initial Interpretation).

Synchrotron Facilities

Most XAFS experiments are carried out at synchrotron beamlines over which the user typically has little direct control. To carry out an effective experiment, it is important to understand some of the common beamline characteristics. These must be measured or obtained from the beamline operator.

Energy Resolution

Bragg reflection by silicon crystals is the nearly universal choice for monochromatizing the x rays at energies >2 keV. These crystals are nearly always perfect and, if thermal or mounting strains are avoided, have a very well defined energy resolution. For Si(111), the resolution is $\Delta E/E = 1.3 \times 10^{-4}$. Higher-order reflections such as Si(220) and Si(311) can have even better resolution (5.6×10^{-5} and 2.7×10^{-5}, respectively). This is the resolution for an ideally collimated beam. All beamlines have some beam divergence, $\Delta\theta$. Taking the derivative of the Bragg condition, this will add an additional contribution $\Delta E = \Delta\theta \cot(\theta_b)$ where θ_b is the monochromator crystal Bragg angle. Typically, these two contributions can be added in quadrature to obtain the total energy spread in the beam. The beam divergence is determined by the source and slit sizes and can also be affected by any focusing optics that precede the monochromator.

At lower energies, other types of monochromators will likely be employed. These are commonly based on gratings but can also use more exotic crystals such as quartz, InSb, beryl, or YB_{66}. In these cases, it is generally necessary to obtain the resolution information from the beamline operator.

Harmonic Content

As the later discussion on thickness effects will make clear, it is extremely important to understand the effects of harmonics on the experiment planned. These are most serious for transmission experiments but can be a problem for the other methods as well. Both crystals and gratings can diffract energies that are multiples of the fundamental desired energy. These generally need to be kept to a low level for accurate measurements. Often the beamline mirrors can be used to reduce harmonics if their high-energy cutoff is between the fundamental and harmonic energies. When this is not possible (or for unfocused beamlines), detuning of crystal monochromators is another common method. Nearly all scanning monochromators use two or more crystal reflections to allow energy selection while avoiding wide swings in direction of the output beam. Typically the harmonic reflection curves are much narrower than for the fundamental. This means that by setting the diffraction angles of the two crystals to slightly different values the intensity of the harmonic reflections can be dramatically reduced while only losing 20% to 50% of the fundamental intensity. Nearly all XAFS double-crystal monochromators allow for this possibility.

Detuning only works well for ideal crystals and for higher energies. It is generally good practice to determine the harmonic content of the beam if it is not already known. The simplest method is to insert a foil whose edge is near the harmonic energy. For Si(111) the second harmonic is forbidden, so this would involve choosing a material whose edge is ~3 times the desired energy. When the monochromator is scanned through the desired energy range, the harmonic content can be accurately estimated from the edge step of this test sample. Other methods include using an energy-analyzing detector such as a solid-state detector or Bragg spectrometer.

Energy Calibration

All mechanical systems can have some error, and it is important to verify the energy calibration of the beamline. For a single point this can be done using a standard foil containing the element planned for study. It is also important that the energy scale throughout the scan is correct. Most monochromators rely on gear-driven rotation stages, which can have some nonlinearity. This can result in nonlinearity in the energy scale. To deal with this, many modern monochromators employ accurate angle encoders. If an energy scale error is suspected, a good first check is to measure the energy difference between the edges of two adjacent materials and compare with published values. Unfortunately it is sometimes difficult to determine exactly which feature on the edge corresponds to the published value. Another approach is the use of Bragg reflection calibrators, available at some facilities.

Monochromator Glitches

An annoying feature of perfect crystal monochromators is the presence of sharp features in the output intensities, often referred to as "glitches." These are due to the excitation of multiple-diffraction conditions at certain energies and angles. Generally, these are sharp dips in the output intensity due to a secondary reflection removing energy from the primary. For ideal detectors and samples these should cancel out, but for XAFS measurements cancellation the 10^{-4} level is needed to make them undetectable. This is difficult to achieve. It is especially difficult for unfocused beamlines since the intensity reduction may only affect a part of the output beam, and then any sample nonuniformity will result in noncancellation. A sharp glitch that affects only one or two points in the spectrum can generally be handled in the data analysis. Problematic glitches extend over a broader energy range. These can be minimized only by operating the detectors at optimum linearity and making samples as uniform as possible. Usually a particular set of crystals will have only a few problematic glitches, which should be known to the beamline operator. The presence of glitches makes it essential

that the I_0 spectra be recorded separately. Then it can be assured that weak features in the spectra are not spurious by checking for correlation with glitches.

METHOD AUTOMATION

Most XAFS facilities are highly automated. At synchrotron facilities the experiments are typically located inside radiation enclosures to which access is forbidden when the beam is on. Therefore, it is important to automate sample alignment. Usually, motorized sample stages are provided by the facility, but for large or unusual sample cells these may not be satisfactory. It is important to work with the facility operators to make sure that sample alignment needs are provided for. Otherwise tedious cycles of entering the enclosure, changing the sample alignment, interlocking the radiation enclosure, and measuring the change in the signal may be necessary.

Since beamlines are complex and expensive, it is usually necessary that the installed control system be used. This may or may not be flexible enough to accommodate special needs. While standard experiments will be supported, it is difficult to anticipate all the possible experimental permutations. Again, it is incumbent upon the users to communicate early with the facility operators regarding special needs. This point has already been made several times but, to avoid disappointment, cannot be emphasized enough.

DATA ANALYSIS AND INITIAL INTERPRETATION

XAFS data analysis is a complex topic that cannot be completely covered here. There are several useful reviews in the literature (Teo, 1986; Sayers and Bunker, 1988; Heald and Tranquada, 1990). There are also a number of software packages available (see Internet Resources listing below), which include their own documentation. The discussion here will concentrate on general principles and on the types of preliminary analysis that can be conducted at the beamline facility to assess the quality of the data.

There are four main steps in the analysis: normalization, background removal, Fourier transformation and filtering, and data fitting. The proper normalization is given in Equation 3. In practice, it is simpler to normalize the measured absorption to the edge step. For sample thickness x,

$$\chi_{\exp}(k) = \frac{\mu(k)x - \mu_0(k)x}{\Delta\mu(0)x} \qquad (11)$$

where $\Delta\mu(0)x$ is the measured edge step. This can be determined by fitting smooth functions (often linear) to regions above and below the edge. This step normalization is convenient and accurate when it is consistently applied to experimental data being compared. To compare with theory, the energy dependence of $\mu_0(k)$ in the denominator must be included. This can be determined from tabulated absorption coefficients (McMaster et al., 1969; see Internet Resources). For data taken in fluorescence or electron yield, it is also necessary to compensate for the energy dependence of the detectors. For a gas-filled ionization chamber used to monitor I_0, the absorption coefficient of the gas decreases with energy. This means the I_0 signal would decrease with energy even if the flux were constant. Again, tabulated coefficients can be used. The fluorescence detector energy dependence is not important since it is detecting the constant-energy fluorescence signal. This correction is not needed for transmission since the log of the ratio is analyzed. For this case, the detector energy dependence becomes an additive factor, which is removed in the normalization and background removal process.

Background subtraction is probably the most important step. The usual method is to fit a smooth function such as a cubic spline through the data. The fitting parameters must be chosen to only fit the background while leaving the oscillations untouched. This procedure has been automated to a degree in some software packages (Cook and Sayers, 1981; Newville et al., 1993), but care is needed. Low-Z backscatterers are often problematic since their oscillation amplitude is very large at low k and damps out rapidly. It is then difficult to define a smooth background function that works over the entire k region in all cases. Often careful attention is needed in choosing the low-Z termination point. The background subtraction stage is also useful in pointing out artifacts in the data. The background curve should be reasonably smooth. Any unusual oscillation or structure should be investigated. One natural cause of background structure is multielectron excitations. These can be ignored in many cases but may be important for heavier atoms.

Once the background-subtracted $\chi(k)$ is obtained, its Fourier transform can be taken. As shown in Figure 6, this makes visible the different frequency components in the spectra. It also allows a judgment of the success of the background subtraction. Poor background removal will result in strong structure at low r. However, not all structure at low r is spurious. For example, the rapid decay of low-Z backscatterers can result in a low-r tail on the transform peak. To properly judge the source of the low-r structure, it is useful to transform theoretical calculations of similar cases for comparison.

Before Fourier transforming, the data is usually multiplied by a factor k^w, W = 1, 2, or 3. This is done to sharpen the transform peaks. Generally the transform peaks will be sharpest if the oscillation amplitude is uniform over the data window being transformed. Often, W = 1 is used to compensate for the $1/k$ factor seen in Equation 3. For low-Z atoms and systems with large disorder, higher values of W can be used to compensate for the additional k-dependent fall-off. High values of W also emphasize the higher-k part of the spectrum where the heavier backscatterers have the largest contribution. Thus, comparing transforms with different k weighting is a simple qualitative method of determining which peaks are dominated by low- or high-Z atoms. In addition to k weighting, other weighting can be applied prior to transforming. The data should only be transformed over the range for which there is significant signal. This can be accomplished by truncating $\chi(k)$ with a rectangular window prior to transforming. A sharp rectangular window can induce truncation ripples

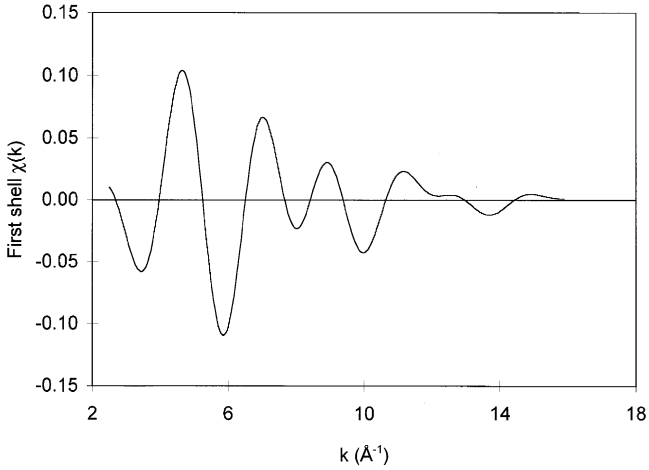

Figure 10. Inverse Fourier transform of the region 0.8 to 2 Å for the Cu data in Figure 6. This region contains contributions from three different Cu-O distances in the first coordination sphere.

in the transform. To deal with this, most analysis packages offer the option of various window functions that give a more gradual truncation. There are many types of windows, all of which work more or less equivalently.

The final stage of analysis is to fit the data either in k or r space using theoretical or experimentally derived functions. If k-space fitting is done, the data are usually filtered to extract only the shells being fit. For example, if the first and second shells are being fit in k space, an r-space window is applied to the r-space data, which includes only the first- and second-shell contributions, and then the data are transformed back to k space. This filtered spectra only includes the first and second shell contributions, and it can be fit without including all the other shells. An example of filtered data is shown in Figure 10. An important concept in fitting filtered data is the number of independent data points (Stern, 1993). This is determined by information theory to be $N_1 = 2\Delta k \Delta r/\pi + 2$, where Δk and Δr are the k- and r-space ranges of the data used for analysis. If fitting is done in r space, Δr would be the range over which the data are fit, and Δk is the k range used for the transform. The number of independent parameters N_I is the number that are needed to completely describe the filtered data. Therefore, any fitting procedure should use fewer than N_I parameters.

The relative merits of different types of fitting are beyond the scope of this unit, and fitting is generally not carried out at the beamline while data is being taken. It is important, however, to carry the analysis through the Fourier transform stage to assess the data quality. As mentioned, systematic errors often show up as strange backgrounds or unphysical transform peaks, and random statistical errors will show up as an overall noise level in the transform.

The most widely used theoretical program is FEFF (Zabinsky et al., 1995). It is designed to be relatively portable and user friendly and includes multiple scattering. It is highly desirable for new users to obtain FEFF or an equivalent package (Westre et al., 1995) and to calculate some example spectra for the expected structures.

The most common causes of incorrect data can all be classified under the general heading of thickness effects or thickness-dependent distortions. A good experimental check is to measure two different thicknesses of the same sample: if thickness effects are present, the normalized XAFS amplitude for the thicker sample will be reduced. Thickness effects are caused by leakage radiation, such as pinholes in the sample, radiation that leaks around the sample, or harmonic content in the beam. All of these are essentially unaffected by the sample absorption. As the x-ray energy passes through the edge, the transmission of the primary radiation is greatly reduced while the leakage is unchanged. Thus, the percentage of leakage radiation in the transmitted radiation increases in passing through the edge, and the edge step is apparently reduced. The greater the absorption, the greater is this effect. This means the peaks in the absorption are reduced in amplitude even more than the edge if leakage is present. In the normalized spectrum such peaks will be reduced. The distortion is larger for thick samples, which have the greatest primary beam attenuation. It can be shown statistically that the optimum thickness for transmission samples in the absence of leakage is about $\mu x = 2.5$. In practice, a $\mu x \sim 1.5$ is generally a good compromise between obtaining a good signal and avoiding thickness effects.

An analogous effect occurs in fluorescence detection. It is generally referred to as self-absorption. As the absorption increases at the edge, the penetration of the x rays into the sample decreases, and fewer atoms are available for fluorescing. Again, peaks in the absorption are reduced. Obviously this is a problem only if the absorption change is significant. For very dilute samples the absorption change is too small for a noticeable effect. Self-absorption is the reason that fluorescence detection should not be applied to concentrated samples. In this context "concentrated" refers to samples for which the absorption step is $>\sim$10% of the total absorption. When sample conditions preclude transmission measurements on a concentrated sample, electron yield detection is a better choice than fluorescence detection. For electron yield detection, the signal originates within the near-surface region where the x-ray penetration is essentially unaffected by the absorption changes in the sample. Thus, in electron yield detection, self-absorption can almost always be ignored.

SAMPLE PREPARATION

XAFS samples should be as uniform as possible. This can be a significant challenge. Typical absorption lengths for concentrated samples are from 3 to 30 μm. Foils or liquid solutions are a simple approach but cannot be universally applied. It can be difficult to grind and disperse solid particles into uniform layers of appropriate thickness. For example, to achieve a 10-μm layer of a powdered sample, the particle size should be of order 2 to 3 μm. This is difficult to achieve for many materials. Some common sample preparation methods include rubbing the powder into low-absorption adhesive tape or combining the powder with a low-absorption material such as graphite or BN prior

to pressing into pellets. The tape method has been especially successful, probably because the rubbing process removes some of the larger particles leaving behind a smaller average particle size adhered to the tape. Nevertheless, if less than about four layers of tape are required to produce a reasonable sample thickness, then the samples are likely to be unacceptably nonuniform. XAFS signals can be significantly enhanced by cooling samples to liquid nitrogen temperatures. This can also be a constraint on sample preparation since tape-prepared samples can crack, exposing leakage paths, upon cooling. This can be avoided by using Kapton-based tape, although the adhesive on such tapes can have significant absorption.

Materials with layered or nonsymmetric structures can result in anisotropic particles. These will tend to be oriented when using the tape or pellet method and result in an aligned sample. Since all synchrotron radiation sources produce a highly polarized beam, the resulting data will show an orientation dependence. This can be accounted for in the analysis if the degree of orientation is known, but this can be difficult to determine. For layered materials, one solution is to orient the sample at the "magic" angle (54.7°) relative to the polarization vector. This will result in a signal equivalent to an unoriented sample for partially oriented samples.

Sample thickness is less of a concern for fluorescence or electron yield samples, but it is still important that the samples are uniform. For electron yield, the sample surface should be clean and free of thick oxide layers or other impurities. Sample charging can also be a factor. This can be a major problem for insulating samples in a vacuum. It is less important when a He-filled detector is used. Also, the x-ray beam is less charging than typical electron beam techniques, and fairly low conductivity samples can still be successfully measured.

SPECIMEN MODIFICATION

In general, x rays are less damaging than particle probes such as the electrons used in electron microscopy. However, samples can be modified by radiation damage. This can be physical damage resulting in actual structural changes (usually disordering) or chemical changes. This is especially true for biological materials such as metalloproteins. Metals and semiconductors are generally radiation resistant. Many insulating materials will eventually suffer some damage, but often on timescales that are long compared to the measurement. Since it is difficult to predict which materials will be damaged, for potentially sensitive materials, it is wise to use other characterization techniques to verify sample integrity after exposure or to look for an exposure dependence in the x-ray measurements.

PROBLEMS

The two most common causes of incorrect data are sample nonuniformity and thickness effects, which have already been discussed. Other problems can occur that are exacerbated by the need to run measurements at remote facilities under the time constraints of a fixed schedule. The critical role played by beam harmonics has already been discussed. Eliminating harmonics requires the correct setting of beamline crystals or mirrors. It is easy to do this incorrectly at a complex beamline. Another area of concern is the correct operation of detectors. The high fluxes at synchrotrons mean that saturation or deadtime effects are often important. For ion-chamber detectors it is important to run the instrument at the proper voltage and to use the appropriate gases for linear response. Similarly, saturation must be avoided in the subsequent amplifier chain. Single-photon detectors, if used, are often run at count rates for which deadtime corrections are necessary. For fluorescence experiments this means that the incoming or total count rate should be monitored as well as the fluorescence line(s) of interest.

Guidance on many of these issues can be obtained from the beamline operators for typical running conditions. However, few experiments are truly typical in all respects, and separate tests may need to be made. In contrast to laboratory experiments, the time constraints of synchrotron experiments make it tempting to skip some simple tests needed to verify that undistorted data is being collected. This should be avoided if at all possible.

X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS

INTRODUCTION

Diffuse scattering from crystalline solid solutions is used to measure local compositional order among the atoms, dynamic displacements (phonons), and mean species-dependent static displacements. In locally ordered alloys, fluctuations of composition and interatomic distances break the long-range symmetry of the crystal within local regions and contribute to the total energy of the alloy (Zunger, 1994). Local ordering can be a precursor to a lower temperature equilibrium structure that may be unattainable because of slow atomic diffusion. Discussions of the usefulness of local chemical and displacive correlations within alloy theory are given in Chapter 2 (see PREDICTION OF PHASE DIAGRAMS and COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS). In addition to local atomic correlations, neutron diffuse scattering methods can be used to study the local short-range correlations of the magnetic moments. Interstitial defects, as opposed to the substitutional disorder defects described above, also disrupt the long-range periodicity of a crystalline material and give rise to diffusely scattered x rays, neutrons, and electrons (electron scattering is not covered in this unit; Schweika, 1998).

Use of tunable synchrotron radiation to change the x-ray scattering contrast between elements has greatly improved the measurement of bond distances between the three types of atom pairs found in crystalline binary alloys (Ice et al., 1992). The estimated standard deviation of the first-order (first moment) mean static displacements from this technique approaches ± 0.001 Å (0.0001 nm), which is an order of magnitude more precise than results obtained with extended x-ray absorption fine structure (EXAFS; XAFS SPECTROSCOPY) measurements. In addition, both the radial and tangential displacements can be reliably determined to five or more near-neighbor shells (Jiang et al., 1996). In a binary A-B alloy, the number of A or B near-neighbor atoms to, for example, an A atom can be determined to even less than 1 atom in 100. The second moment of the static displacements, which gives rise to Huang scattering, is also measurable (Schweika, 1998). Measurements of diffuse scattering can also reveal the tensorial displacements associated with substitutional and interstitial defects. This information provides models of the average arrangements of the atoms on a local scale.

An example of chemical local ordering is given in Figure 1, where the probability P^{AB}_{lmn} of finding a B atom out to the sixth lmn shell around an A atom goes from a preference for A atoms (clustering) to a preference for B atoms (short-range order) for a body-centered cubic (bcc) $A_{50}B_{50}$ alloy. The real-space representation of the atom positions is derived from a Monte Carlo simulation of the P^{AB}_{lmn} values (Gehlen and Cohen, 1965) from the measurement of the intensity distribution in reciprocal space (Robertson et al., 1998). In the upper panel, the probability of finding a B atom as the first neighbor to an A atom is 40% (10% clustering; $P^{AB}_{111} = 0.4$). Atoms are located on a (110) plane so that first-neighbor pairs are shown. The middle panel depicts the random alloy where $P^{AB}_{lmn} = -0.5$ for the first six shells (lmn). The lower panel shows the case where $P^{AB}_{lmn} = 0.6$ (a preference for unlike atom pairs). The intensity distribution in the (100) plane of reciprocal space (with the fundamental Bragg maxima removed) is shown in the right column of Figure 1. Note that a preference for like nearest neighbors causes the scattering to be centered near the fundamental Bragg maxima, such as at the origin, 0,0. A preference for unlike first-neighbor pairs causes the diffuse scattering to peak at the superlattice reflections for an ordered structure. Models, such as those shown in Figure 1, are used to understand materials properties and their response to heat treatment, mechanical deformation, and magnetic fields. These local configurations are useful to test advances in theoretical models of crystalline alloys as discussed in COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS.

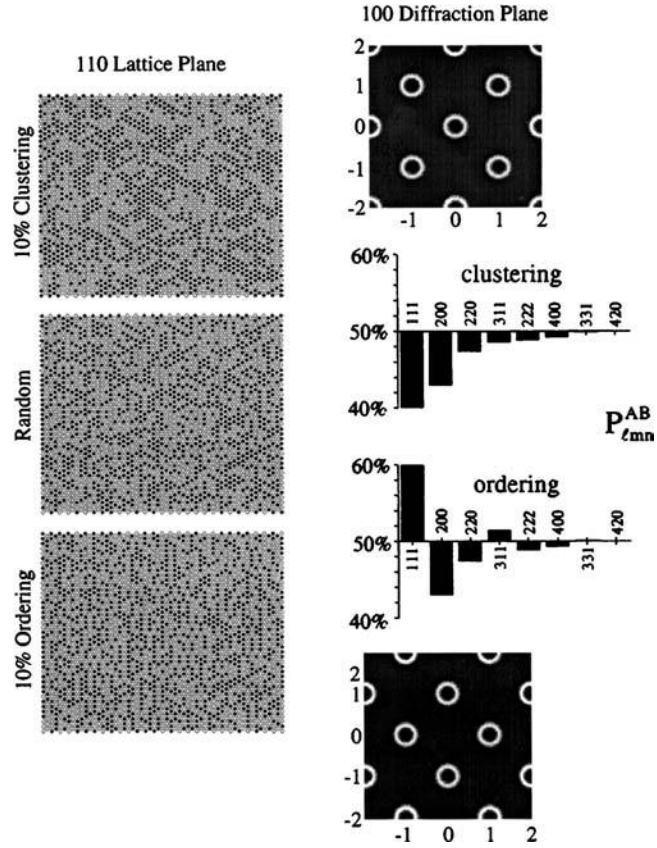

Figure 1. Direct and reciprocal space representations for a clustering, a random, and an ordering $A_{50}B_{50}$ bcc alloy. Courtesy of Robertson et al. (1998).

The diffraction pattern from a crystalline material with perfect periodicity, such as nearly perfect single-crystal Si, consists of sharp Bragg maxima associated with long-range periodicity. With Bragg's law, we can determine the size of the unit cell. Because of thermal motion, atom positions are smeared and Bragg maxima are reduced. In alloys with different atomic sizes, static displacements will also contribute to this reduction. This intensity, which is lost from the Bragg reflections, is diffusely distributed.

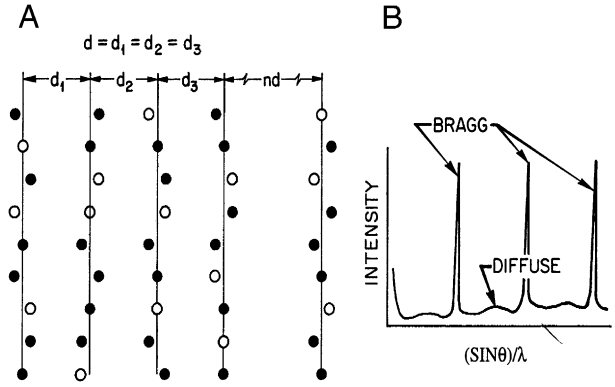

Figure 2. Displacements about the average lattice preserve the regular spacing between atomic planes such that $d = d_1 = d_2 = d_3 = \ldots$. The average lattice is obtained from the positions of the sharp Bragg reflections (**B**). Information about short-range correlations among the atoms is contained in the diffusely distributed intensity between the Bragg peaks. Courtesy of Ice et al. (1998).

Shown schematically in Figure 2A is a solid solution of two kinds of atoms displaced from the sites of the average lattice in such a way that the average plane of atoms is regularly spaced with a constant "*d*" spacing existing over hundreds of planes. As shown schematically in Figure 2B, there is weak diffuse scattering but no broadening of the fundamental Bragg reflections, as would be the case for more extended defects such as stacking faults, high dislocation densities, displacive transformations, and incoherent precipitates, among others (Warren, 1969). In cases where the fundamental Bragg reflections are broadened, our uncertainty in the size of the average lattice increases and the precision of the measured pair separation is reduced.

This unit will concentrate on the use of diffuse x-ray and neutron scattering from single crystals to measure local chemical correlations and chemically specific static displacements. Particular emphasis will be placed on the use of resonant (anomalous) x-ray techniques to extract information on atomic size from binary solid solutions with short-range order. Here the alloys have a well-defined average lattice but have local fluctuations in composition and displacements from the average lattice. In stoichiometric crystals with long-range periodicity, sharp superlattice Bragg reflections appear. If the compositional order is correlated only over short distances, the superlattice reflections are so broadened that measurements throughout a symmetry related volume in reciprocal space are required to determine its distribution. In addition, the displacement of the atom pairs (e.g., the A-A, A-B, and B-B pairs in a binary alloy) from the sites of the average lattice because of different atom sizes also contributes to the distribution of this diffuse scattering. By separating this diffuse intensity into its component parts—that associated with the chemical preference for A-A, A-B, and B-B pairs for the various near-neighbor shells and that associated with the static and dynamic displacements of the atoms from the sites of the average lattice—we are able to recover pair correlation probabilities for the three kinds of pairs in a binary alloy. The interpretation of diffuse scattering associated with dynamic displacements of atoms from their average crystal sites will be discussed only briefly in this unit.

Competitive and Related Techniques

Other techniques that measure local chemical order and bond distances exist. In EXAFS, outgoing photoejected electrons are scattered by the surrounding near neighbors (most from first and to a lesser extent from second nearest neighbors). This creates modulations of the x-ray absorption cross-section, typically extending for ~1000 eV above the edge, and gives information about both local chemical order and bond distances (see XAFS SPECTROSCOPY for details). Usually, the phase and amplitudes for the interference of the photo-ejected electrons must be extracted from model systems, which necessitates measurements on intermetallic (ordered) compounds of known bond distances and neighboring atoms. The choice of an incident x-ray energy specific to an elemental absorption edge makes EXAFS information specific to that elemental constituent. For an alloy of A and B atoms, the EXAFS for an absorption edge of an A atom would be sensitive to the A and B atoms neighboring the A atoms. Separation of the signal into A-A and B-B pairs is typically done by using dilute alloys containing 2 at.% or less of the constituent of interest (e.g., the A atoms). The EXAFS signal is then interpreted as arising from the predominately B neighborhood of an A atom, and analyzed in terms of the number of B first and second neighbors and their bond distances from the A atoms. Claims for the accuracy of the EXAFS method vary between 0.01 and 0.02 Å for bond distance and ~10% for the first shell coordination number (number of atoms in the first shell; Scheuer and Lengeler, 1991). For crystalline solid-solution alloys, the crystal structure precisely determines the number of neighbors in each shell but not the kinds for nondilute alloys. For most alloys, the precision achieved with EXAFS is inadequate to determine the deviations of the interatomic spacings from the average lattice. Whenever EXAFS measurements are applicable and of sufficient precision to determine the information of interest, the ease and simplicity of this experiment compared with three-dimensional diffuse scattering measurements makes it an attractive tool. An EXAFS study of concentrated Au-Ni alloys revealed the kind of information available (Renaud et al., 1988).

Mössbauer spectroscopy is another method for obtaining near-neighbor information (MOSSBAUER SPECTROMETRY). Measurements of hyperfine field splitting caused by changes in the electric field gradient or magnetic field because of the different charge or magnetic states of the nuclear environments give information about the near-neighbor environments. Different chemical and magnetic environments of the nucleus produce different hyperfine structure, which is interpreted as a measure of the different chemical environments typical for first and second neighbors. The quantitative interpretation of Mössbauer spectra in terms of local order and bond distances is often ambiguous. The use of Mössbauer spectroscopy is limited

to those few alloys where at least one of the constituents is a Mössbauer-active isotope. This spectroscopy is complimentary but does not compete with diffuse scattering measurements as a direct method for obtaining detailed information about near-neighbor chemical environments and bond distances (Drijver et al., 1977; Pierron-Bohnes et al., 1983).

Imaging techniques with electrons, such as Z contrast microscopy and other high-resolution electron microscopy techniques (see Chapter 11), do not have the resolution for measuring the small displacements associated with crystalline solid solutions. Imaging for high-resolution microscopy requires a thin sample about a dozen or more unit cells thick with identical atom occupations, and precludes obtaining information about short-range order and bond distances. Electron diffuse scattering measurements are difficult to record in absolute units and to separate from contributions to the diffuse background caused by straggling energy loss processes. Electron techniques provide extremely useful information on more extended defects as discussed in Chapter 11.

Field ion microscopy uses He or Ne gas atoms to image the small radius tip of the sample. Atom probes provide direct imaging of atom positions. Atoms are pulled from a small radius tip of the sample by an applied voltage and mass analyzed through a small opening. The position of the atom can be localized to ~5 Å. Information on the species of an atom and its neighbors can be recovered. Reports of successful analysis of concentration waves and clusters in phase separating alloys have occurred where strongly enriched clusters of like atoms are as small as 5 Å in diameter (Miller et al., 1996). However, information on small displacements cannot be obtained with atom probes. Scanning tunneling (see SCANNING TUNNELING MICROSCOPY) and atomic force microscopy can distinguish between the kinds of atoms on a surface and reveal their relative positions.

PRINCIPLES OF THE METHOD

In this section, we formulate the diffraction theory of diffuse scattering in a way that minimizes assumptions and maximizes the information obtained from a diffraction pattern without recourse to models. This approach can be extended with various theories and models for interpretation of the recovered information. Measurements of diffusely scattered radiation can reveal the kinds and number of defects. Since different defects give different signatures in diffuse scattering, separation of these signatures can simplify recovery of the phenomenological parameters describing the defect.

Availability of intense and tunable synchrotron x-ray sources, which allow the selection of x-ray energies near absorption edges, permits the use of resonant scattering techniques to separate the contribution to the diffuse scattering from different kinds of pairs (e.g., the A-A, A-B, and B-B pairs of a binary alloy). Near an x-ray K absorption edge, the x-ray scattering factor of an atom can change by ~8 electron units (eu) and allows for scattering contrast control between atoms in an alloy. Adjustable contrast, either through resonant (anomalous) x-ray scattering or through isotopic substitution for neutrons, allows for precision measurement of chemically specific local-interatomic distances within the alloy. Figure 3 gives the real-space notation used in describing the atom positions and its reciprocal space notations used in describing the intensity distribution.

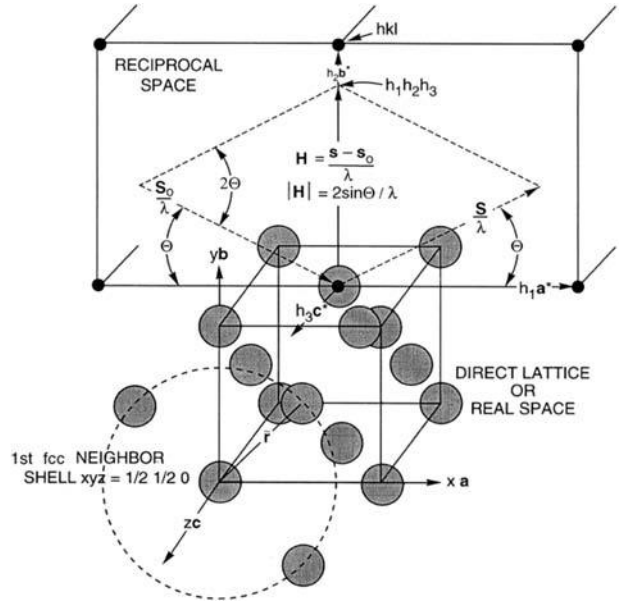

Figure 3. The atom positions for a face-centered cubic (fcc) structure are used to illustrate the notation for the real-space lattice. The unit cell has dimensions $\mathbf{a} = \mathbf{b} = \mathbf{c}$. The corresponding reciprocal space lattice is $\mathbf{a}^*, \mathbf{b}^*, \mathbf{c}^*$. A position in reciprocal space at which the scattered intensity, $I(\mathbf{H})$, is measured for an incoming x ray in the direction of $\mathbf{S}_0$ of wavelength λ and detected in the outgoing direction of $\mathbf{S}$ would be $\mathbf{H} = (\mathbf{S}-\mathbf{S}_0)/\lambda = h_1\mathbf{a}^* + h_2\mathbf{b}^* + h_3\mathbf{c}^*$. At Bragg reflections, $h_1h_2h_3$ are integers and are usually designated hkl, the Miller indices of the reflection. This notation follows that used in the International Tables for Crystallography. Courtesy of Sparks and Robertson (1994).

X Rays Versus Neutrons

The choice of x rays or neutrons for a given experiment depends on instrumentation and source availability, the constituent elements of the sample, the information sought, the temperature of the experiment, the size of the sample, and isotopic availability and cost, among other considerations. Neutron scattering is particularly useful for measurements of low-Z materials, for high-temperature measurements, and for measurements of magnetic ordering. X-ray scattering is preferred for measurements of small samples, for measurement of static displacements, and for high $\mathbf{H}$ resolution.

Chemical Order

Recovery of the local chemical preference for atom neighbors has been predominately an x-ray diffuse scattering measurement, although x-ray and neutron measurements are complimentary. More than 50 systems have been studied with x rays and around 10 systems with neutrons.

The choice between x-ray and neutron methods often depends upon which one gives the best contrast between the constituent elements and which one allows the greatest control over contrast-isotopic substitution for contrast change with neutrons (Cenedese et al., 1984) or resonant (synonymous with dispersion and anomalous) x-ray techniques with x-ray energies near to absorption edge energies (Ice et al., 1994). In general, x-ray scattering is favored by virtue of its better intensity and collimation, which allow for smaller samples and better momentum-transfer resolution. Neutron diffuse scattering has the advantage of discriminating against thermal diffuse scattering (TDS); there is a significant change in energy (wavelength) when neutrons are scattered by phonons (see PHONON STUDIES). For example, phonons in the few tens of millielectron volt energy range make an insignificant change in the energy of kiloelectron volt x rays but make a significant change in the ~35-meV energy of thermal neutrons, except near Bragg reflections. Thus, TDS of neutrons is easily rejected with crystal diffraction or time-of-flight techniques even at temperatures approaching and exceeding the Debye temperature. With x rays, however, TDS can be a major contribution and can obscure the Laue scattering. Magnetic short-range order can also be studied with neutrons in much the same way as the chemical short-range order. However, when the alloy is magnetic, extra effort is needed to separate the magnetic scattering from the nuclear scattering that gives the information on chemical pair correlations.

Neutrons can be used in combination with x rays to obtain additional scattering contrast. The x-ray scattering factors increase with the atomic number of the elements (since it increases with the number of electrons), but neutron scattering cross-sections are not correlated with the atomic number as they are scattered from the nucleus. When an absorption edge of one of the elements is either too high for available x-ray energies or too low in energy for the reciprocal space of interest, or if enough different isotopes of the atomic species making up the alloy are not available or are too expensive, then a combination of both x-ray and neutron diffuse scattering measurements may be a way to obtain the needed contrast. A more in-depth discussion of the properties of neutrons is given in Chapter 13. Information on chemical short-range order obtained with both x rays and neutrons and a general discussion of their merits is given by Kostorz (1996).

Local chemical order among the atoms including vacancies has been measured for ~70 metallic binary alloys and a few oxides. Only two ternary metallic systems have been measured in which the three independent pair probabilities between the three kinds of atoms have been recovered: an alloy of $Cr_{21}Fe_{56}Ni_{23}$ with three different isotopic contents studied with neutron diffuse scattering measurements (Cenedese et al., 1984) and an alloy $Cu_{47}Ni_{29}Zn_{34}$ studied with three x-ray energies (Hashimoto et al., 1985).

Bond Distances

In binary alloys, recovery of the bond distances between A-A, A-B, and B-B pairs requires measurement of the diffuse intensity at two different scattering contrasts to separate the A-A and B-B bond distances (as shown, later the A-B bond distance can be expressed as a linear combination of the other two distances to conserve volume). Such measurements require two matched samples of differing isotopic content to develop neutron contrast, whereas for x rays, the x-ray energy need only be changed a fraction of a kilovolt near an absorption edge to produce a significant contrast change (Ice et al., 1994). Of course, one of the elemental constituents of the sample needs to have an absorption edge energy above ~5 keV to obtain sufficient momentum transfer for a full separation of the thermal contribution. However, more limited momentum-transfer data can be valuable for certain applications. Thus binary solid solutions where both elements have atomic numbers lower than that of Cr (Z=24) may require both an x-ray and a neutron measurement of the diffuse intensity to obtain data of sufficient contrast and momentum transfer. To date, there have been about 10 publications on the recovery of bond distances. Most have employed diffuse x-ray scattering measurements, but some employed neutrons and isotopically substituted samples (Müller et al., 1989).

Diffuse X-ray (Neutron) Scattering Theory for Crystalline Solid Solutions

In the kinematic approximation, the elastically scattered x-ray (neutron) intensity in electron units per atom from an ensemble of atoms is given by

$$I(\mathbf{H})_{\text{Total}} = \left| \sum_p f_p e^{2\pi i \mathbf{H}\bullet\mathbf{r}_p} \right|^2 = \sum_p \sum_q f_p f_q^* e^{2\pi i \mathbf{H}\bullet(\mathbf{r}_p - \mathbf{r}_q)} \quad (1)$$

Here f_p and f_q^* denote the complex and complex-conjugate x-ray atomic scattering factors (or neutron scattering lengths), p and q designate the lattice sites from 0 to $N-1$, $\mathbf{r}_p$ and $\mathbf{r}_q$ are the atomic position vectors for those sites, and $\mathbf{H}$ is the momentum transfer or reciprocal lattice vector $|\mathbf{H}| = (2 \sin \theta)/\lambda$ (Fig. 3). For crystalline solid solutions with a well-defined average lattice (sharp Bragg reflections), the atom positions can be represented by $\mathbf{r} = \mathbf{R}+\boldsymbol{\delta}$, where $\mathbf{R}$ is determined from the lattice constants and $\boldsymbol{\delta}$ is both the thermal and static displacement of the atom from that average lattice. Equation 1 can be separated into terms of the average lattice $\mathbf{R}$ and the local fluctuations $\boldsymbol{\delta}$,

$$I(\mathbf{H})_{\text{Total}} = \sum_p \sum_q f_p f_q^* e^{2\pi i \mathbf{H}\bullet(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)} e^{2\pi i \mathbf{H}\bullet(\mathbf{R}_p - \mathbf{R}_q)} \quad (2)$$

We limit our discussion of the diffraction theory to crystalline binary alloys of A and B atoms with atomic concentration C_A and C_B, respectively, and with complex x-ray atomic scattering factors of f_A and f_B (neutron scattering lengths b_A and b_B). Since an x-ray or neutron beam of even a millimeter diameter intercepts $>10^{20}$ atoms, the double sum in Equation 2 involves $>10^{21}$ first-neighbor atom pairs (one at p, the other at q); the sum over all the atoms is a statistical description, which includes all possible atom pairs that can be formed (i.e., A-A, A-B, B-A, B-B;

Warren, 1969). A preference for like or unlike neighboring pairs is introduced by the conditional probability term P_{pq}^{AB}. This term is defined as the probability for finding a B atom at site q after having found an A atom at site p (Cowley, 1950). The probability for A-B pairs is $C_A\ P_{pq}^{AB}$, which must equal $C_B\ P_{pq}^{BA}$, the number of B-A pairs. Also, $P_{pq}^{BB} = 1 - P_{pq}^{BA}, P_{pq}^{AA} = 1 - P_{pq}^{AB}$; $C_A + C_B = 1$. With the Warren-Cowley definition of the short-range order (SRO) parameter (Cowley, 1950), $\alpha_{pq} \equiv 1 - P_{pq}^{AB}/C_B$. Spatial and time averages taken over the chemically distinct A-A, A-B, or B-B pairs with relative atom positions $p-q$, produce the total elastically and quasielastic (thermal) scattered intensity in electron units for a crystalline solid solution of two components as

$$\begin{aligned} I(\mathbf{H})_{\text{Total}} = \sum_p \sum_q \Big[& (C_A^2 + C_A C_B \alpha_{pq}) |f_A|^2 \langle e^{2\pi i \mathbf{H}\bullet(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)} \rangle^{AA} \\ & + C_A C_B (1 - \alpha_{pq}) f_A f_B^* \Big(\langle e^{2\pi i \mathbf{H}\bullet(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)} \rangle^{BA} \\ & + \langle e^{2\pi i \mathbf{H}\bullet(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)} \rangle^{AB} \Big) + (C_B^2 + C_A C_B \alpha_{pq}) |f_B|^2 \\ & \times \langle e^{2\pi i \mathbf{H}\bullet(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)} \rangle^{BB} \Big] \times e^{2\pi i \mathbf{H}\bullet(\mathbf{R}_p - \mathbf{R}_q)} \end{aligned} \tag{3}$$

where $|f_A|$ and $|f_B|$ denote the absolute value or moduli of the complex amplitudes.

From the theoretical development given in Appendix A, a complete description of the diffusely distributed intensity through the second moment of the displacements is given as

$$\frac{I(\mathbf{H})_{\text{Diffuse}}}{N} = \frac{I(\mathbf{H})_{\text{SRO}}}{N} + \frac{I(\mathbf{H})_{j=1}}{N} + \frac{I(\mathbf{H})_{j=2}}{N} \tag{4}$$

where

$$\frac{I(\mathbf{H})_{\text{SRO}}}{N} = \sum_{lmn} C_A C_B |f_A - f_B|^2 \alpha_{lmn} \cos \pi (h_1 l + h_2 m + h_3 n) \tag{5}$$

$$\begin{aligned} \frac{I(\mathbf{H})_{j=1}}{N} = & -\text{Re}\big[f_A (f_A^* - f_B^*)\big] \big[h_1 Q_x^{AA} + h_2 Q_y^{AA} + h_3 Q_z^{AA}\big] \\ & + \text{Re}\big[f_B (f_A^* - f_B^*)\big] \big[h_1 Q_x^{BB} + h_2 Q_y^{BB} + h_3 Q_z^{BB}\big] \end{aligned} \tag{6}$$

and

$$\begin{aligned} \frac{I(\mathbf{H})_{j=2}}{N} = & |f_A|^2 \big(h_1^2 R_X^{AA} + h_2^2 R_Y^{AA} + h_3^2 R_Z^{AA}\big) \\ & + f_A f_B^* \big(h_1^2 R_X^{AB} + h_2^2 R_Y^{AB} + h_3^2 R_Z^{AB}\big) \\ & + |f_B|^2 \big(h_1^2 R_X^{BB} + h_2^2 R_Y^{BB} + h_3^2 R_Z^{BB}\big) \\ & + |f_A|^2 \big(h_1 h_2 S_{XY}^{AA} + h_1 h_3 S_{XZ}^{AA} + h_2 h_3 S_{YZ}^{AA}\big) \\ & + f_A f_B^* \big(h_1 h_2 S_{XY}^{AB} + h_1 h_3 S_{XZ}^{AB} + h_2 h_3 S_{YZ}^{AB}\big) \\ & + |f_B|^2 \big(h_1 h_2 S_{XY}^{BB} + h_1 h_3 S_{XZ}^{BB} + h_2 h_3 S_{YZ}^{BB}\big) \end{aligned} \tag{7}$$

Here the individual terms are defined in Appendix A. As illustrated in Equations 4, 5, 6, and 7, local chemical order (Warren-Cowley α's) can be recovered from a crystalline binary alloy with a single contrast measurement of the diffuse scattering distribution, provided the displacement

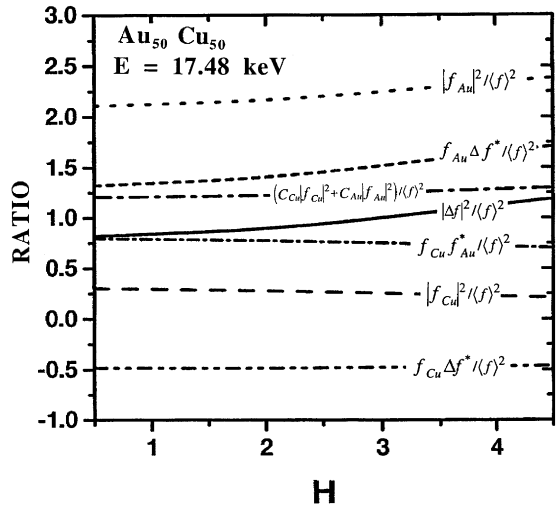

Figure 4. Variation in the ratio of the x-ray atomic scattering factor terms as a function **H**. The divisor $\langle f\rangle^2 = |C_{Cu}f_{Cu} + C_{Au}f_{Au}|^2$ was chosen to reduce the **H** dependence of all the terms for an incident energy of Mo $K_\alpha = 1.748$ keV. The relatively larger x-ray atomic scattering factor of Au, $f_{Au} = 79$ versus Cu, $f_{Cu} = 29$ at $\mathbf{H} = 0$, would require a divisor more heavily weighted with f_{Au}, such as $|f_{Au}|^2$ to reduce the **H** dependence of those terms.

contributions are negligible. This was the early practice until a series of papers used symmetry relationships among the various terms to remove the $I(\mathbf{H})_{j=1}$ term in two dimensions (Borie and Sparks, 1964), in three dimensions (Sparks and Borie, 1965), and to second moment in all three dimensions: $I(\mathbf{H})_{\text{SRO}}$, $I(\mathbf{H})_{j=1}$, $I(\mathbf{H})_{j=2}$ (Borie and Sparks, 1971), henceforth referred to as BS. The major assumption of the BS method is that the x-ray atomic scattering factor terms $|f_A - f_B|^2$, $\text{Re}[f_A(f_A^* - f_B^*)]$, $\text{Re}[f_B(f_A^* - f_B^*)]$, $|f_A|^2$, $|f_B|^2$, and $f_A f_B^*$ of Equations 4, 5, 6, and 7 have a similar **H** dependence so that a single divisor renders them independent of **H**. With this assumption, the diffuse intensity can be written as a sum of periodic functions given by Equation 34. For neutron nuclear scattering, this assumption is excellent; neutron nuclear scattering cross-sections are independent of **H**, and in addition, the TDS terms C and D can be filtered out. Even with x rays, the BS assumption is generally a good approximation. For example, as shown in Figure 4 for Mo K_α x rays and even with widely separated elements such as Au-Cu, a judicious choice of the divisor allows the BS method to be applied as a first approximation over a large range in momentum transfer. In this case, division by $f_{Au}(f_{Au} - f_{Cu}) = f_{Au}\Delta f$ would be a better choice since the Au atom is the major scatterer. Iterative techniques to further extend the BS method have not been fully explored. This variation in the scattering factor terms with **H** has been proposed as a means to recover the individual pair displacements (Georgopoulos and Cohen, 1977).

Equations 5, 6, and 7 are derived from the terms first given by BS, but with notation similar to that used by Georgopoulos and Cohen (1977). There are 25 Fourier series in Equations 5, 6, and 7. For a cubic system with centrosymmetric sites, if we know Q_X^{AA}, then we know Q_Y^{AA} and

Q_Z^{AA}. Similarly, if we know Q_X^{BB}, R_X^{AA}, R_X^{BB}, R_X^{AB}, S_{XY}^{AA}, S_{XY}^{BB}, and S_{XY}^{AB}, then we know all the Q, R, and S parameters. Thus with the addition of the α series, there are nine separate Fourier series for cubic scattering to second order.

As described in Appendix A (Derivation of the Diffuse Intensity), the nine distinct correlation terms from the α, Q, R, and S series can be grouped into four unique **H**-dependent functions, A, B, C, D within the BS approximation. By following the operations given by BS, we are able to recover these unique **H** dependent functions and from these the nine distinct correlation terms. For a binary cubic alloy, one x-ray map is sufficient to recover A, B, C, and D and from A($h_1h_2h_3$), the Warren-Cowley α's. Measurements at two x-ray energies with sufficient contrast are required to separate the A-A and B-B pair contributions to the B($h_1h_2h_3$) terms, and three x-ray energies for the A-A, A-B, and B-B displacements given in Equation 29 and contained in the terms C and D of Equation 34.

In an effort to overcome the assumption of **H** independence for the x-ray atomic scattering factor terms and to use that information to separate the different pair contributions, Georgopoulos and Cohen (1977), henceforth GC, included the variation of the x-ray scattering factors in a large least-squares program. Based on a suggestion by Tibballs (1975), GC used the **H** dependence of the three different x-ray scattering factor terms to separate the first moment of the displacements for the A-A, A-B, and B-B pairs. Results from GC's error analysis (which included statistical, roundoff, x-ray scattering factors, sample roughness, and extraneous backgrounds) showed that errors in the x-ray atomic scattering factors had the largest effect, particularly on the Q terms. They concluded, based on an error analysis of the BS method by Gragg et al. (1973), that the errors in the GC method were no worse than for the BS method and provided correct directions for the first moment displacements.

Improvements in the GC method, with the use of Mo K_α x rays to obtain more data and the use of a Householder transformation to avoid matrix inversion and stabilization with ridge-regression techniques, still resulted in unacceptably large errors on the values of the R and S parameters (Wu et al., 1983). To date, there have been no reported values for the terms R and S that are deemed reliable. However, the Warren-Cowley α's are found to have typical errors of ~10% or less for binary alloys with a preference for unlike first-neighbor pairs with either the BS or GC analysis. For clustering systems, the BS method was reported to give large errors of 20% to 50% of the recovered α's (Gragg et al., 1973). Smaller errors were reported on the α's for clustering systems with the GC method (Wu et al., 1983). With increasing experience and better data from intense synchrotron sources, errors will be reduced for both the BS and GC methods.

Another methodology to recover the pair correlation parameters uses selectable x-ray energies (Ice et al., 1992). Of most practical interest are the α's and the first moment of the static displacements as given in Equations 27 and 28. When alloys contain elements that are near one another in the periodic table, the scattering factor term $f_A - f_B$ can be made to be nearly zero by proper choice of x-ray energy nearby to an x-ray absorption. In this way,

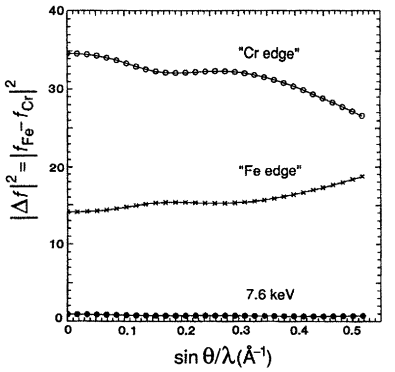

Figure 5. For elements nearby in the periodic table, x-ray energies can be chosen to obtain near null Laue scattering to separate intensity arising from quadratic and higher moments in atomic displacements. Courtesy of Reinhard et al. (1992).

the intensities expressed in Equations 27 and 28 are made nearly zero and only that intensity associated with Equation 29 remains. Then, the term $I(\mathbf{H})_{j=2}$ can be measured and scaled to diffuse scattering measurements made at other x-ray energies (which emphasize the contrast between the A and B atoms) and subtracted off. This leaves only the $I(\mathbf{H})_{SRO}$ term, Equation 5, and the first moment of the static displacements $I(\mathbf{H})_{j=1}$, Equation 6. Shown in Figure 5 are the values of $|f_{Fe} - f_{Cr}|^2$ for x-ray energies selected for maximum contrast at 20 eV below the Fe K and Cr K edges. The near null Laue energy, or energy of minimum contrast, was 7.6 keV.

The major assumption in this null Laue or 3 λ method is that the $I(\mathbf{H})_{j=2}$ and higher moment terms scale with x-ray energy as $|C_A f_A + C_B f_B|^2$, which implies that the A and B atoms have the same second and higher moment displacements or that the different elements have the same x-ray atomic scattering factors. This assumption is most valid for alloys of elements with similar atomic numbers, which have similar masses (similar thermal motion), atom sizes (small static displacement), and numbers of electrons (similar x-ray scattering factors). This 3 λ method has been used to analyze four different alloys, $Fe_{22.5}Ni_{77.5}$ (Ice et al., 1992), $Cr_{47}Fe_{53}$ (Reinhard et al., 1992), $Cr_{20}Ni_{80}$ (Schönfeld et al., 1994), and $Fe_{46.5}Ni_{53.5}$ and recalculated $Fe_{22.5}Ni_{77.5}$ (Jiang et al., 1996). An improvement in the null Laue method by Jiang et al. (1996) removed an iteration procedure to account for the residuals left by the fact that $f_A - f_B$ was not strictly zero over the measured volume.

The same techniques used for x-ray diffuse scattering analysis can also be applied to neutron scattering measurements. Neutrons have the advantage (and complication) of being sensitive to magnetic order as described in Appendix B. This sensitivity to magnetic order allows neutron measurements to detect and quantify local magnetic ordering but complicates analysis of chemical ordering.

Error analysis of the null Laue method has been given by Jiang et al. (1995) and by Ice et al. (1998). The statistical uncertainties of the recovered parameters can be estimated by propagating the standard deviation $\pm\sqrt{n}$ of the total number of counts n for each data point through the

[a]For statistical and possible systematic errors associated with counting statistics n, the real part of the resonant x-ray scattering factor f' the scaling parameter P_0 to absolute intensities, inelastic resonant Raman scattering (RRS) and Compton contributions, and concentration C_A. Total error is shown in parentheses and 0 indicates uncertainties < 0.00005 Å.

nonlinear least-squares processing of the data. Systematic errors can be determined by changing the values of input variables such as the x-ray atomic scattering factors, backgrounds, and composition; then the data is reprocessed and the recovered parameters are compared.

Because the measured pair correlation coefficients are very sensitive to the relative and to a lesser degree the absolute intensity calibration of data sets collected with varying scattering contrast, the addition of constraints greatly increases reliability and reduces uncertainties. For example, the uncertainty in recovered parameters due to scaling of the measured scattering intensities is determined as input parameters are varied. Each time, the intensities are rescaled so that the I_{SRO} values are everywhere positive and match values at the origin of reciprocal space measured by small-angle scattering. The integrated Laue scattering over a repeat volume in reciprocal space is also constrained to have an average value of $C_A C_B |f_A - f_B|^2$ (i.e., $\alpha_{000} = 1$). These two constraints eliminate most of the systematic errors associated with converting the raw intensities into absolute units (Sparks et al., 1994). The intensities measured at three different energies are adjusted to within ~1% on a relative scale and the intensity at the origin is matched to measured values. For these reasons, the systematic errors for α_{000} are estimated at ~1%.

For the null Laue method, errors on the recovered α's and ΔX's arising from statistical and various possible systematic errors in the measurement and analysis of diffuse scattering data are given in Tables 1 and 2 for the $Fe_{46.5}Ni_{53.5}$ alloy (Jiang et al., 1995; Ice et al., 1998). Details of the conversion to absolute intensity units are given

elsewhere (Sparks and Borie, 1965; Ice et al., 1994; Warren, 1969; Reinhard et al., 1992). A previous assessment of the systematic errors, without the constraint of forcing $\alpha_{000}=1$ and keeping the intensity at the origin and fundamentals a positive match to known values, resulted in estimated errors approximately two to five times larger than those reported here (Jiang et al., 1995). Parameters necessary to the analysis of the data (other than well-known physical constants) with our best estimate of their standard deviations and their contributing standard deviations to the α and DX parameters are listed in Tables 1 and 2. From a comparison of theoretical and measured values, we estimate a 0.2-eu error on the real part of the x-ray atomic scattering factors, a 1% error in the P_0 calibration for converting the raw intensities to absolute units (eus), a 1-eu error in separating the inelastic resonant Raman scattering (RRS; Sparks, 1974), a 0- to 1-eu **H** dependent Compton scattering error (Ice et al., 1994), and an error of $\pm$0.3 at.% in composition (Ice et al., 1998). Systematic errors are larger than the statistical errors for the first three shells.

The asymmetric contribution of the first moment of the static displacements, $I_{j=1}$, Equation 13, to the diffuse intensity $I_{\mathrm{SRO}}+I_{j=1}$ for an $Fe_{63.2}Ni_{36.8}$ alloy is displayed in Figure 6. Without static displacements the I_{SRO} maxima would occur at the (100) and (300) superlattice positions. The static atomic displacements for the alloy are similar to those given in Table 2. Such large distortions of the short-range order diffuse scattering caused by displacements of $<$0.02 Å (0.002 nm) emphasizes the sensitivity of this technique. With a change in the x-ray energy from 7.092 to 8.313 keV, f_{Ni} becomes smaller than f_{Fe}. Figure 6 displays a reversal in the shift of the position of the diffuse scattering maxima. Two of these x-ray energies

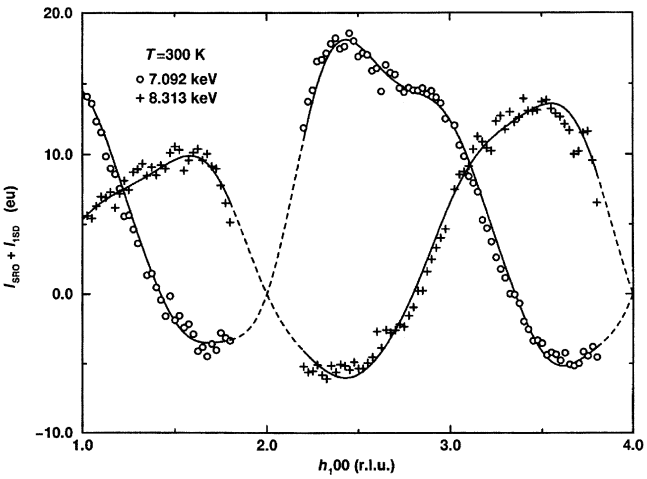

Figure 6. Diffusely scattered x-ray intensity from an $Fe_{63.2}Ni_{36.8}$ Invar alloy associated with the chemical order I_{SRO} and the first moment of the static displacements $I_{J=1}$ versus h in reciprocal lattice units (r.l.u.) along the [h00] direction. A major intensity change is affected by the choice of two different x-ray energies. The solid lines calculated from the α and δ parameters recovered from the 3λ data sets closely fit the observed data given by o and +. The dashed lines are calculated intensity through the fundamental reflections. Courtesy of Ice et al. (1998).

for the 3λ method are chosen to emphasize this contrast and a third nearest the null Laue energy for removal of the TDS. The total estimated standard deviation on the values of the α's and in particular the ΔX's give unprecedented precision for the displacements with errors $\pm$0.003 Å and less.

PRACTICAL ASPECTS OF THE METHOD

Local chemical order (Warren-Cowley α's) from a crystalline binary alloy can be recovered with a single contrast measurement of the diffuse scattering distribution. Recovery of the two terms of the first moment of the static displacements $\langle \Delta X^{\mathrm{AA}}_{lmn} \rangle$ and $\langle \Delta X^{\mathrm{BB}}_{lmn} \rangle$ requires two measurements of sufficiently different contrast in $f_{\mathrm{A}}\Delta f^*$ and $f_{\mathrm{B}}\Delta f^*$ to separate those two contributions (Ice et al., 1992). Scattering contrast can be controlled in at least three ways: (1) by selecting x-ray energies near to and far from an absorption edge energy (resonance or anomalous x-ray scattering, Ice et al., 1994); (2) by measuring diffuse scattering over a wide Q range where there is a significant change in the atomic form factors (Georgopoulos and Cohen, 1977); or (3) with neutrons by isotopic substitution (Cenedese et al., 1984).

The measurement of weak diffuse scattering normally associated with local order and displacements requires careful attention to possible sources of diffusely distributed radiation. Air scatter and other extraneous scattering from sources other than the sample, inelastic contributions such as Compton and resonant Raman, surface roughness attenuation, and geometrical factors associated with sample tilt must be removed. These details are important for placing the measured diffuse scattering in absolute units: a necessary requirement for the recovery of the α's and displacements.

Measurement of Diffuse X-ray Scattering

Methods for collecting diffuse x-ray scattering data from crystalline solid solutions have been discussed by Sparks and Borie (1965), Warren (1969), and Schwartz and Cohen (1987). As demonstrated in Equations 18 and 20, the x-ray scattering intensity from a solid solution alloy contains components arising from long-range periodicity of the crystalline lattice, correlations between the different atom types, and displacements of the atoms off the sites of the average lattice.

Because of the average periodicity of the crystalline solid solution lattice, the x-ray scattering repeats periodically in reciprocal space. The equations for recovering the various components are best conditioned when the data are collected in a volume of reciprocal space that contains at least one repeat volume for the diffuse scattering (Borie and Sparks, 1971). The volume required depends on the significance of the displacement scattering. If static displacements can be ignored and thermal scattering is removed, the smallest repeat volume for SRO is sufficient. This minimum volume increases as higher-order displacement terms become important, but in no case exceeds one-fourth of the volume bounded by $\Delta h_1 = 1$, $\Delta h_2 = 1$, and $\Delta h_3 = 1$.

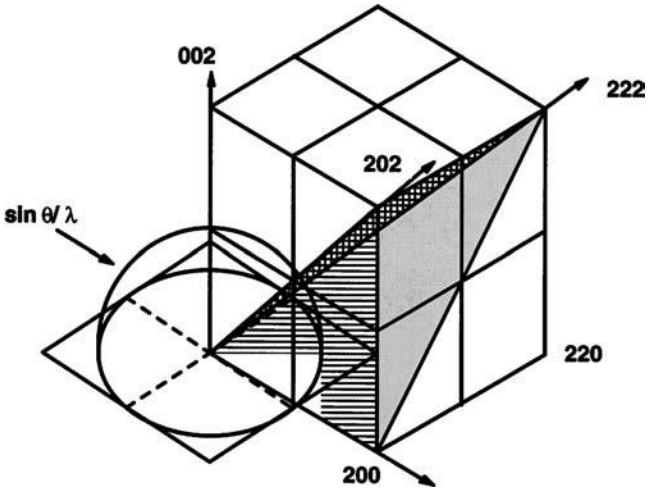

Figure 7. The diffuse intensity is mapped in a volume of reciprocal space bounded by three mirror planes that contain all the information available for a cubic alloy.

A conservative approach is to measure the scattered intensity in a volume of reciprocal space that extends from the origin to as far out in $|\mathbf{H}|$ space as possible, but contains the minimum repeat volume for cubic symmetry. As illustrated in Figure 7, the repeat volume for cubic crystals is 1/48 of the reciprocal space volume limited by the maximum momentum transfer, $\sin\theta/\lambda = 1/\lambda$. This repeat unit contains all the accessible information about the structure of a crystal with average cubic symmetry. As it takes several days to prepare for the experiment and its setup, actual collection of the data is not the time-limiting step with x rays, and as much data as possible should be collected in an effort to accumulate 1000 or more counts at each of several thousand positions.

The various points h_1, h_2, h_3 in reciprocal space are measured by orienting the sample and detector arm with a four-circle diffractometer. Diffuse scattering data are typically collected at intervals of $\Delta h = 0.1$ in a volume of reciprocal space bounded by $4 \geq h_1 \geq h_2 \geq h_3 \geq 1$. Regions of detailed interest are measured at intervals of $\Delta h = 0.05$. There are on the order of 7000 data points collected for a diffuse volume at each x-ray energy. Angular dependence of the absorption corrections is eliminated by measuring diffuse scattering in a bisecting geometry where the redundancy of the three sample-orienting circles is used to maintain the same incident and exit angle for the radiation with respect to the surface.

Shown in Figure 8 is the typical optical train for the measurement of diffuse x-ray scattering. Every effort should be made to ensure that the detector receives the radiation from the sample with the same collection efficiency regardless of the sample orientation. The sample needs to be replaced with a well-calibrated standard to convert the flux incident on the sample to absolute units. As all scattering measurements are made for fixed I_0 monitor counts, any changes to the optical train such as slit positions (excepting scatter slit) and sizes, distances, detectors, and changes in energy require replacing the sample with the scattering standard for recalibration of the incident flux against the I_0 monitor counts.

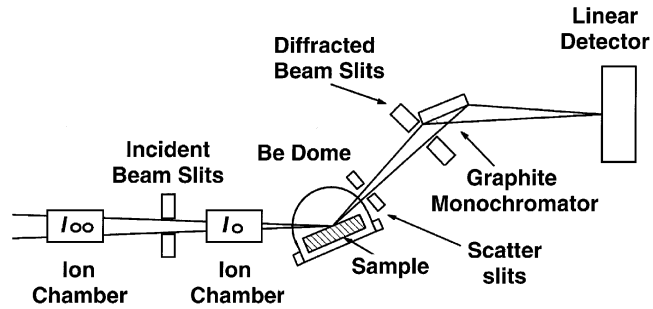

Figure 8. Optical setup for resonant diffuse x-ray scattering measurement.

New challenges arise from the application of resonant (anomalous) x-ray scattering to the study of local order in crystalline solid solutions: (1) the need to work near absorption edges that can create large fluorescent and resonant Raman backgrounds, and (2) the need to know the resonant (anomalous) scattering factors and absorption cross-sections to ~1%, especially at x-ray energies near absorption edges. Background problems due to inelastic scattering are exacerbated. Experimental measurement to recover the elastic scattering from these inelastic contributions (Compton, fluorescence, and resonant Raman) requires a combination of spectroscopy and diffraction.

Removal of Inelastic Scattering Backgrounds

Photoelectric absorption is the dominant x-ray cross-section for elements with $Z > 13$ and x-ray energies $E < 20$ keV. The resultant fluorescence is typically orders of magnitude larger than the diffuse elastic scattering. Fluorescence can be removed by the use of an energy-sensitive detector when the incident x-ray energy is far enough above the photoabsorption threshold that the detector's energy resolution is adequate for separation.

Maximum change in scattering amplitude is obtained when measurements are made with the x-ray energy very near and then far from an absorption edge, as shown in Figure 9. The size of the f' component roughly doubles as the energy gap between the incident x-ray energy E_I and the absorption edge E_K is halved. Near an edge, the size of the inelastic background grows rapidly due to RRS (Sparks, 1974; Eisenberger et al., 1976a,b; Åberg and Crasemann, 1994). RRS is interpreted as the filling of a virtual hole by a bound electron. As with fluorescence, the x-ray energy spectra is distinctive with peaks corresponding to the filling of the virtual hole, say in the K shell, by various higher lying shells: K filled from L, or K filled from M shells, often referred to as K-L and K-M RRS. Unlike fluorescence, the energy of the RRS peaks shift with incident x-ray energy, and the energy of the nearest RRS K-L line is only a few tens of electronvolts from the incident x-ray energy (Åberg and Crasemann, 1994). This large inelastic background must either be removed experimentally or be calculated and subtracted.

The resolution of a solid-state detector at ~150 eV is inadequate to resolve all the RRS K-M component from the elastic peak when excited near the threshold and can

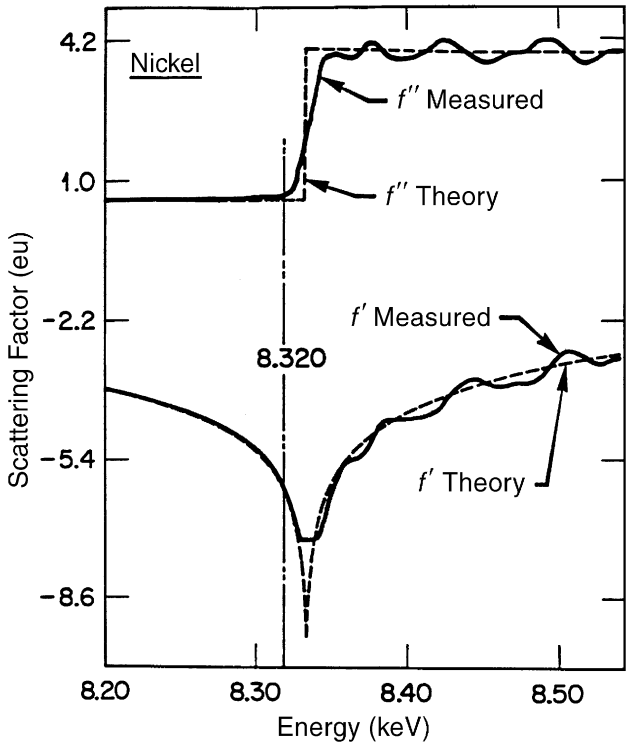

Figure 9. Variation of f' and f'' near the K absorption edge of nickel. Dashed lines are the theoretical calculation from Cromer and Liberman (1970; 1981). Courtesy of Ice et al. (1994).

only resolve the Compton inelastic scattering at high scattering angles. A typical energy spectrum excited by 8.0-keV x rays on a $Ni_{77.5}Fe_{22.5}$ single crystal measured with a Si(Li) detector is shown in Figure 10. Near and below the Fe edge of 7.112 keV, the RRS *K-M* component cannot be resolved from the elastic scattering peak. The RRS *K-M* component can be removed by measuring the RRS *K-L* component and assuming the *K-LK-M* ratio remains constant. The Compton scattering component at low scattering angles is removed by using theoretical tables.

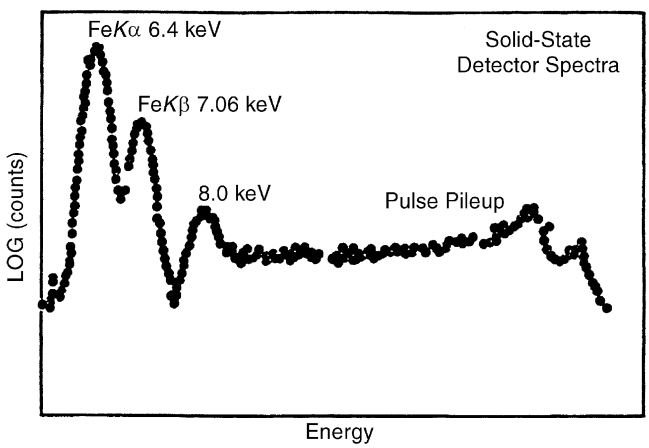

Figure 10. Energy spectrum measured with a solid-state detector from Ni-Fe alloy excited by 8.0-keV x rays. Courtesy of Ice et al. (1994).

Disadvantages to the use of solid-state detectors include the statistical and theoretical uncertainty of the inelastic contributions. Another disadvantage is the large deadtime imposed by the fluorescence K signal in a solid-state detector, which restricts the useful flux on the sample.

Resolution on the order of 10 to 30 eV is necessary to cleanly separate the resonant Raman and Compton scattering from elastic scattering. A crystal spectrometer improves the energy resolution beyond that available with a solid-state detector. Perfect crystal spectrometers are highly inefficient compared to mosaic crystal spectrometers due to their smaller integrated reflectivity. This inefficiency is usually unacceptable for the typical weak diffuse x-ray scattering. A mosaic crystal x-ray spectrometer (Ice and Sparks, 1990) has been found to be a more practical device. The advantages of a mosaic crystal spectrometer is that it is possible to obtain energy resolutions similar to that of a perfect crystal spectrometer, but with an overall angular acceptance and efficiency similar to those of a solid-state detector. A schematic is shown in Figure 11A.

Figure 11B,C illustrates the ability of the graphite spectrometer to resolve Ni K_{α_1} from K_{α_2} and to resolve RRS from elastic scattering near the Ni K edge. Good efficiency is possible if the x-ray energy, E_I, lies within a bandpass, ΔE, set by the crystal Bragg angle θ_B and the rocking curve width $\Delta\omega_R$; $\Delta E = \Delta\omega_R E \cot\theta_B$. The diffracted beam is parafocused onto a linear detector and the beam position is correlated to x-ray energy. The energy resolution and energy scale of the spectrometer are determined by varying the energy of the incident beam and observing the peak position of the elastic peak. At 8 keV, the bandpass, ΔE, of a graphite crystal with a 0.4° full-width at half-maximum (FWHM) mosaic spread is ~250 eV. The energy resolution is limited by the effective source size viewed by the energy analyzer and by imperfections in the crystal. Energy resolutions of 10 to 30 eV are typical with a 0.3- to 1.5-mm high beam in the scattering plane at the sample.

Elastic scattering is resolved from the Compton scattering at higher scattering angles and *K-L* RRS at all angles. When an x-ray energy is selected near but below the absorption edge of the higher Z element, the lower Z element will fluoresce. The mosaic crystal spectrometer can discriminate against this fluorescence and avoid deadtime from this emission. This graphite monochromator gives an overall decrease of 3 to 4 in counting efficiency compared with a solid-state detector, but provides a much cleaner signal with greatly reduced deadtime.

A consideration when using a crystal spectrometer is the sensitivity of the energy resolution to the effective source size. As the source size increases, the energy resolution decreases and increasingly small incident beams are required for good energy resolution (Ice and Sparks, 1990). In addition, the effective source size as viewed by the crystal spectrometer depends on the spread of the incident beam on the sample and the angle of the detector axis to the sample surface. These geometrical factors are governed by the scattering angle, θ, and the chi tilt, χ, as shown in Figure 12.

Diffuse scattering is normally collected in the bisecting mode as intended here. The size and shape of the beam

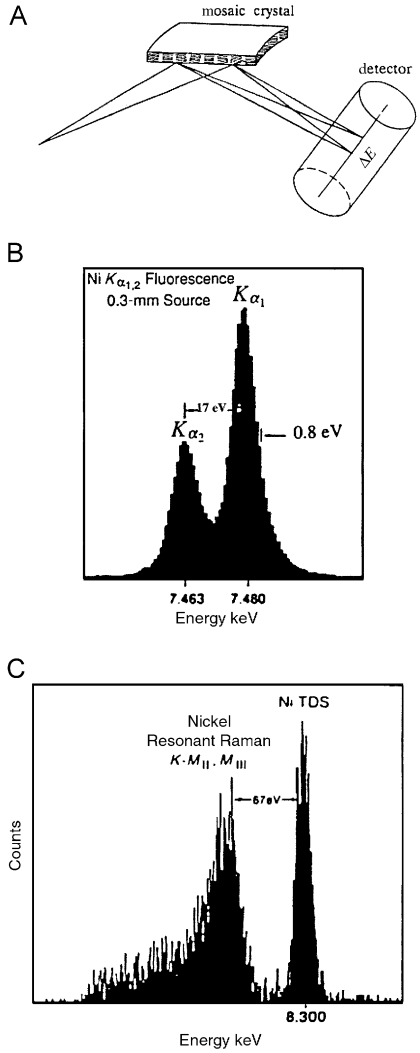

Figure 11. (**A**) Scattered radiation is energy analyzed with a mosaic graphite crystal dispersing radiation along a position sensitive detector to resolve (**B**) fluorescence and (**C**) resonant Raman and Compton scattering. Courtesy of Ice and Sparks (1990).

intercept with the sample surface is determined by the beam height h, width w, and the sample angles θ and ω. As shown in the insert of Figure 12, the intercept is a parallelogram that extends along the beam direction by $h/\sin\theta$ due to the beam height and $w\tan(\omega-\pi/2)/\sin\theta$ due to the beam width. In the reference frame of the detector, the length of the parallelogram is projected into a root-mean-square source height of

$$\sigma_s = \frac{\sqrt{[2w\tan(\chi-\pi/2)\cos\theta]^2 + h^2}}{12} \qquad (8)$$

The measured energy resolution for a 1.5×1.5-mm^2 beam at $\chi = 55^\circ$ is plotted in Figure 12 as a function of scattering angle θ. Deviations from $\chi=90^\circ$, where the sample normal lies in the scattering plane, are held to a minimum by choosing a crystal surface normal centered in the volume of reciprocal space to be measured. This reduces

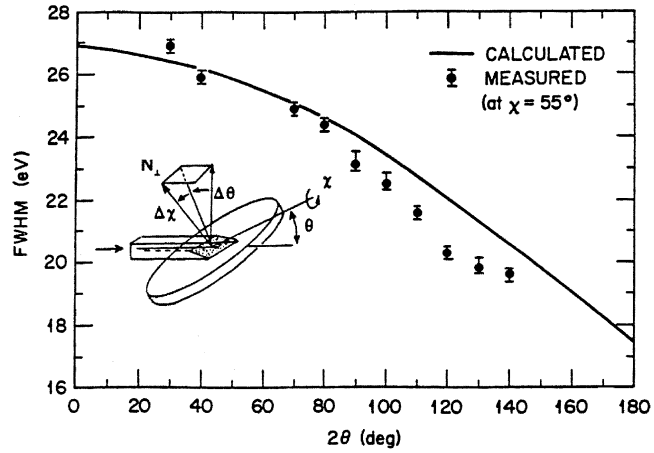

Figure 12. Incident beam spread on the sample depends on χ and θ, which orient the surface normal with respect to the incident beam. As the beam spread on the sample is proportional to the effective source size viewed by the spectrometer, the energy resolution changes as χ and θ change. The measured energy resolution (points) is plotted for $\chi = 55^\circ$ and compared with the theoretical prediction (line).

surface roughness corrections and maintains good energy resolution. Actual spectra collected during a diffuse scattering measurement are shown in Figure 13. Crystal analyzers will perform even better with third-generation synchrotron sources that have smaller source size and higher flux. Measurement of the fluorescent intensity or RRS throughout the volume used for the data with the identical optical train provides a correction for this beam spread, sample roughness, and alignment errors.

A model is used to describe the energy distributions of the RRS shown in Figures 13A,B as observed with the graphite spectrometer. The model contains a truncated Lorentzian centered at the energy for the RRS peak (Sparks, 1974; Ice et al., 1994). The high-energy cutoff is determined from energy conservation. The spectra are corrected for the graphite monochromator efficiency, which has a Gaussian distribution centered on the elastic scattering peak. The spectra are also corrected for the finite spectrometer resolution by convolving the Gaussian shape of the elastically scattered peak. The simple model for the resonant Raman peak shape allows for a good fit to the experimental resonant Raman peak observed with the graphite monochromator, as shown in Figures 13A,B.

Compton scattering can be removed from the elastic scatter by subtracting tabulated theoretical Compton intensities. It is possible to experimentally separate the elastic scattering peak from the Compton peak except at the lowest scattering angles. A correction for overlap of the two peaks at small angles is achieved by modeling the energy dependence of the Compton profile. The doubly differential Compton scattering cross-section is calculated using the impulse approximation (IA; Carlsson et al., 1982; Biggs et al., 1975). The Compton scattering is calculated for each subshell, and energy conservation is used to restrict the high-energy tail from each shell. The total spectrum is determined by adding the contribution from

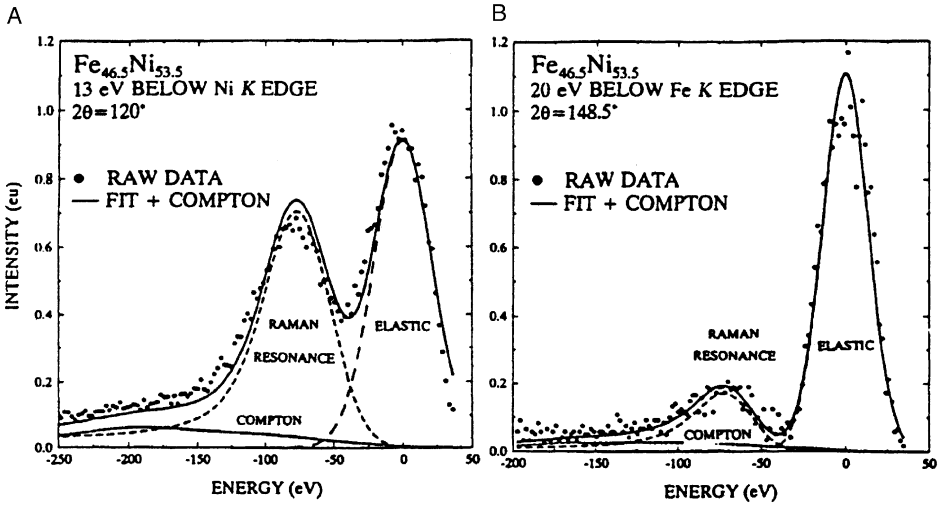

Figure 13. Energy spectrum of scattered radiation when the incident energy is (**A**) 13 eV below the Ni *K* edge and (**B**) 20 eV below the Fe *K* edge of a Fe-Ni crystal. Courtesy of Ice et al. (1994).

each shell and from each atom type. This cross-section is subtracted from the measured data normalized to absolute electron units per atom, which leaves only a resonant Raman peak and an elastic scattering peak. The slight overlap of the Compton peak with the elastic peak is typically small compared with statistical uncertainties.

Comparison of the calculated to the observed Compton spectrum can be achieved with x-ray energies sufficiently removed from an edge that the resonant Raman contribution is negligible. At 8.000 keV, the resonant Raman contribution from an Fe-Ni sample is centered far below the elastic peak and outside the spectrometer window. The IA-calculated Compton profiles are observed to be in qualitative agreement with the observed spectra, but the intensity is overestimated at low angles and underestimated at high angles. Particularly noticeable is a low-energy tail at high scattering angles. A more exact theory without the impulse approximation might improve matters.

Determination of the Resonant Scattering Terms f' and f''

The widely used Cromer-Liberman tabulation (Cromer and Liberman, 1981; Sasaki, 1989) of f' and f'' explicitly ignores the presence of pre-edge unfilled bound states (bound-to-bound transitions), lifetime broadening of the inner-shell hole, and x-ray absorption fine structure (XAFS; XAFS Spectroscopy). These assumptions are justified ~100 eV below and ~1 keV above an edge, but not near an absorption edge (Lengeler, 1994; Chantier, 1994). Of particular concern is the underestimation of the absorption coefficient and f' just below an absorption edge due to the Lorentzian hole width of an inner shell. This is illustrated in Figure 14. An inner-shell hole with a 2-eV broadened lifetime and a *K* edge jump ratio of 8 will increase the absorption cross-section by ~11% at 20 eV below the nominal edge and by 2% at 100 eV below the edge. Theoretical tabulations that ignore the lifetime broadened hole width must be corrected, as they underestimate the absorption coefficient (and f') just below an edge and overestimate f'' above the edge. Theoretical tabulations also do not include unfilled pre-edge states or absorption fine structure that is highly sample dependent. Thus, it is necessary to determine the photoelectric absorption cross-section, μ/ρ, experimentally for each sample, to calculate f'' with the optical theorem (James, 1948), and then to calculate f' from f'' with the Kramers-Kronig relationship.

The practical method of measuring the sample-specific absorption cross-section is to measure the relative absorption cross-section across the edge of each of the elements of the sample over a range of ~100 to 1000 eV. These data are normalized to theoretical data far from the edge (Kawamura and Fukamachi, 1978; Dreier et al., 1983; Hoyt et al., 1984). Measurements are made with a thin foil of the sample in transmission geometry. The measured value of f' is obtained by adding the difference integration to tabulated values of f', as shown in Figure 9.

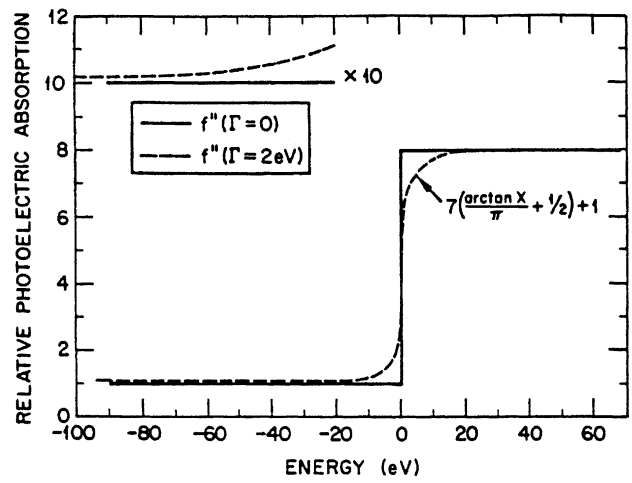

Figure 14. The usual tabulated values of the resonant (anomalous) scattering terms are not corrected for hole width (lifetime), which causes a Lorentzian broadening of the absorption edge and affects the values of f' and f'' near the edge. Courtesy of Ice et al. (1994).

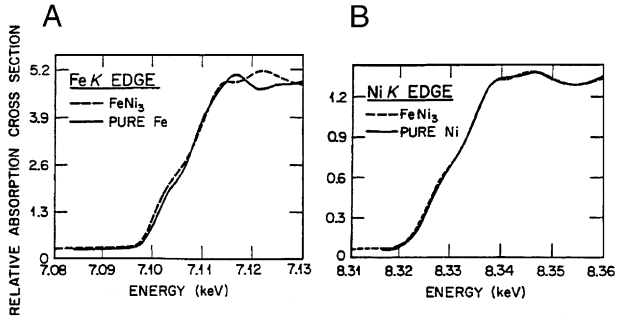

Figure 15. The absorption edge energy shifts are very small for metallic alloys with differing nearest neighbors. Courtesy of Ice et al. (1994).

We find f' is 5 to 10 times less sensitive than f'' to lifetime broadening of the inner-shell hole. For example, the effect of a 2-eV lifetime on f' at 20 eV below the edge is only 2% and at −100 eV the effect is only 0.3%. The value of f' is sensitive to the position of the average inflection point of the absorption edge. A shift of 5 eV results in a 4% to 5% change in f' at 20 eV below the edge. Errors in the absolute energy calibration are removed when the energy of the incident radiation is fixed to the same absorption edge energy as the calculation of f' and f''.

As shown in Figure 15A,B, the absorption edge energies for Fe and Ni in a fully ordered $FeNi_3$ foil do not shift compared to the absorption edge energies of pure Fe or Ni foils. However, the local environment of the Fe atoms in $FeNi_3$ are sufficiently different that calculated or measured values of f' and f'' for pure Fe would be in error close to the Fe absorption edge. For samples where there is a large charge transfer (change in oxidation state), this difference becomes even larger.

Absolute Calibration of the Measured Intensities

Conversions to absolute units depend on previously calibrated standards to place the intensity in electron units (Suortti et al., 1985). Calibrated powder standards account for the monitor efficiency, the beam path transmission, and the efficiency and solid angle of the detector. The largest uncertainty is in the values of the linear x-ray absorption cross-sections, μ, near an absorption edge for both the powder and the sample. This problem is reduced by using a powder similar in elemental composition to the sample or by careful calibration of the sample absorption. Comparison between standardizations with various powder samples are consistent to within 3% to 5% (Suortti et al., 1985).

The relative scaling factors between different energy sets can be refined with great sensitivity by restricting the short-range-order intensity as discussed previously and as described below. For alloys that cluster, the Laue scattering can be obscured by proximity of the fundamental Bragg peaks. Higher-resolution measurements such as small-angle x-ray scattering (SAXS) techniques may then be required to recover the Laue scattering. SAXS can be used to measure the total SRO scattering at the origin, and the relative scaling factors of data sets can be adjusted so that $\alpha_{000}=1$, and the fitted SRO diffuse scattering,

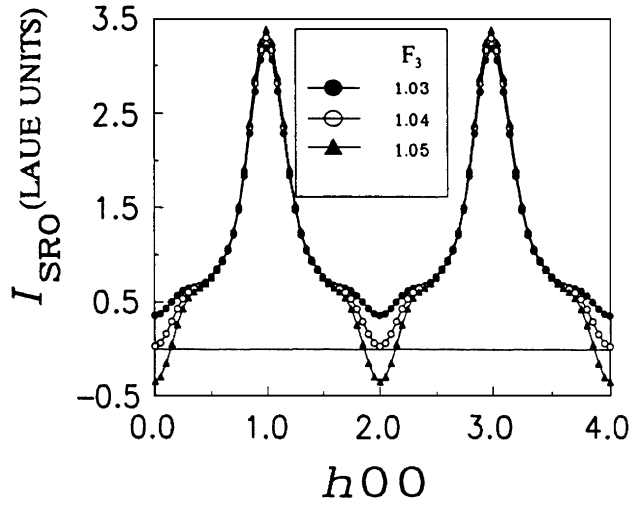

Figure 16. Fitted I_{SRO} along the $h00$ line for three relative scale factors on the near zero contrast data of a $Ni_{77.5}Fe_{22.5}$ sample. With a scale factor of 1.04, I_{SRO} is near zero at the origin and fundamental Bragg peaks as measured by SAXS. Courtesy of Sparks et al. (1994).

approach the SAXS value obtained near the origin. This scaling method is illustrated in Figure 16 for a $Ni_{77.5}Fe_{22.5}$ alloy. As shown in Figure 16, a small change in the relative scaling (here the zero contrast or near null Laue scale factor) makes a big change in the SRO scattering near the origin. Fe-Ni alloys are known to show negligible scattering near the origin (Simon and Lyon, 1991). Scale factors are adjusted to set the SRO scattering to near zero at the Bragg peaks. Nonlinear fitting routines that refine the relative intensities and include these and other restrictions may be possible with more reliable data sets from third-generation synchrotron sources.

DATA ANALYSIS AND INITIAL INTERPRETATION

Most x-ray detectors are count-rate limited, and measured x-ray scattering intensities must be corrected for detector-system deadtime (Ice et al., 1994). With proportional counters and solid-state detectors, the measured deadtime is typically 3 times the amplifier shaping constant. For most measurements, this results in deadtimes of ~1 to 10 μs/count.

Detector survival can also be challenged by intense x-ray beams and requires that the sample orientation and detector position be controlled such that a Bragg reflection from the cyrstal does not enter the detector. Bragg reflections can contain in excess of 10^9 x rays per second at synchrotron sources, which can paralyze or damage detectors. Position-sensitive wire proportional counters are especially vulnerable, and count rates below 10^4 counts/s are generally advisable to prevent damage to the wire or coated filament. Just falshing throug a Bragg reflection when changing orientation can damage the wire anode of a linear-senitive proportional counter, which materially degrades its spatial resolution. Extreme caution is necessary when measurements are taken near Bragg reflections with flux-sensitive detectors.

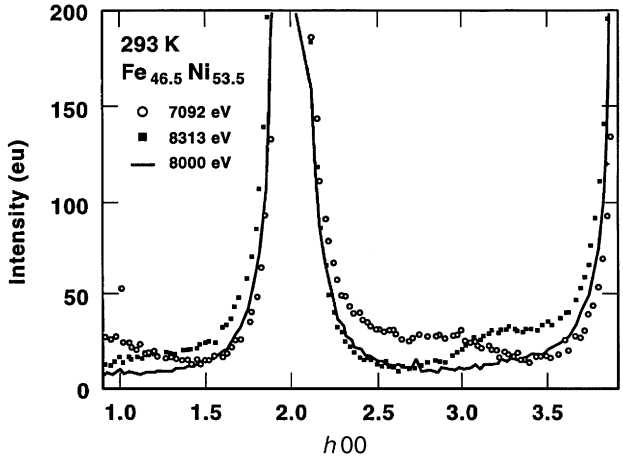

Figure 17. Total elastically scattered x-ray intensity along the $\langle h00 \rangle$ measured at 293 *K* for the three x-ray energies listed. Note the shift in contrast for intensities measured with energies 20 eV below the Fe *K* edge at 7092-eV and the Ni *K* edge at 8313 eV, which changes the sign of $\mathrm{Re}(f_{\mathrm{Ni}}-f_{\mathrm{Fe}})$. The outlying data point at the {100} position is from harmonic energy contamination of the incident radiation and such points are removed before processing. Courtesy of Jiang et al. (1996).

Mirrors and crystal monochromators can pass a significant number of harmonics (multienergy x rays), which are then diffracted by the sample at positions of h/n, k/n, l/n, where n is an integer and hkl are the Miller indices of the Bragg reflections. Any sharp spikes observed in the measurement of diffuse intensities at these positions are suspect and must be removed before processing the data to recover the local correlations. At the position (100) in Figure 17, we note an outlying data point that can be attributed to the Bragg diffraction from the (200) reflection of an x-ray energy twice that of the nominal energy. Such spurious data can also be caused by surface films left from chemical treatment or oxidation.

An example of the raw data measured for three different x-ray energies from an $Fe_{46.5}Ni_{53.5}$ alloy single crystal is shown in Figure 17 (Jiang et al., 1996). The solid line in Figure 17 is the near null Laue measurement, which can be used to remove the quadratic and higher-order displacement terms from the other data sets. The assumption made is that for elements with similar masses and small static displacements the second and higher moment terms are the same for both atoms species so that for $I_{j\geq 2}$, the intensity scales as $\langle f \rangle^2$ This method avoids the need to calculate thermal scattering from a set of force constants with the Born-von Karman central forces model that assumes harmonic vibrations and Hooke's law forces between the atoms independent of their environment (Warren, 1969). Theoretically calculated TDS increasingly deviates from measured TDS on approach to the Brillouin zone boundaries. This is not unexpected as local structure is important near the zone boundaries. A comparison of x-ray null Laue results with neutron diffuse scattering measurements, which are not complicated by TDS, gives very similar α's for Fe_3Ni (Jiang et al., 1996).

An example of the measured diffuse scattering data in the h_1h_20 plane (labeled here as H_1, H_2, 0) for three x-ray energies is shown in Figure 18 for an alloy of $Fe_{27.5}Ni_{77.5}$ (Ice et al., 1992). The x-ray energy at 8.000 keV (Fig. 18B) is the near null Laue energy ($f_{\mathrm{Ni}} - f_{\mathrm{Fe}} \sim 0$), where I_{SRO} is nearly zero compared with the intense SRO maxima such as (100), (110), and (210) at 7.092 keV of Figure 18A. With the data in electron units and with inelastic scattering removed, the data are now processed to recover the α and δ values. As discussed previously (see Principles of the Method), we have the choice of different processing methods.

1. The null Laue method (also referred to as the 3λ method). This method is used when the elements of an alloy are sufficiently near each other in the periodic table that their dynamic displacements are similar and $I_{j\geq 2}$ scales as $(C_{\mathrm{A}}f_{\mathrm{A}}+C_{\mathrm{B}}f_{\mathrm{B}})^2$ for the different energies; $I_{j\geq 2}$ can be experimentally measured at a low x-ray scattering contrast and then substracted from the diffuse scattering with high elemental contrast (Ice et al., 1992; Reinhard et al., 1992; Schoenfield et al., 1994; Jiang et al., 1996). The null Laue method is implemented using a nonlinear least-squares approach.
2. Collection of sufficient data such that the BS separation technique can first be used to recover I_{SRO}, $I_{j=1}$, $I_{j=2}$, and higher terms separately for each of the three x-ray energies. Then a least-squares program is used to recover the α's from I_{SRO}. The α's are used to recover the displacements from $I_{j=1}$ and the second moments from $I_{j=2}$ as given in Equations 4, 5, 6, and 7. As the assumption is made that the x-ray atomic scattering factors are independent of **H**, an interactive technique is required to remove that

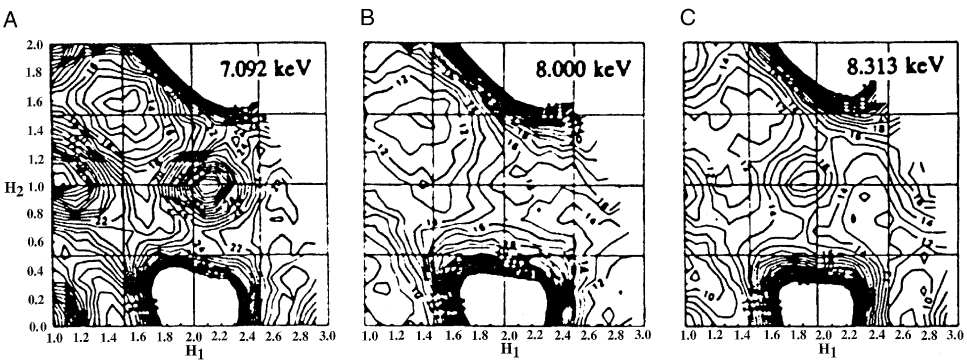

Figure 18. Diffuse x-ray scattering intensities from $Fe_{22.5}Ni_{72.5}$ in the $h_3 = 0$ plane collected with x-ray energies of (**A**) 7.092, (**B**) 8.000, and (**C**) 8.313 keV. Courtesy of Ice et al. (1992).

assumption. This is possibly the most robust of the methods as it does not have the assumption of method 1. Therefore it can be extended to include the $I_{j=3}$ and $I_{j=4}$ terms to account for higher moments of the displacements including second-order TDS, which becomes important for measurements made at temperatures approaching the Debye temperature. Furthermore, data for each energy can be separately into I_{SRO} and displacement scattering and checked for the correct normalization factors before different energy sets are subjected to a simultaneous least-squares program to recover the A-A, A-B, and B-B pair correlations.

3. The GC method of analysis, which uses data measured at only one energy for 25 symmetry-related points for each of the 25 terms expressed in Equations 4, 5, 6, and 7. These symmetry-related points are chosen such that the values of I_{SRO}, and the Q, R, and S terms are of the same or of opposite magnitude. Only their scattering factors and **H** dependence differ. In this way, the terms of Equations 4, 5, 6, and 7 are obtained from a system of linear equations stabilized by a ridge regression technique. These terms are then inverted to recover their Fourier coefficients. Results with this technique have been mixed. An analysis of $AuCu_3$ data (Butler and Cohen, 1989) concluded that the Au-Au bond distance was shorter than that for Cu-Cu. This result is contrary to the experimental findings that ordering of $AuCu_3$ reduces the lattice constant as more first-neighbor Au-Cu pairs are formed and that the addition of the ~14% larger Au atoms to Cu increases the lattice constant because of the larger Au-Au bond distance. Theoretical considerations have also concluded that the Au-Au bond distance is the largest of the three kinds (Chakraborty, 1995; Horiuchi et al., 1995). Apparently, the **H** variation of $f_{Au}\Delta f^*$ and $f_{Cu}\Delta f^*$ shown in Figure 4 is not sufficiently different to provide for a meaningful separation of the Au-Au and Cu-Cu bond distances. In a direct comparison with the 3λ technique on an alloy of $Ni_{80}Cr_{20}$, the GC result gave a Ni-Ni bond distance with a different sign, which was contrary to other information (Schöenfeld et al., 1994). In addition, published GC values for $\langle(\Delta X)^2\rangle$ coefficients are not reliable (Wu et al., 1983). Though first-order TDS is included in the separation, higher-order TDS is calculated from force constants and subtracted.

Interpretation of Recovered Static Displacements

The displacements are defined as deviations from the average lattice and are given by

$$\mathbf{r}_p - \mathbf{r}_q = (\mathbf{R}_p - \mathbf{R}_q) + (\boldsymbol{\delta}_p - \boldsymbol{\delta}_q) \tag{9}$$

As we can move the frame of reference so that its origin always resides on one of the atoms of the pair, such that $\mathbf{r}_p \equiv \mathbf{r}_0$, $\mathbf{R}_p \equiv \mathbf{R}_0$, and $\boldsymbol{\delta}_p \equiv \boldsymbol{\delta}_0$, then

$$\mathbf{r}_p - \mathbf{r}_q = \mathbf{r}_0 - \mathbf{r}_q = \mathbf{r}_0 - \mathbf{r}_{lmn} = -\mathbf{r}_{lmn} \tag{10}$$

and with the atom pair identified by ij

$$\mathbf{r}^{ij}_{lmn} = \mathbf{R}_{lmn} + \boldsymbol{\delta}^{ij}_{lmn} \tag{11}$$

where $\mathbf{R}_{lmn}$ is independent of the kinds of atom pairs since it is defined by the average lattice (i.e., Bragg reflection positions). The average value of the measured $\mathbf{r}_{lmn}$ for all the N pairs contributing to the measured intensity is

$$\langle \mathbf{r}^{ij}_{lmn} \rangle = \frac{1}{N^{ij}} \sum_{ij} \langle \mathbf{R}_{lmn} + \boldsymbol{\delta}^{ij}_{lmn} \rangle = \mathbf{R}_{lmn} + \langle \boldsymbol{\delta}^{ij}_{lmn} \rangle \tag{12}$$

Here $\langle \boldsymbol{\delta}^{ij}_{lmn} \rangle$ is the variable recovered from the diffuse scattering. As shown in Equation 25, we recover the Cartesian coordinates of the average displacement vector,

$$\langle \boldsymbol{\delta}^{ij}_{lmn} \rangle \equiv \langle \Delta X^{ij}_{lmn} \rangle \mathbf{a} + \langle \Delta Y^{ij}_{lmn} \rangle \mathbf{b} + \langle \Delta Z^{ij}_{lmn} \rangle \mathbf{c} \tag{13}$$

For cubic systems, when the atom has fewer than 24 neighboring atoms in a coordination shell (permutations and combinations of $\pm l$, $\pm m$, $\pm n$), $\langle \boldsymbol{\delta}^{ij}_{lmn} \rangle$ must be parallel to the lattice vector $\mathbf{R}_{lmn}$. This maintains the statistically observed long-range cubic symmetry even though on a local scale this symmetry is broken. For lmn multiplicities $\geq$24, the displacements on average need not be parallel to the average interatomic vector $\mathbf{R}_{lmn}$ to preserve cubic symmetry (Sparks and Borie, 1965).

Measurements of diffuse scattering from single crystals provides the components of the atomic displacements $\langle \Delta X \rangle$, $\langle \Delta Y \rangle$, and $\langle \Delta Z \rangle$ whereas the spherical average usually obtained from EXAFS and x-ray measurements on amorphous materials and crystalline powders gives only the magnitude of the radial displacements. Thus, diffuse x-ray scattering from single crystals provides new information about the vector displacements associated with near-neighbor chemistry.

Measured displacements such as those presented in Table 2 provide unique insight into how atoms move off their lattice sites when local symmetry is broken. Local symmetry is broken when a multicomponent crystalline material is above the ordering temperature (with less-than-perfect long-range order) and/or off stoichiometry. With perfect long-range order the atoms are constrained to lie precisely on the sites of the average lattice by balanced forces. In alloys, where the local symmetry is broken, we gain new insights into the chemically distinct bonding, including the interatomic bond distances and whether the displacements have both radial and tangential components. With reference to Figure 23, the displacement for the [110] nearest-neighbor atoms is on average radial with a magnitude given by $|\langle \boldsymbol{\delta}_{110} \rangle| = \sqrt{2}|\Delta X_{110}|$.

We note that the Fe-Fe first-neighbor pair distances given in Table 2 are 0.021(3) Å $\times \sqrt{2} = 0.030(4)$ Å further apart then the average lattice and that second neighbor pairs are closer by (−) 0.023(1) Å. Average bond distances along the interatomic vector between nearest-neighbor pairs for this fcc lattice are obtained by adding the $\sqrt{2}|\Delta X_{110}|$ to the average interatomic vector $\mathbf{R}_{110}$, as defined in Figure 19. The parameter $|\mathbf{R}_{110}|$ is just the

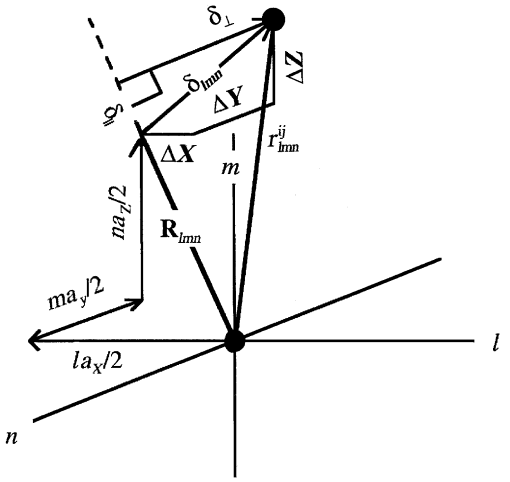

Figure 19. Construction of the vectors recovered from diffuse scattering measurements on single crystals. The parameter $\mathbf{R}_{lmn}$ is obtained from the lattice parameter $|\mathbf{a}|$, and the average components of the displacement δ^{ij}_{lmn} are recovered from measurements of the diffuse scattering. Courtesy of Ice et al. (1998).

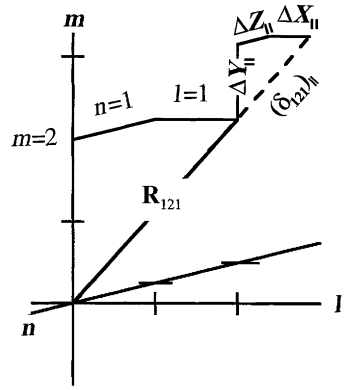

Figure 20. Radial displacements (parallel to the interatomic vector $\mathbf{R}_{lmn}$) between the atom pairs require that the relative magnitudes of the displacement components be in the same proportion as the average lattice vector; $\Delta X:\Delta Y:\Delta Z = l:m:n$. As shown for $lmn = 211$, a radial displacement requires $|\Delta X| = 2|\Delta Y|$ and $|\Delta X| = 2|\Delta Z|$. For $lmn = 121$, $|\Delta X| = |\Delta Y|/2$ and $|\Delta X| = |\Delta Z|$. For a cubic lattice, we can interchange l, m, and n and similarly $\Delta X, \Delta Y$, and ΔZ. Thus there is only one value ΔX for lmn multiplicities <24 (i.e., 110, 200, and 222), two values for ΔX when lmn has multiplicities equal to 24 ($l \neq m$ and $l = m, n$), and three values for ΔX with multiplicities equal to 48. Courtesy of Ice et al. (1998).

cubic lattice constant $|\mathbf{a}|$ times $1/\sqrt{2}$. From the construction shown in Figure 19, it follows that the vector distance between a pair of atoms, $\mathbf{r}^{ij}_{lmn}$, has radial and tangential displacement components with magnitudes given by

$$\left|\boldsymbol{\delta}^{ij}_{lmn}\right|_{||} = \frac{\boldsymbol{\delta}^{ij}_{lmn} \bullet \mathbf{R}_{lmn}}{|\mathbf{R}_{lmn}|} \tag{14}$$

and

$$\left|\boldsymbol{\delta}^{ij}_{lmn}\right|_{\perp} = \sqrt{|\boldsymbol{\delta}^{ij}_{lmn}|^2 - |\boldsymbol{\delta}^{ij}_{lmn}|^2_{||}} \tag{15}$$

The radial (||) and tangential ($\perp$) components of the displacements recovered from diffuse scattering measurements on single crystals are shown in Figure 19.

As the $Fe_{46.5}Ni_{53.5}$ alloy is cubic (face centered), the ΔY and ΔZ displacements are derived from the ΔX's given in Table 2 by permutation of the indices. (Henceforth, we will omit the <> on the displacements for simplicity.) For example, ΔX_{321} has the identical value as ΔY_{231} and ΔZ_{123}, and $\Delta X_{321}=\Delta X_{312}=\Delta Y_{231}=\Delta Y_{132}=\Delta Z_{123}=\Delta Z_{213}$. In addition, $\Delta X_{321}=-\Delta X_{\bar{3}21}$ and similarly for the other combinations as illustrated in Figure 20. The nearest-atom pairs that could have, on average, nonradial components are those in the third neighboring shell, lmn=211 (Sparks and Borie, 1965). If the displacements between atom pairs is on average along their interatomic vector, then $\Delta X_{211} = 2\ \Delta X_{121}$ (Fig. 20). For the Fe-Fe pair displacements given in Table 2, ΔX_{211}= 0.0005(2)Å and $2\,\Delta X_{121}$=0.0028(8)Å; thus the (211) Fe-Fe pair displacements have a significant tangential component. From Equations 14 and 15, the magnitude of the displacement between (211) Fe-Fe pairs along the radial direction $|\boldsymbol{\delta}^{\text{Fe-Fe}}_{211}|_{||}$ is 0.0016 (7)Å and $|\boldsymbol{\delta}^{\text{Fe-Fe}}_{211}|_{\perp}$ tangential is 0.0013(7)Å. Thus the (211) Fe-Fe neighbors have a similar radial and tangential component to their displacements. For the (310) Fe-Fe pair displacements, $\Delta X_{310} \cong 3\ \Delta X_{130}$ within the total estimated error, and on average (310) displacements are predominantly radial. These measured displacements provide new information not obtained in other ways about the local atomic arrangements in crystalline solid solutions.

Results for the few crystalline binary alloys that have had their individual pair displacements measured with this 3λ technique are summarized in Figure 21. Here the ΔX static displacements are plotted as a function of the radial distance $\frac{1}{2}\sqrt{l^2+m^2+n^2}$. When there is more than one value for ΔX, the plots show the various values. Most striking is the observation that for the three ordering alloys the near- neighbor Fe-Ni and Cr-Ni bond distances are the smallest of the three possible pairs (Fig. 21). However, for the clustering $Cr_{47}Fe_{53}$ alloy the Cr-Cr nearest-neighbor bond distances are closest and the Cr-Fe are furthest apart. More details, including the short-range-order parameters α and numerical values of the displacements for each shell, are given in the original papers. These pair displacement observations provide a more rigid test of theoretical predictions than variations of the average lattice parameter with concentrations (Froyen and Herring, 1981; Mousseau and Thorpe, 1992).

METHOD AUTOMATION

Because of the large number of data that is collected (~7000 data points per diffuse scattering volume, each consisting of a multichannel energy spectrum with 200 to 500 channels), data collection is under computer control. The program most widely used for converting the reciprocal space coordinates to Eulerian angles and then stepping the three- (or four-) axis diffractometer to this list of

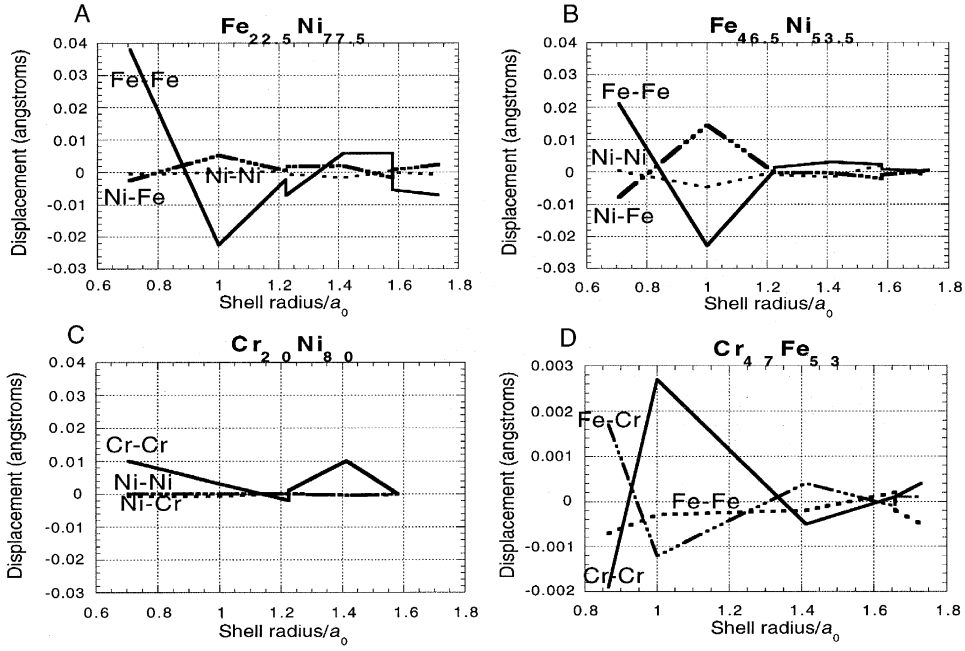

Figure 21. Displacement from the average lattice sites for chemically specific pairs. Shell radius divided by the lattice parameter a_0 becomes 1 for second neighbors (seperated by the cube edge). Courtesy of Ice et al. (1998).

coordinates is SPEC (Certified Scientific Software). Because the diffuse scattering is a slowly varying function without sharp peaks, it is fastest to take the data while the diffractometer is moving and avoid the time-consuming starting and stopping of the diffractometer. The reciprocal space coordinate is estimated from the midrange of the angular scans during data collection. When using the BS separation procedure, it is necessary to have the diffuse scattering data on a uniform cubic grid in reciprocal space. Least-squares procedures do not have this requirement. Since the experiment is enclosed in a radiation hutch, computerized control of all slits, sample positioning, and electronic components in the hutch is desirable.

SAMPLE PREPARATION

The most detailed measurements of diffuse x-ray scattering are made on homogeneous single crystals with polished and etched surfaces. These samples must be carefully prepared and handled to minimize surface roughness effects, surface contamination, and inhomogeneities. To prepare a sample, a single crystal of the intended composition and $\geq$99.9% purity metals should be homogenized for $\geq$3 days at $\sim$50° to 100°C below the crystal melting point in an atmosphere that protects its composition. This step is intended to create a single crystal with uniform chemical composition. For a crystal with cubic symmetry, the crystal should be oriented and then cut with a surface near the <421> normal. This orientation minimizes the goniometer χ range, improves the energy resolution of measurements with a crystal spectrometer, and improves access to a cubic symmetry volume of reciprocal space. The surface of the crystal should be $\sim$20 mm in diameter to ensure that the incident beam is completely intercepted by the sample at all orientations. Electrical discharge machining or chemical sawing minimizes surfaces strains and distortions and is preferred to standard machining. After chemical polishing to remove distorted metal, the crystals should be heat treated to the desired state of thermodynamic equilibrium before quenching. Metallographic polishing is followed by chemical dissolution or electropolishing to produce a mirror smooth surface with nondistorted metal (see SAMPLE PREPARATION FOR METALLOGRAPHY). Verification of negligible distortion is obtained by optical microscopy of subgrain boundary images. Because surface roughness reduces x-ray scattering intensity at low angles, smooth surfaces reduce the corrections to the absolute intensity measurements. The effect of sample roughness on intensity can be checked with fluorescence or RRS measurements to determine if there is any angular variation with respect to **H** in the bisecting geometry (Sparks et al., 1992). The acceptable mosaic spread of the crystals measured from x-ray rocking curves depends on the **H** resolution necessary to resolve the features of interest, but can be as large as $\sim$2 degrees. Verification of the composition to $\pm$ 0.2 at.% or less is needed to reduce the uncertainty in the data analysis. A check of the weight of the raw materials against the weight of the single-crystal ingot will determine if more extensive chemical analysis is necessary.

PROBLEMS

The fundamental problem of diffuse x-ray scattering is that the measurements must be made in absolute units and must be consistent over large ranges in reciprocal space and with different experimental conditions (x ray,

neutron, energy, etc.). Even small systematic uncertainties increase the uncertainties in the recovered local correlations. Special procedures can sometimes be used to calibrate the relative normalization between different experimental conditions, but the reality remains that great care is required to collect meaningful data. For example, near an absorption edge, uncertainties in the scattered intensity can occur because the values of f' and f'' change rapidly with small fluctuations in incident photon energy, as seen in Figure 9. The intensities of RRS also increases as the incident photon energy approaches an absorption edge. As a compromise, the incident energies are usually chosen ~20 eV below an absorption edge. This requires that the x-ray optics, which select the x-ray energy from the white synchrotron spectrum, be very stable so as to control the selected energy fluctuations to less than about ±1 eV.

Similarly, environments must maintain a clean surface free of condensates and oxidation that can add unwanted scattered intensity to measurements. Extremely thin coverages of a few tens of monolayers can contribute noticeable intensity. Equilibrium temperatures can sometimes be difficult to define on quenched samples. For example, quenching to a desired equilibrium local-ordered state may not be possible due to rapid kinetics; quenched-in vacancies enhance diffusion, which can alter chemical order at the actual temperature of interest for local order. Kinetic studies or measurements at the higher temperature are required to ensure that equilibrium order is achieved. Even if diffusion, which changes the α's on cooling, is not a problem, changes in lattice constant on cooling may affect the static displacements. It is better to have the sample in a known state of equilibrium so that the recovered parameters can be directly compared to theory. A discussion of the effect of quenching parameters on the diffuse scattering from an Al-Cu sample has been given by Epperson et al. (1978), and a study of the kinetics of short-range ordering in $Ni_{0.765}Fe_{0.235}$ has been given by Bley et al. (1988).

The complexities of actually performing and interpreting a three-dimensional diffuse scattering experiment require a major commitment of time and resources. To ensure success, we suggest that beginners collaborate with one of the referenced authors who has experience in this science and who has access to the specialized instrumentation and software required for successful diffuse scattering experiments.

ACKNOWLEDGMENTS

We wish to express our appreciation to the early pioneers of diffuse scattering and to our many contemporaries who have contributed to this subject. Research was sponsored by the Division of Materials Sciences, U.S. Department of Energy, under contract DE-AC05-96OR22464 with Lockheed Martin Energy Research. Research was performed at the Oak Ridge National Laboratory Beamline X-14 at the National Synchrotron Light Source, Brookhaven National Laboratory, sponsored by the Division of Materials Sciences and Division of Chemical Sciences, U.S. Department of Energy.

KEY REFERENCES

Cowley, J.M. 1975. Diffraction Physics. North-Holland, Amsterdam, The Netherlands.

This reference is a good basic introduction into diffraction physics and x-ray techniques.

Materlik, G., Sparks, C. J., and Fisher, K. (eds.).. 1994. Resonant Anomalous X-ray Scattering. North-Holland, Amsterdam, The Netherlands.

This reference is a collection of recent work on the theory and application of resonant x-ray scattering techniques. It provides the most complete introduction to the application of anomalous (resonant) scattering techniques and how the field has been revolutionized by the availability of intense synchrotron radiation sources.

Schwartz and Cohen, 1987. See above.

This is another introductory text on x-ray diffraction with an emphasis on the application to materials. The section on diffuse x-ray scattering is especially strong and the notation is the same as used in this unit.

Schweika, 1998. See above.

This monograph provides an excellent reference to the interplay between experiment and theory in the field of local atomic order in alloys.

Warren, 1969 (reprinted 1990). See above.

This reference provides an authoritative treatment of all phases of diffuse x-ray scattering, including thermal diffuse scattering, TDS, short-range order, and atomic size displacement scattering. Although it does not include a modern outlook on the importance of resonant scattering, it provides a clear foundation for virtually all modern treatments of diffuse scattering from materials.

APPENDIX A: DERIVATION OF THE DIFFUSE INTENSITY

Our interest is in the diffusely distributed intensity. To separate Equation 3 into an intensity that may be sharply peaked and one that is diffusely distributed, we follow the method of Warren (1969). This method expands $e^{2\pi i\mathbf{H}\bullet(\boldsymbol{\delta}_p-\boldsymbol{\delta}_q)}$ in a Taylor series about $\boldsymbol{\delta}_p - \boldsymbol{\delta}_q$ and examines the displacement terms as the separation of atom pairs becomes large, $p-q\rightarrow\infty$. As the x-ray or neutron beam intercepts many atoms and the atoms undergo many thermal vibrations during the period of the intensity measurement, both a spatial and a time average are taken. These are indicated by $< >$. The spatial and time average of the jth-order Taylor series expansion of the exponential displacement term is

$$\langle e^{e\pi i\mathbf{H}} \bullet (\boldsymbol{\delta}_p - \boldsymbol{\delta}_g)\rangle \equiv \langle e^{iX_{pq}}\rangle = 1 + i\langle X_{pq}\rangle - \frac{\langle X_{pq}^2\rangle}{2} - \frac{i\langle X_{pq}^3\rangle}{3!} + \cdots + \frac{i^j\langle X_{pq}^j\rangle}{j!} \tag{16}$$

The time average for harmonic thermal displacements causes odd-order terms to vanish. With the definition $\langle X_{pq}\rangle = \langle X_p - X_q\rangle$, so that $\langle (X_p - X_q)^2\rangle = \langle X_p^2\rangle + \langle X_q^2\rangle - 2\langle X_pX_q\rangle$, and for sharply peaked Bragg reflections, where $p-q\rightarrow\infty$, the displacements become uncorrelated so that $\langle X_pX_q\rangle = 0$. Therefore, $\langle X_{pq}^2\rangle_{p-q\rightarrow\infty} = \langle X_p^2\rangle + \langle X_q^2\rangle$, and with the harmonic approximation we can estimate the long-range dynamical displacement term by

$$\langle e^{iX_{pq}}\rangle_{p-q\rightarrow\infty} \cong e^{-\frac{1}{2}(\langle x_p^2\rangle + \langle x_q^2\rangle)} = e^{-(M_p+M_q)} \tag{17}$$

Here M_p is the usual designation for the Debye-Waller temperature factor (Warren, 1990, p. 35). The subject is treated by Chen in KINEMATIC DIFFRACTION OF X RAYS. We also include the mean-square static displacements in M. Experience has shown the validity of the harmonic approximation in Equation 17 to account for the reduction in the intensity of the Bragg reflections as a function of $\mathbf{H}$. With the understanding that when there is an A atom at site p or q, M_p or M_q is written as M_A, and similarly M_B when there is a B at p or q, the fundamental Bragg intensity for an alloy is given by the substitution of Equation 17 into Equation 3 as

$$I(\mathbf{H})_{\mathbf{Fund}} = |C_\mathrm{A}f_\mathrm{A}e^{-M_\mathrm{A}} + C_\mathrm{B}f_\mathrm{B}f_\mathrm{B}e^{-M_\mathrm{B}}|^2 \sum_p \sum_q e^{2\pi i\mathbf{H}\bullet(\mathbf{R}_p-\mathbf{R}_q)} \tag{18}$$

This expression accounts for the reduced intensity of the fundamental Bragg reflections due to thermal motion and static displacements of the atoms. Fundamental reflections scale as the average scattering factor and are insensitive to how the chemical composition is distributed on the lattice sites. When the alloy has long-range order among the kinds of atoms, the α_{pq}'s do not converge rapidly with larger p, q and account for the superstructure Bragg reflections that depend on how the atoms are distributed among the sites. We are now concerned with the distribution of this thermal and static scattering. To recover the diffuse intensity, we subtract $I(\mathbf{H})_\mathrm{Fund}$ from $I(\mathbf{H})_\mathrm{Total}$ in Equation 3. To avoid making the harmonic approximation of Equation 17, we subtract $I(\mathbf{H})_\mathrm{Fund}$ term by term and take

the limit as $p-q \rightarrow \infty$. For example, to second order we have

$$\langle e^{iX_{pq}} \rangle_{p-q\rightarrow\infty} = 1 - \frac{1}{2}\left(\langle X_p^2 \rangle + \langle X_2^q \rangle\right) \tag{19}$$

By substitution of Equation 19 for each of the $\langle e^{iX_{pq}} \rangle$ terms in Equation 3 and assignment of the proper atom identity for different pairs, and recalling that as $p-q \rightarrow \infty$, $\rightarrow \infty$, α_{pq}=0, we subtract this expression for $I(\mathbf{H})_{\text{Fund}}$ from $I(\mathbf{H})_{\text{Total}}$ and write the diffuse scattering to second order in the displacements as

$$\begin{aligned} I(\mathbf{H})_{\text{Diffuse}} = \sum_p \sum_q \Big\{ & (C_\text{A}^2 + C_\text{A}C_B\alpha_{pq})|f_\text{A}|^2 \\ & \times \left(1 + i\langle X_p^\text{A} - X_q^\text{A}\rangle - \frac{1}{2}\langle (X_p^\text{A} - X_q^\text{A})^2\rangle\right) \\ & - C_\text{A}^2|f_\text{A}|^2\left(1 - \langle X^2\rangle^\text{A}\right) + C_\text{A}C_\text{B}\,(1-\alpha_{pq})f_\text{A}f_\text{B}^* \\ & \times \left(1 + i\langle X_p^\text{B} - X_p^\text{A}\rangle - \frac{1}{2}\langle (X_p^\text{B} - X_q^\text{A})^2\rangle\right) \\ & - 2C_\text{A}C_\text{B}f_\text{A}f_\text{B}^*\left(1 - \frac{1}{2}\langle X^2\rangle^\text{A} - \frac{1}{2}\langle X^2\rangle^\text{B}\right) \\ & + C_\text{A}C_\text{B}\,(1-\alpha_{pq})f_\text{A}f_\text{B}^* \\ & \times \left(1 + i\langle X_p^\text{A} - X_q^\text{B}\rangle - \frac{1}{2}\langle (X_p^\text{A} - X_q^\text{B})^2\rangle\right) \\ & + (C_\text{B}^2 + C_\text{A}C_\text{B}\alpha_{pq})|f_\text{B}|^2 \\ & \times \left(1 + i\langle X_p^\text{B} - X_q^\text{B}\rangle - \frac{1}{2}\langle (X_p^\text{B} - X_q^\text{B})\rangle\right) \\ & - C_\text{B}^2|f_\text{B}|^2\left(1 - \langle X^2\rangle^\text{B}\right)\Big\} e^{2\pi i\mathbf{H}\bullet(\mathbf{R}_p - \mathbf{R}_q)} \end{aligned} \tag{20}$$

Our use of the double sum requires that the pairs of atoms be counted in both directions, that is, a p, q pair will become a q, p pair such that $i(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q) = -i(\boldsymbol{\delta}_q - \boldsymbol{\delta}_q)$ as shown in Figure 22. As seen in Equation 2, the $I(\mathbf{H})_{\text{Total}}$ double sum is made up of p, q elements that are the product of four complex numbers: the two complex scattering factors and the two complex phase factors. For every p, q pair there is a corresponding q, p pair where the two scattering factors and the two phase factors are the p, q pair complex conjugates; hence the p, q and q, p elements add up to a real number. This means that the terms in the series expansion of the fluctuation displacements must add in

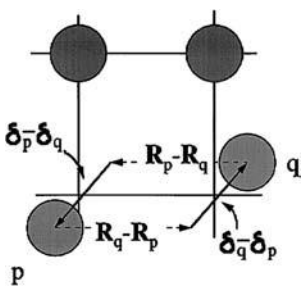

Figure 22. Schematic illustration showing that since all the pairs of atoms are counted as to kind and displacement in both directions, odd-power terms in the displacements are replaced with their negatives $i(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q) = -i(\boldsymbol{\delta}_q - \boldsymbol{\delta}_q)$ and $\mathbf{R}_p - \mathbf{R}_q = -(\mathbf{R}_q - \mathbf{R}_p)$ so that the imaginary terms cancel.

pairs to give real intensity and from Equation 20, the j = odd order displacement terms have a $\sin 2\pi(\mathbf{H}\bullet\mathbf{R})$ $\langle (X_p^\text{A} - X_q^\text{A})^j\rangle$ dependence and the j = even-order terms have a $\cos 2\pi(\mathbf{H}\bullet\mathbf{R})$ $\langle (X_p^\text{A} - X_q^\text{A})^j\rangle$ dependence; the imaginary components cancel.

From the definition of an average lattice, the weighted average of the displacements for all the kinds of pairs formed for any coordination shell is zero (Warren et al., 1951),

$$\begin{aligned} 2(\alpha_{pq} - 1)\langle \boldsymbol{\delta}_p^\text{A} - \boldsymbol{\delta}_q^\text{B}\rangle = & \left(\frac{C_\text{A}}{C_\text{B}} + \alpha_{pq}\right)\langle \boldsymbol{\delta}_p^\text{A} - \boldsymbol{\delta}_q^\text{A}\rangle \\ & + \left(\frac{C_\text{B}}{C_\text{A}} + \alpha_{pq}\right)\langle \boldsymbol{\delta}_p^\text{B} - \boldsymbol{\delta}_q^\text{B}\rangle \end{aligned} \tag{21}$$

If a crystal structure has more than one kind of site symmetry (sublattices with different site symmetries), than Equation 21 may be true for only that sublattice with all the same site symmetries. Different-sized atom species will most likely have a preference for the symmetry of a particular sublattice. This preference could produce long-range correlations and superstructure reflections from which site occupation preferences can be recovered. Disorder among the atoms on any one sublattice and between sublattices will produce scattering from which pair correlations can be recovered. Discussion of this issue is beyond the scope of this unit. A study of a partially ordered non-stoichiometric bcc NiAl crystal, where one of the two sublattices with the same site symmetry is partly occupied by vacancies, has been discussed in Georgopoulos and Cohen (1981). A general review of the application of diffuse scattering measurements to more complicated structures with different site symmetries shows a wider use of models to reduce the number of variables necessary to describe the local pair correlations (Welberry and Butler, 1995).

Equation 20 can be expressed in a more tractable form through three steps: (1) Replace the double sum over atomic sites p and q by N single sums around an origin site where the relative sites are identified by lattice difference lmn such that $\mathbf{R}_p - \mathbf{R}_q = \mathbf{R}_0 - \mathbf{R}_{lmn}$. This approximation neglects surface effects. (2) Use trigonometric functions to simplify the phase factors. (3) Substitute Equation 21 into Equation 20. With these steps, the diffuse intensity can be expressed as,

$$\begin{aligned} \frac{I(\mathbf{H})_{\text{Diffuse}}}{N} = & \sum_{lmn} C_\text{A}C_\text{B}|f_\text{A} - f_\text{B}|^2\alpha_{lmn}\cos 2\pi\mathbf{H}\bullet(\mathbf{R}_0 - \mathbf{R}_{lmn}) \\ & - \sum_{lmn}[(C_\text{A}^2 + C_\text{A}C_\text{B}\alpha_{lmn})\,\text{Re}(f_\text{a}(f_\text{A} - f_\text{B})^*) \\ & \times \langle X_0^\text{A} - X_{lmn}^\text{A}\rangle - (C_\text{B}^2 + C_\text{A}C_\text{B}\alpha_{lmn})\text{Re}(f_\text{B}(f_\text{A} - f_\text{B})^*) \\ & \times \langle X_0^\text{B} - X_{lmn}^\text{B})\rangle]\sin 2\pi\mathbf{H}\bullet(\mathbf{R}_0 - \mathbf{R}_{lmn}) \\ & + \sum_{lmn}\Big[C_\text{A}^2|f_\text{A}|^2\Big(\langle X^2\rangle^\text{A} - \left(1 + \frac{C_\text{B}}{C_\text{A}}\alpha_{lmn}\right) \\ & \times \frac{1}{2}\langle (X_0^\text{A} - X_{lmn}^\text{A})^2\rangle\Big) + C_\text{A}C_\text{B}f_\text{A}f_\text{B}^*(\langle X^2\rangle^\text{A} + \langle X^2\rangle^\text{B} \\ & - (1-\alpha_{lmn})\,\langle (X_0^\text{B} - x_{lmn}^\text{A})^2\rangle) + C_\text{B}^2|f_\text{B}|^2\Big(\langle X^2\rangle^\text{B} \\ & - \left(1 + \frac{C_\text{A}}{C_\text{B}}\alpha_{lmn}\right)\frac{1}{2}\langle (X_0^\text{B} - X_{lmn}^\text{B})^2\rangle\Big)\Big] \\ & \times \cos 2\pi\mathbf{H}\bullet(\mathbf{R}_0 - \mathbf{R}_{lmn}) \end{aligned} \tag{22}$$

Equation 22 is a completely general description of the diffuse scattering from any crystal structure through the second moment of the static and thermal displacements. We now apply this to binary solid solutions, which have received the most attention among crystalline solid solutions.

It is helpful to choose real-space basis vectors **a**, **b**, **c** that reflect the long-range periodicity of the crystal structure. This long-range periodicity in turn is reflected in the intensity distribution in the reciprocal space lattice with basis vectors $\mathbf{a}^* = 1/\mathbf{a}$, $\mathbf{b}^* = 1/\mathbf{b}$, and $\mathbf{c}^* = 1/\mathbf{c}$, as shown in Figure 3. For an alloy that is on average statistically cubic, such as that shown in Figure 3, we define

$$\mathbf{R}_0 - \mathbf{R}_{lmn} \equiv \frac{l}{2}\mathbf{a} + \frac{m}{2}\mathbf{b} + \frac{n}{2}\mathbf{c},\ \mathbf{H} \equiv h_1\mathbf{a}^* + h_2\mathbf{b}^* h_3\mathbf{c}^* \quad (23)$$

so that

$$2\pi\mathbf{H} \bullet (\mathbf{R}_0 - \mathbf{R}_{lmn} = \pi(h_1 l + h_2 m + h_3 n) \quad (24)$$

In addition,

$$\boldsymbol{\delta}_{lmn} \equiv \Delta X_{lmn}\mathbf{a} + \Delta Y_{lmn}\mathbf{b} + \Delta Z_{lmn}\mathbf{c} \quad (25)$$

so that

$$X_0 - X_{lmn} \equiv 2\pi\mathbf{H} \bullet (\boldsymbol{\delta}_0 - \boldsymbol{\delta}_{lmn}) \equiv 2\pi[h_1(\Delta X_0 - \Delta X_{lmn}) + h_2 + (\Delta Y_0 - \Delta Y_{lmn}) + h_3(\Delta Z_0 - \Delta Z_{lmn})] \quad (26)$$

This definition of $\mathbf{R}_0 - \mathbf{R}_{lmn}$ causes the continuous variables $h_1 h_2 h_3$ in reciprocal space to have the integer values of the Miller indices at reciprocal lattice points. We further specify that the site symmetry is cubic such as for the bcc Fe structure and fcc Cu structure. With these definitions, the various diffuse x-ray scattering terms in Equation 22 can be written, starting with the local chemical order term as

$$\frac{I(\mathbf{H})_{\mathrm{SRO}}}{N} = \sum_{lmn} C_\mathrm{A}C_\mathrm{B}|f_\mathrm{A} - f_\mathrm{B}|^2\alpha_{lmn}\cos\pi(h_1 l + h_2 m + h_3 n) \quad (27)$$

which was first given by Cowley (1950). For bcc Fe and fcc Cu structures, $\alpha_{lmn} = \alpha_{\overline{lmn}} = \alpha_{l\bar{m}n} = \alpha_{lm\bar{n}} = \alpha_{l\overline{mn}} = \alpha_{\overline{lmn}} = \alpha_{\overline{l}mn}$ and the cosine term takes the form $\cos\pi h_1 l \cos\pi h_2 m \cos\pi h_3 n$.

For the first-order displacement term,

$$\frac{I(\mathbf{H})_{j=1}}{N} = -\mathrm{Re}\left(f_\mathrm{A}\left(f_\mathrm{A}^* - f_\mathrm{B}^*\right)\right)\left[h_1 Q_x^{\mathrm{AA}} + h_2 Q_Y^{\mathrm{AA}} + h_3 Q_Z^{\mathrm{AA}}\right] + \mathrm{Re}\left(f_\mathrm{B}(f_\mathrm{A}^* - f_\mathrm{B}^*)\right)\left[h_1 Q_X^{\mathrm{BB}} + h_2 Q_Y^{\mathrm{BB}} + h_3^{\mathrm{BB}}\right] \quad (28)$$

where

$$Q_X^{\mathrm{AA}} = 2\pi\sum_{lmn}\left(C_\mathrm{A}^2 + C_\mathrm{A}C_\mathrm{B}\alpha_{lmn}\right)\langle\Delta X_{lmn}^\mathrm{A}\rangle_0^\mathrm{A}\sin\pi h_1 l \times\cos\pi h_2 m\cos\pi h_3 n$$

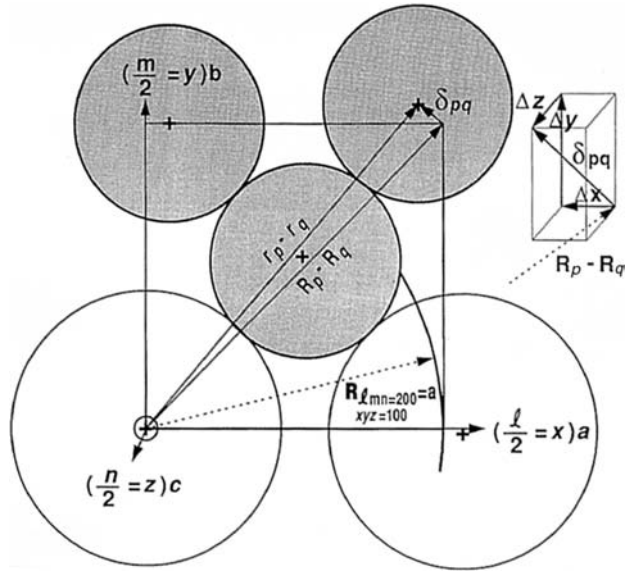

Figure 23. The rectangular square of solid lines is the average lattice about which the atom centers (+) are displaced by the amount $\boldsymbol{\delta}_{pq}$. Shown in the smaller box on the right are the rectangular components of the displacement, $\Delta x, \Delta y$, and Δz. Courtesy of Jiang et al. (1996).

and

$$Q_X^{\mathrm{BB}} = 2\pi\sum_{lmn}\left(C_\mathrm{B}^2 + C_\mathrm{A}C_\mathrm{B}\alpha_{lmn}\right)\langle\Delta X_{lmn}^\mathrm{B}\rangle_0^\mathrm{B}\sin\pi h_1 l \times\cos\pi h_2 m\cos\pi h_3 n$$

and similarly for the other terms as given by Borie and Sparks (1964) and Georgopoulos and Cohen (1977). Where

$$\langle\Delta X_{lmn}^\mathrm{A}\rangle_0^\mathrm{A} = \langle\Delta X_0^\mathrm{A} - \Delta X_{lmn}^\mathrm{A}\rangle$$

Equation 28 is a result given by Borie and Sparks (1964) that avoids an earlier assumption of radial displacements first given by Warren et al. (1951). Shown in Figure 23 is a schematic of the displacements described by Equation 28.

Diffuse scattering from the second-order displacement term can be expanded as,

$$\begin{aligned}\frac{I(\mathbf{H})_{j=2}}{N} = {} & |f_A|^2\left(h_1^2 R_X^{\mathrm{AA}} + h_2^2 R_Y^{\mathrm{AA}} + h_3^2 R_Z^{\mathrm{AA}}\right) \\ & + f_\mathrm{A}f_\mathrm{B}\left(h_1^2 R_X^{\mathrm{AB}} + h_2^2 R_Y^{\mathrm{AB}} + h_3^2 R_Z^{\mathrm{AB}}\right) \\ & + |f_\mathrm{B}|^2\left(h_1^2 R_X^{\mathrm{BB}} + h_2^2 R_Y^{\mathrm{BB}} + h_3^2 R_Z^{\mathrm{BB}}\right) \\ & + |f_\mathrm{A}|^2\left(h_1 h_2 S_{XY}^{\mathrm{AA}} + h_1 h^3 S_{XZ}^{\mathrm{AA}} + h_2 h_3 S_{YZ}^{\mathrm{AA}}\right) \\ & + f_\mathrm{A}f_\mathrm{B}^*\left(h_1 h_2 S_{XY}^{\mathrm{AB}} + h_1 h_3 S_{XZ}^{\mathrm{AB}} + \mathrm{h_2 h_3 S_{YZ}^{AB}}\right) \\ & + |f_\mathrm{B}|^2\left(h_1 h_2 S_{XY}^{\mathrm{BB}} + h_1 h_3 S_{XZ}^{\mathrm{BB}} + h_2 h_3 S_{YZ}^{\mathrm{BB}}\right)\end{aligned} \quad (29)$$

where

$$R_X^{\mathrm{AA}} = 4\pi^2 C_\mathrm{A}^2\sum_{lmn}\left\{\langle\Delta X^2\rangle^\mathrm{A} - \left(1 + \frac{C_\mathrm{B}}{C_\mathrm{A}}\alpha_{lmn}\right) \times\left[\langle(\Delta X^2)_{lmn}^\mathrm{A}\rangle_0^\mathrm{A} - \langle\Delta X_0^\mathrm{A}\Delta X_{lmn}^\mathrm{A}\rangle\right]\right\} \times\cos\pi(h_1 l + h_2 m + h_3 n)$$

and similarly for R_Y and R_Z with Y and Z replacing X, respectively, or $R_X^{\mathrm{AA}}\ (h_1h_2h_3) = R_Y^{\mathrm{AA}}(h_2h_3h_1)$. The R^{BB} terms are given by

$$R_X^{\mathrm{BB}} = 4\pi^2 C_{\mathrm{B}}^2 \sum_{lmn}\left\{\langle\Delta X^2\rangle^{\mathrm{B}} - \left(1+\frac{C_{\mathrm{A}}}{C_{\mathrm{B}}}\alpha_{lmn}\right) \times \left[\langle(\Delta X^2)_{lmn}^{\mathrm{B}}\rangle_0^{\mathrm{B}} - \langle\Delta X_0^{\mathrm{B}}\Delta X_{lmn}^{\mathrm{B}}\rangle\right]\right\} \times \cos\pi(h_1 l + h_2 m + h_3 n) \quad (30)$$

For the R^{AB} terms, we have

$$R_X^{\mathrm{AB}} = 4\pi^2 C_{\mathrm{A}} C_{\mathrm{B}} \sum_{lmn}\Big[\langle\Delta X^2\rangle^{\mathrm{A}} + \langle\Delta X^2\rangle^{\mathrm{B}} - (1-\alpha_{lmn}) \times (\langle(\Delta X^2)_{lmn}^{\mathrm{A}}\rangle_0^{\mathrm{B}} + \langle(\Delta X^2)_0^{\mathrm{B}}\rangle_{lmn}^{\mathrm{A}} - 2\langle\Delta X_0^{\mathrm{B}}\Delta X_{lmn}^{\mathrm{A}}\rangle)\Big] \times \cos\pi(h_1 l + h_2 m + h_3 n) \quad (31)$$

and similar terms for R_Y^{AB} with Y replacing X and for R_Z^{AB} with Z replacing X. For the cross terms

$$S_{XY}^{\mathrm{AA}} = 4\pi^2 C_{\mathrm{A}}^2 \sum_{lmn}\left(1+\frac{C_{\mathrm{B}}}{C_{\mathrm{A}}}\alpha_{lmn}\right)\langle\Delta X_0^{\mathrm{A}} - \Delta X_{lmn}^{\mathrm{A}}\rangle \times \langle\Delta Y_0^{\mathrm{A}} - \Delta Y_{lmn}^{\mathrm{A}}\rangle\cos\pi(h_1 l + h_2 m + h_3 n) \quad (32)$$

and similarly for S_{XZ}^{AA} and S_{YZ}^{AA} with XY replaced with XZ and YZ, respectively. The terms S_{XY}^{BB}, S_{XZ}^{BB}, and S_{YZ}^{BB} are derived from the S^{AA} terms by replacing AA with BB and by replacing C_{A}^2, with C_{B}^2 and $C_{\mathrm{A}}/C_{\mathrm{B}}$ with $C_{\mathrm{B}}/C_{\mathrm{A}}$. For the term S_{XY}^{AB}, we write

$$S_{XY}^{\mathrm{AB}} = 8\pi^2 C_{\mathrm{A}} C_{\mathrm{B}} \sum_{lmn}(1-\alpha_{lmn})\langle(\Delta X_0^{\mathrm{B}} - \Delta X_{lmn}^{\mathrm{A}}) \times (\Delta Y_0^{\mathrm{B}} - \Delta Y_{lmn}^{\mathrm{A}})\rangle\cos\pi(h_1 l + h_2 m + h_3 n) \quad (33)$$

and similarly for S_{XZ}^{AB} and S_{YZ}^{AB}, where XZ and YZ replace XY, respectively. The periodicity of the terms in Equations 27, 28, and 29, and the assumption that the scattering factor terms can be made independent of $\mathbf{H}$, permit us to write their sum as

$$\frac{I(\mathbf{H})_{\mathrm{Diffuse}}}{N|f(\mathbf{H}|^2)} = \mathrm{A}(h_1h_2h_3) + h_1\mathrm{B}(h_1h_2h_3) + h_2\mathrm{B}(h_2h_3h_1) + h_3\mathrm{B}(h_3h_1h_2) + h_1^2\mathrm{C}(h_1h_2h_3) + h_2^2\mathrm{C}(h_2h_3h_1) + h_3^2\mathrm{C}(h_3h_1h_2) + h_1h_2\mathrm{D}(h_1h_2h_3) + h_1h_3\mathrm{D}(h_2h_3h_1) + h_2h_3\mathrm{D}(h_3h_1h_2) \quad (34)$$

where $\mathrm{A}(h_1, h_2, h_3)$ is given by Equation $27 \div |f(\mathbf{H})|^2$, and $\mathrm{B}(h_1h_2h_3)$ contains the two terms $-f_{\mathrm{A}}\Delta f^* Q_X^{\mathrm{AA}} + f_{\mathrm{B}}\Delta f^* Q_X^{\mathrm{BB}}$ given by Equation $28 \div |f(\mathbf{H})|^2$, and likewise for the other terms.

