

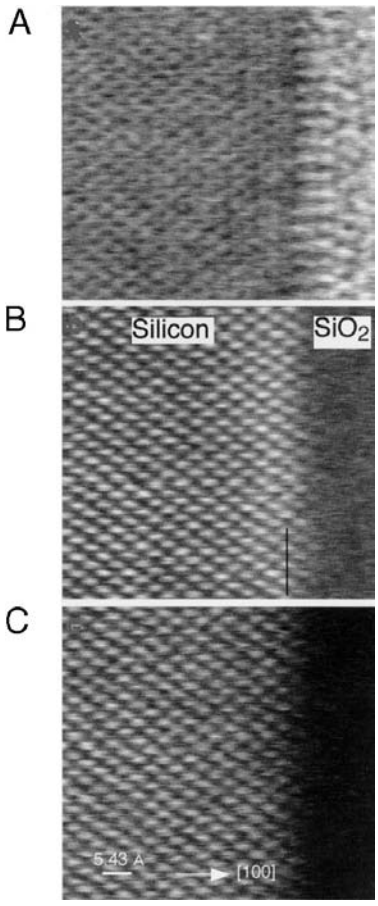

Figure 27. STEM images of a Si-SiO_2 interface: (**A**) bright-field phase-contrast image; (**B**) *Z*-contrast image with 25 mrad inner detector angle showing strain contrast. The vertical line marks the last Si plane used for strain profiling. (**C**) *Z*-contrast image with 45 mrad inner detector angle.

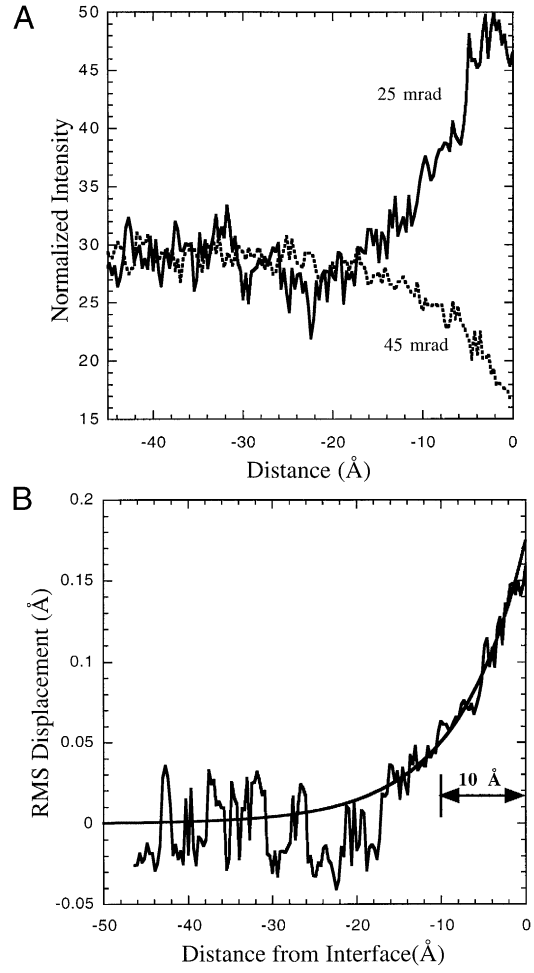

Figure 28. (**A**) Intensity profiles across the *Z*-contrast images of Figure 27. The high-angle profile shows the dechanneling effect near the interface, which can be used to normalize the profile obtained with a lower detector angle. (**B**) Root-mean-squared atomic displacement due to static strain induced by the Si-SiO_2 interface and an exponential decay fitted to the data. Profile ends at the vertical line shown in Figure 27.

angles. A strain effect will appear bright at low detector angles, changing to dark at high detector angles. True segregation of heavy impurities will appear bright at both detector angles.

SAMPLE PREPARATION

Specimen preparation requirements for STEM are essentially the same as for HREM—a similar sample thickness, but generally the thinner the better to avoid problems with projection. However, some differences are required for working with small probes. In particular, the crystal surface must be as free of damage as possible. Ion milling leaves a thin amorphous layer, which broadens the probe before it reaches the crystal surface below. As the resolution is directly determined by the probe size, this leads to loss of contrast and perhaps no atomic resolution at all, whereas it might hardly be noticed in a phase-contrast image. Low-voltage final milling is essential for STEM, and samples made by cleaving or chemical means will give the best results. Nevertheless, most of the images shown in this unit were obtained from samples that had been ion milled. The amorphous layer increases the intensity fluctuations between identical columns as the probe profile is affected by the randomly located atoms above each column.

SPECIMEN MODIFICATION

Damage is usually expected to be a major concern with the high brightness of a small probe, but it should be remembered that for a coherent probe at the electron optical limit, a high demagnification is used and probe currents are in the region of 10 to 100 pA, small compared with the nanoampere currents used typically in microanalysis. There is only one electron in the column at a time, and some excitations, such as electron-hole pairs, may have time to decay before the next electron arrives. For this reason, many damage processes have a threshold beam current, and generally damage by an atomic resolution probe is not a limiting factor for imaging. Nevertheless, when imaging grain boundaries, it is sometimes observed that the structure at the boundary becomes amorphous after a few scans (Maiti et al., 1999). In STEM, because the only area illuminated is that scanned by the beam, it is possible to "walk" the probe down the boundary, taking images from a fresh area each time. In EELS studies damage is a more serious concern, because of the longer exposure times needed for data collection and also because the light elements are the first to suffer displacement damage.

PROBLEMS

Perhaps the main problem with the *Z*-contrast technique has been the lack of available instruments except in selected centers. Now that dedicated instruments are no longer required and the technique is being incorporated into the conventional TEM column, it should see more widespread use.

Because the STEM instrument is serial, with data recorded pixel by pixel, those familiar with CTEM will find a number of differences. One difference is certainly the noisy appearance of the raw *Z*-contrast image, although the atomic positions can be determined through maximum-entropy analysis to an accuracy of ± 0.1 Å, comparable to that of the best conventional methods. Reconstructed images are less noisy, although the noise in the original data now appears as random displacements of the "noise free" atomic columns.

Sample drift also appears in a very different manner than in CTEM. Drift blurs the image in CTEM, whereas in STEM it distorts the image. One can view this as an advantage or disadvantage, but the result is that STEM images often show angular distortion or wavy atomic planes due to specimen drift. This makes it difficult to determine rigid shifts across grain boundaries by the usual methods. One would usually rotate the scan direction so that the fast scan is across the boundary, giving the best measurement of expansion or contraction. One can also compare images taken at different rotations.

Vacuum is a critical requirement for STEM studies, as hydrocarbons are attracted to the small probe and can build up rapidly during high-magnification viewing or analysis when the probe scans only a small area. Sometimes this problem can be alleviated by "flooding," irradiating the sample at the maximum available current by removing all apertures and reducing the demagnification. Obviously, besides polymerizing the hydrocarbons, this may also damage the sample. Usually the vacuum in modern instruments is sufficiently good that the specimen itself becomes the major source of carbon contamination. Use of oil-free specimen preparation techniques is useful, particularly if samples are sensitive to carbon, as in the case of the high-temperature superconductors. Plasma cleaning can be useful, or even a gentle bake in air using an oven or by placing the specimen on a light bulb can be very effective in eliminating contamination. Only those hydrocarbons that adsorb strongly to the sample at room temperature are a problem; lighter species evaporate in the vacuum while heavier species are immobile. Hence, only a moderate temperature is required.

ACKNOWLEDGMENTS

The author is grateful to their colleagues P. D. Nellist, D. E. Jesson, M. F. Chisholm, N. D. Browning, Y. Yan, Y. Xin, B. Rafferty, G. Duscher, and E. C. Dickey for research collaborations. This research was supported by Lockheed Martin Energy Research Corp., under Department of Energy Contract No. DE-AC05-96OR22464, and by appointments to the ORNL Postdoctoral Research Associates Program administered jointly by ORNL and ORISE.

APPENDIX A: INCOHERENT IMAGING OF WEAKLY SCATTERING OBJECTS

For a very thin specimen, effects of probe dispersion and absorption may be ignored, and the scattered amplitude y_s in the direction $\mathbf{K}_f$ is obtained immediately from the first Born approximation (Pennycook et al., 1997),

$$\psi_s(\mathbf{K}_f) = \frac{m}{2\pi\hbar^2}\int e^{-i\mathbf{K}_f\bullet\mathbf{R}}V(\mathbf{R})P(\mathbf{R}-\mathbf{R_0})d\mathbf{R} \qquad (10)$$

where $V(\mathbf{R})$ is the specimen potential integrated along the beam direction, called the projected potential. Integrating the scattered intensity $|\psi_s|^2$ over all final states $\mathbf{K}_f$ and using the identity

$$\int e^{-i\mathbf{K}_f\bullet(\mathbf{R}-\mathbf{R}')}d\mathbf{K}_f = (2\pi)^2\delta(\mathbf{R}-\mathbf{R}') \qquad (11)$$

the total scattered intensity is given as

$$I(\mathbf{R_0}) = \int O(\mathbf{R})P^2(\mathbf{R}-\mathbf{R_0})d\mathbf{R} \qquad (12)$$

$$= O(\mathbf{R}) * P^2(\mathbf{R}_0) \qquad (13)$$

a convolution of the probe intensity profile $P^2(\mathbf{R})$ with an object function $O(\mathbf{R})$ given by

$$O(\mathbf{R}) = \left(\frac{\chi}{2E}\right)^2 V^2(\mathbf{R}) \qquad (14)$$

where $\sigma = \chi/2E$ is the interaction constant and E is the beam energy. Therefore, provided *all* scattered electrons could be collected, we see immediately that incoherent imaging would be obtained with a resolution controlled by the incident probe intensity profile.

For many years it was considered that incoherent imaging at atomic resolution was impossible in principle because much of the total scattered intensity occurs at small angles, in the same angular range as the unscattered beam (e.g., Ade, 1977). There is no way to distinguish unscattered electrons from elastically scattered electrons, which was referred to as the hole-in-the-detector problem. However, realizing that the Rayleigh bright-field detector is equivalent to the annular dark-field detector in Figure 5, it is clear that the problem does not arise in the dark-field case and perfect incoherent imaging may be achieved.

APPENDIX B: STEM MANUFACTURERS

Dedicated STEM Instruments

Conventional phase-contrast and diffraction contrast modes are available, but all images are recorded in the scanning mode. Instruments have cold field emission guns and are typically equipped with EELS and x-ray analysis capabilities.

VG Microscopes: No longer commercially available, but often can be found in user centers. The entire microscope is bakeable, resulting in a clean vacuum.

Hitachi: http://www.hii.hitachi.com/prdem.htm

TEM/STEM Instruments

JEOL: http://www.jeol.com/navbar/tembar.html

Hitachi: http://www.hii.hitachi.com/prdem.htm

Philips: http://www.feic.com/tecnai/main.htm

The Philips and JEOL instruments have a Schottky source. Hitachi instruments have a cold field emission source. Note that manufacturers specify resolution in different ways. The best comparison is to find the objective lens spherical aberration coefficient and use the definitions of resolution given in Table 1.

SCANNING TUNNELING MICROSCOPY

INTRODUCTION

Scanning tunneling microscopy (STM) is a technique for the determination of the structure of surfaces, with spatial resolution on the angstrom scale. In an oversimplified description, STM allows imaging of the surface of conductive materials down to the atomic level.

The technique is based on the measurement and control of the current of electrons tunneling between a sharp stylus (hereafter called the tip) and the sample surface. During imaging, the tip is separated a few angstroms (3 to 10 Å) from the surface, while it is being rastered with the help of piezoelectric transducers. The area scanned is tens to thousands of angstroms on a side. STM has the advantage over other microscopies that its operation does not require any special environmental conditions. Imaging can be performed in vacuum, at high pressures (including air), and in liquids. The choice of the environment is determined mostly by the requirements of the sample and its surface condition.

Acquisition of STM images is relatively simple with modern instruments. Most of the experimental time is spent on sample preparation and tip conditioning in the appropriate environment (ultrahigh vacuum, electrochemical cell, or controlled atmosphere). Tip conditioning and noise reduction can sometimes add considerable time, depending on factors such as the nature of the experiment and reactivity of the sample. This time depends also on the type of information being sought. A medium-resolution (0.5 to 1 Å in z, i.e., normal to the surface) large-area image of a few hundred angstroms is relatively easy to obtain. In such a case, however, similar information can be obtained with atomic force microscopy (AFM), which is easier to use. It is in the atomic-resolution area that STM excels over any other surface microscopy, because atom-to-atom corrugations <0.5 Å—and sometimes <0.1 Å, as in the case of close-packed metal surfaces—need to be resolved. Therefore, the requirements for both instrument and sample preparation are substantially more stringent.

STM was discovered at the beginning of the 1980s and has since experienced an explosive development in both instrumentation and applications (Olgetree and Salmeron, 1990; Wiesendanger, 1994). It has given rise to numerous related techniques generally referred to as scanning probe microscopies (SPM). The most popular of these is AFM. The related technique known as scanning electrochemical microscopy is covered in detail elsewhere (SCANNING ELECTROCHEMICAL MICROSCOPY).

In considering the ultimate resolution obtainable with the STM, it is important to consider the role of tip geometry. The schematic drawing at the bottom of Figure 1 illustrates the basic point: on flat parts of the sample, where one tip atom is responsible for the tunneling, STM reaches its maximum performance. On rough surfaces, however, the tunneling point on the tip apex changes as it moves over sharp corners and changing slopes. The image is then a convolution of the tip and surface shapes, and the final resolution is determined by the tip radius and profile. STM is thus not the best technique to probe, for example, highly corrugated surfaces, deep-patterned surfaces, or powdered and porous materials.

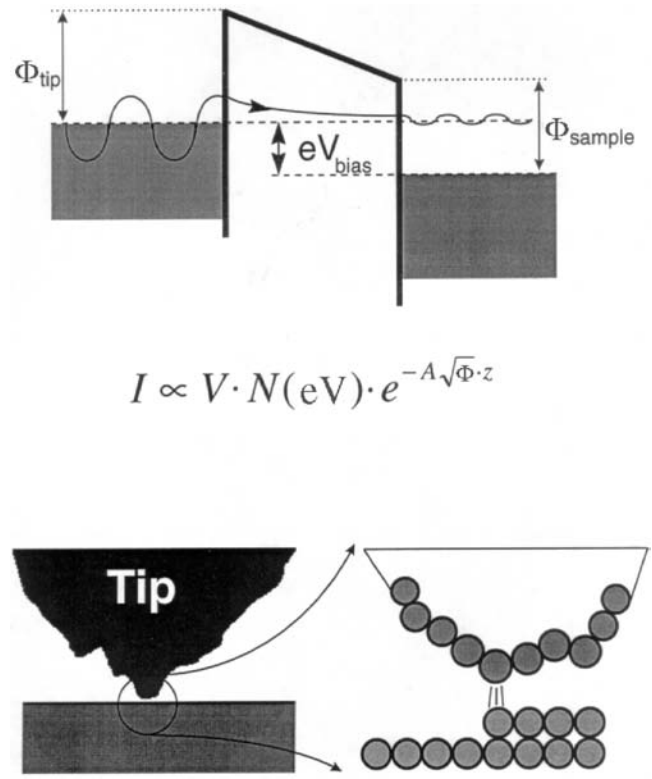

Figure 1. Top: Schematic energy diagram of the tip and sample in an STM experiment. Electrons tunnel from the negatively-biased tip (left) to the sample (right). Only the electrons within the eV range of states in the tip participate in the tunneling. The tunnel barrier is related to the work function Φ of the material involved. Bottom: Schematic of the shape of a tip near a flat surface. At the atomic scale shown on the right, the most protruding atom concentrates the tunnel current. Secondary images can be obtained if another protruding atom can enter within tunneling range in surface irregularities.

Complementary and Competitive Techniques

Atomic force microscopy (AFM) is a technique that has many characteristics in common with STM, although the physical processes involved are quite different. In AFM, there is also a sharp tip but it is mounted on a very flexible cantilever. As in the STM, it is rastered over the surface by means of piezoelectric transducers. Tip-surface interaction forces are sensed in AFM by the deflection of the lever, instead of the tunneling current. AFM is therefore ideal for studies of insulating materials that are not directly accessible to STM imaging.

The resolution of AFM in its most usual operation modes (contact, friction, or tapping) is not truly atomic, as is the case with STM. The forces of interaction produce a contact spot that is several tens of angstroms in diameter, depending on the applied load. Thus atomic-size point defects are not observed in AFM. However, new non-contact imaging techniques using resonant-lever modulation are being developed, and true atomic resolution, i.e., the visualization of point defects, has been demonstrated (Giessibl, 1995; Kitamura and Iwatsuki, 1995; Sugawara et al., 1995). These developments should be incorporated in commercial instruments soon.

Because contact with the (inert) tip is part of the standard operation of the AFM, the technique is less sensitive to chemical instabilities, and to some forms of mechanical vibration noise, than STM. For the routine examination of samples with a resolution of a few nanometers in x-y and angstroms in z, AFM is clearly advantageous over STM.

Electrons in the far field regime, as opposed to tunneling in the near field, are used in transmission electron microscopy (TEM) to provide angstrom-resolved projections of bulk atomic rows in crystalline samples (see SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING). TEM has been used on several occasions in an edge-on configuration to resolve surface atomic features. The sample requirements for TEM are quite strict, as samples must be thinned down to a few hundred angstroms to allow transmission of the electron beam. TEM is excellent, for example, for use in studies of bulk phases of crystalline

Table 1. Comparison of Various Microscopies

Technique[a]	Probe/Principle	Environment	Sample Requirements	Resolution (Å)	
				xy	z
STM	Electron tunneling	Air, vacuum, liquid	Flat, conductor	~1–2	$\sim 10^{-2}$
AFM	Forces: attractive, repulsive contact, noncontact	Air, vacuum, liquid	Flat, insulator, conductor	~10	0.1
TEM	Electron transmission	High vacuum	Solid, ~100 Å thin	~2	—
SEM	Secondary electrons	High vacuum	Solid, conductive	20	—
SAM	Auger emission	Ultrahigh vacuum	Conductive	100	—
SIMS	Ion sputtering	Ultrahigh vacuum	Most samples	1000	—

[a]Abbreviations: STM, scanning tunneling microscopy; AFM, atomic force microscopy; TEM, transmission electron microscopy; SEM, scanning electron microscopy; SAM, scanning Auger microscopy; SIMS, scanning secondary ion mass spectroscopy.

precipitates, in metallurgy or in small particles supported on amorphous or crystalline materials. It is also used extensively in studies of biomaterials supported on carbon films. A thin coating (~50 Å) of heavy metal is usually necessary to provide contrast.

Scanning electron microscopy (SEM) is based on the measurement of the secondary electron yield of conductive substrates (see SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING). This yield changes both as a function of composition and local surface slope. The spatial resolution of SEM is determined by the spot size of the electron beam (~20 Å in the best instruments), and by the diffusion of the secondary electrons before exiting the sample. The SEM operates in vacuum and the best results are obtained with conductive substrates. Combined with x-ray emission detection for elemental composition determination, it is a powerful technique for material studies.

At lower resolutions, a number of other techniques should be considered: scanning Auger microscopy (SAM; see AUGER ELECTRON SPECTROSCOPY), scanning secondary ion mass spectroscopy (SIMS), and small-spot x-ray photoelectron spectroscopy (XPS). These techniques offer the great advantage of spectroscopic information in addition to imaging. Table 1 is a compendium of several commonly used techniques for real-space imaging.

PRINCIPLES OF THE METHOD

A schematic view of the operation of the STM is shown in Figure 1. On top is an energy diagram of the sample and tip. The wavefunction of a tunneling electron is represented by the wavy lines inside the solids connected by a decaying line in the intervening gap. The negative bias applied to the tip causes a net flow of electrons to the sample. The electrons leave occupied levels in an energy band of width eV between the Fermi levels of tip and surface, with V being the bias voltage, and tunnel through the potential barrier separating the two materials to occupy empty levels at the sample side. The reverse situation occurs if the bias is positive. Both the height of the tunneling barrier and the separation between the two surfaces enter into the exponential dependence of the current

$$I \propto V \cdot N(\mathrm{eV}) \cdot e^{-A\sqrt{\Phi}\cdot z} \tag{1}$$

where A is a number of order 1 with units $(\mathrm{eV})^{-1/2}$ Å^{-1}, Φ the tunneling barrier height in eV and z the separation in Å. The strong z dependence of I is at the origin of the very high z-distance resolution of the STM. In properly designed microscopes, where the noise level is determined by the Johnson noise of the preamplifier gain resistance, the z resolution can be 1/1000 Å. The in-plane resolution is determined, as illustrated at the bottom of Figure 1, by the atomic arrangement at the tip apex. In the optimal case of a single-atom-terminated tip, it is the electronic "size" of this atom (~1 to 2 Å) that determines the x-y resolution. The nature of the tip (geometry and chemical composition) is paramount in determining the quality of the images. Except in special cases, the nature of the tip is unknown, and the operation of the STM to date is still subject to some degree of empiricism. This empiricism is the art of tip preparation, for which no well-proven recipes exist yet. In practice, however, atomically resolved images are often obtained due to the exponential dependence of I on z, which naturally selects the most protruding atom as the imaging element.

Equation 1 is the well-known quantum mechanical result that relates the tunneling probability of electrons through a one-dimensional potential energy barrier of width z (the tip-sample separation) and height Φ. The value of Φ is related to the work functions of the tip and sample materials and is due to the overlap of the potential energy curves of the electrons beyond the surface atoms. Its value is therefore on the order of a few electron volts.

Typical values of I, V, z and Φ are $I = \sim 1$ nA, $V = \sim 10$ mV to 3 V, $z = \sim 5$ to 15 Å, and $\Phi = \sim 4$ to 5 eV. Equation 1 is valid in the limit of low applied voltages ($V \ll \Phi$), and so it can be viewed as the relation between bias current and gap resistance R. The value of R is the most practical way to characterize the tunneling gap, since it can be directly measured ($R = V/I$).

STM images are typically acquired in a wide range of R values, from MΩ to GΩ and even TΩ. To put the value of R in perspective, it should be compared with the quantum resistance unit $2e^2/h$, which is 12.9 kΩ and observed in single-atom contacts. Between this value and a few tens of MΩs, the risk of strong tip-surface interactions, leading to such problems as sample indentation or tip and surface modifications through atom transfer, is considerable. In surfaces that have low chemical activity or that are covered with passivating layers, contact imaging is sometimes possible in a friction-like regime without permanent modification of the tip. This type of imaging, usually by interposed atoms or molecules between the tip and surface, is not uncommon, even if often not explicitly known to many experimenters.

A clear signature of contact STM imaging is the value of the barrier height Φ, obtained in I versus z measurements. In these, the tip is advanced toward or away from the surface while the current I is measured. The slope of log I versus z should be ~ 2 Å^{-1}, corresponding to a value of $\Phi = \sim 4-5$ eV for clean, true tunneling gaps. This corresponds to a change of about one decade of current per angstrom. Values in the range of a few tenths of an electron volt and below are signatures of "contact" imaging. An example of these two situations is shown in Figure 2, which corresponds to a nominally clean Pt tip and a Pd substrate (Behler et al., 1997a). The explanation for the low barrier height is the elastic deformation of tip and sample due to the contact forces through interposed material in the gap. Because of these elastic deformations, the change in gap width is always less than the change in tip or sample position calculated from the voltages applied to the piezo transducers.

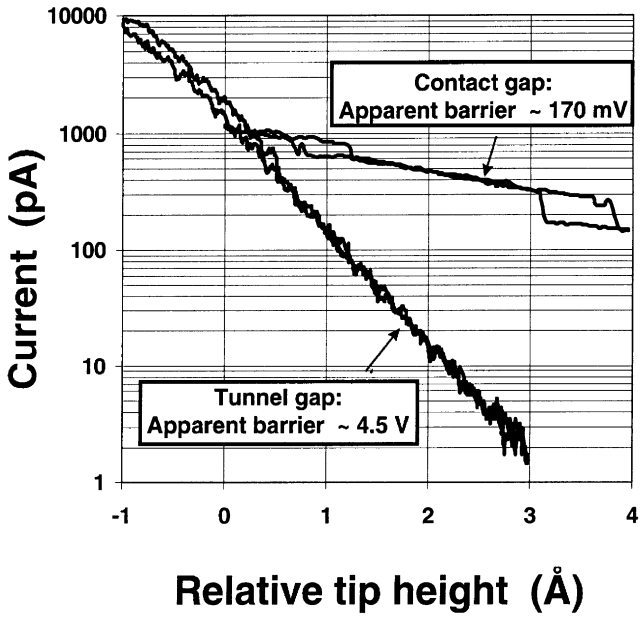

Figure 2. Current versus distance for a tunneling junction of a Pt tip on a Pd(111) crystal surface in ultrahigh vacuum. A true vacuum tunneling produces a change of current of roughly a decade per Å, and corresponds to an apparent barrier height of 4.5 eV. A contact gap, characteristic of dirty junctions, gives a much smaller current decay and apparent barrier heights of less than 1 eV. From Behler et al. (1997a).

The discussion below (see Data Analysis and Initial Interpretation) contains additional information on the physical nature of the tunneling process and its relation to the actual image contrast.

PRACTICAL ASPECTS OF THE METHOD

Acquisition of STM Images

As mentioned above, the tip (or sample) scans over areas that range from a few Å to several μm in x and y, while an electronic feedback control keeps the tunnel current constant. The acquisition of images is done electronically by means of computers interfaced with an STM controller using data conversion cards. The number of data points is variable, but 128×128, 512×512, or 1024×1024 pixels per image are common. On each pixel, the value of z is stored as a 12- or 16-bit number. The resulting data files are 200 kb to 1 Mb in size.

Many variant modes of operation are used, depending on the experiment. Besides the "topographic" mode in which $z(x,y)$ profiles are acquired at constant I, one can also acquire $I(x,y)$ profiles at constant z. The latter is the so-called "current" mode and is useful in fast scanning of atomically flat surfaces. Here the feedback control response time is slow relative to the scanning time, so that only the average value of I is kept constant.

More specialized operation modes include multiple bias imaging, in which interlaced curves at different preset values of V are acquired, and the current image tunneling spectroscopy (CITS) mode, in which the current corresponding to a few selected V values is collected at each pixel during a brief interruption of the feedback control (Hamers, 1992). These two imaging modes have been used principally in investigations of semiconductor surfaces. At selected points of the surface, complete $I(V)$ curves can be obtained for a more detailed study of the band structure (Feenstra et al., 1987). This type of experiment is fraught with difficulties, however, since at the interesting voltages (those of a few volts) that are necessary to access states in the conduction and valence bands, the strong electric field at the tip can easily modify its structure, making reproducibility problematic in many cases. The large information content of the images acquired in these modes can only be displayed in multiple images (one for each value of V) or by post-analysis of the $I(V)$ curves to extract the density-of-states information.

Types of Materials and Problems

The study of semiconductor surfaces is one area where STM has been applied most intensely. Once clean and well-prepared, semiconductor surfaces are relatively easy to image. Large surface reconstructions occur in many of these materials, due to the strong directionality of the tetrahedral covalent bonds, coupled with the tendency to minimize the number of broken bonds. This produces rather large corrugations, from 0.2 to 1 Å in z, and relatively large unit cells in the x-y plane, which makes it

possible to obtain good atomic resolution images even in instruments with modest stability performance. In addition, semiconductor surfaces tend to be less reactive than metals.

Metal surfaces are another important class of materials studied with STM. The applications include surface chemistry, i.e., the study of chemisorbed structures, and electrochemistry. These topics are covered in detail in many recent reviews (Ogletree and Salmeron, 1990). Here we will comment only on some peculiarities in imaging these materials, which should be kept in mind when considering and planning an STM experiment. The most important characteristic of metal surfaces is that their corrugation is substantially smaller than that of semiconductors. This is due to the delocalized nature of the metallic bond. The conduction electrons that are responsible for the tunneling signal are spread over the unit cell, rather than spatially concentrated in covalent bonds. The resulting electronic corrugation is always small, particularly in the close-packed surfaces—i.e., the (111) planes of fcc metals, the (110) planes in bcc metals, and (0001) or basal planes in hcp metals, which are also the most widely studied because of their stability. Corrugations ranging from 0.01 to 0.2 Å are typical. The more open surfaces tend to have more corrugation and are then easier to resolve atomically.

Adsorbates can change the corrugation substantially, since in many cases they give rise to localized, covalent-type bonds. The apparent height of isolated atoms or molecules can vary from a few tenths of an angstrom to several angstroms. Imaging of isolated adsorbates, however, is not an easy task even for strongly bound elements. The reason is the high diffusion rate, at room temperature, of the adatoms. For example, the binding energy of sulfur on Re is very high, ~4.5 eV for the (0001) plane (Dunphy et al., 1993). However, its diffusion energy barrier is ~0.7 eV, which implies a residence time of 100 ms on a site at room temperature. Thus, during scanning, the S adatoms are changing positions continuously, making imaging problematic. More weakly bound adsorbates, e.g., CO molecules, might therefore appear invisible in the STM images because of rapid diffusion. In all these situations, sample cooling is necessary, sometimes to very low temperatures. The pioneering work of Eigler and his collaborators demonstrated the great advantages of low temperature STM for fundamental studies (Eigler and Schweizer, 1990; Zeppenfeld et al., 1992; Heller et al., 1994). As a result, the design and construction of cryogenic STMs has recently increased.

Imaging while the sample is at high temperature imposes strict demands on the design of the microscope head, because of large thermal drifts (Curtis et al., 1997; Kuipers et al., 1993; Kuipers et al., 1995). In vacuum, good shielding, together with careful choice of construction materials with the appropriate expansion coefficients, have made it possible to obtain images up to several hundreds of degrees Celsius (McIntyre et al., 1993). Under high pressures (a few torr to several atmospheres), convection in the gas phase adds to the problem of thermal drifts, and limitations in the highest temperatures are to be expected.

Similar considerations apply to metals in an electrochemical cell, although heating and cooling of the sample is not feasible except in a very narrow temperature window. Therefore, imaging of diluted or isolated adsorbates is difficult or impossible.

Oxides tend to be insulating, and therefore the surfaces of bulk oxide materials cannot be easily imaged by STM. Exceptions include the cases of small bandgap oxides and of oxides that can be made conductive by defect doping. Such is the case for TiO_2 (Rohrer et al., 1990; Onishi and Iwasawa, 1994; Sander and Engel, 1994; Murray et al., 1995), UO_2 (Castell et al., 1996), Fe_3O_4 (Jansen et al., 1996), and others. Nonconductive oxides, in the form of very thin layers, have also been studied by deposition or growth onto metal substrates.

Biological material can, in principle, be imaged with STM. However, the normally poor electrical conductivity of these materials, and the need to adsorb them on flat conductive substrates, impose severe constrictions. As a result, today these materials are preferentially studied with AFM techniques.

Other applications of STM include the study of epitaxial growth of metals and oxides on metals and the mapping of superconducting and normal-conducting areas in superconductors by using a bias voltage above or below the superconducting gap (Hess et al., 1989; Hess et al., 1990a,b). Recently, there has been increasing use of STM as a microfabrication (Quate, 1989) or atomic manipulation tool (Eigler and Schweizer, 1990; Stipe et al., 1997; Bartels et al., 1998).

METHOD AUTOMATION

A major component of any STM instrument is the software for data acquisition and analysis. With the help of such software, color-coded, picture-like graphic displays of the images can be produced. Top views, as well as three-dimensional representations, including artificial light shading, are commonly used to enhance contrast, as in the example of Figure 3. The selection of the color or gray-scale mapping is arbitrary and left to the subjective taste of the operator. Image processing features (e.g., smoothing, filtering, and flattening) are common, as well as analysis capabilities for extracting cursor profiles along selected paths over the image. Other features included in most software packages are Fourier analysis and height histograms, among others. Today's sophisticated programs have rendered the task of analysis and data display relatively easy, and have made possible the beautiful images of atomic-surface landscapes (see the examples in Figure 3) that are currently produced in many STM laboratories.

Complete automation of an STM experiment is not common for either commercial or home-made instruments. The nature of the STM experiment itself is not easily conducive to automation. This is because the atomic structure of the surfaces under study is a delicate function of preparation and environmental conditions. Exceptions are the most chemically inert surfaces such as graphite, MoS_2, and others of limited intrinsic interest, except

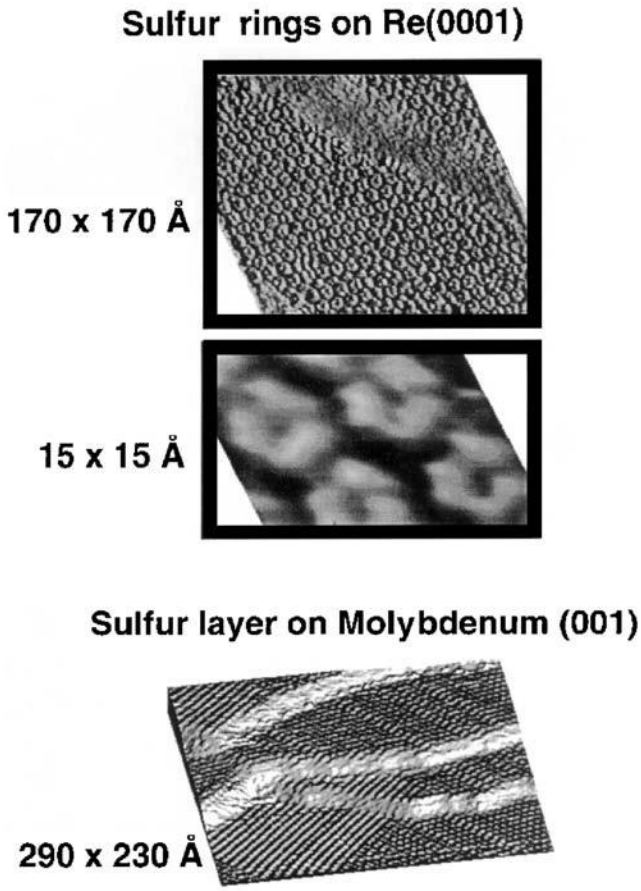

Figure 3. Examples of STM images obtained in vacuum. The top image was obtained on a Re(0001) surface covered by a saturation layer of sulfur. Sulfur is seen forming nearly hexagonal rings. Notice the blurred area corresponding to a monoatomic step. The radius of the tip determines the resolution in this case. The middle image shows a magnified view of the atomic arrangement. The bottom image was obtained on a Mo(001) surface, again with a saturation layer of sulfur. Sulfur atoms are seen forming two domains at a 90°angle. Steps 2-, 3- and 4-atoms high separate the terraces.

when used as substrates for other adsorbed material. Thus, it is not possible in general to simply insert a sample into a sample holder and have the instrument position the sample and acquire atomically resolved images. The approach of the tip from a large distance (centimeters or millimeters) down to a few angstroms from the surface is risky and often accompanied by some instability when nearing the "in range" or tunneling position that leads to atom exchanges and tip or surface modification. STM is thus an operator-intensive technique, as it requires considerable experience and exercise of scientific judgment for its successful realization.

DATA ANALYSIS AND INITIAL INTERPRETATION

The fundamental question in image interpretation is, of course, the relation between the measured topography, i.e., the $z(x,y)$ profile and the actual "height" or position of the atomic features. Contrast and symmetry are largely determined by the bonding orbitals of the atoms or molecules being imaged, and by the chemical nature of the tip termination. In its simplest interpretation, the $z(x,y)$ profile corresponds to the electronic corrugation of the surface at a constant integrated density of states between the Fermi levels of the tip and sample (see diagram in Figure 1). The latent capability of the STM to provide both topographic and electronic maps of the surface cannot therefore be fully realized without a theory of the tunneling process.

While an exact theory does not yet exist, several approximations have been useful in interpreting the images. The first one came from Tersoff and Hamann (1985), who assumed no interaction between the tip and surface. The tunneling current in this model, for a tip with electron states of s symmetry, is proportional to the density of states near the Fermi edge at the position of the tip center (considered to be terminated in a sphere). Other theoretical treatments have also been developed and can be found in recent reviews (Güntherodt and Wiesendanger, 1993). A recent one, called electron scattering quantum chemistry (ESQC), deserves special mention because of its relative simplicity and good results (Sautet and Joachim, 1988; Cerda et al., 1997). It is based on the combination of an exact treatment of the electron transport through the tunneling gap with approximate quantum chemistry methods (e.g., extended Hückel) to calculate the Hamiltonian matrix elements. It does not require the neglect of tip-surface interactions, and the structure of the tip is explicitly taken into account in the calculation of the image. It has been used in chemisorbed systems with remarkable success.

The strong electronic contribution to the image contrast sometimes gives rise to counterintuitive observations. For example, O atoms are usually imaged as holes (lower

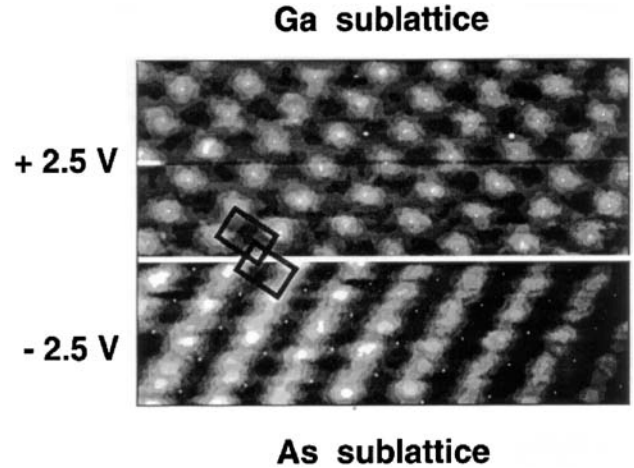

Figure 4. STM image of the cleavage face of an n-type GaAs sample. The bias applied to the sample was switched from $+2.5$ to -2.5 V near the center of the image. At positive bias, electrons tunnel from the tip states to empty states of the GaAs. These states are due to empty Ga dangling bonds, which have a lobe localized nearly atop the Ga atoms. At negative bias, electrons leave As dangling bonds, which are also localized near the As atoms. The two images represent the sublattices of these two atoms, which are offset in the manner indicated by the two boxes representing the surface unit cell.

tunneling probability) rather than protrusions (Kopatzki and Behm, 1991; Wintterlin et al., 1988; Sautet, 1997). Interference, when the tip overlaps several adsorbate atoms, can give rise to strong effects. These effects are manifested sometimes in a contrast distribution inside the unit cell that does not reflect the number of maxima expected from the atomic composition. For example, S on Mo(001) forms a c(2×4) structure, with 3 S atoms in the unit cell and yet, only one maximum is observed in the images (see Fig. 3), giving the apparent impression that only one S atom is present (Sautet et al., 1996).

Electronic effects in the STM images are particularly strong for semiconductor surfaces, due to the existence in these materials of energy gaps and surface states close to the Fermi level that are filled or empty. This is the case of GaAs(110), for example, where a filled dangling bond located on the As atom is imaged at negative sample bias while an empty dangling bond, located at the Ga atom position, is imaged at the opposite polarity (Feenstra and Stroscio, 1987). This is shown in Figure 4.

SAMPLE PREPARATION

The preparation of samples for STM is not different from that in other microscopies. In UHV-STM (ultrahigh vacuum STM), samples are prepared following well established surface-science methods. These include such techniques as sputtering, annealing, characterization by Auger electron spectroscopy (AES; see AUGER ELECTRON SPECTROSCOPY), or low-energy electron diffraction (LEED; see LOW-ENERGY ELECTRON DIFFRACTION), whenever appropriate. Air or high-pressure environments require special procedures, sometimes in combination with sample preparation in environmental chambers. In electrochemical cells equipped with STM, cleaning is part of the oxidation-reduction cycles and can be tested by well-established electrochemical voltammograms (see SCANNING ELECTROCHEMICAL MICROSCOPY).

It is the preparation of tips that is a distinct procedure of STM. Ideally single-atom-terminated tips are desired. However, short of performing field ion microscopy examination prior to or after imaging, no technique or procedure has been developed that meets universal standards of characterization. Tip preparation is thus, regrettably, a technique that is still largely empirical and varies from laboratory to laboratory.

The most widely used tip materials are W and Pt. The first is easily prepared using electrochemical etching methods with alkaline solutions (KOH or NaOH) to thin, cut, and sharpen a wire. Tips with radii from a few tens to a few hundreds of angstroms can thus be produced. If the wire is a single crystal of (111) orientation, single-atom-terminated tips of defined structure can, in principle, be prepared (Kuk, 1992). Pt alloyed with Ir or Rh is also a popular tip material. Such Pt alloys might be preferable in applications with reactive atmospheres and in air, where W tips can oxidize and more easily produce insulating layers. Pt tips can be prepared by electrochemical etching using molten ($\sim$300°C) mixtures of 3:1 $NaNO_3$:NaCl as the electrolyte bath. The sharpened tips usually are subjected to additional conditioning in vacuum, through heating by resistive or electron-beam methods and/or electron field emission on a sacrificial substrate. The purpose of these final treatments is to remove contaminant layers that can diffuse to the tip apex during imaging.

Unfortunately, even these procedures are no guarantee of a "good" tip, which is defined as one that produces stable, well resolved images. Deterioration and accidental changes occur by brief contacts (induced by vibrational noise) with the sample, by capture of contaminant atoms or molecules that form unstable bonds with the tip, and by loss of material. The cleaner and better controlled the sample and environment, the higher is the success rate of tip preparation and utilization. Often, lost performance can be restored by application of voltage pulses to the tip (>1 to 2 V), or by intentional contact with the sample. In the end, as previously pointed out, tip preparation is still an empirical procedure in most STM operations, and performance is decided in a somewhat subjective manner by the operator. For example, tips may be considered "good" and one-atom terminated when sharp and stable images with symmetric "atoms" are obtained. Satisfaction of that criterion, however, does not guarantee that "good" images acquired with different single-atom-terminated tips will have reproducible heights of the atoms, with z variations of a few tenths of an angstrom possible.

PROBLEMS

The immediate signature of a defective STM is the observation of an unstable tunneling gap. This is visible in the high noise level in the z height or the tunneling current signals. The cause may vary from the trivial—such as broken wires, cracked piezos, depolarization, or poor mechanical isolation between head and/or sample and the rest of the apparatus—to the more subtle and problematic, related to uncontrolled chemical processes occurring at the tip or sample. The tunneling gap, which must be stable within a small fraction of an angstrom, is subject to several instabilities. These instabilities can excite mechanical resonances in the head and sample support, which in turn can introduce a phase change in the feedback response. When this change becomes larger than 90°, positive feedback occurs and the tip oscillation is then driven instead of suppressed by the electronic control.

A chemically unstable gap can occur as a result of the continuous transfer of atoms or molecules at the surface or at the tip apex in dirty samples or tips. Sample and tip cleaning, as well as improvement of the environmental conditions, are then in order.

An excellent test of gap stability and a good troubleshooting exercise that should be common practice with students and technicians using STM is the analysis of the harmonic content of the current signal. This analysis gives a good deal of information about the sources and origin of the noise. It is performed by the application of fast Fourier transform (FFT) techniques, which are (or should be) a common feature of most data acquisition and software systems. The feedback control signal (usually the z height, in the form of a voltage applied to the z piezo scanner) can also be analyzed in this way, but it responds only within the frequency range of the feedback bandwidth, which is

rather small. Thus, at low gain, the z response of an unstable gap has the appearance of a saw tooth—the large error signal charges the feedback capacitor in the integrator at a nearly linear rate until saturation. At high gain, the feedback control–gap circuit can enter into resonance and cause the tip to oscillate against the surface. If the frequency of the offending noise is within the feedback bandwidth, the gain can be adjusted to suppress the noise in either z or I, but not both, since this does not solve the problem.

The best way to analyze the noise is to look at the FFT of the tunnel current, with the feedback at low gain or disabled. A clean, stable and well behaved gap should show no peaks in the crucial region of 1 to 500 Hz, since this is the region covered by the feedback response time and is also the region of typical scanning frequencies. An example of FFT analysis is shown in Figure 5, obtained with a beetle-type STM head developed by Besocke and Wolf (Frohn et al., 1989). This head consists of three piezo tubes attached perpendicularly to a disk, forming an equilateral triangle. The free end of each of these piezos moves when voltages are applied, allowing it to displace and rotate. A fourth piezo tube, at the center of the disk, supports the tip and can be used for scanning. The top curve corresponds to a noisy gap, with a z noise of a few angstroms, and is due to a loose sample holder. Loose parts tend to enhance the noise in the low-frequency region, below a few tens of hertz. Other poor conditions can derive from such factors as wires touching the chamber or a cracked piezo. The bottom curve shows the FFT of the same head after fastening all the parts that were loose. Peaks at the frequency of the power line (60 Hz or 50 Hz) are due mostly to ground loops and can be eliminated. The FFT spectrum will also show high frequency peaks due to the natural resonances of the STM scanner head, which should be greater than 1 kHz (the higher the better.) In the example of Figure 5, they are above 4.5 kHz. There are several studies published about this subject that the reader can consult for additional details (Behler et al., 1997b).

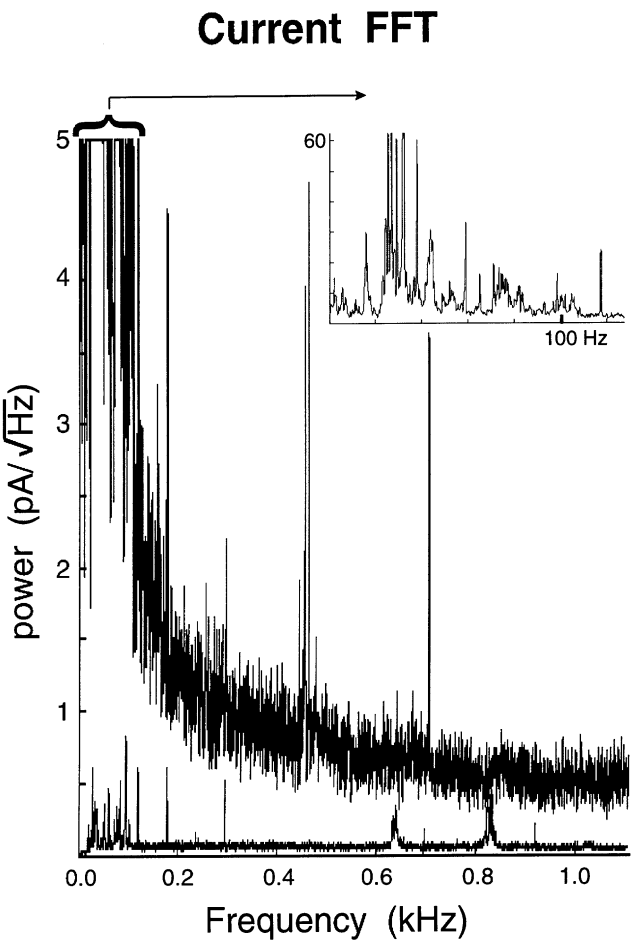

Figure 5. Example of Fourier transform analysis of the tunneling current for a beetle-type STM tip. The top curve was obtained in a highly noisy situation. In this case, the noise was due to the loose condition of the sample holder. Low-frequency noise is dominant, in the region 0 to 50 Hz (see top right inset). This noise couples strongly with the scanning rate at similar frequencies. Rattling of the entire head, which is simply resting on the sample holder in this design, is also excited and produces the peaks at ~500 and ~700 Hz. The spectrum below this was obtained after tightly securing the sample holder. The overall noise decreased by almost 3 orders of magnitude.

LOW-ENERGY ELECTRON DIFFRACTION

INTRODUCTION

Low-energy electron diffraction (LEED) is a powerful method for determining the geometric structure of solid surfaces. The phenomenon was first observed by Davisson and Germer in 1927 and provided the earliest direct experimental proof of the wavelike properties of electrons. LEED has since evolved into one of the most powerful and widespread tools of the surface scientist. It is similar to x-ray diffraction (XRD) in the type of information that it provides, and XRD will be frequently referred to for analogy throughout this unit. The most obvious difference is that a beam of electrons, rather than x rays, is used. Since electrons have a mean free path (or attenuation length) measured in angstroms (Å) as opposed to microns (μ) for x rays, LEED is particularly sensitive to surface geometry.

LEED is a structural technique that can provide essentially two levels of information. In both cases, it is most commonly used to determine the structure of a solid surface when the bulk structure of the material is already known by other means (e.g., XRD). It is possible, and indeed straightforwardly simple, to use LEED to determine both the absolute dimensions of the surface unit cell and the unit cell symmetry. One can easily deduce that, for example, a surface has a two-dimensional (2D) unit cell twice as large as that of the bulk; this often allows a reasonable guess at the true structure. Sometimes it is sufficient to know that a particular phase is present without knowing the details of the structure. For example, the (2×4) reconstruction of GaAs (nomenclature explained below) has been found to be optimal for device growth (Farrow, 1995). Determination of the exact atomic positions is more difficult, but quantitative experiments can elucidate this second level of information. Sophisticated calculations, generally run on a workstation, can provide atomic coordinates with a typical precision of ± 0.05 Å, which is generally more than adequate to determine the adsorption site of a molecule or the atomic positions in a reconstructed surface.

Many different surfaces can be examined by LEED, and their terminology must be understood. We assume familiarity with the basic crystal structures [face-centered cubic (fcc), zincblende, etc.]. A particular crystal face is specified by its Miller indices. These are of the form (hkl), and the ideal bulk termination can be determined in the following way: place one corner of the unit cell at the origin of a Cartesian coordinate system and construct a plane that intersects the axes at the reciprocal of the respective Miller index (see SYMMETRY IN CRYSTALLOGRAPHY). In the general case, this plane would pass through the points $(1/h, 0, 0)$, $(0, 1/k, 0)$, and $(0, 0, 1/l)$. A Miller index of zero indicates that the plane is parallel to that axis. Further examples can be found in any solid-state textbook (e.g., Ashcroft and Mermin, 1976; Kittel, 1986). It is conceptually useful to regard a surface as being composed of stacked planes of atoms, each parallel to the topmost surface plane (see SYMMETRY IN CRYSTALLOGRAPHY).

The structure of an actual surface is usually very different from an ideal termination of the bulk. The low-Miller-index surfaces—(100), (110), (111)—are relatively flat, but higher-index surfaces generally have a large number of steps and often kinks as well. Adatoms and adsorbed molecules also appear in many systems. Figure 1 illustrates some of these features. LEED is sensitive to any such structures that recur at regular intervals, that is, with measurable periodicity.

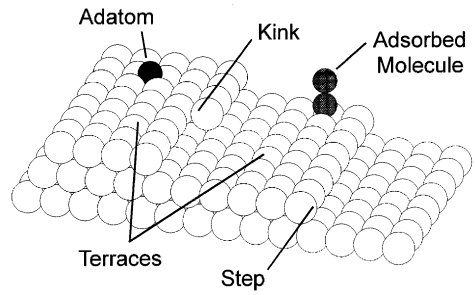

Figure 1. A model of the most common surface features.

LEED is a mature area of surface science and it is useful to consider the state of the art in this field. A great deal of work has been done on clean metal and semiconductor surfaces, and much of this is considered "done"; current work in this area consists mostly of refinements. Most low-index clean metal surfaces are found to merely relax the spacing between the topmost layers. Higher-index metal surfaces tend to be less closely packed and more prone to reconstruction. Clean semiconductor surfaces almost always reconstruct. Adsorbed atoms and molecules are sometimes found to lift reconstructions, and they often modify the dimensions and orientation of the surface unit cell themselves. Several atoms and simple molecules (H, O, S, CO, C_2H_4) have been investigated on low-Miller-index surfaces of semiconductors (Si, GaAs) and most transition metals. An important direction of current research is the growth of ordered crystalline epitaxial films for a variety of purposes. They serve as models for catalytic systems (Boffa et al., 1995), model magnetic structures, or avenues for studying otherwise intractable systems (Roberts et al; 1998), to name a few examples. Other recent advances seek to extend the power of the technique to systems with disorder in geometry (Döll et al., 1997; Starke et al., 1996) or composition (Gauthier et al., 1985; Crampin et al., 1991). Because of the time-consuming trial-and-error computations involved in a structural determination, there is also interest in developing a LEED-based holographic technique for rapid adsorption site determination (Saldin, 1997).

Complementary and Related Techniques

Information similar or complementary to that provided by LEED can be obtained by other techniques. For example, XRD provides the same information as LEED, but without surface selectivity. Similar surface-specific diffraction information can be obtained from such methods as photoelectron diffraction (Woodruff and Bradshaw, 1994; Fadley et al., 1995), small-angle x-ray diffraction (SAXD; SURFACE X-RAY DIFFRACTION), x-ray standing waves (XSW;

Woodruff and Delchar, 1994, pp. 97-104), Rutherford backscattering spectroscopy (RBS; Van Der Veen, 1985), and reflection high-energy electron diffraction (RHEED). The great advantage of LEED over these other diffraction methods is its ease of use and the simplicity of the instrumentation required. X-ray standing wave experiments require a monochromatic x-ray source of a brilliance only to be found at a synchrotron, and small-angle x-ray scattering requires very precise control over sample alignment. RBS needs a mega-electron-volt (MeV) Van de Graaff generator or an ion implantation machine, equipment only found at specialized facilities, to create the needed beam of high-energy ions (50 keV to 2 MeV H^+ or He^+) to probe the surface. In contrast, the majority of all ultrahigh-vacuum (UHV) surface analysis chambers are typically fitted with a relatively simple set of LEED optics, and sample alignment of $\sim 0.5^\circ$ precision is easily attained with standard equipment. RHEED is relatively simple to implement, but it suffers from the disadvantage that full structural determinations are far from routine, and it is generally applicable only in a qualitative mode. Nevertheless, it finds wide application particularly in the study of semiconductor growth because it allows for easy *in situ* study of MBE growth processes. Under some circumstances, RBS, also known as high-energy ion scattering (HEIS), can be used to infer surface structure. This is generally done by channeling ions between the aligned rows of atoms along major crystal axes in the substrate lattice and looking for scattering from displaced surface atoms that block those channels. By channeling along several axes, displaced surface and often second larger atoms can be located by triangulation. This has the advantage of being a real-space technique, rather than a diffraction-based reciprocal-space technique and can distinguish foreign adatoms under available conditions.

Methods that provide information complementary to LEED are of greater interest. The chief weakness of LEED is shared with all other diffraction techniques: it requires single-crystal samples and selectively views only the well-ordered portions of the sample. Neither disordered regions nor intimate details of atomic motion can generally be examined, except in an average sense. For a complete structural picture, the combination of LEED with microscopy techniques is especially powerful; scanning tunneling microscopy (STM; SCANNING TUNNELING MICROSCOPY) and atomic force microscopy (AFM) are especially useful in this regard. This has been addressed in a recent review (Van Hove et al., 1997). Another useful technique is SEXAFS, which is merely surface extended x-ray absorption fine structure (EXAFS) analysis (Koningsberger and Prins, 1988). This technique is a local probe of structure and provides a radial distribution function rather than crystallographic data. It is possible to use SEXAFS to determine structures just as in LEED, but its real utility is its applicability to disordered systems where diffraction cannot be done. SEXAFS also suffers from reliance on synchrotron light sources. Electron microscopy (EM; SCANNING ELECTRON MICROSCOPY, TRANSMISSION ELECTRON MICROSCOPY, SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING) is useful for investigating structures on larger scales, and sophisticated EM instruments can provide atomic resolution as well. Unlike LEED, neither SEXAFS nor EM requires a flat sample in order to work. However, it should be stressed that an inherent problem in all microscopy techniques is the question of representative sampling. LEED rapidly examines a sample of macroscopic proportions ($\sim$1 to 10 mm^2, the spot size of the electron beam).

Finally, LEED is a purely structural technique. Information about bond energies or strengths is simply not available, except insofar as correlations can be drawn with changes in bond lengths. In general, dynamic information is also not available. Temperature-dependent measurements can determine the mean amplitudes of isotropic thermal vibrations, and some efforts have been made to investigate anisotropic vibrations, but this work is in its early stages (Löffler et al., 1995). Certainly, none of this can compete with, for example, femtosecond laser spectroscopic methods for true molecular dynamic information.

PRINCIPLES OF THE METHOD

As the name implies, LEED operates on the basis of diffraction of low-energy electrons, typically in the range of 20 to 400 eV (1 eV = 1.602×10^{-19} J) from solid surfaces. Electrons in this energy range have wavelengths close to an angstrom and thus diffract from crystalline arrays of atoms. Electrons in this energy range are also very surface sensitive. Electrons can act as quantum mechanical waves with a De Broglie wavelength given by $\lambda(\text{Å}) = \sim \sqrt{150.4/E(\text{eV})}$, so energies in the range 20 to 400 eV are typically used to diffract from crystalline solids with lattice constants of typically several angstroms ($1 = 10^{-10}$m). This technique is surface sensitive because electrons in this energy range have a short inelastic mean free path ($\sim$3 to 20 Å) in all known materials. Seah and Dench (1979) have fit an analytic expression to the available experimental data that is plotted in Figure 2. This "universal curve" can be qualitatively understood by recognizing that the dominant mechanism for inelastic scattering is loss of energy to a plasmon. At lower energies, insufficient

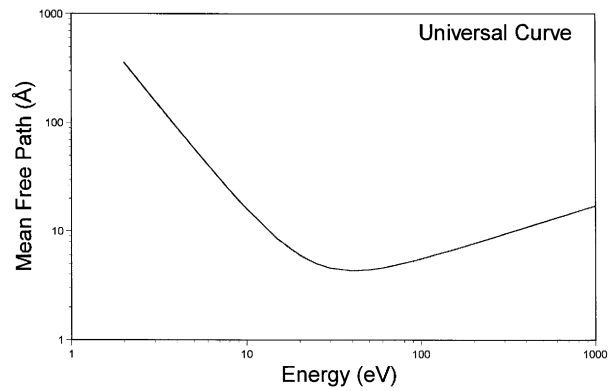

Figure 2. The "universal curve" of the mean free path of electrons in a solid, as a function of electron kinetic energy. (After Seah and Dench, 1979.) The mean free path represents a distance over which the flux of electrons drops to $1/e$ of its original value. The kinetic energy is that measured in vacuum.

energy exists to efficiently excite a plasmon, and at higher energies, the electron may well escape the solid before any excitation occurs. Once the electrons escape the solid, their mean free path in air requires pressures below $\sim 10^{-4}$ Torr for typical operating distances. Lower pressures are generally required for most experiments because of the need to keep samples clean; ultrahigh-vacuum conditions ($\leq 10^{-9}$ Torr) are generally recommended.

LEED is distinguished from more conventional diffraction techniques in that only the surface layers contribute to the diffraction pattern. This has consequences in the types of pattern that are seen. In conventional x-ray diffraction, for example, the real-space three-dimensional (3D) crystalline lattice generates a 3D lattice in reciprocal space (cf. X-RAY TECHNIQUES and SYMMETRY IN CRYSTALLOGRAPHY). The Laue condition for diffraction gives rise to the construction of an Ewald sphere that may or may not intersect another point on the reciprocal lattice. Put plainly, for arbitrary conditions of wavelength (or energy) and incident angle, diffraction will not necessarily occur from a 3D crystal. In practice, this means it is necessary to examine the reflection of x rays from a single crystal at many different angles in order to observe all possible diffraction spots. (Those familiar with typical experiments might notice that x-ray diffraction from a single crystal commonly is seen at all orientations; however, all spots are not seen at the same time. The common appearance of several spots under arbitrary conditions is usually due to deviations of the experiment from "ideal" conditions—finite divergence of the x-ray beam, polychromatic x-ray source.) Diffraction from a rigorously 2D crystal, however, guarantees that the diffraction condition will be met (above some critical energy). To see how this is so, examine the reciprocal lattice vectors, $\mathbf{b}_1$, $\mathbf{b}_2$, and $\mathbf{b}_3$ of a real-space lattice with lattice vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$. The relation is

$$\mathbf{b}_1 = \frac{\mathbf{a}_2 \times \mathbf{a}_3}{\mathbf{a}_1 \bullet (\mathbf{a}_2 \times \mathbf{a}_3)} \qquad \mathbf{b}_2 = \frac{\mathbf{a}_3 \times \mathbf{a}_1}{\mathbf{a}_1 \bullet (\mathbf{a}_2 \times \mathbf{a}_3)}$$
$$\mathbf{b}_3 = \frac{\mathbf{a}_1 \times \mathbf{a}_2}{\mathbf{a}_1 \bullet (\mathbf{a}_2 \times \mathbf{a}_3)} \qquad (1)$$

The periodicity of a 2D lattice in the direction normal to the lattice plane can be considered infinite. Thus, let $\mathbf{a}_3 = d\mathbf{n}$, where $\mathbf{n}$ is a unit vector normal to the surface plane. As $d \to \infty$ (the limit of infinite interplanar separation), the magnitude of $\mathbf{b}_3$ approaches zero, resulting in continuous rods, rather than points, in reciprocal space. This means that, once the Ewald sphere is sufficiently large (for sufficiently short wavelength), diffraction will always be observed for arbitrary orientation of the incident angle. That is, one is guaranteed to always see spots on the LEED screen for a sufficiently large energy of the electron beam.

The assumption of a rigorously 2D lattice is somewhat incorrect as a model for real 2D diffraction. Real crystals do have periodicity in the direction normal to the surface, but that periodicity terminates abruptly at the surface. This termination manifests as the rods in reciprocal space becoming "lumpy," and diffraction in certain directions being favored. This is realized in the LEED pattern as variations of the intensities of spots with the kinetic energy of the electrons. It is precisely this variation that allows extraction of detailed crystallographic parameters. Certain spots in the pattern will occasionally vanish to zero intensity, but these are isolated instances of angle and beam energy, and the spot will otherwise be generally visible. It happens to turn out that there are almost always conditions under which all of the spots can be seen.

Qualitative Observations

There are essentially two levels of information that can be extracted from a LEED experiment: the qualitative and the quantitative. Qualitatively, a LEED experiment will determine the symmetry of a surface structure. Consider, e.g., Figure 3. Shown in part A is the diffraction pattern obtained from a square 2D lattice [perhaps the (100) plane of a face- or body-centered cubic (bcc) metal] along with the corresponding real-space structure. Part B shows the diffraction pattern due to a so-called (2×2) pattern of adsorbates on the substrate crystal (notation explained below). One such real-space structure is also illustrated in B; adsorbates have been arbitrarily placed atop the atoms.

Also shown in Figure 3 is the indexing usually applied to the diffracted beams. The specularly reflected beam is placed at the center of the coordinate system, and two of the beams with the lowest value of $|\boldsymbol{k}|$ are selected as the (10) and (01) beams. Other beams are labeled according to the coordinate system generated. Negative indices are generally indicated by a bar over the appropriate number. When an adsorbate or reconstruction exists and induces extra spots, the most common method of indexing assigns fractional values to the new spots.

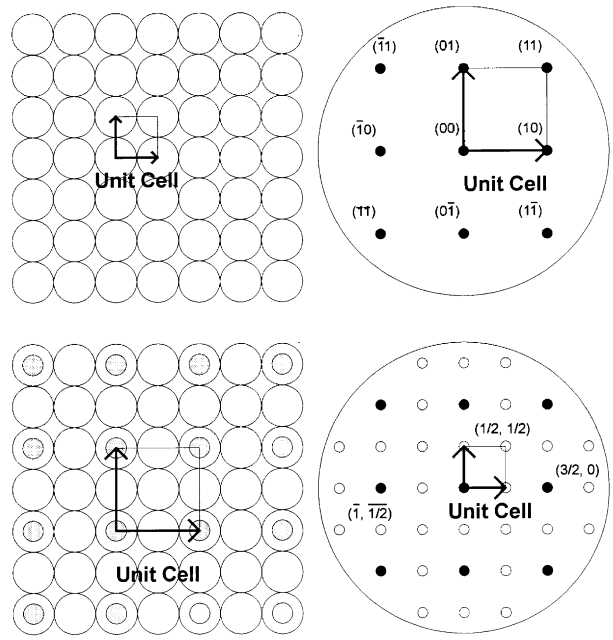

Figure 3. An illustration of the relationship between real and reciprocal space. In (**A**), we see a clean surface of square symmetry, with atoms represented as circles. In (**B**), we see the same surface with a p(2×2) unit cell. The translational symmetry has been lowered by an adsorbate arbitrarily placed atop an atom. Typical spot indexing is indicated by a label above the appropriate beam.

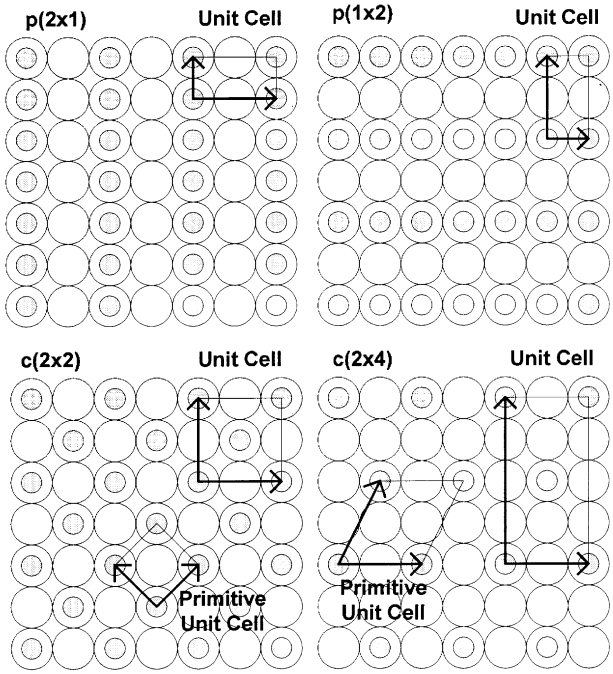

Figure 4. Some simple, single-domain real-space structures on a substrate of square symmetry. The Wood notation for each is given above the structure. These real-space models correspond to the diffraction patterns in Figure 5.

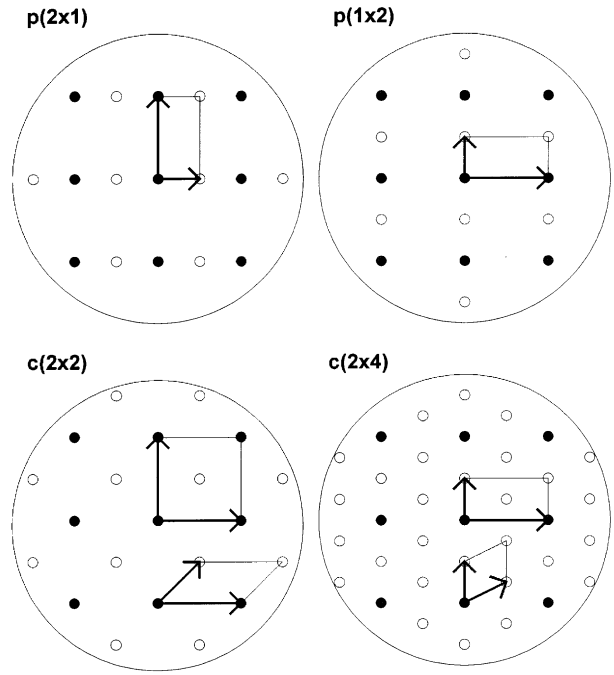

Figure 5. Some simple, single-domain reciprocal space structures on a substrate of square symmetry. These diffraction patterns correspond to the real-space models in Figure 4. Note that the $p(2 \times 1)$ and $p(1 \times 2)$ structures are not incorrectly reversed; the long dimension in real space is the short dimension in reciprocal space. The centered structures, $c(2 \times 2)$ and $c(2 \times 4)$, have two unit cells indicated. The lower one is the primitive unit cell, while the upper one is a larger cell that more obviously preserves the symmetry of the real-space unit cell.

The notation used above, the so-called Wood notation (after Wood et al., 1963), relates the periodicity of the overlayer to that of the substrate. It is commonly found that an overlayer adopts lattice vectors that are integral multiples of the substrate unit vectors. For example, in the (2×2) case above, the overlayer has a unit cell that is twice as large in both dimensions as the substrate unit cell. Figure 4 illustrates, again on a "square" lattice substrate, a $p(2 \times 1)$, a $p(1 \times 2)$, a $c(2 \times 2)$, and a $c(2 \times 4)$ structure. Their diffraction patterns are illustrated in Figure 5. Figures 6 and 7 illustrate the real-space lattice and diffraction patterns, respectively, for a $p(1 \times 2)$, $p(2 \times 2)$, $(\sqrt{3} \times \sqrt{3})R30^\circ$, and $c(2 \times 4)$ overlayer on a surface of hexagonal symmetry [e.g., the (111) plane of an fcc metal]. Notice that all of the "c" structures have an adsorbate at the center of the unit cell as well as at the corners. If one examines the square $c(2 \times 2)$ structure more closely, one can also construct a smaller unit cell that is square, contains only one adsorbate, but is rotated 45° with respect to the substrate. The sides of this square are $\sqrt{2}$ times longer than the dimensions of the substrate unit cell, so this cell can be described as $(\sqrt{2} \times \sqrt{2})R45^\circ$ as well.

More formally, Wood's notation can be described as $j[(b_1/a_1) \times (b_2/a_2)]R\theta$, where j is either p or c, a_n and b_n are substrate and overlayer unit cell lengths, respectively, and θ is the angle through which the cell must be rotated to produce the overlayer unit cell. The notation "$R\theta$" indicates that the unit cell of the substrate must be rotated by an angle θ to give unit cell vectors parallel to those of the overlayer. Typically, $R\theta$ is omitted when θ is zero. The preceding "p" signifies a primitive unit cell, while "c"

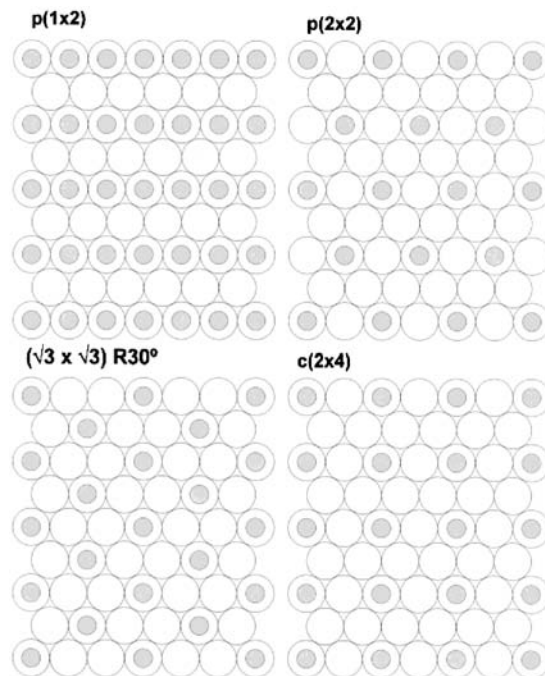

Figure 6. Some simple, single-domain real-space structures on a substrate of pseudo-hexagonal symmetry. The Wood notation for each is given above the structure. These real-space models correspond to the diffraction patterns in Figure 7.

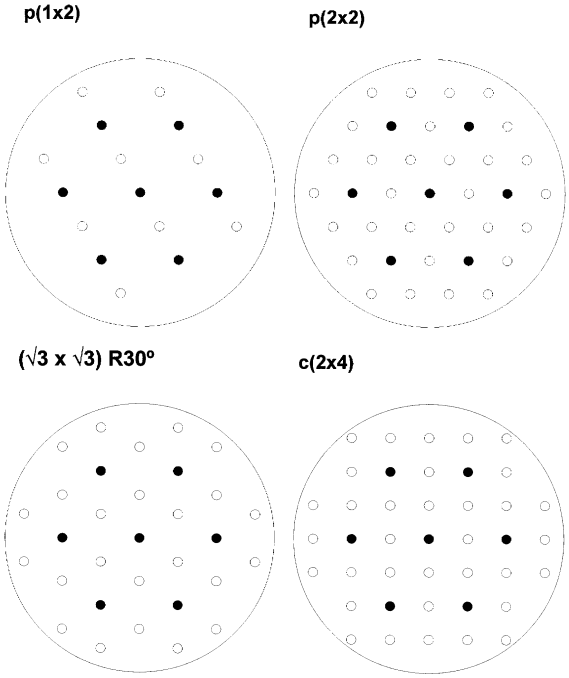

Figure 7. Some simple, single-domain reciprocal space structures on a substrate of square symmetry. These diffraction patterns correspond to the real-space models in Figure 6.

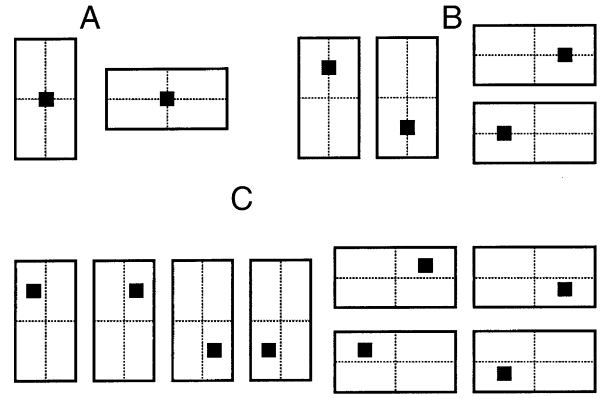

Figure 8. The various possible domains for a (1×2) unit cell on a substrate of square symmetry [e.g., (100) face of a bcc or fcc lattice]. Two domains are possible in (**A**), where the unit cell has the maximum possible symmetry, including two mirror planes and a 2-fold rotation axis. In (**B**), four possible unit cells have only one mirror plane. In (**C**), eight unit cells are possible with no internal symmetry. These unit cells can be distinguished by quantitative LEED structural analysis, but their diffraction patterns are qualitatively identical with that shown in the upper right of Figure 9.

represents a "centered" unit cell with a lattice point at the center of the cell identical to the ones at the corners. The p is sometimes omitted from descriptions of structures as well, although its omission does not always mean that p is implied. It should be apparent that in all cases, a centered cell can be decomposed into smaller primitive cells, but the c usage survives—if only because it is intuitively easier to recognize centered cells than their primitive counterparts.