APPENDIX B: NEUTRON MAGNETIC DIFFUSE SCATTERING

The elastic diffuse scattering of neutrons from binary alloys with magnetic short-range order is composed of three parts: the nuclear scattering, the magnetic scattering, and the nuclear magnetic interference scattering. The nuclear scattering length for neutrons is analogous to the x-ray atomic scattering factor for x rays. Thus the information obtained is the same for chemical short-range order and displacements as discussed for x rays. Because neutrons have a magnetic moment, there is also magnetic scattering associated with the unpaired electron spins (see MAGNETIC NEUTRON SCATTERING). If the direction of magnetization is perpendicular to the scattering plane, the magnetic scattering cross-section (in barns) for an A-B alloy of atomic concentration C_{A} of A atoms is given by

$$I_{\mathrm{M}}(\mathbf{H}) = C_{\mathrm{A}} C_{\mathrm{B}} T(\mathbf{H})(0.270)^2 \quad (35)$$

Here, $T(\mathbf{H})$ is the moment-moment correlation function expressed in terms of $\mu_{lmn} f_{lmn}(\mathbf{H})$, where μ_{lmn} is the magnetic moment of the atom on site lmn and $f_{lmn}(\mathbf{H})$ its magnetic form factor (the magnetic scattering comes from the unpaired electrons rather than the nucleus so that it has a scattering angle dependent form factor much like that for x rays):

$$\mu_{lmn} = \mu_{lmn} f_{lmn}(\mathbf{H}) \quad (36)$$

$$C_{\mathrm{A}} C_{\mathrm{B}} T(\mathbf{H}) = \sum_{lmn} e_{lmn}^{2\pi i \mathbf{H}\cdot\mathbf{R}} \langle\mu_{lmn}(\mathbf{H})[\mu_{000}(\mathbf{H}) - \langle\mu(\mathbf{H})\rangle]\rangle \quad (37)$$

The nuclear magnetic interference term $I_{\mathrm{NM}}(\mathbf{H})$ is proportional to a site occupation-magnetic moment correlation $M(\mathbf{H})$. For a magnetization perpendicular to the scattering plane, we have

$$I_{\mathrm{NM}}(\mathbf{H}) = C_{\mathrm{A}} C_{\mathrm{B}} \Delta b(0.540) M(\mathbf{H}) \quad (38)$$

and

$$C_{\mathrm{A}} C_{\mathrm{B}} M(\mathbf{H}) = \sum_{lmn} e_{lmn}^{2\pi i \mathbf{H}\cdot\mathbf{R}} \langle(\alpha_{lmn} - 1)\mu_{000}(\mathbf{H})\rangle \quad (39)$$

Here the quantity in $< >$'s represents the average increase in the moment of the atom at the origin (000) due to the atomic species of the atom located at site lmn.

While the terms $I_{\mathrm{M}}(\mathbf{H})$ and $I_{\mathrm{NM}}(\mathbf{H})$ allow one to study the magnetic short-range order in the alloy, they also complicate the data analysis by making it difficult to separate these two terms from the chemical SRO. One experimental method for resolving the magnetic components is to use polarization analysis where the moment of the incident neutron beam is polarized to be either parallel ($\varepsilon = 1$) or antiparallel ($\varepsilon = -1$) to the magnetization. The total scattering for each case can now be written as

$$I_\varepsilon(\mathbf{H}) = I_{\mathrm{N}}(\mathbf{H}) + \varepsilon I_{\mathrm{NM}}(\mathbf{H}) + I_{\mathrm{M}}(\mathbf{H}) \quad (40)$$

The intensity difference between the two polarization states gives

$$\Delta I_{\mathrm{Total}}(\mathbf{H}) = 2I_{\mathrm{NM}}(\mathbf{H}) \quad (41)$$

and the sum gives

$$\sum_\varepsilon I_\varepsilon(\mathbf{H}) + 2I_{\mathrm{N}}(\mathbf{H}) + 2I_{\mathrm{M}}(\mathbf{H}) \quad (42)$$

If $I_N(\mathbf{H})$ is known from a separate measurement with x rays, all three components of the scattering can be separated from one another.

One of the greatest difficulties in studying magnetic short-range order comes when the moments of the atoms cannot be aligned in the same direction with, for example, an external magnetic field. In the above analysis, it was assumed that the moments are perpendicular to the scattering vector, **H**. The magnetic scattering cross-section is reduced by the sine of the angle between the magnetic moment and the scattering vector. Thus if the magnetization is not perpendicular to the scattering vector, the moments on the atoms must be reduced by the appropriate amount. When the spins are not aligned, the sine of the angle between the moment and the scattering vector for each individual atom must be considered. In this case, it becomes necessary to construct computer models of the spin structure to extract $M(\mathbf{H})$ and $T(\mathbf{H})$. More in-depth discussion is given in MAGNETIC NEUTRON SCATTERING.

RESONANT SCATTERING TECHNIQUES

INTRODUCTION

This unit will describe the principles and methods of resonant (anomalous) x-ray diffraction as it is used to obtain information about the roles of symmetry and bonding on the electronic structure of selected atoms in a crystal. These effects manifest themselves as crystal orientation-dependent changes in the diffracted signal when the x-ray energy is tuned through the absorption edges for those atoms. Applications of the method have demonstrated it is useful in: (1) providing site-specific electronic structure information in a solid containing the same atom in several different environments; (2) determining the positions of specific atoms in a crystal structure; (3) distinguishing electronic from magnetic contributions to diffraction; (4) isolating and characterizing multipole contributions to the x-ray scattering that are sensitive to the local environment of atoms in the solid; and (5) studying the ordering of $3d$ electron orbitals in the transition metal oxides.

These effects share a common origin with x ray resonant magnetic scattering. Both are examples of anomalous dispersion, both are strongest near the absorption edge of the atoms involved, and both display interesting dependence on x-ray polarization.

Resonant electronic scattering is a microscopic analog of the optical activity familiar at longer wavelengths. Both manifest as a polarization-dependent response of x-ray or visible light propagation through anisotropic media. The former depends on the local environment (molecular point symmetry) of individual atoms in the crystalline unit cell, while the latter is determined by the point symmetry of the crystal as a whole (Belyakov and Dmitrienko, 1989, Section 2). This analogy led to a description of "polarized anomalous scattering" with optical tensors assigned to individual atoms (Templeton and Templeton, 1982). These tensors represent the anisotropic response when scattering involves electronic excitations between atomic core and valence states that are influenced by the point symmetry at the atomic site. In the simplest cases (dipole-dipole), these tensors may be visualized as ellipsoidal distortions of the otherwise isotropic x-ray form factor. Symmetry operations of the crystal space group that affect ellipse orientation can modify the structure factors, leading to new reflections and angle dependencies.

Materials Properties that Can Be Measured

Resonant x-ray diffraction is used to measure the electronic structure of selected atoms in a crystal and for the direct determination of the phases of structure factors. Results to date have been obtained in crystalline materials possessing atoms with x-ray absorption edges in an energy range compatible with Bragg diffraction. As shown by examples below (see Principles of the Method), resonant diffraction is a uniquely selective spectroscopy, combining element specificity (by selecting the absorption edge) with site selectivity (through the choice of reflection). The method is sensitive to the angular distribution of empty states near the Fermi energy in a solid. Beyond distinguishing common species at sites where oxidation and/or coordination may differ, it is sensitive to the orientation of molecules, to deviations from high symmetry, to the influence of bonding, and to the orientation (spatial distribution) of d electron orbital moments when these valence electrons are ordered in the lattice (Elfimov et al., 1999; Zimmermann et al., 1999).

The second category of measurement takes advantage of differences in the scattering from crystallographically equivalent atoms. Because of its sensitivity to molecular orientation, resonant scattering can lead to diffraction at reflections "forbidden" by screw-axis and glide-plane crystal symmetries (SYMMETRY IN CRYSTALLOGRAPHY). Such reflections can display a varying intensity as the crystal is rotated in azimuth about the reflection vector. This results from a phase variation in the scattering amplitude that adds to the position-dependent phase associated with each atom. This effect can lead to the determination of the position-dependent phase in a manner analogous to the multiple-wavelength anomalous diffraction (MAD) method of phase determination.

Secondary applications involve the formulation of corrections used to analyze anomalous scattering data. This includes accounting for orientation dependence in MAD measurements (Fanchon and Hendrickson, 1990) and for the effects of birefringence in measurements of radial distribution functions of amorphous materials (Templeton and Templeton, 1989).

Comparison with Other Methods

The method is complementary to standard x-ray diffraction because it is site selective and can provide direct information on the phase of structure factors (Templeton and

Templeton, 1992). A synchrotron radiation source is required to provide the intense, tunable high-energy x-rays required. Highly polarized beams are useful but not required.

Perhaps the technique most closely related to resonant diffraction is angle-dependent x-ray absorption. However, as pointed out by Brouder (1990), except in special cases, the absorption cross-section reflects the full crystal (point) symmetry instead of the local symmetry at individual sites in the crystal. In diffraction, the position-dependent phase associated with each atom permits a higher level of selectivity. This added sensitivity is dramatically illustrated by (but not limited to) reflections that violate the usual extinction rules.

Resonant diffraction thus offers a distinct advantage over spectroscopy methods that provide an average picture of the material. It offers site specificity, even for atoms of a common species, through selection of the diffraction and/or polarization conditions. When compared to electron probe spectroscopies, the method has sensitivity extending many microns into the material, and does not require special sample preparation or vacuum chambers.

Drawbacks to the method include the fact that signal sizes are small when compared to standard x-ray diffraction, and that the experimental setup requires a good deal of care, including the use of a tunable monochromator and in some cases a polarization analyzer.

General Scope

This unit describes resonant x-ray scattering by presenting its principles, illustrating them with several examples, providing background on experimental methods, and discussing the analysis of data. The Principles of the Method section presents the classical picture of x-ray scattering, including anomalous dispersion, followed by a quantum-mechanical description for the scattering amplitudes, and ends with a discussion on techniques of symmetry analysis useful in designing experiments. Two examples from the literature are used to illustrate the technique. This is followed by a discussion of experimental aspects of the method, including the principles of x-ray polarization analysis. A list of criteria is given for selecting systems amenable to the technique, along with an outline for experimental design. A general background on data collection and analysis includes references to sources of computational tools and expertise in the field.

PRINCIPLES OF THE METHOD

Resonant x-ray diffraction is used to refine information on the location of atoms and the influence of symmetry and bonding for specific atoms in a known crystal structure. Measurements are performed in a narrow range of energy around the absorption edges for the atoms of interest. The energy and crystal structure parameters determine the range of reflections (regions in reciprocal space) accessible to measurement. The point symmetry at the atom location selects the nature (i.e., the multipole character) of the resonance-scattering amplitude for that site. This amplitude is described by a symmetric tensor, and the structure factor is constructed by summing these tensors, along with the usual position-dependent phase factor, for each site in the unit cell. The tensor structure factor is sensitive to the nonisotropic nature of the scattering at each site and this leads to several important phenomena: (1) the usual extinction rules that limit reflections (based on an isotropic response) can be violated; (2) the x-ray polarization may be modified by the scattering process; (3) the intensity of reflections may vary in a characteristic way as the crystal is rotated in azimuth (maintaining the Bragg condition) about the reflection vector; and (4) these behaviors may have a strong dependence on x-ray energy near the absorption edge.

Theory

The classical theory of x-ray scattering, carefully developed in James' book on diffraction (James, 1965), makes clear connections between the classical and quantum mechanical descriptions of anomalous scattering. The full description of resonant (anomalous) scattering requires a quantum-mechanical derivation beginning with the interaction between electrons and the quantized electromagnetic field, and yielding the Thomson and resonant electronic scattering cross-sections. An excellent modern exposition is given by Blume (1985). Several good discussions on the influence of symmetry in anomalous scattering, including an optical model of the anistropy of x-ray susceptibility, are given by Templeton (1991), Belyakov and Dmitrienko (1989), and Kirfel (1994). The quantum mechanical description of symmetry-related effects in anisotropic scattering is included in the work by Blume (1994) on magnetic effects in anomalous dispersion. This has been extended in a sophisticated, general group-theoretical approach by Carra and Thole (1994).

We describe x-ray diffraction by first considering the atomic scattering factor in classical terms and the corrections associated with anomalous scattering. This is followed by the quantum description, and finally the structure factor for resonant diffraction is calculated.

Classical Picture

The scattering of x rays from a single free electron is given by the Thomson scattering cross-section; the geometry is illustrated in Figure 1.

The oscillating electric field (**E**) of the incident x-ray, with wave vector **k** and frequency ω, causes a sinusoidal

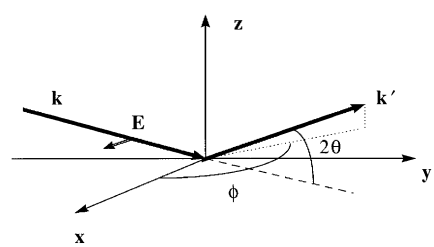

Figure 1. Geometry of x-ray scattering from a single electron. The notation is explained in the text.

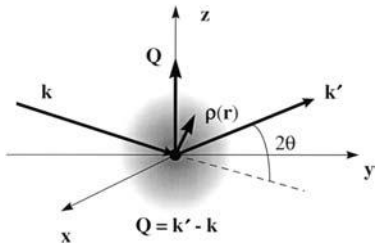

Figure 2. The geometry used in the calculation of the atomic scattering form factor for x rays. The diffraction vector is also defined and illustrated.

acceleration of the electron (with charge $-e$) along the field direction. This produces a time-dependent dipole moment of magnitude $e^2/(m\omega^2)$, which radiates an electromagnetic field polarized so that no radiation is emitted along the direction **E**. This polarization effect (succinctly given in terms if the incident and scattered polarization directions as $\varepsilon \bullet \varepsilon'$) yields a $\sin\phi$ dependence where ϕ is the angle between the incident polarization and the scattered wave vector $\mathbf{k}'$. The Thomson scattered radiation is 180° out of phase with the incident electric field, and has an intensity

$$I_{\text{Thomson}} = I_0[(e^2/mc^2)\sin\phi/R]^2 \tag{1}$$

where the incident intensity $I_0 = |\mathbf{E}|^2$, e, and m are the electron charge and mass, c the speed of light, and R is the distance between the electron and field point where scattered radiation is measured.

When electrons are bound to an atom, the x-ray scattering is changed in several important ways. First, consider an electron cloud around the nucleus as shown in Figure 2. James treats the cloud as a continuous, spherically symmetric distribution with charge density $\rho(\mathbf{r})$ that depends only on distance from the center. The amplitude for x rays scattered from an extended charge distribution into the $\mathbf{k}'$ direction is calculated by integrating over the distribution, weighting each point with a phase factor that accounts for the path length differences between points in the cloud. This is given by

$$f_0 = \int \rho(\mathbf{r}) e^{iQ\cdot\mathbf{r}} dV \tag{2}$$

with **Q** the reflection vector of magnitude $|\mathbf{Q}| = 4\pi\sin\theta/\lambda$, and 2θ and λ the scattering angle and wavelength, respectively.

The atomic scattering form factor, f_0, defined by this integral, is equal to the total charge in the cloud when the phase factor is unity (in the forward scattering direction), and approaches zero for large 2θ. Values of f_0 versus $\sin\theta/\lambda$ for most elements are provided in tables and by algebraic expressions (MacGillavry and Rieck, 1968; Su and Coppens, 1997). The form factor is given in electron units, where one electron is the scattering from a single electron.

An important assumption in this chapter is that the x-ray energy is unchanged by the scattering (i.e., elastic or coherent). Warren (1990) describes the relation between the total intensity scattered from an atom and the coherent scattering. He defines the "modified" (i.e., incoherent or Compton) intensity as the difference between the atomic number and the sum of squares of form factors, one for each electron in the atom.

A second effect of binding to the nucleus must be considered in describing x-ray scattering from atomic electrons. This force influences the response to the incident electric field. James gives the equation of motion for a bound electron as

$$d^2\mathbf{x}/d^2t + \kappa d\,\mathbf{x}/dt + \omega_s^2\mathbf{x} = (e/m)\mathbf{E}e^{i\omega t} \tag{3}$$

where $\mathbf{x}$, κ, ω_s are, respectively, the electron position, a damping factor, and natural oscillation frequency for the bound electron. Using the oscillating dipole model, he gives the scattered electric field at unit distance in the scattering plane (i.e., normal to the oscillator) as

$$A = e^2/(mc^2)[\omega^2 E/(\omega_s^2 - \omega^2 + i\kappa\omega)] \tag{4}$$

The x-ray scattering factor, f, is obtained by dividing A by $-e^2/(mc^2)E$, the scattering from a single electron. This factor is usually expressed in terms of real and imaginary components as

$$f = \omega^2/(\omega^2 - \omega_s^2 - i\kappa\omega) \equiv f' + if'' \tag{5}$$

This expression, and its extension to the many-electron atom discussed by James, are the basis for a classical description of resonant x-ray scattering near absorption edges. The dispersion of x rays is the behavior of f as a function of ω (where the energy is $\hbar\omega$), and "anomalous dispersion" refers to the narrow region near resonance ($\omega = \omega_s$) where the slope $df/d\omega$ is positive. Templeton's review on anomalous scattering describes how f' and f'' are related to refraction and absorption, and gives insight into the analytic connection between them through the Kramers-Kronig relation.

Returning to the description of scattering from all the electrons in an atom, it is important to recognize that the x-ray energies required in most diffraction measurements correspond to $\omega \gg \omega_s$ for all but the inner-shell electrons of most elements. For all but these few electrons, f is unity and their contribution to the scattering is well described by the atomic form factor. The scattering from a single atom is then given by

$$f = f_0 + f' + if'' \tag{6}$$

To this approximation, the dependence of scattering amplitude on scattering angle comes from two factors. The first is the polarization dependence of Thomson scattering, and second is the result of interference because of the finite size of the atomic charge density which effects f_0. This is the classical description assuming the x-ray wavelength is larger than the spatial extent of the resonating electrons. We will find a very different situation with the quantum-mechanical description.

Quantum Picture

The quantum mechanical description of x-ray scattering given by Blume may be supplemented with the discussion by Sakurai (1967). Both authors start with the Hamiltonian describing the interaction between atomic electrons and a transversely polarized radiation field

$$H = \sum_{\mathrm{j}} \left[(\mathbf{p}_{\mathrm{j}} - (e/c)\mathbf{A}(\mathbf{r}_{\mathrm{j}}))^2/(2m) + \sum_{\mathrm{i}} V(\mathbf{r}_{\mathrm{ij}}) \right] \qquad (7)$$

where $\mathbf{p}_{\mathrm{j}}$ is the momentum operator and $\mathbf{r}_{\mathrm{j}}$ is the position of the jth electron, $\mathbf{A}(\mathbf{r}_{\mathrm{j}})$ is the electromagnetic vector potential at $\mathbf{r}_{\mathrm{j}}$, and $V(\mathbf{r}_{\mathrm{ij}})$ is the Coulomb potential for the electron at $\mathbf{r}_{\mathrm{j}}$ due to all other charges at $\mathbf{r}_{\mathrm{i}}$. We have suppressed terms related to magnetic scattering and to the energy of the radiation field. Expanding the first term gives

$$H' = \sum_{\mathrm{j}} [e^2/(2mc^2)\mathbf{A}(\mathbf{r}_{\mathrm{j}})^2 - e/(mc)\mathbf{A}(\mathbf{r}_{\mathrm{j}}) \cdot \mathbf{p}_{\mathrm{j}}] \qquad (8)$$

The interaction responsible for the scattering is illustrated in Figure 3, and described as a transition from an initial state $|\mathbf{I}\rangle = |\ \mathrm{a};\ \mathbf{k},\ \varepsilon\rangle$ with the atom in state a (with energy E_{a}) and a photon of wave vector $\mathbf{k}$, polarization ε, and energy $\hbar\omega_{\mathrm{k}}$ to a final state $|F\rangle$ with the atom in state b (of energy E_{b}) and a photon of wave vector $\mathbf{k}'$, polarization ε', and energy $\hbar\omega_{\mathrm{k}'}$.

The transition probability per unit time is calculated using time-dependent perturbation theory (Fermi's golden rule) to second order in $\mathbf{A}$ (Sakurai, 1967, Sections 2-4,2-5)

$$W = (2\pi/\hbar)\left| e^2/(2mc^2) \sum_{\mathrm{j}} \langle F/\mathbf{A}(\mathbf{r}_{\mathrm{j}}) \cdot \mathbf{A}(\mathbf{r}_{\mathrm{j}})|I\rangle + (e/mc)^2 \right.$$
$$\left. \sum_{\mathrm{n}} \left\{ \frac{\langle F| \sum_{\mathrm{j}} \mathbf{A}(\mathbf{r}_{\mathrm{j}}) \cdot \mathbf{p}_{\mathrm{j}}|n\rangle\langle n| \sum_{\mathrm{l}} \mathbf{A}(\mathbf{r}_{\mathrm{l}}) \cdot \mathbf{p}_{|rml}|I\rangle}{E_{\mathrm{I}} - E_{\mathrm{n}}} \right\} \right|^2 \delta(E_{\mathrm{I}} - E_{\mathrm{F}}) \qquad (9)$$

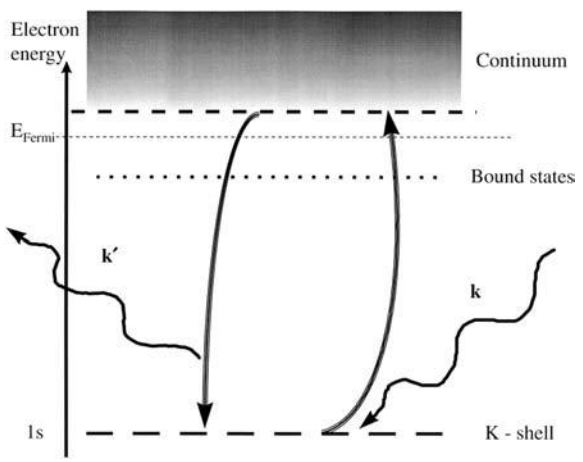

Figure 3. Schematic diagram illustrating the electronic transitions responsible for resonant scattering. An x-ray photon of wave vector $\mathbf{k}$ excites a core electron to an empty state near the Fermi level. The deexcitation releases a photon of wave vector $\mathbf{k}'$.

where the delta function insures that energy is conserved between the initial state of energy $E_{\mathrm{I}} = E_{\mathrm{a}} + \hbar\omega_{\mathrm{k}}$, and the final one with $E_{\mathrm{F}} = E_b + \hbar\omega_{\mathrm{k}'}$, $|n\rangle$ and E_n are the wave functions and energies of intermediate (or virtual) states of the system during the process.

To get the scattered intensity (or cross-section), W is multiplied by the density of allowed final states and divided by the incident intensity. Blume uses a standard expansion for the vector potential, and modifies the energy resonant denominator for processes that limit the scattering amplitude. Sakurai introduces the energy width parameter, Γ, to account for "resonant fluorescence" (Sakurai, 1967). In the x-ray case, the processes that limit scattering are both radiative (such as ordinary fluorescence), and nonradiative (like Auger emission). They are discussed by many authors (Almbladh and Hedin, 1983). When the solid is returned to the initial state ($|a\rangle$), the differential scattering cross-section, near resonance, is

$$d^2\sigma/d\Omega\, dE = e^2/(2mc^2) \left| \langle a| \sum_j e^{i\mathbf{Q}\cdot\mathbf{r}_j}|a\rangle \varepsilon' \cdot \varepsilon - \hbar/m \right.$$
$$\left. \sum_{\mathrm{n}} \left[\frac{\langle a| \sum_{\mathrm{j}} (\varepsilon' \cdot \mathbf{p}_{\mathrm{j}} e^{i\mathbf{k}'\cdot\mathbf{r}} j)|n\rangle\langle n| \sum_{\mathrm{l}} (\varepsilon \cdot \mathbf{p}_{\mathrm{j}} e^{i\mathbf{k}\cdot\mathbf{r}_{\mathrm{l}}})|a\rangle}{E_{\mathrm{a}} - E\mathrm{n} + \hbar\omega_{\mathrm{k}} - i(\Gamma/2)} \right] \right|^2 \qquad (10)$$

where $\mathbf{Q} = \mathbf{k} - \mathbf{k}'$. It is useful to express the momentum operator in terms of a position operator using a commutation relation (Baym, 1973, Equations 13-96). The final expression, including an expansion of the complex exponential is given by Blume (1994) as

$$d^2\sigma/(d\Omega\, dE)$$
$$= e^2/(2mc^2) \left| \langle a| \sum_{\mathrm{j}} e^{i\mathbf{Q}\cdot\mathbf{r}_{\mathrm{j}}}|a\rangle \varepsilon' \cdot \varepsilon \frac{m}{\hbar^2} \frac{\sum_{\mathrm{n}} (E_{\mathrm{a}} - E_{\mathrm{n}})^3}{\hbar\omega} \right.$$
$$\left. \times \frac{\langle a| \sum_{\mathrm{j}} (\varepsilon' \cdot \mathbf{r}_{\mathrm{j}})(1 - i\mathbf{k}' \cdot \mathbf{r}_{\mathrm{j}}/2)|n\rangle\langle n| \sum_{\mathrm{l}} (\varepsilon \cdot r_{\mathrm{l}})(1 + i\mathbf{k} \cdot \mathbf{r}_{\mathrm{l}}/2)|a\rangle}{E_{\mathrm{a}} - E_{\mathrm{n}} + \hbar\omega_{\mathrm{k}} - i(\Gamma/2)} \right|^2 \qquad (11)$$

The amplitude, inside the squared brackets, should be compared to the classical scattering amplitude given in Equation 6. The first term is equivalent to the integral which gave the atomic form factor; the polarization dependence is that of Thomson scattering. The second term, the resonant amplitude, is the same form as Equation 5

$$\omega^2/\omega_{\mathrm{k}}^2 - \omega_{\mathrm{ca}}^2 - i(\Gamma/\hbar\omega)_{\mathrm{k}} \qquad (12)$$

Now, however, the ground-state expectation value,

$\langle \mathrm{a}|$ transition operator $|\mathrm{a}\rangle$, can have a complicated polarization and angular dependence.

The transition operator is a tensor that increases in complexity as more terms in the expansion of the exponentials (Equation 10) are kept. Blume (1994) and Templeton (1998) identify the lowest-order term (keeping only the 1 yields a second-rank tensor) as a dipole excitation and dipole deexcitation. Next in complexity is the dipole-quadrupole terms (third-rank tensors); this effect has

been observed by Templeton and Templeton (1994). The next order (fourth-rank tensor) in scattering can be dipole-octapole or quadrupole-quadrupole; the last term has been measured by Finkelstein (Finkelstein et al., 1992). An important point is that different multipole contributions make the scattering experiment sensitive to different features of the resonating atoms involved. The atom site symmetry, the electronic structure of the outer orbitals, and the orientational relationship between symmetry equivalent atoms combine to influence the scattering.

A METHOD FOR CALCULATION

Two central facts pointed out by Carra and Thole (1994) guide our evaluation of the resonant scattering. The first is a selection rule; the scattering may exist only if the transition operator is totally symmetric (i.e., if it is invariant under all operations which define the symmetry of the atomic site). This point is explained in Landau and Lifshitz (1977) and many books on group theory (Cotton, 1990). The second point is that the Wigner-Eckart Theorem permits separation of the scattering amplitude into products of angle- and energy-dependent terms. The method outlined below involves an evaluation of this angular dependence. We cannot predict the strength of the scattering (the energy-dependent coefficients); this requires detailed knowledge of electronic states that contribute to the scattering operator.

The first task is to determine the multipole contributions to resonant scattering that may be observable at sites of interest in the crystal; the selection rule provides this information. The rule may be cast as an orthogonality relation between two representations of the point symmetry. Formula 4.3–11 in Cotton (1990) gives the number of times the totally symmetric representation (A_1) exists in a representation of this point symmetry. It is convenient to choose spherical harmonics as basis functions for the representation because harmonics with total angular momentum L represent tensors of rank L.

First calculate the trace $\chi(\mathbf{R}i)$ of each symmetry operation, $\mathbf{R}i$, of the point group. Because the trace of any symmetry operation of the totally symmetric representation equals 1, Cotton's formula reduces to

$$N(A_1) = (1/h)\sum_{\mathrm{i}}[\chi(\mathbf{R}i)] \tag{13}$$

where $N(A_1)$ is the number of times the totally symmetric representation is found in the candidate representation, h is the number of symmetry operations in the point group, and the sum is over all group operations. If the result is nonzero, this number equals the number of independent tensors (of rank L) needed to describe the scattering.

The second task is to construct the angle-dependent tensors that describe the resonant scattering. There are a number of approaches (Belyakov and Dmitrienko, 1989; Kirfel, 1994; Blume, 1994; Carra and Thole, 1994), but in essence this problem is familiar to physicists, being analogous to finding the normal modes of a mechanical system, and to chemists as finding symmetry-adapted linear combinations of atomic orbitals that describe states of a molecule. To calculate where, in reciprocal space, this scattering may appear, and to predict the polarization and angular dependence of each reflection, we use spherical harmonics to construct the angle-dependent tensors. This choice is essential for the separation discussed above, and simplifies the method when higher-order (than dipole-dipole) scattering is considered.

Our method uses the projection operator familiar in group theory (see Chapter 5 in Cotton, 1990; also see Section 94 in Landau and Lifshitz, 1977). We seek a tensor of rank L, which is totally symmetric for the point group of interest. The projection operator applied to find a totally symmetric tensor is straightforward; we average the result of applying each symmetry operation of the group to a linear combination of the $2L + 1$ spherical harmonics with quantum number L, i.e.,

$$f(L) = (1/h)\sum_{\mathrm{n}}\left[\mathbf{R}(n)\left\{\sum_{\mathrm{m}} a_{\mathrm{m}} Y(L,m)\right\}\right] \tag{14}$$

where a_{m} is a constant which may be set equal to 1 for all m, and $Y(L,m)$ is the spherical harmonic with quantum numbers L and m. If our "first task" indicated more than one totally symmetric contribution to the scattering amplitude, the other tensors must be orthogonal to $f(L)$ and again totally symmetric.

The third task is to calculate the contribution this atom makes to the structure factor. In calculating $f(L)$, we assumed an oriented coordinate system to evaluate the symmetry operations. If this orientation is consistent with the oriented site symmetry for this atom and space group in the International Tables (Hahn, 1989), then the listed symmetry operations can be used to transform the angle-dependent tensor from site to site in the crystal. The structure factor of the atoms of site i, for reflection $\mathbf{Q}$ is written

$$F(i;\mathbf{Q}) = \sum_{\mathrm{j}}\left[\left\{f_{0\mathrm{j}} + \sum_{\mathrm{p}} f_{\mathrm{pj}}(L)\right\} e^{i\mathbf{Q}\bullet\mathbf{r}_{\mathrm{j}}}\right] \tag{15}$$

where $f_{0\mathrm{j}}$ is the nonresonant form factor for this atom, and $f_{\mathrm{pj}}(L)$ is the pth resonant scattering tensor for the atom at $\mathbf{r}_{\mathrm{j}}$; both terms are multiplied by the usual position-dependent phase factor. The tensor transformations are familiar in Cartesian coordinates as a multiplication of matrices (Kaspar and Lonsdale, 1985, Section 2.4). Here, having used spherical harmonics, it is easiest to use standard formulas (Sakurai, 1985) for rotations and simple rules for reflection and inversion given in APPENDIX A of this unit.

When more then one atom contributes to the scattering, these structure factors are added together to give a total $F(\mathbf{Q})$.

The final task is to calculate the scattering as a function of polarization and crystal orientation. For a given L, our resonant $F_{\mathrm{L}}(\mathbf{Q})$ is a compact expression

$$F_{\mathrm{L}}(\mathbf{Q}) = \sum_{\mathrm{m}}[b_{\mathrm{m}} Y(L,m)] \tag{16}$$

with b_m the sum of contributions to the scattering with angle dependence $Y(L,m)$. To evaluate the scattering, we express each $Y(L,m)$ as a sum of products of the vectors in the problem. The products are obtained by standard methods using Clebsch-Gordan coefficients, as described in Sakurai (1985, Section 3.10). For $L = 2$ (dipole-dipole) scattering, the two vectors are the incident and scattered polarization, for $L = 3$ a third vector (the incident or outgoing wave vector) is included, and for $L = 4$ both wave vectors are used to characterize the scattering. The crystal orientation (relative to these defining vectors) is included by applying the rotation formula (see APPENDIX C in this article) to $F_L(\mathbf{Q})$.

Illustrations of Resonant Scattering

The following two examples illustrate the type of information available from these measurements; the first describes an experiment sensitive to $L = 2$ scattering, while the second presents results from $L = 4$ work.

***L* = 2 measurements**. Wilkinson et al. (1995) illustrate how resonant scattering can be used to separately measure parameters connected to the electronic state of gold at distinct sites. The diffraction measurements were performed at the gold L_{III} edge in Wells' salt ($Cs_2[AuCl_2][AuCl_4]$). Both sites, I and III in Figure 4, have D_{4h} symmetry, but the first has a linear coordination of neighbors (along the tetragonal c axis), while the coordination is square planar (parallel to the crystalline a-b plane) at the second site.

Application of Equation 13 shows that one $L = 2$ tensor is required (for each of the two sites) to describe the anisotropic scattering. The construction formula, Equation 14, gives the angular dependence, which is proportional to $Y(2,0)$. This agrees with the anisotropic (the traceless symmetric) part of the matrix given (in Cartesian form) by Wilkinson et al. (1995) in their Equation 1. Subtracting one-third of the trace of this matrix from each component gives $f_{xx} = f_{yy} = -2 \cdot f_{zz}$, which is equivalent to $Y(2,0) \propto 2z^2 - (x^2 + y^2)$. Further discussion on the angular dependence for dipole scattering is found in APPENDIX B of this article. The angular function at each gold site is represented by the lobe-shaped symbols in Figure 4. This angular dependence is then used to calculate the structure factor, which is a sum of three terms: one for each of the two gold atomic sites and a third for the remaining atoms in the unit cell. The 16 symmetry operations of this space group (#139 in Hahn, 1989) leave the angular function unchanged, so the structure factor for the two gold sites may be written

$$\mathbf{F_{gold}} = [\mathbf{Q}(h,k,l)] \propto \cos[(\pi/2)(h+k+l)] \times \{2f_0\mathbf{I}\cos[\pi l/2] + \mathbf{F}_{\mathrm{I}}e^{-i(\pi l/2)} + \mathbf{F}_{\mathrm{III}}e^{+i(\pi l/2)}\} \quad (17)$$

where $\mathbf{F}_{gold}$, $\mathbf{F}_{\mathrm{I}}$, $\mathbf{F}_{\mathrm{III}}$, and $\mathbf{I}$ are second-rank tensors and the reciprocal lattice vector $\mathbf{Q}(h,k,l) = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$. $\mathbf{I}$, the diagonal unit tensor, represents the isotropic nature of the gold atom form factor. Wilkinson et al. (1995) point out that the resonant scattering is proportional to the sum (difference) of $\mathbf{F}_{\mathrm{I}}$, $\mathbf{F}_{\mathrm{III}}$ for reflections with l = even (odd), so that separation of the two quantities requires data for both types of reflections. Figure 4 shows that $\mathbf{F}_{\mathrm{I}}$ and $\mathbf{F}_{\mathrm{III}}$ share a common orientation in the unit cell. The tensor structure factor is thus easily described in a coordinate system that coincides with the reciprocal lattice. Wilkinson et al. (1995) use σ for the direction along **c*** and π for directions in the basal plane. To avoid confusion with notation for polarization, we will use s and p instead of σ and π.

With the crystal oriented for diffraction, the resonant scattering amplitude depends on the orientation of the tensors with respect to the polarization vectors. $\mathbf{F_{gold}}(\mathbf{Q})$ should be re-expressed in the coordinate system where these vectors are defined (see APPENDIX C in this article). The amplitude is then written

$$A = \boldsymbol{\varepsilon}' \cdot \mathbf{F}_{\mathrm{lab}}(\mathbf{Q}) \cdot \boldsymbol{\varepsilon} \quad (18)$$

where $\boldsymbol{\varepsilon}'$ and ε are the scattered and incident polarization vectors and matrix multiplication is indicated. The amplitude expressed in terms of the four (2-incoming, 2-outgoing) polarization states is shown in Table 1, where F_{ij} are cartesian tensor components in the new (laboratory) frame, and 2θ is the scattering angle.

This scheme for representing the scattering amplitude makes it easy to predict basic behaviors. Consider a vertical scattering plane with **Q** pointing up, and the incident

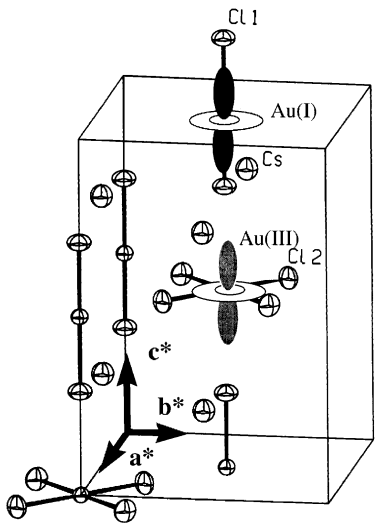

Figure 4. The crystal structure of Wells' salt contains two sites for gold; the labeling indicates the formal valence of the two atoms. At each of these two sites, the lobe-shaped symbol indicates the angular dependence for resonant scattering of rank $L = 2$.

Table 1. Amplitude Expressed in Terms of the Four (2-Incoming, 2-Outgoing) Polarization States[a]

	$\boldsymbol{\varepsilon} = \boldsymbol{\sigma}$	$\boldsymbol{\varepsilon} = \boldsymbol{\pi}$
$\boldsymbol{\varepsilon}' = \boldsymbol{\sigma}'$	F_{11}	F_{13}
$\boldsymbol{\varepsilon}' = \boldsymbol{\pi}''$	$F_{31}\cos(2\theta)$-$F_{33}\cos(2\theta)$	$F_{21}\sin(2\theta)$-$F_{23}\sin(2\theta)$

[a] $\boldsymbol{\sigma}(\boldsymbol{\pi})$ points normal (parallel) to the scattering plane.

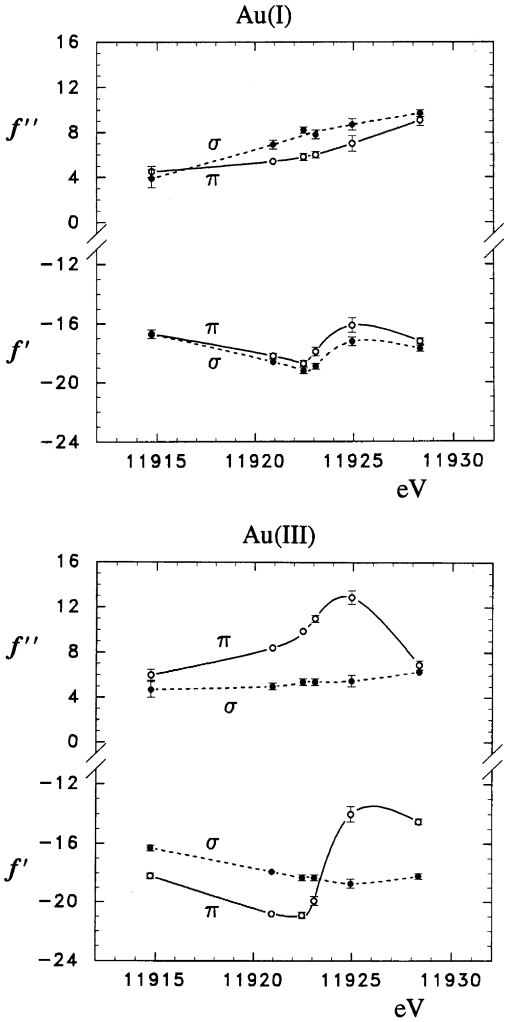

Figure 5. The energy dependence of the real and imaginary parts of the anomalous scattering from the two gold sites in Wells' salt is given in electron units. The symbols σ and π (referred to in the text as *s* and *p*) correspond to the tensor components along the $\mathbf{c}^*$ axis and in the basal plane in Figure 4.

polarization (**σ**) normal to the plane. For any $\mathbf{Q}(h,k,l)$, one can rotate the crystal around that reflection vector until the donut shaped *p* lobe of the tensor is along the incident polarization; the measurement is then most sensitive to this feature. Only for $\mathbf{Q}(h,k,0)$ reflections can scattering from the *s* lobe be isolated. This analysis also suggests the benefits of selectively measuring the polarization of the scattered beam. By looking only at the **σ′**-scattered polarization, one can, in the first case, completely separate out *p*-lobe scattering; in the second case both contributions can be determined (by the azimuth scan; see Practical Aspects of the Method) at a single reflection. By selecting the π′-scattered polarization, one eliminates the Thomson (f_0) contribution at allowed reflections.

Wilkinson et al. (1995) do not use polarization analysis, but instead measure a series of reflections, at angular orientations that favor either tensor component, and extract four values for the anomalous scattering at each gold site (Templeton and Templeton, 1982, 1985, 1992). Their results, plotted versus energy in Figure 5, show a clear distinction between the two sites. The gold (III) site exhibits a strongly anisotropic near-edge behavior (the difference $|f_p - f_s|$ is >15% of the total resonant scattering) which the authors suggest may result from an electronic transition between the $2p_{3/2}$ and empty $3d_{x^2-y^2}$ orbitals. The gold(I) site on the other hand would (formally) have a filled *d* shell, and in fact shows a much smaller anisotropic difference (<4%).

***L* = 4 measurements**. The second example illustrates $L = 4$ scattering where polarization analysis is critical to measurement success.

The measurements were performed on a single crystal of hematite (Fe_2O_3), at x-ray energies corresponding to the iron K-edge (Finkelstein et al., 1992). The results show: (1) resonant scattering is a sensitive measure of crystal field splitting of the iron 3*d* level; (2) an intensity variation with azimuth identifies the symmetry at the iron site and separates chemical from magnetic contributions to the scattering; and (3) that polarization analysis is a powerful tool for selection and quantitative evaluation of these signals.

The structure of hematite is trigonal (space group #167; Hahn, 1989), with a single iron site of symmetry C_3, positioned at *c*/6 separation along the crystalline *c* axis. The structure, illustrated in Figure 6, indicates that the oxygen atoms of each molecule are mirror reflected from site to site by 3-fold vertical glide planes.

A single reflection, the $(00.3)_{\text{Hexagonal}}$ (probing lattice planes of *c*/3 spacing normal to the *c* axis), was measured

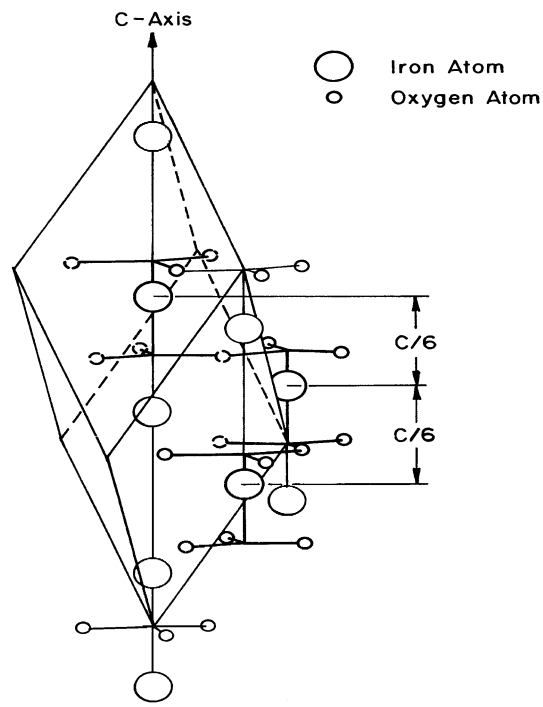

Figure 6. The crystal structure of hematite is displayed with a rhombohedral unit cell. Each iron atom is surrounded by an approximate octahedral arrangement of oxygen atoms.

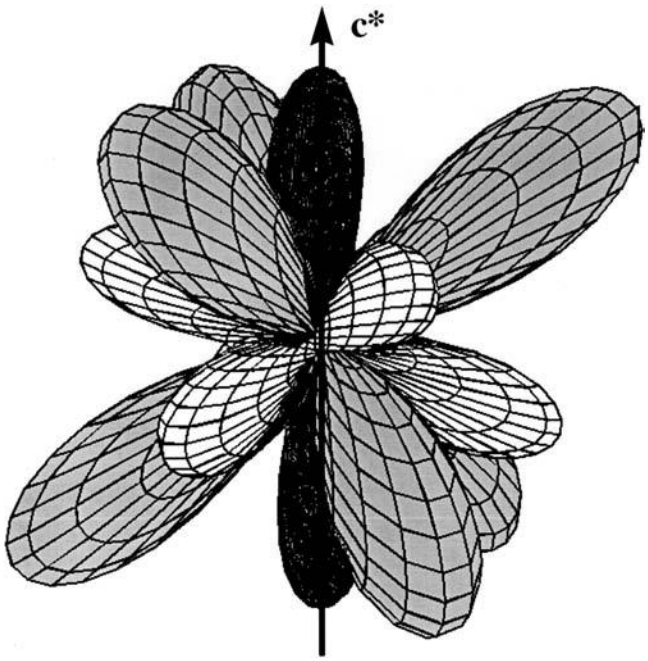

Figure 7. A geometrical representation of the angular dependence for $L = 4$ resonant scattering in O_h symmetry. The object has 3-fold rotational symmetry about the $\mathbf{c}^*$ axis. The black lobes are rotationally symmetric; the scattering amplitude associated with gray and white lobes is opposite in sign.

at a series of energies and azimuth angles around this axis. This reflection is "forbidden" by general conditions of the space group, but magnetically "allowed" because the iron atoms are antiferromagnetically ordered.

The iron has a formal valence of +3, implying a half-filled $3d$ shell. The site symmetry is very close to cubic (O_h), and to this approximation the $3d$ levels are crystal field split into e_g bonding states (with electron density directed toward oxygen neighbors), and t_{2g} antibonding states (with the density directed between these neighbors). $1s \rightarrow 3d$ resonant scattering is sensitive to the filling and directionality of these states.

In O_h symmetry Equation 10b.3.13, excludes $L = 2$ and 3, but permits $L = 4$ scattering with one tensor contributing. Equation 14 gives an angle-dependent tensor proportional to

$$\sqrt{(7/10)}Y(4,0) + Y(4,3) - Y(4,-3) \qquad (19)$$

The angular properties of this tensor are illustrated in Figure 7.

The shape of this object is a geometrical measure of the sensitivity which this type of scattering has to electronic transitions between the $1s$ and $3d$ states. By considering this object positioned at each iron site, the explanation for 3 out of 4 experimental observations is immediately apparent: (1) the "forbidden" reflection is allowed because the orientation of oxygen atoms changes the sign of the scattering amplitude from site to site; (2) this amplitude changes sign every 60° as the crystal is rotated about the c axis; (3) this behavior depends on electronic transitions (with $\Delta L = 2$; quadrupole excitation and deexcitation) and it therefore occurs only at a well-defined resonance energy.

A fourth experimental fact, that the resonant behavior was visible as a rotation of the x-ray polarization (from primarily σ to π'), can be explained when the tensor is expanded using the methods in Sakurai (1985). The quantitative details, worked out by Hamrick (1994) and by Carra and Thole (1994), show that the energy dependences of this resonance are exceedingly sensitive to the magnitude of the crystal field splitting. The resonant scattering amplitude was equivalent to less than about 0.08 electrons! However, by analyzing the scattered beam for the rotated polarization, the signal intensity was found to be 45 times that of the background.

PRACTICAL ASPECTS OF THE METHOD

Instrumentation

These measurements are made with synchrotron radiation because an intense, energy-tunable incident x-ray beam is required. It is useful to work in a vertical scattering geometry to take advantage of the small divergence and high degree of horizontal, linear polarization available from synchrotron sources. A standard silicon (111) double crystal monochromator is commonly used for energy tuning. Focusing optics, when used, can deliver substantially more flux to small sample crystals, but can also lead to several problems. In particular, strong horizontal focusing (i.e., sagittal focusing) increases the beam divergence normal to the scattering plane and therefore increases the likelihood of multiple-beam (Renninger) reflection contamination in the scattered signal. In addition, when polarization analysis is employed to improve sensitivity, the analyzer may not fully accept the increased divergence. The use of a vertical reflection mirror for harmonic rejection and focusing (if available) is generally an advantage. Many experiments have been performed with bend magnet radiation, and most of these with an incident energy resolution not better than $1 - 5 \times 10^{-4}$. The ideal monochromator would be tunable, and provide a beam with an energy width and stability matched to the core-hole energy associated with the absorption edge under study.

A four-circle diffractometer is essential for access to a wide range of reflections from one sample. With appropriate software, it permits flexible scanning of reciprocal space, including the important azimuthal scan discussed below. For more challenging experiments, the diffractometer may need to accommodate a polarization analyzer. The technique of polarization analysis is also discussed in this section. It is often useful to simultaneously monitor fluorescence from the sample as diffraction data are collected. In so doing, one may: (1) reduce errors caused by energy drifts (through periodic energy scans that monitor the position of the absorption edge) and (2) conveniently obtain a measurement of f'' useful for signal normalization; also (3) as discussed earlier, measurement of the angular behavior of f'' gives an essentially independent measure of the average site anisotropy for the absorbing species (Brouder, 1990).

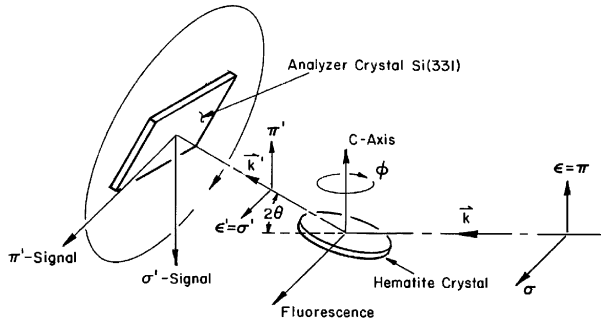

Figure 8. The experimental arrangement for resonant scattering measurements may include an analyzer for selecting polarization in the signal beam.

Figure 8 illustrates the geometry of the scattering experiment, including the placement of polarization analyzer and fluorescence detector. The samples are usually single crystals mounted on a eucentric goniometer for convenient orientation of crystal faces. The azimuth scan is performed to measure the anisotropic nature of the atomic environment. The sample is oriented so that the Bragg angle is maintained as it is rotated about the axis of the reflection vector. Because tensor scattering effects are small, one often chooses weak or space-group forbidden reflections for these studies. In this case an appropriate choice of azimuth is important for eliminating the influence of Renninger reflections, which are localized and predictable (Cole et al., 1962) in both energy and angle.

Polarization Analysis

The principles and methods of x-ray polarization analysis are discussed by several authors (Blume and Gibbs, 1988; Belyakov and Dmitrienko, 1990; Shen and Finkelstein, 1993; Finkelstein et al., 1994). Although tensor scattering effects can appear even with an unpolarized incident beam, it is important to know the beam polarization for accurate analysis of the data. Further, it has been shown (Finkelstein et al., 1992) that polarization analysis of the diffraction signal can significantly improve sensitivity and provide a detailed characterization of the scattering effects. In particular, resonant scattering is one of only a few effects that rotate the incident polarization; thus a search for resonant scattering is facilitated by a polarized incident beam and an analyzer set to accept the orthogonal polarization state.

The linear polarization analyzer, illustrated in Figure 9, is basically a 3-circle diffractometer mounted on the 2-theta (detector) arm of the 4-circle instrument. The heart of the analyzer is a crystal that intercepts signal from the sample and diffracts it into a detector set near 90° to the signal beam. The analyzer can be rotated about the beam by changing chi. When the analyzer and sample diffraction planes are parallel, the measurement is sensitive to σ polarization. When rotated 90° about chi, the analyzer passes the rotated or π polarized radiation. The linear polarization state (relative to these planes) is characterized by the Stokes-Poincaré parameter

$$P_1 = (I_\sigma - I_\pi)/(I_\sigma + I_\pi) \qquad (20)$$

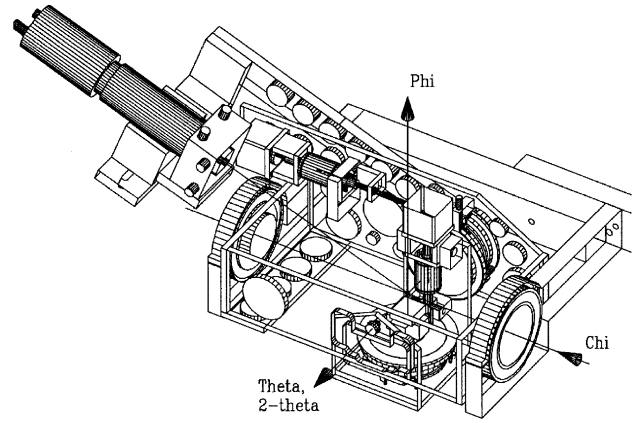

Figure 9. An x-ray polarimeter uses diffraction, with a Bragg angle (theta) near 45° to measure the direction of linear polarization in a beam. The device is rotated (in Chi) about the beam for this purpose.

where P_1 is +1 for a beam fully σ-polarized, and P_1 is equal to −1 if the beam is fully π polarized. Three parameters are required to completely characterize the beam polarization, but for the purposes of these experiments, knowledge of the incident and scattered P_1 is usually sufficient.

Besides possessing high reflectivity, the polarization-analyzing crystal should have an angular acceptance matched to the signal beam and a Bragg angle close to 45° for the energy being measured. If the first condition is not met, the analyzer must be scanned through its reflection (rocking) curve to ensure accurate measurement. When set to pass π-polarized radiation, the analyzer is considerably less sensitive to noise sources. This may help in the search for resonant signals, but is of only limited value if the incident beam horizontal divergence is large. In the case where an energy scan, at constant sample **Q** (also known as a DAFS scan; Stragier, et al., 1992) is required, the monochromator, sample and detector arm (2-theta) angles, as well as the analyzer crystal angle must move in synchronization.

Experiment Preparation

Resonant scattering experiments are generally nontrivial to perform and require significant advanced planning. No well established techniques exist for estimating signal size, but the method for calculation outlined earlier can provide a map for candidate reflections. Several recent attempts have demonstrated how difficult it is to explore higher multipole scattering processes without employing the methods of polarization analysis. Some general rules, gleaned from the literature, may help define appropriate characteristics for systems under consideration for study.

Sample size and crystal perfection have not generally limited these measurements. Crystal structures with compound symmetry elements (glide planes, and screw axes) are good candidates for study. The resonant scattering from atoms related by these elements may differ because of differences in orientation from atom to atom.

Structure-factor relationships are an important experimental consideration. Forbidden reflections, which are excited at resonance (by the previous mechanism), are a sensitive measure of the local environment. Weak allowed reflections reveal tensor scattering effects through azimuthal and polarization anisotropy. $L = 3$ scattering may occur only from sites with no center of symmetry. Templeton (1994) has shown that this leads to an interesting selectivity of the scattering process.

The width, strength, and orientational dependence of absorption edge features influence the resonant scattering amplitude. Because absorption (f'') and refraction (f') are related through the Kramers-Kronig dispersion relation, x-ray dichroism (polarization-dependent absorption) is a good predictor of birefringence (polarization-dependent scattering). In general, the higher the edge energy, the broader the intrinsic (core-hole) width and the weaker the resonant response. M and L edges have yielded the largest signals, followed by first row transition metal K edges. In this regard, another predictor of resonant behavior in diffraction comes from examining the optical activity of the molecules that compose the crystal. The highest-order multipole scattering observed corresponds to $L = 4$. This effect was measured to be less than 0.08 electrons in amplitude, but was visible through polarization analysis. $L = 3$ scattering has ranged in size from 0.5 to 3 electrons, while $L = 2$ scattering amplitudes (including the isotropic component) as large as 30 electrons have been observed.

Multiple beam reflections must be accounted for in experiment design and analysis. It is important to note that this effect can also be responsible for a rotation of the scattered beam polarization.

Experiment Design

A reasonable approach to the design of these experiments is to begin by constructing maps of reciprocal space. Strong, weak, and forbidden nonresonant reflections should be noted. This is followed by adding the location of resonant reflections and their associated multipole order. The map is then sectioned into regions consistent with the resonant energy and range of scattering angles available. Principle directions (faces of the crystal) should be indicated to help define orientations for azimuthal scanning.

For polarization analysis, the appropriate analyzer crystal will have a strong reflection with approximately a 45° Bragg angle at the resonant energy. The angular acceptance of this crystal should be consistent with beam divergence and it should not fluoresce at the energies of interest. The analyzer should be used with a high count rate detector (ion chamber) to measure the incident beam polarization and can also determine energy resolution and divergence, as well as the absolute energy (*http://www.chess.cornell.edu/technical/hardware/special_setups/energy_analyzer.html*). The incident beam is also used to align the detector for accurate measurement of both polarization states. A low-count-rate detector (scintillation counter) is then installed for the diffraction measurements.

METHOD AUTOMATION

Single-crystal data are collected with a 4-circle diffractometer and an energy scanning monochrometer. Automated procedures for controlling the diffractometer allow the experimenter to: (1) collect a large numbers of reflections, one energy at a time; (2) perform a scan in azimuth around a reciprocal lattice vector set to maintain the Bragg diffraction condition; and (3) coordinate the diffractometer and monochromator in such a way that an energy scan is performed while one reflection is excited (i.e., at constant **Q**). These capabilities are available through software available at most synchrotron radiation beamlines set up for 4-circle diffraction, with an energy-tunable monochromator.

The first data collection scheme, applied to resonant scattering in work at a synchrotron, was by Phillips (Phillips, et al., 1978) using a CAD-4 diffractometer. Methods of azimuth scanning were developed for surface x-ray diffraction studies (Mochrie, 1988) and are built into 4-circle control programs such as FOURC (Certified Scientific Software). An implementation of this method, used with the FOURC program, is documented on the CHESS World Wide Web site available at *http://www.chess. cornell.edu/CHESS_spec/azimesh.html*. The third data collection mode (sometimes referred to as a DAFS scan) is again built into some commercial control programs. In FOURC the monochromator energy scan ("Escan") permits the optional argument "fixQ" which moves the 4-circle to maintain a constant reflection condition. For information on this scan see *http://www.chess.cornell.edu/Certif/spec/help/mono.html*.

DATA ANALYSIS AND INITIAL INTERPRETATION

The tools required for a preliminary analysis of resonant scattering measurements have generally been developed by individual investigators. A good, general-purpose scientific graphics and analysis package, which includes a capability for nonlinear least-squares fitting, will suffice for all but the most specialized data manipulations.

Basic corrections to the data include the scaling of signals to account for: (1) changes of incident beam intensity with time and energy; (2) sharp variations in sample absorption because measurements are always taken near absorption edges; (3) standard geometrical corrections to the scattering from different reflections; and (4) efficiency (throughput) of the polarization analyzer. It is also crucial to set up criteria for eliminating data that are too weak (often due to misalignments in monochromator, diffractometer, or analyzer) or too strong (a typical effect when working close to multiple-beam reflections) to be considered reliable.

Accurate measurements of absorption, obtained by monitoring fluorescence from the sample, are extremely useful for several purposes. First, because they may be combined with numerical values for absorption coefficients far from these edges (calculated in programs like those by Cromer and Liberman (Cromer, 1983) available on the WWW at *http://www.cindy.lbl.gov/optical_constants/*)

to calculate the energy dependence of f'. These methods are discussed in the Templeton (1991) review of anomalous scattering. Second, the angular dependence of f'' (Brouder, 1990) is an important source of supplementary information.

Problems with multiple beam reflections (when measuring weak or "forbidden" reflections) can be reduced by mapping their locations before data are collected.

The work on hematite, discussed earlier, shows how important it is to know the polarization content and energy resolution of the incident beam. The former is required when an analyzer is used to determine polarization-dependent cross-sections. The latter is needed for determining information from resonance widths.

Finally, the angular dependence of azimuthal scans at resonant reflections may be compared to models derived using the calculational method (discussed earlier) by nonlinear least-squares analysis.

ACKNOWLEDGMENTS

The author is indebted to B.T. Thole, R. Lifshitz, M. Hamrick, M. Blume, and S. Shastri for helping him appreciate the theory of resonant scattering. He also thanks A.P. Wilkinson, L.K. Templeton, D.H. Templeton, A. Kirfel, Q. Shen, and E. Fontes, for contributions to the manuscript, and is grateful to E. Pollack, L. Pollack, and A.I. Goldman for their guidance in improving the manuscript. This work is supported by the National Science Foundation through CHESS, under Grant No. DMR 93-11772.

APPENDIX A: TRANSFORMING THE TENSOR STRUCTURE FACTORS

The tensor structure factor is constructed by adding the partial structure factors for each unique site in the unit cell. Each of these contributions has a form given by Equation 15, above. To calculate each contribution, the tensor derived using Equation 14 is transformed from site to site according to the space group symmetry operations.

Assume a tensor is written as a sum of spherical harmonics ($|L,m\rangle$) and defined in a Cartesian coordinate system (x,y,z). A general rotation is performed using the rotation operator $\mathbf{D}(\alpha,\beta,\gamma)$ and Euler angles (α,β,γ). See Sakurai (1985), Sections 3.3, 5, and 9. This is represented as

$$\mathbf{D}(\alpha,\beta,\gamma)|L,m\rangle = \sum_{\mathrm{m}'} \mathrm{D}^{(\mathrm{L})}_{\mathrm{m}',\mathrm{m}}(\alpha,\beta,\gamma)|L,m'\rangle \qquad (21)$$

where

$$\begin{aligned}\mathrm{D}^{(\mathrm{L})}_{\mathrm{m}',\mathrm{m}}(\alpha,\beta,\gamma) &= e^{-i(m'\alpha+m\gamma)} \sum_k (-1)^{k-m-m'} \\ &\times \frac{\sqrt{[(L+m)!(L-m)!(L+m')!(L-m')!]}}{(L+m-k)!k!(L-k-m')!(k-m+m')!} \\ &\times (\cos\beta/2)^{2\mathrm{L}-2\mathrm{k}+\mathrm{m}-\mathrm{m}'}(\sin\beta)^{2\mathrm{k}-\mathrm{m}-\mathrm{m}'} \qquad (22)\end{aligned}$$

For inversions the rule is

$$|L,m\rangle \rightarrow (-1)^{\mathrm{L}}|L,m\rangle \qquad (23)$$

For reflections in a plane normal to the z axis: $z \rightarrow -z$, so

$$|L,m\rangle \rightarrow (-1)^{(L+M)}|L,m\rangle \qquad (24)$$

For reflections in a plane parallel to the z axis and at angle to the x axis, the azimuthal angle of the harmonic $\phi \rightarrow 2\delta - \phi$, so

$$|L,m\rangle \rightarrow (-1)^{\mathrm{m}} e^{\mathrm{i}2\mathrm{m}\delta}|L,-m\rangle \qquad (25)$$

APPENDIX B: ANGULAR DEPENDENT TENSORS FOR L=2

It should be pointed out that the angular function $Y(2,0)$ describes $L = 2$ anisotropic scattering for all seven tetragonal and all twelve trigonal/hexagonal point groups. In fact, one can find the form of $L = 2$ angular dependence for all 32 point groups in character tables that list the "binary products of coordinates" for the totally symmetric representation. Such tables indicate there are four other possible $L = 2$ angular functions, one for each of the remaining families (triclinic, monoclinic, orthorhombic, and cubic). One may also see that the $L = 2$ angular dependence for all cubic groups is isotropic (i.e., $\propto x^2 + y^2 + z^2$), which means that resonant scattering from these sites cannot display anisotropy. More information on these functions can be found in books that discuss the properties of crystals via group theory (Nowick, 1995).

APPENDIX C: TRANSFORMATION OF COORDINATES

Describing the scattering experiment involves transforming the resonant scattering structure factor, usually

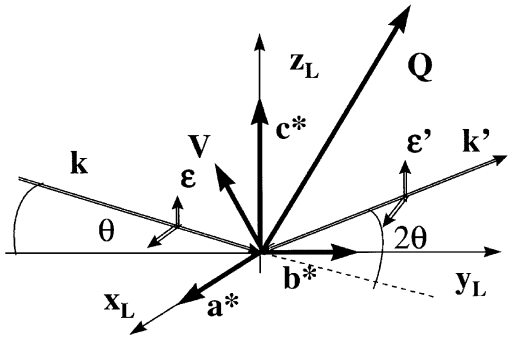

Figure 10. Two vectors describe the orientation of a crystal. If the reciprocal lattice of the crystal parallels the "laboratory" coordinate system, then the transformation formula (below) will reorient $\mathbf{Q}$ to be along $\mathbf{z}_L$ for diffraction and set $\mathbf{V}$ at azimuth ψ.

defined in a coordinate system fixed to the crystal, into a system fixed with respect to the scattering geometry (i.e., the "laboratory frame"). The methods involved are found in references used to calculate diffractometer angle settings in 4-circle crystallography (Busing and Levy, 1967). Here, these ideas merit special consideration because the tensor nature of the structure factors lead to an important additional dependence of the scattering on crystal orientation.

Figure 10 shows a rectilinear reciprocal lattice (a crystal coordinate system) coincident with a laboratory coordinate system. The orientation of vectors representing the scattering geometry are tied to the laboratory system.

Two vectors in the crystal system are needed to describe its orientation; the reflection vector $\mathbf{Q}(h,k,l)$, and a noncolinear reference vector $\mathbf{V}(h_V,k_V,l_V)$. The condition for Bragg diffraction ($\sin\theta_B = \lambda Q/2$) and the constraint that $\mathbf{Q}$ points along $\mathbf{z}_L$, allows any orientation of $\mathbf{V}$ on a cone about $\mathbf{Q}$. The azimuth angle (ψ) fixes the crystal orientation by specifying the projection of $\mathbf{V}$ normal to $\mathbf{z}_L$; $\psi = 0$ when this projection is along $-\mathbf{y}_L$ and increases with clockwise rotation about $\mathbf{Q}$.

The tensor structure factor (usually derived in crystal coordinates) is expressed in the laboratory frame through a coordinate transformation based on Euler angles (Sakari 1985, Section 3.3). In matrix form the transformation is written

$$\begin{bmatrix} \cos\alpha\cos\beta\cos\gamma & \sin\alpha\cos\beta\cos\gamma & -\sin\beta\cos\gamma \\ -\sin\alpha\sin\gamma & +\cos\alpha\sin\gamma & \\ -\cos\alpha\cos\beta\sin\gamma & -\sin\alpha\beta\sin\gamma & \sin\gamma\sin\beta \\ -\sin\alpha\cos\gamma & +\cos\alpha\cos\gamma & \\ \sin\beta\cos\alpha & \sin\beta\sin\alpha & \cos\beta \end{bmatrix} \quad (26)$$

where α and β (the usual azimuthal and polar angles of spherical coordinates) describe the orientation of $\mathbf{Q}$ relative to crystal axes. These angles may be expressed in components of the reflection vectors as $\cos\beta = 1c^*/Q$, and $\tan\alpha = (k\,b^*)/(h\,a^*)$. The angle γ is related to the experimental azimuth, ψ, through the relation

$$\sin(\gamma - \psi) = (l_v c^* - (\mathbf{V}\cdot\mathbf{Q}/Q)\cos\beta)/[(\mathbf{V}\cdot\mathbf{Q}/Q - V)\sin\beta] \quad (27)$$

MAGNETIC X-RAY SCATTERING

INTRODUCTION

For an x ray incident on a solid, the dominant scattering process is Thomson scattering, which probes the charge density of that solid. It is this interaction that provides the basis for the vast majority of x-ray scattering experiments, supplying a wealth of information on crystal structures and the nature of order in solid-state systems (see, e.g., XAFS SPECTROSCOPY, X-RAY AND NEUTRON DIFFUSE SCATTERING and RESONANT SCATTERING TECHNIQUES). However, in addition to such scattering, there are other terms in the cross-section that are sensitive to the magnetization density. Scattering associated with these terms gives rise to new features in the diffraction pattern from magnetic systems. This is magnetic x-ray scattering. For antiferromagnets, for which the magnetic periodicity is different from that of the crystalline lattice, such scattering gives rise to magnetic superlattice peaks, well separated from the charge Bragg peaks. For ferromagnets, the magnetic scattering is coincident with the charge scattering from the underlying lattice, and difference experiments must be performed to resolve the magnetic contribution.

The magnetic terms in the cross-section are much smaller than the Thomson scattering term, and pure magnetic scattering is typically 10^4 to 10^6 times weaker than the charge Bragg peaks. Nevertheless, this scattering is readily observable with synchrotron x-ray sources, and successful experiments have been performed on both antiferromagnets and ferromagnets. The technique has undergone a rapid growth in the last decade as a result of the availability of synchrotrons and the consequent access to intense, tunable x-ray beams of well-defined energy and polarization.

The basic quantity measured in a magnetic x-ray scattering experiment is the instantaneous magnetic moment-moment correlation function. In essence, the technique takes a snapshot of the Fourier transform of the magnetic order in a system. This means that the principal properties measured by magnetic scattering are quantities connected with the magnetic structure—including the ordering wave-vector, the magnetic moment direction, the correlation length, and the order parameter characterizing the phase (for example, this latter might be the staggered magnetization in the case of an antiferromagnet or the uniform magnetization for a ferromagnet). These are obtained from the position, intensity, and lineshape of

the magnetic peaks. The scattering is very weak and therefore not affected by extinction effects, so that the temperature dependence of the order parameter may be measured very precisely, leading, for example, to an accurate determination of the order parameter critical exponent, β. However, used alone, x-ray magnetic scattering can typically determine the order parameter only to within an arbitrary scale factor, because of the difficulty in obtaining an absolute scale for the scattered intensities.

There are two regimes of importance in magnetic x-ray scattering, characterized by the incident photon energy relative to the positions of the absorption edges in the system under study. These are the nonresonant and resonant limits to the cross-section.

Nonresonant magnetic scattering is observed when the incident photon energy is far from any absorption edges. It is energy independent, and has the advantages of being (in principle) present for all magnetic ions and of having a simple cross-section. The non-resonant cross-section contains terms due to both the orbital, $\vec{Z}$, and spin, $\vec{S}$, components of the magnetic moment. These each contribute, with different polarization dependences, to the scattering, and it is therefore possible to separate the two contributions empirically. This ability is one of the technique's unique strengths. However, nonresonant magnetic scattering is extremely weak, and for the signal to be observable samples of high crystallographic quality are required in order to match the high collimation of the synchrotron source. The size of the signal varies as the square of the moment; therefore large-moment systems are good candidates for study.

Conversely, resonant magnetic scattering is observed when the incident photon energy is tuned to an absorption edge of an ion with which there is an associated magnetic polarization. It arises from second-order scattering processes. Under certain circumstances, enhancements in the magnetic scattering may be observed at such edges. These enhancements can be very large; increases of a factor of 50 have been observed at the L edges of the rare earths, and of several orders of magnitude at the M edges of the actinides. Such enhancements make the technique particularly useful for the study of weakly scattering systems—e.g., thin films, very small samples, critical fluctuations, and magnetic scattering from surfaces. Resonant scattering is sensitive to the total moment at a given site and it is not possible to extract $\vec{L}$ and $\vec{S}$ in the same way as it is for non-resonant scattering.

The resonant energy depends on the atomic species, and therefore resonant magnetic scattering is element specific—by tuning the incident photon energy to the absorption edge of a particular element, one can study the magnetic order of that sublattice with very little contribution from other magnetic sublattices. This is a particular strength of resonant scattering, in contrast to magnetic neutron scattering (MAGNETIC NEUTRON SCATTERING), which is sensitive to the total moment of ++ all sublattices contributing at a particular wave-vector. In addition, resonant scattering is also orbital specific—i.e., the magnetic polarization of different electronic orbitals may be probed independently. For example, in the elemental rare earths, both the (itinerant) $5d$ orbitals and the (localized) $4f$ orbitals carry an ordered moment. At an L_2 or L_3 edge, these states are reached through dipole or quadrupole transitions, respectively. Typically the dipole and quadrupole resonances differ in energy by 5 to 10 eV (Bartolomé et al., 1997), and have different polarization dependencies. They may therefore be separated empirically in a relatively straightforward manner. Recent experiments, for example, have exploited these features to elucidate the RKKY interaction in multicomponent systems (Pengra et al., 1994; Everitt et al., 1995; Langridge et al., 1999; Vigliante et al., 1998).

Both nonresonant and resonant magnetic scattering techniques offer extremely high reciprocal space resolution as a result of the intrinsic collimation of the synchrotron radiation. Typically, the resolution widths are $\sim 10^{-4}$ Å^{-1}. Thus, magnetic x-ray scattering is useful for detailed quantitative measurements of such properties as incommensurabilities, correlation lengths, and scattering lineshapes. In addition, the poor energy resolution of x-ray scattering experiments, relative to the relevant magnetic excitations, ensures that the quasi-elastic approximation is rigorously fulfilled and that the instantaneous correlation function is measured.

In many ways, x-ray magnetic scattering is complementary to the more established technique of neutron magnetic scattering (MAGNETIC NEUTRON SCATTERING). This latter probe measures many of the same properties of a system, and each technique has its own strengths and weaknesses. It is frequently of value to perform experiments using both techniques on the same sample.

Neutron scattering offers bulk penetration and a large magnetic cross-section, making it more generally applicable than x-ray magnetic scattering. In addition, inelastic magnetic neutron scattering is readily observable (in samples of sufficient volume) allowing the study of spin dynamics. Absolute intensities may be obtained, so it is also possible to measure ordered moments. As a result, unless there are special circumstances, it is generally preferable to solve the magnetic structure using neutron scattering. Here, powder neutron diffraction (NEUTRON POWDER DIFFRACTION) is particularly powerful. In contrast, powder magnetic x-ray diffraction is, typically, prohibitively small. However, neutron scattering is not inherently element specific, nor can it resolve $\vec{L}$ and $\vec{S}$ contributions simply, or study small-volume samples. Further, it requires a reactor or spallation source to perform the experiments. The reciprocal space resolution is typically lower by a factor of 10 than that achievable with x-rays, and there are some elements that have high neutron absorption cross-sections (e.g., Gd and Sm), which are difficult to study with neutrons but that have relatively large x-ray magnetic cross-sections. In addition, in some cases, the incident neutron flux will activate the sample, which can cause problems for subsequent experiments on the same sample. Finally, for high-quality samples, the magnetic elastic intensity can be affected by extinction, making quantitative determinations of the order parameter and lineshape difficult.

In summary, magnetic x-ray scattering is particularly suitable when high-resolution, or elemental or orbital-specific information is required, or when small samples

are involved, or if one needs to separate the $\vec{L}$ and $\vec{S}$ contributions to the ordered moment.

There are other techniques that can measure quantities related to those obtained by x-ray magnetic scattering. These include x-ray magnetic circular dichroism (XMCD), discussed in X-RAY MAGNETIC CIRCULAR DICHROISM, which is closely related to resonant magnetic x-ray scattering. XMCD is particularly useful for obtaining moment directions and $\vec{L}$ and $\vec{S}$ contributions in ferromagnets. Like resonant magnetic scattering it is both elemental and orbital specific. In addition, bulk techniques (Chapter 6) such as SQUID (superconducting quantum interference device; THERMOMAGNETIC ANALYSIS) magnetometry, and heat capacity measurements can provide insight into the magnetic behavior of a particular system, including the total (uniform) magnetization and the existence of phase transitions. These techniques also have the advantage of being available in a home laboratory, and are less demanding in their crystallographic quality requirements. However, such techniques cannot provide the microscopic information on the magnetic order that is available from scattering (x-ray and neutron) techniques.

In any discussion of magnetic x-ray scattering, one is inevitably led to considering the polarization states of the photon. The two important cases are linear and circular polarization. The degree of linear polarization is characterized by

$$P_\zeta = \frac{I_{\text{hor}} - I_{\text{vert}}}{I_{\text{hor}} + I_{\text{vert}}} \quad (1)$$

where I_{hor} is the horizontally polarized and I_{vert} the vertically polarized intensity. Similarly, the degree of circular polarization is defined by

$$P_\eta = \frac{I_{\text{left}} - I_{\text{right}}}{I_{\text{left}} + I_{\text{right}}} \quad (2)$$

where I_{left} is the intensity of the left circularly polarized light and I_{right} the intensity of the right circularly polarized light. In the case of linear polarization, the polarization state is often described relative to the scattering plane. Polarization perpendicular to the scattering plane is referred to as σ polarization; polarization parallel to the scattering plane is called π polarization.

It is also useful to review the nomenclature for absorption edges, which are labeled by the core hole created in the absorption process. The principal quantum number ($n = 1,2,3,4\ldots$) of the core-hole is labeled by K,L,M,N,.... and the angular momentum s, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$,... by 1,2,3,4,5... Thus the L_3 edge corresponds to the excitation of the $2p_{3/2}$ electron.

This unit provides an overall background to the theoretical and experimental principles of nonresonant and resonant magnetic x-ray scattering. The more general applications of the resonant terms in the cross-section will not be discussed here; some of them are covered in RESONANT SCATTERING TECHNIQUES and X-RAY MAGNETIC CIRCULAR DICHROISM. The experimental techniques are very similar to standard synchrotron x-ray diffraction experiments; therefore discussion of the beamlines and spectrometers will be limited, with only those elements particular to magnetic scattering, such as polarization analyzers, discussed in any detail. At high incident photon energy, it is possible to perform inelastic experiments utilizing the nonresonant magnetic scattering terms in the cross-section. This allows for the measurement of magnetic Compton profiles (projections of the momentum density of the magnetic electrons, along a given direction). Magnetic Compton scattering may only be applied to ferromagnets, because of the incoherent nature of the inelastic scattering, and the technique differs in many aspects of its practical implementation from the diffraction experiments discussed here. It will therefore not be covered in this unit. Reviews may be found in Schülke (1991) and Lovesey and Collins (1996).

The history of the field will not be covered in this unit. Brief reviews have been given in Brunel and de Bergevin (1991), Gibbs (1992), and McMorrow et al. (1999).

PRINCIPLES OF THE METHOD

Theoretical Concepts

As mentioned in the introduction, magnetic x-ray scattering arises from terms in the scattering cross-section that are dependent on the magnetic moment. For nonresonant scattering, these terms can be most simply be understood using a classical picture of scattering from free electrons (de Bergevin and Brunel, 1981a,b). The different classical scattering mechanisms are shown in Figure 1. Charge (Thomson) scattering is illustrated in the uppermost (a) diagram of Figure 1, in which the electric field of the

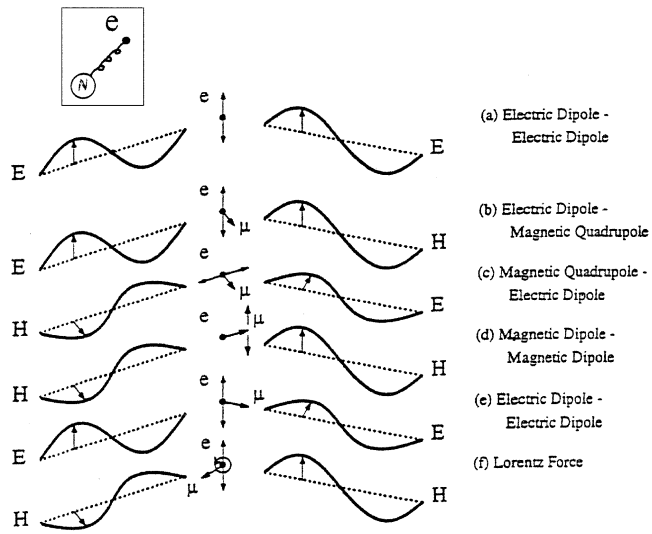

Figure 1. Classical picture of the dominant mechanisms for an x-ray scattering from an electron (*e*). In (**a**) the x-ray is scattered from the electronic charge, while in (**b-f**) the magnetic moment of the electron is involved. Mechanisms (**b-d**) result in spin-dependent scattering, while (**e-f**) are for a moving magnetic dipole with finite orbital angular momentum. Mechanism (**a**) represents resonant scattering from an electron bound to an atomic nucleus (*N*) as shown in the inset. Figure adapted from McMorrow et al. (1999).

incident photon accelerates the electronic charge, leading to electric dipole radiation in the form of the scattered photon. The terms that give rise to nonresonant magnetic scattering are illustrated in Figure 1, diagrams b to f. These arise from the (weaker) interaction between the electric and magnetic fields of the photon and the magnetic moment of the electron. The scattering due to nonresonant interactions is reduced relative to charge scattering, by a factor proportional to $(\hbar\omega/mc^2)^2$, which is $\approx 10^{-4}$ for an incident photon energy of $\hbar\omega = 10$ keV (here h is Planck's constant, $\hbar = h/2\pi$, ω is the frequency, m is the electron mass, and c is the speed of light).

Resonant scattering arises from the fact the electrons are not free, but bound to the nucleus. The resulting quantized bound states give rise to well defined transition energies, and resonant scattering results when these transitions are selectively excited. Maintaining the classical picture, this may be visualized with a ball and spring model and its associated resonant frequencies (see insert over diagram "a" of Fig. 1).

The scattering mechanisms of Figure 1 may be calculated quantum mechanically within second-order perturbation theory with the appropriate choice of interaction Hamiltonian (Blume, 1985, 1994).

The cross-section for elastic scattering of x-rays is

$$\left(\frac{d\sigma}{d\Omega}\right) = r_0^2 \left| \sum_n e^{i\vec{Q}\cdot\vec{r}_n} f_n(\vec{k},\vec{k}',\hbar\omega) \right|^2 \tag{3}$$

where $\vec{Q}$ is the momentum transfer in the scattering process, $r_0 = 2.8 \times 10^{-15}$ m is the classical electron radius, $\vec{k}$ and $\vec{k}'$ are the incident and scattered wave-vectors of the photon, $d\sigma$ is the differential cross-section of the scattering center for scattering into the solid angle element $d\Omega$. The scattered amplitude from site $\vec{r}_n$ is f_n. It may be expressed as the sum of several contributions

$$f_n(\vec{k},\vec{k}',\hbar\omega) = f_n^{\text{charge}}(\vec{Q}) + f_n^{\text{non-res}}(\vec{Q},\vec{k},\vec{k}') + f_n^{\text{res}}(\vec{k},\vec{k}',\hbar\omega) \tag{4}$$

where, for incident and scattered photon polarization states described by the unit vectors $\hat{\varepsilon}$ and $\hat{\varepsilon}'$, respectively

$$f_n^{\text{charge}}(\vec{Q}) = -\rho_n(\vec{Q})\hat{\varepsilon}\cdot\hat{\varepsilon}' \tag{5}$$

is the Thomson scattering, which is proportional to the Fourier transform of the charge density, $\rho(\vec{Q})$. The dot product of the polarization vectors requires that the polarization state not be rotated by the scattering. The nonresonant magnetic scattering amplitude, $f_n^{\text{non-res}}$ and the resonant magnetic scattering amplitude, which is contained in the anomalous (energy dependent) terms, f_n^{res}, are considered in the following section.

Nonresonant Scattering. The nonresonant scattering amplitude may be written (Blume, 1985)

$$f_n^{\text{non-res}}(\vec{Q}) = -i\left(\frac{\hbar\omega}{mc^2}\right)\left[\frac{1}{2}\vec{L}_n(\vec{Q})\cdot\vec{A} + \vec{S}_n(\vec{Q})\cdot\vec{B}\right] \tag{6}$$

where $\frac{1}{2}\vec{L}_n(\vec{Q})$ and $\vec{S}_n(\vec{Q})$ are proportional to the Fourier transforms of the orbital and spin magnetization densities, respectively. The vectors $\vec{A}$ and $\vec{B}$ contain the polarization dependences of the two contributions to the scattering. Importantly, these two vectors are not equal and have distinct $\vec{Q}$ dependences. Hence, by measuring the polarization of a scattered beam for a number of magnetic reflections, one may obtain the ordered $\vec{L}$ and $\vec{S}$ moments for the system. For synchrotron diffraction experiments with linear incident polarization, $\vec{A}$ and $\vec{B}$ are most usefully expressed in terms of linear polarization basis states (Blume and Gibbs, 1988). In this basis, the charge scattering may be written as

$$\langle M_{\text{charge}}\rangle = \rho(\vec{Q})\begin{pmatrix} 1 & 0 \\ 0 & \cos 2\theta \end{pmatrix} \tag{7}$$

where 2θ is the angle between $\vec{k}$ and $\vec{k}'$. Note, this matrix is diagonal, reflecting the fact that the polarization state is not rotated by the charge scattering process. In this same basis the non-resonant magnetic scattering operator is

$$\langle M_{\text{non-res}}\rangle = \begin{pmatrix} \langle M_{\sigma\sigma}\rangle\langle M_{\pi\sigma}\rangle \\ \langle M_{\sigma\pi}\rangle\langle M_{\pi\pi}\rangle \end{pmatrix} = -i\left(\frac{\hbar\omega}{mc^2}\right)\times \begin{pmatrix} \sin 2\theta S_2 & -2\sin^2\theta[\cos\theta(L_1+S_1) - \sin\theta S_3] \\ 2\sin^2\theta[\cos\theta(L_1+S_1) + \sin\theta S_3] & \sin 2\theta[2\sin^2\theta L_2 + S_2] \end{pmatrix} \tag{8}$$

in the coordinate system of Figure 2. Here and throughout this unit, the $\langle\ \rangle$ symbol represents the ground state expectation value of an operator. Note that non-resonant magnetic scattering is only sensitive to the components of the orbital angular momentum perpendicular to the

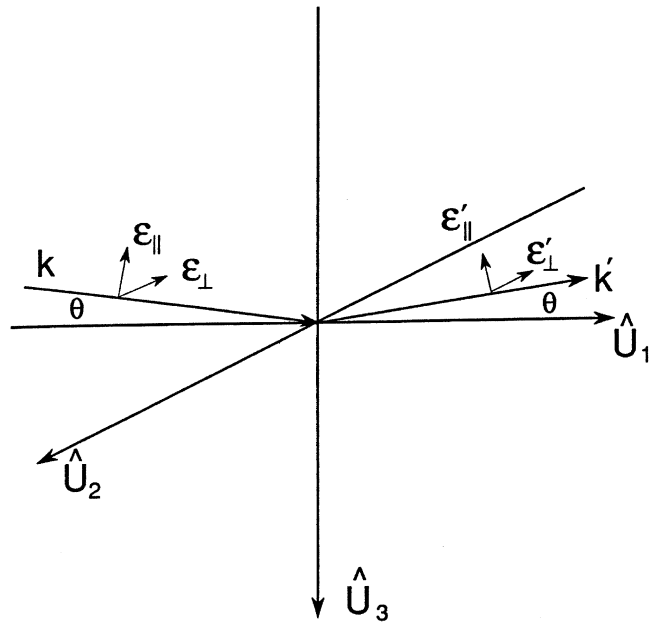

Figure 2. The coordinate system used in this unit, after Blume and Gibbs (1988). Note that the momentum transfer $\vec{Q}$ is along $-\hat{U}_3$.

momentum transfer (i.e., the components L_1 and L_3). For pure magnetic scattering, then

$$\frac{d\sigma}{d\Omega} = r_o^2 \left(\frac{\hbar\omega}{mc^2}\right)^2 \mathrm{tr}\langle M_{\text{non-res}}\rangle \rho \langle M^{\dagger}_{\text{non-res}}\rangle \tag{9}$$

where tr is the trace operator, $\langle M^{\dagger}_{\text{non-res}}\rangle$ is the Hermitian adjoint of $\langle M_{\text{non-res}}\rangle$ and ρ is the density matrix for the incident polarization. For example, for linear incident polarization

$$\rho = \frac{1}{2}\begin{pmatrix} 1+P_\zeta & 0 \\ 0 & 1-P_\zeta \end{pmatrix} \tag{10}$$

The general case is given in Blume and Gibbs (1988). With this form, the $\sigma \rightarrow \sigma$ scattering is given by $|\langle M_{\sigma\sigma}\rangle|^2$, the $\sigma \rightarrow \pi$ by $|\langle M_{\sigma\pi}\rangle|^2$ and so on.

Equation 9 allows for the straightforward determination of the polarization dependence of the scattering for a given scattering geometry and magnetic structure. As an illustrative example, consider the case of MnF_2, an Ising antiferromagnet for which the spins are oriented along the c axis, and the orbital moment is quenched, $L_1 = L_2 = L_3 = 0$. The ordering wave vector is perpendicular to the c axis. If the scattering geometry is arranged such that the c axis is perpendicular to the scattering plane, then $S_2 = S$ and $S_1 = S_3 = 0$. The scattering matrix, Equation 8, is then diagonal, and for a σ incident beam, all the scattering is into the σ channel. If the sample is then rotated about the scattering vector such that the spins are then in the scattering plane, i.e., $S_1 = S$ and $S_2 = S_3 = 0$, then the diagonal elements are zero and all the scattering rotates the photon polarization state by 90°, i.e., the scattering is entirely $\sigma \rightarrow \pi$ and $\pi \rightarrow \sigma$. Further, the scattered intensity is reduced by a factor of $\sin^2\theta$, relative to the previous geometry. In typical experiments, this is a small number, and, as a result, non-resonant magnetic scattering is largely sensitive to the component of the spin perpendicular to the scattering plane.

These predictions have been largely experimentally verified in MnF_2 (Goldman et al., 1987; Hill et al., 1993; Brückel et al., 1996).

An estimate of the size of pure non-resonant magnetic scattering, relative to that of charge scattering (ignoring polarization factors) may be obtained from Blume (1985)

$$\frac{\sigma_{\text{mag}}}{\sigma_{\text{charge}}} = \left(\frac{\hbar\omega}{mc^2}\right)^2 \left(\frac{N_{\text{m}}}{N}\right)^2 \left(\frac{f_{\text{m}}}{f}\right)^2 \langle \mu^2 \rangle \tag{11}$$

where N_{m}/N is the ratio of the number of magnetic electrons to the total number of electrons, f_{m}/f is the ratio of the magnetic to charge form factors, and μ^2 is the average magnetic moment. For Fe and 10 keV photons

$$\frac{\sigma_{\text{mag}}}{\sigma_{\text{charge}}} \sim 4 \times 10^{-6} \langle \mu^2 \rangle \tag{12}$$

In fact, this ratio may be further reduced for a particular Bragg magnetic reflection because the magnetic form factor falls off faster than the charge form factor. While, to a large extent, the small amplitude of the non-resonant scattering may be countered by the use of the intense incident x-ray flux available at synchrotrons, it is generally true that samples of relatively small mosaic spread (e.g., $<0.1°$) are required in order to make full use of this incident intensity. Nevertheless, even quite small moments have been observed. For example, non-resonant magnetic scattering from the spin density wave in chromium, which has an ordered moment of 0.4 μ_B/atom, gave rise to count rates on the order of 10 counts per sec at a bending magnet beamline at the National Synchrotron Light Source (Hill et al., 1995a) and >1000 counts per second at an undulator beamline at the European Synchrotron Radiation facility (Mannix, 2001).

Resonant Scattering. The resonant terms arise from second-order scattering processes which may, in a loose sense, be thought of as the absorption of an incident photon, the creation of a short lived intermediate (excited) state, and the decay of that state, via the emission of an elastically scattered photon, back into the ground state. For Bragg scattering, this process is coherent and the phase relationship between the incident and scattered photons is preserved. A schematic energy level diagram illustrating this process for a rare-earth ion is shown in Figure 3.

The resonant scattering amplitude is (Blume, 1994)

$$f_n^{\text{res}}(\vec{k},\vec{k}',\hbar\omega) = -\frac{1}{m}\sum_c \left(\frac{E_a - E_c}{\hbar\omega}\right) \frac{\langle a|O_\lambda(\vec{k})|c\rangle\langle c|O^{\dagger}_{\lambda'}(\vec{k}')|a\rangle}{E_a - E_c - \hbar\omega} + \frac{1}{m}\sum_c \left(\frac{E_a - E_c}{\hbar\omega}\right) \frac{\langle a|O^{\dagger}_{\lambda'}(\vec{k}')|c\rangle\langle c|O_\lambda(\vec{k})|a\rangle}{E_a - E_c + \hbar\omega - i\frac{\Gamma}{2}} \tag{13}$$

where $E_a, |a\rangle$, and $E_c, |c\rangle$, are the energies and wavefunctions of the initial and intermediate states, respectively, Γ is the inverse lifetime of the intermediate state, and the operator $O_\lambda(\vec{k})$ is given by

$$O_\lambda(\vec{k}) = \sum_n e^{i\vec{k}\cdot\vec{r}_n}(\vec{P}_n \cdot \hat{\varepsilon}_\lambda - i\hbar\hat{\varepsilon}_\lambda \cdot (\vec{k} \times \vec{S}_n)) \tag{14}$$

The two terms of Equation 13 give rise to anomalous dispersion, i.e., they contain all the energy dependence of the scattering. They have come to play an increasingly important role in x-ray scattering experiments with the availability of energy tunable x-ray sources at synchrotron beamlines. Some of these applications are discussed in the units on resonant scattering techniques (RESONANT SCATTERING TECHNIQUES). In the limit of zero momentum transfer, these terms give rise to XMCD effects (X-RAY MAGNETIC CIRCULAR DICHROISM).

In a resonant experiment, the incident photon energy, $\hbar\omega$ is tuned to the absorption edge, such that $\hbar\omega = E_c - E_a$, and the second of the two terms in Equation 13 is enhanced. In this limit, it is common to ignore the first, non-resonant term of Equation 13 (Blume, 1994). That resonant effects may contain some sensitivity to the magnetization was first suggested by Blume (1985) and observed by Namikawa et al. (1985). It was explored in

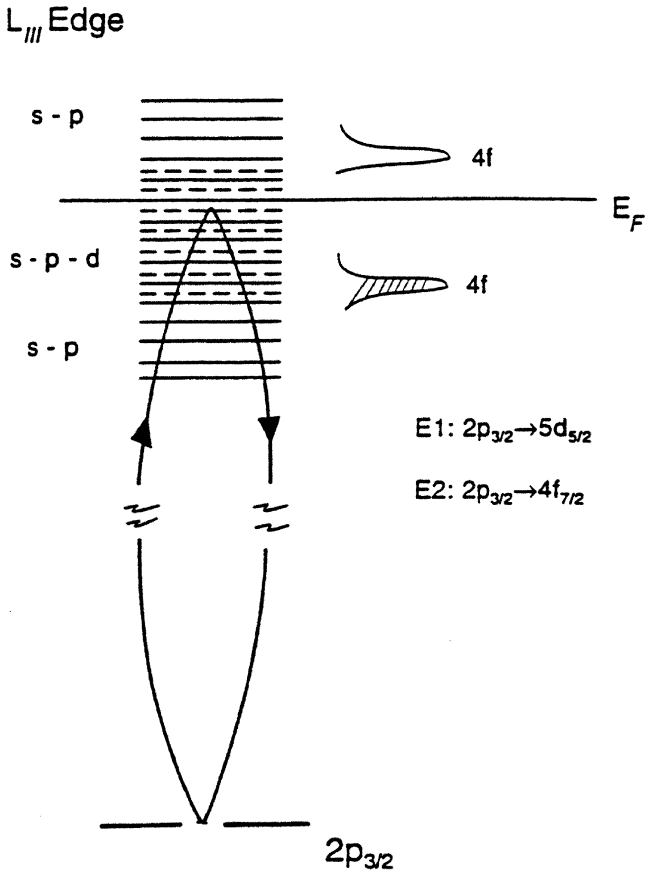

Figure 3. A schematic single-electron picture of the resonant scattering process, illustrated for a rare earth, at the L_3 edge. A $2p_{3/2}$ electron is excited into an unoccupied state above the Fermi level by the incident photon. The $5d$ states are reached through electric dipole transitions and the $4f$ through electric quadrupole transitions. In the elemental rare earths, the $5d$ states form delocalized bands, polarized through an exchange interaction with the localized, magnetic $4f$ electrons. Resonant elastic scattering results when the virtually excited electron decays by filling the core hole and emitting a photon. Figure taken from Gibbs (1992).

detail by Hannon et al. (1988) following the experimental work of Gibbs et al. (1988).

The magnetic sensitivity arises from spin-orbit correlations, which must be present in at least one of the two levels involved in the resonant process, and from exchange effects. "Exchange effects" refers to any phenomena originating from the anti-symmetry of the wave function under the exchange of electrons. This includes the exclusion principle, which only allows transitions to unoccupied spin orbitals in partially filled spin polarized valence states, as well as the exchange interaction between electrons in different orbitals. Resonant magnetic scattering is often referred to as x-ray resonant exchange scattering (XRES), as a result of the requirement that exchange effects be present.

Almost all of the experimental phenomena observed in resonant magnetic scattering can be explained in terms of a one-electron picture of electric multipole transitions (Hannon et al., 1988; Luo et al., 1993). Magnetic multipole transitions are smaller by a factor of $\hbar\omega/mc^2$ and have not been considered in the literature to date. In this picture, the size of the resonant enhancement of the magnetic scattering depends on the radial matrix elements ($\langle c|r^{\mathrm{L}}|a\rangle$, where $L = 1, 2..$ for dipole, quadrupole... transitions), the magnetic polarization of the intermediate state, the value of the intermediate-state lifetime, and the energy width of the incident photon. Thus the largest enhancements are expected when large matrix elements couple states with strong polarizations.

Such a situation occurs at the M_4 and M_5 edges in the actinides, for which dipole allowed transitions couple to the magnetic $5f$ electrons. Enhancements of several orders of magnitude are typical at such edges, allowing extremely small moments to be studied. For example, in URu_2Si_2, scattering from an ordered moment of $0.02\mu_B$ was observed (Isaacs et al., 1990).

Conversely, at the L_2 and L_3 edges of the rare-earths, the dipole transitions are $2p \leftrightarrow 5d$. The $5d$ electrons are polarized through an exchange interaction with the localized, magnetic $4f$ electrons, and the induced moment is relatively small, $\approx 0.2\mu_B$. In addition, the radial matrix elements are 5 to 10 times smaller than at the $M_{4,5}$ edges (Hamrick, 1994) and smaller enhancements are therefore expected. Enhancement factors of $\sim$50 were observed at the Ho L_3 edge (Gibbs et al., 1988, 1991). Quadrupolar transitions at the rare-earth $L_{2,3}$ edges, however, couple to the magnetic $4f$ levels, $2p \leftrightarrow 4f$. To some extent the greater polarization of the $4f$ orbitals compensates for the much smaller quadrupole matrix elements, and this scattering is also observable. In Ho, it is $\approx$5 times weaker than the dipole scattering at the first harmonic, after correction for absorption (Gibbs et al., 1988). Table 1 summarizes the absorption edges for various elements and approximate enhancement factors, together with a typical reference.

One property of resonant scattering is that it does not contain a magnetic form factor, in contrast with non-resonant scattering and magnetic neutron diffraction. In essence, this is because of the two-step nature of the scattering event. The lack of a magnetic form factor is in fact beneficial when observing magnetic reflections at large $\vec{Q}$, something that is often necessary when studying off-specular peaks in a reflection geometry.

In order to extract quantities such as ordered moments and moment directions, the cross-section needs to be considered in more detail (Hannon et al., 1988; Carra et al., 1993; Luo et al., 1993). Absolute moments of one species have been estimated in multicomponent systems by comparison with signals from a known moment in the other species, measured in the same experiment, e.g., in alloy systems such as Dy/Lu (Everitt et al., 1995). However, the large number of estimates and approximations that are required, especially when the intermediate states are delocalized and band structure calculations must be invoked, mean that this method is at best semiquantitative. Work along these lines in Ho/Pr alloys (Vigliante et al., 1998) highlights another problem with extracting such quantitative information, i.e., a breakdown of the one-electron, atomic picture. This is manifest most

Table 1. Resonant Energies and Approximate Enhancements for Various Atomic Absorption Edges

obviously in the branching ratio (the ratio of scattered intensities obtained at a pair of resonances resulting from excitations of two spin-orbit split core-holes, e.g., the L_2 and L_3 or the M_4 and M_5 edges). In the simplest theories (Hannon et al., 1988), these are predicted to be near unity. In fact, empirically, they are known to vary across the rare-earth series, with the heavy rare earths supporting $L_2/L_3 < 1$ and the light rare earths having $L_2/L_3 > 1$ (Gibbs et al., 1991; Hill et al., 1995b; D. Watson et al., 1996; Vigliante et al., 1998). Further, the ratio has even been observed to be temperature dependent. These results point to a need for more detailed theoretical work (e.g., van Veenendaal et al., 1997). However, until a full understanding of the scattered amplitude (and electronic structure used in the calculations) is obtained, the resonant scattered intensity must be interpreted with some caution. A very recent example of an attempt along these lines is the work of Neubeck et al. (2001).

The polarization dependence of the resonant scattering is a function of moment direction and scattering geometry. For dipole (E1) scattering, it is

$$f_{n\mathrm{E1}}^{\mathrm{X\,RES}} = F^{(0)}\begin{pmatrix} 1 & 0 \\ 0 & \cos 2\theta \end{pmatrix} - iF^{(1)}\begin{pmatrix} 0 & z_1\cos\theta + z_3\sin\theta \\ z_3\sin\theta - z_1\cos\theta & -z_2\sin 2\theta \end{pmatrix} + F^{(2)}\begin{pmatrix} z_2^2 & -z_2(z_1\sin\theta - z_3\cos\theta) \\ +z_2(z_1\sin\theta + z_3\cos\theta) & -\cos^2\theta(z_1^2\tan^2\theta + z_3^2) \end{pmatrix} \tag{15}$$

in the same coordinate system and basis as previously (Hannon et al., 1988; Pengra et al., 1994; Hill and McMorrow, 1996). The z_i are the components of a unit vector aligned along the quantization axis at site n and the $F^{(L)}$ are the resonant matrix elements. The first term contains no dependence on the magnetic moment and therefore only contributes to the charge Bragg peaks. The second term is linear in z and for an antiferromagnet will produce new scattering at the magnetic wave-vector. The final term is quadratic in z. This will produce scattering at twice the ordering wave vector. For an incommensurate antiferromagnet, this will give rise to a second-order resonant harmonic.

By way of an example, consider the case of a basal plane spiral, such as occurs in Ho, Tb, and Dy. In this structure the moments are confined to the *a*-*b* plane of the hcp crystal structure, in ferromagnetic sheets. The direction of the magnetization rotates from basal plane to basal plane, creating a spiral structure propagating along the *c* axis. The modulation vector then lies along (00L). The magnetic moment takes the form

$$\hat{z}_n = \cos(\tau \cdot \mathbf{r}_n)\hat{U}_1 + \sin(\tau \cdot \mathbf{r}_n)\hat{U}_2 \tag{16}$$

where τ is the period of the spiral, $\mathbf{r}_n$ the coordinate of the nth atom, and $\hat{U}_1$ and $\hat{U}_2$ are unit vectors defined in Figure 2.

Now, the full x-ray scattering cross-section may be written as

$$\frac{d\sigma}{d'} = \sum_{\lambda\lambda'} P_\lambda |\langle\lambda'|\langle M_{\mathrm{charge}}\rangle|\lambda\rangle - i\frac{\hbar\omega}{mc^2}\langle\lambda'|\langle M_{\mathrm{non-res}}\rangle|\lambda\rangle + \langle\lambda'|\langle M_{E1}^{\mathrm{X\,RES}}\rangle|\lambda\rangle + \langle\lambda'|\langle M_{\mathrm{E2}}^{\mathrm{X\,RES}}\rangle|\lambda\rangle + \cdots I^2 \tag{17}$$

where λ, λ' are incident and scattered polarization states and P_λ the probability for incident polarization λ. As before, $\langle\ \rangle$ represents the ground-state expectation value of the respective operators i.e.,

$$\langle M_{\mathrm{E1}}^{\mathrm{X\,RES}}\rangle = \langle a|\sum_n e^{i\mathbf{Q}\cdot\mathbf{r}_n} f_{n\mathrm{E1}}^{\mathrm{X\,RES}}|a\rangle \tag{18}$$

and E1 and E2 are the dipole and quadrupole terms, respectively. For the purposes of this example, we assume that the dipole contribution is dominant and ignore any interference effects. This will be valid at resonance and away from charge Bragg peaks. Then from Equation 15

$$M_{\mathrm{E1}}^{\mathrm{X\ RES}} = \sum_n e^{i\mathbf{Q}\cdot\mathbf{r}_n} \begin{pmatrix} z_2^2 F^{(2)} & -iz_1\cos\theta F^{(1)} - z_2 z_1 \sin\theta F^{(2)} \\ iz_1\cos\theta F^{(1)} + z_2 z_1 \sin\theta F^{(2)} & iz_2 \sin 2\theta F^{(1)} - z_1^2 \sin^2\theta F^{(2)} \end{pmatrix} \tag{19}$$

For simplicity, we take $P_\lambda = \delta_{\lambda\sigma}$, i.e., an incident beam of linear polarization perpendicular to the scattering plane. Then, only $\sigma \rightarrow \sigma$ and $\sigma \rightarrow \pi$ terms contribute and

$$\frac{d\sigma}{d\Omega} = |\langle a| \sum_n e^{i\mathbf{Q}\cdot\mathbf{r}_n} z_2^2 F^{(2)} |a\rangle|^2 + |\langle a| \sum_n e^{i\mathbf{Q}\cdot\mathbf{r}_n} (iz_1\cos\theta F^{(1)} + z_2 z_1 \sin\theta F^{(2)} |a\rangle|^2 \tag{20}$$

Substituting $z_1 = \cos(\tau \cdot \mathbf{r}_n), z_2 = \sin(\tau \cdot \mathbf{r}_n)$ and writing the sine and cosine terms as the sums of complex exponentials, we obtain the cross-section for a flat spiral with incident radiation perfectly polarized perpendicular to the scattering plane

$$\left.\frac{d\sigma}{d\Omega}\right)_{\mathrm{E1}}^{\mathrm{X\ RES}} = \frac{1}{4}F^{2(2)}\delta(\mathbf{Q}-\mathbf{G}) + \frac{1}{4}\cos^2\theta F^{2(1)}\delta(\mathbf{Q}-\mathbf{G}\pm\tau) + \frac{1}{16}(1+\sin^2\theta)F^{2(2)}\delta(\mathbf{Q}-\mathbf{G}\pm 2\tau) \tag{21}$$

where $\mathbf{G}$ is a reciprocal lattice vector. The intensity of the observed scattering will only be proportional to the above expression if both polarization components of the scattered beam are collected with equal weight. This is the case if no analyzer crystal is employed. If one is used, then the polarization component that is in the scattering plane of the analyzer must be weighted by a factor $\cos^2 2\theta_{\mathrm{A}}$, where θ_{A} is the Bragg angle of the analyzer crystal. From Equation 21, we see that in addition to producing scattering at the Bragg peak, the resonant dipole contribution produces two magnetic satellites at $\pm\tau$ and $\pm 2\tau$ on either side of the Bragg peak. The scattering at $\pm 2\tau$ are the resonant harmonics. Note that these are distinct from any diffraction harmonics that may arise from a nonsinusoidal modulation of the magnetization density.

For quadrupole transitions, the situation is still more complex (Hannon et al., 1988; Hill and McMorrow, 1996) and terms up to $O(z^4)$ are obtained, giving rise to up to four orders of resonant harmonics. The presence of third and fourth resonant harmonics is a clear indication of quadrupole transitions.

Finally, the original formulation of the resonant cross-section (Hannon et al., 1988) has been re-expressed in terms of effective scattering operators following theoretical work performed for the XMCD cross-section (Thole et al., 1992; Carra et al., 1993; Luo et al., 1993; Carra and Thole, 1994). These scattering operators are constituted from spin-orbital moment operators of the valence shell involved in the scattering process and are valid in the short collision time approximation. They offer the possibility of relating resonant elastic and inelastic scattering measurements directly to physically interesting properties of the system.

Observation of Ferromagnetic Scattering. Given the presence of terms in the cross-section sensitive to the magnetization density, the observation of pure magnetic scattering is, in principle, straightforward for antiferromagnets because the superlattice peaks are well separated from the much stronger charge Bragg peaks of the underlying chemical lattice. For ferromagnets, however, the situation is complicated by the fact that the magnetic and charge scattering are superposed.

At first glance, the situation might seem hopeless, since one is apparently required to resolve a signal of one part in 10^6. However, the presence of the charge scattering at the same position does allow for the possibility of observing the interference between the charge and magnetic scattering amplitudes. For example, if the charge and magnetic scattering were in phase, then

$$\frac{d\sigma}{d\Omega} = |f_c + f_m|^2 = f_c^2 + f_m^2 + 2f_c f_{\mathrm{m}} \tag{22}$$

where $f_{\mathrm{m}}(f_{\mathrm{c}})$ is the magnetic (charge) scattering amplitude. The interference term is linear in f_{m} and not quadratic as for pure magnetic scattering, and this scattering is therefore much stronger, on the order of 10^{-3} of the charge scattering. In addition, it changes sign when the sign of the magnetization is changed, allowing the magnetic scattering to be distinguished from the charge scattering in a difference experiment. Unfortunately, the charge and magnetic scattering are in fact precisely 90° out of phase for plane-polarized incident light (in centrosymmetric structures), and thus there is no interference between them.

The interference can be recovered, however, if there is a phase shift between the magnetic and charge amplitudes—e.g., by utilizing resonant effects, or, in non-centrosymmetric structures, by use of circularly polarized light. For non-resonant magnetic scattering, the last option is the only generally applicable alternative. Circularly polarized light also allows for the possibility of reversing the sign of the magnetic scattering by "flipping" the helicity of the incident beam, as well as by reversing the magnetization.

In practice, difference experiments are performed in which the scattered intensity is measured in each of the two configurations and the asymmetry ratio

$$R = \frac{I_+ - I_-}{I_+ + I_-} \tag{23}$$

is calculated, where I_+ and I_- are the intensities measured in the two configurations. This approach eliminates many sources of systematic errors.

For the observation of non-resonant ferromagnetic scattering, the preferred incident beam has some degree of linear polarization as well as a finite circular polarization. The asymmetry ratio is then maximized by scattering in

the plane of the linear polarization of the beam at a scattering angle of $2\theta = 90°$, thus minimizing the charge scattering related to the linear polarization of the incident beam. In this limit, for non-resonant magnetic scattering (Lovesey and Collins, 1996)

$$R = -2\left(\frac{\hbar\omega}{mc^2}\right)\frac{P_\eta}{1+P_\eta}\left(\frac{F_S}{F_c}\sin\alpha + \frac{F_L}{F_c}(\sin\alpha + \cos\alpha)\right) \quad (24)$$

where F_S, F_L, and F_c are the structure factors for the spin, orbital and charge densities respectively, α is the angle between the spin and orbital moments (assumed collinear) and the incident beam, P_ζ is the degree of linear polarization (also see Equation 1), and P_η is the degree of circular polarization (also see Equation 2). Since the scattering is within the plane of linear polarization, $P_\zeta < 0$, and therefore R is maximized by maximizing P_ζ while maintaining a non-zero circular polarization. By measuring the asymmetry ratio for two different angles, α, and taking the ratio of these quantities, then the only unknown is the ratio of the spin to orbital structure factors. This data may then be used together with polarized beam neutron experiments, which determine $(F_S + F_L)$, to obtain F_S and F_L separately, without the need to characterize the polarization state.

Observation of Ferromagnetic Scattering: Resonance Effects. The anomalous dispersion effects associated with absorption edges open up new possibilities for inducing interference between charge and magnetic scattering amplitudes, and thus for studying ferrimagnetism and ferromagnetism. Such techniques can be placed into two classes: the interference of non-resonant magnetic scattering with resonant charge scattering and the interference of resonant magnetic scattering with non-resonant charge scattering. Lovesey and Collins (1996) refer to these as magnetic-resonant charge interference scattering and resonant magnetic-charge interference scattering, respectively. In each case, the phase shift is induced through the anomalous terms, and thus circularly polarized light is not required. In the former case, for which the non-resonant magnetic scattering terms are utilized, it is still possible, in principle, to separate the $\vec{L}$ and $\vec{S}$ contributions to the scattering.

In order for the results of such experiments to be cleanly interpreted, it is important that the experiment be performed in the appropriate limit of the magnetic scattering terms (i.e., resonant or non-resonant). For example, in order to ensure that non-resonant magnetic scattering is dominant, but still be able to take advantage of the resonant phase shift in the charge scattering amplitude, one could use an absorption edge of a nonmagnetic ion, or move far enough above an edge associated with a weak enhancement (such as a K edge in a transition metal), so that the resonant magnetic scattering is negligible. This latter approach was utilized in the first magnetic scattering experiments on ferromagnets (de Bergevin and Brunel, 1981a,b; Brunel, 1983).

Alternatively, the different polarization dependence of resonant and non-resonant magnetic scattering may be used to select a particular channel, utilizing the fact that for interference to occur it must be allowed by both magnetic and charge scattering. Recall that charge scattering (Equation 7) permits only $\sigma \rightarrow \sigma$ and $\pi \rightarrow \pi$ processes and that in a difference experiment, the only terms which contribute to the observed signal are odd in z_n. Now, for dipole resonant scattering, $\sigma \rightarrow \sigma$ processes are forbidden in the first-order term (Equation 15) and therefore resonant magnetic-charge interference is only observed in the $\pi \rightarrow \pi$ channel (ignoring second-order terms). Conversely, non-resonant magnetic scattering may contribute to both $\sigma \rightarrow \sigma$ and $\pi \rightarrow \pi$ channels (Equation 15) and so, for example, the $\sigma \rightarrow \sigma$ channel may be used to select the non-resonant magnetic-charge interference.

PRACTICAL ASPECTS OF THE METHOD

Experimental Hardware

Although the first x-ray magnetic scattering experiments were performed with laboratory sources, the inherent advantages of synchrotron sources—the high flux and collimation, energy tunability, and the possibility of manipulating the incident polarization state—make such facilities nearly ideal for the study of magnetic phenomena with x rays. For all practical purposes, therefore, a synchrotron source is a requirement for a successful experiment. There are three sources of synchrotron radiation in current storage rings. These are the dipole bending magnet, which applies a circular acceleration to the electron beam, and the so-called insertion devices: wigglers and undulators. These latter are linear periodic arrays of alternating bending magnets. A wiggler of N poles will provide N times the flux of a single bending magnet of the same field strength, with the same spectral distribution. An undulator is similar to a wiggler except that the amplitude of the oscillations is much smaller. The amplitude is constrained such that, when viewed far from the source, the radiation from each oscillation is coherent with the others. In such a limit, the flux scales as N^2, and emission is peaked around harmonics of a fundamental (Brown and Lavender, 1991).

The experimental hardware may be broken down into three broad classes of components:

1. *The beamline.* This delivers the x-rays to the sample and is comprised of various optical elements, including monochromator and (typically) focusing mirror, together with evacuated beam transport tubes and possibly a further optical element to alter the polarization state, such as a phase plate.
2. *The spectrometer.* This instrument manipulates the sample and the detector, providing the ability to determine the angle of incidence and exit of the x rays, to a precision of $\sim 0.001°$, allowing the experimenter to explore reciprocal space, often as a function of incident energy. The spectrometer may also include a polarization analyzer for detecting the polarization state of the scattered beam.
3. *The sample environment.* Frequently in magnetic experiments this is a cryostat of some kind.

In the following, the practical aspects of the beamline and the spectrometer are discussed.

The Beamline. Synchrotron beamlines are large, expensive pieces of equipment. They must accept the incident white light spectrum and its associated heat load from the x-ray source and deliver a monochromatic, stable beam to the sample. Optical elements upstream of and including the monochromator must be cooled to prevent problems associated with heating, such as degradation of the optical elements and the loss of flux delivered to the sample due to mismatches of Bragg reflecting crystals that are experiencing different heat loads. At second-generation sources this is typically accomplished with water cooling. The third-generation sources such as the European Sychrotron Radiation Facility (ESRF) in France, the Advanced Photon Source (APS) in the U.S.A., and the Spring-8 synchrotron in Japan) experience greater heat loads and power densities, and cooling with liquid nitrogen is a common solution.

Typical beamlines suitable for magnetic x-ray scattering are composed of a number of components. The mirror (or pair of mirrors) acts as a low-pass filter, eliminating the high-energy component of the white beam; the mirrors are frequently used as focusing elements. They are operated in a grazing incidence geometry such that the angle of incidence is below the critical angle of reflection for the x-ray energies of interest, and these energies are passed with a reflectivity approaching unity. However, for the higher energies, which have a lower critical angle, the angle of incidence will exceed the corresponding critical angle and photons of these wavelengths will be increasingly attenuated.

The high-energy part of the spectrum is particularly troublesome for a magnetic scattering experiment because of the property whereby the monochromator passes higher-order components of the beam. A typical monochromator, e.g., Si(111) or Ge(111), set to pass λ will also pass $\lambda/2$, $\lambda/3\ldots$ (in varying amounts), since the Bragg conditions for these energies will be met simultaneously by the (222), (333)... reflections. These components of the incident beam will produce charge scattering at apparent fractional Bragg positions, when indexed based on a wavelength of λ. Such harmonics may superpose magnetic scattering for commensurate magnetic systems. Typically, this problem is overcome through a combination of one or more of the following techniques. Firstly, the mirror and inherent energy dependence of the incident spectrum reduce the incident intensity at the higher energies. Secondly, the (222) reflection is all but forbidden in the diamond structure, so that after two reflections from a Si(111) or Ge(111) double-bounce monochromator, and (if used) a (111) reflection in an analyzer crystal, it is greatly reduced. Thirdly, the energy resolution of the detector can further discriminate between the λ and λ/n components (though if the harmonic content of the signal is too great, the detector will saturate, and this approach will not work). Fourth, the monochromator may be detuned. This final method is based on the fact that the rocking widths (Darwin curves) of the higher-order reflections are sharper than that of the fundamental. Thus, if one operates the monochromator with the second crystal slightly rotated away from the θ_B, the reflectivity for the higher-order components may be greatly reduced with only a slight loss of intensity of the fundamental.

For resonant scattering experiments, the monochromator needs to be a scanning, fixed exit monochromator. The energy resolution of the monochromator is crucial in determining the size of any resonant enhancement, and, to maximize the enhancement, it should be approximately matched with the width of the resonance, i.e., to the core-hole lifetime of the associated transition. For $3d$ transition metal K edges, this is 1 to 2 eV, and for the rare earth L edges and the actinide M edges it is ≈ 5 eV.

Other elements in the beamline include various defining slits. Those upstream of the monochromator and mirrors determine the fraction of the full beam accepted by the optical elements. This is useful in quantitative polarization analysis experiments, where the vertical and horizontal divergences must be closely controlled. A final set of slits before the sample are used to trim the beam of diffuse scattering arising from imperfections in the optical elements and to define the footprint of the beam on the sample. This is of importance when measuring integrated intensities of a number of Bragg peaks. The last component of the beamline, immediately preceding the sample, is an incident beam monitor that is used to normalize scattered count rates.

Bending magnets, wigglers, and undulators are all planar devices—i.e., the electron orbit is only perturbed in the horizontal plane, and the radiation produced is therefore horizontally polarized in the same plane. The degree of polarization represents a figure of merit for performing polarization analysis experiments. It is largely dependent on the type and stability of the source, although subsequent optics can modify it. For example, for a bending magnet source at the National Synchrotron Light Source (NSLS; Brookhaven National Laboratory, U.S.A.), $P_\zeta = 0.9$. For a wiggler $P_\zeta = 0.99$, and for an undulator source at the ESRF, $P_\zeta = 0.998$. This greater degree of polarization, together with smaller horizontal and vertical divergences at the third-generation sources, make undulator beamlines significantly better for quantitative polarization analysis. The degree of linear polarization can be further improved by choosing a monochromator Bragg reflection close to 45°—or by inserting a second (polarizing) monochromator just upstream of the sample, also with a $\theta_B \approx 45°$. This will further reduce the π component of the incident polarization. This approach has been employed successfully in the study of ferromagnets.

While a linearly polarized beam is often sufficient for magnetic scattering, as discussed above (see Principles of the Method, Theoretical Concepts) the observation of ferromagnetic order via interference between non-resonant magnetic and charge scattering requires circular polarization. There are three main methods for obtaining circularly polarized light in the hard x-ray regime at a synchrotron (see also X-RAY MAGNETIC CIRCULAR DICHROISM).

1. Firstly, although bending magnet radiation is horizontally polarized on-axis, it is circularly polarized out of the plane of the synchrotron. This results from the fact that the electron motion appears elliptical when viewed from above or below the plane, and thus the off-axis radiation is elliptically polarized, with opposite polarization states being

obtained above and below the plane. Techniques based on this fact have been relatively popular, because of the ready access to bending magnet sources. The degree of circular polarization increases rapidly from zero to near unity as the linear, horizontal polarization drops to zero. The disadvantage of this method is that the flux also drops very rapidly, and even at the small viewing angles involved (a few tenths of a milliradian) intensity losses at factors of 5 to 10 must be suffered to gain appreciable circular polarization. In addition, the technique is more sensitive to beam motion, since such motions cause a change in both intensity and polarization. Finally, in order to switch the handedness of the polarization, the whole experiment must be realigned from above the plane to below the plane. This is a cumbersome procedure at best, and one liable to incur systematic errors.

2. A second source of circularly polarized light in the hard x-ray regime is to use purpose-built insertion devices. Planar wigglers and undulators do not produce circularly polarized light when viewed from out of the plane of the orbit, because they are comprised of equal numbers of left and right oscillations and the net helicity is zero. However, it is possible to design periodic magnet structures such that circularly polarized light is produced on-axis. These include crossed undulator pairs (i.e., a vertical undulator followed by a horizontal undulator close enough together for the radiation to remain coherent) and elliptical wigglers for which the electron motion is helical. These devices produce intense beams with high degrees of polarization, combined with the ability, in some cases, to rapidly switch the polarization state. However, they are expensive, and it can be difficult to preserve the circular polarization through the optical elements. To date there have been only a few magnetic scattering beamlines built around such devices in the hard x-ray regime.

3. A third device converts linear polarization into circular polarization, with some cost in intensity. This is a quarter wave plate. In the optical regime, such devices are constituted from birefringent materials—i.e., optically anisotropic materials whose thickness is chosen such that a linearly polarized wave sent in at 45° to the optical axes has its two components phase-shifted by $\pi/2$ relative to one another, thus producing circularly polarized radiation. In the hard x-ray regime, a similar result may be achieved by utilizing the fact that dynamical diffraction is birefringent. In this case, birefringent refers to the fact that the refractive index is different for polarizations parallel or perpendicular to the diffracting planes. Thus, by arranging the Bragg planes to be at 457° with respect to the plane of linear polarization, an x-ray phase plate may be constructed. The most effective devices employ a transmission Bragg geometry, for which the phase shift between the π and σ components is inversely proportional to the angle of offset from the Bragg peak. The resulting transmitted beam is circularly polarized, and the circularly polarized flux is maximized by minimizing absorption losses. X-ray phase plates have been constructed from silicon, germanium, and diamond (Hirano et al., 1993, 1995). For sufficiently thin crystals, transmission factors of 10% to 20% are achievable. Since these devices may be employed on-axis of insertion device beamlines, a relatively high circularly polarized flux is obtained. These devices are particularly well suited for use with undulator radiation, where the collimation of the beam does not compromise the polarization by providing a spread in angles incident on the phase plate. For example, a diamond (111) phase plate 0.77 mm thick, installed at the undulator beamline, ID10, at the ESRF, achieved a degree of circular polarization $P_\eta = 0.96$, with a transmission of 17% (Sutter et al., 1997). The crystal was offset 0.016° from the Bragg peak. Typically, such phase plates are the last optical component before the sample.

Finally, we note that for experiments performed at the M edges of the actinides, the problem of absorption becomes acute, and this must be reflected in the beamline design. The number and total thickness of all x-ray windows should be minimized. At 3.7 keV, the absorption length of Be is $\Lambda = 0.5$ mm, and for Kapton $\Lambda = 0.05$ mm. For comparison, the same numbers at 8 keV are $\Lambda(\text{Be}) = 5$ mm and $\Lambda(\text{Kapton}) = 0.7$ mm. This puts constraints on the design of the experiment. For example, in their work on uranium arsenides, McWhan et al. (1990) utilized a beamline configuration with only one Be window and a further 500 μm of Be and 39 μm of Kapton between the source and detector. In addition, a helium-filled bag was placed over the spectrometer, so that the beam path was either through vacuum or helium.

The Spectrometer. Often, no special equipment is required for the magnetic scattering spectrometer. For the study of antiferromagnets, in particular, a standard x-ray diffraction spectrometer, such as those manufactured by Huber GmbH (*http://www.xhuber.com*) is sufficient. Larger, more robust spectrometers have also been made for magnetic scattering beamlines by, for example, Franke GmbH (X22C, NSLS; *http://www.franke-gmbh.de*) and Micro-Control (ID20, ESRF). These have the advantage that they can support large cryostats, for example. The latter design also allows for diffraction in both σ-incident and π-incident geometries with the same spectrometer.

Two types of detector are commonly used. The NaI photomultiplier tube is frequently the workhorse of such experiments, with a relatively low dark current (<0.1 counts per sec) and a high efficiency in the regimes of interest. However, it has poor energy resolution ($\Delta E/E \sim 0.3$). This is a particular problem for resonant experiments if an analyzer is not used, because of the large background arising from the fluorescent decays associated with the creation of the core hole. In addition, harmonic rejection of such detectors is not always sufficient. In such circumstances, a solid-state detector is used. This has an energy

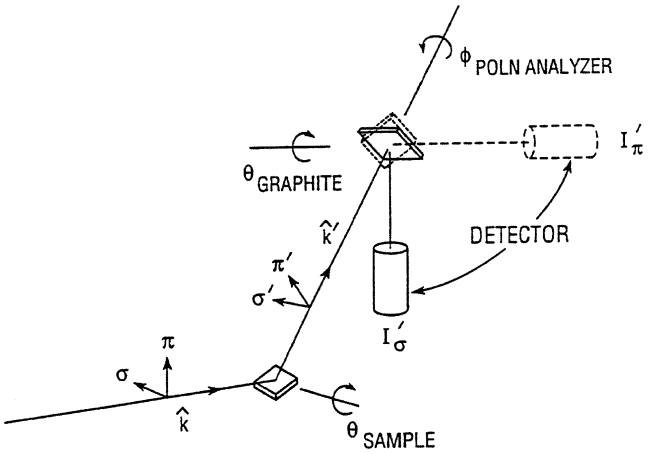

Figure 4. Linear polarization analyzer. When the analyzer, with a Bragg angle of 45°, is set to diffract in the scattering plane (solid lines), the σ' component of the scattered beam is detected and the π' component suppressed. Rotating the analyzer crystal by 90° about the scattered photon wave-vector, $\vec{k}'$, ($\phi_{poln\ analyzer} = 90°$) selects the π' component of the scattered beam (dotted lines). Figure taken from Gibbs et al. (1988).

resolution, $\Delta E/E$, of approximately 0.02, which allows for the removal of the fluorescent background with electronic discrimination. Often the fluorescence is in fact recorded simultaneously with the elastic signal by means of a multichannel analyzer. This then provides an on-line calibration of the energy. In addition, this signal is directly proportional to the intensity incident on the sample and may be used to normalize the scattered count rate. This method is of particular value when measuring the integrated intensity for a number of Bragg peaks with different beam footprints on the sample.

For polarization analysis experiments, a polarimeter must be mounted on the 2θ arm of the spectrometer. A number of ways of measuring the polarization have been developed, including methods to determine the complete polarization state with multiple beam diffraction methods (Shen et al., 1995). However, for analyzing linear polarization, the simplest method is to choose an analyzer crystal with a Bragg angle of $\theta_A = 45°$. This geometry is illustrated in Figure 4, taken from Gibbs et al. (1988). With the analyzer crystal set to diffract in the scattering plane, the linear component perpendicular to the diffraction plane (σ component) is reflected, while the parallel (π) component is suppressed. If the analyzer crystal is rotated by 90° about the scattered beam, the π component is reflected and the σ component is suppressed. Several devices have been built based on such an approach (see, e.g., Gibbs et al., 1989, and Brückel et al., 1996).

In order to perform quantitative polarization analysis, one must measure the integrated intensities of both the σ and π scattered components. How this is achieved depends on the relative divergences in the vertical and horizontal directions (which depend on the sample and beamline optics) and the mosaic of the analyzer crystal. For example, in the early work on holmium (Gibbs et al., 1991), the perpendicular and parallel divergences of the scattered beam were 0.05° and 0.03°, respectively,

Table 2. Selected Crystals and the Energy for Which $\theta_{anal} = 45°$

Crystal	Energy (keV)	Crystal	Energy (keV)
Al(111)	3.75	PG(006)	7.85
LiF(200)	4.35	Ge(333)	8.05

and a pyrolytic graphite crystal was used as an analyzer ($\theta_A = 45°$ at $E = 7.85$ keV). This has a mosaic of 0.3° and therefore effectively integrates over the scattered beam. In this limit, it is sufficient to rock the sample in both configurations to obtain integrated intensities.

The choice of analyzer crystal is dictated by the need to obtain a reflection close to 45° at the energy of interest, and to match the experimental conditions. A number of crystals are listed in Table 2.

Inevitably, a compromise must be made, typically in the Bragg angle of the crystal. The leakage rate, i.e., the fraction of intensity from the other polarization channel that is reflected, is equal to $\cos^2(2\theta_A)$. For a Bragg angle of $\theta_A = 43°$, the leakage is $\approx 0.5\%$, so such a crystal is relatively tolerant of errors (the actual leakage also depends on the analyzer mosaic and the beam divergence).

Specific Experimental Examples

X-ray magnetic scattering offers a wealth of information on the magnetic order of a system, and the combination of resonant and non-resonant techniques make it widely applicable. It is therefore not possible to adequately represent all the practical aspects of the various implementations of the principles discussed above (see Principles of the Method). In the following, four broad classes of experiments are identified. In each case, a few examples are given to illustrate some of the strengths of the particular technique, together with some of the different experimental realizations.

Non-resonant Scattering: Antiferromagnets. The implementation for non-resonant magnetic scattering from antiferromagnets is relatively straightforward. The experiments are done at fixed incident energy, well away from any absorption edges; the magnetic signal is well separated from charge scattering (even for long period incommensurate structures) and the scattering may be interpreted directly in terms of magnetic densities. The principal difficulty lies in the weakness of the signal and the need to separate it from the background (diffuse) charge scattering. This is simplest to achieve in samples of high crystallographic quality, well matched to the incident beam divergence. For systems with long-range magnetic order, this will maximize the peak count rate. The situation may be further improved by employing an analyzer crystal on the 2θ arm, in front of the detector. This sharpens the longitudinal resolution and discriminates against any broad diffuse background. In addition, the

effective energy resolution is then ~10 eV, and this will eliminate any fluorescence background. For samples of reasonable quality (mosaic <0.1°), the use of a Ge(111) analyzer, for example, will dramatically improve the signal-to-noise ratio of a magnetic peak with long-range order, at a cost of a factor of ~5 in the counting rate. If there is a significant amount of charge scattering present (for example, when studying thin films, reflectivity from the various interfaces may be the dominant contribution to the background), then it may be preferable to employ a polarization analyzer and record only the photons of rotated polarization. Depending on the degree of incident polarization, as well as the magnetic structure, this can provide gains in data quality. For non-resonant scattering, one is free to pick the energy at which the experiment is performed, such that an appropriate analyzer crystal has a Bragg angle of exactly 45°.

As mentioned in the introduction, the weakness of the scattering can also be an advantage, because it ensures that extinction effects, which can prevent reliable determination of intensities, are negligible. This has been exploited in a number of experiments in which precise measurements of the evolution of the order parameter are required.

One such example is the series of experiments performed on dilute antiferromagnets in an applied field. These are believed to be realizations of the random field Ising model and have attracted a great deal of interest, including numerous neutron scattering investigations. These latter, however, are hindered by extinction effects and by an inability to study the long length scale behavior. In addition, the samples must be doped with non-magnetic ions in order to induce the required phenomena and concentration gradients in the samples can then be a serious problem, masking the intrinsic behavior close to the phase transition. This illustrates another strength of x-ray magnetic scattering for these experiments, that is the small penetration depths (~5 μm in this case), which significantly reduce the effects of any concentration gradients. The experiments were performed on MnF_2 and FeF_2, doped with Zn, utilizing a superconducting magnet to apply fields up to 10 T (Hill et al., 1993, 1997). The cryostat constrained the scattering plane to be horizontal, that is a π incident geometry was utilized.

One problem in this work that is worth mentioning (Hill et al., 1993) arose because the crystals order as commensurate antiferromagnets, but have two magnetic ions per unit cell, so that the periodicity is not doubled by the magnetic order. Magnetic scattering can then only be observed at reflections for which the charge structure factor is identically zero. Under these conditions, multiple charge scattering can be a problem (see Problems), and efforts must be taken to reduce such scattering.

Non-resonant experiments to separate $\vec{L}$ and $\vec{S}$ contributions to the ordered moment in an antiferromagnet have also been performed. These require measuring the integrated magnetic intensities, in both scattered polarization channels, for a number of Bragg peaks. Integrated intensities are obtained by rocking the sample and/or the polarization analyzer in an appropriate manner (see, e.g., Langridge et al., 1997). These must be corrected for any differences in the rocking widths of the analyzer in the two configurations. Any charge scattering background may be subtracted off by performing the same measurements above the Nel temperature. The integrated intensity must also be corrected for absorption. The magnetic structure must already be known and Equation 6 is then used to relate the intensities to the quantities $\vec{L}$ and $\vec{S}$. Typically, intensities are not put on an absolute scale because of the difficulty in making extinction corrections for the strong charge Bragg peaks. Thus, often it is the ratio $\vec{L}/\vec{S}$ which is determined, or more precisely, $(\mu_L f_L(\vec{Q}))/(\mu_S f_S(\vec{Q}))$, where $f_{L,S}(\vec{Q})$ are the orbital and spin form factors, and $\mu_{L,S}$ the atomic orbital and spin moments. Such experiments require a high degree of incident polarization in order to simplify the analysis and thus benefit greatly from the third-generation sources. Examples of measurements of this type that have been carried out on antiferromagnets include work on holmium (Gibbs et al., 1988, 1991; C. Sutter, unpublished observation), uranium arsenide (McWhan et al., 1990; Langridge et al., 1997), and NiO (Fernandez et al., 1998).

The non-resonant cross-section, (Equation 6) is energy independent, and this may be exploited to work at very high incident photon energies ($\hbar\omega \geq 80$ keV). While experiments at these energies bring new difficulties, there are obvious advantages, primarily the greater penetration depth (~mm rather than ~μm), which ensures that bulk-like properties are measured. In addition, the larger penetration depth can provide enhancements in the scattered count rate, relative to that at medium x-ray energies. This is because for weak reflections that are limited by absorption, such as magnetic peaks, the integrated scattered intensity is proportional to the scattering volume. Thus, quite large increases can be realized in going from medium to high energies due to this volume enhancement (in contrast to the case for strong charge reflections, for which the intensity is limited by extinction effects). However, care must be taken to match the instrumental resolution (which is typically extremely good at high x-ray energies) with the quality of the sample to take advantage of any increases.

The principles of high-energy x-ray magnetic scattering experiments are identical to those described previously; however, there are some differences in implementation. Firstly, the need for specialized x-ray windows is eliminated and simple Al windows on cryostats may be used (e.g., at 80 keV, 10 mm of Al results in a 40% loss of intensity). This can bring improvements in parameters such as temperature stability. The experiments are typically performed in transmission, and the need to worry about sample surface preparation is eliminated. At high energies, the Bragg angles are correspondingly reduced; for low index reflections, the non-resonant cross-section greatly simplifies. Neglecting terms containing $\sin^2\theta$, then

$$\langle M_{\mathrm{m}} \rangle = i\left(\frac{\hbar\omega}{mc^2}\right)\begin{pmatrix} \sin 2\theta S_2 & 0 \\ 0 & \sin 2\theta S_2 \end{pmatrix} \qquad (25)$$

and the experiments are only sensitive to the spin component perpendicular to the scattering plane. For linear incident polarization, the scattering does not alter the

polarization state. In this limit, one cannot distinguish the magnetic scattering from charge scattering through the use of polarization analysis. On the other hand, one obtains the spin density, without the need for polarization analysis to separate the orbital contribution. High-energy experiments can then be combined, in principle, with neutron diffraction experiments to derive $\vec{L}$ and $\vec{S}$.

A disadvantage of working at such high energies is the limited number of beamlines capable of providing a high flux at the relevant wavelengths. In addition, higher-order contamination can be a significant problem because of the lack of x-ray mirrors, and multiple scattering, if present, is significantly worse at high energies. Nevertheless, successful experiments have been performed (Lippert et al., 1994; Strempfer et al., 1996; 1997; Vigliante et al., 1997; Strempfer et al., 2001).

Non-resonant Scattering: Ferromagnets. Non-resonant magnetic scattering can be used to determine $\vec{L}$ and $\vec{S}$ in ferromagnets. One particular implementation for such an experiment, first proposed by Laundry et al. (1991), utilizes a white, elliptical polarized beam incident on a single crystal and an energy dispersive detector positioned at a scattering angle of 90°. The advantages of this method are that it is relatively insensitive to sample motion upon reversal of the magnetization, that the scattering is performed at the optimum angle of 90°, and that several reflections may be collected at once. The disadvantages are that strong fluorescence lines may superpose some Bragg peaks and that high count rates may saturate the detector, giving rise to dead-time errors. If measurements are made for two different magnetization angles, α (Equation 24), then the $\vec{L}$ and $\vec{S}$ contributions may be separated. In an experiment on $HoFe_2$, Collins et al. (1993) chose $\alpha = 0$ and 90°, as shown in Figure 5. The ratio of the asymmetry ratios then determines the spin-orbital ratio

$$\frac{F_S}{F_L} = \frac{R(\alpha = 90^\circ)}{R(\alpha = 0)} - 1 \tag{26}$$

The measurements of Collins et al. (1993) were in approximate agreement with band-structure calculations. The disadvantage of this method is the need for two easy magnetization axes 90° apart and the requirement that the material be magnetically soft. It should also be mentioned that in cases for which absorption edges are accessible, the technique of XMCD (X-RAY MAGNETIC CIRCULAR DICHROISM) can provide an alternative to such approaches and can determine $\langle L_z \rangle$ and $\langle S_z \rangle$ independently, in an element-specific manner, in ferromagnets.