It should likewise be apparent that structures are possible that cannot be described using Wood's simple notation. When the angle between the unit vectors of the overlayer is different from the angle between the unit vectors of the substrate, the two unit cells cannot be related by a simple expansion and/or rotation. In such cases, matrix notation must be used. The matrix used is the most general relation between the substrate unit vectors, $\mathbf{a}_1$ and $\mathbf{a}_2$, and the overlayer unit vectors, $\mathbf{b}_1$ and $\mathbf{b}_2$ (expressed in terms of a common basis):

$$\begin{pmatrix} \boldsymbol{b}_1 \\ \boldsymbol{b}_2 \end{pmatrix} = \begin{pmatrix} \boldsymbol{m}_{11} & \boldsymbol{m}_{12} \\ \boldsymbol{m}_{21} & \boldsymbol{m}_{22} \end{pmatrix} \begin{pmatrix} \boldsymbol{a}_1 \\ \boldsymbol{a}_2 \end{pmatrix} \qquad (2)$$

This has the advantage of always being applicable, but the disadvantage of being more cumbersome.

Another important point concerns the existence of multiple domains of a surface structure. In general, a particular overlayer geometry is energetically equivalent when operated on by one of the symmetry elements of the substrate. If the symmetry of the overlayer is lower than that of the substrate, several domains are possible. For example, on a bcc (100) face, two distinguishable domains of a (1×2) structure exist, which can be termed (1×2) and (2×1), as seen in Figure 4. The bcc (100) surface has a 4-fold rotation axis and four mirror planes, while the (1×2) cell has at most a 2-fold axis and two mirror planes. The importance of this is that at least two domains of the (1×2) will be present on any real sample. Figure 8 illustrates all of the possible domains of a (1×2) superstructure on a bcc (100) substrate. The fewer symmetry elements possessed by the unit cell, the more possible domains will be present. In cases of lower symmetry, the large number of domains will only be observed in the quantitative structure of the $I(E)$ spectra, and the qualitative appearance of the diffraction pattern is indistinguishable from a unit cell with the maximum possible symmetry. Most domains turn out to be larger than the coherence length (see below) but smaller than the typical beam spot size of ~1 mm. This means that all possible domains will be illuminated by the electron beam, and diffraction from all of them will appear on the LEED screen. As a result, the pattern observed from a low-symmetry structure on the LEED screen may not be a Bravais lattice, but a superposition of such lattices. Figure 9 illustrates the patterns typically seen from some common multidomain structures.

Quantitative Measurements

Quantitative crystallographic information is also accessible. Atomic positions can be determined to within several hundredths of an angstrom by modeling the intensities of the diffraction spots observed. These intensity versus beam energy curves are typically called $I(E)$ curves (as well as "*I-V* curves," referring to the intensity and electron beam voltage). In principle, the formalism is similar to

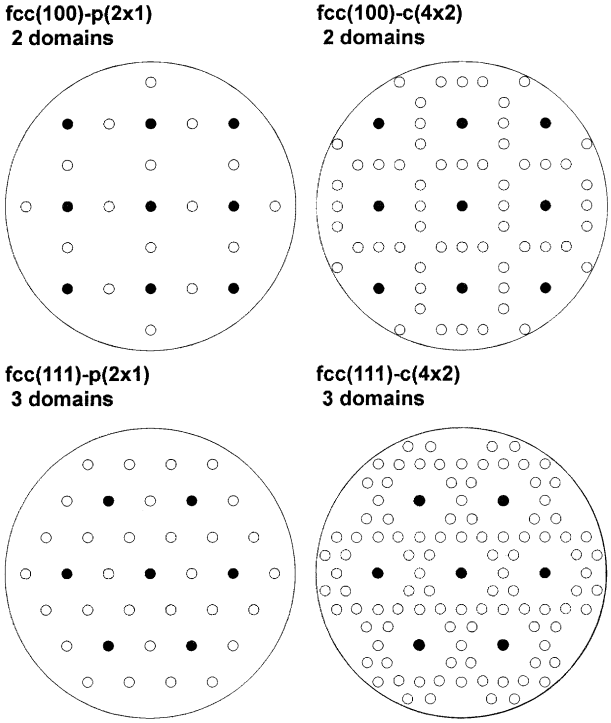

Figure 9. Diffraction patterns of some common multidomain structures. Note that the fcc(111)-p(2×1) structure is indistinguishable from the fcc(111)-p(2×2) structure in Figure 7. However, the fcc(100)-p(2×1) can be distinguished from the p(2×2) structure on the same substrate seen in Figure 3.

x-ray diffraction, but important differences exist owing primarily to the effect of multiple scattering. Because of the low cross-section for x-ray scattering, one may assume that an x ray scatters only once before exiting a crystal, but the cross-section for electron scattering approaches the geometric cross-section of an atom. As a result, multiple scattering is a common occurrence and its effects cannot be ignored. A practical result of this is that an x-ray diffraction pattern can be solved, in principle, by a direct Fourier transform of the pattern. However, a great deal of information is convolved in the process of multiple scattering, and the best that can be achieved is comparison of experimental data with a reference calculation. As an illustration, consider that the wave function of an electron undergoes a phase shift when scattering from an atom, modeled as a square well in Figure 10. This phase shift is indistinguishable from a phase shift due to the electron traversing a longer distance, and this ambiguity denies the possibility of directly determining a lattice spacing as one might do, for example, from x-ray diffraction data. Hence, peaks in the $I(E)$ curves cannot be fit by a simple Bragg law, and sophisticated multiple scattering calculations must be performed.

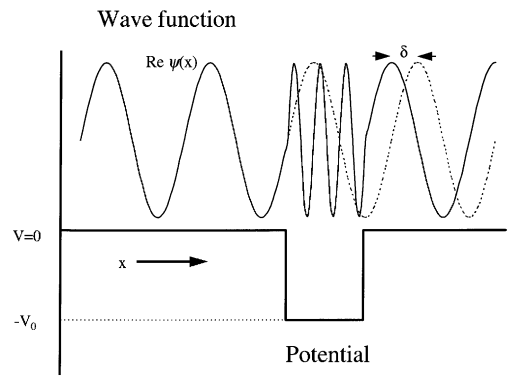

Figure 10. A simple model illustrating the phenomenon of a phase shift. A plane wave passing over a square well will change its wavelength in the region of the well. After exiting the well, its phase will have advanced by an amount indicated by δ.

PRACTICAL ASPECTS OF THE METHOD

Performing the actual LEED experiment is reasonably straightforward. It requires an ultrahigh-vacuum chamber fitted with a single-crystal sample, electron gun, display system, and provisions for intensity measurements. These will be discussed in turn.

The sample is usually a single crystal of some electrically conducting material. Doped semiconductors can also be used easily. The sample must usually be cleaned of surface contaminants prior to use, and one typically needs facilities such as an ion bombardment gun and sample heating capabilities to anneal out defects caused by ion bombardment. Sample cleanliness is usually monitored by such techniques as Auger electron spectroscopy (AES; AUGER ELECTRON SPECTROSCOPY) or x-ray photoelectron spectroscopy (XPS). Since thermal vibrations are known to diminish the intensity of all diffraction peaks, LEED experiments should be done with the sample as cold as is practical. Typically, liquid nitrogen cooling is used during the recording of the pattern, even if higher temperatures are required to prepare the desired surface structure. Another important consideration is that the diffraction pattern is typically viewed from behind the sample, resulting in a need to reduce the bulk of the manipulator as much as possible for maximum viewability (the advent of so-called "rear-view" optics has relaxed this requirement on some systems).

Another requirement for the sample manipulator is the ability to rotate the sample around a minimum of two perpendicular axes. This is necessary to achieve the normal incidence condition useful for quantitative work, although this is not strictly required for qualitative data. The reason for positioning the crystal normal to the incoming electron beam is 2-fold: (1) normal incidence is the easiest angle to specify exactly, so that high angular precision can be ensured; quantitative calculations require a precision of half a degree or better; and (2) normally, incident electron beams also maximize the symmetry of the resulting diffracted beams; making full use of symmetry is a great advantage when doing a quantitative analysis, as will be discussed later. Since finding normal incidence is a nontrivial task, two methods of checking for normal incidence are described briefly. Both depend on the fact that, for a normally incident beam of electrons, the intensities of the diffracted beams have the same symmetries as the crystal plane being investigated. For example, an

fcc(100) face has a 4-fold symmetry axis and four mirror planes, and an fcc(111) plane has a 3-fold symmetry axis and three mirror planes. The simplest method is useful only for highly symmetric surfaces—at normal incidence the intensities of symmetrically equivalent beams are equal. For example, four symmetrically equivalent spots in the diffraction pattern from an fcc(100) surface, say the (10) set of beams [e.g., as distinct from the (11) or (20)], should have equal intensity. If the left pair of spots were brighter than the right pair of spots, some sort of left/right angular adjustment would need to be made. The other method is to allow beams with identical values of $|\Delta\mathbf{k}_{\|}|$ to approach the edge of the screen, which is generally a cylindrically symmetric section of a sphere. These beams should all arrive at the edge of the screen at the same time, as the energy of the incident beam is varied.

The electron guns typically employed are widely used and only a few brief comments are warranted. Since LEED examines back-reflected electrons, the gun is usually mounted inside the display apparatus. As a result, only electrostatic deflection is used to reduce the effect of stray fields on the diffraction pattern. The filament is usually tungsten, although sometimes LaB_6 has been used for its low work function. One problem that can arise is that the light emitted from the hot filament can make the fluorescent screen of the display system difficult to see. For this reason, the filament is typically mounted off of the axis of the gun and the emitted electrons deflected onto the axis. Another consideration is that the beam current is not usually constant as the accelerating voltage is increased. This is important in quantitative measurements because increased beam current will result in increased intensity in the diffracted beams; this can artificially influence the position of peaks in the $I(E)$ curves. There are various ways to control this, but the simplest method is to directly measure the beam current as a function of energy and correct the $I(E)$ curves accordingly.

The display system must provide for measurement of the intensities of diffracted beams. The earliest methods for doing so employed a Faraday cup that could be moved to the proper position. It is currently much more popular to use a fluorescent screen held at high voltage (3 to 7 kV), which glows when struck by electrons with brightness proportional to current. A typical modern apparatus is shown in Figure 11. The hemispherical phosphorescent screen is preceded by a series (two, three, or four) of concentric hemispherical wire meshes or grids, with four grids being most common. The sample is ideally placed at the center of curvature of the instrument. The grid closest to the sample is generally held at ground/earth potential, as is the sample, so that diffracted beams propagate through a field-free region between the two. The second grid is held at a potential a few volts below that of the beam to energy select out all inelastically scattered electrons. In a four-grid system, the second and third grids are held at the same potential to improve the quality of energy selection, and the fourth grid is grounded to isolate the energy selection potential from the high voltage placed on the phosphorescent screen. Two grids are generally sufficient for LEED work, but the four-grid system offers improved energy selection. This is useful because the same apparatus is often also used for AES measurements, for which energy selection is crucial.

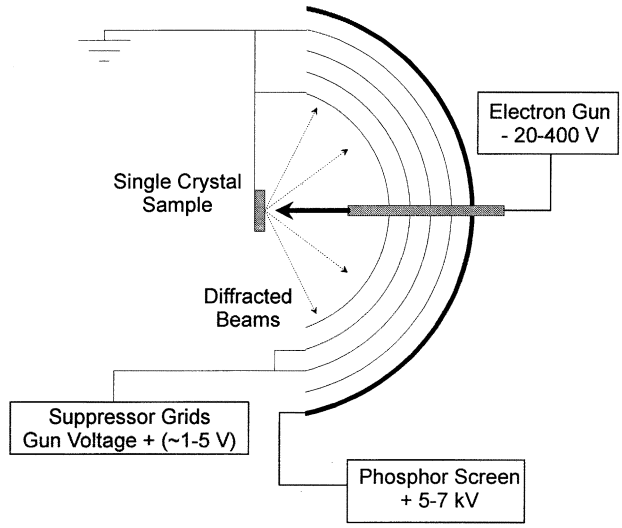

Figure 11. A schematic of the apparatus used in LEED studies. Voltages are indicated on the diagram. Most older instruments view the screen from behind the sample, but newer rear-view optics view the screen from the right side of the diagram.

Several methods have been employed for the direct measurement of spot intensities. The earliest methods involved the use of a Faraday cup that was moved to intersect the diffracted electron beam. This presented difficulties in part because it is difficult to measure currents of the low-energy electrons employed in LEED. Later refinements introduced the postacceleration to a phosphorescent screen described above. A spot photometer could be used to track each diffracted beam and directly measure the $I(E)$ spectrum. However, this process was found to be slow, owing to the need to manually readjust the photometer at each new energy value. Moreover, this method requires that separate acquisitions be made of every spot in the pattern. A method that is currently in wider use involves photographing the screen at regular intervals as the beam energy is increased. This allows for parallel measurement of all visible spots, and delays measurement of intensities until after the rapid data acquisition. This was pioneered by Stair et al. (1975) with a Polaroid camera, but a digital camera interfaced to a computer is more popular currently. In the authors' experience, a common 35-mm camera designed for personal use is not usually sufficient to capture the low light levels emitted by typical fluorescent screens, and a more sensitive device must be employed. The authors successfully used both a manually shuttered Polaroid camera (for rapid development and evaluation) and a computer-controlled CCD camera.

It is important to know the boundaries of LEED's capabilities. As a rule of thumb, LEED interrogates an ordered region of the surface ~100 Å across, and is sensitive to ~5% to 10% of a monolayer. The limitation on lateral resolution is a typical number for most instruments, and it is determined by deviations from the "ideal" beam—a monochromatic plane wave described as A

$\exp(i\mathbf{k} \bullet \mathbf{r})$, with well-defined energy, $\hbar^2|\mathbf{k}|^2/2m_e$, wave vector $\mathbf{k}$ and position in space $\mathbf{r}$. The two important factors characterizing deviations are the finite energy spread of the electron beam, deviating from monochromaticity, and the finite angular divergence of said beam, owing to the filament typically being an imperfect plane wave source. Qualitatively, these imperfections will give rise to unpredictable lateral variations in the phase of the beam; the lateral distance at which the phase relationship becomes arbitrary is generally termed the instrument response function, or coherence length. The coherence length is generally around a few hundred angstroms; an estimate is given in Appendix A.

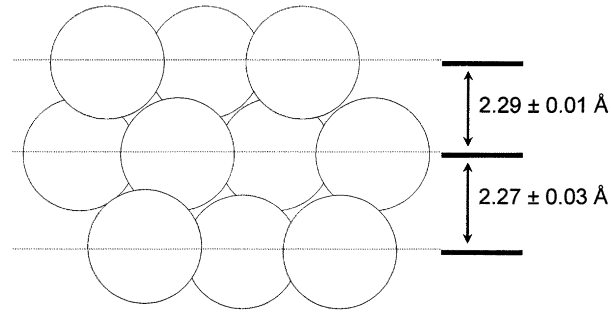

Figure 12. A side view of the Pt(111) surface along the $\{1\bar{1}0\}$ direction. (After Materer et al., 1995.) The bulk interlayer distance is 2.2650 Å.

METHOD AUTOMATION

It is possible and desirable, although not strictly necessary, to acquire LEED data using a computer. The bare minimum requirements for qualitative data can be met with a simple camera. However, as noted above, a common 35-mm camera designed for personal use may not prove sufficient due to the low light level of the phosphorescent screen. Quantitative data requires detailed measurements of spot intensities. It is recommended that a camera interfaced to a computer be capable of at least 8 bits of intensity resolution with adjustable gain and dark level.

Two approaches to automated data acquisition are generally used. One is a procedure whereby a single spot is tracked by a camera while the energy is scanned. This has the advantage of directly measuring the desired $I(E)$ curve in real time. Another popular method is to use a camera to photograph the entire LEED screen at particular energies (e.g., 2-eV steps) and perform an off-line measurement of the intensities later. This method has the advantage of photographing all spots at once for maximum efficiency and not requiring particular effort to track individual spots. Since measuring all of the spots in parallel is also more rapid, instrument drift is minimized. We typically implement the latter method with a CCD camera, a personal computer with a frame-grabber expansion card, and our own software for image acquisition.

DATA ANALYSIS AND INITIAL INTERPRETATION

Two different sorts of data analysis are appropriate to LEED experiments: qualitative and quantitative. Knowledge of the symmetry of the diffraction pattern can yield powerful restrictions on the atomic geometry of the surface. These prove invaluable in reducing the number of candidate structures examined by calculations. The two different forms of analysis will be examined in turn.

Qualitative Analysis

The qualitative features of LEED are the easiest and most commonly applied. As illustrated above, the diffraction pattern reveals a great deal of information about the symmetry of the overlayer structure. This is often enough to make a reasonable guess at a structure or to help deduce a coverage. However, it is dangerous to make blind assumptions about coverage without corroborating information. A less obvious qualitative feature is the $I(E)$ spectra themselves—these can be used as a "fingerprint" of a particular surface structure in much the same way that vibrational spectra are unique to a particular molecule.

This process is perhaps best illustrated by the following examples: Pt(111)-(1×1), Si(100)-(2×1), β-SiC(100)-(2×1), Pt(111)-p(2×2)-C_2H_3, and Ni(100)-(2×2)-2C. These structures can be seen in Figures 12 to 16, respectively. All of these structures have been solved by quantitative LEED techniques, and are examined in light of what qualitative information could be deduced. They also illustrate some of the more important points to bear in mind when investigating a structure.

The Pt(111) surface (Fig. 12) has the simplest possible overlayer structure (Materer et al., 1995). The (1×1) translational symmetry prohibits almost all lateral reconstructions, and the most reasonable structures to consider involve simply relaxations of interlayer spacings. In principle, a shift of the topmost layer of surface atoms to a different registry [at bridge sites or hexagonal close-packed (hcp) hollows instead of fcc hollows] is possible, but it has not been observed in any system examined to date. This structure is also in line with other known metal surface structures; the (111) plane of an fcc metal is the most dense, and lateral reconstructions are rare. Some (100) faces have been known to reconstruct [e.g., the Pt(100)-hex reconstruction; Van Hove et al., 1981], and (110) faces commonly exhibit reconstructions [e.g., Ir(110)-(2×1); Chan and Van Houe, 1986]. For bcc metals, the (110) surface is the most dense and the (111) is the least dense, and the propensity for reconstruction varies accordingly.

The Si(100) structure (Fig. 13; Holland et al., 1984) is simple in that no adsorbate is involved, merely a reconstruction of the substrate. The major question is the geometry of the topmost layers. Semiconductor surface reconstructions can be understood as driven to minimize the number of "dangling bonds." While metals are understood to have nearly isotropic bonding, semiconductors tend to have bonds that are more covalent in nature and highly directional. Consequently, the simple octet rule of "four bonds" from organic chemistry also applies well to silicon surfaces. Si(100) eliminates its "dangling bonds"

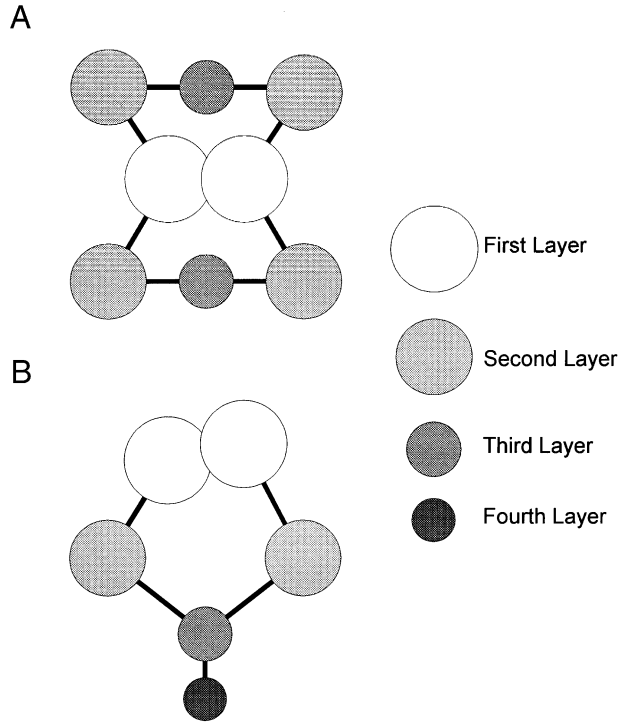

Figure 13. A top (**A**) and side view (**B**) of a single unit cell of the Si(100)-(2 × 1) reconstruction. The details of this structure are still a matter of debate, but the most recent evidence agrees that the surface dimer is tilted. Reconstructions have been found penetrating as far as the fifth atomic layer (Holland et al., 1984.)

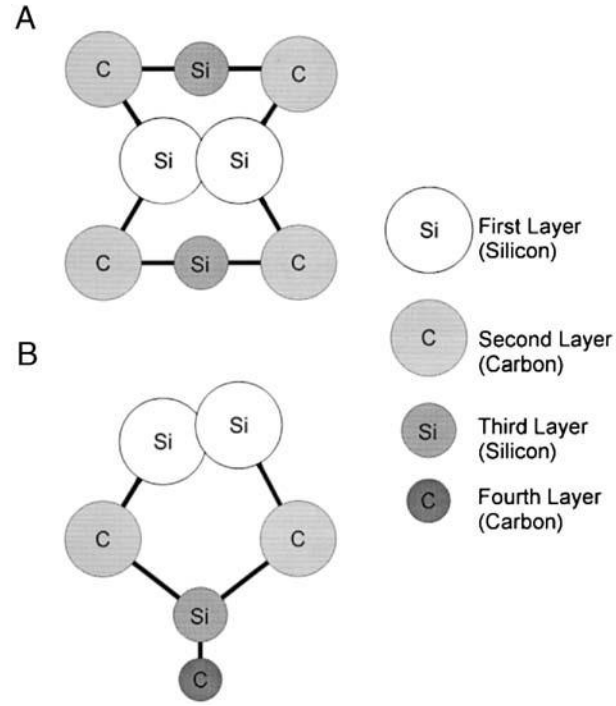

Figure 14. A top (**A**) and side view (**B**) of a single unit cell of the SiC(100)-(2 × 1) reconstruction. (After Powers et al., 1992.) Note the correspondence with Figure 13.

by forming dimers, which halves the number of unoccupied bonds.

The SiC(100) structure (Fig. 14; Powers, et al., 1992) is remarkably similar to the Si(100) structure, which is an example of the extent to which chemical analogy is useful. In the bulk, the (100) planes of SiC are composed of alternating layers of pure Si or pure C composition. However, one should also consider the possibility that chemical mixing will occur at the surface. It turns out that in this case, independent evidence (from Auger spectroscopy) was available to indicate that the face was Si terminated, reducing the number of possible structures to be considered. This illustrates that it is generally advisable to obtain as much information as possible about a surface structure so that some possibilities can be ruled out.

The p(2 × 2) ethylidyne ($CH_3-C\equiv$) structure on Pt(111) (Fig. 15) is representative of adsorbate-induced structures (Starke et al., 1993). The LEED pattern would naively seem to suggest a coverage of 0.25 monolayers (ML), with one molecule adsorbed per unit cell. However, models with 0.75 or 0.50 ML coverage can also be constructed consistent with this symmetry, and one is urged not to leap too rapidly to such a conclusion. Another complication of this system is that a p(2 × 2) structure on an fcc(111) surface is indistinguishable from three rotationally equivalent domains of a p(2 × 1) structure. This ambiguity requires that both models be considered, and in fact, there was a debate in the literature at one time as to which was correct before a general agreement was reached. Part of the data that resolved this ambiguity was a careful calibration of the coverage. The measured coverage of 0.25 ML is consistent with a p(2 × 2) but not a p(1 × 2) structure. Another interesting point is that the calculated structure based on quantitative LEED only indicates the positions of the carbon atoms. Hydrogen atoms are very light, and hence poor scatterers of electrons. It is generally considered impossible to locate hydrogen atoms by LEED, except indirectly by their effects on the positions of heavier atoms.

The case of carbon on Ni(100) (Fig. 16; Gauthier et al., 1991) is interesting because the apparent structure, which resembles a p(2 × 2), leads one to the wrong conclusion upon simplistic assessment. Instead of a coverage of 0.25 or 0.75 ML, it turns out to be 0.50 ML. A critical clue is found in the systematic extinctions of certain spots in the LEED pattern. The (0, n/2) and (n/2, 0) fractional-order spots all vanish when the diffraction pattern is viewed with the electron beam at normal incidence to the crystal. This is characteristic of glide-plane symmetry elements, and these elements place severe restrictions on the possible structures. It is important to note that if the electron beam is not at normal incidence, the symmetry of the beam with respect to the glide planes is broken and the extinguished spots reappear.

Quantitative Analysis

Quantitative structural determinations represent the pinnacle of what LEED can currently achieve. A full tutorial in the theory, programming, and use of LEED computer codes is beyond the scope of this unit, and one is referred to Pendry (1974), Clarke (1985), Van Hove and Tong

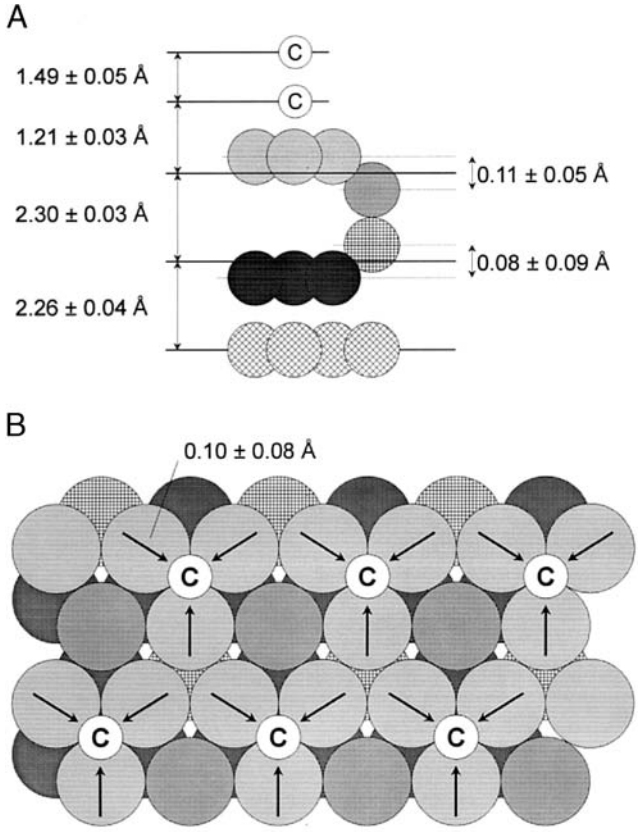

Figure 15. A side (**A**) and top view (**B**) of the structure of ethylidyne on platinum, Pt(111)-p(2 × 2)-C_2H_3. The hydrogen atoms have been omitted since the original investigation (Starke et al., 1993) was not able to locate them; this might have been due to either poor scattering characteristics of the light atoms or dynamic motion that was averaged out in the diffraction experiment. The distances shown are not to scale and are exaggerated to display some of the subtle atomic displacements detected.

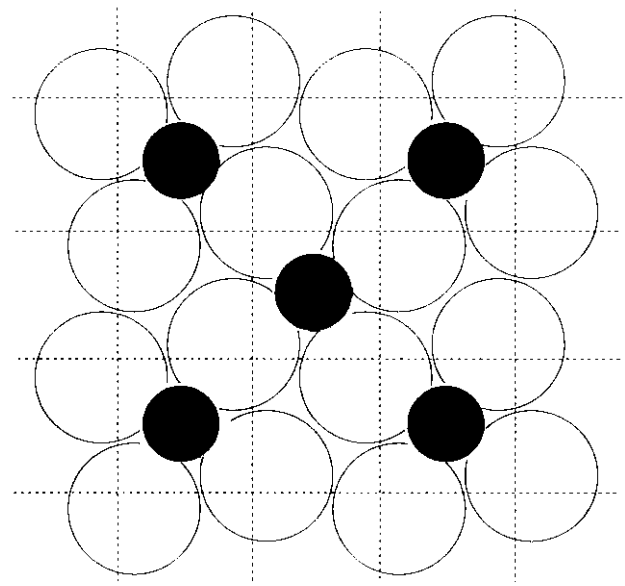

Figure 16. A top view of the Ni(100)-(2 × 2)-2C structure. Carbon atoms are represented as small black circles, and the glide planes are indicated by dotted lines.

(1979), and Van Hove et al. (1986) for the details. However, the outline and important elements of the theory will be described.

The objective of a LEED calculation is to compute the intensities of diffracted beams as a function of the beam energy. These intensities are evaluated for a particular geometry and compared with the experimentally measured data. If the agreement is not satisfactory, the intensities are recomputed for a different trial geometry, and this process of trial and error is repeated until a best agreement is found.

The scattering of LEED electrons is modeled quantum mechanically as reflection from the topmost layers of the surface. The electron beam is generally modeled as a plane wave, $A \exp(i\mathbf{k} \bullet \mathbf{r})$, where $\mathbf{k}$ is complex. The surface is typically modeled with a muffin-tin, one-electron potential. The calculation is typically organized in a hierarchical fashion by determining the scattering of electrons from atoms, organizing those atoms into 2D layers, and finally evaluating the scattering between successive layers. An atomic-like potential for the surface atoms is embedded in and matched to a constant muffin-tin potential, which also includes an imaginary component to simulate the damping of the electron wave by inelastic scattering. The real part of the potential is a calculational device, and it has only limited physical significance, although qualitatively one would expect its value to change for a particular system in correlation with work function changes. The energy of a LEED electron inside the crystal, between the ion cores, is

$$\frac{\hbar^2 k^2}{2m_e} = \frac{\hbar^2}{2m_e}(k_r + ik_i)^2 = \frac{\hbar^2}{2m_e}(k_r^2 - k_i^2) + i\frac{\hbar^2}{m_e}k_r k_i = E + V_{0r} + iV_{0i} \quad (3)$$

thus,

$$\frac{\hbar}{2m_e}(k_r^2 - k_i^2) = E + V_{0r} \quad \text{and} \quad \frac{\hbar^2}{m_e}k_r k_i = V_{0i} \quad (4)$$

where V_{0r} is the real part of the potential, V_{0i} is the imaginary part, k_r is the real part of the complex magnitude of the wave vector of the electron, k_i is the imaginary part, and E is the electron kinetic energy outside of the crystal. Typically, V_{0i} is ~1 to 5 eV, and V_{0r} is generally used as a fitting parameter. An estimate of V_{0i} can be obtained from the width of the observed peaks; approximately, $\Delta E_{\text{FWHM}} \approx V_{0i}$ (Van Hove et al., 1986, p. 119). LEED electrons are not terribly sensitive to valence electrons, so some liberties can be taken with the details of the atomic part of the potential. Most commonly, one uses the results of a band structure calculation as the source of the atomic potentials, such as those of Moruzzi et al. (1978). However, LEED is sufficiently sensitive to valence electrons that

simple free atom calculations do not give good results (Van Hove, 1986, p. 121). Further details of the calculations are given in Appendix B.

In order to actually perform a structural search, some quantitative measure of the goodness of fit of two sets of $I(E)$ curves must be devised. This is typically done by means of an R factor, as is used in x-ray crystallography. The simplest criterion one might imagine is a squared difference, as is employed in a least-squares type of fit. Many other R factors have been proposed and used as well. One particularly popular one was suggested by Pendry (1980), who recognized that peak positions contain most of the important information and chose to emphasize position at the expense of intensity. In part, this is useful because peak positions are determined primarily by geometric factors, but the factors affecting intensity include nonstructural parameters, such as thermal motion, that introduce artificial biases. Pendry's R factor (R_P) is based on the logarithmic derivative of the intensity, $L = (I)^{-1}(dI/dE)$, evaluated as part of a Y function, $Y = L/(1 + V_{0i}^2 L^2)$ so as to avoid singularities near zero intensity. The R factor is defined as

$$R_P = \frac{\int (Y_{expt} - Y_{theo})^2 \, dE}{\int (Y_{expt}^2 + Y_{theo}^2) \, dE} \tag{5}$$

The values for Pendry's R factor range from 0 to 1, with 0 being a perfect correlation between theory and experiment and 1 being no correlation.

Another major advance has been the development by Rous and Pendry (1989) of Tensor LEED, a perturbative method that greatly accelerates structural searches. This method computes a tensor (hence the name) that describes the effect on the LEED matrices of small geometric displacements. Since the full dynamical calculations of $I(E)$ spectra are the most time-consuming step in a fit, this method accelerates a search by allowing a single reference calculation to cover a wide range of parameter space. Instead of requiring an inefficient grid search of parameter space at, say, 0.05-Å intervals, Tensor LEED calculations allow all structures within a certain radius of convergence to be rapidly tested. This radius has been estimated as ~0.3 to 0.4 Å (Rous, 1992), although more conservative estimates are often recommended. In any event, it is wise to check the results of a Tensor LEED calculation by starting a new reference calculation at the last minimum, followed by a new minimization, and perhaps iterating this once or twice.

An important consideration is what kind of experimental data set is required for these calculations. This is usually estimated by examining the total data range for each of the contributing $I(E)$ curves and summing them together to obtain a cumulative energy range. Cumulative ranges of at least 1000 eV are recommended, and more is always better, especially when many parameters are to be fit. A method of estimating the uncertainty in a structural determination was developed by Pendry (1980), and it scales inversely with the cumulative energy range. The sampling of points in experimental spectra should be at least every 3 eV, and 1 to 2 eV is preferable, because peaks in $I(E)$ spectra are generally ~4 to 5 eV wide. This brief, but comprehensive, overview of the theoretical aspects involved in a detailed structural solution provides the reader with adequate insight to critically examine the current LEED literature.

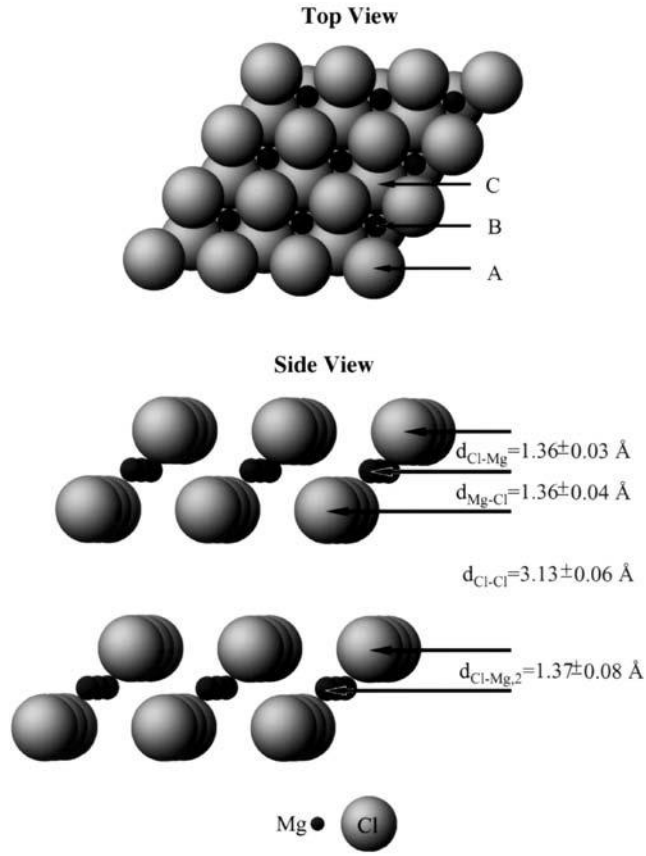

Figure 17. Top view (top) of the α-$MgCl_2$(0001) surface with labels indicating the lateral stacking of the ions. Ionic radii were reduced by 15% for clarity. Side view (bottom) of the α-$MgCl_2$ (0001) surface with the surface termination on top and with the ionic radii reduced by 50%. Refined interlayer spacings are labeled with there respective error bars. Bulk interlayer spacing values are $d_{Mg-Cl,bulk} = d_{Cl-Mg,bulk} = 1.33$ Å and $d_{Cl-Cl,bulk} = 3.22$ Å. The labels A, B, C in the top view indicate the different layers in the side view.