Resonant Scattering: Antiferromagnets. The principal difference between a resonant and a non-resonant magnetic scattering experiment is the need for a scanning monochromator. The incident energy resolution should match the width of the resonance to attain the greatest enhancement, or exceed it, if information on lifetimes is required. In order to compare the experimentally measured resonances with the theoretical predictions of Equation 15, integrated magnetic intensities must be recorded at each energy and corrected for absorption. While calculations for the energy dependence of the absorption exist (Cromer and Lieberman, 1981), these are not reliable in the vicinity of the edge, where they are most important. Ideally, to obtain the appropriate corrections, the absorption would be measured directly through a thin film of the sample material. By reference to calculations made far from the edge, such data may be brought to an absolute scale and $\mu(E)$ obtained. However, this is not always possible, and various schemes have been attempted to circumvent this problem. One is to obtain μ from measurements of the fluorescence intensity, I_f using the relation

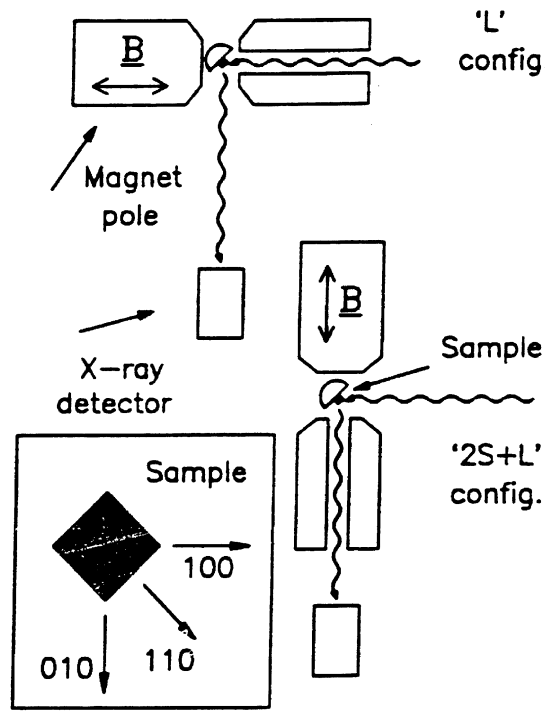

Figure 5. Schematic of the diffraction geometry used in Collins et al. (1993), for scattering from ferrimagnetic $HoFe_2$. In the top configuration, with the sample magnetized along the incident beam direction, the scattering is only sensitive to the orbital moment density. In the second configuration (bottom), the sample is magnetized perpendicular to the incident beam and contributions from both $\vec{L}$ and $\vec{S}$ are observed. The sample is a single crystal and the incident beam is "white" (unmonochromatized).

$$I_f(E) = C \frac{\mu_R(E)}{\mu_S(E_f) + \mu_S(E) \dfrac{\sin\psi}{\sin\phi}} \tag{27}$$

where $\mu_S(E)$ is the absorption of the sample at photon energy E, E_f is the fluorescence energy, μ_R is the absorption of the resonance ion and ψ and ϕ are the angles of incidence and fluorescent beams, respectively. The fluorescence is measured as a function of incident energy by placing an open detector at 90° to the scattering plane (to minimize charge scattering) and with the discriminator set to select the fluorescent energy. The constant, C, may

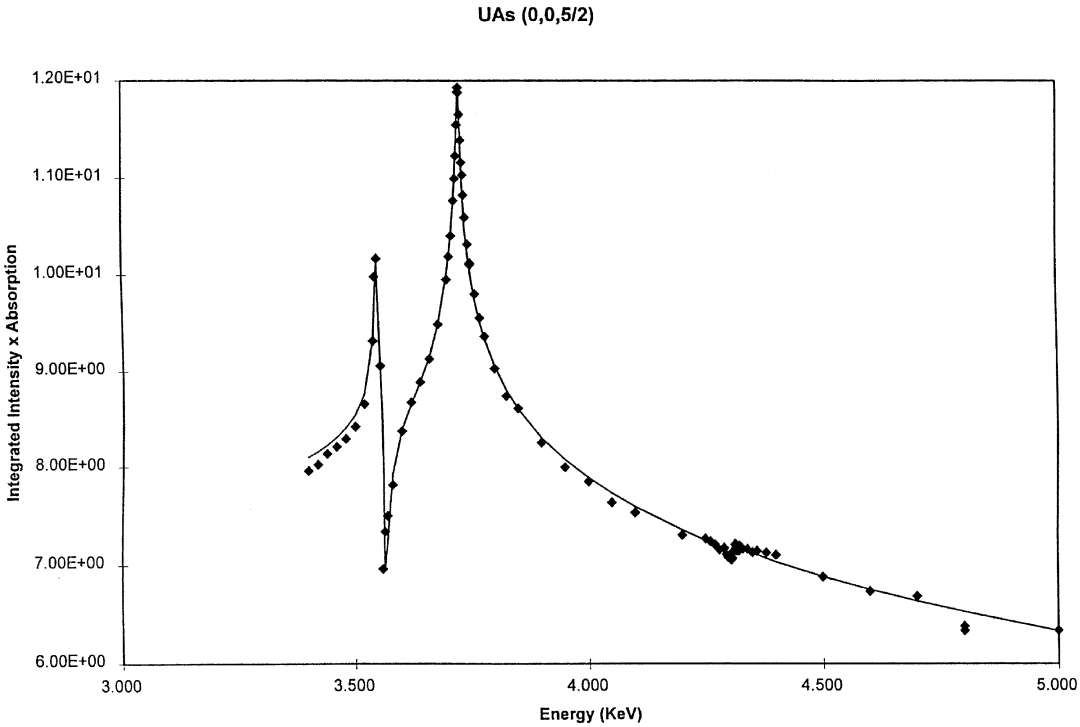

Figure 6. The energy dependence of the magnetic scattering at the (0,0,2.5) antiferromagnetic Bragg peak in uranium arsenide as the incident energy is scanned through the U M_5, M_4, and M_3 edges. Each data point represents an integrated intensity and is corrected for absorption. The solid line is a fit to three dipole oscillators (McWhan, 1998).

be obtained by normalizing the data to the calculated values far from the edges (see, e.g., McWhan et al., 1990; McWhan, 1998). This method has its limitations, and other approaches have also been tried (e.g., Tang et al., 1992; Sanyal et al., 1994). For a Bragg peak along the surface normal, and a flat sample, the absorption correction corresponds to simply multiplying the integrated intensity by μ. The angular factors of the cross-section, Equation 15, will also contribute some energy dependence, together with the Lorentz factor $1/\sin 2\theta$.

Figure 6 shows the absorption-corrected energy dependence of the (0,0,2.5) magnetic Bragg peak in uranium arsenide on scanning the incident energy through the U M_5, M_4, and M_3 edges (McWhan et al., 1990). The solid line is a fit to three coherent dipole resonances, together with the appropriate angular factors. These data were taken with an incident energy resolution of 1 eV, and the authors were thus able to extract branching ratios and lifetimes for the various resonances, though these are sensitive to the absorption correction and are therefore only semiquantitative. The overall energy dependence illustrated in Figure 6 is also sensitive to the exchange splitting present in the excited state, and these data led McWhan and co-workers to conclude that it was smaller than 0.1 eV.

The position of the resonance is a function of atomic species and valence state, and thus this technique also provides a means for investigating magnetic order in mixed valent compounds. For example, McWhan et al. (1993) studied TmSe. In this material both Tm^{2+} and Tm^{3+} configurations exist, each of which may carry a magnetic moment. The resonance energies of the two ions differ by 7 eV, as determined by x-ray absorption spectroscopy (XAS) which is comparable to the energy width of the resonances. Thus, by tuning the incident photon energy to one or other of the dipole transitions of the two ionic configurations, the dominant contribution to the cross-section may be varied from one configuration to the other, and the magnetic order of the two valences may be studied separately. The (003) magnetic reflection showed two peaks as a function of energy, demonstrating that both valence states exhibit long-range magnetic order.

Both non-resonant and resonant magnetic x-ray scattering may be used to determine moment directions in ordered structures, and this has been demonstrated for a number of antiferromagnets. To do this, integrated intensities of a number of magnetic Bragg peaks are measured, and then the Q dependence of the intensities is fit to expressions such as Equation 9 and Equation 15. Detlefs et al. (1996, 1997) demonstrated this approach in studies of RNi_2B_2C, with R = Gd, Nd, and Sm. For R=Gd and Sm, the structure could not be solved using neutron scattering techniques because of the high neutron absorption of the Gd and Sm, together with the B. The different polarization dependences of the non-resonant, resonant dipole, and resonant quadrupole scattering were exploited to solve the structures from a relatively small data set. Before a direct comparison with the cross-section can be made, a variety of other angular factors must be included. For a Bragg peak at an angle α away from the surface

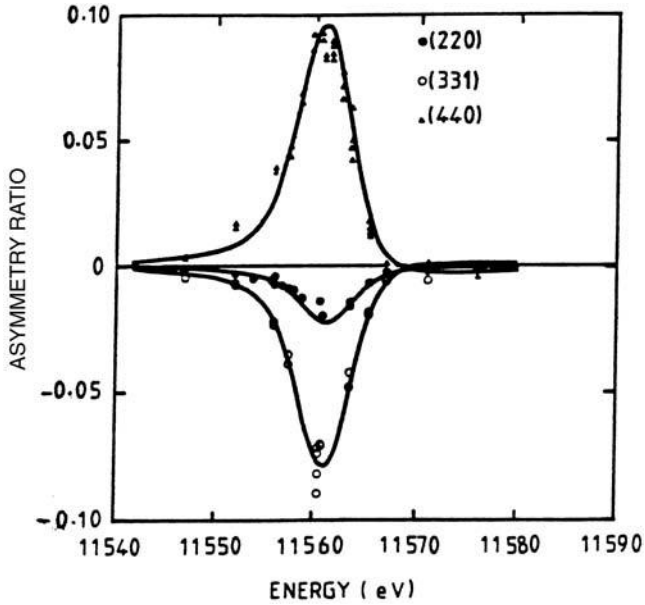

Figure 7. The energy dependence of the asymmetry ratios for the (220), (331) and (440) Bragg peaks of the ferromagnet, $CoPt_3$. Data show a large resonant enhancement at the Pt L_3 edge and are well fit by a single $2p \rightarrow 5d$ dipole transition. Taken from de Bergevin et al. (1992).

normal and scattering from a flat fully illuminated sample, then

$$I \propto \left| \sum_n e^{i\vec{Q}\cdot\vec{r}_n} f_n^{res} \right|^2 \frac{\sin(\theta+\alpha)\sin(\theta-\alpha)}{2\mu\sin\theta\,\cos\alpha\,\sin 2\theta} \qquad (28)$$

where the Lorentz factor has also been included. A more detailed study has been carried out on pure Nd (D. Watson et al., 1998).

These measurements are made simpler by the lack of a magnetic form factor for resonant scattering, and the fact that the $F^{(L)}$ of Equation 15 are independent of the scattering angle. Apart from an overall scale factor, then, the only unknowns are the spin components, z_1, z_2, and z_3. A coordinate transformation, which depends on θ, is then required to rotate into the coordinate system of the sample, obtaining the moment directions relative to the crystallographic axes.

Other experiments on antiferromagnets have studied thin films, ultra-small samples, multilayers, and compounds with more than one magnetic species. These take advantage of the small penetration depth, high-resolution, and element specificity of the technique. However, in implementation, they do not involve concepts different from those already discussed.

Resonant Scattering: Ferromagnets. The first experimental observation of magnetic scattering with x-rays from ferro- and ferrimagnets is credited to de Bergevin and Brunel (1981a,b), who utilized Cu K_α radiation to study powdered samples of zinc-substituted magnetite, $Fe_{2-x}\ Zn_xO_4$, and Fe. Interference was induced through the proximity to the iron K edge. Studies of interfacial magnetism were first performed in ferromagnetic multilayers, namely Gd-Y (Vettier et al., 1986), utilizing non-resonant magnetic-charge interference scattering. The interference was induced by tuning through the Gd L_2 and L_3 edges.

More recently, de Bergevin et al. (1992) carried out a study of $CoPt_3$ utilizing resonant magnetic scattering at the Pt L_3 edge. The asymmetry ratio was determined for three Bragg peaks, and as a function of energy (Fig. 7). The data are well fit by a single dipole ($2p \leftrightarrow 5d$) resonance, with a peak scattering amplitude of $0.8r_0$.

Surface Magnetic Scattering. The large resonant enhancements in the cross-section allow the measurement of the very weak signals associated with the surface magnetization density profile. To a first approximation, the experimental techniques for such work are identical to those developed for surface x-ray scattering (SURFACE X-RAY DIFFRACTION), with the additional complication of a strong energy dependence to the scattering.

Briefly, for a semi-infinite crystal, the diffraction pattern consists of rods of scattering, known as truncation rods, which pass through the Bragg points and which are parallel to the surface normal (Fig. 8A). Characterizing the intensity along such rods provides information on the decay of the charge density near the surface. Similarly, magnetic truncation rods are present when a magnetic lattice is terminated, and the decay of the magnetic intensity is related to the profile of that magnetic interface. For a step function interface, the diffraction pattern is the convolution of a reciprocal lattice of delta function Bragg peaks with the Fourier transform of the step function, $1/q$. This gives a $1/(\Delta q_z)^3$ broadening of each Bragg point, where Δq_z is the deviation from the Bragg peak, along the surface normal. If a broader interface is present, the Fourier transform will be sharper than $1/q$ and the intensity fall-off around each Bragg point will be faster (Robinson, 1991). Thus, measuring the intensity fall-off measures the Fourier transform of the magnetic interface profile, which may in principle be different from the chemical interface.

For an antiferromagnet, there is both a magnetic contribution to the charge rods, as well as pure magnetic rods, as shown in Figure 8A, taken from G. Watson et al. (1996b; 2000). In addition to scans around Bragg points, the surface magnetic behavior may also be probed explicitly by employing the grazing incidence scattering geometry shown in Figure 8B. α_j and α_s are the angles of the incident and scattered beams with respect to the surface, respectively. In the figure, most of the momentum transfer is in the plane of the crystal $\vec{q}_\parallel$, with a small component along the surface normal, $\vec{q}_z$. For example, such a situation occurs for scans along the (0,1,L) magnetic rod, with L small. In such a geometry, it is possible to take advantage of the well known enhancement in the scattering, when $\alpha_i = \alpha_s = \alpha_c$, the critical angle. Such techniques have been demonstrated in the antiferromagnet UO_2, working at the U M_4 edge (G. Watson et al., 1996b; 2000). The energy dependence of scans taken along a magnetic rod (0,1,L) are shown in Figure 9 (G. Watson et al., 1996b; 2000). These data illustrate that the critical angle, for which the intensity is a maximum, is also a function of the incident energy, since $\alpha_c^2 \sim (Z + f'')\rho\lambda$, where Z is the total charge, ρ is the average atomic density and, f'' the

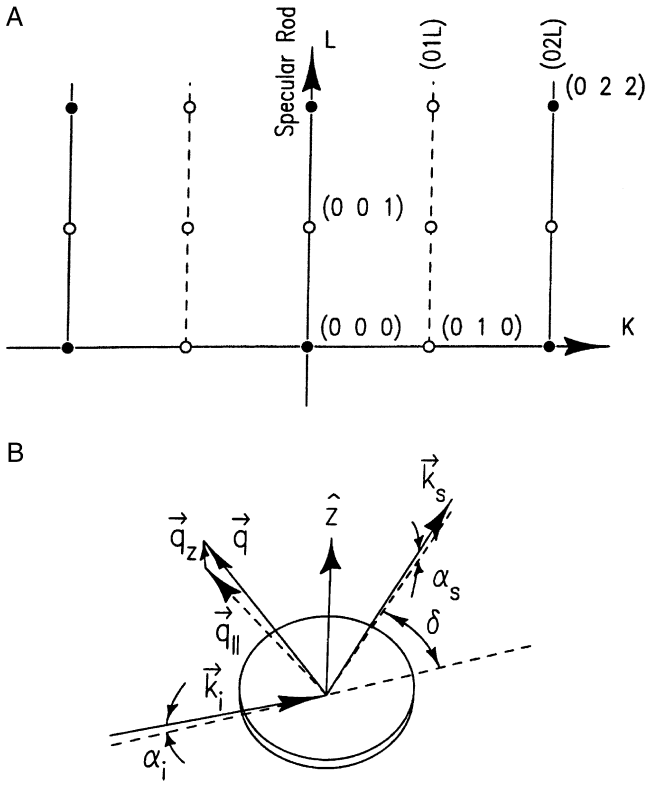

Figure 8. (**A**) Schematic of reciprocal space for a semiinfinite antiferromagnet, illustrated for UO_2. In addition to the charge (closed circles) and antiferromagnetic (open circles) bulk Bragg peaks, there are rods of scattering connecting the Bragg points and running parallel to the surface (vertical lines). The dotted lines are pure magnetic rods of scattering. The specular rod (00L) corresponds to scattering in which there is no in-plane momentum transfer, and the angle of incidence equals the angle of reflection. (**B**) Scattering geometry for surface magnetic scattering. α_i and α_S are the angles of incidence and exit, normal to the surface, and δ is the in-plane scattering angle. In this diagram, the momentum transfer $\vec{q}$ is largely in-plane, $\vec{q}_{\|}$, with a small component normal to the surface, $\vec{q}_z$. Figure taken from G. Watson et al. (1996b).

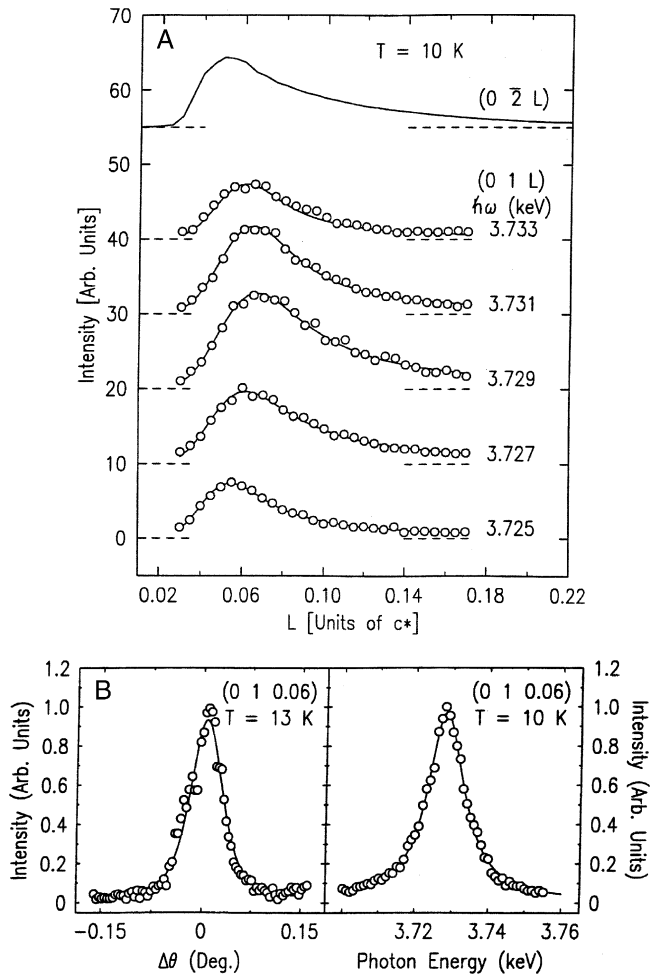

Figure 9. (**A**) Energy dependence of scans along the (0,1,L) magnetic rod in UO_2. The data exhibit an enhancement at an energy dependent critical angle, α_c. For comparison, the same scan is shown for along the (0,2,L) charge rod, solid line. (**B**) Transverse scan across the (0,1,L) magnetic rod. (**C**) Intensity of the magnetic rod as a function of incident photon energy. Figure taken from G. Watson et al. (1996b).

real part of $f_n^{\rm res}$ of Equation 4. Measurements of α_c thus provide an independent measure of f'. Scans across the magnetic rod provide information on the disorder of the magnetic layer normals. In UO_2, such scans were found to be identical to those of the charge rods (Fig. 9). The scattered intensity may be described by

$$\frac{I(k_i,k_s)}{I_0} = \frac{A}{A_0}\sin\alpha_i\,\sin\alpha_s|T(\alpha_i)|^2|T(\alpha_s)|^2 \times \left|\sum_{n=0}^{\infty} r_0 f_n^{\rm res}\rho_n^{\rm M}(q_{\|})e^{iq_z z_n}\right|^2 \quad (29)$$

where $T(\alpha)$ is the Fresnel transmission coefficient, A/A_0 the ratio of the illuminated area to the cross-sectional area of the beam, I_0 the incident flux, $r_0 f_n^{\rm res}$ the magnetic scattering amplitude, and $\rho_n^{\rm M}$ the magnetic density in the nth layer with wave-vector $q_{\|}$. The fits to this form in Figure 9A assume a perfectly sharp magnetic interface, and describe the data well. This technique can be used to determine the temperature and depth dependence of the magnetic order parameter profile. By varying L, the effective penetration depth varies. For example, in UO_2, for $L = 0.075, 0.15$, and 1, the corresponding penetration depth was 50, 120, and 850Å, respectively.

Similar studies of surface magnetism have been carried out in ferromagnets, for which the asymmetry ratio is measured along the truncation rod. This was first done in the soft x-ray regime at the Fe $L_{2,3}$ edges (Kao et al., 1990) and Co $L_{2,3}$ edges (Kao et al., 1994) in which the specular magnetic reflectivity was measured (i.e., (0,0,L) scans). This describes the magnetic order normal to the surface. Recent studies of Co multilayers have focused on the off-specular diffuse scattering, which describes the roughness of the interface (Mackay et al., 1996). In this work, the magnetic interfaces were found to be less rough than the structural interfaces. Finally, working at the Pt L_3 edge, Ferrer et al. (1996) have measured complete magnetic truncation rods in ferromagnetic $Co_3Pt(111)$ and Co/Pt(111) ultra-thin films (Ferrer et al., 1997). The advantage of resonant mag-

netic scattering in such studies is the technique's element specificity, allowing multicomponent systems to be resolved and buried interfaces to be studied, in contrast to scanning probe techniques. In addition, it is essential to characterize the structural interface(s) in order to fully understand the magnetic interface. X-ray scattering techniques are able to characterize both the structural and magnetic interfaces with the same depth sensitivity and resolution, in the same experiment.

DATA ANALYSIS AND INITIAL INTERPRETATION

Quantities such as ordering wave vector, ordered moment, and moment direction may be obtained from the position and integrated intensity of magnetic reflections. For more detailed information on the magnetic correlations, e.g., to extract forms for the moment-moment correlation function, as well as parameters such as correlation lengths and critical exponents, then it is necessary to fit the lineshapes of the magnetic peaks. The observed intensity, $I\vec{Q}$, is given by the convolution of the cross-section, $d\sigma(\vec{Q})/d$, and the instrumental resolution $R(\vec{q})$

$$I(\vec{Q}) = \int R(\vec{q}) \frac{d\sigma(\vec{Q}-\vec{q})}{d\Omega} d\vec{q} \qquad (30)$$

A common problem in the analysis of x-ray data is the accurate determination of $R(\vec{q})$. Ideally, a perfect δ-function scatterer (e.g., a silicon single crystal) is placed in the sample position and the resolution is measured at the relevant momentum transfers. The problem is that it is, in general, not possible to find a suitable test sample. A number of approaches are therefore adopted. For studies of critical fluctuations in the vicinity of a phase transition, it is common to take the scattering below T_N to be long-range ordered, i.e., resolution limited. Fits to scans through this Bragg peak can then be used to parameterize the resolution function and in fitting the experimental data, following Equation 30. In other cases, nearby Bragg peaks can be used, again as a lower bound on the resolution function (the intrinsic resolution is equal to or better than the apparent widths of the Bragg peaks). The longitudinal resolution width (i.e., along the momentum transfer) is controlled by the monochromator and analyzer, if present, or the angular acceptance of the detector, if not. For a given monochromator-analyzer combination, the longitudinal resolution is a minimum at the nondispersive condition, i.e., when the scattering vectors of the monochromator, sample, and analyzer are equal, and in alternating directions. For a beamline with a double crystal monochromator and analyzer, the in-plane resolution functions are often Lorentzian squared functions. The out-of-plane resolution is determined by collimating slits and can be approximated by a triangular function. In such a case, with the assumption that the resolution function is separable

$$R(\vec{q}) = \left(\frac{1}{w_x^2 + q_x^2}\right)^2 \left(\frac{1}{w_y^2 + q_y^2}\right)^2 \left(1 - \left|\frac{q_z}{w_z}\right|\right) \qquad (31)$$

where the x and y directions are transverse and longitudinal to the momentum transfer, and q_z is perpendicular to the scattering plane. For example, in a study of the critical fluctuations on holmium, Thurston et al. (1994) employed a Ge(111) analyzer and double bounce Ge(111) monochromator, and obtained resolution half-widths of 2.9×10^{-4}, 4.5×10^{-4}, and 4.3×10^{-3}Å^{-} in the transverse, longitudinal, and out-of-plane directions, respectively, at $Q = 1.92$Å^{-1}.

Approximating the out-of-plane resolution with a triangular function, as in Equation 31, has the advantage that the integration in the q_z direction may be performed analytically, for certain cross-sections, reducing the fitting of the data to a 2-D numerical integration and lessening the fitting time. Note that it is crucial that a full 3-D convolution procedure be carried out in fitting the data in order to obtain meaningful correlation lengths, even if the data themselves are only obtained in one direction.

Strictly, the cross-section is proportional to the dynamic structure factor, $S(\vec{Q}, \omega)$, where ω is the energy transfer of the scattering process. However, typically the energy resolution of an x-ray experiment is relatively broad (e.g., 1 to 10 eV) compared to the relevant magnetic energy scales, and all the magnetic fluctuations are integrated over, reducing $S(\vec{Q}, \omega)$ to the static structure factor, $S(\vec{Q})$. This is the quasi-elastic approximation. In turn, this structure factor may be expressed as

$$\frac{d\sigma}{d\Omega} = S(\vec{Q}) \propto \langle f(\vec{Q}) f(-\vec{Q}, t=0) \rangle = \langle |f(\vec{Q})|^2 \rangle \qquad (32)$$

i.e., the instantaneous correlation function. For non-resonant magnetic scattering, this may be directly related to a particular moment-moment correlation function for a given scattering geometry. In the MnF_2 example (see Principles of the Method), for which $\vec{L} = 0$, then for σ incident polarization, $S(\vec{Q}) = \langle \vec{S}_\perp(\vec{Q}) \vec{S}_\perp(-\vec{Q}) \rangle$, where $\vec{S}_\perp$ is the component of the spin perpendicular to the scattering plane, and we have ignored terms of order $\sin^2\theta$ in the scattering amplitude. For resonant scattering, the situation is more complex, (see e.g., Luo et al., 1993; Hill and McMorrow, 1996), though for first-order dipole scattering, and σ incident polarization, $f(\vec{Q}) \propto \hat{z}(\vec{Q}) \cdot \hat{k}_f$, the projection of the moment direction along the scattered photon direction.

The form of $S(\vec{Q})$ depends on the system under study. Thermal critical fluctuations, for example, are expected to give a Lorentzian-like behavior

$$S(\vec{Q}) \sim \frac{k_B T \chi(T)}{1 + (Q - Q_0)^2 / \kappa^2} \qquad (33)$$

where Q_0 is the Bragg position, and $\kappa = 1/\xi$ is the inverse correlation length. Fits to the temperature dependence of the parameters, $\chi = \chi_0((T - T_N)/T_N)^{-\gamma}$ and $\xi = \xi_0((T - T_N)/T_N)^{-\nu}$ allow for the determination of the critical exponents γ and ν. The order parameter exponent, β, is determined from fits to the temperature dependence of the integrated intensity below T_N, i.e., $I = I_0((T_N - T)/T_N)^{2\beta}$. Conversely, static random disorder may give rise to Lorentzian-squared lineshapes. One of the strengths of high-resolution x-ray scattering is the ability to distinguish between such behavior, even at relatively long length scales, e.g., close to a phase transition. This ability

has revealed new phenomena; for example the critical fluctuations immediately above a magnetic phase transition have been shown to exhibit two length scales (Thurston et al., 1993, 1994).

SAMPLE PREPARATION

The range of experimental conditions and techniques described in this unit make it very difficult to make any useful general statements about what is required by way of sample preparation. However, perhaps the most important point to emphasize is that the better the sample is characterized before any synchrotron beamtime, the higher the chances of success. Particularly important properties to be characterized include the sample orientation and crystallographic quality, and the magnetic properties, through, for example bulk magnetization measurements to obtain transition temperatures, magnetic anisotropies etc. (see MAGNETROMETRY, THERMOMAGNETIC ANALYSIS and TECHNIQUES TO MEASURE MAGNETIC DOMAIN STRUCTURES). For reflection experiments, surface (and near-surface) quality can be all-important. Careful polishing of the appropriate surface (ideally one with a surface normal parallel to the direction of interest in reciprocal space) can provide large rewards in terms of signal to noise. However, the appropriate polishing method is extremely sample dependent, with electro-polishing or the use of diamond paste (with perhaps a 1 mm grit size) among the most common techniques used (see SAMPLE PREPARATION FOR METALLOGRAPHY).

PROBLEMS

Other Sources of Weak Scattering

One of the biggest problems in x-ray magnetic scattering experiments is distinguishing the weak magnetic scattering from other possible sources of scattering that may produce peaks coincident with it. In general, there is no single test that is always definitive, and it is necessary to use a combination of tests, together with prior knowledge of the system. Possible sources of scattering are discussed under the following subheadings.

Multiple Scattering. This is the scattering that results from two (or more) successive Thomson scattering events. It occurs when a second reciprocal lattice point, $\vec{q}_2$, intercepts the Ewald sphere, in addition to the point of interest, $\vec{q}_1$. Then double scattering of the form $\vec{q}_2 + \vec{q}_3$ occurs, where $\vec{q}_3 = \vec{q}_1 - \vec{q}_2$ is another allowed reciprocal lattice vector. It is a particular problem in systems for which the magnetic unit cell is the same size as the chemical unit cell. At synchrotrons, multiple scattering count rates can exceed 10^4 photons per sec. The problem can be worse in crystals of lower crystallographic quality, or in lower-resolution configurations for which the requirements for making two successive Bragg reflections are less stringent. It is also aggravated at higher incident x-ray energies, because the radius of the Ewald sphere is larger and the probability of more than one reciprocal lattice point intercepting it becomes correspondingly larger. There are two possible means of eliminating multiple scattering. First, by rotating the Ewald sphere around the momentum transfer, $\vec{q}_1$, thus moving the $\vec{q}_2$ lattice point off the Bragg condition, while leaving the scattering vector unchanged. Typically, only small rotations are required and the scattering geometry relative to the moment directions need not be changed significantly. The second alternative is to vary the incident photon energy. This alters the radius of the Ewald sphere, sweeping it through reciprocal space, thus moving off the $\vec{q}_2$ lattice point. Such a tactic is not an option for resonant experiments.

Unless there is a structural phase transition associated with the magnetic ordering, the multiple scattering is likely to be temperature independent.

Higher Harmonic Contamination of the Beam. This was already discussed in the section on beamlines. It can produce scattering at non-integer, but commensurate reciprocal, lattice points, but may be readily identified by the energy of the scattered photons, even with a NaI detector. It is typically temperature independent.

Magnetoelastic Scattering. This is charge scattering that arises from a lattice modulation induced by the magnetic order. A magnetoelastic coupling can occur when, for example, there is a distance dependence to the exchange interaction, though other mechanisms are possible (see e.g., McMorrow et al., 1999). A magnetization density wave can then induce a displacement wave in the lattice with an amplitude which can depend only on the relative change in magnitude of the magnetization wave. In such a situation, it is straightforward to show (e.g., Lovesey and Collins, 1996) that for a transverse magnetization density wave, a distortion is induced at twice the wave-vector (i.e., half the wavelength) with an amplitude that varies as the magnetization squared. The diffracted intensity then varies as the moment to the fourth power. Thus, although the scatterings from both modulations will go to zero at the same temperature, they will have very different temperature dependences, and may be distinguished in this manner. In addition, of course, the charge scattering does not rotate the polarization state of the photon.

In general, more complicated modulations are possible, and the magnetoelastic scattering need not occur at twice the wave-vector of the magnetic scattering. Such is the case for the spin structure in holmium, for example (Gibbs et al., 1988, 1991). Below $T_N = 132$ K, holmium forms a basal plane spiral. At low temperatures, the magnetic wave-vector, τ_m, exhibits a tendency to lock into rational fractions of the c axis reciprocal lattice vector, $c* = 2\pi/c$. This is a result of a bunching (in pairs) of the moments in each successive ab plane about the six easy axes of magnetization, 60° apart. These pairs are known as doublets. If only a single spin (layer) is associated with a given easy axis, then this is known as a singlet, or spin slip. Ordered arrays of such spin slips give rise to the magnetic wave-vectors observed. In addition, at each spin slip, the phase of the magnetic modulation takes a jump in going from layer to layer and thus the magneto-elastic coupling is changed. This can give rise to a lattice distortion, with a new periodicity, τ_l, where $\tau_l = 12\tau_m - 2$ (Bohr et al., 1986). In general then, the magnetoelastic scattering can appear close to the magnetic scattering, and can even be

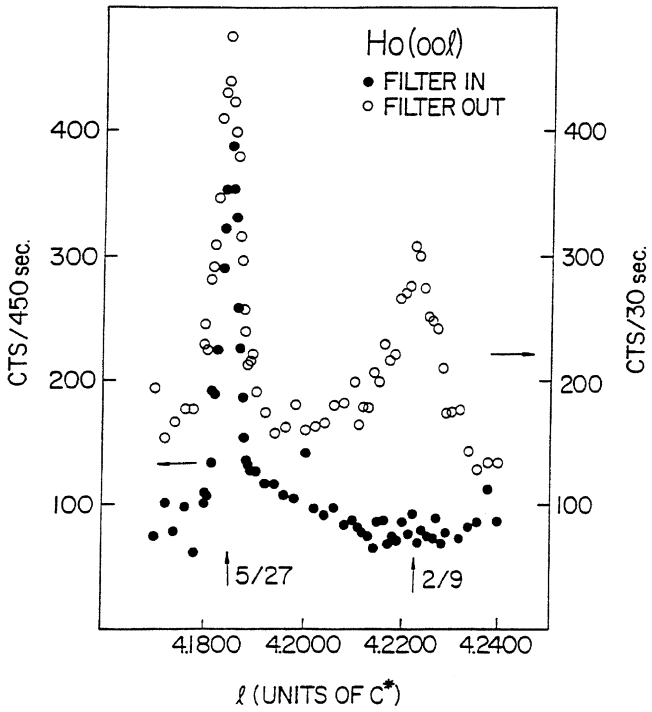

Figure 10. Magnetic and charge scattering in holmium. Data were taken at 7847 eV (off resonance). The open circles are recorded with no polarization analyzer and exhibit two peaks, at $\tau_m = 5/27$ and $\tau_I = 2/9$. With the polarization analyzer in, and set to record the $\sigma \rightarrow \pi$ scattering processes, only the τ_m peak is observed (closed circles). This is consistent with τ_m being magnetic scattering, and τ_I arising from charge scattering due to a lattice distortion induced by the magnetic order (Gibbs et al., 1985).

coincident with it (e.g., if $\tau_m = 2/11$). Polarization analysis is therefore required to distinguish the scattering arising from these two modulations, as illustrated in Figure 10, from Gibbs et al. (1985). The magnetic scattering observed at 5/27 is observed both with and without the analyzer. Conversely, the 2/9 peak is not seen in the $\sigma \rightarrow \pi$ channel and therefore corresponds to charge scattering. This peak is broader than the magnetic peak because of disorder in the spin slip structure, which is not reflected in the magnetic spiral.

Finally, there may be other couplings induced by the magnetic order that give rise to charge scattering. For example, in non-resonant magnetic scattering studies of $Fe_{0.75}Co_{0.25}TiO_3$, Harris et al. (1997) observed a quadratic increase in the scattering at the antiferromagnetic Bragg position (1,1,2.5), as a function of applied field, H. This effect was not seen in neutron data, and was attributed to a magneto-elastic distortion of the same wave-vector as the antiferromagnetic order. This can arise from terms in the free energy of the form $\rho_s M_s M$, where ρ_s is the staggered charge density, M_s the staggered magnetization, and M the uniform magnetization. If the cost of the distortion due to the elastic energy, $1/2\rho_s^2$, is included and the total minimized with respect to ρ_s, then it follows that $\rho_s \sim M_s M$. The intensity of the scattering from the charge density is then $I_{charge} \sim (M_s M)^2$ and that from the magnetic density, $I_{mag} \sim M_s^2$. Therefore, in this case, the two intensities have the same temperature dependence. However, in an applied field, the uniform magnetization will grow linearly (for small fields) and so the charge scattering will increase as H^2 (note that for $H = 0$, the charge scattering should go to zero). In addition, polarization analysis should be able to distinguish between scattering mechanisms in this case. The magnetoelastic scattering was not seen in the neutron diffraction experiments because of the weakness of the coupling between the neutrons and the charge density waves, relative to the strength of the magnetic interaction.

Near-Surface Effects

With the exception of high energy non-resonant scattering, all x-ray magnetic scattering experiments are performed in a reflection geometry, and penetration depths vary from perhaps ~10 μm in some non-resonant experiments to ~1000 Å, or less, in some resonant cases. While this surface sensitivity can be a boon, it can also cause varying degrees of complications in studying "bulk-like" behavior. The near-surface region can differ from the bulk in strain field densities, stochiometry, and different lattice connectivities (due to surface roughness), in addition to the intrinsic surface effects related to the termination of the lattice. Such effects can in turn alter the magnetic behavior of the near-surface region. This can be relatively benign, e.g., producing a single-domain state in cases where there would otherwise be a random distribution amongst energetically equivalent wave-vectors (e.g., Hill et al., 1995a; D. Watson et al., 1996), or more severe, introducing entirely new phenomena, such as the second length scale in magnetic critical fluctuations (e.g., Thurston et al., 1993, 1994; G. Watson et al., 1996a) or altering the observed magnetic state entirely (e.g., Hill et al., 1993). To date, little systematic work has been performed to assess the effect of surface preparation on "bulk" magnetic behavior and there is no general prescription for the correct surface preparation for a given x-ray experiment: It is something that must be approached on a case-by-case basis, and is beyond the scope of this unit. The purpose of this section is simply to emphasize the problem and to encourage careful characterization of the near-surface region for each experiment.

X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ANALYSIS

INTRODUCTION

X-ray diffraction (see SYMMETRY IN CRYSTALLOGRAPHY, X-RAY POWDER DIFFRACTION and SURFACE X-RAY DIFFRACTION) and x-ray-excited fluorescence analysis are powerful techniques for the nondestructive measurement of crystal structure and chemical composition. X-ray fluorescence analysis is inherently nondestructive, with orders-of-magnitude lower power deposited for the same detectable limit as with fluorescence excited by charged particle probes (Sparks, 1980). X-ray diffraction analysis is sensitive to crystal structure with orders-of-magnitude greater sensitivity to crystallographic strain than electron probes (Rebonato et al., 1989; Chung and Ice, 1999). When a small-area x-ray microbeam is used as the probe, chemical composition ($Z > 14$), crystal structure, crystalline texture, and crystalline strain distributions can be determined. These distributions can be studied both at the surface of the sample and deep within the sample (Fig. 1). Current state-of-the-art can achieve an ~1-μm diameter x-ray microprobe and an ~0.1 μm diameter x-ray microprobe has been demonstrated (Bilderback et al., 1994; Yun et al., 1999).

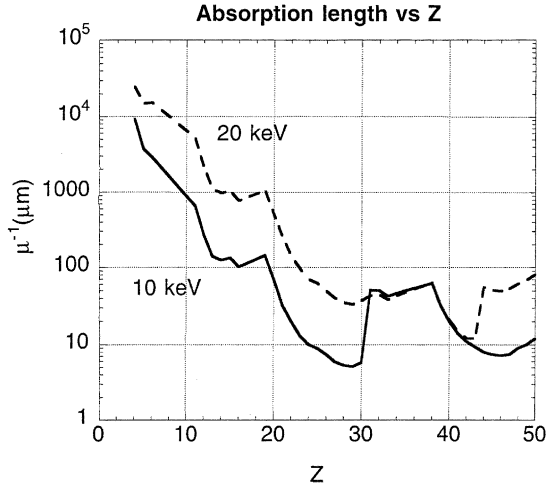

Figure 1. Absorption depth for 10- and 20-keV x rays as a function of elemental composition, *Z*.

Despite their great chemical and crystallographic sensitivities, x-ray microprobe techniques have until recently been restricted by inefficient x-ray focusing optics and weak x-ray sources; x-ray microbeam analysis was largely superseded by electron techniques in the 1950s. However, interest in x-ray microprobe techniques has now been revived (Howells and Hastings, 1983; Ice and Sparks, 1984; Riekel, 1992; Thompson et al., 1992; Chevallier and Dhez, 1997; Hayakawa et al., 1990; APS Users Meeting Workshop, 1997) by the development of efficient x-ray focusing optics and ultra-high-intensity synchrotron x-ray sources (Buras and Tazzari, 1984; Shenoy et al., 1988). These advances have increased the achievable microbeam flux by more than 12 orders of magnitude (Fig. 2; also see Ice, 1997); the flux in a tunable 1 μm-diameter beam on a so-called third-generation synchrotron source such as the Advanced Photon Source (APS) can exceed the flux in a fixed-energy mm^2 beam on a conventional source. These advances place x-ray microfluorescence and x-ray microdiffraction analysis techniques among the most powerful techniques available for the nondestructive measurement of chemical and crystallographic distributions in materials.

This unit reviews the physics, advantages, and scientific applications of hard x-ray ($E > 3$ keV) microfluorescence and x-ray microdiffraction analysis. Because practical x-ray microbeam instruments are extremely rare, a special emphasis will be placed on instrumentation, accessibility, and experimental needs which justify the use of x-ray microbeam analysis.

Competitive and Related Techniques

Despite their unique properties, x-ray microprobes are rare and the process of gaining access to an x-ray

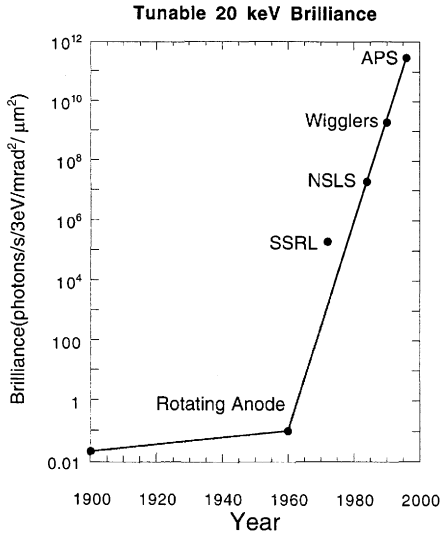

Figure 2. X-ray brilliance over the last 100 years shows an increase of more than 12 orders of magnitude since the use of hard x-ray synchrotron radiation sources began in the late 1960s. Both x-ray microdiffraction and x-ray microfluorescence have brilliance (photons/s/eV/mm^2/mrad^2) as the figure of merit (Ice, 1997).

microprobe can be difficult. For many samples, alternative techniques exist with far greater availability. Destructive methods such as laser ionization with mass spectrometry, as well as atom probe methods (Miller et al., 1996) can yield information on composition distributions. Atom probe measurements in particular can measure the atom-by-atom distribution in a small volume but require extensive sample preparation.

Auger spectroscopy (AUGER ELECTRON SPECTROSCOPY) and Rutherford backscattering techniques (HEAVY-ION BACKSCATTERING SPECTROMETRY) are other possible methods for determining elemental distributions. Auger analysis is inherently surface-sensitive, whereas Rutherford backscattering measurements can probe below the sample surface. Although these techniques are generally considered very sensitive, x-ray analysis can be even more sensitive.

The most directly comparable analysis techniques are charged particle microprobes such as electron or proton microprobes (Sparks, 1980; LOW-ENERGY ELECTRON DIFFRACTION and NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION). Whereas proton microprobes are almost as rare as x-ray microprobes, electron microprobes are widely used to excite fluorescence for chemical analysis. Electron microbeams are also used to measure crystallographic phase and texture, and strain resolution to 2×10^{-4} has been demonstrated (Michael and Goehner, 1993). Advanced electron microbeams can deliver 10^{12} to 10^{15} electrons/μm^2 and can be focused to nanometer dimensions. Electron microbeams are available at many sites within the United States and around the world.

Sparks (1980) has compared the relative performance of x ray, proton, and electron microprobes for chemical analysis. He specifically compared the intrinsic ability of x ray and charged particle microprobes to detect trace elements in a matrix of other elements. He also compared their relative abilities to resolve small-dimensioned features. In summary he finds that x rays have major advantages: (1) x rays are very efficient at exciting electrons in atoms, thereby creating inner-shell holes; (2) x-ray excitation produces very low backgrounds; (3) beam spreading with x rays is low; and (4) x-ray microprobe analysis requires minimum sample preparation.

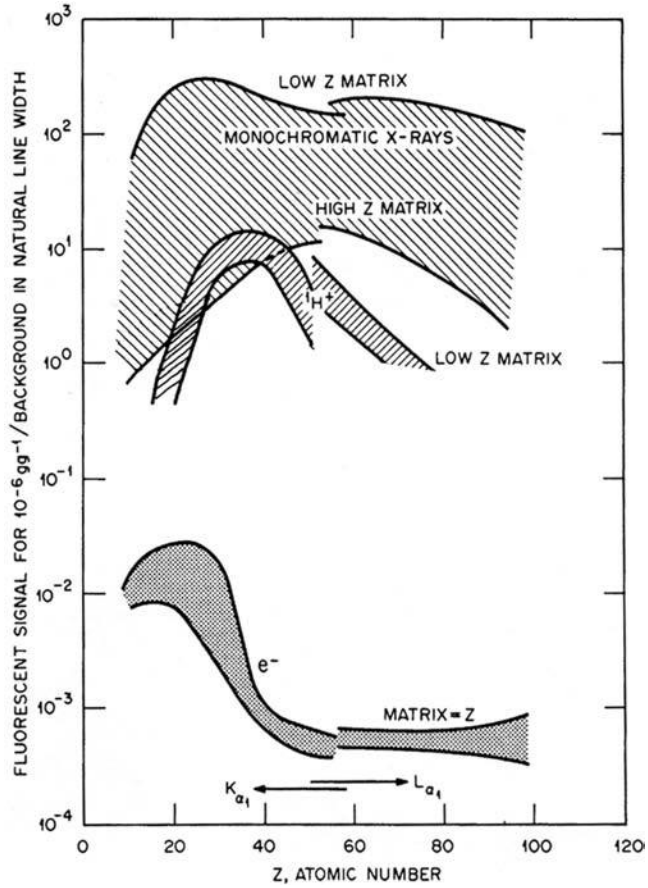

Figure 3. Comparison of the fluorescence signal-to-background ratio for various excitation probes at a concentration of 10^{-6} gg^{-1} for an x-ray detection system with an energy resolution of the natural line width (Sparks, 1980).

A comparison of the signal-to-background ratio for various probes is shown in Figure 3. Monochromatic x-ray excitation produces the best fluorescence signal-to-background. Proton excitation produces signal-to-background ratios between that of x-ray- and electron-induced fluorescence. For low-Z elements, proton microbeams can sometimes approach the signal-to-background of x-ray microbeams.

A rather direct comparison of the elemental sensitivity of various microbeam probes can be made by comparing their minimum-detectable limits (MDL). We adopt the MDL definition of Sparks (1980) for fluorescence analysis

$$C_{\mathrm{MDL}} = 3.29\, C_{\mathrm{Z}} \frac{\sqrt{N_{\mathrm{b}}}}{N_{\mathrm{s}}} \qquad (1)$$

Here C_{MDL} is the minimum detectable limit, C_{Z} is the mass fraction in a calibrated standard, N_{b} is the

Table 1. Estimated MDL/s from (Sparks, 1980), Scaled to 10^{12} Monochromatic Photons/s/μm^2

Probe	MDL (ppm/s)[a]
Proton	~10 to 100
Electron	~5 to 30
Filtered x ray	~1 to 8
Monochromatic x ray	~0.005 to 0.08

[a]This comparison assumes that the matrix and trace element have similar Z and that an advanced multielement solid-state detector is used where deadtime does not limit performance. With a low-Z matrix or with an advanced crystal spectrometer, the MDL can be lower.

background counts beneath the fluorescence signal, and N_s is the net counts at the fluorescence energy. Lowest MDL results when the ratio $N_s/\sqrt{N_b}$ is large (good signal-to-background and high flux), and when N_s/C_Z is large (efficient inner-shell hole production and high flux).

Electron and proton microprobes cannot match the achievable MDL of an advanced x-ray microprobe; compared to x rays, the inner-shell hole production cross-section and signal-to-background of an electron probe are too low and the proton probe flux density on the sample is too low. An advanced x-ray microprobe with 10^{12} photons/s/μm^2 has about a 10^3 lower MDL for most elements than a charged particle probe and can achieve the same MDL as electron probes with 10^4 less energy deposited in the sample (Table 1).

For thin samples, the spatial resolution of electron probes is far better than that of either x-ray or proton microprobes. In terms of their practical spatial resolution for thick samples, however, x-ray microprobes are competitive or superior to charged particle probes. Although electron probes can be focused to nanometer dimensions, beam spreading in thick samples degrades their effective resolution. For example, in a thick Al sample, a nanometer electron probe spreads to an effective size of ~2-μm diameter. In Cu and Au samples the same beam spreads to 1- and 0.4-μm diameter, respectively (Goldstein, 1979; Ren et al., 1998). Proton microprobes can be made very small, but the fluxes are so low that few instruments exist with probe dimensions approaching 1-μm diameter (Lindh, 1990; Doyle et al., 1991).

X-ray beams are now so intense that their flux density is approaching the maximum that can usefully be applied to most samples. For example, the estimated thermal rise of a thin target under an advanced x-ray microbeam is shown in Figure 4. Existing x-ray microbeams have highly monochromatic flux densities approaching 10^{12} photons/s/μm^2 and can go to 10^{13} to 10^{14} photons/s/μm^2 with larger band-pass optics. With 10^{14} photons/s/μm^2, the flux must be attenuated for most samples. Alternatively, the probe area can be decreased or the dwell time on the sample can be reduced to prevent sample melting.

Despite its many advantages, however, x-ray microbeam analysis remains an emerging field with very little available instrumentation. The effort required to gain access to x-ray microbeam facilities must therefore be weighed against the benefits. X-ray microfluorescence analysis becomes justified when the MDL from other techniques is inadequate. It may also be justified when the probe must penetrate the sample surface, when the analysis must be highly nondestructive, when the analysis must be quantitative, or when the measurement must be done in the presence of an air, water, or other low-Z overlayer.

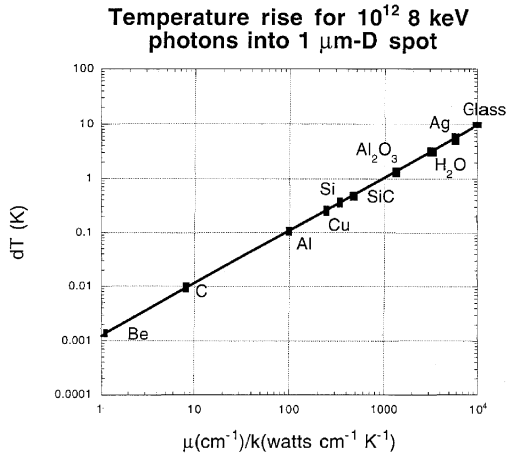

Figure 4. Thermal rise as a function of thermal conductivity K and absorption coefficient, μ (Ice and Sparks, 1991). Note that existing x-ray microbeams have achieved 10^{12} photons/s/μm^2 and are anticipated to reach 10^{13}–10^{14} photons/s/μm^2 for some applications.

Average crystallographic grain orientations can be studied with large probes such as standard x-ray beams or neutron beams. Individual grain orientations can also be determined to ~1° with electron back-reflection measurements and strain resolution to 2×10^{-4} has been reported (Michael and Goehner, 1993). However, large beam probes cannot study individual grain-grain correlations, and electron probes are predominantly surface sensitive, and in most cases have both strain and orientation precision two orders of magnitude worse than for x-ray microdiffraction. Microdiffraction analysis therefore becomes justified when the strain resolution $\Delta d/d$ must be better than $\sim 5 \times 10^{-4}$. Microdiffraction analysis is also justified for the study of crystallographic properties beneath the surface of a sample, for the measurement of texture in three dimensions or for nondestructive analysis of insulating samples where charge buildup can occur.

PRINCIPLES OF THE METHOD

A typical x-ray microbeam experiment involves three critical elements: (1) x-ray condensing or aperturing optics on a high-brilliance x-ray source, (2) a high-resolution sample stage for positioning the sample, and (3) a detector system with one or more detectors (Fig. 5). The x-ray beam axis and focal position is determined by the optics of the particular arrangement. Different locations on the specimen are characterized by moving the specimen under the fixed x-ray microprobe beam. Details of the detector arrangement and the principles involved depend strongly on the particular x-ray microprobe and on whether elemental distributions or crystallographic information is to be collected.

Both x-ray microdiffraction and x-ray microfluorescence are brilliance (photons/s/eV/mm^2/mrad^2) limited (Ice, 1997). For x-ray microdiffraction, momentum

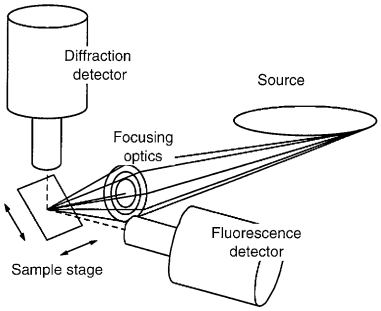

Figure 5. Key elements of an x-ray microbeam experiment.

transfer resolution is limited by spread in wavelength and angular divergence on the sample. Count rate is limited by flux per unit area. For x-ray microfluorescence, best signal-to-background occurs when the x-ray bandwidth $\Delta E/E$ is $\leq$3% (Sparks, 1980). Spatial resolution for thick samples degrades when the divergence of the beam exceeds $\sim$10 mrad. The principles of x-ray microfluorescence and x-ray microdiffraction analysis are briefly outlined below.

X-Ray Microfluorescence Analysis

The unique advantages of x-ray probes arise from the fundamental interaction of x rays with matter. Below the electron-positron pair production threshold, the interaction of x rays with matter is dominated by three processes: photoabsorption (photoelectric effect), elastic scattering, and inelastic (Compton) scattering (Veigele et al., 1969). Of these three processes, photoabsorption has by far the largest cross-section in the 3- to 100-keV range.

Photoabsorption and Compton scattering are best understood in terms of a particle-like interaction between x rays and matter (Fig. 6). The quantized energy of an x-ray photon excites an electron from a bound state to an unbound (continuum) state, while the photon momentum is transferred either to the atomic nucleus (photoeffect) or

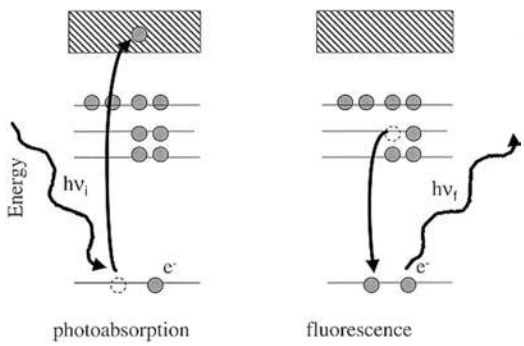

Figure 6. Schematic of x-ray photoabsorption followed by fluorescence. An x-ray photon of energy $h\nu_i$ is absorbed by the atom, which ejects an electron from an inner shell of the atom. The atom fills the electron hole by emitting an x ray with an energy $h\nu_f$; $h\nu_f$ is characteristic to the atom and has an energy equal to the energy difference between the initial and final hole-state energies. Alternatively the atom fills the inner-shell hole by emitting an energetic electron (Auger effect; Bambynek et al., 1972 also see AUGER ELECTRON SPECTROSCOPY).

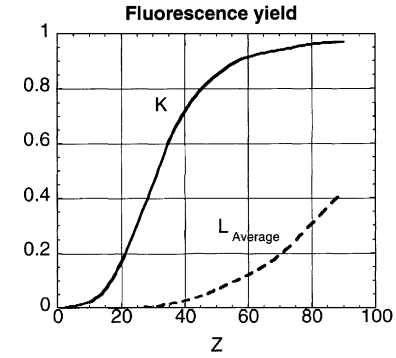

Figure 7. Fit to experimental fluorescence yields for K and L holes. (Bambynek et al., 1972.)

to the electron (Compton scattering). X-ray fluorescence is the name given to the elementally distinct or "characteristic" x-ray spectrum that is emitted from an atom as an inner-shell hole is filled.

Fluorescence Yields. An inner-shell hole can also be filled by nonradiative mechanisms (Auger and Coster-Kronig effects; Bambynek et al., 1972). Here the singly ionized atom fills the inner shell hole with a higher-energy electron and emits an energetic (Auger/Coster-Kronig) electron with a characteristic energy that is determined by the initial and final energy of the atom. The fraction of holes that are filled by x-ray fluorescence decay is referred to as the fluorescence yield. In general, nonradiative processes become increasingly likely as the initial-hole binding energy decreases (Fig. 7). We note that for K holes with binding energies above 5 keV, the x-ray fluorescence yields are more than 20%. For L holes with binding energies greater than 5 keV, all fluorescence yields exceed 10%. The fluorescence yields of deep inner-shell holes can exceed 90%.

Characteristic Radiation. The characteristic x-ray energies emitted when the initial hole decays by fluorescence serve as a "fingerprint" for the element and are quite distinct. Fluorescence spectra are labeled according to the electron hole being filled and the strength of the decay channel. For example, as shown in Figure 8, $K\alpha_1$ fluorescence arises when an L_{III} ($2P_{3/2}$) electron fills a K hole.

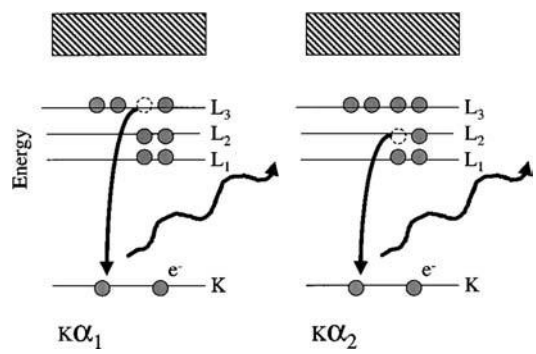

Figure 8. Fluorescence decay channels for K holes.

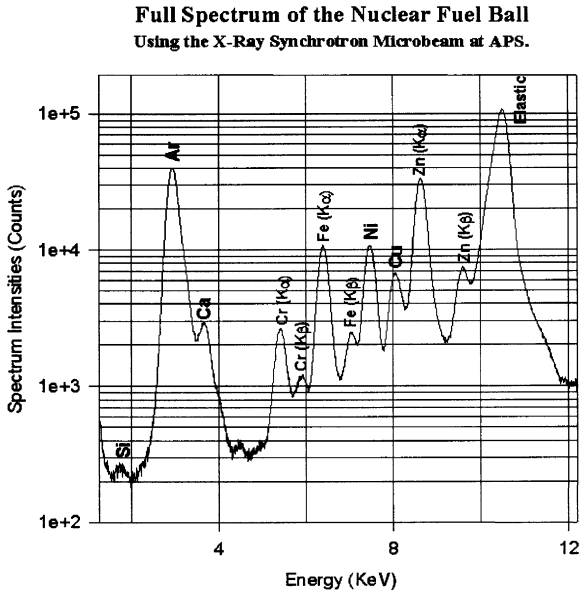

Figure 9. Fluorescence spectra from the SiC shell of an advanced nuclear fuel particle. The trace elements in the sample emit characteristic x-ray lines when excited with x rays.

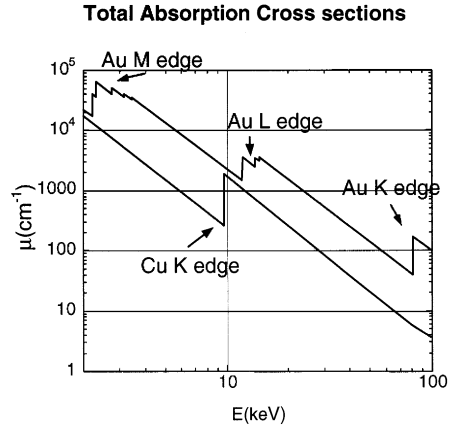

Figure 10. Photoabsorption cross-section for Cu and Au.

This transition is the strongest fluorescence decay channel for K holes. A similar nomenclature is used for L holes, etc.

Because chemical effects on inner-shell wavefunctions are small, x-ray absorption cross-sections, fluorescence yields, and characteristic x-ray spectra are virtually unchanged by the sample environment except very near threshold. However, the measured-fluorescence signal can strongly depend on absorption and secondary excitation due to the sample matrix.

A typical spectrum from a low-Z matrix with trace elements is shown in Figure 9. The characteristic lines have a natural bandwidth of a few eV that is smeared by the energy resolution of the detector. Even in this case where the trace elements are nearby in the periodic table, the fluorescence signature of each element is distinct. Crystal spectrometers with higher energy resolution can be used in more complicated cases with overlapping L lines to resolve nearby fluorescence lines.

Photoabsorption Cross-Sections. To a first approximation, only x-rays with sufficient energy to excite an electron above the Fermi level (above the occupied electron states) can create an inner-shell hole. As a consequence, the photoabsorption cross-section for x-rays has thresholds that correspond to the energy needed to excite an inner-shell electron into unoccupied states. As shown in Figure 10, the photoabsorption cross-section exhibits a characteristic saw-tooth pattern as a function of x-ray energy. Highest x-ray efficiency for the creation of a given hole is just above its absorption edge energy. Maximum elemental sensitivity with minimum background results when the x-ray microprobe energy is tuned just above the absorption edge of the element of interest (Sparks, 1980). Because x rays are highly efficient at creating inner-shell holes, x-ray excited fluorescence has a very high signal-to-noise ratio (Fig. 3) and the energy deposited in the sample is low for a given signal.

Micro-XAFS. The saw-tooth pattern of Figure 10 shows the typical energy dependence of x-ray absorption cross-sections over a wide energy range, but does not include lifetime broadening of the inner shell hole, the density of unfilled electron states near the Fermi energy, or the influence of photoelectron backscattering. These various processes lead to fine structure in the photoabsorption cross-section which can be used to determine the valence state of an element, its local neighbor coordination, and bond distances. Near-edge absorption fine structure (NEXAFS) is particularly sensitive to the valence of the atom. Extended x-ray absorption fine structure (EXAFS) is sensitive to the near-neighbor coordination and bond distance. Fluorescence measurements have the best signal-to-background ratio for XAFS of trace elements. It is therefore possible to use XAFS techniques with an x-ray microprobe to determine additional information about the local environment of elements within the probe region. More detail about XAFS techniques is given in XAFS SPECTROSCOPY.

Penetration Depth. The effective penetration depth of a fluorescence microprobe depends on the energy of the incident and fluorescent x rays, the composition of the sample, and the geometry of the measurement. As shown in Figure 10, x-ray absorption decreases with an $\sim E^{-3}$ power dependence between absorption edges. For a low-Z matrix, the penetration depth of an x-ray microfluorescence beam can be tens of millimeters into the sample, while for a high-Z matrix the penetration can be only a few microns (Fig. 1).

With a thick sample, the fluorescence signal and effective depth probed depends on the total scattering angle and on the asymmetry of the incident-to-exit beam angles (Sparks, 1980). To a first approximation, the fluorescence signal is independent of total scattering angle but depends on the asymmetry between the incident angle ψ and the exit angle ϕ (Fig. 11).

$$C_Z \propto \left(\mu_i + \mu_f \frac{\sin\psi}{\sin\phi}\right) \qquad (2)$$

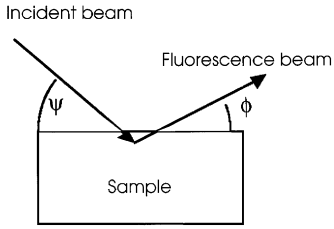

Figure 11. Depth penetrated by a fluorescence microprobe depends on the total absorption cross-section of the incident and fluorescence radiation and on the incident and exit angles with respect to the sample surface.

Here μ_i is the linear absorption coefficient for the incident beam and μ_f is the total absorption coefficient for the fluorescence beam. The approximation of Equation 2 is only valid for uniformly smooth sample surfaces. Where sample granularity and surface roughness are large, the fluorescence signal decreases as the glancing angle decreases (Campbell et al., 1985; Sparks et al., 1992). The effective depth probed depends both on the total scattering angle $\psi + \phi$ and on the asymmetry between ψ and ϕ.

The characteristic depth of an x-ray microprobe is given by

$$x = \left(\frac{\mu_i}{\sin\psi} + \frac{\mu_f}{\sin\phi}\right) \quad (3)$$

Shallow depth penetration can be achieved with glancing angle and asymmetric geometries. With smooth surfaces, even greater surface sensitivity can be achieved by approaching or achieving total external reflection from the surface (Brennan et al., 1994). With total external reflection, the surface sensitivity can approach 1 nm (10 Å) or better (Fig. 12).

Backgrounds. Background signal is generated under fluorescence lines by various scattering and bremstrahlung processes. With a white or broad bandpass incident beam, elastically scattered x-rays including those with the same energy as the fluorescent line can be directly scattered into the detector. This scattering can be greatly reduced by operating at a 2θ scattering angle of 90° in the plane of the synchrotron storage ring where linear beam polarization inhibits elastic and Compton scattering. A much better way to reduce background is through the use of a monochromatic x-ray beam. As shown in Figure 2, monochromatic x-ray beams produce the best signal-to-background because the background under a fluorescence peak must arise from multiple scattering events, bremstrahlung from photoelectrons, or other cascade processes.

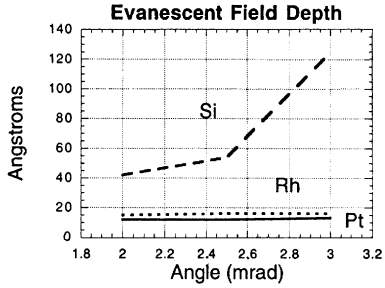

Figure 12. Evanescent wave depth of 10 keV x rays into Si, Rh, or Pt as a function of glancing angle.

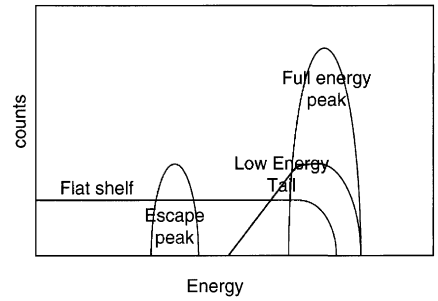

Figure 13. Schematic of low-energy tails in a solid state detector.

Detectors. Two kinds of detectors are used for observing fluorescence. Solid-state detectors are most widely used because they are efficient and can simultaneously detect many elements in the sample. A state-of-the-art solid-state detector with a 1-cm^2 active area has ~130-eV resolution at 5.9 keV with a 5000 counts-per-second (cps) counting rate. Much higher counting rates are possible by compromising the energy resolution and by using multiple detector arrays. For example, 30-element arrays with 500,000 cps counting rates/element can achieve 15,000, 000 cps. One drawback with solid-state detectors is additional background for trace elements, which is introduced by high intensity peaks in the spectra. As shown in Figure 13, the response of a solid-state detector to an x ray of a single energy typically has both short- and long-range low-energy tails due to insufficient charge collection (Cambell, 1990). These can be the dominant contribution to background under a trace element.

Wavelength dispersive spectrometers can also be used to measure fluorescence (Ice and Sparks, 1990; Koumelis et al., 1982; Yaakobi and Turner, 1979). These detectors have much poorer collection efficiency but much better energy resolution (lower background) and are not paralyzed by scattering or by fluorescence from the major elements in the sample. Because wavelength dispersive detectors only count one fluorescent energy at a time, they are not count-rate limited by fluorescence or scattering from the major elements in the sample matrix.

X-Ray Microdiffraction Analysis

X-ray microdiffraction is sensitive to phase (crystal structure), texture (crystal orientation), and strain (unit cell distortion) (Ice, 1987; Rebonato et al., 1989). Diffraction (Fig. 14) is best understood in terms of the wave-like nature of x rays. Constructive and destructive interference from x-ray scattering off the charge-density distribution varies the x-ray scattering efficiency as a function of angle and wavelength. This so-called diffraction pattern can be Fourier transformed to recover charge-density

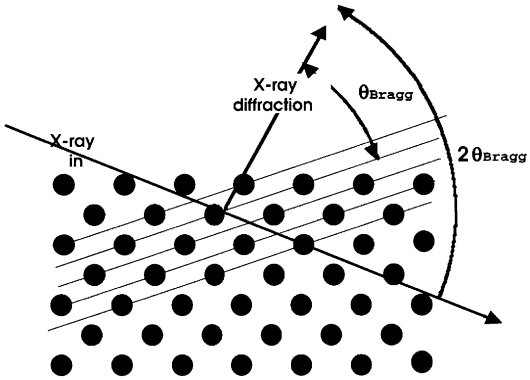

Figure 14. X-ray diffraction from a crystal becomes large at Bragg angles where the crystal lattice spacing, d, the wavelength, λ, and the angle of the incident beam with respect to the crystal lattice planes, θ_{Bragg}, satisfy Bragg's law (Equation 4).

information. Although the basic diffraction process is identical for all diffraction probes (e.g., x rays, electrons, or neutrons), x rays have three very favorable attributes for the characterization of crystal structure: (1) the wavelength is similar to the atomic spacing of matter; (2) the cross-section is sufficiently low that multiple scattering effects are often small; and (3) the cross-section of elastic scattering is a large fraction of the total interaction cross-section of x rays, which contributes to low noise. In addition, x-ray scattering contrast can be adjusted by tuning near to x-ray absorption edges (Materlik et al., 1994).

Strong diffraction occurs when the incident beam satisfies Bragg's law

$$2d \sin\theta = n\lambda \tag{4}$$

Here d is a crystal lattice spacing, λ is the x-ray wavelength, and θ is the so-called "Bragg angle" between the incident beam and the crystal plane. X-ray microdiffraction can yield detailed information about the sample unit cell and its orientation. If the x-ray wavelength is known, the angle between the incident and an intense exit beam (2θ) determines the spacing, d. The relative orientation of crystals (mosaic spread or texture) can be determined by observing the rotation angles of a sample needed to maximize scattered intensity. These two methods are useful for studies of polycrystalline materials that have a strong preferred orientation.

For unknown crystal orientation, the unit-cell parameters and crystallographic orientation of a single crystal can be determined from the x-ray energy and the angles of three noncolinear reflections (Busing and Levy, 1967). In standard crystallography, reflections are found by rotation of the sample under the beam. With microdiffraction x-ray measurements on polycrystalline samples, however, the imprecision of mechanical rotations will cause the sample to translate relative to the beam on a micron scale. In addition, for complex polycrystalline samples with many grains, the penetration of the x-ray beam into the specimen ensures that the sample volume (and therefore microstructure) will vary as the sample rotates. The changing grain illumination makes a standard crystallographic solution impossible. These two problems can be overcome by the use of Laue diffraction with white or broad-bandpass x-ray beams. With Laue diffraction, no sample rotations are required. Development is in progress to automatically index the overlapping reflections of up to 10 crystals (Marcus et al., 1996; Chung, 1997; Chung and Ice, 1998; Wenk et al., 1997).

X-ray microdiffraction also allows for three-dimensional imaging of crystal structure as demonstrated in some first experiments (Stock et al., 1995; Piotrowski et al., 1996). For these measurements, the sample-to-detector distance is changed and the origin of the reflecting crystal along the microprobe beam is determined by ray tracing. Spatial resolution of less than 2 μm along the microbeam direction has recently been demonstrated (Larson et al., 1999).

PRACTICAL ASPECTS OF THE METHOD

Sources

Only second- and third-generation synchrotron sources have sufficient x-ray brilliance for practical x-ray microprobe instrumentation. Worldwide, there are only three third-generation sources suitable for hard x-ray microprobes: the 6-GeV European Synchrotron Radiation Facility in Grenoble France (Buras and Tazzari, 1984), the 7-GeV Advanced Photon Source at Argonne, Illinois (Shenoy et al., 1998), USA, and the 8-GeV Spring-8 under construction in Japan. Although third-generation sources are preferred, x-ray microprobe work can also be done on second-generation sources like the National Synchrotron Light Source (NSLS), Brookhaven, New York. A list of contacts at synchrotron radiation facilities with x-ray microbeam instrumentation is given in Table 2.

Optics

Tapered Capillaries. The development of intense synchrotron x-ray sources, with at least 12 orders of magnitude greater brilliance than conventional x-ray sources (Fig. 2), has revived interest in x-ray optics. At least three microbeam-forming options have emerged with various strengths and weaknesses for experiments (Ice, 1997). Tapered capillary optics have produced the smallest x-ray beams (Stern et al., 1988; Larsson and Engström, 1992; Hoffman et al., 1994). Bilderbach et al. (1994) have reported beams as small as 50 nm full width at half-maximum (FWHM). This option appears to be the best for condensing beams below 0.1 μm. One concern with capillary optics, however, is their effect on beam brilliance. Ray tracing and experimental measurements have found that the angular divergence following a capillary has a complex annular distribution. This distribution arises from roughness inside the capillary and from the nonequal number of reflections of different rays as they are propagated along the capillary.

Zone Plates. Hard x-ray zone plates are a rapidly emerging option for focusing synchrotron radiation to μm dimensions (Bionta et al., 1990; Yun et al., 1992). This

[a]The top four facilities are on hard x-ray third-generation sources. The ALS x-ray microprobe is on a third-generation VUV ring with a small emittance beam which acts like a high-performance second generation ring for hard x-rays. The remaining beamlines are on second-generation rings.

option appears especially promising for focusing monochromatic radiation ($\Delta E/E = \sim 10^{-4}$). These devices are simple to align, allow good working distance between the optics and the sample, and have already achieved submicron spots. Although zone plates are inherently chromatic, they can in principle be used with tunable radiation by a careful translation along the beam direction. State-of-the-art zone plates provide the most convenient optics for monochromatic experiments even though their focusing efficiency has not reached the 40% to 60% efficiency promised by more advanced designs.

Kirkpatrick-Baez Mirrors. Kirkpatrick-Baez (KB) mirrors provide a third highly promising option for focusing synchrotron radiation (Yang et al., 1995; Underwood et al., 1996). A Kirkpatrick-Baez mirror pair consists of mirrors that condense the beam in orthogonal directions. Both multilayer and total-external-reflection mirrors have been used for focusing synchrotron radiation. Multilayer mirrors appear most suitable for fluorescence measurements with a fixed wide-band-pass beam and where large divergences can be accepted. Total-external-reflection mirrors appear to offer the best option for focusing white beams to μm dimensions. The key challenge with KB mirrors is achieving low figure and surface roughness with elliptical surfaces. There are numerous parallel efforts currently underway to advance mirror figuring for advanced KB focusing schemes.

Refractive Lenses. In addition to the focusing schemes mentioned above, there are two new options that have recently emerged from experiments at the European Synchrotron Radiation Facility (ESRF). These are compound refractive lenses and Bragg-Fresnel optics. Compound refractive lenses are very interesting because they are relatively easy to manufacture (Snigirev et al., 1996). Estimates of their theoretical efficiency, however, indicate that they cannot compete with the theoretical efficiency of KB mirrors or zone plates.

Bragg-Fresnel Optics. Bragg-Fresnel optics are also an interesting option used both at LURE (Chavallier et al., 1995, 1996) and the ESRF (Aristov, 1988). With Bragg-Fresnel optics, the phase-contrast steps are

lithographically etched into a multilayer or monolithic Si substrate. This offers a rugged coolable substrate and serves to simultaneously focus and monochromatize the beam. Some of the alignment simplicity of zone plates is lost with these devices because the beam is deflected, but they have the advantage that the 0th order (direct beam) is spatially removed from the focus and can therefore be easily stopped.

MICROBEAM APPLICATIONS

Microprobe analysis has already been applied to many problems with second- and third-generation x-ray beams (Jones and Gordon, 1989; Rebonato et al., 1989; Langevelde et al., 1990; Thompson et al., 1992; Wang et al., 1997). Studies include measurement of strain and texture in integrated circuit conduction paths (Wang et al., 1996, 1997), the measurement of buried trace elements in dissolution reactions (Perry and Thompson, 1994), and determination of chemistry in small regions. Three simple examples are given to illustrate possible applications.

Example 1: Trace Element Distribution in a SiC Nuclear Fuel Barrier

TRISO-coated fuel particles contain a small kernel of nuclear fuel encapsulated by alternating layers of C and SiC as shown in Figure 15A. The TRISO-coated fuel particle is used in an advanced nuclear fuel designed for passive containment of the radioactive isotopes. The SiC layer provides the primary barrier for radioactive elements in the kernel. The effectiveness of this barrier layer under adverse conditions is critical to containment.

Shell coatings were evaluated to study the distribution and transport of trace elements in the SiC barrier after being subjected to various neutron fluences (Naghedolfeizi et al., 1998). The C buffer layers and nuclear kernels of the coated fuel were removed by laser drilling through the SiC and then leaching the particle in acid (Myers et al., 1986). Simple x-ray fluorescence analysis can detect the presence of trace elements, but does not indicate their distribution. Trace elements in the SiC are believed to arise at least in part as daughter products from the fission process; lower trace-element concentrations are found in unirradiated samples. The radial distribution of these elements in the SiC shells can be attributed to diffusion of elements in the kernel due to thermal and radiation-enhanced diffusion. Other elements in the shells may originate in the fabrication of the TRISO (three-layer coatings of pyrolytic carbon and SiC) particles.

Linear x-ray microprobe scans were made through the SiC shell. X-ray fluorescence is an ideal tool for this work because it is nondestructive (no spread of contamination), it is sensitive to heavy elements in a low-Z matrix, and it provides a picture of the elemental distribution. Results of a simple line scan through a leached shell are shown in Figure 15B. This scan was made with 2-μm steps and an ~1-μm probe. As seen in Figure 15B, very localized Fe-rich regions <1-μm broad are observed throughout the shell. This behavior is typical of other trace elements observed in the shell.

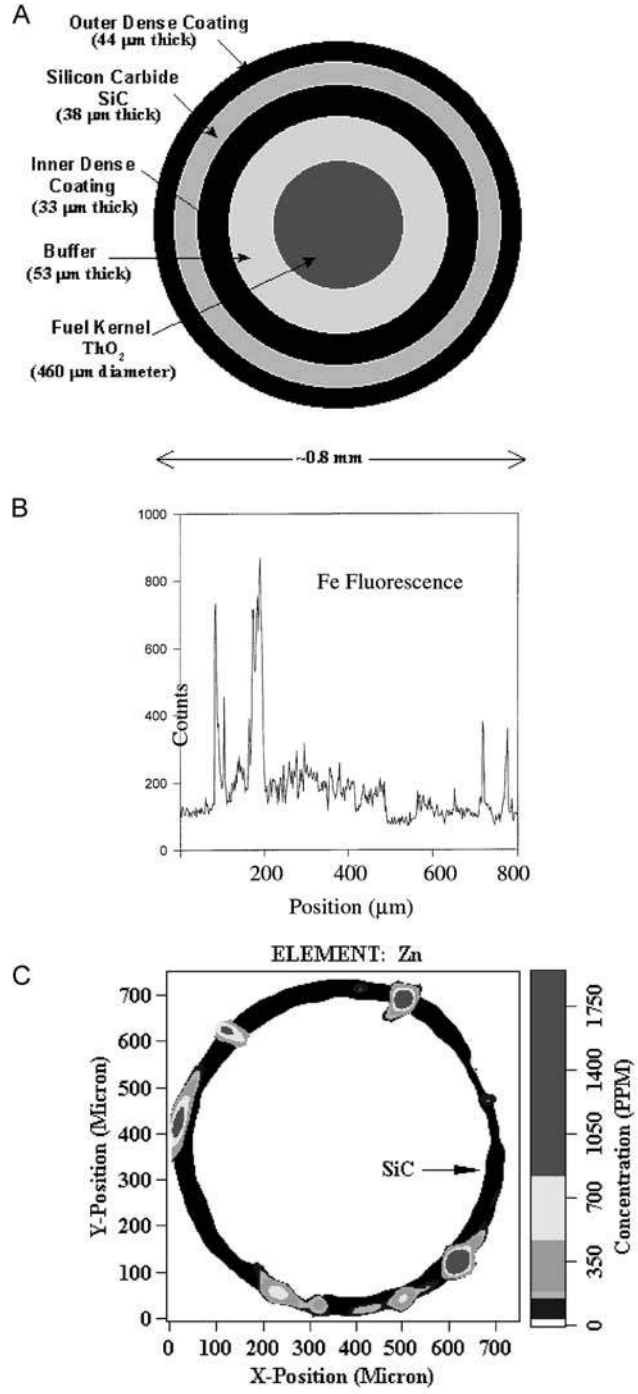

Figure 15. (**A**) Schematic of TRISO fuel element. (**B**) The Fe fluorescence during a line scan through a SiC shell shows a complicated spatial distribution with sharp features less than 1 μm wide. (**C**) Zn distribution in a SiC shell after reconstruction from x-ray microfluorescence data (Naghedolfeizi et al., 1998). The spatial resolution was limited because time restricted the number of steps. **See color figure.**

The spatial distribution can be further investigated by extending the x-ray microprobe analysis to x-ray microfluorescence tomography (Biosseau, 1986; Naghedolfeizi et al., 1998). Although x-ray fluorescence tomography is

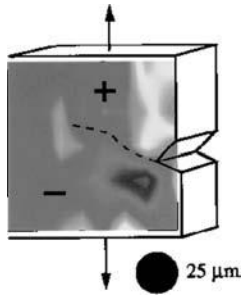

Figure 16. Strain map in a Mo single crystal (Rebonato et al., 1989) showing $\Delta d/d$ for the (211) planes when the crystal is pulled. A region of contraction (below the dashed line) and a region of elongation (above the dashed line) are observed. The reduction in d beneath the dashed line arises from the orientation of the observed Bragg plane with respect to the free surface. The probe size of ~25 μm was barely small enough to detect the strain features. **See color figure.**

inherently time-consuming, the method yields three-dimensional distributions of trace elements. For example, the Zn distribution in a plane of the SiC shell is illustrated in Figure 15C. Note that the measurements are quantitative.

Example 2: Change in the Strain Distribution Near a Notch During Tensile Loading

Early experiments with second-generation sources demonstrated some of the features of x-ray microprobe–based diffraction: good strain resolution, ability to study strain in thick samples, ability to study dynamics of highly strained samples, and the ability to distinguish lattice dilation from lattice rotations. For example, a measurement of differential strain induced by pulling on a notched Mo single crystal (Rebonato et al., 1989) shows lattice dilation above the notch and a lattice contraction below the notch (Fig. 16). This behavior would be totally masked with a topographic measurement because of the high density of initial dislocations. In addition, the measurement allowed the lattice rotations to be separated from the lattice dilations. Finally, the measurements are quantitative, and even in this early experiment yielded strain sensitivity $\Delta d/d$ of $\sim 5 \times 10^{-4}$.

Example 3: Strain Distribution in an Advanced Ferroelectric Sample

$BaTiO_3$ has a tetragonal structure in the ferroelectric state. For a single-crystal thin film deposited on Si, the tetragonal axis can lie either in the plane of the thin film or normal to the surface. The direction of the tetragonal axis is referred to as the "poled" direction. In general, the poling is in the plane of the surface, but electrical measurements indicate that the poled state of the $BaTiO_3$ can be switched if the size of the $BaTiO_3$ film is small enough. X-ray microdiffraction provides a means to study the distribution of poled $BaTiO_3$ in small circular pads. The measurement sampled regions with $\sim 1 \times 10$ μm^2 spatial resolution. In the experiment, an x-ray microbeam was scanned across monolithic films of the $BaTiO_3$ film (reference film) and across small ~60-μm diameter mesasurements (Fig. 17A). The diffraction pattern from the film was recorded on a charge-coupled device (CCD) x-ray detector.

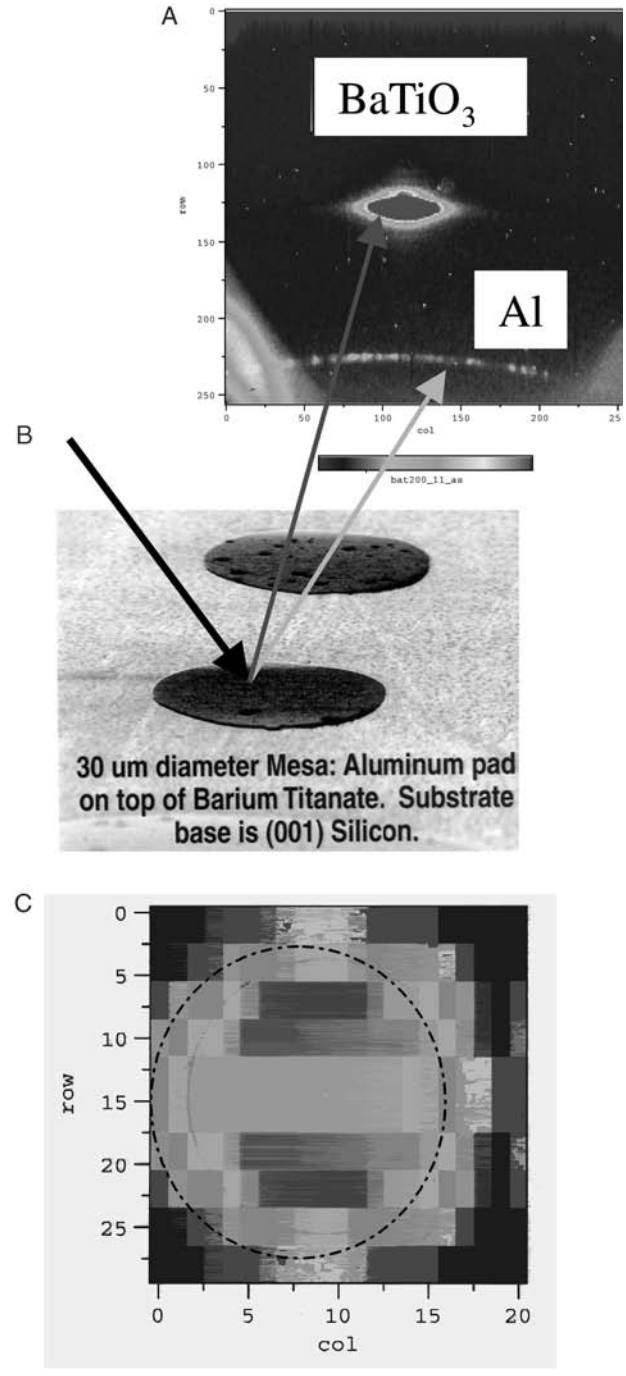

Figure 17. (**A**) Mesas of $BaTiO_3$ show interesting poling behavior. (**B**) Schematic of microdiffraction process with x-ray microdiffraction image from an advanced thin film. The CCD image shows the single-crystal reflection and the powder-like image from the Al overlayer. (**C**) Strain map across the mesa. The strain map has a range of only 5×10^{-4} and an uncertainty of $\sim 1 \times 10^{-5}$. **See color figure.**

A typical diffraction pattern, shown in Figure 17B, illustrates many of the powerful attributes of microdiffraction. The $BaTiO_3$ 002/200 Bragg peak appears as a lenticular intense pattern in the CCD image even though it is covered with a 200-nm cap of aluminum. The strain in the thin film can be measured to $\Delta d/d = \sim 1 \times 10^{-5}$. This is sufficient to easily resolve the ~1% difference in the lattice parameter between 002 or 200 poled $BaTiO_3$. Texture, particle size, and strain of the powder-like aluminum overlayer can be inferred directly from the 111 and 200 Debye rings as seen in the lower part of Figure 17B. Even better strain resolution can be obtained by measurement of higher order reflections.

This example clearly indicates the need for an x-ray diffraction microprobe. Small spot size is required to study the distribution of poled material near small dimensioned features of the film. Good strain resolution is required to differentiate between the various poling options. A penetrating probe is required to measure the film in an unaltered state below a 200-nm cap of aluminum.

METHOD AUTOMATION

X-ray microfluorescence and x-ray microdiffraction data collection at synchrotron sources occurs remotely in a hostile, high-radiation environment. Experiments are located inside shielded hutches that protect the researcher from the x rays near the experiment, but which restrict "hands-on" manipulation of the experiment. Fluorescence and simple diffraction data are typically collected by step-scanning the sample under the beam. A record is made of the fluorescence spectrum or the diffraction pattern from the sample at hundreds to thousands of positions. Fluorescence data collection and analysis is typically performed using specially designed one-of-a-kind programs. Some recent efforts have been directed to incorporate commercial fluorescence data analysis and collection software, but no standard has yet evolved. The general-purpose program SPECT has however been adopted on several beamlines worldwide for general purpose data collection and is used on a number of beamlines worldwide for collection of both microdiffraction and microfluorescence data.

Because the field has been revolutionized by new sources and instrumentation, there is increased urgency to further automate and standardize the data collection of both microfluorescence and microdiffraction analysis. The actual data collection program can be quite simple for both microfluorescence and microdiffraction. However, data analysis can be complicated, especially for microdiffraction. Improved computer processing and storage power is certain to make a major impact on the way data is collected, analyzed and stored. For example, to avoid the storage of huge data files, fluorescence spectra are often stored as "regions of interest." This procedure works well in many cases, but can lose important information for overlapping characteristic lines. A better solution is to record complete spectra or to fit the spectra "on the fly" to separate overlapping peaks. The availability of large storage devices and faster computers make these intrinsically superior options increasingly attractive.

Until recently, there has been little or no specialized software for x-ray microdiffraction. With monochromatic microdiffraction experiments, a key problem is the sphere of confusion of the diffractometer. Recent efforts have resulted in the development of automated methods of mapping the sphere of confusion of a diffractometer, to greatly reduce the experimental uncertainty of the relative beam/sample position (Noyan et al., 1999).

With microdiffraction experiments, a key challenge is automated indexing of Laue reflections. This quite general problem appears feasible for wide-band-pass x-ray beams and for samples where the unit cell is known (but not the grain orientation or strain) (Marcus et al., 1996; Chung, 1997; Wenk et al., 1997; Chung and Ice, 1999). Recent advances in specialized computer software for pattern recognition and microdiffraction data analysis has now demonstrated the ability to automatically separate the overlapping Laue patterns from 5 to 20 grains and to automatically determine strain to 2×10^{-5} to 2×10^{-4} and to localize the diffracting grain position along the incident beam to ~2 μm. The key elements of the so called ORDEX (Oak Ridge inDEXing) program used for automated indexing of overlapping Laue patterns on beamline 7 of the Advanced Photon Source have been described by Chung and Ice (1999). Parallel software development efforts are also underway at the European Synchrotron Radiation Facility and at the Advanced Light Source.

SAMPLE PREPARATION

One major advantage of x-ray microprobe analysis is the minimal sample preparation required. In general, samples need to be small due to the short working distances between the focusing optics and the focal plane. Samples should also be mounted on low background-producing materials to reduce x-ray scatter and fluorescence (e.g., Mylar or Kapton for fluorescence and single-crystal Si for diffraction). In most cases, no additional preparation is required, and samples can be run in air, under water, or coated with low-Z barriers for radioactive containment or to prevent oxidation. Of course, what the x-ray microbeam measures is the elemental and crystallographic distributions in the sample as it is mounted. If, for example, a sample is machined, its surface will include a heavily damaged and chemically contaminated layer that may or may not be of interest to the experiment. In addition, because of the sensitivity of x-ray microfluorescence to trace elements, particular care must be taken during sample mounting to prevent contamination of the sample. For example, samples should be handled with low-Z plastic tweezers to avoid metal contamination from metallic tweezers.

Surface roughness and variations in sample thickness can also complicate the data analysis. In general, the analysis of fluorescence data is easier if the sample is homogeneous, smooth, and of uniform thickness. If the sample is very thick (semi-infinite) or very thin (negligible absorption), the data analysis is particularly easy. For most microdiffraction experiments to date, relative reflectivities are sufficient, so absorption corrections are not critical to the success of the experiment.

To aid in sample throughput, some microbeam instruments have mounting systems that allow the sample to be mounted on an optical microscope remote from the x-ray microprobe. The position of the sample with respect to a fiducial in the remote microscope holder can be accurately reproduced on the x-ray microbeam positioning stage. Features of interest can be identified off line and their coordinates noted for later x-ray microcharacterization.

DATA ANALYSIS AND INITIAL INTERPRETATION

Microfluorescence

For many samples, x-ray microflurorescence can yield rather direct information about trace element distributions. X-ray fluorescence data can be placed on an absolute scale if the approximate composition of the sample is understood and the incident flux known/measured. With a solid-state detector, the major components of the sample are readily identified for $Z > 12$. The composition can be used to estimate the linear absorption coefficient and therefore the sample volume probed by the x-ray beam. If the matrix is known, the absorption can be calculated from standard tables or can be found on various web sites. Because of uncertainties in the absorption coefficients of x-rays, first-principles methods are only good to ~5% (Sparks, 1980; Lachance and Claisse, 1995). More precise absolute measurements can be obtained with prepared standards. Standard samples can be obtained from the National Institutes of Standards and Technology (NIST) or by careful dilution of trace elements in a matrix of known composition.

Initial fluorescence data analysis can be made by simply selecting a region of interest that incorporates the fluorescence lines of interest and nearby regions for background subtraction. The elemental concentration in the probe volume can be approximated from the estimated linear absorption coefficients of the incident and fluorescence beams and the net counts in the line. Sparks (1980) gives a general formula for the mass concentration of element z, C_z, as a function of the experimental geometry

$$C_z = \frac{I_Z 4\pi R^2(\mu_{S,0} + \mu_{S,i}\sin\psi/\sin\phi)\rho_S}{P_0 D_Z \sigma_{zij}\langle 1 - \exp\{1[(\mu_{S,0} + \mu_{S,i}\sin\psi/\sin\phi)/\rho_S]\rho_S T\sin\psi\}\rangle} \quad (5)$$

Here R is the specimen-to-detector distance, I_Z is the fluorescence intensity per area at the detector, $\mu_s,_0/\rho_s$ and $\mu_{s,i}/\rho_s$ are the sample mass absorption coefficients for the incident and fluorescence radiation, P_0 is the incident power, D_Z is an absorption correction for attenuation between the sample and the detector, σ_{zij} is the fluorescence cross-section for the exciting energy, and $\rho_s T$ is the mass per unit area of the sample.

The precision of the measurement can be improved by fitting the fluorescence lines with linear (assumed shape) or nonlinear least-squares techniques. All fluorescence lines have a natural Lorenztian shape which is a consequence of the lifetime of the inner-shell holes that give rise to the fluorescence. For most measurements, however, the Lorenztian shape is dominated by the Gaussian resolution of the wavelength- or energy-dispersive spectrometer. Fluorescence lines are therefore typically fit to Gaussian or Voight functions. The Lorentzian tail of a fluorescence line is mainly of importance for estimating the background it contributes under a weak line.

Microdiffraction

With a monochromatic x-ray beam, relative texture and strain information can be obtained rather directly from measured microdiffraction scattering angle and the x-ray wavelength (see X-RAY POWDER DIFFRACTION, XAFS SPECTROSCOPY and RESONANT SCATTERING TECHNIQUES). X-ray microdiffraction can measure absolute strain to better than 1 part in 10^5, but is often used for high-precision measurements of strain or rotation differences, rather than absolute measurements. If the sample grain size is sufficiently small compared to the probe volume, standard powder diffraction methods can be used to determine the lattice constants of the sample (X-RAY POWDER DIFFRACTION). However, it is useful to utilize a position-sensitive area detector to collect a large fraction of the Debye ring for data analysis. Each powder ring can be fit to optimize the statistical determination of the d spacing. The shape and intensity distribution of each ring also can be used to help determine the local texture and strain tensor of the sample. Standard samples are particularly useful for putting strain measurements on an absolute scale.

With white-beam microdiffraction, each grain intercepted by the beam produces a Laue pattern. This ensures that the deviatoric strain tensor information can be recovered for each grain, but complicates the analysis, since many grains simultaneously contribute to the Laue spectra. Often grains from various layers can be identified according to characteristics of the layer (i.e., intense sharp peaks from large grains, fuzzy weak peaks from small grains). Whatever the process, the key step is to identify which reflections are associated with a single grain and to index the reflections for each grain. This problem has now been solved for many systems with an automated indexing program that can simultaneously index ~5 to 20 grains or subgrains (Chung and Ice, 1999). With this program, the detector sample alignment is first calibrated using a perfect crystal of Ge, then the program automatically determines the grain orientation and strain. Typically, the orientation can be determined to better than 0.01° and the strain can be determined to less than 1 part in 10^4. This precision already is better than for virtually all other probes, and can be further refined in some directions by moving the detector back both to localize the origin of the diffracted beam and also to gain angular precision in the measurement.

PROBLEMS

As described previously, the two key problems of x-ray microbeam analysis are the limited number of useful sources and the difficulty of fabricating efficient x-ray

optics. In addition to these two problems, there are several annoying problems that complicate the use of x-ray microbeam techniques. One difficulty with x-ray microbeam experiments is identification of the x-ray beam position on the sample. Because of the small beam size, even intense x-ray microbeams are difficult to view on fluorescent screens with visible light optics, and even when they are visualized, the transfer from beam position on a fluorescence screen to beam position on a sample can be difficult. For some experiments, it is necessary to place markers on the sample to help in locating the x-ray beam. For example, a cross-hair of a fluorescing heavy metal can be used to locate the beam position with respect to an interesting region.

Another annoying problem with x-ray microbeam analysis is the difficulty of monitoring the absolute beam intensity on the sample. Because the distance from the focusing optics to the focus is typically short, there is little room to install a transmission beam monitor. Even when such a monitor is installed, great care must be taken to avoid contamination of the monitor signal due to backscatter from the sample.

The problem of backscatter contamination into a transmission monitor is but one example of a general class of shielding problems that arise due to the proximity of sample, detector, and optics. In general, great care is required to reduce parasitic backgrounds associated with the beam path through x-ray optics and any air path to the sample. Typically, scatter from beam-defining slits and upstream condensing optics can swamp a CCD detector unless care is taken to shield against such direct scattering. The short working distance between the optics and the sample also require care to avoid collisions.

ACKNOWLEDGMENTS

Research sponsored in part by the Laboratory Directed Research and Development Program of the Oak Ridge National Laboratory and the Division of Material Sciences, U.S. Department of Energy under contract DE-AC05-96OR22464 with Lockheed Martin Energy Research Corporation. Research carried out in part on beamline 10.3.1 at the ALS and on beamline 2ID at the APS. Both facilities are supported by the U.S. Department of Energy.

X-RAY MAGNETIC CIRCULAR DICHROISM

INTRODUCTION

X-ray magnetic circular dichroism (XMCD) is a measure of the difference in the absorption coefficient ($\mu_c = \mu^+ - \mu^-$), with the helicity of incident circularly polarized light parallel (μ^+) and antiparallel (μ^-) to the local magnetization direction of the absorbing material. These measurements are typically made at x-ray energies spanning an absorption edge, as illustrated in Figure 1, where a deep atomic core electron is photoexited into the valence band. Because the binding energy of these core electrons is associated with specific elements, XMCD can be used to separately measure the magnetic contributions from individual constituents in a complex material, by tuning the incident beam energy to a specific edge. Furthermore, different absorption edges of the same element provide information on the magnetic contributions of different kinds of valence electrons within a single element.

XMCD measurements yield two basic types of magnetic information, both of which are specific to the element and orbital determined by the choice of measured absorption edge. First, the strength of the dichroic signal is proportional to the projection of the magnetic moment along the incident x-ray beam direction. Thus, the signal can be used to determine magnetization direction for a sample in remanence or changes in the sample magnetization upon varying the applied magnetic field or temperature. Secondly, XMCD can be used to separate the orbital $\langle L_z \rangle$ and spin $\langle S_z \rangle$ contributions to the magnetic moment. This is possible through sum rules (Thole et al., 1992; Carra et al., 1993) that relate these contributions to the integrated dichroic signal. It is this elemental and orbital specificity and the ability to deconvolve the magnetic moment into its orbital and spin components that makes XMCD a unique tool for the study of magnetic materials.

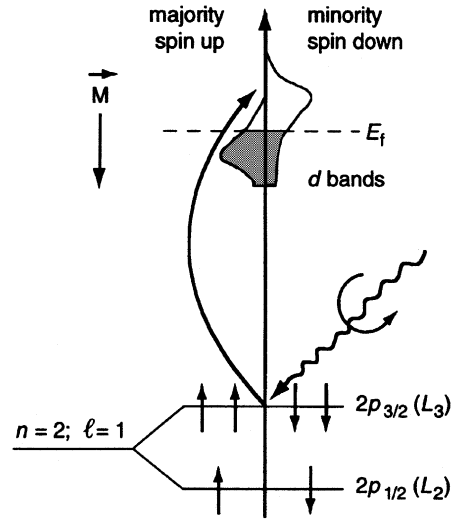

Figure 1. Schematic illustration of the energy bands and transitions involved in XMCD measurements. A circularly polarized photon excites a photoelectron from a spin-orbit-split core state to a spin-polarized valence band.

In discussing x-ray spectra, one must refer quite frequently to the x-ray absorption edges; the terminology for labeling these edges should therefore be made clear from the outset of this discussion. The common convention has been to denote the principal quantum number ($n = 1, 2, 3, 4, \ldots$) of the core state by K, L, M, N,... and the total angular momentum ($s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, etc.) of the core state by 1, 2, 3, 4,.... Therefore, an edge referred to as the L_3 edge would denote an absorption threshold with an initial $2p_{3/2}$ core state. Table 1 lists the elements and edges for which XMCD measurements have been taken along with the corresponding transition, energy range, and reference to a typical spectrum. Most XMCD work in the soft x-ray regime (E < 2000 eV) has centered on the $3d$ transition metal (TM) $L_{2,3}$ edges and rare earth (RE) $M_{4,5}$ edges. These edges probe the largely localized TM $3d$ and RE $4f$ states, which are the primary magnetic electrons in almost all magnetic materials. The relatively large magnetic moments of these states lead to large dichroic effects in this energy regime. Hard x-ray measurements ($E > 2000$ eV) have focused on the TM K edge and the RE $L_{2,3}$ edges, which probe much more diffuse bands with small magnetic moments leading to smaller dichroic effects. Although the edges probed and thus the final states are different for these regimes, the physics and

analysis of the spectra is essentially the same, and they differ only in the techniques involved in spectrum collection.

This unit will concentrate on the techniques employed in the hard x-ray regime, but considerable mention will be made of soft x-ray results and techniques because of the fundamental importance in magnetism of the final states probed by edges in this energy regime. Emphasis will be given to the methods used for the collection of XMCD spectra rather than to detailed analysis of specific features in the XMCD spectra of a particular edge. More detailed information on the features of XMCD spectra at specific edges can be found in other review articles (Krill et al., 1993; Stahler et al., 1993; Schütz et al., 1994; Stöhr and Wu, 1994; Pizzini et al., 1995).

Competitive and Related Techniques

Many techniques provide information similar to XMCD, but typically they tend to give information on the bulk macroscopic magnetic properties of a material rather than microscopic element–specific information. It is apparent that the basic criteria for choosing XMCD measurements over other techniques are the need for this element-specific information or for a separate determination of the orbital and spin moments. The need to obtain this information must be balanced against the requirements that XMCD measurements must be performed at a synchrotron radiation facility, and that collection of spectra can take several hours. Therefore, the amount of parameter space that can be explored via XMCD experiments is restricted by the amount of time available at the beamline.

The methods most obviously comparable to XMCD are the directly analogous laser-based methods such as measurement of Faraday rotation and magneto-optical Kerr effect. These techniques, while qualitatively similar to XMCD, are considerably more difficult to interpret. The transitions involved in these effects occur between occupied and unoccupied states near the Fermi level, and therefore the initial states are extended bands that are much more difficult to model than the atomic-like core states in XMCD measurements. In fact, recent efforts have focused on using XMCD spectra as a basis for understanding the features observed in laser-based magnetic measurements. Another disadvantage of these measurements is that they lack the element specificity provided by XMCD spectra, because they involve transitions between all the conduction electron states. A final potential drawback is the surface sensitivity of the measurements.

Because the size of the dichroic signal scales with sample magnetization, XMCD spectra can also be used to measure relative changes in the magnetization as a function of temperature or applied field. This information is similar to that provided by vibrating sample or SQUID magnetometer measurements. Unlike a magnetometer, which measures the bulk magnetization for all constituents, dichroism measures the magnetization of a particular orbital of a specific element. Therefore, XMCD measurements can be used to analyze complicated hysteresis behavior, such as that encountered in magnetic multilayers, or to measure the different temperature dependencies of each component in a complicated magnetic compound. That these measurements are generally complementary to those obtained with a magnetometer should nevertheless be stressed, since it is frequently necessary to use magnetization measurements to correctly normalize the XMCD spectra taken at fixed field.

The size of the moments and their temperature behavior can also be ascertained from magnetic neutron or nonresonant magnetic x-ray diffraction. These two techniques are the only other methods that can deconvolve the orbital and spin contributions to the magnetic moment. For neutron diffraction, separation of the moments can be accomplished by measuring the magnetic form factor for several different momentum transfer values and fitting with an appropriate model, while for non-resonant magnetic x-ray scattering the polarization dependence of several magnetic reflections must be measured (Blume and Gibbs, 1988; Gibbs et al., 1988). The sensitivity of both these techniques, however, is very limited and thus measurements have been restricted to demonstration experiments involving the heavy rare earth metals with large orbital moments ($\mu_{orb} \sim 6\,\mu_B$). XMCD on the other hand provides orbital moment sensitivity down to $\sim 0.005\,\mu_B$ (Samant et al., 1994). Furthermore, for compound materials these measurements will not be element specific, unless a reflection is used for which only one atomic species produces constructive interference. This is usually only possible

for simple compounds and generally not possible for multilayered materials. As diffractive measurements, these techniques have an advantage over XMCD in that they are able to examine antiferromagnetic as well as ferromagnetic materials. But, the weakness of magnetic scattering relative to charge scattering for nonresonant x-ray scattering makes the observation of difference signals in ferromagnetic compounds difficult.

A diffractive technique that does provide the element specificity of XMCD is x-ray resonant exchange scattering (XRES; Gibbs et al., 1988). XRES measures the intensity enhancement of a magnetic x-ray diffraction peak as the energy is scanned through a core hole resonance. This technique is the diffraction analog of dichroism phenomena and involves the same matrix elements as XMCD. In fact, theoretical XRES calculations reduce to XMCD at the limit of zero momentum transfer. At first glance, this would seem to put XMCD measurements at a disadvantage to XRES measurements, because the former is just a simplification of the later. It is this very simplification, however, that makes possible the derivation of the sum rules relating the XMCD spectrum to the orbital and spin moments. Most XRES measurements in the hard x-ray regime have been limited to incommensurate magnetic Bragg reflections, which do not require circularly polarized photons. In these cases, XRES measurements are more analogous to linear dichroism, for which a simple correlation between the size of the moments and the dichroic signal has not been demonstrated. Lastly, even though the XRES signal is enhanced over that obtained by nonresonant magnetic scattering, it is still typically lower by a factor of 10^4 or more than the charge scattering contributions. Separating signals this small from the incoherent background is difficult for powder diffraction methods, and therefore XRES, and magnetic x-ray scattering in general, have been restricted to single-crystal samples.

Spin-polarized photoemission (SPPE) measures the difference between the emitted spin-up and spin-down electrons upon the absorption of light (McIlroy et al., 1996). SPPE spectra can be related to the spin polarization of the occupied electron states, thereby providing complimentary information to XMCD measurements, which probe the unoccupied states. The particular occupied states measured depend upon the incident beam energy, UV or soft x-ray, and the energy of the photoelectron. Soft x-ray measurements probe the core levels, thereby retaining the element specificity of XMCD but only indirectly measuring the magnetic properties, through the effect of the exchange interaction between the valence band and the core-level electrons. UV measurements, on the other hand, directly probe the partially occupied conduction electron bands responsible for the magnetism, but lose element specificity, which makes a clear interpretation of the spectra much more difficult. The efficiency of spin-resolving electron detectors for these measurements, however, loses 3 to 4 orders of magnitude in the analysis of the electron spin. This inefficiency in resolving the spin of the electron has prevented routine implementation of this technique for magnetic measurements. A further disadvantage (or advantage) of photoemission techniques is their surface sensitivity. The emitted photoelectrons typically come only from the topmost 1 to 10 monolayers of the sample. XMCD, on the other hand, provides a true bulk characterization because of the penetrating power of the x-rays. Magnetic sensitivity in photoemission spectra has also been demonstrated using circularly polarized light (Baumgarten et al., 1990). This effect, generally referred to as photoemission MCD, should not be confused with XMCD, because the states probed and the physics involved are quite different. While this technique eliminates the need for a spin-resolving electron detector, it does not provide a clear relationship between measured spectra and size of magnetic moments.

PRINCIPLES OF THE METHOD

XMCD measures the difference in the absorption coefficient over an absorption edge upon reversing the sample magnetization or helicity of the incident circularly polarized photons. This provides magnetic information that is specific to a particular element and orbital in the sample. Using a simple one-electron theory it is easy to demonstrate that XMCD measurements are proportional to the net moment along the incident beam direction and thus can be used to measure the variations in the magnetization of a particular orbital upon application of external fields or change in the sample temperature. Of particular interest has been the recent development of sum rules which can be used to separate the orbital and spin contributions to the magnetic moment. XMCD measurements are performed at synchrotron radiation facilities, with the specific beamline optics determined by the energy regime of the edge of interest.

Basic Theory of X-Ray Circular Dichroism

Although a number of efforts had been made over the years to characterize an interplay between x-ray absorption and magnetism, it was only in 1986 that the first unambiguous evidence of magnetization-sensitive absorption was observed in a linear dichroism measurement at the $M_{4,5}$ edges of Tb metal (Laan et al., 1986). This measurement was quickly followed by the first observation of XMCD at the K edge of Fe and, a year later, of an order-of-magnitude-larger effect at the L edges of Gd and Tb (Schütz et al., 1987, 1988). Large XMCD signals directly probing the magnetic $3d$ electrons were then discovered in the soft x-ray regime at the $L_{2,3}$ edge of Ni (Chen et al., 1990).

The primary reason for the lack of previous success in searching for magnetic contributions to the absorption signal is that the count rates, energy tunability, and polarization properties required by these experiments make the use of synchrotron radiation sources absolutely essential. Facilities for the production of synchrotron radiation, however, were not routinely available until the late 1970s. The mere availability of these sources was clearly not sufficient, because attempts to observe XMCD had been made prior to 1988 without success (Keller, 1985). It was only as the stability of these sources increased that the systematic errors which can easily creep into difference measurements were reduced sufficiently to allow the XMCD effect to be observed.

The basic cause of the enhancement of the dichroic signal that occurs near an absorption edge can be easily understood using a simple one-electron model for x-ray absorption (see Appendix A). While this model fails to explain all of the features in most spectra, it does describe the fundamental interaction that leads to the dichroic signal, and more complicated analyses of XMCD spectra are typically just perturbations of this basic model. In this crude treatment of x-ray absorption, the transition probabilities between spin-orbit-split core states and the spin-polarized final states are calculated starting from Fermi's golden rule. The most significant concept in this analysis is that the fundamental cause of the XMCD signal is the spin-orbit splitting of the core state. This splitting causes the difference between the matrix elements for the left or right circularly polarized photons. In fact, the presence of a spin-orbit term is a fundamental requirement for the observation of any magneto-optical phenomena regardless of the energy range. Without it no dichroic effects would be seen.

Specifically, the example illustrated in Appendix A demonstrates that, for an initial $2p_{1/2}$ (L_2) core state, left (right) circularly polarized photons will make preferential transitions to spin-down (-up) states. The magnitude of this preference is predicted to be proportional to the difference between the spin-up and spin-down occupation of the probed shell and as such the net moment on that orbital. Therefore the measured signal scales with the local moment and can be used to determine relative changes in the magnetization upon applying a magnetic field or increasing the sample temperature. Furthermore, the XMCD signal for an L_3 edge is also predicted to be equal and opposite that observed at an L_2 edge. This 1:−1 dichroic ratio is a general rule predicted for any pair of spin-orbit-split core states [i.e., $2p_{1/2,\ 3/2}$ ($L_{2,3}$), $3d_{3/2,\ 5/2}$ ($M_{4,5}$), etc.].

Although this simple model describes the basic underlying cause of the XMCD effect, it proves far too simplistic to completely explain most dichroic spectra. In particular, this model predicts no dichroic signal from K-edge measurements, because the initial state at this edge is an s level with no spin-orbit coupling. Yet it is at this edge that the first (admittedly weak) XMCD effects were observed. Also, while experimental spectra for spin-orbit-split pairs have been found to be roughly in the predicted 1:−1 ratio, for most materials they deviate considerably. To account for these discrepancies, more sophisticated models need to incorporate the following factors, which are neglected in the simple one-electron picture presented.

1. The effects of the spin-orbit interaction in the final states.
2. Changes in the band configuration due to the presence of the final state core hole.
3. Spin-dependent factors in the radial part of the matrix elements.
4. Contributions from higher-order electric quadrupole terms, which can contribute significantly to the XMCD signal for certain spectra.

The first two of these factors are significant for all dichroic spectra, while the later two are particularly relevant to RE L-edge spectra.

First consider the effects of the spin-orbit interaction in the final states. The inclusion of this factor can quickly explain the observed dichroic signal at TM K-edge spectra (i.e., repeat the example in Appendix A with initial states and final states inverted). This observation of a K-edge dichroic signal illustrates the extreme sensitivity of the XMCD technique, because not only do $4p$ states probed by this edge posses a relatively small spin moment ($\sim 0.2\ \mu_B$), but the substantial overlap with neighboring states results in a nearly complete quenching of the orbital moment. This orbital contribution ($\sim 0.01\ \mu_B$), however, is nonzero, and thus a nonzero dichroic signal is observed.

The influence of the final state spin-orbit interaction also explains the deviations from the predicted 1:−1 ratio observed at L and M edges. The spin-orbit term tends to enhance the L_3- (M_5-) edge dichroic signal at the expense of the L_2 (M_4) edge. In terms of the simple one-electron model presented, the spin-orbit interaction effectively breaks the degeneracy of the m_l states, resulting in an enhancement of the XMCD signal at the L_3 edge. An example of this enhancement is shown in Figure 2, which plots XMCD spectra obtained at the Co L edges for metallic Co and for a Co/Pd multilayer (Wu et al., 1992). The large enhancement of the L_3-edge dichroic signal indicates that the multilayer sample possesses an enhanced Co $3d$ orbital moment compared to that of bulk Co.

A quantitative relationship between the degree of this enhancement and the strength of the spin-orbit coupling is expressed in terms of sum rules that relate the integrated dichroic (μ_c) and total (μ_o) absorptions over a

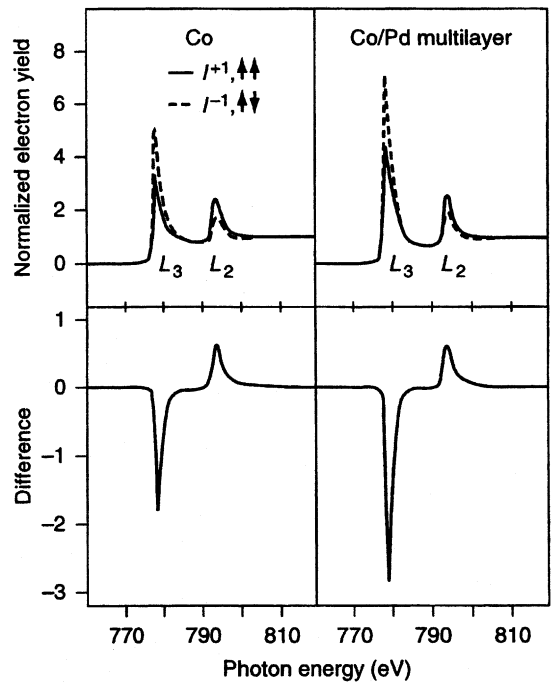

Figure 2. Normal and dichroic absorption at the Co $L_{2,3}$ edges for Co metal and Co/Pd multilayers. Courtesy of Wu et al. (1992).

spin-orbit-split pair of core states to the orbital and spin moments of that particular final state orbital (Thole et al., 1992; Carra et al., 1993). The integrated signal rather than the value at a specific energy is used in order to include all the states of a particular band. This has the added benefit of eliminating the final state core-hole effects, thereby yielding information on the ground state of the system. Although the general expressions for the sum rules can appear complicated, at any particular edge they reduce to extremely simple expressions. For instance, the sum rules for the $L_{2,3}$ edges simplify to the following expressions:

$$\frac{\int_{L_3+L_2} \mu_c dE}{\int_{L_3+L_2} 3\mu_o dE} = \frac{\langle L_z \rangle / 2}{(10 - n_{occ})}, \quad (1)$$

$$\frac{\int_{L_3} \mu_c dE - 2\int_{L_2} \mu_c dE}{\int_{L_3+L_2} 3\mu_o dE} = \frac{\langle S_z \rangle + 7\langle T_z \rangle}{(10 - n_{occ})} \quad (2)$$

Here $\langle L_Z \rangle$, $\langle S_Z \rangle$, and $\langle T_Z \rangle$ are the expectation values for the orbital, spin, and spin magnetic dipole operators in Bohr magnetons [$\boldsymbol{T} = \frac{1}{2}(\boldsymbol{S} - 3\hat{\boldsymbol{r}}(\hat{\boldsymbol{r}} \cdot \boldsymbol{S})$] and n_{occ} is the occupancy of the final-state band (i.e., $10 - n_{occ}$ corresponds to the number of final states available for the transition). The value of n_{occ} must usually be obtained via other experimental methods or from theoretical models of the band occupancy, which can lead to uncertainties in the values of the moments obtained via the sum rules. To circumvent this, it is sometimes useful to express the two equations above as a ratio:

$$\frac{\int_{L_3+L_2} \mu_c dE}{\int_{L_3} \mu_c dE - 2\int_{L_2} \mu_c dE} = \frac{\langle L_z \rangle}{2\langle S_z \rangle + 14\langle T_z \rangle} \quad (3)$$

This yields an expression that is independent of the shell occupancy and also eliminates the need to integrate over the total absorption, which can also be a source of systematic error in the measurement. Comparison with magnetization measurements can then be used to obtain the absolute value of the orbital moment. Applying the sum rules to the spectra shown in Figure 2 yields values of 0.17 and 0.24 μ_B for the orbital moments of the bulk Co and Co/Pd samples, respectively. This example again illustrates the sensitivity of the XMCD technique, because the clearly resolvable differences in the spectra correspond to relatively small changes in the size of the orbital component.

Several assumptions go into the derivation of the sum rules, which can restrict their applicability to certain spectra; the most important of these is that the two spin-orbit split states must be well resolved in energy. This criterion means that sum rule analysis is restricted to measurements involving deep core states and is generally not applicable to spectra taken at energies below ~250 eV. Moreover, the radial part of the matrix elements is assumed to be independent of the electron spin and identical at both edges of a spin-orbit-split pair. This is typically not the case for the RE L edges, where the presence of the open $4f$ shell can introduce some spin dependence (Konig et al., 1994).

Also, the presence of the magnetic dipole term $\langle T_Z \rangle$ in the these expressions poses problems for determining the exact size of the spin moment or the orbital-to-spin ratio. The importance of the size of this term has been a matter of considerable debate (Wu et al., 1993; Wu and Freeman, 1994). Specifically, it has been found that, for TM $3d$ states in a cubic or near-cubic symmetry, the $\langle T_Z \rangle$ term is small and can be safely neglected. For highly anisotropic conditions, however, such as those encountered at interfaces or in thin films, $\langle T_Z \rangle$ can become appreciable and therefore would distort measurements of the spin moment obtained from the XMCD sum rules. For RE materials, $\langle T_Z \rangle$ can be calculated analytically for the $4f$ states, but an exact measure of the relative size of this term for the $5d$ states is difficult to obtain.

PRACTICAL ASPECTS OF THE METHOD

The instrumentation required to collect dichroic spectra naturally divides XMCD measurements into two general categories based on the energy ranges involved: those in the soft x-ray regime, which require a windowless UHV-compatible beamline, and those in the hard x-ray regime, which can be performed in nonevacuated environments. The basic elements required for an XMCD experiment, however, are similar for both regimes: i.e., a source of circularly polarized x-rays (CPX), an optical arrangement for monochromatizing the x-ray beam, a magnetized sample, and a method for detecting the absorption signal. The main differences between the two regimes, other than the sample environment, lie in the methods used to detect the XMCD effect.

Circularly Polarized X-Ray Sources

In evaluating the possible sources of CPX, the following quantities are desirable; high circular polarization rate (P_c), high flux (I), and the ability to reverse the helicity. For a given source, though, the experimenter must sometimes sacrifice flux in order to obtain a high rate of polarization, or vice versa. Under these circumstances, it should be kept in mind that the figure of merit for circularly polarized sources is $P_c^2 I$, because it determines the amount of time required to obtain measurements of comparable statistical accuracy on different sources (see Appendix B). Laboratory x-ray sources have proved to be impractical for XMCD measurements because they offer limited flux and emit unpolarized x-rays. The use of a synchrotron radiation source is therefore essential for performing XMCD experiments. Three different approaches can be used to obtain circularly polarized x-rays from a synchrotron source: using (1) off-axis bending magnet radiation, (2) a specialized insertion device, such as an elliptical multipole wiggler, or (3) phase retarders based on perfect crystal optics.

In a bending magnet source, a uniform circular motion by the relativistic electrons or positrons in the storage ring is used to generate synchrotron radiation. This radiation, when observed on the axis of the particle orbit, is purely linearly polarized in the orbital plane (σ polarization).

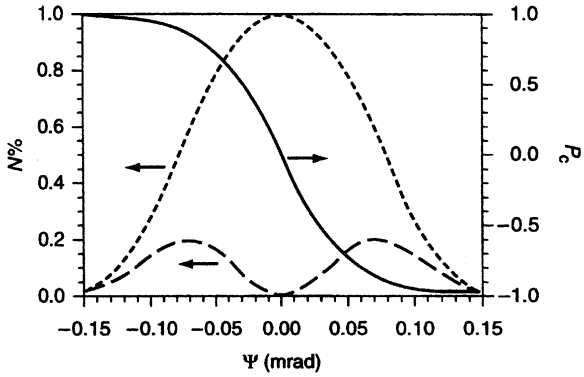

Figure 3. Horizontally (short dashes) and vertically (long dashes) polarized flux along with circular polarization rate (solid) from an APS bending magnet at 8.0 keV.

Appreciable amounts of photons polarized out of the orbital plane (π polarization) are only observed off-axis (Jackson, 1975). These combine to produce a CPX source because the σ- and π-polarized photons are exactly $\delta = \pm\pi/2$ radians out of phase. The sign of this phase difference depends on whether the radiation is viewed from above or below the synchrotron orbital plane. Therefore, the off-axis synchrotron radiation will be elliptically polarized, with a helicity dependent on the viewing angle and a degree of circular polarization given by

$$P_c = \frac{2E_\sigma E_\pi}{|E_\sigma|^2 + |E_\pi|^2} \sin\delta, \qquad (4)$$

where E_σ and E_π are the electric field amplitudes of the radiation. An example of this is shown in Figure 3, which plots the σ and π intensities along with the circular polarization rate as a function of viewing angle for 8.0 keV x-rays at an Advanced Photon Source bending magnet (Shenoy et al., 1988).

Although simple in concept, obtaining CPX in this fashion does have some drawbacks. The primary one is that the off-axis position required to get appreciable circular polarization reduces the incident flux by a factor of 5 to 10. Furthermore, measurements taken at the sides of the synchrotron beam where the intensity changes more rapidly are particularly sensitive to any motions of the particle beam. Moreover, the photon helicity cannot be changed easily because this requires moving the whole experimental setup vertically. This movement can result in slightly different Bragg angles incident on the monochromator, thereby causing energy shifts that would have to be compensated for. Attempts have been made to overcome this by using slits, which define beams both above and below the orbital plane simultaneously in order to make XMCD measurements. These efforts have had limited success, however, since they are particularly sensitive to sample inhomogeneity (Schütz et al., 1989b).

Standard planar insertion devices are magnetic arrays placed in the straight sections of synchrotron storage rings to make the particle beam oscillate in the orbital plane. Because each oscillation produces synchrotron radiation, a series of oscillations greatly enhances the emitted flux over that produced by a single bending magnet source. These devices produce linearly polarized light on axis, but the off-axis radiation of a planar device, unlike that of a bending magnet, is not circularly polarized, because equal numbers of right- and left-handed bends in the particle orbit produce equal amounts of left- and right-handed circular polarization, yielding a net helicity of zero. Specialized insertion devices for producing circularly polarized x-rays give the orbit of the particle beam an additional oscillation component out of the orbital plane (Yamamoto et al., 1988). In this manner, the particle orbit is made to traverse a helical or pseudo-helical path to yield a net circular polarization on axis of these devices. When coupled with a low-emittance synchrotron storage ring, these devices can provide a high flux with a high degree of polarization. The main disadvantage of these devices is that their high cost has made the beamlines dedicated to them rather rare. Also, to preserve the circular polarization through monochromatization, specialized optics are required, particularly for lower energies (Malgrange et al., 1991).

Another alternative for producing CPX is using x-ray phase retarders. Phase retarders employ perfect crystal optics to transform linear to circular polarization by inducing a $\pm\pi/2$ radian phase shift between equal amounts of incoming σ- and π-polarized radiation. (Here σ and π refer to the intensities of the radiation polarized in and out of the scattering plane of the phase retarder, and should not be confused with the radiation emitted from a synchrotron source. Unfortunately, papers on both subjects tend to use the same notation; it is kept the same for this paper in order to conform with standard practice.) Equal σ and π intensities incident on the phase retarder are obtained by orienting its plane of diffraction at a 45° angle with respect to the synchrotron orbital plane. As the final optical element before the experiment, it offers the greatest degree of circular polarization incident on the sample. Thus far phase-retarding optics have only been developed for harder x-rays, with soft x-ray measurements restricted to bending-magnet and specialized-insertion-device CPX sources.

Typically materials in the optical regime exhibit birefringence over a wide angular range; in the x-ray regime, however, materials are typically birefringent only at or near a Bragg reflection. For the hard x-ray energies of interest in XMCD measurements, a transmission-phase retarder, shown in Figure 4, has proved to be the most suitable type of phase retarder (Hirano et al., 1993). In this

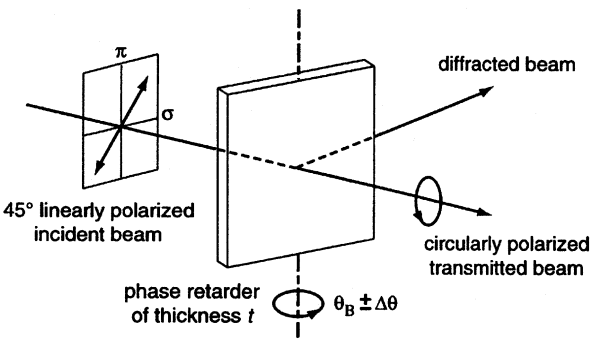

Figure 4. Schematic of a transmission phase retarder.

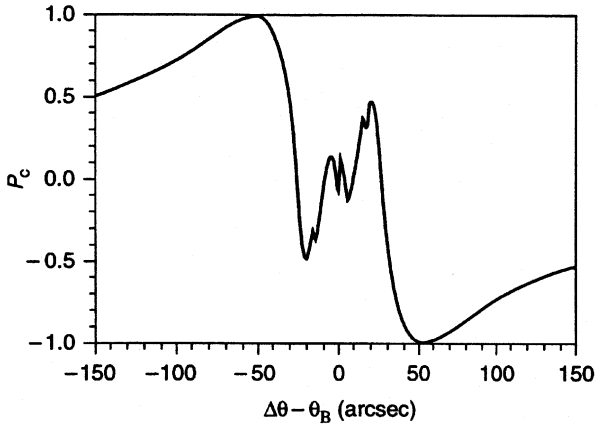

Figure 5. Calculated degree of circular polarization of the transmitted beam for a 375-μm-thick diamond (111) Bragg reflection at 8.0 keV.

phase retarder, a thin crystal, preferably of a low-Z material to minimize absorption, is deviated ($\Delta\theta \sim 10$ to 100 arcsec) from the exact Bragg condition, and the transmitted beam is used as the circularly polarized x-ray source. Figure 5 plots the predicted degree of circular polarization in the transmitted beam as a function of the off-Bragg position for a 375-μm-thick diamond (111) crystal and 8.0 keV incoming x-ray beam. Note that, for a particular crystal thickness and photon energy, either helicity can be obtained by simply reversing $\Delta\theta$. Further, when used with a low-emittance source, a high degree of polarization ($P_c > \sim 0.95$) can be achieved with a transmitted beam intensity of ~10% to 20% of the incident flux. This flux loss is comparable to that encountered using the off-axis bending magnet radiation. The phase retarder, however, provides easy helicity reversal and can be used with a standard insertion device to obtain fluxes comparable to or greater than those obtained from a specialized device (Lang et al., 1996). The main drawback of using a phase retarder as a CPX source is that the increased complexity of the optics can introduce a source of systematic errors. For instance, if the phase retarder is misaligned and does not precisely track with the energy of the monochromator, the $\pm\Delta\theta$ movements of the phase retarder will not be symmetric about the Bragg reflection. This leads to measurements with different P_c values and can introduce small energy shifts in the transmitted beam.

Detection of XMCD

The most common method used to obtain XMCD spectra is to measure the absorption by monitoring the incoming (I_o) and transmitted (I) fluxes. The absorption in the sample is then given by:

$$\mu_o t = \ln\left(\frac{I_o}{I}\right) \tag{5}$$

The dichroism measurement is obtained by reversing the helicity or magnetization of the sample and taking the difference of the two measurements ($\mu_c = \mu^+ - \mu^-$). Typically the thickness of the sample, t, is left in as a proportionality factor, because its removal requires an absolute determination of the transmitted flux at a particular energy. Some experimenters choose to remove this thickness factor by expressing the dichroism as a ratio between the dichroic and normal absorption, μ_c/μ_o. Absorption not due to resonant excitation of the measured edge, however, is usually removed by normalizing the pre-edge of the μ_o spectra to zero; therefore, expressing the XMCD signal in terms of this ratio tends to accentuate features closer to the absorption onset.

Rather than taking the difference of Eq. 5 for two magnetizations, the dichroic signal is also frequently expressed in terms of the asymmetry ratio of the transmitted fluxes only. This asymmetry ratio is related to the dichroic signal by Eq. 6.

$$\begin{aligned}\frac{I^+ - I^-}{I^+ + I^-} &= \frac{e^{-\mu^+ t} - e^{-\mu^- t}}{e^{-\mu^+ t} + e^{-\mu^- t}} = \frac{e^{0.5\mu_c t} - e^{-0.5\mu_c t}}{e^{0.5\mu_c t} + e^{-0.5\mu_c t}} \\ &= -\tanh(0.5\mu_c t) \cong -f0.5\mu_c t \end{aligned} \tag{6}$$

The last approximation can be made, because reasonable attenuations require $\mu_o t \sim 1$ to 2 and $\mu_c < \sim 0.05\,\mu_o t$. The factor f is introduced in an *ad hoc* fashion to account for the incomplete circular polarization in the incident beam and the finite angle (θ) between the magnetization and beam directions, $f = P_c \cos\theta$. In some cases, the factor f also includes the incomplete sample magnetization (M') relative to the saturated moment at $T = 0$ K. If the experimenter is interested in obtaining element specific magnetizations as a function of field or temperature, however, the inclusion of this factor would defeat the purpose of the measurement.

This type of measurement is illustrated in Figure 6, which shows a plot of a hysteresis measurement taken using the dichroic signal at the Co and Fe L_3 edges of a Co/Cu/Fe multilayer (Chen et al., 1993; Lin et al., 1993). In this compound the magnetic anisotropy of the Co layer is much greater than that of the Fe layer. Thus, in an applied magnetic field, the directions of Fe moments reverse before those of Co moments. By monitoring the strength of the dichroic signal as a function of applied field for the Fe and Co L_3 edges, the hysteresis curves of each constituent were traced out. Similarly, XMCD can also be used to measure the temperature variation of the magnetization of a specific constituent in a sample. This is demonstrated in Figure 7 (Rueff et al., 1997), which shows the variation of the dichroic signal at the Gd L edges as a function of temperature for a series of amorphous GdCo alloys. These XMCD measurements provide orbital- and element-specific information complementary to that obtained from magnetometer measurements.

Measurement Optics

Two basic optical setups, shown in Figure 8, are used for the measurement of x-ray attenuations. The scanning monochromator technique (Fig. 8a) selects a small energy range ($\Delta E \sim 1$ eV) to impinge on the sample, and the full

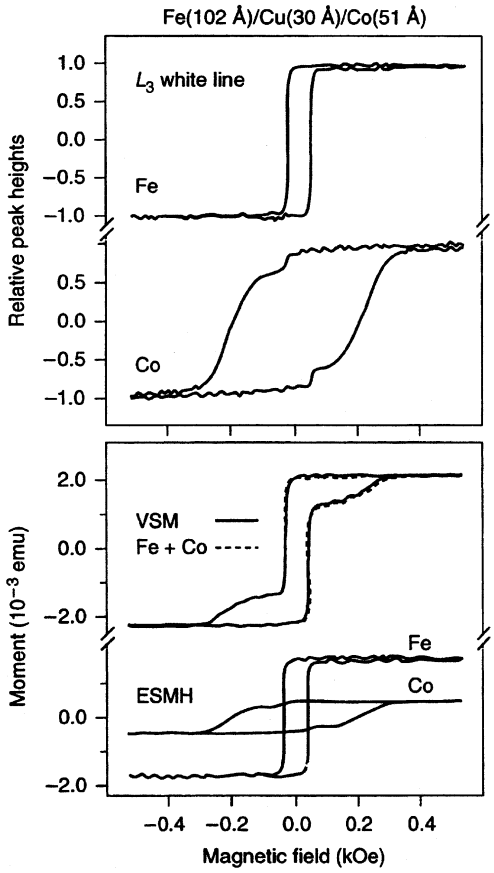

Figure 6. Hysteresis measurements of the individual magnetizations of Fe and Co in a Fe/Cu/Co multilayer obtained by measuring the L_3 edge XMCD signal (top), along with data obtained from a vibrating sample magnetometer (VSM) and a least-squares fit to the measured Fe and Co hysteresis curves (bottom). spectrum is acquired by sequentially stepping the monochromator through the required energies. In the dispersive monochromator technique (Fig. 8b), a broad range of energies ($\Delta E \sim 200$ to 1000 eV) is incident on the sample simultaneously and the full spectrum is collected by a position-sensitive detector. Both of these setups are common at synchrotron radiation facilities where they have been widely used for EXAFS measurements. Their conversion to perform XMCD experiments usually requires minimal effort. The added aspects are simply use of CPX, using the methods discussed above, and a magnetized sample.

Although the scanning monochromator technique can require substantial time to step through the required beam energies, the simplicity of data interpretation and compatibility with most synchrotron beamline optics have made it by far the most common method utilized for XMCD measurements. Typically, these measurements are taken by reversing the magnetization (helicity) at each energy step, rather than taking a whole spectrum, then changing the magnetization (helicity) and repeating the measurement. The primary reason for this is to minimize systematic errors that can be introduced as a result of the decay or movements of the particle beam.

In the hard x-ray regime, because of the high intensity of the synchrotron radiation, the incident (I_o) and

attenuated (I) beam intensities are usually measured using gas ionization chambers. For these detectors, a bias (500 to 2000 V) is applied between two metallic plates and the x-ray beam passes though a gas (generally nitrogen) flowing between them. Absorption of photons by the gas creates ion pairs that are collected at the plates, and the induced current can then be used to determine the x-ray beam intensity. Typical signal currents encountered in these measurements range from $\sim 10^{-9}$ A for bending magnet sources to $\sim 10^{-6}$ A for insertion-device sources. While these signal levels are well above the electronic noise levels, $\sim 10^{-14}$ A, produced by a state-of-the-art current amplifier, other noise mechanisms contribute significantly to the error. The most common source of noise in these detectors arises from vibrations in the collection plates and the signal cables. Vibrations change the capacitance of the detection system, inducing currents that can obscure the signal of interest—particularly for measurements made on a bending magnet source, where the signal strength is smaller. This error can be minimized by rigidly mounting the ion chamber and minimizing the length of cable between the ion chamber and the current amplifier. Even when these effects are minimized, however, they still tend to be the dominant noise mechanism in XMCD measurements. This makes it difficult to get an *a priori* estimate of the error based on the signal strength. Therefore, the absolute error in an XMCD measurement is frequently obtained by taking multiple spectra and computing the average and variance in the data.

Using a scanning monochromator, one can also indirectly measure the effective absorption of a sample by monitoring the fluorescence signal. Fluorescence radiation results from the filling of the core hole generated by the absorption of an x-ray photon. The strength of the fluorescence will thus be proportional to the number of vacancies in the initial core state and therefore to the absorption. An advantage of this technique over transmittance measurements is that fluorescence arises only from the element at resonance, thereby effectively isolating the signal of interest. In a transmittance measurement, on the other hand, the resonance signal from the absorption edge sits atop the background absorption due to the rest of the constituents in the sample.

Fluorescence measurements require the use of an energy-sensitive detector to isolate the characteristic lines from the background radiation of elastically and Compton scattered radiation. Generally Si or Ge solid-state detectors have been used for fluorescence detection, since they offer acceptable energy resolution ($\Delta E \sim 200$ eV) and high efficiencies. The count rate offered by these solid-state detectors, however, is typically restricted to <500 kHz. Fluorescence signals this strong are easily obtained even using bending magnet sources; thus, the detector becomes the rate-limiting factor for data acquisition. Considering that a typical XMCD difference signal for a RE L edge is $\sim 0.5\%$, obtaining a 10% accuracy for this difference requires a total count of $\sim 4 \times 10^6$. Thus, acquiring this accuracy over the entire scanned range, which may contain ~ 100 points, can require data acquisition times on the order of several hours, irrespective of the CPX source utilized.

A further complication encountered with fluorescence data is that the signal must be corrected for the self absorption of the sample. For a thick sample, this correction is given by:

$$\mu_o(E) = \frac{I_f}{I_o} \sim \frac{\mu_o(E)\sin\theta}{\mu_T(E)/\sin\theta + \mu_T(E_f)/\sin\varphi} \qquad (7)$$

where $\mu_T(E)$ is the total absorption at energy E, E_f is the fluorescence energy, θ is the entrance angle of the incident x-rays, and ϕ is the exit angle of the fluorescent x-rays. From the count rates involved and the process needed to deconvolve the true absorption from the measured fluorescence signal, it is clear that this technique is at a disadvantage compared to a straightforward transmission measurement. Fluorescence measurements, however, are the preferred technique when examining dilute systems or thin magnetic films on thick substrates. For these samples, $\mu_T(E)$ is nearly constant, so the correction in Eq. 7 becomes negligible. Further, the difference signals in transmission arising from dilute constituents are minimal; thus, they benefit greatly from isolation of absorption only due to the atomic species of interest achieved with the fluorescence technique.

Another indirect measure of the absorption spectra used for XMCD is the measurement of the total electron yield from a sample. In this method, an electrical lead is attached directly to the sample, and a metallic enclosure with an entrance hole for the beam surrounds it. The enclosure is kept at a small bias (~ 10 V) with respect to the sample, effectively turning the sample itself into an ionizing detector. This technique is quite similar to fluorescence measurements, in that, instead of probing the radiative decay of the core hole, it probes the decay of the core hole via Auger transitions. The main contribution to the total yield signal, however, does not arise directly from the Auger electrons themselves or even from the ejected photoelectrons, but rather from the secondary inelastically scattered electrons. Despite the complications encountered with secondary electron processes, it has been shown that the total yield signal obtained is proportional to the x-ray absorption (Gudat and Kunz, 1972). To minimize possible systematic errors, the incident beam intensity is monitored using a similar detection method. A partially transmitting wire mesh is placed in the incident beam, again surrounded by a metal enclosure with an applied bias, and the induced current measured to determine I_o.

Electron yield measurements are the detection method most often utilized in the soft x-ray regime, because the photon attenuation lengths at these energies (~ 100 Å) make transmittance measurements difficult. Furthermore, the probability of fluorescence decay relative to Auger decay of the core hole becomes small below ~ 2000 eV. The main drawback (or advantage) of this technique is its high surface sensitivity, since nearly all the Auger electrons originate within ~ 50 Å of the surface.

A particularly novel use of electron yield detection in XMCD has been imaging of magnetic domains (Stöhr et al., 1993). In this technique, a photoelectron microscope is used to detect the secondary electrons from a particular

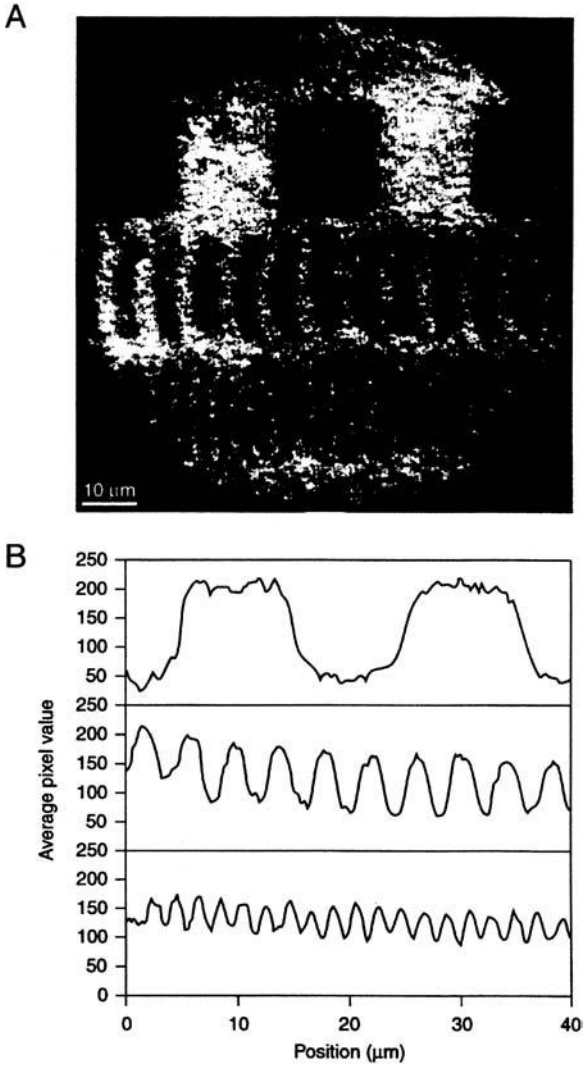

Figure 9. Image of the magnetic domains in Co/Pt multilayer obtained from XMCD signal detected using a photoelectron microscope (**A**). Also shown are integrated traces of the image (**B**). spot on the sample, thereby obtaining a two-dimensional absorption profile (Tonner et al., 1994). By tuning the energy to an absorption edge with a strong XMCD signal and utilizing CPX, magnetization-sensitive contrast in the resultant image is obtained. This is demonstrated in Figure 9, which shows just such an image taken at the Co L edges of a CoPtCr film. In this particular material, the magnetic domains align themselves perpendicular to the plane of the sample. Therefore, taking the difference in the signal measured with either helicity produces a picture of the magnetic domains of the sample. Figure 9 is a combination of the images taken at both the L_2 and L_3 edges. Domain sizes down to $10\,\mu m \times 0.5\,\mu m$ are clearly visible. The uniqueness of this measurement over the same information available from other techniques is again the element specificity of XMCD. Thus the degree of magnetic alignment of individual constituents can be measured.

An alternative to the scanning monochromator is the use of energy dispersive optics (Baudelet et al., 1991). In a dispersive arrangement a curved crystal is used to monochromatize the beam. The angle that the incident beam makes with the diffraction planes ($\theta' \rightarrow \theta''$) varies across the crystal, and thus a range of energies ($E' \rightarrow E''$) are diffracted (Fig. 8b). The dispersion of the monochromator crystal is such that the photon energies vary approximately linearly with angle, focusing to a point ($\sim$100 μm) $\sim$3 to 4 m from the monochromator, where the sample is generally placed. A position-sensitive detector placed behind the sample can then be used to collect the full spectrum. There are several advantages to using dispersive optics for collecting XMCD data. The foremost is that acquiring the spectra requires no motorized motions, eliminating the time required to scan the monochromator and thereby greatly enhancing data collection rates. Another advantage is that the small focal spot reduces errors caused by sample nonuniformity. The disadvantage of the technique is that the data analysis is in general more complicated than for data obtained using a scanning monochromator. The charge-coupled device detectors generally used for these measurements possess an inherent readout noise that must be carefully subtracted. This subtraction can be further complicated by structure that may be introduced into this noise over time by the x-ray beam; thus, the noise must be monitored periodically throughout the data collection process by collecting background spectra. Furthermore, the I_o spectrum may not be uniform with energy, as a result of variations in the reflectivity of the monochromator crystal or post-monochromator mirror optics; therefore, an image of the incident beam must also be taken. This technique has almost exclusively been used with off-axis bending-magnet CPX sources, although recently the applicability of phase retarders with dispersive optics has been demonstrated (Giles et al., 1994).

Sample Magnetization

Once the CPX source and optics have been chosen, the sample must be magnetized. The analysis presented in Appendix A assumed that the magnetization and photon helicity were collinear. A more detailed calculation demonstrates that for dipolar transitions the magnitude of the XMCD signal should scale with the cosine of the angle between the magnetization and beam. Therefore, in order to maximize the possible signal, the magnetic field should be as close to the beam direction as possible. Problems arise, however, in applying a field exactly parallel to the beam direction. Demagnetization effects make thin foils extremely difficult to magnetize normal to the foil plane and thus they are usually magnetized in plane. In a transmittance measurement the x-ray beam must be incident at some angle to the plane of the sample, which results in a finite angle between the beam and the field directions ($\sim 25^\circ \rightarrow 45^\circ$). Even when a solenoid coaxial with the incident x-ray beam is used to provide the magnetic field, the sample plane should not be perpendicular to the solenoid axis but rather at some angle. In this arrangement,

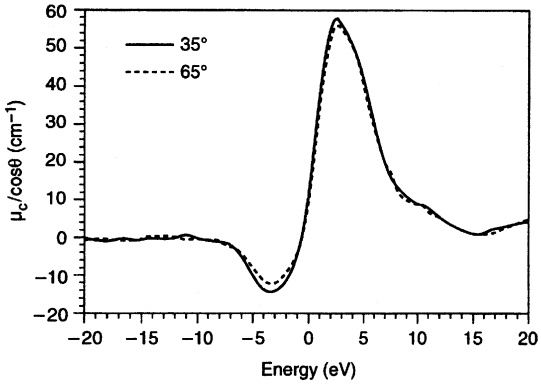

Figure 10. XMCD spectra at the Dy L_3 edge of a $Dy_{0.4}Tb_{0.6}$ alloy for different angles between the incident beam and magnetization directions, showing the contributions arising from quadrupole transitions. Courtesy of Lang et al. (1995).

unless the solenoid generates a very high magnetic field ($|B| > 1$ T), the direction of the local magnetization direction will generally lie along the sample plane rather than along the field direction.

Varying the angle that the beam makes with the sample magnetization can also be used as a means of identifying features in the dichroic spectra that do not arise from dipolar transitions which scale with the cosine. Figure 10 shows the XMCD signal taken for two different angles at the Dy L_3 edge in a $Dy_{0.4}Tb_{0.6}$ alloy (Lang et al., 1995). These spectra are normalized to the cosine of the angle between the beam and the magnetization directions; therefore, the deviation in the lower feature indicates nondipolar-like behavior. This feature has been shown to arise from quadrupolar transitions to the 4*f* states and is a common feature in all RE $L_{2,3}$-edge XMCD spectra (Wang et al., 1993). Although quadrupolar effects in the absorption spectrum are smaller than dipolar effects by a factor of $\sim$100, their size becomes comparable in the difference spectrum due to the strong spin-polarization of the RE 4*f* states. The presence of quadrupolar transitions can complicate the application of sum rule to the analysis of these spectra but also opens up the possibility of obtaining magnetic information on two orbitals simultaneously from measurements at only one edge.

METHOD AUTOMATION

Acquisition of XMCD spectra requires a rather high degree of automation, because the high intensities of x-ray radiation encountered at synchrotron sources prevent any manual sample manipulation during data acquisition. The experiment is normally set up inside a shielded room and all experimental equipment operated remotely through a computer interface. These interfaces are typically already installed on existing beamlines and the experimenter simply must ensure that the equipment that they are considering for the experiment is compatible with the existing hardware. Note that the time required to enter and exit the experimental enclosure is not minimal. Therefore, computerized motion control of as many of the experimental components (i.e., magnet, sample, slits, etc.) as possible is desirable.

The typical beamline equipment used in XMCD data acquisition includes motorized stages, various NIM (nuclear instrumentation module electronic standard) electronic components, power supplies, and cryostats with associated temperature controllers. The data acquisition system for the collection of the XMCD spectra should be fully automated. The computer should step through the required energies if a scanning monochromator is used, alternate the magnet field or helicity, and record the detector counts. In addition, since obtaining enough statistical accuracy in full XMCD spectra frequently requires repeated scanning for a substantial time, the software should also collect multiple scans and save the data without manual intervention.

DATA ANALYSIS AND INITIAL INTERPRETATION

The first thing to realize when taking an initial qualitative look at an XMCD spectrum is that these measurements probe the unoccupied states, whose net polarization is opposite that of the occupied states. Thus, the net difference in the XMCD signal reflects the direction of the so-called minority spin band, because it contains the greater number of available states. It is therefore easy to make a sign error for the dichroic spectra, and care should be taken when determining the actual directions of the moments in a complicated compound. To prevent confusion, it is essential to measure the direction of the magnetic field and the helicity of the photons used from the outset of the experiment.

If XMCD is being used to measure changes in the magnetization of the sample, the integrated dichroic signal should be used rather than the size of the signal at one particular energy for two reasons in particular. The integrated signal is less sensitive to long-term drifts in the experimental apparatus than are measurements at one nominal energy. And, systematic errors are much more apparent in the entire spectrum than at any particular energy. For instance, the failure of the spectrum to go to zero below or far above the absorption edge would immediately indicate a problem with the data collection, but would not be detected by measurement at a single energy.

When analyzing spectra taken from different compounds, one should note that a change in the magnitude of the dichroic signal at just one edge does not necessarily reflect a change in the size or direction of the total magnetic moment. Several factors complicate this, some of which have already been mentioned. For example, the development of an orbital moment for the spectra shown in Figure 2 greatly enhanced the signal at the L_3 edge but diminished the signal at the L_2 edge. Therefore, although the size of the total moment remains relatively constant between the two samples, the dichroic signal at just one edge shows substantial changes that do not necessarily reflect this. The total moment in this case must be obtained through the careful application of both sum rules or comparison with magnetometer measurements. The strength of the TM *K*-edge dichroism also tends not to

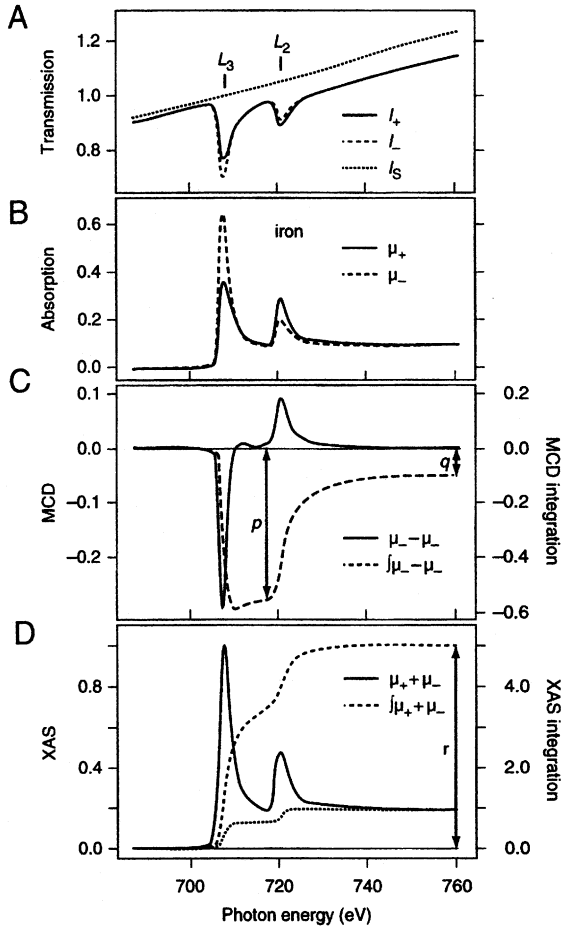

Figure 11. Steps involved in the sum rule analysis of the XMCD spectra demonstrated for a thin layer of metallic Fe. (**A**) Transmitted intensity of parylene substrate and substrate with deposited sample. (**B**) Calculated absorption with background subtracted. (**C**) Dichroic spectra and integrated dichroic signal. (**D**) Absorption spectra and edge-jump model curve along with integrated signal. Courtesy of Chen et al. (1995).

reflect the size of the moment for different materials. This is particularly true for the Fe *K*-edge spectra which demonstrate a complete lack of correlation between the size of the total Fe moment and the strength of the dichroic signal, although better agreement has been found for Co and Ni (Stahler et al., 1993). In addition, RE $L_{2,3}$-edge spectra show a strong spin dependence in the radial matrix elements that can in some cases invert the relationship between the dichroic signal and the size of the moment (Lang et al., 1994). These complications notwithstanding, the dichroic spectra at one edge and within one compound should still scale with changes in the magnetization due to applied external fields or temperature changes.

If the XMCD signal is not complicated by the above effects and both edges of a spin-orbit-split pair are measured, the sum rules may be applied. The steps involved in the implementation of the sum rules are illustrated in Figure 11 for a thin Fe metal film deposited on a parylene substrate (Chen et al., 1995). The first step in sum rules analysis is removal from the transmission signal of all absorption not due to the particular element of interest. In this example, this consists of separately measuring and subtracting the substrate absorption (Fig. 11a), leaving only the absorption from the element of interest (Fig. 11b). In compound materials, however, there are generally more sources of absorption than just the substrate material, and another method of background removal is necessary. The common method has been subtraction from the signal of a λ^3 function fit to the pre-edge region of the absorption spectrum.

The next step in the application of the sum rules is determining the integrated intensities of the dichroic signal. The easiest method is to plot the integral of the dichroic spectrum as a function of the scanning energy (Fig. 11c). The integrated values over each edge can then be directly read at the positions where the integrated signal becomes constant. In the figure, p corresponds to the signal from the L_3 edge alone and q corresponds to the integrated value over both edges. Although there is some uncertainty in the appropriate value of the p integral, since the dichroic signal of the L_3 edge extends well past the edge, choosing the position closest to the onset of the L_2 edge signal minimizes possible errors. This uncertainty diminishes for edges at higher energies where the spin-orbit splitting of the core levels becomes more pronounced.

The final step in the sum rule analysis is obtaining the integral of the absorption spectrum (Fig. 11d). At first glance, it seems that this integral would be nonfinite because the absorption edges do not return to zero at the high-energy end of the spectrum. The sum rule derivation, however, implicitly assumes that the integral includes only absorption contributions from the final states of interest (i.e., the 3*d* states in this example). It is well known that the large peaks in the absorption spectrum just above the edge, sometimes referred to as the "white line," are due to the strong density of states of *d* bands near the Fermi energy, while the residual step-like behavior is due to transitions to unbound free electron states. To deconvolve these two contributions, a two-step function is introduced to model the absorption arising from the transitions to the free electron states. The absorption-edge jumps for this function are put in a 2:1 ratio, expected because of the 2:1 ratio in the number of initial-state electrons. The steps are also broadened to account for the lifetime of the state and the experimental resolution. The integral r shown in Fig 11d is then obtained by determining the area between the absorption curve and the two-step curve. Once the integrals r, p, and q are determined, they can easily be put into Eqs. 1, 2, and 3 to obtain the values of the magnetic moments.

SAMPLE PREPARATION

XMCD measurements in the hard x-ray regime require little sample preparation other than obtaining a sample thin enough for transmission measurements. Measurements in the soft x-ray regime, on the other hand, tend to require more complicated sample preparation to account for UHV conditions and small attenuation lengths. Hard x-ray XMCD measurements therefore tend to be favored if

the same type of information (i.e., relative magnetization) can be obtained using edges at the higher energies. The incident photon fluxes typically do not affect the sample in any way, so repeated measurements can be made on the same sample without concern for property changes or degradation.

Attenuation lengths (i.e., the thickness at which $I/I_o \approx 1/e$) for hard x-rays are generally on the order of $\sim$2 to 10 μm. While it is sometimes possible to roll pure metals to these thicknesses, the rare earth and transition metal compounds generally studied in XMCD are typically very brittle, so that rolling is impractical. The sample is therefore often ground to a fine powder in which the grain size is significantly less than the x-ray attenuation length ($\sim$1 μm). This powder is then spread on an adhesive tape, and several layers of tape combined to make a sample of the proper thickness. Most of the absorbance in these tapes is usually due to the adhesive rather than the tape itself; thus, a commercial tape brand is as effective as a specialized tape such as Kapton that minimizes x-ray absorbance. An alternative to tape is to mix the powder with powder of a light-Z material such as graphite and make a disk of appropriate thickness using a press. A note of warning: the fine metallic powders used for these measurements, especially those containing RE elements, can spontaneously ignite. Contact with air should therefore be kept to a minimum by using an oxygen-free atmosphere when applying the powder and by capping the sample with a tape overlayer during the measurements.

The techniques used to detect the XMCD signal in the soft x-ray energy regime are generally much more surface sensitive. Therefore, the surfaces must be kept as clean as possible and arrangements made to clean them in situ. Alternatively, a capping layer of a nonmagnetic material can be applied to the sample to prevent degradation. Surface cleanliness is also a requirement for the total electron-yield measurements; that is, the contacts used to measure the current should make the best possible contact to the material without affecting its properties. For transmittance measurements in this regime, the thinness of the sample attenuation lengths ($\sim$100 Å) makes supporting the sample impractical. Thus, samples are typically deposited on a semitransparent substrate such as parylene.

PROBLEMS

There are many factors that can lead to erroneous XMCD measurements. These generally fall into two categories, those encountered in the data collection and those that arise in the data analysis. Problems during data collection tend to introduce distortions in the shape or magnitude of the spectra that can be difficult to correct in the data analysis; thus, great care must be taken to minimize their causes and be aware of their effects.

Many amplitude-distorting effects encountered in XMCD measurements, and in x-ray absorption spectroscopy in general, come under the common heading of "thickness effects." Basically these are systematic errors that diminish the relative size of the observed signal due to leakage of noninteracting x-rays into the measurement. Leakage x-rays can come from pinholes in the sample, higher-energy harmonics in the incoming beam, or the monochromator resolution function containing significant intensity below the absorption-edge energy. While these effects are significant for all x-ray spectroscopies, they are particularly important in the near-edge region probed by XMCD.

First, to minimize pinhole effects, the sample should be made as uniform as possible. If the sample is a powder, it should be finely ground and spread uniformly on tape, with several layers combined to obtain a more uniform thickness. All samples should be viewed against a bright light and checked for any noticeable leakages. The sample uniformity should also be tested by taking absorption spectra at several positions on the sample before starting the XMCD measurements. Besides changes in the transmitted intensity, the strength and definition of sharp features just above the absorption edge in each spectrum provide a good qualitative indication of the degree of sample nonuniformity.

Another source of leakage x-rays is the harmonic content of the incident beam. The monochromator used for the measurement will pass not only the fundamental wavelength but multiples of it as well. These higher-energy photons are unaffected by the absorption edges and will cause distorting effects similar to those caused by pinholes. These harmonics are an especially bothersome problem with third-generation synchrotron sources because the higher particle-beam energies found at these sources result in substantially larger high-energy photon fluxes. Harmonics in the beam are generally reduced by use of an x-ray mirror. By adjusting the reflection angle of the mirror, near-unit reflectivity can be achieved at the fundamental energy, while the harmonic will be reduced by several orders of magnitude. Another common way of eliminating harmonics has been to slightly deviate the angle of the second crystal of a scanning monochromator (Fig. 8a) so that it is not exactly parallel to the first. The monochromator (said to be "detuned") then reflects only a portion of the beam reflected by the first crystal, typically $\sim$50%. The narrower reflection width of the higher-energy photons makes harmonics much more sensitive to this detuning. Thus while the fundamental flux is reduced by a factor of $\sim$2, the harmonic content of the beam will be down by several orders of magnitude. Eliminating harmonics in this manner has a distinct disadvantage for XMCD measurements, however, because it also reduces the degree of circular polarization of the monochromatized beam. Therefore, monochromator detuning should not be used with off-axis bending-magnet or specialized-insertion-device CPX sources.

A third important consideration in minimizing thickness effects is the resolution of the monochromator. After passing through the monochromator, the beam tends to have a long-tailed Lorentzian energy distribution, meaning that a beam nominally centered around E_o with a resolution of ΔE will contain a substantial number of photons well outside this range. When E_o is above the edge, the bulk of the photons are strongly attenuated, and thus those on the lower end of the energy distribution will constitute a greater percentage of the transmitted intensity.

Typically a monochromator with a resolution well below the natural width of the edge is used to minimize this effect. This natural width is determined by the lifetime of the corresponding core state under study. For instance, a typical RE L-edge spectrum with a core-hole broadening of $\sim$4 eV is normally scanned by a monochromator with $\sim$1 eV resolution. Increasing the resolution, however, typically increases the Bragg angle of the monochromator, which reduces the circular polarization of the transmitted beam.

While all the methods for reducing the thickness effects mentioned above should be used, the primary and most efficient way to minimize these effects is to adjust the sample thickness so as to minimize the percentage of leakage photons. This is accomplished by optimizing the change in the transmitted intensity across the edge. It should be small enough to reduce the above thickness effect errors yet large enough to permit observation of the signal of interest. It has been found in practice that sample thicknesses (t) of $\sim$1 attenuation length ($\mu t \sim 1$) below the absorption edge and absorption increases across the edge of $<$1.5 attenuation lengths ($\Delta\mu t < 1.5$) minimize the amplitude distortions.

Another source error in the XMCD measurement is sharp structure arising from spurious reflections in the monochromator or phase retarder, if used. These effects are usually called "glitches" because they have a small energy width and typically affect one data point. Generally the monochromator or phase plate must be adjusted by rotation about its diffraction vectors to move the offending glitch out of the energy range of interest. If this is not possible, an algorithm must be incorporated into the data reduction to omit the offending point. Similar glitch effects occur during data collection if data acquisition at one point started before a scanning monochromator had had time to settle into the relaxed position, causing the data point for one magnetization (helicity) to be taken under different conditions than the other. This can become particularly bothersome if the monochromator has some sort of feedback mechanism to maintain stability. These type of glitches can be minimized by introducing a 0.5- to 1.0-s delay between motor motions and triggering of the detectors.

The electromagnets used to magnetize samples are also a frequent cause of systematic errors in XMCD spectra. The efficiency of a gas ionization detector can be affected by the presence of a magnetic field. The resultant induced nonlinearities in these detectors can be as great as or greater than the dichroic signal itself. Therefore, for measurements taken by switching the magnetization of the sample, the detectors should be placed well away from the magnets. If this is not possible, the detectors or the magnet should be shielded with a high-permeability metal foil to minimize stray magnetic fields. Similarly, other detectors not directly sensitive to magnetic fields can nevertheless be indirectly influenced by the effects that the electromagnet power supplies can have on their electronic components. Strong electromagnets draw substantial currents, which can induce voltage drops in the circuit that powers them. To minimize cross-talk between the detector electronics and the power supply, they should be connected to different power sources. It is important to note that this does not simply mean lines on different circuit breakers, but rather entirely different, isolated lines. This problem can be particularly bothersome for solid-state detectors in which the switching of a magnet power supply can induce a change in the gain of a spectroscopy amplifier, thereby shifting the position of a fluorescence line or other measured signal.

Besides the errors encountered in the acquisition of the data, several errors can be introduced in the analysis of the spectra, especially in implementing the sum rules. Foremost among these are uncertainties in the values of the beam polarization and the sample magnetization. Both these factors scale directly with the size of the dichroic signal, and any uncertainty in them directly correlates with the size of the error of a magnetic moment obtained from XMCD. The rate of circular polarization is generally calculated from known parameters since it is difficult to measure directly. Because these calculations make assumptions about storage-ring parameters and the degree of perfection of the beamline optics, the error in the values for the polarization rate tend to be quite large and frequently dominate the error in a measurement of the absolute size of the magnetic moment. For measurements of the relative changes in the XMCD spectra, however, this uncertainty is eliminated since the polarization does not change. The magnetization of the sample is usually obtained from magnetometer measurements, but for a multiconstituent sample with different temperature dependencies estimation of each sublattice magnetization can prove difficult.

Systematic errors can also occur at each step in the implementation of the sum rules. As noted in the discussion of Figure 11, the values of the integrals p, q, and r may vary slightly depending on the energy chosen to extract the integrated value. The greatest uncertainty in the sum rule analysis, however, arises in the integration of the absorption signal, which involves two steps, each of which can introduce uncertainties into the measurement. The first step is subtraction of the background absorption and the second (which causes a greater uncertainty) is modeling of the absorption from transitions to free electron states with a two-step function. Although the two-step function itself should be an adequate model of the transitions involved, the error arises in the placement of the inflection point of the two steps. This has generally been chosen to be at the maximum in the absorption spectrum, but this choice is rather arbitrary. A way around introducing this error is to use Eq. 3 to determine an orbital to spin ratio rather than the absolute moments themselves.

ACKNOWLEDGMENTS

The author would like to thank Professor A.I. Goldman for offering suggestions on and proofreading this work, as well as Dr. C.T. Chen and Dr. J. Stöhr for providing copies of their figures for publication herein. This work was supported in part by the U.S. Department of Energy, Office of Basic Energy Sciences, under contract No. W-31-109-ENG-38.

A good overall theoretical treatment of XMCD, with emphasis on the interpretation of 3d L edge spectra.

APPENDIX A: ONE-ELECTRON PICTURE OF DICHROISM

This appendix provides a simple theory to explain the origin of dichroic signals. In this theory, the x-ray absorption is treated within the one-electron picture and the electric dipole approximation is assumed to be valid. The explanation below follows the same reasoning as put forth by Brouder and Hikam (1991) and Smith et al. (1992), and the reader should refer to these papers for a more detailed explanation of all the edges.

Using the first-order term in Fermi's golden rule, the x-ray absorption cross-section due to dipole transitions may be written as follows (Brouder, 1990):

$$\sigma(\varepsilon,\omega) = 4\pi^2\alpha\hbar\omega \sum_{f,m_j,\beta} |\langle f|\varepsilon^\beta \cdot \boldsymbol{r}|jm_j\rangle|^2 \delta(E_f - E_i - h\omega) \quad (8)$$

where the α is the fine-structure constant.

Here the common bracket notation is followed in which the expression above represents an integral over the spacial and spin dimensions of the system and $|jm_j\rangle$ and $|f\rangle$ represent the initial- and final-state wave functions involved in the transition. Because the initial atomic core states are strongly spin-orbit coupled, the wave functions are expressed in terms of the total angular momentum j. As an example of an absorption calculation, consider the above expression for an L_2 edge with initial $2p_{1/2}$ core state. By the dipole selection rules, the final states accessible from this edge would be either the s or d states. As a general rule, however, the transitions to the $\ell - 1$ states are suppressed by 1 to 2 orders of magnitude compared to the $\ell + 1$ states due to the negligible overlap of the former with the initial level. Thus to a very good approximation only transitions to the d states need be considered. Neglecting any spin-orbit coupling in the final states, the

final d-band states can be written as the product of spatial and spin wave functions:

$$\langle f| = \varphi_{\ell m}(r)\langle s| \sim 2m_\ell \langle\uparrow(\downarrow)| \tag{9}$$

where $m = -2, -\ell, \ldots, 2$ are the magnetic quantum numbers and $\uparrow$ and $\downarrow$ refer to the spin-up and spin-down states. The electric dipole operator $(\varepsilon \cdot r)$ for left (right) circularly polarized photons can be expressed in terms of spherical harmonics by:

$$\boldsymbol{\varepsilon}^{\pm} \cdot \mathbf{r} = \pm\left[\frac{4\pi}{3}\right]^{\frac{1}{2}} rY_{1\pm1} \tag{10}$$

Here the sign $(+,-)$ in the polarization vector (spherical harmonic) refers to (left-, right-) handed circular polarization. To obtain matrix elements involving three spherical harmonics, the initial $|jm_j\rangle$ states ($m_j = \pm 1/2$ for an L_2 edge) can be expanded in terms $|lm_l\rangle$ of wave functions using Clebsch-Gordan coefficients:

$$\left|\frac{1}{2}-\frac{1}{2}\right\rangle = \phi_{1\frac{1}{2}}(r)\left[\sqrt{\frac{1}{3}}Y_{10}|\downarrow\rangle - \sqrt{\frac{2}{3}}Y_{1-1}|\uparrow\rangle\right] \tag{11}$$

$$\left|\frac{1}{2}\frac{1}{2}\right\rangle = \phi_{1\frac{1}{2}}(r)\left[-\sqrt{\frac{1}{3}}Y_{10}|\uparrow\rangle - \sqrt{\frac{2}{3}}Y_{11}|\downarrow\rangle\right] \tag{12}$$

If we assume that the spin functions are orthogonal and the radial parts of the wave functions are independent of spin, we can define quantities $\rho^{\uparrow}$ and $\rho^{\downarrow}$ that incorporate all the constants and the radial matrix elements. Here $\rho^{\uparrow}(\rho^{\downarrow})$ represents a transition to a spin-up (-down) state and, to a first-order approximation, can be considered proportional to the spin-up (-down) spin density of unoccupied states. Taking a sum on initial and final states, Eq. 8 for left circularly polarized light (ε^+) reduces to:

$$\begin{aligned}\sigma^{+}_{L_2} \sim{}& \frac{1}{3}|\langle 21|11|10\rangle|^2\rho^{\downarrow} + \frac{2}{3}|\langle 20|11|1-1\rangle|^2\rho^{\uparrow} \\ &+\frac{1}{3}|\langle 21|11|10\rangle|^2\rho^{\uparrow} + \frac{2}{3}|\langle 22|11|11\rangle|^2\rho^{\downarrow}\end{aligned} \tag{13}$$

The integrals denote the product of three spherical harmonics of index $|lm_l\rangle$. Here all the null matrix elements of terms with spin opposite to the factors in Eqs. 11 and 12 above have been omitted, and the selection rule $m_f = m_i + 1$ for the integration of three spherical harmonics has been used. Upon performing the integrations and normalizing, Eq. 13 reduces to:

$$\sigma^{+}_{L_2} \sim \frac{3}{5}\rho^{\downarrow} + \frac{12}{5}\rho^{\uparrow} + \frac{3}{5}\rho^{\uparrow} + \frac{2}{5}\rho^{\downarrow} = \rho^{\uparrow} + 3\rho^{\downarrow} \tag{14}$$

Thus left circularly polarized x-rays will be three times more likely to make a transition to a spin-down state than a spin-up state. Repeating the above steps for right-handed circular polarization yields exactly the opposite result,

$$\sigma^{-}_{L_2} \sim 3\rho^{\uparrow} + \rho^{\downarrow} \tag{15}$$

Therefore, right circularly polarized light will make preferential absorption to spin-up states. The same procedure can be repeated for the L_3 edge with an initial $2p_{3/2}$ state to obtain the following results for left and right circular polarization, respectively:

$$\sigma^{+}_{L_3} \sim 5\rho^{\uparrow} + 3\rho^{\downarrow}, \quad \sigma^{-}_{L_3} \sim 3\rho^{\uparrow} + 5\rho^{\downarrow} \tag{16}$$

Here the assumption has been made that the $2p_{1/2}$ and $2p_{3/2}$ radial matrix elements are essentially equal.

$$\rho^{\uparrow(\downarrow)}_{1/2} = \rho^{\uparrow(\downarrow)}_{3/2} = \rho^{\uparrow(\downarrow)} \tag{17}$$

Using Eqs. 14, 15, and 16, the following expressions for the XMCD at $L_{2,3}$ edges can be written as shown in Eq. 18.

$$\begin{aligned}\mu_c(L_2) &\sim \sigma^{+} - \sigma^{-} \sim -2\left(\rho^{\uparrow} - \rho^{\downarrow}\right), \\ \mu_c(L_3) &\sim \sigma^{+} - \sigma^{-} \sim 2\left(\rho^{\uparrow} - \rho^{\downarrow}\right)\end{aligned} \tag{18}$$

Therefore XMCD is, to a first-order approximation, proportional to the spin density of unoccupied states, and the ratio of the signal from the $L_{2,3}$ spin-orbit split states is 1:−1.

APPENDIX B: FIGURE OF MERIT FOR CPX

The figure of merit for CPX sources ($P_c^2 I$) can be obtained by expressing the measured signal as a sum of terms arising from charge and magnetic effects,

$$I^{\pm} \sim \sigma_c I + \sigma_m I, \quad \sigma_c \gg \sigma_m \tag{19}$$

Here $I^{\pm}$ indicates the measured intensities taken with opposite helicities (or magnetizations), I is the incoming beam intensity, and σ_c and σ_m are the charge and magnetic cross-sections. This expression applies not only to XMCD measurements but more generally to other techniques that utilize CPX for magnetic measurements (i.e., magnetic Compton scattering and nonresonant magnetic x-ray scattering). For ferromagnetic materials, the magnetic cross-section depends linearly on P_c (or the magnetization), and thus can be separated out, $\sigma_m \sim P_c\sigma'_m$ making the difference-to-sum ratio

$$\frac{I^{+} - I^{-}}{I^{+} + I^{-}} \sim \frac{2P_c\sigma'_m I}{2\sigma_c I} \sim P_c\frac{\sigma'_m}{\sigma_c} \tag{20}$$

Therefore the measured signal depends linearly on the degree of circular polarization. The percentage error in this quantity, which is the quantity to be minimized in any experimental measurement, is obtained by adding the errors in the numerator and denominator in quadrature:

$$\left(\Delta\%\left(\frac{I^{+} - I^{-}}{I^{+} + I^{-}}\right)\right)^2 = \left(\frac{\sqrt{I^{+} - I^{-}}}{I^{+} + I^{-}}\right)^2 + \left(\frac{\sqrt{I^{+} - I^{-}}}{I^{+} - I^{-}}\right)^2 \tag{21}$$

The first term above will always be much smaller than the second, and thus can be neglected, yielding:

$$\Delta\%\left(\frac{I^+ - I^-}{I^+ + I^-}\right) \cong \frac{\sqrt{I^+ + I^-}}{I^+ - I^-} \sim \frac{\sqrt{2\sigma_c \bar{I}}}{2P_c\sigma_m I} \sim \frac{1}{P_c\sqrt{\bar{I}}} \qquad (22)$$

Therefore, the minimum error in the measurement is achieved by maximizing $P_c \cdot \sqrt{\bar{I}}$. Although this quantity is sometimes referred to as a figure of merit, the experimenter is generally more interested in the amount of time required to perform a measurement on one source compared to another. The time in this quantity is implicitly included in the flux, and therefore to obtain a source comparison for comparable times the quantity above must be squared, yielding a figure of merit of $P_c^2 I$.

X-RAY PHOTOELECTRON SPECTROSCOPY

INTRODUCTION

X-ray photoelectron spectroscopy (XPS) uses x rays of a characteristic energy (wavelength) to excite electrons from orbitals in atoms. The photoelectrons emitted from the material are collected as a function of their kinetic energy, and the number of photoelectrons collected in a defined time interval is plotted versus kinetic energy. This results in a spectrum of electron counts (number per second) versus electron kinetic energy (eV). Peaks appear in the spectrum at discrete energies due to emission of electrons from states of specific binding energies (orbitals) in the material. The positions of the peaks identify the chemical elements in the material. Peak areas are proportional to the number of orbitals in the analysis volume and are used to quantify elemental composition. The positions and shapes of the peaks in an XPS spectrum can also be analyzed in greater detail to determine the chemical state of the constituent elements in the material, including oxidation state, partial charge, and hybridization.

X-ray photoelectron spectroscopy is widely applied to all types of solids, including metals, ceramics, semiconductors, and polymers, in many forms, including foils, fibers, and powders. It has also been used to obtain spectra of gas-phase compounds. In general, it is a nondestructive method of analysis. When applied to solids, XPS is a surface-sensitive technique. The nominal analysis depth is on the order of 1 to 10 nm (10 to 100 monolayers). Surface sensitivity can be increased by collecting the emitted photoelectrons at to glancing angles to the surface. Typical spatial resolutions on a sample surface are on the order of 1 to 5 mm, with so-called small-spot systems having spatial resolutions as low as 25 μm. Analysis times range from under 5 min to identify the chemistry and composition of a sample to 1 hr or more for characterizing chemical states of trace elements.

The best sensitivity of XPS for quantifying elemental composition in solids is on the order of 0.1 at. %. All elements with atomic number greater than three can be detected. The detection sensitivity varies for each element, with some elements requiring greater concentrations to reach a nominal detection threshold in a reasonable analysis time. Relative uncertainties in atomic compositions are typically $\sim\pm$ 10% for samples with homogeneous compositions throughout the sampling volume. This error can be reduced by analyzing standards to calibrate the sensitivity factors of the instrument for each element. Materials with heterogeneous distributions of elements represent a greater challenge to obtaining accurate compositions with XPS. Samples with contaminant or other thin film overlayers will always be found to have attenuated concentration values for the supposed bulk material, and samples exposed to air before analysis typically show accentuated carbon and oxygen concentrations. Atomic concentrations reported from XPS analysis should be understood to be indicative of those from a hypothetical sample of homogeneous composition throughout the sampling volume, unless otherwise stated.

Thin film samples can be analyzed with XPS to determine film thickness. Typical methods of analysis involve measuring composition either as a function of sputter depth into the sample (sputter profiling) or as a function of electron emission angle (angle-resolved XPS). The former method requires the use of a noble-gas ion-etching process to sputter away successive layers of the sample, and is therefore destructive. Sputter profiling is limited in film thickness only by the patience of the user and the robustness of the instrumentation. Angle-resolved XPS is limited to films with a thickness that is on the order of the sampling depth of XPS (1 to 10 nm). Both techniques have other limitations, primarily involving surface roughness for angle-resolved XPS and both surface roughness and film thickness for sputter profiling.

The chemical state information obtained with XPS includes oxidation states or hybridization states for chemical bonds of the elements. Typical examples include determining whether a constituent element is or is not oxidized in a metal alloy or characterizing whether carbon is present as a carbonyl, ether, or ester linkage in a polymer. Application of peak fitting routines is generally required to distinguish peaks from overlapping oxidation or hybridization states. Assignment of chemical state using XPS is not without ambiguities, because other factors besides chemical environment shift the peaks in an XPS spectrum. The use of references with known composition and chemistry can usually help resolve these ambiguities.

The primary limitation of XPS is the need for ultrahigh vacuum conditions during analysis. This generally limits the type of material to those with a low vapor pressure ($<10^{-8}$ mbar) at room temperature and limits the sample size to that which will fit through the introduction ports on the vacuum chamber. Some compounds, such as polymers, can also degrade under the x-ray flux. Another limitation in interpretation of spectra from insulator and semiconductor samples arises from sample charging. This is an

artifact that can be corrected either during or after data acquisition, although the extent of the correction is often not straightforward to determine.

For those wishing to find further information on XPS, a discussion of the available literature is provided at the end of this unit (see Key References).

Competitive and Related Techniques

A common technique that is sometimes considered to compete with XPS for quantitative chemical analysis of materials surfaces is Auger electron spectroscopy (AES; AUGER ELECTRON SPECTROSCOPY). By comparison to XPS, AES is more surface sensitive, with sampling depths typically below 1 nm. Sub-micron spatial resolutions are also possible with AES. In this regard, AES is often the preferred technique for compositional analysis of surfaces in metallurgy. The disadvantage of AES in comparison to XPS is that AES must be done on conductive materials because it uses electrons as the excitation source; it cannot analyze ceramic or polymeric materials as well as XPS can, if at all. In terms of sample damage, AES is also more destructive of ceramic or polymeric materials and molecular layers adsorbed on surfaces. Both XPS and AES have comparable accuracies for quantitative analysis of elemental composition. The sensitivity of AES is better for light elements. Finally, XPS is generally considered as being able to provide much richer information about the chemical state of the elements in the material, although reports have shown exceptions to this (Sekine et al., 1996). This often makes XPS a better technique than AES for analysis of the chemistry of fundamental processes occurring at or on surfaces, such as chemical bonding, adhesion, or corrosion. The two techniques actually complement each other very closely, especially for analytical determination of elemental compositions at the surface of a material. Although the terminology ESCA was introduced for and has become synonymous primarily with XPS because of the resolution of the elemental chemical state information it provides, AES can also be considered as an electron spectroscopy for chemical analysis (ESCA), especially in cases were it is more widely used as an analytical tool for quantitative surface analysis than is XPS.

Another common technique that competes with XPS for analysis of elemental composition is energy-dispersive spectroscopy (EDS; see ENERGY-DISPERSIVE SPECTROMETRY) or energy-dispersive x-ray analysis (EDXA). The EDS technique is commonly available with scanning electron microscopes. By comparison to XPS, EDS has better spatial resolution on the surface but probes deeper into the bulk of the material, on the order of microns. No chemical state (oxidation state) information about the elements can be obtained with EDS. Finally, XPS has a better (elemental) resolution of the lighter elements.

A technique that is closely related to XPS is ultraviolet photoelectron spectroscopy (UPS; see ULTRAVIOLET PHOTOELECTRON SPECTROSCOPY). In UPS, the source is ultraviolet light rather than x rays. The principles of the two techniques are practically the same; both are based on photoemission. Because the UPS source has a lower energy than typical XPS sources, UPS can only probe electrons in the valence band energy region of a material. The sensitivity of UPS to changes in the valence band structure of an element is greater than that of XPS. Therefore, UPS is often a used for determination of band structures of materials, especially semiconductors.

Other techniques of interest in relation to XPS are x-ray adsorption fine structure (XAFS; see XAFS SPECTROSCOPY), extended XAFS (EXAFS), and near-edge XAFS (NEXAFS). These techniques use x-rays of variable energy from synchrotron sources, whereas in XPS, the source energy (wavelength) remains constant. The information obtained from XAFS and NEXAFS pertains more to the fundamental nature of the chemical bond for a specific element in a material rather than the composition of the material. The average coordination number (number of bonds) surrounding a specific atom (element) in a material can be determined with EXAFS.

PRINCIPLES OF THE METHOD

X-ray photoelectron spectroscopy is based on the principle of photoemission. The process is illustrated in Figure 1 for electrons in atomic orbitals. The principles are nearly the same for molecular orbitals and free electron or valence bands. A photon (x ray) of frequency $\nu = c/\lambda$, where λ is its wavelength, has a kinetic energy of $h\nu$. As this photon passes through a material, it can interact with the electrons in the material. Absorption of the x ray by an atom can lead to an electronic excitation of the atom. The photon absorption process conserves energy, leaving an electron in the atom to a first approximation with a kinetic energy (KE or E_K) that is equal to the energy of the incident photon less the initial binding (electronic ground state) energy (BE or E_B) of the electron, $E_K = h\nu - E_B$. Under proper circumstances, when the electron does not scatter

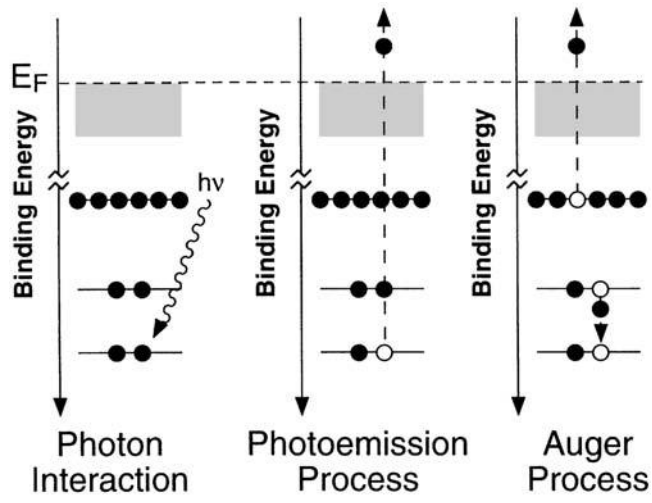

Figure 1. Schematics of the excitation process leading to photoemission of a core electron and the subsequent Auger relaxation process that can occur. Core-level electrons are solid circles, holes are open circles, and the valence band is a shaded box. The position of the Fermi energy is shown by the dotted line at E_F.

back, it acquires a sufficient velocity to escape from the material. In most common XPS instruments, electrostatic or electromagnetic analyzers focus the escaping electrons (photoelectrons) at a specific KE from the sample onto an electron detector. The number of electrons that arrive at the detector is counted for a certain time interval, and the electron counting is subsequently repeated at a new KE value. Alternatively, the number of electrons at the detector is counted concurrently while sweeping the energy selection range of the analyzer. Either method produces a spectrum of number of electrons emitted from the sample per unit time (electron counts per time, or I_i^e) versus the KE of the electron. The KE scale of the spectrum is converted to a BE scale using energy conservation. Peaks appear in the spectrum at energies where electronic excitation has occurred.

The electronic excitation by the photon leaves behind a hole (a site of positive charge). How this hole is subsequently filled is important in the overall energy balance, as discussed in the section on high-resolution scans. One important relaxation process that can occur is the Auger process. This is shown in the third panel in Figure 1. An upper lying (lower BE) electron drops into the hole, perhaps from the valence band as shown. The energy released by this process causes ejection of a second electron called the Auger electron. The Auger process is independent of how the initial hole was created. When electrons rather than x-rays are used to excite the initial core electron, the method is called Auger electron spectroscopy (AES), as detailed in AUGER ELECTRON SPECTROSCOPY. Auger electron peaks will also appear in XPS spectra, and their analysis in this case is considered under the acronym, x-ray induced AES (XAES). The position of an XAES peak relative to a corresponding photoemission peak is used to define a characteristic parameter called the Auger parameter. The Auger parameter is affected by the chemistry of the material. Further consideration of the use of the Auger parameter is given elsewhere (Briggs and Seah, 1994).

Not all photons that enter a material are successful at causing a photoemission event. The probability of such an event occurring is represented by the photoelectron cross-section, σ. Photoelectron cross-sections provide a start in determining the flux, J_i^e, of emitted electrons from a given orbital (or band) for a given x-ray flux F and given number of orbitals n present in the material. The relationship is $J_i^e \propto F\sigma n$, where the electron flux J_i^e has units of electrons/m^2/sec, F has units of photons/m^2/sec, and n is the number of orbitals per unit area viewed by the analyzer (orbitals/m^2). Although the cross-section has explicit units of area (m^2), it contains implicit units of (number of photoelectrons)/(number of photons)(number of orbitals, as can be derived from the flux equation).

The XPS Survey Spectrum

Using the above information, we can prepare a schematic of what might be expected for an XPS spectrum from a pure material, Au, under ideal conditions. A survey, or wide-range scan covers the majority or all of the levels that can be excited by the x-ray energy being used. In what follows, we will use a scale of BE rather than KE. Further consideration of how the x-ray source energy influences the BE scan range and spectrum shape is presented in the section on practical aspects of XPS.

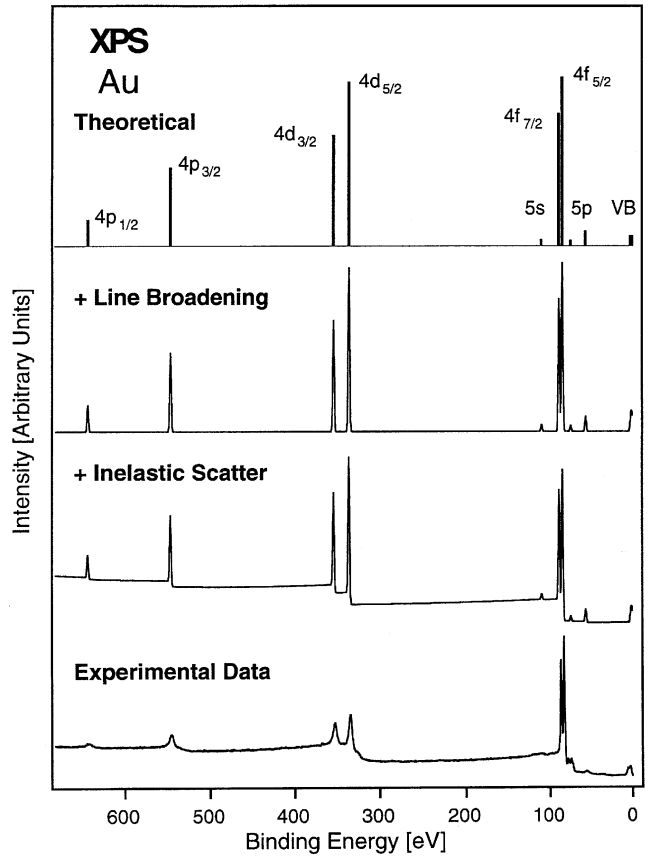

Figure 2. A series of XPS spectra for Au, generated from a theoretical standpoint and incorporating two factors associated with the overall photoemission process from a solid. An experimental XPS spectrum of Au is included for comparison.

Binding energies for electrons in Au can be obtained from standard handbooks (Lide, 1993; Moulder et al., 1995), and values of σ have also been calculated (Scofield, 1976). Using this information, we can generate a theoretical XPS survey spectrum in the BE range 0 to 650 eV for an assumed ideal, monochromatic x-ray source (with an as yet unspecified energy). The result is presented in the uppermost plot in Figure 2. It is essentially a series of delta function lines appearing at the respective BE values for each orbital. The heights of the lines are scaled in proportion to σ for each orbital.

One noticeable feature of the theoretical spectrum is a splitting of p through f orbitals into two peaks. This is due to coupling between the electron spin and orbital angular momenta for these orbitals. The s orbitals do not split because they have no orbital angular momentum. One of two methods can be applied to determine the magnitude of this coupling, j-j coupling or L-S (Russell-Sanders) coupling. The former predominates for atomic numbers below ~20. In j-j coupling, the magnitude of total angular momentum for a given electron is the vector sum of its spin and orbital angular momenta. Since s orbitals have

no angular momentum, electrons in spin-up or spin-down configurations have the same magnitude of total angular momentum. In p orbitals, vector coupling of spin-up or spin-down states with the ± 1 orbital angular momentum vectors gives total angular momentum of either 1/2 (from $|1 - 1/2|$ or $|-1 + 1/2|$) or 3/2 (from $|1 + 1/2|$ or $|-1 - 1/2|$). These two spin-orbit couplings have different binding energies in the magnetic field of the nucleus, leading to the splitting of the levels. In L-S coupling, the total angular momentum of is determined by summing (vectorially) the total spin angular momentum (S) and the total orbital angular momentum (L) after the electron is removed. Similar splitting of orbitals arises. The nomenclature used in XPS to designate the spin-orbit splitting is applied as though j-j coupling predominates and is adopted from spectroscopy (rather than from x-ray notation). It uses principal quantum number, orbital designation (s, p, d, f), and $|1 \pm s|$. For example, the $3p_{3/2}$ peak designates electrons from p orbital of the $n = 3$ level with a total angular momentum of either $|1 + 1/2|$ (spin-up in an "upwardly" aligned p orbital) or $|-1 - 1/2|$ (spin down in a "downwardly" aligned p orbital).

The width of the spin-orbit splitting depends on the magnitude of the coupling between electron spins and orbital angular momentum. This coupling is proportional to $\langle 1/r^3 \rangle$, the expectation value of $1/r^3$, where r is the radius of the orbital. In practical terms, for a given element, the width of the spin-orbit splitting decreases with increasing principal quantum number ($4p$ levels are split more than $5p$ levels), and with increasing angular momentum quantum number ($4p$ levels are split more than $4f$ levels). The strength of the spin-orbit splitting also increases with increasing atomic number because the nuclear charge increases. For example, the experimentally determined $4f$ level splittings of the series Ir–Pt–Au (increasing atomic sizes) are ~3.0 eV, 3.4 eV, and 3.7 eV. The splitting of valence band levels increases within a homologous series going down a period—for example Cu $2p$ (20 eV), Ag $3p$ (30 eV), and Au $4p$ (100 eV)—because the increase due to an increase in nuclear charge overrides the decrease due to an increase in principal quantum number. The spin-orbit split levels have different relative occupancies, roughly in proportion to the respective degeneracies of the levels. Thus, p 1:2, d 2:3, and f 3:4. These relative occupancies are included in the theoretical spectrum in Figure 2 by means of the relative cross-sections.

When the energy of the excitation source $h\nu$ is greater than the work function of the sample, electrons from valence bands (VB) will also be emitted from the sample. This is the principle behind the photoelectric effect. The valence bands are the topmost bonding levels with energies just above the Fermi energy (E_F). In the representative model spectrum for Au, the VB has been modeled as a band of finite width, just above 0 eV in BE, the nominal position of E_F. Excitation from the VB levels is typically better examined with UPS because the excitation cross-sections are greater. Both XPS and UPS provide useful information about the chemical state of a material, with XPS is the only appropriate method of the two for investigations of changes in core levels and UPS applicable to the valence-band region. Studies of valence bands during gas adsorption and reaction phenomena on single crystal surfaces benefit by using both XPS and UPS. The two techniques are also useful for studying the valence band chemistry of polymeric materials.

Photoemission of electrons from solids will not produce the delta function responses shown in Figure 2 for the theoretical spectrum. Even under the assumption of ideal sources and analyzers, we must account for finite lifetime broadening effects. These effects are tied to the time needed for the ion created by the XPS process to relax back to its ground state, neutral atom condition. Heisenberg's uncertainty principle specifies $\Delta E_t \geq \hbar/2\Delta t_l$, where ΔE_l is the expected broadening of the emission feature due to a lifetime uncertainty of Δt_l. Shorter lifetimes lead to larger energy spreads in the photoemission distribution for the respective level. Core and valence band hole lifetimes are on the order of 10^{-14} to 10^{-16} sec, leading to lifetime broadenings on the order of 0.05 to as much as 5 eV. In general, lifetime broadening will be be greater for photoemission from lower-lying (higher BE) levels than from upper-level (valence) levels, because the lower lying holes relax in a shorter time. As discussed in the section on high-resolution spectra, ions created in solids by the photoemission process will also relax differently from those created in gas-phase compounds, leading to a shifting of the apparent BE and to wider photoemission peaks from solids as compared to those from gases. Gas phase photoelectron peaks can have peak widths that reach the theoretical thermal broadening limit of kT (Boltzmann's constant times temperature), or ~0.025 eV at room temperature.

Lifetime broadening was simulated by convolving a Gaussian with a 2 eV half-width with the theoretical spectrum in Figure 2. This does not cover the full range of broadening effects, primarily because the true broadening is not constant for all levels. Lifetime broadened photoemission lineshapes may also contain some Lorentzian character. This is discussed further below (see Data Analysis and Initial Interpretation).

One remaining factor can be illustrated for photoemission from solids using the survey scan range shown in Figure 2. As a photoelectron leaves a solid, it may lose energy to its surroundings. At this point, we will only consider inelastic scattering of the exciting photoelectron, as shown in Figure 3. The scattering occurs through interaction of the outgoing electron with phonon (vibrational) modes of the material. Those electrons that lose too

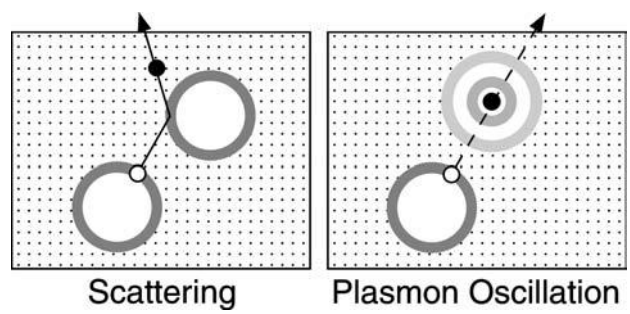

Figure 3. A pictorial representation of electron scatter and the bulk plasmon loss processes that can occur as an electron travels through a solid.

much energy through inelastic collisions will not leave the solid and are of no concern. Those electrons that lose energy yet still can leave the solid are collected at lower KE values than those at which they started. They contribute to an increase in the background on the higher BE side of the main photoemission peak and are not considered part of the primary photoemission process.

In general, the background due to inelastically scattered electrons extends over a range as much as 500 eV in BE above a primary photoelectron peak (which is up to 500 eV in KE below the E_K of the photoelectron). The shape of the loss signal over this range of energy depends on the material being analyzed and the initial E_K of the photoelectron. Each photoemission peak represents an additional source of electrons that can scatter as they leave the solid. Therefore, inelastic scattering leads to an overall increase in the background signal with increasing BE in an XPS spectrum.

Electrons will also scatter inelastically in multiple collisions as they travel through the solid. Because this is a cumulative process, the number of inelastically scattered electrons begins to increase again at low KE values. A peak in number of multiply scattered electrons is reached ~20 to 50 eV in E_K. This peak is called the secondary electron peak. Secondary electron emission decreases to zero at a value of zero E_K. The consequence of the secondary electron peak is that the background intensity in an XPS spectrum will begin to increase dramatically as BE approaches within ~100 eV of the source energy ($h\nu$). This will be shown in spectra presented in the section on practical aspects of the technique.

A simulated electron loss curve was convolved with the lifetime-broadened spectrum in Figure 2. The shape of the energy loss curve was simulated to give a resulting spectrum with a comparable background to an experimental spectrum around the Au 4*f* peaks. The actual shape of the inelastic loss spectrum and the secondary background can be measured with electron energy loss spectroscopy (EELS; see SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING). The hypothetical loss spectrum did not account for the secondary electron peak. The result, and the experimental spectrum for Au, are included in Figure 2.

Lifetime broadening and inelastic electron scattering, when convolved with a theoretically generated spectrum of delta functions, can been seen to account for a significant amount of the overall shape of a survey scan in XPS. Some of the remaining differences between the generated and experimental spectra in Figure 2 arise from factors that depend on the source and analyzer. These factors are discussed below (see Practical Aspects of the Method), where the utility of survey scans is also considered. Further differences between generated and experimental spectra become apparent when we focus on the exact shape of a specific photoelectron peak, the background immediately near this peak, and the peak position. These factors are considered below.

The XPS High-Resolution Spectrum

A high-resolution XPS spectrum is one that defines a narrow energy region, nominally 10 to 20 eV, around a photoemission peak. High-resolution spectra are taken to obtain improved quantitative analysis for elements in the material as well as chemical state information about the elements. In the following, we concentrate on the photoemission principles that define the shape of the peak in a high-resolution scan. How high-resolution spectra are analyzed to determine the composition of a material will be discussed below (see Data Analysis and Initial Interpretation).

The chemical state of an element affects the position and shape of its photoemission peak. The chemical state is an initial-state effect, in that it is defined before the photoemission process occurs. Unfortunately, the chemical state of an atom is not the only factor involved in shifting or broadening an XPS peak. Factors that occur after the photoemission process can also influence the apparent BE of the photoelectron. These factors are called final-state effects. Final-state effects will now be considered.

Final-State Effects. Final state effects can be classified into five types, plasmon loss, Auger excitation, relaxation, shake-up or shake-off, and multiplet splitting. All but the first one are concerned with how the core hole, that is left immediately after the photoemission process, is filled. They all shift, and in some cases broaden, the XPS peak.

The plasmon loss process is illustrated in Figure 3. It is a loss process that is similar to inelastic scattering discussed above, and it also leads to an increase in background intensity in survey scans. It occurs when the outgoing photoelectron interacts with the free electrons in a solid material (often called the free electron gas). Unlike what is traditionally considered under the term inelastic scattering, however, the plasmon loss process is quantized and does not extend over a broad energy range below the principal photoemission peak.

Two types of plasmon loss processes are recognized, bulk and surface. In bulk plasmon loss, the outgoing photoelectron loses energy by interacting via collective oscillations with the free electron gas in the bulk of material. These oscillations will be at resonance at the so-called bulk plasmon frequency, ω_p, for the free electron gas. Therefore, the probability that an exiting photoelectron loses energy will be greatest for loss energies defined approximately by $\Delta E_{loss} = h\omega_p$. Values of ω_p can be readily calculated for simple free electron gas models for various materials (Ibach and Lüth, 1990). They range from 3 to 20 eV and decrease with decreasing free electron density (in correspondence with the decrease in ω_p). The increasing magnitude of ω_p is what causes ceramics (and polymers) to be transparent just above or in the infrared range (the lowest energy), semiconductors to become transparent near (lower energy) ultraviolet frequencies, and metals to be opaque to high frequencies (energies) of radiation (up to x-ray frequencies). Surface plasmon losses occur when the outgoing photoelectron interacts with surface plasmon states in the material. The corresponding energies are generally lower than those for the respective bulk plasmon loss.

The net effect of the (bulk or surface) plasmon-loss process is the creation of a new peak or peaks at higher apparent BE (lower E_K) than the main XPS peak. The loss peak

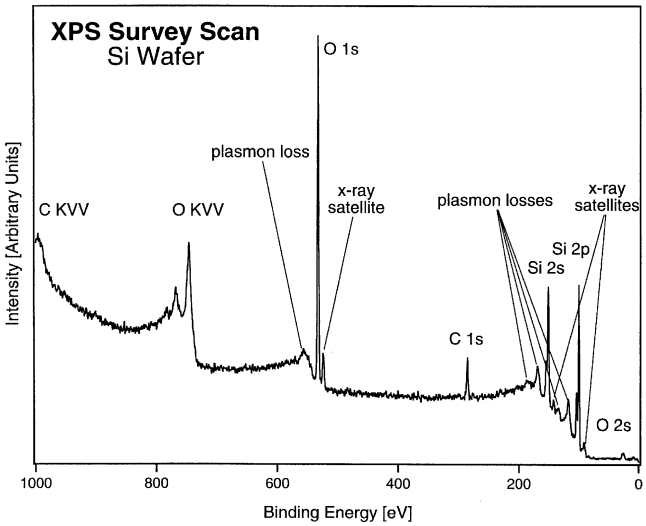

Figure 4. A survey scan from a Si wafer showing plasmon loss peaks that appear above the main Si peaks and O 1*s* peak. X-ray satellites are also labeled.

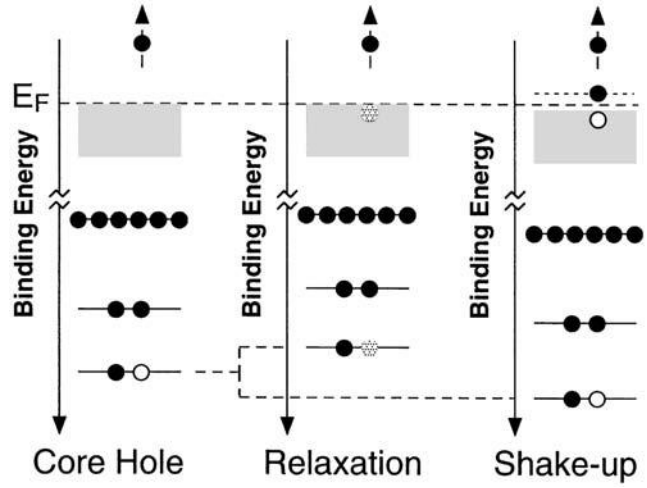

Figure 5. Schematics of the relaxation and shake-up processes in solids and their effects on the position of the core level created by the photoemission event.

will be closer to the primary photoelectron peak in ceramics than in metals. Because the plasmon-loss process is quantized, peaks can also appear at integer multiples of ω_p. This will give rise to a series of peaks at equally spaced increments in BE above the primary XPS peak. The intensity of these multiple plasmon-loss peaks decreases with distance from the primary peak. An example is shown for Si in Figure 4. The Si 2*p* peak has multiple plasmon loss peaks. The position of a plasmon loss peak relative to a primary photoemission peak will depend on the type of material. The loss peak will be furthest away (toward higher BE) from the primary peak in materials with high free-electron densities, such as metals. It will be closest to the main peak in ceramics and polymers. Plasmon loss peaks are broader and generally lower in intensity than the primary XPS peak. They can be distinct in survey scans as well as in high-resolution spectra, as seen in Figure 4. As with inelastically scattered (background) electrons, bulk and surface plasmon loss peaks are not included in the calculations of the total number of electrons emitted from a given orbital for a given element in the sample. In other words, they are not considered in calculating atomic concentrations of elements.

The Auger excitation process is shown in the third panel of Figure 1. It is a means of removing the initial photoemission core hole. The Auger excitation process leaves the original atom in a doubly charged state. This energy reconfiguration will affect the measured BE of the outgoing photoelectron. The consequences are such that the energy gained by filling the initial core hole with an electron is subsequently lost by creation of the second core hole, for a balance that is nearly zero.

The relaxation process is a partial filling of the positive charge in the initial hole. This is represented in Figure 5 by a partial shading of the initial core hole after the photoemission event. The relaxation process can occur via a rehybridization of the atom, in which case it is an intraatomic process. This is illustrated in the figure by a removal of partial charge from the valence band. Relaxation can also occur by extraatomic (also called interatomic) processes, in particular through a process equivalent to diffusion of the localized core hole throughout the valence band of the material.

Relaxation processes typically occur instantaneously in comparison to the lifetime of the core hole and always lead to a decrease in apparent BE for the outgoing photoelectron. This is shown in Figure 5 by the shift of the orbital positions toward the Fermi energy due to the relaxation process. A useful if somewhat naive analogy is to consider relaxation as leaving the atom less positively charged than immediately after the electron is ejected. The outgoing electron senses this as an increase in negative charge, and is correspondingly repelled to higher E_K. Higher E_K translates to lower apparent BE in the XPS spectrum.

The magnitude of the decrease in BE due to relaxation can be on the order of several electron volts. It is distinctly apparent in comparison of gas-phase and solid-phase XPS spectra from compounds. Relaxation is also one reason why work functions of bulk materials are lower than the first ionization energies of the corresponding isolated (gas phase) atoms. Relaxation shifts in photoemission peaks also manifest themselves in XPS spectra from small particles versus bulk solids, although only at particle sizes approaching the scale of nanoclusters. This can occur with samples such as metal particles on heterogeneous catalysts or isolated clusters embedded in a different matrix material. Finally, the magnitude of the relaxation shift can be different for atoms in different chemical environments.

Relaxation occurs to the same extent for all atoms in a material to the extent that the atoms are in the same chemical and structural state. It therefore does not typically result in a new feature (peak) in an XPS spectrum. It may only be apparent in comparing of the position of a photoemission peak from one sample to another. As noted above, it is most prominent when comparing spectra from gas phase and bulk materials or from particles of different

sizes or in different matrices. In materials having clusters of different sizes or particles in different chemical states, variations in the extent of relaxation due to these chemical or structural inhomogeneities can lead to relatively minor peak-broadening effects.

The fourth final-state effect is either the shake-up or shake-off process. This is shown in the third panel in Figure 5. The process involves rehybridization of the ion in such a way as to excite an upper-lying (valence band) electron. In the shake-up process, illustrated in Figure 5, the electronic excitation leads to promotion of a valence-band electron, for example, from the highest occupied molecular orbital (HOMO), to an unoccupied state above the Fermi energy (the lowest unoccupied molecular orbital or LUMO). In the shake-off process, the electron is promoted to a higher virtual state, although it does not necessarily leave the vicinity of the material (in which case, it could be considered an Auger electron).

Both shake-up and shake-off processes shift the BE of the initial hole to higher values. One view of why this is so is shown in Figure 5. The creation of a localized, occupied state above the initial E_F of the material causes an upward shift of E_F. This is equivalent to shifts in E_F that occur when semiconductors are doped. The upward shift in E_F causes the increase in E_B of all electrons in states below E_F. Other factors, such as changes in orbital energies during the rehybridization process, are also involved.

Unlike relaxation, which leads to an overall increase in the background of a spectrum, the shake-up or shake-off processes lead to the appearance of a new peak, called a satellite peak (not to be confused with satellite lines due to the x-ray source). The position of the satellite peak can be up to a few electron volts in BE above the primary photoelectron peak. In some cases, the intensity of the satellite peak can be comparable to that of the main peak. The satellites can also be turned off or on by the chemical state of the element. An example of this is seen in high-resolution spectra of the Cu $2p_{3/2}$ peaks for unoxidized and oxidized foils shown in Figure 6. Satellites are only weakly visible above the main peak for the sputtered foil. The spectrum from the oxidized foil clearly shows two shake-off satellites at ~7 and 10 eV above the main Cu $2p_{3/2}$ peak.

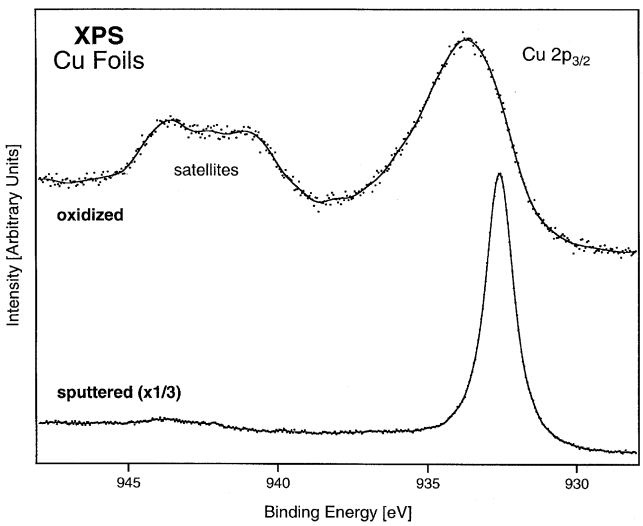

Figure 6. High-resolution spectra from sputtered and oxidized Cu foils showing how the intensity of the Cu $2p_{3/2}$ satellite peaks can be influenced by chemical state.

Because the shake-up and shake-off processes occur after the photoemission process, the electrons that appear as satellite peaks in the XPS spectra should actually be considered as an integral part of the photoemission event. In particular, with reference to the equation $I_i^e \propto F\sigma n$, this means the electrons contributing to the satellite peaks should also be counted to determine the total number of orbitals, n, that produced the photoelectrons. In simpler terms, satellite peaks must generally be considered in all calculations of atomic concentrations. We will return to this point in considering data analysis of high-resolution spectra for atomic concentrations. Looking ahead, it suggests that acquisition of high-resolution spectra should always favor a wider range on the high BE side of a principal photoemission peak in order to cover potential changes in the appearance of satellites that may be present.

The concluding final state effect for consideration is multiplet splitting. Multiplet splitting occurs when the hole created by the photoemission process leaves behind an unpaired electron. The basis for the process is similar to that leading to the spin-orbit splitting of p, d, and f levels discussed in conjunction with survey scans (see discussion of The XPS Survey Spectrum). Multiplet spitting is especially important for photoemission from filled s levels, since photoemission always leaves behind an unpaired electron. The unpaired electron can couple with the nuclear and remaining electron spins as either a spin-up or a spin-down state. These two couplings will have different energies, and thereby shift the position of the orbital. The magnitude of the splitting is on the order of a few electron volts. It can be turned off and on by the chemical state of the atom, as with satellites. The width of the multiplet splitting will be largest for valence s levels, and it decreases in magnitude with increasing BE.

Initial-State Effects. Initial-state effects influence the BE of the orbital before the photoemission process occurs. Three types of initial state effects are recognized: chemical state shifts, inhomogeneous matrix broadening, and charging shifts. The first two are considered below. Charging is an artifact that will be dealt with in the section on problems associated with XPS (see Problems).

Chemical state information is typically what is sought from a high-resolution XPS scan. The spectra in Figure 6 show that we can clearly distinguish between the chemical states of Cu and CuO, for example. The shapes of the Cu $2p$ peaks and their positions are distinctly different for Cu in the neutral (0) and charged (+2) oxidation states. The enhancement of the shake-up satellite adds a distinct signature to the peak shape. Differentiation of chemical state information is unfortunately not this straightforward for all elements, as the background information on final state effects already suggests.

The chemical state of an atom depends on the type of bond it forms: metallic, covalent, or ionic. Dispersive or hydrogen bonding also plays a role, as does the

hybridization in covalently bonded systems. These factors affect the partial charge on the atom. In metals, atoms are expected to be neutral (have an oxidation state of zero). In covalent materials, atoms can have partial charges due to electronegativity differences as well as differences in hybridization. At extremes of electronegativity difference, ionic bonding leads to consideration of the formal oxidation state (charge) of the atom.

Although bonding occurs almost exclusively through valence electrons, the E_B of core levels are also affected, as seen clearly in Figure 6, where Cu 2*p* peaks are shown for Cu^0 and Cu^{2+} states. This can be simply illustrated based on the picture of the electrons in orbitals as charges contained on hollow, conductive shells. The core electrons are contained spatially on shells within the outer valence shells. The work needed to remove the inner shell (core) electrons is affected proportionally by changes in the potentials on the valence shell. In atoms that acquire a partial negative valence charge, the core levels will shift to lower E_B because less work is needed. The core levels in atoms that become more positively charged will correspondingly shift to higher E_B. The analogy presented to explain peak shifts due to relaxation effects is also useful to consider here. An outgoing photoelectron will sense an increase in negative valence charge on an atom as it leaves the atom. This causes the outgoing photoelectron to gain KE in comparison to one that has been ejected from a neutral atom. This leads to a decrease in the measured BE of a photoelectron from a negatively charged ion relative to one from the same orbital in a neutral atom. The opposite shift (toward higher BE values) occurs for electrons leaving ions of greater positive charge.

The chemical shift due to a change in valence charge can be expressed as

$$\Delta E_B = k\Delta\left(\frac{q}{r}\right) + \sum_{j\neq i} k\frac{\Delta q_i}{r_{ij}} \qquad (1)$$

where ΔE_B is the chemical state shift, $k\Delta q$ is the change in valence charge on the atom, and r is the radius of the valence orbital. An increase in negative charge is considered as a positive value of Δq. The summation accounts for interaction with charges from surrounding atoms. This model considers the core level as being confined within a uniformly charged shell of radius r. The radius of the valence orbital will also change as the valence charge changes. Neglecting this effect for small changes in charge, we can replace the valence radius by its expectation (average) value, $\langle r_2\rangle$. We can also neglect the second term when Δq is small, since the r_{ij} values will be larger than $\langle r_2\rangle$. This leads to

$$\Delta E_B \approx k\left(\frac{\Delta q}{\langle r_2\rangle}\right) \qquad (2)$$

A consequence of this is that for the same amount of valence charge shift the chemical state shift in photoelectron E_B will be larger for atoms of smaller radius. Alternatively, less valence charge perturbation is needed to give the same shift in E_B in smaller atoms. We expect therefore to be better able to distinguish subtle changes in chemical state for light elements (with smaller atomic radii) as opposed to heavy elements (with larger atomic radii). This has practical applications in analysis of polymer materials. Although changes in valence charge due to rehybridization can be relatively small, shifts in the peak positions of core levels for carbon, oxygen, and nitrogen often readily observable for different hybridizations. An example of this is shown in Figure 7. After deconvolving the various overlapping peaks, we can clearly see contributions from carbon in aliphatic, ester, and carbonyl hybridization states in the C 1*s* peak from the polymer material.

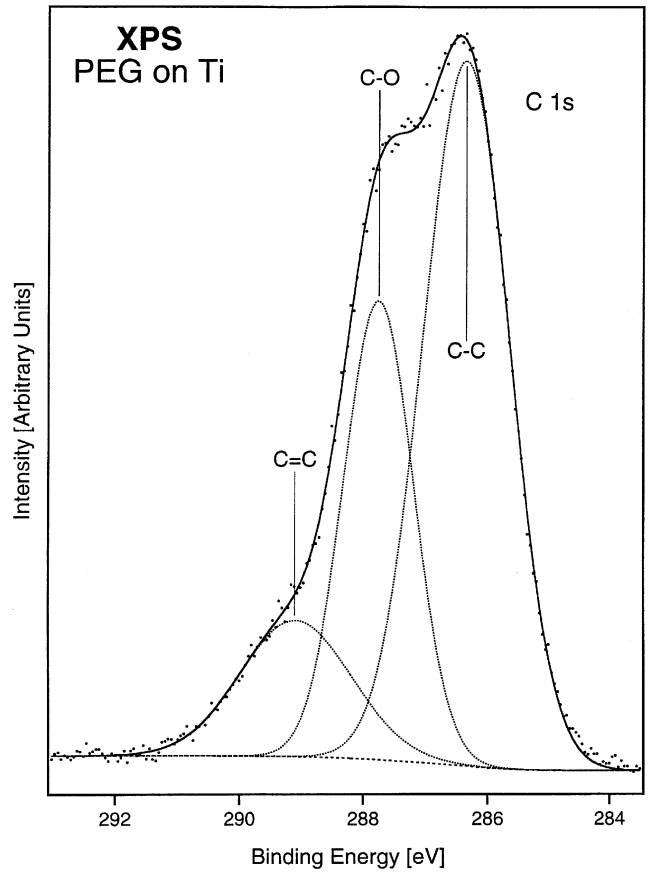

Figure 7. A C 1*s* peak from poly(ethylene glycol) (PEG) adsorbed on a Ti surface. The peak has been resolved into components for the various hybridization states.

We may want to compare shifts in E_B values for an element in two different materials. In this case, Equation 1 becomes

$$E_{B_2} - E_{B_1} = k\left(\frac{\Delta q_2}{\langle r_2\rangle} - \frac{\Delta q_1}{\langle r_1\rangle}\right) + (V_2 - V_1) \qquad (3)$$

where E_{B_i} is the binding energy of a given orbital in chemical state i. The first difference term accounts for differences in valence charge between the two atoms, and the V_i terms are abbreviations of the summation term in Equation 1. They essentially account for differences in Madelung potentials for the atom in the two different states.

Tabel 1. Peak Shifts Measured Going from a Pure Metal to an Oxide[a]

Compounds	Orbital	ΔBE (eV)	R (nm)
Fe/FeO	Fe $2p_{3/2}$	2.9	0.126
Cu/CuO	Cu $2p_{3/2}$	1.8	0.128
Os/OsO_2	Os $4f_{7/2}$	1.3	0.135
Pt/PtO	Pt $4f_{7/2}$	3.2	0.139
$Pt/Pt(OH)_2$	Pt $4f_{7/2}$	1.6	0.139

[a] The corresponding atomic radius of the metal atom is included.

Madelung potentials at a localized atom will change if the matrix surrounding the atom contains ionic or charged constituents and the crystalline symmetry of the matrix changes as viewed from the atom.

The effects of both valence potential and Madelung potential terms may cancel each other. This can lead to counterintuitive peak shifts based solely on considerations of chemical bonding. An example is found by comparison of the position for the Cu $2p_{3/2}$ peak in Cu (932.7 eV), Cu_2O (932.4 eV), and CuO (933.8 eV). The Cu $2p$ peak shifts first to slightly lower BE values going from Cu to Cu_2O, then shifts to higher BE values with the bonding of one more oxygen atom. The initial reversal in E_B of the peak shift going from Cu to Cu_2O may be due to differences in the Madelung potential term in Equation 3 or to differences in relaxation effects for the metal and metal oxide matrices.

Further examples of peak shifts for elements in different chemical states are given in Table 1 (Krause and Ferreira, 1975). The shift in BE going through the sequence $Fe/FeO \rightarrow Cu/CuO \rightarrow Os/OsO$ is increasing with decreasing atomic (or ionic) size ($Fe \rightarrow Cu \rightarrow Os$), suggesting an overriding role due to differences in the valence charges. By comparison, in the $Fe/FeO \rightarrow Pt/PtO$ sequence, BE increases with decreasing atomic size ($Fe \rightarrow Pt$), suggesting a greater role for the Madelung terms. Finally, the BE values in the $Fe/FeO \rightarrow Pt/Pt(OH)_2$ sequence are again more in line with a trend of decreasing shift with increasing atomic size ($Fe \rightarrow Pt$).

The second prominent initial-state effect, inhomogeneous matrix broadening, arises because not all atoms are in exactly equivalent bonding configurations in a material. The BE of an orbital will differ from atom to atom because of localized differences either in composition or structure surrounding each atom. This causes variations in the chemical potential or Madelung potential at each site. A specific orbital will therefore have a value of E_B specific to its atom.

In practice, the shifts in E_B of atomic orbitals due to micro-scale inhomogeneities in otherwise homogeneous materials are well below the detection limits of standard XPS instruments. Since the number of micro-inhomogeneities in a material is expected to be distributed as a Gaussian about a mean type, we expect to see peak broadening in the XPS high-resolution spectra rather than peak shifts. An example of this might be expected in comparisons of XPS spectra from a material with a glassy structure versus a spectrum from the same material in its single-crystal or polycrystalline state.

PRACTICAL ASPECTS OF THE METHOD

The practical aspects of XPS will be covered by first considering the instrumentation, including the source, analyzer, and detector. We will then consider unique aspects of the x-ray interaction with the sample for applications to obtain quantitative composition, chemical state, and film thickness information. Limitations of the method with regard to determining these parameters are discussed below (see Problems). The final part of this section covers important practical aspects related to the use of XPS for analysis of the four basic types of materials: metals, semiconductors, ceramics, and polymers.

Instrumentation

Facilities for XPS analysis consist primarily of an x-ray source, electron analyzer, and electron detector. This is all housed in an ultrahigh vacuum (UHV) chamber with nominal operating pressures below $\sim 10^{-8}$ mbar. One reason for UHV conditions is that mean free paths of the photoelectrons are inversely proportional to gas pressure. At room temperature and atmospheric pressure, the mean free path of an electron in air is only hundreds of nanometers. It is tens of kilometers at 10^{-8} mbar. Significant gas ionization can also occur for electrons traveling in gases above $\sim 10^{-4}$ mbar pressure. Another reason UHV conditions are often important during XPS analysis is to keep the sample surface clean. The impact rate of gas molecules with a surface is also inversely proportional to gas pressure. A common method of estimating coverage is to consider the general rule of thumb that 1 cm^2 of an initially pristine surface can be covered in 1 sec by a monolayer of absorbed gas when put under a pressure of 10^{-6} mbar of gas. Note that this rule of thumb is obtained from the historically important unit of dose called the Langmuir, defined using the pressure unit Torr as 1 liter $= 10^{-6}$ Torr sec/cm^2, where 1 Torr = 1.33 mbar. Suppose that analysis of 1 cm^2 of surface is to take 1 hr. To avoid having the analysis area completely covered by a monolayer of absorbed gas in this time requires that we work at gas pressures below $3 - 4 \times 10^{-10}$ mbar. Although typical survey scans usually take only a few minutes with modern instrumentation, high-resolution spectra can require an hour or more in some cases, and XPS can be sensitive enough to detect the growth of the monolayer in this time. The final reason for using UHV conditions is that laboratory x-ray sources will be damaged at higher pressures, especially when the background gas contains significant concentrations of water vapor or oxygen (see GENERAL VACCUM TECHNIQUES for details on achieving and maintaining UHV conditions).

Sources. Laboratory x-ray sources consist of an electron filament in close proximity to a metal surface. The filament is typically a tungsten wire that is heated by passing a current through it. A high voltage, on the order of 10 to 20 kV, is applied between the filament and the metal to accelerate electrons from the filament to the metal. The current that flows between the filament and the target metal (the anode) is the emission current. Electrons strike the metal

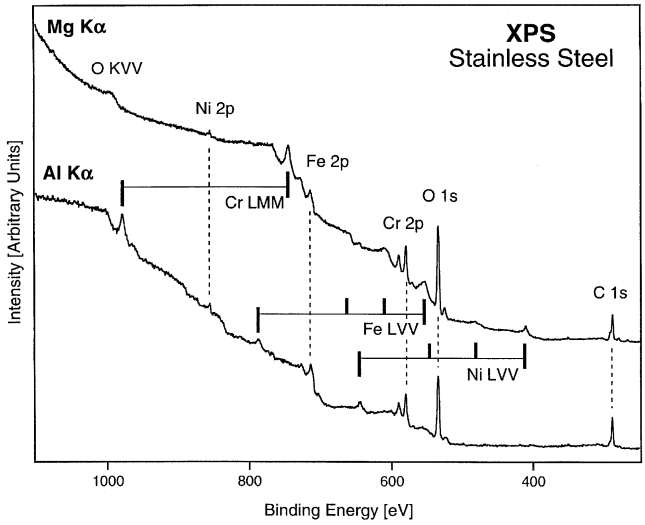

Figure 8. Spectra measured on a stainless steel alloy using either Mg Kα or Al Kα radiation. The shifts of the Auger lines are noted, while the photoemission peaks are seen to stay in one place on the binding energy scale. The background energy between the two spectra is also different at high binding energy due to the onset of the secondary loss peak.

anode and, in deaccelerating, produce x rays. Two types of x rays are produced, Bremsstrahlung ("braking radiation") and emission lines. Bremsstrahlung is a broad background underlying the emission lines and is independent of the choice of metal. Because it is low in intensity and broad in energy, Bremsstrahlung has no utility for XPS. The frequency (energy) of the principal emission line from a laboratory x-ray source is characteristic of the anode metal. The two most frequently used laboratory anodes in XPS are Al and Mg, with primary Kα emission lines at 1486.6 eV and 1253.6 eV, respectively. Other metals are sometimes used to have lower or higher excitation energies. Many laboratory XPS systems have a dual-anode arrangement that permits selection of one or another type of anode metal. The advantages of this arrangement are shown in Figure 8.

The peaks from AES electrons will always appear at constant E_K regardless of the excitation source. Their peak positions will therefore shift on the BE scale as a function of excitation source energy. This is clearly seen in Figure 8, where the AES peaks have shifted by 233 eV to higher BE when Al Kα is used as the excitation source rather than Mg Kα. The true photoemission peaks remain at the same position in BE. In cases where Auger peaks overlap with principal photoemission peaks, having a second x-ray source of a different excitation energy can sometimes help resolve any ambiguities in peak assignments.

The background intensity also increases more sharply at higher BE values for the XPS spectrum taken with an Mg x-ray source compared to that using an Al source. This is due to the onset of the secondary electron peak. For the Mg source, the increase in secondary electron background should start at ~1150 eV (1253 to 100), whereas for the Al source, it should start at ~1380 eV. This means that an Al source can be used to probe core levels at higher values of BE than a Mg source can. This is the same principle that limits UPS to valence band spectra.

Dual x-ray sources (Mg and Al) are typically used in conjunction with one another to shift Auger peaks out of the way of primary photoemission peaks. X-ray anodes with lower excitation energy, such as Ti at 395.3 eV, are also useful. The cross-section for photoemission of electrons from low E_B orbitals is sometimes greater at lower excitation energy, leading to greater sensitivity. In other words, a lower amount (concentration) of an element is needed in a material to give a specific signal intensity in an XPS spectrum when its cross-section is higher. The tradeoff to this is, as the excitation energy of the x-ray source decreases, fewer of the higher atomic number elements can be detected.

Principal emission lines from laboratory x-ray anodes are not monochromatic. A lineshape analysis shows they have a characteristic spreading about the principal emission energy. The x-ray half-width of Al anodes is ~0.85 eV and of Mg is ~0.7 eV, for example. This leads to further broadening of the photoemission peaks in the XPS spectra beyond lifetime broadening effects. The total peak broadening due to lifetime and x-ray source effects will be $\Delta E_T^2 = \Delta E_1^2 + \Delta E_s^2$, where ΔE_s is the source broadening. For a state with an intrinsic width of 0.10 eV, its XPS peak measured with MgKα will have a width of 0.71 eV. Laboratory x-ray sources also have x-ray satellite emission lines, typically at higher energy from the main emission line. Both Al and Mg have a number of such secondary emission lines (Krause and Ferreira, 1975). Their intensities are generally ~10% or lower than that from the primary x-ray emission line from the source. The secondary emission lines from an x-ray source lead to additional photoemission peaks at lower BE in the XPS spectra. These peaks are called x-ray satellites. For example, Kβ lines appear in the XPS spectra in Figure 4 at BE values ~7 eV lower than each of the principal peaks. X-ray satellite peaks should not be confused with the satellite peaks that are characteristic of final state shake-up and shake-off processes. The former appear at lower BE values than the principal photoemission peak and the latter at higher BE values.

In operating laboratory x-ray sources, one characteristically defines any two of the parameters of applied voltage (V), filament emission current (I_F), or x-ray power (P) to define the operating characteristics of the source. They are related as $P = I_F V$. For a given x-ray source geometry, setting any two of these parameters defines the flux of x rays to the sample.

Most XPS systems in use today are equipped with an x-ray monochromator between the x-ray source and the sample. A typical x-ray monochromator is essentially an array of x-ray diffracting elements (quartz crystal strips for example) positioned to diffract the principal emission line from a conventional x-ray source onto the sample. Systems using a monochromator have a number of distinct advantages over conventional laboratory x-ray sources. First, the monochromator removes the x-ray satellite lines and significantly reduces Bremsstrahlung background radiation, leading to cleaner spectra, especially in survey

scan mode. Secondly, an x-ray monochromator reduces the broadening of the x-ray source line significantly, making the resolution of overlapping features in high-resolution XPS spectra an easier task. Finally, a monochromator reduces the potential for sample damage, in one case because of lower overall x-ray flux and in another because inadvertent bombardment by electrons through damaged x-ray windows is no longer possible. Although use of a monochromator decreases the net x-ray flux to the sample, the output flux of modern x-ray sources and the sensitivity of electron detectors have improved to the point where this loss is overridden by the improvement in signal quality that is obtained. For these reasons, monochromatic x-ray sources are to be preferred for XPS analysis in all cases where a choice is offered.

Synchrotron radiation is also a viable source of x-ray radiation. Because the use of synchrotron radiation involves a movable monochromator between the beam line and the analysis system, the advantages are its tunability through a range of x-ray energies, high flux, narrow linewidth, low background intensity, and absence of satellites. The disadvantages are that one must schedule time on a synchrotron facility and be adept at the use of such facilities. Collaboration with research groups doing comparable studies is encouraged at the outset. The tunability of the x-ray energy from synchrotron sources is often exploited for x-ray absorption fine structure (XAFS; see XAFS SPECTROSCOPY) or near-edge XAFS (NEXAFS) studies. Both techniques are related to XPS. They look at the intensity of photoemitted electrons from a sample at a well-defined BE as a function of the energy of the incident x-ray. Further information is provided in XAFS SPECTROSCOPY.

Analyzers. Two types of analyzers are widely used for XPS analysis, the cylindrical mirror analyzer (CMA) and the hemispherical sector analyzer (HSA), shown in the schematic in Figure 9. Historically, the HSA pre-dates the CMA in design (Palmberg et al., 1969; Siegbahn et al., 1969a,b; Palmberg, 1975). The CMA is popular for AES systems, and further details of its configuration and operation can be found elsewhere (Palmberg et al., 1969; Palmberg, 1975). The HSA has become the norm for XPS analysis and will be considered exclusively in the following discussion.

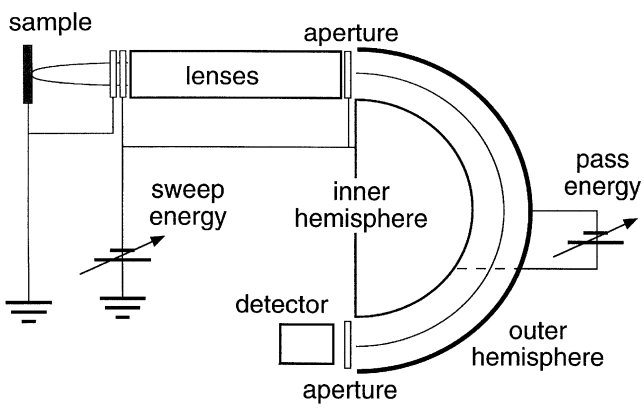

Figure 9. A schematic representation of the key parts of a hemispherical sector analyzer (HSA).

The HSA is recognized on XPS systems by its distinctive clam-shell appearance. This hemispherical portion of the analyzer serves as an electron monochromator. It is typically preceded in the electron path by a series of electrostatic lenses and is followed by an electron detector.

Photoelectrons leaving the sample are collected by the lens system. The frontmost lens is at sample potential (ground) to provide a field-free region between the analyzer and sample. The lenses focus the electrons spatially to the front aperture of the HSA and may provide image magnification. In principle, an image of the aperture is focused by the lenses onto the sample, and the bounds of this image define the analysis area. Retarding fields in front and back of the lenses serve as energy selectors. These retarding fields are swept in potential (voltage) to determine the cutoff of electron E_K values that reach the analyzer. In doing this, the lenses retard the electrons in KE; they do not perform any further energy discrimination. Electrons reach the analyzer with a full range of E_K values above that selected by the sweep energy on the lenses.

The function of the HSA is to select electrons of a particular E_K to pass to the detector. The optimal E_K for an electron to pass through an HSA (or CMA) is called the pass energy, E_p. It is defined for an HSA of inner and outer radii R_i and R_o, respectively, according to

$$E_p = K_s \Delta V$$
$$K_s = \left(\frac{R_o}{R_i} - \frac{R_i}{R_o}\right)^{-1} \quad (4)$$

where K_s is a spectrometer constant and ΔV is the potential difference between the inner and outer hemispheres (outer minus inner potential). For a given set of voltages (potentials) on the inner and outer shells of an ideal HSA of a specific size, only electrons at E_p in KE will pass through to the detector. Those electrons with KE higher than E_p are lost to the outer hemisphere of the HSA, and those that travel too slowly are lost to the inner hemisphere.

All hemispherical sector analyzers allow electrons with E_K values that are not exactly at E_p to reach the detector. This is determined solely by the geometry of the analyzer. The range of E_K values that are passed, $E_p \pm \Delta E_A$, describes the absolute energy resolution, ΔE_A, of the HSA. The primary geometric parameter of concern in establishing ΔE_A is the acceptance angle, α, of electrons at the entrance slit of the HSA. Electrons with E_K equal to E_p that enter the HSA normal to its entrance slit ($\alpha = 0$) will always be transmitted; this defines the ideal case. To increase the number of electrons that can be transmitted through the HSA, we can also allow it to transmit electrons with E_K equal to E_p that enter at an angle α from the normal to the entrance slit. This is determined in practice by specifying the lens and aperture designs according to electromagnetic principles, which typically requires expansion of the governing equations for electron travel in a Taylor series about α. The optimal design for an HSA is to be focusing to second order in α.

When this second-order focusing constraint is applied, a limit on ΔE_A is obtained. It is found to be a function of the entrance slit width W and geometric radius of the optimal path through the analyzer R_p in the form

$$\frac{\Delta E_A}{E_p} \propto \sqrt{W/R_p} \tag{5}$$

where $\Delta E_A/E_p$ is the relative resolution. An optimally designed HSA is therefore not perfectly monochromatic; it introduces peak broadening of the order of ΔE_A. The total peak broadening in an experimental XPS spectrum due to lifetime, source, and analyzer effects is therefore $\Delta E_T^2 = \Delta E_l^2 + \Delta E_s^2 + \Delta E_A^2$. Analyzers with larger values of R_p or smaller values of E_p will give smaller values of ΔE_A, meaning better absolute energy resolution. In practice, typical XPS systems with an HSA are designed with $\Delta E_A/E_p \sim 0.1$. Specialty XPS instruments exist with far better relative resolutions, in which case the diameters of the hemispheres are significantly larger.

The transmission function of the HSA is an important factor to consider for quantitative analysis with XPS (Nöller et al., 1974). It defines how well the lenses and analyzer transmit an electron that leaves the sample at a given E_K. Three cases have been recognized: (a) where the lenses define the transmission, (b) where the lenses define the transmission only along one plane perpendicular to the sample along the lens axis, and (c) where the analyzer defines the transmission. In general, for XPS analysis using an HSA, the HSA defines the transmission except at low E_K (high E_B).

The HSA can typically be operated in one of two modes. In one, the analyzer transmission function is held constant. The transmission function of the HSA varies as $1/E_K$ and as $1/\sqrt{E_p}$. In fixed analyzer transmission mode, the value of E_p is varied to give a constant transmission function over the entire sweep range of KE in the spectrum. The pass energy increases with increasing KE in the spectrum. Because $\Delta E_A/E_p$ depends only on the analyzer geometry, the absolute resolution ΔE_A correspondingly varies with KE in the scan. In practice, this leads to broader peaks at low BE (high KE, where ΔE_A is large) compared to high BE. Constant transmission function mode can be used for AES analysis with an HSA. Peak widths in AES are much broader than those in XPS, and the variation in ΔE_A as a function of E_p is correspondingly not as important. In addition, having a low transmission function at low KE in the scan significantly reduces the overall size of the secondary background signal (below ~50 eV in KE). While constant analyzer transmission mode may have some utility for XPS survey scans, it is to be avoided for high-resolution XPS scans and in all cases where accurate elemental compositional information is desired.

The more common mode of operation of an HSA for XPS analysis is to hold E_p constant while the input sweep energy is varied. In practice, this is done by retarding the electrons through the lenses so that electrons leaving the sample at the desired EK arrive at the entrance slit to the analyzer with EK equal to E_p. Because E_p is constant throughout a scan, ΔE_A is constant over the entire BE range of the XPS sweep. Constant pass energy mode is the one to use for high-resolution scans where constant absolute energy resolution is essential in order to obtain reliable chemical state information. In addition, for automated analysis, elemental compositions must be determined from scans taken with the XPS instrument in constant pass energy mode.

In constant pass energy mode, the transmission function of an HSA typically varies approximately as $1/E_K$, which is the KE of the electrons at the entrance to the lens. This means that even if the flux of electrons emitted from a sample is constant over the entire KE range, the apparent intensity of electrons measured with an HSA in constant E_p mode will decrease with decreasing BE. In experimental spectra, peaks at high BE will be accentuated by the HSA relative to those at low BE. This effect will be considered again in later discussions regarding quantitative analysis using XPS, especially for ARXPS.

At a given value of KE in a scan, the transmission also varies as $1/\sqrt{E_p}$, so that lower values of E_p will give better absolute energy resolution and higher analyzer transmission. This latter point can lead to confusion because, in practice, when E_p is decreased, absolute resolution (ΔE_A) increases but the measured signal intensity decreases (suggesting that transmission function decreases). The resolution of this apparent contradiction is to realize that all electrons that exit the HSA are counted as part of the signal at the given KE in the scan, regardless of what their E_K actually was. In other words, the intensity that is measured at the detector as belonging to a signal at E_K, $I^m(E_K)$, is actually the integrated signal between $E_K \pm \Delta E_A$

$$I^m(E_K) \propto \int_{E_K - E_A}^{E_K + E_A} J^e(E)\,dE \tag{6}$$

As analyzer pass energy is decreased, the relative fraction of electrons that are transmitted by the analyzer (the transmission function) increases (in proportion to $\sqrt{E_p}$). However, the integration range in the above equation decreases (in proportion to E_p). Because the latter effect dominates, measured intensity decreases.

Survey scans are typically taken at a higher pass energy where the signal intensity $I^m(E_K)$ is large but the absolute energy resolution ΔE_A is poor. The objective is to obtain a high signal-to-noise ratio in a relatively short time; the objective is not primarily to resolve overlapping peaks. This was the case for the experimental spectrum in Figure 2. High-resolution scans are generally run at lower E_p to obtain peak resolutions approaching the inherent lifetime and source broadening limit. This means that high-resolution scans typically require longer acquisition times to get comparable signal-to-noise ratios.

Hemispherical analyzers for XPS analysis are more frequently being designed to be spatially focusing. This is because x-ray flux cannot be easily focused, and we often want to analyze only specific spatial regions on a sample. One way to achieve spatial focusing with an HSA is to insert mechanical apertures with various diameter entrance slits into the electron path through the lens,

typically at a point just prior to the analyzer. The image of this aperture is focused back to the sample, and smaller apertures select smaller spots on the sample. While this method has, in principle, no lower limit in object size at the sample, it is limited by the sensitivity of the detector systems. The nominal spot sizes that can be obtained using such mechanical aperture systems are on the order of millimeters, with hundreds of microns being possible only with extremely long (tens of hours) signal acquisition time.

Small-spot, or imaging XPS refers to systems that have electrostatic or electromagnetic lenses that spatially focus the analyzer entrance aperture to a defined spot at the sample (Seah and Smith, 1988; Drummond et al., 1991). No mechanical apertures are used, and the (mechanical) entrance slit width is always a constant size. Small-spot systems in use today can obtain spatial resolutions at the sample on the order of a hundred microns routinely, with acquisition times well within an hour for high-resolution scans. Lower limits in analysis spot size at the sample are currently $\sim$25 μm.

Another advance in analyzer and electrostatic lens design has led to XPS systems that can scan the analysis spot over the sample while acquiring data. Scanning XPS systems are typically coupled to small-spot analysis capabilities. This allows acquisition of chemical state maps over a sample. In this case, the intensity of photoelectrons at specific BE values is plotted versus spatial position. Within the spatial resolution limit of the instrument, scanning XPS can be used to determine such information as the uniformity of coatings on surfaces.

Detectors. Three types of electron detectors are common on XPS systems: electron multipliers, channeltrons, and channel plate arrays. The electron multiplier functions in a manner similar to an amplifier tube, often using multiple amplifier stages connected in series. The channeltron is a smaller, single-component system. The channel plate array is a circular, wafer-shaped detector with a multitude of narrow channels that each function, in a sense, as a separate channeltron. All three detectors have gain factors on the order of 10^3 to 10^6, meaning that one electron in will produce 10^3 to 10^6 electrons out. All of the detectors run at high voltage, often as much as 5 kV. They all require secondary amplification stages external to the detector to boost the output signal further. The external amplifiers are typically connected as closely as possible to the output stage of the detector to reduce concurrent amplification of circuit noise.

An increasingly common arrangement in XPS systems is to use multiple electron detectors arranged for position-sensitive detection. This makes use of the fact that electrons leave the exit aperture of the analyzer at different angles depending on their E_K. Multiple detectors can be configured to collect and process these electrons simultaneously, thereby increasing the signal-to-noise ratios obtained for comparable acquisition times with single-detector schemes.

For the electron multiplier or channeltron, position sensitivity is realized by positioning multiple detectors at key positions clustered around the exit aperture. At any instant, as one detector positioned off-center from the aperture is collecting electrons at $E_p + \Delta E_A$, the on-axis detector(s) collect electrons at E_p, and an opposing detector to the first collects electrons at $E_p - \Delta E_A$. With channel plate arrays, the entire channel plate detector can be hard-wired to become a position-sensitive detector. The positions of electrons arriving on diametrically opposing sides of the circular array are typically sensed and recorded by a four-element resistive network attached in a four-fold symmetrical pattern to the outer edge of the channel plate.

Electron Detection. The final consideration with regard to instrumentation in XPS is how the E_K of the photoelectron is sensed. This is not the same as how the analyzer selects for a particular KE of incoming photoelectrons. The latter is done by applying a retarding field to the lens system, as discussed above. Photoelectrons are counted when they successfully travel through the lens and analyzer systems because they have the appropriate E_K. However, photoelectrons have a different KE as seen from the reference frame of the sample versus the reference frame of the analyzer. The reason for this is shown schematically in Figure 10.

Photoelectrons leave the sample with a E_K determined by their initial E_B, the excitation energy $h\nu$, and the work function of the sample, ϕ_s. The work function of the sample is the difference between the Fermi energy of the sample E_F and the vacuum level. The vacuum level at the sample is where the photoelectrons have zero E_K as seen by the sample.

When the photoelectrons reach the detector, they will have traveled through an analyzer with an overall work function of ϕ_A. The analyzer work function is a constant that is independent of all intervening potentials (voltages) between the sample and the detector. A constraint on a properly configured electron analysis

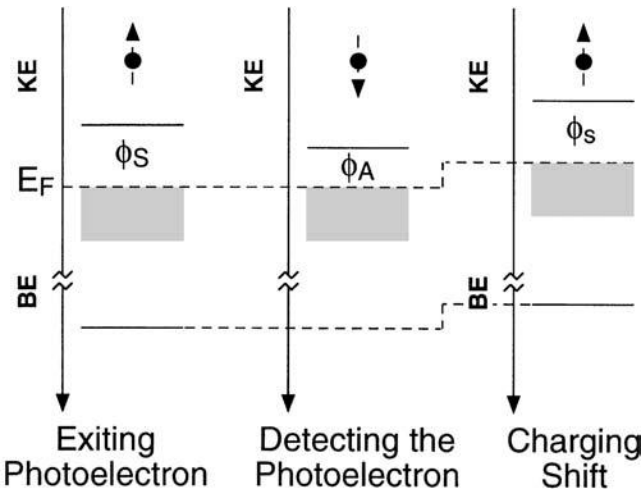

Figure 10. A schematic representation of the translation of electron kinetic energy (KE) to binding energy (BE), with consideration of the work functions of the sample and analyzer. How sample charging affects the considerations is represented by the panel on the far right.

instrument is that the Fermi energy of the sample and the system are equal, and electrons are "detected" (counted) when they reach the Fermi energy of the system. Because the work functions of the sample and analyzer are generally different, the electron will appear to have either a greater KE (as shown in Fig. 10) or lower KE from the perspective of the analyzer. The perspective of the analyzer, not the sample, is the one that counts in sensing the E_K of the electron as it passes through the analyzer.

Combining all of the above considerations, we can write a series of equations that lead to the formal relationship between the E_B of the electron in the sample and the E_K of the electron as it is sensed by the analyzer, where the S and A subscripts denote sample and analyzer, respectively.

$$E_{KS} = h\nu - (E_B + \phi_s)$$
$$E_{KA} = E_{KS} - (\phi_A - \phi_S)$$
$$E_{KA} = h\nu - E_B - \phi_A$$
$$E_B = h\nu - E_{KA} - \phi_A$$

The final equation above states that we must know the work function of the analyzer to know the absolute values of E_B for electrons in samples. In practice, the analyzer work function is a calibration constant for the instrument. It is determined by aligning peak positions from a sample with those of a reference. The typical calibration sample is Au, with the position of the Au $4f_{7/2}$ peaks being set at 84.0 eV. The issue of instrument calibration will be addressed more thoroughly in the section on problems with the technique.

As an example of the above equations in practice, consider a C 1*s* electron with $E_B = 284.6$ eV excited by Mg Kα radiation (1253.6 eV) from a sample with a work function of 5.0 eV and measured through an analyzer with a work function of 4.0 eV. The electron will appear to have $E_{KS} = 1253.6 - (284.6 + 5.0) = 964.0$ eV from the sample. It will appear to have E_{KA} 965.0 eV to the analyzer and will be recorded at this value if KE is used as the scale on the XPS spectrum. In a properly calibrated spectrometer, the E_B of this electron will be determined to be $1253.6 - 965.0 - 4.0 = 284.6$ eV.

Maintenance. The importance of maintaining a well-calibrated instrument for any analytical technique cannot be overemphasized. The sections that follow will highlight how instrument parameters affect quantitative results in XPS analysis. Both compositional (peak areas) and chemical (peak positions) information can be unknowingly distorted by improper or inattentive maintenance and calibration of an XPS instrument. A number of articles are available that specifically discuss calibration procedures in greater detail. In particular, the series of articles by Seah and others is highly recommended for consideration of instrument parameters that affect determination of compositional information with XPS (Anthony and Seah, 1984a,b; Seah et al., 1984; Seah, 1993). A corresponding set from Anthony and Seah is recommended for discussion of calibration of energy scales (which affect chemical information; Anthony and Seah, 1984a,b). A summary article pertaining to both AES and XPS was also published (Seah, 1985). Those who are involved in daily operation of XPS systems are strongly encouraged to apply the procedures set forth in these articles as part of their instrument maintenance and calibration routines. Laboratory experiments can also be designed around these articles as a method of introducing graduate students to the rigor needed for accurate and reproducible quantitative analysis of peak parameters with XPS.

Applications

In analysis of solid materials, the two primary uses of XPS are to determine elemental compositions and to characterize the chemical states of elements. Other applications include determining film thickness or composition profiles at the surface of a material, either through nondestructive or destructive means, and characterizing molecular orientation for adsorbates on surfaces.

The discussion below considers the practical factors that are involved in determining compositions and chemistry using XPS. The use of XPS for determining film thickness and molecular orientation in absorbed layers is also outlined. Finally, a brief review of materials-specific considerations is presented.

Elemental Compositions. The basis behind the use of XPS to determine elemental compositions is provided above (see Principles of the Method). A relatively more rigorous development is given in what follows, using what has been learned from both the principles of the technique and practical aspects of the instrumentation. Those interested in further details and alternate derivations are referred to the reference list (see Key References) and to Jablonski and Powell (1993). The formulation below starts from the perspective of an ideal analyzer viewing an ideal sample at an angle that is fixed relative to the surface plane. Nonideal factors introduced by practical analyzers will then be introduced. Considerations of nonideal samples will be covered at the end.

The flux of electrons emitted from a given orbital for a given element, i, in a sample, J_i^e (electrons/m^2-sec), for a given x-ray flux F (photons/m^2-sec) can be written as

$$J_i^e = F\sigma n_i \qquad (7)$$

where σ (in units of m^2) is the cross-section and n_i (in units of 1/m^2) is the number of orbitals per unit area over which the x-ray beam impinges. We can recast this expression in terms of elemental (atomic) concentrations in a bulk solid by accounting for the volume sampled. For the electron KE values of interest in XPS, x rays penetrate much further into a sample (on the order of microns) than the electrons can escape. Therefore, the total flux of electrons from a bulk sample is limited by the probability of the electron escaping. As discussed above (see Principles of the Method), inelastic scattering and plasmon loss processes are the two main factors that remove photoelectrons from consideration as part of a primary photoelectron peak, where the former dominates. In analogy with scattering processes in ideal gases, the escape probability can be

represented by a mean free path, λ_i (in units of m), for the electrons to travel before scattering. The escape probability decays exponentially with distance traveled relative to λ_i. Therefore

$$J_i^e = F\sigma \int_0^\infty C_i(z)\, \exp(-z/\lambda_i) dz \quad (8)$$

Assuming a homogeneous composition C_i (in units of atoms/m^3) of element i throughout the material, this equation becomes

$$J_i^e = F\sigma\lambda_i C_i \quad (9)$$

This represents the total photoemission flux from orbital i in a homogeneous sample.

A wide range of references are available on the subject of electron mean free paths in materials (Tanuma et al., 1988, 1991a,b, 1996; Marcu et al., 1993). Electron mean free paths increase sharply with decreasing KE at low E_K because the quantum-mechanical wavelength of the electron increases, and this reduces the inelastic scattering efficiency. They increase as $\sqrt{E_K}$ at high KE because the electrons essentially travel further between scattering events. The minimum mean free path is ~0.2 to 0.3 nm in the range of 30 to 100 eV. Mean free paths are also dependent on the type of material, its compositional homogeneity, crystal structure, and microstructure. Variations in electron mean free paths by factors of 2 to 3 are not uncommon from material to material for the same photoelectron E_K from a specific orbital in a given element.

Once the electrons are emitted from the sample, they must pass through the analyzer and be detected. This gives rise to considerations of nonidealities in the instrument, in particular of the analysis system. The relationship between emitted flux J_i^e and measured intensity I_i^m (number per unit time) can be expressed succinctly as

$$I_i^m = f_s f_n \theta_s TDAJ_i^e \quad (10)$$

where A is the sampling area on the surface, D is the transmission coefficient of the detector, T is the transmission coefficient of the lens and analyzer, θ_s is a collection efficiency factor for the frontmost lens of the spectrometer, f_n is a response function for the lens, analyzer, and detector, and f_s is a response function for the system electronics. The five coefficients other than sampling area generally depend on E_K of the incoming photoelectron (as viewed by the analyzer). They range between zero and unity. How they depend on E_K cannot always be exactly determined. This introduces errors in the consideration of atomic concentration, as discussed below (see Data Analysis and Initial Interpretation).

The transmission function of the analyzer has been discussed in the previous section and is typically the most prominent factor considered in the above equation. The detector response function D defines the gain of the detector as a function of the E_K of the electron at the detector. It is typically important to consider only when the pass energy varies, which should not occur during quantitative XPS analysis. In most practical cases, it is not possible or even really necessary to determine D separately from the value of T.

The angular efficiency factor θ_s is an abbreviated form of an integral over the solid angle of view of the analyzer, often called the analyzer acceptance angle. It accounts for any potential dependence of photoemission intensity from a solid on the analysis angle, often called the electron take-off angle. In some cases, this factor is also abbreviated as $d\sigma/d\Omega$ and termed the differential cross-section as a function of measurement angle. Even for pure elements as solids, photoemission intensity does indeed depend on emission angle, and therefore on take-off angle, especially for single crystal substrates. This is due both to the angular dependence of photoemission from orbitals of nonspherical shape as well as to diffraction phenomena. The angular efficiency factor is for the most part only important in analysis using XPS when considering spectra from highly ordered (single crystal) materials as a function of take-off angle or when considering variations in intensity as a function of analyzer acceptance angle. The former is typically a far more widely performed measurement than the latter.

The two response-function terms, f_n and f_s, account for non-idealities in the instrument and the electronics respectively. Basically, these terms account for temporal variations in such things as stray magnetic field strengths within the analyzer or fluctuations in voltage precision and stability as a function of sweep energy. Typically, they are also not readily separable from the value of T.

The overall transmission function of an analyzer, $T' = f_n f_s \theta TD$, can be determined by using ideal electron sources with known emission behavior as a function of E_K. A typical methodology might involve the use of an electron gun and analysis of the intensity of elastically scattered electrons from a sample reaching the detector as a function of electron E_K. An alternate method is to compare a measured spectrum $I^m(E_K)$ from one instrument to a spectrum that is known to represent the expected emission spectrum $J^e(E_K)$ from a well-defined sample. Overall instrument response functions are useful for fundamental studies into the behavior of an XPS instrument. They are typically not recorded as part of the everyday operation of the system. As will be seen below, the behavior is instead lumped into one factor, the sensitivity factor S_i, that is provided in tabular form by the instrument manufacturer.

Substituting the electron flux equation for a homogeneous sample into the above equations leads to a relationship between measured electron intensity and the concentration of an element in a homogeneous material.

$$I_i^m = F\sigma f_a AT\lambda_i C_i \quad (11)$$

where the angular efficiency as well as the detector and instrument response functions have been lumped into the factor f_a. The factor AT, the product of the viewing area of the analyzer and its transmission function, is called the analyzer étendue, G. As mentioned previously, for an HSA operating in constant pass energy mode under conditions where the analyzer defines the transmission function, G varies approximately as $1/E_K$.

The practical applications of XPS for determining atomic concentrations start from the above equation. It is typically presented in a far more abbreviated form, namely

$$I_i^m = FS_iC_i \tag{12}$$

where S_i is the instrument-dependent sensitivity factor for orbital i in an element. In practice, sensitivity factors should be provided by instrument vendors for each orbital in all elements. In most cases, sensitivity factors are only provided for the most prominent orbitals. As seen from the above discussion, they are not directly transferable from one instrument to another, since they contain instrument response and transmission functions. Also, sensitivity factors are confined to a particular sample-analyzer geometry. Finally, they do not take into account nonidealities in the sample, especially in regard to composition and structure. Despite all these apparent limitations, the use of tabulated sensitivity factors for an instrument has become the accepted practice for determining atomic concentrations with XPS, as discussed below (also see Data Analysis and Initial Interpretation).

Equation 12 can be used in three ways. The first is to determine absolute atomic (mole) fractions, x_i for an element in a material. In this regard, we can write

$$x_i = \frac{I_i{}^m/S_i}{\sum I_i^m/S_i} \tag{13}$$

showing in principle that only sensitivity factors and measured intensities are required to determine atomic concentrations of a material. This equation is based on analysis of a material with a homogeneous composition throughout. This restriction will be relaxed below in the discussion on other applications of XPS.

To obtain absolute accuracy in atomic compositions using the above equation, we must have values of S_i that were obtained (a) from a sample of similar if not identical atomic composition and structure to the one we are analyzing and (b) from a sample-analyzer configuration equivalent to that used to determine S_i. While the second condition can generally be met without much difficulty, meeting the first condition can be difficult if not impossible. Therefore, the above equation can be considered an approximation for almost all real-case systems. Given the extent of variations that are possible in λ_i and θ_i from one material to another, relative inaccuracies in x_i can be as much as $\pm 20\%$ using the above equation. A worthwhile note from this discussion is that absolute atomic fractions determined from XPS will be accurate to better than $\sim \pm 1\%$ only if they have been derived after a painstakingly thorough calibration of the XPS instrument concerned. This issue is separate from the precision of the measurements and will be highlighted again below (see Data Analysis and Initial Interpretation).

A far more useful form of Equation 12 (Briggs and Seah, 1994) can be derived by considering analysis to obtain "relative" atomic concentrations. Then, we can write

$$\frac{x_i}{x_j} = \frac{I_i^m/S_i}{I_j^m/S_j} = \frac{S_j}{S_i}\left(\frac{I_i^m}{I_j^m}\right) = R_{ji}\left(\frac{I_i^m}{I_j^m}\right) \tag{14}$$

where R_{ji} is the relative sensitivity factor of element (orbital) j to element i. Be aware in applications of this form whether you are using R_{ji} or R_{ij}, which are related as $R_{ji} = 1/R_{ij}$. Relative sensitivity factors are far less dependent on variations in sample composition and structure, as well as instrument configuration, than absolute concentrations. Changes in these factors tend to cancel each other in taking the ratio. Therefore, while uncertainties in absolute concentrations determined using XPS can be high, the uncertainties in relative atomic concentrations are in many cases bounded primarily by errors in measurement precision (repeatability). This often means that relative atomic concentrations determined with XPS can be compared more reliably from sample to sample and from system to system than absolute atomic concentrations.

The final form of Equation 12 (Briggs and Seah, 1994) that is of practical use arises when taking samples of known (and uniform) atomic composition for comparison to samples of unknown (and uniform) composition with similar micro- and molecular structure. In this case, the formulation can be recast to give

$$\frac{x_i}{x_{io}} = \left(\frac{I_i^m}{I_{io}^m}\right)\left(\frac{S_{io}}{S_i}\right) \tag{15}$$

where the "o" subscript indicates the sample with known composition. A particularly useful form of this equation for illustration purposes and applications arises when the known material is pure and we are comparing with binary (two-element) materials. The equation can then be rewritten as

$$\begin{gathered}\frac{x_A}{x_B}\left(\frac{x_{Ao}}{x_{Bo}}\right) = \left(\frac{S_B/S_{Bo}}{S_A/S_{Ao}}\right)\left(\frac{I_A^m/I_{Ao}^m}{I_B^m/I_{Bo}^m}\right) \\ \frac{x_a}{x_B} = f_{BA}^m\left(\frac{I_A^m/I_{Ao}^m}{I_B^m/I_{Bo}^m}\right)\end{gathered} \tag{16}$$

where F_{BA}^m is known as the matrix factor for the binary system. The matrix factor accounts primarily for the changes produced by putting element B in a matrix of element A. It is not always unity. To a first approximation, it can be taken as a ratio of the square root of the molar specific volumes of the elements

$$F_{BA}^m \approx \sqrt{\frac{\hat{V}_B}{\hat{V}_A}} \approx \left(\frac{R_B}{R_A}\right)^{3/2} \tag{17}$$

or the corresponding atomic radii for similar crystal systems. To use this equation, we would first measure intensities for the principal XPS peaks from pure materials, I_{Ao}^m and I_{Bo}^m. Then, intensities from samples of known composition, I_A^m and I_B^m would be measured to calculate the matrix factor for the binary system. Thereafter, alloy composition can be calculated directly from measured peak intensities of unknown binary alloys. This equation is limited primarily to homogeneous alloy systems.

Care must be used in reporting atomic compositions determined with XPS. They must be understood to be accurate only for a sample that has a uniform composition throughout the entire sampling volume. This is rarely

the case with real-world samples. Concentrations can vary dramatically across an analysis area, for example when analysis is done across grain boundaries in metals or across copolymer regions in polymers. One must keep in mind that even the best spatial resolution of ~25 μm obtainable with small-spot XPS is often larger than spatial variations in composition across the surfaces of most real-world samples. Conventional XPS systems can have analysis areas at the sample as large as a few mm^2. In cases where the sample is known to have lateral variations in composition, the atomic concentrations determined with XPS will generally be spatially averaged values.

Concentrations also vary with sample depth. In this regard, a key parameter is the average sampling depth in comparison to the depth over which the composition varies. The average sampling depth depends on the mean free path λ_i of the electrons. For example, most samples quickly become covered by an overlayer of carbonaceous and water contamination upon exposure to air. This overlayer, if thicker than λ_i, will mask the true composition of the underlying material, and anomalously high values of atomic concentration for oxygen and carbon will result. Other examples of potential problems that can arise in determining compositions when using XPS spectra from samples with nonuniform composition profiles have been pointed out elsewhere (Tougaard, 1996).

Further discussion on how to extract information about compositional variations with sample depth is given in the following section titled Other Applications. Analysis of XPS spectra to obtain values for I_i^m is also considered (see Data Analysis and Initial Interpretation). Methods for preparing samples to reduce the contaminant overlayer are given in the section on sample preparation.

Chemical State. Obtaining chemical state information from an XPS spectrum can often be as important as obtaining elemental composition. Any application that must consider the relative amounts of different oxide, valence, or hybridization states of an element will be interested in using XPS to determine chemical state. Specific examples of this for different families of materials (metals, ceramics, semiconductors, polymers, and composites) are found in almost any journal that publishes studies from XPS (see Key References).

The BE of a photoemission peak is affected by the chemical state of the element (see Principles of the Method). When an atom acquires a partial positive charge due to bonding or rehybridization, we expect a shift to higher BE values. Correspondingly, a shift to lower BE values is expected when an atom becomes negatively charged. Variations in the chemical state of atoms throughout the material can also affect the width of the photoemission peak.

As also pointed out (see Principles of the Method), other factors besides the chemical state of the element influence both the BE and width of a photoemission peak. The Madelung potential term arises when the lattice structure about the atom changes. The extent of intra- or extra-atomic relaxation may also change. This means, a peak shift to higher or lower BE values cannot always be interpreted as arising solely from a change in chemical state.

In practice, one should therefore not view XPS as an unambiguous means of identifying unknown chemical states of elements. The better approach is to have initial information regarding the bonding of the element in the material. This information should then serve as a guide to select the main factors that could cause peak shifts or peak broadening for photoemission from the sample. Other factors that lead to peak shifts and broadening are considered below (see Problems). Finally, an enormous number of reference sources are available that contain XPS peak positions and even reference spectra from compounds (see Key References). The reader is also encouraged in this regard to search the Internet. These reference texts and pertinent literature on the sample being analyzed should be consulted for fuller insight into peak assignments.

For further discussion on resolving overlapping peaks via peak fitting procedures and on deconvolving instrument response functions and source broadening effects from high-resolution XPS spectra (see Data Analysis).

Other Applications. Two other applications of XPS deserve mention. Both are extensions of the use of XPS to determine atomic concentrations. They apply in cases where composition varies with sample depth, $C_i(z)$. The first is the use of what is commonly termed sputter profiling. The second is called angle-resolved XPS (ARXPS). Both methods rely on the limitation that sampling depth in XPS is only on the order of the electron mean free path, λ_i.

Sputter profiling is a destructive technique. Details are provided in the reference from Briggs and Seah (1994). It is useful for mapping any form of concentration profile as a function of depth. In sputter profiling, the sample is bombarded with high-energy ions, typically Ar^+. This etches away layers of the sample. Sputtering rates can be controlled to remove on the order of sub-monolayers of material with careful calibration of the sputter gun and its configuration relative to the sample. Sputter depth profiling consists of performing a series of analysis-sputter cycles on a sample. Sputter rates and times during each cycle are set by the user. Typical results from sputter profiling are plots of I_i^m, x_i, or peak positions versus sample depth. Sample depth is obtained from sputter time by calibrating the sputter rate. This is done by using a layered sample with a known thickness. Oxide layers on Si wafers and oxide layers on Ta are most common and can be readily obtained through commercial vendors.

A number of factors limit the utility of sputter profiling with XPS (Hofmann, 1993; Wetzig et al., 1997), including sample surface roughness (Gunter et al., 1997) and compositional heterogeneity. Both contribute to nonuniform sputtering rates across a sample surface, especially in systems where sputtering is done at an incident angle that is not normal to the sample surface. A common method of overcoming this limitation, at least for rough sample surfaces, is to rotate the sample under the sputter gun. Another limit on sputter profiling is the inconsistency between sampling depth and sputter depth per cycle. Generally, the sputter depth per analysis cycle is set to be lower than the sampling depth (mean free path of the escaping

electrons). This leads to the effect that I_i^m will start to decrease or increase before the depth is reached where concentration actually increases or decreases. This problem is essentially due to a convolution of the true concentration profile $C_i(z)$ with functions representing the effective sampling depth during analysis $f_d(z)$ as well as any non-uniformities in sputtering depth $f_n(z)$, giving a measured concentration profile $C_i^m = C_i(z) \oplus f_d(z) \oplus f_n(z)$. A number of methods exist for handling the deconvolution of $f_d(z)$ and $f_n(z)$ from C_i^m in a simple or rigorous manner (Blaschuk, 2001; Hofmann, 2001; Lesch et al., 2001). Ion bombardment can also cause remixing at the sputter crater of components in a heterogeneous sample, and segregation of specific bulk elements to surfaces and interfaces can occur (Hofmann, 1992). These factors will lead to false composition readings during sputter profiling. Finally, care must be taken during sputter profiling to make sure that sputtering is done uniformly over an area that is larger than the analysis area.

With the exception of nonuniform sputtering rates, the above limitations are less important in sputter profiling during AES analysis. The analysis area and sampling depth are both much smaller in AES than they are in XPS. Therefore, in cases where it can be used, AES is generally preferred for sputter profiling, especially when only composition (not chemical state information) is desired. The only other concern prior to sputter profiling is to determine whether any of the AES or XPS peaks of interest overlap. This can sometimes rule out or favor one technique over the other. For example, N peaks overlap with Ti peaks in AES but not in XPS, so nitrided Ti samples would be better analyzed with depth profiling using XPS.

In ARXPS, compositions are measured as a function of sampling angle relative to the surface plane, often called the analyzer take-off angle. For samples with layered compositions, changing the analyzer take-off angle results in changes in measured intensity, I_i^m, because emitted flux, J_i^e, varies from elements within the different layers. Measurements of I_i^m as a function of take-off angle can be used to determine values for layer thickness. Other applications include the determination of molecular orientation in ordered adlayers and crystal packing symmetry in lattices. Two extensive reviews by C. Fadley of the principles and applications of ARXPS are recommended as a starting point for further details (Fadley, 1976, 1984).

One case is useful to present as an illustration of the methodology. This is an example for a bilayer material, such as occurs when a coating, oxide, or contaminant layer covers a surface. An illustration of the set up is shown in Figure 11. The overlayer has a thickness, d; the outmost surface and boundary interface are assumed to be flat on the microscale, and the boundary between the overlayer and the underlying substrate is abrupt (a step function).

Consideration of this situation starts with modification of Equation 8 to account for a change in the effective path length the electrons must travel to escape. The path length is dependent on the take-off angle, θ, of the photoelectrons. We define take-off angle relative to the surface plane, so that glancing angle analysis occurs as θ approaches zero (some texts define take-off angle with respect to the surface normal). Under these conditions, for a fixed value of

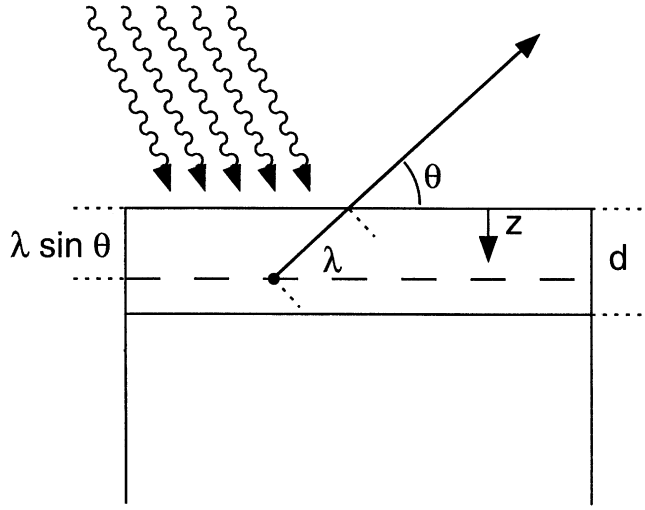

Figure 11. An example of a simple system that illustrates the application of angle resolved XPS. An overlayer of thickness d is being analyzed at a take-off angle θ with respect to the surface plane.

θ and a semi-infinite sample, we can write Equation 8 for the overlayer o and underlying substrate s to be

$$J_o^e = F\sigma_o \int_0^d C_o(z)\, \exp(-z/\lambda_o \sin\theta) dz \qquad (18)$$

$$J_s^e = F\sigma_s \int_d^\infty c_s(z)\, \exp(-z/\lambda_s \sin\theta) dz \qquad (19)$$

We assume the overlayer and substrate have uniform composition throughout. We can then obtain representative equations for the measured intensity of photoelectrons from an orbital in the overlayer or in the substrate as

$$I_o^m = F\sigma_0 f_{a,o} G_o C_o \lambda_o (1 - \exp(-d/\lambda_o \sin\theta) \qquad (20)$$

$$I_s^m = F\sigma_s f_{a,s} G_s C_s \lambda_s \exp(-d/\lambda_s \sin\theta) \qquad (21)$$

Note that, factors dealing with the behavior of the instrument, f_a and G, as well as the cross-section σ depend on E_K of the electron and the orbital being considered, respectively.

A ratio of measured intensity for a photoemission peak in the overlayer I_o^m to that from the underlying substrate I_s^m has the form

$$\frac{I_o^m}{I_s^m} = \left(\frac{\sigma_o}{\sigma_s}\right)\left(\frac{G_o}{G_s}\right)\left(\frac{\lambda_o(1 - \exp(-d/\lambda_o \sin\theta))}{\lambda_s \exp(-d/\lambda_s \sin\theta)}\right)\left(\frac{C_o}{C_s}\right) \qquad (22)$$

In this equation, the parameter sought is d, the overlayer thickness. This can be determined if we obtain I_o^m/I_s^m as a function of θ, and know all the other parameters. In practice, the ratios of cross-sections and transmission functions are usually taken as unity to simplify the expression. The concentration ratios are either set equal to unity as well or are estimated from materials properties. An example of the use of this equation is provided below (see Data Analysis).

Photoemission intensity for one peak from an overlayer can also be compared relative to the intensity from same peak for the pure sample of the element concerned using the above equations. This leads to

$$\frac{I_o^m}{I_p^m} = \frac{\lambda_o(1 - \exp(-d/\lambda_o \sin\theta))}{\lambda_p \sin\theta}\left(\frac{\bar{V}_p}{\bar{V}_o}\right)x_o \qquad (23)$$

where x_o is the mole fraction of the element in the overlayer and the $V]_i$ values are the molar specific volumes of the element in the overlayer or pure material.

Angle-resolved XPS can also be used to determine the bonding angle of a molecular adsorbate on a surface. Consider a linear-chain molecule that can bond in either an up or down configuration on a surface, and imagine that one end is tagged with a different element than the other. If we form a monolayer on a microscopically flat surface, analysis with XPS at glancing take-off angle will accentuate the signal from the element that is at the outermost position in the absorbed layer. This has applications for molecular coatings and polymers where information about the chemistry of the exposed surface relative to that for the underlying surface layer is of utmost importance. On microscopically flat surfaces, ARXPS can often be used to distinguish between perpendicular and horizontal configurations of molecules. It can also be used to determine the bond angle of molecular adsorbates in certain cases where the adsorbate has well-defined long-range order. These types of angle-resolved XPS measurements should be confirmed using other techniques.

Surface roughness complicates the analysis with ARXPS. In addition, the angular resolution of the data can never be any better than the acceptance angle of the front lens on the analyzer. Most commercial systems have an acceptance angle of 15° to 20°. This may not present problems for film thickness measurements, but is too wide for sophisticated ARXPS measurements of bond angles for molecular adsorbates. Some HSA-equipped XPS instruments have variable magnifications for the lenses. The acceptance angle of the analyzer will always be larger at higher magnifications. Both surface roughness and an overly wide analyzer acceptance angle lead to a fall off of intensity from theoretically expected values as take-off approaches glancing angles.

Materials-Specific Considerations

Almost all of the previously mentioned journals (see Introduction) present articles on XPS as applied to all classes of materials. The scope ranges from fundamental (*Surf. Sci.* or *Surf. Interface Sci.*) to more applied (*Appl. Surf. Sci.* or *J. Vac. Sci. Technol.*). The use of XPS for analysis of biomaterials surfaces is also becoming more widely represented in *Colloid Interface Sci.* and *J. Biomed. Mater. Research.*

With regard to metals, the ASM Handbook (ASM Handbook Committee, 1986) is a reasonable starting point for practical applications of XPS in metallurgy. Analysis of metals that are used in routine applications is often not straightforward with XPS. Most metals will have oxide or contaminant overlayers on their surfaces, and surface segregation is also common in alloys. Structural variations, such as grains, precipitates, or other microconstituents can also be present, especially in multi-component metal alloys. These factors will all affect the measured intensity of a photoelectron peak I_i^m by introducing nonidealities into the equations that were derived primarily for analysis of homogeneous samples. In addition, as seen in Figure 8, the more elements that are in a metal sample, the greater is the chance that Auger peaks will interfere with XPS peaks in the spectrum. This can make the determination of composition and chemical state difficult. Finally, on metals with oxide layers, the oxide layer can act as an electrical insulator, leading to peak shifts due to differential charging (see Problems).

As mentioned above (see Competitive and Related Techniques), better spatial and depth resolution are typically obtained using AES. This may be preferred for analysis of metals, especially for compositional analysis across grains or within two-phase regions. Because of the larger sampling depth and spot size of XPS, compositions will be averaged in these cases. The distinct advantage of XPS over AES for analysis of polycrystalline metals is that the oxidation states of metals are generally much easier to resolve with XPS, though this is not always the case (Sekine et al., 1996). Assignment of peak shifts to changes in metal oxidation state can be complicated when multiple oxidation states exist. Peak fitting is generally required to resolve the overlapping features. The use of sputtering to remove the outermost contamination layer, as well as glancing angle analysis to become more sensitive to surface compositions, can often help.

Analysis of semiconductors is relatively routine with XPS. The overriding concern is generally to remove the outermost contamination layer. With extrinsic semiconductors, sensitivity factors for the dopant concerned should be compared to those for the intrinsic material, keeping in mind that lower sensitivity factors mean greater amounts (concentrations) of dopant will be needed to give the same signal-to-noise ratio in an XPS spectrum. The mean free paths of the relevant photoelectrons in the material should be considered when analyzing for dopant compositions that may vary with depth. Sample charging can occur in XPS of semiconductors. In this regard, though, XPS presents fewer problems than AES.

With ceramics, XPS is generally the only spectroscopic laboratory method that can be used to determine (surface) composition and chemical state information. Analysis with AES is typically not feasible because of sample charging. Even with XPS, ceramic samples charge considerably, leading to peak shifts.

In regard to analysis of polymers with XPS, the articles by D.T. Clark are good, though somewhat dated, starting points (Clark and Feast, 1978; Clark, 1979). Analysis of polymers with XPS is a common method of determining both concentrations and hybridization states of elements in the material. As shown in Figure 7, XPS can easily resolve certain hybridization states of carbon. It can also resolve variations in functional groups attached to the carbon. In most cases, shifts of the C 1*s* peak can be assigned solely to changes in the electronegativity of the surrounding atoms. The primary difficulty with polymer samples is charging. Some polymer samples are also damaged by high x-ray flux.

Metal and semiconductor single-crystal samples are often used as model systems for analysis with XPS. Quantification of the rates of chemical reaction processes and determination of the fundamental nature of chemical bonds formed by adsorbates to surfaces are two areas that benefit by the use of XPS on such model systems. Single-crystal metals and semiconductors have also been used to develop much of the theoretical basis behind the shape of the XPS spectrum. Angle-resolved XPS also benefits by using microscopically if not atomically flat surfaces.

METHOD AUTOMATION

All XPS systems in operation today are run by computers, with many modern systems being entirely automated after introduction of the sample. The user generally has to define a number of parameters to control the instrument. On older-generation instruments, some of the parameters may be input manually. In most cases, those parameters that are input manually are not supposed to vary from run to run.

Starting with the source, after selecting an anode type (in systems with more than one anode), one typically defines any two of three operating parameters of x-ray source voltage, emission current, or power. This defines the type of x ray (its primary energy $h\nu$) and the flux F. We are typically not interested in knowing the absolute value of F for the x-ray source, only in knowing that it is the same value from analysis to analysis. Most XPS instruments also allow the user to select an analysis area on the sample, either using manual apertures or through computer settings to control focus voltages to the lenses of the analyzer. Modern systems also allow the user to position the sample in different locations and possibly different orientations under the analyzer using computer control.

The scan parameters are set next. Among these parameters are: the sweep starting and/or ending energy, $\mathrm{BE}_{\mathrm{start}}$ and $\mathrm{BE}_{\mathrm{end}}$; sweep width, $\Delta\mathrm{BE}_{\mathrm{sweep}}$; step size, $\delta\mathrm{BE}_{\mathrm{step}}$, or number of points per sweep n_{pps}; dwell time at each step, t_{dwell}, or the total time per sweep, t_{sweep},; and finally the number of scans, n_{scans}, or total analysis time t_{total}. These parameters are related as listed below.

$$\Delta\mathrm{BE}_{\mathrm{sweep}} = |\mathrm{BE}_{\mathrm{end}} - \mathrm{BE}_{\mathrm{start}}|$$
$$\Delta\mathrm{BE}_{\mathrm{step}} = \Delta\mathrm{BE}_{\mathrm{sweep}}/n_{\mathrm{pps}}$$
$$t_{\mathrm{sweep}} = n_{\mathrm{pps}}\, t_{\mathrm{dwell}}$$
$$t_{\mathrm{total}} = t_{\mathrm{sweep}}\, n_{\mathrm{scans}}\, n_{\mathrm{sweeps}}$$

Not all of these parameters are used by all systems. Some are set automatically by the system depending on the type of scan (survey or high-resolution, for example). In this regard, the remaining input parameter is the pass energy E_{p}.

In addition to automated data acquisition, most instruments with computer control can be programmed to cycle through a series of spectra and determine peak parameters. This is generally done during sputter profiling or angle-resolved XPS. The instrument automatically shows profiles of composition as a function of sputter time (or depth) or take-off angle.

Automation of the data acquisition sequence leads to problems when the results deviate from those expected or when the system has problems during operation. The former case arises, for example, when samples have different degrees of charging, shifting the peaks out of preprogrammed sweep ranges. In some cases, trying to abort or break an established acquisition routine can lead to the loss of the settings, or worse, loss of data, especially on older-generation instruments. The user is therefore cautioned to be well aware of the potential variations that could arise before automating data acquisition.

Automation of data analysis does not typically present as many problems. The user can always repeat the analysis using different parameters. Unfortunately, some older XPS systems with automated data analysis may not allow this luxury, so caution is again warranted. Also, one should always do spot checks on the analysis results after an automated analysis. The computer is not an "all-knowing" instrument, and exceptions to the standard methods of data analysis can always arise.

DATA ANALYSIS AND INITIAL INTERPRETATION

Analysis of an XPS spectrum starts by determining parameters for the photoemission peaks. The three primary parameters that define a photoemission peak in XPS are its area A_{pi}, position BE_{i}, and full-width-at-half-maximum (FWHM) Δw_{i}. Additional consideration may be given to peak shape, as discussed below (see Peak Integration and Fitting). To obtain accurate values for these peak parameters, we have to process the XPS spectrum correctly. This means applying methodologies that are well grounded in the principles of the method. Data analysis may be preceded or followed by application of methodologies to improve the appearance of a spectrum. Finally, interpretation of the results should keep in mind the uncertainties that arise during data analysis.

The following discussion first presents the methods used to determine peak parameters from XPS spectra. This is followed by a discussion of methods that can be used to improve the appearance of an XPS spectrum. We then consider how to interpret the results, with particular emphasis on uncertainty analysis. The concluding presentation in this section offers an example of the analysis of ARXPS data to determine the film thickness of an oxide layer on a Si wafer.

Analysis

The most routine analysis of an XPS spectrum involves identifying the peaks with their corresponding elements. Tables of peak positions are available to help with this task. Most XPS systems also have software libraries of peak positions that will automatically mark elements in a spectrum. This automation is only as good as the software routines for locating peaks; it should not be taken as a definitive indication of the presence of an element, and it may miss small peaks on noisy backgrounds. The best method of determining unambiguously that an element is present is to cross-correlate for all peaks that

should appear for that particular element. For example, if a peak at 100 eV is identified as the Si 2*p*, a corresponding 2*s* peak should be found at ~150 eV with the appropriately scaled height. Auger peaks should also be present if the scan range covers them.

We generally also want to obtain elemental compositions from an XPS spectrum. This requires quantitative analysis of the spectrum. Quantitative analysis for compositions is based on background subtraction and peak integration. In cases where more than one chemical state is present for a given element, we may need to fit the peaks with components. Finally, we may want to quantify the positions and half-widths of peaks in order to compare changes from sample to sample. The practical aspects associated with these procedures are discussed in the sections immediately below.

Background Subtraction. The area of a photoemission peak is determined by subtracting an appropriate background and integrating (numerically) under the resultant curve. The background underlies the true spectral features, as illustrated in Figure 2. The types of background shapes that can be used range from a constant to a complex shape and are based to some degree on theoretical considerations of the inelastic scattering processes that generate a background in XPS spectra. The choice of a background shape can affect the resulting peak parameters. Although this effect is often below the precision (repeatability) of the measurements from sample to sample, proper attention should be paid to the application of appropriate background subtraction methods with XPS spectra. This is especially true in cases where peak fitting is to be done and where subtle changes in peak parameters, especially peak position or FWHM, are important to resolve.

A constant or linear background removes a straight line from under a spectrum, typically bringing the lowest value(s) in the spectrum to a value of zero. The constant background removes a constant offset throughout the spectrum. The higher-BE side of a primary photoemission peak will generally have a greater intensity due to inelastically scattered electrons and potentially to satellite peaks. A linear background rather than a constant one would therefore appear to be a better choice in most cases. This is the case for both spectra in Figure 6. The intensities on the left and right sides of the peaks in Figure 7 are nearly equal, so a constant offset could be removed. In both of these cases though, better choices for background shapes exist. In practice, a constant or linear background should only be applied as an approximation when the background intensity on the left and right sides of the photoemission features under consideration are nearly identical or have identical slopes.

A widely applied background shape with some degree of theoretical support is the integrated or Shirley background (Shirley, 1972). It is based on the principle that background intensity I_i^b (BE) at a given BE is proportional to the total intensity of photoelectrons at higher E_B. This is similar to the nature of the inelastic scattering process that leads to a significant portion of the background in XPS. The intensity of scattered (background) electrons increases at lower KE (higher BE) away from a photoemission peak in proportion to the intensity of photoelectrons at higher E_K (lower E_B). The Shirley background is derived analytically from a formulation similar to

$$I_i^b(\mathrm{KE}) = C\int_{\mathrm{KE}}^{\infty}(I_i^m(E) - I_i^b(E))dE \qquad (24)$$

The integration is best represented in KE space, since higher E_K electrons contribute to the background at a given KE. The value C is essentially a normalization constant to bring the background into alignment at the endpoints. This function can be readily coded into XPS analysis software and is therefore routinely available with the instrument or as part of off-line data analysis software. The above equation must be solved iteratively using numerical integration, and has no user-defined parameters other than the start and end ranges of the background. Some older XPS instruments may only use a simpler single-pass numerical integration for increased processing speed.

Disagreements exist about the accuracy of the Shirley background routine. It has been shown to distort peak parameters (peak positions) in certain critical cases. In the experience of the author, the potential errors introduced by the use of the iterative Shirley background versus a supposedly more accurate background shape are usually well within the systematic errors of determining peak parameters for most routine XPS experiments. Only when a high degree of accuracy is essential during peak fitting should the user generally have to consider other (more accurate) background shapes.

The Shirley background is only appropriate for fitting as a baseline to high-resolution peaks. The algorithm does not normally converge well over the wide BE range of a survey scan. Application of the Shirley background also leads to problems in cases where the signal intensity increases or decreases dramatically on either side of a photoemission peak. This happens when a photoemission peak of interest sits as a shoulder on a sloping background from a significantly larger peak. The resulting complex background shape is a convolution of the overlapping peak intensity and the normal (inelastic) background. Off-line processing routines exist to handle such complex background shapes. Whenever possible, data acquisition should encompass a full range of all overlapping peaks to avoid this problem.