The analysis of the $MgCl_2$ multilayer surface structure (Roberts et al., 1998) will be used as an example of a typical LEED publication. Figure 17 illustrates the objective of a LEED $I(E)$ analysis—the surface structure itself. The use of top and side views familiarizes the reader with the crystallography of $MgCl_2$. In this example, the hexagonal surface symmetry is clearly evident in the top view (Fig. 17 top) along with the relative lateral positions of the atoms. Additionally, it is correctly assumed that the lateral coordinates were held at their bulk values. This is indicated by the absence of any explicit labeling of atomic positions. The side view (Fig. 17 bottom) shows the layered alternating stacking of the Mg and Cl ions along with the interlayer spacings, the only structural parameters varied, in the refined region with their respective error bars. The

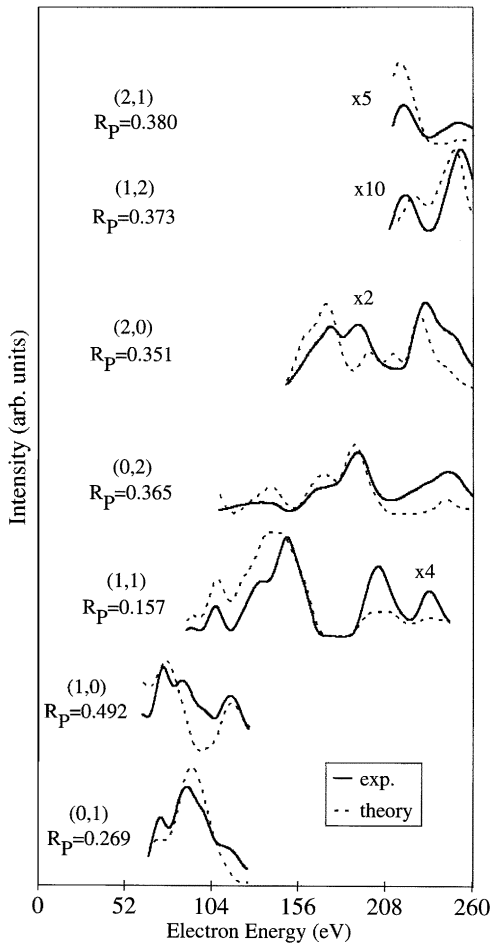

Figure 18. Comparison of the theoretical (dashed lines) and experimental (solid lines) $I(E)$ curves for the fully optimized α-$MgCl_2$(0001) surface. All beams used in the calculation are plotted along with their indices.

spacings below the refined region are again assumed to have bulklike separations because no explicit values are given for these parameters.

The accompanying figure to the structural illustration of all finished calculations is the comparison of the experiment and theoretical $I(E)$ curves (Fig. 18). Although the goodness of fit is quantified by the overall R factor (here $R_P = 0.32$), a visual inspection of the experimental data allows one to determine if the researcher made the correct choice in the number of refinable structural parameters. For $MgCl_2$, the total experimental energy range of 658 eV is smaller than for most data sets, because of the material's extreme sensitivity to the electron beam. This small data set limited the optimization to only four interlayer spacings. Additional structural parameters would have resulted in refined values with very large uncertainties, although the overall R factor would be lowered due to the fact that more variables were used to fit the experimental $I(E)$ curves. When inspecting the $I(E)$ curves, the quality of the theoretical fit to the data should not be judged by how well the theoretical beam intensities correlate to the experimental intensities, since the reason for the inequity between these intensities is directly related to the nature of the Pendry R factor. This R factor is sensitive to the shape of the $I(E)$ curve with respect to energy and not to their intensities. Consequently, a good fit is determined if the minima and maxima of the theoretical curves occur at the same energies as in the experimental curves. The comments and questions that arose from this specific example are common to all LEED-determined structures and provide a more profound understanding of the analysis than could be obtained from just looking at the overall R factor.

Since these calculations are computationally expensive, the tractability of the problem is always a consideration. The difficulty of calculations scales primarily with the number of atoms in a unit cell, usually as the square or cube of that number. Some examples of recent calculations follow. A study of Pt(111)-p(2 × 2)-NO and Ni(111)-c(4 × 2)-2 NO required calculation times of 4 to 5 h for one geometry on an IBM RISC 6000 (Materer et al., 1994). On the same computer, a study of Rh(110)-(2 × 1)-2 O required 1.5 h to calculate a single geometry, and 200 s to complete a search of nearby structures using a Tensor LEED algorithm (Batteas et al., 1995). One benchmark structure is the Si(111)-(7 × 7) reconstruction (Tong et al., 1988), which takes ~1 day on an IBM RISC 6000. A (1 × 1) cell of $MgCl_2$, a simple structure (Roberts et al., 1998), took ~15 min of computational time on a DEC Alpha, using current LEED codes utilizing all benefits afforded by the high symmetry. If symmetry is ignored, the same full dynamical calculation takes ~1 h. For comparison, the DEC Alpha used is observed to be roughly 10 to 20 times faster than the quoted IBM machine. The Si(111)-(7 × 7) structure takes ~1 h to compute on the DEC Alpha, using all available symmetries.

SAMPLE PREPARATION

The basic requirements of a sample are that it be flat, well ordered, and able to reflect diffracted electrons. Samples are typically polished to at least an optically fine finish (1.0 μm or better polishing paste) and mounted in a UHV chamber. Preparation of clean, well-ordered samples for UHV surface science work is somewhat of an art unto itself. Beyond the advice given by Musket et al. (1982), the best that can be said is that one should experiment for oneself. Generally, cycles of noble gas ion bombardment (e.g., 0.5 to 3.0 keV Ar^+), annealing (usually 500 to 2000°C, depending on the material), and gas treatments (usually H_2 or O_2) are used. Ion bombardment can be thought of as "atomic sandblasting" and is good for removing gross contaminants no greater than a few microns in thickness. If contaminants are thick enough to be visible to the naked eye, other methods of cleaning should be used. It is sometimes useful to "momentum match" the ion used to the type of contaminant expected (e.g., Ar^+ for S, Ne^+ for C), but the relative cost of the various rare gases is more often the deciding factor. Annealing heals the damage caused by ion bombardment, and it also allows diffusion of impurities to take place. It is not uncommon for a new crystal to

require several weeks to clean for the first time, while the near-surface region is depleted of contaminants. Subsequent cleaning occurs far quicker, however, and it can usually be accomplished in ~1 h on a daily basis. Chemical treatments are useful in especially difficult cases, if an impurity can be volatilized by reaction (e.g., burning carbon to CO and CO_2). Not all of these steps are necessarily required or even useful in every case.

SPECIMEN MODIFICATION

The only modification to the specimen typically observed is possible electron beam damage. Most of the time, this is not a serious concern, especially when fairly heavy atoms are involved (e.g., reconstructed metals or semiconductors). Damage has more commonly been observed as a result of more energetic beams than those used for LEED (e.g., during Auger electron spectroscopy; see AUGER ELECTRON SPECTROSCOPY), but it is a serious issue for insulating overlayers in some cases. In a recent study of ice multilayers on Pt(111) (Materer et al., 1997), electron beam damage was so severe that a LEED experiment could only be done by use of special Digital LEED equipment (Ogletree et al., 1992).

PROBLEMS

There are several kinds of difficulties that experimenters often face. The most basic is that of finding an ordered structure in a given adsorbate-substrate system. This is the most difficult to address because the specifics vary from one system to another. One must begin with a substrate that is itself well ordered. The spots on the display system should be sharp, nearly as narrow as the incident beam, and the space between the spots should have minimal background intensity. Unless the substrate reconstructs, the pattern seen should form a simple Bravais lattice corresponding to the face of the crystal being studied. If the sample is polycrystalline, one may see either a uniformly bright background or many spots that cannot be reconciled with a single Bravais lattice, perhaps without any obvious pattern at all. The second alternative can usually be distinguished from an unknown substrate reconstruction by the fact that even a complex multiple-domain reconstruction will generally give a pattern with all or most of the bulk rotational and mirror-plane symmetry elements of this crystal plane when a normal incidence electron beam is used. Polycrystalline samples tend to lack recognizable symmetry elements.

Once the substrate crystallinity is assured, a common approach is to adsorb the desired overlayer at as cold a temperature as practical, and begin inspecting the LEED pattern. Frequently, one must warm the sample somewhat to anneal the structure into place. At very cold temperatures, molecules frequently adsorb wherever they strike the surface, and thermal energy must be supplied to overcome kinetic barriers to diffusion so that the well-ordered thermodynamic ground state can be attained. The annealing temperature must be kept low enough that the adsorbate not desorb from the surface. The results of a temperature programmed desorption (TPD) experiment are thus frequently useful in designing a "recipe" for sample preparation (see Woodruff and Delchar, 1994, for more about TPD). Another, more subtle problem is that the adsorbate might itself rearrange on the surface. For example, ethylene adsorbed on Pt(111) at room temperature gives a p(2 × 2) LEED pattern, but it was not obvious until some time later that the ordered species was ethylidyne, $CH_3{-}C{\equiv}$, rather than ethylene itself. Since these transformations are typically thermally driven, one again would wish to use the minimum temperature necessary to anneal an overlayer to avoid side reactions of the adsorbate.

One of the best indicators of reliable data is a close correspondence between the $I(E)$ curves of symmetrically equivalent beams. For example, at normal incidence, the (10), (01), $(\bar{1}0)$, and $(0\bar{1})$ beams are all symmetrically equivalent on an fcc(100) surface. These curves are usually averaged together to reduce noise, but they should look very similar to begin with. Another delicate factor is the integration of intensities. In the photographic method, one integrates the intensity of the spot profile found within a particular window as the total intensity of the spot, since the spot is of finite dimensions. One should take care that the integration windows do not overlap or include intensity from other spots. A less obvious precaution is to normalize the $I(E)$ spectra to the intensity of the primary electron beam. The beam current will generally change as a function of beam voltage, and this can artificially influence the position of peak maxima. Electron beam damage sometimes occurs, as mentioned above. This can be detected by making repeated measurements in ascending and descending order of electron energy. If the two spectra look different, damage has occurred.

Although obtaining an ordered structure represents the greatest challenge to surface crystallographers, finding the sample position where the incident beam is normal to the crystal is always tedious, especially if the overlayer and/or substrate is susceptible to damage from the electron beam. The procedure previously presented for checking normal incidence does have one pitfall—small residual electromagnetic fields inside the chamber can cause deflections in the diffracted beams particularly at low energies. This effect can be circumvented by using higher-order beams to confirm normal incidence of the electron beam on the sample.

APPENDIX A: ESTIMATION OF COHERENCE LENGTH

The following quantitative estimate is after Pendry (1974): variations in the wave vector parallel and perpendicular to the beam can be estimated from the dot- and cross-product, respectively, between $\mathbf{k}$ and $\Delta\mathbf{k}$. The parallel deviations can be described as

$$|\mathbf{k}|^{-2}\overline{(\Delta\mathbf{k}\bullet\mathbf{k})^2} = |\mathbf{k}|^2\,\overline{(\Delta E)^2}/(4E^2) \tag{6}$$

since

$$\hbar|\mathbf{k}|^2 = 2m_eE \tag{7}$$

where $\overline{(\Delta E)^2}$ is the mean-square spread in energy. Perpendicular variations can be described as

$$|\mathbf{k}|^{-2}\overline{|\Delta\mathbf{k}\times\mathbf{k}|^2} = \overline{(\Delta\theta)^2}|\mathbf{k}|^2 \tag{8}$$

where $\overline{(\Delta\theta)^2}$ is the mean-square angular spread of the beam. On the surface, two points separated by a distance $\mathbf{l}$ differ in phase by $\mathbf{l}\bullet\mathbf{k}$, and the mean-square deviation from this phase is given by

$$\overline{(\Delta\phi)^2} = \overline{(\Delta\theta)^2}\frac{1}{2}|\mathbf{k}|^2|\mathbf{l}|^2\sin^2(\alpha)+\overline{(\Delta E)^2}(2E)^{-2}|\mathbf{k}|^2|\mathbf{l}|^2\cos^2(\alpha) \tag{9}$$

where α is the angle between $\mathbf{l}$ and $\mathbf{k}$. When the mean-square phase deviation approaches π^2, all phase relationship has vanished. The coherence length becomes

$$l_c = \frac{2\pi|\mathbf{k}|}{[2\overline{(\Delta\theta)^2}\sin^2(\alpha)+\overline{(\Delta E/E)^2}\cos^2(\alpha)]^{1/2}} \tag{10}$$

Choosing, e.g., $\Delta\theta \cong 0.001$ radians, $\Delta E \cong 0.2$ eV, $E = 150$ eV and $\alpha = 45^\circ$ gives

$$l_c \cong 500\text{Å} \tag{11}$$

APPENDIX B: DETAILS OF CALCULATIONS

The details of the atomic scattering event are only important at the level of a "black box"—knowing what goes in and comes out. Consequently, knowledge of the wave function of the electron beam within the atom is unnecessary; knowledge of the amount by which the phase of the scattered wave was advanced is all that is useful or required, and this describes the scattering completely. These phase shifts, δ_l are components of the atomic scattering t matrix, which has the form

$$t_l = \frac{\hbar^2}{2m_e}\left(\frac{1}{k_0}\right)\sin(\delta_l)\exp(i\delta_l) \tag{12}$$

where $k_0 = |\mathbf{k}|$, $\hbar \equiv h/2\pi$ (where h is Planck's constant), and m_e is the mass of the electron. Note that it has been found convenient to represent scattering from an assumed spherical atom by a spherical wave formalism. This necessitates decomposing the incident plane waves into spherical partial waves for purposes of the scattering event. In a practical calculation, one cannot carry out the spherical wave expansion to infinite orders of precision, so one may approximate the maximum required angular momentum, l by $l_{\max} \approx k_0 \times r_{\text{mt}}$, where r_{mt} is the muffin-tin radius of the atom in question. Of course, this is only a rule of thumb, and one should check that the inclusion of higher-order terms does not change the results of a calculation.

Once the atomic scattering parameters have been determined, an atomic layer is constructed. Usually, it is simple to divide the crystal into layers, although sometimes it is necessary to create a "composite layer" of inequivalent atoms at either the same or similar heights; this is most frequently true for the topmost layer and for closely spaced planes. Scattering matrices are determined for each plane, $M_{\text{gg}}^{\pm\pm}$, which relate the amplitudes of a scattered wave with momentum $k_{\text{g}}^{\pm}$ to that of an incident wave with momentum $k_{\text{g}}^{\pm}$. In the previous notation, "+" is taken to signify a wave propagating into the crystal while "−" denotes an outgoing wave, and k_{g} is the momentum of an electron having experienced parallel momentum transfer of $\mathbf{g}$, one of the reciprocal lattice vectors of the crystal. A matrix inversion formalism can be used for this calculation, using a spherical wave representation

for each of the subplanes of a composite layer. This approach was developed by Beeby (1968) and generalized by Tong and Van Hove (1977) for use with all beams. The following are defined in atomic units $\hbar = m_e = 1$ in a spherical wave representation [$L = (l,m)$] directly after Van Hove and Tong (1979):

$t_l^i = \frac{1}{2k_0}\exp(i\delta_l)\sin(\delta_l)$: Scattering t-matrix for a single atom in subplane i.

$\tau_{LL'}^i$: Scattering matrix that contains all scattering paths within subplane i.

$T_{LL'}^i$: Scattering matrix that includes all those scattering paths within the composite layer that end at subplane i.

$G_{ll'}^{ji}$: Structural propagator describing all unscattered propagations from atoms in subplane i to atoms in subplane j.

The diffraction matrix is defined as

$$M_{gg}^{\pm\pm} = -\frac{16\pi^2 i}{Ak_{g'\perp}}\sum_{LL'} Y_L(k_{g'}^{\pm})\sum_{i=1}^{N}\{\exp[i(\pm k_g^{\pm} \mp k_{g'}^{\pm})\cdot r_i]T_{LL'}^i\} \times Y_{L'}^8(k_{g'}^{\pm}) + \delta_{g'g}\delta_{\pm\pm} \quad (13)$$

with

$$G_{LL'}^{ji} = \hat{G}_{LL'}^{ji}\exp[-ik_g^{\pm}\cdot(r_j - r_i)] \quad (14)$$

$G_{LL'}^{ji}$ may be expressed as a sum over reciprocal lattice points with

$$\hat{G}_{LL'}^{ji} = \frac{16\pi^2 i}{A}\sum_g \frac{\exp[ik_g^{\pm}\cdot(r_j - r_i)]}{k_g^{\pm}} Y_L^*(k_g^{\pm})Y_{L'}(k_g^{\pm}) \quad (15)$$

where Y_{lm} is a spherical harmonic, A is the unit cell area, and r_i and r_j are the positions of arbitrary reference atoms in subplanes i and j, respectively. The subplane τ matrix is

$$\tau_{LL'}^i = [(I - t^i G^{ii})^{-1}]_{LL'} t_l^i \quad (16)$$

where I is the multiplicative identity matrix. According to Beeby (1968), the matrices $T^1, \ldots, T^N$ are obtained directly from the equation

$$\begin{pmatrix} T^1 \\ T^2 \\ \vdots \\ T^N \end{pmatrix} = \begin{pmatrix} I & -\tau^1 G12 & \ldots & -\tau^1 G1N \\ -\tau^2 G21 & I & \ldots & -\tau^2 G2N \\ \vdots & \vdots & & \vdots \\ -\tau^N G^{N1} & -\tau^N G^{N2} & \ldots & I \end{pmatrix}^{-1} \begin{pmatrix} \tau^1 \\ \tau^2 \\ \vdots \\ \tau^N \end{pmatrix} \quad (17)$$

This completes the calculation of $M_{g'g}^{\pm\pm}$.

The final step is to calculate the interlayer scattering, which is typically done using the renormalized forward scattering (RFS) method developed by Pendry (1974). The RFS method takes advantage of the physical fact that forward scattering is much more probable than backscattering (backscattered flux is typically 1% to 5% incident flux), and the reflectivity is expanded in terms of the number of reflections experienced by the electron wave. Note that only an odd number of reflections will contribute to any observed diffraction beam. This method can be implemented by allowing the transmitted (forward scattered) waves to propagate through the crystal until their amplitude decays to a negligible value due to inelastic effects. The backscattered waves are then propagated back through the crystal, and the exiting amplitudes become the first-order result. The second order is obtained by allowing each of the backscattered waves to reflect twice more and exit the crystal, and so on for higher orders. This is continued until convergence is attained, when the reflected amplitude changes negligibly from a previous pass. This method tends to converge because inelastic damping prohibits very high-order waves from surviving. The formalism makes use of two iterative expressions for the interlayer amplitudes, one for penetration

$$a_{(i)g}^{\text{new}} = \sum_{g'}[M_{gg'}^{++}P_{g'}^{+(i-1)}a_{(i-1)g} + M_{gg'}^{+-}P_{g'}^{-(i)}a_{(i)g'}] \quad (18)$$

and one for emergence (Van Hove et al., 1986)

$$a_{(i)g}^{\text{new}} = \sum_{g'}[M_{gg'}^{--}P_{g'}^{-(i+1)}a_{(i+1)g'} + M_{gg'}^{-+}P_{g'}^{+(i)}a_{(i)g}] \quad (19)$$

where $P_g^{\pm -i}$ are plane wave propagators between appropriate reference points on successive layers and $a_{(i)g}^{\text{new}}$ is constantly overwriting $a_{(i)g}$. RFS typically requires 12 to 15 layers and 3 to 4 orders to achieve convergence (Van Hove et al., 1986, p. 174). This method also requires that layer spacings be greater than $\sim$1 Å, or too many plane waves are required for convergence. In these cases, alternative methods such as layer doubling must be employed.

ENERGY-DISPERSIVE SPECTROMETRY

INTRODUCTION

Energy-dispersive x-ray spectrometry (EDS) is a technique for measuring the intensity of x-ray emission as a function of the energy of the x-ray photons (Fitzgerald et al., 1968; Goldstein et al., 1992). The excitation source for the x-rays can be energetic electrons, photons, or ions, and the target can be solid, liquid, or gas, although solid targets are the norm in virtually all materials science applications. The measured x-ray intensity can be related to the concentration (i.e., mass or atomic fraction) for each

element present by performing physical/empirical matrix corrections to account for the interelement modification of the generated x radiation caused by (1) primary radiation stopping power and ionization effects, (2) attenuation of secondary characteristic x-rays during their passage through matter, and (3) any inefficiencies in detection. In this chapter, various aspects of the process of obtaining high-quality x-ray spectra, the interpretation of spectra, and the accurate extraction of x-ray intensities from spectra will be considered.

Materials analysis techniques that employ EDS include the following.

Electron excitation: (1) electron probe x-ray microanalysis (EPMA)/analytical scanning electron microscopy (ASEM), where EDS complements wavelength-dispersive x-ray spectroscopy (WDS); (2) analytical electron microscopy (AEM).

Photon excitation: X-ray fluorescence (XRF).

Ion excitation: particle-induced x-ray emission (PIXE).

This chapter will concentrate on EDS performed in electron-beam instruments (Williams et al., 1995). The general principles of EDS x-ray detection, processing, display, and spectral manipulation are similar for all analytical techniques regardless of the excitation source. The procedures for quantitative analysis depend in detail on the excitation process. Quantitative x-ray microanalysis by electron excitation is considered in detail in the section on Electron Probe Microanalysis. Those aspects of quantitative x-ray microanalysis that are particular to EDS spectral measurement will be considered.

Measurement Challenge. All elements except H and He produce characteristic x rays. Because of self-absorption in the target and absorption in the components of the spectrometer/detector, the practical minimum photon energy that is accessible by any analytical spectrometry technique is ~0.1 keV, which excludes measurement of Li (0.052 keV). Measurement of all elements beginning with the Be K-shell (0.108 keV) is possible, with heavy elements typically detected with their M- or L-shell lines (with an upper bound of ~15 keV for the L-shell). For certain applications, photon energies as high as 100 keV may be of interest (e.g., K-lines of any element excited with the AEM operating at electron energies of 200 keV or higher). The ideal form of x-ray spectrometry would measure photons (1) in the range 100 eV to 100 keV with high-energy resolution to avoid spectral peak interferences and to reduce the contribution of background processes to the peaks; (2) with true parallel detection of different photon energies to maximize measurement efficiency and to improve the utility for qualitative analysis; or (3) if serial detection of photons is the only possibility, then with a short measurement time constant to minimize coincidence events; and (4) with no added artifacts in the spectrum. These factors will be considered for semiconductor detector-based EDS systems in current use, and for other types of EDS detectors now under development for future application to analytical systems.

PRINCIPLES OF THE METHOD

The basic principles of the measurement process for the semiconductor energy-dispersive x-ray spectrometer are illustrated in Figure 1A, and a schematic diagram of a generic semiconductor EDS system is shown in Figure 1B (Goldstein et al., 1992). An x ray with energy E_v is absorbed photoelectrically by an atom in a semiconductor crystal (Si or Ge) creating a photoelectron with energy $E_v - E_c$, where E_c is the critical ionization energy (binding energy) for the shell (e.g., $E_K = 1.84$ keV for the Si K-shell) and leaving the absorbing atom in an excited, ionized state. Consider a detector fabricated with Si. The Si atom will subsequently de-excite through electron shell transitions that will cause the subsequent emission of

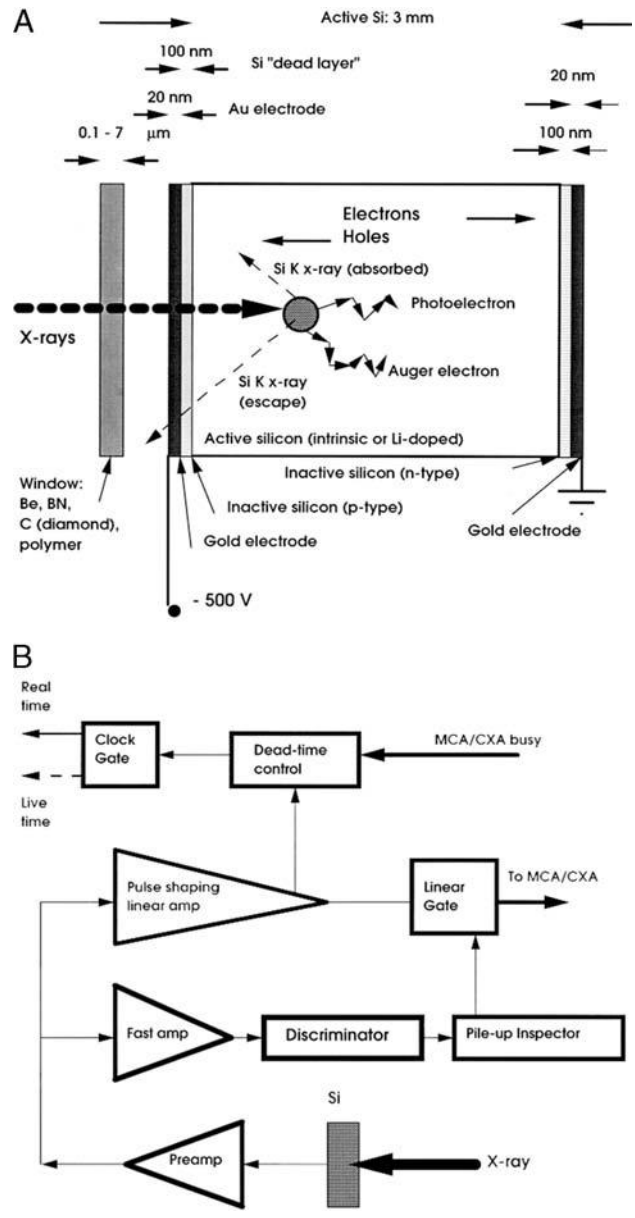

Figure 1. (**A**) The measurement process for the semiconductor energy-dispersive x-ray spectrometer. (**B**) Schematic diagram of a generic semiconductor EDS spectrometry system.

either an Auger electron (e.g., Si KLL) or a characteristic x-ray (Si Kα, $E = 1.74$ keV or Si Kβ, E = 1.83 keV). If an x-ray is emitted it may be reabsorbed in a photoelectric event with a lower binding energy shell (e.g., Si L-shell) with the emission of another photoelectron and subsequently another Auger electron. This cascade of energetic electron generation within the semiconductor is completed within picoseconds. The energetic electrons subsequently scatter inelastically with a very short mean free path (tens of nanometers or less) while traveling in the crystal, giving up their energy to crystal electron and phonon excitations. In particular, electrons from the filled valence level in the semiconductor crystal can be promoted to the empty conduction band where they are free to move under an applied electric field, leaving behind a positive "hole" in the valence band, which can also move. By placing a bias potential (500 to 1000 V) across the faces of the crystal, the free electrons and holes can be separated before they recombine. Creation of an electron-hole pair in silicon requires ~3.6 eV, so that a 3.6-keV photon will create ~1000 electron-hole pairs. The charge carriers drift out of the detector in a time of hundreds of nanoseconds. Measuring the collected charge gives a value proportional to the energy of the original photon. This is the critical measurement in x-ray EDS. A detailed description of the amplification and charge measurement electronics of the EDS system is beyond the scope of this unit. It is critical that a high-gain, low-noise amplification process be employed, since the detection of a photon involves measuring a deposited charge of $\sim 10^{-16}$ C and this measurement must be completed in ~50 μs (Williams et al., 1995).

An EDS system consists of several key components, Figure 1B: (1) A semiconductor crystal detector, typically housed with a field-effect transistor (FET) preamplifier in a cryostat cooled with liquid nitrogen to maintain a temperature of ~100 K or lower at the detector to minimize thermal noise. (Some systems use electrical Peltier cooling and operate at higher temperature and noise to avoid the need for liquefied gas.) (2) A high-voltage power supply to provide the detector bias (~ 500 V). (3) A slow main amplifier, which takes the pulses from the preamplifier and provides further amplification and pulse shaping. (4) A fast pulse inspection function, which monitors the charge state of the detector as a function of time and is used to reduce pileup events. (5) A "deadtime" correction function, which compensates for the time when the detector is processing a pulse and unavailable for other pulses by adding time to the clock to achieve the specified "live" accumulation time. (6) A computer-assisted analysis system [multichannel analyzer (MCA) or computer x-ray analyzer (CXA)] for spectrum display and manipulation. With the rapid evolution of computer control of measurement systems, many of these functions may take place within the computer control system, and in modern systems virtually all are controlled by software commands. Moreover, digital pulse processing, in which the entire preamplifier waveform is digitized by a high-speed circuit for subsequent processing, is emerging as a means to improve pulse handling and deadtime correction (Mott and Friel, 1995).

The EDS x-ray spectrum presented to the analyst by the computer-assisted analyzer consists of a histogram of channels calibrated in energy units containing counts corresponding to the detection of individual photons. An example of an EDS spectrum of a pure element, titanium, excited with an incident beam energy of 20 keV is shown in Figure 2A and expanded vertically in 2B. Consider this spectrum in terms of the measurement challenge posed above. The semiconductor EDS detector fulfills the first requirement that a wide energy range be accessible. Photons in the range 100 to 20 keV can be readily measured with a Si EDS detector, as shown in the logarithmic display in Figure 2C, and with decreasing efficiency, photon energies as high as 30 keV can be measured. The range can be extended to 100 keV with the use of Ge as a higher-density detector. It is this "energy-dispersive" character that provides the greatest value in practical analytical x-ray spectrometry, because it enables access to the entire periodic table (except H, He, and Li) with every spectral measurement. A complete qualitative analysis can (and should!) be performed at every sample location analyzed. With EDS measurements, constituents should not be missed unless they suffer severe interference from another peak or are present at concentrations below the limit of detection for the measurement conditions chosen.

Concerning the second criterion, the resolution (i.e., width) of x-ray peaks measured by EDS is relatively coarse and is limited by the statistical nature of the charge generation and collection process. A typical figure of merit used to define the resolution of a system is the width of the Mn Kα peak (chosen because of the use of the ^{55}Fe radioactive source, which decays by electron capture with subsequent emission of Mn K-radiation). The resolution of a typical Si EDS is measured as the full width of the peak at half the peak intensity (full width half-maximum, FWHM) and is typically ~130 to 140 eV at Mn Kα (5890 eV) for Si detectors operating in the optimum resolution (i.e., long integration time constant) or a fractional width of 2.3%. This compares to the natural peak width of ~ 2 eV; i.e., the line is broadened by a factor of ~75. The Ge EDS can achieve an improved resolution of ~120 eV. The resolution is energy dependent and is described approximately by the following expression (Fiori and Newbury, 1978):

$$\mathrm{FWHM} = [2.5(E - E_{\mathrm{ref}}) + \mathrm{FWHM}^2_{\mathrm{ref}}]^{0.5} \qquad (1)$$

where the reference peak is usually Mn Kα. This relatively poor energy resolution leads to a significant number of peak overlaps in practical analysis situations (e. g., S K, Mo L, and Pb M), and also constrains the limit of detection (concentration) when a significant background process is present, as in the case of the electron-excited bremsstrahlung (continuum) radiation.

Considering the third criterion for parallel collection, when the accumulation of an EDS spectrum is observed, the EDS appears to provide parallel collection across the entire energy range. Actually, the term "energy dispersive" in the name of the technique is traditional and not strictly correct. No dispersion in the classic spectroscopic sense actually occurs in the measurement of the x-ray spectrum with EDS. [In the older literature, the more descriptive term "nondispersive" was often applied

(Heinrich, 1981).] The photons are detected individually, and the EDS detection process can only accommodate one photon at a time since the entire volume of the monolithic semiconductor crystal is involved. While a photon of any energy within the range specified above can be detected at any given time, detection is a serial process, so that if a second photon enters the detector while the first is being processed, the measurement of one or both may be corrupted. Because it takes time for the charge to drift out of the detector and an even longer time to measure that charge accurately, the EDS detection process is paralyzable. As more and more photons enter the detector, the output count rate first increases with increasing input count rate, but eventually reaches a maximum and decreases with any further increase in the input count rate.

The final criterion for defect-free spectra is also not satisfied for semiconductor EDS, because of the formation of certain parasitic peaks during the detection process (escape and sum peaks), the nonuniform efficiency with

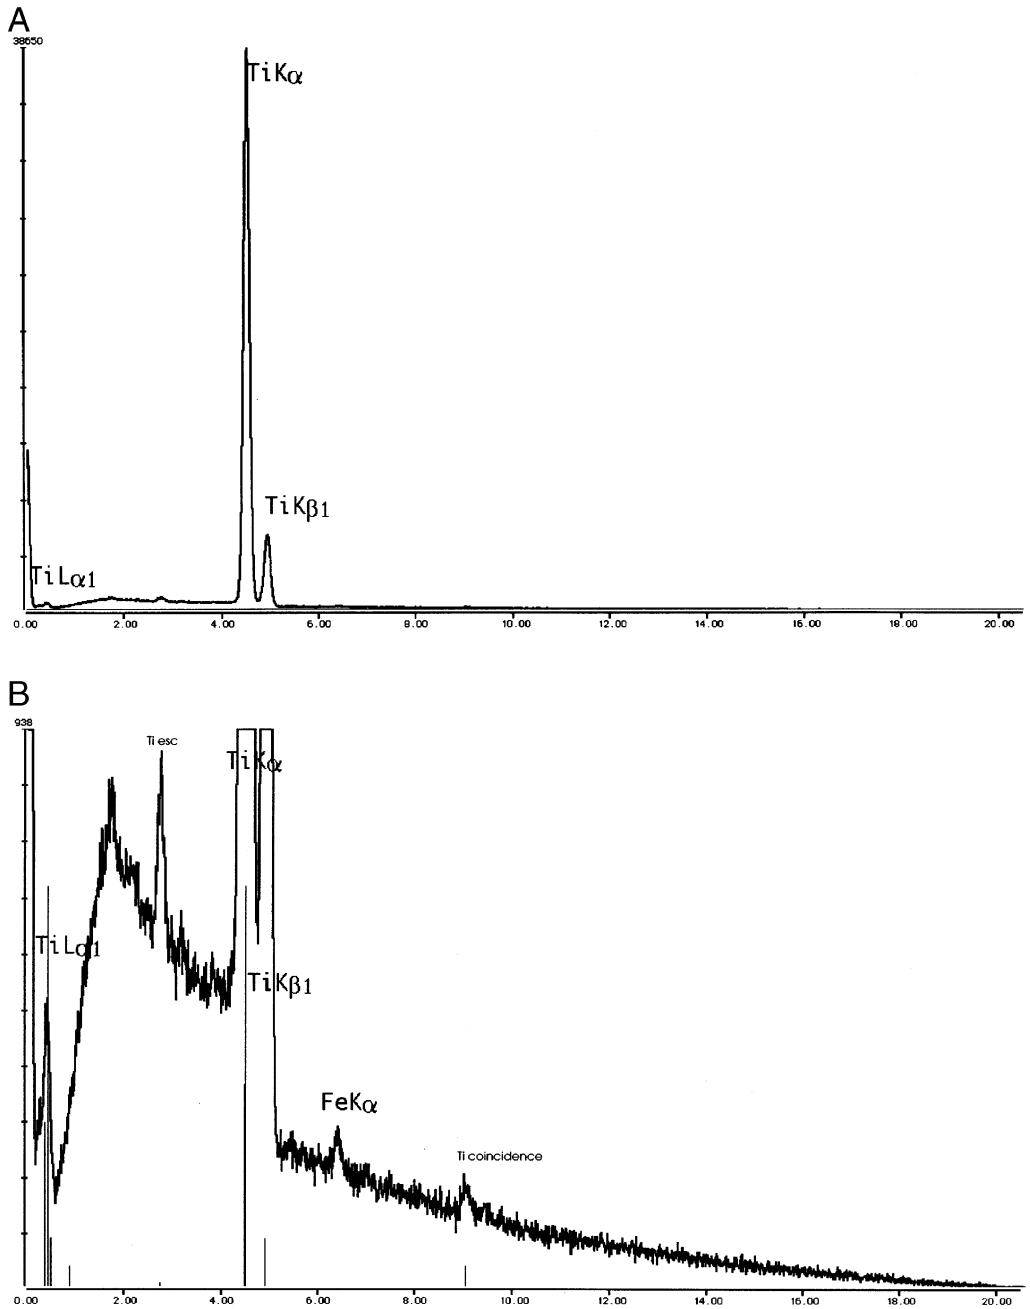

Figure 2. EDS spectrum of a pure element, titanium, excited with an incident beam energy of 20 keV. Figure 2 (*Continued*)

photon energy, and the fundamental distortion imposed upon the spectrum by the relatively coarse resolution function.