The Tougaard background shape for XPS has the strongest basis in theory (Tougaard, 1988). It is derived on first-principles consideration of the intensity of inelastically scattered electrons as a function of decreasing KE away from the E_K of the primary photoelectron. The resultant analytical expression in its general form is an integral over peak intensity that has two materials dependent fitting parameters, B and C.

$$I_i^o(\mathrm{KE}) \approx C\int_{\mathrm{KE}}^{\infty}\frac{E-\mathrm{KE}}{\left[B+(E-\mathrm{KE})^2\right]^2}I_i^m(E)dE \qquad (25)$$

The fitting parameters relate to the nature of the inelastic scattering in the material of concern and are usually left to be determined by measurements with techniques

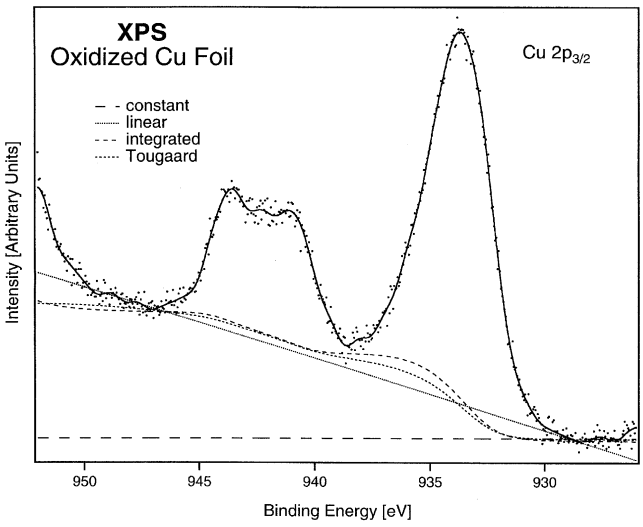

Figure 12. Examples of constant, linear, and integrated (Shirley) types of background shapes fit to a Cu $2p_{3/2}$ peak and the companion satellite for CuO.

such as EELS (see SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING). Since this degree of rigor is beyond the scope of interest for typical XPS users, the Tougaard background is usually used with predefined "universal" values of fitting parameters, in particular $B \approx 1643$ eV^2. The value of C is primarily a normalization constant to fit the background at the ends of the spectrum under consideration. The resulting background shape is similar to the Shirley background.

Examples of a constant, linear, iterative integrated (Shirley), and Tougaard backgrounds applied to the CuO peak shown earlier are given in Figure 12. This figure clearly shows the potential for error that can arise when a proper background is not used prior to further processing of a spectrum. The constant background is inappropriate for determination of peak area. Compare the linear, integrated, and Tougaard backgrounds. The resulting integrated area under the entire Cu $2p_{3/2}$ peak may be different in the three cases; however the extent of the differences is likely to be within the reproducibility of the measurements.

Peak Integration and Fitting. Once a suitable background is removed, A_{pi} can be found by numerical integration. The units of A_{pi} are typically counts-eV/sec. This is directly proportional to measured intensity $I_{\mathrm{i}}^{\mathrm{m}}$ in the corresponding equations above (see Practical Aspects of the Method). The additional factor of eV cancels in the calculation of concentration or concentration ratio.

Broad peaks may be deconvolved into (fitted by) more than one component peak to help resolve overlapping peaks. The spectrum in Figure 7 shows resolution of the broad photoemission feature into three component peaks. The following guidelines apply when doing peak fitting: (1) peak fitting should always be done after removing an appropriate background; (2) the shape of the component peak matters; (3) the initial conditions used to start the peak fit should be best approximations to the expected chemistry of the sample; and (4) peak parameters should be appropriately constrained during the fitting process.

With regard to background subtraction, many peak-fitting algorithms in use today for analysis of XPS spectra do not include the capability to automatically fit an appropriate background while optimizing fit parameters for component peaks. In such cases, the appropriate background must be carefully chosen and removed beforehand to obtain consistent, accurate results from peak fitting. Note in Figure 12 that differences are to be expected in the final results for peak fitting when different backgrounds are used, because the initial peak shapes will be different. In particular, small peaks that are shoulders on larger peaks can be accentuated or lost merely by shifting the position or changing the shape of the background that is removed. Calibration of the combined baseline subtraction and peak-fitting methodologies with samples of known chemistry and composition is recommended. Examples where simultaneous fitting of baselines and peaks was done specifically to obtain detailed information about sample chemistry have been reported (Castle et al., 1990; Castle et al., 2000; Salvi et al., 2001).

A large number of peak shapes can be used to fit to a feature in an XPS spectrum. All peak shapes have at least three parameters: peak height, peak FWHM (or half-width), and peak position. Peak half-width is half of the FWHM value. Additional parameters are used to mix fractional amounts of the different peak shapes and to define such factors as asymmetry or tail height and extent. The doublet is a peak shape that is particular to XPS spectra. It is used to fit to the multiplet split p, d, or f peaks, and it is essentially defined as two peaks separated by a certain distance.

The Appendix provides further information about peak shapes commonly used to fit XPS spectra. This information should clarify how the parameters are used to define the peak shape. In confronting the wide range of peak shapes, the first-time XPS user is cautioned to proceed conservatively. The Gaussian and Gaussian-Lorentzian mixed peak shapes (and their doublets) provide adequate representation of XPS peak shapes for almost all routine analysis work. The peak shapes with greater degrees of freedom should be used only with a clear understanding of the physical significance behind their application. In other words, do not choose a peak shape with more free parameters than can be reasonably justified within the confines of the chemistry and physics of the system with the goal of covering all potential contingencies. Rather, expand the degrees of freedom (number of peak-fit parameters) from a minimum to a larger set when no other options appear adequate to cover the case being examined.

During peak fitting, any or all of the parameters that define a specific component peak are allowed to vary until an optimal resultant peak shape, compared to the input raw spectrum, is obtained. The computational methods involved in optimizing the parameters are beyond the scope of this unit. Suffice it to say that local and global optima exist in the space of the fit parameters. Therefore, do not use more peaks than absolutely justified, and always start with peak parameters that provide the best representation of the chemistry as known from the sample. Starting

with too many peaks or with parameters that are too far from the expected values could lead to an end result that is far removed from physical reality. This problem can be avoided in almost all cases in a straightforward manner. At the start, use a minimum number of peaks and peak parameters in order to obtain a resultant "fit" spectrum that represents the raw data well at the outset. This may require iterative, manual adjustments of the initial peak parameters. With practice, this step will become a matter of good practice during peak fitting.

In correspondence with setting the initial peak parameters correctly, allowing too many parameters to vary during the optimization can lead the optimization routine astray. The fitting may fall into an unrealistic local minimum or, in some cases, fail to converge properly. Most peak-fitting routines allow the user to constrain the peak parameters either to stay within certain bounds or to stay constant during peak fitting. As the number of potential peak-fitting parameters increases, the number of parameters that are constrained should also increase.

In conclusion, with regard to peak fitting to XPS spectra, let the expected chemistry of the material be the guide in defining and accepting the peak parameters, instead of letting the fitting results determine the chemistry. Further information about the steps involved during peak fitting of XPS spectra is available in a flowchart and comparative study (Crist, 1998). In addition, reports of methods that have been used to validate algorithms for peak fitting to XPS spectra (Seah and Brown, 1998) should be consulted when user-defined routines are developed or used. Finally, as a way to define the level of confidence in the methods being used during peak fitting, standardized XPS test data have been developed for peak fitting (Conny and Powell, 2000).

Peak Position and Half-Width. The remaining peak parameters, BE_i and Δw_i, are determined by the position of the peak maximum and the width at half maximum height, respectively. Unlike peak area, they can routinely be determined by eye from XPS spectra. Be careful in such cases. A common mistake made in setting the positions of components in an overlapping feature by eye is to set the peak positions too close together. Underlying component peaks, when properly resolved using peak fitting, will end up being further apart than the result obtained "by hand." This is especially true in cases where one or more of the peaks is a shoulder on a larger peak. Consider in particular the spectrum in Figure 7. Look carefully at where the component peak positions actually are, according to the peak fit components, in comparison to where an otherwise untrained observer might set them "by eye" on the spectrum of the raw data.

In conjunction with the above, before calculating the FWHM of a peak "by hand," remember to consider the peak height after removing a background. This is done by drawing a baseline by hand, typically a sloping, linear background (not just a constant baseline). Someone doing an analysis of an XPS spectrum by hand for the first time is apt to make a common mistake with overlapping peaks by drawing two separate, linear baselines, one under each overlapping peak. While this may be an appropriate method for such techniques as infrared spectroscopy, where the baseline shape can be dramatically curved throughout a narrow spectral range, it is entirely inappropriate in XPS spectra, where the baseline extends smoothly under all peaks associated with the spectral feature. Review again the sloping linear baseline shown in Figure 6 as a reference; the slope is not disjoint at the junction of the two satellite peaks.

Depending on the computuation package used for peak fitting, peak parameters may be selected through autodetection routines. One method to locate a peak is by the position of maxima in a residual spectrum. The residual spectrum is determined as the difference between the original spectrum and the summation envelope of peaks already fit to the original spectrum. The FWHM for the peak in the original data can also be estimated by the peak width at half the height of the residual spectrum peak. Another method is by scanning derivatives of a spectrum for minima and zero crossings. Assymetries in the shapes of the derivatives can help determine whether closely overlapping peaks exist in a spectrum that otherwise appears to be a single peak. Numerical differentiation is inherently a smoothing process that requires good S/N in the original spectrum to avoid distoration of the derivatives (smoothing) or loss of signal (increase in noise). Either method may have difficulties resolving peaks that closely overlap. New methods that involve wavelet transformation may also prove useful in autodetection of peaks in a spectrum (Ehrentreich et al., 1998) and for improving the fitting process (Zhang et al., 2000).

Principal Component Analysis. Principal component analysis (PCA) is a strong multivariate statistical data analysis tool applied to a variety of fields from science to engineering (Rummel, 1990). It is a potent technique in the arsenal of chemometrics (Malinowski and Howery, 1980) and surface spectroscopies (Solomon, 1987). It has been applied to resolve problems in XPS (Sastry, 1997; Artyushkova and Fulghum, 2001; Richie et al., 2001; Gilbert et al., 1982; Simmons et al., 1999; Balcerowska and Siuda, 1999; Clumpson, 1997; Holgado et al., 2000) and the related surface spectroscopic technique AES (Balcerowska et al., 1999; Passeggi, 1998). Applications of PCA to XPS include reduction of noise (Sastry, 1997), resolution (deconvolution) of overlapped spectra (Gilbert et al., 1982), resolution of XPS spectra into surface and bulk components (Simmons et al., 1999), subtraction of inelastic background signals (Balcerowska and Siuda, 1999), and detection of principal components (Clumpson, 1997; Holgado et al., 2000).

In mathematical terminology, PCA transforms the space of data from a set of possibly correlated variables into a smaller number of uncorrelated variables. This is expressed simply in matrix format as

$$|S| + |W|\Lambda|P| \tag{26}$$

where $|S|$ is data (as a matrix), $|\Lambda|$ is a weightings matrix, $|L|$ is an eigenvalue matrix, and $|P|$ is the matrix of principal components. The eigenvalue matrix is a square diagonal matrix that is obtained from the data through singular

value decomposition, the principal component matrix has the same dimensions as the data matrix, and the weightings determine how each principal component (scaled by its eigenvalue) is factored to obtain each part of the data. The eigenvalues λ_i in $|\Lambda|$ are arranged in order from largest to smallest across the diagonal. This means, components in $|P|$ are arranged in order from most to least significant in contributing to $|S|$. The statistical significance of each component in $|P|$ can also be determined through indicator functions.

In terms of spectroscopy, PCA transforms a set of spectra from a system into a set of independent, representative spectra for the system (the principal spectra). The principal spectra can serve to regenerate all of the features in any of the original spectra. The data matrix $|S|$ contains the experimental spectra (m spectra of n data points each), all from the same region (BE range in XPS). The principal component matrix $|P|$ contains spectra (m spectra of n data points each) in order starting from one that contributes the most to $|S|$. Peaks that appear consistently throughout spectra in $|S|$ will appear in the first principal spectrum in $|P|$. The least significant principal spectrum in $|P|$ generally will only be noise because the magnitude of noise contributes stochastically throughout all spectra in $|S|$.

The utility of PCA in XPS is primarily to decompose high-resolution spectra. Recall that high-resolution spectra are typically taken to determine oxidation or hybridation states of an element, and the desired information is traditionally obtained using peak fitting. Principal component analysis can be considered to have three advantages over peak fitting. Peak fitting often requires that certain parameters of component peaks be well-defined and constrained to obtain realistic results, whereas PCA requires no *a priori* or constrained information about the principal spectra. Peak fitting typically requires subjective input from the user during the analysis, whereas PCA is entirely objective in its analysis. Finally, peak fitting requires significantly more time to analyze one spectrum than PCA takes to return results from a set of spectra. To its disadvantage for applications in XPS, PCA does not return results that can be directly and unambiguously related to specific information about the chemistry of the system. For example, PCA often returns principal spectra that show negative going peaks and therefore would otherwise appear to be entirely unrealistic.

The number of spectra m provided in $|S|$ is important in order to be able to perform proper PCA. It should be significantly (from a statistical sense) larger than the number of significant principal spectra expected in $|P|$. If m is too small, then all spectra in $|P|$ will appear to be equally significant in contributing to $|S|$. As a guide, m should usually be at least a factor of three or more times larger than the number of significant spectra expected from $|P|$. For XPS, the number of significant spectra expected from $|P|$ can be taken as the number of component peaks that will otherwise be fit to a spectrum in $|S|$ with peak fitting. For peak fitting, the minimum value of m is the number of samples with different types of chemistry. To increase this minimum m to a more reliable value for PCA, spectra can be acquired from different samples of the same type, from different regions of the same sample, or even from different orientations (analyzer acceptance angles) of the same region on a sample.

In summary, peak fitting and PCA are complementary and supplementary tools to analyze XPS spectra. Peak fitting requires subjectivity and time to analyze the data (fit peaks to a spectrum), whereas PCA requires subjectivity to interpret the results (determine the physical significance of the principal spectra) and time to obtain the data. The results from PCA are obtained objectively and can guide the otherwise subjective analysis done with peak fitting. For peak fitting results to be statistical reliable, the number of component peaks fit to any spectrum in $|S|$ cannot exceed the number of significant principal spectra determined by PCA to be in $|P|$. In XPS, when more component peaks are used to peak fit than can be supported by PCA, the chemistry of the samples has been unjustifiably represented. Alternatively, when fewer components are used to peak fit than number of significant components found by PCA, certain chemical states of the element being considered have been neglected.

Appearance. When signal quality is poor, as can be the case in spectra from elements at low concentrations, improving the appearance of an XPS spectrum is sometimes considered an important part of data analysis and interpretation. Methods that increase the signal-to-noise ratio, S/N, are applied with the goal of enhancing the results. The use of signal smoothing procedures to improve the precision of quantitative results, particularly elemental compositions as well peak positions and half-widths, must be approached with care. While signal smoothing can be a useful tool, over-reliance on smoothing is a mistake.

The first concern in data acquisition should be to obtain a spectrum with sufficient S/N to obtain reliable quantitative information. The S/N ratio is, in practical terms, the height of a photoemission peak after subtracting a background divided by the root mean square of the intensity of the random noise at a location somewhere near the photoemission peak. The random noise is a stochastic process proportional to a deviation about a mean signal. Increasing the acquisition time in a data channel proportionally decreases the variance of a signal about the mean. Noise therefore increases as the square root of acquisition time. Signal increases proportionally with acquisition time. Therefore S/N increases as the square root of total acquisition time. The formulations provided in the previous section can be used to determine the corresponding relationships to scan, sweep, and dwell time as well as number of scans or sweeps. The value of S/N increases as the square root of any one of these when all others are held constant. In practice, S/N ratios of $\sim$2 to 3 are necessary lower bounds for determining peak parameters. Spectra with such low values of S/N are generally not suitable, however, to determine peak parameters reliably. A more reasonable S/N is above $\sim$10. The raw data in Figure 7 has a value of S/N value of $\sim$75 to 80, while that for CuO in Figure 6 has a value of $\sim$20 to 25. To obtain a comparable value of S/N for these two spectra, we would have to acquire the latter spectrum (Figure 6) for a 16- to 25-fold longer acquisition time.

Smoothing routines are used when data acquisition has failed to obtain sufficient *S*/*N*. Smoothing algorithms are, however, not without their problems. Those that depend on *n*-point averaging methods are notorious for changing peak parameters. Although this change may be below the level of uncertainty in measuring the peak parameters, a change will occur. The FWHM of a peak will be affected in all cases. For overlapping peaks, peak positions will shift, and asymmetrical peaks will change shape. A theoretically more rigorous smoothing algorithm is performed in the time (Fourier) domain using appropriately defined Fourier filter functions. This has been shown to distort peak shapes less. Finally, the advent of algorithms to perform noise reduction in chemical spectroscopy using PCA (Sastry, 1997) or wavelet analysis (Jetter et al., 2000; Shunsuke, 2000; Harrington, 1998) may offer a choice of a better post-processing method to improve the S/N in XPS spectra without distorting peak parameters.

Smoothing is to be avoided in cases where rigorous and exacting quantitative analysis of XPS spectra is desired. Nothing substitutes in this case for acquiring more data to increase *S*/*N* in the raw spectrum. Peak fitting is also best done to raw (noisy) data. To a first order, the optimization algorithms essentially "do not care" about the level of random noise in a spectrum. Smoothing of noisy spectra is appropriate to provide the viewer with a guide to follow the otherwise noisy signal. This is what has been done in Figure 6. The author strongly recommends that, when smoothing is used as an integral method of the data analysis and interpretation, both smoothed and raw (noisy) spectra always be shown simultaneously in the published XPS spectra.

One primary objective of high-resolution analysis with XPS is to obtain spectra that are not distorted by line shape broading due to the x-ray source or analyzer. On systems without a monochromator, computer software methods exist to deconvolve the line shape of the x-ray source. They depend traditionally on iterative routines or operate in the Fourier domain (Jansson, 1984). They all require accurate representations of the line shapes of the x-ray source, as published elsewhere (Krause and Ferreira, 1975). They are not without their problems. Spectra with low S/N or with inadvertent "spikes" will not deconvolve well. Methods to deconvolve x-ray lineshapes are falling out of favor, especially as monochromatic x-ray sources become more popular. Alternative (neither Fourier or iterative) deconvolution techniques however are being used successfully to improve peak resolution. They include the maximum entropy method (Pia and McIntyre, 2001; Pia and McIntyre, 1999; Pratt et al., 1998; Splinter and McIntyre, 1998; Schnydera et al., 2001) and PCA (Gilbert et al., 1982; Simmons et al., 1999). These methods appear to avoid some of the problems with the traditional Fourier or interative deconvolution methods and can be used to remove broadening effects from the analyzer.

Finally, some older XPS systems without a monochromator offer a software option to remove x-ray satellite lines. While this can be useful in survey scans, it has little utility in high-resolution scans. The scan range can be set to avoid the x-ray satellite. If an x-ray satellite interferes with a principal photoemission peak and accurate quantitative analysis is desired, the better option is to use an XPS system with a monochromatic x-ray source.

Interpretation

The results obtained from XPS are a list of the elements present, the compositions, and the positions and halfwidths of their associated peaks. How this information is to be interpreted is an important aspect of the proper use of XPS. The first section below deals with interpretation of the compositions from XPS. This is followed by a discussion about defining chemical states.

Compositions. As pointed out in the section on practical aspects of the technique, compositions determined by XPS are to be interpreted as arising from homogeneous samples. This leads to problems when the sample composition is not uniform. In particular, most samples analyzed immediately after insertion into the vacuum system will contain a layer of carbonaceous material, adsorbed water, and oxides depending on the type of material. The contaminant layer can be a few monolayers thick in some cases. This approaches the mean free path of most low KE electrons. Attenuation of peak intensities from the underlying material is therefore to be expected. The consequence of this is that atomic concentrations will have relative uncertainties approaching ±10% or more in most practical cases.

Consider a rather simple example. A monolayer of (graphitic) carbon on an iron surface will have thickness of ~0.1 nm. The prominent Fe 2*p* line appears at ~706 eV in BE. For Mg Kα radiation, this corresponds to ~550 eV in KE, for a mean free path of ~1 nm. The intensity of electrons from in the Fe 2*p* peak will be attenuated by a monolayer of carbon to ~91% at 90° take-off angle, 87% at 45°, and 56% at 10°. Based on Equation 15 and assuming sensitivity factors do not change, the same sample of otherwise pure Fe with only a uniform monolayer of carbon on its surface would therefore appear to have compositions of 9%, 13%, and 44% carbon at the respective take-off angles.

Most contaminant layers are thicker than a monolayer. Doubling the thickness of the layer nearly doubles the respective carbon compositions. For this reason, unexpectedly high values of atomic concentrations for carbon and oxygen on samples just inserted into the vacuum system are not unusual. Values as high as 50% to 60% carbon due to a contaminant overlayer are not uncommon, even on supposedly well cleaned surfaces. Metals (other than Au) will also always be covered by an oxide layer. Methods that can be used to reduce this contaminant overlayer are discussed in the section on sample preparation.

The C 1*s* peak appears at ~284 to 286 eV in BE. All photoemission peaks at higher BE than the C 1*s* line will likely have lower mean free paths. The concentrations of the corresponding elements will therefore be attenuated relative to carbon. The peak intensities for those elements below the C 1*s* peak in BE will be attenuated less.

An important objective of XPS analysis for sample composition should also be to estimate the uncertainties in composition values. A thorough guide to uncertainty analysis of data can be found elsewhere (Taylor, 1997).

Uncertainties in atomic concentrations determined from XPS generally contain two contributions, random (statistical) uncertainties and measurement errors. Statistical uncertainties are reduced by repeating the measurements multiple times. Certainly, more than one sample should be analyzed to obtain valid concentrations for the sample. A general guide in numerical data analysis is that at least ten measurements of a value are needed to begin to have a sample size that statistically approaches the behavior of a true representative set for the system. Small-sample statistics must otherwise be applied. In this regard, methods to report on the confidence level for values and to propagate uncertainties in values through calculations should be followed. For any composition value reported, one should, at the minimum, always report an average, the calculated standard deviation, and the number of samples used to obtain the value.

The extent of uncertainty in composition that arises due to measurement errors in an XPS spectrum is considered below for illustration. First, assume an ideal sample, where the composition is homogeneous throughout. For any one given measurement made to determine concentration with XPS, the relative uncertainty in absolute concentration scales in proportion to the relative uncertainty in measuring the peak area and the sensitivity factor. The peak area A_i and element sensitivity factor S_i enter in the calculation of atomic composition x_i (atom or mole percent) as a ratio $K_i = A_i/S_i$. The errors in measuring peak areas and element sensitivity factors may be correlated because they are measured using the same devices in both cases. For such situations, an upper boundary on the relative uncertainty in composition due to measure errors can be established as

$$\frac{\Delta x_i}{x_i} \leq \frac{\Delta K_i}{K_i} + \frac{\sqrt{\Sigma \Delta K_j^2}}{x_i K_i} \tag{27}$$

where $\Delta K_i^2 = K_i^2[(\Delta A_i/A_i)^2 + (\Delta S_i/S_i)]^2$. Note that the terms in the above equation would be added in quadrature if the measurement errors for area and for sensitivity factor respectively were uncorrelated from all other values in their sets. The above formulation is still valid to establish a conservative upper boundary for the influence of measurement errors on composition. Relative errors in S_i values can be as much as $\pm 10\%$, especially when the instrument has not been calibrated. The greater the number of elements considered, the greater the summation over all values of relative uncertainty in sensitivity factor will become. Therefore, the relative uncertainty in any one composition will increase as more components are considered. Relative errors in peak areas depend on how the measurement was made (by hand or by computer, for example) and on the choice of background. They can be reduced by making sure that the absolute peak area, A_i, is as large as possible. The effects of excessive noise on a spectrum complicate matters and will generally act to increase the value of $\Delta A_i/ = A_i$.

With an assumption that sensitivity factors are accurate, $(\Delta S_i/S_i = 0)$, $\Delta K_i/K_i = \Delta A_i/A_i$, and assuming all peaks areas are measured to the same degree of relative uncertainty, $f_a = \Delta A/A$, and recalling for any two elements that $K_A/K_B = x_A/x_B$, the above equation can be recast to

$$\frac{\Delta x_i}{x_i} \leq f_a \left[1 + \frac{\sqrt{\Sigma x_j^2}}{x_i^2}\right] \tag{28}$$

This shows that, all else being equal, components with the lowest composition x_i will have the largest relative uncertainty in their composition $\Delta x_i/x_i$. It also shows that, as more components are incorporated in a calculation of composition, the relative uncertainty in the absolute composition of any one component $\Delta x_i/x_i$ increases. The above equation also can be applied for the case where peak areas are measured with infinite accuracy and only sensitivity factors have measurement errors, in which case f_a is the relative error in sensitivity factor. Relative uncertainties in concentration ratios for any two components A and B are expressed as

$$R_{\mathrm{AB}} = \left(\frac{x_{\mathrm{A}}}{x_{\mathrm{B}}}\right) \leq \frac{\Delta K_{\mathrm{A}}}{K_{\mathrm{A}}} + \frac{\Delta K_{\mathrm{B}}}{K_{\mathrm{B}}} \tag{29}$$

When either sensitivity factors or peak areas are considered infinitely accurate, this expression becomes

$$R_{\mathrm{AB}} \leq f_{\mathrm{a,A}} + f_{\mathrm{a,B}} \tag{30}$$

where $f_{a,i}$ is the relative error in determining the peak area or sensitivity factor for component i. An important point of this equation is that, to a first approximation, uncertainties in the ratios of component compositions are not affected by the number of components being considered or the absolute compositions of the components. For this reason, composition ratios from XPS can be considered more significant (less uncertain) than absolute concentrations.

Order of magnitude numerical calculations can serve to illustrate the above formulations. First consider how increasing the number of components in a system increases the relative uncertainty in the composition of each component. When either sensitivity factors or areas are considered accurate, for systems with n components of equal composition (ideal stoichiometric compounds), the relative uncertainty on any one composition becomes $f_a(1 + n\sqrt{n})$, where f_a is the relative uncertainty in either sensitivity factor or peak area. The multiplier to f_a is 3.8, 6, 9, and 12 for systems of two to five components of equal composition, respectively. Specifically, for a 1:1 stoichiometric binary material such as CuO or NaCl, when the relative error in measuring peak areas or elemental sensitivity factors is 5% ($f_a = 0.05$), the relative uncertainty in measuring the composition of either component will be $\pm 19\%$. Therefore, the composition for either component in such a binary could only be measured to an accuracy $x = 0.50 \pm 0.10$ (atom fraction) using XPS. For this case, XPS measurements of compositions between 40 atomic percent and 60 atomic percent could not be distinguished

as statistically different. By further example, for a five-component material of equal compositions measured with a 5% relative error on peak areas or sensitivity factors, the absolute composition of any one component could only be measured to a precision of 0.20 ± 0.12 atomic percent. Incorporation of the errors for both area and sensitivity factors in the above formulation only serves to increase the overall inaccuracy in measuring the true value of composition. These examples illustrate clearly why absolute atomic concentrations reported from XPS should typically be considered to have a relative uncertainty (imprecision) of at least $\pm 10\%$ due to measurement errors. Calibration or otherwise clear validation of the sensitivity factors for the spectrometer being used and affirmation of stringent care in measuring peak areas should typically be sought before accepting reports of atomic concentrations with relative uncertainties lower than $\pm 10\%$.

A corresponding example for the concentration ratio R_{AB} can be developed. When either peak areas or sensitivity factors are accurate, the relative error in any value of R_{AB} is the sum of relative errors in the individual terms. For the above systems of two to five components, in cases where $f_a = 0.05$ for all components, the value of R_{AB} will be 0.10, or 10%. For the binary CuO, the ratio of copper to oxygen can be measured at best to an accuracy of 1.0 ± 0.1. For a five-component system of equal compositions throughout, the ratio of any two compositions can be measured at best to an accuracy of 1.0 ± 0.1. The relative error in measuring a concentration ratio does not depend on the number of components included in the analysis. This illustration can serve to help save analysis time. Suppose that changes in concentrations of only two components are of overriding importance in the analysis of a multicomponent system. Only XPS spectra from those two components will need to be obtained. Although absolute concentrations will not be possible to determine, the ratio of concentrations will be a reliable indicator of the behavior of the system.

Chemical State Information. In regard to elemental and chemical state identification, reference spectra have been published. One standard for reference spectra from elements are the handbook from Perkin-Elmer Corporation (Moulder et al., 1995). A reference book has also recently been made available on polymers (Kratos Analytical, 1997). Further reference libraries of XPS spectra are available from commercial vendors such as XPS International (*http://www.xpsdata.com/*); the journal *Surface Science Spectra* publishes experimental XPS spectra taken under well-defined conditions (sample type and treatment and instrument parameters) as references for other researchers.

Unambiguous interpretation of shifts and broadening of primary photoemission peaks in XPS spectra should be based on systematic elimination of the various factors that contribute to these effects. The first factor to consider and eliminate is the potential for sample charging. This artifact has been mentioned already and will be discussed in detail in the section on problems with the technique. The following discussion is based on the assumption that sample charging does not occur or that peak shifting or broadening effects due to sample charging have been eliminated or, more likely, appropriately accounted for. Consideration is based first on comparison of XPS spectra from a "bulk" material for a before and after situation—before a treatment and after the treatment. Overlayers are considered separately. Comparison of XPS spectra from one experimental system to another, in order to find similarities in the chemistry of the materials, is then considered.

For the same instrument conditions, relatively small amounts of peak broadening without a commensurate peak shift or appearance of a new peak is indicative of a movement toward greater heterogeneity in the sample chemistry or structure. The effects may go hand in hand. A change in structure may also be associated with subtle changes in the type of bonding between constituent elements in the material. These effects are often only worth pursuing in detail for samples with otherwise well defined chemistry and structure.

Peak broadening to such an extent that a new peak appears in close conjunction with the initial peak usually indicates a change in the chemistry in a portion of the material. The new peak may overlap with the initial peak so that peak fitting is required to resolve it. As long as some indication of the initial peak is present, assignment of the new peak to chemical state effects can usually be done with confidence. Note that changes in structure without changes in chemistry of a bulk material can also give rise to a new peak. Such changes are not as prevalent in materials.

When a peak shifts or significantly changes shape such that the initial peak disappears, the chemistry or structure (or both chemistry and structure) of a bulk material has changed. In some cases, these factors cannot be separated. Reference XPS spectra should be consulted. The changes may be obvious, as shown in the comparison of the Cu 2*p* peaks in Figure 6. In cases where reference spectra are not available, the chemistry and structure of the material are best probed with other techniques that provide supplemental information (e.g., x-ray diffraction for structure).

Thin film overlayers have unique properties that make interpretation of changes in their XPS spectra more difficult. Oxide layers on metals and other comparable insulator-like overlayers are prone to charging, especially as their thickness increases. Molecular overlayers on surfaces can show peak shifts due to changes in the degree of extra-atomic relaxation in the layer, and changes in the shapes of satellite peaks are often associated with changes in chemistry. Angle-resolved XPS is one method that can be used to accentuate "bulk" versus near surface behavior. Where possible, thin film adsorbates should also be analyzed with techniques such as attenuated total reflectance Fourier transform infrared (ATR-IR) spectroscopy, glancing angle FTIR, EELS, AES (AUGER ELECTRON SPECTROSCOPY), surface Raman (RAMAN SPECTROSCOPY OF SOLIDS), or thin film x-ray diffraction (XRD; X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ALALYSIS) to confirm proposed changes in chemistry or structure.

In conclusion, analysis of chemical state information using XPS is rarely without ambiguities in complex

Table 2. Peak Areas, Element Sensitivity Factors, and Atomic Compositions from Analysis of Si Wafer Using XPS

Orbital	Peak Area (Counts-eV/sec)	Sensitivity Factor	Atomic Concentration (Atomic %)
O 1*s*	94960	0.711	42
C 1*s*	11964	0.296	13
Si 2*p*	48366	0.339	45

systems. The technique should not be viewed as a definitive one. Analysis of the material with as many techniques as appropriate to the system at hand, and comparison to published reference spectra or spectra from similar materials, is often highly recommended.

Example. The example presented here concerns analysis of an Si wafer for composition, chemical state information, and oxide film thickness. A survey scan, obtained with a PHI 5400 system using Mg radiation at 15 kV and 325 W at a take-off angle of 45° and pass energy of 89.5 eV, is shown in Figure 4. The main photoemission peaks and Auger KVV transitions are labeled. Plasmon loss peaks predominate for both the O 1*s* and Si peaks. The x-ray satellite peaks are also visible for these lines. Peak areas, sensitivity factors, and compositions determined from the survey scan are given in Table 2.

High-resolution scans of the Si 2*p* peak taken with a pass energy of 8.95 eV at three different take-off angles are shown in Figure 13. Two distinct states of Si are apparent. The peak at higher BE is from SiO_2, and the lower BE state is from Si. The SiO_2 peak is from the oxide layer on top of the wafer. The relative intensities of the two peaks change as a function of take-off angle. At glancing angle ($\Theta = 10°$), the peak from SiO_2 predominates because analysis is more surface sensitive. The asymmetry in the Si peak for the Si state, clearly visible at 45° and 90° take-off angles, is due to the close overlap of the Si $2p_{3/2}$ and $2p_{1/2}$ peaks.

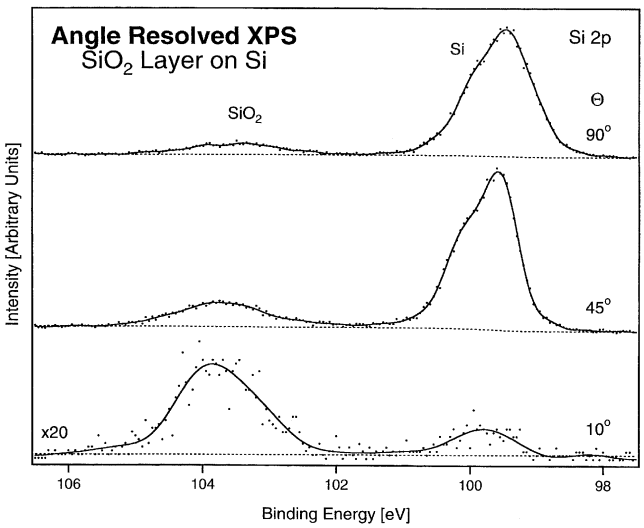

Figure 13. High-resolution scans of the Si 2*p* peak from a Si wafer at three different take-off angles. The oxide and neutral states of Si are clearly visible.

The areas under the two peaks were determined at each take-off angle by numerical integration (trapeziod rule) with computer software. The ratios of the SiO_2/Si peak areas were 4.71 (10°), 0.248 (45°), and 0.125 (90°). This data can be used in Equation 22 to determine the thickness of the oxide film. In this case, the cross-sections and mean free paths for the overlayer and substrate peaks can be taken to be the same since they are both the same orbital. Because an HSA was used for analysis, the ratio of étendue values is an inverse ratio of the KE of the peaks, which in this case is

$$\frac{G_o}{G_s} = \frac{E_{Ks}}{E_{Ko}} \approx \frac{(1253.6 - 99.4)}{(1253.6 - 103.4)} \approx 1.0 \tag{31}$$

Equation 22 therefore reduces to

$$\frac{I_o^m}{I_s^m} \approx \frac{(1 - \exp(-d/\lambda\sin\theta))}{\exp(-d/\lambda\sin\theta)} \left(\frac{C_o}{C_o}\right) \tag{32}$$

This can be rewritten as

$$\frac{d}{\lambda} = \ln\left[\frac{(A_o/A_s)}{(C_o/C_s)} + 1\right]\sin\theta \tag{33}$$

We can estimate the ratio of atomic concentrations for Si in the oxide layer and the underlying substrate to a first approximation. This can be done by using the densities and atomic concentrations in the layers

$$C_o/C_s = (x_{si}\rho_o M_s/\rho_s M_o) \tag{34}$$

where x_{Si} is the mole fraction of Si in the oxide (0.33 for SiO_2), ρ_i is the mass density of i, and M_i is the molar mass. If the mass densities of Si and SiO_2 are taken to be equal, the value of C_o/C_s is ~0.16. Using the area ratios from above, the ratio of film thickness to mean free path is determined to be 0.59 (10°), 0.66 (45°), and 0.58 (90°). The average ratio is 0.61 ± 0.04. Escape depths for the Si 2*p* peak are ~2.0 to 3.0 nm. Using an average of 2.5 nm, the oxide film thickness is found to be 1.5 ± 0.2 nm.

Before reviewing a more rigorous approach to analysis of the above ARXPS data, we can consider where mistakes are typically made in the above simple analysis. The first common mistake is to proceed without confirming that the ratios of cross-sections, mean free paths, analyzer étendues, and concentrations are unity. In the above calculation, since closely spaced peaks from the same orbital were used, all of the ratios but that for the atomic concentration could be safely approximated as unity. Had the ratio of concentrations also been taken as unity, the film thickness to mean free path ratios would have been determined to be 0.30 (10°), 0.16 (45°), and 0.12 (90°). This would have led to a reported oxide film thickness of 0.5 ± 0.2 nm. The significant difference between this value and the above, due to a failure to account for concentration differences, should be noted. When ARXPS data from two different peaks are used, the other ratios will not

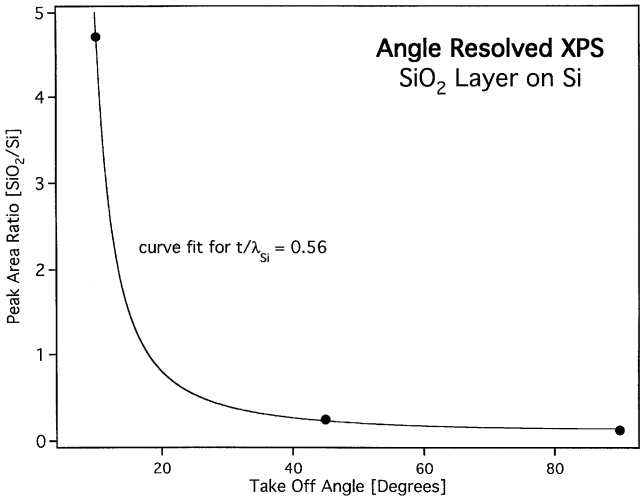

Figure 14. Results from nonlinear curve fitting of the peak area ratios to the equation for angle-resolved XPS. The solid line shows the fit for the given ratio of film thickness to electron mean free path.

necessarily be unity either. A second common mistake is to use ARXPS data from one take-off angle and apply Equation 22 in a significantly reduced form

$$d/\lambda = \ln[(A_o/A_s) + 1] \tag{35}$$

This equation can only be used for data taken at 90° take-off angle under situations where the above mentioned ratios can confidently be set to unity. As seen by the above sample calculations, gross inaccuracies can be expected in all other cases.

A better approach to the determination of film thickness from ARXPS data is to use the full compliment of data for non-linear curve fitting to Equation 22. The ratios of terms can either be determined or left lumped as a single fitting parameter. An example of the results using this method is shown in Figure 14. The three area ratios were fit to Equation 22 using a non-linear χ^2 optimization routine. The ratios of cross-sections, étendues, and concentrations were lumped into a single parameter, the mean free paths from the oxide and substrate were taken to be equal, and the other fitting parameter was the ratio of film thickness to electron mean free path. The results show good agreement with a fit to d/λ of 0.56. The lumped parameter was close to unity. As the figure shows, ARXPS data should be taken near glancing take-off angles for the best sensitivity to film thickness. The data above ~45° contribute far less to the shape of the fitting curve. The confidence in the fitting would be improved by having data at 10° increments from 10° to 90°. Deviations that arise in fitting ARXPS data will also be more apparent at low take-off angles, as discussed in the section on problems with XPS.

SAMPLE PREPARATION

Materials surfaces exposed to atmospheric conditions will contain a layer of contaminants, primarily adsorbed water and hydrocarbons. One objective of sample preparation prior to analysis with XPS could be to remove this layer without affecting the chemistry of the underlying material. For samples with intentionally applied molecular adsorbate layers, treatments that remove the contaminant layer may also remove the adsorbed layer, so that special precautions may be needed. Sample preparation should also focus on obtaining a representative cross-section of the material for analysis. When the extent of spatial variations in composition across a sample are expected to be larger than the analysis area at the sample surface, the recommended practice is to analyze over multiple regions on the sample surface. Finally, the optimal place for preparing a sample is often in the same vacuum chamber as the XPS analysis.

Because of constraints on the sample introduction ports of typical XPS vacuum chambers, samples are usually restricted to be a certain size. Typical sample sizes are ~3 to 5 mm thick and small enough to fit in a circle of 1 to 3 cm diameter (depending on the XPS instrument). Some newer XPS systems have been designed to handle larger size samples, up to 10 to 15 cm diameter (for example, for the Si wafer industry). The geometry of the sample is sometimes also restricted. Flat samples (like a hockey puck) are ideal in all systems. Curved surfaces and crevices present problems because either the x-ray source or the analyzer can be "shadowed" by the sample. Analysis cannot be done on hidden inner surfaces of samples.

Samples must be low out-gassing materials so that the pumps on the XPS chamber can maintain a suitable vacuum during sample analysis. This generally means they should have vapor pressures well below 10^{-8} mbar. Some XPS systems include a cold stage that cools the sample during analysis, potentially to as low as liquid N_2 temperatures. This can be beneficial in reducing the vapor pressure of otherwise high-vapor-pressure materials. Polymer samples are notorious for their outgassing problems. Small samples and thin films are best to use in this case, to minimize the total amount of material that outgasses. Porous materials and powders often present the same problems with extensive outgassing. They can often be analyzed if they have been well outgassed beforehand. This can often be done using a sample-preparation chamber that is attached to the main vacuum chamber containing the XPS instrumentation. In certain cases where ultraclean vacuum conditions in the main XPS analysis chamber are essential (with pressures below 10^{-9} mbar), samples such as polymers and powders that can potentially outgas a great deal are not permitted into the main chamber for XPS analysis. The policies on this vary from laboratory to laboratory.

For bulk-like sample analysis with XPS, the first step in sample preparation is to select a representative sample of the material being considered. Homogeneity of sample composition and structure are important factors. Samples with heterogeneities in composition or structure, such as grains or phase microstructures in metals or phase domains in copolymers, can be analyzed successfully either by analyzing over a larger area relative to the size of the grains or domains or by selectively analyzing over a statistically meaningful number of well-defined smaller

areas across the sample surface. Samples with thin film overlayers should be considered as candidates for sputter profiling or angle-resolved XPS.

Cleaning samples for bulk-like analysis does not typically require a significant effort unless the material is corroded or dirty. Sample surfaces can generally be washed and degreased by standard means using solvents such as water, methanol, or acetone. The solvents should be low in their content of residual contaminants—distilled, deionized water and research grade solvents are recommended. Cleaning the sample with an aqueous detergent wash and distilled water rinse in an ultrasonic cleaner has more recently become a recommended final step. In addition, the use of an ozone-generating UV lamp to reactively remove hydrocarbons is becoming more widely adopted. Polishing is not always necessary; however rough or pitted surfaces tend to entrap contaminants more readily than smooth surfaces. If polishing is done, extra care should be given to making sure to clean the polishing compound from the sample surface.

Prior to XPS analysis for bulk-like information, the thin outermost contaminant layer on a sample can often be removed by reactive ion etching. Sputter cleaning to remove the first few surface layers on a sample is often a routine part of the XPS analysis procedure. Excessively rough or pitted samples will not sputter-clean adequately. Insulator and polymer samples also present problems. These materials generally charge while being sputtered. This can cause uneven sputter rates across the surface. Polymers can also degrade during sputtering.

Preparation of samples with thin-film, adsorbed layers is generally done using well-defined recipes specific to each system. When ultraclean surfaces are a requirement and sputter cleaning is not a viable cleaning method, well-defined sample-preparation methods using ultraclean chemicals can be essential. Even the simple task of rinsing a sample in a beaker of solvent subjects its surface to the potential for further contamination. Under normal conditions, the air-liquid interface of solvents in beakers collects a layer of adsorbed contaminants, and these contaminants can transfer to a sample surface when it is passed through the air-liquid interface. As illustrated above (see Practical Aspects of the Method), even a monolayer of contaminants attenuates the underlying signal intensity, leading to inaccurate results.

Some XPS facilities are equipped with a stage where the sample can be heated while it is in the vacuum. This can be used to desorb chemically adsorbed overlayers. Some XPS systems also have sample-preparation chambers where the samples can be exposed to reactive gases (oxygen). This can be used to react off contaminant layers. Finally, XPS systems can also be equipped with all manner of tools within the vacuum system to cleave, cut, notch, or slice a sample. This is the best method to obtain a pristine surface.

Preparation of powder samples for XPS analysis presents unique problems. In almost all cases, free-standing powders are not put into the main vacuum system for XPS analysis. Should the powders spill, the potential for damage to vacuum components inside the chamber, especially the pumping units, is far too high. Therefore, powders must be mounted securely to a holder in some manner. Common techniques for mounting powders include the use of double-sided tape, mounting wax, and soft metal foils. Double-sided tape is usually of a special quality that is used extensively in vacuum systems because of its low outgassing properties. Powders can also be pressed or sprinkled into thermoset or thermoplastic mounting waxes that are subsequently allowed to cure or harden. Finally, soft metal foils, in particular indium or gold, are often used to mount powders. The powder is pressed firmly into the metal. Typically, only a single layer or two of particles that are uniformly distributed across the sample surface is necessary to get a reasonable signal. In cases where the powder is somewhat self-adherent when compacted, a thicker layer can often be formed on the tape, wax, or metal foil. In all of these cases, the resulting mounted powder sample should be tapped firmly while its surface is in a vertical orientation in order to remove all loosely adhering particles.

Particles may also be mounted as free-standing samples after being tightly compacted into free-standing pellets. The pellets should be stable to the routine stresses involved in handling and mounting. They should not crumble easily. When pellets are used, they can also be mounted in sample holders that have wells to hold the pellet. Finally, powders have also been mounted by compacting them somewhat and then containing them in a specially designed cup-like holder under a wire gauze. This requires the same care to contain loose particles from spilling as all the other methods.

One disadvantage of mounting particles in any form other than pellets is that the mounting material will inevitably appear in the XPS spectrum. Double-sided tape contains carbon, silicon (adhesives), and oxygen. So do most mounting waxes. The indium foil will have an oxide coating. This problem must be handled on a case-by-case basis. Another problem is that powders in any form are notorious for having a carbonaceous overlayer, and sputter cleaning is not usually a viable option. Finally, porous powders can have problems with outgassing, and XPS will not provide a representative analysis of materials within pores due to limitations on electron escape depth.

SPECIMEN MODIFICATION

Under proper conditions, XPS typically does not modify the sample. Polymers are, however, sensitive to photo-induced reactions during XPS analysis. In cases where the photoemission yield or secondary electron background is high, damage to polymers may occur by electron-induced chemical degradation. Photostimulated desorption of gaseous adlayers on surfaces can also occur for all materials. Finally, if electron beam neutralizers are used to reduce sample charging, the electron current can cause the sample to degrade.

PROBLEMS

The most significant problem in XPS analysis is sample charging. As photoelectrons are emitted from the sample,

a continual current (sample current) must flow from ground. Insulating and even semiconducting samples also have measurable capacitance in addition to resistance properties. Oxide layers on metals behave in the same way. This leads to a build-up of charge on these samples, typically on the surface being analyzed. The charge build-up is always positive, leading to a shift of the photoelectrons to lower KE and therefore higher BE. The shift is uniform across the entire XPS spectrum by as much as 2 to 3 eV. Inhomogeneous samples can also have differential charging across the sample surface. This leads to peak broadening, since the extent of charging is not uniform across the sampled areas.

Three methods are available to take care of sample charging. One method draws on experiences in SEM and AES. The sample surface is coated with a thin (sub-monolayer) film of conductive metal, typically Au. This method requires a metal-deposition system that can coat samples. Such systems are commonly found at scanning electron microscopy (SEM) facilities.

A second method is to supply additional electrons to the sample from a secondary source. This is usually done using an electron gun or an electron-emitting filament. The electrons that are supplied are flooded at a very low E_K, below $\sim$50 eV. There are afew problems with this method. First, even at low E_K, electrons are damaging to some classes of materials, particularly polymers and sometimes ceramics. Secondly, the exact amount of electron flood current to supply is dependent on the sample type and surface condition. Trial and error experiments can be required to find the flood current that exactly compensates for the positive charge build-up on a surface. Changing the sample or sample orientation relative to the flood gun will change the current needed. Finally, when sample charging is inhomogeneous, an electron flood gun will not reduce peak broadening. Despite these limitations, electron flood guns are commonly used to correct for sample charging in many XPS systems.

The third method is to post-process the spectrum. Since charging shifts the spectrum uniformly, post-correction requires shifting all of the peaks back (to lower BE values) by a uniform amount. The problem with this method is that a reference is needed to align the peak positions. Without prior knowledge of the exact oxidation states of all principal peaks in the spectrum, the amount of charging correction shift to apply is entirely arbitrary. The most common standard internal reference to compensate for charging is to align the main C 1*s* peak to a value for graphitic carbon, 284.6 eV. Two problems arise with this. First, not all carbon is graphitic in nature. The C 1*s* peak position is particularly sensitive to changes in hybridization state, as seen in Figure 7. This means that the internal reference state may not be correct for the sample at hand. The second problem is that even when graphitic carbon is present, differential charging and the presence of other states of carbon will broaden the C 1*s* peak. If this broadening is asymmetric, the C 1*s* peak position will only be exact if it is determined by rigorous peak fitting procedures.

None of the above methods to correct for sample charging are reliable in all situations. When reporting peak positions from samples that may have charging shifts, one potentially better method of comparing chemical differences from sample to sample is to report relative peak positions. Define one peak that does not change position from sample to sample as an E_B standard for the set of experiments. Report all other E_B values relative to this standard peak. Changes in offsets from the reference peak should be a better indication of any possible changes in chemical state or final state effects. This is comparable to what is done in determining Auger parameters, where photoemission peak positions are calculated relative to respective XAES peaks.

As reported above (see Practical Aspects of the Method), the accuracy of the energy calibration of the XPS instrument should always be confirmed. Three common errors arise: offset, sloping, and nonlinear scaling. Offset errors are typically due to an incorrect setting of the analyzer work function. This will cause all of the peak positions to be off by a constant amount, toward either lower or higher BE. Offset errors are corrected by calibrating the work function of the instrument using the peak position of a well-established standard, typically the Au $4f_{7/2}$ line. Sloping errors typically arise when the electronics for the instrument have linear deviations from their required output voltages. This will cause peaks on one side of the calibration peak to shift to higher BE values and those on the other to shift to lower values, for example. This error is corrected by calibrating the instrument electronics for linearity across a wide BE range using at least two appropriately spaced reference peak positions. Finally, nonlinear scaling errors arise due to nonlinearities in the electronics. They will cause the BE of peaks to fall on a curved rather than straight line in a plot of measured BE versus expected BE.

One caution in operating XPS systems with conventional x-ray sources is to always confirm the integrity of the x-ray source window. The window is a thin metal foil at the end of the x-ray source between the electron filament and the sample. This x-ray window is thin enough to be nearly transparent to x rays, yet opaque to electrons. A typical x-ray window is Al. Small pinholes in the window will allow electrons from the x-ray filament to bombard the sample. This leads to an increase in the overall background of the spectrum without increasing the overall signal. The flood of high-KE electrons can also damage the sample, particularly polymers. The x-ray window evaporates over time and should be replaced as needed.

A second problem with laboratory x-ray sources arises as the anode degrades with time. The active metal coating (Mg or Al) on the anode (which is typically a block of Cu) evaporates with time or will oxidize if high water vapor or oxygen partial pressures are continually present. This problem leads to a significant decrease in S/N and signal relative to background intensity in the XPS spectrum. In systems with dual anodes (Mg/Al being most common), the metals from the two separate anodes can diffuse across the boundary separating them. This will cause the appearance of ghost peaks in survey scans. For example, when a Mg anode becomes contaminated with Al, every photoemission peak in a spectrum taken with the Mg anode will have a "ghost" peak at a value that is 233 eV higher in BE. The relative height of the ghost to the main peak

will depend on the extent of contamination. To check for ghost peaks when using a Mg/Al dual anode system, look for the most intense photoemission peak, then look either 233 eV higher or lower in BE, depending on the original anode, to determine whether cross-contamination has occurred.

Finally, a concern that must be kept in mind when analyzing ARXPS data is that film roughness and analyzer acceptance angle will both act to degrade the quality of the results. The analyzer acceptance angle limits the angular resolution and lowest take-off angle that can be measured. Commercial instruments typically have half angles of acceptance at the input lens on the order of 10°; therefore measurements below ~10° in take-off angle will show a significant decrease in signal intensity, and angular steps less than ~10° will not add any significantly new information. Instruments are available with half angles of acceptance as low as 2°. Film roughness will also cause a deviation from Equation 22. Measured peak intensity ratios will be lower than the expected values at low take-off angles, and can be higher than expected at near normal take-off angles. Film thickness values estimated using Equation 22 that are less than the anticipated mean surface roughness of the film should be suspect.

SUMMARY

The overall protocol for XPS analysis is generally to define the sample, determine the preparation and cleaning methods, mount and pre-pump the sample, load and align it, set up the analysis parameters, and obtain the XPS spectrum. After the sample has been prepared and cleaned outside of the vacuum system, the rest of the procedure can take anywhere from 15 min to a day to complete. Outgassing of the sample in a prep-vacuum preparation chamber is usually essential for porous or low-vapor-pressure materials.

A typical sequence of automated sample analysis on a modern XPS instrument proceeds after inserting a sample or set of samples. The user then defines, for each sample, the number of spatial regions and their locations, the number of acquisition sets, and the parameters for each set. High-resolution scans can be taken in sequence within a data acquisition set. This mode is called multiplex analysis on some instruments. Sputter profiling or angle-resolved analysis adds additional parameters for each acquisition set, such as the duty cycle of the sputter gun or the take-off angles for analysis. On modern instruments and with a well-established routine, a user can in principle load a set of samples, program the XPS instrument for data acquisition and analysis, and walk away.

ACKNOWLEDGMENTS

The bulk of this unit was written against a background of questions that arose during a graduate lecture course on surface spectroscopic techniques taught at the University of Alabama in Huntsville in the spring of 1998. The input of the class was beneficial in defining the scope of this tutorial. The ARXPS data were obtained by a group of students as part of the laboratory assignment for the course. Critical reviews of the manuscript by M. A. George and J. C. Gregory are greatly appreciated.

Handbook which is an essential source for reference XPS spectra of the elements

Walls, J. M. 1989. Methods of Surface Analysis: Techniques and Applications. Cambridge University Press, Cambridge, U.K..

Recommended for reader who is approaching XPS for the first time. Provides a well-rounded overview of the technique as a complement to the detail offered in Briggs and Seah (1994).

Brundle, C. R. and Baker, A. D. 1978. Electron Spectroscopy—Theory, Technique, and Applications. Academic Press, London.

Carlson, T. A. 1975. Photoelectron and Auger Spectroscopy. Plenum Press, New York.

Watts, J. F. 1990. An Introduction to Surface Analysis by Electron Spectroscopy. Oxford Science Publications, Oxford.

Woodruff, D. P. and Delchar, T. A. (eds.). 1988. Modern Techniques in Surface Science. Cambridge University Press, Cambridge, U.K.

The above four references include text and serial chapters that have been written over the past 25 years above XPS; some are no longer in print.

Brundle, C. R., Evans, J. C. A., and Wilson, S. (eds.). 1992. Encyclopedia of Materials Characterization: Surfaces, Interfaces, Thin Films. Butterworth-Heinemann, Boston.

Cahn, R. W. and Lifshin, E. (eds.). 1993. Concise Encyclopedia of Materials Characterization, 1st ed. Pergamon Press, New York.

Sibilia, J. P. (ed.) 1988. A Guide to Materials Characterization and Chemical Analysis. VCH Publishers, New York.

Vickerman, J. C. 1997. Surface Analysis: The Principal Techniques. John Wiley & Sons, New York.

Wachtman, J. B. and Kalman, Z. H. 1993. Characterization of Materials. Butterworth-Heinemann, Stoneham, Mass.

Walls, J. M. and Smith, R. (eds.). 1994. Surface Science Techniques. Elsevier Science Publishing, New York.

The above six publications are encyclopedic references that generally provide less depth on the specific topic of XPS but may provide a better perspective on its relation to other spectroscopic and analytical techniques. Walls and Smith (1994), Vickerman (1997), Brundle et al. (1992), and Cahn and Lifshin (1993) provide, potentially, the best overview. Sibilia (1988) is somewhat more limited in its coverage, and Wachtman and Kalman (1993) is relatively less practical (and correspondingly more abstract) in its style.

Gunter et al., 1997. See above.

Prutton, M. 1994. Introduction to Surface Physics. Oxford University Press, New York.

Somorjai, G. A. 1994. Introduction to Surface Chemistry and Catalysis. John Wiley & Sons, New York.

The above five publications include a discussion section on XPS while providing a comprehensive background on surface chemistry or surface physics.

Articles pertaining to the principles and applications of XPS are frequently presented in the journals Applied Surface Science, Colloid and Surface Science, Journal of Vacuum Science & Technology, Surface and Interface Science, and Surface Science.

INTERNET RESOURCES

http://srdata.nist.gov/xps/

This Web page at the National Institute of Standards and Technology (NIST) is particularly worth citing. It contains positions of XPS and XAES peaks for elements in various compounds as well as plot (Wagner plots) of the Auger parameter for elements in various compounds.

APPENDIX: PEAK SHAPES

In general, a peak shape is named for the analytical function that defines it. Common peak shapes include the Gaussian, Lorentzian, and Voigt. Mixtures of these, such as a Gauss + Lorentz, and variations of these, such as an assymetric Lorentz or assymetric Voigt, are also widely used. For fitting to XPS spectra, special peak shapes such as a Gauss + tails (Briggs and Seah, 1994) or the Doniach-Sunjic (Bruhwiler and Schnatterly, 1988; Doniach and Sunjic, 1970) have also been developed. Some peak shape functions can be derived directly from a first-principles analysis of the response expected from the spectroscopic event (excitation of a photoelectron). These include the Gaussian and Lorentzian functions. Alternatively, analytical functions for peak shapes such as the Gaussiann + tails include formulations from semi-empirical analysis of experimental data.

Peak shapes can be classified in many ways. One method is according to the number of parameters needed to define the shape analytically. In this respect, at least four classes of peak shapes are commonly used to fit peaks in chemical spectroscopies, starting from those that require three parameters to those that must use six. Each class may contain more than one peak shape, but all peak shapes within a given class use the same number of parameters to define them.

The principal parameters used in an analytical function to define a peak shape in spectroscopy are the peak height, half-width or full-width at half-maximum, position, area, assymetry or shape factor, and mixing ratio. Certain types of XPS peaks are also defined by relative parameters from another peak, such as relative height or offset (relative position). This happens for spin-split doublets (for example, $p_{3/2}$ and $p_{1/2}$ peaks) and for satellites (shake-up and loss peaks). Finally, peak fitting can be done using an experimental spectrum or set of spectra rather than analytical peak shapes. Such reference style peaks require only two parameters to fit to an experimental spectrum: their height and their offset relative to the spectrum.

The above discussion suggests that XPS peak shapes can be categorized globally into three styles, single peaks, relative peaks (such as spin-split doublets), and reference peaks (using a full experimental spectrum). The first two styles are obtained from analytical functions and will be called singlets and ntuplets for the number of peaks they define in a spectrum. Reference-style peaks are derived from experimental data and will not be considered in any further detail in the discussion below. In principle, an ntuplet-style peak uses n times as many parameters as its comparably shaped singlet, where n is the number of ntuplets. Rather than expand the number of peak classes beyond four to accommodate this (potentially unlimited) expansion of parameters, classification of a peak shape is restricted to the number of principal parameters it

requires. Singlet and ntuplet peak styles correspondingly then each contain only four different peak classes. As an example, a Gaussian singlet style peak and a Gaussian doublet-style peak (an ntuplet style with two peaks) are in the same peak class because they both use the same number of principal parameters (three as shown below). The doublet will require an additional set of three relative parameters to define shape of the second (relative) peak.

The four peak classes of XPS peak shapes are labeled A through D below. For each class, examples of analytical functions are given for singlet style peak shapes. A representative doublet style is given for a Gaussian peak shape (the first peak shape in class A). Where possible, the formula are given in a format suitable for input into a symbolic math or graphing package for programming purposes. In all of the functions, S_{ps} is the analytical signal for the peak shape with a name that is abbreviated as ps, x is the energy scale (assumed to be in eV binding energy in XPS), w is the full width of the peak at exactly half of its height (full-width at half-maximum or FWHM in eV), p is the peak position (eV), and a is the peak area (counts-eV/sec). Other parameters are defined as needed.

The classification scheme above and the functions provided below are by no means unique or unequivocal.

Class A (3 Parameters)

Two of the peak shapes in this class, Gaussian and Lorentzian are the most commonly used in spectroscopy.

Gaussian. Many processes that lead to a signal in chemical spectroscopy are random in nature and result statistically in a Gaussian signature. In statistical analysis, a normal probability curve is a Gaussian function defined by its mean value or position μand its standard deviation, σ, which is measured as the half-width of the Gaussian peak at a distance of about 61% of the peak height. The normal probability curve also has an integrated area of unity.

The normal probability function is not useful for fitting peaks to spectroscopic data. Almost all spectroscopic peaks have areas that are not identically equal to unity, and w (the FWHM or the width at 50% of the height) of a spectroscopic peak an experimental spectrum is more easily measured than σ (the width of the corresponding Gaussian function at about 61% of its height). The Gaussian functions given below are therefore defined in terms of spectroscopic parameters, especially w.As a point of reference for a Gaussian function, the FWHM is $w = 2\sigma\sqrt{2\ln(2)}$. Also, for any form of the Gaussian, the relationship between h, σ, w, and a is $a = 2\sqrt{2\pi}h\sigma = \sqrt{\pi\ln(2)}hw$.

Three parameters define a normal probability Gaussian curve, μ, σ, and an area of unity. Therefore p and any two parameters from the set of h, w,and a are needed to define a spectroscopic Gaussian peak. Correspondingly, three different Gaussian shape peak functions exist in Class A depending on which two parameters are chosen in addition to p.

Position/height/full-width-half-maximum. A singlet style peak is represented as

$$S_{GPHF} = h\exp\left(-4\frac{\ln(2)(x-p)^2}{w^2}\right) \tag{36}$$

For this peak, the area is

$$a = hw\sqrt{\pi}/2\sqrt{\ln(2)} \tag{37}$$

An example of a doublet style where both peaks have the same Gaussian shape is given below. In the function, D_{DGHF} is the signal, r_h is the relative height, o is the offset, and r_w is the relative fwhm of the doublet peak

$$\begin{aligned} D_{DPHE} = {} & h\exp\left(-4\frac{\ln(2)(x-p)^2}{w^2}\right) \\ & + r_h h\exp\left(-4\frac{\ln(2)(x-p-o)^2}{(r_w w)^2}\right) \end{aligned} \tag{38}$$

Position/area/full-width-half-maximum

$$S_{GPAF} = \left(\frac{ea\sqrt{\ln(2)}}{w\sqrt{\pi}}\right)\exp\left(-4\frac{\ln(2)(x-p)^2}{w^2}\right) \tag{39}$$

The height of this peak is

$$h = 2a\sqrt{\ln(2)}/w\sqrt{\pi} \tag{40}$$

Position/height/area

$$S_{GPHA} = h\exp\left(-2\frac{h^2\pi(x-p)^2}{a^2}\right) \tag{41}$$

The FWHM of this peak is

$$w = 2a\sqrt{\ln(2)}/h\sqrt{\pi} \tag{42}$$

Lorentzian. The Lorentzian peak shape is also fundamental to chemical spectroscopy. It is often considered a more natural line shape for chemical spectroscopy than the Gaussian function because the broadening it displays is characteristic of the lifetime broadening found in quantized energy states. The Lorentzian function gives a broader peak at the base than does the Gaussian. Two variations of this peak shape exist:

Position/height/full-width-half-maximum

$$S_{LPHF} = h\Big/\left(4\frac{(x-p)^2}{w^2}+1\right) \tag{43}$$

The area of this peak is $a = \pi w/2$.

Position/height/area

$$S_{\mathrm{LPHA}} = h \Big/ \left(\frac{(x-p)^2 \pi^2}{a^2} + 1 \right) \tag{44}$$

The FWHM of this peak is $w = 2a/\pi$.

Class B (4 Parameters)

These peak shapes include a fourth parameter that is either f_a—*a peak shape assymetry factor—or* f_g, a fractional Gaussian. In these peak shapes, h and w do not always define the actual height and half-width of the peak as measured in the resultant curve.

Gaussian + Lorentzian. This is a combination of the two Class A peak shapes. The f_g value ranges from 0 (pure Lorentzian) to 1 (pure Gaussian). Two different variations can be formed

$$S_{\mathrm{G+L(A)}} = f_g S_{\mathrm{GPHF}} + (1 - f_g) S_{\mathrm{LPHF}} \tag{45}$$

$$S_{\mathrm{G+L(B)}} = f_g S_{\mathrm{GPHA}} + (1 - f_g) S_{\mathrm{LPHA}} \tag{46}$$

Voigt. The Voigt function has the form

$$S_{\mathrm{V}} = \left(\frac{1}{\alpha} \right) \int_{-\infty}^{\infty} \frac{h \exp(-y^2)}{w_{\mathrm{L}}^2 + ((x-p)/w_{\mathrm{G}}) - y)^2} dy \tag{47}$$

$$\alpha = \int_{-\infty}^{\infty} \frac{\exp(-y^2)}{w_{\mathrm{L}}^2 + y^2} dy \tag{48}$$

where w_{L} and w_{G} are Lorentzian and Gaussian components of the FWHM of the peak. While an analytical solution for α exists, the remaining integral cannot be solved analytically. The Voigt peak shape is therefore typically obtained numerically. One method is to use a lookup function fVoigt(p_1, f_a), where $f_a$is a shape function and the value of p_1 is defined below

$$S_{\mathrm{v}} = \mathrm{f\,Voigt}(p_1, f_{\mathrm{a}}) \tag{49}$$

$$p_1 = 2 \sqrt{\ln(2) \frac{(x-p)}{w}} \tag{50}$$

The function f Voigt returns a value after numerical interpolation from a table. The shape factor f_a varies from 0 to infinity. Larger values give flatter, broader peaks (less Gaussian in shape).

Assymetric Lorentzian. This form of the Lorentzian gives a skew to the higher x side of the peak as the assymetry factor f_a varies from 0 to 1. A value of 0 gives a symmetrical Lorentzian, as can be shown by analytical geometry. As f_a increases from 0, the location of the maximum of the peak shifts toward greater x and the value of h no longer denotes the true peak height. For f_a above 0.5, the function returns to a symmetrical, flat, broad peak shape centered at p

$$S_{\mathrm{AL}} = \left(\frac{h}{\alpha} \right) \cos\left(-f_a + (1 - f_a) \arctan\left(2 \frac{x-p}{w} \right) \right) \tag{51}$$

$$\alpha = 2 \sqrt{\frac{(x-p)^2}{w^2}} + 1 \tag{52}$$

The area of the peak when $f_{\mathrm{a}} = 0$ is $a = \pi w/2$ and otherwise goes to infinity as f_{a} goes to unity.

Doniach-Sunjic. This peak shape has been used to fit the d and f levels of transition metals (Bruhwiler and Schnatterly 1988; Doniach and Sunjic 1970). The actual height, FWHM, and position of the resultant principle peak are only equal to the input values when the assymetry factor $f_{\mathrm{a}} = 0$. As f_{a} increases, the peak becomes assymetrical at higher x values above p and the maximum in the peak shifts toward higher values of x away from p

$$S_{\mathrm{DS}} = \frac{h}{\alpha} \cos\left(\frac{\pi f_{\mathrm{a}}}{2} + (1 - f_{\mathrm{a}}) \arctan(p - x, w) \right) w^{1 - f_{\mathrm{a}}} \tag{53}$$

$$\alpha = ((p-x)^2 + w^2)^{(1-f_{\mathrm{a}})/2} \times \cos\left(\frac{\pi f_{\mathrm{a}}}{2} + (1 - f_{\mathrm{a}}) \arctan(0, w) \right) \tag{54}$$

In the above expression, arctan (y, x) computes the principal value of the argument of the complex number $x + iy$ so that $-\pi < arctan(y,x) \leq \pi$. When f_{a} is unity, the Doniach-Sunjic peak shape is undefined (the function returns a horizontal line at a value of h). The area of this peak is $a = \pi h w$ for $f_{\mathrm{a}} = 0$ and goes to infinity as f_{a} goes to unity.

Class C (5 Parameters)

The simplest peaks in this class are just combinations of the Class A peak shapes and the assymetric Class B peak shapes. One additional parameter f_g defines the mixing ratio.

Gaussian + assymetric Lorentzian

$$S_{\mathrm{G+AL}} = f_g S_{\mathrm{GPHF}} + (1 - f_g) S_{\mathrm{AL}} \tag{55}$$

Class D (6 Parameters)

These peak shapes include parameters to define tails. Tails are assymetric extensions on one side of the peak. In XPS spectroscopy, tails are used to model the increase in intensity on the high binding energy side of the peak due to inelastic scattering.

Gaussian + Tails. Three additional parameters define the shape of the tail. They are c_t—constant tail height fraction—e_t—exponential tail height—and *fc*—fraction of constant tail (versus exponential tail). The tail function signal

S_{TF} is set to zero on the low x side of the peak position p using the logical test $(x \geq p)$.

$$S_{TF} = F_c c_t + (1 - f_c) \exp\left(-\frac{|x-p|}{e_t}\right)(x \geq p) \quad (56)$$

$$S_{GPHF+T} = S_{GPHF}(1 - S_{TF}) + hS_{TF} \quad (57)$$

SURFACE X-RAY DIFFRACTION

INTRODUCTION

Surface X-ray Diffraction

Surface x-ray diffraction allows the determination of atomic structures of ordered crystal surfaces in an analogous way to x-ray crystallography for the determination of three-dimensional crystal structures. In doing this, crystallographic parameters such as lattice constants and Debye-Waller factors (thermal vibration amplitudes) are also accessed, so surface x-ray diffraction should be considered as a valid method for measuring these quantities too. Surface x-ray diffraction also probes surface morphological properties, such as roughness and facet formation, and allows the investigation of their thermodynamic and kinetic aspects, such as the study of phase transitions in surfaces.

Because x rays probe deep inside matter, buried interfaces can be treated in exactly the same manner as surfaces, so throughout this unit the words *surface* and *interface* will be used synonymously. In fact, some of the best applications of the method are for buried interfaces, where complementary electron-based probes such as low-energy electron diffraction (LEED; LOW-ENERGY ELECTRON DIFFRACTION and reflection high-energy electron diffraction cannot reach.

Surface x-ray diffraction is not a laboratory technique. While there are one or two exceptions of installations in individual laboratories, the majority are associated with national or international facilities. Even the very early experiments carried out by Eisenberger and Marra (1981) used synchrotron radiation. By now, facility-based science is already rather common and will become more so in the future, as it has considerable economies of scale and advantages of centralized operational safety. The practice of surface x-ray diffraction should necessarily be considered as a facility-based operation, and it will be assumed that the reader will have access as a "user" to one of these facilities. This is usually handled by the submission of a proposal to be judged on the importance of the science to be carried out. Access is then usually free of charge.

Because surface x-ray diffraction is facility based, it is not a technique for which one can purchase the equipment piecemeal from a vendor. Every surface x-ray diffraction installation is slightly different, but most were derived from and are based on the description that follows, which is the X16A facility of the National Synchrotron Light Source (NSLS). Others, such as the Advanced Photon Source (APS, Argonne), the European Synchrotron Radiation Facility (ESRF, Grenoble), Hamburger Synchrotronstrahlungslabor (HASYLAB, Hamburg), Daresbury Laboratory, Photon Factory (PF, Tsukuba), and Laboratoire pour l'Utilisation de Rayonnement Synchrotron (LURE, Orsay), use basically the same control and analysis programs and procedures as those described here.

Competitive and Related Techniques

The need to travel to a facility to make surface x-ray diffraction measurements can be inconvenient, to say the least, so it is important to discuss its strengths and weaknesses compared with other techniques. Scanning probe methods, such as scanning tunneling microscopy (STM, SCANNING TUNNELING MICROSCOPY and atomic force microscopy (AFM), are extensively used in surface science. These imaging methods are unbeatable for detecting singular events on surfaces, and the "microscopist's eye" will often detect a wide variety of local behavior. Thus STM has been very important in understanding instabilities of surfaces, step properties, and island morphologies during growth. When "average" quantities are needed for understanding general behavior, such as thermodynamics, the averaging must be carried out explicitly; diffraction methods will access ensemble-average quantities directly and will filter out the exceptions. This is particularly important when studying the dynamical behavior associated with phase transitions, where the correlations within a moving arrangement of atoms can still be detected by diffraction. At their limit, scanning probe microscopies can reach atomic resolution, but they always detect the outermost features on a surface and will not see below the surface. Diffraction methods can attain atomic positions to an accuracy of 0.01 Å routinely, while scanning microscopies can only achieve that in the surface-normal direction under certain circumstances.

The direct competitors with surface x-ray diffraction are thus the various forms of electron diffraction (Electron Techniques), which provide information of an analogous form: LEED, reflection high-energy electron diffraction (RHEED), and transmission electron diffraction (TED). Since electrons interact more strongly with matter than do x rays, there are some important differences. First, electron diffraction is dynamical and requires a nonlinear theory to explain the intensity of the diffraction seen. This has been accomplished by deriving a careful theoretical description of the electron as it interacts with the sample in the case of LEED and to a lesser extent for RHEED. After 20 years of development, the method has reached the point where structures can be refined as well as just calculated, and thermal vibrations can now be included. With x rays, the simpler kinematical description can be used, which makes the calculations very easy, so that powerful refinement procedures can be followed. Transmission electron diffraction is near to this kinematical

limit also, and the linear approximation has been successfully used to obtain surface structures. The potential user can make a choice between a hard experiment and an easy analysis in the case of x rays or between an easy experiment and a hard analysis in the case of electron diffraction.

Second, for the same reason, the penetration of x rays is significantly larger than electrons. The sensitivity of LEED and RHEED is limited to about four atomic layers, and the accuracy becomes reduced in the lower layers. To examine interfaces, LEED has been used, but it requires physical removal of half of the sample. X rays are not limited in this way and have many applications for interfaces: an important example is the electrochemical interface, which can be studied in situ. Transmission electron diffraction falls in between: samples must be thinned to 100 to 1000 Å but can still contain interfaces. The small differences in accuracy that can be obtained in surface structure determination by the different diffraction techniques can be attributed to the accessible range of reciprocal space. X-ray diffraction and TED tend to have higher accuracy parallel to the surface, because the largest component of momentum transfer is usually in that direction. Low-energy electron diffraction is a backscattering technique, which tends to give more accurate coordinates in the normal direction.

It used to be said that the momentum resolution of x rays was an unmatchable asset, but this has become less important in recent years. First, the spot profile analysis LEED (SPA-LEED) method was developed by Sheithauer et al. (1986) as well as the spot profile analysis RHEED (SPA-RHEED) method by Müller and Henzler (1995). These offer momentum resolution, which is comparable to x-ray diffraction, and are commercially available from Omicron. Surface-phase transitions can now be studied as well with LEED or RHEED as with x-ray diffraction. Second, the merit of probing correlations extending over large distances in real space has diminished with the widespread availability of STM and AFM, which routinely scan the same range.

PRINCIPLES OF THE METHOD

Surface is a generic word that is often used as an antonym to bulk. Deviations from physical properties of bulk matter are often attributed to (i.e., blamed on) "surface effects." The study of surfaces is therefore a productive way of understanding these deviations. The study of surfaces always starts with their structure, and that is what is probed with surface x-ray diffraction. Typical examples of surfaces, generalized to include internal interfaces, are shown in Figure 1.

The general subject of diffraction will not be reviewed here since it appears elsewhere in this volume and also is covered in several excellent textbooks (James, 1950; Warren, 1969; Guinier, 1963; Lipson and Cochran, 1966; Woolfson, 1997). It is assumed that the reader is comfortable with the construction of a three-dimensional (3D) reciprocal space and the idea that the diffraction from a crystal is localized to a set of specific "Bragg" points forming a reciprocal lattice. Reciprocal space is spanned by the vectorial

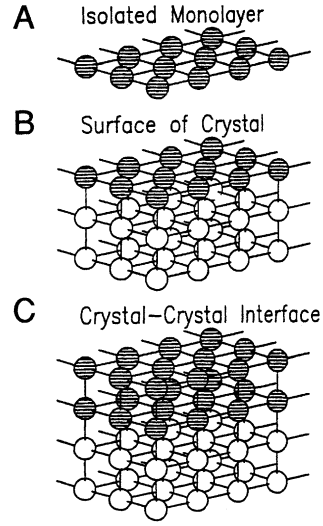

Figure 1. Entities that can be studied with surface x-ray diffraction. (**A**) isolated monolayer (2D crystal). (**B**) Same as A but connected to a crystalline substrate. (**C**) Same as A but at the interface between two different crystals. From Robinson and Tweet (1992).

quantity **q**, which is the momentum transfer of the diffraction experiment. The axes of reciprocal space are chosen to lie along simple directions within the reciprocal lattice. The coordinates are then normalized so that the Bragg points appear at simple integers, called Miller indices, *hkl*. This construction of reciprocal space was introduced in SYMMETRY IN CRYSTALLOGRAPHY and will be assumed henceforth.

In surface x-ray diffraction, it is conventional to choose a coordinate system in reciprocal space that places the third index of the momentum transfer, q_z, perpendicular to the surface. This is usually compatible with the Miller index notation because the naturally occurring surfaces are usually close-packed planes of atoms, which have small-integer Miller indices according to the usual construction. This convention often requires use of an unusual setting of the bulk crystal unit cell, e.g., hexagonal for a cubic (111) surface or tetragonal for a cubic (110) surface. The convention is exactly the same as that used in LEED; see LOW-ENERGY ELECTRON DIFFRACTION. Another common terminology is to separate the components of momentum transfer, **q**, parallel and perpendicular to the surface by writing $\mathbf{q} = (q_P, q_z)$. Here q_P strictly represents both in-plane components. The reason for this separation is that a surface is a highly anisotropic object with completely different properties in the two directions.

Diffraction from Surfaces

The most important characteristic of diffraction from surfaces is illustrated as a 3D sketch in Figure 2, which corresponds roughly to Figure 1 transformed into reciprocal space. Bulk crystal diffraction is concentrated at points of reciprocal space because of the 3D periodicity of the crystal. A surface or interface has reduced dimensionality, so its diffraction is no longer confined to a point but extends continuously in the direction perpendicular to the plane of

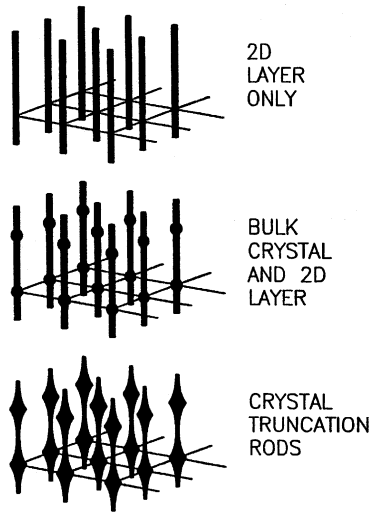

Figure 2. Schematic of the diffraction from the objects in Figure 1. The 3D points of reciprocal space are indicated as circles; 2D rods of reciprocal space are indicated as bars. From Robinson and Tweet (1992).

the surface or interface. These lines of diffraction, sharp in two in-plane directions and diffuse in the perpendicular direction, are called rods. The diffraction pattern of a two-dimensional (2D) crystal, as illustrated in Figure 2, is a 2D lattice of rods in reciprocal space.

A surface rarely exists as an isolated entity (Fig. 1A) but is normally intimately connected to a substrate of bulk crystalline material (Fig. 1B) or materials (Fig. 1C). The diffraction is then a superposition of 3D and 2D features, points and rods, as shown. However, the periodicities of the two lattices are the same (by construction), and so their diffraction patterns will be intimately related. This causes the lateral positions of the features to align so that the intensity distributions merge together. The 2D rods line up between the 3D points, and the two features simply merge together. The resulting object in reciprocal space, illustrated in the bottom panel of Figure 2, is called a crystal truncation rod (CTR). An example of an experimental study of a CTR is given below (see Practical Aspects of the Method).

Crystal truncation rods have been treated theoretically as extensions of bulk diffraction by Andrews and Cowley (1985), Afanas'ev and Melkonyan (1983), and Robinson (1986), and their connection to the surface structure has been derived. The sensitivity to the surface is found to vary smoothly along the rod. Near the divergence of the intensity at the 3D Bragg points, the intensity of the CTR depends only on the bulk structure, through its bulk structure factor. According to the kinematic theory of diffraction, the intensity follows a $(q_z - G_z)^{-2}$ law near each bulk Bragg peak at position $\mathbf{G} = (G_P, G_z)$. In the more precise dynamical theory discussed by Afanas'ev and Melkonyan (1983), this nonphysical divergence at $q_z = G_z$ becomes finite and follows a Darwin curve instead, but the asymptotic behavior remains the same as in the kinematic theory.

The connection between the intensity distribution along a CTR and the corresponding surface structure is

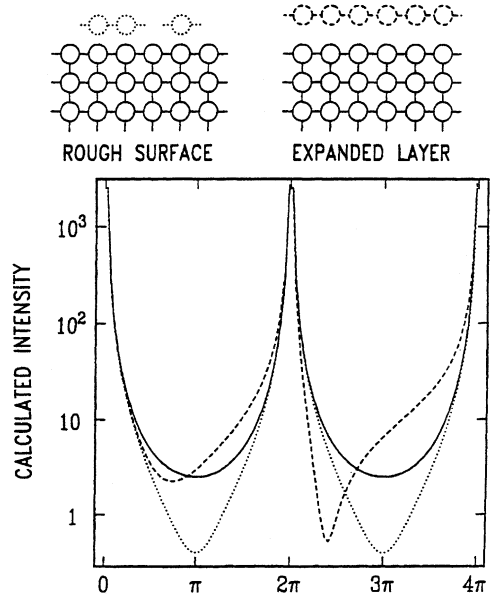

Figure 3. Calculated CTRs for an ideally terminated surface (solid curve), a surface with modified top-layer spacing (dashed), and a rough surface (dotted). The intensity is plotted as a function of perpendicular momentum transfer, q_z, in normalized units.

illustrated by a simple calculation in Figure 3. The full curve is for an ideally terminated simple-cubic lattice of atoms; its functional form is just $1/(\sin q_z)^2$, whose divergence at Bragg points $q = 2n\pi$ is clearly visible. The dashed curve corresponds to an outward displacement of a single layer of atoms at the surface; the intensity curve near the Bragg peaks, where there is little surface sensitivity, is barely changed, but the intensity at the CTR minimum is strongly modified. Finally, the dotted curve is for a rough surface, modeled by random omission of a fraction of the atoms in the top layer; here, again, the biggest effect is at the CTR minimum, this time with a symmetric drop of the intensity curve.

A simple rule of thumb is that the measurement is the most surface sensitive at the position on the CTR that is furthest from the bulk Bragg peaks, where the intensity is also weakest. This rule applies not only to the structure itself but also to the sensitivity to fluctuations in the surface, e.g., its roughness. In performing an experiment, one is frequently faced with a choice between surface sensitivity and signal level, since one quantity trades off directly with the other.

Measurement of Surface X-ray Diffraction

The surface x-ray diffraction signal can be measured with a standard diffractometer. For reasons explained below (see Practical Aspects of the Method), it is common to use a diffractometer with extra degrees of freedom. Synchrotron radiation is highly desirable as it results in convenient signal levels around hundreds to thousands of counts per second. The primary responsibility of the diffractometer is to select $\mathbf{q}$ by suitable choice of its angles while keeping the beam always on the center of the sample.

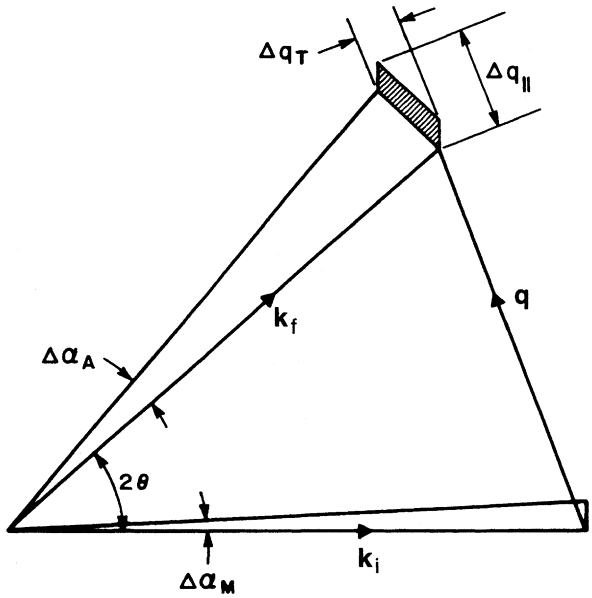

Figure 4. Construction of the resolution function within the scattering plane of a diffractometer. From Robinson (1990b).

Measurements then consist of scans of the **q** vector through the various features of the surface x-ray diffraction.

The shape and size of the resulting scans depend on the nature of the diffraction features being measured, e.g., due to the degree of order in the surface. The results also depend on the resolution function of the instrument, which is always convolved with the true diffraction pattern. The resolution function is controllable to a certain extent by instrumental parameters, particularly slits that define the beam divergence in different directions. The usual construction is shown in Figure 4, which is based on the vector construction of **q** in terms of the incident and exit wave vectors $\mathbf{k}_i$ and $\mathbf{k}_f$: $\mathbf{q} = \mathbf{k}_i - \mathbf{k}_f$. The variation of $\mathbf{k}_i$ is represented by the angular width of directions allowed by the entrance slits and monochromator, $\Delta\alpha_M$, while the variation of $\mathbf{k}_f$ is defined by $\Delta\alpha_A$. The resulting resolution function is the shaded parallelogram at the top of the picture. Simple geometry shows that its dimensions parallel and perpendicular to the vector **q** are given by Moncton and Brown (1983):

$$\Delta q_{||} = k(\Delta\alpha_M + \Delta\alpha_A)\cos\theta$$
$$\Delta q_T = k(\Delta\alpha_M + \Delta\alpha_A)\sin\theta \qquad (1)$$

where $k = 2\pi/\lambda$ is the length of both wave vectors and θ is half the diffraction angle 2θ.

Note that this picture applies to the scattering plane of the diffractometer, spanned by the 2θ angle of the diffractometer, and the notations Δq_P and Δq_T refer to parallel with (or radial) and transverse to the direction of **q**. The scattering plane is not the same as the surface plane of the sample, except in the grazing incidence geometry defined below, which is often used for precisely that reason. The third dimension of the resolution function, denoted $\Delta q_\perp$, is also defined by slits, this time in the direction perpendicular to the scattering plane; the resolution function then becomes a parallelogram-based prism by simple extension of Figure 4 to 3D. This out-of-plane resolution is often the largest of the three because, in the grazing incidence geometry, the diffraction features are extended rods in that direction, and a considerable enhancement of intensity is thereby attained.

Many setups, including the one at X16A, gain additional flexibility by dividing the $\Delta q_\perp$ range into narrower sections by use of a linear position-sensitive detector (PSD). The x-ray counts recorded by the PSD are assigned a "position" along the detector by the height of its output pulse. This is accumulated in a multichannel analyzer (MCA) and then read out in bins, each corresponding to a section of $\Delta q_\perp$. The total counts in each bin are saved in the output file, to allow the data to be subsequently broken down into different q_z positions with a correspondingly narrower $\Delta q_\perp$. Since surface x-ray diffraction in the grazing incidence geometry should give features that are broad in q_z, all the bins should rise and fall together in intensity and give independent structure factors at different q_z values. However, if a powder grain or multiple scattering glitch happens to accidently satisfy the diffraction condition during some surface measurement, it will be recorded in only one MCA bin and can be suppressed.

Surface Crystallographic Measurements

A subset of the general class of surface x-ray diffraction measurements is that pertaining to atomic structure determination alone. Here it is assumed that the surface under investigation is well enough ordered that the widths of all diffraction features are limited by the resolution function alone. This means that, in this case, any disorder that happens to be present is undetectable, and the surface is indistinguishable from ideal. It has been shown by Robinson (1990b) that in this limit the integrated intensity of the diffraction features is independent of the (unseen) disorder and so is representative of the crystallographic structure factor alone. Measurements of structure factors can then be analyzed in terms of the atomic structure of the surface, in a close analogy to bulk x-ray crystallography described by Woolfson (1997) or Lipson and Cochran (1966).

If the disorder is visible in the form of peak broadening that is not too severe, it may still be possible to reach the ideal limit by deliberately worsening the resolution function. While it is often hard to control $\Delta\alpha_M$ since this is a function of the beamline optics, $\Delta\alpha_A$ can be opened up significantly by opening the 2θ detector slits. In all cases, the test for this desirable situation is that all diffraction features are resolution limited in their width. There are other limits in which the structure factor can be reliably measured if the peaks are significantly broader than the resolution function, then their peak intensity is representative of the square of the structure factor, provided a different, but calculable, correction is used.

The measurements needed for crystallography are most easily obtained by rocking scans of the principal diffractometer angle θ. In the detailed protocols below, the name

of the θ angle known to the usual computer software is TH; these names will be cross-referenced where appropriate. This ensures that the narrow direction of the resolution function sweeps roughly perpendicular to the peak. If the peak is slightly misaligned, such a scan will usually catch it either earlier or later and still give the correct structure factor; this will not work if the misalignment is too severe, say more than two peak widths away, because, in general, there would be components of the misalignment in all possible directions. The use of a rocking scan is also prescribed by the definition of integrated intensity, the quantity coupled to the structure factor, as explained by Robinson (1990b) (see Appendix B). This corrects for all kinds of disorder, including mosaic spread, provided this is not too severe. It is also the most reliable way to estimate the background underlying the peak.

Grazing Incidence

It was explained (see Diffraction from Surfaces, above) that the use of grazing incidence orients the resolution function in a favorable direction for surface x-ray diffraction. This means that the incident beam, the exit beam, or both make a very small angle with the surface to be measured. This presents a special challenge in the diffractometry which is discussed below (see Practical Aspects of the Method). It also has other consequences.

The diffraction under grazing incidence conditions is no longer strictly kinematical because such a beam will partly reflect from the surface and also undergo a slight refraction as it crosses to the interior of the crystal. The effect, described by classical optics by Born and Wolf (1975), is small until the incidence angle α_i (or exit angle α_f) becomes comparable with the critical angle for total external reflection, α_C, which is of order a few tenths of a degree for most situations. When $\alpha_i < \alpha_C$, the beam is completely reflected from the sample and only an evanescent wave continues inside. This can be used to considerable advantage when extreme surface sensitivity is desired, since the typical penetration depth is of the order of 100 Å. Fortunately, Vineyard (1982) introduced a sound theoretical basis called the distorted-wave Born approximation for working with the effects of the critical angle. This approximation provides the grazing incidence method with great power.

The distorted-wave Born approximation has an additional consequence for surface x-ray diffraction: the intensity of the diffraction becomes modified under grazing incidence conditions. Born and Wolf (1975) show that the effect can be reduced to a simple transmission function for the intensity, $|T(\alpha)|^2$, as a function of either α_i or α_f, which accounts for the refraction effects. An example of calculations of $|T(\alpha)|^2$ is given in the upper panel of Figure 5. As can be seen, there is a potential factor of 4 enhancement for both the incident and exit beams. The practical drawbacks with the factor of 16 are that it is only attainable when the collimation of both beams is severely restricted and the alignment is very difficult to achieve. The lower panel of Figure 5 shows the effect of the distortion on the α_f profile of an in-plane bulk Bragg peak, which in the absence of the refraction effect would lie at $\alpha_f = 0$. Careful examination of the experimental curve can be used to identify whether the crystal diffracts from all layers up to its surface or whether there are inactive "dead" layers present, as shown.

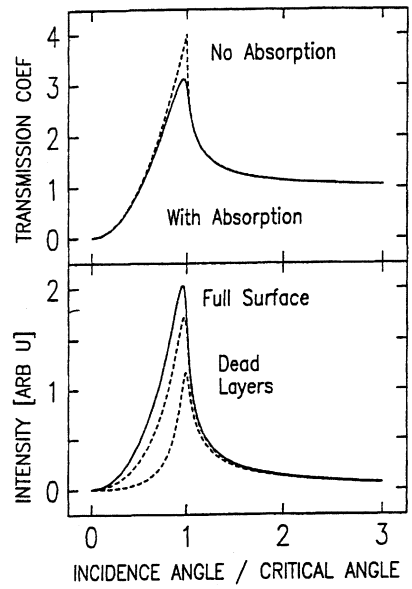

Figure 5. Calculations of $|T(\alpha)|^2$ and the profile of an in-plane diffraction peak for gold at $\lambda = 1.5$ Å. The dashed curves show the effect of 5 Å and 20 Å of inactive dead layers of gold present above the crystalline part of the sample. Adapted from Dosch et al. (1991).

PRACTICAL ASPECTS OF THE METHOD

An overview of the generic vacuum diffractometer configuration is given in Figure 6. This instrument, which operates at beamline X16A at NSLS, is the most widely used design. All of the instrumental functions described in this section are generic to all installations of surface x-ray diffraction, although some specific details of the X16A instrument are given for clarity of illustration. Further machine-dependent details can be found below in the detailed protocols in the Appendices.

The overall size of the instrument in Figure 6 is ~2 m long by 1 m wide and it resides at the beamline endstation. The instrument slides on air bearings, which allows it to be slid quickly into and out of the beamline hutch at the beginning and end of each experimental run. The configuration consists of an ultrahigh-vacuum (UHV) chamber (left side) coupled to a precision diffractometer. These two components will be described separately.

Vacuum System

On the left side, looking towards the x-ray source, lies the main vacuum chamber, which is used for sample preparation. It has turbomolecular (TMP), ion, and sublimation pumps (See GENERAL VACCUM TECHNIQUES) located in a cross below the level of the main chamber. The TMP and ion pumps have gate valves that allow them to be isolated, for protection against power failure for the TMP and to

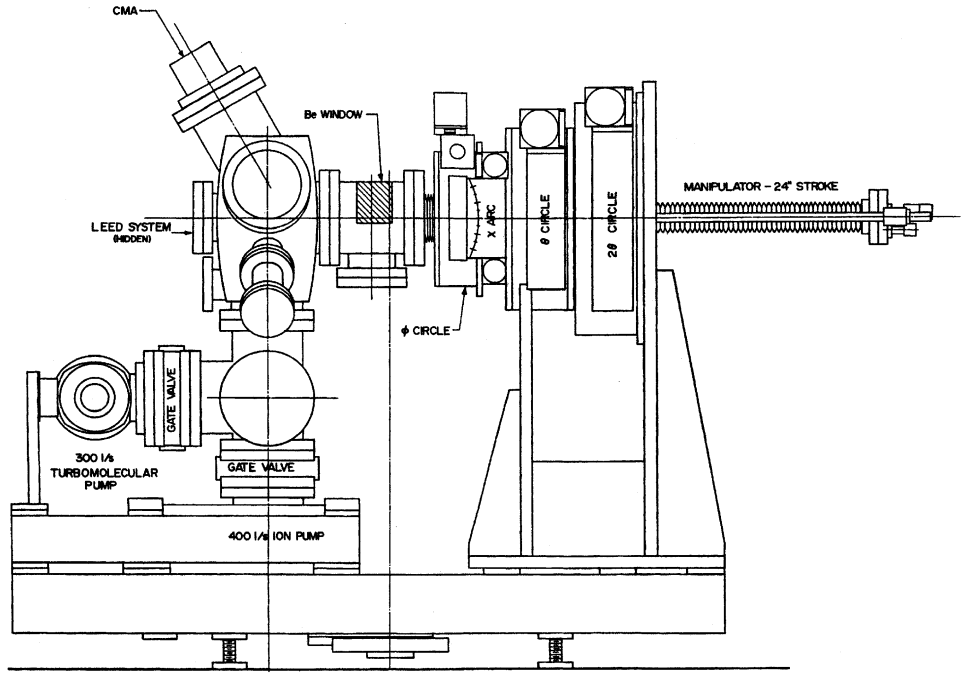

Figure 6. Overview of the vacuum diffractometer configuration used at the X16A facility at NSLS by Fuoss and Robinson (1984). Other installations vary slightly from this design.

reduce exposure to certain gases (e.g., Ar for sputtering and O_2 for dosing) for the ion pump. Numerous flanges are pointing at the sample, allowing the installation of various instruments for sample preparation and diagnosis. Samples are prepared by combinations of sputtering using an ion-bombardment gun, annealing by use of filaments, dosing with gases controlled by leak valves, and evaporation of substances using dosers. Dosers include commercial Knudsen cells and electron-beam evaporators, heated crucibles of molten materials, simple filaments coated with metal films, and getter-type alkali sources. Diagnosis is by means of LEED, Auger electron spectroscopy (AES; see AUGER ELECTRON SPECTROSCOPY), and residual gas analysis (RGA). Most conventional surface science preparations can be carried out using combinations of these tools.

Most importantly, the capability of performing an x-ray diffraction experiment in situ is provided in the chamber. X rays can enter and leave the chamber through a semicylindrical beryllium window, shown in the center of Figure 6. The window was brazed onto the vacuum wall at high temperature, so it is completely UHV compatible. It has 0.5 mm wall thickness so it transmits at least 95% of x rays with energies above 8 keV. In the diffraction position, the sample lies at the extreme right-hand side of the window with its flat face, upon which the surface has been prepared, facing left. The sample is rigidly connected to the diffractometer to the right. A manipulator wand located behind the diffractometer allows the sample to be detached from its rigid diffractometer mount and carried under UHV to the various instruments in the preparation chamber. There is a bellows and rotating seal coupling between the diffractometer and the chamber, which allows the passage of the diffractometer motions. These last essential features were specifically designed for the surface x-ray diffractometer and so will be discussed next.

Because preparation of 10^{-10} Torr pressure is time consuming, a loadlock is used to allow simple manipulations of samples, thermocouples, and heaters to be carried out without venting the main UHV chamber. The basic principle of operation is shown in Figure 7. For example, load locking is very useful for batch processing a series of samples or for introducing samples that cannot be baked at 150°C. Most instruments for surface x-ray diffraction provide some sort of load lock for rapid sample turnaround. Specific details for the operation of the X16A vacuum system are given later in the detailed protocol (see Appendix A), including the load-lock procedure, the venting procedure, and the bakeout procedure.

Sample Manipulator

Once it is retracted, the manipulator moves entirely with the sample on the diffractometer. A spring-loaded kinematical mount comprising three balls resting in 3 V-grooves 120° apart ensures that any flexure of the long arm of the manipulator is decoupled from the sample, which is thereby allowed to rest against the diffractometer ϕ axis. To carry the sample into the preparation chamber, the manipulator is extended by collapsing the 0.8-m-long bellows using a motor and gear on a threaded shaft. Electrical connections to the sample traverse the full length of the manipulator from its accessible rear flange. The last 75 mm of the shaft is illustrated in Figure 7. It is crammed with intricate features that give it great versatility: a 90° elbowlike flexure driven by a push-rod running down the length of the manipulator that allows the sample to face the LEED and AES; a spring-loaded decoupling joint associated with the kinematic mount (not shown); a vacuum sealing flange penetrated by electrical and thermal feedthroughs for the load-lock system described below; and at the end 25 mm of clear space that allows the user to assem-

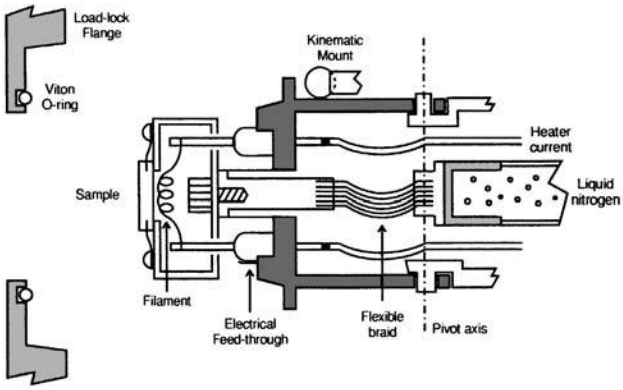

Figure 7. Detail of the manipulator head shown in cross-section. The pivot allows the sample to point at 90° to the main axis to be presented to surface characterization instruments. The viton seal of the load lock, through which the sample is passed, is shown on the left. The mating surface is halfway down the manipulator head and contains vacuum feedthroughs for cooling and electrical connections to the sample. All parts to the left of this are accessible to the user during the load-lock procedure.

ble his or her sample with the appropriate heaters, coolers, and sensors.

The rotating seal design is shown in Figure 8. It allows the passage of rotations across the vacuum wall using a rigid shaft that has neither play nor backlash. It achieves this with three concentric sliding seals made of Teflon between which differential vacua are applied, the first stage at 10^{-3} Torr with a roughing pump, the second at 10^{-6} torr with a TMP pump. If any seal momentarily leaks during rotation, the pressure burst on the UHV side is minimized by the use of these differentials.

Five-Circle Diffractometer

The diffractometer geometry is illustrated with the aid of Figure 9. This corresponds to a "five-circle" geometry, which was invented for surface diffraction by Vlieg et al. (1987). The standard names given to the angle variables describing the diffractometer setting are the same as the names of the axes in the figure. The principal axes are called (confusingly) θ and 2θ due to their association with the two-circle diffractometer setting describing Bragg's law. The symbols ϕ and χ are Euler angles of the sample with respect to the main horizontal (θ) axis. Finally α is the rotation of the entire instrument about the vertical axis. Historically at X16A, α was an afterthought, added to the instrument when it was found that the original four axes were too restrictive in their coverage of reciprocal space in the out-of-plane direction. Later instrument designs have incorporated α axes as a matter of course.

The convention for the zero settings of the axes is defined as follows: $\alpha = 0$ when the incident beam is perpendicular to the main horizontal axis. The remaining definitions all correspond to $\alpha = 0$: $2\theta = 0$ (dial = 270 for the X16A instrument) when the incident beam strikes the center of the detector; $\theta = 0$ (dial = 270) when the χ axis lies exactly along the incident beam direction; $\chi = 0$ when θ and ϕ are collinear; and $\phi = 0$ is arbitrary and usually chosen to be the same as the mechanical dial setting. The names used by the usual computer program for these angular settings are TTH, TH, PHI, CHI, and ALP, as discussed below (see Appendix C).

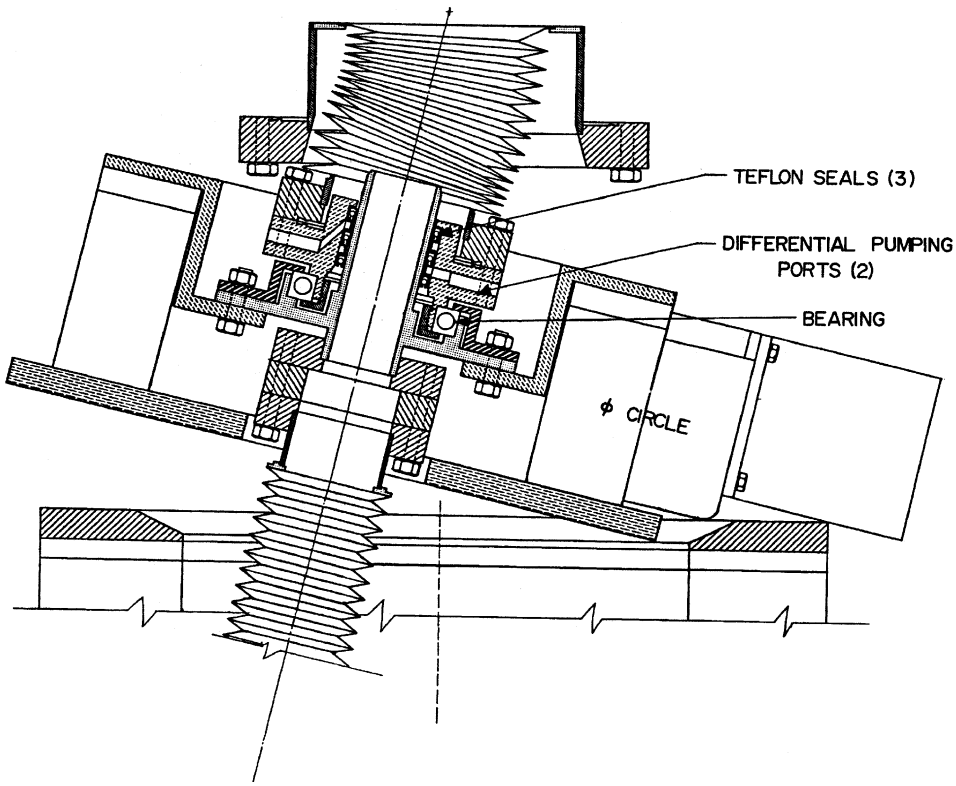

Figure 8. Cross-sectional view of the bellows and rotating vacuum seal that couple the rigid motions of the diffractometer to the sample in UHV. From Fuoss and Robinson (1984).

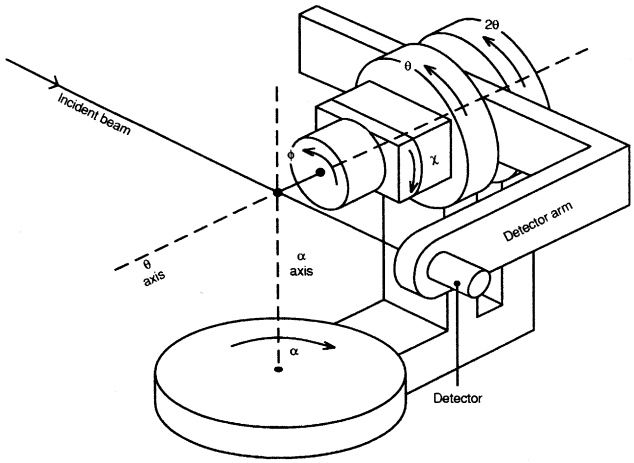

Figure 9. Isometric view of the five-circle diffractometer. The names of the axes and their positive directions of turning are indicated.

The additional degrees of freedom over the four circles of a nonspecialized diffractometer are needed for two reasons: (1) the additional constraints on the diffractometer setting due to grazing incidence or exit conditions and (2) the limited range of the angles due to potential collisions with the vacuum chamber.

The χ axis is particularly affected by the second constraint since it is limited to $\pm 0^\circ$ at X16A by the coupling bellows and also by the manipulator. There is also a "six-circle" geometry due to Abernathy (1993) with an extra angular out-of-plane degree of freedom for the detector, called GAMMA, a "Z-axis" geometry due to Bloch (1985) that is a subset of six-circle geometry without the ϕ and χ motions, and also a "2+2" geometry used for surface diffraction by Evans-Lutterodt and Tang (1995).

Laser Alignment

Many of the typical measurement methods of surface x-ray diffraction employ the grazing angle geometry (see Principles of the Method) on the incident beam, the exit beam, or both. It is therefore crucial that the physical orientation of the sample's surface be well known. To allow for the general case (rather commonly occurring) that the surface orientation is not a simple crystallographic orientation, perhaps due to miscut, it is important that the optical surface orientation be defined independently of the crystallographic orientation. This step is known as "laser alignment."

A laser beam is directed roughly down the main (θ) axis of the instrument and reflected from the polished sample surface and allowed to strike a screen located behind the laser. If the θ axis is rotated, the reflected spot will precess in a circular orbit. The center of this circle is the correct laser reflection angle if the sample face were exactly perpendicular to the axis. The beam can then be directed onto this center by adjustment of the diffractometer ϕ and χ angles until the laser spot remains stationary upon rotating θ. These settings, called fphi and fchi in the detailed protocol below (see Appendix C), are then a unique representation of the sample's optical orientation and are entered into the diffractometer control program so that the incident and exit angles can be precisely controlled.

Sample Crystallographic Alignment

Sample alignment is normally achieved by finding the diffractometer settings for diffraction from a small number of bulk Bragg peaks. If the lattice parameters are known, a complete orientation matrix is specified by the positions of just two Bragg peaks using the method of Busing and Levy (1967). If the lattice parameters are not known, it is necessary to specify the positions of at least three noncoplanar Bragg peaks. The orientation and calculation of arbitrary settings will be made by the control program once this information has been furnished.

The usual procedure for locating the Bragg peaks is to manually vary the diffractometer angles to maximize the diffracted intensity. This is less straightforward with a five- or six-circle diffractometer than with the more standard four-circle instrument, simply because there are more degrees of freedom in which the user can get lost. A reflection has 3 degrees of freedom, so the five-circle diffractometer has two motions too many. In particular, the detector moves on two axes, one of which (α) also moves the sample: there is no longer a simple connection between Bragg's law and the detector motion. Here are some guidelines on the suggested method of finding peaks:

1. Set up a "dummy" orientation matrix (OM) with the best known values of the lattice parameters (see Appendix C). Two mutually perpendicular in-plane reflections can be specified as having the laser orientation angles. From here, the setting of a suitable bulk out-of-plane Bragg peak can be calculated. In-plane peaks are hard to find because both incident and exit beams must be exactly grazing; out-of-plane peaks have a much wider choice of possible settings. Set the diffractometer at that position.
2. The desired reflection can be found by rotating the sample about its surface normal using either ϕ or θ. The peaks are so strong with synchrotron radiation that the motors can be searched at top speed; the reflection will "flash" on the detector oscilloscope or rate meter. There is usually sufficient thermal diffuse scattering (TDS) for a peak to be found in this way, even when it is several degrees away from the line that is searched.
3. Ride up the TDS until the center of the Bragg peak is found. Diffracted beam attenuators will be needed at this stage. Centering can be quickly and automatically carried out with "line-up" (lup) scans of a single motion (see Appendix C), after which the program calculates the center of mass and sends the motion there.
4. When using a PSD with an entrance window that is wide along the q_z direction, the peak may appear at any position along the length (q_z). Since the diffractometer is aligned to the center point of the detector, the contents of the PSD in the MCA must be viewed

(function key F1 or F2) and the peak made to walk to the center. Alternatively, a region of interest should be defined about the center and only the counts in this region used for reflection centering.

5. Once a peak is centered, it is better to rotate the dummy matrix manually to the corresponding orientation. This way both defining reflections are rotated together. If merely one of the reflections is overwritten, the resulting two-peak orientation matrix may be very unrealistic and will make it hard to find the second peak. Alternatively, the second dummy reflection can be chosen to coincide with the surface normal direction.

Once two peaks are found, the orientation matrix is complete and can be used to find any further points in reciprocal space. There will always be small errors of both crystal and diffractometer alignment, which may accumulate and result in poor prediction of further Bragg peaks. There are two ways of avoiding this problem:

a. Use alignment peaks that are most relevant to the features to be measured. For example, a good alignment for measuring a CTR would be to choose two Bragg peaks through which the rod passes.
b. Use multiple-peak alignment. Diffractometer alignment errors can be partially compensated by using the crystallographic unit cell parameters as free variables. An excellent orientation matrix will always be obtained by using a least-squares refinement of the best lattice passing through many Bragg peaks, especially if they are at large diffraction angles.

DATA ANALYSIS AND INITIAL INTERPRETATION

The following summarizes the different ways to present surface x-ray diffraction data to express one or other sensitivities or strengths of the technique. Different material properties of a given surface or interface would require entirely different kinds of measurement to be made. Each subsection lists a different form of presentation of the data that the reader might encounter in the published literature, then describes the typical measurement involved, and finally cross-references the typical diffractometer scans (Appendix C) and typical data analysis steps (Appendix B) that might have been followed. At the end of the section, a worked example is given.

Rod Profiles

Crystallographic measurements referred to above (see Principles of the Method) are used for surface and interface structure determination. The same procedures apply to CTRs or superstructure reflections. The general form of the data is to convey the magnitude of the structure factor along a line of points in reciprocal space, running along a line perpendicular to the surface. Theta-rocking scans (see Appendix C) are taken at a range of q_z values or Miller index L. These are numerically integrated and background subtracted, e.g., using the program PEAK (see Appendix B). For reliability, it is essential to measure multiple reflections related by the surface symmetry. When these symmetry equivalents are merged together, e.g., using the program AVE (Appendix B), their reproducibility is thereby determined and then used to specify the experimental error in the structure factor magnitude. Further details, including the equations defining the error estimate are given by Robinson (1990b).

The data are usually plotted as smooth curves against the perpendicular momentum transfer, L. Since the structure factor is a continuous function, enough L points must be measured to be sure that the profiles are smoothly varying and that all oscillatory features are resolved. This last caution is particularly apt in the case of thin films, which have many closely spaced thickness fringes; in this case, some researchers choose to simply scan along the q_z ridge of intensity in a "direct rod scan" and then to offset the θ angle and repeat the scan to estimate the background.

The rod profiles are then fit to the functional form of the structure factor of an atomic model of the surface, as outlined above (see Principles of the Method). In the kinematical limit, both for CTRs and superstructure rods, this is given by a complex linear sum over atoms representing the superposition of atomic form factors. Closed-form expressions are needed for the form of the CTRs to account for the infinite sum. The surface roughness must also be accounted for at this stage. The program ROD, written by E. Vlieg and described in Coppens et al. (1992) (see Appendix B), is a widely used computer program for this purpose. Atomic models of bulk and surface regions are specified in parametric form in a very general format. The parameters of the model are then refined by a least-squares minimization to give the atomic coordinates on the model.

It should be noted that surfaces are very different from bulk matter in the specification of atomic models. Each layer of the structure is expected to have a different Debye-Waller factor representing its atomic vibration amplitude. These Debye-Waller factors usually increase significantly in magnitude in passing from the bulk outward in the structure. Another common feature of surfaces is partial occupancy of lattice sites. It is also common to find more than one site, each partially occupied, for a structure with disorder. All of these situations are handled by the ROD program (see Appendix B). Finally, surface atoms are prime candidates for anharmonicity, since they have neighbors on one side but not the other. Surface anharmonicity has been analyzed in the pioneering work of Meyerheim et al. (1995).

Reflectivity

The specular reflectivity is the special case of the CTR emanating from the origin of reciprocal space. While it can be measured in the way described in the previous section, this can also be achieved with the simple two-circle method if the sample is mounted perpendicular to the θ axis. It is customary to plot reflectivity data as the square of the reflection coefficient versus total momentum transfer, q_z. This gives a normalization to the data different

from the crystallographic standard described above: an ideally terminated surface would have an intensity dropping as q_z^{-4} in these units, according to the Fresnel law of reflection. To emphasize the differences, the reflectivity divided by the (calculated) Fresnel reflectivity is often what is plotted. There is a correction for the total external reflection region at small angle, which can be understood with a simple dynamical treatment.

Als-Nielsen (1987) has derived a "master formula" for the analysis of reflectivity data in terms of the spatial derivative of the electron density profile of the surface. When q_z is small, the resolution is insufficient for atoms or atomic layers to be located, so the electron density is parameterized as a series of slabs of variable density connected by error function shaped transition regions of variable width. These parameters are then refined by least squares to fit the data and obtain the electron density profile explicitly.

Reflectivity is the method of choice for measuring the sharpness of the layer profiles of artificial multilayer structures that are chemically modulated by varying their composition during deposition. Thick multilayers of electron-dense materials require a full dynamical treatment for correct analysis, in which transmission and reflection coefficients of each layer interact self-consistently. The theory was worked out by Parratt (1954) and has been implemented by Wormington et al. (1992). It is also commercially available as a software product called REFS from Bede Scientific.

Surface Diffuse Scattering

Surface roughness can be measured quantitatively using the CTR profiles, as mentioned above (see Principles of the Method). It is also measured routinely by the reflectivity method above. In either case, the intensity that is missing from the CTR or the reflectivity, resulting in a lower signal, reappears as diffuse scattering nearby. This was clearly explained in terms of the lateral correlations associated with the roughness in an important paper by Sinha et al. (1988).

The surface diffuse scattering can be measured most easily near the origin of reciprocal space by means of wide θ scans (see Appendix C). Such scans have several characteristic features that have simple interpretations: in the center there appears the CTR or the specular reflectivity as a sharp spike; at the two ends of the scan lie the "Yoneda wings," where the diffuse intensity rises by the $|T(\alpha)|^2$ transmission function as $\alpha_i \approx \alpha_C$ or $\alpha_f \approx \alpha_C$; in between lies the surface diffuse scattering. Multilayer samples are found to have rich surface diffuse scattering patterns that provide information about the correlations between the positions of the various layers making up the multilayer.

Reciprocal Lattice Mapping

In some surfaces undergoing phase transitions or morphological changes, there is valuable information in just the diffraction peak positions, widths, and intensities. For example, surface diffraction is extremely sensitive to the appearance of new periodicities in surfaces, and this has been exploited extensively. The measurement consists of recording wide scans, e.g., using the *iscan* and *jscan* described below (see Appendix C), along simple directions of reciprocal space. Such curves would be plotted as a function of temperature, time, or other control variables. Sometimes two-dimensional scans (*kscan*) are also made to map out all the identifying features. A crystal analyzer, which provides much higher **q**-resolution, may be needed to separate finely spaced features.

The materials properties of interest that can be derived from such measurements concern grain shapes and sizes and the degree to which these are strained. The positions of Bragg peaks in any diffraction experiment determine the lattice parameters of the sample crystal; e.g., high-resolution x-ray diffraction is probably the most accurate of all and can achieve 1 part in 10^5 using the Bond method. Such measurements provide information about strain and its distribution within the sample. Similarly, accurate measurements of diffraction line widths, through the Scherrer formula, determine the size of the diffracting grain. In both these situations it is routine to use a careful lineshape anaylsis to extract the most reliable sample parameters. The semi-automatic program ANA described below (see Appendix B) provides a battery of possible lineshapes that apply to different kinds of diffracting objects or distributions of objects.

Grazing Incidence Measurements

Grazing incidence measurements fall into two categories. The first is a simple extension to all of the above techniques to determine materials properties as a function of depth inside a sample. Grazing incidence of exit conditions is then employed to vary the penetration depth into the bulk, which can be calculated reliably from the known refractive index and absorption values of the material at the x-ray energy used. The distribution of depths sampled is always exponential, so it is never possible to select a particular depth of interest; for this purpose it would be necessary to use a nonlinear technique such as ion scattering (see Chapter 12). Dosch (1992) has suggested the use of Laplace transforms to deconvolve the depth information.

Since the incident and exit angles always have to be under control in a surface x-ray diffraction experiment, it is a routine extension of the normal procedure to deliberately control them. For example, with the diffractometer control program "super," the penetration depth can be chosen by setting the target value of the incident or exit angle, α_i or α_f (B or B2 in Appendix C). A useful extension is to make a *vscan* at a fixed reciprocal lattice position as a function of α_i or α_f.

The second category of grazing incidence measurement is to use the PSD to record an entire α_f profile in a single measurement. This method was pioneered for the study of surface-phase transitions in a depth-resolved way by Dosch (1987, 1992). It has the advantage that diffractometer motions are not required during measurement of small changes with temperature. More recently the method has been improved by Salditt et al. (1996) to record and analyze diffuse scattering from multilayer samples as a function of exit angle α_f in a PSD by making wide θ scans at fixed α_i.

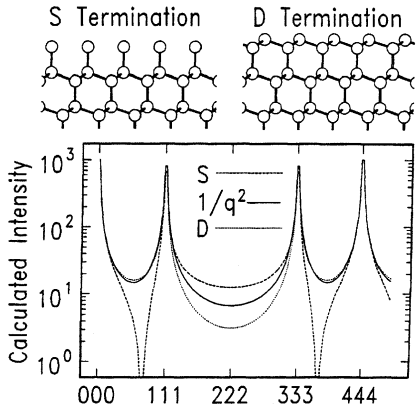

Figure 10. Top: the possible S and D terminations of the Si(111) surface. Bottom: calculated specular reflectivity for the two terminations according to the CTR theory and by superposition of $1/q^2$ intensity distributions.

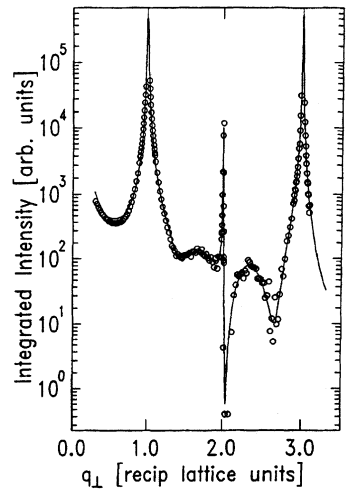

Figure 11. Measured x-ray reflectivity of a UHV-prepared Si(111) sample using a PSD. The solid line is the least-squares fit to a model based on the DAS model for the 7 × 7 reconstructed surface due to Takayanagi et al. (1985). From Robinson et al. (1994).

Worked Example: the Si(111) Surface

When the bulk crystal has a sufficiently simple structure, in the case of all primitive crystal structures, or the NaCl structure, there is only one possible way to cut the lattice to reveal a surface. However, in this case, the CTR presented above (see Principles of the Method) is technically indistinguishable from a simple superposition of $1/q^2$ intensity tails around each Bragg peak, as discussed by Robinson (1990a). Whenever the crystal has a multiple-atom basis that allows for more than one possible termination, the shape of the CTRs depends on which termination exists and is then clearly distinguishable from the superposition of $1/q^2$ intensity tails.

Such is the case of Si(111), where two possible terminations can exist, as illustrated in Figure 10. The double-layer (D) termination occurs when bonds perpendicular to the surface are cut; the single-layer (S) termination occurs when we break the bonds inclined at 19° to the surface, as shown. The density of dangling bonds is three times greater for the latter case, so it might be considered less likely to occur. The calculated CTRs are plotted for the two cases in the lower half of Figure 10. Up to a factor-of-10 difference in the two structure factors is seen to occur.

In reciprocal space, the specular reflectivity line is the direction with the momentum transfer, $\mathbf{q}$, entirely perpendicular to the surface. This corresponds exactly to the zeroth-order CTR diffraction and so can be thought of as a CTR; the analysis of these data is particularly simple because only the vertical components of the atomic coordinates enter, by virtue of the section-projection theorem of Fourier transforms. The question, then, is how is the real Si(111) surface, prepared in UHV, terminated? This is complicated by the fact that it is reconstructed with 7×7 translational symmetry.

Example of Measurements from Si(111)7 × 7

Figure 11 shows the measurements of the specular CTR of Si(111)7×7 using an improved data collection method. An x-ray PSD was placed so that it cuts across the diffracted beam. The background is then measured simultaneously with the integrated intensity of the diffracted beam and can be immediately subtracted. It is clear from the data that neither the S nor D simple termination adequately describes the surface. The figure also shows the result of a least-squares fit to the data, which passes through the points respectably well. The model used was the dimer-adatom-stacking fault (DAS) model for the Si(111)7 × 7 reconstructed surface due to Takayanagi et al. (1985). The heights of the atoms and the vibration amplitudes in the top four layers were adjusted for a good fit using the program ROD described in Appendix B.

Figure 11 also shows an additional sharp feature in the center of the scan at the position of the specular 222 Bragg reflection. This is indeed the specular 222 Bragg reflection, which is forbidden in diffraction from the ideal diamond lattice but is not perfectly extinguished for two reasons suggested by Keating et al. (1971):

1. The vibrations of the ions in the lattice are not spherically symmetric but tend to bulge out along the tetrahedral directions (four of the eight {111} directions) opposite to each bond; the anisotropy is along different directions for the two atoms in the basis, meaning they are crystallographically inequivalent.
2. The electrons forming the sp^3-hybridized bonds between the Si atoms are not spherically symmetric either but have a tetrahedral shape, again meaning the two atoms are crystallographically inequivalent. This affects 4 of the 14 electrons in the Si form factor so it is a relatively large effect.

It was shown many years ago by Keating et al. (1971) that contribution 1, which is temperature dependent, is dominant in neutron diffraction, while contribution 2 is more important in x-ray diffraction experiments. We therefore included extra bond charges in our model to fit this 222 peak in our data. It is orders of magnitude weaker

than the bulk diffraction but still stronger than the surface component of the CTR. A particularly noteworthy feature is the interference between the tails of the 222 and the CTR.

PROBLEMS

This section is a critical appraisal of the weaknesses of the surface x-ray diffraction technique. It might be used in evaluating published work, e.g., in searching for alternative explanations of results obtained with the method.

Surface Crystallographic Refinement

Crystallography has an inherent "phase problem." It is the structure factor amplitudes that are measured, not the phases. The solution of an atomic structure amounts to testing hypothetical models for agreement with the measurements. It is assumed that a good fit will only occur for one model, which therefore finds unique values for the missing phase information.

The difficulty with this logic is that it depends upon the quality and quantity of the data. For good, numerous data, experience has shown that there is usually a unique solution. In fact, many researchers are frustrated by the situation that they cannot find a model that agrees with their data! This is a heuristic support for the notion of uniqueness. "Direct methods" of structure solution, which exist for small-molecule crystallography (Woolfson, 1997), are being developed for surfaces but are not yet ready for widespread use.

The problem arises when there are insufficient data for the solution to be determined. The accepted rule of thumb (Lipson and Cochran, 1966) is for the structure to be overdetermined by a factor of 3:1. This means that for every structural degree of freedom in the model, there must be three independent measurements. It is presumed that nonuniqueness of the solution would be extremely unlikely when three separate measurements must all agree with each other for every parameter determined. For this to work, the counting must be done honestly: we will consider first the question of counting model freedoms and then that of counting the data.

It is possible to tie structural parameters together to reduce the degrees of freedom, but this always requires assumptions or constraints on the possible structures that might exist. Chemical constraints such as bond lengths and angles are usually safe, but sometimes unorthodox chemistry can take place at surfaces. This is often done through a Keating model (Keating, 1966) where a penalty for nonstandard bond lengths and angles is added to the χ^2 functional used for least-squares minimization. Another common constraint is to collect the less-sensitive parameters, such as Debye-Waller factors, into groups applying to several related atoms. Yet another constraint is to enforce exponential decay of relaxation parameters from the surface toward the bulk; this amounts to assuming the form of the solution of the Poisson equation describing continuum elasticity in the material. In each case, if the hypothesis leading to the constraint is questionable, then the conclusions drawn are questionable.

A similar logic concerns counting the data. This relates also to their accuracy, which can be measured in the way described above (see Practical Aspects of the Method). The situation is more complicated for surface than for bulk crystallography because the data are in the form of "rod profiles," which are continuous functions of L. The amount of information in a given rod profile can be counted, but this must be done carefully: every distinct maximum and minimum in the rod counts as one independent data point. Whether or not an extremum is distinct is closely tied to the size of the error bars of the measurement.

In principle, all error analysis should be handled through the definition of the normalized χ^2 functional, which is weighted by a factor $1/(N - P)$, where N and P are the number of data and number of parameters that we have just defined. The danger is that, while P is usually correct, N is frequently overestimated because it counts separately all the data points along each rod, rather than just the number of extrema. Nonspecialists and specialists alike quote a small goodness of fit χ^2 (near 1.0) value as an endorsement of the correctness of a structure. This is nonsense! A small χ^2 simply means that the data have been exhausted and the model is sufficiently detailed; it does not necessarily mean it is right. An easy way to obtain a small χ^2 is to measure very few data!

In examining published work, there are certain indications that the refinement of the structure had been difficult. Debye-Waller factors are sometimes omitted because they refine to negative values when included. Negative Debye-Waller factors are unphysical and so usually indicate some other deficiency in the model. Another bad sign in a structural model is when many atoms with partial occupancy have been included. Partial occupancy is common on surfaces, because of their nature: when a crystal is cut, it must have a boundary, but not necessarily one with an ordered structure.

Other Surface Crystallography Problems

Regarding the question of the quality of structure factor data, some aspects are specific to the case of surfaces. Apart from gross misalignments, there are subtle ways that additional errors can be introduced. When grazing incidence is used, the slightest variation of α_i from one measurement to the next causes a different value of the $|T(\alpha)|^2$ prefactor and hence the observed structure factor. In an extreme case, misalignment can cause α_i to become negative and the beam to disappear below the horizon. Sample curvature can aggravate the problem, leading to a different distribution of α_I values along different incidence azimuths. The only safe way to avoid the problem is to measure symmetry-equivalent reflections and record the data reproducibility.

When CTR data are included, there are several dangers associated with measuring very close to bulk Bragg peaks. Highly structured background is commonly found and must be carefully subtracted. The problems are compounded when the out-of-plane detector resolution is opened up to improve counting rates. There can be a significant distortion of the data from the L variation of the intensity across the detector slit. The safest strategy is to

avoid including data near the Bragg peaks, except where absolutely necessary.

Another problem can arise from unavoidable beam harmonics. The detectors are not always capable of discriminating $\lambda/3$ (and $\lambda/4$, etc.) contributions completely. This means that any measurement at or near an integer fraction of a bulk Bragg peak can give a strong "glitch." For simplicity, it is common to avoid all measurements at small-integer fractions of L.

A different source of possible misconception concerns symmetry. There are many cases of published work where the surface structure has lower symmetry than that of the underlying bulk crystal. For example, all reconstructed surfaces have lower translational symmetry than the bulk, and this is accepted for chemical reasons. The general rule is that a surface structure should have as high a symmetry as possible, compatible with the symmetry of its parent bulk. Only when this is shown to be impossible should the symmetry be broken. Then one symmetry element at a time should be removed from the model, since each symmetry that is lost can greatly increase the number of degrees of freedom.

A common source of confusion is that the symmetry of a surface is not immediately obvious from the symmetry of the diffraction pattern. Domain formation is common on surfaces, where differently oriented regions nucleate in different locations. It is usual to average the intensity contributions from each of the orientational domains, rather than the structure factor. This amounts to the assumption that the domains are far apart, beyond the coherence length of the measurement. The opposite limit of microdomains within the coherence length is usually apparent from a broadening of the peak lineshapes. This can be handled by mixed structures with partial occupancy once the peaks have been integrated correctly to account for their enlarged widths.

Lineshape Analysis

The purpose of analyzing lineshapes is to extract parameters that relate to materials properties so that they can be tracked as the sample is varied in some way. It is usually the peak position and/or width that is of interest. Typically the fitting is done directly to the output data stream in a semi-automatic way, e.g., using the program ANA described in the detailed protocol in Appendix B. If the curve that is used for fitting has the wrong shape, systematic errors will be introduced that may or may not have consequences. For this reason, a battery of lineshapes is usually available, sometimes with several adjustable parameters. A good example of a generally useful lineshape is the Lorentzian function raised to a power:

$$p(x) = A[(x - B)^2 + C^2]^{-D} \qquad (2)$$

where A, B, C, and D are adjustable parameters (B and C are the position and width most often sought). The danger here is that of parameter coupling or nonorthogonality, particularly between parameters C and D. If D is just allowed to vary from one fit to the next, and then later ignored, unwarranted changes in C may occur that are not really present in the data. Here, the solution is to find a value of D that applies to most of the data, then fix the parameter for fitting the data series to look for the trends.

A different situation applies to the handling of background, which is seen as a nonvanishing intensity in the extension of the tails of a peak. The background is due to unwanted additional scattering sources within the sample or the instrument. Usually the background is subtracted by extrapolation. The background can have a profound effect on the stability of fitting lineshapes such as the Lorentzian function raised to a power above, especially if D is the parameter of interest. The best advice here is to measure a lot of background extending far away from the peak; this has a surprisingly beneficial effect in constraining the fits of functions with long tails such as this.

The best procedure for measuring diffuse scattering is again to control and understand the background. By its nature, there is no perfect way to separate diffuse scattering from background. The most difficult situation is that of small-angle scattering near the direction of the incident beam, which applies to the nonspecular reflectivity region for surfaces discussed above (see Data Analysis and Interpretation). Here, the potential sources of background extend all the way back up the beamline to the entrance slits and beyond. A common hazard in diffuse scattering measurements is the tails of the resolution function, which appear to be CTRs pointing in apparently unusual directions. In fact, they are the CTRs of the crystals in the monochromator or analyzer rather than those of the sample!

DETAILED PROTOCOLS

The exact procedure will vary slightly from installation to installation, but the general principles will be the same. To be specific, we discuss here the procedure for the X16A surface diffractometer at NSLS. The generalization to other installations will usually be obvious. Details of the vacuum procedure are given in Appendix A, the data analysis programs in Appendix B, and the diffractometer control program in Appendix C.

Alignment of the Beamline

The X16A beamline, like many others used for diffraction, consists of a grazing incidence toroidal mirror and double-crystal monochromator. It is the responsibility of the NSLS facility staff to help the user get to the point of operating the beamline. This requires verification of all safety-related hardware on a "safety checklist" and that the condition of all cooling and vacuum systems be "green" before the safety shutter will open.

The mirror focusing is 1:1 and so should produce a focal spot on the sample ~1 mm wide by 0.5 mm high. The focal length is fixed and requires the correct incidence angle of 5.65 mrad, which fixes the final height of the focused beam. It is important to ensure that the height is correct by using a focusing screen near the sample position and a TV camera with a close-up lens. The beam image is a U-shaped

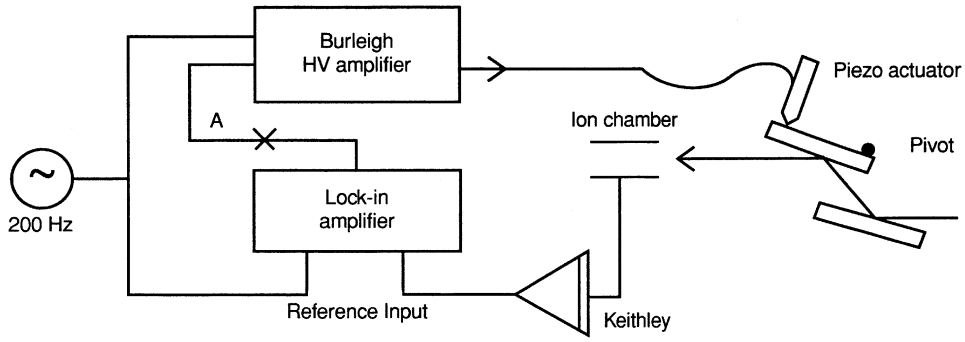

Figure 12. Monochromator feedback circuit. Point A is where the feedback loop should be broken in order to detune the monochromator.

"smile" when the incidence angle is too low and an inverted smile when the incidence angle is too high. The locus of focal images traces out an X shape on the screen upon tilting the mirror, with the optimum focus at the intersection of the X. A tilted smile means the mirror is not steered correctly and requires rotation about the vertical axis. The mirror bend should then be adjusted for the smallest vertical profile, and the beam position should be scanned to verify it is not being cut by any nearby aperture edges.

The double-crystal monochromator is controlled by five manual adjustments. The energy is set by a stepping motor on the back of the tank that is driven by a manual pulser. This can also be controlled by pulses from the beamline computer if needed. The energy reading is a dial counter, which is converted to kilo-electron-volts on a chart in the beamline log book. The θ and χ angles of each crystal are controlled by stepper motors driven by a shaft-encoder knob and selected by one of the four red "engage" buttons. The four angles are also read out by absolute encoders. It is very important not to move these in-vacuum motors far from their starting positions because there are no limit switches. After changing energy, it is necessary to bring the two crystals parallel again by adjustment of θ_2 until a signal is seen in the ion chamber. Side-to-side steering of the beam position is achieved by χ_1, which is generally used to bring the beam onto the sample (see below).

The monochromator feedback circuit is shown in Figure 12. The second crystal is modulated at 200 Hz by a piezoactuator. When its rocking curve is correctly centered on that of the first crystal, the lock-in amplifier reads zero output; if the angle is misset, a positive or negative error signal is generated that corrects the angle. The loop gain and integration time may have to be adjusted for correct performance. To detune the monochromator (e.g., to remove harmonics in the beam), the loop must be broken at point *A* and the crystal angle set manually.

Alignment of the Diffractometer

The intersection of the five axes of the diffractometer is at its center, and this must be positioned accurately on the beam's focal spot. This must be correct to within 100 μm. The beam direction must also be perpendicular to the θ and α axes to within 0.1° and 0.3°, respectively. Because a surface x-ray diffractometer has a sample in a UHV environment also at its center, this presents a special challenge.

The vertical position is set by four screw jacks under the diffractometer table. These are manually or stepping-motor driven in two pairs, front and back, to allow the table to be tilted until the beam is perpendicular to the α axis. The tilt is equal to the beam's known 11.3 mrad angle to the horizontal and preset using a spirit level and rulers. The horizontal position is set coarsely using surveying marks and finely by moving the beam with the χ_2 monochromator adjustment. The perpendicularity of the theta axis is determined by the choice of the zero of α.

The essential alignment tool is an "off-axis pinhole" that is an L-shaped bracket with a 1-mm pinhole drilled through it. This bolts onto the ϕ circle of the diffractometer so that it wraps around the outside of the UHV chamber and presents itself to the incoming or outgoing beam, as shown in Figure 13. The distance from the pinhole to the mounting surface is accurately machined so that it corresponds to the manufactured radius of the χ arcs. Because of its offset from the center, the position of the pinhole with respect to the beam is scanned by moving the ϕ and χ axes of the diffractometer.

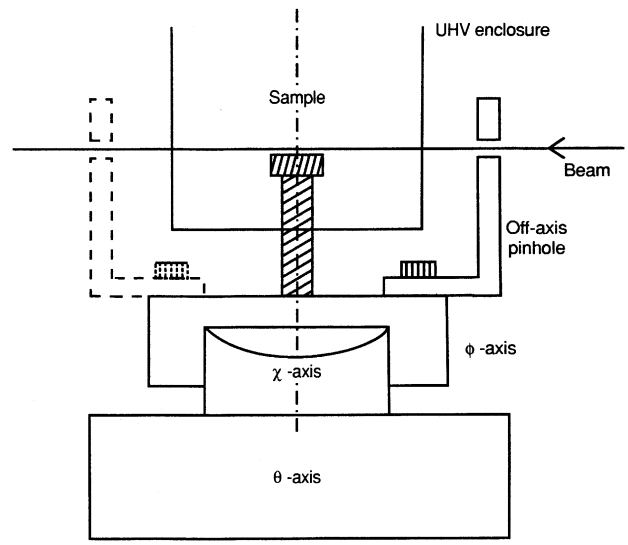

Figure 13. Off-axis pinhole designed to mark the center of the diffractometer without breaking the vacuum. The dashed position is reached by a 180° rotation of the θ axis.

Because the sample is blocking the true center position so that the x-ray beam cannot pass, the alignment must be carried out at a controlled location just above it. This is done by tilting the diffractometer χ by a known amount (usually 1°) from its calibrated zero and moving the beam with the χ_2 (monochromaor) to correspond. The center position of an arbitrarily placed starting beam is determined in (ϕ, χ) space with the pinhole on one side of the sample and then again on the other side. An exact 180° rotation of θ takes the pinhole from front to back, as shown in Figure 13. Half the difference between the two ϕ values multiplied by the lever arm L is the error in the table height, which is thereby corrected. Half the difference between the two χ values is the deviation of the beam from perpendicularity with the θ axis, which defines the zero of α.

Once these corrections have been made, the pinhole is exactly aligned with the diffractometer center, offset horizontally to avoid the sample. The beam, passing through the pinhole, can then be used to set precisely the vertical incident and exit beam collimation slits. If the pinhole is then removed and the beam moved until it grazes across the sample at the center, the horizontal slits can be set too. This is also the opportunity to set up the channel definitions of the PSD (if used), by marking off known distances from the calibrated center line.

The centering of the α axis with respect to the other four is also adjustable, owing to its historical origin as an auxiliary sample motion. The adjustment is by means of a motorized linear translation across the beam and slotted screw-holes in the direction parallel to the beam. Previous settings of these adjustments are recorded in the logbook, and these should be used as starting values. The alignment should not be needed often as the performance does not depend critically upon it; the usual symptom of misalignment is a loss of intensity at large values of perpendicular momentum transfer. It is carried out using the off-axis pinhole once this has been centered exactly on the beam following the procedure above. Then θ is rotated by exactly 90° so that the pinhole is pointing straight up, thereby marking a point exactly above the intersection point of the axes, as can be seen in Figure 9. The center of the α axis is then brought to intersect this marked point by using the translations. This is most easily performed with a high-magnification TV camera hanging down from the hutch roof: when α is rotated by hand, the pinhole position should be invariant.

Angle Calculations

The principal purpose of the diffractometer control program is to make the angle calculations that map the reciprocal crystal coordinates onto the angle setting of the diffractometer. This calculation depends on the mode of operation of the instrument, which is the "five-circle" mode for the installation discussed here. The program also contains the software drivers for the axis motors corresponding to the diffractometer angles so that these can be moved by the program. It also generates the most useful kinds of scans automatically and keeps track of the orientation matrix. Its other major task is to produce the output files that contain the results of the experiments organized in a readable format. Here we make reference to the diffractometer control program "super," but many of the basic principles are common to other programs, e.g., the commercial "spec" program used elsewhere and available from Certified Scientific Software. Details of the command structure of "super" are included in Appendix C.

Angle calculations in the five-circle mode are described in a paper by Vlieg et al. (1987). The diffractometer has 5 degrees of freedom in the most general five-circle mode (alm = 2) and 4 degrees of freedom when alm = 1 (see Appendix C, Basic Super Variables). Three of these are needed to select a point of measurement in (3D) reciprocal space; one more is used to constrain the incidence or exit angle (see bem in Appendix C, Basic Super Variables). The 5th degree of freedom is used to help control the resolution function, bearing in mind that the diffraction features to be measured are highly elongated into "rods" along the direction perpendicular to the surface: the program arranges for the crystallographic c^* axis to lie in a horizontal plane. When the diffraction rods (assumed parallel to c^*) are horizontal, the vertical high-resolution direction lies exactly across them.

The constraints on the five-circle diffractometer will allow inclination of the incident beam (ALP), but not the exit beam (GAMMA), from the sample plane. Because of the limits on CHI, the sample must lie within some degrees from perpendicular to the main TTH/TH axis. A consequence of these constraints is that most reciprocal space is accessible only in the bem = 2 mode (see Appendix C, Basic Super Variables) in which grazing exit conditions are maintained. This has the advantage that the PSD can then record the exit beam transmission profile for all reciprocal lattice settings. The exit angle (set by the variable B2) arises from setting TH near TTH + 90° and tilting CHI to a value near the negative of B2, as can be seen with the aid of Figure 9. The exact values depend on how close the "laser alignment" (see Practical Aspects of the Method) angles are to the ideal flat setting, fchi = 0. For this reason the θ axis should be expected to work roughly in the range $90° < TH < 150°$ and the limits should be set to accept this range, e.g., $-30° < TH < 150°$.

ACKNOWLEDGMENTS

It is a pleasure to thank the various people who have helped develop this technique and the X16A facility over the past 15 years. Paul Fuoss helped develop the beamline and original surface diffractometer hardware. Elias Vlieg invented the five-circle mode and wrote the data analysis programs. Robert Fleming wrote the diffractometer control program. Alastair MacDowell developed the manipulator design. During the design and construction stages, the following people worked very hard: Warren Waskiewicz, Laura Norton, Steve Davey, and Jason Stark. In later years the input and contributions of the following people have been invaluable: Ken Evans-Lutterodt, Rolf Schuster, Peter Eng, Peter Bennett, and Don Walko. Finally, the vision and foresight of the Bell-Labs

management to finance the whole project, at a time when it was unclear that it would work, deserves great commendation.

APPENDIX A: VACUUM PROCEDURE

In order that samples have a chance to remain clean for the duration of an experiment, surface science experiments are usually carried out at pressures of 10^{-10} Torr or below, called the ultrahigh-vacuum (UHV) regime. Under these conditions, according to the kinetic theory of gases, an atom on the surface will be impacted by a residual gas atom from the vacuum about every 30 to 60 min. The vacuum protocols described here apply to the X16A facility at NSLS and are rather specific in this section. At other facilities, the principles will be the same, but the details will be a little different. In the latter case, the information provided here will enable the reader to assess the level of complexity involved in carrying out experiments under UHV.

Load-Lock Procedure

Because preparation of 10^{-10} Torr pressure is time consuming (see below), a load-lock procedure has been developed that allows simple manipulation of samples, thermocouples, and heaters to be carried out without venting the main UHV chamber. The principle of operation is shown in Figure 7. Load locking is very useful for batch processing a series of samples, e.g., or for introducing samples that cannot stand to be baked at 150°C.

To load a sample, first ensure that the loading chamber is under vacuum. Its turbopump should have been at full speed for at least 10 min. Then open the gate valve that separates the loading chamber from the main UHV chamber. The pressure may rise into the 10^{-8} Torr range.

Set the diffractometer to the precalibrated angle settings recorded in the logbook or use the preassigned macro definition, called "load." The manipulator is now exactly in line with the sealing surface and can be extended fully until the motor will not move further. As always, when moving the manipulator, it is imperative to watch the progress so as to avoid unexpected collisions. The centering can be verified by observing the final sealing approach through the load-lock window.

Once sealed, the loading chamber is vented with air by (1) depowering the turbopump, (2) isolating the roughing pump (it is not necessary to turn it off), (3) waiting for the pump to slow down significantly (~2 min), and (4) slowly unscrewing its black venting screw while observing the pressure in the main chamber. If the pressure rises, immediately reverse the procedure and reseat the sample.

If the procedure goes well, the UHV conditions of the main chamber will be retained by the electrical and thermal feedthroughs in the design of the manipulator head. The loading chamber can then be unbolted to allow changing of or modification to the sample.

The reverse procedure is to bolt the loading chamber back over the finished sample, open the valve to the roughing pump, and start up the turbopump. Anywhere from 5 to 30 min after the pump reaches full speed, the manipulator can be retracted into the main chamber and the gate valve closed. The pressure may rise momentarily into the 10^{-7}-torr range before dropping to 10^{-10} again. The fresh sample and filaments will now need to be outgassed by heating.

Venting Procedure

When more serious vacuum interventions are required, the entire chamber will need to be vented. The procedure here is similar to that described above, except there are more precautions.

First, turn off all filaments inside the main chamber and disconnect their power cables to avoid accidental activation. The ion gauge is protected and so may be left on. Close the gate valve to the ion pump if this is not to be vented also; otherwise turn off the power here as well.

Manually override the protection circuit to the turbopump gate valve, so that it does not close when the pump is turned off. This is done by powering the solenoid directly. Then the main chamber is vented with nitrogen gas supplied to its vent valve as follows:

1. Depower the turbopump.
2. Isolate the roughing pump (it is not necessary to turn it off).
3. Wait for the pump to slow down significantly (~2 min).
4. Switch on its venting circuit on the turbo control panel.

The pressure has equilibrated with the atmosphere when the bellows become limp. Overpressurization is avoided by a check valve in the nitrogen feed.

Bakeout Procedure

While the main chamber is open, the following routine maintenance may need to be carried out:

1. Replace the sublimation pump filaments.
2. Check the body of the manipulator for shorts or frayed wiring.
3. Recharge evaporation sources.
4. Clean any evaporated deposits from the interior of the windows.

The vacuum restart procedure is the reverse of the venting procedure given above (see Venting Procedure). The next step is the bakeout, which requires considerable disassembly of the diffraction parts of the experiment in order that they do not obstruct the ovens or get unnecessarily hot themselves. The following settings are advised:

1. The variables TTH, TH, CHI, and ALP should be set to zero (270 on dials of TH and TTH). The motor power can now be turned off.
2. The PSD high voltage should be turned off before moving it for storage.
3. Flight path vacuum should be turned off at its Nupro valve. The entire diffractometer TTH arm can now be dismounted and stored.
4. The turbopump gate valve should be in the protect mode (i.e., connected to its controller).

It is necessary to heat all of the chamber walls to 150°C for ~12 hr. This is achieved with ~1000 W of power distributed as follows:

1. Snap together the toggles that hold together the oven walls, which encase the main chamber. Any gaps can be filled with aluminum foil.
2. Lay the heater tape along the length of the manipulator and encase it with its clamshell oven. Any excess tape can be wrapped around the exposed feedthroughs.
3. Place the heater tape around the bellows/seal (between the diffractometer and the chamber).
4. Apply the following power settings: 110 V to each of two oven heaters and one ion pump heater, 60 V to heater tape around chi-bellows/seal; set the manipulator to 110 V if the tape is small (100 W) or to 70 V if the tape is large (300 W).

To shut down the bakeout, it is adequate to follow these quick steps:

1. Turn off all power.
2. About 30 to 60 min later, partially open roof of oven and unwrap the manipulator.
3. Another 30 to 60 min later, finish dismounting the oven.

The expected performance of the pressure will be in the 10^{-7}-torr range at the start, rising to 10^{-6} when hot and eventually dropping to 10^{-7} at the end of the bake. After the heat is turned off, the pressure will fall steadily and reach 10^{-10} Torr in $\sim$12 h.

APPENDIX B: DATA ANALYSIS PROGRAMS

A suite of data analysis programs have been written to perform the various steps of data analysis. The plot program ANA is the most generally useful, while the full set of four programs are needed for a complete surface crystallographic analysis. They were all written by Elias Vlieg and are much more widely used than just at X16A, so their description here will be generally applicable. The programs are designed to work with the data file structure of "super" (Appendix C) but also accept input in other formats, including "spec."

The programs are interactive with the user. The commands to all programs are either keyed in at a prompt or redirected from a macro (*.mac) file. Each entered line is a continuous string of commands and arguments delimited by spaces. The commands are mostly English or Dutch verbs and may be highly abbreviated, usually to a single letter. This is made possible by the use of a hierarchical "menu" structure that defines the logical sequence of allowed commands. Each command is followed immediately by its arguments (separated by spaces) or by a <CR> to be prompted for the arguments. For example, the setup commands specific to plotting in ANA are unreachable at the main level but are reached by typing *p(lot)*. At any level the command *h(elp)* will provide a list of available commands and *l(ist)* will provide current values and status.

Upon exit from any of the programs (except AVE), an executable macro file is generated that records the current options that have been defined during the last session. This file is automatically executed when the program is restarted so that the previous configuration is restored. In the following descriptions the commands are defined by their full names with the minimum abbreviation indicated using the syntax *p(lot)*.

Plot program ANA

This program maintains five data buffers into which spectra can be read. It uses the same buffers for generated fitting curves, so these can be superimposed. A variety of read formats are supported.

The *s(et)* menu is for setting parameters and modes. The *r(ead)* submenu is used to define filenames and column numbers for input. The *f(it)* submenu sets the mode of fitting, e.g., the weighting scheme.

The *r(ead)* menu is for reading in a spectrum and is followed by a format type, a scan number or filename, and a destination buffer number. Example formats are: *s(uper), c(olumn), x(y),* and *(s)p(ec)*.

The *o(perate)* menu is for manipulating spectra. Mathematical operations are available through the *ad(d), su(m), mu(ltiply),* and *sh(ift)* commands. Another functions is *l(ump)* for combining adjacent groups of data points within a spectrum. The function *me(rge)* combines two spectra, accounting for monitor counting time and removing duplicate data points; *w(rap)* removes 360° cuts in data; and *d(elete)* removes selected data points while *c(ut)* removes data points above or below a certain specified value.

The *p(lot)* menu makes graphs on the screen that can accumulate multiple entries for later printing or conversion to other image formats. A wide selection of *c(urve), s(ymbol),* and *li(nestyle)* options are supported. Curves can be *p(lot)*ed fresh or else *o(verlay)*ed and *ax(es)* and *te(xt)* can be supplied and modified. Logarithmic and linear scales can be chosen with, e.g., *ylog* and *xlin*. The program uses a commercial package called "graphi-c" for its plotting functions, and all file conversions of graphical output (including printing) must be handled through its internal mechanisms: hitting the space bar (a few times) allows access to the print menu of "graphi-c", and the simplest printout is activated by *l* for large or *m* for medium size.

The *f(it)* menu performs least-squares fitting to a library of functions. The command is followed by a code for the fit function required, which is assembled from *g(aussian), l(orentzian), v(oigt), p(owerlaw),* or *k(ummer)* components using commas as delimiters. Finally, the input and output spectrum numbers must be given. For example, the command "f g,l,l 1 2" will fit the sum of a gaussian and two lorentzians to the data in spectrum 1 and put the fit curve in spectrum 2. A two-parameter linear background is always assumed in addition to the chosen functions. Once inside the fit menu, the options are to *g(uess)* starting values of the parameters, specify a *v(alue)* by hand, and then *f(ix)* or *l(oosen)* these values. Finally, *r(un)* executes the least-squares fit and lists the parameter values.

A useful shortcut is the *a(utoplot)* menu with only two commands, *d(ata)* and *f(it)*. This generates a generic format plot with useful text information superimposed, such as the fitted values of the parameters.

Integration Program PEAK

This is a batch program for converting rscans and jscans (see Appendix C, Important Scan Types) into structure factors. It is assumed that the scans cut directly across the desired diffraction features whose intensity is then related to the square of the structure factor; misalignment will, of course, lead to underestimation of the structure factor. It is also assumed that the scan reaches far enough that the background can be estimated by linear interpolation between its two ends. The "stretching" feature of "super"

(see Appendix C, Important Scan Types) is designed to facilitate this.

The program is also responsible for four standard corrections to the data:

1. area correction, due to the changes in the active area of the sample as the diffractometer angles change, introduced by Robinson (1990b);
2. Lorentz factor correction, to convert an angular scan into an integral in reciprocal space, as in Warren (1969);
3. polarization correction, as in James (1950); and
4. monitor and stepsize normalization to account for different counting times and scanning rates that may have been used for different parts of the data.

Under the *c(olumn)* menu, it is necessary that all the diffractometer angles be identified by their column sequence number in the scan file. These must not change from one scan to the next.

The remaining parameters are entered at the command line. The *le(ft)* and *ri(ght)* numbers of points are to be considered as background; all points in between are integrated numerically to a total intensity. The *s(cantype)* can be *r(ocking)* or *i(ndex)* and will affect the Lorentz factor; all other scans found in the batch input will be ignored. For the area correction, the incident beam is taken to have dimensions *wi* vertically by *hi* horizontally, the sample has width *ws*, and the vertical exit beam slit is *we*.

The *r(un)* command followed by starting and ending scan numbers will perform the integration. Two output files are generated. The *.inf file has a line of information about each scan found, such as the date, background, and peak levels. The *.pk file contains the scan number hkl, the structure factor, and the structure factor error as the first three columns.

Averaging Procedure AVE

This procedure uses the *.pk output of PEAK to locate and compare all the symmetry equivalents. It determines an overall estimate of the average systematic error, ε, assumed to be a constant fraction of each individual structure factor value. The value of ε is taken to be a quality factor (R value on structure factors) in assessing the data, as discussed in Robinson (1990b). The program then passes through the data a second time to generate a weighted average value (file *.wgt) of each inequivalent structure factor with an enlarged error bar that combines its statistical errors input with its overall systematic error estimated in the first pass.

The *.ave output listing is very useful for finding bad data. It lists together all reflections that are equivalent according to the specified symmetry. Any that fall out of line are flagged with warnings indicating they should be checked. They are identified by scan number in the listing. This is also a useful way of testing the symmetry of the data, if this is unknown from context, since the program can be run with different preassigned choices of assumed symmetry.

The *s(et)* menu has submenus for defining *c(olumns)*, *s(ymmetry)* from the list of all 17 possible plane groups from p1 to p6mm, and *a(veraging)* parameters and modes. Under *a(veraging)* is the *c(utoff)* parameter, which is the number of times that a structure factor must be larger than its statistical error for it to be used in the estimation of ε. The default value (number of standard deviations) is 2σ, and this should be increased to 10σ if the data are not strongly affected by counting statistics.

Fitting Procedure ROD

This is a large refinement program for fitting a structural model to crystallographic data. It is specific to surface diffraction in that it calculates CTR rather than bulk diffraction structure factors. It differentiates the "bulk" and "surface" parts of the structure and includes a simple description of surface roughness that is usually necessary to get a good fit. The bulk cell is periodic and invariant; it only contributes to the CTRs. The atoms in the surface cell can be selectively refined in position, occupancy, and Debye-Waller factor. It is important that the z coordinates in the surface be a smooth continuation from those of the bulk.

The input files needed for ROD are as follows. All are expected to have a header line that is ignored on input. The second line of the first two files must contain the six unit cell parameters in real space, a, b, and c (in angstroms) and α, β, and γ (in degrees). The program checks that both are the same:

1. bulk unit cell coordinates, *.bul;
2. surface unit cell coordinates, *.sur (fixed), or *.fit (parameterized);
3. structure factor data, *.dat (renamed from *.wgt above); and
4. model parameters, *.par (optional).

In order that small data sets can be compatible with large models, ROD allows a very flexible parameterization scheme. The same displacement, occupancy, and DW parameters can be assigned to more than one atom. This is very convenient for structures that contain repeated motifs or different symmetries of components within the whole unit cell. In fact, the program does not handle symmetry at all, since this can always be built into the model; all structures are assumed to have triclinic, 1×1 unit cells.

APPENDIX C: SUPER COMMAND FORMAT

Commands have a variable number of arguments, depending upon the specific application. Arguments follow on the same line as the command and are separated by spaces or commas. Most commands will prompt the user for the required arguments if no arguments are given. Multiple commands may be placed on one line provided they are separated by a semi-colon.

Values of important control parameters are stored as "variables." To obtain the current value of a variable,

type its name followed by =. To change the value stored in a variable, type the new value after the =, e.g., as = 1.65. Rudimentary algebra is also allowed, e.g., as = bs * 3. Space characters are required as delimiters around the mathematical operation.

A manual of allowed commands will be available at the beamline. A list of all valid "super" commands can be obtained by typing "help" at the "super" prompt or using the F8 key. Pressing F5 lists the orientation matrix and the values of string variables. The values of all other variables are listed using F6.

Basic Super Commands

mv Move motors (four arguments: TTH, TH, PHI, CHI).
ct Count (one optional argument = preset).
br Go to position defined by H, K, and L (three arguments).
wh Print current H, K, and L and values of the motor angles (no arguments).
ca Calculate motor angles from H, K, and L (three arguments).
ci Calculate H, K, and L from motor angles (five arguments).
end Exit the program.

Basic Super Variables

as Crystal reciprocal lattice parameter a^*
bs Crystal reciprocal lattice parameter b^*
cs Crystal reciprocal lattice parameter c^*
al Crystal reciprocal lattice angle α^*
be Crystal reciprocal lattice angle β^*
ga Crystal reciprocal lattice angle γ^*
wv Incident wave vector $(2\pi/\lambda)$
nobs Number of alignment reflections used to calculate OM
h1, k1, l1, h2, k2, ... HKLs of orientation reflections
t1, u1, p1, c1, a1, u2, p2, ... 2-Theta, theta, phi, chi, and alpha of orientation reflections
B Target value of incidence angle, α_i
B2 Target value of exit angle, α_f
alm Mode of calculating ALP for five-circle geometry (alm = 1 means ALP is frozen at its current value; alm = 2 means ALP is calculated)
bem Mode of constraining incidence angle for five-circle geometry (bem = 1 means *incidence* angle α_i is fixed at target value B; (bem = 2 means *exit* angle α_f is fixed at target value B2; bem = 3 means incidence and exit angles are made equal)
fchi CHI angle of optical surface orientation (laser alignment)
fphi PHI angle of optical surface orientation (laser alignment)

Orientation Matrix

There are two ways of achieving the sample orientation, depending on whether the reciprocal lattice parameters are known or unknown. In the more commonly used "lattice parameters known" mode, the six reciprocal lattice parameters are entered manually using syntax name = value. The names of the six reciprocal lattice constants are as, bs, cs, al, be, and ga. Two orientation reflections are required with h, k, l, TTH, TH, PHI, CHI, and ALP specified for each reflection. The meaning of the angles is slightly different in different modes of calculating the orientation matrix. We refer here only to the five-circle mode, which is set by the command *frz 5*.

Individual variables in the orientation matrix can be changed using syntax name = value. The variable names in this case consist of a single letter and a number (e.g., t1, t2, t3, ...). The number refers to the number of the orientation reflection. The letters are assigned as follows for the five-circle mode: t = 2-theta, u = theta, p = phi, c = chi, a = alpha, h,k,l = Miller indices, g = gamma (fixed out-of-plane detector position), and z = zeta (fixed sample offset angle).

The orientation reflections may also be entered using the *or* (orient) command. To enter the parameters for the current diffractometer position, type *or* followed by the number of the reflection (in this case 1 or 2) and the hkl. One may also manually enter all variables on one line by typing

or # h k l TTH TH PHI CHI ALP

The orientation matrix is a general 3×3 matrix with 9 degrees of freedom described by Busing and Levy (1967). Six degrees of freedom are constrained by the reciprocal lattice parameters, 2 more come from the first orientation reflection (the two polar angles), and the final degree of freedom comes from the second orientation reflection (the second reflection specifies the azimuthal rotation about the first vector). The direction of the first orientation reflection, called the primary reflection, will always be reproduced exactly. The angles of the second reflection may not necessarily be consistent with the lattice parameters, and consequently the program may not reproduce the angles of the secondary reflection exactly. The *sor n m* command allows reflections n and m to be swapped.

The "lattice parameters unknown" mode is set by toggling the *om* command. Then the six reciprocal lattice parameters are determined directly from the five angles specified for each of the orientation reflections (TTH, TH, PHI, CHI, and ALP). To define the nine matrix elements of the orientation matrix, at least three non-coplanar reflections must be used, so nobs = 3. If nobs3, the best matrix is constructed from the full list of nobs reflections using a least-squares fit and will usually improve as more reflections are added. Reciprocal lattice parameters that are consistent with the three observed reflections will then be calculated. In general, the reciprocal lattice parameters will correspond to a triclinic cell with interfacial angles nearly equal to those expected from the symmetry. As guide to selecting suitable reflections, an error is calculated for each, which is the distance (in reciprocal angstroms) of the reflection from the reciprocal lattice point derived from the orientation matrix. The orientation parameters may be entered manually or by using the *or* command.

Important Scan Types

ascan Angle scan—Scan four diffractometer motors TTH, TH, PHI, CHI.

mscan Motor scan—Scan up to three arbitrary motors.

iscan Index scan—Input three starting HKLs and three delta HKLs for the increments between points.

jscan Centered index scan—Like iscan except scan is *centered* on the given starting hkl value.

kscan Centered two-dimensional index scan—Like jscan it is *centered* on the given starting hkl value. Two sets of delta HKL step sizes are given.

rscan Rocking scan—Input HKL value, motor number (or hkl) and one delta value for the increment. The scan moves either one motor or one hkl component and is centered at the given HKL value.

lup Line-up scan—Input motor number and delta angle. Similar to a rocking scan, but the scan is centered at the current position of the motors. At the end of the scan, the motors move to the peak position, calculated as the center of gravity of the counts measured.

fpk Find peak scan—Like lup, except fewer para meters are required and the data are not saved on disk. After the scan, the motors moved to the peak calculated from the first moment.

vscan Variable scan—Input HKL, variable name, and starting value. The scan increments the value of the variable and moves the motors to the given HKL.

vlup Centered vscan—Input HKL, variable name, delta, and npts. The scan increments the value of the variable and moves the motors to the given HKL. The scan is centered on the current value of the variable beforehand, which is reset to the center of gravity afterward.

pkup Peakup reflection—The scan does a series of lup scans centered at each orientation reflection. At the end of the series, the angles of the orientation reflection are updated to reflect the new peak position.

The scan types *rscan* and *jscan* embody automatic "stretching" of the background, whereby the step size at the beginning and end of the scan is increased by a factor of 3. The *lup* and *vlup* scans are very useful during the alignment stages of the experiment because of their autocentering feature; they can also be used to make automatic realignments during an unattended batch procedure. All scans generate a video display of the data as they accumulate, which can be viewed at any time using the function keys: F1 (F2) to see the spectrum of the multichannel analyzer as it accumulates and F3 (F4) to see a histogram of the recorded counts on a linear (log) scale.

A scan may be executed by typing the command name followed by a list of arguments. To obtain help on the command format, type the name of the scan without arguments and the program will prompt you. Any scan can be interrupted during execution by ^C and continued by typing *co*. A series of commands (including scans) can be executed by using either the *sc* command or the *ex* command.

To use the *sc* command, one first has to enter a list of commands into the scan table. The list can contain almost any command executable from the command line. A scan list can be created in three ways. The most direct method is to use the *ds* (define scans) command. Alternatively, one can use the *es* (edit scans) command to edit the scan table directly. The command *gs* filename (get scans) will read a new scan table file. Once the scan table has been entered, a list of commands or scans can be executed with the *sc* command, which accepts a series of numbers in arbitrary order corresponding to the position of the command in the scan table. Before execution begins, the program does a "dry run" to check for setting calculation errors and limit problems. If the execution is halted, the *co* command will resume execution.

A series of commands or scans can also be executed with the *ex* command. This command diverts program input to a script file and executes the commands in order. There is no limit to the number of commands in the file. In contrast to *sc*, the *ex* command does not do a dry run before execution begins. If a problem is encountered during execution, the program skips to the next command in the list.

X-RAY DIFFRACTION TECHNIQUES FOR LIQUID SURFACES AND MONOMOLECULAR LAYERS

INTRODUCTION

X-ray and neutron scattering techniques are probably the most effective tools employed to determine the structure of liquid interfaces on molecular-length scales. These are not different in principle from conventional x-ray diffraction techniques that are usually applied to three-dimensional crystals, liquids, solid surfaces etc. However, special diffractometers that enable scattering from fixed horizontal surfaces are required to carry out the experiments. Indeed, systematic studies of liquid surfaces had not begun until the introduction of the first liquid surface reflectometer (Als-Nielsen and Pershan, 1983).

A basic property of a liquid-gas interface is the length scale over which the molecular density changes from the bulk value to that of the homogeneous gaseous medium. Molecular size and capillary waves, which depend on surface tension and gravity, are among the most important factors that shape the density profile across the interface and the planar correlations (Evans, 1979; Braslau et al., 1988; Sinha et al., 1988). In some instances the topmost layers of liquids are packed differently than in the bulk, giving rise to layering phenomena at the interface. Monolayers of compounds different than the liquid can be spread at the gas-liquid interface, and are termed Langmuir monolayers (Gaines, 1966; Swalen et al., 1987). The spread compound might "wet" the liquid surface to form a film of homogeneous thickness or cluster to form an inhomogeneous rough surface. The x-ray reflectivity (XR)

technique allows one to determine the electron density across such interfaces, from which the molecular density and the total thickness can be extracted. The grazing angle diffraction (GID) technique is commonly used to determine lateral arrangements and correlations of the topmost layers at interfaces. GID is especially efficient in cases where surface crystallization of the liquid or spread monolayers occurs. Both techniques (XR and GID) provide structural information that is averaged over macroscopic areas, in contrast to scanning probe microscopies (SPMs), where local arrangements are probed (see, e.g., SCANNING TUNNELING MICROSCOPY). For an inhomogeneous interface, the reflectivity is an incoherent sum of reflectivities, accompanied by strong diffuse scattering, which, in general, is difficult to interpret definitively and often requires complementary techniques to support the x-ray analysis. Therefore, preparation of well-defined homogeneous interfaces is a key to a more definitive and straightforward interpretation.

Competitive and Related Techniques

Although modern scanning probe microscopies (SPMs) such as scanning tunneling microscopy (STM; SCANNING TUNNELING MICROSCOPY; Binning and Rohrer, 1983) and atomic force microscopy (AFM; Binning, 1992) rival x-ray scattering techniques in probing atomic arrangements of solid surfaces, they have not yet become suitable techniques for free liquid surfaces (but see X-RAY DIFFRACTION TECHNIQUES FOR LIQUID SURFACES AND MONOMOLECULAR LAYERS). The large fluctuations due to the two-dimensional nature of the liquid interface, high molecular mobility, and the lack of electrical conductivity (which is necessary for STM) are among the main obstacles that make it difficult to apply these techniques to gas-liquid interfaces. In dealing with volatile liquids, inadvertent deposition or wetting of the probe by the liquid can occur, which may obscure the measurements. In addition, the relatively strong interaction of the probe with the surface might alter its pristine properties. For similar and other reasons, electron microscopy (see Section 11a) and electron diffraction techniques (LOW-ENERGY ELECTRON DIFFRACTION), which are among the best choices for probing solid surfaces, are not suitable to most liquid surfaces, and in particular aqueous interfaces. On the other hand, visible light microscopy techniques such as Brewster angle microscopy (BAM; Azzam and Bashara, 1977; Henon and Meunier, 1991; Hönig and Möbius, 1991) or fluorescence microscopy (Lösche and Möhwald, 1984) have been used very successfully in revealing the morphology of the interface on the micrometer-length scale. This information, in general, is complementary to that extracted from x-ray scattering. These techniques are very useful for characterizing inhomogeneous surfaces with two or more distinct domains, for which XR and GID results are usually difficult to interpret. However, it is impossible to determine the position of the domains with respect to the liquid interface, their thicknesses, or their chemical nature. Ellipsometry (ELLIPSOMETRY) is another technique that exploits visible light to allow determination of film thickness on a molecular length scale; it assumes that one knows the refractive index of the substrate and of the film (Azzam and Bashara, 1977; Ducharme et al., 1990). Either of these values might be different from the corresponding bulk value, and therefore difficult to determine.

In the following sections, theoretical background to the x-ray techniques is presented together with experimental procedures and data analysis concerning liquid surfaces. This unit is intended to provide a basic formulation which can be developed for further specific applications. Several examples of these techniques applied to a variety of problems are presented briefly to demonstrate the strengths and limitations of the techniques. It should be borne in mind that the derivations and procedures described below are mostly general and can be applied to solid surfaces, and, vice versa, many results applicable to solid surfaces can be used for liquid surfaces. X-ray reflectivity from surfaces and GID have been treated in recent reviews (Als-Nielsen and Kjaer, 1989; Russell, 1990; Zhou and Chen, 1995).

PRINCIPLES OF THE METHOD

We assume that a plane harmonic wave of frequency ω and wave-vector $\mathbf{k}_0$ (with electric field, $\mathbf{E} = \mathbf{E}_0 e^{i\omega t - i\mathbf{k}_0 \cdot r}$) is scattered from a distribution of free electrons, with a number density $N_e(\mathbf{r})$. Due to the interaction with the electric field of the x-ray wave, each free electron experiences a displacement proportional to the electric field, $\mathbf{X} = (-e/m\,\omega^2)\mathbf{E}$. This displacement gives rise to a polarization $\mathbf{P}(\mathbf{r})$ distribution vector

$$\mathbf{P}(\mathbf{r}) = N_e(\mathbf{r}) e \mathbf{X} \tag{1}$$

in the medium. For the sake of convenience we define the scattering length density (SLD), $\rho(\mathbf{r})$, in terms of the classical radius of the electron $r_0 = e^2/4\pi\varepsilon_0 mc^2 = 2.82 \times 10^{-13}$ cm as follows

$$\rho(\mathbf{r}) = N_e(\mathbf{r}) r_0 \tag{2}$$

The polarization then can be written as

$$\mathbf{P}(\mathbf{r}) = \frac{-N_e(\mathbf{r}) e^2}{\omega^2 m_e}\mathbf{E} = -\frac{4\pi\varepsilon_0}{k_0^2}\rho(\mathbf{r})\mathbf{E} \tag{3}$$

The scattering length density (or the electron density) is what we wish to extract from reflectivity and GID experiments and relate it to atomic or molecular positions at liquid interfaces. The displacement vector $\mathbf{D}$ can now be constructed as follows

$$\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}(\mathbf{r}) = \varepsilon(\mathbf{r})\mathbf{E} \tag{4}$$

where $\varepsilon(\mathbf{r})$ is the permittivity of the medium, usually associated with the refractive index $n(\mathbf{r}) = \sqrt{\epsilon(\mathbf{r})}$. To account for absorption by the medium we introduce a phenomenological factor β that we calculate from the linear absorption coefficient μ (given in tables in Wilson, 1992) as follows: $\beta = \mu/(2k_0)$. Then the most general permittivity for x-rays becomes

$$\varepsilon(\mathbf{r}) = \varepsilon_0\left[1 - \frac{4\pi}{k_0^2}\rho(\mathbf{r})\right] + 2i\beta \tag{5}$$

Table 1. Electron Number Density, SDL, Critical Angles and Momentum Transfers, and Absorption Term for Water and Liquid Mercury

	$N_e(e/\mathring{A}^3)$	$\rho_s(\mathring{A}^{-2}\times_{10^{-5}})$	$Q_c(\mathring{A}^{-1})$	$\alpha_c(deg.)for\ \lambda=_{1.5404}\mathring{A}$	$\beta(\times_{10^{-8}})$
H_2O	0.334	0.942	0.02176	0.153	1.2
Hg	3.265	9.208	0.06803	0.478	360.9

Typical values of the SLD (ρ) and the absorption term (β) for water and liquid mercury are listed in Table 1. In the absence of true charges in the scattering medium (i.e., a neutral medium) and under the assumption that the medium is nonmagnetic (magnetic permeability $\mu = 1$) the wave equations that need to be solved to predict the scattering from a known SLD can be derived from the following Maxwell equations (Panofsky and Phillips, 1962)

$$\nabla \cdot \mathbf{D} = 0 \qquad \nabla \cdot \mathbf{H} = 0$$
$$\nabla \times \mathbf{E} = -\partial \mathbf{H}/\partial t \quad \nabla \times \mathbf{H} = \partial \mathbf{D}/\partial t \tag{6}$$

Under the assumption of harmonic plane waves, $\mathbf{E} = \mathbf{E}_0 e^{i\omega t - i\mathbf{k}\cdot\mathbf{r}}$, the following general equations are obtained from Equation 6

$$\nabla^2\mathbf{E} + [k_0^2 - 4\pi\rho(\mathbf{r})]\mathbf{E} = -\nabla(\nabla\ \ln\ \varepsilon(\mathbf{r}) \cdot \mathbf{E}) \tag{7}$$
$$\nabla^2\mathbf{H} + [k_0^2 - 4\pi\rho(\mathbf{r})]\mathbf{H} = -\nabla\ \ln\ \varepsilon(\mathbf{r}) \times (\nabla \times \mathbf{H}) \tag{8}$$

In some particular cases the right hand side of Equations 7 and 8 is zero. We notice then, that the term $4\pi\rho(\mathbf{r})$ in the equation plays a role similar to that of a potential $V(\mathbf{r})$ in wave mechanics. In fact, for most practical cases the right hand side of Equation 7 and Equation 8 can be approximated to zero; thus the equation for each component of the fields resembles a stationary wave equation. In those cases, general mathematical tools, such as the Born approximation (BA) and the distorted wave Born approximation (DWBA; see DYNAMICAL DIFFRACTION and SURFACE X-RAY DIFFRACTION) can be used (Schiff, 1968).

Reflectivity

In reflectivity experiments a monochromatic x-ray beam of wavelength λ [wavevector $k_0 = 2\pi/\lambda$ and $\mathbf{k_i} = (0, k_y, k_z)$] is incident at an angle α_i on a liquid surface and is detected at an outgoing angle α_r such that $\alpha_i = \alpha_r$, as shown in Figure 1, with a final wave vector $\mathbf{k_f}$. The momentum transfer is defined in terms of the incident and reflected beam as follows

$$\mathbf{Q} = \mathbf{k_i} - \mathbf{k_f} \tag{9}$$

where in the reflectivity case $\mathbf{Q}$ is strictly along the surface normal, with $Q_z = 2k_0 \sin\alpha = 2k_z$.

Single, Ideally Sharp Interface: Fresnel Reflectivity. Sol-
Solving the scattering problem exactly for the ideally sharp interface, although simple, is very useful for the derivation of more complicated electron density profiles across interfaces. The wavefunctions employed are also essential for inclusion of dynamical effects when dealing with non-specular scattering, i.e., GID and diffuse scattering. The following relates to the case of an s-polarized x-ray beam (see the Appendix at the end of this unit for a similar derivation in the case of the p-polarized x-ray beam).

For a stratified medium with an electron density that varies along one direction, z, $\rho(\mathbf{r}) = \rho(\mathbf{z})$, assuming no absorption, i.e., $\beta = 0$, an s-type polarized x-ray beam with the electrical field parallel to the surface (along the x axis; see Fig. 1) obeys the stationary wave equation as derived from Equation 7 and is simplified as follows

$$\nabla^2 E_x + [k_0^2 - V(z)]E_x = 0 \tag{10}$$

with an effective potential $V(z) = 4\pi\rho(z)$. The general solution to Equation 2 is then given by

$$E_x = E(z)e^{ik_y y} \tag{11}$$

where the momentum transfer along y is conserved when the wave travels through the medium, leading to the well-known Snell's rule for refraction. Inserting Equation 11 in

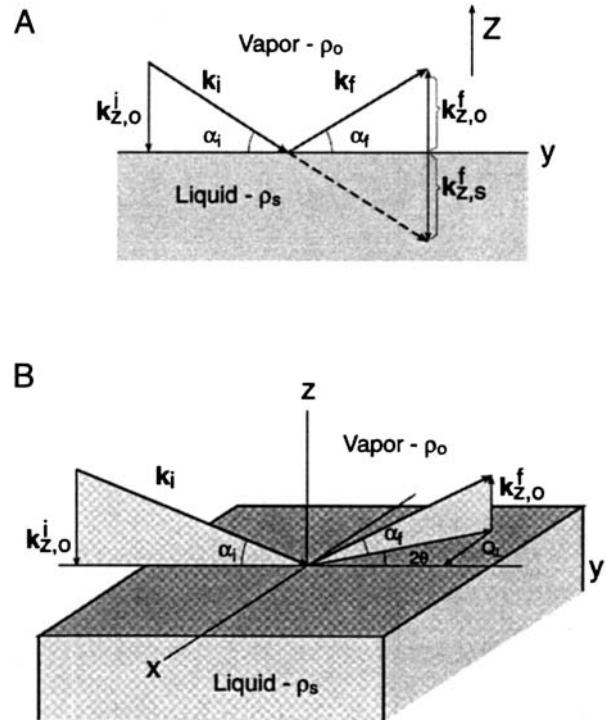

Figure 1. The geometry of incident and scattered beam in (**A**) specular reflectivity and (**B**) non-specular scattering experiments.

Equation 10 leads to a one-dimensional wave equation through a potential $V(z)$

$$\frac{d^2E}{dz^2} + [k_z^2 - V(z)]E = 0 \tag{12}$$

The simplest case of Equation 12 is that of an ideally flat interface, separating the vapor phase and the bulk scattering length density ρ_s, at $z = 0$. The solution of Equation 12 is then given by

$$E(z) = \begin{cases} e^{ik_{z,0}z} + r(k_{z,s})e^{-ik_{z,0}z} & z \geq 0 \text{ in gas} \\ t(k_{z,s})e^{ik_{z,s}z} & z \leq 0 \text{ in liquid} \end{cases} \tag{13}$$

where

$$k_{z,s} = \sqrt{k_{z,0}^2 - 4\pi\rho_s} = \sqrt{k_{z,0}^2 - k_c^2} \tag{14}$$

with $k_c \equiv 2\sqrt{\pi\rho_s}$. By applying continuity conditions to the wavefunctions and to their derivatives at $z = 0$, the Fresnel equations for reflectance, $r(k_{z,s})$, and transmission, $t(k_{z,s})$, are obtained

$$r(k_{z,s}) = \frac{k_{z,0} - k_{z,s}}{k_{z,0} + k_{z,s}}, \qquad t(k_{z,s}) = \frac{2k_{z,0}}{k_{z,0} + k_{z,s}} \tag{15}$$

The measured reflectivity from an ideally flat interface, R_F, is usually displayed as a function of the momentum transfer $Q_z = k_{z,0} + k_{z,s} \approx 2k_{z,0}$, and is given by

$$R_F(Q_z) = |r(k_{z,s})|^2 \tag{16}$$

Below a critical momentum transfer, $Q_c \equiv 2k_c \equiv 4\sqrt{\pi\rho_s}$, $k_{z,s}$ is an imaginary number and $R_F(Q_z) = 1$; thus, total external reflection occurs. Notice that whereas the critical momentum transfer does not depend on the x-ray wavelength, the critical angle for total reflection does, and it is given by $\alpha_c \approx \lambda\sqrt{\rho_s/\pi}$. Typical values of critical angles for x-rays of wavelength $\lambda_{CuKa} = 1.5404$ Å are listed in Table 1. For $Q_z \gg Q_c$, $R_F(Q_z)$ can be approximated to a form that is known as the Born approximation

$$R_F(Q_z) \sim \left(\frac{Q_c}{2Q_z}\right)^4 \tag{17}$$

This form of the reflectivity at large Q_z values is also valid for internal scattering, i.e., reflectivity from liquid into the vapor phase. However, total reflection does not occur for the internal reflectivity case. Calculated external and internal reflectivity curves from an ideally flat surface, R_F, displayed versus momentum transfer (in units of the critical momentum transfer) are shown in Figure 2A. Both reflectivities converge at large momentum transfer where they can be both approximated by Equation 17. The dashed line in the same figure shows the approximation $(Q_c/2Q_z)^4$, which fails in describing the reflectivity close to the critical momentum transfer.

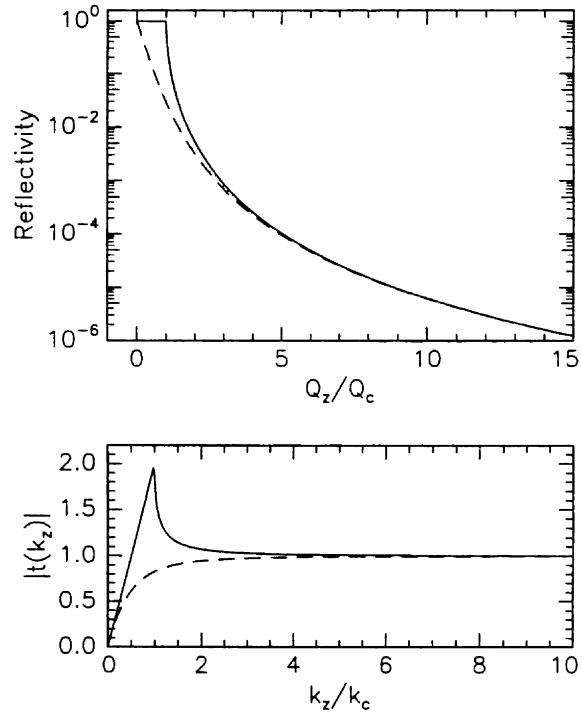

Figure 2. Calculated reflectivity curves for external (solid line) and internal (dashed line) scattering from an ideally flat interface versus momentum transfer given in units of the critical momentum transfer, $Q_c = 4(\pi\rho_s)^{1/2}$. The dotted line is kinematical approximation $(Q_c/2Q_z)^4$. The lower panel shows the amplitude of the wave in the medium for external (solid line) and external reflection (dashed line).

The photon transmission at a given $k_{z,s}$ is given by

$$T(k_{z,s}) = |t(k_{z,s})|^2 \frac{\mathrm{Re}(k_{z,s})}{\mathrm{Re}(k_{z,0})} \tag{18}$$

where the ratio on the right hand side accounts for the flux through the sample. In the case of external reflection, and for values of $k_{z,0}$ that are smaller than k_c, the real part of $k_{z,s}$ is zero, and there is no transmission, whereas above the critical angle, $k_{z,s}$ is real, and the transmission is given by

$$T(k_{z,s}) = \frac{4k_{z,0}k_{z,s}}{(k_{z,0} + k_{z,s})^2} \quad \text{for} \quad k_{z,0} > k_c \tag{19}$$

and the conservation of photons is fulfilled in the scattering process

$$T(k_{z,s}) + R(k_{z,s}) = 1 \tag{20}$$

In Figure 2B the transmission amplitude $|t(k_{z,s})|$ for external (solid line) and for internal (dashed line) reflections are shown. This amplitude modulates non-specular scattering processes at the interface as will be discussed later in this unit.

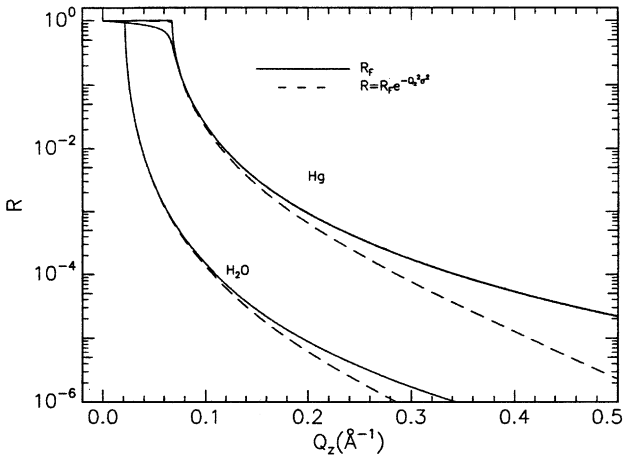

Figure 3. Calculated reflectivities from H_2O and liquid mercury (Hg) showing the effects of absorption and surface roughness. The absorption modifies the reflectivity near the critical momentum transfer for mercury with insignificant effect on the reflectivity from H_2O. The dashed line shows the calculated reflectivity from the same interfaces with root mean square surface roughness, $\sigma = 3$ Å.

The effect of absorption on the reflectivity can be incorporated by introducing β into the generalized potential in Equation 11, so that

$$k_{z,s} = \sqrt{k_{z,0}^2 - k_c^2 + 2i\beta} \tag{21}$$

is used in the Fresnel equations (Equation 15). Calculated reflectivities from water and liquid mercury, demonstrating that the effect of absorption is practically insignificant for the former, yet has the strongest influence near the critical angle for the latter, are shown in Figure 3.

Multiple Stepwise and Continuous Interfaces. On average, the electron density across a liquid interface is a continuously varying function, and is a constant far away on both sides of the interface, as shown in Figure 4.

The reflectivity for a general function $\rho(z)$ can be then calculated by one of several methods, classified into two major categories: dynamical and kinematical solutions. The dynamical solutions (see DYNAMICAL DIFFRACTION) are in general more exact, and include all the features of the scattering, in particular the low-angle regime, close to the critical angle where multiple scattering processes occur. For a finite number of discrete interfaces, exact solutions can be obtained by use of standard recursive (Parratt, 1954) or matrix (Born and Wolf, 1959) methods. These methods can be extended to compute, with very high accuracy, the scattering from any continuous potential by slicing it into a set of finite layers but with a sufficient number of interfaces. On the other hand, the kinematical approach (see KINEMATIC DIFFRACTION OF X-RAYS) neglects multiple scattering effects and fails in describing the scattering at small angles.

1. *The matrix method.* In this approach the scattering length density with variation over a characteristic length d_t is sliced into a histogram with N interfaces.

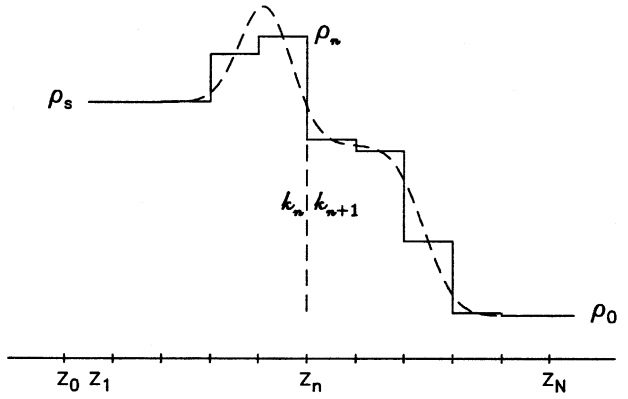

Figure 4. An illustration of a continuous scattering length density, sliced into a histogram.

The matrix method is practically equivalent to the Parratt formalism (Born and Wolf, 1959; Lekner, 1987). For each interface, the procedure described previously for the one interface is applied. Consider an arbitrary interface, n, separating two regions of a sliced SLD (as in Fig. 4), with ρ_{n-1}, and ρ_n at position $z = z_n$, with the following wavefunctions

$$\begin{array}{ccc|cc} \rho_{n-1} & & & & \rho_n \\ R_{n-1,n}e^{-ik_{n-1}z} & \leftarrow & | & \leftarrow & R_{n,n+1}e^{-ik_n z} \\ T_{n-1,n}e^{-ik_{n-1}z} & \rightarrow & | & \rightarrow & T_{n,n+1}e^{ik_n z} \\ & z = z_n & & & \end{array} \tag{22}$$

where

$$k_n \equiv \sqrt{k_{z,0}^2 - 4\pi\rho_n} \tag{23}$$

The effect of absorption can be taken into account as described earlier. For simplicity, the subscript z is omitted from the component of the wavevector so that $k_{z,n} = k_n$. The solution at each interface in terms of a transfer matrix, M_n, is given by

$$\begin{pmatrix} T_{n-1,n} \\ R_{n-1,n} \end{pmatrix} = \begin{pmatrix} e^{-i(k_{n-1}-k_n)z_n} & r_n e^{-i(k_{n-1}+k_n)z_n} \\ r_n e^{i(k_{n-1}+k_n)z_n} & e^{i(k_{n-1}-k_n)z_n} \end{pmatrix} \begin{pmatrix} T_{n,n+1} \\ R_{n,n+1} \end{pmatrix} \tag{24}$$

where

$$r_n = \frac{k_{n-1} - k_n}{k_{n-1} + k_n} \tag{25}$$

is the Fresnel reflection function through the z_n interface separating the ρ_{n-1} and ρ_n SLDs. The solution to the scattering problem is given by noting that beyond the last interface, (i.e., in the bulk), there is a transmitted wave for which only an arbitrary amplitude of the form $\binom{1}{0}$ can be assumed (i.e., the reflectivity is normalized to the incident beam anyway). The effect of all interfaces is calculated as follows

$$\begin{pmatrix} T_{0,1} \\ R_{0,1} \end{pmatrix} = (M_1)(M_2)\ \ldots(M_n)\ \ldots(M_{N+1}) \begin{pmatrix} 1 \\ 0 \end{pmatrix} \tag{26}$$

with

$$r_{N+1} = \frac{k_N - k_s}{k_N + k_s} \tag{27}$$

in the M_{N+1} matrix given in terms of the substrate k_s. The reflectivity is then given by the ratio

$$R(Q_z) = \left|\frac{R_{0,1}}{T_{0,1}}\right|^2 \tag{28}$$

Applying this procedure to the one-box model of thickness d with two interfaces yields

$$R(Q_z \equiv 2k_s) = \left|\frac{r_1 + r_2 e^{i2k_s d}}{1 + r_1 r_2 e^{i2k_s d}}\right|^2 \tag{29}$$

Figure 5 shows the calculated reflectivities from a flat liquid interface with two kinds of films (one box) of the same thickness d but with different scattering length densities, ρ_1 and ρ_2. The reflectivities are almost indistinguishable when the normalized

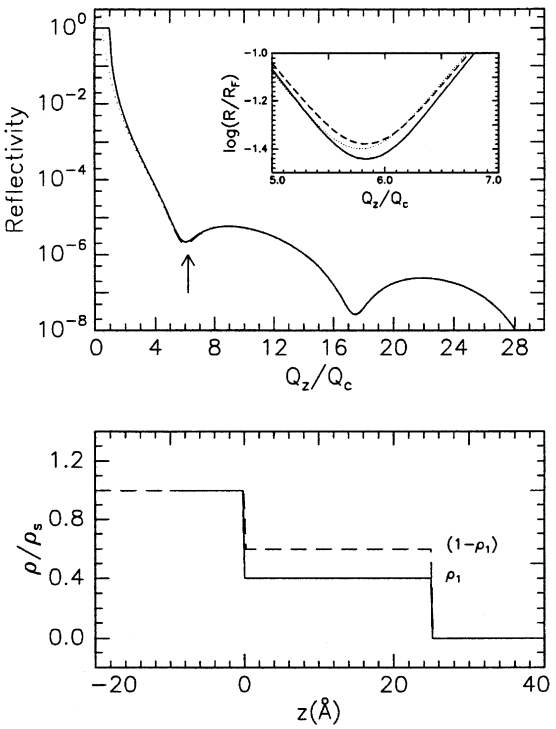

Figure 5. Calculated reflectivities for two films with identical thicknesses but with two distinct normalized electron densities, ρ_1 (solid line) and $1 - \rho_1$ (dashed line), and corresponding calculated reflectivities using the dynamical approach ($\sigma = 0$). The two reflectivities are almost identical except for a minute difference near the first minimum (see arrow in figure). The Born approximation (dotted line) for the two models yields identical reflectivities. The inset shows the normalized reflectivities near the first minimum. As Q_z is increased, the three curves converge. This is the simplest demonstration of the phase problem, i.e., the nonuniqueness of models where two different potentials give the same reflectivities.

SLDs (ρ_i/ρ_s) of the films are complementary to one ($\rho_1/\rho_s + \rho_2/\rho_s = 1$), except for a very minute difference near the first minimum. In the kinematical method described below, the two potentials shown in Figure 5 yield identical reflectivities.

The matrix method can be used to calculate the exact solution from a finite number of interfaces, and it is most powerful when used with computers by slicing any continuous scattering length density into a histogram. The criteria for determining the optimum number of slices to use is based on the convergence of the calculated reflectivity at a point where slicing the SLD into more boxes does not change the calculated reflectivity significantly.

2. *The kinematical approach.* The kinematical approach for calculating the reflectivity is only applicable under certain conditions where multiple scattering is not important. It usually fails in calculating the reflectivity at very small angles (or small momentum transfers) near the critical angle. The kinematical approach, also known as the Born approximation, gives physical insight in the formulation of $R(Q_z)$ by relating the Fresnel normalized reflectivity, R/R_F, to the Fourier transform of spatial changes in $\rho(z)$ across the interface (Als-Nielsen and Kjaer, 1989) as discussed below.

As in the dynamical approach, $\rho(z)$ is sliced so that

$$k(z) = \sqrt{k_{z,0}^2 - 4\pi\rho(z)} \quad \frac{dk}{dz} = -\frac{2\pi}{k(z)}\frac{d\rho}{dz} \tag{30}$$

and the reflectance across an arbitrary point z is given by

$$r(z) = \frac{k(z+\Delta z) - k(z)}{k(z+\Delta z) + k(z)} \approx -\frac{4\pi}{4k(z)^2}\frac{d\rho}{dz}dz \approx (Q_c/2Q_z)^2 \frac{1}{\rho_s}\frac{d\rho}{dz}dz \tag{31}$$

In the last step of the derivation, $r(z)$ was multiplied and divided by ρ_s, the SLD of the subphase, and the identity $Q_c^2 \equiv 16\pi\rho_s$ was used. Assuming no multiple scattering, the reflectivity is calculated by integrating over all reflectances at each point, z, with a phase factor $e^{iQ_z z}$ as follows

$$R(Q_z) = R_F(Q_z)\left|\frac{1}{\rho_s}\int\left(\frac{d\rho}{dz}\right)e^{iQ_z z}dz\right|^2 = R_F(Q_z)|\Phi(Q_z)|^2 \tag{32}$$

where $\Phi(Q_z)$ can be regarded as the generalized structure factor of the interface, analogous to the structure factor of a unit cell in 3-D crystals. This formula also can be derived by using the Born approximation, as is shown in the following section.

As an example of the use of Equation 32 we assume that the SLD at a liquid interface can be approximated by a sum of error functions as follows

$$\rho(z) = \rho_0 + \sum_{j=1}^{N}\frac{(\rho_j - \rho_{j-1})}{2}\left[1 + \mathrm{erf}\left(\frac{z - z_j}{\sqrt{2\sigma_j}}\right)\right] \tag{33}$$

where ρ_0 is the SLD of the vapor phase and $\rho_N = \rho_s$. Using Equation 32 the reflectivity is given by

$$R(Q_z) = R_{\mathrm{F}}(Q_z)\left|\sum_j \left(\frac{\rho_j - \rho_{j-1}}{\rho_s}\right) e^{-\frac{(Q_z\sigma_j)^2}{2}} e^{iQ_z z_j}\right|^2 \tag{34}$$

Assuming one interface at $z_1 = 0$ with surface roughness $\sigma_1 = \sigma$, the Fresnel reflectivity, $R_F(Q_z)$, is simply modified by a Debye-Waller-like factor

$$R(Q_z) = R_{\mathrm{F}}(Q_z)e^{-(Q_z\sigma)^2} \tag{35}$$

The effect of surface roughness on the reflectivities from water and from liquid mercury surfaces, assuming Gaussian smearing of the interfaces, is shown by the dashed lines in Figure 3. Braslau et al. (1988) have demonstrated that the Gaussian smearing of the interface due to capillary waves in simple liquids is sufficient in modeling the data, and that more complicated models cannot be supported by the x-ray data.

Applying Equation 34 to the one-box model discussed above (see Fig. 5), and assuming conformal roughness, $\sigma_j = \sigma$, the calculated reflectivity in terms of SLD normalized to ρ_s is

$$R(Q_z) = R_{\mathrm{F}}(Q_z)[(1-\rho_1)^2 + \rho_1^2 + 2\rho_1(1-\rho_1)\cos(Q_z d)]e^{-(Q_z\sigma)^2} \tag{36}$$

In this approximation, the roles of the normalized SLD of the one box, ρ_1, and of the complementary model, $\rho_2 = 1 - \rho_1$, are equivalent. This demonstrates that the reflectivities for both models are mathematically identical. This is the simplest of many examples where two or more distinct SLD models yield identical reflectivities in the Born approximation. When using the kinematical approximation to invert the reflectivity to SLD, there is always a problem of facing a nonunique result. For discussion of ways to distinguish between such models see Data Analysis and Initial Interpretation.

In some instances, the scattering length density can be generated by several step functions that are smeared with one Gaussian (conformal roughness $\sigma_j = \sigma$), representing different moieties of the molecules on the surface. The reflectivity can be calculated by using a combination of the dynamical and the kinematical approaches (Als-Nielsen and Kjaer, 1989). First, the exact reflectivity from the step-like functions ($\sigma = 0$) is calculated using the matrix method, $R_{\mathrm{dyn}}(Q_z)$, and the effect of surface roughness is incorporated by multiplying the calculated reflectivity with a Debye-Waller-like factor as follows (Als-Nielsen and Kjaer, 1989)

$$R(Q_z) = R_{\mathrm{dyn}}(Q_z)e^{-(Q_z\sigma)^2} \tag{37}$$

Non-Specular Scattering

The geometry for non-specular reflection is shown in Figure 1B. The scattering from a 2-D system is very weak, and enhancements due to multiple scattering processes at the interface are taken advantage of. As is shown in Figure 1B the momentum transfer $\mathbf{Q}$ has a finite component parallel to the liquid surface ($\mathbf{Q}_\perp \equiv \mathbf{k}_\perp^i - \mathbf{k}_\perp^{\mathbf{f}}$), enabling determination of lateral correlations in the 2-D plane. Exact calculation of scattering from surfaces is practically impossible except for special cases, and the Born approximation (BA; Schiff, 1968) is usually applied. When the incident beam or the scattered beam are at grazing angles (i.e., near the critical angle), multiple scattering effects modify the scattering, and these can be accounted for by a higher-order approximation known as the distorted wave Born approximation (DWBA). The features due to multiple scattering at grazing angles provide evidence that the scattering processes indeed occur at the interface.

The Born Approximation. In the BA for a general potential $V(\mathbf{r})$ the scattering length amplitude is calculated as follows (Schiff, 1968)

$$F(\mathbf{Q}) = \frac{1}{4\pi}\int V(\mathbf{r})e^{i\mathbf{Q}\cdot\mathbf{r}}d^3\mathbf{r} \tag{38}$$

where, in the present case, $V(\mathbf{r}) = 4\pi\rho(\mathbf{r})$. From the scattering length amplitude, the differential cross-section is calculated as follows (Schiff, 1968)

$$\frac{d\sigma}{d\Omega} = |F(\mathbf{Q})|^2 = \int [\rho(\mathbf{0})\rho(\mathbf{r})]e^{i\mathbf{Q}\cdot\mathbf{r}}d^3\mathbf{r} \tag{39}$$

where $[\rho(0)\ \rho(\mathbf{r})] \equiv \int[\rho(\mathbf{r}' - \mathbf{r})\rho(\mathbf{r}')]d^3\mathbf{r}'$ is the density-density correlation function. The measured reflectivity is a convolution of the differential cross-section with the instrumental resolution, as discussed below and in the literature (Schiff, 1968; Braslau et al., 1988; Sinha et al., 1988).

The scattering length density, ρ, for a liquid-gas interface can be described as a function of the actual height of the surface, $z(x,y)$, as follows

$$\rho(\boldsymbol{\mu}, z) = \begin{cases} \rho_s & \text{for} \quad z < z(\boldsymbol{\mu}) \\ 0 & \text{for} \quad z > z(\boldsymbol{\mu}) \end{cases} \tag{40}$$

where $\mu = (x, y, 0)$ is a 2-D in-plane vector. The height of the interface z is also time and temperature dependent due to capillary waves, and therefore thermal averages of z are used (Buff et al., 1965; Evans, 1979). Inserting the SLD (Equation 40) in Equation 39 and performing the integration over the z coordinate yields

$$F(\mathbf{Q}_\perp, Q_z) = \frac{\rho_s}{iQ_z}\int e^{i[\mathbf{Q}_\perp\cdot\boldsymbol{\mu} + Q_z z(\boldsymbol{\mu})]}d^2\boldsymbol{\mu} \tag{41}$$

where $\mathbf{Q}_\perp = (Q_x, Q_y, 0)$ is an in-plane scattering vector. This formula properly predicts the reflectivity from an ideally flat surface, $z(x,y) = 0$ within the kinematical approximation

$$F(\mathbf{Q}_\perp, Q_z) = \frac{4\pi^2\rho_s}{iQ_z}\delta^{(2)}(\mathbf{Q}_\perp) \tag{42}$$

with a 2-D delta-function ($\delta^{(2)}$) that guarantees specular reflectivity only. The differential cross-section is then given by

$$\frac{d\sigma}{d\Omega} = \pi^2 \left(\frac{Q_c^2}{4Q_z}\right)^2 \delta^{(2)}(\mathbf{Q}_\perp) \tag{43}$$

where $Q_c^2 \equiv 16\pi\rho_s$. This is the general form for the Fresnel reflectivity in terms of the differential cross-section $d\sigma/d\Omega$, which is defined in terms of the flux of the incident beam on the surface. In reflectivity measurements, however, the scattered intensity is normalized to the intensity of the incident beam, and therefore the flux on the sample is angle-dependent and is proportional to $\sin\alpha_i$. In addition, the scattered intensity is integrated over the polar angles α_f and 2θ with $k_0^2 \sin\alpha_f d\alpha_f d(2\theta) = dQ_x dQ_y$. Correcting for the flux and integrating

$$R_F(Q_z) \approx \sigma_{tot}(Q_z) = \int\int \left(\frac{d\sigma}{d\Omega}\right) \frac{dQ_x\, dQ_y}{4\pi^2 k_0^2 \sin\alpha_i \sin\alpha_f} = \left(\frac{Q_c}{2Q_z}\right)^4 \tag{44}$$

as approximated from the exact solution, given in Equation 17.

Taking advantage of the geometrical considerations above, the differential cross-section to the reflectivity measurement can be readily derived in the more general case of scattering length density that varies along z only, (i.e., $\rho(z)$). In this case, Equation 38 can be written as

$$\frac{d\sigma}{d\Omega} = 4\pi^2 \delta^{(2)}(\mathbf{Q}_\perp) \left| \int \rho(z) e^{iQ_z z} dz \right|^2 \tag{45}$$

If we normalize $\rho(z)$ to the scattering length density of the substrate, ρ_s, and use a standard identity between the Fourier transform of a function and its derivative, we obtain

$$\frac{d\sigma}{d\Omega} = \pi^2 \left(\frac{Q_c^2}{4Q_z}\right)^2 \left| \int \frac{1}{\rho_s} \frac{d\rho(z)}{dz} e^{iQ_z z} dz \right|^2 \delta^{(2)}(\mathbf{Q}_\perp) \tag{46}$$

which, with the geometrical corrections, yields Equation 32.

Thermal averages of the scattering length density under the influence of capillary waves and the assumption that the SLD of the gas phase is zero can be approximated as follows (Buff et al., 1965; Evans, 1979)

$$\rho(\mathbf{r}) \sim \frac{\rho_s}{2} \left(1 + \mathrm{erf}\left[\frac{z}{\sqrt{2}\sigma(\boldsymbol{\mu})}\right]\right) \tag{47}$$

where $\sigma(\mu)$ is the height-height correlation function.

Inserting Equation 47 into Equation 39, and integrating over z, results in the differential cross-section

$$\frac{d\sigma}{d\Omega} \sim \frac{Q_c^4}{Q_z^2} \int e^{i\mathbf{Q}_\perp \cdot \boldsymbol{\mu} - Q_z^2 \sigma^2(\boldsymbol{\mu})} d^2\boldsymbol{\mu} \tag{48}$$

and assuming isotropic correlation function in the plane yields (Sinha et al., 1988)

$$\frac{d\sigma}{d\Omega} \sim \frac{Q_c^4}{Q_z^2} \int \mu J_0(Q_\perp \mu) e^{-Q_z^2 \sigma^2(\mu)} d\mu \tag{49}$$

where J_0 is a Bessel function of the first kind. This expression was used by Sinha et al. (1988) to calculate the diffuse scattering from rough liquid surfaces with a height-height density correlation function that diverges logarithmically due to capillary waves (Sinha et al., 1988; Sanyal et al., 1991).

Distorted Wave Born-Approximation (DWBA). Due to the weak interaction of the electromagnetic field (x-rays) with matter (electrons), the BA is a sufficient approach to the scattering from most surfaces. However, as we have already encountered with the reflectivity, the BA fails (or is invalid) when either the incident beam or the scattered beam is near the critical angle where multiple scattering processes take place. The effect of the bulk on the scattering from the surface can be accounted for by defining the scattering length density as a superposition of two parts, as follows

$$\rho(\mathbf{r}) = \rho_1(z) + \rho_2(\boldsymbol{\mu}, z) \tag{50}$$

Here $\rho_1(z)$ is a step function that defines an ideally sharp interface separating the liquid and gas phases at $z = 0$, whereas the second term, $\rho_2(\mu, z)$, is a quasi–two-dimensional function in the sense that it has a characteristic average thickness, d_c, such that $\lim_{z \to \pm d_c/2} \rho_2(\mu, z) = 0$. It can be thought of as film-like and is a detailed function with features that relate to molecular or atomic distributions at the interface. Although the definition of ρ_2 may depend on the location of the interface, ($z = 0$) in ρ_1, the resulting calculated scattering must be invariant for equivalent descriptions of $\rho(\mathbf{r})$. In some cases ρ_2 can be defined as either a totally external or totally internal function with respect to the liquid bulk, (i.e., ρ_1). In other cases, especially when dealing with liquid surfaces, it is more convenient to locate the interface at some intermediate point coinciding with the center of mass of ρ_2 with respect to z. The effect of the substrate term $\rho_1(z)$ on the scattering from ρ_2 can be treated within the distorted wave Born approximation (DWBA) by using the exact solution from the ideally flat interface (see Principles of the Method) to generate the Green function for a higher-order Born approximation (Rodberg and Thaler, 1967; Schiff, 1968; Vineyard, 1982; Sinha et al., 1988). The Green function in the presence of an ideally flat interface, ρ_1, replaces the free particle Green function that is commonly used in the Born approximation. The scattering amplitude in this case is given by (Rodberg and Thaler, 1967; Schiff, 1968)

$$F_{DWBA}(\mathbf{Q}) = F_F(Q_z) + F_2(\mathbf{Q}) = -i\pi Q_z r_F(Q_z) + \int \tilde{\chi}^*_{k'}(\mathbf{r}) \rho_2(\mathbf{r}) \chi_k(\mathbf{r}) d\mathbf{r} \tag{51}$$

where the exact Fresnel amplitude $F_F(Q_z)$ is written in the form of a scattering amplitude so that Equation 51 reproduces the Fresnel reflectivity in the absence of ρ_2.

The exact solution of the step function ρ_1, $\chi_k(\mathbf{r})$, is given by

$$\chi_k(\mathbf{r}) = e^{ik^i_{\perp}\cdot\mu}\begin{cases} e^{ik^i_{z,0}z} + r^i(k^i_{z,s})e^{-ik^i_{z,0}z} & \text{for } z > 0 \\ t^i(k^i_{z,s})e^{ik^i_{z,s}z} & \text{for } z < 0 \end{cases} \tag{52}$$

and the $\tilde{\chi}^*_k(\mathbf{r})$ is the time-reversed and complex conjugate solution of an incident beam with $-\mathbf{k}_i$,

$$\tilde{\chi}^*_k(\mathbf{r}) = e^{-ik^f_{\perp}\cdot\mu}\begin{cases} e^{-ik^f_{z,0}z} + r^f(k^f_{z,0})e^{ik^f_{z,0}z} & \text{for } z > 0 \\ t^f(k^f_{z,0})e^{-ik^f_{z,0}z} & \text{for } z < 0 \end{cases} \tag{53}$$

In Equation 53, it is assumed that the scattered beam is detected only for $z > 0$, i.e., above the liquid surface. The notation for transmission and reflection functions indicate scattering of the wave from the air onto the subphase and vice-versa according to

$$k^i_{z,s} = \sqrt{(k^i_{z,0})^2 + k_c^2} \tag{54}$$

and

$$k^f_{z,0} = \sqrt{(k^f_{z,s})^2 + k_c^2} \tag{55}$$

respectively. In the latter case, total reflectivity does not occur except for the trivial case $k^f_{z,s} = 0$, and no enhancement due to the evanescent wave is expected. In this approximation, the final momentum transfer in the Q_z direction is a superposition of momentum transfers from ρ_2 (the film) and from the liquid interface, ρ_1. For instance, there could be a wave scattered with $Q_z = 0$ with respect to ρ_2 but reflected from the surface with a finite Q_z. This is due to multiple scattering processes between ρ_2 and ρ_1 and, therefore, in principle the amplitude of the detected beam contains a superposition of different components of the Fourier transform of $\rho_2(q_z)$ and interference terms between them. Detailed analysis of Equation 51 can be very cumbersome for the most general case, and is usually dealt with for specific cases of ρ_2. Assuming that the scattering from the film is as strong for $_Qz$ as for $-Q_z$ (as is the case for an ideal 2-D system with equal scattering along the rod, i.e., ρ_2 is symmetrical under the inversion of z), we can write $\tilde{\rho}_2(\mathbf{Q}_\perp, Q_z) \approx \tilde{\rho}_2(\mathbf{Q}_\perp, -Q_z)$. In this simple case, the cross-section can be approximated as follows (Vineyard, 1982; Sinha et al., 1988; Feidenhas'l, 1989)

$$\frac{d\sigma}{d\Omega} = |t^i(k^i_{z,s})\tilde{\rho}_2(\mathbf{Q}_\perp, Q'_z)t^f(k^f_{z,s})|^2 + |t^i(k^i_{z,s})\tilde{\rho}_2(\mathbf{Q}_\perp, Q''_z)t^f(k^f_{z,0})|^2 \tag{56}$$

where $\mathbf{Q}_\perp \equiv \mathbf{k}^{\mathbf{i}}_\perp - \mathbf{k}^{\mathbf{f}}_\perp$ and $Q'_z = k^i_{z,0} - k^f_{z,s}$ and $Q''_z = k^i_{z,s} - k^f_{z,0}$. Notice that the transmission functions modulate the scattering from the film (ρ_2), and in particular they give rise to enhancements as $k^i_{z,s}$ and $k^f_{z,s}$ are scanned around the critical angle as depicted in Figure 2B. Also,

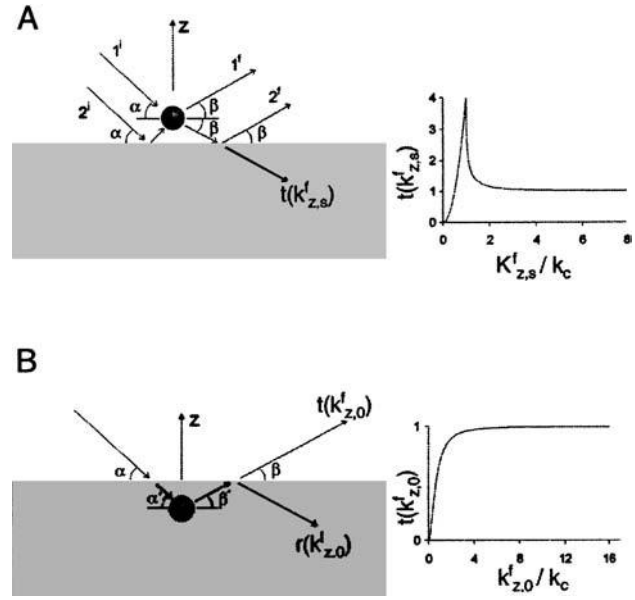

Figure 6. Illustration of wave paths for exterior (**A**) and interior (**B**) scatterer near a step-like interface. In both cases the scattering is enhanced by the transmission function when the angle of the incidence is varied around the critical angle. However, due to the asymmetry between external and internal reflectivity, the rod scan of the final beam modulates the scattering differently, as is shown on the right-hand side in each case.

it is only by virtue of the z symmetry of the scatterer that such enhancements occur for an exterior film. From this analysis we notice that there will be no enhancement due to the transmission function of the final wave for an interior film.

To examine the results from the DWBA method, we consider scattering from a single scatterer near the surface. The discussion is restricted to the case where the detection of the scattered beam is performed in the vapor phase only. The scatterer can be placed either in the vacuum ($z > 0$) or in the liquid (see Fig. 6). When the particle is placed in the vacuum there are two major relevant incident waves: a direct one from the source, labeled 1^i in Figure 6A, and a second one reflected from the surface before scattering from ρ_2, labeled 2^i. Assuming inversion symmetry along z, both waves scatter into a finite $\mathbf{Q}_\perp$ with similar strengths at Q_z and $-Q_z$, giving rise to an enhancement near the critical angle if the incident beam is near the critical angle. Another multiple scattering process that gives rise to enhancement at the critical angle is one in which beam 1^i does not undergo a change in the momentum transfer along z ($Q_z^{\text{film}} \approx 0$) before scattering from the liquid interface. The effect of these processes gives rise to enhancements if either the incident beam or the reflected beam are scanned along the z direction. Slight modifications of the momentum transfer along the z direction, such as

$$Q'_z = k^i_z + \sqrt{(k^f_z)^2 - k_c^2} \tag{57}$$

are neglected in the discussion above. The effective amplitude from the scatterer outside the medium is given by the following terms

$$|e^{iQ_z z} + e^{iQ'_z z} r(k^f_{z,s})| \approx |t(k^i_{z,s})| \tag{58}$$

where the approximation is valid since the phase factors can be neglected, and $Q_z \approx Q'_z$. At large angles the reflectivity is negligible and the transmission function approaches $t(k_{z,s}) \approx 1$. Similar arguments hold for the outgoing wave. Neglecting the small changes in the momentum transfer due to dynamical effects, the transmission function modulates the scattering as is shown in solid line in Figure 2B.

The scattered wave from a particle that is embedded in the medium is different due to the asymmetry between external and internal reflection from the liquid subphase. The wave scattered from the particle rescatters from the liquid-gas interface. Upon traversing the liquid interface, the index of refraction increases from $n = 1 - (2\pi/k_0^2)\rho$ to 1, and no total internal reflection occurs, as discussed earlier; thus there is no evanescent wave in the medium. The transmission function for this wave is given by $t(-k^i_{z,s})$, like that of a wave emanating from the liquid interface into the vapor phase. In this case, the transmission function is a real function for all $k^i_{z,s}$ and does not have the enhancements around the critical angle (as shown in Fig. 6B), with zero intensity at the horizon.

Grazing Incidence Diffraction (GID), and Rod Scans. In some instances, ordering of molecules at liquid interfaces occurs. Langmuir monolayers spread at the gas-water interface usually order homogeneously at high enough lateral pressures (Dutta et al., 1987; Kjaer et al., 1987, 1994). Surface crystallization of n-alkane molecules on molten alkane has been observed recently (Wu et al., 1993b; Ocko et al., 1997). In these cases, ρ_2 is a periodic function in x and y, and can be expanded as a Fourier series in terms of the 2-D reciprocal lattice vectors $\tau_\perp$ as follows

$$\rho_2(\boldsymbol{\mu}, z) = \sum_{\tau_\perp} F(\tau_\perp, z) e^{i\tau_\perp \cdot \boldsymbol{\mu}} \tag{59}$$

Inserting Equation 59 in Equation 56 and integrating yields the cross-section for quasi–2-D Bragg reflection at $\mathbf{Q}_\perp = \boldsymbol{\tau}_\perp$

$$\frac{d\sigma}{d\Omega} \sim P(\mathbf{Q}) |t(k^i_{z,s})|^2 \langle |F(\tau_\perp, Q_z)|^2 \rangle \mathrm{DW}(Q_\perp, Q_z) |t^f(k^f_{z,s})|^2 \delta(\mathbf{Q} - \boldsymbol{\tau}_\perp) \tag{60}$$

where P($\mathbf{Q}$) is a polarization correction and the 2-D unit cell structure factor is given as a sum over the atomic form factors $f_j(Q)$ with appropriate phase

$$F(\tau_\perp, Q_z) = \sum_j f_j(Q) e^{i\tau \cdot r_j + Q_z z_j} \tag{61}$$

The structure factor squared is averaged for multiplicity due to domains and weighted for orientation relative to the surface normal. The ordering of monolayers at the air-water interface is usually in the form of 2-D powder consisting of crystals with random orientation in the plane. From Equation 60 we notice that the conservation of momentum expressed with the delta-function allows for observation of the Bragg reflection at any Q_z. A rod scan can be performed by varying either the incident or reflected beam, or both. The variation of each will produce some modulation due to both the transmission functions and to the average molecular structure factor along the z-axis. The Debye-Waller factor (see KINEMATIC DIFFRACTION OF X-RAYS), DW($\mathbf{Q}_\perp$, Q_z), which is due to the vibration of molecules about their own equilibrium position with time-dependent molecular displacement $\mathbf{u}(t)$ is given by

$$\mathrm{DW}(\mathbf{Q}_\perp, Q_z) \sim e^{-(C_\perp Q_\perp^2 \langle \mathbf{u}_\perp^2 \rangle + Q_z^2 \sigma^2)} \tag{62}$$

The term due to capillary waves on the liquid surface is much more dominant than the contribution from the in-plane intrinsic fluctuations. The Debye-Waller factor in this case is an average over a crystalline size and might not reflect surface roughness extracted from reflectivity measurements, where it is averaged over the whole sample.

PRACTICAL ASPECTS OF THE METHOD

The minute sizes of interfacial samples on the sub-microgram level, combined with the weak interaction of x-rays with matter, result in very weak GID and reflectivity (at large Q_z) signals that require highly intense incident beams, which are available at x-ray synchrotron sources (see SURFACE X-RAY DIFFRACTION). A well prepared incident beam for reflectivity experiments at a synchrotron (for example, the X22B beam-line at the National Synchrotron Light Source at Brookhaven National Laboratory; Schwartz, 1992) has an intensity of 10^8 to 10^9 photons/sec, whereas, for a similar resolution, an 18-kW rotating anode generator produces 10^4 to 10^5 photons/sec. Although reflectivity measurements can be carried out with standard x-ray generators, the measurements are limited to almost half the angular range accessible at synchrotron sources, and they take hours to complete compared to minutes at the synchrotron. GID experiments are practically impossible with x-ray generators, since the expected signals (2-D Bragg reflections, for example) normalized to the incident beam are on the order of 10^{-8} to 10^{-10}.

Reflectivity

X-ray reflectivity and GID measurements of liquid surfaces are carried out on special reflectometers that enable manipulation of the incident as well as the outgoing beam. A prototype liquid surface reflectometer was introduced for the first time by Als-Nielsen and Pershan (1983). In order to bring the beam to an angle of incidence α_i with respect to the liquid surface, the monochromator is tilted by an angle χ either about the axis of the incident beam (indicated by χ_1 in Fig. 7) or about the axis normal to the reciprocal lattice wave vector of the monochromator, $\tau_0(\chi_2)$. Figure 7 shows the geometry that is used to deflect

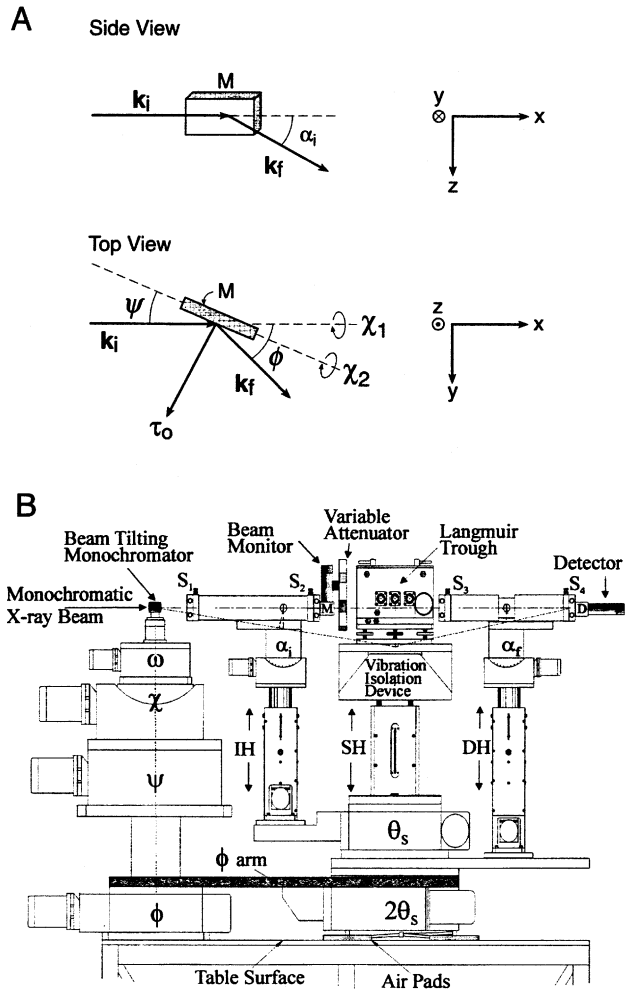

Figure 7. (**A**) Monochromator geometry to tilt a Bragg reflected beam from the horizon on a liquid surface. Two possible tilting configurations about the primary beam axis and about an axis along the surface of the reflecting planes are shown. (**B**) A side view diagram of the Ames Laboratory Liquid Surfaces Diffractometer at the 6-ID beam line at the Advanced Photon Source at Argonne National Laboratory.

the beam from the horizontal onto the liquid surface at an angle, α_i, by tilting the monochromator. At the Bragg condition, the surface of the monochromator crystal is at an angle ψ with respect to the incoming beam. Tilting over the incident beam axis is like tracing the Bragg reflection on the Debye-Scherer cone so that the ψ axis remains fixed, with a constant wavelength at different tilting angles. The rotated reciprocal lattice vector and the final wave vector in this frame are given by

$$\tau_0 = \tau_0(-\sin\psi, \cos\psi\cos\chi_1, \cos\psi\sin\chi_1)$$

$$\mathbf{k}_f = k_0(\cos\alpha_i\cos\phi, \cos\alpha_i\sin\phi, \sin\alpha_i) \qquad (63)$$

where ϕ is the horizontal scattering angle. The Bragg conditions for scattering are given by

$$\mathbf{k}_i + \tau_0 = \mathbf{k}_f; \qquad |\mathbf{k}_f| = k_0 \qquad (64)$$

Using Equations 63 and 64, the following relations for the monochromator axes are obtained

$$\begin{aligned} \sin\psi &= \frac{\tau_0}{2k_0} \\ \sin\chi_1 &= \frac{k_0}{\tau_0}\cos\psi\sin\alpha_i \\ \cos\phi &= \left(1 - \frac{\tau_0^2}{2k_0^2}\right)\Big/\cos\alpha_i \end{aligned} \qquad (65)$$

and we notice that the monochromator angle ψ is independent of α_i. However, the scattering angle ϕ has to be modified as α_i is varied. This means that the whole reflectometer arm has to be rotated. Similarly, for the configuration where the monochromator is tilted over the axis normal to τ_0 we get

$$\begin{aligned} \sin\psi &= \frac{\tau_0}{2k_0\cos\chi_2} \\ \sin\chi_2 &= \frac{k_0}{\tau_0}\sin\alpha_i \\ \cos\phi &= \left(1 - \frac{\tau_0^2}{2k_0^2}\right)\Big/\cos\alpha_i \end{aligned} \qquad (66)$$

From these relations, the conditions for a constant wavelength operation for any angle of incidence, α_i, can be calculated and applied to the reflectometer. Here, unlike the previous mode, deflection of the beam to different angles of incidence requires both the adjustment of ψ and of ϕ in order to maintain a constant wavelength. If ψ is not corrected in this mode of operation, the wavelength varies as χ is varied. This mode is sometimes desirable, especially when the incident beam hitting the monochromator consists of a continuous distribution of wavelengths around the wavelength at horizontal scattering, $\chi_2 = 0$. Such continuous wavelength distribution exists when operating with x-ray tubes or when the tilting monochromator is facing the white beam of a synchrotron. Although the variation in the wavelength is negligible as χ_2 is varied, without the correction of ψ, the exact wavelength and the momentum transfer can be computed using the relations in Equation 65 and Equation 66. In both modes of monochromator tilting, the surface height as well as the height of the slits are adjusted with vertical translations.

Figure 7, panel B, shows a side-view diagram of the Ames Laboratory Liquid Surfaces Diffractometer at the 6-ID beam line at the Advanced Photon Source at Argonne National Laboratory. A downstream Si double-crystal monochromator selects a very narrow-bandwidth energy ($\sim$1 eV) beam (in the range 4 to 40 keV) from an undulator-generated beam. The highly monochromatic beam is deflected onto the liquid surface to any desired angle of incidence, α_i, by the beam-tilting monochromator; typically Ge(111) or Ge(220) crystals are used. To simplify its description, the diffractometer can be divided into two main stages, with components that may vary slightly depending on the details of the experiment. In the first stage, the incident beam on the liquid surface is optimized. This part consists of the axes that adjust the beam tilting

monochromator (ψ, ϕ, χ), incident beam slits (S_i), beam monitor, and attenuator. The ω axis, below the monochromator crystal, is adjusted in the initial alignment process to ensure that the tilting axis χ is well defined. For each angle of incidence α_i, the ψ, ϕ, χ and the height of the incident beam arm (IH) carrying the S_1, S_2 slits, are adjusted. In addition, the liquid surface height (SH) is brought to the intersecting point between the incident beam and the detector arm axis of rotation $2\theta_s$. In the second stage of the diffractometer, the intensity of the scattered beam from the surface is mapped out. In this section, the angles α_f and $2\theta_s$ and the detector height (DH) are adjusted to select and detect the outgoing beam. The two stages are coupled through the ϕ-arm of the diffractometer. In general, θ_s is kept idle because of the polycrystalline nature of monolayers at liquid surfaces. Surface crystallization of alkanes proceeds with the formation of a few large single crystals, and the use of θ_s is essential to orienting one of these crystals with respect to the incoming beam. The scattering from liquid metals is complicated by the fact that their surfaces are not uniformly flat. For details on how to scatter from liquids with curved surfaces see Regan et al. (1997).

For aqueous surfaces, the trough (approximate dimensions $\sim 120 \times 270 \times 5$ mm^3) is placed in an airtight aluminum enclosure that allows for the exchange of the gaseous environment around the liquid surface. To get total reflectivity from water below the critical angle (e.g., $\alpha_c = 0.1538^\circ$ and 0.07688° at 8 keV and 16 keV respectively), the footprint of the beam has to be smaller than the specimen surface. A typical cross-section of the incident beam is 0.5×0.1 mm^2 with approximately 1010 to 1011 photons per second (6-ID beamline). At about $0.8\alpha_c$, the footprint of the beam with a vertical size (slit S_2) of about 0.1 mm is $\sim$47 and $\sim$94 mm at 8 keV and 16 keV, respectively, compared to 120 mm liquid-surface dimension in the direction of the primary beam. Whereas a 0.1 mm beam size is adequate for getting total reflectivity at 8 keV (exploiting about half of the liquid surface in the beam direction), a 0.05-mm beam size is more appropriate at 16 keV. This vertical beam size (slit S_2) can be increased at larger incident angles to maintain a relatively constant beam footprint on the surface.

The alignment of the diffractometer encompasses two interconnected iterated processes. First, the angles of the first stage (α_i, ψ, ϕ, χ, and ω) are optimized and set so that the x-ray flux at the monitor position is preserved upon deflection of the beam (tracking procedure). Second, the beam is steered so that it is parallel to the liquid surface. It should be emphasized that the beam, after the tracking procedure, is not necessarily parallel to the liquid surface. In this process, reflectivities from the liquid surface at various incident angles are employed to define the parallel beam, by adjustment of the angles and heights of the diffractometer. Then, repeatedly, the first and second processes are iterated until convergence is achieved (i.e., until corrections to the initial positions of motors are smaller than the mechanical accuracies).

The divergence of the monochromatic incident beam on the surface is determined by at least two horizontal slits located between the sample and the source. One of these slits is usually located as close as possible to the sample, and the other as close as possible to the source. These two slits determine the resolution of the incident beam. By deflecting the beam from the horizontal, the shape of the beam changes, and that may change incident beam intensity going through the slits; therefore the use of a monitor right after the slit in front of the sample is essential for the absolute determination of the reflectivity. The size of the two slits defining the incident beam is chosen in such a way that the footprint of the beam is much smaller than the width of the reflecting surface, so that total reflectivity occurs. Figure 8 shows the reflected beam and the direct beam from a flat surface of water, demonstrating total reflectivity at $Q_z = 0.85Q_c$. In this experiment the detector slit is wide open at $\sim$10 times the opening of the sample slit. As is demonstrated, the effect of absorption is negligible for water, and roughness is significantly reduced by damping surface waves. The damping can be achieved by reducing the height of the water film to $\sim$0.3 mm and placing a passive as well as an active antivibration unit underneath the liquid sample holder, suppressing mechanical vibrations (Kjaer et al., 1994).

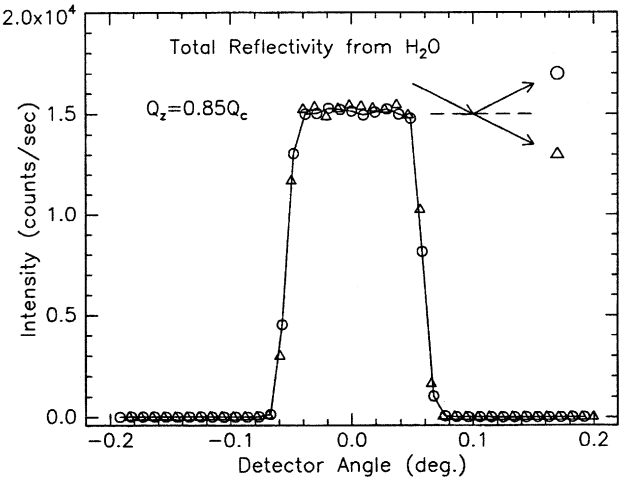

Figure 8. Superposition of the reflected beam (circles) below the critical angle and direct beam (triangles), demonstrating total reflectivity of x-rays from the surface of water. Severe surface roughness reduces the intensity and widens the reflected signal. A reduction from total reflectivity can also occur if the slits of the incident beam are too wide, so that the beam-footprint is larger than the surface sample.

Non-Specular Scattering: GID, Diffuse Scattering, and Rod Scans

X-ray GID measurements are performed at angles of incidence below the critical angle $\approx 0.9\alpha_c$. Operating with the incident beam below the critical angle enhances the signal from the surface with respect to that of the bulk by creating an evanescent wave in the medium that is exponentially decaying according to

$$E(z) = t(k_{z,s})e^{-z/\Lambda} \tag{67}$$

where

$$\frac{1}{\Lambda} = \sqrt{k_c^2 - k_{z,0}^2} \tag{68}$$

For water at $k_z \approx 0.9k_c$, $\Lambda \sim 100$ Å.

As illustrated in Figure 1, the components of the momentum transfer for GID are given by

$$\begin{aligned} Q_z &= k_0(\sin\alpha_i + \sin\alpha_f) \\ Q_x &= k_0(\cos\alpha_i - \cos\alpha_f)\cos 2\theta \\ Q_y &= k_0 \cos\alpha_f \sin 2\theta \end{aligned} \tag{69}$$

In most cases, the 2-D order on liquid surfaces is powder-like, and the lateral scans are displayed in terms of $Q_\perp$ which is given by

$$Q_\perp = k_0\sqrt{\cos^2\alpha_i + \cos^2\alpha_f - 2\cos\alpha_i\cos\alpha_f\cos 2\theta} \tag{70}$$

To determine the in-plane correlations, the horizontal resolution of the diffractometer can be adjusted with a Soller collimator consisting of vertical absorbing foils stacked together between the surface and the detector. The area that is probed at each scattering angle 2θ is proportional to $S_0/\sin 2\theta$, where S_0 is the area probed at $2\theta = \pi/2$. The probed area must be taken into account in the analysis of a GID scan that is performed over a wide range of angles.

Position-sensitive detectors (PSD) are commonly used to measure the intensity along the 2-D rods. It should be kept in mind that the intensity along the PSD is not a true rod scan of a Bragg reflection at a nominal $Q_\perp$ because of the variation in $Q_\perp$ as α_f is varied, as is seen in Equation 69.

DATA ANALYSIS AND INITIAL INTERPRETATION

The task of finding the SLD from a reflectivity curve is similar to that of finding an effective potential for Equation 7 from the modulus of the wave-function. Direct inversion of the scattering amplitude to SLD is not possible except for special cases when the BA is valid (Sacks, 1993, and references therein). If the modulus and the phase are known, they can be converted by the method of Gelfand-Levitan-Marchenko (Sacks, 1993, and references therein) to SLD (GLM method). However, in reflectivity experiments, the intensity of the scattered beam alone is measured, and phase information is lost.

Step-like potentials have been directly reconstructed recently by retrieving the phase from the modulus—i.e., reflectivity—and then using the GLM method (Clinton, 1993; also Sacks, 1993, and references therein). Model-independent methods which are based on optimization of a model to reflectivity, without requiring any knowledge of the chemical composition of the SLD at the interface, were also developed recently (Pedersen, 1992; Zhou and Chen, 1995). Such models incorporate a certain degree of objectivity. These methods are based on the kinematical and the dynamical approaches for calculating the reflectivity. One method (Pedersen, 1992) uses indirect Fourier transformation to calculate the correlation function of $d\rho/dz$, which is subsequently used in a square-root deconvolution model to construct the SLD model. Zhou and Chen (1995), on the other hand, developed a groove tracking method that is based on an optimization algorithm to reconstruct the SLD using the dynamical approach to calculate the reflectivity at each step.

The most common procedure to extract structural information from reflectivity is the use of standard nonlinear least squares refinement of an initial SLD model. The initial model is defined in terms of a P-dimensional set of independent parameters, $\mathbf{p}$, using all the information available in guessing $\rho(z, \mathbf{p})$. The parameters are then refined by calculating the reflectivity ($R[Q_z^i\mathbf{p}]$) with the tools described earlier, and by minimizing the $\chi^2(\mathbf{p})$ quantity

$$\chi^2(\mathbf{p}) = \frac{1}{N-P}\sum_{i=1}\left[\frac{R_{\exp}(Q_z^i) - R(Q_z^i, \mathbf{p})}{\varepsilon(Q_z^i)}\right]^2 \tag{71}$$

where $\varepsilon(Q_z^i)$ is the uncertainty of the measured reflectivity, $R_{\exp}(Q_z^i)$, and N is the number of measured points. The criteria for a good fit can be found in Bevington (1968). Uncertainties of a certain parameter can be obtained by fixing it at various values and for each value refining the rest of the parameters until χ^2 is increased by a factor of at least $1/(N-P)$.

The direct methods and model-independent procedures of reconstruction SLD do not guarantee uniqueness of the potential—i.e., there can be multiple SLD profiles that essentially yield the same reflectivity curve, as discussed with regard to Figure 5, for example. The uniqueness can be achieved by introducing physical constraints that are incorporated into the parameters of the model. Volume, in-plane density of electrons, etc., are among such constraints that can be used. Applying such constraints is discussed briefly below; see Examples (also see Vaknin et al., 1991a,b; Gregory et al., 1997). These constraints reduce the uncertainties and make the relationship of the SLD to the actual molecular arrangement apparent. In the dynamical approach, no two potentials yield exactly the same reflectivity, although the differences between two models might be too small to be detected in an experiment.

An experimental method for solving such a problem was suggested by Sanyal et al. (1992) using anomalous x-ray reflectivity methods. Two reflectivity curves from the same sample are measured with two different x-ray energies, one below and one above an absorption edge of the substrate atoms, thereby varying the scattering length density of the substrate. Subsequently the two reflectivity curves can be used to perform a direct Fourier reconstruction (Sanyal et al., 1992), or refinement methods can be used to remove ambiguities. This method is not efficient when dealing with liquids that consist of light atoms, because of the very low energy of the absorption edge with respect to standard x-ray energies. Another way to overcome the problem of uniqueness is by performing reflectivity experiments on similar samples with x-rays and with neutrons. In addition, the SLD, $\rho(z)$ across the

interface can be changed significantly, in neutron scattering experiments, by chemical exchange of isotopes that change $\rho(z)$, but maintain the same structure (Vaknin et al., 1991b; Penfold and Thomas, 1990). The reflectivities (x-ray as well as neutrons) can be fitted to one structural model that is defined in terms of geometrical parameters only, calculating the SLDs from scattering lengths of the constituents and the geometrical parameters (Vaknin et al., 1991b,c).

Examples

Since the pioneering work of Als-Nielsen and Pershan (1983), x-ray reflectivity and GID became standard tools for the characterization of liquid surfaces on the atomic length scales. The techniques have been exploited in studies of the physical properties of simple liquids (Braslau et al., 1988; Sanyal et al., 1991; Ocko et al., 1994), Langmuir monolayers (Dutta et al., 1987; Kjaer et al., 1987, 1989, 1994; Als-Nielsen and Kjaer, 1989; Vaknin et al., 1991b), liquid metals (Rice et al., 1986; Magnussen et al., 1995; Regan et al., 1995), surface crystallization (Wu et al., 1993a,b, 1995; Ocko et al., 1997), liquid crystals (Pershan et al., 1987), surface properties of quantum liquids (Lurio et al., 1992), protein recognition processes at liquid surfaces (Vaknin et al., 1991a, 1993; Lösche et al., 1993), and many other applications. Here, only a few examples are briefly described in order to demonstrate the strengths and the limitations of the techniques. In presenting the examples, there is no intention of giving a full theoretical background of the systems.

Simple Liquids. The term simple liquid is usually used for a monoatomic system governed by van der Waals–type interactions, such as liquid argon. Here, the term is extended to include all classical dielectric (nonmetallic) liquids such as water, organic solvents (methanol, ethanol, chloroform, etc.), and others. One of the main issues regarding dielectric liquids is the determination of the average density profile across the interface, $N(z)$. This density is the result of folding the intrinsic density $N_I(z)$ of the interface due to molecular size, viscosity, and compressibility of the fluid with density fluctuations due to capillary waves, $\Delta N_{\mathrm{CW}}(z)$. The continuous nature of the density across the interface due to capillary waves was worked out by Buff, Lovett, and Stillinger (BLS; Buff et al., 1965) assuming that $N_I(z)$ is an ideal step-like function. The probability for the displacement is taken to be proportional to the Boltzmann factor, $e^{-\beta U(z)}$, where U is the free energy necessary to disturb the surface from equilibrium state—i.e., $z(x,y) = 0$—and $\beta = 1/k_{\mathrm{B}}T$ where k_{B} is Boltzmann's constant. The free energy of an incompressible and nonviscous liquid surface consists of two terms; a surface tension (γ) term, which is proportional to the changes in area from the ideally flat surface and a gravitational term as follows

$$U = \int (\gamma[\sqrt{1 + |\nabla z|^2} - 1] + \frac{1}{2} m_s g z^2) d^2\boldsymbol{\mu} \approx \frac{1}{2} \int (\gamma |\nabla z|^2 + m_s g z^2) d^2\boldsymbol{\mu} \quad (72)$$

where m_{s} is the mass density of the liquid substrate. By using standard Gaussian approximation methods, Buff et al. (1965) find that

$$U(z) \sim \frac{z^2}{2\sigma_0^2} \quad (73)$$

Convolution of the probability with a step-like function, representing the intrinsic density of the liquid surface yields the following density function

$$N(z) = N_{\mathrm{s}} \mathrm{erfc}\left(\frac{z}{\sqrt{2}\sigma}\right) \quad (74)$$

with a form similar to the one given in Equation 47. The average surface roughness at temperature T, is then given by

$$\sigma_{\mathrm{CW}}^2 = \frac{k_{\mathrm{B}}T}{2\pi\gamma} \ln\left(\frac{L}{a_0}\right) \quad (75)$$

where a_0 is a molecular diameter and L is the size of the surface. Notice the logarithmic divergence of the fluctuations as the size of the surface increases, as expected of a 2-D system (Landau and Lifshitz, 1980). This model was further refined by assuming that the intrinsic profile has a finite width (Evans, 1979). In particular if the width due to the intrinsic profile is also expressed by a Gaussian then, the effective surface roughness is given by

$$\sigma_{\mathrm{eff}}^2 = \sigma_{\mathrm{I}}^2 + \sigma_{\mathrm{CW}}^2 \quad (76)$$

and the calculated reflectivity is similar to Equation 35 for an interface that is smeared like the error function

$$R_{\mathrm{CW}} = R_{\mathrm{F}}(Q_z) e^{-\alpha_{\mathrm{eff}}^2 Q_z^2} \quad (77)$$

Figure 9 shows the reflectivity from pure water measured at the synchrotron (D. Vaknin, unpub. observ.) where it is shown that, using Equation 77 for fitting the reflectivity data is satisfactory. This implies that the error function type of density profile (BLS model) for the liquid interface is sufficient. Only the surface roughness parameter, σ, is varied to refine the fit to the data ($\sigma = 2.54$ Å). This small roughness value depends on the attenuation of capillary waves by minimizing the depth of the water to $\sim$0.3 mm by placing a flat glass under the water (Kjaer et al., 1994). The validity of a Gaussian approximation of $N(z)$ (BLS model) was examined by various groups and for a variety of systems (Braslau et al., 1988; Sanyal et al., 1991; Ocko et al., 1994). Ocko et al. (1994) have measured the reflectivity of liquid alkanes over a wide range of temperatures, verifying that the surface roughness is of the form given in Equations 75 and 76.

Experimentally, the reflectivity signal at each Q_z from a rough interface is convoluted with the resolution of the spectrometer in different directions. The effect of the resolution in Q_z can be calculated analytically or convoluted numerically. For simplicity, we consider that the resolution functions can be approximated as a Gaussian with a

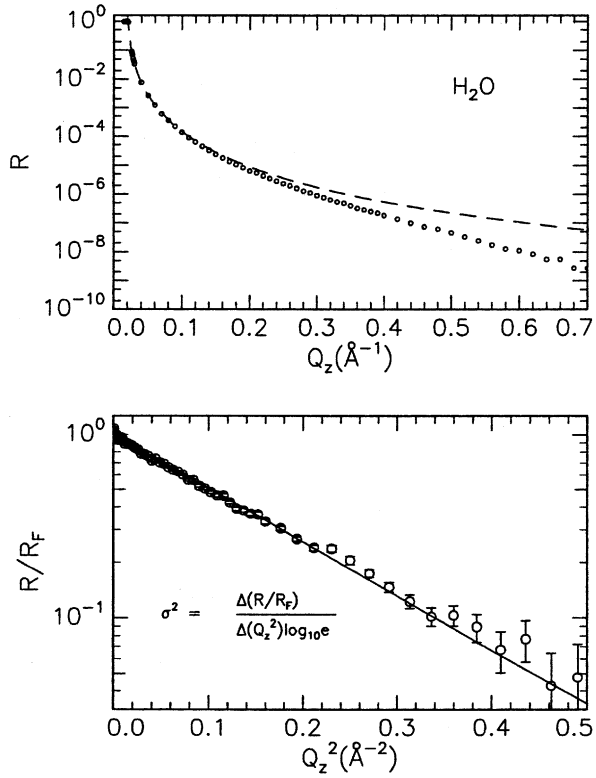

Figure 9. Experimental reflectivity from the surface of water. The dashed line is the calculated Fresnel reflectivity from an ideally flat water-interface, R_F. The normalized reflectivity versus Q_z^2 is fitted to a the form $R/R_F = e^{-(Q_z\sigma)^2}$, demonstrating the validity of the capillary-wave model (Buff et al., 1965).

width of ΔQ_z along Q_z can be taken as $e^{-Q_z^2/\Delta Q_z^2}$ with appropriate normalization factor (Bouwman and Pederesen, 1996). The resolution, ΔQ_z, is Q_z-dependent as the angles of incidence and scattering are varied (Ocko et al., 1994). However, if we assume that around a certain Q_z value the resolution is a constant and we measure σ_{exp}, the convolution of the true reflectivity with the resolution function yields the following relation

$$\frac{1}{\sigma_{exp}^2} \approx \frac{1}{\sigma_{eff}^2} + \Delta Q_z^2 \tag{78}$$

from which the effective roughness can be extracted as follows

$$\sigma_{eff} \approx \frac{\sigma_{exp}}{\sqrt{1 - \sigma_{exp}^2 \Delta Q_z^2}} \tag{79}$$

Thus, if the resolution is infinitely good, i.e., with a $\Delta Q_z = 0$, the measured and effective roughness are the same. However, as the resolution is relaxed, the measured roughness gets smaller than the effective roughness. The effect of the resolution on the determination of true surface roughness was discussed rigorously by Braslau et al. (1988).

Diffuse scattering from liquid surfaces is practically inevitable, due to the presence of capillary waves. Calculation of the scattering from disordered interfaces of various characteristics are treated in Sinha et al. (1988). In the Born approximation, true specular scattering from liquid surfaces exists only by virtue of the finite cutoff length of the mean-square height fluctuations (Equation 75). In other words, the fluctuations due to capillary waves diverge logarithmically, and true specular reflectivity is observed only by virtue of the finite instrumental resolution. The theory for the diffuse scattering from fractal surfaces and other rough surfaces was developed in Sinha et al. (1988).

Langmuir Monolayers. A Langmuir monolayer (LM) is a monomolecular amphiphilic film spread at the air-water interface. Each amphiphilic molecule consist of a polar head group (hydrophilic moiety) and a nonpolar tail, typically hydrocarbon (hydrophobic) chains (Gaines, 1966; Swalen et al., 1987; Möhwald, 1990). Typical examples are fatty acids, lipids, alcohols, and others. The length of the hydrocarbon chain can be chemically varied, affecting the hydrophobic character of the molecule. On the other hand, the head group can be ionic, dipolar, or it may have with a certain shape that might attract specific compounds present in the aqueous solution. One important motivation for studying LMs is their close relationship to biological systems. Membranes of all living cells and organelles within cells consist of lipid bilayers interpenetrated with specific proteins, alcohols, and other organic compounds that combine to give functional macromolecules which determine transport of matter and energy through them. It is well known that biological functions are structural, and structures can be determined by XR and GID. In addition, delicate surface chemistry can be carried out at the head-group interface with the molecules in the aqueous solution. From the physics point of view, the LM belongs to an important class of quasi–2-D system, by means of which statistical models that depend on the dimension of the system can be examined.

In this example, results from a simple lipid, dihexadecyl hydrogen phosphate (DHDP), consisting of a phosphate head group (PO_4^-) and its two attached hydrocarbon chains, are presented. Figure 10A displays the normalized reflectivity of a DHDP monolayer at the air-water interface at a lateral pressure of 40 mN/m. The corresponding electron density profile is shown in the inset as a solid line. The profile in the absence of surface roughness ($\sigma = 0$) is displayed as a dashed line. The bulk water subphase corresponds to $z < 0$, the phosphate headgroup region is at $0 \geq z \geq 3.4$ Å, and the hydrocarbon tails are at the 3.4 Å $\geq z \geq$ 23.1 Å region. As a first-stage analysis of the reflectivity, a model SLD with minimum number of boxes, $i = 1, 2, 3\ldots$, is constructed. Each box is characterized by a thickness d_i and an electron density $N_{e,i}$, and one surface roughness, σ for all interfaces. Refinement of the reflectivity with Equation 37 shows that the two-box model is sufficient. In order to improve the analysis, we can take advantage of information we know of the monolayer, i.e., the constituents used and the molecular area determined from the lateral-pressure versus molecular area isotherm. If the monolayer is homogeneous and not necessarily ordered, we can assume an average area per

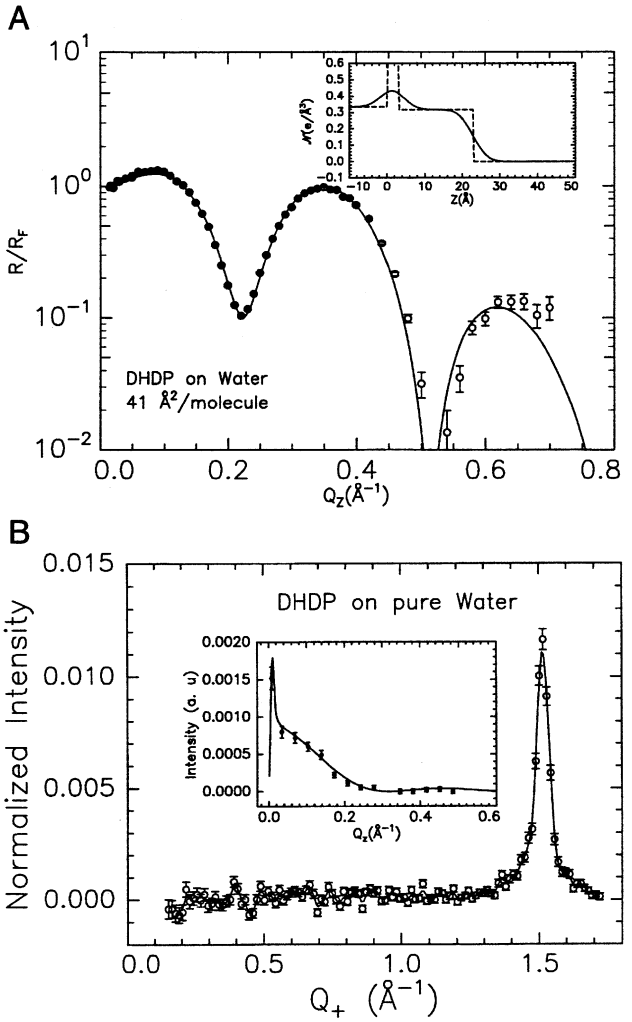

Figure 10. (**A**) Normalized x-ray reflectivity from dihexadecyl phosphate (DHDP) monolayer at the air-water interface with best-fit electron density, N_e, shown with solid line in the inset. The calculated reflectivity from the best model is shown with a solid line. The dashed line in the inset shows the box model with no roughness $\sigma = 0$. (**B**) A diffraction from the same monolayer showing a prominent 2-D Bragg reflection corresponding to the hexagonal ordering of individual hydrocarbon chains at $Q_{\perp}^{B} = 1.516$ Å^{-1}. The inset shows a rod scan from the quasi-2D Bragg reflection at $Q_{\perp}^{B}$, with a calculated model for tilted chains denoted by solid line (see text for more details).

molecule at the interface A, and calculate the electron density of the tail region as follows

$$\rho_{\text{tail}} = N_{e,\text{tail}}\, r_0/(A d_{\text{tail}}) \tag{80}$$

where $N_{e,\text{tail}}$ is the number of electrons in the hydrocarbon tail and d_{tail} is the length of the tail in the monolayer. The advantage of this description is two-fold: the number of independent parameters can be reduced, and constraints on the total number of electrons can be introduced. However, in this case, the simple relation $\rho_{\text{head}} = N_{e,\text{phosphate}}/(A d_{\text{head}})$ is not satisfactory, and in order to get a reasonable fit, additional electrons are necessary in the head-group region. These additional electrons can be associated with water molecules that interpenetrate the head-group region, which is not densely packed. The cross-section of the phosphate head group is smaller than the area occupied by the two hydrocarbon tails, allowing for water molecules to penetrate the head group region. We therefore introduce an extra parameter N_{H_2O}, the number of water molecules with ten electrons each. The electron density of the head group region is given by

$$\rho_{\text{head}} = (N_{e,\text{phosphate}} + 10N_{H_2O})/(A d_{\text{head}}) \tag{81}$$

This approach gives a physical insight into the chemical constituents at the interface. In modeling the reflectivity with the above assumptions, we can either apply volume constraints or, equivalently, examine the consistency of the model with the literature values of closely packed moieties. In this case the following volume constraint can be applied

$$V_{\text{headgroup}} = A\, d_{\text{head}} = N_{H_2O} V_{H_2O} + V_{\text{phosphate}} \tag{82}$$

where $V_{H_2O} \approx 30$ Å^2 is known from the density of water. The value of $V_{\text{phosphate}}$ determined from the refinement should be consistent within error with known values extracted from crystal structures of salt phosphate (Gregory et al., 1997).

Another parameter that can be deduced from the analysis is the average tilt angle, t, of the tails with respect to the surface. For this the following relation is used

$$d_{\text{tail}}/l_{\text{tail}} = \cos t \tag{83}$$

where l_{tail} is the full length of the extended alkyl chain evaluated from the crystal data for alkanes (Gregory et al., 1997). Such a relation is valid under the condition that the electron density of the tails when tilted is about the same as that of closely packed hydrocarbon chains in a crystal, $\rho_{\text{tail}} \approx 0.32 e/\text{Å}^3 r_0$, as observed by Kjaer et al. (1989). Such a tilt of the hydrocarbon tails would lead to an average increase in the molecular area compared to the cross-section of the hydrocarbon tails (A_0)

$$A_0/A = \cos t \tag{84}$$

Gregory et al. (1997) found that at lateral pressure $\pi = 40$ mN/m, the average tilt angle is very close to zero ($\approx 7 \pm 7^{\circ}$), and extracted an $A_0 \approx 40.7$ Å^2 compared with a value of 39.8 Å^2 for closely packed crystalline hydrocarbon chains. The small discrepancy was attributed to defects at domain boundaries.

The GID for the same monolayer is shown in Figure 10B, where a lowest-order Bragg reflection at 1.516 Å^{-1} is observed. This reflection corresponds to the hexagonal ordering of the individual hydrocarbon chains (Kjaer et al., 1987, 1989) with lattice constant $d = 4.1144$ Å, and molecular area per chain $A_{\text{chain}} = 19.83$ Å^2. Note that in DHDP the phosphate group is anchored to a pair of hydrocarbon chains with molecular area $A = 39.66$ Å^2, and it is surprising that ordering of the head group with a larger unit cell (twice that of the hydrocarbon unit cell) is not observed, as is evident in Figure 10B. Also shown in

the inset of Figure 10B is a rod scan of the Bragg reflection. To model the rod scan in terms of tilted chains, the procedure developed in Kjaer et al. (1989) is followed. The structure factor of the chain can be expressed as

$$F_{\text{chain}}(\mathbf{Q}'_{\perp}, Q'_z) = F(Q_{\perp}) \frac{\sin(lQ'_z/2)}{(lQ'_z/2)} \tag{85}$$

where $F(Q'_{\perp})$ is the in-plane Fourier transform of the cross-section of the electron density of chain, weighted with the atomic form factors of the constituents. The second term accounts for the length of the chain, and is basically a Fourier transform of a one-dimensional aperture of length l. If the chains are tilted with respect to the surface normal (in the $y-z$ plane) by an angle t, the $\mathbf{Q}'$ should be rotated as follows

$$\begin{aligned} Q'_x &= Q_x \cos t + Q_z \sin t \\ Q'_y &= Q_y \\ Q'_z &= -Q_x \sin t + Q_z \cos t \end{aligned} \tag{86}$$

Applying this transformation to the molecular structure factor, Equation 85, and averaging over all six domains (see more details in Kjaer et al., 1989) with the appropriate weights to each tilt direction, we find that at 40 mN/m the hydrocarbon chains are practically normal to the surface, consistent with the analysis of the reflectivity.

In recent Brewster Angle Microscopy (BAM) and x-ray studies of C_{60}-propylamine spread at the air-water interface (see more details on fullerene films; Vaknin, 1996), a broad in-plane GID signal was observed (Fukuto et al., 1997). The GID signal was analyzed in terms of a 2-D radial distribution function that implied short-range positional correlations extending to only few molecular distances. It was demonstrated that the local packing of molecules on water is hexagonal, forming a 2-D amorphous solid.

Surface Crystallization of Liquid Alkanes. Normal alkanes are linear hydrocarbon chains $(CH_2)_n$ terminating with CH_3 groups similar to fatty acids and lipids. The latter compounds, in contrast to alkanes, possess a hydrophilic head group at one end. Recent extensive x-ray studies of pure and mixed liquid alkanes (Wu et al., 1993a,b, 1995; Ocko et al., 1997) reveal rich and remarkable properties near their melting temperature, T_f. In particular, a single crystal monolayer is formed at the surface of an isotropic liquid bulk up to $\approx 3^{\circ}$C above T_f for a range of hydrocarbon number n. The surface freezing phenomenon exists for a wide range of chain lengths, $16 \geq n \geq 50$. The molecules in the ordered layer are hexagonally packed and show three distinct ordered phases: two rotator phases, one with the molecules oriented vertically ($16 \geq n \geq 30$), and the other tilted toward nearest neighbors ($30 \geq n \geq 44$). The third phase ($44 \geq n$) orders with the molecules tilted towards next-nearest neighbors. In addition to the 2-D Bragg reflections observed in the GID studies, reflectivity curves from the same monolayers were found to be consistent with a one-box model of densely packed hydrocarbon chains, and a thickness that corresponds to slightly tilted chains. This is an excellent demonstration of a case where no other technique but the x-ray experiments carried out at a synchrotron could be applied to get the detailed structure of the monolayers. Neutron scattering from this system would have yielded similar information; however, the intensities available today from reactors and spallation sources are smaller by at least a factor of 10^5 counts/sec for similar resolutions, and will not allow observation of any GID signals above background levels.

Liquid Metals. Liquid metals, unlike dielectric liquids, consist of the classical ionic liquid and quantum free-electron gas. Scattering of conduction electrons at a step-like potential (representing the metal-vacuum interface) gives rise to quantum interference effects and leads to oscillations of the electron density across the interface (Lang and Kohn, 1970). This effect is similar to the Friedel oscillations in the screened potential arising from the scattering of conduction electrons by an isolated charge in a metal. By virtue of their mobility, the ions in a liquid metal can in turn rearrange and conform to these oscillations to form layers at the interface, not necessarily commensurate with the conduction electron density (Rice et al., 1986). Such theoretical predictions of atomic layering at surfaces of liquid metals have been known for a long time, and have only recently been confirmed by x-ray reflectivity studies for liquid gallium and liquid mercury (Magnussen et al., 1995; Regan et al., 1995). X-ray reflectivities of these liquids were extended to $Q_z \sim 3\text{Å}^{-1}$, showing a single peak that indicates layering with spacing on the order of atomic diameters. The exponential decay for layer penetration into the bulk of Ga (6.5Å) was found to be larger than that of Hg (~3Å). Figure 11 shows a peak in the reflectivity of liquid Ga under in situ UHV oxygen-free surface cleaning (Regan et al., 1995, 1997). The normalized reflectivity was fitted to a model scattering length density shown in Figure 11B, of the following oscillating and exponentially decaying form (Regan et al., 1995)

$$\rho(z)/\rho_s = \text{erf}[(z - z_0)/\sigma] + \theta(z) A \sin(2\pi z/d) e^{-z/\xi} \tag{87}$$

where $\theta(z)$ is a step function, d is the inter-layer spacing, ξ is the exponential decay length, and A is an amplitude. Fits to this model are shown in Figure 11 with $d = 2.56$ Å, $\xi = 5.8$ Å. The layering phenomena in Ga showed a strong temperature dependence. Although liquid Hg exhibits layering with a different decay length, the reflectivity at small momentum transfers, Q_z, is significantly different than that of liquid Ga, indicating fundamental differences in the surface structures of the two metals. The layering phenomena suggest in-plane correlations that might be different than those of the bulk, but had not been observed yet with GID studies.

SPECIMEN MODIFICATION AND PROBLEMS

In conducting experiments from liquid surfaces, the experimenter faces problems that are commonly encountered in other x-ray techniques. A common nuisance in

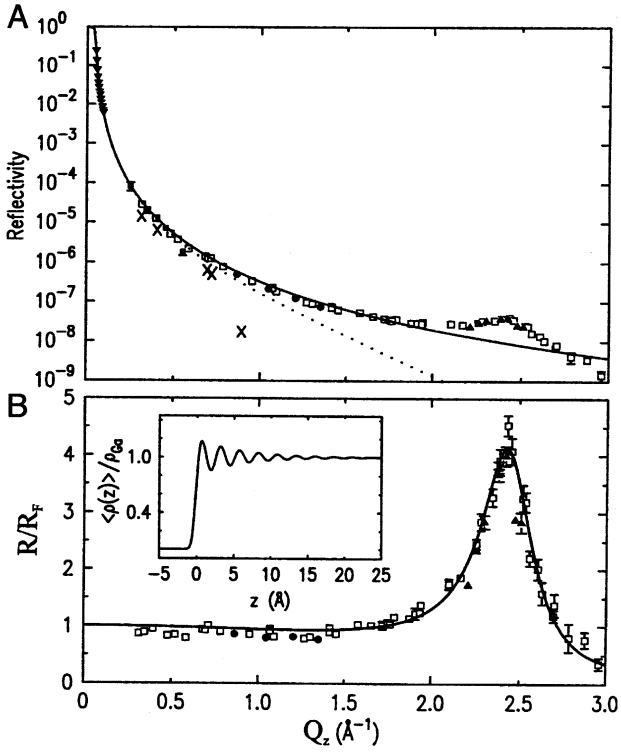

Figure 11. (**A**) Measured reflectivity for liquid gallium (Ga). Data marked with X were collected prior to sample cleaning whereas the other symbols correspond to clean surfaces (for details see Regan et al., 1995). Calculated Fresnel reflectivity from liquid Ga surface convoluted with a surface roughness due to capillary waves ($\sigma = 0.82$ Å), and the atomic form factor for Ga is denoted with a solid line. (**B**) The normalized reflectivity, with a solid line that was calculated with the best fit by an exponentially decaying sine model shown in the inset (courtesy of Regan et al., 1995).

an undulator beam line is the presence of high harmonic components that accompany the desired monochromatic beam. These high harmonics can skew the data as they affect the counting efficiency of the detector, can damage the specimen or the detector, and can increase undesirable background. The higher harmonic components can be reduced significantly (but not totally eliminated) by inserting a mirror below the critical angle for total reflection, or by detuning the second crystal of the double-crystal monochromator (XAFS SPECTROSCOPY). However, there are also problems that are more specific to reflectivity and GID in general, and to liquid surfaces in particular. Such problems can arise at any stage of the study, initially during the alignment of the diffractometer, or subsequently during data collection, and also in the final data analysis.

Poor initial alignment of the diffractometer will eventually result in poor data. Accurate tracking, namely small variation (5% to 15%) in the count rate of the monitor as the incident angle α_i is varied (workable range of α_i is 0° to 10°) is a key to getting reliable data. Although seemingly simple, one of the most important factors in getting a good alignment is the accurate determination of relevant distances in the diffractometer. For the specific design in Figure 7B, these include the distances from the center of the tilting monochromator to the center of the IH elevator and to the sample SH, or the distances from the center of the liquid surface to the detector (S_4) and to the elevator (DH). These distances are used to calculate the translations of the three elevators (IH, SH, and DH) for each angle. Although initial values measured directly with a ruler can be used, effective values based on the use of the x-ray beam yield the best tracking of the diffractometer.

Radiation damage to the specimen is a common nuisance when dealing with liquid surfaces. Many of the studies of liquid surfaces and monolayers involve investigations of organic or biomaterials that are susceptible to chemical transformations in general and, in particular, in the presence of the intense synchrotron beam. Radiation damage is of course not unique to monolayers on liquid surfaces; other x-ray techniques that involve organic materials (protein, polymer, liquid crystals, and others) face similar problems. Radiation damage to a specimen proceeds in two steps. First, the specimen or a molecule in its surroundings is ionized (by the photoelectric, Auger, or Compton effects) or excited to higher energy levels (creating radicals). Subsequently, the ionized/excited product can react with a nearby site of the same molecule or with a neighboring molecule to form a new species, altering the chemistry as well the structure at the surface. In principle, recovery without damage is also possible, but there will be a recovery time involved. The remedies that are proposed here are in part specific to liquid surfaces and cannot be always fulfilled in view of the specific requirements of an experiment. To minimize the primary effects (photoelectric, Auger, and Compton scattering) one can employ one or all of the following remedies. First, the exposure time to the x-ray beam can be minimized. For instance, while motors are still moving to their final positions, the beam can be blocked. Reduced exposure can be also achieved by attenuating the flux on the sample to roughly match it to the expected signal, so that the full intense beam is used only for signals with cross-sections for scattering that require it. That, of course, requires rough knowledge of signal intensity, which is usually the case in x-ray experiments. Monolayers on liquid surfaces are inevitably disposable and it takes a few of them to complete a study, so that in the advanced stage of a study many peak intensities are known. Another approach to reducing the effect of the primary stage is by operating at high x-ray energies. It is well known that the cross-section for all the primary effects is significantly reduced with the increase of x-ray energy. If the experiment does not require a specific energy, such as in resonance studies (anomalous scattering), it is advantageous to operate at high x-ray energies. However, operation at higher x-ray energies introduces technical difficulties. Higher mechanical angular resolutions, and smaller slits, are required in order to achieve reciprocal space resolutions comparable to those at lower energies. As discussed above, slit S_2 at 16 keV has to be set at about 50 μm width, which cannot be reliably achieved with variable slits. Finally, reducing the high harmonic component in the x-ray beam will also reduce the primary effect of the radiation.

Reducing the effects of secondary processes also depends on the requirements of a specific experiment. Air surrounding the sample has probably the worst effect on the integrity of an organic film at the liquid interface. The x-ray radiation readily creates potent radicals in air (such as monatomic oxygen) that are highly diffusive and penetrant and can interact with almost any site of an organic molecule. Working in an He environment or under vacuum can significantly reduce this source of radiation damage. Another approach to consider for reducing the secondary effect of radiation is scattering at low temperatures. It is well documented in protein crystallography that radiation damage is significantly reduced at liquid nitrogen temperatures. However, such low temperatures are not a choice when dealing with aqueous surfaces, and variations in temperature can also lead to dramatic structural transition in the films which may alter the objectives of the study.

The liquid substrate, even water, can create temporary radicals that can damage the monolayer: in particular, the head group region of lipids. Water under intense x-ray radiation can give many reactive products such as H_2O_2 or monatomic oxygen that can readily interact with the monolayer. Thus, some radiation damage, with an extent that may vary from sample to sample, is inevitable, and fresh samples are required to complete a study. Moving the sample underneath the footprint is a quick fix in that regard, assuming that the radiation damage is mostly localized around the illuminated area. To accomplish that, one can introduce a translation of the trough (perpendicular to the incident beam direction at $\alpha_i = 0$) to probe different parts of the surface. It should be noted that for lipid monolayers, a common observation suggests that radiation damage is much more severe at lower in-plane densities than for closely packed monolayers.

Another serious problem concerning scattering from surfaces is background radiation that can give count rates comparable to those expected from GID or rod scan signals. Background can be classified into two groups, one due to room background and the other due to the sample and its immediate surroundings. Although it is very hard to locate the sources of room background, it is important to trace and block them, as they reduce the capability of the diffractometer. The specimen can give unavoidable background signal due to diffuse or incoherent scattering from the liquid substrate, and this needs to be accounted for in the interpretation of the data. An important source of background is the very immediate environment of the liquid surface that does not include the sample but is included in the scattering volume of the beam: worst of all is air. Working under vacuum is not an option with monolayers, and therefore such samples are kept under an He environment. Air scattering in the trough can give rise to background levels that are at least two or three orders of magnitude higher than the expected signal from a typical 2-D Bragg reflection in the GID.

As discussed previously (see Data Analysis and Initial Interpretation), reflectivity data can give ambiguous SLD values, although that rarely happens. More often, however, the reflectivity is overinterpreted, with details in the SLD that cannot be supported by the data. The reflectivity from aqueous surfaces can be at best measured up to a momentum transfer Q_z of ~ 1 Å^{-1}, which, roughly speaking, in an objective reconstruction of the SLD, should give uncertainties on the order of $2\pi/Q_z \sim 6$ Å. It is only by virtue of complementary knowledge on the constituents of the monolayer that these uncertainties can be lowered to about 1 to 2 Å. Another potential pitfall for overinterpretation lies in the fact that in the GID experiments only a few peaks are observed, and without the knowledge on the 3-D packing of the constituents it is difficult to interpret the data unequivocally.

ACKNOWLEDGMENTS

The author would like to thank Prof. P. S. Pershan for providing a copy of Fig. 11 for this publication. Ames Laboratory is operated by Iowa State University for the U.S. Department of Energy under Contract No. W-7405-Eng-82. The work at Ames was supported by the Director for Energy Research, Office of Basic Energy Sciences.

KEY REFERENCES

Als-Neilsen and Kjaer, 1989. See above.

An excellent, self-contained, and intuitive review of x-ray reflectivity and GID from liquid surfaces and Langmuir monolayers by pioneers in the field of liquid surfaces.

Braslau et al., 1988. See above.

The first comprehensive review examining the properties of the liquid-vapor interface of simple liquids (water, carbon tetrachloride, and methanol) employing the reflectivity technique. The paper provides many rigorous derivations such as the Born approximation, the height-height correlation function of the surface, and surface roughness due to capillary waves. Discussion of practical aspects regarding resolution function of the diffractometer and convolution of the resolution with the reflectivity signal is also provided.

Sinha et al., 1988. See above.

This seminal paper deals with the diffuse scattering from a variety of rough surfaces. It also provides a detailed account of the diffuse scattering in terms of the distored-wave Born approximation (DWBA). It is relevant to liquid as well as to solid surfaces.

APPENDIX: P-POLARIZED X-RAY BEAM

A p-polarized x-ray beam has a magnetic field component that is parallel to the stratified medium (along the x axis, see Fig. 1), and straightforward derivation of the wave equation (Equation 7) yields

$$\frac{d}{dz}\left(\frac{dB}{\varepsilon dz}\right) + [k_z^2 - V(z)]B = 0 \tag{88}$$

By introducing a dilation variable Z such that $dZ = \varepsilon dz$, Equation 88 for B can be transformed to a form similar to Equation 12

$$\frac{d^2B}{dZ^2} = \left[\frac{k_z^2 - V(z)}{\varepsilon}\right]B = 0 \tag{89}$$

The solution of Equation 89 for an ideally flat interface in terms of $r_p(k_{z,s})$ and $t_p(k_{z,s})$ is then simply given by

$$r_p(k_{z,s}) = \frac{k_{z,0} - k_{z,s}/\varepsilon}{k_{z,0} + k_{z,s}/\varepsilon}, \quad t_p(k_z, s) = \frac{2k_{z,0}}{k_{z,0} + k_{z,s}/\varepsilon} \tag{90}$$

The critical momentum transfer for total external reflectivity of the p-type x-ray beam is $Q_c = 2k_c = \sqrt{4\pi\rho_s}$, identical to the one derived for the s-type wave. Also, for $2k_z^B \gg Q_z \gg Q_c$, (k_z^B is defined below), $R_F(Q_z)$ can be approximated as

$$R_F(Q_z) \sim \left(\frac{Q_c}{2Q_z}\right)^4 \left(\frac{2}{1+\varepsilon}\right)^2 \tag{91}$$

The factor on the right hand side is equal to 1 for all practical liquids, and thus the Born approximation is basically the same as for the s-polarized x-ray beam (Equation 17). The main difference between the s-type and p-type waves occurs at larger angles near a Brewster angle that is given by $\theta_B = \sin^{-1}(k_z^B/k_0)$. At this angle, total transmission of the p-type wave occurs ($r_p(k_z, s) = 0$). Using Equations 14 and 90, k_z^B can be derived

$$\frac{k_z^B}{k_0} = \frac{1}{\sqrt{2 - 4\pi\rho_s/k_0^2}} \tag{92}$$

The Brewster angle for x-rays is then given by $\theta_B = \sin^{-1}(k_z^B/k_0) \approx \pi/4$. This derivation is valid for solid surfaces, including crystals, where the total transmission effect of the p-polarized wave at a Bragg reflection is used to produce polarized and monochromatic x-ray beams.

ELECTRON TECHNIQUES

INTRODUCTION

This part describes how electrons are used to probe the microstructures of materials. These methods are arguably the most powerful and flexible set of tools available for materials characterization. For the characterization of structures internal to materials, electron beam methods provide capabilities for determining crystal structure, crystal shapes and orientations, defects within the crystals, and the distribution of atoms within these individual crystals. For characterizing surfaces, electron methods can determine structure and chemistry at the level of the atomic monolayer.

The methods in this part use electrons with kinetic energies spanning the range from 1 to 1,000,000 eV. The low energy range is the domain of scanning tunneling microscopy (STM). Since STM originates with quantum mechanical tunneling of electrons through potential barriers, this method differs from the others in this part, which employ electron beams incident on the material. Progressively higher energies are used for the electron beams of low energy electron diffraction (LEED), Auger spectrometry, reflection high energy electron diffraction (RHEED), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Electron penetration through the solid increases strongly over this broad energy range. STM, Auger, and LEED techniques are used for probing the monolayer of surface atoms (although variants of STM can probe sub-surface structures). On the other hand, the penetration capability of high energy electrons makes TEM primarily a bulk technique. Nevertheless, even with TEM it is often unrealistic to study samples having thicknesses much greater than a fraction of a micron.

Since electron beams can be focused with high accuracy, the incident beam can take various forms. A tightly focused beam, rastered across the sample, is one useful form. The acquisition of various signals in synchronization with this raster pattern provides a spatial map of the signal. Signals can be locations of characteristic x-ray emission, secondary-electron emission, or electron energy losses, to name but three. A plane wave is another useful form of the incident electron beam. Plane wave illumination is typically used for image formation with conventional microscopy and diffraction. It turns out that for complementary optical designs, the same diffraction effects in the specimen that produce visible features in images will occur with either a point- or plane-illumination mode. There are, however, advantages to one mode of operation versus another, and instruments of the scanning type and imaging type are typically used for different types of measurements. Atomic resolution imaging, for example, can be performed with a plane wave illumination method in high resolution electron microscopy (HREM), or with a probe mode in Z-contrast imaging. A fundamental difference between these techniques is that the diffracted waves interfere coherently in the case of HREM imaging, and the phase information of the scattering is used to make interference patterns in the image. On the other hand, the operation of the scanning transmission electron microscope for Z-contrast imaging makes use of incoherent imaging, where the intensities of the scatterings from the individual atoms add independently to the image.

Electron scattering from a material can be either elastic or inelastic. In general, elastic scattering is used for imaging measurements, whereas inelastic scattering provides for spectroscopy. (Electron beam techniques are enormously versatile, however, so there are many exceptions to this generality.) Chemical mapping, for example, makes images by use of inelastic scattering. For chemical mapping, the energy loss of the electron itself may be used to obtain the chemical information, as in electron energy loss spectrometry (EELS). Alternatively, the subsequent radiations from atoms ionized by the inelastic scattering may be as signals containing the chemical information. A component of the characteristic atomic x-ray spectrum, measured with an energy dispersive x-ray spectrometer (EDS), is a particularly useful signal for making chemical maps with a scanning electron microscope. The intensity of selected Auger electrons emitted from the excited atoms provides the chemical mapping capability of scanning Auger microscopy. Auger maps are highly surface-sensitive, since the Auger electrons lose energy as they traverse only a short distance through the solid.

The chapters in this part enumerate some requirements for sample preparation, but it is remarkable that any one of these techniques permits studies on a large variety of samples. All classes of materials (metals, ceramics, polymers, and composites) have been studied by all of these electron techniques. Except for some problems with the lightest (or heaviest) elements in the periodic table, the electron beam techniques have few compositional limitations. There are sometimes problems with how the sample may contaminate the vacuum system that is integral to all electron beam methods. This is especially true for the surface techniques that employ ultrahigh vacuums.

When approaching a new problem in materials characterization, electron beam methods (especially SEM), provide some of the best reward/effort ratios of any materials characterization technique. Many, if not all, of the techniques in this part should therefore be familiar to everyone interested in materials characterization. Some of the methods are available through commercial laboratories on a routine basis, such as SEM, EDS and Auger spectroscopy. TEM services can sometimes be found at companies offering asbestos analysis. Manufacturers of electron beam instruments may also provide analysis services at reasonable rates. All the electron methods of this part are available at materials research laboratories at universities and national laboratories. Preliminary assessments of the applicability of an electron method to a materials problem can often be made by contacting someone at a local institution. These institutions usually have established policies for fees and service for outside users. For value in capital investment, perhaps a scanning electron

microscope with an energy dispersive spectrometer is a best buy. The surface techniques are more specialized, and the expense and maintenance of their ultrahigh vacuum systems can be formidable. TEM is also a technique that cannot be approached casually, and some contact with an expert in the field is usually the best way to begin.

SCANNING ELECTRON MICROSCOPY

INTRODUCTION

The scanning electron microscope (SEM) is one of the most widely used instruments in materials research laboratories and is common in various forms in fabrication plants. Scanning electron microscopy is central to microstructural analysis and therefore important to any investigation relating to the processing, properties, and behavior of materials that involves their microstructure. The SEM provides information relating to topographical features, morphology, phase distribution, compositional differences, crystal structure, crystal orientation, and the presence and location of electrical defects. The SEM is also capable of determining elemental composition of micro-volumes with the addition of an x-ray or electron spectrometer (see ENERGY-DISPERSIVE SPECTROMETRY and AUGER ELECTRON SPECTROSCOPY) and phase identification through analysis of electron diffraction patterns (see LOW-ENERGY ELECTRON DIFFRACTION). The strength of the SEM lies in its inherent versatility due to the multiple signals generated, simple image formation process, wide magnification range, and excellent depth of field.

Lenses in the SEM are not a part of the image formation system but are used to demagnify and focus the electron beam onto the sample surface. This gives rise to two of the major benefits of the SEM: range of magnification and depth of field in the image. Depth of field is that property of SEM images where surfaces at different distances from the lens appear in focus, giving the image three-dimensional information. The SEM has more than 300 times the depth of field of the light microscope. Another important advantage of the SEM over the optical microscope is its high resolution. Resolution of 1 nm is now achievable from an SEM with a field emission (FE) electron gun. Magnification is a function of the scanning system rather than the lenses, and therefore a surface in focus can be imaged at a wide range of magnifications from 3× up to 150,000×. The higher magnifications of the SEM are rivaled only by the transmission electron microscope (TEM) (see TRANSMISSION ELECTRON MICROSCOPY and SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING), which requires the electrons to penetrate through the entire thickness of the sample. As a consequence, TEM sample preparation of bulk materials is tedious and time consuming, compared to the ease of SEM sample preparation, and may damage the microstructure. The information content of the SEM and TEM images is different, with the TEM image showing the internal structure of the material.

Due to these unique features, SEM images frequently appear not only in the scientific literature but also in the daily newspapers and popular magazines. The SEM is relatively easy to operate and affordable and allows for multiple operation modes, corresponding to the collection of different signals. The following sections review the SEM instrumentation and principles, its capabilities and applications, and recent trends and developments.

PRINCIPLES OF THE METHOD

Signal Generation

The SEM electron beam is a focused probe of electrons accelerated to moderately high energy and positioned onto the sample by electromagnetic fields. The SEM optical column is utilized to ensure that the incoming electrons are of similar energy and trajectory. These beam electrons interact with atoms in the specimen by a variety of mechanisms when they impinge on a point on the surface of the specimen. For inelastic interactions, energy is transferred to the sample from the beam, while elastic interactions are defined by a change in trajectory of the beam electrons without loss of energy. Since electrons normally undergo multiple interactions, the inelastic and elastic interactions result in the beam electrons spreading out into the material (changing trajectory from the original focused probe) and losing energy. This simultaneous energy loss and change in trajectory produces an interaction volume within the bulk (Fig. 1). The size of this interaction volume can be estimated by Monte Carlo simulations, which incorporate probabilities of the multiple possible elastic and inelastic interactions into a calculation of electron trajectories within the specimen.

The signals resulting from these interactions (e.g., electrons and photons) will each have different depths within the sample from which they can escape due to their unique

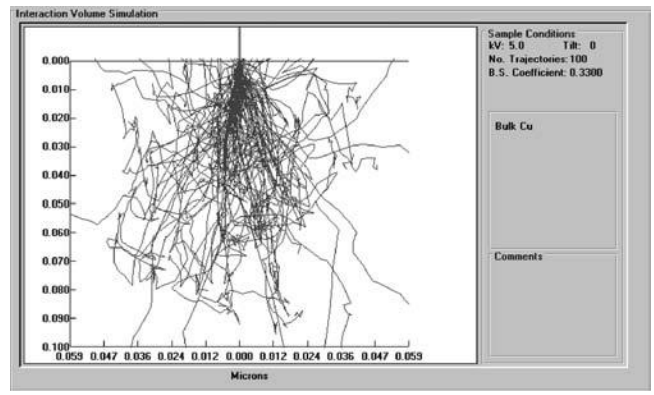

Figure 1. A Monte Carlo simulation of electron beam interaction with a bulk copper target at 5 keV shows the interaction volume within the specimen. The electron trajectories are shown, and the volume is symmetric about the beam due to the normal incidence angle (derived from Goldstein et al., 1992; Monte Carlo simulation using Electron Flight Simulator, Small World, D. Chernoff).

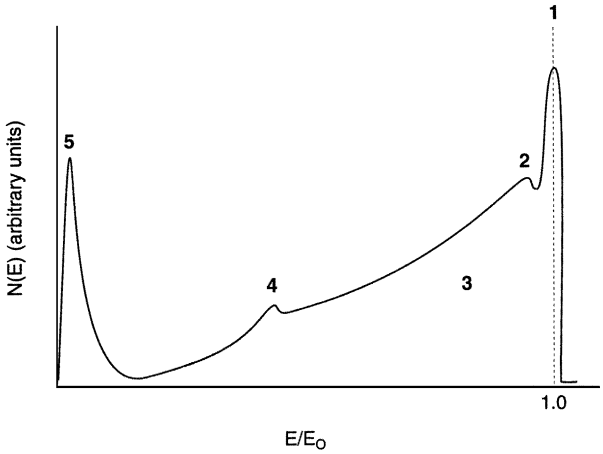

Figure 2. Distribution of relative energies (E/E_0; E_0 = incident beam energy) of electrons ejected from a surface by an incident electron beam (not to scale). The peak (1) is the elastic peak, BSEs that have lost no energy in the specimen. Slightly lower in energy is the plasmon loss region (2). The BSEs (3) are spread over the entire energy range from 0 eV to the energy of the incident beam. The characteristic Auger electron peak (4) is usually a small peak superimposed on the backscattered curve. Secondary electrons emitted from specimen atoms are responsible for the large peak at low energy (5).

physical properties and energies. For example, a secondary electron (SE) is a low-energy (2- to 5-eV) electron ejected from the outer shell of a sample atom after an inelastic interaction. These low-energy electrons can escape the surface only if generated near the surface. Thus we have an "interaction volume" in which beam electrons interact with the specimen and a "sampling volume" from which a given signal escapes the solid, which is some fraction of the interaction volume. It is this sampling volume and the signal distribution within it that determine the spatial resolution of the technique (Joy, 1984). We can thus expect different spatial resolutions for the various types of signals generated in the SEM.

Backscattered electrons (BSEs) are electrons from the incident probe that undergo elastic interactions with the sample, change trajectory, and escape the sample. These make up the majority of electrons emitted from the specimen at high beam voltage, and their average energy is much higher than that of the SEs (Fig. 2). The depth from which BSEs escape the specimen is dependent upon the beam energy and the specimen composition, but >90% generally escape from less than one-fifth the beam penetration depth. The intensity of the BSE signal is a function of the average atomic number (Z) of the specimen, with heavier elements (higher Z samples) producing more BSEs. It is thus a useful signal for generating compositional images, in which higher Z phases appear brighter than lower Z phases. The BSE intensity and trajectory are also dependent upon the angle of incidence between the beam and the specimen surface. The topography, or physical features of the surface, is then imaged by using these properties of the BSE signal to generate BSE topographic images. Due to the relatively high energy of the BSE signal, the sampling volume (sample depth) is greater than that of SEs.