1. *Escape Peaks.* The escape peak arises because during the photon capture process within the detector, the de-excitation of the Si (or Ge) atom leads to the emission of a Si Kα photon (or Ge Lα and Ge Kα) in ~10% of the events. A material is relatively transparent to its own characteristic x rays, so the range of Si Kα in Si is much greater than that for the Si photoelectrons and Si Auger electrons, and moreover, the Si Kα x-ray does not lose significant energy by inelastic scattering within the detector. While the Si Kα x ray can be absorbed photoelectrically in an interaction with a Si L-shell electron, there is a significant chance that it will escape the detector, which robs the photon being measured of 1.74 keV of energy. These deficient pulses form a parasitic peak displaced by 1.74 keV below the parent peak, as noted in the spectrum of pure titanium shown in Figures 2B and C. The relative size of the escape peak depends on the average depth of capture of the primary photon within the detector crystal, so that peaks with energies just above the silicon K edge (1.84 keV) show the largest escape peaks. For P Kα (2.015 keV), the escape peak is ~2% of the parent peak intensity, while for photons above 5 keV, the escape peak becomes less significant, e.g., 0.5% for Fe Kα.
2. *Sum Peaks.* The pulse-inspection circuitry constantly monitors the rate of change of charge flow from the detector. After a photon arrival is detected and the measurement process is initiated, any subsequent photon detection during the pulse processing time changes the rate of charge flow from the detector and triggers a decision to retain or exclude the initial photon measurement in process. This pulse inspection circuit has a finite time resolution, so that it is possible for two photons to enter the detector so close in time that they cannot be distinguished. In such a case, their energies are added, creating a coincidence or "sum" peak. It is possible for any two photons to coincide, but it is only the high-abundance peaks that can give rise to noticeable spectral defects, as marked in Figures 2B and C. Coincidence peaks become progressively greater in relative height as the input count rate increases. For system deadtime below ~30%, the coincidence effect will be negligible, especially if the target contains several major elements so that the effective peak count rate is reduced compared to that for a pure element. Note that for equivalent counting rates, sum peaks become relatively more significant as the photon energy decreases, because the charge pulse produced by a low-energy photon is closer to the fundamental noise level and the coincidence exclusion circuit is therefore less efficient at distinguishing photon events. For low-energy photons (<1 keV), the pileup inspector may not function at all.
3. *Nonuniform Detection Efficiency.* Any photon in the energy range 100 to ~15 keV that actually enters the active volume of the detector is captured with near unit efficiency. Photons >15 keV in energy are increasingly lost with increasing energy due to penetration through a Si detector, while for a Ge detector, useful efficiency remains out to 100 keV. However, photons below ~4 keV suffer significant loss due to absorption in the spectrometer components: aluminum reflective coatings, window materials, gold surface electrodes, and silicon "dead" (actually,

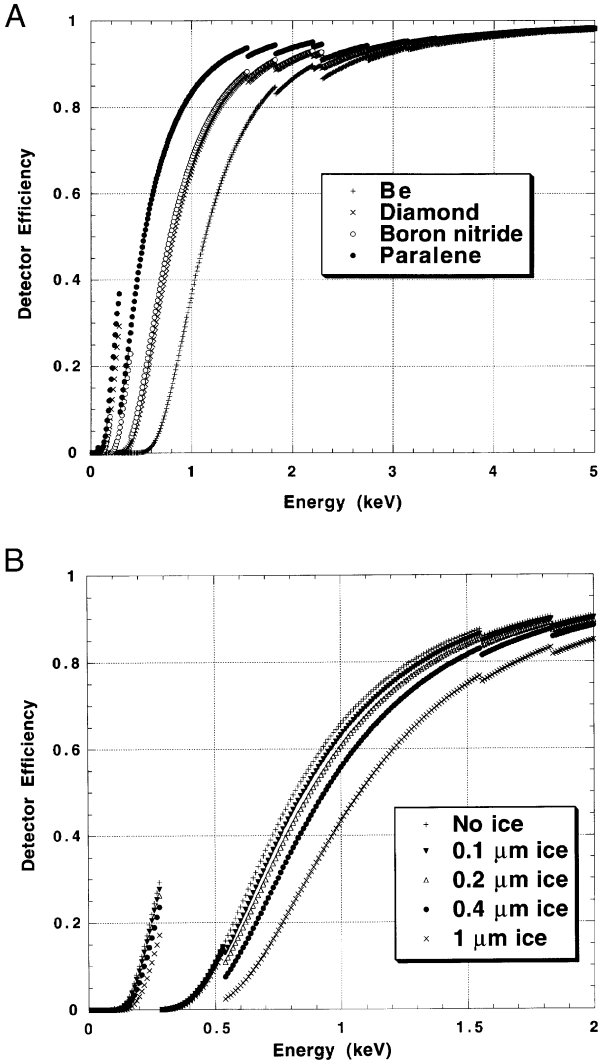

Figure 3. (**A**) Detector efficiency for various windows: boron nitride (0.5 μm), diamond (0.4 μm), beryllium (7.6 μm), and paralene (0.3 μm) (Al window coating = 0.02 μm; Au electrode = 0.01 μm; Si dead layer = 0.03 μm). The absorption edge at 0.28 keV is due to the presence of carbon in some of the windows. Edges due to the Au electrode and the Si dead layer can also be seen in the figure. (**B**) Detector efficiency for a diamond (0.4 μm) thin window showing the effect of ice buildup.

partially active) layers, as well as pathological layers due to possible contamination on the window, and ice on the detector. Efficiency curves are presented in Figure 3A for various windows (Be, diamond, boron nitride, and polymer) on a Si detector with a 20-nm gold electrode, a 30-nm silicon dead layer, and a 20-nm Al reflective coating. The effect of ice buildup on the detector efficiency (diamond window) is shown in Figure 3B.

4. *Spectrum Distortion.* The action of the detector resolution function on the spectrum is illustrated in Figure 4, where the "true" spectrum calculated theoretically (using NIST-NIH Desktop Spectrum Analyzer; Fiori et al., 1992) following absorption in the specimen is compared with the actual EDS spectrum after all stages of the measurement process. The broadening of the peaks from "line" spectra (the characteristic peaks are shown as single lines because the true peak width is actually less than the 10-eV channel width) into Gaussian peaks 10 to 15 channels wide is evident. Less evident is the effect of spectrometer broadening on background distort ion, where the absorption edges are broadened. The parasitic escape and pileup peaks also contribute to spectrum distortion.

PRACTICAL ASPECTS OF THE METHOD

Optimizing EDS Collection

To obtain the best possible x-ray spectra for subsequent analysis, the analyst must carefully choose and/or adjust several aspects of the operation of the EDS system.

Resolution/Count Rate Range. The effective resolution of an EDS system depends on the time spent measuring each pulse (the "shaping time"). A tradeoff can be made between the maximum acceptable count rate and the resolution. Operating at the best resolution limits the maximum input count rate to $\leq$3 kHz. If the x-ray peaks of interest are well separated, it may be acceptable to operate with poorer resolution to obtain a higher acceptable counting rate, 10 kHz or higher. Whatever the choice, it is critical that the analyst be consistent when collecting a series of spectra, especially if measurements are taken over a period of time and compared to digitally archived standards.

Energy Calibration. The charge deposited in the detector must be accurately converted to the equivalent energy in a linear fashion. At the beginning of each measurement campaign, the user should check that the calibration (peak position) is correct within $\pm$10 eV using known x-ray peaks from standards. Accurate calibration is critically important for both qualitative and quantitative analysis. Adjustments of the zero and coarse/fine gain may be necessary via hardware or software settings to achieve accurate calibration. Ideally, the test peaks should span the analytical range, e.g., 100 to 12 keV. A typical first choice for this task is pure copper, which provides peaks at 0.93 keV (Cu Lα), 8.04 keV (Cu Kα), and 8.68 keV (Cu Kβ). Note that a prudent analyst will also check selected lines at intermediate energies [e.g., Si Kα (1.74 keV), Ti Kα (4.51 keV), and Fe Kα (6.40 keV)], as well as higher-energy lines [e.g., Pb Lα (10.549 keV)]. It is commonly observed that even with a linear calibration established above 1 keV, the energy response may be nonlinear for photons below 1 keV. Due to the effects of incomplete charge collection for low-energy photons that are absorbed near the front electrode of the crystal, the peak position (and shape) may deviate significantly. Calibrating with a peak in this range is likely to introduce a nonlinearity for intermediate energies. The best procedure is to calibrate with the low reference peak chosen at 1 keV or above and then to check the position of important low-energy peaks, e.g., C K (0.282 keV) and O K (0.523 keV).

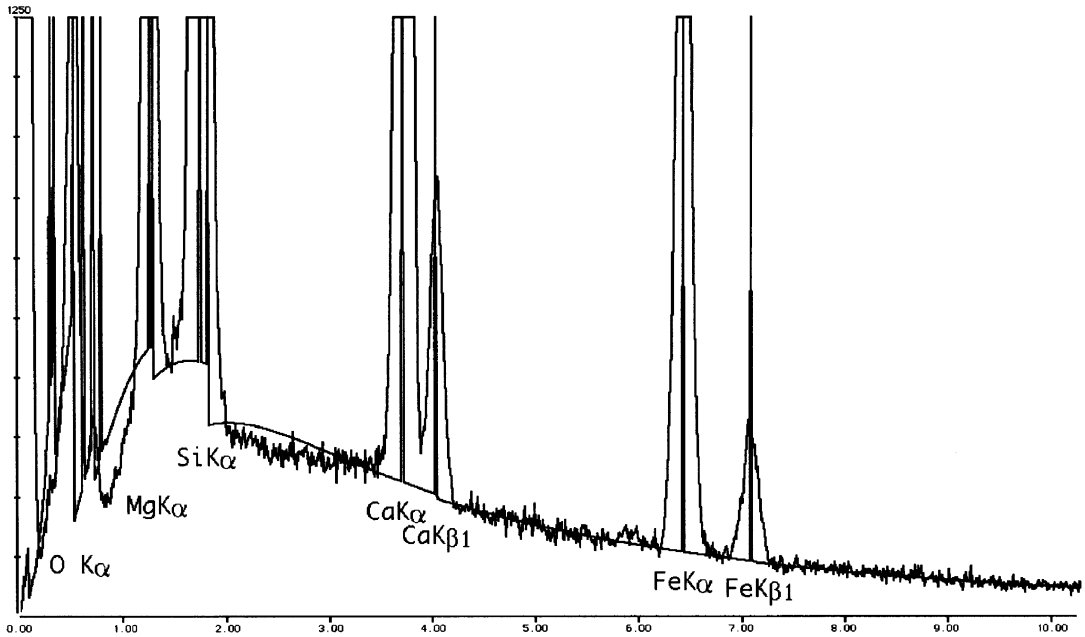

Figure 4. Comparison of experimentally measured spectrum (noisy) with theoretical spectrum as generated in the target (smooth). Specimen, NIST Standard Reference Material K-411 glass [Mg (0.08885); Si (0.254); Ca (0.111); Fe (0.112); O (0.424) mass fraction]; beam energy, 20 keV.

Deadtime Correction. The basis of quantitative analysis methods is the measurement of the x-ray intensity produced with a known dose (i.e., beam current $\times$ integration time). However, because the EDS has a paralyzable deadtime, the effective integration time would depend on the count rate if a simple clock (real) time were used for the measurement. The deadtime correction circuit automatically determines how long the detector is busy processing pulses and therefore unavailable to detect the arrival of another photon, and then adds on additional time units to the specified time of accumulation to compensate for this deadtime. The performance of the deadtime correction function can be checked by noting that all signals scale linearly with the beam current. An accurate current meter should be used to measure the beam current in a Faraday cup. Choosing a fixed "live time" (i.e., deadtime-correction applied), spectra should be collected from a pure-element standard (e.g., Cu or Fe) with progressive increases in the beam current. The x-ray counts in any peak (or background region) should increase linearly with the beam current to indicated system deadtime of $\geq$50%. Note that operation with the dose rate chosen to keep the deadtime $<$30% is advisable, since at higher deadtime artifacts such as coincidence peaks and pileup distortions in the background will occur.

METHOD AUTOMATION

Computers play an extensive role in energy-dispersive x-ray spectrometry, and in fact the advance of laboratory computerization has been a driving force in the incorporation of dedicated automation systems in electron microscope/EDS laboratories throughout the history of the technique (Williams et al., 1995). In current instrumentation, the computer plays a role at all stages of EDS detector control, digital pulse processing, spectrum display, qualitative and quantitative analysis, and archiving of spectral data. The multichannel analyzer (MCA) has given way to the computer-assisted x-ray analyzer (CXA), which is capable of controlling both the full functions of the scanning electron microscope (SEM) or analytical electron microscope (AEM) and the EDS system for unattended, automatic operation. Spectra can be collected from an operator-specified list of predetermined sites on the specimen, or in the most advanced systems, objects of a certain class, such as particles, can be automatically detected and located in electron images and then analyzed according to a specified protocol.

DATA ANALYSIS AND INITIAL INTERPRETATION

Qualitative Analysis

Qualitative analysis is the identification of the spectral peaks present and their assignment to specific elements. While state-of-the-art computer-assisted analysis systems will automatically identify peaks, a prudent analyst will always check on the suggested solutions to see if they agree with the analyst's assessment. This is particularly true for the low intensity peaks, which might correspond to minor (e.g., 1 to 10 wt.%) and trace (e.g., $<$1 weight percent) constituents, but which might also arise as minor family members, escape peaks, or sum peaks of high-concentration constituents. Automatic qualitative analysis usually operates on the basis of a look-up table in which the detected peak is compared with an energy database

and then all possible elements within a specified range, e.g., ±50 eV, are reported. These automatic results should only be considered as a guide, and the analyst must take the responsibility to confirm or deny each suggested possibility with manual qualitative analysis. One possible strategy for manual qualitative analysis is described below (Fiori and Newbury, 1978).

Before attempting manual qualitative analysis, it is critical that the analyst first determine the reliability of the database of x-ray information available in the computer-assisted analysis system in use. Certain minor lines in the L and M families (especially L1 and M_2N_4) produce low-relative-intensity peaks but yet are well separated in energy from the main family lines and therefore are readily visible. Such lines may not be included in the database and consequently will not appear in the "KLM" line markers for the display. If those lines are unavailable in the database, it is almost certain that they will be misidentified and assigned to another element. To evaluate the situation, the analyst should examine spectra measured from pure heavy metals (e.g., Ta, Au, Pb) to test the particular implementation of KLM markers as well as the automatic qualitative-analysis procedure against complex families of x-ray peaks. An example of a complete treatment of the lines is shown for the bismuth L and M families in Figure 5. The relative weights for the L- and M-family lines may also be of questionable value, and should only be considered as a crude guide. In addition, the analyst should test the response of the automatic qualitative analysis procedure against escape peaks and sum peaks with pure-element spectra, e.g., Al, Si, and Ti.

The basis for robust qualitative analysis is the identification, when possible, of multiple lines for each element and the careful location and notation of all minor-family-member and artifact peaks (Fiori and Newbury, 1978). To improve confidence in the identification of light elements that only produce a single line in the low photon-energy range (<3 keV), it is necessary to carefully exclude possible L- and M-line interferences from heavy elements. Finally, the identification of low-intensity peaks as arising from minor and trace constituents can only be made with confidence if all minor family members from high-intensity parent peaks have been located and properly assigned, as well as the corresponding escape and sum peaks. Adequate peak statistics must be obtained, which may require additional spectrum accumulation for identification of minor and trace constituents.

1. First identify the high-intensity peaks that arise from major constituents. The analyst should start at the upper end of the spectrum (>5 keV) and work down in photon energy because the members of each x-ray family are most widely separated above 5 keV and are almost always resolvable by semiconductor EDS, thus giving greater confidence to elemental assignments by providing two or more peaks for identification.
2. Once a tentative assignment has been made to a peak, all other family members must be located, e.g., Kα-Kβ; Lα-Lβα-Lγ-Lη-Ll; Mα-Mβ-Mγ-Mζ-M_2N_4. Both energy position and relative height (weights of lines) are important in making an assignment.
3. For x-ray peaks above 5 keV, if a K family is identified, then a lower-energy L family of the same element will also be present and must be located and identified. Similarly, if an L family above 5 keV is identified, there must be a corresponding M family at lower energy.
4. The escape peaks and sum peaks corresponding to each high-intensity peak must be located and marked. Note that both the escape and sum peaks increase in relative significance as the parent peak energy decreases.

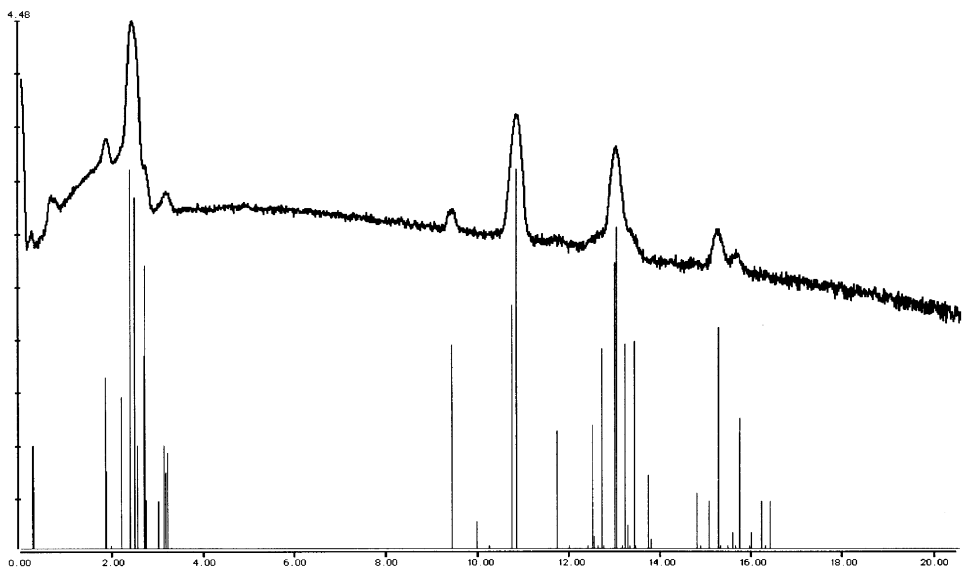

Figure 5. EDS spectrum of bismuth (logarithmic scale), showing KLM markers depicting the full M and L families. Beam energy, 25 keV.

5. Low-atomic-number elements ($Z < 15$) will produce a single unresolved K peak, since the Kα-Kβ peaks become progressively closer in energy and the relative Kα/Kβ ratio increases to more than 50:1 as the atomic number decreases. For fluorine and below, only one K peak exists. Thus, light elements can only be identified with a single peak, which reduces the confidence with which such assignments can be made. This is especially true for photon energies <1 keV, where x-ray absorption in the specimen significantly reduces the measured peak height relative to the higher-energy portion of the spectrum. Thus, care in identifying the higher-atomic number-elements that produce low-energy L- and M-family members is critical.
6. After the spectrum has been examined for major constituents and all possible peaks located and marked, the remaining low-intensity peaks can be assigned to minor and trace constituents following the same strategy. Note that because of the lower intensity of the peaks produced by minor and trace constituents, it may not be possible to locate and identify more than one peak per element, thus reducing the confidence with which an assignment can be made. If it is necessary to increase the confidence level that a minor or trace constituent is present, a longer accumulation time may be required to improve the counting statistics and reveal additional peaks against the statistical fluctuations in the background.
7. A final question should always be considered: What minor/trace elements could be obscured by the high-intensity peaks of the major constituents, e.g., Ti-K and Ba-L, Ta-M, and Si-K?

Quantitative Analysis

The first step in achieving accurate quantitative analysis is the extraction of the characteristic x-ray intensities from the EDS spectrum (Heinrich and Newbury, 1991; Goldstein et al., 1992; Williams et al., 1995). The relatively poor resolution in EDS results in low spectral peak-to-background ratios and frequent severe peak interferences. Careful spectral deconvolution is a critical step in any quantification scheme. Several mathematical tools are used in various combinations in different deconvolution strategies.

Background Removal

Characteristic peaks can be separated from background by two approaches: modeling and filtering.

In background modeling, a physical model for the background parameterized in terms of primary radiation energy, x-ray energy, and specimen composition is used to predict the background intensity as a function of energy, constrained to match the experimental spectrum at two or more energy values. Figure 6 shows the results of a background fit using the background model of Small et al. (1987) to a multielement glass (NIST K309). An excellent fit is found across the full energy range, with the only significant deviation occurring below the oxygen K line (0.523 keV). When background modeling the spectrum from an unknown specimen, the composition is initially estimated as part of a quantitative analysis procedure and an iteration procedure is followed as the specimen composition is refined. An accurate background fit is most critical for minor and trace constituents. High-intensity peaks are less sensitive to the background, so that the estimate/iteration approach is effective for unknowns.

In background filtering, a mathematical algorithm that acts as a frequency filter is applied to the spectrum (Goldstein et al., 1992). Transformed to frequency space, the peaks in the spectrum reside in the high-frequency component, while the background represents the low-frequency component. These components can be separated using a top-hat filter, which acts by transforming the contents of

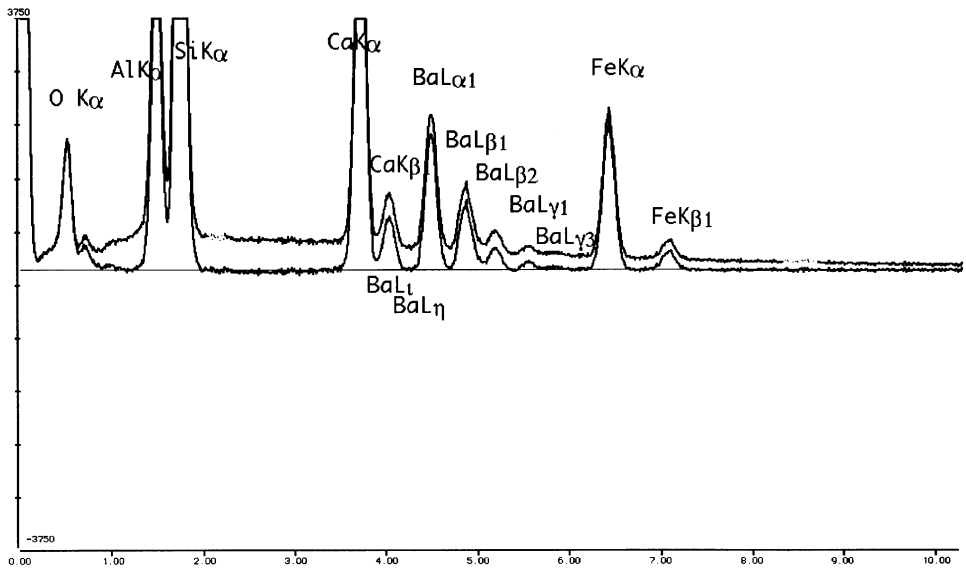

Figure 6. Result of a background fit to a complex specimen. NIST glass K309 [Al (0.079 mass fraction); Si (0.187); Ca (0.107); Fe (0.105); Ba (0.134); O (0.387)]. Beam energy, 20 keV.

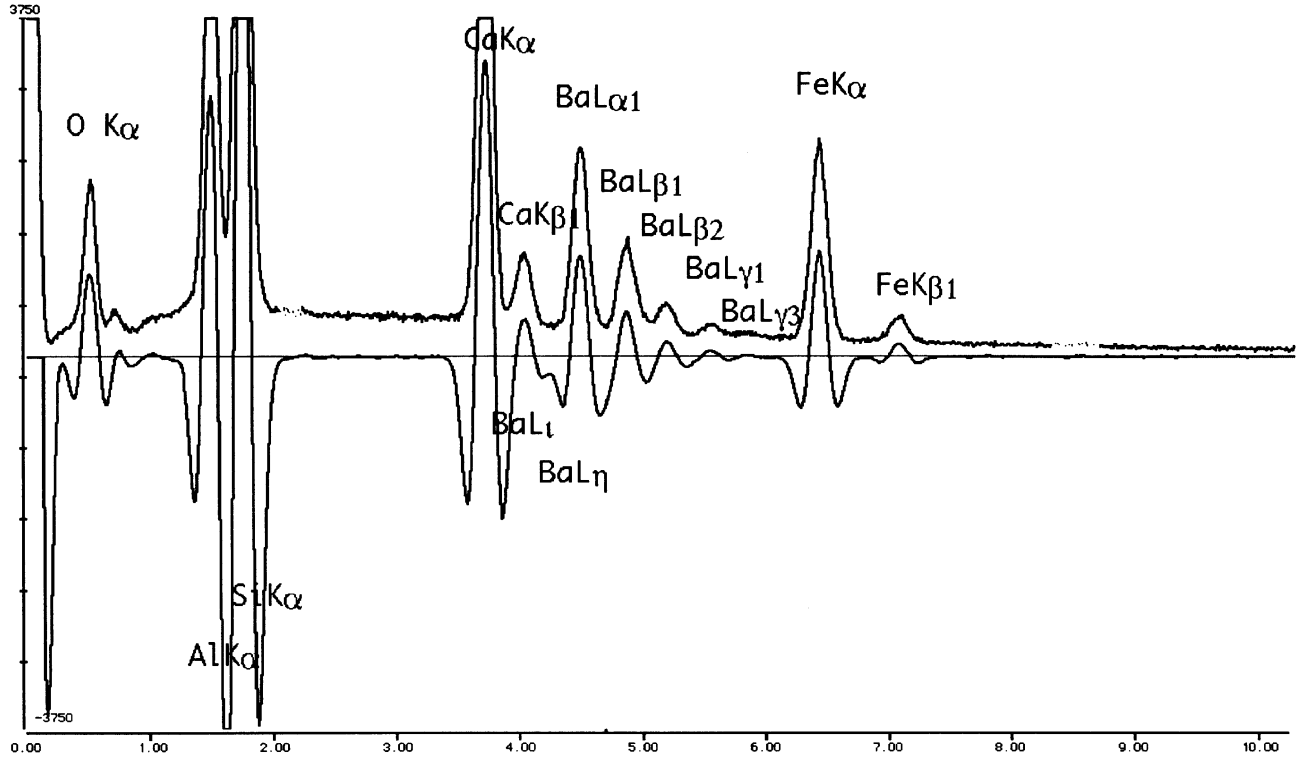

Figure 7. Result of the application of a top-hat digital filter to a complex specimen. NIST glass K309 [Al (0.079 mass fraction); Si (0.187); Ca (0.107); Fe (0.105); Ba (0.134); O (0.387)]. Beam energy, 20 keV.

a channel with a sum of scaled values from adjacent channels. Figure 7 shows the effect of a top-hat filter on the K309 spectrum.

Deconvolution of Peak Overlaps

Most commercial software systems utilize peak fitting by the method of multiple linear least squares (MLLS). In MLLS, a peak reference is first prepared that contains the full peak shape for an element separated from the background and without interference from other elements. Ideally this reference is measured on the same EDS system that is used to measure the unknown. The reference contains the measured response of the particular EDS for all peaks in the family in the energy range of interest. The reference shows the true response of the EDS to each peak, including any deviations from the ideal Gaussian shape, such as incomplete charge collection, which is a function of the particular detector. To deconvolve an unknown, references for all elements expected in a specified energy region of interest are collectively fit to the unknown peak bundle. The goodness of fit between the synthesized spectrum and the real spectrum is determined on a channel-by-channel basis, using a statistical criterion such as the chi-squared value. The only variable is the peak amplitude for each component, so combinations of the references can be synthesized by linear superposition. An example of MLLS fit to the Sr-L, W-M region of a $SrWO_4$ spectrum is shown in Figure 8, which contains both the original spectrum and the background remaining after peak stripping. Because linear mathematics is used, MLLS fitting can be very fast, requiring <1 sec per spectral region of interest. It is critical that the MLLS references be appropriate to the EDS system in use in terms of calibration and peak shape (resolution). Any deviation in system response will impact the accuracy of an MLLS deconvolution. It is extremely useful to be able to inspect the spectrum after MLLS peak stripping to detect failures in the fitting. A fit to the Ti Kα,β peaks in $SrTiO_3$ with a good peak reference derived from TiO_2 measured in the same sequence is shown in Figure 9A. Both the original spectrum and the residuals following peak stripping are shown. The effect of a 10-eV (one-channel) shift in the position of the recorded spectrum relative to the reference is shown in Figure 9B, and a 20-eV difference in resolution (unknown broader than reference) is shown in Figure 9C. The value of examining the residuals following any spectrum modification operation such as stripping is well illustrated by these examples.

Sequential simplex fitting is an alternative approach to peak deconvolution that does not require prior determination of peak references (Fiori et al., 1981). The simplex approach requires an assumption of the peak shape, taken as a Gaussian for EDS x-ray peaks. A test spectrum is synthesized for the elements being fit, and the correspondence to the measured spectrum is compared on a channel-by-channel basis. The simplex is a nonlinear fitting procedure, and can simultaneously be fit for three variables for each peak: position (energy calibration), width (resolution), and amplitude. Thus, simplex fitting can respond

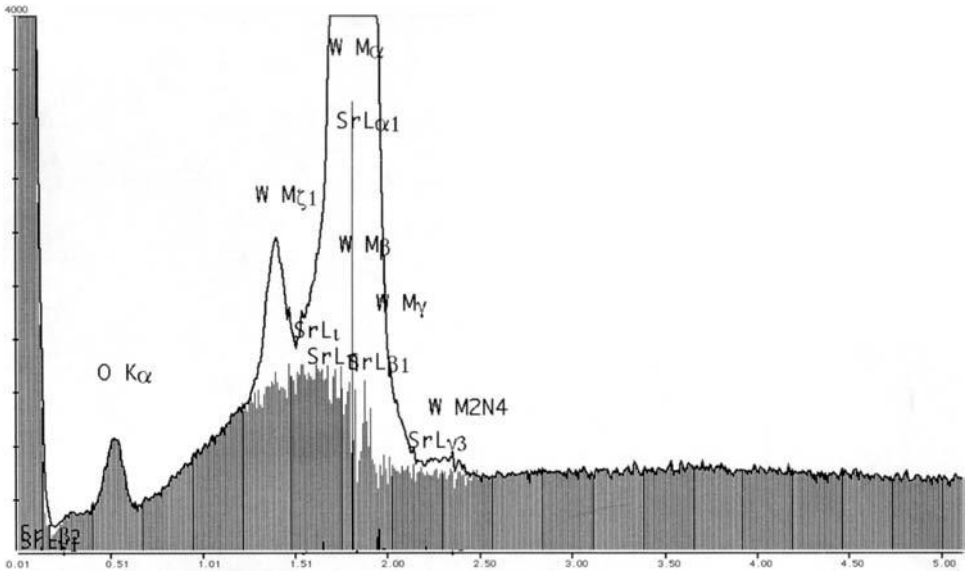

Figure 8. Multiple linear least-squares stripping of the W M family and the Sr L family in SrWO4. Beam energy, 20 keV. Solid black trace, original spectrum; gray spectrum, background remaining after stripping.

to instability in the EDS system. Because of the more complex, nonlinear calculations, the simplex procedure is significantly slower, by a factor of 10 or more, than the MLLS approach.

Matrix Corrections

Once characteristic x-ray intensities have been extracted from spectra of unknowns and standards, quantitative analysis proceeds in the same way for EDS as for wavelength-dispersive x-ray spectrometry (WDS) in electron probe microanalysis. The central paradigm of quantitative electron-excited x-ray microanalysis with WDS or EDS is the measurement of the unknown and standards under identical conditions of beam energy, spectrometer efficiency, known electron dose, and spectral deconvolution. The first step is the determination of the ratio of intensities for the same x-ray peak in the unknown and the standard, which to a first approximation is equal to the ratio of the elemental concentrations in weight fractions (Castaing, 1951):

$$k = I_{\text{unk}}/I_{\text{std}} \sim C_{\text{unk}}/C_{\text{std}} \qquad (2)$$

Note that in this ratio the efficiency of the detector cancels quantitatively because the same x-ray peak is measured for the unknown and for the standard.

The concentration ratio is not exactly equal to the k ratio because of the action of matrix (interelement) effects (Goldstein et al., 1992). Matrix effects arise because of compositionally dependent differences between the sample and standard in the following processes.

1. ***Electron Scattering.*** The backscattering of high-energy electrons increases with the atomic number of the target (and therefore varies depending on composition). Backscattering reduces the ionization power of the beam electrons.
2. ***Electron Stopping.*** The loss of energy from the beam electrons due to inelastic scattering depends upon the composition. The efficiency of the ionization depends upon the ratio of the electron energy to the critical excitation energy of the atomic shell of interest. Differences in electron stopping with composition modify the ionization power.
3. ***X-ray Absorption.*** Characteristic x rays are produced over a range of depth in the target and must travel through the solid to reach the detector. X rays are subject to photoelectric absorption, and this absorption depends on the path length and the mass-absorption coefficients, which are compositionally dependent.
4. ***Secondary X-Ray Fluorescence.*** X rays that are higher in energy than the excitation energy of a particular atomic shell can be photoelectrically absorbed through interaction with that shell, leading to subsequent emission of the shell's characteristic x ray. This secondary fluorescence can be induced by higher-energy characteristic x rays or by continuum (bremsstrahlung) x rays.

These four effects can be expressed as a series of multiplicative correction factors that convert the k ratio of intensities to the equivalent ratio of weight concentrations.

$$C_{\text{unk}}/C_{\text{std}} = kZAF \qquad (3)$$

The Z, A, and F factors can be derived from first-principles physical calculations (such as Monte Carlo electron-trajectory simulations), but because of the difficulty in determining certain critical parameters with adequate

accuracy, the matrix factors are often based at least partially upon experimental measurements of the required data.

Since the Z, A, and F factors depend upon the composition, which is initially unknown, a starting estimate of the composition is obtained by normalizing the set of measured k values for all elements in the specimen:

$$C_{i,n} = i_i/\Sigma k \tag{4}$$

From this initial estimate of composition, a set of correction factors is calculated and the corresponding k values are calculated and compared with the measured k values. This procedure is iterated until convergence is achieved, which is generally within three iterations. Note that for oxidized systems, the low energy of the oxygen characteristic x ray (0.523 keV) leads to severe absorption in the target and in the detector components, and consequently a large uncertainty in the calculated absorption correction. It is thus common practice to include oxygen by the method of assumed stoichiometry, where based upon the analysis of the cations, an appropriate amount of oxygen is added according to the assumed cation valences.

An example of a quantitative analysis of a microhomogeneous standard reference material (SRM 482; NIST) is listed in Table 1. The SRM values are listed along with the value determined by EDS analysis. The standards were pure elements, and matrix corrections were calculated with the NIST ZAF procedure (Myklebust et al., 1979; Fiori et al., 1992). Note that the relative errors are defined as

$$\text{rel err } (\%) = 100\% \times (\text{measured} - \text{true})/\text{true} \tag{5}$$

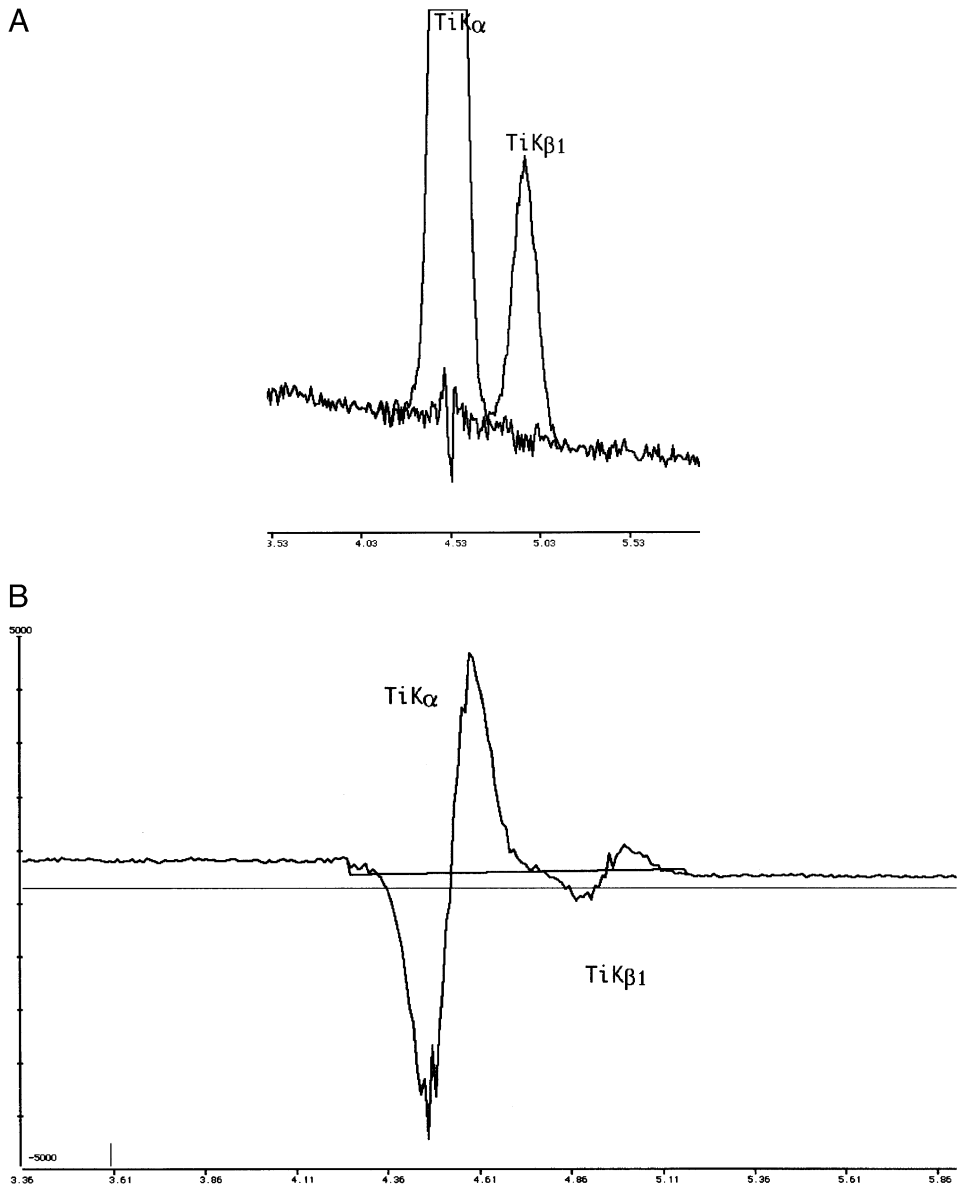

Figure 9. (**A**) Multiple linear least-squares fit to the titanium Kα-Kβ peaks with good peak references. (**B**) Effect of a one-channel (10-eV) shift between the reference and the experimental spectrum on multiple linear least-squares fitting. Specimen, Ti; beam energy, 20 keV. (**C**) Effect of a 20-eV difference in resolution between the reference and the experimental spectrum on multiple linear least-squares fitting. Specimen, Ti; beam energy, 20 keV.