Secondary electrons are due to inelastic interactions, are low energy (typically 2 to 5 eV), and are influenced more by surface properties than by atomic number. The SE is emitted from an outer shell of a specimen atom upon impact of the incident electron beam. The term "secondary" thus refers to the fact that this signal is not a scattered portion of the probe, but a signal generated within the specimen due to the transfer of energy from the beam to the specimen. In practice, SEs are arbitrarily defined as those electrons with <50 eV energy (Fig. 2). The depth from which SEs escape the specimen is generally between 5 and 50 nm due to their low energy. Secondary electrons are generated by both the beam entering the specimen and BSEs as they escape the specimen; however, SE generation is concentrated around the initial probe diameter. The SE sampling volume is therefore smaller than the BSE and provides for a high-resolution image of the specimen surface. Secondary electron intensity is a function of the surface orientation with respect to the beam and the SE detector and thus produces an image of the specimen morphology. The SE intensity is also influenced by chemical bonding, charging effects, and BSE intensity, since BSE-generated SEs are a significant part of the SE signal.

Characteristic x rays and Auger electrons are generated by inelastic interactions of the probe electrons in which an inner shell electron is emitted from a specimen atom (ionization). Following the creation of a hole in an inner shell, the atom relaxes by a transition in which an outer shell electron fills the inner shell (relaxation). Since the outer shell electron was at a higher energy level, this relaxation results in a release of energy from the atom (emission). This emission may be in the form of a photon (x ray) or may go into the emission of an electron (the Auger electron, AUGER ELECTRON SPECTROSCOPY) from the atom. These two processes therefore compete, since a single ionization can result in either an x ray or an Auger electron. The x-ray energy would then equal the difference in binding energy of the two electron levels within the atom and is thus characteristic of that element. The Auger electron generated from this ionization is emitted from an outer shell. It would thus have a kinetic energy equal to that of the x ray minus the binding energy of the outer shell from which it is emitted. The Auger sample depth (1 to 3 nm) is much less than the x-ray sample depth (0.1 to 100 μm) since electrons have a higher probability of interaction with the specimen than photons (x rays) of similar energy, and energy loss interactions will render them non-characteristic. X rays may interact with the specimen through absorption, in which the entire energy is absorbed by the specimen, but do not undergo partial energy loss interactions. These signals can be used for imaging as well as the identification of elements within the sample volume (see ENERGY-DISPERSIVE SPECTROMETRY and AUGER ELECTRON SPECTROSCOPY). It is common for the SEM in a materials laboratory to include an x-ray spectrometer as one of the detectors, and scanning Auger microanalysis combines the SEM with an electron spectrometer. Electron energy loss spectroscopy is a transmission electron technique,

since multiple energy loss interactions occur for a single beam electron in the bulk samples characteristic of SEM and deconvolution of these energy losses is not possible.

Other signals originating from electron beam interactions with the sample include plasmons, phonons, bremsstrahlung radiation (noncharacteristic x rays), and cathodoluminescence. Cathodoluminescence is the emission of light from a material under the electron beam. The wavelength of the light is a function of the material's band gap energy, since the generation involves the production and recombination of electron-hole pairs. Cathodoluminescence is therefore useful in the characterization of semiconductors, especially in cases where a contactless, high-spatial-resolution method is needed (Yacobi and Holt, 1986).

The sample may also absorb a significant portion of the electron beam current, and the specimen current image can thus provide the same information as the combined BSE and SE signals (Newbury, 1976). Charge collection scanning electron microscopy with the specimen as the detector can also be used to study the electron-beam-induced current/ conductivity (EBIC), which has been used to determine carrier lifetime, diffusion length, defect energy levels, and surface recombination velocities and to locate *p-n* junctions and recombination sites (Leamy, 1982).

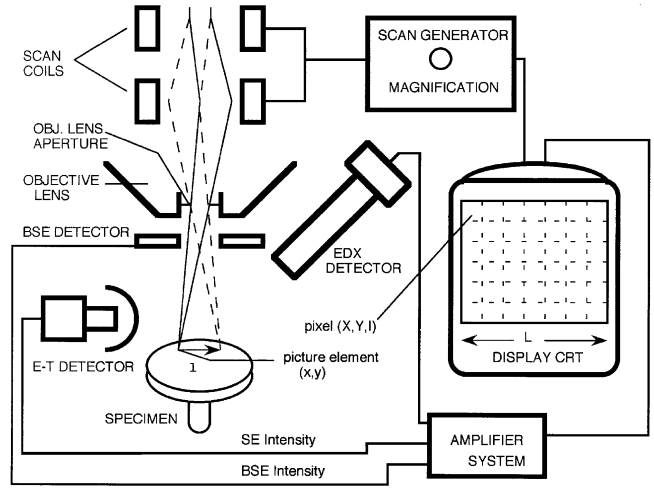

Figure 3. Schematic of the image formation system of the SEM. The electron beam is shown at two positions in time, scanned in the X direction to define the distance l on the specimen surface. Reproduction of this scan on the CRT, with a width L, gives a magnification $M = L/l$. The picture element is an area on the specimen surface, its location given by (x, y). Signal from this area (SE, BSE, x ray, or other) is transferred to the CRT and converted to an intensity value for pixel (X, Y, I). This simple image formation process is highly versatile in that the magnification is only a function of the scan length on the sample, and any signal may be used to provide the intensity variation, thus producing an image. (E-T, Everhart-Thornley.)

Image Formation

Image construction in the SEM is accomplished by mapping intensity of one of these signals (usually SE and/or BSE) from the specimen onto a viewing screen or film (Fig. 3). There is a point-to-point transfer of this intensity information, since the SEM scan generator simultaneously drives an electron beam across the surface of the specimen and an electron beam on the viewing cathode-ray tube (CRT) or recording device. The intensity information from the detector is translated to a gray scale, with higher signal intensity being brighter on the display. The image is therefore an array of pixels, with each pixel defined by x and y spatial coordinates and a gray value proportional to the signal intensity. Magnification of the image is defined as the length of the scan line on the monitor or recording device divided by the length of the scan line on the specimen. Magnification is therefore independent of the lenses. Magnification is adjusted by changing the size of the area scanned on the specimen while the monitor or film size is held constant. Thus a smaller area scanned on the sample will produce a higher magnification. This is a major strength of SEM imaging, and with optimized beam conditions and focus, the image magnification can be changed through its entire range without loss of image quality. A typical magnification range for the SEM is 10× to 100,000×; however, the higher magnifications are dependent upon acquiring sufficient resolution.

The region on the specimen from which information is transferred to a single pixel of the image is called a picture element. The size of the picture element is determined by the length of the scan on the specimen divided by the number of pixels in a line of the image. Picture element therefore refers to a position on the specimen, and pixel refers to the corresponding portion of the recorded image. The intensity of the signal is recorded for a single pixel of the image while the beam is addressed to the center of a single picture element. Consider a digital image that is 10 cm on a side and 100× magnification. The image represents an area on the sample that is 1 mm (1000 μm) wide, and the scale for the image is 1 cm = 100 μm. The picture element width is 1000 μm (the length of the scan on the specimen) divided by the number of pixels in the digital image. A common digital resolution for the SEM is 1024×1024, and thus the picture element width for the 100× image would be 0.98 μm. The picture element width would be 0.098 μm at 1000× and 0.0098 μm (9.8 nm) at 10,000×. The SEM image will appear in focus if the sampling volume is smaller in diameter than this picture element size. If the probe diameter or resultant sampling volume is larger than the picture element, blurring of the image occurs due to overlap of information from neighboring picture elements. This results in loss of resolution. When magnification is increased, the picture element size is reduced, and this overlap of information can result. The sampling volume is therefore a limiting factor on resolution for the SEM.

The SEM image conveys three-dimensional information due to the depth of field in the image. The depth of field depends upon the electron beam divergence angle, which is defined by the diameter of the objective lens aperture and the distance between the specimen and the aperture (Fig. 4). This angle is exceptionally small compared to that in a light microscope and results in a small change

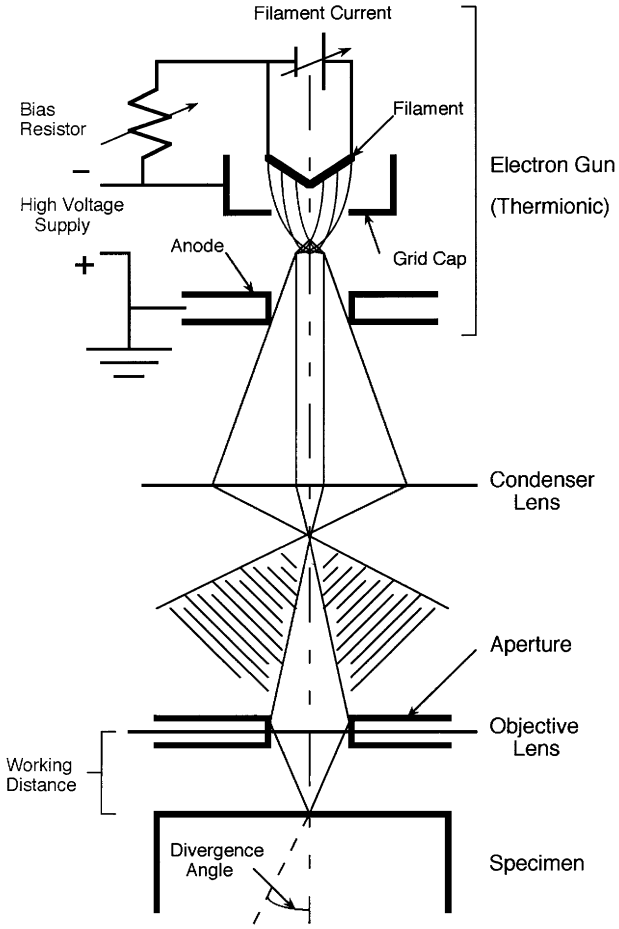

Figure 4. Schematic of the probe-forming system of the SEM. The thermionic electron gun is a triode system, with the initial crossover of electrons from the filament due to the field created by the filament, grid cap, and anode. This initial beam diameter is reduced by the condenser and objective lenses. A portion of the beam (shaded in the schematic) will not pass through the final aperture. Increasing the strength of the condenser lens will decrease the probe diameter but will also decrease the probe current. The objective lens will produce a smaller probe diameter when the working distance is reduced (the lens is stronger) and provide higher resolution. A longer working distance will reduce the divergence angle and therefore increase depth of field in the image.

in diameter of the beam with change in distance (depth) from the lens. This means that the sampling volume can likewise remain small over this range of depth. All points will appear in focus where the sampling volume diameter is smaller than the picture element. Depth of field is increased by reducing the beam divergence angle, which can be done by increasing the working distance or decreasing the aperture diameter. The excellent depth of field in SEM images is as important to the usefulness of scanning electron microscopy as the resolution and provides the topographic/morphological information well known to anyone who has admired any SEM image. Depth of field is typically between 10% and 60% of the field width.

Resolution

The resolving power of the SEM is dependent upon the sampling volume, since this sampling volume is the portion of the specimen from which the signal originates. It was stated under Image Formation above that the image appears in focus if the sampling volume is smaller than the picture element. This is also a statement of the resolution; if the sampling volume is smaller than the feature of interest, then the feature can be resolved, or distinguished from its surroundings. This simple model of resolution works well for most situations, but for higher magnifications the actual signal distribution within the sampling volume becomes critical, since the signal density is not uniform across the sampling volume. The sampling volume is a function of the probe (energy and diameter) and the specimen (composition and orientation). Resolution is therefore not an instrument constant, and it varies significantly with application. Microscope manufacturers quote a resolution value that is determined under ideal conditions on a specimen produced specifically for the purpose of testing high resolution. These values are used to characterize the instrument rather than to predict results expected from a given specimen. It is the job of the microscopist to prepare the sample and control the instrument in such a way as to provide the optimum or maximum resolution.

Modern SEMs with field emission electron guns (FESEMs) are capable of resolutions near 1 nm on appropriate samples using the SE signal. Tungsten filament instruments can routinely obtain resolutions of 3 to 4 nm on appropriate specimens. Samples that require special conditions, such as low voltage or low dosage, and samples that are inherently poor signal generators due to their composition may fall far short of this resolution. The signal from these specimens can often be enhanced by depositing a thin film of metal such as chromium or gold onto the surface. This increases contrast in the SE signal and allows for higher resolution imaging. Operating conditions that favor one signal, for instance, the high beam currents and energies used for x-ray analysis, can also reduce image resolution. High-resolution BSE images can be obtained by selecting only high-energy BSEs (low-energy-loss BSEs), since these have undergone few interactions with the sample and are thus from a smaller sampling volume.

PRACTICAL ASPECTS OF THE METHOD

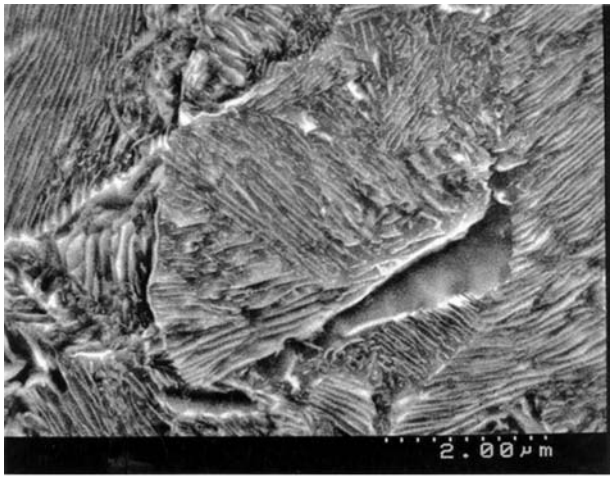
SEM Instrumentation

The production of an electron probe requires an electron gun to emit and accelerate electrons and a series of lenses to de-magnify and focus the beam (Fig. 4). "Scanning" involves positioning of the probe on the specimen surface by electromagnetic (or electrostatic) deflection and simultaneously positioning a beam that carries signal intensity information onto a viewing device (camera or monitor). When the two beams are scanned in a regular pattern covering a rectangular area (raster), the signal output onto the viewing monitor becomes a map of signal intensity coming from the sample, and this "map" is the SEM image.

This can be done in an analog or digital manner. Scanning a small area on the sample and mapping the resultant signal intensity information onto a larger viewing surface result in magnification.

Three types of electron guns are in common use today: tungsten and lanthanum hexaboride thermionic electron guns, and the field emission gun. Tungsten and lanthanum hexaboride are used as filaments in thermionic electron guns, in which the filament (cathode) is heated by applying a current. Emission of electrons occurs at high temperatures and requires that the gun be operated in a high vacuum to avoid oxidation. The emitted electrons are accelerated to high energy by the application of a negative voltage to the cathode and a bias voltage to the grid cap with the anode grounded. This triode system accelerates the electrons and provides an initial focusing into a probe. Tungsten is popular for its low cost, ease of replacement, and high current yield, while lanthanum hexaboride provides a brighter source (higher current density) useful for higher resolution. In the field emission gun, a fine tip is placed near a grid and electrons escape the surface due to the high extracting field strength created by the first grid. A second grid provides the accelerating voltage. Field emission requires ultrahigh vacuum and is more expensive, but it provides much higher brightness with a resultant increase in resolution.

Scanning, positioning, and focusing of the electron beam after it leaves the electron gun is accomplished by the use of electromagnetic or electrostatic fields. A simple electromagnetic lens requires only a coil of wire wrapped concentrically around the optic axis. A current through this coil produces a field that deflects electrons toward the center of the lens. This field focuses the electrons into a smaller area, thus reducing the diameter of the electron beam produced by the electron gun. Lenses in modern instruments are far from simple, utilizing shroud and pole piece designs that maximize lens strength while minimizing lens aberrations (spherical, chromatic, and diffraction; see Goldstein et al., 1992).



The "lenses" in the SEM all combine to produce a fine probe diameter. The condenser lens (often a system of several lenses adjusted by a single control) is used as the primary means of reducing the beam diameter produced by the electron gun. The condenser lens is usually directly below the electron gun and above a series of apertures necessary to define a small probe diameter (Fig. 4). Increasing the strength of the condenser lens will decrease the probe diameter but will also decrease the probe current due to interception of part of the beam by these apertures. This decrease in probe current with reduction of the probe diameter is a serious limitation in the SEM, since signal intensity is a fraction of probe intensity. High resolution requires a small probe diameter as well as a signal of high enough intensity that the differences in intensity are within the detector's range. It is this limitation that makes the brightness of the electron gun such an important consideration. The control knob for the condenser lens system may be labeled "spot size," "beam current," "probe diameter," or various other similar descriptive terms referring to its dual but interconnected effect on the beam.

The SEM objective lens is in basic respects no different than the condenser lens, in that it reduces and focuses the probe. Its position in the instrument, however, is such that its primary purpose is to reduce the probe to the smallest diameter at the surface of the sample (Fig. 4), which results in the clearest, or "focused," image. In the SEM there is no image formed behind the lenses as in the optical microscope. The lenses act on the electron beam rather than on the image. The objective lens aperture, often called the probe-forming aperture, defines the convergence (divergence) angle of the probe, which is important for the depth of field. Adjustment of the objective lens does not have a large effect on beam current as adjustment of the condenser lens does.

Electromagnetic or electrostatic fields that are not concentric with the optic axis will deflect the electron beam. This is utilized to center the beam onto the optic axis (alignment) and to scan or position the beam on the sample surface. Alignment coils are commonly utilized to position the electron beam coming from the electron gun along the optic axis of the instrument. These coils may also be used to "blank" the beam by directing it away from the sample toward a grounded aperture. The scan coils are usually located near or within the objective lens assembly and are used for many of the operator-controlled functions of the SEM. The scan coils control the position of the beam on the sample and are used for scanning of the beam to produce an image, determining magnification of the image, electronic shifting of the imaged area, and positioning a probe for x-ray analysis, among other functions. A final component of the optical system, the stigmator, utilizes paired coils arranged around the optic axis to eliminate astigmatism. Astigmatism arises due to irregularities in the electron-lens fields, which can be caused by aperture irregularities or contamination. The operator corrects for this irregularity by providing an equal but opposite irregularity with the coils of the stigmator. This operation should be done in conjunction with focusing, since it is necessary for producing a small, symmetric probe diameter on the sample surface.

Contrast and Detectors

Microstructure for most solids can be imaged in the SEM with minimum specimen preparation, although interpretation of the microstructure can be aided by careful attention to specimen preparation, such as the polishing and etching of metals (Fig. 5). The SEM offers a choice of detectors and operating parameters that can be taken advantage of to produce a variety of images showing microstructure. Contrast in the SEM image is the difference in intensity, or brightness, of the pixels that make up the image. The difference in intensity represents a difference in signal from corresponding picture elements on the specimen. This signal intensity is dependent upon the signal generated within the specimen and the type of detector used. It is therefore necessary to recognize both the beam-specimen interaction that produces the signal and the detection and amplification process that converts the signal intensity to image brightness. Contrast components of the signal electrons—their number, trajectory,

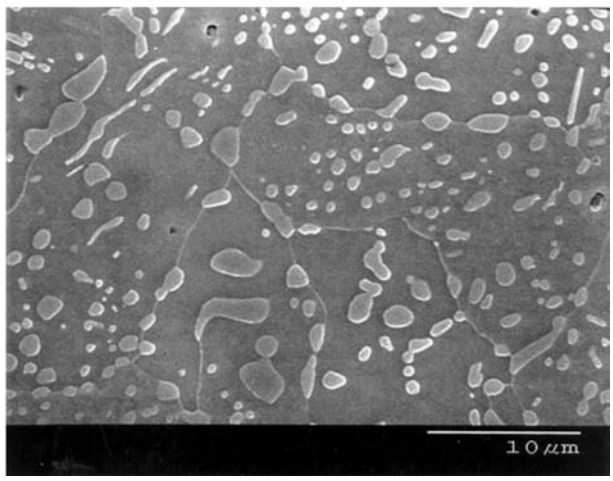


Figure 5. Microstructures of two steel samples of identical chemical composition (0.97% carbon by weight) but with different cooling and annealing histories. Scanning electron microscopy reveals the characteristic structure that makes the steel in the top image extremely hard and brittle, while the steel in the bottom image can be used for springs and is comparatively soft (Killick, 1996).

and energy—are a useful means to describe and understand how this information from the specimen is translated to an intensity value on the image. The number component is expressed by higher numbers of electrons from the specimen resulting in higher brightness on the image. Trajectory is equally important, since detectors have limited size and shape and therefore detect only a portion of the signal emitted. A high signal generated in the specimen that is directed away from the detector will result in a low detected signal. The energy component is also critical, since the ability to collect and detect the signal is a function of the signal energy. The combination of these three components (number, trajectory, and energy) creates a unique situation for each probe-specimen-detector combination. The most widely used images produced by SEM imaging are the SE image, the BSE compositional image, and the BSE topographic image. It is important to note that many images will have a

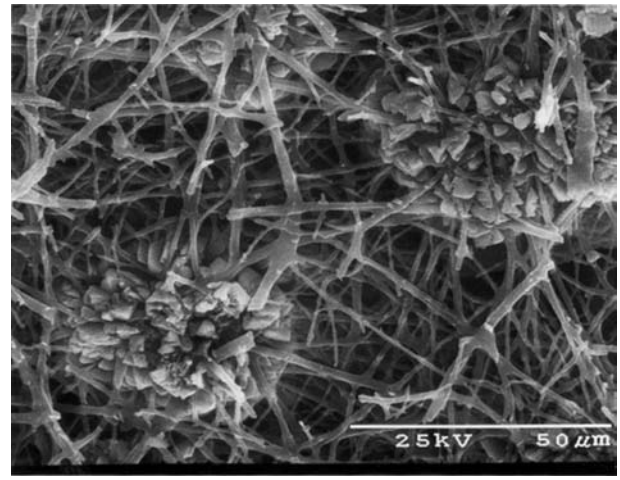

Figure 6. Secondary electron image of the internal structure of a dove eggshell. Note the bright edges of the fibers (collagen) and the differing brightness from crystal faces of the calcium carbonate.

combination of contrast components that contribute to the final image and that the description here has summarized only the most common images.

The most popular and useful detector for observing surfaces and morphology is the Everhart-Thornley (ET) detector, composed of a scintillator, collector, light pipe, and photomultiplier tube. Electrons striking the positively biased scintillator are converted to a burst of photons that travel through the light pipe to the photomultiplier tube, where the signal is amplified. The collector is a grid or collar around the scintillator that is positively biased to draw the low-energy SEs toward the detector. The image produced from the ET detector with a positively biased collector is dominated by SE contrast, and this detector is often referred to as the SE detector. The SE image is dominated by surface features due to the shallow escape depth of SEs and the dependence of the SE signal on the incidence angle of the probe with the specimen (Fig. 6). Surfaces tilted away from the normal to the beam allow for more SE escape. A noticeable feature of the SE image is that edges appear bright. This is due to the escape of SEs from the top and side surfaces when the interaction volume intercepts these two surfaces. A surface facing away from the detector can still appear illuminated, since some portion of the SEs can be detected due to the bias on the collector. The traditional SEM instrument has an ET detector within the specimen chamber. The ET detector can also be placed within the optical column of the SEM, and with an alteration to the lens design, the SE signal can be trapped within the field of the objective lens and collected by the biased detector. The SE image from the ET detector, often coupled with enhancement of the signal by deposition of metal thin films on the specimen, results in high-resolution SEM images.

Common BSE detectors are the solid-state detector and the scintillator detector. These detectors are not responsive to low-energy electrons and therefore exclude the SE signal. Both detectors are designed such that they can be placed above the specimen, where the geometric collection

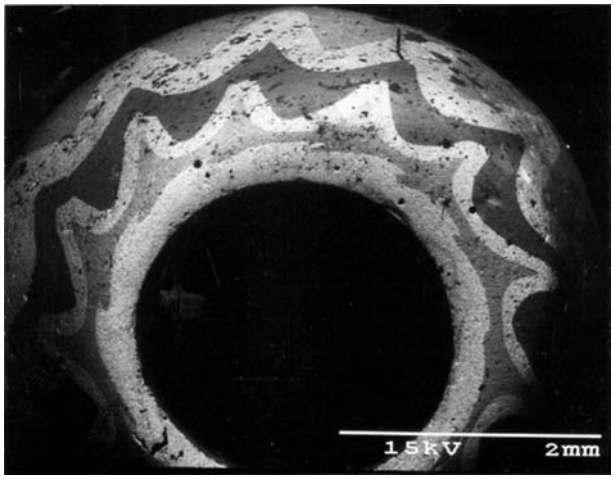

Figure 7. Backscattered electron image of a glass trade bead. The bands are different colored glasses. In this image, contrast is due to the different intensities of BSEs, which are due to differences in the average atomic number of the glasses. X-ray analysis coupled with this image provides a complete characterization of the specimen.

efficiency can be optimized to collect a high proportion of the BSE signal. The solid-state detector is based on the principle that high-energy electrons striking the silicon produce electron-hole pairs in the material. A bias on the detector separates the electrons and holes, and the resultant charge can be collected. The intensity of the charge is proportional to the energy of the incoming electrons (in silicon it takes $\sim$3.6 eV to produce one electron-hole pair) and the number of electrons striking the detector. The solid-state detector is usually an array of detectors that are symmetrically placed around the optic axis, and the signals can be mixed in additive or subtractive modes to enhance different contrast components. The scintillator detector relies on the interaction of BSEs with the detector to produce photons, similar to the ET detector. Unlike the ET detector, however, SEs are not detected due to their lower energy. The geometry or position of the detector itself can be altered to select for contrast components.

Both of these BSE detectors can be operated in two modes. In the first mode, placing the BSE detector above the specimen and symmetrically around the optic axis will eliminate the trajectory component of contrast by collecting all trajectories equally. This produces the BSE compositional image, in which the "number" component of contrast predominates and the signal intensity increases with increasing average atomic number of the sample (Fig. 7). This imaging strategy works best with flat, polished surfaces where information on the distribution of phases is easily interpreted. In the second mode, the trajectory of the signal can be accentuated by nonsymmetric detector geometry. This is accomplished in the solid-state detector by subtracting the signal from one part of the array from the other or by differential weighting of the signals from different sides of the specimen chamber. The scintillator detector can be partially removed from its position directly above the sample to create this same enhancement of trajectory differences. The resulting BSE topographic image shows in high contrast minor irregularities on the surface. Figure 7 exhibits this topographic contrast, with surface pitting shown in sharp relief, superimposed upon a background of compositional contrast. Since the BSE trajectories are essentially straight due to their high energy, this image also shows "shadowing" where material between the detector and a surface region will block the signal reaching the detector. The ET detector can also be used to produce this BSE topographic image, but its small size and position away from the specimen leads to poor collection efficiency and therefore a noisy image.

Special Techniques and Recent Innovations

The SEM is an exceptionally adaptable and versatile instrument, and many special application areas have been developed. Its unequaled depth of field can be enhanced by stereographic techniques, in which two images of the same area are recorded at different specimen tilt angles (Gabriel, 1985). The resulting stereopair can be viewed with the aid of filters or a stereo viewer to produce a three-dimensional image. Measurements of distances in three dimensions are possible if the initial geometry is recorded, and software programs are available to simplify the task. Metrology, particularly the measurement of critical dimensions in microelectronic devices, is possible with refined SEM scanning systems and appropriate standards and control. The SEM, by nature, is a bulk analysis technique, and many *in situ* experiments can be devised. Electronic testing in the SEM has the benefit of precise placement of the probe (beam), control of the beam voltage and/or current, and avoidance of mechanical damage and impedance loading associated with mechanical probes (Menzel and Buchanan, 1987). Physical testing of materials within the SEM chamber is also possible, with heating, cooling, strain, and fracture stages custom built for the microscope.

The diffraction of electrons by a crystalline sample can lead to electron channeling patterns in the SEM image (Joy et al., 1982; Newbury et al., 1986) or Kikuchi patterns in the BSE distribution (Adams et al., 1993; Michael and Goehner, 1993; Thaveeprungsriporn et al., 1994; Goehner and Michael, 1996). Electron diffraction techniques in the SEM can be used to identify phases, determine their orientation, and study crystal damage and defects (Dingley, 1981).

Variable-pressure SEM is a technique in which the specimen chamber pressure is controlled independently of the SEM column (Mathieu, 1996). The introduction of air (or other gases) into the specimen chamber neutralizes charging on the surface of insulating materials, allowing them to be imaged and analyzed (with decreased resolution) without having to deposit a conducting thin film (Fig. 8). The higher chamber pressures also allow for the observation of materials with high vapor pressures, including biological material, without extensive sample preparation to remove volatile components. A special form of variable-pressure scanning electron microscopy is referred to as environmental scanning electron microscopy, in which

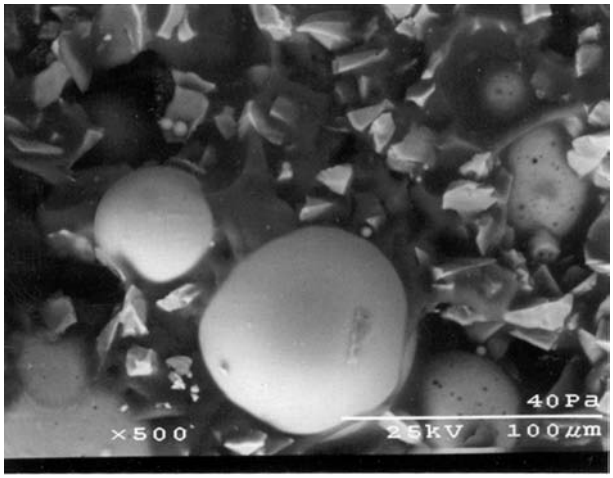

Figure 8. Variable-pressure SEM image of an abrasive. The abrasive is composed of an epoxy resin, silicon nitride particles, and ceramic balloons. The ability to control the pressure in the chamber of the SEM (40 Pa for this image) allows for operation in an atmosphere capable of eliminating charge buildup on the specimen. This specimen is also a problem for conventional SEM due to outgassing of the epoxy and ceramic balloons. (Image by David Johnson, University of Arizona.)

chamber atmosphere can also be altered (Danilatos, 1988, 1993).

The FESEM deserves special mention due to its enormous impact on the field. The field emission (FE) electron gun allows for the creation of an exceptionally bright (small with high-current-density) electron beam. This in itself has made scanning electron microscopy competitive with transmission electron microscopy for materials characterization in the nanometer range (Fig. 9). The FE source is often coupled with a special lens design such

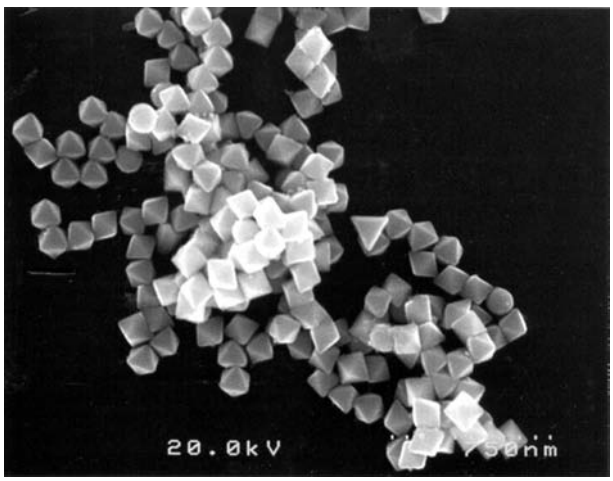

Figure 9. Field emission SEM image of gold particles in dichromic glass taken at 400× magnification. The image is at the upper range of magnification for an SEM with a thermionic electron gun but a normal range for the FESEM. The particle geometry and size are apparent, and also some irregularities on the surfaces and where two particles join. (Image by Toshinori Kokubu and G. Chandler, University of Arizona.)

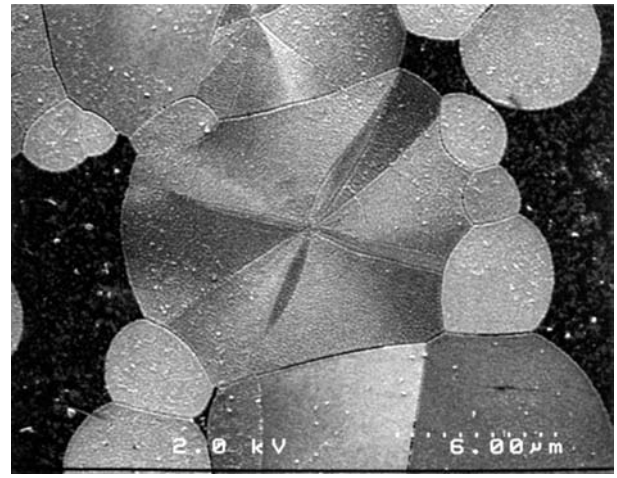

Figure 10. Low-voltage image of PZT on platinum. The low accelerating voltage used here (2 kV) gives excellent surface contrast of this thin material. (Image by Mike Orr and G. Chandler, University of Arizona.)

that the specimen is in the field of the lens and the detector is within the column rather than the sample chamber. The FESEM also has the ability to produce a small probe diameter at low voltage, opening the way to many applications that were difficult with thermionic electron guns (Greenhut and Friel, 1997). Low-voltage scanning electron microscopy has the advantage of revealing more details of the surface since there is less penetration of the beam into the specimen (Fig. 10) and is less damaging to the material. The SE yield from the specimen is a function of voltage, and at lower beam voltages the specimen reaches a point at which emission of secondary and backscattered electrons equals the beam current. This is a unique voltage for each material at which there is no specimen charging, and the surface can be imaged without a conductive coating. This phenomenon has also been used as a voltage contrast mechanism in materials such as copolymers and ceramic composites that were traditionally difficult to observe with the SEM.

METHOD AUTOMATION

The SEM used as a research tool typically requires the operator to make many value judgments during a viewing session. There are many situations, however, where automated routines are useful. Instruments with automatic electron gun start-up, automatic focus and astigmatism correction, and automatic contrast and brightness may be the choice for situations in which repetitive sampling is necessary, such as in quality control. Systematic sampling, in which a motorized stage positions the specimen below the beam or the beam is moved to positions on the specimen, is available and useful for precise, repetitive analysis. Automatic search routines are available that can identify points of interest with the SEM image and return to those areas for compositional analysis with a spectrometer. The SEM is commonly fitted with automated sample handling in industrial settings such as

microelectronic fabrication plants. Instrument manufacturers offer extensive options for automated specimen preparation, handling, manipulation, sampling, instrument operation, and data collection, presentation, storage, processing, and analysis.

DATA ANALYSIS AND INITIAL INTERPRETATION

Interpretation of SEM images is dependent upon the geometry of the probe, specimen, and detector. The specimen appears to the viewer as if looking down the optic axis, with the illumination coming from the detector. This is most clearly seen in the BSE topographic image but is also important for the SE image. The most common imaging mode utilizes SEs for information on the surface morphology (Fig. 6). This SE image is often an extremely complex convolution of contrast-producing factors but is amazing for its ease of interpretation. Surfaces at different angles to the probe produce different brightness levels and edges appear brighter. "Holes" are darker while raised areas are brighter. The image generally looks like a black-and-white optical view of the surface.

The BSE signal can also be used to show surface topography but is perhaps more often used to show atomic number contrast, in which areas of higher average atomic number produce more BSEs, and thus appear brighter, than lower atomic number regions. Figure 7 shows this contrast clearly on a glass trade bead. The bead was produced by wrapping layers of different colored glass around a core, forming the pattern seen in the image. The contrast in this image is not due to color differences but is produced by different intensities of electrons backscattering from the layers with different average atomic number.

The SE image is sensitive to changes in potential on (or near) the surface of the specimen. This can create problems when viewing insulators, but it can also be used to enhance features of the specimen. In Figure 11, the probe energy was set to create a buildup of electrons within an insulating layer below the surface of the specimen. This charged area then emits more SEs than surrounding, grounded material and appears brighter. The same example can be given to demonstrate that features below the surface can contribute to the image contrast. The operator can control the depth that the beam penetrates by changing the energy of the electron probe through changing voltage.

Specimens with multiple phases or grains, twinning, and other microstructure not associated with composition may exhibit contrast due to causes such as differences in crystal orientation or magnetic domain. These contrast mechanisms are superimposed upon the SE or BSE contrast, and careful attention to sample preparation and instrument set-up is necessary for interpretation (Newbury et al., 1986).

Imaging with the SEM has benefited greatly from the incorporation of digital techniques. Multiple low-dosage frames can be averaged to produce a low-noise image on specimens that are sensitive to electron dosage. Digital filtering techniques bring out details in the signals, which can vary over many orders of magnitude, and are not visible when converted directly to a visible gray scale as in conventional photography. The independent collection and storage of multiple signals (SE, BSE, and x ray) from a digital array can greatly enhance the productivity and utility of the SEM and allows for postsampling manipulation and study of the results. Digital images from the SEM can be analyzed with numerous commercially available and free-ware software products.

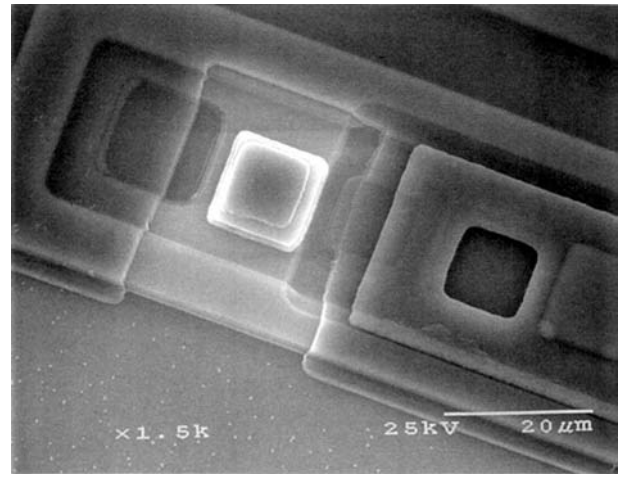

Figure 11. Secondary electron image of microelectronic device. The accelerating voltage of the electron beam was set such that a large portion of the beam electrons were absorbed within an insulating material below the surface. The resulting buildup of charge creates a potential that causes an increased emission of SEs, thus providing a way to highlight the structure. (Image by Ward Lyman, University of Arizona.)

SAMPLE PREPARATION

Surface topology, such as in fractography, may require no sample preparation if the specimen can withstand the low chamber pressure and electron beam bombardment of the SEM. The microstructure may be greatly enhanced, however, by such methods as polishing and selective etching of the surface, as with the metals in Figure 5. Most SEMs have sample chambers with limited dimensions, and the specimen must be affixed to a stage holder for orientation and manipulation within the chamber. Conductive adhesives with low vapor pressure or mechanical devices are used to mount the specimen. Special chambers and stages are available to suit most needs.

The most common form of sample preparation for the SEM is the deposition of a metal thin film onto the specimen surface. Vacuum evaporation and ion sputtering of metals are common methods of depositing these thin films (Goldstein et al., 1992). The metal thin film provides electrical conductivity, enhances the signal (if a higher-Z metal is used), and may add strength to the specimen. If x-ray spectroscopy is coupled with scanning electron microscopy, the metal film may be replaced with a carbon thin film or deposited to a thickness that is not detectable by the spectrometer. The deposition of very thin (1-nm)

films of metal may be necessary to obtain the highest resolution from an FESEM.

Materials with volatile or high-vapor-pressure components, such as biological specimens, must be prepared for viewing in the SEM. Sample preparation is often tedious and extensive, and special protocols are required to preserve the material's structure while eliminating the unwanted components. Elimination of water from biological specimens, for example, may employ freeze drying, critical point drying, or chemical means. Cryo-microscopy, in which a liquid nitrogen- or liquid helium-cooled stage is employed, is an option for especially challenging materials. Polymers often require some protection from the beam, and staining techniques similar to those employed for biological materials can increase contrast in the image.

Specimens such as living organisms, museum pieces, or very large objects can be surface replicated using polymer films or dental casting resins if they cannot be placed within the SEM chamber. These materials will closely replicate the surface features of the specimen and, after hardening, can be coated with a metal thin film for SEM viewing.

Extensive expertise on sample preparation is available through the Microscopy Society of America Listserver (see Internet Resources).

SPECIMEN MODIFICATION

Scanning electron microscopes vary widely in the specimen chamber pressure but are traditionally in the high-vacuum range due to requirements of the electron optics. This limits materials that can be analyzed using the SEM; however, extensive sample preparation protocols have been developed for this purpose. The variable-pressure and environmental SEMs are designed to allow operation at higher pressures (still vacuum) and can therefore eliminate some sample preparation.

The electron beam can deposit significant energy within the specimen, and damage may occur due to heating, buildup of electrical charge, or breaking of bonds. Sample preparation, in particular coating with thin metal films, can eliminate many of these problems. Electron beam lithography in integrated circuit production is an example of where this damage is used to produce a pattern in a thin polymer film. Controlled scanning of the beam over the surface produces a pattern within the film. It is then exposed to a mild etch, so that the regions "damaged" by the electron beam etch at a different rate than regions not exposed, and the pattern becomes a mask for subsequent deposition procedures.

Specimens observed in the SEM often become contaminated with a thin film of carbon deposited on the area being scanned with the beam. This is often explained as being due to oil vapor from the vacuum system entering the specimen chamber. This will occur even in oil-free systems if the specimen itself has carbon compounds on its surface. Under electron beam bombardment, these molecules are broken down into constituent species, and while oxygen and nitrogen are removed by the vacuum system, the carbon remains on the surface. Migration of carbon compounds toward the area under electron beam bombardment creates a buildup of carbon.

PROBLEMS

The sense of perspective described above (see Data Analysis and Interpretation) can be critical for specimens with simple surface geometry, since topography can appear inverted to some observers if the image is rotated 180°. Three-dimensional images produced by viewing stereopairs also require that the operator control this geometry of probe, specimen, and detector and in addition record sample tilt and tilt axis alignment.

Image quality in the SEM usually refers to the amount of noise, or graininess, of the image. There is a trade-off in SEM imaging between resolution and image quality in which higher resolution is only obtained by accepting noisier images. This situation is due to the SEM optics described earlier (see Practical Aspects of the Method), in which a stronger condenser lens results in a smaller probe diameter and a decreased probe current. The decrease in probe current will result in a decrease in signal being generated. Noise is inherent in any electronic system, and decreasing the signal will decrease the signal-to-noise ratio. Thus, when one decreases the probe diameter to obtain higher resolution, the signal must be amplified more, and the noise is apparent in the image. This results in grainy images. The use of higher-brightness electron guns, especially the FE sources, makes dramatic improvements in the image quality at higher magnifications by increasing the current density (brightness) of the probe.

The scan length on the specimen can be calculated from two measurements and used to provide an estimate of the magnification. Working distance is the distance between the specimen and the objective lens. Assuming the image is in focus, the current supplied to the objective lens can be sampled to estimate the working distance. A similar reading of the scanning coil current will give an estimate of the scan deflection angle. The length of the scan line on the sample can then be calculated from this angle and the working distance. The magnification readout on most instruments is a calculated value derived from these two measurements, and instruments vary significantly in their accuracy. This problem can easily be overcome by the use of standards to calibrate magnification. Images are also subject to distortions due to irregular scanning, variations in the working distance due to sample topography or tilt, and the projection of the scan (angular) onto a flat surface (film). The projection distortion lessens as magnification increases (scan angle decreases), and distortions are normally apparent only when viewing highly symmetrical samples such as grids. Use of the SEM for critical dimension measurement therefore requires special instruments and techniques.

Traditionally, SEM images were produced at high voltages, where probe electrons could build up a significant charge on insulating materials. This surface charge can manifest itself in many ways in the image. A negatively charged surface usually appears brighter due to increased

emission of SEs from the region. The positioning of the beam on the surface may be altered by a nonuniform charge, creating a distorted image. Beam energy is altered by specimen bias from charge buildup and will affect imaging and spectroscopy. Particles on the specimen surface that collect charge can produce a local field that deflects the SE signal away from the detector, resulting in a "shadowed" region. Sporadic discharge of electrons from a charged surface may create bright dots and lines on the image that are not associated with the sample topography. Due to these many detrimental effects of charging, specimens are often coated with thin films of heavy metals (or carbon if x-ray analysis is desired) to provide a conductive path to ground. Newer instruments, particularly the FESEM, have the ability to produce images at low accelerating voltages. Specimen charging can be reduced or eliminated with control of the accelerating voltage, and positive charging is possible when the intensity of secondary and backscattered electron emission exceeds the probe current. Constructive use of sample charging is used to create contrast in materials such as ceramics and microelectronics.

Contamination on the surface of the specimen plays a critical role in SE images, since the signal is influenced most by the surface characteristics. The most troublesome contamination is the buildup of carbon on the surface. Carbon compounds from oil vapor in the vacuum pumps, exposure to atmosphere, specimen handling, and solvents used to clean the specimen can migrate toward the area that the beam is striking. The high-energy electrons from the beam can break bonds within these materials, producing a carbon buildup on the surface and gases that are easily removed by the vacuum pumps. It is common to see this carbon buildup on the surface of the specimen while viewing the live image. This contaminant layer obscures and blurs the surface detail, and the image becomes darker, since much of the signal is within this low-Z material on the surface. Contamination becomes worse at lower voltages. Careful attention to sample preparation and handling, rapid signal collection, and the use of clean vacuum techniques (see GENERAL VACCUM TECHNIQUES) will combat contamination problems.

This site is hosted by Argonne National Laboratory and is a complete guide to the Internet for microscopy. The site is also home of the Microscopy Society of America listserver, providing a forum for novice and expert microscopists to ask questions of their colleagues. Other links at this site include the MSA software library, ftp sites, a list of upcoming meetings, conferences and workshops, and lists of national and international www sites. This provides access to educational, government, commercial, and society resources.

APPENDIX: GUIDELINES FOR SELECTING AN SEM

The selection of a SEM can be quite involved, with ten companies offering new instruments, and some of these having as many as 15 models from which to choose. The market is highly competitive, and a thorough search by the purchaser will be very beneficial. Many options may be available from companies specializing in custom equipment rather than from the instrument manufacturer, and a potential purchaser should also contact these vendors for information. A quick look at the Microscopy Society of America web pages and a few days on their list server should give one a feeling for the variety of options available. Table 1 lists some features that a buyer should check, although it is not possible to include all options, adaptations, add-on systems, and interfaces available. The list of criteria allows for a comparison between microscopes, and the buyer must use some ranking system for the individual items, such as imperative, useful, a nice feature, or unnecessary. A cost analysis should also be conducted, and the many laboratories that offer SEM services are an alternative to purchase. The determination of employee needs, training, maintenance and repair costs, and instrument reliability/lifetime should be a part of consideration to purchase and are not covered here. A list such as the one below must be customized for each individual purchase, and performance of the microscope on real samples should always be the final test. Most manufacturers will arrange for a demonstration of their product, and the buyer should prepare well for this demonstration, including bringing in your most problematic specimens. Some general notes on the major systems of the SEM are included here for background information on the criteria.

Vacuum System and Specimen Handling

The vacuum system for the SEM is designed to meet the requirements of the electron gun and probe-forming system, while the buyer must decide if the system is compatible with requirements of the specimen. Traditional SEM pressures are on the order of 1×10^{-6} torr, with the electron gun and specimen chamber kept at the same pressure. Modern instruments may offer differential pumping systems such that ultrahigh vacuum can be obtained for a field emission source, or low-vacuum "environmental" chambers can be maintained for the specimen chamber, while other portions of the system are held at traditional high-vacuum levels. The cleanliness of the vacuum system and component gases may be equally important to a particular application as the pressure. Oil-free pumping systems, special sample introduction systems, inert gas back-filling, or environmental chambers with control of gas composition are examples of the options available.

The specimen-handling system is closely related to the vacuum system and should therefore be designed/chosen with the specimen and the vacuum in mind. Most instruments are equipped with specimen stages that are adequate for manipulating a specimen within the chamber but will not provide the fine control necessary for many special techniques. Stage options are available for eucentric geometry, large samples, *in situ* experiments, fine movement, cryo-microscopy, nonstandard detection systems, and other special requirements. Introduction of a specimen into the instrument can also be accomplished in a variety of ways, from manually opening the entire chamber to completely automated handling and transfer from one instrument/device to another under, e.g., vacuum or at low temperature.

Electron Gun

Three electron gun types are commonly available today. The tungsten filament thermionic source is inexpensive, requires little in the way of vacuum systems, produces a stable beam current, and is appropriate for most routine SEM imaging. The lanthanum hexaboride thermionic source offers higher brightness than the tungsten source, with resulting higher resolution. It requires lower operating pressures, and although it has a longer lifetime, replacement cost is high. The field emission electron gun is much more expensive but produces the brightest and smallest probe diameter and thus the highest resolution. The FE electron gun is also the choice for low-voltage applications.

Imaging System

The manufacturer will usually quote a resolution for the microscope that is a "best case" situation and is normally obtained using the SE signal on a high-contrast, standard specimen. The resolution of an image from the SEM is dependent on the beam parameters (accelerating voltage, beam diameter), the signal and detector used (SE, BSE, x ray), and the characteristics of the specimen (composition, structure, preparation). It is therefore imperative

Table 1. Some Criteria for Evaluation of a Scanning Electron Microscope

that the instrument be tested with "real" specimens if resolution is a critical factor in the selection.

All modern instruments will offer a wide array of capabilities to the user and will meet basic needs. Criteria such as magnification range and scanning speeds are important to consider, but the operator's preference and attention to most common usage should guide choices. Several types of detector are available and may be offered as options by the manufacturer or as an add-on system from a third party. Probably the most rapidly changing portion of the SEM is the system for recording, storing, and presenting images. Many laboratories are currently using a dual-system approach, with traditional photography and digital imaging available on the instrument. There are no standards for software control, digital image format, image data format, or printing. The SEM control and recording systems are rapidly evolving, and one should pay close attention to possible interfacing and compatibility problems with existing or desired equipment, computers, and software.

TRANSMISSION ELECTRON MICROSCOPY

INTRODUCTION

Transmission electron microscopy (TEM) is the premier tool for understanding the internal microstructure of materials at the nanometer level. Although x-ray diffraction techniques generally provide better quantitative information than electron diffraction techniques, electrons have an important advantage over x rays in that they can be focused using electromagnetic lenses. This allows one to obtain real-space images of materials with resolutions on the order of a few tenths to a few nanometers, depending on the imaging conditions, and simultaneously obtain diffraction information from specific regions in the images (e.g., small precipitates) as small as 1 nm. Variations in the intensity of electron scattering across a thin specimen can be used to image strain fields, defects such as dislocations and second-phase particles, and even atomic columns in materials under certain imaging conditions. Transmission electron microscopy is such a powerful tool for the characterization of materials that some microstructural features are defined in terms of their visibility in TEM images.

In addition to diffraction and imaging, the high-energy electrons (usually in the range of 100 to 400 keV of kinetic energy) in TEM cause electronic excitations of the atoms in the specimen. Two important spectroscopic techniques make use of these excitations by incorporating suitable detectors into the transmission electron microscope.

1. In energy-dispersive x-ray spectroscopy (EDS), an x-ray spectrum is collected from small regions of the specimen illuminated with a focused electron probe using a solid-state detector. Characteristic x rays of each element are used to determine the concentrations of the different elements present in the specimen (Williams and Carter, 1996). The principles behind this technique are discussed in details (ENERGY-DISPERSIVE SPECTROMETRY).
2. In electron energy loss spectroscopy (EELS), a magnetic prism is used to separate the electrons according to their energy losses after having passed through the specimen (Egerton, 1996). Energy loss mechanisms such as plasmon excitations and core-electron excitations cause distinct features in EELS. These can be used to quantify the elements present as well as provide information about atomic bonding and a variety of other useful phenomena.

In scanning transmission electron microscopy (STEM), a focused beam of electrons (typically <1 nm in diameter) is scanned in a television-style raster pattern across the specimen, as in a scanning electron microscope (SCANNING ELECTRON MICROSCOPY). In synchronization with the raster scan, emissions resulting from the interaction of the electron beam with the specimen are collected, such as x rays or secondary or backscattered electrons, to form images. Electrons that pass through the specimen can also be detected to form images that are similar to conventional TEM images. An annular detector can be used to collect the scattered transmitted electrons, which leads to Z-contrast imaging (discussed in SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING). The STEM mode of operation is particularly useful for spectroscopic analysis, since it permits the acquisition of a chemical map of the sample typically with a resolution of a few nanometers. For example, one can make an image of the distribution of Fe in a sample by recording, in synchronization with the raster pattern, either the emission from the sample of Fe $K\alpha$ x rays (with the EDS spectrometer) or transmitted electrons with energy losses greater than that of the Fe L edge (with the EELS spectrometer). The STEM mode of operation is different from the conventional TEM mode in that the objective lens is operated in tandem with the illumination lens system to assist in the formation of a focused electron probe on the specimen (Keyse et al., 1998).

A fully equipped transmission electron microscope has the capability to record the variations in image intensity across the specimen using mass thickness or diffraction contrast techniques, to reveal the atomic structure of materials using high-resolution (phase-contrast) imaging or Z-contrast (incoherent) imaging, to obtain electron diffraction patterns from small areas of the specimen using a selected-area aperture or a focused electron probe, and to perform EELS and EDS measurements with a small probe. Additional lenses can be installed in conjunction with an EELS spectrometer to create an energy filter, enabling one to form energy-filtered TEM images (EFTEM—Krivanek et al., 1987; Reimer, 1995). These images enable mapping of the chemical composition of a specimen with nanometer spatial resolution. A block diagram of such a transmission electron microscope is shown in Figure 1.

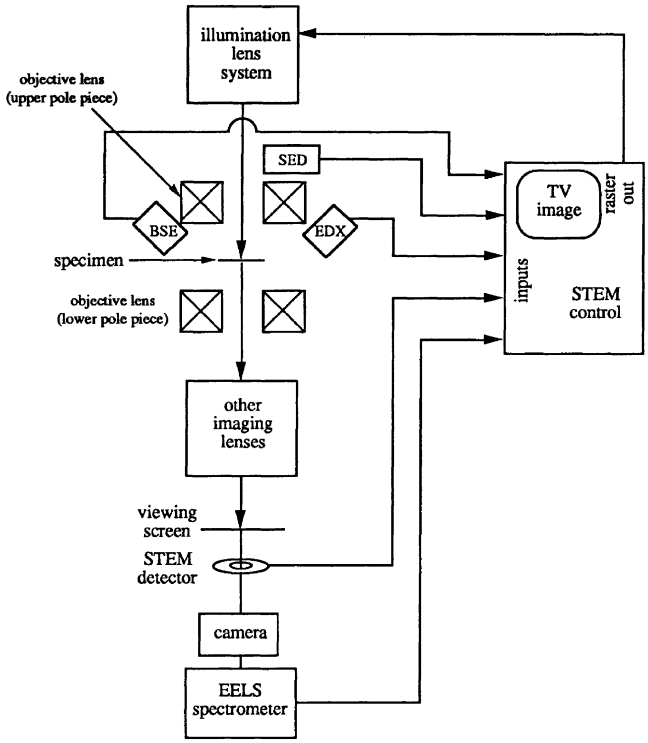

Figure 1. Typical transmission electron microscope with STEM capability. It is also possible to perform scanning electron microscopy (SEM) in a STEM using backscattered electron (BSE) and secondary electron detectors (SEDs) located above the specimen.

In addition to the main techniques of (1) conventional imaging, (2) phase-contrast imaging, (3) *Z*-contrast imaging, (4) electron diffraction, (5) EDS, and (6) EELS, in TEM many other analyses are possible. For example, when electrons pass through a magnetic specimen, they are deflected slightly by Lorentz forces, which change direction across a magnetic domain wall. In a method known as Lorentz microscopy, special adjustments of lens currents permit imaging of these domain walls (Thomas and Goringe, 1979). Phase transformations and microstructural changes in a specimen can be observed directly as the specimen is heated, cooled, or deformed in the microscope using various specimen stages (Butler and Hale, 1981). Differential pumping can be used to allow the introduction of gases into the microscope column surrounding a thin foil, making it possible to follow chemical reactions in TEM *in situ*. Many of these techniques can be performed at spatial resolutions of a few tenths of a nanometer. The possibilities are almost endless, and that is why TEM continues to be an indispensible tool in materials research. Since it is not possible to cover all of these techniques, this unit focuses on the theory and practice of conventional TEM electron diffraction and imaging techniques, including some examples of high-resolution TEM (HRTEM). A few imaging and diffraction techniques offer the resolution and versatility of TEM and are competitive or complementary in some respects.

Transmission electron microscopy is not able to readily image single point defects in materials. In contrast, the field ion microscope (FIM) can be used to study vacancies and surface atoms and therefore extends the available resolution to atomic dimensions (Miller and Smith, 1989). When combined with a mass spectrometer, the FIM becomes an atom probe (APFIM), easily capable of compositional analysis of regions ~1 nm wide and now approaching atom-by-atom analysis of local areas of samples. In the FIM, a high potential is applied to a very fine pointed specimen. A low pressure of inert gas is maintained between the specimen and imaging screen/spectrometer. Positively charged gas ions generated by the process of field ionization are used to produce images of the atoms on the surface of the specimen. Successive atom layers of material may be ionized and removed from the specimen surface by the process of field evaporation, enabling the three-dimensional (3D) structure of the material to be imaged in atomic detail and also to provide the source of ions for mass spectrometry.

Another instrument capable of imaging the internal structure of materials is the scanning acoustic microscope (SAM). In this microscope, a lens is used to focus the acoustic emission from an ultrasonic transducer onto a small region of a specimen through a coupling medium such as water. The same lens can be used to collect the acoustic echo from defects below the surface of the specimen. Either the lens or the specimen is scanned mechanically to form a two-dimensional (2D) image, the resolution of which depends on the wavelength of the acoustic wave in the specimen and thus on the frequency of the ultrasound and the velocity of sound in the specimen. Since the depth to which sound waves can penetrate decreases as their frequency increases, the choice of frequency depends on a compromise between resolution and penetration. Typical values might be a resolution of 40 to 100 μm at a depth of 5 mm below the surface for 50-MHz frequency, or a resolution of 1 to 3 μm at a similar depth for a frequency of 2 GHz. The resolution is clearly not as good as in TEM although the depth penetration is greater.

Lastly, x-ray diffraction and microscopy are alternative techniques to TEM and offer the advantage of greater penetration through materials. The main obstacle to high spatial resolution in both techniques is the difficulty of focusing x-ray beams, since x rays are uncharged and cannot be focused by electromagnetic or electrostatic lenses. While x-ray diffraction is commonly used for characterization of bulk samples in materials science and can be used to determine the atomic structures of materials (McKie and McKie, 1986), x-ray microscopy is not common, largely due to the better resolution and versatility of TEM.

PRINCIPLES OF THE METHOD

Here we develop the theoretical basis necessary to understand and quantify the formation of diffraction patterns and images in TEM. The theory developed is known as the "kinematical theory" of electron diffraction, and the contrast that arises in TEM images due to electron diffraction is "diffraction contrast." These concepts are then utilized in examples of the method and data analyses.

Structure Factor and Shape Factor

In both real space and in reciprocal space, it is useful to divide a crystal into parts according to the formula (Fultz and Howe, 2000)

$$\mathbf{r} = \mathbf{r}_g + \mathbf{r}_k + \delta_{\mathbf{r}_{g,k}} \quad (1)$$

For a defect-free crystal the atom positions $\mathbf{R}$ are given by

$$\mathbf{R} = \mathbf{r}_g + \mathbf{r}_k \quad (2)$$

where the lattice is one of the 14 Bravais lattice types (see SYMMETRY IN CRYSTALLOGRAPHY) and the basis is the atom group associated with each lattice site (Borchardt-Ott, 1995). Here we calculate the scattered wave ψ ($\Delta\mathbf{k}$) for the case of an infinitely large, defect-free lattice with a basis:

$$\psi(\Delta\mathbf{k}) = \sum_{\mathbf{R}} f_{at}(\mathbf{R}) \exp(-i2\pi\ \Delta\mathbf{k} \cdot \mathbf{R}) \quad (3)$$

where the scattered wave vector $\Delta\mathbf{k}$ is defined as the difference between the diffracted wave vector $\mathbf{k}$ and the incident wave vector $\mathbf{k}_0$ (refer to Fig. 2), or

$$\Delta\mathbf{k} = \mathbf{k} - \mathbf{k}_0 \quad (4)$$

and $f_{at}(\mathbf{R})$ is the atomic scattering factor for electrons from an atom. We decompose our diffracted wave into a lattice component and a basis component with

$$\psi(\Delta\mathbf{k}) = \sum_{(\mathbf{r}_g + \mathbf{r}_k)} f_{at}(\mathbf{r}_g + \mathbf{r}_k) \exp[-i2\pi\ \Delta\mathbf{k} \cdot (\mathbf{r}_g + \mathbf{r}_k)] \quad (5)$$

Since the atom positions in all unit cells are identical, $f_{at}(\mathbf{r}_g + \mathbf{r}_k)$ cannot depend on $\mathbf{r}_g$, so $f_{at}(\mathbf{r}_g + \mathbf{r}_k) = f_{at}(\mathbf{r}_k)$, and thus

$$\psi(\Delta\mathbf{k}) = \sum_{\mathbf{r}_g} \exp(-i2\pi\ \Delta\mathbf{k} \cdot \mathbf{r}_g) \sum_{\mathbf{r}_k} f_{at}(\mathbf{r}_k) \exp(-i2\pi\ \Delta\mathbf{k} \cdot \mathbf{r}_k) \quad (6)$$

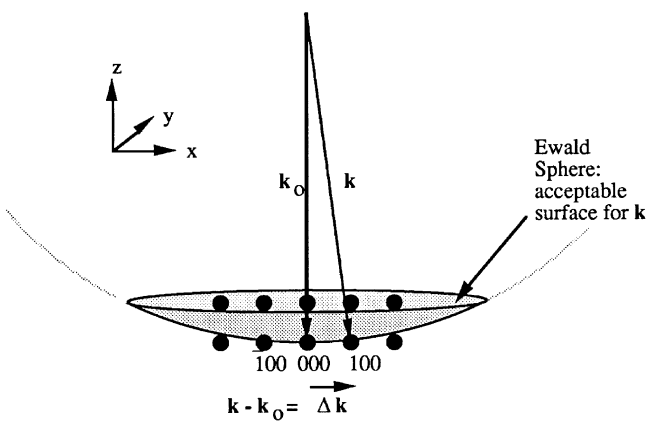

Figure 2. Ewald sphere construction showing incident $\mathbf{k}_0$ and scattered $\mathbf{k}$ wave vectors joined tail to tail and definition of $\Delta\mathbf{k}$.

or, simplifying,

$$\Psi(\Delta\mathbf{k}) = \mathcal{S}(\Delta\mathbf{k})\mathcal{F}(\Delta\mathbf{k}) \quad (7)$$

In writing Equation 7, we have given formal definitions to the two summations in Equation 6. The first sum, which is over all the lattice sites of the crystal (all unit cells), is known as the shape factor $\mathcal{S}$. The second sum, which is over the atoms in the basis (all atoms in the unit cell), is known as the structure factor $\mathcal{F}$. The notation ($\Delta\mathbf{k}$) is used to indicate the dependence of these terms on $\Delta\mathbf{k}$. The decomposition of the diffracted wave into the shape factor and the structure factor parallels the decomposition of the crystal into a lattice plus a basis.

Calculation of the structure factor $\mathcal{F}(\Delta\mathbf{k})$ for a unit cell is discussed in detail in KINEMATIC DIFFRACTION OF X RAYS and in standard books on diffraction (Schwartz and Cohen, 1987) and is not developed further here. Because in TEM we examine thin foils often containing small particles with different shapes, it is useful to examine the shape factor $\mathcal{S}(\Delta\mathbf{k})$ in Equations 6 and 7 in further detail. The shape factor $\mathcal{S}(\Delta\mathbf{k})$ is not very interesting for an infinitely large crystal where it becomes a set of delta functions centered at the various values of $\Delta\mathbf{k}$, where $\Delta\mathbf{k} = \mathbf{g}$ ($\mathbf{g}$ is a reciprocal lattice vector), but it is interesting for small crystals, which give rise to various spatial distributions of the diffracted electron intensity. The full 3D expression for the kinematical diffracted intensity due to the shape factor is given as

$$\mathcal{S}^*\mathcal{S}(\Delta\mathbf{k}) = \frac{\sin^2(\pi\ \Delta k_x a_x N_x)}{\sin^2(\pi\ \Delta k_x a_x)} \frac{\sin^2(\pi\ \Delta k_y a_y N_y)}{\sin^2(\pi\ \Delta k_y a_y)} \frac{\sin^2(\pi\ \Delta k_z a_z N_z)}{\sin^2(\pi\ \Delta k_z a_z)} \quad (8)$$

where a_x, a_y, and a_z are the magnitudes of the primitive translation vectors of the unit cell expressed along orthonormal x, y, and z axes; N_x, N_y, and N_z are the number of unit cells along the same axes, i.e., $a_x N_x = t_x$, the crystal thickness along the x direction and similarly for y and z; and Δk_x, Δk_y, and Δk_z are the components of $\Delta\mathbf{k}$ expressed along the x, y, and z axes. Equation 8 is valid for a crystal shaped as a rectangular prism.

The function in Equation 8 becomes large when the denominator goes to zero. This occurs when the argument of the sine function is equal to π or to some integral multiple of it, expressed (in the x direction only) as

$$\Delta k_x a_x = \text{integer} \quad (9)$$

Since similar conditions are expected for y and z, this condition requires that $\Delta\mathbf{k}$ is a reciprocal lattice vector $\mathbf{g}$. In other words, the kinematical intensity $\mathcal{S}^*\mathcal{S}$ is large when the Bragg condition is exactly satisfied. Since the denominator varies slowly with respect to the numerator, we can make the following approximation, which is valid near the center of the main peaks (expressed in only one direction):

$$\mathcal{S}^*\mathcal{S}(\Delta\mathbf{k}) \cong \frac{\sin^2(\pi\ \Delta k\ aN)}{(\pi\ \Delta k\ a)^2} \quad (10)$$

This function describes an envelope of satellite peaks situated near the main Bragg diffraction peaks. By examining

the numerator, we see that the positions of the satellite peaks get closer to the main peak in proportion to $1/Na$, and the position of the first minimum in the intensity is located on either side of the main peak at the position $\Delta k = 1/Na$. Similarly, the widths of the main peaks and satellite peaks also decrease as $1/Na$. Thus, large crystal dimensions in real space lead to sharp diffracted intensities in reciprocal space, and vice versa (Hirsch et al., 1977; Thomas and Goringe, 1979).

Ewald Sphere Construction

The Bragg condition for diffraction, $\Delta\mathbf{k} = \mathbf{g}$, where $\mathbf{g}$ is a reciprocal lattice vector and $\Delta\mathbf{k}$ is any possible scattered wave vector, can be implemented in a geometrical construction due to Ewald (McKie and McKie, 1986). The Ewald sphere depicts the incident wave vector $\mathbf{k}_0$ and all possible $\mathbf{k}$ for the diffracted waves. The tip of the wave vector $\mathbf{k}_0$ is always placed at a point of the reciprocal lattice that serves as the origin. To obtain $\Delta\mathbf{k} = \mathbf{k} - \mathbf{k}_0$, we would normally reverse the direction of $\mathbf{k}_0$ and place it tail to head with the vector $\mathbf{k}$, but in the Ewald sphere construction in Figure 2, we draw $\mathbf{k}$ and $\mathbf{k}_0$ tail to tail. The vector $\Delta\mathbf{k}$ is the vector from the head of $\mathbf{k}_0$ to the head of $\mathbf{k}$. If the head of $\mathbf{k}$ touches any reciprocal lattice point, the Bragg condition ($\Delta\mathbf{k}$ = $\mathbf{g}$) is satisfied and diffraction occurs. In elastic scattering, the length of $\mathbf{k}$ equals the length of $\mathbf{k}_0$, since there is no change in wavelength (magnitude of the wave vector). The tips of all possible $\mathbf{k}$ vectors lie on a sphere whose center is at the tails of $\mathbf{k}$ and $\mathbf{k}_0$. By this construction, one point on this sphere always touches the origin of the reciprocal lattice. Whenever another point on the Ewald sphere touches a reciprocal lattice point, the Bragg condition is satisfied and diffraction occurs. As illustrated in Figure 2, the Bragg condition is approximately satisfied for the (100) and ($\bar{1}00$) diffraction spots.

The Ewald sphere is strongly curved for x-ray diffraction because $|\mathbf{g}|$ (typically 5 to 10 nm^{-1}) is comparable to $|\mathbf{k}_0|$. Electron wave vectors, on the other hand, are much longer than the spacings in the reciprocal lattice (100-keV electrons have a wavelength of 0.0037 nm). So, for high-energy electrons, the Ewald sphere is approximately a plane, and consequently, $\Delta\mathbf{k}$ is nearly perpendicular to $\mathbf{k}_0$. In practice, the diffracted intensity distribution, such as that in Equation 8, is located in a finite volume around the reciprocal lattice points, so $\Delta\mathbf{k}$ need not equal $\mathbf{g}$ exactly in order for diffraction to occur. The shape factor intensity $\mathcal{S}^*\mathcal{S}(\cdot\mathbf{k})$ serves in effect to broaden the reciprocal lattice points. With a crystal oriented near a zone axis, i.e., along a direction parallel to the line of intersection of a set of crystal planes, the Ewald sphere passes through many of these small volumes around the reciprocal lattice points, and many diffracting spots are observed. Figure 3 provides an example of Ewald sphere constructions for two orientations of the specimen with respect to $\mathbf{k}_0$, together with their corresponding selected-area diffraction (SAD) patterns. Figure 3 is drawn as a 2D slice (the x-z plane) of Figure 2. The crystal on the right is oriented precisely along a zone axis, but the crystal on the left is not.

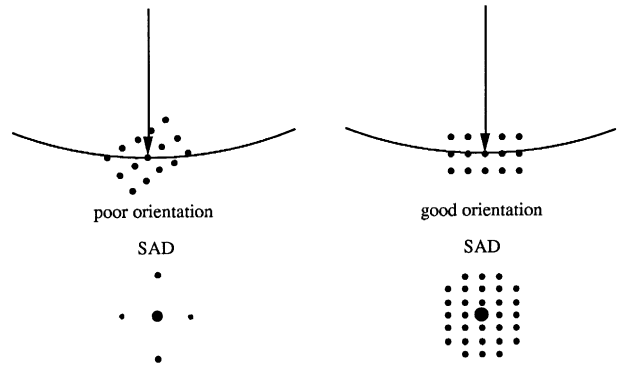

Figure 3. Two orientations of reciprocal lattice with respect to Ewald sphere and corresponding SAD patterns.

Deviation Vector and Deviation Parameter

From the previous discussion, it is apparent that the diffracted intensity observed in an electron diffraction pattern depends on exactly how the Ewald sphere cuts through the diffracted intensity around the Bragg position. To locate the exact position of intersection, we introduce a new parameter, the deviation vector $\mathbf{s}$, defined as

$$\mathbf{g} = \Delta\mathbf{k} + \mathbf{s} \tag{11}$$

where $\mathbf{g}$ is a reciprocal lattice vector and $\Delta\mathbf{k}$ is the diffraction vector whose end lies on the Ewald sphere ($\Delta\mathbf{k} = \mathbf{k} - \mathbf{k}_0$). For high-energy electrons, the shortest distance between the Ewald sphere and a reciprocal lattice point $\mathbf{g}$ is parallel to the $\mathbf{z}$ direction, so we often work with only the magnitude of $\mathbf{s}$, i.e., $|\mathbf{s}| = s$, referred to as the deviation parameter. We choose a sign convention for s that is convenient when we determine s by measuring the positions of Kikuchi lines (Kikuchi, 1928). Positive s means that $\mathbf{s}$ points along positive $\mathbf{z}$. (By convention, $\mathbf{z}$ points upward toward the electron gun.) Figure 4 shows that s is positive when the reciprocal lattice point lies inside the Ewald sphere and negative when the reciprocal lattice point lies outside the sphere.

The parameter s is useful because it is all that we need to know about the diffraction conditions to calculate the kinematical shape factor. Using Equation 11 for $\Delta\mathbf{k}$ in Equation 7 yields

$$\mathcal{S}(\Delta\mathbf{k}) = \sum_{\mathbf{r}_g} \exp(-i2\pi\mathbf{g}\cdot\mathbf{r}_g)\exp(+i2\pi\mathbf{s}\cdot\mathbf{r}_g) \tag{12}$$

$$\mathcal{F}(\Delta\mathbf{k}) = \sum_{\mathbf{r}_k} f_{at}(\mathbf{r}_k, \Delta\mathbf{k})\exp(-i2\pi\mathbf{g}\cdot\mathbf{r}_k)\exp(+i2\pi\mathbf{s}\cdot\mathbf{r}_k) \tag{13}$$

$$\mathcal{F}(\Delta\mathbf{k}) \cong \sum_{\mathbf{r}_k} f_{at}(\mathbf{r}_k, \Delta\mathbf{k})\exp(-i2\pi\mathbf{g}\cdot\mathbf{r}_k) = \mathcal{F}(\mathbf{g}) \text{ or } \mathcal{F}_g \tag{14}$$

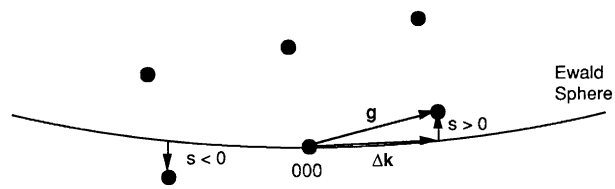

Figure 4. Convention for defining deviation vector $\mathbf{s}$ and deviation parameter s, from Ewald sphere to reciprocal lattice spot $\mathbf{g}$.

where we made the last approximation for the structure factor $\mathcal{F}(\mathbf{g})$ because $\mathbf{s} \cdot \mathbf{r}_k$ is small when the unit cell is small. Since $\mathbf{g}$ is a reciprocal lattice vector, $\exp(-i2\pi\mathbf{g} \cdot \mathbf{r}_g) = 1$ for all $\mathbf{r}_g$, which simplifies the shape factor to

$$\mathcal{S}(\Delta\mathbf{k}) = \mathcal{S}(\mathbf{s}) \sum_{\mathbf{r}_g} \exp(+i2\pi\mathbf{s} \cdot \mathbf{r}_g) \tag{15}$$

and the diffracted wave $\psi(\mathbf{g}, \mathbf{s})$, which is a function of the reciprocal lattice vector and deviation parameter, becomes

$$\psi(\mathbf{g}, \mathbf{s}) = \mathcal{F}_g \sum_{\mathbf{r}_g} \exp(+i2\pi\mathbf{s} \cdot \mathbf{r}_g) \tag{16}$$

The shape factor depends only on the deviation vector $\mathbf{s}$ and not on the particular reciprocal lattice vector $\mathbf{g}$. When we substitute for the components of $\mathbf{s}$ and $\mathbf{r}_g$ along the x, y, and z axes, we obtain an equation for the shape factor intensity that is similar to Equation 8:

$$\mathcal{S} * \mathcal{S}(\mathbf{s}) = \frac{\sin^2(\pi s_x a_x N_x)}{\sin^2(\pi s_x a_x)} \frac{\sin^2(\pi s_y a_y N_y)}{\sin^2(\pi s_y a_y)} \frac{\sin^2(\pi s_z a_z N_z)}{\sin^2(\pi s_z a_z)} \tag{17}$$

For high-energy electron diffraction, we can make the following simplifications: (1) the deviation vector is very nearly parallel to the z axis, so s_z is simply equal to s; (2) the denominator is given as $(\pi s_z)^2$; and (3) the quantity $a_z N_z$ is the crystal thickness t. Ignoring the widths along x and y of the diffracting columns, a useful expression for the shape factor intensity is

$$\mathcal{S} * \mathcal{S}(\mathbf{s}) = \frac{\sin^2(\pi s t)}{(\pi s)^2} \tag{18}$$

Combining Equations 14 and 18 then gives the resulting diffracted intensity for the vector $\mathbf{g}$:

$$\mathbf{I}_g = |\psi(\mathbf{g}, \mathbf{s})|^2 = |\mathcal{F}(\mathbf{g})|^2 \frac{\sin^2(\pi s t)}{(\pi s)^2} \tag{19}$$

This intensity depends only on the diffracting vector $\mathbf{g}$ and the deviation parameter s. Below we present many examples of how $\mathbf{I}_g$ depends on the deviation parameter s and the sample thickness t. The dependence of $\mathbf{I}_g$ on the position (x,y) of the diffracting column provides diffraction contrast in bright-field (BF) or dark-field (DF) images. In a two-beam condition, where only the incident beam and one diffracting beam have appreciable intensity, the intensities of the transmitted beam $\mathbf{I}_0$ and diffracted beam $\mathbf{I}_g$ are complementary, and with the incident intensity normalized to 1, we have the relationship

$$\mathbf{I}_0 = 1 - \mathbf{I}_g \tag{20}$$

The kinematical diffraction theory developed above is valid when the intensity of the diffracted beam is much less than the transmitted beam, or

$$\mathbf{I}_g \ll \mathbf{I}_0 \tag{21}$$

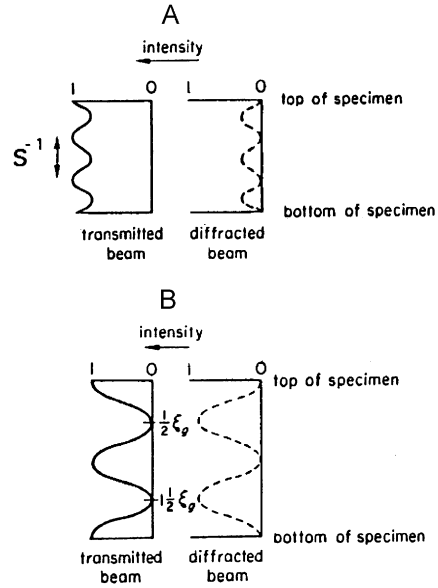

Figure 5. Extinction distance and amplitudes of transmitted and diffracted beams for two-beam condition in relatively thick crystal (**A**) under kinematical conditions with $s \gg 0$ and (**B**) under dynamical conditions with $s = 0$. (After Edington, 1974.)

When this condition is not satisfied, one must resort to the dynamical theory of electron diffraction (DYNAMICAL DIFFRACTION; Hirsch et al., 1977; Williams and Carter, 1996). Equations 19 through 21 tell us that, for a foil of constant thickness t, we expect the intensities of the transmitted and diffracted beams to vary with depth in the foil and the period of depth variation is approximately s^{-1}. This behavior is illustrated schematically in Figure 5A. The larger is the deviation parameter, the smaller is the period of oscillation and vice versa.

Extinction Distance

A more general way of writing Equation 19 is

$$\mathbf{I}_g = \left(\frac{\pi}{\xi_g}\right)^2 \frac{\sin^2(\pi s t)}{(\pi s)^2} \tag{22}$$

where the extinction distance ξ_g is given by the expression

$$\xi_g = \frac{\pi V \cos\theta}{\lambda \mathcal{F}_g} \tag{23}$$

and V is the volume of the unit cell, θ is the Bragg angle for the diffraction vector $\mathbf{g}$, λ is the electron wavelength, and $\mathcal{F}_g$ is the structure factor for the diffracting vector $\mathbf{g}$. Note that ξ_g increases with increasing order of diffracting vectors because $\mathcal{F}_g$ decreases as θ increases.

The quantity ξ_g defined in Equation 23 is an important length scale in the kinematical and dynamical theories of electron diffraction. The extinction distance is defined as twice the distance in the cystal over which 100% of the incident beam is diffracted when $s = 0$ and the Bragg condition is satisfied exactly. The magnitude of ξ_g depends on

Table 1. Extinction Distances ξ_g (nm) for fcc Metals with 100-kV Electrons (from Hirsch et al., 1977)

Diffracting Plane	Al	Ni	Cu	Ag	Pt	Au	Pb

the atomic form factors; the stronger the scattering, the shorter is ξ_g. Table 1 shows some values of ξ_g for different diffracting planes in pure metals with a face-centered cubic (fcc) crystal structure (Hirsch et al., 1977). Notice how ξ_g increases with the indices of the diffracting vectors *hkl* and decreases with increasing atomic number. The values of ξ_g generally range from a few tens to a few hundred nanometers.

The extinction distance defines the depth variation of the transmitted and diffracted intensities in a crystal when the diffraction is strong. The extinction distance ξ_g applies to the dynamical situation where $s = 0$, as illustrated in Figure 5B, not just the kinematical situation where $s \gg 0$. In the development of the dynamical theory of electron diffraction, the dependence of the diffracted intensity on the deviation parameter and sample thickness is much the same as in Equation 22 with the following modification: The extinction distance in Equation 23 is made dependent on s by transforming ξ_g into an effective extinction distance, ξ_{geff},

$$\xi_{geff} = \frac{\xi_g}{\sqrt{1 + s^2\xi_g^2}} \tag{24}$$

and another quantity known as the effective deviation parameter is defined as

$$s_{eff} = \sqrt{s^2 + \xi_g^{-2}} \tag{25}$$

Equation 24 shows that the effective extinction distance $\xi_{geff} = \xi_g$ when $s = 0$, but ξ_{geff} decreases with increasing deviation from the exact Bragg position. With large deviations, $s \gg 1/\xi_g$, and $\xi_{geff} = s^{-1}$, so the kinematical result is recovered for large s.

Diffraction Contrast from Lattice Defects

The following are important variables in the diffraction contrast from defects in crystals:

$\mathcal{F}(\mathbf{g}) \equiv$ structure factor of unit cell
$t \equiv$ specimen thickness
$\Delta\mathbf{k} \equiv$ diffraction vector
$\mathbf{g} \equiv$ reciprocal lattice vector
$\mathbf{s} \equiv$ deviation vector ($\mathbf{g} = \Delta\mathbf{k} + \mathbf{s}$)
$\mathbf{r} \equiv$ actual atom centers
$\mathbf{R} \equiv$ atom centers in a perfect crystal ($\mathbf{R} = \mathbf{r}_g + \mathbf{r}_k$, where $\mathbf{r}_g$ refers to the lattice and $\mathbf{r}_k$ to the basis)
$\delta\mathbf{r} \equiv$ displacements of atoms off the ideal atom centers ($\mathbf{r} = \mathbf{R} + \delta\mathbf{r}$).

Note that the actual atom centers $\mathbf{r}$ as defined above are the locations of the atoms off of the atom positions in a perfect crystal $\mathbf{R}$ that are given by the lattice (plus basis) points, i.e., the ideal mathematical positions. Spatial variations in these variables (e.g., an x dependence) can produce diffraction contrast in an image. Examples include the following:

$\mathcal{F}$: $d\mathcal{F}/dx$ causes chemical (compositional) contrast,
t: dt/dx causes thickness contours,
$\mathbf{g}$: $d\mathbf{g}/dx$ causes bend contours,
$\mathbf{s}$: $d\mathbf{s}/dx$ causes bend contours, and
$\delta\mathbf{r}$: $d\delta\mathbf{r}/dx$ causes strain contrast.

Up to this point, we have only considered diffraction occurring from perfect crystals. We now consider the displacements in atom positions $\delta\mathbf{r}$ caused by strain fields around defects in a crystal. These displacements represent the time-averaged position of the atoms during electron scattering. We decompose $\mathbf{r}$ into components from the lattice vectors, basis vectors, and distortion vectors as

$$\mathbf{r} = \mathbf{r}_g + \mathbf{r}_k + \delta\mathbf{r} \tag{26}$$

and we use the familiar expression for our diffracting vector as the difference of a reciprocal lattice vector and a deviation vector:

$$\Delta\mathbf{k} = \mathbf{g} - \mathbf{s} \tag{27}$$

By using Equations 26 and 27 and noting that $\mathbf{r} = \mathbf{R} + \delta\mathbf{r}$, we can rewrite Equation 3 as

$$\psi(\Delta\mathbf{k}) = \sum_{\mathbf{r}} f_{\text{at}}(\mathbf{r}) \exp[-i2\pi(\mathbf{g} - \mathbf{s}) \cdot (\mathbf{r}_{\text{g}} + \mathbf{r}_{\text{k}} + \delta\mathbf{r})] \quad (28)$$

We then arrange Equaton 28 into a product of a structure factor $\mathcal{F}(\Delta\mathbf{k})$ and something like a shape factor, as we did previously. In doing so, we assume that the distortion $\delta\mathbf{r}$ is the same for all atoms in a particular unit cell,

$$\psi(\Delta\mathbf{k}) = \sum_{\mathbf{r}_{\text{g}}} \exp[-i2\pi(\mathbf{g} - \mathbf{s}) \cdot (\mathbf{r}_{\text{g}} + \delta\mathbf{r})] \times \sum_{\mathbf{r}_{\text{k}}} f_{\text{at}}(\mathbf{r}_{\text{k}}) \exp[-i2\pi(\mathbf{g} - \mathbf{s}) \cdot \mathbf{r}_{\text{k}}] \quad (29)$$

When there are only a few atoms in the unit cell, we can neglect the factor of $\exp(i2\pi\mathbf{s} \cdot \mathbf{r}_{\text{k}})$. We then identify the second sum in Equation 29 as the familiar structure factor of the unit cell $\mathcal{F}(\Delta\mathbf{k})$, and rewriting Equation 29 gives

$$\psi(\Delta\mathbf{k}) = \sum_{\mathbf{r}_{\text{g}}} \exp[-i2\pi(\mathbf{g} \cdot \mathbf{r}_{\text{g}} + \mathbf{g} \cdot \delta\mathbf{r} - \mathbf{s} \cdot \mathbf{r}_{\text{g}} - \mathbf{s} \cdot \delta\mathbf{r})] \mathcal{F}(\Delta\mathbf{k}) \quad (30)$$

First, note that the product $\mathbf{g} \cdot \mathbf{r}_{\text{g}}$ is an integer, so it yields a factor of unity in the exponential. Second, because both $\mathbf{s}$ and $\delta\mathbf{r}$ are small, their product is negligible compared to the other two terms in the exponential in Equation 30. Thus, one obtains

$$\psi_{\text{g}} - F(\mathbf{g}) \sum_{\mathbf{r}_{\text{g}}} \exp[-i2\pi(\mathbf{g} \cdot \delta\mathbf{r} - \mathbf{s} \cdot \mathbf{r}_{\text{g}})] \quad (31)$$

It is convenient and appropriate to substitute $\mathcal{F}(\mathbf{g})$ for $\mathcal{F}(\Delta\mathbf{k})$ in Equation 31, since we use all of the diffracted intensity around a specific reciprocal lattice point in forming a DF image, as defined in the next section. Equation 31 is useful for determining the diffraction contrast from defects such as dislocations, stacking faults, and precipitates. Such defects possess strain fields, and it is these strain fields that produce diffraction contrast in TEM images. Equation 31 shows that, in addition to the local atomic displacements $\delta\mathbf{r}$, the defect image is also controlled by the deviation vector $\mathbf{s}$.

The diffraction condition $\mathbf{g} \cdot \delta\mathbf{r} = 0$ is particularly important for the study of defects with diffraction contrast. The condition $\mathbf{g} \cdot \delta\mathbf{r} = 0$ is a null-contrast condition. For this condition, $\delta\mathbf{r}$ lies in the diffracting plane, and the interplanar spacing d (and thus $|\mathbf{g}|$) is therefore unaltered. The condition $\mathbf{g} \cdot \delta\mathbf{r}$ is the condition for zero diffraction contrast originating from the displacement $\delta\mathbf{r}$. Even when $\mathbf{g} \cdot \delta\mathbf{r}$ is not exactly zero, the magnitude of $\mathbf{g} \cdot \delta\mathbf{r}$ must be sufficient to change the local intensity from the background level so that contrast is visible in the image. This typically requires an intensity change of $\sim$10%. A rule of thumb is that if $\mathbf{g} \cdot \delta\mathbf{r} \leq \frac{1}{3}$, there is no visible contrast associated with $\delta\mathbf{r}$. This criterion is adequate for the analysis of diffracton contrast from many defects of interest in materials, such as dislocations, dislocation loops, precipitates, stacking faults, domain boundaries, and grain and interphase boundaries, and its use is illustrated below (see Data Analysis and Initial Interpretation).

PRACTICAL ASPECTS OF THE METHOD

Bright-Field/Dark-Field Imaging

A ray diagram for making an image with a conventional TEM (CTEM) containing two lenses is shown in Figure 6B. In this diagram, the intermediate lens is focused on the image plane of the objective lens. We assume the illumination system provides rays (electrons) that travel straight down the microscope (parallel to the optic axis) before hitting the specimen. In Figure 6A, all transmitted and diffracted rays leaving the specimen are combined to form an image at the viewing screen, much as in a conventional optical microscope. In this simple mode of imaging, the specimen generally shows little contrast because all of the diffracted intensity reaches the viewing screen. By tracing the individual rays in Figure 6A, one can see how each point in the back focal plane of the objective lens contains rays from all parts of the specimen. Not all of the rays in the back focal plane are therefore required to form an image. An image can be formed with only those rays passing through one point in the back focal plane. What distinguishes the points located in the back focal plane is that all rays entering a given point have been scattered by the specimen into the same angle. By positioning an objective aperture at a specific location in the back focal plane, an image will be made with only those electrons that have been diffracted by a specific angle. (A similar principle applies in EFTEM, except that an aperture is used to allow electrons of only a certain energy loss to form the image.) This defines two basic imaging modes, which are also illustrated in Figure 6:

1. When the objective aperture is positioned to pass only the transmitted (undiffracted) electrons, a BF image is formed, as illustrated in Figure 6B.
2. When the objective aperture is positioned to pass only some diffracted electrons, a DF image is formed, as illustrated in Figure 6C.

The best way to form a DF image is to tilt the incident illumination on the specimen by an angle equal to the angle of the particular diffraction used for making the DF image, as illustrated in Figure 6C. On the back focal plane, the position of the transmitted beam was tilted into the position of the diffracted spot on the left, and the diffracted spot on the right is now used to form the DF image. Notice how these diffracted rays remain near the optic axis. This minimizes the detrimental effect of spherical aberration on the image resolution (see below). The following section illustrates how one can visualize tilting either the specimen or the electron beam in the TEM mode using the Ewald sphere construction discussed previously.

In most CTEM studies of crystalline materials, features in the image originate primarily from diffraction contrast.

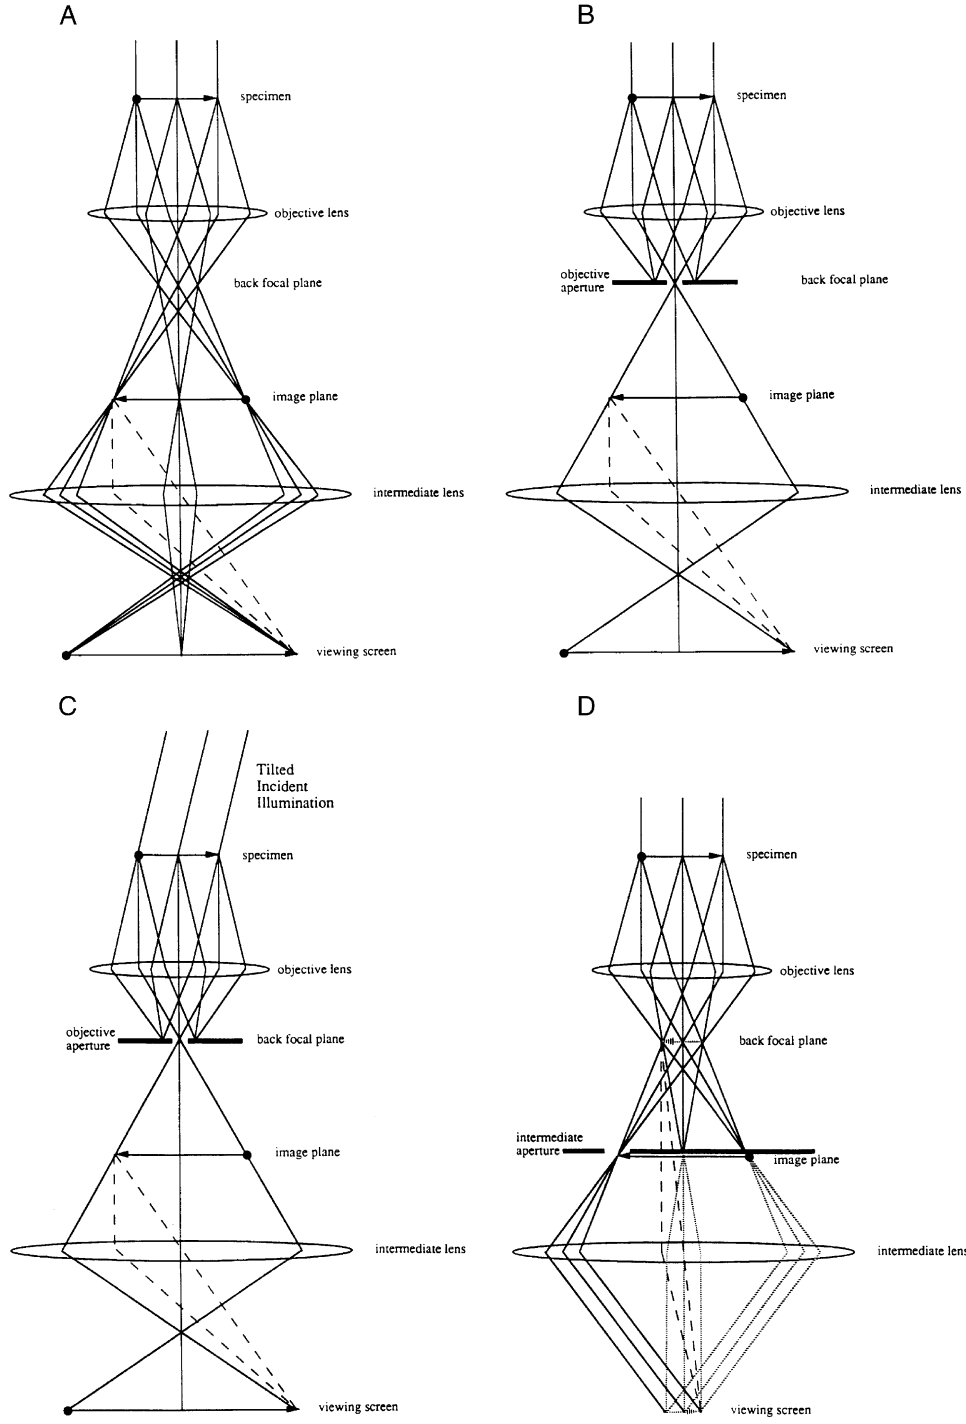

Figure 6. (**A**) Image mode for TEM containing objective and intermediate lens (**B**) BF imaging mode, (**C**) axial DF imaging mode, and (**D**) SAD mode in TEM.

Diffraction contrast is the variation in the diffracted intensity of particular electrons across the specimen, observed by inserting an objective aperture into the path of the beam. Upon doing so, features in the image become far more visible; without the objective aperture, the image tends to be gray and featureless. The physical reason that the diffraction contrast of a BF (or DF) image (Fig. 6B or C) is so much better than that of an apertureless image (Fig. 6A) is as follows: When there is a large intensity in the diffracted beams, there is a large complementary loss of intensity in the transmitted beam, so either the BF or DF image alone will show strong diffraction contrast. Without the objective aperture, however, the diffracted intensity recombines with the transmitted intensity at the viewing screen. This recombination eliminates the observed diffraction contrast.

For thick specimens, an apertureless image mainly shows contrast caused by incoherent scattering in the

sample. This generic type of contrast is called mass-thickness contrast because it increases with the atomic mass (squared) and the thickness of the material (Reimer, 1993). Mass-thickness contrast is particularly useful in biology, where techniques have been developed for selectively staining the different cell organelles with heavy elements to increase their mass-thickness contrast. In the case of very thin specimens (say $<\sim$10 nm), if a large objective aperture is used (or no aperture at all, as in Fig. 6A) and the transmitted and diffracted electron beams (waves) are allowed to recombine (interfere), the resulting image contrast depends on the relative phases of the beams involved; this mode of imaging is often called phase-contrast imaging. If the microscope resolution is less than the atomic spacings in the sample and both the sample and microscope conditions are optimized, phase-contrast imaging can be used to resolve the atomic structures of materials. This forms the basis of HRTEM.

In the microscope, typical objective apertures range from $\sim$0.5 to 20 μm in diameter. The apertures are moveable with high mechanical precision and can be positioned around selected diffraction spots in the back focal plane of the objective lens. The practice of positioning an objective aperture requires changing the operating mode of the microscope to the diffraction mode (described in the next section). In the diffraction mode, the images of both the diffraction pattern and the aperture are visible on the viewing screen, and the objective aperture can then be moved until it is in the desired position. Once the objective aperture is positioned properly, the microscope is switched back into the image mode, and either a DF or a BF image is formed.

Tilting Specimens and Tilting Electron Beams

Many problems in the geometry of diffraction can be solved by employing an Ewald sphere and a reciprocal lattice. When working problems, it is important to remember the following:

1. The Ewald sphere and the reciprocal lattice are connected at the origin of the reciprocal lattice. Tilts of either the Ewald sphere or the reciprocal lattice are performed about this pivot point.
2. The reciprocal lattice is affixed to the crystal (for cubic crystals the reciprocal lattice directions are along the real-space directions). Tilting the specimen is represented by tilting the reciprocal lattice by the same angle and in the same direction.
3. The Ewald sphere surrounds the incident beam and is affixed to it. Tilting the direction of the incident beam is represented by tilting the Ewald sphere by the same amount.

These three facts are useful during practical TEM work. It is handy to think of the viewing screen as a section of the Ewald sphere, which shows a disk-shaped slice of the reciprocal lattice of the specimen. When we tilt the sample, the Ewald sphere and the viewing screen stay fixed, but the different points on the reciprocal lattice of the sample move into the viewing screen. For small tilts of the specimen, the diffraction pattern does not move on the viewing screen, but the diffraction spots change in intensity. Alternatively, when we tilt the incident beam, we rotate the transmitted beam and the Ewald sphere. We can think of this operation as moving the disk-shaped viewing screen around the surface of the Ewald sphere. The diffraction spots therefore move in a direction opposite to the tilt of the incident beam, and the diffraction pattern moves as though the central beam were pivoting about the center of the sample.

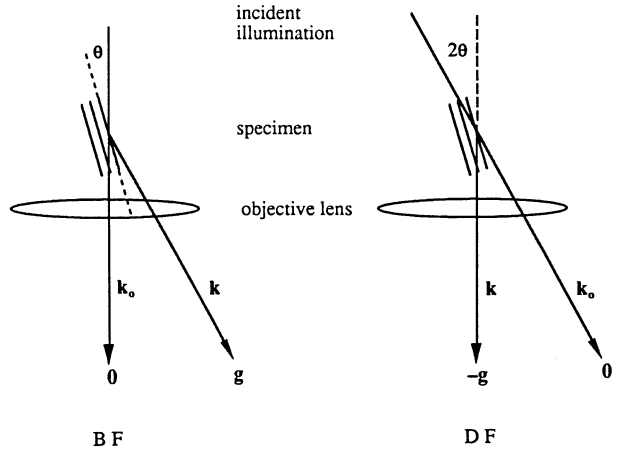

Figure 7. Procedures for axial BF and DF imaging. Specimen remains stationary as beam is tilted 2θ to center $-\mathbf{g}$ diffracted spot on optic axis.

Tilted Illumination and Diffraction: How to Do Axial DF Imaging

To form DF images with good resolution, it is necessary to ensure that the image-forming diffracted rays travel straight down the optic axis. This requires that the direction of the incident electrons ($\mathbf{k}_0$) be tilted away from the optic axis by an angle 2θ, as shown in Figure 7. After tilting the illumination, there is a difference in the positions and intensities of the diffraction spots for the BF and DF modes. By tilting the illumination, we in fact tilt the Ewald sphere about the origin of the reciprocal lattice, as shown in Figure 8. Seen on the viewing screen, we tilt the transmitted beam into the former position of the diffraction spot **g**. In doing so, the diffraction spot **g** moves far from the optic axis, but the diffraction spot $-\mathbf{g}$ becomes active, and its rays travel along the optic axis. This procedure seems counterintuitive, so why did we use it? The answer is that if the active diffraction spot **g** is tilted into the center of the viewing screen, the diffraction spot **g** becomes weak, and the diffraction spot 3**g** becomes strong. Since the diffraction spot **g** is weak, it would be difficult to use for making a DF image. This latter procedure can be useful to improve resolution in DF analysis of defects and is referred to as weak-beam dark-field (WBDF) imaging (Cockayne et al., 1969).

Selected-Area Diffraction

Figure 6D is a ray diagram for making a diffraction pattern with the simplified two-lens transmission electron

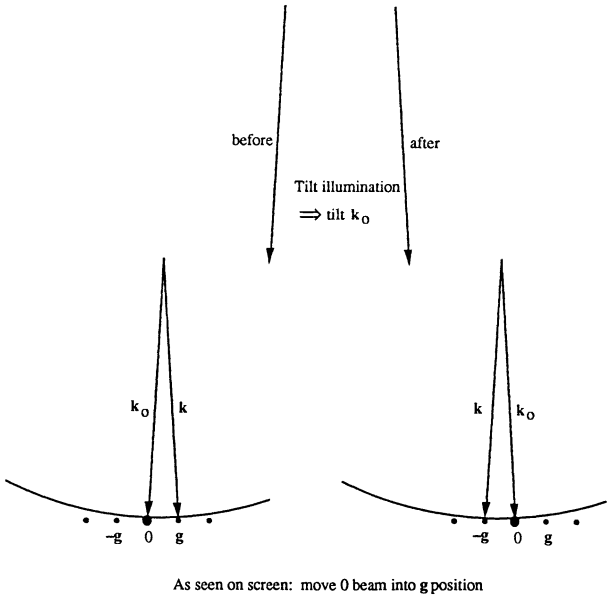

Figure 8. Procedure to set up axial DF image as in Figure 7. As seen on viewing screen, transmitted beam is moved into former position of diffracted spot **g** and $-\mathbf{g}$ diffracted spot becomes intense.

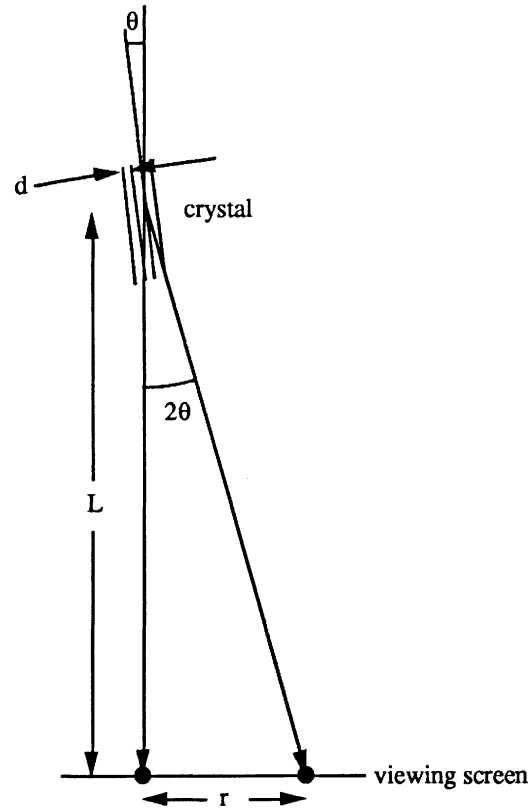

Figure 9. Geometry for electron diffraction and definition of cameral length L.

microscope. The intermediate lens is now focused on the back focal plane of the objective lens. The transmitted beam and all of the diffracted beams are imaged on the viewing screen. In this configuration, a second aperture, called an intermediate (or selected-area) aperture, can be positioned in the image plane of the objective lens, and this provides a means of confining the diffraction pattern to a selected area of the specimen. This technique of SAD is usually performed in the following way. The specimen is first examined in image mode until a region of interest is found (the tip of the solid arrow in the image plane in Fig. 6D). The intermediate aperture is then inserted and positioned around this feature. Owing to spherical aberration, it may be necessary to slightly underfocus the objective lens to ensure that the SAD pattern comes from the region of interest (Hirsch et al., 1977; Thomas and Goringe, 1979). The microscope is then switched into the diffraction mode. The SAD pattern that appears on the viewing screen originates from the area selected in the image mode (the tip of the solid arrow in the image plane). Selected-area diffraction can be performed on regions a micrometer or so in diameter, but spherical aberration of the objective lens limits the technique to regions not much smaller than this. For diffraction work from smaller regions, it is necessary to use small-probe techniques such as convergent-beam electron diffraction (CBED).

We can use the separation of the diffraction spots on the viewing screen to determine interplanar spacings in crystals, and this can be used to help determine the lattice parameter of a crystal or to identify an unknown phase. To do this, we need to know the camera length of the microscope. Consider the geometry of the SAD pattern in Figure 9, which shows the camera length L that is characteristic of the optics of the microscope. Bragg's law is given as

$$2d \sin \theta = n\lambda \tag{32}$$

where d is the interplanar spacing, λ is the electron wavelength, and n is an integer. The value of θ is on the order of a degree for low-order diffraction spots from most materials using 100-keV electrons ($\lambda = 0.0037$ nm). For such small angles,

$$\sin \theta \sim \tan \theta \sim \frac{1}{2}\tan(2\theta) \tag{33}$$

and from the geometry in Figure 9,

$$\tan 2\theta = \frac{r}{L} \tag{34}$$

where r is the separation of the diffraction spots on the viewing screen. If we substitute Equation 34 into Bragg's law (Equation 32) and arrange terms, we obtain

$$rd = \lambda L \tag{35}$$

Equation 35 is referred to as the camera equation. It allows one to determine an interplanar spacing d by measuring the separation of diffraction spots r in the

transmission electron microscope (or on a photographic negative). To do this, we need to know the product λL, known as the camera constant (in units of nanometers-centimeters), and its approximate value ($\pm 5\%$) can be found on a console display of a modern transmission electron microscope. For higher precision, one should perform a calibration of the camera constant using a standard such as an evaporated Au film and insert the unknown specimen into the microscope, keeping the lens conditions fixed while adjusting the specimen focus using the height (Z) control on the goniometer. Better still is to evaporate the film directly on part of the unknown specimen, or if the unknown is a precipitate in a matrix, for example, the matrix material can be used for calibration, as illustrated below (see Data Analysis and Initial Interpretation).

Indexing Diffraction Patterns

The reciprocal lattices of materials are three dimensional, so their diffraction patterns are three dimensional. Diffraction data from TEM are obtained as near-planar sections through diffraction space. The magnitude of the diffraction vector, $|\Delta\mathbf{k}|$, is obtained from the angle between the transmitted and diffracted beams. The interpretation of these data is simplified because the large electron wave vector provides an Ewald sphere that is nearly flat. This allows the convenient approximation that the diffraction pattern is sampling the diffaction intensities from a planar section of the reciprocal lattice. Two degrees of orientational freedom are required for the sample in TEM. These degrees of freedom are typically obtained with a double-tilt specimen holder, which provides two tilt axes oriented perpendicular to each other. Modern TEMs provide two methods for obtaining diffraction patterns from individual crystallites. One method is SAD, which is useful for obtaining diffraction patterns from regions as small as 0.5 μm in diameter. The second method is CBED (or microdiffraction/nanodiffraction), in which a focused electron beam is used to obtain diffraction patterns from regions as small as 1 nm. Both techniques provide a 2D pattern of diffraction spots, which can be highly symmetrical when a single crystal is oriented precisely along a zone axis orientation, as on the right in Figure 3.

We now describe how to index the planar sections of single-crystal diffraction patterns; i.e., label the individual diffraction spots with their appropriate values of h, k, and l. It is helpful to imagine that the single-crystal diffraction pattern is a picture of a plane in the reciprocal space of the material. (See SYMMETRY IN CRYSTALLOGRAPHY for more details on point groups.) Indexing begins with the identification of the transmitted beam, or the (000) diffraction spot. This is usually the brightest spot in the center of the diffraction pattern. Next, we need to index two independent (i.e., noncolinear) diffraction spots nearest to the (000) spot. Once these two vectors are determined, we can make linear combinations of them to obtain the positions and indices of all the other diffraction spots. To complete the indexing of a diffraction pattern, we also specify the normal to the plane of the spot pattern; this normal is the zone axis. By convention, the zone axis points toward the electron gun (i.e., upward in most transmission electron microsopes). The indexing of a diffraction pattern is not unique. If a crystal has high symmetry, so does its reciprocal lattice (although these symmetries may be different). A high symmetry leads to a multiplicity of different, but correct, ways to index a given diffraction pattern. For example, a vector cube axis can be a [100], [010], or [001] vector. Once the orientation of the diffraction pattern is specified, it is important to index the pattern consistently.

Most of the work in indexing diffraction patterns involves measuring angles and distances between diffraction spots and then comparing these measurements to geometrical calculations of angles and distances. When indexing a diffraction pattern, one must remember that structure factor rules eliminate certain diffraction spots. For consistency, one must also satisfy the "right-hand rule," which is given by the vector cross-product relation: $\mathbf{x} \times \mathbf{y} \parallel \mathbf{z}$. The procedures are straightforward for low-index zone axes of simple crystal structures but become increasingly difficult for crystal structures with low symmetry and for high-index zone axes, where many different combinations of interplanar spacings and angles provide diffraction patterns that look similar. In these cases, a computer program to calculate such diffraction patterns is extremely helpful (see Method Automation; also see Data Analysis and Initial Interpretation).

The procedure to index a diffraction pattern is illustrated by example below. Suppose we need to index the diffraction pattern in Figure 10A and we know that it is from an fcc crystal. The first step is to consult a reference and find an indexed diffraction pattern that looks like the one in Figure 10A. In this method, we guess the zone axis and its diffraction pattern. This method is most useful when the diffraction pattern shows an obvious symmetry, such as a square or hexagonal array of spots for a cubic crystal. With experience, one eventually remembers the symmetries for common fcc and body-centered cubic (bcc) diffraction patterns shown in Table 2. Without turning immediately to published SAD patterns, however, we first note that the pattern in Figure 10A is less symmetrical than those in Table 2. Nevertheless, we note that the

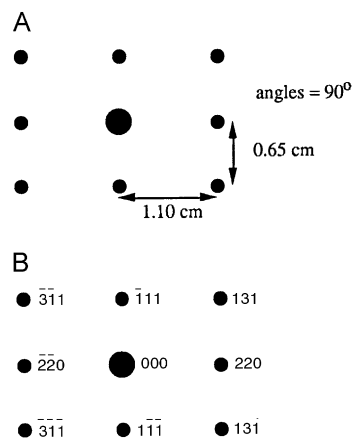

Figure 10. (**A**) An fcc diffraction pattern ready for indexing and (**B**) successful indexing of diffraction pattern in (**A**).

Table 2. Some Symmetrical Diffraction Patterns

Zone Axis	[100]	[110]	[111]
Symmetry	square	rectangular 1:$\sqrt{2}$ for bcc (almosthexagonal for fcc)	hexagonal

density of spots seems reasonably high, so we expect that we have a fairly low-order zone axis. The lowest order zone axes are

[100] [110] [111] [210] [211] [310]
[200] [220] [222]
[300]

Since the [200], [220], and [222] vectors point along the directions of [100], [110], and [111], we need only consider the lower index [100], [110], and [111] directions as candidate zone axes. We eliminate the first three zone axes because the pattern does not have the required symmetry as listed in Table 2. The diffraction pattern from the [310] zone axis is not rectangular, so the [210] and [211] patterns seem most promising.

If we knew the camera constant λL, it would be appropriate to work with absolute distances for the spot spacings. In this case, we could rearrange the camera equation $rd = \lambda L$ (Equation 35) to obtain the measured distance r of a diffraction spot from the transmitted beam by

$$r = \frac{\lambda L}{a}\sqrt{h^2 + k^2 + l^2} \tag{36}$$

Here we work with relative spacings instead. Equation 36 shows that the ratio of the spot distances must equal the ratio of $\sqrt{h^2 + k^2 + l^2}$. We first measure the spacings to the vertical and horizontal spots as reference distances (0.65 and 1.10 cm, respectively, from Fig. 10A originally). We then seek the ratios of $\sqrt{h^2 + k^2 + l^2}$ from the allowed (hkl) of an fcc crystal by making a list of possible distances, as shown in Table 3, and looking for two diffraction spots, preferably low-order ones, whose spacings are in the ratio of $0.65/1.10 = 0.591$. One can find by trial and error that $\sqrt{3}/\sqrt{8} = 0.61$. This ratio corresponds to the (111) and (220) diffraction spots, which seem promising candidates for further work. Note also that the diffraction pair (200) and (311), the pair (200) and (222), and the pair (220) and (422) also have good ratios of their spot spacing, but they contain higher order reflections.

Table 3. List of Allowed fcc (hkl) Reflections and Their Relative Interplanar Spacings

Allowed fcc (hkl)	$\sqrt{h + k^2 + l^2}$	Relative Spacing
(111)	$\sqrt{3}$	= 1.732
(200)	$\sqrt{4}$	= 2.000
(220)	$\sqrt{8}$	= 2.828
(311)	$\sqrt{11}$	= 3.317
(222)	$\sqrt{12}$	= 3.464
(400)	$\sqrt{16}$	= 4.000
(331)	$\sqrt{19}$	= 4.359
(420)	$\sqrt{20}$	= 4.472
(422)	$\sqrt{24}$	= 4.899

We need to choose specific vectors in the $\langle 111\rangle$ and $\langle 220\rangle$ families that provide the correct angles in the diffraction pattern. There are a number of ways to do this; here we use $[\bar{1}11]$ and [220]. Note that $[\bar{1}11] \cdot [220] = 0$, so these spots are consistent with the observed 90° angles. It turns out that we can eliminate two of our other three candidate pairs of diffraction spots—the pair (200) and (311) and the pair (200) and (222)—because no vectors in their families are at 90° angles. (For nonperpendicular normalized vectors, we find the angle between them by taking the arccosine of their dot product.) Now we complete the diffraction pattern by labeling the other diffraction spots by vector addition, as illustrated in Figure 10B. Finally, we get the zone axis of the crystal from the vector cross-product:

$$[220] \times [\bar{1}11] = (2-0)\hat{x} + (0-2)\hat{y} + (2--2)\hat{z} = [2\bar{2}4] = [1\bar{1}2] \tag{37}$$

The astute reader may wonder what happened to the candidate pair of (220) and (422) reflections, which also have good ratios of their spot spacings, and a 90° angle is formed by [220] and $[2\bar{2}4]$. We could have gone ahead and constructed a candidate diffraction pattern with these diffraction vectors. The zone axis is

$$[220] \times [2\bar{2}4] = (8-0)\hat{x} + (0-8)\hat{y} + (-4-4)\hat{z} = [8\bar{8}\bar{8}] = [1\bar{1}\bar{1}] \tag{38}$$

This should seem suspicious, however, because a $\langle 111\rangle$ zone axis provides a diffraction pattern with hexagonal symmetry (Table 2), quite unlike the rectangular symmetry of Figure 10. These {220} diffracted spots make a hexagonal pattern around the transmitted beam. Once the zone axis is identified, it is important to check again all expected diffraction spots and ensure that the diffraction pattern accounts for all of them. Once we have done so, it is clear that the (220) and (422) spots are inappropriate for indexing the pattern in Figure 10.

Having gone through the exercise of indexing the diffraction pattern in Figure 10, one can appreciate how tedious the practice could be for low-symmetry patterns with nonorthogonal vectors. As mentioned above, several excellent computer programs are available to help simplify the task (but do not trust them blindly). It is also important to note that the eye is able to judge distances to ~0.1 mm, particularly with the aid of a 10× calibrated magnifier, so the measurement accuracy of spot spacings in a diffraction pattern is typically about that good. A diffraction spot 10 mm from the center of the pattern yields a measurement error of 1%. For the highest accuracy in determining spot spacings, it is often preferable to measure the distance between sharper, higher order spots and then divide by the number of spots separating them (plus 1). Photographic printing can distort spot spacings, so measurements should be performed directly on negatives or the photographic enlarger should be checked for possible distortions.

Kikuchi Lines and Specimen Orientation

Electron Diffuse Scattering. In thick specimens, features are seen in electron diffraction patterns in addition to the usual Bragg diffraction spots and their fine structure. Inelastic scattering contributes a diffuse background to the diffraction pattern, even at moderate specimen thicknesses. More interestingly, intersecting sets of straight lines appear on top of the diffuse background. These are called Kikuchi lines (Kikuchi, 1928). They may be either bright or dark and are straight and regularly arranged. We can explain the existence of Kikuchi lines by a combination of two electron-scattering processes, the first one inelastic, followed by elastic Bragg diffraction. Although the first electron-scattering process is inelastic, a 100-keV electron does not lose too much energy, typically < 30 eV, owing to plasmon excitation, so the magnitude of its wave vector is nearly unaffected. Even for an energy loss of 1 keV, a 100-keV electron will undergo a change in wave vector of only $\sim 0.5\%$. The direction of the inelastically scattered electron deviates from the direction of the incident beam, but usually only by a small amount. There is a distribution of directions for inelastically scattered electrons, but it is important to note that this distribution is peaked along the incident direction, as illustrated at the top of Figure 11A. A diffuse background in the diffraction pattern originates from the inelastically scattered electrons that are not Bragg diffracted but are forward peaked, as shown at the bottom in Figure 11A. This diffuse background has a higher intensity for thicker specimens, at least until electron transparency is lost.

Origin of Kikuchi Lines. Kikuchi lines are features in the inelastic background that show the crystallographic structure of the sample. To create Kikuchi lines, a few of the inelastically scattered electrons must undergo a second scattering, which is an elastic Bragg diffraction event. It is important to recognize that most of the inelastically scattered electrons have lost relatively little energy and undergo a minimal change in their wavelength λ. Of these electrons, some may be diverted by the first inelastic scattering event so they become incident at a Bragg angle to some crystal planes. These electrons can then be Bragg diffracted.

The two rays drawn in Figure 11B (labeled "two inelastically scattered rays") are special ones, being rays in the plane of the paper that are oriented properly for Bragg diffraction by the crystal planes (hkl). Notice the two directions for the electrons coming out of the crystal, labeled K_{hkl} and $\mathbf{K}_{\bar{h}\bar{k}\bar{l}}$ in Figure 11B. The beam $\mathbf{K}_{hkl}$ consists of electrons that were Bragg diffracted out of the forward-scattered inelastic beam plus those electrons that were scattered inelastically at a modest angle but not diffracted. The other beam $\mathbf{K}_{\bar{h}\bar{k}\bar{l}}$ consists of the forward-scattered electrons plus those electrons that were Bragg diffracted into the forward direction (after first having been inelastically scattered by a modest angle). The important point is that the forward beam is stronger, so there are more electrons lost by secondary Bragg diffraction from the forward beam, $\mathbf{K}_{\bar{h}\bar{k}\bar{l}}$, than vice versa. Electron intensity in the diffuse background is therefore taken from the beam $\mathbf{K}_{\bar{h}\bar{k}\bar{l}}$ and added to the beam $\mathbf{K}_{hkl}$. As shown at the bottom of Figure 11B, the diffuse background has a deficit of intensity on the right and an excess of intensity on the left. The excess and deficit beams are separated by the angle 2θ.

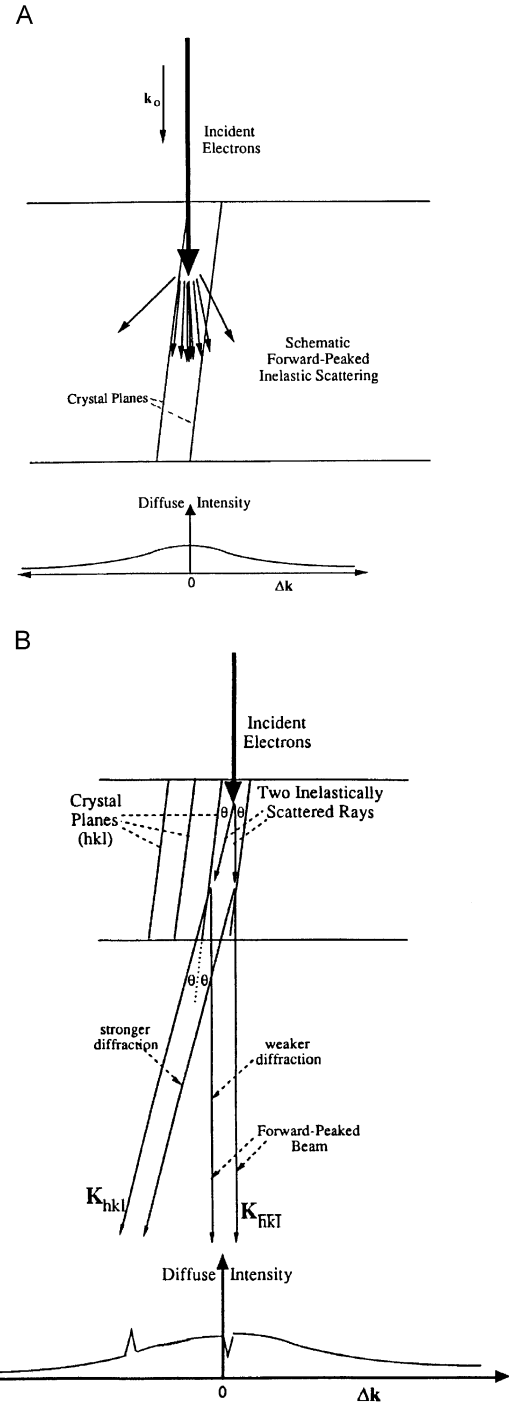

Figure 11. (**A**) Top: Electron paths through specimen. Bottom: Diffuse intensity recorded in diffraction pattern from forward-peaked inelastic scattering. (**B**) Origin of Kikuchi lines. Top: Electron paths through specimen for electrons subject to inelastic scattering followed by secondary Bragg diffraction. Bottom: Pattern of scattered intensity showing sharp modulations in diffuse intensity caused by Bragg diffraction.

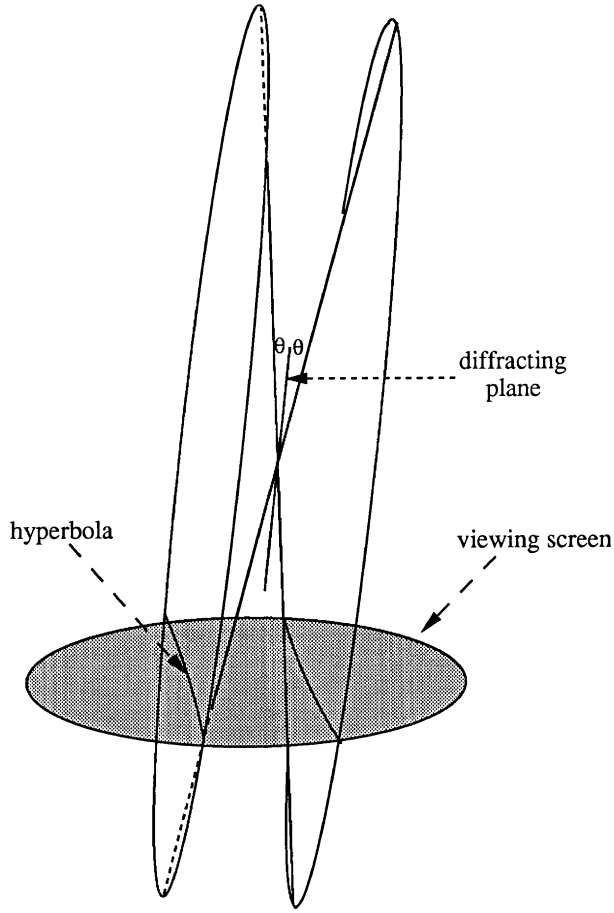

Figure 12. Intersection of Kossel cones with viewing screen of TEM.

Excesses and deficits in the inelastic background intensity can be produced in any direction that is at the Bragg angle to the crystal planes. In three dimensions, the set of these rays form pairs of Kossel cones, which are oriented symmetrically about the diffracting planes. All lines from the vertices of these cones make the Bragg angle θ with respect to the diffracting plane. In Figure 12, note how the minimum angle between the surfaces of the two cones is 2θ. The intersections of these two cones with the viewing screen of the microscope are nearly hyperbolas. Since θ is so small and the viewing screen is so far away, these hyperbolas appear as straight lines. The line closer to the transmitted beam is darker than the background (the deficit line); the other line is brighter (the excess line).

Because Kikuchi lines originate from inelastically scattered electrons, their intensity increases with the diffuse background in the diffraction pattern. Kikuchi lines are found to be weak or nonexistent in very thin regions of a specimen where the diffraction spot pattern is without much diffuse background. As one translates a specimen in TEM to observe thicker regions, the Kikuchi lines become more prominent, often becoming more observable than the diffraction spots themselves. The Kikuchi lines decrease in intensity when the sample becomes so thick that it is no longer electron transparent. Lastly, we note that by the explanation of Figure 11, there should be no excess or deficit bands in the symmetric case where the Kikuchi lines straddle the transmitted beam. Kikuchi lines are in fact observed, however, showing that our simple explanation of their origin is not adequate. A much more complicated explanation based on dynamical diffraction theory with absorption is necessary to fully account for the intensities of Kikuchi lines (Hirsch et al., 1977; Williams and Carter, 1996). Regardless of this, we can use the crystallographic symmetry of the Kikuchi lines in the TEM analysis of crystals.

Indexing Kikuchi Lines. For a specific set of crystal planes (hkl), the complement of the two vertex angles of the Kossel cones is 2θ (see Fig. 12). This is the same angle as between the transmitted beam and the (hkl) diffracted beam. On the viewing screen, the separation between the two Kikuchi lines will therefore be the same as the separation of the (hkl) diffraction spot from the (000) spot. We can index the Kikuchi lines by measuring their separations in much the same way as we index diffraction spots. For two different pairs of Kikuchi lines, from the planes $(h_1k_1l_1)$ and $(h_2k_2l_2)$, their separations between excess and deficit lines p_1 and p_2 are in the ratio

$$\frac{p_1}{p_2} = \frac{\sqrt{h_1^2 + k_1^2 + l_1^2}}{\sqrt{h_2^2 + k_2^2 + l_2^2}} \tag{39}$$

Figure 13 shows ratios of $\sqrt{6}$, 2, and $\sqrt{2}$ for indexed (211), (200), and (110) Kikuchi line pairs. The angles between the Kikuchi line pairs can be measured with precision. High-energy electrons have very obtuse vertex angles for their Kossel cones (small 2θ); it is useful to think of the Kossel cones as extensions of the crystal planes onto the viewing screen. At the same time it is useful to think of

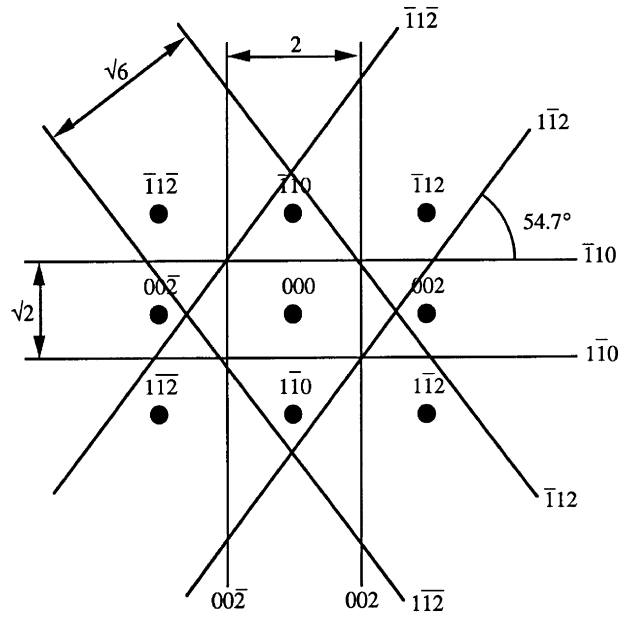

Figure 13. Some indexed Kikuchi lines for bcc diffraction pattern on a[110] zone axis.

the diffraction spots as representing the normals to the diffracting planes. It is then clear that the angles between intersecting Kikuchi line pairs will be the same as the angles between their corresponding diffraction spots, at least so long as the Kikuchi lines are not too far from the center of the viewing screen. These angles are helpful for indexing Kikuchi lines in the same way that the angles between pairs of diffraction spots were useful for indexing diffraction patterns above. For example, the angle ϕ between the $(1\bar{1}2)$ and $(1\bar{1}0)$ Kikuchi lines is given as

$$\phi = \arccos\left(\frac{1}{\sqrt{6}}(1\bar{1}2)\cdot\frac{1}{\sqrt{2}}(1\bar{1}0)\right) = 54.7^\circ \qquad (40)$$

Specimen Orientation and Deviation Parameter. Kikuchi lines are useful for precise determination of the specimen orientation in TEM. Recall that when we tilt the specimen, we tilt its reciprocal lattice. Tilts of the reciprocal lattice with respect to a stationary Ewald sphere do not cause any substantial changes in the positions of the diffraction spots, but the individual spots increase or decrease in intensity. Conversely, the positions of the Kikuchi lines vary sensitively with the specimen tilt and make an excellent tool for accurately determining specimen orientation. We see from Figure 12 that as the diffracting plane is tilted, the Kossel cones move by exactly the same angle. The Kikuchi lines behave as though they were affixed to the bottom of the crystal. Usually, we use a rather long camera length for diffraction work, so there is significant movement of the Kikuchi lines on the viewing screen when the specimen is tilted.

Figure 14 shows how the Kikuchi lines can be used to determine the sign and magnitude of the deviation parameter s, which quantifies how accurately the Bragg condition is satisfied for a particular reflection $\mathbf{g}$ (discussed above). This in turn determines the diffraction contrast and appearance of BF and DF TEM images. As illustrated in Figure 14, the distance between the Kikuchi lines of order $\mathbf{g}$ is r, where

$$r = 2\theta L \qquad (41)$$

This is the same distance r between the 000 and $\mathbf{g}$ (hkl) diffraction spots given in Equation 36, and L is the camera length shown in Figure 9.

Consider first the special situation where the Kikuchi lines intersect the transmitted beam and the diffraction spot $\mathbf{g}$ exactly, as shown in Figure 14A. This special situation corresponds to the exact Bragg condition because the transmitted beam is oriented at the angle θ with respect to the diffracting planes. In this special case, $\mathbf{s} = 0$. Now tilt the crystal counterclockwise into the arrangement on the right. The angle of tilt is

$$\phi = \frac{x}{L} \qquad (42)$$

where x is the distance between the diffracted spot and its corresponding bright Kikuchi line. Since the Kikuchi lines move as though they are affixed to the crystal, the bright

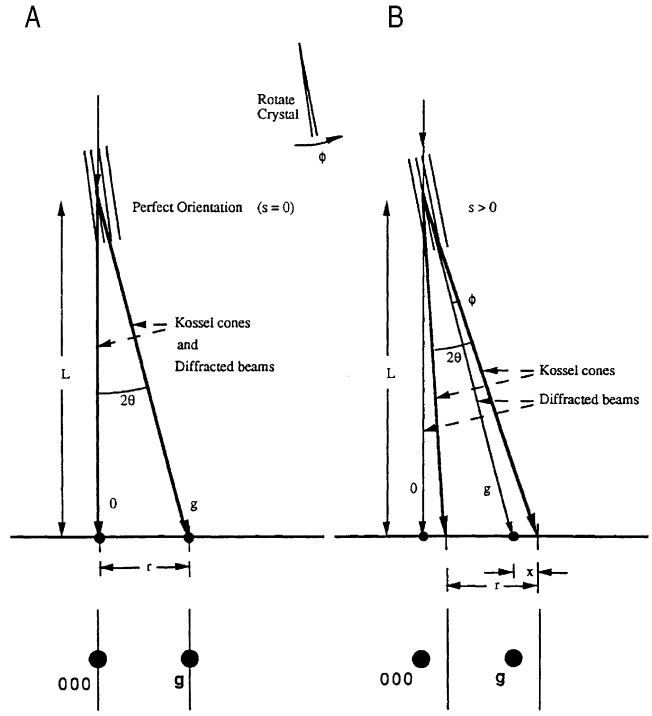

Figure 14. Geometry of crystal rotation and position of Kikuchi lines with respect to diffraction spots. Bottom portion of each figure illustrates positions of Kikuchi lines and diffraction spots as seen on viewing screen. (**A**) Intersection of Kikuchi lines with $\mathbf{g}$ vector occurs when specimen is at exact Bragg orientation for that $\mathbf{g}$ vector. (**B**) When crystal in (**A**) is rotated counterclockwise by angle ϕ, Kikuchi lines move right, in the same sense as crystal rotation.

Kikuchi line moves to the right of the spot, as illustrated in Figure 14B. When we rotate the crystal by the angle ϕ, we also rotate the reciprocal lattice with respect to the Ewald sphere by the same amount, as shown in Figure 15. By using Figure 15, we can find the relation between the magnitudes of $\mathbf{s}$ and $\mathbf{g}$:

$$\phi = \frac{s}{g} \qquad (43)$$

where g is the magnitude of $\mathbf{g}$, i.e., $|\mathbf{g}|$. Combining Equations 42 and 43 yields

$$\frac{s}{g} = \frac{x}{L} \qquad \text{or simply} \qquad s = \frac{gx}{L} \qquad (44)$$

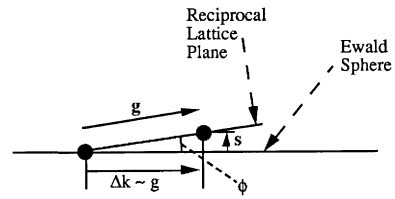

Figure 15. Relationship between deviation vector $\mathbf{s}$ and rotation of crystal by angle ϕ (as in Fig. 14).

where x is the distance from the bright Kikuchi line to the corresponding spot **g**. Note that it is possible to eliminate the camera length from Equation 44 by inserting Equation 41 for L, so the magnitude of **s** is given by

$$s = g2\theta\frac{x}{r} \tag{45}$$

Equation 45 shows how one can obtain a value for the deviation parameter s from the position of the Kikuchi lines with respect to the diffraction spots. Because θ (in radians) is small, we can determine very small values of s with accuracy. In electron diffraction, typical units for both s and g are reciprocal nanometers.

The Sign of *s*. We say that $s > 0$ if the excess Kikuchi line lies outside its corresponding diffraction spot **g**. In this case, the reciprocal lattice point lies inside the Ewald sphere, as was the case in Figures 14B and 15. Alternatively, we say that $s < 0$ if the excess Kikuchi line lies inside its corresponding diffraction spot, and we say that $s = 0$ when the Kikuchi line runs exactly through its corresponding diffraction spot, e.g., Figure 14A. The convention is that s points from the Ewald sphere to the reciprocal lattice point, and s is positive if **s** points upward along the positive z axis. This is consistent with the relationship $\mathbf{g} = \Delta\mathbf{k} + \mathbf{s}$ given previously in Equation 11, and shown in the Ewald sphere construction in Figure 4.

Lens Defects and Resolution

Important performance figures in TEM are the smallest spatial features that can be resolved in a specimen, or the smallest probes that can be formed on a sample. Electromagnetic lenses have aberrations that limit their performance, and to understand resolution, we must first understand lens aberrations. We can then consider the cumulative effect of all lens defects on the performance of a TEM.

Spherical Aberration. Spherical aberration distorts the focus of off-axis rays. The further the ray deviates from the optic axis, the greater is its error in focal length. All magnetic lenses have a spherical aberration coefficient that is positive so that those rays furthest from the optic axis are focused most strongly. The angle of illumination into the lens is defined as the aperture angle α; in paraxial imaging conditions, α is small. For reference, we define the true (or Gaussian) image plane as the image plane for paraxial imaging conditions. Spherical aberration causes an enlargement of the image of a point P to a distance QQ', as illustrated in Figure 16. The minimum enlargement of point P occurs just in front of QQ' and is termed the disk of least confusion. For a magnetic lens, the diameter d_s of the disk of least confusion caused by spherical aberration corresponds to a distance d_s on the specimen (Hirsch et al., 1977; Reimer, 1993; Williams and Carter, 1996):

$$d_s = 0.5C_s\alpha^3 \tag{46}$$

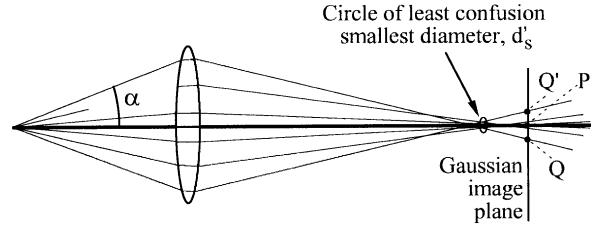

Figure 16. Lens with positive spherical aberration, i.e., positive C_s, forming disk of confusion with diameter d_s.

where C_s is the spherical aberration coefficient (usually 1 to 2 mm) and α is the semiangle of convergence of the electron beam.

Chromatic Aberration. Magnetic lenses are not achromatic. Electrons entering the lens along the same path but having different energies have different focal lengths. The spread in focal lengths is proportional to the spread in energy of the electrons. There are two main sources of this energy distribution. First, the electron gun does not produce monochromatic electrons. Typically, $<\pm 1$ eV of energy spread can be attributed to irregularities of the high-voltage supply. There is also a thermal distribution of electron energies as the electrons are thermionically emitted from a hot filament, which contributes on the order of ± 0.1 eV of energy spread. With high beam currents, there are also Coulomb repulsions of the electrons at the condenser cross-over. This contributes an energy spread of ± 1 eV through a phenomenon known as the Boersch effect. The second main cause of nonmonochromaticity of electrons is the specimen itself. Inelastic scatterings of the high-energy electrons by plasmon excitations are a common way for electrons to lose 10 to 20 eV. Thin specimens will help minimize the blurring of TEM images caused by chromatic aberration. The disk of least confusion for chromatic aberration has a diameter d_c at the specimen,

$$d_c = \frac{\Delta E}{E}C_c\alpha \tag{47}$$

where $\Delta E/E$ is the fractional variation in electron beam voltage and C_c is the chromatic aberration coefficient ($\sim$1 mm).

Diffraction from Apertures. Diffraction of the electron wave from the edge of an aperture contributes a disk of confusion corresponding to a distance at the specimen of d_d:

$$d_d = \frac{0.61\lambda}{\alpha_{OA}} \tag{48}$$

where λ is the electron wavelength and α_{OA} is the aperture angle of the objective lens. Equation 48 is the classic Rayleigh criterion that sets the resolution in light optics (Smith and Thomson, 1988). In essence, Equation 48 states that when the intensity between two point (Gaussian) sources of light reaches 0.81 of the maximum intensity of the sources, they can no longer be resolved.

Astigmatism. Astigmatism occurs when the focusing strength of a lens varies with angle θ around the optic axis, again leading to a spread of focus and a disk of least confusion. Two lenses of the transmission electron microscope require routine correction for astigmatism. To obtain a circular probe on the specimen, we must correct for astigmatism in the second condenser lens. Similarly, objective lens astigmatism blurs the image and degrades resolution, and it is important to correct astigmatism of the objective lens. Unlike spherical aberration, it is possible to use stigmators to correct for astigmatism. This correction can in fact be performed so well that astigmatism has a negligible effect on image resolution.

A stigmator in a modern transmission electron microscope is a pair of magnetic quadrupole lenses arranged one above the other and rotated with respect to each other. Correction of objective lens astigmatism is one of the more difficult skills to learn in electron microscopy. This correction is particularly critical in HRTEM, where the image detail depends on the phases of the beams and hence on the symmetry of the magnetic field of the objective lens about the optic axis. The astigmatism correction is tricky because three interdependent adjustments are needed: (1) main focus (adjustment of objective lens), (2) adjustment of x stigmator, and (3) adjustment of y stigmator. These adjustments must be performed in an iterative manner using features in the image as a guide. The procedure to accomplish this is a bit of an art and a matter of personal preference. A holey carbon film is an ideal specimen for practicing this correction. When the objective lens is overfocused (strong current) or underfocused (weak current) with respect to the Gaussian image plane, dark and bright Fresnel fringes, respectively, appear around the inside of a hole.

Resolution. Here we collect the results of lens defects (besides astigmatism) described above to obtain a general expression for the resolution of the transmission electron microscope for its two important modes of operation. In one case, we are concerned with the smallest probe that we can put on a specimen. In high-resolution imaging, we are concerned with the smallest feature in the specimen that can be resolved. We begin by obtaining an expression for the minimum probe diameter on a specimen, d_0.

If no aberrations were present in the optics of an electron microscope, the minimum probe size at the specimen could be readily calculated. The probe diameter d_0 is related to the total probe current I_p by the expression (Reimer, 1993)

$$I_\mathrm{p} = \frac{1}{4}\pi d_0^2 j_0 \tag{49}$$

where j_0 is the current density (in amperes per square centimeter) in the probe and I_p is j_0 times the area of the probe. Conservation of gun brightness on the optic axis implies that

$$j_0 = \pi\beta\alpha_\mathrm{p}^2 \tag{50}$$

where α_p is the semiangle of beam convergence of the electron probe on the specimen and β is the brightness, defined as current density per solid angle. Substituting the second expression into the first and solving for d_0 yield

$$d_0 = \frac{\sqrt{4I_\mathrm{p}/\beta}}{\pi\alpha_\mathrm{p}} = \frac{C_0}{\alpha_\mathrm{p}} \tag{51}$$

So for a given probe current I_p, small values of the probe diameter d_0 are obtained by increasing the brightness β and semiangle of convergence α_p. Because of lens aberrations, however, α_p has a maximum value, and β is limited by the design of the electron gun.