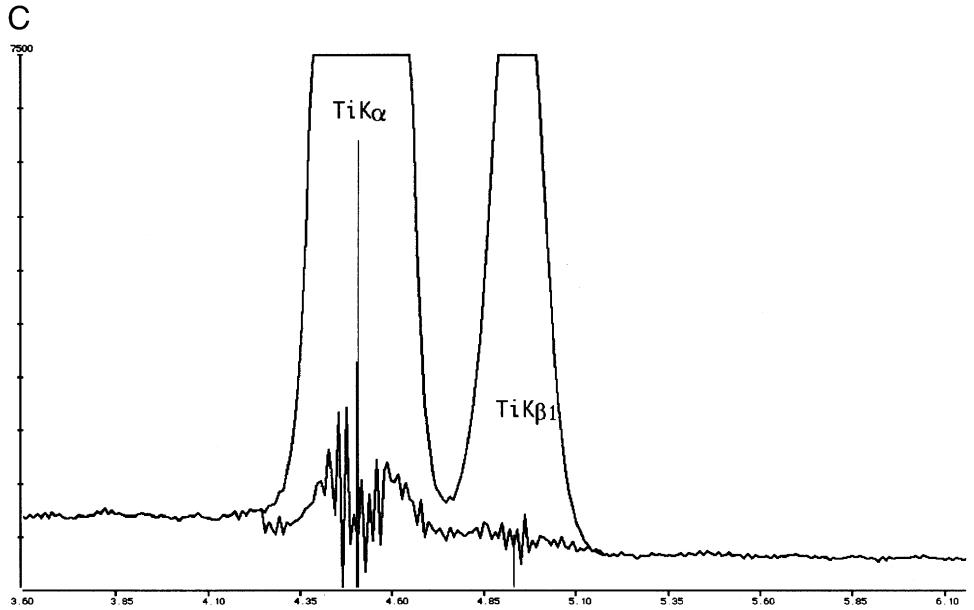

Figure 9 (*Continued*)

In no case is the error >1.6% relative. This is comparable to the errors that are encountered with WDS analysis of the same materials.

When large numbers of analyses of known materials spanning a large fraction of the periodic table are performed, the distribution of analytical errors can be determined. For such studies, spectra are recorded with a large number of counts to reduce the statistical variation to a negligible level compared to the systematic errors. An example of this distribution for the case of binary metallic alloys analyzed with pure-element standards is shown in Figure 13A. This distribution predicts that in 95% of the analyses performed, the relative errors are less than ±5%. For EDS analysis, this distribution is expected for concentrations greater than 0.05 mass fraction (or 5% by weight) and with minimal peak interference. As the concentration is reduced below a mass fraction of 0.05, the uncertainty in the background correction becomes more significant, and the level of error will depend strongly on the photon energy.

Standardless Analysis

An increasing trend in recent years in performing quantitative electron probe x-ray microanalysis with energy-dispersive x-ray spectrometry has been the substitution of "standardless" methods in place of the traditional approach of measuring standards containing the elements of interest on the same analytical instrument under the same excitation and detection conditions. In standardless methods, the standard intensities necessary for quantification are either calculated from first principles, considering all aspects of x-ray generation, propagation through the solid target, and detection ("true standardless"); or else they are derived from a suite of experimental measurements performed remotely and adjusted for the characteristics of the local instrument actually used to measure the unknowns ("fitted standards"). With either route to obtaining "standard intensities," the resulting k values (intensity of the unknown/intensity of the standard) are then subjected to matrix corrections with one of the usual approaches—e.g., ZAF or $\phi(\rho z)$.

The apparent advantages of standardless analysis are considerable. Instrument operation can be extremely simple. There is no need to know the beam current, and indeed, it is not even necessary for the beam current to be stable during the spectrum accumulation, a real asset for instruments such as the cold-field emission gun SEM where the beam current can be strongly time dependent. Moreover, the detector solid angle is of no consequence to

Table 1. Electron-Excited EDS X-Ray Microanalysis of SRM 482 (Au-Cu)[a]

Cu SRM	Cu Conc	Rel Err %	Au SRM	Au Conc	Rel Err %	Total
0.198	0.198	0	0.801	0.790	−1.4	0.988
0.396	0.399	0	0.603	0.594	−1.6	0.993
0.599	0.605	1.0	0.401	0.402	0.1	1.007

the quantitative procedure. Both the beam-current uncertainty and the detector solid-angle uncertainty are effectively hidden by normalizing the analytical total to a predetermined value, e.g., unity when all constituents are measured. When the spectrum has been accumulated to the desired level of statistical precision, the analyst needs to specify only the beam energy and x-ray takeoff angle, and list of elements to be quantified (or this list can be derived from an automatic qualitative analysis). The software then proceeds to calculate the composition directly from the spectrum, as described below, and in the resulting output report the concentration is often specified to 3 or 4 significant figures. The measurement precision for each element, calculated from the integrated peak and background counts, is also reported. The precision is really only limited by the patience of the analyst and the stability of the specimen under electron bombardment, so that relative precision values below 1% (1 σ) can be readily achieved, even for minor constituents. While such excellent measurement precision is invaluable when sequentially comparing different locations on the same specimen, the precision is no indication of accuracy. When standardless analysis procedures are tested to produce error histograms like that in Figure 13A, the errors are found to be substantially larger (Newbury et al., 1995; Newbury, 1999).

First-Principles Standardless Analysis

Calculating an equivalent standard intensity from first principles requires solution of Equation 6 (Goldstein et al., 1992):

$$I_{\text{std}} = \left[(\rho N_0/A)\omega \int_{E_0}^{E_c} \frac{Q}{(dE/ds)} dE\right] Rf(\chi)\varepsilon(E)_{\text{v}} \qquad (6)$$

where the terms in brackets represent the excitation function: ρ is the density, N_0 is Avogadro's number, A is the atomic weight, ω is the fluorescence yield, Q is the ionization cross-section, dE/ds is the stopping power, E is the electron energy, E_0 is the incident-beam energy, and E_c is the critical excitation energy. The other terms correct for the loss of x-ray production due to electron backscattering (R), the self-absorption of x rays propagating through the solid [$f(\chi)$], and the efficiency of the detector, $\varepsilon(E_{\text{v}})$, as a function of photon energy, E_{v}. It is useful to consider the confidence with which each of these terms can be calculated.

Excitation. There are three critical terms in the excitation function: the ionization cross-section, fluorescence yield, and stopping power.

Ionization cross-section. Several parameterizations of the K-shell ionization cross-section are plotted in Figure 10. The variation among these choices exceeds 25%. While it is not possible to say that any one of these is correct, it is certain that they cannot all be correct. Moreover, because of the continuous energy loss in a solid target, the cross-section must be integrated from E_0 to E_c, through the peak in Q and the rapid decrease to $U = 1$ (where U is overvoltage $U = E_0/E_c$). This region of the cross-section is poorly characterized, so that it is difficult to choose among the cross section formulations based on experimental measurements. The situation for L- and M-shell cross-sections is even more unsatisfactory.

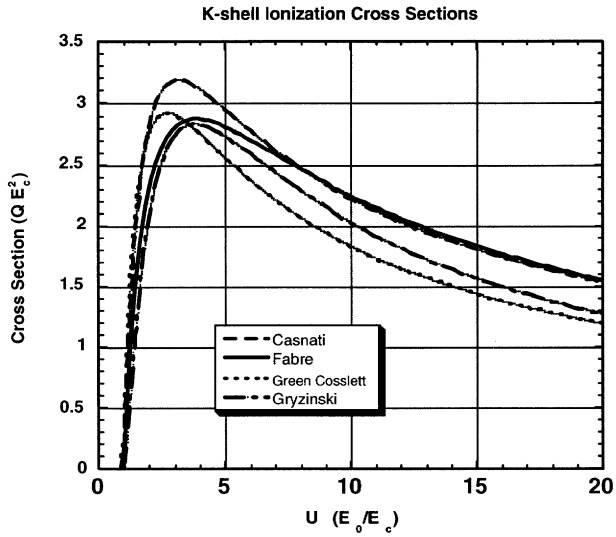

Figure 10. Ionization cross-sections (Casnati, S4; Fabre, S5; Green-Cosslett, S6; and Gryzinski, S7) as a function of overvoltage U, as formulated by different authors.

Fluorescence yield. Figure 11 plots various experimental determinations of the K-shell fluorescence yield. Again, a variation of >25% exists for many elements. The situation for L- and M-shell transitions is even less certain.

Stopping power. The classic Bethe formulation of the stopping power becomes inaccurate at low beam energies (<5 keV), and eventually with decreasing energy becomes

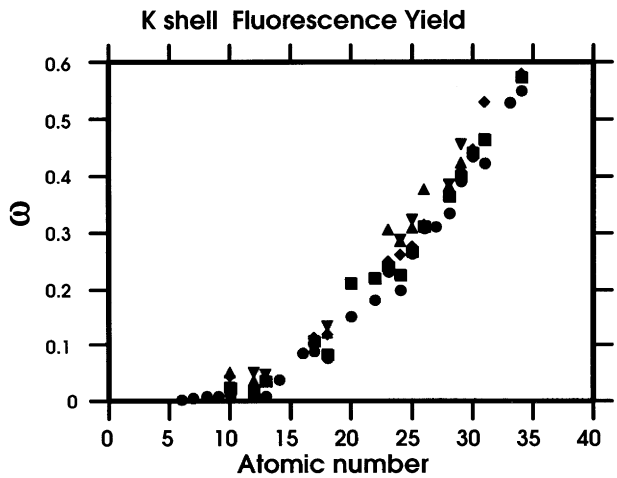

Figure 11. K-shell fluorescence yield as a function of atomic number. Symbols indicate measurements by different workers, as derived from the compilation in Fink et al. (1966).

physically unrealistic with a sign change. The accuracy of the stopping power matters for calculating Equation 5, because the cross-section must be integrated down to E_c, which for low-energy x-rays (e.g., C, N, O, F) involve electron energies in this regime. Several authors (e.g., Heinrich and Newbury, 1991) have suggested modifications to the Bethe formulation to correct for the low-beam-energy regime. Unfortunately, the base of experimental measurements necessary to select the best choice is just being developed.

Backscatter Loss. The backscatter loss correction factor R was initially formulated based upon experimental measurements of the total backscatter coefficient and the differential backscatter coefficient with energy (Heinrich, 1981). While careful, extensive measurements of total backscatter were available in the literature, the database of the differential backscatter coefficient with energy, a much more difficult experimental measurement, was limited to a few elements and was available at only one emergence angle. The development of advanced Monte Carlo simulations has permitted the rigorous calculation of R over all scattering angles and energy losses so that this factor is now probably known to an accuracy within a few percent across the periodic table and the energy range of interest (Heinrich and Newbury, 1991).

X-Ray Self-Absorption. The self-absorption of x rays in the hypothetical standard is calculated based upon the distribution in depth of x-ray production, a parameter that has been extensively studied by experimental measurement of layered targets and by Monte Carlo electron-trajectory simulation. The formulation of the absorption factor due to Heinrich and Yakowitz, as used in the NIST ZAF matrix correction, is employed (Heinrich, 1981). Fortunately, the absorption correction is generally small for the x rays of a pure element, so that at least for higher-energy characteristic x rays, e.g., photon energies >3 keV, there is little error in this factor. However, the self-absorption increases both as photon energy decreases and as incident electron energy increases, so that the error in calculating the intensity emitted from an element emitting low-energy photons, such as carbon, can be significant.

Detector Efficiency. The last term in Equation 5 is one of the most difficult with which to deal. In the traditional k value approach, the detector efficiency cancels quantitatively in the intensity ratio and can be ignored because the same x-ray peak is measured for the unknown and the standard under identical (or at least accurately reproducible) spectrometer conditions. When standardless analysis is performed, this cancellation can not occur because x-ray peaks of different energies are effectively being compared, and therefore accurate knowledge of the detector efficiency becomes critical. Detector efficiency is mainly controlled by absorption losses in the window(s) and detector structure. The expression for detector efficiency, Equation 7, consists of a multiplicative series of absorption terms for each component: detector window (denoted "win" in the subscripted terms in Equation 6), gold surface electrode ("Au"), semiconductor ("Si" or "Ge") dead layer ("DL"; actually a partially active layer below the electrode and the source of incomplete charge phenomena), and a transmission term for the detector thickness. Additionally, for most practical measurement situations there may be pathological absorption contributions from contamination on the detector crystal, usually arising from ice buildup due to pinhole leaks in the window or support ("ice"), and from contamination on the detector window usually deposited as hydrocarbons from the microscope environment ("con").

$$\begin{aligned}\varepsilon(E_v) = \exp[&(-\mu/\rho)_{win}\rho_{win}\mathrm{win} + (-\mu/\rho)_{Au}\rho_{Au}\mathrm{Au} \\ &+ (-\mu/\rho)_{Si}\rho_{Si}\mathrm{SiDL} + (-\mu/\rho)_{con}\rho_{con}t_{con} \\ &+ (-\mu/\rho)_{ice}\rho_{ice}t_{ice}\}]^*[1 - \exp(\mu/\rho)_{Si}\rho_{Si}t_{Si}] \quad (7)\end{aligned}$$

In Equation 7, the mass absorption coefficients are those appropriate to the photon energy, Ev, of interest. An example of the detector efficiency as a function of photon energy for several window materials is shown in Figure 3A. The choice of the window material has a strong effect on the detector efficiency for photon energies <3 keV, and accurate knowledge of the window and detector parameters is vital for accurate interelement efficiency correction across the working range of the detector, typically 100 to 12 keV. The pathological change in the detector efficiency with the accumulation of ice is illustrated in Figure 13B. The buildup of ice and other contaminants and the resulting loss in efficiency is referred to as "detector aging." Detector aging can result in significant loss of low-energy photons (<3 keV) relative to higher-energy photons (3 to 12 keV). Detector aging due to ice buildup can often be reversed by following the manufacturer's recommended procedure for warming the detector.

Fitted-Standards Standardless Analysis

The fitted-standards technique is the more widely used approach for implementing standardless analysis on commercial computer-assisted EDS analyzer systems. In the fitted standards technique, a suite of pure element standards covering K-, L-, and M-family x-rays is measured at one or more beam energies on an electron-beam instrument equipped with an EDS detector whose efficiency is known from independent measurements or at least can be estimated from knowledge of the detector construction. An example of such a measurement for a portion of the K-series from pure elements measured at 20 keV is shown in Figure 12A. In the fitted standards technique, missing elements can be calculated by mathematically fitting the available peaks and interpolating (e.g., in Fig. 12A, the intensity for gallium could be estimated by fitting the smoothly varying data and interpolating). From the smooth change in peak height with atomic number seen in Figure 12A, such an interpolation should be possible with reasonable accuracy. The situation is not as satisfactory in the L and M families, as illustrated in Figures 12B and 12C, because the cross-section/fluorescence yield

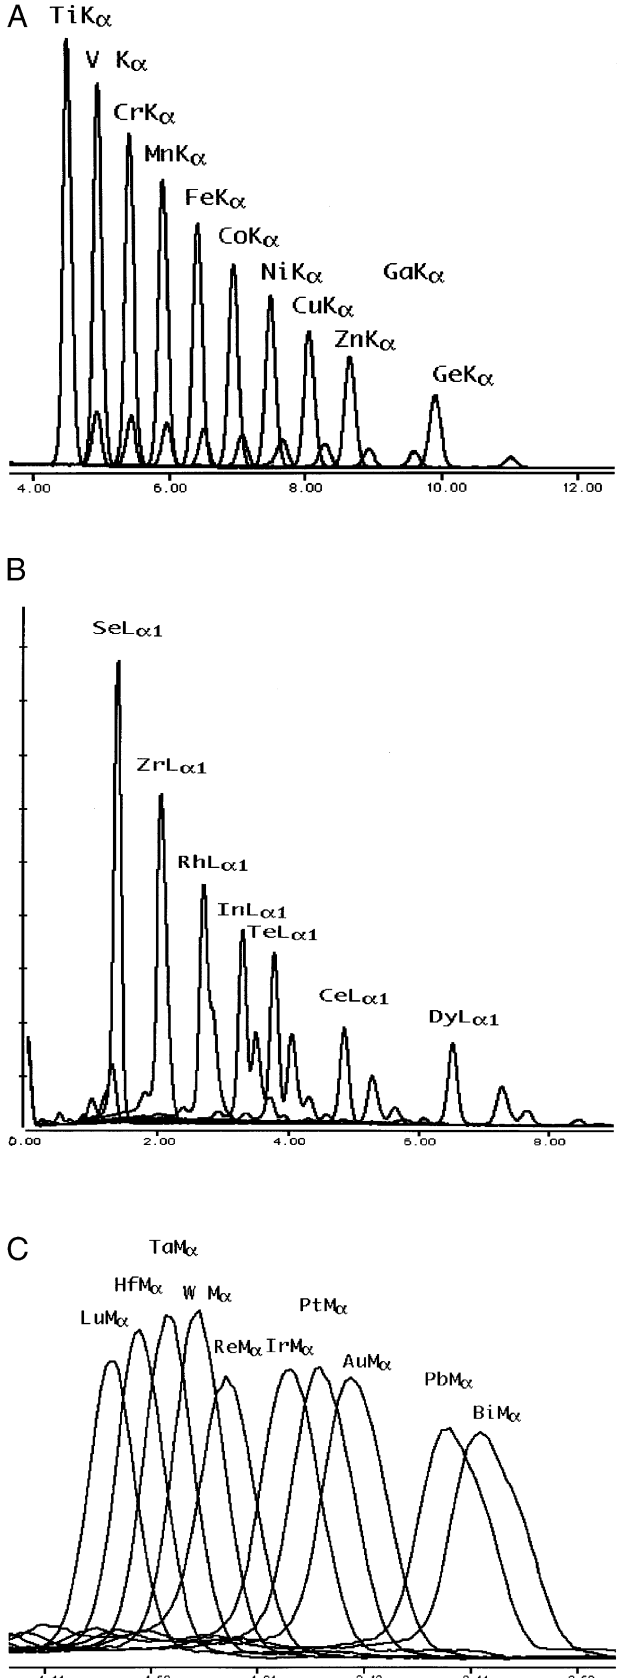

Figure 12. (**A**) K-family peaks from transition elements; E_0, 20 keV. (**B**) L-family peaks; E_0, 20 keV. (**C**) M-family peaks; E_0, 20 keV.

product is a much more complicated function of the atomic number.

If the analysis must be performed at a beam energy other than that of the spectral database, then Equation 6 must be used to shift the fitted standards intensities appropriately. Similarly, if a different EDS detector is used, the detector efficiency must be corrected for the differences in efficiency between the two detectors using Equation 7. The fitted-standards standardless procedure is expected to be more accurate than the "first-principles" standardless procedure because it is tied to actual experimental measurements that directly incorporate the effects of the cross-section/fluorescence yield product, at least over the range of the elements actually measured.

Testing the Accuracy of Standardless Analysis

The accuracy of standardless analysis procedures has been tested by carrying out analyses on microhomogeneous materials of known composition (Newbury et al., 1995): NIST Microanalysis Standard Reference Materials (SRM; Newbury, 1999), NIST Microanalysis Research Materials (RM), stoichiometric binary compounds (e.g., III-V compounds such as GaAs and II-VI compounds such as SrTe), and other materials such as ceramics, alloys, and minerals for which compositions were available from independent chemical analysis and for which microhomogeneity could be established (Newbury et al., 1995). Compositions were carefully chosen to avoid serious spectral overlaps (as in, e.g., PbS and MoS_2). Light elements such as boron, carbon, nitrogen, oxygen, and fluorine were also eliminated from consideration because of large errors due to uncertainties in mass absorption coefficients. In oxidized systems, the oxygen was calculated by means of assumed stoichiometry, but the resulting oxygen values were not included in the error histograms because of their dependence on the cation determinations.

Figure 13B shows an error histogram for the first-principles standardless analysis procedure embedded in the National Institute of Standards and Technology–National Institutes of Health Desktop Spectrum Analyzer (DTSA) x-ray spectrometry software engine. The error distribution shows symmetry around 0% error, but in comparing this distribution with that for the conventional standards/ZAF procedure shown in Figure 13A, the striking fact is that the error bins are 10 times wider for first-principles standardless analysis. Thus, the 95% error range is $\sim \pm 50\%$ relative rather than $\pm 5\%$ relative.

The error distribution for a commercial standardless procedure based upon the fitted-standards approach is shown in Figure 13C. This distribution is narrower than the first principles standardless approach, but the error bins are still 5 times wider than those of the conventional standards/ZAF procedure, so that the 95% error range is $\pm 25\%$ compared to $\pm 5\%$. It must be emphasized that this distribution represents a test of only one of the many implementations of standardless analysis in commercial software systems and that more extensive testing is needed.

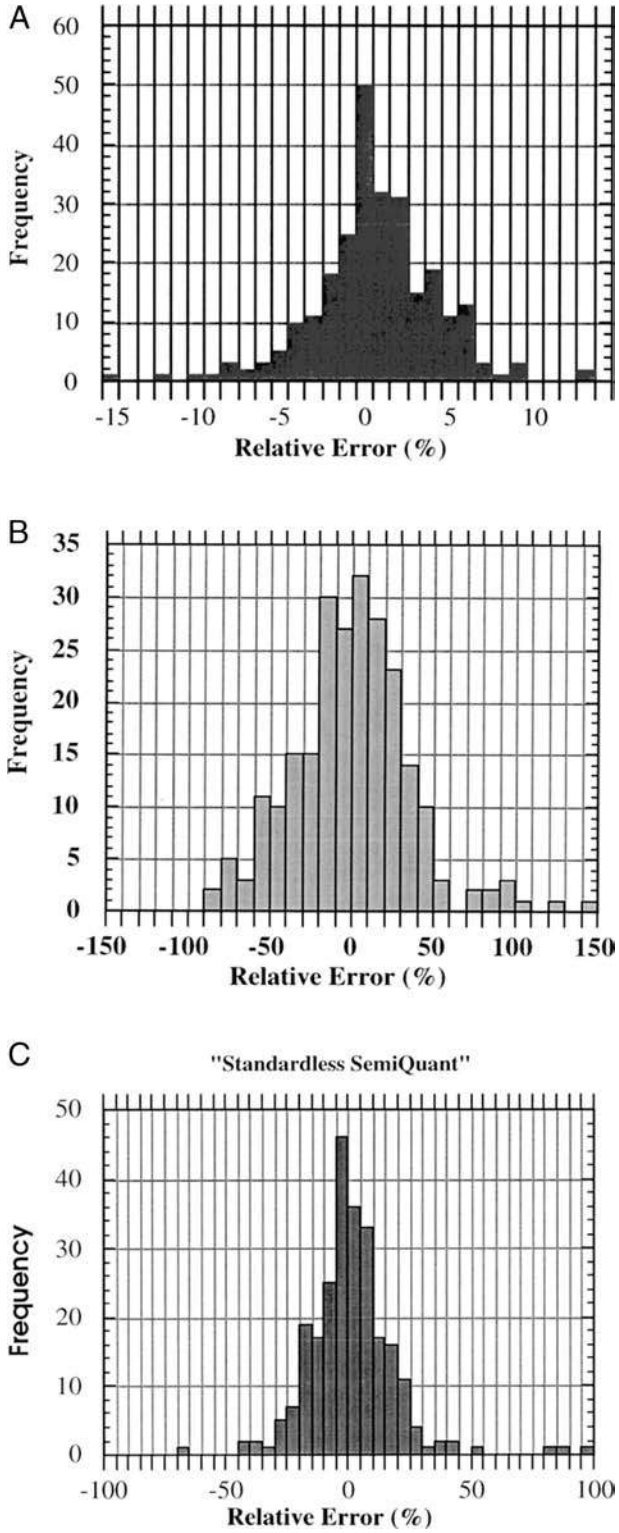

Figure 13. (**A**) Distribution of errors observed in the analysis of binary metal alloys against pure element standards (Heinrich-Yakowitz binary data ZAF; Heinrich, 1981). Beam energy, 20 keV. (**B**) Error distribution for the first-principles standardless analysis procedure embedded in the NIST-NIH Desktop Spectrum Analyzer x-ray spectrometry software system. Beam energy, 20 keV. (**C**) Error distribution for a fitted-standards standardless analysis procedure embedded in a commercial x-ray spectrometry software system (beam energy, 20 keV).

Using Standardless Analysis

Given the broad width of these error distributions for standardless analysis, it is clear that reporting composition values to 3 or 4 significant figures can be very misleading in the general case. At the same time, the error distributions show that there are significant numbers of analyses for which the relative errors are acceptably small, <10%. Usually, these analyses involve elements of similar atomic number (e.g., Cr, Fe, and Ni in stainless steel) for which the x-ray peaks are of similar energy and are therefore excited and measured with similar efficiency. Users of standardless analysis must be wary that any confidence obtained in such analyses does not extend beyond those particular compositions. The most significant errors are usually found when elements must be measured involving a mix of K-, L-, and M-shell x rays. The errors in the tails of the distributions are so large that the utility of concentration values obtained in this fashion is very limited.

Standardless analysis does have a legitimate value. If a microhomogeneous material with a known composition similar to the unknown specimen of interest is available, then the errors due to standardless analysis can be assessed and included with the report of analysis. For example, if the Fe-S system is to be studied, then analyzing the minerals pyrite (FeS_2) and troilite (FeS) would serve as a good test to challenge the standardless analysis procedure.

The analyst should never attempt to estimate relative concentrations merely by inspecting a spectrum. There are simply too many complicated physical effects of relative excitation, absorption, and detection efficiency to allow such a quantitative detail to be obtained from a casual inspection of a spectrum. Standardless analysis incorporates enough of the corrections to allow a sensible classification of the constituents of the specimen into broad categories, e.g.:

major: (>10 wt.%)
minor: (1 to 10 wt.%)
trace: (<1 wt.%)

In the absence of a known material to test a standardless analysis procedure, it is recommended that these broad classification categories be used instead of numerical concentration values, which may imply far more apparent accuracy than is justified and which may lead to a loss of confidence in quantitative electron-probe microanalysis when an independent test is conducted.

Limits of Detection with EDS X-Ray Microanalysis. The ultimate limit of detection is determined by statistical variance of the background counts within the peak region of interest. As such, the concentration limit of detection (C_{DL}) for a peak that does not suffer from interference from a nearby high-intensity peak depends on the peak-to-background ratio (Ziebold, 1967):

$$C_{DL} \geq 3.3a/[n\tau P(P/B)]^{0.5} \quad (8)$$

where a is a factor relating the concentration to the measured intensity ratio and is generally close to unity, n is

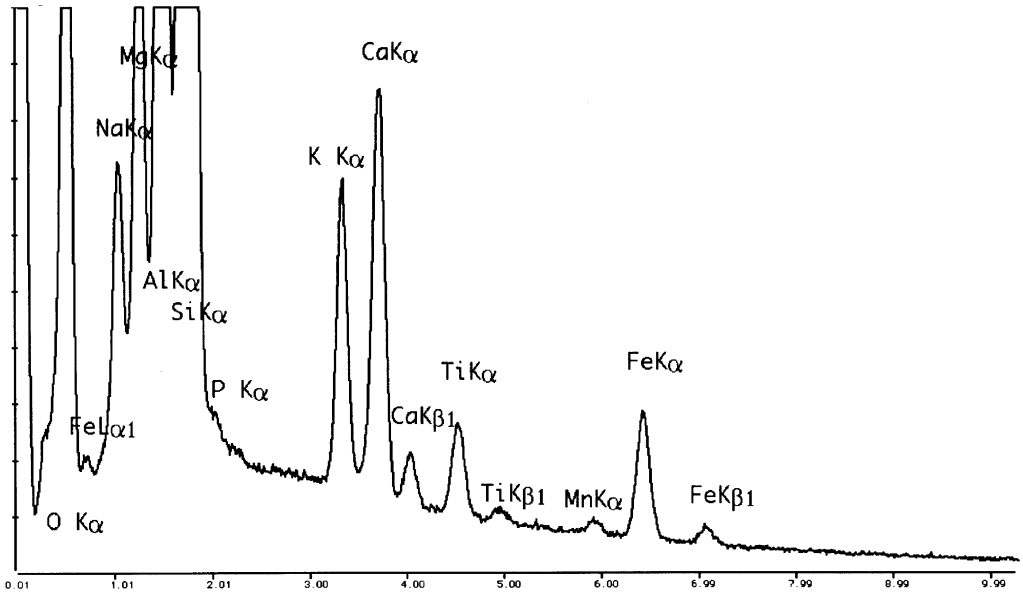

Figure 14. EDS spectrum of NIST glass K961; beam energy, 15 keV. Composition: O (0.470); Na (0.0297); Mg (0.0301); Al (0.0582); P (0.0022); K (0.0249); Ca (0.0357); Ti (0.012); Mn (0.0032); Fe (0.035) (mass fraction).

the number of replicate measurements, τ is the measurement time, and P and B are the peak and background count rates, respectively. While the detection limit can be lowered by using longer counting times, the appearance of this term within the square root limits the improvement. For practical counting conditions ($\tau < 1000$ s) and deadtime ($< 30\%$), the limit of detection for EDS varies from concentration levels of 0.0005 to 0.002 (mass fraction) depending on the analytical line and the matrix. An example of a spectrum showing minor and trace elements is presented in Figure 14. Note the obvious detection of Mn (0.0032 mass fraction), while P (0.0022) suffers severe interference from the major Si peak.

SAMPLE PREPARATION

The ideal form of the specimen for x-ray analysis with any type of primary excitation (electrons, photons, or ions) is a flat, mechanically polished surface with topography reduced below 50 nm (Goldstein et al., 1992). The requirement for flatness arises because of the strong absorption of x rays, particularly for photon energies <4 keV and increasing in severity as the photon energy decreases. Low-energy x rays, e.g., C-K, N-K, and O-K, are particularly strongly absorbed. Even with a flat surface, 90% or more of the x rays generated within the target are absorbed along the exit path toward the EDS detector. The effect of surface topography is to introduce an uncontrolled geometric variable that can modify the x-ray spectrum independent of the composition, which in conventional analysis is assumed to be the only variable. An example of the magnitude of the effect of anomalous absorption is shown in Figure 15, which shows two spectra obtained from a "123" $YBa_2Cu_3O_7$ high-T_c superconductor. The spectrum obtained with the beam placed on the polished surface shows significant x-ray counts at all photon energies, while the spectrum obtained in the crack shows significant attenuation of the low-energy photons, which is caused by the additional path length through the solid. Note that if only the "in-crack" spectrum were available, it would not be readily apparent that the anomalous absorption situation existed. The low-energy photon peaks from Y-L, Cu-L, and O-K can easily be detected, but their intensities are not representative of the polished material, and if quantification were attempted, the concentrations calculated from these peaks would be below the correct value by a large factor.

SPECIMEN MODIFICATION

Generally, EDS performed with electron bombardment does not lead to significant changes for most specimen compositions, such as metal alloys, ceramics, glasses, and minerals. Important exceptions occur, however, where charged ionic species can move under the influence of charge injected by the beam and for certain classes of specimens for which radiation damage can result in the generation and loss of volatile components (Joy et al., 1986; Goldstein et al., 1992).

Ionic Migration

Insulating materials can accumulate charge under electron bombardment, leading to the development of local fields strong enough to deflect the incident beam. To minimize the effects of charging on the primary beam, a thin ($\sim$ 10- to 20-nm) conducting coating such as carbon is typically applied to the surface of the specimen and this layer is connected to an electrical ground. However, beam electrons passing through this layer can accumulate within

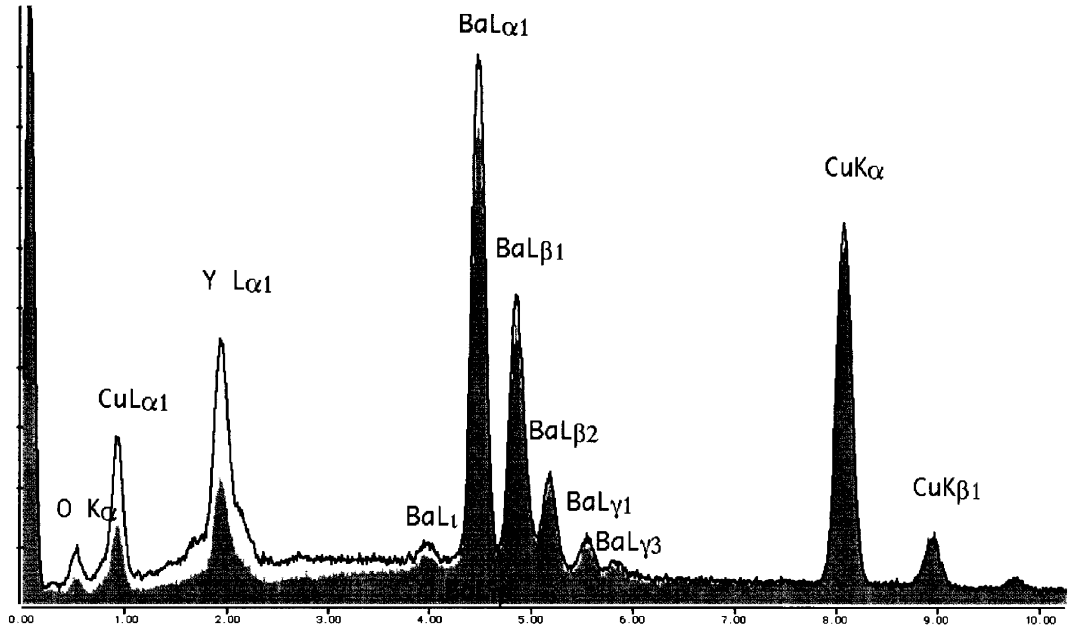

Figure 15. Comparison of spectra obtained on polished surface (trace) and in crack (solid gray). Specimen: $YBa_2Cu_3O_7$ high-T_c superconductor. Beam energy, 25 keV.

the specimen and create a significant internal electric field. Sodium, for example, is known to be capable of motion under such fields, which can be detected as a time dependency in the x-ray signal. The degree of sodium migration depends on the specimen composition.

Loss of Volatile Components

Some specimen compositions are sensitive to radiation damage, which can produce broken chemical bonds or free radicals, for example. Biological and organic specimens are particularly prone to the loss of water and other volatile components under electron bombardment. Even after chemical substitution to stabilize such specimens, significant modification may occur during electron bombardment. To correct for such mass loss in the quantification of minor and trace constituents, Hall (1968) developed a method of normalizing the characteristic peaks to a band of high-energy bremsstrahlung radiation that scaled with the total mass of the electron-excited volume.

PROBLEMS

Energy-dispersive x-ray spectrometry systems are capable of stable, long-term operation with a high degree of reproducibility. In the next section operational quality-assurance protocols will be described. However, occasional deviations will occur, even in an otherwise properly operating EDS system, and it is the responsibility of the user to recognize such pathological conditions. The careful user of EDS will develop the ability to recognizing such deviations. One of the best ways to do this is to record and archive spectra from high-purity elements and simple binary compounds and carefully study the forms of the spectra. Modern computer-assisted x-ray analyzers provide ready means for comparing spectra both visually and mathematically. An archive of reference spectra obtained on the local instrument is invaluable for rapid comparison with spectra obtained under current operating conditions.

Pathological Conditions

Ground Loops. The EDS detector-amplifier chain operates at extremely high gain and may therefore be sensitive to other sources of electromagnetic radiation. Improperly shielded cables may act as antennae, introducing spectral degradation through resolution loss, background distortion, false peaks, and other artifacts. Another source of interference arises from "ground loops"—AC currents flowing between two points at nominal ground potential. It is critical to prevent electrical contact between the EDS detector snout and the microscope column. A high value of electrical resistance should be maintained to isolate the EDS from the microscope. The EDS (as well as microscope power supplies) should all be connected to a common high-quality ground. An example of spectra obtained with and without a ground loop operating is shown in Figure 16. Note the high and complex background when the ground loop is present. It is highly recommended that when a new EDS system is being installed, the EDS performance first be checked on the bench (i.e, with the EDS system isolated from the microscope) with a radioactive source (e.g., ^{55}Fe). Upon installation on the microscope, the EDS system should be checked again with the radioactive source placed in the microscope specimen position. Ideally, these two spectra should be identical. Any degradation in EDS performance (resolution, deadtime, etc.) is probably due to ground loops and should be corrected by careful cable shielding and routing to avoid proximity to power supplies, etc. If no degradation is found, the microscope should then be fully activated with the vacuum system in full operation and the electron beam on but blanked to prevent it from hitting the specimen (the

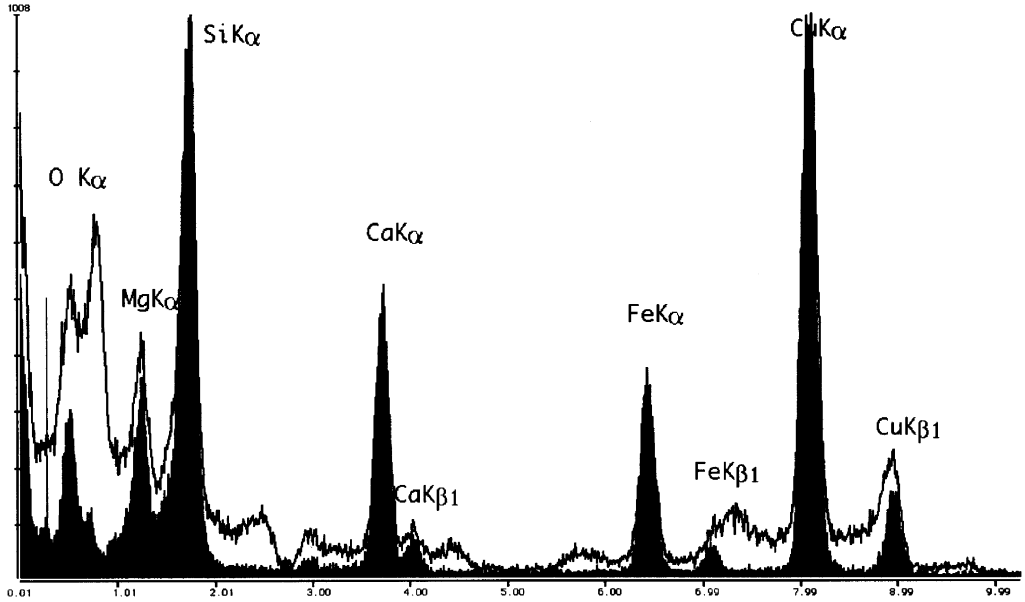

Figure 16. Pathological artifact: Action of ground loop in a low-resistance path between the EDS and the microscope chassis distorting the spectrum. Trace, spectrum with ground-loop active; solid filled areas, spectrum with ground loop eliminated.