A general expression for the minimum probe size and image resolution can be obtained by summing in quadrature all diameters of the disks of least confusion, d_s, d_c, d_d, and d_0, as

$$d_\mathrm{p}^2 = d_\mathrm{s}^2 + d_\mathrm{c}^2 + d_\mathrm{d}^2 + d_0^2 \tag{52}$$

Substituting the diameters of these disks of least confusion from Equations 46, 47, 48, and 51 yields

$$d_\mathrm{p}^2 = \frac{C_0^2 + (0.61\lambda)^2}{\alpha_\mathrm{p}^2} + 0.25C_\mathrm{s}^2\alpha_\mathrm{p}^6 + \left(\alpha_\mathrm{p}C_\mathrm{c}\frac{\Delta E}{E}\right)^2 \tag{53}$$

For a thermionic gun with a large probe current, $C_0 \gg \lambda$ and the contributions of d_d and d_c can be neglected. In this case, the diameters d_0 and d_s superpose to produce a minimum probe diameter d_min at an optimum aperture angle α_opt for a constant I_p. The optimum aperture angle is found by setting $(d/d\alpha_\mathrm{p})d_\mathrm{p} = 0$, giving

$$\alpha_\mathrm{opt} = \left(\frac{4}{3}\right)^{1/8}\left(\frac{C_0}{C_\mathrm{s}}\right)^{1/4} \tag{54}$$

and substitution in Equation 53 yields

$$d_\mathrm{min} = \left(\frac{4}{3}\right)^{3/8} C_0^{3/4}C_\mathrm{s}^{1/4} \cong 1.1C_0^{3/4}C_\mathrm{s}^{1/4} \tag{55}$$

In the case of image resolution in TEM (or for a field emission gun where the total probe current is lower so that $C_0 \ll \lambda$), the contributions of d_0 and d_c can be neglected. Superposition of the remaining terms again yields a minimum that is less than with d_0. In this case, α_opt and d_min are given by

$$\alpha_\mathrm{opt} = 0.9\left(\frac{\lambda}{C_\mathrm{s}}\right)^{1/4} \tag{56}$$

$$d_\mathrm{min} = 0.8\lambda^{3/4}C_\mathrm{s}^{1/4} \tag{57}$$

These expressions can be used to calculate the optimum aperture angle and the resolution limit (or minimum probe size) of a transmission electron microscope. (Note that the same equations with slightly different values of the leading constants, which are all near 1, are found in the literature depending on the exact expressions used for the

quantities in Equation 52.) In a modern field emission gun TEM, it is common to achieve spatial resolutions <0.2 nm and probe sizes of 0.5 nm for a 200-keV microscope with $C_s = 1.0$ mm. It is important to note that these quantities represent the instrumental resolution limits and are well-defined, calculated quantities. The actual resolution that one can achieve for any given sample depends on a variety of specimen parameters, such as the sample thickness, the diffracting conditions, and how localized scattering is in the sample, so that the image resolution actually achieved in a typical BF or DF image is usually one or two orders of magnitude larger than the instrument resolution. For example, the width of the dark contrast associated with an edge dislocation in a BF image is $\sim \xi_g/3$ (Hirsch et al., 1977), or 10 nm wide for low-index reflections in metals (refer to Table 2).

Detailed alignment procedures for the transmission electron microscope are provided by the instrument manufacturers. In addition, the book by Chescoe and Goodhew (1984) and Chapters 5 to 9 in Williams and Carter (1996) explain the basic TEM components and their alignment procedures.

METHOD AUTOMATION

Transmission electron microscopy traditionally has been operator intensive with little computer automation except during postmicroscope analysis of data or when the microscope is operated in the scanning (STEM) mode. This trend is changing rapidly since the evolution of digital charge-coupled diode (CCD) cameras and faster computers now makes it possible to acquire and process images in real time on the microscope (Egerton, 1996; Williams and Carter, 1996). Companies such as Gatan offer several different types of CCD cameras and software packages such as Autotuning and DigitalMicrograph, which allow the user to correct objective lens astigmatism and process images on the microscope. Some TEM manufacturers have hardware/software that can be installed to step a probe across the sample to perform x-ray analyses across an interface or to automatically measure the spot spacings and angles in a diffraction pattern on the screen, for example. The specimen stages in TEM can now be computer controlled, allowing the user to input or recall particular specimen positions and/or tilts in the microscope. In addition, considerable effort is being made to establish remote microscopy centers in national electron microscope laboratories (Voelkl et al., 1998). Microscopes are becoming automated in many other ways, and it is likely that this trend will continue, although the operator will still need to plan the desired investigation.

DATA ANALYSIS AND INITIAL INTERPRETATION

The theories underlying electron diffraction and imaging were outlined (see Principles of the Method) and practical considerations associated with implementation of the theory in TEM were described (see Practical Aspects of the Method). The present section uses several examples to illustrate how we can analyze and interpret typical data from TEM. It should be emphasized that a variety of computer programs are available to calculate, process, and analyze diffraction patterns and images.

Effect of Shape Factor

One of the most important aspects in our discussion of the shape factor in Equations 8 to 10 was that the width of diffracted intensity in reciprocal space, i.e., the SAD pattern, varies inversely with the dimensions of a crystal in real space. This shape factor effect is often observed in diffraction patterns from multiphase materials containing small plate-shaped or rod-shaped precipitates, as illustrated below.

Figure 17 shows an example of the shape factor effect in an Al-Cu alloy, where very thin Cu-rich precipitates form in the Al-rich matrix. These precipitates, called Guinier-

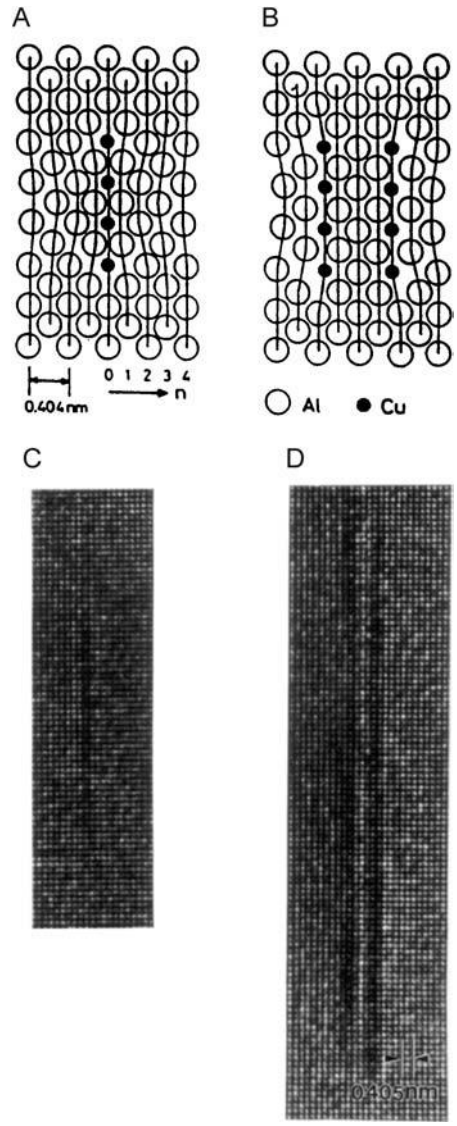

Figure 17. (**A**) Illustration of GP(1) zone, (**B**) illustration of GP(2) zone, (**C**) HRTEM image of GP(1) zone in Al-Cu, and (**D**) HRTEM image of GP(2) zone in Al-Cu. (From Chang, 1992.)

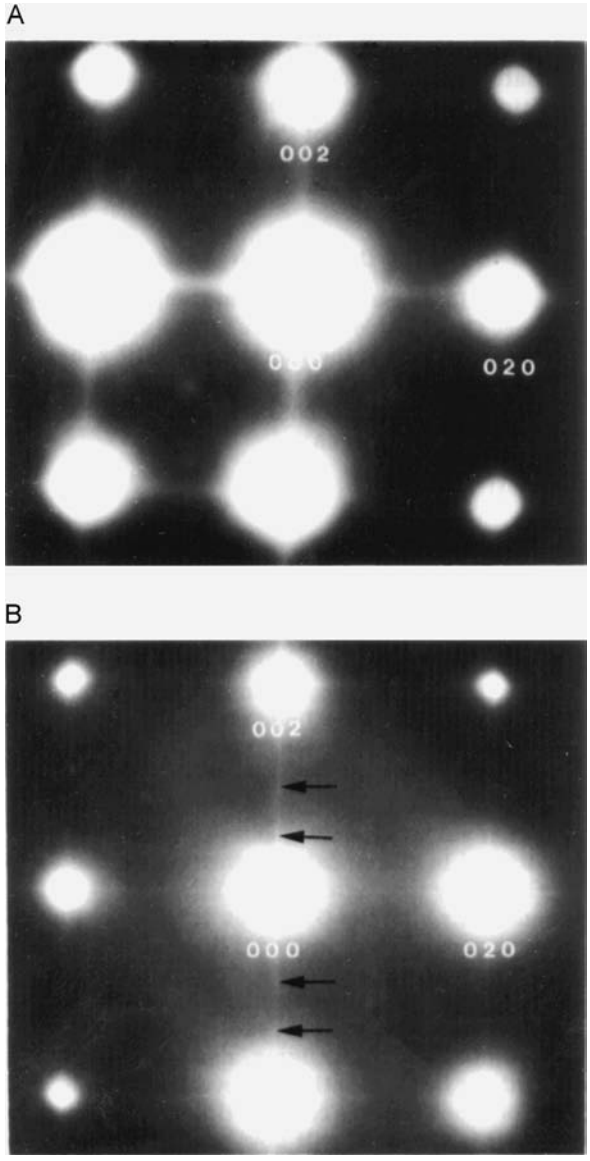

Figure 18. SAD pattern from sample containing (**A**) GP(1) zones and (**B**) GP(2) zones in Al-Cu alloy. (From Rioja and Laughlin, 1977.)

Preston (GP) zones, lie on the {100} planes and have a thin disk shape. When the disks have a thickness of only an atom or two, the broadened diffraction spots appear as streaks rather than as discrete spots, and two types of GP zones are found. As illustrated in Figures 17A and B, a GP(1) zone consists of a single layer of Cu atoms that have substituted for Al on a {100} plane, while a GP(2) zone contains two such Cu layers separated by three {100} planes of Al atoms. Experimental HRTEM images of these two types of GP zones, taken along a ⟨100⟩ matrix direction in an Al–4 wt% Cu alloy, are shown in Figures 17C and D (Chang, 1992). The atomic columns in the high-resolution images are white and the Cu-rich layers appear as darker planes in the images.

Figure 18 shows two diffraction patterns from samples that were aged to contain GP(1) and GP(2) zones. In Figure 18A, the streaks from the single layer of Cu atoms are practically continuous along the two ⟨100⟩ directions in the plane of the figure because the precipitate is essentially a monolayer of Cu atoms, as in Figures 17A and C. In Figure 18B, the streaks along ⟨100 are no longer continuous but have maxima at 1/4⟨100⟩ positions in the diffraction pattern. This periodicity arises because the Cu planes in the GP(2) zone are spaced four {100} planes apart, as illustrated in Figures 17B and D. (Note that the precipitate reflections still appear as streaks because these plates are very thin.) This illustrates the important point that for every real-space periodicity in a specimen, there is a corresponding reciprocal space intensity, and diffraction patterns and corresponding images should be carefully compared to interpret microstructures.

Variations in Specimen Thickness and Deviation Parameter

As described below (see Sample Preparation), many TEM specimens are thinned to perforation using techniques such as electropolishing or ion milling, so that the specimens are thin foils that vary in thickness from the edge of the perforation (hole) inward. In such specimens, it is common to observe thickness fringes running parallel to the edge of the hole, particularly when the specimen is oriented in a strong two-beam diffracting condition with $s = 0$ for a particular $\mathbf{g}$. These fringes are a result of the variation in diffracted intensity $\mathbf{Ig}$ (and $\mathbf{I}_0$) in Equation 22 as a function of t for constant s, i.e., for a fixed specimen orientation. Figures 19A and B show complementary BF and DF images of thickness fringes in Al, taken by placing a small objective aperture around the optic axis and tilting the beam to obtain the DF image, as illustrated in Figures 6 through 8. Note that the intensity in the BF and DF images is complementary, as expressed by Equation 20. For a constant value of s, the intensity varies periodically with t, becoming zero each time the product st in Equation 22 is an integer, as illustrated schematically in Figure 5. Thus, the fringes in a DF image are dark for a thickness $t = n/s$, where n is an integer and bright for $t = (n + \frac{1}{2})/s$; the reverse is true for a BF image. We can determine the magnitude of $\mathbf{s}$ from the position of the Kikuchi line in a diffraction pattern (refer to Equation 45 and Fig. 14). If we also know the value of ξ_g (Table 1), we can estimate the sample thickness anywhere in the foil based on the position of the thickness fringes. If $s = 0$ in a BF image, the foil is $\frac{1}{2}\xi_g$ thick in the middle of the first dark fringe, $\frac{3}{2}\xi_g$ in the middle of the second dark fringe, etc. (Fig. 19C); the reverse is true for the DF image. It is possible to calculate the periodicity of the fringes for quantitative comparison with experimental images such as those in Figure 19 using Equations 22 to 25. If the sample is tilted in the microscope, the thickness fringes remain parallel to the edge of the foil, but their spacing changes because s is changing.

Transmission electron microscopy foils of ductile materials such as metal alloys often bend during specimen preparation or handling, so that bend contours are observed in the TEM foil. These intensity fringes are a result of the variation in diffracted intensity $\mathbf{Ig}$ (and $\mathbf{I}_0$) in Equation 22 as a function of s for constant t, i.e., changing specimen

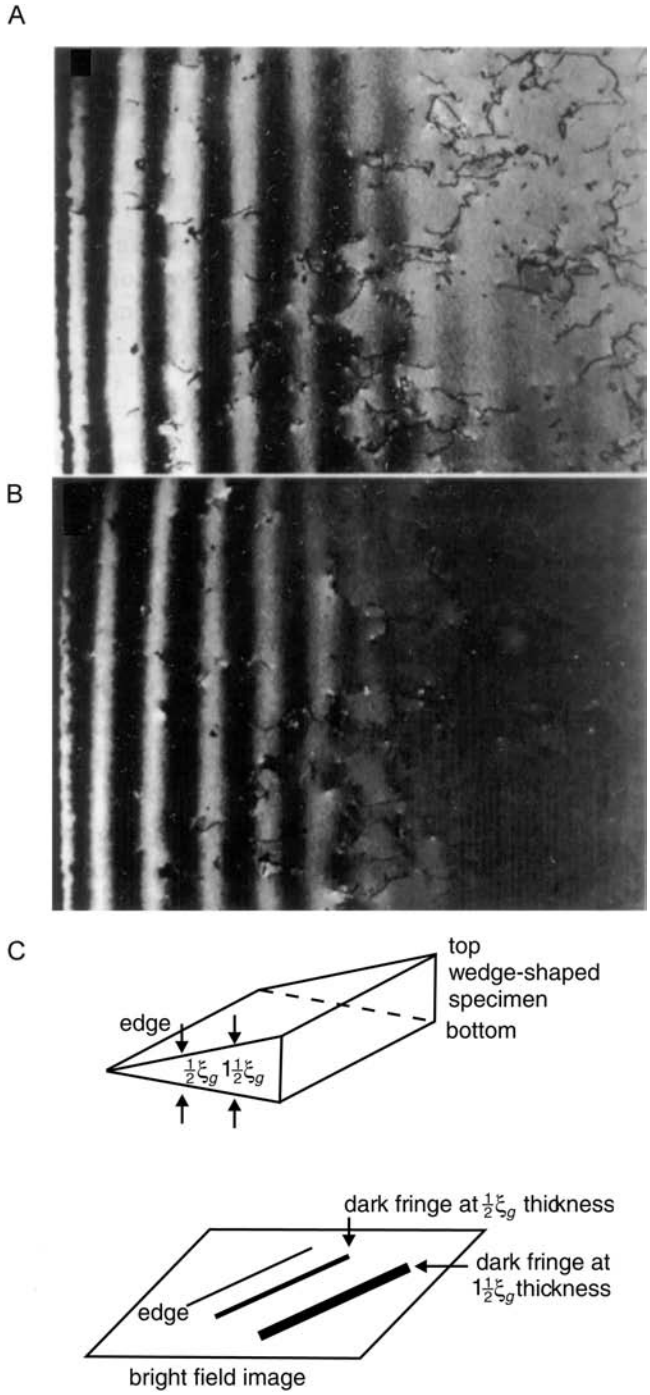

Figure 19. Complementary (**A**) BF and (**B**) DF images of thickness fringes in Al taken under dynamical conditions with $s = 0$, and (**C**) schematic showing position of fringes in BF image relative to wedge-shaped specimen. Foil edge is on left.(From Edington, 1974.)

orientation for a fixed thickness. Figure 20 shows complementary BF and DF images of bend contours in a metal foil taken under conditions similar to those in Figure 19. The specimen thickness is approximately constant horizontally across the field of view, and the specimen is slightly curved (bent) about a vertical axis in the center of the images. Thus, for a constant value of t, the intensity varies periodically with s horizontally across the images. However, unlike thickness fringes where t continually increases, s varies from negative to zero to positive as the specimen bends through orientation space. The DF image in Figure 20B shows only the left contour as a bright line for the diffracting planes $-\mathbf{g}$. Diffracted intensity $\mathbf{I}_{-g}$ has a symmetric profile about the maximum at $s = 0$, indicated by a line in the figure. In contrast to the thickness fringes in Figure 19, the corresponding BF image in Figure 20A is not symmetric across $-g$ (or $\mathbf{g}$) or complementary to the DF image, for reasons that can be accounted for by the dynamical theory of electron diffraction. Examining the BF image in Figure 20A shows that the crystal is generally darker between $\mathbf{g}$ and $-\mathbf{g}$ when $s < 0$ than when $s > 0$, with the darkest line of intensity lying approximately at $s = 0$, again indicated by lines in the figure. Unlike thickness fringes, bend contours can lie along any direction with respect to the edge of the foil and generally move across the sample when it is tilted.

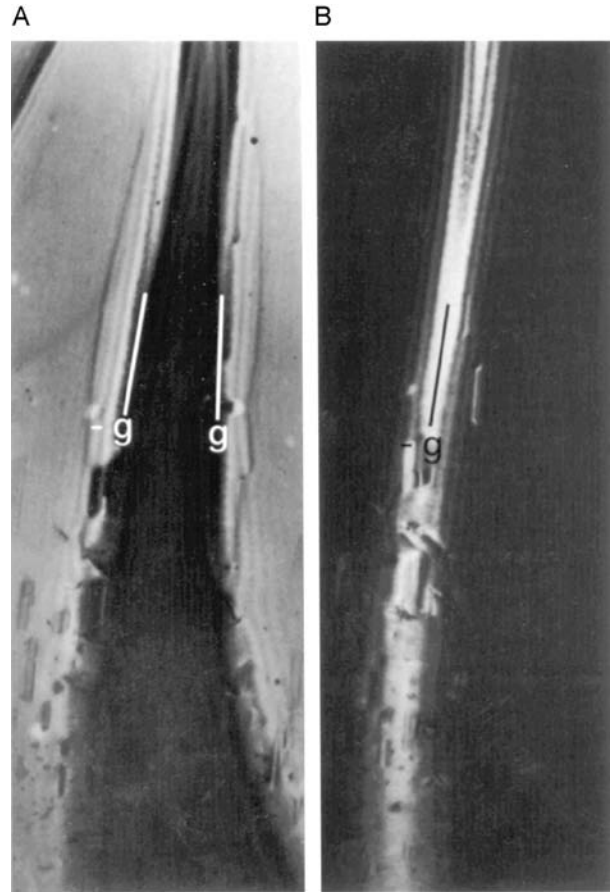

Figure 20. Complementary (**A**) BF and (**B**) DF images of bend contour, with thickness constant horizontally across images. Left side of bend contour in (**A**) is bright in (**B**). (From Thomas and Goringe, 1979.)

Use of Bright-Field, Dark-Field, and Selected-Area Diffraction as Complementary Techniques

Using BF/DF imaging and SAD as complementary techniques to understand the microstructures of materials is one

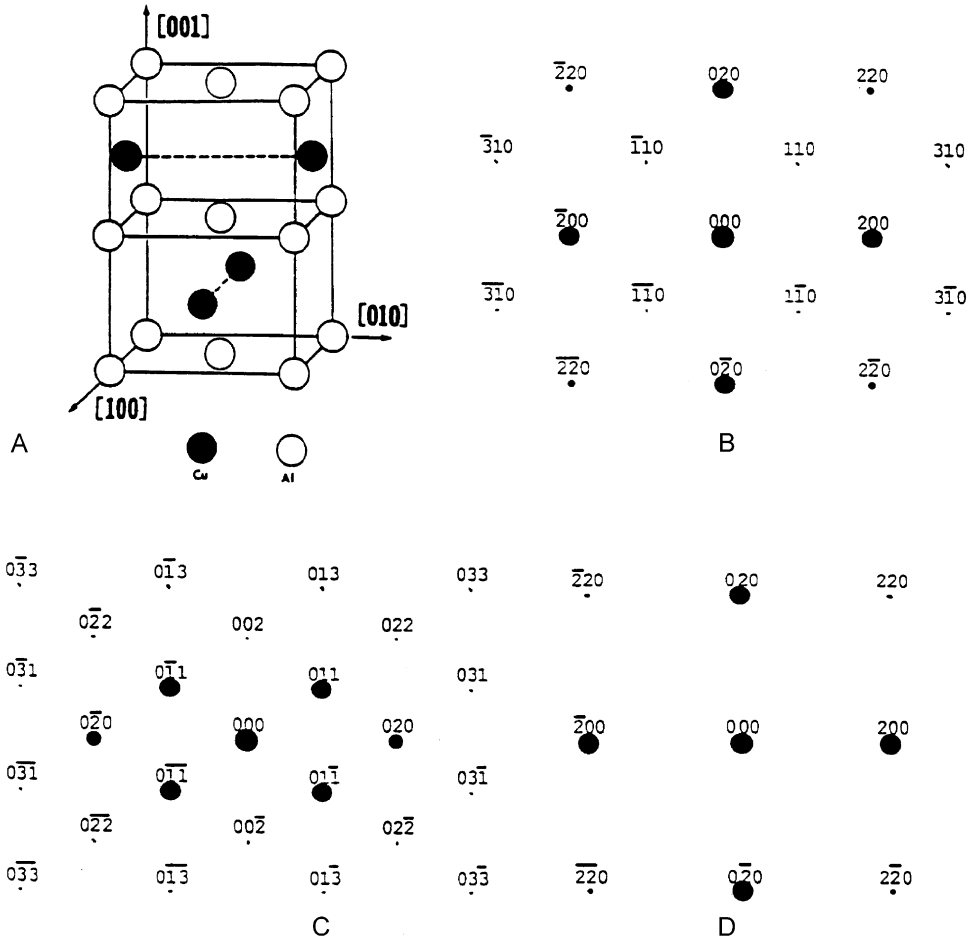

Figure 21. (**A**) Crystal structure of the θé phase, (**B**) calculated diffraction pattern for θé phase along [001] and (**C**) along [100], and (**D**) calculated diffraction pattern for [100] Al.

of the most important aspects of CTEM. Here we illustrate the use of these techniques to understand the microstructure of an Al-Cu alloy (the same alloy described in the discussion of shape factors above) heat treated to form θ′ precipitate plates on the {100} planes in the fcc Al-rich matrix. The θ′ plates have the tetragonal crystal structure illustrated in Figure 21A with a composition of Al_2Cu. The [001] axis of the θ′ plates contains the fourfold axis while the [100] and [010] axes of the θ′ phase have twofold rotation axes and are crystallographically indistinguishable. Diffraction patterns calculated for the θ′ phase along the [001] and [100] zone axes are shown in Figures 21B and C, and a calculated [100] diffraction pattern for Al is shown in Figure 21D.

The θ′ phase forms in the Al-rich matrix such that the [001] axis of θ′ aligns along each of the three possible ⟨100⟩ directions in the matrix. When the sample is viewed along a ⟨100⟩ matrix direction, one variant of the θ′ plates is seen face-on, while the other two variants are seen edge-on. Figure 22A shows a BF TEM image of all three variants of the θ′ precipitates, and Figure 22B shows a corresponding SAD pattern, taken with a large aperture containing all three variants of precipitates. The square pattern of bright spots is from the Al-rich matrix, which is the majority phase, while the weaker spots, particularly noticeable in the middle of the square pattern of Al spots, arise from the three variants of θ′ plates. A schematic of the diffraction pattern that distinguishes the three variants of spots from the θ′ plates is shown in Figure 22C.

It is possible to determine which precipitate spots in the SAD pattern correspond to each variant by forming DF images with the precipitate spots. This procedure is illustrated in Figure 22D, where a small objective aperture was centered on the optic axis and the electron beam was tilted (see Practical Aspects of the Method) to move the precipitate spot indicated by an arrow in Figures 22B and C into the aperture. As a result, only the vertical plates in Figure 22D appear bright, verifying that the reflection came from that variant. It is also possible to determine which precipitate spots correspond to a particular variant of θ′ by placing a selected-area aperture around one variant and recording its corresponding SAD pattern. This procedure is illustrated in Figures 22E and F, where an aperture placed around the vertical plate reveals that its spots form the rectangular diffraction pattern outlined in Figure 22F. This pattern is identical to the calculated pattern for θ′ in Figure 21C. This procedure can be repeated on the other variants to account for all of the precipitate spots in Figure 22A.

It is also possible to determine the lattice parameters of the θ′ phase using the Al-rich matrix spots for calibration and Equation 35. For example, Al has a lattice parameter

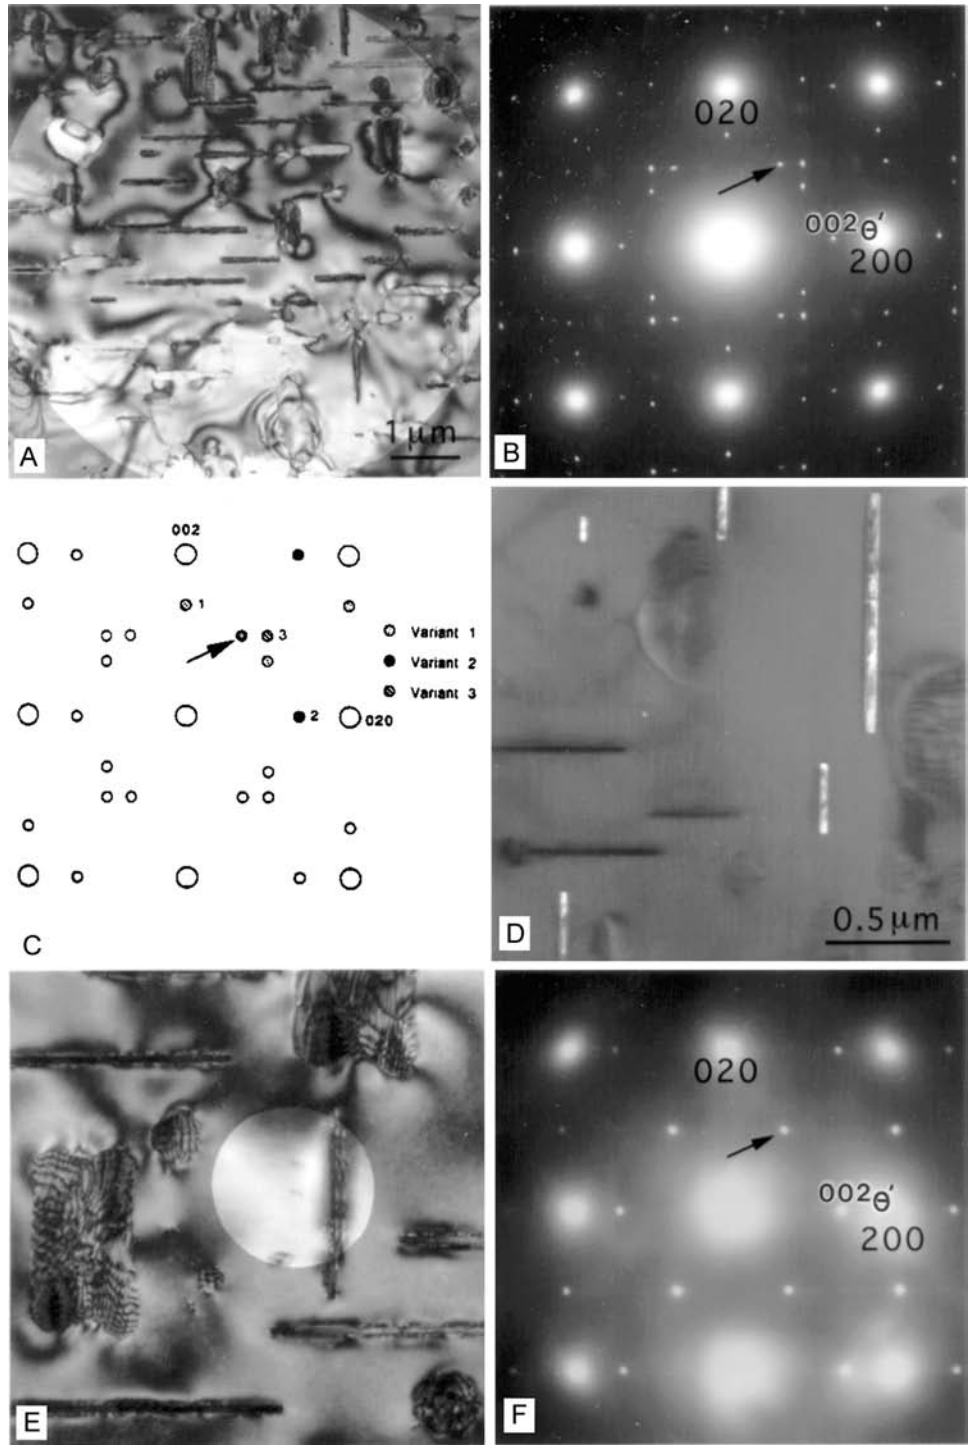

Figure 22. (**A**) BF TEM image of θ′ plates viewed along $a\langle 100\rangle$ Al direction; (**B**) corresponding SAD pattern containing weak spots from all three variants of θ′ plates and stronger spots from Al matrix (labeled); (**C**) schematic of diffraction pattern in (**B**) with arrow indicating which precipitate spot was used for axial DF imaging; (**D**) corresponding DF image showing bright, vertical θ′ plates; (**E**) SAD placed around vertical θ′ plate (revealed by double exposure); and (**F**) corresponding SAD pattern, similar to that in Figure 21C.

of 0.40496 nm so that the {200} interplanar spacing $d_{\{200\}} = 0.2025$ nm. The {200} spots in Figure 22B have a spacing $r = 21.0$ mm on the original image. Substituting these values for r and $d_{\{200\}}$ into Equation 35 gives $\lambda L = 0.425\ \text{nm}\cdot\text{cm}$. The [002] spots of the θ′ phase (labeled in Fig. 22F) have a spacing $r = 14.8$ mm, which, when substituted into Equation 35 with λL then gives $d_{(002)} = 0.575$ nm. This is 0.8% different than the reported value for the c lattice parameter of the θ′ phase of 0.58 nm (Weatherly and Nicholson, 1968). Since the [200] spots of θ′ phase coincide with the {200} spots of the Al matrix, the a lattice parameter of θ′ must be approximately the same as that of Al, or 0.40496 nm. This good matching of lattice parameters between the two phases is why the phase forms as plates on the {100} planes of Al.

Use of $\mathbf{g}\cdot\delta\mathbf{r} = 0$ in Defect Analysis

The same θ′ plates discussed above can be used to illustrate the application of the $\mathbf{g}\cdot\delta\mathbf{r}$ criterion for defect

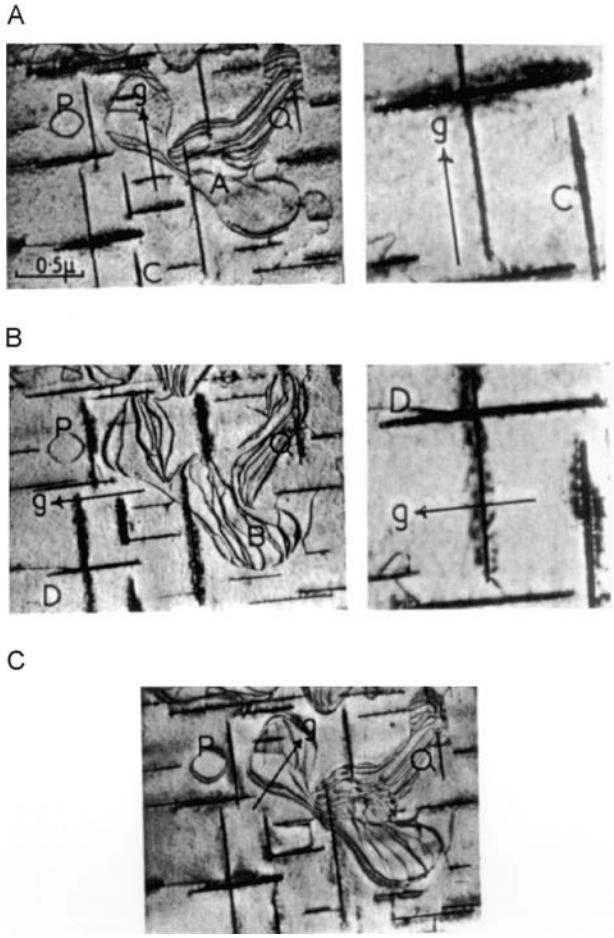

Figure 23. Burgers vector determination for misfit dislocations A, B, C, and D on flat faces of θ′ plates in Al-Cu alloy aged 1 day at 275°C. P represents dislocations around periphery of plates and Q complex dislocations arising from agglomeration of two plates: (**A**) $\mathbf{g} = [200]$, dislocations A visible with enlargement showing dislocations C; (**B**) $\mathbf{g} = [020]$, dislocations B visible with enlargement showing dislocations D; (**C**) $\mathbf{g} = [220]$, all dislocations visible. (From Weatherly and Nicholson, 1968.)

analysis in TEM (see Diffraction Contrast from Lattice Defects, above). Figure 23 shows the three variants of θ′ plates viewed along a ⟨100⟩ matrix direction at fairly high magnification (Weatherly and Nicholson, 1968). Four types of dislocation arrays are visible in the BF TEM images.

1. Complex arrays with no simple Burgers vector (for a definition of the Burgers vector, refer to Hull and Bacon, 1984) that seem to be associated with the agglomeration of two or more θ′ plates (Q in Fig. 23).
2. Dislocations associated with the periphery of the θ′ plate (P in Fig. 23). These frequently show a characteristic double or triple image and a line of no contrast that is typical of pure edge dislocations having a Burgers vector parallel to the electron beam (Hirsch et al., 1977). The Burgers vector of these dislocations is $a[001]$ for a precipitate plate lying parallel to (001); these dislocations accommodate the large misfit (∼4.3%) associated with the peripheral interface of the plate and the c direction of the θ′ lattice.
3. Dislocations associated with the flat face of the θ′ plate (A and B in Fig. 23). These are affected by the contours of the θ′ plates but lie predominantly in the [100] and [010] directions for a plate on (001). It is shown below that the Burgers vectors of these dislocations are $a[100]$ and $a[010]$.
4. Dislocations associated with plastic deformation of the foil (either accidental or deliberate). They tend to lie in the [110] or [110] directions for a θ′ plate on (001) and have Burgers vectors of the type $a/2[110]$.

Here we concentrate on the genuine misfit dislocations associated with the flat interface of the θ′ plate, type 3. The Burgers vector analysis that follows is thus confined to dislocations lying away from the periphery of the plates.

The four sets of dislocations A, B, C, and D are marked in Figure 23. If the dislocations are discrete loops wrapped around the θ′ plates, an analysis in a [001] foil gives a complete determination. The results in Figure 23 show that when $\mathbf{g} = [\bar{2}00]$, dislocations A and C are visible (Fig. 23A); when $g = [0\bar{2}0]$, dislocations B and D are visible (Fig. 23B); and when $\mathbf{g} = [\bar{2}20]$, all four loops are visible (Fig. 23C). Applying the $\mathbf{g} \cdot \delta\mathbf{r} = 0$ criterion (which becomes the $\mathbf{g} \cdot \mathbf{b} = 0$ criterion since the displacement $\delta\mathbf{r} = \mathbf{b}$, where $\mathbf{b}$ is the Burgers vector) for dislocation invisibility to the network AB, it must consist of dislocations with Burgers vectors in directions $\pm[h0l]$ and $\pm[h0l]$, where h, k, and l are undetermined. The θ′ plate with the dislocations marked D lies on (100) and, by analogy with the θ′ plate on (001), must be covered by a network of dislocations with Burgers vectors in directions $\pm[hk0]$ and $\pm[h0l]$. The dislocations marked D have Burgers vectors in directions $\pm[hk0]$ because they are visible when $\mathbf{g} = [0\bar{2}0]$. Because dislocations D are invisible when $\mathbf{g} = [\bar{2}00]$, $l = 0$. Hence the network AB for a θ′ plate on (001) has Burgers vectors in directions $\pm[100]$ and $\pm[010]$. There are no contrast effects associated with the interface to suggest that the Burgers vectors of the dislocations are not lattice translation vectors, and hence the most likely Burgers vectors are $\pm a[100]$ and $\pm a[010]$ for a (001) plate. The dislocations are mainly edge in character since their line direction is perpendicular to the Burgers vectors and are mainly accommodating a small misfit (<1%) in the plane of the flat interface.

Kikuchi Lines and the Effect of Deviation Parameter on Defect Contrast

One of the most important uses of the deviation parameter s is for obtaining and quantifying high-quality TEM images of defects in materials. Figure 24 shows three diffraction conditions with (a) $s = 0$, (b) $s < 0$, and (c) $s > 0$ and the corresponding BF images of dislocations in Al, respectively. Note that the best images are formed when $s > 0$, because the dislocations display sharp, strong contrast above a bright background. The magnitude of $\mathbf{s}$ must be determined to calculate images of such dislocations (Head et al., 1973).

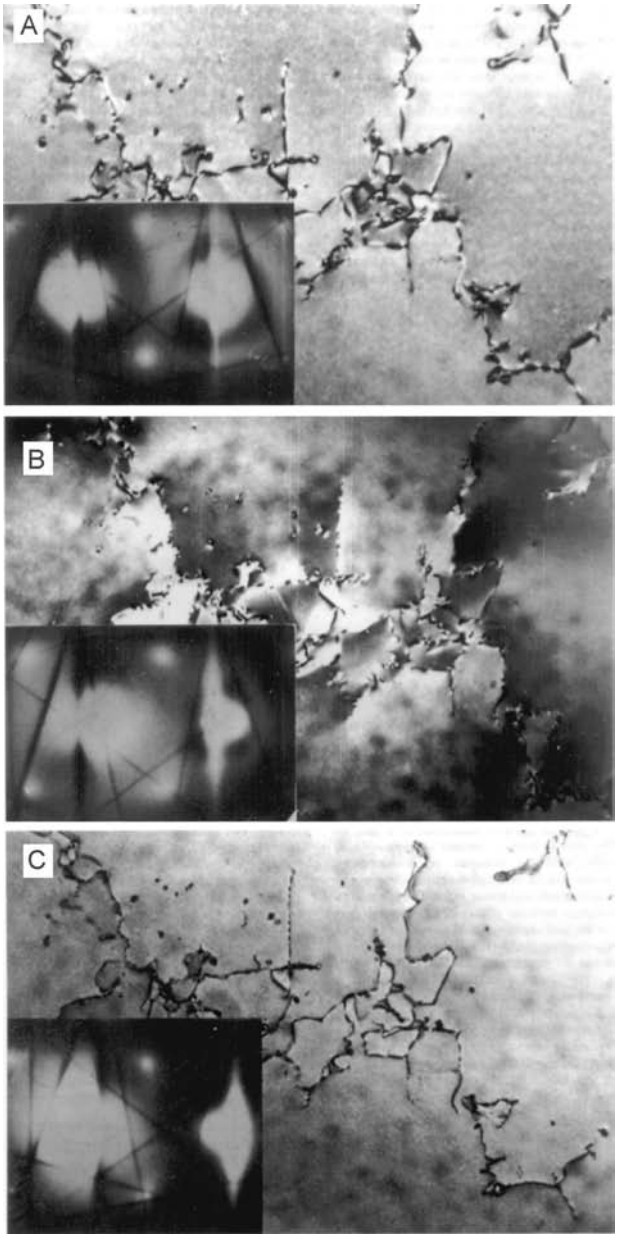

Figure 24. Changes in diffraction patterns and corresponding images of dislocations with changes in s: (**A**) $s = 0$, (**B**) $s60; 0$, and (**C**) $s > 0$. (From Edington, 1974.)

SAMPLE PREPARATION

The ideal TEM specimen is usually a thin, parallel-sided foil that is stable in the electron microscope as well as during storage. A gradually tapered wedge is often obtained in practice, and this too is quite useful. The TEM foil should be representative of the bulk material being studied and thus unaltered by sample preparation. The exact thickness of the specimen depends on the type of analysis desired and may range from a few nanometers for HRTEM to tens of nanometers for CTEM imaging. The surface condition is important, particularly for very thin specimens. It is difficult to meet all of these requirements, but the quality of the results depends on the specimen quality, so specimen preparation is an important aspect of TEM. The range of possible specimen preparation techniques is enormous, and the discussion below is intended to provide an overview of some of the more common techniques available to materials scientists. More comprehensive discussions of specimen preparation procedures are provided by Edington (1974), Goodhew (1984), and Williams and Carter (1996).

There are usually two stages in the preparation of thin specimens from bulk material. The first is to prepare, often by cutting and grinding, a thin slice of the material that is a few millimeters in diameter and a tenth of a millimeter or so thick. The main consideration in the first stage is to avoid using a coarse cutting technique so that damage is introduced throughout the specimen. A diamond wafer saw is often used to cut thin specimens of metals and ceramics, and SiC paper with successively finer grit (e.g., down to 600 grit) is used to grind these materials to the required thickness. The second stage involves thinning this specimen to electron transparency for which several techniques are available. Four of the most common—electropolishing, chemical thinning, ion milling, and Ga^+ ion beam thinning—are briefly described next.

Electropolishing and Chemical Thinning

The most common technique for thinning electrically conductive materials such as metal alloys is electropolishing. The principle behind the method is that the specimen is made the anode in an electrolytic cell so that when current is passed through the cell, the solution dissolves the alloy and deposits it on the cathode. The main considerations in electropolishing are the composition, temperature and flow of the electrolyte across the sample, and the potential difference applied between the sample (anode) and cathode. Under the right conditions, the foil becomes smoother and thinner until perforation is achieved near the center of the specimen. The technique is fairly simple, but sophisticated electropolishing units that allow the operator to carefully control the polishing variables and terminate polishing immediately upon perforation are commercially available. The commercial units are designed to accommodate 3-mm-diameter disks, which is the size required for most TEM specimen holders.

A major limitation of electropolishing is that it cannot be used on nonconducting materials such as ceramics and semiconductors. Chemical thinning, using mixtures of acids without an applied potential, is frequently used for these materials. Both electropolishing and chemical thinning share the advantage that the thinning rate is high, so they are quick and generally nondamaging, although it is possible to preferentially leach out elements or introduce hydrogen into some materials, so as with any technique, one must exercise some caution when utilizing these procedures.

Ion Milling and Focused Ga^+ Ion Beam Thinning

It is common to thin specimens to electron transparency by bombarding them with energetic ions. The ions knock atoms off the surface in a process called sputtering,

gradually thinning the material. The most common ions used are Ar^+, and these are accelerated toward the sample with an applied potential ranging from 4 to 6 keV at angles ranging from 5° to 20° from the sample surface, i.e., at a glancing angle. Usually two ion guns are used so that the sample can be thinned from both sides simultaneously, and the sample is often cooled with liquid nitrogen to temperatures of ~ -180°C to avoid excessive heating by the ion beams. The samples are usually rotated during thinning to prevent preferential sputtering along one direction. The milling rate is usually only a few micrometers per hour, so compared to electropolishing, sample preparation is much more time consuming. Therefore, a dimpler is often used to grind the center of the sample to a few tens of micrometers in thickness to reduce the ion milling time. Ion milling is very useful for thinning nonconducting samples, for thinning materials that consist of phases that electropolish at much different rates, for thinning cross-sectional samples of thin films on substrates such as semiconductor and multilayer materials, or for cleaning the surfaces of samples prepared by other methods. Ion milling produces an amorphous layer on the surfaces of most materials, which can be detrimental to some analyses.

A focused ion beam (FIB) microscope is becoming popular for preparing thin membranes for TEM examination (Basile et al., 1992). A FIB microscope is similar to a scanning electrom microscope (SCANNING ELECTRON MICROSCOPY) except that it uses electrostatic lenses to focus a Ga^+ ion beam on the specimen instead of electromagnetic lenses and electrons. The Ga^+ ions are typically accelerated toward the specimen at 30 keV so that rapid sputtering of the sample occurs. The Ga^+ ion probe can be focused to a size as small as 10 nm, and a computer can be used to raster the beam across the sample in a variety of patterns, so that it is possible to fabricate very specific specimen geometries. This technique can be used on both conducting and nonconducting materials, and it is particularly useful for preparing cross-sectional samples of semiconductors and thin films. There is evidence that FIB milling can produce a damaged layer on the surfaces of materials (Susnitzky and Johnson, 1998), but the extent of this behavior and its relation to specimen and microscope parameters remain to be fully determined.

Another instrument that is particularly useful for thinning semiconductor materials to electron transparency is a tripod polisher (Klepeis et al., 1988). The tripod polisher, so called because it has three micrometer feet, is used to hold the specimen while it is mechanically thinned to electron transparency on a polishing wheel using diamond lapping films. This "wedge technique" can be used to examine particular depths in a sample, such as a microelectronic device. Even if not used for final sample preparation, the use of a tripod polisher can dramatically reduce the time for the final thinning step.

Ultramicrotomy

An ultramicrotome utilizes a fixed diamond knife to slice a thin section from a specimen, which is typically $\sim 0.5 \times 0.5$ mm in cross-section and can be mounted in epoxy for support. The resulting slices are collected in a liquid-filled trough and mounted on copper grids before being inserted into the transmission electron microscope. Ultramicrotomy is widely used to prepare samples of polymers for TEM and can also be used for other materials such as powders, metals, and composites. Slicing generally damages the material (e.g., introducing dislocations into metal alloys), but chemical information is retained, so ultramicrotomy is well suited for preparing thin sections for analytical techniques such as EDS in TEM. Although it only takes a few minutes to obtain a slice from a specimen, considerable expertise is required to mount the specimen and obtain a thin section, so ultramicrotomy can be a fairly time consuming preparation method.

Replication

A thin film of carbon can be deposited on the surface of a specimen, typically by striking an arc between two carbon rods in vacuum. The carbon layer conforms to the shape of the surface and is allowed to build up to a few tens of nanometers in thickness. The carbon film is then scored into squares a few millimeters wide, removed from the surface by etching, and collected on a copper grid for examination in the transmission electron microscope. If the sample contains highly dispersed phases that can be left in relief on the surface by etching, the carbon film can be deposited on the surface, and the phases are then embedded in the carbon film when it is removed from the surface by further etching. This specimen is called an extraction replica. Since the particles are present in the replica, they can be analyzed by diffraction or analytical techniques without interference from the surrounding matrix. A common alternative to carbon media is cellulose acetate, which can be deposited on the sample as a sheet with solvent.

Dispersion

One final technique that is simple and works well for small particles such as catalysts or brittle ceramics that can be ground to a fine powder is to disperse a small quantity of the material in ethanol by sonication and then place a few drops of the dispersion on a carbon support film mounted on a grid. When the solution evaporates, the particles cling to the support film and can be examined in the transmission electron microscope. Depending on the material, it may be preferable to use a solvent other than ethanol or a grid material other than copper, but the procedure is generally the same.

SPECIMEN MODIFICATION

Inelastic collisions of electrons with a specimen often produce the undesirable effect of beam damage. The damage that affects the structure and/or chemistry of the material depends mainly on the beam energy. Damage usually occurs through one of two main mechanisms: (1) radiolysis, in which inelastic scattering breaks chemical bonds in the material, or (2) knock-on damage, in which atoms are displaced off their sites, creating point defects.

The first mechanism generally decreases with increasing beam energy whereas the second increases with increasing beam energy. It is important to remember that, under certain conditions, in TEM it is possible to damage any material. Sometimes this is useful as it allows one to simulate various irradiation conditions or perform *in situ* studies, but more often it produces unwanted side effects. Some of the more important aspects of beam damage are summarized below. This is followed by a brief discussion of intentional specimen modification in TEM during *in situ* experiments.

Specimen heating can occur in TEM. Temperature is difficult to measure experimentally because the temperature is affected by many variables, such as specimen thickness, thermal conductivity, surface condition, contact with the holder, beam energy, and beam current. Hobbs (1979) has performed calculations on the effects of beam current and thermal conductivity on specimen temperature. The results of these calculations indicate that beam heating is generally negligible for good thermal conductors such as metals but substantial for insulating materials. To minimize beam heating, one can (1) operate at the highest accelerating potential to reduce the cross-section for inelastic scattering, (2) cool the specimen to liquid nitrogen or liquid helium temperatures in a cooling holder, (3) coat the specimen with a conducting film, (4) use low-dose imaging techniques, or (5) all of these techniques (Sawyer and Grubb, 1987).

Polymers are highly sensitive to the process of radiolysis in TEM. Electrons usually cause the main polymer chain to break up or side groups to break off, leading to breakdown or crosslinking of the polymer, respectively. In the first case, the polymer continually loses mass under irradiation, whereas in the second case, the polymer ultimately ends up as a mass of carbon. If the polymer is crystalline, radiation damage causes a loss of crystallinity, which can be measured experimentally by the loss of diffraction contrast in the image or the reduction in intensity of diffraction spots in the diffraction pattern and the appearance of an amorphous pattern. Radiolysis can also occur in ionic and covalent materials such as ceramics and minerals. This often results in the formation of new compounds or the amorphization of the original material, processes that can be observed in TEM. Radiolysis is not affected by heat transfer considerations, so the main ways to minimize this process are to increase the accelerating voltage and minimize the specimen thickness and exposure to the electron beam.

Metals are mainly affected by knock-on damage in the transmission electron microscope. Knock-on damage is directly related to the beam energy and the atomic weight of the atoms (Hobbs, 1979). Accelerating potentials $>\sim$200 kV can damage light metals such as aluminum, and the effect on heavier elements continually increases as the beam energy increases above this value. Knock-on damage usually manifests itself by the formation of small vacancy or interstitial clusters and dislocation loops in the specimen, which can be observed by diffraction contrast. The main way to avoid displacment damage is to use lower accelerating voltages. Knock-on damage can also occur in polymers and minerals where there is generally a trade-off between knock-on damage and radiolysis. Since knock-on damage creates vacancies and interstitials, it can be used to study the effects of irradiation *in situ*.

Another important aspect of specimen modification in TEM is the ability to perform *in situ* studies to directly observe the behavior of materials under various conditions (Butler and Hale, 1981). This potentially useful effect for electron irradiation studies was mentioned above. In addition, specimen holders designed to heat, cool, and strain (and combinations of these) a TEM sample in the microscope are available commercially from several manufacturers. It is also possible to introduce gases into the transmission electron microscope to observe chemical reactions *in situ* by using apertures and differential pumping in the microscope. Once they have equilibrated, most commercial TEM holders are sufficiently stable that it is possible to perform EDS and EELS on foils to obtain compositional information *in situ* (Howe et al., 1998). To reproduce the behavior of bulk material in TEM, it is often desirable to perform *in situ* experiments in high-voltage TEM (e.g., 1 MeV) so that foils on the order of 1 μm thick can be used. Using thicker foils can be particularly important for studies such as straining experiments. As with most techniques, one needs to be careful when interpreting *in situ* data, and it is often advisable to compare the results of *in situ* experiments with parallel experiments performed in bulk material. For example, if we want to examine the growth behavior of precipitates during *in situ* heating in TEM, we might compare the size of the precipitates as a function of time and temperature obtained *in situ* in the transmission electron microscope with that obtained by bulk aging experiments. The temperature calibration of most commercial holders seems to be reliable to $\pm 20^{\circ}$C, and calibration specimens need to be used to obtain greater temperature accuracy. One problem that can arise during heating experiments, for example, is that solute may preferentially segregate to the surface. Oxidation of some samples during heating can also be a problem. In spite of all these potential difficulties, *in situ* TEM is a powerful technique for observing the mechanisms and kinetics of reactions in solids and the effects of electron irradiation on these phenomena.

PROBLEMS

A number of limitations should be considered in the TEM analysis of materials, including but not limited to (1) the sampling volume, (2) image interpretation, (3) radiation damage, (4) specimen preparation, and (5) microscope calibration. This section briefly discusses some of these factors. More thorough discussion of these topics can be found in Edington (1974), Williams and Carter (1996), and other textbooks on TEM (see Literature Cited).

It is important to remember that in TEM only a small volume of material is observed at high magnification. If possible, it is important to examine the same material at lower levels of resolution to ensure that the microstructure observed in TEM is representative of the overall specimen. It is often useful to prepare the TEM specimen by more than one method to ensure that the microstructure was

not altered during sample preparation. As discussed above (see Specimen Modification), many materials damage under a high-energy electron beam, and it is important to look for signs of radiation damage in the image and diffraction pattern. In addition, as shown above (see Data Analysis and Initial Interpretation), image contrast in TEM varies sensitively with diffracting conditions, i.e., the exact value of the deviation parameter s. Therefore, one must carefully control and record the diffracting conditions during imaging in order to quantify defect contrast.

It is important to remember that permanent calibration of TEM features such as image magnification and camera length, which are typically performed during installation, are only accurate to within $\pm 5\%$. If one desires higher accuracy, then it is advisable to perform *in situ* calibrations using standards. A variety of specimens are available for magnification calibration. The most commonly used are diffraction grating replicas for low and intermediate magnifications ($100\times$ to $200,000\times$) and direct lattice images of crystals for high magnifications ($>200{,}000\times$). Similarly, knowledge of the camera constant in Equation 35 greatly simplifies indexing of diffraction patterns and is essential for the identification of unknown phases. The accuracy of calibration depends on the experiment, but an error of $\pm 1\%$ can be achieved relatively easily, but this can be improved to $\pm 0.1\%$ if care is used in operation of the microscope and measurement of the diffraction patterns. An example of this calibration was given above (see Data Analysis and Initial Interpretation), and it is common to evaporate a metal such as Au directly onto a sample or to use a thin film as a standard. Permanent calibrations are normally performed at standard lens currents that must be subsequently reproduced during operation of the microscope for the calibration to be valid. This is accomplished by setting the lens currents and using the height adjustment (z control) on the goniometer to focus the specimen. Other geometric factors that can introduce errors into the magnification of diffraction patterns are discussed by Edington (1974). There are also a number of other calibrations that are useful in TEM, including calibration of (1) the accelerating voltage, (2) specimen drift rate, (3) specimen contamination rate, (4) sense of specimen tilt, (5) focal increments of the objective lens, and (6) beam current, but these are not detailed here.

SCANNING TRANSMISSION ELECTRON MICROSCOPY: *Z*-CONTRAST IMAGING

INTRODUCTION

As its name suggests, the scanning transmission electron microscope is a combination of the scanning electron microscope and the transmission electron microscope. Thin specimens are viewed in transmission, while images are formed serially by the scanning of an electron probe. In recent years, electron probes have become available with atomic dimensions, and, as a result, atomic resolution images may now be achieved in this instrument. The nature of the images obtained in scanning transmission electron microscopy (STEM) can differ in significant ways from those formed by the more widespread conventional transmission electron microscopy (CTEM). The key difference lies in their modes of image formation; the STEM instrument can be configured for almost perfect incoherent imaging whereas CTEM provides almost perfect coherent imaging. The latter technique is generally referred to as high-resolution electron microscopy (HREM), though both methods now provide atomic resolution.

The difference between coherent and incoherent imaging was first discussed over one hundred years ago in the context of light microscopy by Lord Rayleigh (1896). The difference depends on whether or not permanent phase relationships exist between rays emerging from different parts of the object. A self-luminous object results in perfect incoherent imaging, as every atom emits independently, whereas perfect coherent imaging occurs if the entire object is illuminated by a plane wave, e.g., a point source at infinity. Lord Rayleigh noted the factor of 2 improvement in resolution available with incoherent

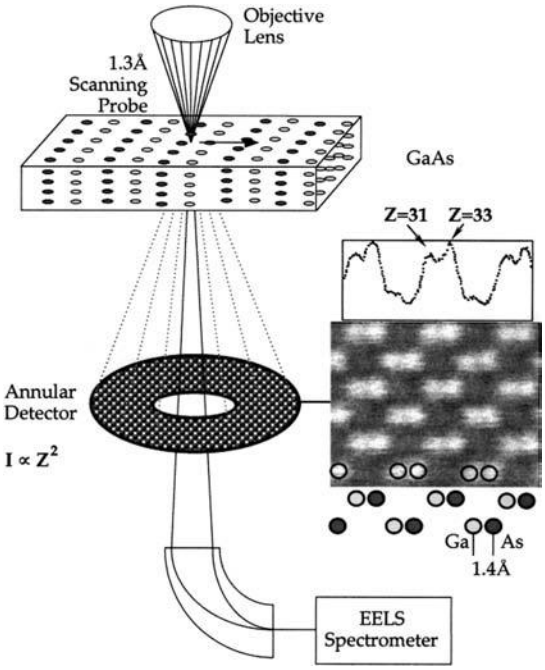

Figure 1. Schematic showing *Z*-contrast imaging and atomic resolution electron energy loss spectroscopy with STEM. The image is of GaAs taken on the 300-kV STEM instrument at Oak Ridge National Laboratory, which directly resolves and distinguishes the sublattice, as shown in the line trace.

imaging and also the lack of artifacts caused by interference phenomena that could be mistaken for real detail in the object. Of particular importance in the present context, he appreciated the role of the condenser lens (1896, p. 175): "It seems fair to conclude that the function of the condenser in microscopic practice is to cause the object to behave, at any rate in some degree, as if it were self-luminous, and thus to obviate the sharply-marked interference bands which arise when permanent and definite phase relationships are permitted to exist between the radiations which issue from various points of the object." A large condenser lens provides a close approximation to perfect incoherent imaging by ensuring a range of optical paths to neighboring points in the specimen.

A hundred years later, STEM can provide these same advantages for the imaging of materials with electrons. A probe of atomic dimensions illuminates the sample (see Fig. 1), and a large annular detector is used to detect electrons scattered by the atomic nuclei. The large angular range of this detector performs the same function as Lord Rayleigh's condenser lens in averaging over many optical paths from each point inside the sample. This renders the sample effectively self-luminous; i.e., each atom in the specimen scatters the incident probe in proportion to its atomic scattering cross-section. With a large central hole in the annular detector, only high-angle Rutherford scattering is detected, for which the cross-section depends on the square of the atomic number (Z); hence this kind of microscopy is referred to as *Z*-contrast imaging.

The concept of the annular detector was introduced by Crewe et al. (1970), and spectacular images of single heavy

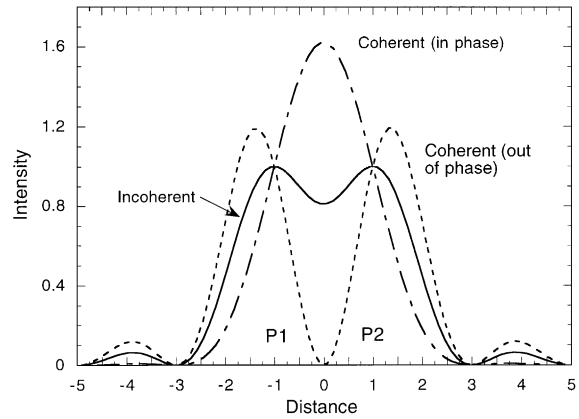

Figure 2. Image intensity for two point objects, P1 and P2, illuminated coherently in phase, 180° out of phase, and with incoherent illumination. (After Lord Rayleigh, 1896.)

atoms were obtained (see, e.g., Isaacson et al., 1979). In the field of materials, despite annular detector images showing improved resolution (Cowley, 1986a) and theoretical predictions of the lack of contrast reversals (Engel et al., 1974), it was generally thought impossible to achieve an incoherent image at atomic resolution (Cowley, 1976; Ade, 1977). Incoherent images of thick crystalline materials were first reported by Pennycook and Boatner (1988), and the reason for the preservation of incoherent characteristics despite the strong dynamical diffraction of the crystal was soon explained (Pennycook et al., 1990), as described below.

An incoherent image provides the most direct representation of a material's structure and, at the same time, improved resolution. Figure 2 shows Lord Rayleigh's classic result comparing the observation of two point objects with coherent and incoherent illumination. Each object gives rise to an Airy disc intensity distribution in the image plane, with a spatial extent that depends on the aperture of the imaging system. The two point objects are separated so that the first zero in the Airy disc of one coincides with the central maximum of the other, a condition that has become known as the Rayleigh resolution criterion. With incoherent illumination, there are clearly two peaks in the intensity distribution and a distinct dip in between; the two objects are just resolved, and the peaks in the image intensity correspond closely with the positions of the two objects. With coherent illumination by a plane-wave source (identical phases at the two objects), there is no dip, and the objects are unresolved. Interestingly, however, if the two objects are illuminated 180° out of phase, then they are always resolved, with the intensity dropping to zero half-way between the two. Unfortunately, this desirable result can only be achieved in practice for one particular image spacing (e.g., by illuminating from a particular angle), and other spatial frequencies will have different phase relationships and therefore show different contrast, a characteristic that is generic to coherent imaging. Note also that the two peaks are significantly displaced from their true positions.

In an incoherent image, there are no fixed phase relationships, and the intensity is given by a straightforward

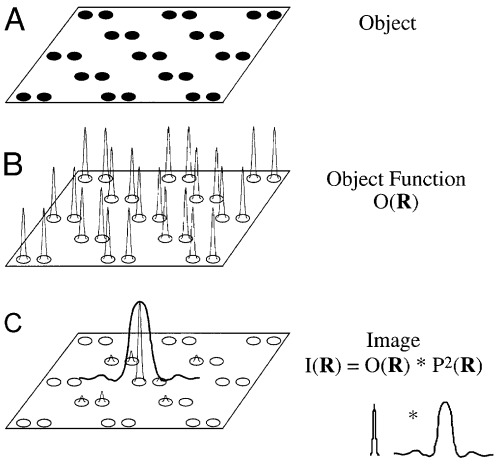

Figure 3. Schematic showing incoherent imaging of a thin specimen with STEM: (**A**) monolayer raft of Si⟨110⟩; (**B**) the *Z*-contrast object function represents the high-angle scattering power localized at the atomic sites; (**C**) illumination of the sites for a 1.26-Å probe located over one atom in the central dumbbell. As the probe scans, it maps out the object function, producing an incoherent image.

convolution of the electron probe intensity profile with a real and positive specimen object function, as shown schematically in Figure 3. With Rutherford scattering from the nuclei dominating the high-angle scattering, the object function is sharply peaked at the atomic positions and proportional to the square of the atomic number. In the figure, a monolayer raft of atoms is scanned by the probe, and each atom scatters according to the intensity in the vicinity of the nucleus and its high-angle cross-section. This gives a direct image with a resolution determined by the probe intensity profile. Later it will be shown how crystalline samples in a zone axis orientation can also be imaged incoherently. These atomic resolution images show similar characteristics to the incoherent images familiar from optical instruments such as the camera; in a *Z*-contrast image, atomic columns do not reverse contrast with focus or sample thickness. In Figure 1, columns of Ga can be distinguished directly from columns of As simply by inspecting the image intensity. Detailed image simulations are therefore not necessary.

This unit focuses on *Z*-contrast imaging of materials at atomic resolution. Many reviews are available covering other aspects of STEM, e.g., microanalysis and microdiffraction (Brown, 1981; Pennycook, 1982; Colliex and Mory, 1984; Cowley, 1997). Unless otherwise stated, all images were obtained with a 300-kV scanning transmission electron microscope, a VG Microscopes HB 603U with a 1.26-Å probe size, and all spectroscopy was performed on a 100-kV VG Microscopes HB 501UX STEM.

Competitive and Related Techniques

The absence of phase information in an incoherent image is an important advance; it allows the direct inversion from the image to the object. In coherent imaging, the structural relationships between different parts of the object are encoded in the phase relationships between the various diffracted beams. These are lost when the intensity is recorded, giving rise to the well-known phase problem. Despite this, much effort has been expended in attempts to measure the phase relationships between different diffracted beams in order to reconstruct the object (e.g., Coene et al., 1992; Orchowski et al., 1995; Möbus, 1996; Möbus and Dehm, 1996).

However, electrons interact with the specimen potential, which is a real quantity. There is no necessity to involve complex quantities; in an incoherent image, there are no phases and so none can be lost. Information about the object is encoded in the image intensities, and images may be directly inverted to recover the object. As seen in Figure 2, intensity maxima in an incoherent image are strongly correlated with atomic positions, so that often this inversion can be done simply by eye, exactly as we interpret what we see around us in everyday life. With the additional benefit of strong *Z* contrast, structures of defects and interfaces in complex materials may often be determined directly from the image.

In a phase-contrast image, the contrast changes dramatically as the phases of the various diffracted beams change with specimen thickness or objective lens focus, which means that it is much more difficult to determine the object uniquely. It is often necessary to simulate many trial objects to find the best fit. The situation is especially difficult in regions such as interfaces or grain boundaries, where atomic spacings deviate from those in the perfect crystal, which can also cause atomic columns to reverse contrast. If one does not think of the correct structure to simulate, obviously the fit will be spurious. Unexpected phenomena such as the formation of new interfacial phases or unexpected atomic bonding are easily missed. Such phenomena are much more obvious in an incoherent image, which is essentially a direct image of atomic structure. As an example, Figure 4 shows the detection of van der Waals bonding between an epitaxial film and its substrate from the measurement of film-substrate atomic separation (Wallis et al., 1997). At 3.2 Å, this is significantly larger than bond lengths in covalently bonded semiconductors, which are typically in the range of 2.3 to 2.6 Å.

Closely related to STEM, scanning electron microscopy (SEM) gives an image of the surface (or near-surface)

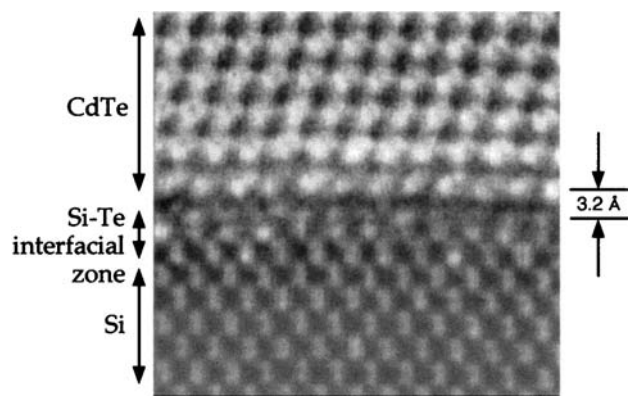

Figure 4. *Z*-contrast image of an incommensurate CdTe(111)/Si(100) interface showing a 3.2-Å spacing between film and substrate indicating van der Waals bonding.

region of a bulk sample, whereas STEM gives a transmission image through a thin region of the bulk, which by careful preparation we hope is representative of the original bulk sample. The information from the two microscopes is therefore very different, as is the effort required for sample preparation. Whereas in STEM we detect the bright field and dark field transmitted electrons to reveal the atomic structure, in SEM we detect secondary electrons, i.e., low-energy electrons ejected from the specimen surface. The resolution is limited by the interaction volume of the beam inside the sample, and atomic resolution has not been achieved. Probe sizes are therefore much larger, ~1 to 10 nm. Secondary electron images show topographic contrast with excellent depth of field. Backscattered primary electrons can also be detected to give a *Z*-contrast image analogous to that obtained with the STEM annular detector, except at lower resolution and contrast. Other signals such as cathodoluminescence or electron beam-induced conductivity can be used to map optical and electronic properties, and x-ray emission is often used for microanalysis. These signals can also be detected in STEM (Pennycook et al., 1980; Pennycook and Howie, 1980; Fathy and Pennycook, 1981), except that signals tend to be weaker because the specimen is thin.

Atomic resolution images of surfaces are produced by scanning tunneling microscopy (STM) and atomic force microscopy (AFM). Here, the interaction is with the surface electronic structure, although this may be influenced by defects in underlying atomic layers to give some subsurface sensitivity. In scanning probe microscopy, it is the valence electrons that give rise to an image; it is not a direct image of the surface atoms, and interpretation must be in terms of the surface electronic structure. The STEM *Z*-contrast image is formed by scattering from the atomic nuclei and is therefore a direct structure image. Valence electrons are studied in STEM through electron energy loss spectroscopy (EELS) and can be investigated at atomic resolution using the *Z*-contrast image as a structural reference, as discussed below. Scanning transmission electron microscopy can study a wider range of samples than STM or AFM as it has no problem with rough substrates and can tolerate substrates that are quite highly insulating.

Data from EELS provide information similar to that from x-ray absorption spectroscopy. The position and fine structure on absorption edges give valuable information on the local electronic structure. The EELS data give such information from highly localized regions, indeed, from single atomic columns at an interface (Duscher et al., 1998a). Instead of providing details of bulk electronic structure, it provides information on how that structure is modified at defects, interfaces, and grain boundaries and insight into the changes in electronic, optical, and mechanical properties that often determine the overall bulk properties of a material or a device.

The detailed atomic level characterization provided by STEM, with accurate atomic positions determined directly from the *Z*-contrast image and EELS data on impurities, their valence, and local band structure, represents an ideal starting point for theoretical studies. This is particularly valuable for complex materials; it would be impractical to explore all the possible configurations of a complex extended defect with first-principles calculations, even with recent advances in computational capabilities. As the complexity increases, so the number of required trial structures grows enormously, and experiment is crucial to cut the possibilities down to a manageable number. Combining experiment and theory leads to a detailed and comprehensive picture of complex atomistic mechanisms, including equilibrium structures, impurity or stress-induced structural transformations, and dynamical processes such as diffusion, segregation, and precipitation. Recent examples include the observation that As segregates at specific sites in a Si grain boundary in the form of dimers (Chisholm et al., 1998) and that Ca segregating to an MgO grain boundary induces a structural transformation (Yan et al., 1998).

PRINCIPLES OF THE METHOD

Comparison to Coherent Phase-Contrast Imaging

The conventional means of forming atomic resolution images of materials is through coherent phase-contrast imaging using plane-wave illumination with an (approximately) parallel incident beam (Fig. 5A). The objective aperture is behind the specimen and collects diffracted beams that are brought to a focus on the microscope screen where they interfere to produce the image contrast. The electrons travel from top to bottom in the figure. Not shown are additional projector lenses to provide higher magnification. In Figure 5B, the optical path of the STEM is shown, with the electrons traveling from bottom to top. A point source is focused into a small probe by the objective lens, which is placed before the specimen. Not shown are the condenser lenses (equivalent to projector lenses in the CTEM) between the source and the objective lens to provide additional demagnification of the source. Transmitted electrons are then detected through a defined angular range. For the small axial collector aperture shown, the two microscopes have identical optics, apart from the fact that the direction of electron propagation is reversed. Since image contrast in the electron microscope is dominated by elastic scattering, no energy loss is involved and time reversal symmetry applies. With equivalent apertures, the image contrast is independent of the direction of electron propagation, and the two microscopes are optically equivalent: the STEM bright-field image will be the same image, and be described by the same imaging theory, as that of a conventional TEM with axial illumination. This is the principle of reciprocity, which historically was used to predict the formation of high-resolution lattice images in STEM (Cowley, 1969; Zeitler and Thomson, 1970).

For phase-contrast imaging, the axial aperture (illumination aperture in TEM, collection aperture in STEM) must be much smaller than a typical Bragg diffraction angle. If β is the semiangle subtended by that aperture at the specimen, then the transverse coherence length in the plane of the specimen will be of order λ/β, where λ is the electron wavelength. Coherent illumination of

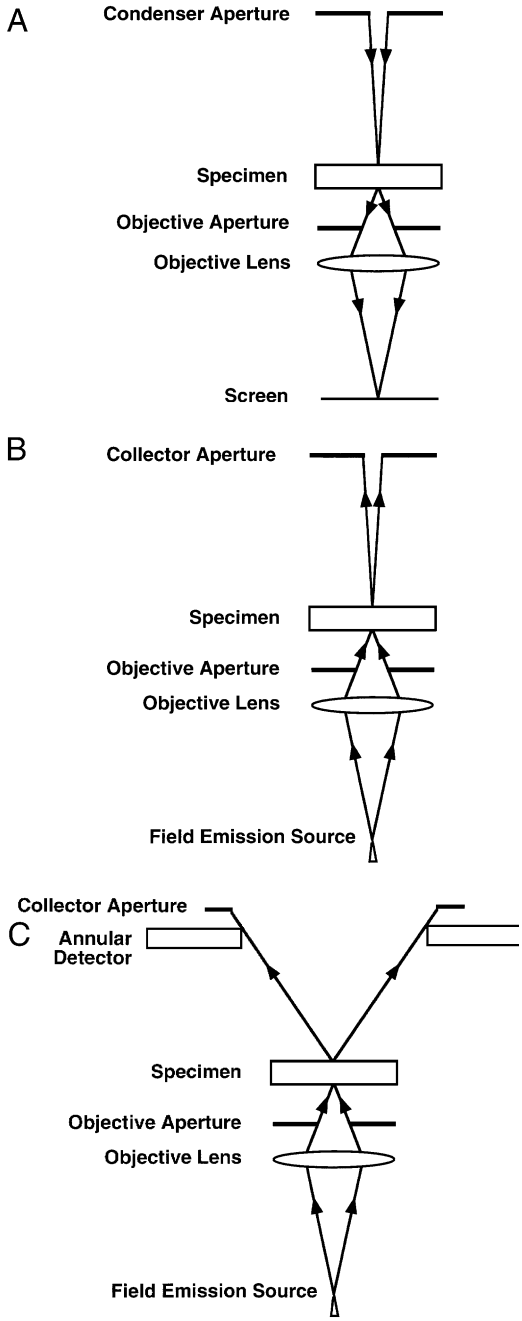

Figure 5. Schematics of the electron-optical arrangement in (**A**) CTEM and (**B**) STEM with a small axial detector. Note the direction of the electron propagation is reversed in the two microscopes. (**C**) A large-angle bright-field detector or annular dark-field detector in STEM gives incoherent imaging.

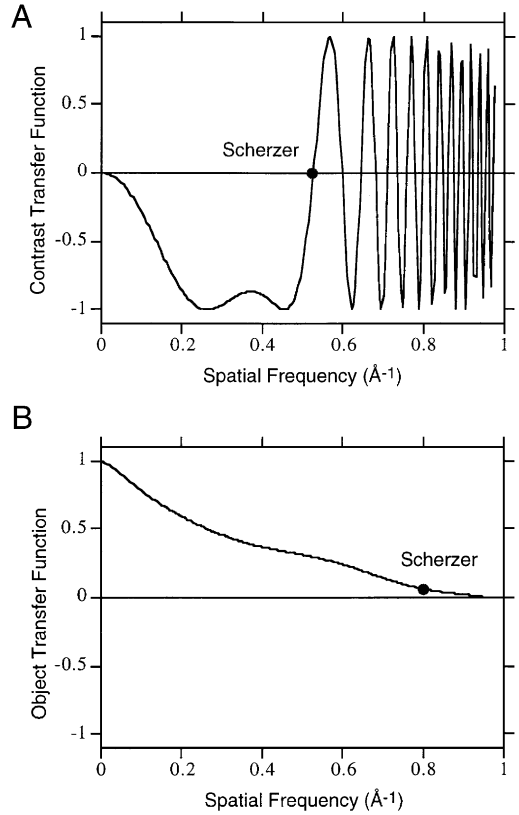

Figure 6. Contrast transfer functions for a 300-kV microscope with an objective lens with $C_s = 1$ mm; (**A**) coherent imaging conditions; (**B**) incoherent imaging conditions. Curves assume the Scherzer (1949) optimum conditions shown in Table 1: (**A**) defocus −505 Å; (**B**) defocus −438 Å, aperture cutoff 0.935 $Å^{-1}$.

neighboring atoms spaced a distance d apart requires $d \ll \lambda/\beta$, or $\beta \ll \lambda/d \approx 2\theta_B$, where θ_B is the Bragg angle corresponding to the spacing d. Similarly, if the collection aperture is opened much wider than a typical Bragg angle (Fig. 5C), then the transverse coherence length at the specimen becomes much less than the atomic separation d, and the image becomes incoherent in nature, in precisely the same way as first described by Lord Rayleigh. Now the annular detector can be seen as the complementary dark-field version of the Rayleigh case; conservation of energy requires the dark-field image $I = 1 - I_{BF}$, where I_{BF} is the bright-field image and the incident beam intensity is normalized to unity. In practice, it is more useful to work in the dark-field mode for weakly scattering objects. If $I \ll 1$, the incoherent bright-field image shows weak contrast on a large background due to the unscattered incident beam. The dark-field image avoids this background, giving greater contrast and better signal-to-noise ratio.

The difference between coherent and incoherent characteristics is summarized in Figure 6, where image contrast is plotted as a function of spatial frequency in a microscope operating at an accelerating voltage of 300 kV. In both modes some objective lens defocus is used to compensate for the very high aberrations of electron lenses, and the conditions shown are the optimum conditions for each mode as defined originally by Scherzer (1949). In the coherent imaging mode (Fig. 6A), the contrast transfer function is seen to oscillate rapidly with increasing spatial frequency (smaller spacings). Spatial frequencies where the transfer function is negative are imaged in reverse contrast; those where the transfer function crosses zero will be absent. For this reason, atomic positions in distorted regions such as grain boundaries may reverse contrast or be absent from a phase-contrast image. In the incoherent mode (Fig. 6B), a smoothly

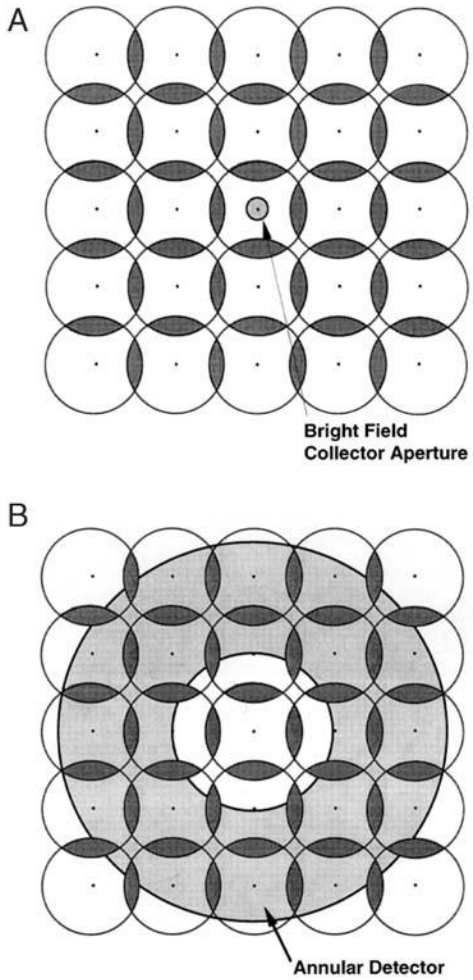

Figure 7. Diffraction pattern in the detector plane from a simple cubic crystal of spacing such that the angle between diffracted beams is greater than the objective aperture radius. (**A**) An axial bright-field detector shows no contrast. (**B**) Regions of overlapping discs on the annular detector produce atomic resolution in the incoherent image.

decaying positive transfer is obtained (referred to as an object transfer function to distinguish from the coherent case), which highlights the lack of contrast reversals associated with incoherent imaging. It is also apparent from the two transfer functions that incoherent conditions give significantly improved resolution.

To demonstrate the origin of the improved resolution available with incoherent imaging, Figure 7 shows the diffraction pattern formed on the detector plane in the STEM from a simple cubic crystal with spacing d. Because the illuminating beam in the STEM is a converging cone, each Bragg reflection appears as a disc with diameter determined by the objective aperture. Electrons, unlike light, are not absorbed by a thin specimen but are only diffracted or scattered. The terms are equivalent, diffraction being reserved for scattering from periodic assemblies of atoms when sharp peaks or discs are seen in the scattered intensity. The periodic object provides a good demonstration of Abbé theory (see, e.g., Lipson and Lipson, 1982) that all image contrast arises through interference; as the probe is scanned across the atomic planes, only the regions of overlap between the discs change intensity as the phases of the various reflections change (Spence and Cowley, 1978).

For the crystal spacing corresponding to Figure 7A, coherent imaging in CTEM or STEM using a small axial aperture will not detect any overlaps and will show a uniform intensity with no contrast. The limiting resolution for this mode of imaging requires diffraction discs to overlap on axis, which means they must be separated by less than the objective aperture radius. Any detector that is much larger than the objective aperture will detect many overlapping regions, giving an incoherent image. Clearly, the limiting resolution for incoherent imaging corresponds to the discs just overlapping, i.e., to a crystal spacing such that the diffracted beams are separated by the objective aperture diameter (as opposed to the radius), double the resolution of the coherent image formed by an axial aperture. The approximately triangular shape of the contrast transfer function in Figure 6B results from the simple fact that a larger crystal lattice produces closer spaced diffraction discs with more overlapping area, thus giving more image contrast.

In practice, of course, one would tend to use larger objective apertures in the phase-contrast case to improve resolution. The objective aperture performs a rather different role in the two imaging modes; in the coherent case the objective aperture is used to cut off the oscillating portion of the contrast at high spatial frequencies, and the resolution is directly determined by the radius of the objective aperture, as mentioned before. In the incoherent case, again it is clear that the available resolution will be limited to the aperture diameter, but there is another consideration. To take most advantage of the incoherent mode requires that the image bear a direct relationship to the object, so that atomic positions correlate closely with peaks in the image intensity. This is a rather more stringent condition and necessitates some loss in resolution. The optimum conditions worked out long ago by Scherzer (1949) for both coherent and incoherent imaging conditions are shown in Figure 5 and summarized in Table 1. The Scherzer resolution limit for coherent imaging is now only 50% poorer than for the incoherent case.

The role of dynamical diffraction is also very different in the two modes of imaging. As will be seen later, dynamical diffraction manifests itself in a *Z*-contrast image as a columnar channeling effect, not by altering the incoherent nature of the *Z*-contrast image, but simply by scaling the columnar scattering intensities. In coherent imaging, dynamical diffraction manifests itself through contrast

Table 1. Optimum Conditions for Coherent and Incoherent Imaging

Parameter	Coherent Imaging	Incoherent Imaging
Resolution limit	$0.66 C_S^{1/4} \lambda^{3/4}$	$0.43 C_S \lambda^{1/4} \lambda^{3/4}$
Optimum defocus	$-1.155\ (C_S \lambda)^{1/2}$	$-(C_S \lambda)^{1/2}$
Optimum aperture	$1.515 (\lambda / C_S)^{1/4}$	$1.414\ (\lambda / C_S)^{1/4}$

reversals with specimen thickness, as the phases between various interfering Bragg reflections change. These effects are also nonlocal, so that atom columns adjacent to interfaces will show different intensity from columns of the same composition far from the interface. Along with the fact that atom columns can also change from black to white by changing the objective lens focus, these effects make intuitive interpretation of coherent images rather difficult. Of course, one usually has a known material next to an interface that can help to establish the microscope conditions and local sample thickness, but these characteristics of coherent imaging make it very difficult to invert an image of an interface without significant prior knowledge of its likely structure. Typically, one must severely limit the number of possible interface structures that are considered, e.g., by assuming an interface that is atomically abrupt, with the last monolayer on each side having the same structure as the bulk. Although some interfaces do have these characteristics, it is also true that many, and perhaps most, do not have such simple structures. In the case of the $CoSi_2$/Si(111) interface, this procedure gives six possible interface models. At interfaces made by ion implantation, however, different interface structures were seen by *Z*-contrast imaging (Chisholm et al., 1994). There are now a large number of examples where interface structures have proved to be different from previous models: in semiconductors (Jesson et al., 1991; McGibbon et al., 1995; Chisholm and Pennycook, 1997), superconductors (Pennycook et al., 1991; Browning et al., 1993a), and ceramics (McGibbon et al., 1994, 1996; Browning et al., 1995).

If we apply reciprocity to the STEM annular detector, it is clear that an equivalent mode exists in CTEM using high-angle hollow-cone illumination. In practice, it has not proved easy to achieve such optics. In any case, a much higher incident beam current will pass through the specimen than in the equivalent STEM geometry, because the illumination must cover an angular range much greater than a typical Bragg angle, whereas the STEM objective aperture is of comparable size to a Bragg angle. Beam damage to the sample would therefore become a serious concern.

Another advantage of the STEM geometry that should be emphasized is that the detection angle can be increased without limit, up to the maximum of 180° if so desired. Lord Rayleigh's illumination was limited to the maximum aperture of the condenser lens, so that at the limit of resolution (with condenser and objective apertures equal), significant partial coherence exists in an optical microscope. In STEM, by increasing the inner angle of the annular detector, the residual coherence can be reduced well below the limiting resolution imposed by the objective aperture. It is therefore a more perfect form of incoherent imaging than fixed-beam light microscopy. However, increasing detector angles will lead to reduced image intensity due to the rapid fall-off in atomic scattering factor, and a backscattered electron detector is really not practical. With high-energy electrons, the full unscreened Rutherford scattering cross-section is seen above a few degrees scattering angle, so higher scattering angles bring no advantage. A useful criterion for the minimum detector aperture θ_i to achieve incoherent imaging of two objects separated by ΔR is

$$\theta_i = 1.22\lambda/\Delta R \qquad (1)$$

where the detected intensity varies by <5% from the incoherent expectation (Jesson and Pennycook, 1993). In this case the Airy disc coherence envelope of the detector (illumination) aperture is half the width of that of the probe-forming (imaging) aperture. This condition therefore corresponds to separating the coherence envelopes by double the Rayleigh criterion.

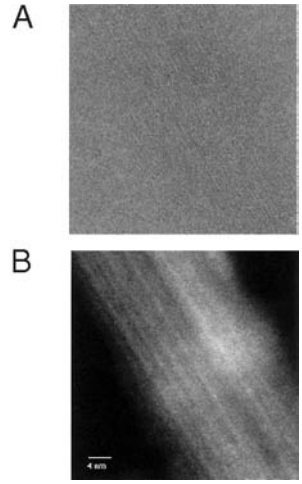

Figure 8. (**A**) Bright-field phase-contrast STEM image of an iodine intercalated bundle of carbon nanotubes showing lattice fringes. (**B**) *Z*-contrast image taken simultaneously showing intercalated iodine.

Another benefit of STEM is that the *Z*-contrast image and the conventional HREM image are available simultaneously. However, phase-contrast images in STEM tend to be substantially noisier than those recorded in TEM using a charge-coupled device (CCD) camera or photographic plate, because STEM is a serial imaging instrument that is far less efficient than the parallel recording capabilities of TEM. An example of simultaneous bright-field and *Z*-contrast imaging of a bundle of iodine-intercalated carbon nanotubes is shown in Figure 8. Because of their cylindrical form, only a few atomic layers are parallel to the electron beam. Nevertheless, lattice fringes from the tubes are seen clearly in the phase-contrast image because it is tuned to the spacing expected and filters out the uniform background near-zero spatial frequency due to all other atoms. On the other hand, the *Z*-contrast image is sensitive to the absolute numbers of atoms under the beam. Here, where there is no significant dynamical diffraction, the *Z*-contrast image can be considered as an image of projected mass thickness. It shows no detectable contrast from the tubes themselves, but the iodine intercalation is now clearly visible. Thus the two kinds of images are highly complementary in this case.

Figure 9 shows a Rh catalyst cluster supported on γ-alumina (Pennycook et al., 1996). In this case, the bright-field image is dominated by phase contrast from

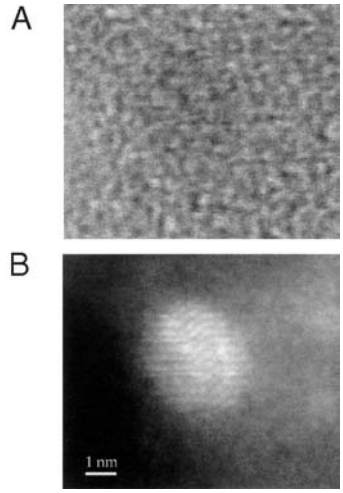

Figure 9. (**A**) Bright-field and (**B**) *Z*-contrast images of an Rh catalyst particle on γ-alumina. The particle is barely detectable in the bright-field image due to the phase contrast of the support, but the dark-field image reveals its atomic structure, internal twins, and external facets.

the carbon film ($Z = 6$) used to support the sample, whereas the Rh particle ($Z = 45$) is clearly visible in the *Z*-contrast image. Of course, if pieces of γ-alumina overlapping holes in the carbon film were chosen, the phase-contrast image would not be so obscured, but nevertheless, bright-field imaging of small metal clusters becomes very difficult for particles $<\sim$1 nm in size, due to the inevitable coherent interference effects from the support and the lack of *Z* contrast (Datye and Smith, 1992). The ultimate example of *Z*-contrast imaging is the detection of single Pt atoms on γ-alumina shown in Figure 10 (Nellist and Pennycook, 1996). Here, again, the two images are very complementary. The orientation of the γ-alumina support can be deduced from the bright-field image, while single atoms, dimers, and trimers are detectable in the *Z*-contrast image. Spacings and angles between the Pt atoms are constrained to match the atomic spacings in the γ-alumina surface, suggesting the possible adsorption sites shown in the schematic.

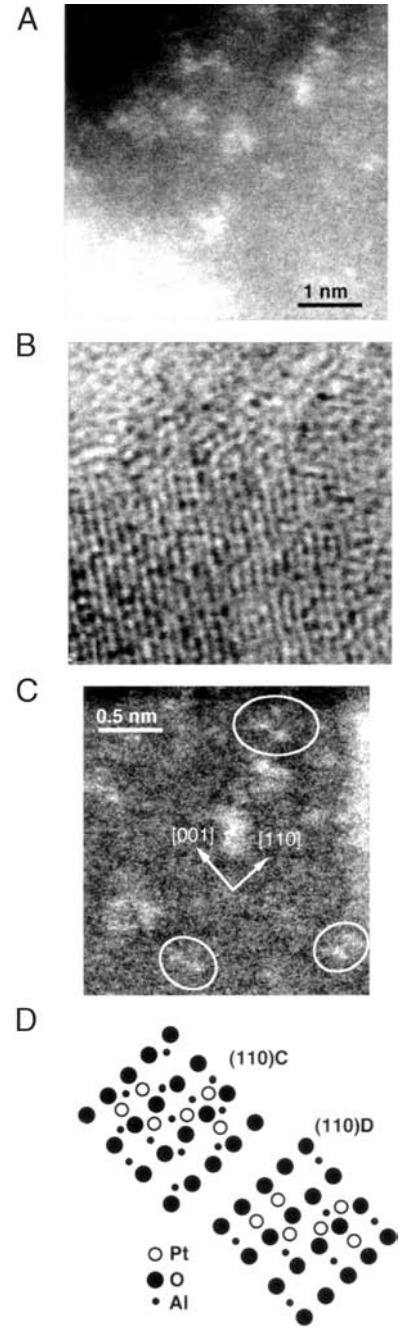

Figure 10. (**A**) *Z*-contrast image of Pt clusters supported on γ-Al_2O_3. (**B**) Bright-field image showing strong {222} fringes of Al_2O_3. (**C**) Higher magnification *Z*-contrast image after high- and low-pass filtering to enhance contrast revealing a Pt trimer and two dimers (circled). (**D**) The spacings and angles between Pt atoms match the orientation of the support, suggesting likely configurations on the two possible (110) surfaces.

Probe Formation

An electron of wavelength λ passing at an angle θ through an objective lens with spherical aberration coefficient C_s set to a defocus of Δf experiences a phase shift γ given by

$$\gamma = \frac{\pi}{\lambda}\left(\Delta f\theta^2 + \frac{1}{2}C_s\theta^4\right) \qquad (2)$$

The amplitude distribution $P(\mathbf{R} - \mathbf{R}_0)$ of the STEM probe at position $\mathbf{R}_0$ on the specimen is obtained by integrating all possible pathways through the objective lens, as defined by the objective aperture,

$$P(\mathbf{R} - \mathbf{R_0}) = \int_{\substack{\text{objective}\\ \text{aperture}}} e^{i[\mathbf{K}\bullet(\mathbf{R}-\mathbf{R_0})+\gamma(\mathbf{K})]} d\mathbf{K} \qquad (3)$$

where $|\mathbf{K}| = \chi\theta$ is the transverse component of the incident electron wave vector $\chi = 2\pi/\lambda$. The intensity distribution is given by $P^2(\mathbf{R} - \mathbf{R}_0)$. A focal series is shown in Figure 11 for a 300-kV STEM instrument with C_s = 1 mm and a Scherzer optimum objective aperture of 9.3 mrad. Notice how the intensity profiles are not symmetric about the Scherzer defocus value of −430 Å. This

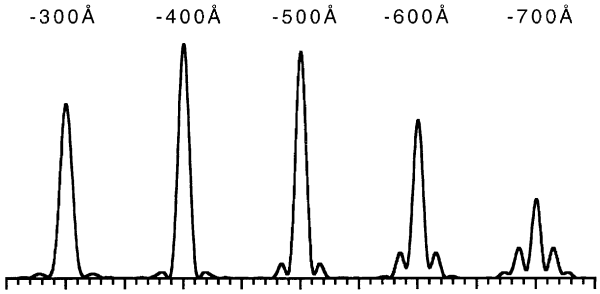

Figure 11. Probe intensity profiles for a 300-kV STEM instrument with $C_s = 1$ mm and a Scherzer optimum objective aperture of 9.4 mrad.

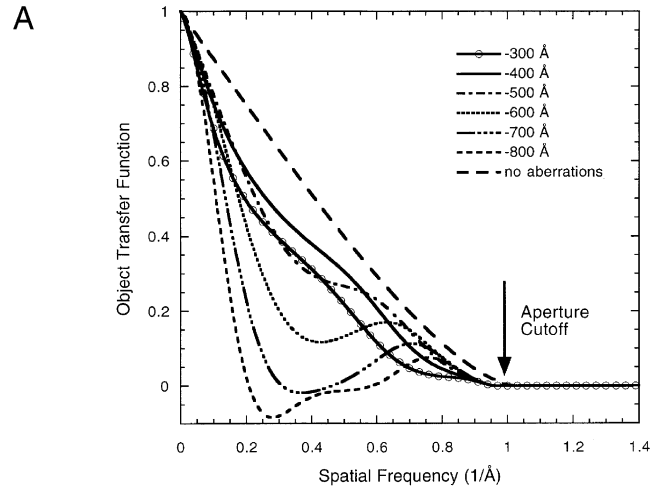

is because the entire probe is (ideally) a single electron wavepacket, all angles fully coherent with each other. The probe is best thought of as a converging, phase-aberrated spherical wave. At a defocus below the Scherzer optimum, the probe is close to Gaussian in nature, while at high defocus values, the probe develops a well-defined "tail," a subsidiary maximum around the central peak. Although the width of the central peak is significantly reduced, actually dropping to below 1 Å at a defocus of −500 Å, now over half the total intensity is in the tails. This gives rise to significant false detail in the image, which makes intuitive interpretation no longer possible, as shown by the corresponding simulated images of Si⟨110⟩ in Figure 12.

The object transfer function for incoherent imaging is the Fourier transform of the probe intensity profile. Figure 13A shows transfer functions corresponding to the focal series of Figures 11 and 12. Also shown is the ideal transfer function without any aberration. These curves show how increasing the defocus enhances the high spatial frequencies but reduces the transfer at lower frequencies. In all cases the transfer reaches zero at the cutoff defined by the aperture. If the aperture size is increased, the transfer function can be extended even further. Figure 13B shows transfer functions obtained with a 13-mrad objective aperture, corresponding to an aperture cutoff of 0.74 Å. At low defocus values there is little transfer at the high spatial frequencies, and an intuitive image is expected but with reduced contrast compared to the optimum aperture.

Experimental verification that the resolution is enhanced under such conditions is seen in Figure 14, which shows images of Si⟨110⟩ obtained with a 17-mrad objective aperture (Nellist and Pennycook, 1998a). Under optimum defocus the dumbbells are well resolved (Fig. 14A) with maxima close to the atomic positions, the expected intuitive image. The Fourier transform of the image intensity, Figure 14B shows the spatial frequencies

Figure 12. Simulated images of Si(110) corresponding to the probe profiles in Figure 11.

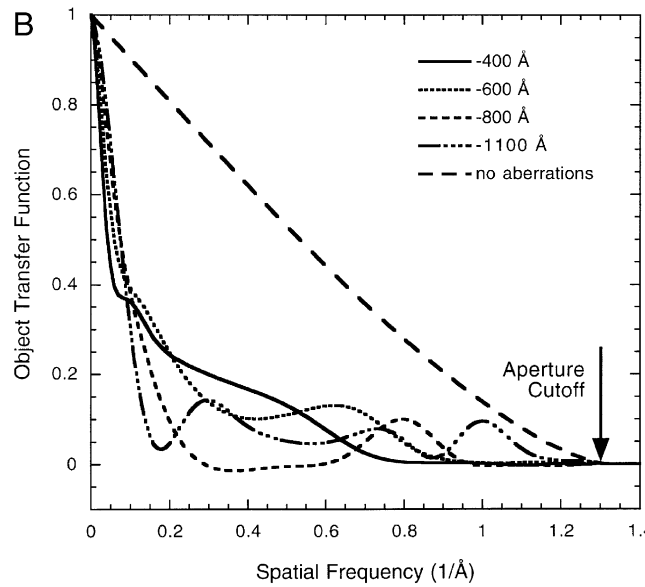

Figure 13. Object transfer functions for (**A**) the optimum condition in Figures 11 and 12; (**B**) extended transfer obtained with an oversized objective aperture of 13 mrad, though contrast at lower spatial frequencies is reduced.

being transferred, which includes the {004} reflection at a spacing of 1.36 Å. On increasing the objective lens defocus (Fig. 14C), the image is no longer intuitive, but many additional spots are seen in the Fourier transform (Fig. 14D). The {444} spot at 0.78 Å is the highest resolution yet achieved in any electron microscope. This result demonstrates very clearly the improved resolution available with incoherent imaging, as first pointed out by Lord Rayleigh.

Incoherent Scattering

Because the probe is necessarily a coherent spherical wave, incoherent imaging must come by ensuring incoherent scattering. Of course, as mentioned earlier, all imaging

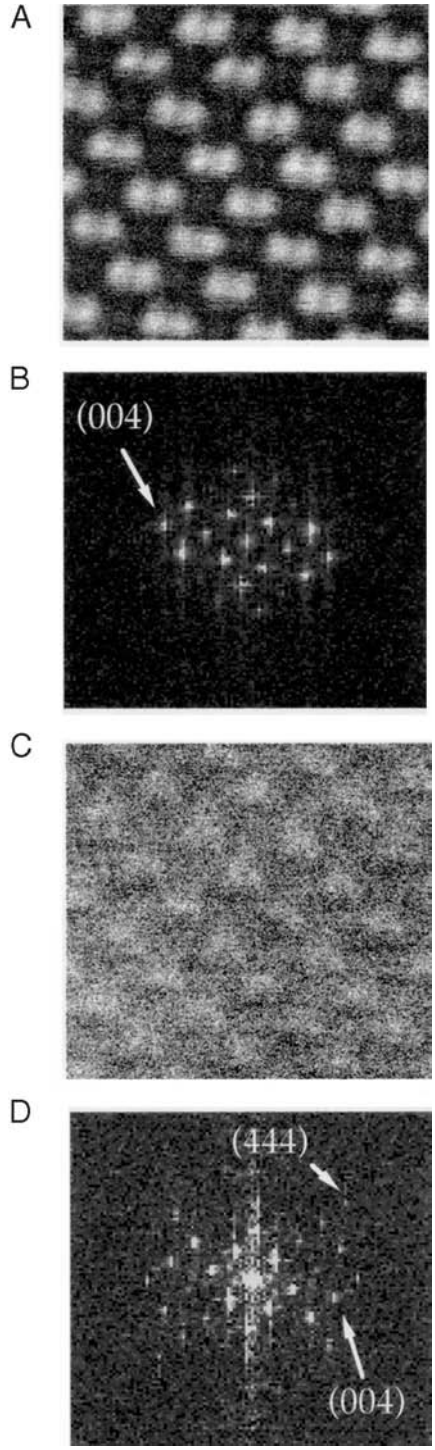

Figure 14. Images and corresponding Fourier transforms of Si<110> obtained with a 17-mrad objective aperture (Nellist and Pennycook, 1998a); (**A, B**) at Scherzer defocus passing the {004} spacing and resolving the dumbbell; (**C, D**) using a high underfocus giving increased transfer at high spatial frequencies, including the {444} spacing at 0.78 Å.

is based on interference, and incoherent characteristics arise when averaging a large number of optical paths of different lengths. For a monolayer raft of weakly scattering atoms, it can be shown rigorously how incoherent imaging can be achieved with a large detector to any desired degree, as shown in Appendix A. A simple justification is that, depending on the projected potential, a monolayer crystal changes only the phase of the electron wave passing through it. Clearly, if only the phase of the spherical wave is altered inside the crystal, the intensity profile will remain the same as that of the incident probe. Each nucleus will scatter in proportion to the intensity of the probe in its vicinity, and incoherent imaging is obtained as shown schematically in Figure 3. The image intensity $I(\mathbf{R})$ is given by a convolution of the probe intensity with the object function $O(\mathbf{R})$,

$$I(\mathbf{R}) = O(\mathbf{R}) * P^2(\mathbf{R}) \tag{4}$$

In the simple case of a monolayer crystal, the object function is just an array of atomic cross-sections that can be approximated as delta functions at the atomic positions.

A typical Bragg angle for a high-energy electron is only $\sim$10 mrad, or $\sim 0.5^\circ$, so that high-angle scattering corresponds to only a few degrees. This means that path differences between atoms separated in the transverse plane are much greater than between atoms separated along the beam direction, as shown in Figure 15. Atoms spaced by x and z in the transverse and longitudinal directions, respectively, when viewed from direction θ, have phase differences of $x \sin\theta$ and $z(1 - \cos\theta)$, respectively. For small scattering angles these are approximately $x\theta$ and $z\theta^2/2$; the latter is much smaller, showing how longitudinal coherence is more difficult to break with the detector alone. Clearly, if the Rayleigh detector is sufficient to ensure incoherence in the x direction, there is no justification for believing that atoms separated by a similar distance in the

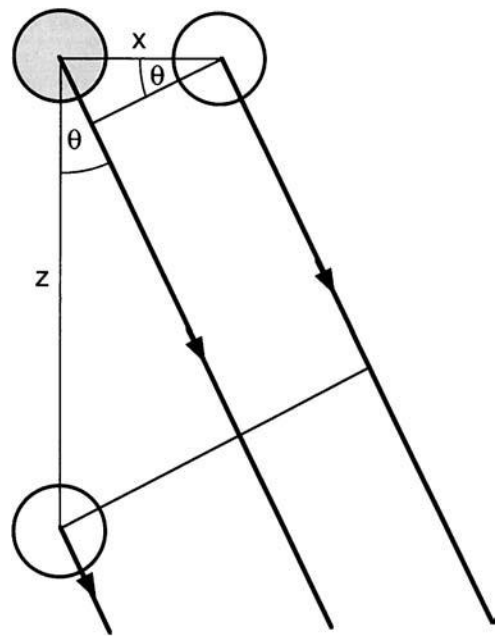

Figure 15. Path differences between scattering from atoms separated by x and z in the transverse and longitudinal directions, respectively.

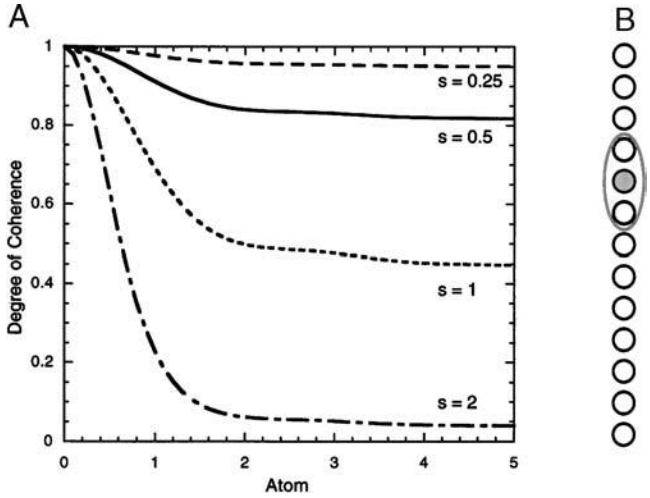

Figure 16. (**A**) Degree of coherence between an atom at the origin and neighboring atoms along a column using a phonon model of thermal vibrations. (**B**) With increasing separation the degree of coherence drops rapidly, defining an effective coherence envelope.

z direction will scatter independently. Indeed, the incoherence in the beam direction comes from another effect, the unavoidable thermal vibrations of the atoms themselves.

Thermal vibrations act to randomize the phase differences between atoms at different heights in the column by inducing transverse atomic displacements. Consider the two atoms separated by z to have an additional instantaneous relative displacement due to thermal motion of u_z and u_x in the longitudinal and transverse directions, respectively. The resulting path differences are $(z + u_z)(1-\cos\theta)$ and $u_x \sin\theta$. Clearly, the longitudinal displacements u_z have relatively little effect as they are much smaller than the atomic separation z, but the transverse displacements u_x are significant. A detailed analysis using a phonon model of thermal vibrations shows that it is indeed transverse modes of phonons with wave vectors in the z direction that are most effective in breaking the coherence along a column (Jesson and Pennycook, 1995). The analysis showed further that the coherence of two atoms separated along the z direction by m unit cells is

$$W_m = \exp\left\{2Ms^2\left[\frac{\mathrm{Si}(\pi m)}{\pi m} - 1\right]\right\} \qquad (5)$$

where Si(x) is the sine integral function, M is the usual Debye-Waller factor, and $s = \theta/2\lambda$ is the scattering vector. Figure 16A shows plots of this function for different values of s showing how the coherence rapidly reduces as the separation of atoms along the column increases. For large separations the degree of coherence approaches the limiting value e^{-2M}, which is the Einstein value for the strength of coherent reflections in his model of independently vibrating atoms. This model, though convenient, does ignore the correlation between near neighbors seen in the figure. The phonon model shows clearly that atoms close together scatter with greater coherence than those far apart, leading to the concept of a longitudinal coherence volume, shown schematically in Figure 16B.

Therefore, the need for large detector angles to ensure *inter*column incoherence (transverse incoherence) will automatically break the *intra*column coherence leading to longitudinal incoherence also. The change in the thickness dependence of the image intensity with increasing annular detector angle is largely governed by longitudinal coherence, changing from predominantly coherent at low angles to predominantly incoherent at large angles. This is illustrated in Figure 17 for a column of Rh atoms 2.7 Å apart illuminated by 300-kV electrons. With low detection angles the scattering is almost entirely coherent, becoming almost entirely incoherent at high detector angles. Intermediate angles exhibit an initial coherent dependence with thickness, changing to an incoherent dependence as the column becomes significantly longer than the correlation length.

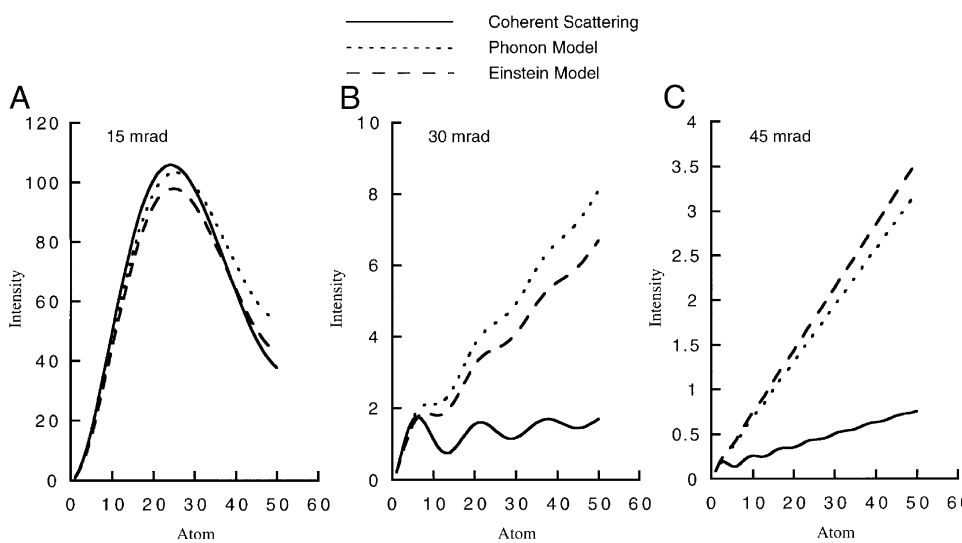

Figure 17. Thickness dependence of the scattering from a column of Rh atoms spaced 2.7 Å apart along the beam direction for (**A**) low, (**B**) medium, and (**C**) high scattering angles. The coherent thickness oscillations at low angles are almost completely suppressed at high angles.

Finally, it should be mentioned that a significant fraction of the thermal displacements of the atoms are due to zero-point fluctuations that will not disappear on cooling the sample. Thus, it should not be assumed that the scattering will become coherent on cooling, although the required detection angles will be increased somewhat.

Dynamical Diffraction

The above analysis makes clear how at high scattering angles thermal vibrations effectively destroy the coherence between atoms in a column. Given the transverse incoherence due to the annular detector, we may therefore think of each atom as scattering independently with an atomic cross-section σ, the electron equivalent of the self-luminous object. Now all that remains is to determine how the probe propagates through the thick crystals typically encountered in materials science studies, i.e., what is the effective illumination of each atom in a column? Electrons interact strongly with matter, undergoing multiple scattering, which is referred to as dynamical diffraction. With amorphous materials, or crystals in a random orientation, the multiple scattering is uncorrelated and leads to beam broadening. In a crystal oriented to a low-order zone axis, the situation is very different since the scattering is strongly correlated, often leading to a periodic behavior with increasing sample thickness. Phase-contrast images usually exhibit periodic contrast changes or reversals. One of the most surprising features of *Z*-contrast images from zone axis crystals is the lack of any apparent change in the form of the image with increasing sample thickness (Pennycook and Jesson, 1990, 1991). The *Z*-contrast image shows no strong oscillatory behavior, just reducing contrast with increasing thickness. The 300-kV STEM instrument at Oak Ridge National Laboratory still resolves the dumbbell spacing of 1.36 Å in a Si⟨110⟩ crystal 1000 Å thick.

The explanation of this remarkable behavior requires a quantum mechanical analysis of the probe propagation. Dynamical diffraction effects can be conveniently described in a Bloch wave formulation, where an incident plane-wave electron is described as a superposition of Bloch states, each propagating along the zone axis with a different wave vector. It is the interference between these Bloch states that leads to dynamical diffraction effects, thickness fringes in a diffraction contrast image, and contrast reversals in a phase-contrast lattice image. Figure 18 shows the first six Bloch states for Si⟨110⟩, which are seen to take the form of molecular orbitals about the atomic strings. Usually, the wave function inside the crystal can be well represented with just a few strongly excited Bloch states, and it is their propagation with different wave vectors through the crystal that leads to depth-dependent dynamical diffraction effects. Note in particular the 1*s* states, which are located over the atomic columns, and overlap little with neighboring columns. They are the most localized states, and we will find they are responsible for the *Z*-contrast image. These 1*s* states exist around every atomic column, and it is because of their localization that we can think of the *Z*-contrast image as a column-by-column image of the crystal. They are also the basis for atomic column spectroscopy, as described under Atomic Resolution Spectroscopy, below. All the other states are much less localized and overlap significantly with neighboring columns, as is clear from the figure. These delocalized states are responsible for the nonlocal effects in phase-contrast imaging, which makes it necessary to simulate images with supercells. Such states are not specific to a particular type of column but are strongly dependent on surrounding columns. They are the reason that atomic columns at an interface in a phase-contrast image may appear different to those in the bulk.

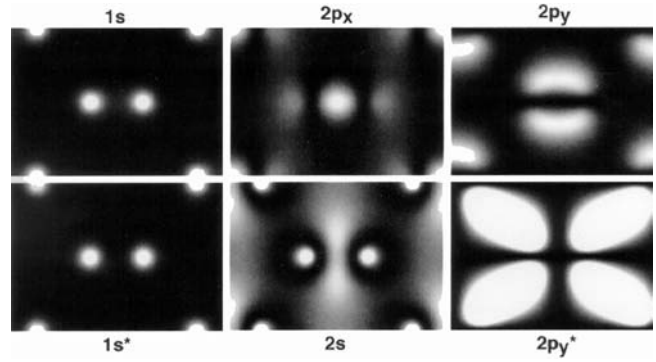

Figure 18. Intensities of the first six Bloch states in Si(110) with their molecular orbital assignments. The 1*s* states are located around the Si atomic columns.

We can now better appreciate the action of the high-angle detector. The 1*s* Bloch states are the most highly *localized* in real space, and therefore the most *extended* in reciprocal space. Only these states have transverse momentum components that extend to the high-angle detector. So the detector acts as an efficient Bloch state filter, with only one type of state per column involved in *Z*-contrast imaging. All states have low-order Fourier components, and so depending on their excitation, they all interfere in a low-angle detector such as used for axial bright-field imaging. This is how the Z-contrast image can show no interference phenomena while simultaneously the bright-field image shows strong interference effects, such as thickness fringes or contrast reversals.

The high-angle scattering comes entirely from the 1*s* states, specifically from their sharp peaks at the atomic columns. The detector therefore acts rather like a detector placed inside the sample at each atomic nucleus. In fact, the high-angle components of 1*s* states scale as Z^2, as would be anticipated on the basis of Rutherford scattering. However, dynamical diffraction does make its presence felt because not all the incident beam excites 1*s* states, and the total amplitude inside the crystal must be described as a sum over Bloch states j propagating with different wave vectors k_z^j along the z direction. The 1*s* states are located over the deepest part of the projected potential and so have the highest kinetic energy and the largest k_z^j. All the other less localized states have very similar k_z^j values, and so in thin crystals they all propagate approximately in phase through the thickness z. Therefore, it is a good

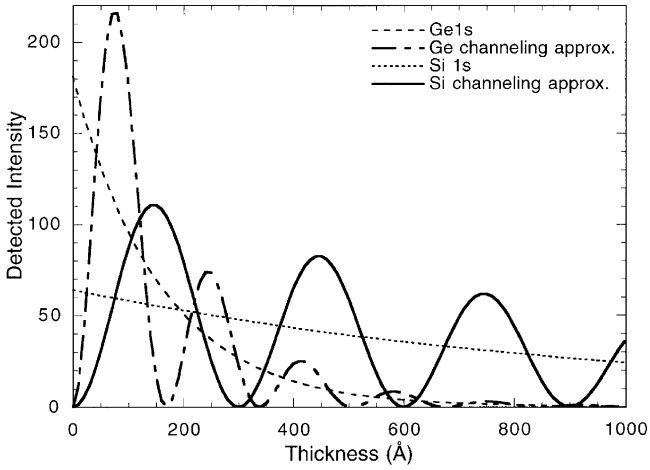

Figure 19. Intensity of coherent scattering reaching the annular detector from Si and Ge⟨110⟩ using the channeling approximation, Equation 6. Parameters: Si, $\xi = 300$ Å, $\mu^{1s} = 0.00048$; Ge, $\xi = 169$ Å, $\mu^{1s} = 0.0032$.

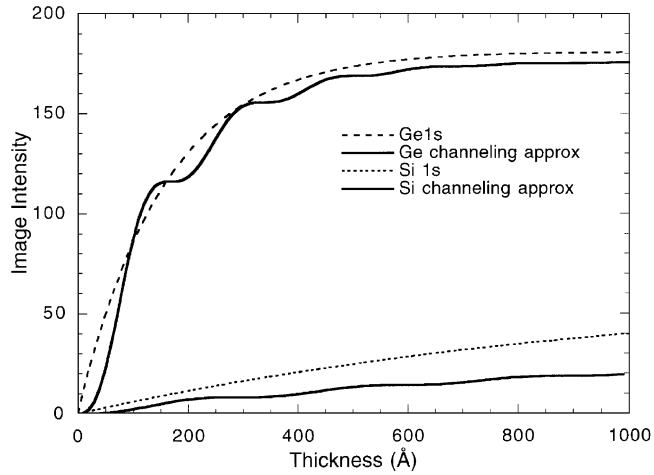

Figure 20. Intensity of incoherent scattering reaching the annular detector from Si and Ge ⟨110⟩ using the channeling approximation, Equation 7. Parameters are the same as Figure 19.

approximation to consider just two components to the electron wave function, the 1*s* state ϕ^{1s} propagating with wave vector k_z^{1s} and a term $1 - \phi^{1s}$ propagating at an average k_z^0. This is referred to as a channeling approximation (Pennycook and Jesson, 1992). The beating between these two components occurs with an extinction distance $\xi = 2\pi/(k_z^{1s} - k_z^0)$, and the total intensity scattered to high angles from a depth z in the dynamical wave field is given by

$$I \propto Z^2 \varepsilon^{av^2} [1 - \cos(2\pi z/\xi)] e^{-2\mu^{1s} z} \tag{6}$$

Here, Z^2 represents the high-angle scattering cross-section of the column; ε^{av} is the 1*s* state excitation averaged over the angular range of the objective aperture. The term in square brackets represents the dynamical oscillations with depth z, and μ^{1s} represents the 1*s* state absorption coefficient that damps the oscillations. Figure 19 shows a plot of this function for Si and Ge in the ⟨110⟩ orientation, compared to the 1*s* state intensities alone.

Experimental images do not show these strong depth oscillations because, as mentioned earlier, most of the scattering reaching the detector is thermal diffuse scattering. This is generated incoherently from the dynamical wave field described in Equation 6 and is therefore given by the integral of Equation 6 over the crystal thickness t. This results in a thickness-dependent columnar object function (Nellist and Pennycook, 1999)

$$O(R,t) \propto \frac{Z^2 \varepsilon^{av^2}}{2\mu^{1s}(\xi^2 \mu^{1s^2} + \pi^2)} \times \left[\pi^2 (1 - e^{-2\mu^{1s} t}) - \xi^2 \mu^{1s^2} e^{-2\mu_i^{1s}} \left(1 - \cos\frac{2\pi t}{\xi}\right) - \pi\xi\mu^{1s} e^{-2\mu^{1s} t} \sin\frac{2\pi t}{\xi} \right] \tag{7}$$

As shown in Figure 20, the thickness integration has removed the strong dynamical oscillations. Again we see that the thermal vibrations are important in breaking the coherence through the thickness t and giving an image intensity that is increasing with thickness. The limiting value is again proportional to Z^2, allowing very simple image quantification. The form of the curve is in good agreement with both experimental observations and multislice simulations for a high detection angle (Loane et al., 1992; Hillyard et al., 1993; Anderson et al., 1997; Hartel et al., 1996). Under these conditions, this channeling approximation is very useful for simulating images and saves enormously on computer time.

For lower detection angles the other states become more important, and a fraction of the coherent exit-face wave function given by Equation 6 must be added. The image contrast begins to show more oscillatory dependence on thickness, and the incoherent characteristics are progressively lost. Other states also become important if the atomic columns are no longer straight but are bent due to the presence of a defect or impurity. Then transitions occur between Bloch states, which is the origin of diffraction contrast imaging in CTEM, and strain contrast effects will also be seen in the annular detector signal, as discussed under Strain Contrast, below. A similar case is that of a single heavy impurity atom at a depth z, which will sample the oscillating wave field of Figure 19 and show depth-dependent contrast (Loane et al., 1988; Nakamura et al., 1997).

Nevertheless, in most cases of high-resolution imaging, the *Z*-contrast image represents a thickness integrated signal, and the oscillatory behavior is strongly suppressed. This is in marked contrast to a phase-contrast image that reflects the exit-face wave function and therefore does show an oscillatory dependence on sample thickness. The *Z*-contrast image is a near-perfect approximation to an ideal incoherent image. It removes the contrast reversals with objective lens focus, the proximity effects due to nonlocal Bloch states, and finally, the depth-dependent oscillations due to dynamical diffraction. The Bloch state description of the imaging process shows clearly the

physical origin of the incoherent characteristics, despite the presence of strong dynamical scattering.

Atomic Resolution Spectroscopy

Scanning transmission electron microscopy provides a sound basis for atomic resolution analysis using x-ray fluorescence or EELS. To date, atomic resolution has been demonstrated only for EELS because of the much lower detection efficiency for x rays (Browning and Pennycook, 1995; Pennycook et al., 1997; Duscher et al., 1998a). Using the incoherent *Z*-contrast image, a stationary probe can be centered over a chosen column by maximizing the annular detector intensity. Provided that incoherent optics are also used for the EELS, i.e., a large collector aperture, the EELS signal from that column will also be maximized at the same probe position, giving an atom column resolved analysis.

Because it is an inner shell electron that is the scatterer rather than the nucleus, the spatial resolution of the spectral information may not be quite as high as that of the *Z*-contrast image, an effect referred to as delocalization. For inner shell excitations, however, the width of the object function is less than an angstrom for most elements, as shown in Figure 21 (Rafferty and Pennycook, 1999). Core loss EELS therefore allows individual atomic columns to be analyzed, as shown in Figure 22. The *Z*-contrast image and spectra from specific atomic columns show the variation in both concentration and valence of Mn in a doped $SrTiO_3$ grain boundary (Duscher et al., 1998a). The highest peak intensity comes from the pair of columns labeled 2, which in the undoped boundary are Ti sites. A much lower concentration is seen at position 3, which represents the Sr sites. The ratio of the two Mn peaks, or white lines, indicates valence and suggests a change from 4+ in the bulk to 3+ at the boundary. Data of this nature are particularly valuable for linking the structure of the grain boundary to its electrical activity.

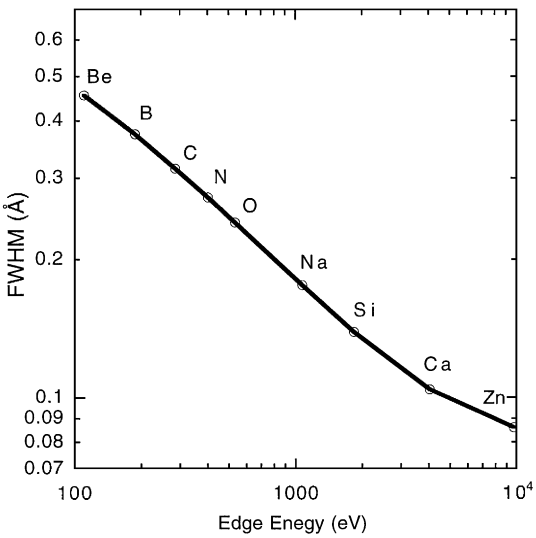

Figure 21. Full-width at half-maxima of EELS object functions for *K*-shell excitations by 300-kV incident electrons.

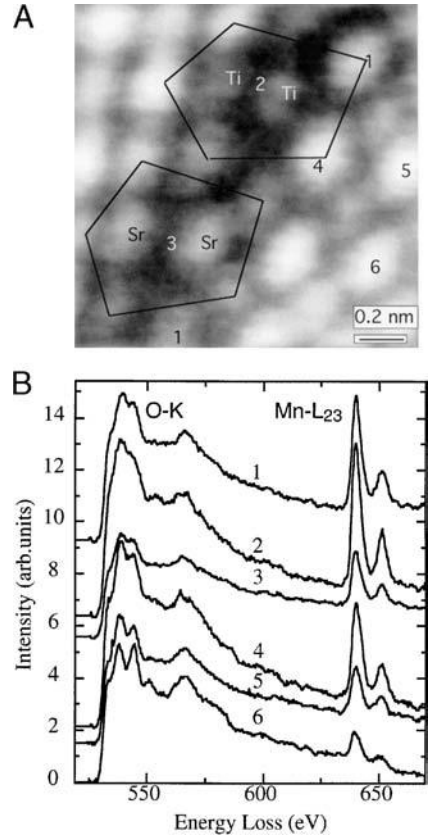

Figure 22. (**A**) *Z*-contrast image from a Mn-doped $SrTiO_3$ grain boundary with EELS spectra from individual atomic columns; (**B**), showing differences in composition and Mn valence at the grain boundary.

With the phase-contrast image of CTEM, it is not so simple to accurately illuminate an individual column. Neither is it practical to form an energy-filtered image at atomic resolution except from low-loss electrons that are intrinsically delocalized, in which case the contrast is due to elastic scattering, but the chemical information is nonlocal. In CTEM the objective lens is behind the specimen (Fig. 5A), so that the collection angle for EELS imaging is restricted to the objective aperture size. Furthermore, the energy loss electrons will suffer chromatic aberration on passing through the lens to form an image. For the energy-filtered image to show atomic resolution, the energy window selected by the filter must be kept small. Core loss cross-sections are orders of magnitude lower than elastic scattering cross-sections that determine the signal-to-noise ratio of the *Z*-contrast image. Attempting to form an image from core loss electrons in CTEM will therefore result in a very noisy image, probably with insufficient statistics to show atomic resolution. Increasing the incident beam current to compensate will increase the chances of beam damage. The information would be more efficiently gathered in the STEM mode by illuminating the chosen column, using the high-intensity *Z*-contrast image as a reference, and collecting the transmission EELS spectrum column by column. The objective lens is before the specimen in STEM, so that

chromatic aberration no longer degrades the spatial resolution, and a large collector aperture can be used to collect a large fraction of the inelastic scattering and partially compensate for the low cross-section.

This combination of the *Z*-contrast image and EELS at atomic resolution is very powerful. It is particularly useful for analyzing elements such as oxygen, which are too light to be seen directly in the *Z*-contrast image (McGibbon et al., 1994; Dickey et al., 1998). In the high-temperature superconductors, a pre-edge feature on the oxygen *K* edge is directly related to the concentration of holes that are responsible for superconductivity. This feature can be used to map hole concentrations at a spatial resolution below the superconducting coherence length (Browning et al., 1993b).

PRACTICAL ASPECTS OF THE METHOD

Besides the need for a high-resolution objective lens, a critical requirement for a probe of atomic dimensions is a field emission source. Without the high brightness such sources offer, there is insufficient current in the probe to focus and stigmate the image and insufficient current for an atomic resolution analysis. The cold field emission source is preferred for EELS because of its smaller energy spread compared to the Schottky-type source, whereas the latter is preferred for general TEM work because it is capable of a higher current mode and therefore gives less noisy images at low magnification when searching the specimen. It is easier to search the sample in the CTEM mode, and once an interesting region is found, the microscope can be switched to the STEM mode for *Z*-contrast imaging.

Formally, atomic-sized probes were only available in dedicated STEM instruments, but in recent years, conventional TEM has dramatically improved its probe-forming capabilities. It it is now possible to obtain true atomic resolution *Z*-contrast capability in a conventional TEM column (James et al., 1998; James and Browning, 1999).

To adjust the STEM instrument, a shadow image or ronchigram is very useful (Cowley 1979, 1986b; Lin and Cowley, 1986). Formed by stopping the STEM probe and observing the intensity in the diffraction plane, it is a powerful means to align the microscope, correct astigmatism, and tilt a specific area precisely on axis. The objective lens strength is used as a nonlinear magnification control. With the probe focused away from the specimen plane, a broad area of sample is illuminated, and the diffraction screen shows a shadow image. This will also contain diffraction information in the form of Kikuchi lines, as different parts of the image are illuminated by electrons at different angles in the defocused probe (see Fig. 23). As the probe is focused on the specimen, the magnification increases, until at focus (infinite magnification) a ronchigram is formed that is an angular map of the objective lens aberrations. A very thin region of sample is required, ideally an amorphous edge or glue, and the optical axis can be seen clearly. Astigmatism can be adjusted by making the phase-contrast features circular, and stability of all lenses and alignments can be checked by wobbling and counting fringes as the probe is displaced. This procedure

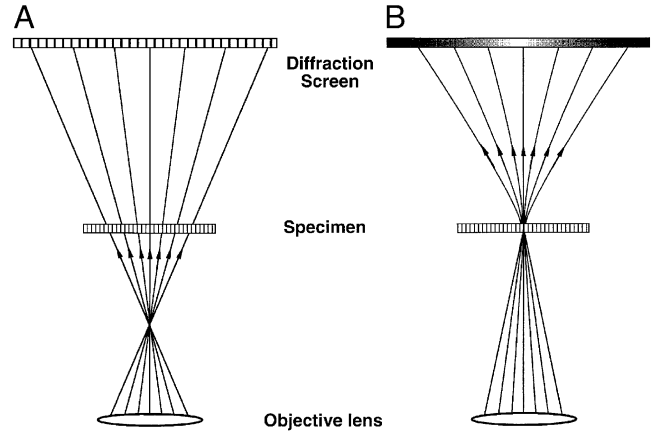

Figure 23. Schematic showing the formation of a shadow image or ronchigram by a stationary probe in the STEM instrument. (**A**) A defocused probe gives a shadow image containing simultaneous image and diffraction information. (**B**) focused probe produces a ronchigram.

gives an accurate alignment and precise position of the objective lens optic axis about which the objective aperture and all detectors are centered. If the microscope has a stage capable of adjusting the sample height, then the shadow image is a useful method to set each sample at the same height and therefore at the same objective lens excitation. In this way all alignments and astigmatism settings are constant and all that remains is to tilt the sample on axis.

With the microscope now adjusted, the scan is turned on and *Z*-contrast images can be collected. Unless there is a large change in height from area to area, the astigmatism should not need adjustment, and any changes in the image will most likely reflect changes in sample tilt. The *Z*-contrast image loses contrast more rapidly than the phase-contrast image with specimen tilt. The first indication is an asymmetry in the image, progressing to a pronounced streaking along the direction of tilt. This can be distinguished from astigmatism because it will not change direction when the objective lens is changed from underfocus to overfocus. Fine focus can be judged by eye, remembering the general characteristics shown in Figure 12, that on weakening the lens (underfocusing), the image contrast first increases, then goes through a maximum at the optimum Scherzer focus, and finally reduces but acquires increasing fine detail, until the image disappears into noise. It should also be remembered that slowing the scan will reduce the image noise quite significantly, although specimen drift becomes a limitation. One can of course also use the conventional phase-contrast image to stigmate and focus, although the noise in a scanned image makes it more difficult to judge minimum image contrast than with conventional TEM.

It should also be realized that in extremely thick regions of sample, the *Z*-contrast image may show contrast reversals, not in the atomic resolution image (usually the region is so thick that an atomic resolution image is no longer possible), but in the relative brightness of materials of different *Z*. In a thick region, the bright-field image has long disappeared, and this effect can be confusing when

searching the sample for the interface of interest. It is caused by multiple elastic scattering that takes electrons off the detector to even higher angles. In the limit there is no more transmission, and obviously the higher Z material will be the first to approach this limit and therefore appear less bright than a material of lower Z.

Finally, the EELS detector needs to be of the highest efficiency possible, which means it should be a cooled CCD parallel detection system (see, e.g., McMullan et al., 1990). Because damage is a more serious concern in EELS, it is also essential to have a time-resolved capability in the system, to allow a series of spectra to be recorded in succession so that they can be compared for signs of damage. If none are seen, they can subsequently be summed to improve statistics. Usually it is in the spectral fine structure that damage effects are first observed, long before the image shows signs of amorphization.

DATA ANALYSIS AND INITIAL INTERPRETATION

Retrieval of the Object Function

The only specimen information lost in recording an incoherent image is at high spatial frequencies, due to the convolution with a probe of finite width. No phase information is lost, as in the recording of a coherent image, because there is no phase information in an incoherent image. It might therefore be assumed that, to retrieve the object, all that would be required would be to deconvolve the probe from the image. Unfortunately this is not useful, as illustrated in Figure 24 (Nellist and Pennycook, 1998b), because there is insufficient information at high frequencies. Although the raw image data in Figure 24A can be Fourier filtered to remove the noise (Fig. 24B), the result of the deconvolution in part C is to produce artifacts between the columns. These arise because, lacking any information at high spatial frequencies, one is forced to cut off the transfer abruptly near the maximum spatial frequency present in the original image. To avoid such artifacts, a slower cutoff can be imposed on the image, but obviously this would then degrade the resolution. In fact, it is not useful to attempt to improve upon the incoherent transfer function in this way, and an alternative method is required to reconstruct the missing high-frequency information.

For atoms far apart, it is reasonable to locate the maximum of each image feature, but this procedure does not work near the limit of resolution because it does not take any account of the probe profile. In Si⟨110⟩, for example, pairs of columns are spaced by distances comparable to the probe size, and the peak image intensity is displaced outward by a few tenths of an angstrom depending on defocus. Maximum entropy (Gull and Skilling, 1984) is a method to accurately account for the effects of the convolution. No prior knowledge concerning the nature of the image is assumed, except that it is incoherent. It does not assume that the object is comprised of atoms, but, given a specified probe profile, it reconstructs the most likely object function consistent with the image data. It produces an object with the least amount of structure needed to account for the image intensity, an object with maximum entropy. Figure 24D shows the reconstructed Si image, obtained by convolving the maximum-entropy object with the probe profile, where the artifacts between the columns are no longer present.

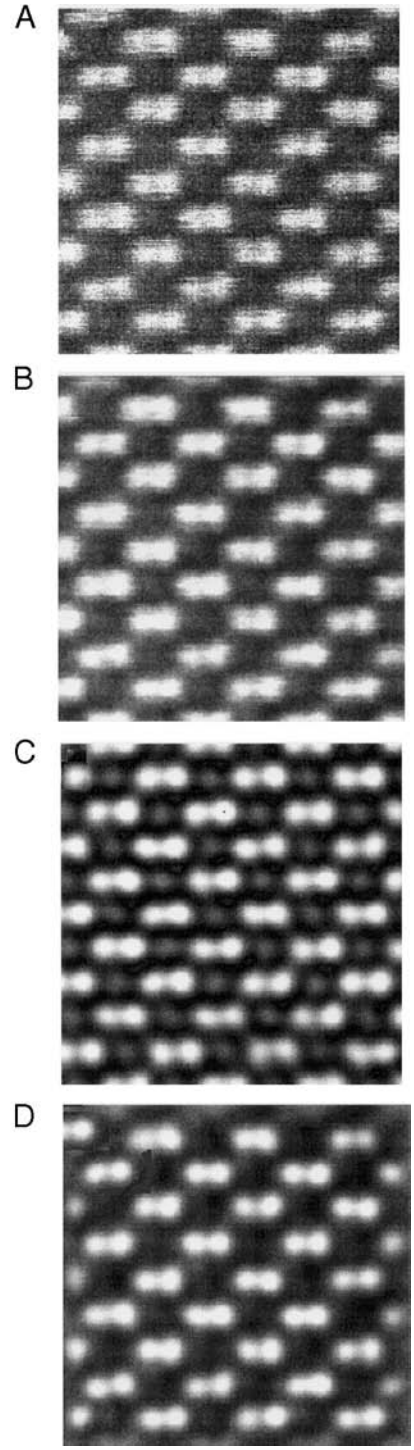

Figure 24. (**A**) Raw Z-contrast image of Si ⟨110⟩; (**B**) low-pass filtered image to reduce noise; (**C**) deconvolution of the probe function leads to artifacts between the columns; (**D**) maximum entropy retrieves the correct object, giving a reconstructed image free of artifacts.

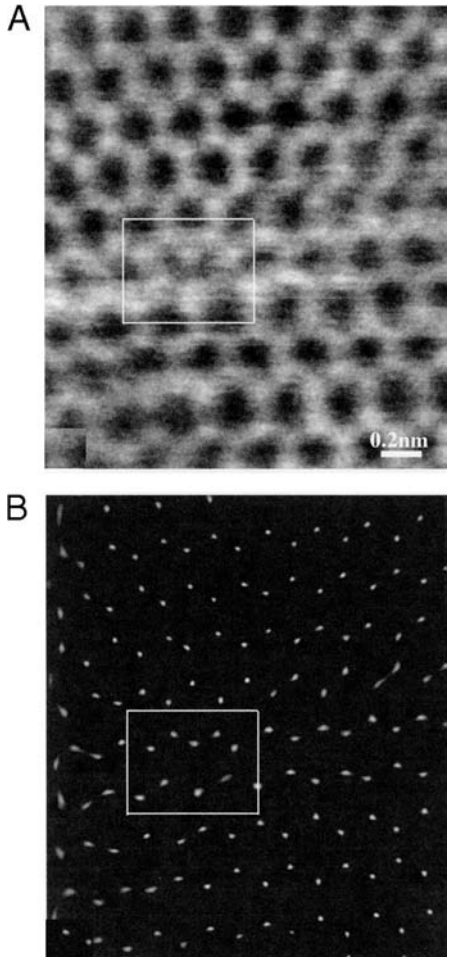

Figure 25. (**A**) *Z*-contrast image of a threading dislocation in a GaN thin film grown on sapphire, viewed along the ⟨0001⟩ direction. (**B**) The 8-fold structure of the core is clear from the maximum-entropy object.

An example of this method applied to a dislocation core in GaN is shown in Figure 25 (Xin et al., 1998). The maximum-entropy object function consists of fine points, the best fit atomic positions, and clearly reveals the core structure of the threading dislocation. The accuracy of the method is easily checked by measuring spacings far from the dislocation core, here, as found typically, $\sim\pm 0.1$ Å for individual columns. More detailed descriptions of the maximum-entropy approach applied to *Z*-contrast images and its accuracy and comparison with alternative schemes are given elsewhere (McGibbon et al., 1999; Nellist and Pennycook, 1998b).

Strain Contrast

Elastic strain fields due to impurities, point defects, or extended defects will affect the image by disturbing the channeling of the probe, even if they do not significantly affect the columnar scattering cross-section. Dislocations are visible because they induce transitions between Bloch states. This is the usual mechanism of diffraction contrast

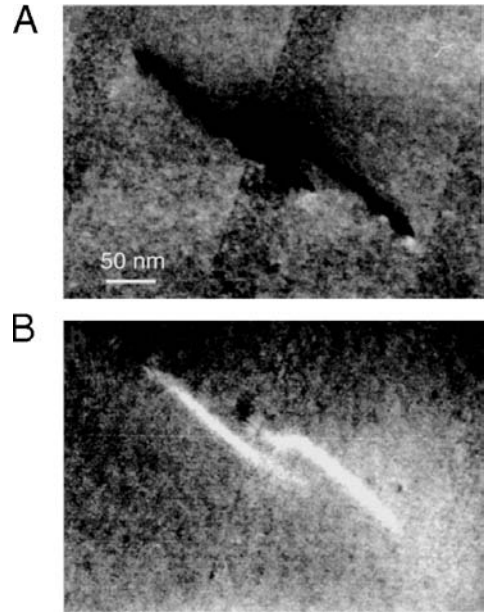

Figure 26. (**A**) STEM bright-field and (**B**) annular dark-field diffraction contrast images of inclined dislocations in a thick Si/Si(B) superlattice.

in CTEM images, but clearly, if the 1*s*-type Bloch states are involved, dislocations will also be visible in the annular detector image. In general, transitions may occur into or out of the *s* states, depending on the depth in the crystal, giving oscillatory contrast from inclined dislocations, as seen in Figure 26 (Perovic et al., 1993a,b). Even dislocations that are viewed end-on may show strain contrast due to the transverse relaxations of the atomic positions that occur near the sample surface. For this reason, grain boundaries, which are closely spaced arrays of dislocations, often appear brighter or darker than the matrix. Strain contrast is relatively long range compared to the lattice parameter and can be removed by Fourier filtering if desired. As shown below, strain contrast depends strongly on detector angle and can be distinguished from compositional changes (*Z* contrast) by comparing images taken with different inner detector angles.

From the discussion of the loss of coherence through atomic vibrations, it is clear that in a zone axis crystal transverse displacements comparable to the atomic vibration amplitude will significantly affect the scattering at high angles. The diffuse scattering cross-section per atom σ depends on scattering angle and temperature through the atomic form factor f and the Debye-Waller factor M^T:

$$\sigma = f^2[1 - \exp(-2M^{\mathrm{T}}s^2)] \qquad (8)$$

where s is the scattering angle, $M^{\mathrm{T}} = 8\pi^2 u_{\mathrm{T}}^2$, and u_{T}^2 is the mean-square thermal vibration amplitude of the atom (Hall and Hirsch, 1965). In the presence of static random atomic displacements, assuming a Gaussian distribution

of strain with a mean-square static displacement of u_s^2, the atomic scattering cross-section will be modified to (Hall et al., 1966)

$$\sigma^s = f^2\{1 - \exp[-2(M^T + M^S)s]\} \quad (9)$$

where $M^s = 8\pi u_s^2$. It is clear from the form of these expressions that both tend to the full atomic scattering cross-section $\sigma = f^2$ at a sufficiently high scattering angle. At lower angles where the Debye-Waller factor is significant, static strains comparable to the thermal vibration amplitude may lead to a significantly enhanced scattering cross-section. Figure 27 shows images of a thermally grown Si-SiO_2 interface. The bright-field phase-contrast image (Fig. 27A) shows dark contrast that could be due to a number of effects, such as strain, thickness variation, bending of the crystal, or a combination of these mechanisms. Figure 27B shows an incoherent dark-field image collected simultaneously using a low (25-mrad) inner radius for the annular detector. Now there is a bright band near the interface indicating additional scattering. With this image alone, this additional scattering could be due either to strain or to the presence of some heavy impurity atoms. However, when the inner detector angle is increased further, to 45 mrad, the bright line disappears (Fig. 27C), showing that the contrast cannot be due to the presence of heavy impurity atoms that would still give increased scattering. The contrast must therefore be due to a static strain effect. Intensity profiles across the two dark-field images are shown in Figure 28A. Taking their ratio normalizes the channeling effect of each column and gives the additional atomic displacement due to strain, as shown in Figure 28B (Duscher et al., 1998b). This is seen to decrease exponentially from the incoherent interface, as would be expected for a uniform array of misfit dislocations.

Strain effects are also commonly seen at grain boundaries and can be distinguished from true *Z* contrast in the same way, by comparing images at different detector