^{55}Fe source). A third radioactive source spectrum should be obtained. If this spectrum is identical to the previous two conditions, then the EDS system is free of ground loops.

Light Leakage. Under electron bombardment, certain specimens (especially minerals, ceramics, and some semiconductors) emit light, a process called cathodoluminescence. The vacuum-isolation window of the EDS is coated with a thin (~20-nm) aluminum layer to reflect visible light. This layer may not provide sufficient attenuation of the light, or there may be leakage through pinholes in the coating. Depending on the light intensity, the spectrum may undergo energy shift (miscalibration) or resolution degradation, and in extreme cases the peaks may undergo enormous distortion, as illustrated in Figure 17 for ZnS. Other sources of light can include inspection lights and the infrared source chamber TV camera. These sources should be shut off during EDS operation. A symptom of light leakage into the EDS detector is anomalously high deadtime, which can reach 100% (no x-ray photons processed) if the light source is strong enough. Note that after the EDS detector is exposed to a high level of light, it may take several minutes to return to stable operation

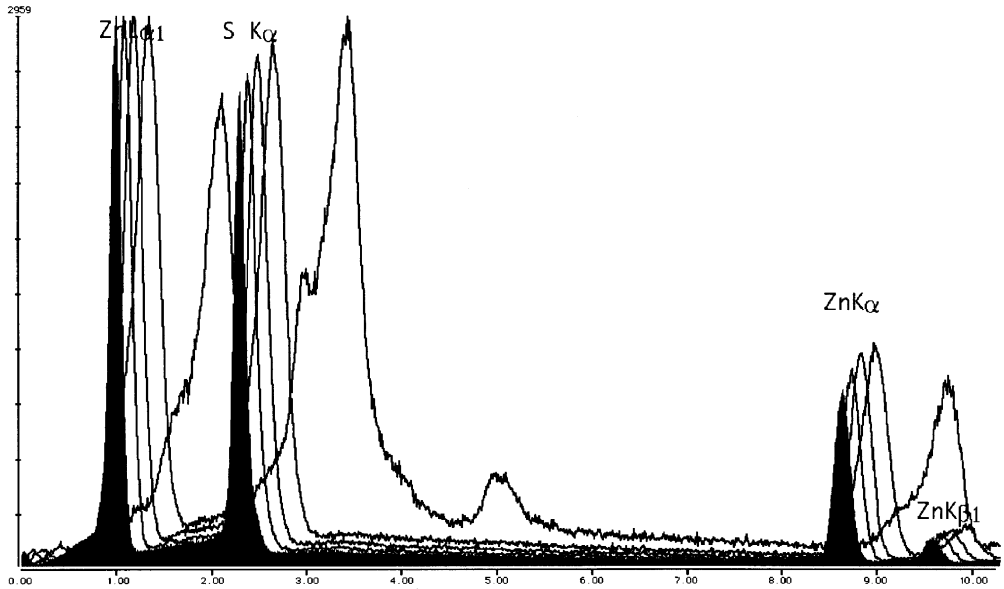

Figure 17. Pathological artifact: Effect of cathodoluminescent light leakage into detector. Specimen, ZnS; beam energy, 20 keV. Solid filled areas, reference ZnS; traces, increasing cathodoluminescence output achieved by increasing scanned area at fixed current.

and can be subject to severe spectral artifacts during this recovery.

Ice Accumulation. Figure 3B shows the calculated decrease in low-energy detection efficiency with the build-up of ice. To monitor this phenomenon in practice, a pure nickel target can provide a spectrum in which the Ni Kα radiation (7.477 keV) is sufficiently energetic that it is unaffected by detector windows and ice layers, while the low-energy Ni Lα (0.849 keV) suffers severe absorption passing through ice, since it is located above the O K edge (0.531 keV). A plot of the Ni Lα/Ni Kα ratio is an effective monitor of detector performance. When the Ni Lα/Ni Kα ratio has fallen by a significant percentage (e.g., arbitrarily 10%, to be determined by the user's established quality-assurance plan) relative to the performance of the new detector, the EDS manufacturer's protocol for conditioning the detector should be followed scrupulously.

Distortions of Low-Energy Peaks. Low-energy photons, less than 1 keV, are measured with charge pulses that are very close in magnitude to the system noise. Several artifacts are observed in this energy range even when the detector is performing optimally for photons above 1 keV in energy. Peaks are distorted from the ideal Gaussian shape by the effects of incomplete charge collection on the low- energy side. This effect depends entirely on the detector construction and cannot be modified. The pulse-pileup inspector is virtually ineffective in this energy range. Pulse pileup effects can be severe, with the result that the peak position and shape may change with input count rate, which can be controlled by the analyst. Both peak shift and peak distortion at high deadtime (50% versus 8%) can be seen in the carbon spectra shown in Figure 18.

Stray Radiation. The operating environment of the EDS system on an electron microscope can be severe. Beam

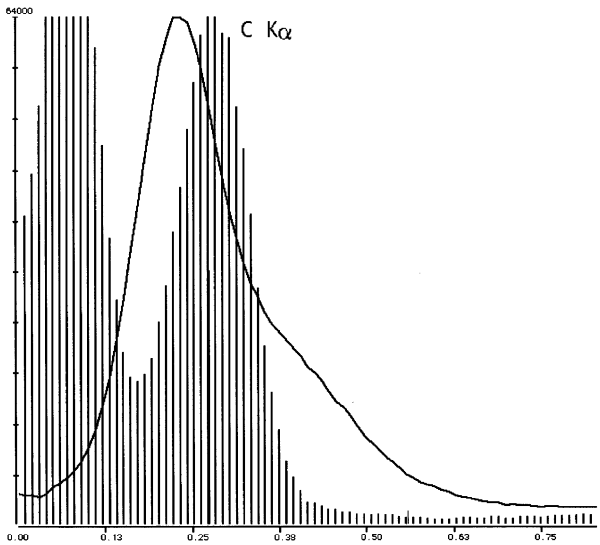

Figure 18. Pathological artifact: Peak shift induced by count-rate effects. Barred spectrum taken at low deadtime (8%); line spectrum taken at high deadtime (50%). Beam energy, 15 keV.

electrons will backscatter from the specimen, and additionally may scatter off microscope components such as apertures and stage materials, especially in a high-energy analytical electron microscope. The EDS is equipped with an "electron trap" (actually a permanent magnet deflector) to prevent energetic electrons (whose prevalence actually exceeds the rate of x-ray production by a large factor) from reaching the detector and dominating or distorting the spectrum. However, these remote sources of electrons can create anomalous contributions to the x-ray spectrum. The EDS is also commonly equipped with a collimator to restrict the contributions of x rays from the remote electron scattering, but typically such collimation is limited to an area with linear dimensions of millimeters centered around the on-axis beam impact point on the specimen. Electrons not in the focused beam that strike the specimen within this collimation acceptance disk will contribute to the spectrum. To assess the magnitude of stray electron contributions, it is highly recommended that an "in-hole" spectrum be obtained. For the solid specimen SEM, a "Faraday cup" should be constructed using materials not present in the microscope construction. A polished block of titanium is a good choice. Into this metal block should be drilled a blind hole and over this hole a microscope aperture with a small opening (<100 μm) should be placed. If possible, the aperture metal should be different from that actually used for apertures in the microscope. Three spectra should then be recorded for the same live time: (1) beam placed on the titanium; (2) beam placed on the aperture; and (3) beam placed in the blind hole. Ideally, the in-hole spectrum should have no counts for either characteristic or bremsstrahlung x rays. It is likely that a small component of x rays representing nonbeam electrons striking the aperture and/or metal block will be detected. This contribution should be $<1\%$ of the intensity recorded when the beam is placed on these materials.

Note that this in-hole procedure detects only electrons not in the focused beam. In normal operation with the beam striking the specimen, significant numbers of backscattered electrons will be generated that will strike the polepiece above the specimen and can rescatter as an uncollimated radiation source raining down on the specimen. To examine this effect, a second specimen should be fabricated consisting of microscopic particles or fibers embedded in a silver-doped conducting epoxy and polished. Choose a particle or fiber whose diameter exceeds the expected interaction volume by at least a factor of 4: e.g., at least 20-μm diameter if the electron x-ray range is 5 μm. With the beam placed on the center on the particle, which should have a composition that does not contain silver, examine a spectrum accumulated with at least 200,000 counts in the full energy range. Any silver radiation must arise from rescattered backscattered electrons. This rescattering component might be reduced if the polepiece can be shielded with a plate consisting of a light element, such as carbon. It is very important never to use carbon paint.

Electron Penetration. Energetic electrons that penetrate the detector window and strike the detector will be measured as if they were x-ray photons, leading to anomalous

spectral background shape (Fiori and Newbury, 1978). To avoid or at least minimize this problem, a permanent-magnet deflector is usually placed in the collimator assembly. During very-high-beam-energy operation in the AEM (100 keV or more), electron penetration into the detector may still occur, especially during surges in beam current that can happen during changes in the operating parameters of the electron lenses, especially under computer automation. Such electron penetration may actually damage the EDS detector.

PROTOCOLS

Measurement protocols have been partially described as part of the previous sections, e.g., the recommendations for testing a new EDS detector system for ground loops, stray radiation, etc., and the recommendations for testing qualitative-analysis procedures. In this section, protocols for quality assurance in operating an EDS system will be summarized.

Quality-assurance operations for an EDS system operating on an electron microscope takes place at several time intervals: once per session, weekly, and long term.

Session

At the start of each measurement session, the analyst must go through a checklist of operational parameters to ensure that the system is operating in the configuration that is required. This is especially true if the facility has multiple users. In the following discussion, please note that terms are used which are as generic as possible to describe the functions. There is no standardization for these terms, and when the historical range of EDS systems is considered, these functions may be implemented with controls ranging from hardware to full software selection and control.

The key elements on this checklist are as follows.

Resolution (Count-Rate Range). The longer the time spent processing a pulse, the more precisely the energy can be determined, and thus the narrower the peak and the better the resolution. Selection of this parameter (e.g., specified as "shaping time," "amplifier time constant," "count rate range," and "resolution") is made depending on the analytical problem. Generally, one will wish to accumulate as many x-ray counts as possible in the available counting time, so it is desirable to operate at the highest allowable count rate and then select a beam current/detector solid angle to achieve that count rate, recognizing that the EDS will operate at the poorest resolution. However, if the elements of interest produce interfering peaks, especially if an element of interest is present as a minor or trace constituent whose peak is close to the intense peak of a major constituent, then the poor-resolution performance at high count-rate range may preclude achieving an adequate detection limit, and it may be necessary to operate at high resolution and a lower limiting count rate. Whatever the choice, the analyst must be consistent when quantitative procedures are followed with archived standards.

EDS Spectrum Channel Width and Number. The width of the individual channel of the EDS histogram can be selected, as well as the number of channels. Typical width choices are 5, 10, 20 and 40 eV. It is important to have as many channels as possible to define the x-ray peak, so a choice of 10 or 5 eV is desirable. If possible, it is also important to record the entire x-ray spectrum up to the beam energy, at least in the SEM case where E_0 is typically between 5 and 30 keV. Thus, it is desirable to record 2048 or 4096 channels. Given the continuing drastic decreases in the cost of computer memory and mass storage, it is advisable to record and archive the complete spectrum from every measurement location.

Calibration. The calibration should be checked on a specimen with characteristic peaks in the 1- to 2-keV and 8- to 10-keV ranges, e.g., Cu Kα (8.04 keV) and Cu Lα (0.928 keV). The calibration should be established within 10 eV of the reference value. After these endpoints have been fixed, several intermediate peaks should be checked, e.g., Si (1.740 keV), Ti (4.508 keV), and Fe (6.400 keV). Noting that the low-energy photon peaks (<1 keV) are likely to be out of calibration, it is useful to record pure carbon (0.282 keV) and an oxygen-containing target, e.g., Al_2O_3 (O = 0.523 keV).

Specimen Position. The first condition to define the detector geometric efficiency (solid angle) is the specimen position. In electron beam systems with an optical microscope, the specimen can be accurately positioned because of the shallow depth of focus of the optical microscope. If only SEM imaging is available, then to position the specimen relative to the EDS in terms of the working distance, the objective lens current can be used to select a particular lens strength. By using a large final aperture to minimize the depth of focus, the specimen position can then be selected with the z motion (along the beam) of the stage.

Detector Solid Angle. The absolute x-ray intensity depends upon the electron dose (current × live time), the detector quantum efficiency, and the detector solid angle. Many detectors are capable of mechanical motion along the axis of the takeoff angle. The solid angle Ω of collection depends on the detector area A (as collimated) and the detector-to-specimen distance, r:

$$\Omega = A/r^2 \tag{9}$$

Because of the strong dependence of the solid angle on the detector-to-specimen distance, it is critical to have a method to accurately reset the detector position. Typically a ruler scale is provided for coarse adjustments, but this may not be adequate for the most accurate work. If the beam current and specimen position can be set accurately and reproducibly, fine adjustment of the solid angle can be based upon the absolute intensity measured in a high-energy x-ray peak, e.g., Cu Kα.

Weekly

The performance of the deadtime correction circuit should be checked by using the beam current (as measured in a

Faraday cup) to independently control the input count rate. The output count in a defined live time should scale with the electron dose (beam current) at least up to an indicated deadtime of 50%, and preferably to even higher deadtime. Detector aging should be monitored with a spectrum of Ni.

Long Term

EDS systems are capable of a high degree of stability provided they are continuously maintained under power. When powered up from a cold start, several hours are typically needed to establish thermal equilibrium in all electronic circuits and thus achieve a stable operating condition. It is therefore not advisable to power the EDS system down as part of routine operation but rather to maintain power at all times. When such a shutdown must be carried out, it is important to reestablish thermal equilibrium before resuming measurement operations. All parameters then should be checked, and adjusted if necessary: resolution, calibration, and deadtime correction.

AUGER ELECTRON SPECTROSCOPY

INTRODUCTION

Auger electron spectroscopy (AES) is a powerful technique for determining the elemental composition of the few outermost atomic layers of materials. Surface layers often have a composition that is quite different from the bulk material, due to contamination, oxidation, or processing. In the most commonly used form of AES, a specimen is bombarded with electrons having an energy between 3 and 30 keV, resulting in the ejection of core-level electrons from atoms to a depth up to $\sim$1 μm. The resulting core vacancy can be filled by an outer-level electron, with the excess energy being used to emit an x ray (the principle of electron probe microanalysis) or another electron (the principle of Auger electron spectroscopy) from the atom. This emitted electron is called an Auger electron and is

named after Pierre Auger who first observed such events in a cloud chamber in the 1920s (Goto, 1995). AES is a surface-sensitive technique, due to the strong inelastic scattering of low-energy electrons in specimens. Auger electrons from only the outermost few atomic layers are emitted from the specimen without energy loss, and contribute to the peaks in a spectrum. Auger electrons that have lost energy in escaping from the specimen will appear as an additional background signal at lower kinetic energies. Obviously, hydrogen and helium cannot be detected, as three electrons are needed for the Auger process. The Auger electron kinetic energies are characteristic of the material, and the measurement of their kinetic energies is used to identify the elements that produce these Auger electrons. As the Auger electron kinetic energies depend on the binding energies of the electron levels involved, changes in surface chemistry (such as oxidation) can produce detectable shifts in Auger kinetic energies, thereby providing useful information about the surface chemistry as well. Auger electrons emitted from the specimen will appear as peaks on a continuous background of secondary electrons and backscattered electrons. Secondary electrons are usually defined as the electron background below 50 eV, and backscattered electrons are those in the background with energies from 50 eV up to the incident beam energy. The concentrations of elements detected can be determined from the intensities of the Auger peaks. An Auger spectrum is usually a plot of the number of electrons detected as a function of kinetic energy, but sometimes it is displayed as the first derivative of the number of electrons emitted, to enhance the visibility of the Auger electrons and to suppress the continuous background of secondary and backscattered electrons. Electron beams can be focused to small diameters, thereby allowing the composition of small areas ($\sim$50 nm and below) on a surface to be determined. This is often called point analysis. The electron beam can be defocused or rastered over small areas to reduce possible electron beam damage where this might be a problem. Analysis can also be performed at preselected points or areas on the specimen. The electron beam can alternatively be scanned in a straight line across part of the specimen surface and Auger data can be acquired as a function of beam position, resulting in what is called an Auger line scan. Auger maps can also be measured, showing the variation in elemental composition (and concentration) across a region of the surface; this is referred to as scanning Auger microscopy (SAM). Variation in composition with depth can be determined by depth profiling, which is usually accomplished by continuously removing atomic layers by sputtering with inert gas ions while monitoring the Auger signals from the newly created surfaces. For most elements, the detection limit with AES is between 0.1 and 1 atom %.

Competitive and Related Techniques

Methods for surface analysis that are alternatives to AES include x-ray photoelectron spectroscopy (XPS), which is also often called electron spectroscopy for chemical analysis (ESCA); low-energy ion scattering (LEIS), which is also called ion scattering spectroscopy (ISS); and secondary ion mass spectrometry (SIMS). XPS/ESCA uses soft x rays to eject electrons from atoms. Compared with AES, the interpretation of XPS/ESCA spectra is generally simpler; it is more easily quantifiable and easier to use when studying insulators, and produces less beam damage. The detection limit of XPS/ESCA is similar to that of AES, but the highest spatial resolution is a few micrometers (as opposed to $\sim$50 nm with AES). Auger peaks will also appear in XPS spectra. In some cases, energetic ions can also produce Auger electrons. ISS is the most surface sensitive of these techniques; low-energy inert gas ion beams measure just the outermost atomic layer; but it is not generally useful for identifying unknown elements at the surface due to its relatively poor specificity. Of these techniques, SIMS has the highest detectability as well as high elemental specificity; it is also capable of detecting atomic parts per million and below. In SIMS, the ions that are sputtered from the surface are detected in a mass spectrometer. Static SIMS is used for identifying the surface composition, whereas dynamic SIMS is used for depth profiling. SIMS can detect hydrogen as well as isotopes of the elements, which AES cannot. SIMS can be quantified for simple, well-characterized specimens, but is not routinely quantifiable for complex surface compositions. A variation of SIMS is sputtered neutral mass spectrometry (SNMS), where the neutral species that are emitted by sputtering are post-ionized, and then measured with a mass spectrometer.

Surface analysis systems cost several hundred thousand U.S. dollars. Systems can be stand-alone (e.g., AES only) or can incorporate more than one technique (such as AES and XPS). Analysis is performed in a vacuum chamber at pressures typically of the order of 10^{-18} Pa. A vacuum is needed since electron beams are involved, and ultrahigh vacuum ($< 10^{-7}$ Pa) is required so the surface composition does not change during analysis. There are several manufacturers of Auger systems, and manufacturers usually offer more than one model. Manufacturers include JEOL (*http://www.jeol.com*), Omicron Associates (*http://www.omicron-instruments.com*), Physical Electronics (*http://www.phi.com*), Staib Instruments (*http://www.staib-instruments.com)*, and VG Scientific (*http://www.vgscientific.com*). These companies, and many others, also manufacture components such as electron sources, electron kinetic energy analyzers, vacuum systems, and systems for computerized data acquisition and processing, which can be assembled to make a customized system. There are several commercial companies that provide analytical services using AES, and costs are typically 1000 to 3000 U.S. dollars per day. Some commercial companies in the United States are Anderson Materials Evaluation (*http://www.andersonmaterials.com*), Charles Evans & Associates (*http:// www.cea.com*), Geller Micro Analytical Lab (*http:// www.gellermicro.com*), and Physical Electronics (*http://www.phi.com*). Samples can usually be mounted and inserted into the analysis chamber in $\sim$30 min. Simple analysis can be performed within another 30 min, whereas depth profiling and Auger mapping can take longer.

Surface topography can be measured using optical microscopy (OPTICAL MICROSCOPY and REFLECTED-LIGHT

OPTICAL MICROSCOPY); scanning electron microscopy (SEM; SCANNING ELECTRON MICROSCOPY); scanning tunneling microscopy (STM; SCANNING TUNNELING MICROSCOPY); and atomic force microscopy (AFM). Scanning Auger microscopy systems have SEM capability, and this is used for locating regions on the surface of the specimen to be studied.

PRINCIPLES OF THE METHOD

An example of the Auger process is shown in Figure 1. With AES, the electron energy levels are denoted by the x-ray notation, K, L, M, etc., corresponding to the principal quantum number 1, 2, 3, etc. Subscripts are based on the various combinations of the orbital angular momentum 0, 1, 2, 3, etc. and the electron spin $+1/2$ or $-1/2$, and have the values 1, 2, 3, 4, 5, etc. The K level is not given a subscript. The L levels are L_1, L_2, and L_3, the M levels are M_1, M_2, M_3, M_4, and M_5, etc. Sometimes the energy levels are close in energy and not resolvable in the measurement, and are then designated as $L_{2,3}$, $M_{2,3}$, $M_{4.5}$, etc. In the example shown in Figure 1, the K and L levels in the atom are shown to be fully occupied by electrons (Fig. 1, panel A). In this example, the initial ionization occurs in the K level (Fig. 1, panel B). Following relaxation and the emission of an Auger electron, the atom has two vacancies in outer levels, the L_2 and the L_3 levels in this example (Fig. 1, panel C). This process can be thought of as consisting of the following processes. (1) An electron drops down from the L_2 level to fill the K level vacancy. (2) Energy equal to the difference in binding energies between the K and the L_2 levels is produced. (3) This energy is sufficient to remove an electron from the L_3 level of the atom, with the excess energy being the energy of the Auger electron. The three atomic levels involved in Auger electron production are used to designate the Auger transition. The first letter designates the shell containing the initial vacancy and the last two letters designate the shells containing electron vacancies created by Auger emission. The Auger electron produced in the example shown in Figure 1 is therefore referred to as a KL_2L_3 Auger electron. When a bonding electron is involved, the letter V is sometimes used (e.g., KVV and LMV). Coupling terms for the electronic orbital angular momentum and spin momentum may also be added where known, e.g., $L_3M_{4,5}M_{4,5}$; ^1D. More complicated Auger processes can also occur; e.g., if an atom is doubly ionized before Auger emission, it will be triply charged after emission (Grant and Haas, 1970). In such cases, the Auger transition can be designated by separating the initial and final states by a dash, e.g., LL-VV would be used for an atom that is doubly ionized in the L shell before Auger emission, and that uses two electrons from the valence shell for the Auger emission. When an Auger relaxation process involves an electron from the same principal shell as the initial vacancy, e.g., L_1L_2M, it is sometimes referred to as a Coster-Kronig transition. If both electrons involved in relaxation are from the same principal shell as the initial vacancy (e.g., $N_5N_7N_7$), it can be called a super Coster-Kronig transition. In some cases, such as MgO, electrons from neighboring atoms can also be involved in the Auger process and are referred to as cross transitions (Janssen et al., 1974). After the initial Auger electron is produced, further Auger relaxations will occur to fill the electron vacancies, resulting in a cascade of Auger electron emissions as vacancies are filled by outer electrons.

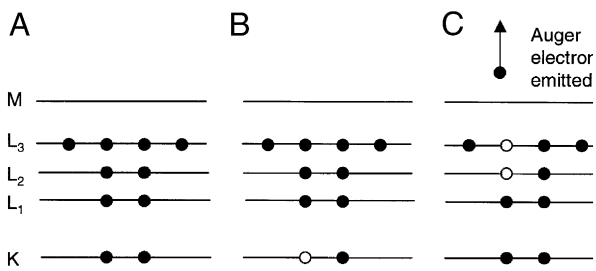

Figure 1. Schematic diagram illustrating the KL_2L_3 Auger process. Atom showing: (**A**) electrons present in filled K and L levels before an electron is removed from the K level; (**B**) after removal of an electron from the K level; and (**C**) following the Auger process, where a KL_2L_3 Auger electron is emitted. In (c), one L-level electron fills the K vacancy and the other L-level electron is ejected due to the energy available on filling the K level.

The energy of the Auger electron will depend on the binding energies, E_b, of the levels involved (and relaxation effects) and not on the energy of the incident beam. In its simplest form, the kinetic energy, E_k, of the Auger electron KL_2L_3 is given approximately by

$$E_k(KL_2L_3) \approx E_b(K) - E_b(L_2) - E_b(L_3) \qquad (1)$$

This equation neglects contributions from the interaction energy between the holes in the L_2 and L_3 levels, as well as intra-atomic and extra-atomic relaxation. Therefore, each element (except hydrogen and helium) will have a characteristic spectrum of Auger electrons, and this forms the basis for qualitative analysis. The intensity of the Auger electrons emitted forms the basis for quantitative analysis. Since binding energies (and relaxation effects) depend on the chemical environment of atoms, information about the chemical environment can often be obtained by studying changes in the kinetic energies of the Auger electrons, which are typically a few electron volts (Haas and Grant, 1969; Haas et al., 1972a,b). Auger transitions involving valence electrons can also exhibit changes in line shape (Haas and Grant, 1970; Haas et al., 1972b). In solids, after an Auger electron is produced, it has to escape from the specimen and pass through the energy analyzer to be measured. All elements except hydrogen and helium can produce Auger electrons, and each has at least one major Auger transition with a kinetic energy below 2000 eV. In AES systems, the electron energy analyzers typically measure electron kinetic energies up to 2000 or 3000 eV. The dominant Auger transitions are KLL, LMM, MNN, etc., with combinations of the outermost levels producing the most intense peaks. These Auger electrons have inelastic mean free paths of only a few atomic layers (Seah and Dench, 1979), and make AES a surface-sensitive technique. Auger electrons produced deeper in

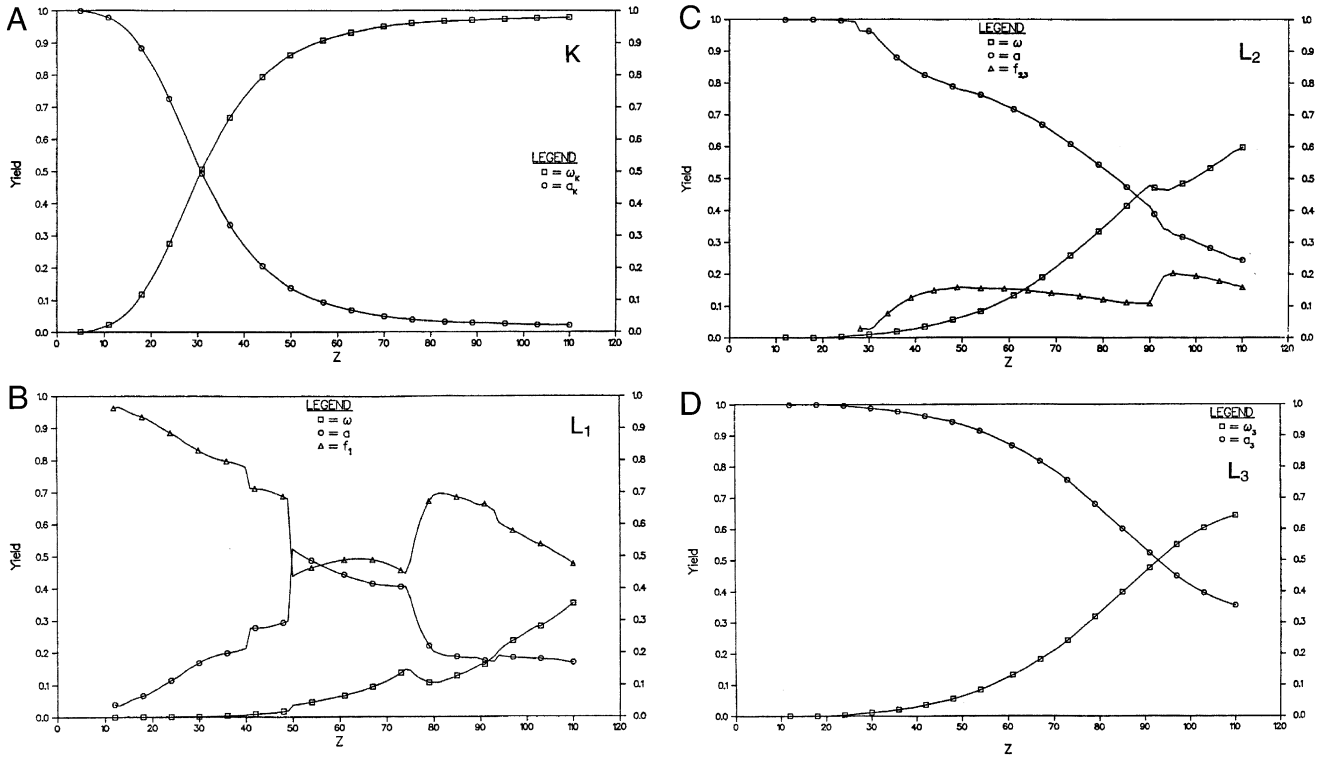

Figure 2. Examples of fluorescent yield and Auger yield as a function of atomic number. Fluorescent yield (boxes), non-Coster-Kronig Auger yield (circles), and Coster-Kronig Auger yield (triangles) for: (**A**) K, (**B**) L_1, (**C**) L_2, and (**D**) L_3 levels as a function of atomic number, Z. Auger electron energy analyzers usually measure kinetic energies up to ~3 keV. For this energy range, K levels in atoms up to atomic number 19 and $L_{2,3}$ levels up to atomic number 50 can be ionized; in these atoms, the fluorescent yields for these levels are much lower than the combined Auger yields. Data from Krause, 1979. (Reprinted with permission.)

the specimen will lose energy in traveling to the surface and appear as a background at lower kinetic energy.

A competing process for Auger electron emission from atoms is x-ray emission. Following the creation of the initial core-level vacancy, a characteristic x ray can be emitted (instead of an Auger electron) when an outer level electron fills this vacancy. The probability for relaxation by Auger emission (called the Auger yield) is much higher than for x-ray emission (called the fluorescent yield) for the energies usually measured in AES (Krause, 1979). Examples of fluorescent yield and Auger yield as a function of atomic number for the K, L_1, L_2, and L_3 levels are shown in Figure 2 (note that Coster-Kronig Auger yields are identified separately from the non-Coster-Kronig Auger yields in this figure).

PRACTICAL ASPECTS OF THE METHOD

As mentioned earlier, most AES work is done with electron-beam excitation. Tungsten filaments, lanthanum hexaboride cathodes, and field emitter tips are all available as electron sources. Lanthanum hexaboride and field emitters have high brightness and are used for high-spatial-resolution instruments. Electron beams can be focused to small areas for point analysis, and rastered in one direction for Auger line scans or in two directions for Auger mapping. Some materials are susceptible to electron beam damage, and care must be exercised in studying them (see Specimen Modification). Insulating specimens can also charge electrically during analysis, resulting in a shift in the measured Auger kinetic energy. Such charging can usually be reduced and/or stabilized using low-energy electron flood guns to replace the lost charge.

A number of electron energy analyzers can be used for AES, the two most popular being the cylindrical mirror analyzer and the spherical sector analyzer. Specimens must be positioned accurately, particularly for single-pass cylindrical mirror analyzers where the measured kinetic energy depends somewhat on specimen position. Positioning is also important in sputter depth profiling where the electron beam, the ion beam, and the specimen must all be aligned at the focus of the analyzer. The electrons transmitted through the analyzer are usually amplified by one or more channel electron multipliers (or microchannel plates) and measured using pulse counting, voltage-to-frequency conversion, or phase-sensitive detection coupled with electron beam or analyzer modulation.

Because of the surface sensitivity of AES, measurements should be made in an ultra-high-vacuum system ($\sim 10^{-7}$ Pa and below) to prevent contamination of the specimens under study. Sputter depth profiling at higher background pressures can be tolerated if the sputter rate is sufficiently high that contamination from the

background gases does not occur. Commercial systems usually include devices for specimen manipulation and treatment (e.g., specimen heating, cooling, and fracture). For many specimens, some treatment, such as inert gas sputtering to remove surface contaminants, might be necessary before meaningful analysis can be made. Some specimens, even though they might appear clean to the eye, may have a thin contaminant layer precluding the detection of any Auger signal from the material of interest. Specimen handling is very important to avoid any contamination of the specimen. Specimens are usually inserted into the analysis chamber through a vacuum interlock.

Auger line scans give the distribution of elements in a straight line across the surface, and Auger maps provide the distribution of elements within a selected area on the surface. The distribution of elements with depth can be obtained by depth profiling. Analysis is rapid, from a few minutes to a few hours depending on the information required, and several specimens can be examined in one day.

Types of Auger Spectra

Auger spectra can be acquired in several ways, but the methods fall into two main categories, namely, (1) the measurement of the total electron signal including Auger electrons and the background from secondary and backscattered electrons, or (2) the measurement of the derivative of this signal using a lock-in amplifier in order to suppress the slowly varying background. Both types of spectra are measured as a function of the kinetic energy of the electrons leaving the sample. Backgrounds can also be suppressed by taking a derivative of the total electron signal obtained in (1) above with a computer. Examples of such spectra are shown in Figure 3, and were taken from a used Cu gasket. Figure 3A is often referred to as a "direct spectrum," and the Auger electrons appear superimposed on the continuous background of secondary and backscattered electrons. This spectrum was obtained in the pulse-counting mode, and the Auger peaks from Cu, Cl, C, N, and O are identified. A large part of the increasing background with increasing kinetic energy is due to the way Auger spectra are usually measured—i.e., with the analyzer energy resolution set at a constant percentage of the measured kinetic energy of the emitted electrons. This results in a continuous, linear change in the measured energy resolution across the spectrum, and therefore the enhancement of the kinetic energy distribution of electrons entering the analyzer, $N(E)$, by a multiple of the kinetic energy, E. This is why the ordinate is usually labeled $E^*N(E)$ in Auger spectra. Figure 3B is referred to as a "derivative spectrum", where the background is reduced and the Auger features are enhanced; note especially the improved N signal. This spectrum was obtained by differentiation of the spectrum in Figure 3A with a computer, and then cutting off some of the large signal at low kinetic energy. The ordinate is then labeled $d[E^*N(E)]/dE$.

Specimen Alignment

The specimen is usually moved to the analyzer focus and approximate analysis position using an optical method

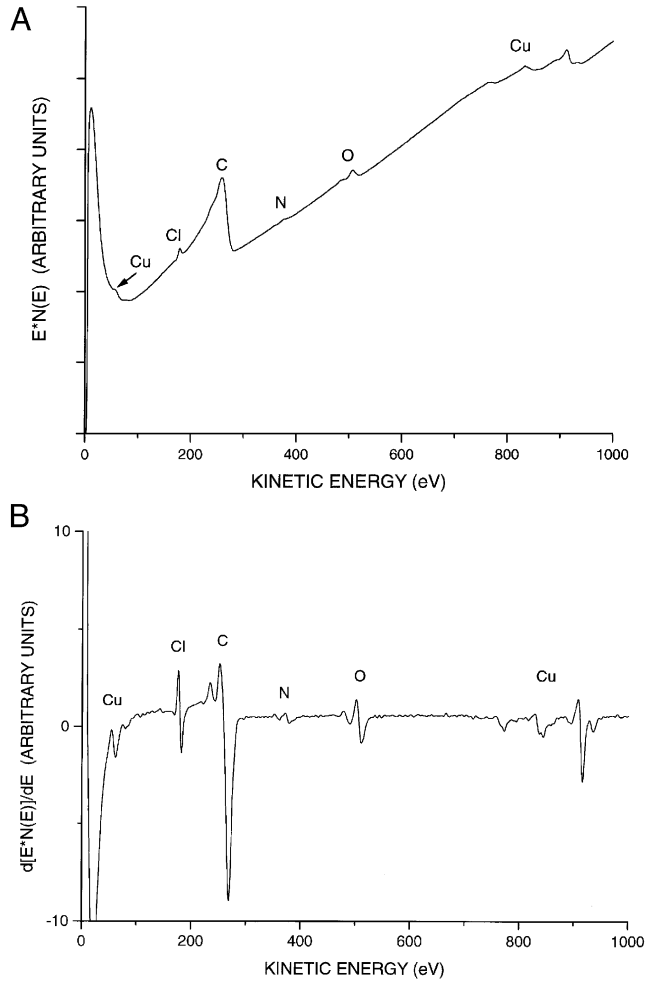

Figure 3. Auger spectra of a used Cu gasket showing: (**A**) the direct spectrum and (**B**) the derivative spectrum. Spectra were obtained using a 40-nA, 5-keV electron beam for excitation, and a hemispherical analyzer with a 1-eV step interval for analysis. The spectrum took 18 min to acquire.

such as a previously calibrated video camera. The electron gun is then switched on, and precise positioning of the specimen is accomplished by using the scanning electron microscopy (SEM) capability of the system. The principles of SEM are discussed in SCANNING ELECTRON MICROSCOPY, and images are obtained from the signal variation with beam position produced by either secondary electrons, backscattered electrons, or specimen current to ground. The analyzer focus can also be checked by maximizing the signal detected by the electron energy analyzer at the same energy as the electron beam, typically 1, 2, or 3 keV. This signal arises from elastically backscattered primary electrons.

Qualitative Analysis

Elements present at the surface are identified from the energies of the Auger peaks in the spectra. An element (or compound) can be considered positively identified if the peak energies, peak shapes, and the relative signal strengths (for multiple peaks) coincide with a standard

reference spectrum of the element (or compound). The procedure starts with the most intense peak in a spectrum and is repeated until all peaks have been identified (Fig. 3). Peak identification depends on an increase in signal intensity above the slowly varying background, and if a computer program is used for peak identification it compares the kinetic energy of the peak with a reference library of associated peaks. If no element lies within a certain energy range from the measured peak, it is not identified by the program. Such problems can arise if the kinetic energy scale is not calibrated, or if the measured kinetic energies shift due to specimen charging. In some cases, peaks can also be misidentified with such software, particularly when different elements have Auger peaks with similar kinetic energies, and the user needs to be aware of this limitation in qualitative analysis. Handbooks of Auger spectra are available and are very useful for helping the novice identify (or confirm) peaks in spectra (Sekine et al., 1982; Childs et al., 1995). The reported Auger peak energies vary by a few electron volts between handbooks, but such variations between handbooks or laboratories should be eliminated in the future, now that energy calibration procedures for AES have been provided for both direct and derivative spectra (Seah et al., 1990). The relative intensities of peaks at widely different kinetic energies will also vary between instruments (and the handbooks) due to instrument design and operating conditions. Therefore, reference spectra should be measured in the same instrument used for the unknown. This problem of intensity variation with kinetic energy can also be reduced by measuring direct spectra of Cu, Ag, and Au in a given instrument, allowing intensity-energy relationships to be derived by comparing such spectra with standard reference AES spectra of Cu, Ag, and Au (Smith and Seah, 1990).

Sets of Auger spectra from some of the elements (Mn, Fe, Co, Ni, and Cu) in the first row of transition elements are shown in direct form in Figure 4, and in derivative form in Figure 5. These spectra were taken from argon-ion sputtered metal foils. The dominant peaks at higher kinetic energy (500 to 1000 eV) are the $L_{2,3}MM$ series, and those at low kinetic energy (40 to 70 eV) are from $M_{2,3}VV$ transitions. The peaks near 100 eV are from M_1VV transitions. Note the rich structure in the $L_{2,3}MM$ series due to the various final M shell vacancies, and how these sets of peaks are similar to each other but move to higher kinetic energy with increasing atomic number. Spectra from other elements will show similar trends in their LMM Auger spectra, as will KLL and MNN transitions. The low-kinetic-energy $M_{2,3}VV$ Auger peaks from the transition metals in Figures 4 and 5 shift by smaller amounts than the $L_{2,3}MM$ peaks, and are not usually used for elemental analysis. The types of Auger spectra shown in these two figures are often referred to as survey spectra and are taken with relatively poor energy resolution and relatively large energy steps so as to optimize the signal-to-noise for a relatively short data acquisition time. Survey spectra are usually the first spectra taken in an analysis, as they provide an overall indication of the surface composition, and are typically taken over an energy range from a few electron volts to 1000 or 2000 eV.

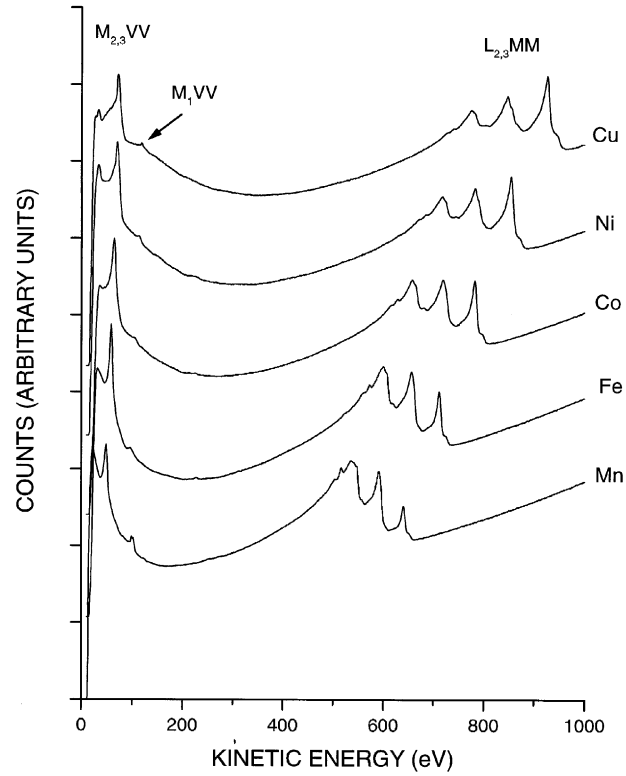

Figure 4. Auger spectra of Mn, Fe, Co, Ni, and Cu taken from argon-sputtered foils, shown in the direct mode. These spectra were obtained with a 40-nA, 5-keV electron beam, and a hemispherical analyzer with a 1-eV step interval. Each spectrum took <2 min to acquire. The Fe, Co, Ni, and Cu spectra are offset for clarity.

The derivative spectra are normally used for peak identification because the Auger features are enhanced in these spectra. The data can also be taken over a longer time to increase the detectability, and higher energy resolution spectra can be obtained if such information is needed. The Auger spectra displayed in Figures 4 and 5 were taken using a hemispherical analyzer with an energy resolution of 0.6% of the kinetic energy and 1.0-eV energy steps applied to the analyzer; each took less than 2 min to acquire with a 40-nA, 5-keV electron beam.

Chemical Effects

Besides identifying the elements present at surfaces, AES can often provide useful information about the chemical environment of surface atoms. Such chemical effects can affect the measured Auger spectrum in a number of ways, e.g., the kinetic energy at which an Auger peak occurs can change, the energy distribution of the Auger electrons can change, or the energy loss structure (see Problems in reference to plasmon loss peaks) associated with Auger peaks can change.

Energy shifts are expected to occur whenever there is charge transfer from one atom to another. Thus, changes in composition of metallic components in metal alloys would not be expected to produce measurable changes in

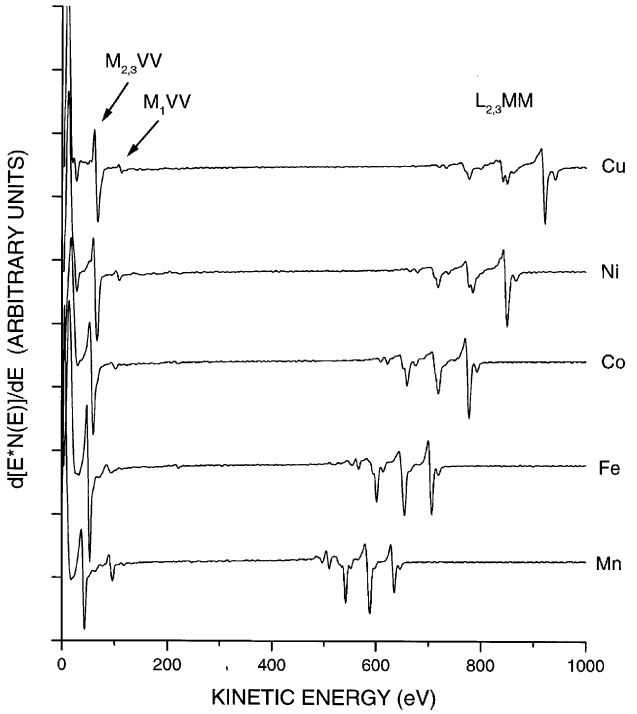

Figure 5. Auger spectra of Mn, Fe, Co, Ni, and Cu taken from argon-sputtered foils, shown in the derivative mode. Derivatives were taken from the direct spectra shown in Figure 4. Note how the spectral features are enhanced in the derivative mode, compared to the direct mode (Fig. 4). The spectra were obtained with a 40-nA, 5-keV electron beam, and each took <2 min to acquire. The spectra are offset for clarity.

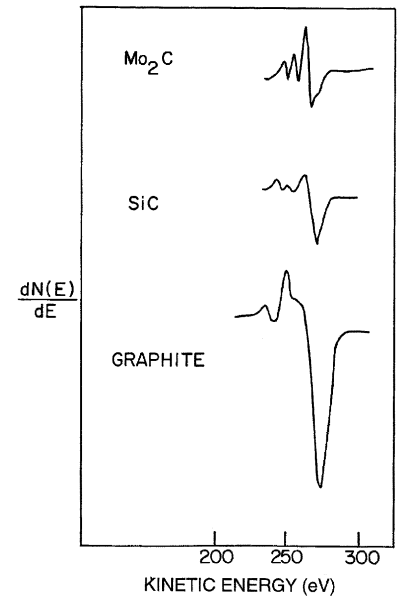

Figure 6. Carbon KVV Auger spectra from molybdeum carbide, silicon carbide, and graphite, showing the different Auger line shapes. Metal carbides usually exhibit the fairly symmetric, three-peak structure of molybdenum carbide, whereas surface contamination from organics usually resembles graphite.

the Auger energies (for core levels) of the components. However, submonolayer quantities of oxygen adsorbed on clean metal surfaces can produce measurable changes in the metal Auger peaks, the shift (from a few tenths of an eV to >1 eV) increasing with coverage (Haas and Grant, 1969). For bulk metal oxides, shifts in the metal Auger peaks are of the order of 10 eV. Changes in the line shape of Auger spectra can also occur due to changes in bonding, particularly when one or two valence electrons are involved in the relaxation process (Haas et al., 1972b). Changes in lineshape of transitions involving valence electrons are usually accompanied by significant shifts in Auger energies as well (Grant and Haas, 1970). Examples of changes in the carbon KVV Auger line shape for different chemical states of carbon are shown in Figure 6, and are due to differences in the density of states in the valence band.

Sensitivity and Detectability

AES measures the composition of the several outermost atomic layers. The sensitivity of the technique should be limited by the shot noise in the electron beam used for Auger electron production. This can be checked by measuring the noise in the direct spectrum, which should follow the square root of the counts detected. Obviously, the longer the time allowed for taking data, the better the detection limit. Also, the sensitivity factor (see Data Analysis) varies for different elements, and for different Auger transitions of the same element. Problems in detectability can also arise due to peak overlap, and this is discussed further below (see Data Analysis). Typical detection limits are in the range of 0.1 to 1 atom %. Remember that H and He are not detected.

Auger Line Scans

With Auger line scans, Auger data are acquired as a function of position across a straight line on the specimen. The maximum length of the line depends on the acceptance area of the analyzer and the deflection capability of the electron gun. The specimen itself is imaged in the SEM mode, and the analysis line is then selected on this image. Also selected is a region (or regions) of the Auger energy spectrum from which to derive the signal that is monitored as the scan progresses.

An SEM image of a Cu grid over a Pd foil, together with a selected line scan position (the white horizontal line near the center), are shown in Figure 7. There is a small vertical displacement between the Cu grid and the Pd foil. The specimen was cleaned by argon-ion bombardment at several azimuths to eliminate shadowing. The Cu and Pd Auger line scans are shown in Figure 8. The Auger line scan signals in this case were the difference between the Auger spectral intensity at the Cu LMM and Pd MNN Auger peak maxima and the backgrounds at the high-kinetic-energy sides of each peak, in the direct spectra. The Cu line scan (solid line) is rather simple, with the signal intensity being high at the Cu grid, as expected. The Pd signal (dashed line) is more complex, being zero at the Cu grid (as

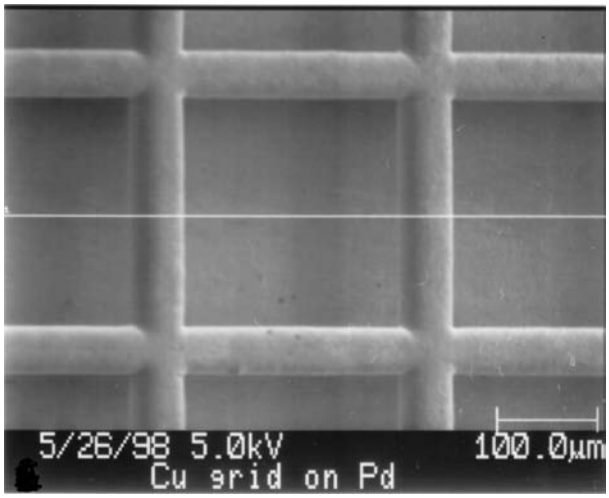

Figure 7. SEM image of a slightly elevated Cu grid over a Pd foil, together with a selected line scan position shown as the white horizontal line near the center. This image was obtained from secondary electrons, using a 5-keV electron beam in the Auger system.

expected), and at a maximum in the region between the Cu grid except for a region to the left of the grid where the signal decreases to near zero. This decrease in signal is due to shadowing of part of the Pd signal by the Cu grid (i.e., blocking Auger electrons from reaching the analyzer), as there is a small gap between the grid and the Pd foil. The specimen was mounted horizontally in the vacuum chamber; the incident electron beam was in the vertical plane that included the line scan, and at an angle of 45° to the horizontal from the left of the image. The analyzer was at an angle of 45° to the horizontal, toward the top of the image.

Several Auger survey spectra are shown in Figure 9 for different positions of the electron beam as it approached

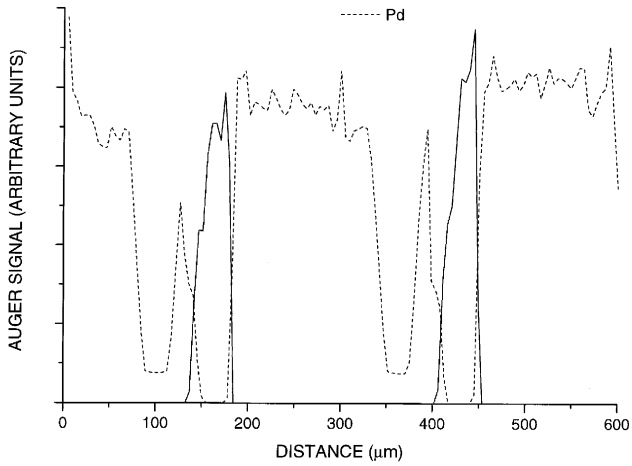

Figure 8. Auger line scans of Cu (solid line) and Pd (dashed line) taken where indicated by the horizontal white line in Figure 7. The Auger line scan signals were, respectively, the difference between the intensity at the Cu LMM or Pd MNN Auger peak maxima and the backgrounds at the high kinetic energy sides of each peak, in the direct spectra. Each scan took 6 min to acquire, using a 40-nA, 5-keV electron beam.

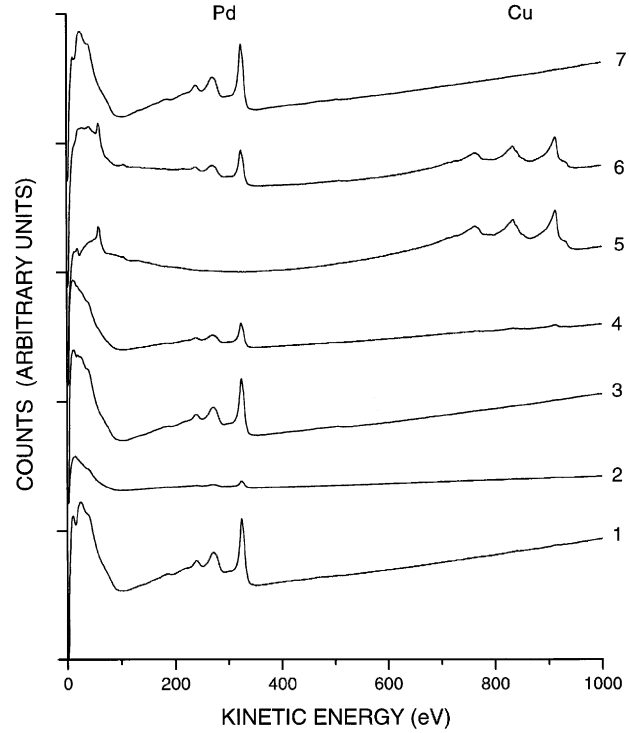

Figure 9. Seven Auger survey spectra in the direct mode, taken at different positions of the electron beam as it approached and crossed the Cu grid at the line scan position shown in Figure 7. The spectra 2 to 7 have been offset for clarity, but were not normalized. Spectra were acquired with a 40-nA, 5-keV electron beam, and each spectrum took ~1 min to acquire.

and crossed the elevated Cu grid. Spectrum number 1 was obtained when the electron beam was on the Pd foil, to the left of the grid as displayed in Figure 7. The Auger peaks between 150 and 350 eV are from Pd. Spectrum 2 was obtained when the electron beam was still on the Pd but underneath the Cu grid, where most of the Pd Auger electrons were blocked by the grid from reaching the analyzer. Spectrum 3 was obtained when the electron beam had passed beneath the elevated Cu grid, but the beam was still not on the grid. Spectrum 4 was obtained when the beam moved partly onto the side of the grid (but shadowing reduced the Cu Auger intensity). Spectrum 5 was obtained when the beam was actually on top of the Cu grid (maximum Cu intensity). Spectrum 6 when obtained when the beam had moved partly off the Cu grid, and spectrum 7 was obtained when the beam was on the Pd foil once more. From these spectra, it can be seen that the initial signal drop in the Pd Auger line scans occurs when the electron beam is not yet on the Cu grid, and is due to shadowing by the grid and not to surface contamination. Other problems in Auger line scans due to topography (not shadowing) and electron backscattering are discussed below (see Data Analysis).

Auger Maps

With Auger maps, Auger data are acquired as a function of position within a defined area on the specimen. The

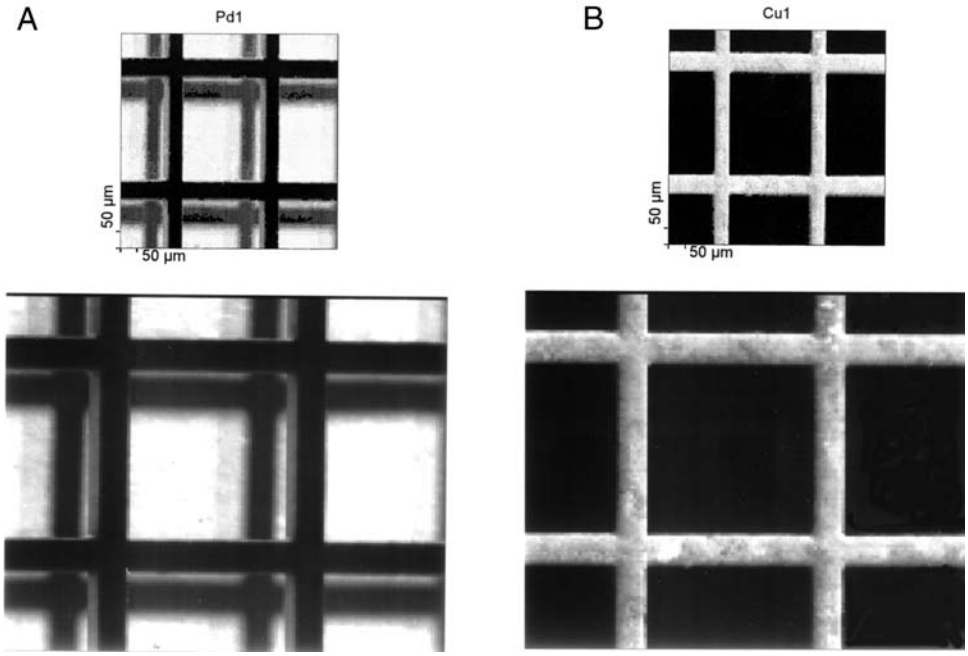

Figure 10. Auger maps of the Cu grid on Pd for, (**A**) Pd, and (**B**) Cu. Bright areas correspond to high signal intensity, and darker areas to lower intensity. These maps were taken with a 40-nA, 5-keV electron beam, with a 128×128 point spatial resolution. Each map took ~25 min to acquire.

maximum dimensions of the area that can be mapped depend on the acceptance area of the analyzer and the deflection capability of the electron gun. The specimen itself is imaged in the SEM mode, and the analysis area is then selected on this image.

Pd and Cu Auger maps of the Cu grid on Pd foil are shown in Figure 10, where the bright areas correspond to higher Auger intensity. The Cu Auger map on the right is rather simple, with the grid being displayed quite clearly. The Pd map is more complex as shadowing also comes into play (see discussion of Auger Line Scans). The region of the Cu grid itself is black, but there is another image of the grid in gray due to the shadowing of this part of the Pd foil by the Cu grid, resulting in a reduction of the Pd Auger signal from this part of the foil.

Auger maps can be displayed in different ways, such as a selected number of gray levels, on a thermal scale, in pseudocolor, or in a selected color for comparing with a map of a different element in the same map area. Auger line scans for each element mapped can also be displayed across a specified line on the appropriate map. As in the case of Auger line scans, corrections of Auger intensity due to topography and electron backscattering are often required (see Data Analysis).

Depth Profiling

In AES, depth profiling is usually accomplished by inert gas ion bombardment to remove successive layers of material from the specimen. The removal of atoms by ion bombardment is also referred to as sputtering. Auger measurements are made either continuously while simultaneously sputtering, or sequentially with alternating cycles of sputtering and analysis. Ar or Xe ions at an energy of a few kilo-electron volts are usually used for sputtering. Typical sputter rates are of the order of 10 nm/min. It is important that the ion beam is correctly aligned to the analysis area on the specimen, and the ion beam is often rastered over a small area of the specimen to ensure that the electron beam used for Auger analysis strikes the flat-bottomed crater formed by the rastering.

Auger survey scans could be taken in depth profiling, but a technique called multiplexing is normally used instead. With multiplexing, several energy spectral windows are preselected, with each one encompassing an Auger peak of the element of interest (Sickafus and Colvin, 1970). This procedure saves time, as only signals from energy regions of interest are measured. This will also provide a higher density of data points in the depth profile, but means that other elements that might be present below the original surface could go undetected.

An Auger sputter depth profile of SiO_2 on Si is shown in Figure 11. The Auger transitions selected were O KLL, Si LMM, and Si KLL. Depth profiles can be plotted with peak height intensities in direct spectra, or with peak-to-peak heights in derivative spectra. The depth profile shown here was obtained using the derivative spectra. The ion beam was rastered over a 2-mm × 2-mm area on the specimen. Auger measurements were made sequentially with sputtering, and the abscissa is plotted as sputter time. Two scans of each Auger transition were obtained before sputtering (one of these is plotted as a negative time). Different compounds sputter at different rates, and it is often not a trivial matter to convert sputter time to depth. Note that near the interface the O signal decreases towards zero, and the Si LMM signal increases

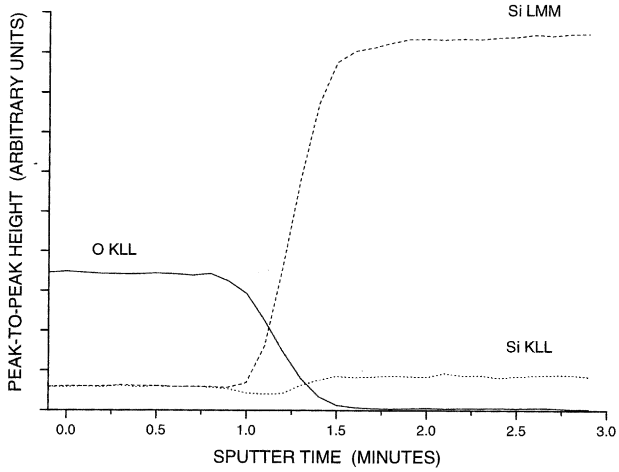

Figure 11. An Auger sputter depth profile of SiO_2 on Si. The Auger transitions selected were O KLL (solid line), Si LMM (dashed line), and Si KLL (dotted line). The profile was obtained by sequentially taking Auger spectra and sputtering. Two scans of each Auger transition were obtained before sputtering (one of these is plotted as a negative time). The sample was sputtered for 0.1 min between measurements. The Auger spectra were taken with a 40-nA, 5-keV electron beam. A 3-keV Ar^+ ion beam, rastered over an area 2 mm×2 mm, was used for sputtering.

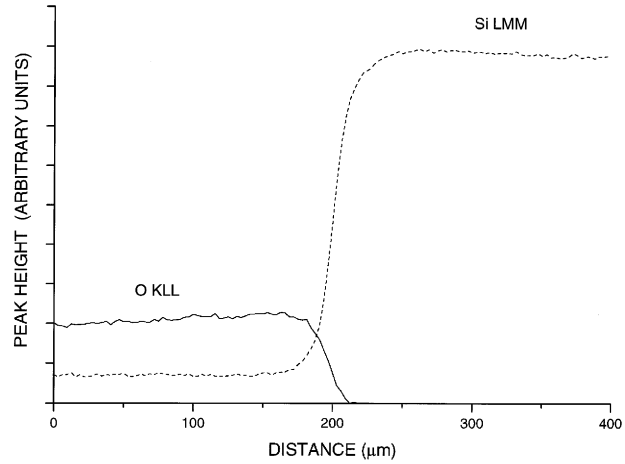

Figure 13. Auger line scans for the O KLL (solid line) and Si LMM (dashed line) Auger transitions taken across the crater edge shown in Figure 12b, using Auger peak heights above background in the direct spectra. The line scans were taken with a 40-nA, 5-keV electron beam, and each scan took ~1 min to acquire.

significantly. The Si KLL signal undergoes a different behavior with an apparent dip at the interface and a small increase in intensity in the pure Si substrate. For discussion of these signal variations, see Data Analysis.

Depth profiles can also be obtained by conducting an Auger line scan across the "crater wall" formed by sputtering (Taylor et al., 1976). An SEM image of the sputtered area for the SiO_2 layer on Si is shown in Figure 12A, with the left-hand crater wall shown expanded in Figure 12B. The Auger line scan was obtained across 400 μm of the left-hand crater wall, as shown in Figure 12B. The Auger line scans for the O KLL and Si LMM Auger transitions are shown in Figure 13 using peak height above background in the direct spectra. Line scans across crater walls are also useful if there was a problem with the alignment of the electron and ion beams, since the Auger line scans are performed on the crater wall after sputtering is finished. In the case of very thin films (up to ~10 nm thickness) where Auger peaks from the substrate can also be detected without sputtering, depth information can be obtained by angle-resolved measurements (the specimen is tilted in relation to the analyzer to change the angle of emission). Other variations on depth profiling include mechanical methods for specimen preparation such as angle lapping (Tarng and Fisher, 1978), where a flat sample is polished at a small angle (~0.5°) to the original surface to expose the depth distribution of elements, and ball cratering (Walls et al., 1979), where a spherical ball grinds a crater into the sample to expose the depth distribution. These two techniques are

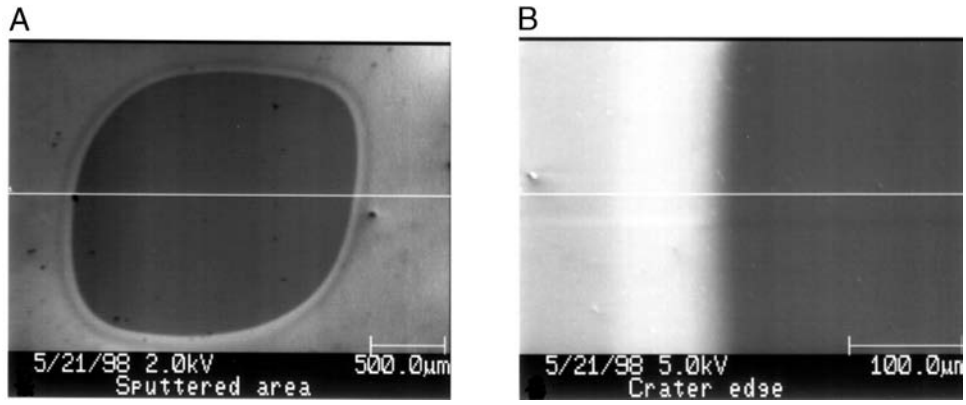

Figure 12. An SEM image of the sputtered area for the SiO_2 layer on Si, following the acquisition of the depth profile, is shown in (**A**). The left-hand crater edge is shown expanded in (**B**), and the horizontal white line in (**B**) is the region that was used for crater edge profiling. The SEM images were taken with (**A**) 2-keV and (**B**) 5-keV electron beams.

typically used where analysis is required to depths >1 μm. The depth resolution in sputter depth profiling is typically several percent of the depth sputtered, but the depth resolution can be improved by rotating the specimen during sputtering (Zalar, 1985).

METHOD AUTOMATION

All modern AES systems operate under computer control, and many repetitive functions can be carried out by the computer.

Specimen introduction is semiautomatic: the specimen insertion chamber can be evacuated automatically, the gate valve between the insertion chamber and the analysis chamber can be pneumatically opened and closed, and the specimen manipulator in the analysis chamber can be parked in the transfer position by computer control. Some AES systems also allow transferability of specimen location information, on a platen obtained prior to insertion, to the specimen manipulator in the analysis chamber.

The electron gun used for producing Auger electrons in the specimen is also controlled by the computer. As electron beam energy is changed, the lens parameters required for focusing, beam alignment in the column, astigmatism correction, etc., are all set to predetermined values. The beam current can also be set to preselected values. Different regions of interest on the specimen surface can also be selected and stored in the computer, so these different regions can be examined in turn automatically during an analysis, e.g., survey spectra could be obtained from the different regions, or individual depth profiles could be obtained from each region during one sputtering operation.

The electron energy analyzer also operates under computer control, although any physical apertures in the analyzer are usually selected manually. The energy resolution of the analyzer is usually controlled by computer, as is the collection and display of the output signal. The kinetic energy range for acquiring data, the kinetic energy step interval, the dwell time at each energy step for acquiring data, and the number of sweeps, among other settings, are all controllable with the computer. The computer also controls the acquisition of Auger line scans and Auger maps.

The computer is also used for data processing. This ranges from simple procedures such as differentiation of spectra to rather complex procedures such as linear least-squares fitting and factor analysis of data. This will be discussed further in the Data Analysis and Initial Interpretation section.

DATA ANALYSIS AND INITIAL INTERPRETATION

Qualitative analysis was discussed earlier (see Practical Aspects of the Method); there are, however, some very useful data analysis methods that need to be mentioned in this section, namely, spectrum subtraction, linear least-squares fitting, and factor analysis. Also, these techniques have all been used to enhance the analysis and interpretation of spectra and to improve detectability.

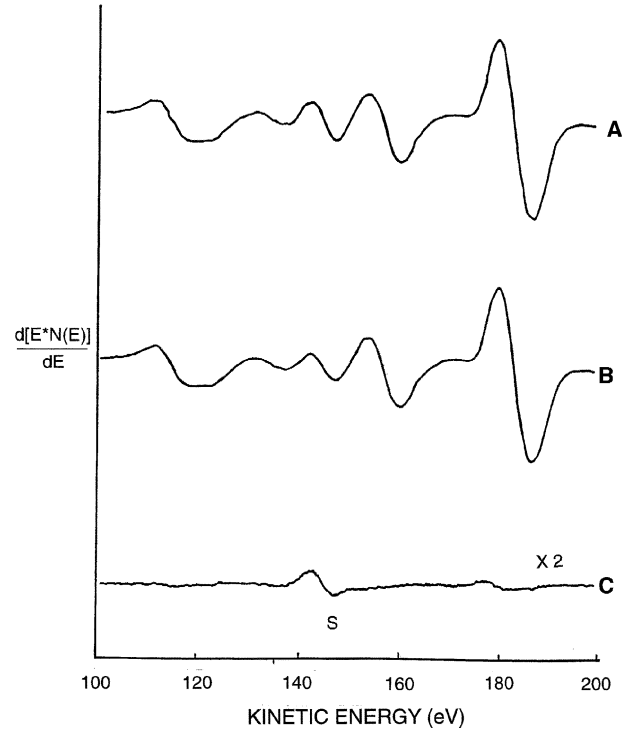

Figure 14. An example of spectrum subtraction: (**A**) the derivative Auger spectrum from a Mo surface, (**B**) the spectrum from pure Mo, and (**C**) the result after subtracting (**B**) from (**A**) to minimize the Mo peak near 180 eV. Note the recovery of an S Auger signal after subtraction.

Spectrum subtraction is a rather simple procedure whereby a spectrum from one element is subtracted from that of another to eliminate overlap problems (Grant et al., 1975a). In this procedure, the spectra must be aligned to allow for any shifts due to chemical effects or specimen charging. If the line shapes are different due to chemical effects, the subtraction will not completely remove the features that are due to the subtracted element. An example of spectrum subtraction is shown in Figure 14, where the S Auger signal (C) is recovered from an Auger spectrum of a Mo surface (A) by subtracting the spectrum from a clean Mo surface (B). The S is then more easily quantified as well.

The different behavior of the Si LMM and Si KLL intensities in the depth profile of SiO_2 on Si (Fig. 11) is due to chemical effects that occur in Si Auger peaks in SiO_2 when compared with pure Si. This depth profile was obtained using derivative Auger data, and the actual Si LMM and KLL spectra used are shown in Figure 15, panels A and B, respectively. Note that in each case the spectra cluster around two different line shapes, which are due to the different Si chemistries in Si and SiO_2. The LMM spectrum from SiO_2 has its main structure ~65 to 75 eV, whereas that from Si is ~80 to 100 eV. Also, the peak-to-peak heights of these LMM transitions increase quite markedly in going from the oxide to the Si substrate. Both of these large differences are due to

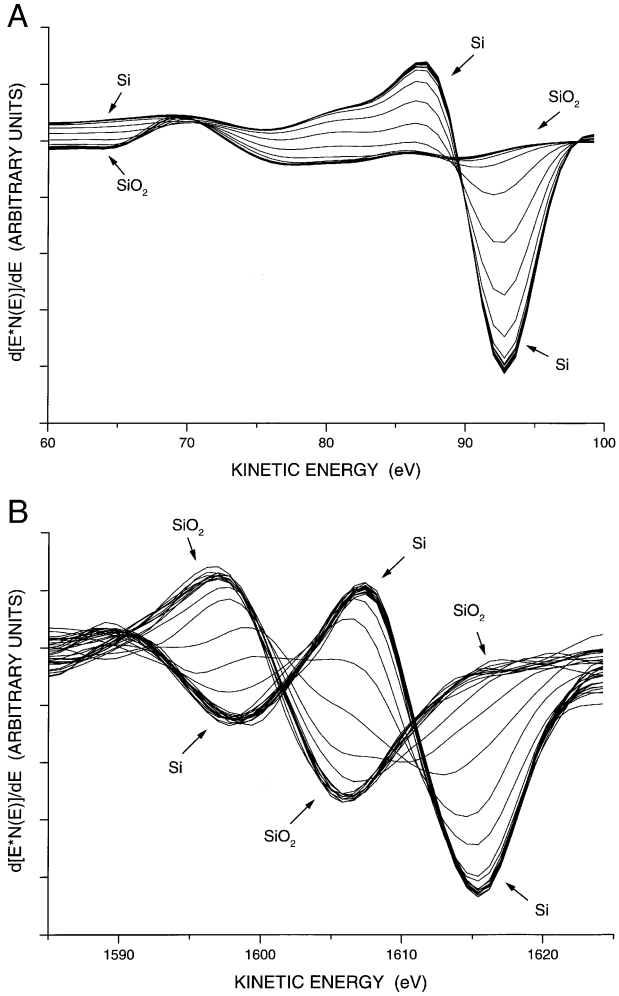

Figure 15. The Si (**A**) LMM, and (**B**) KLL derivative Auger spectra obtained at different depths during the depth profile of SiO_2 on Si shown in Figure 11. Note how in each case the spectra cluster around two different line shapes, corresponding to the Auger transitions in SiO_2 and Si. The few intermediate spectra are from the region near the SiO_2/Si interface.

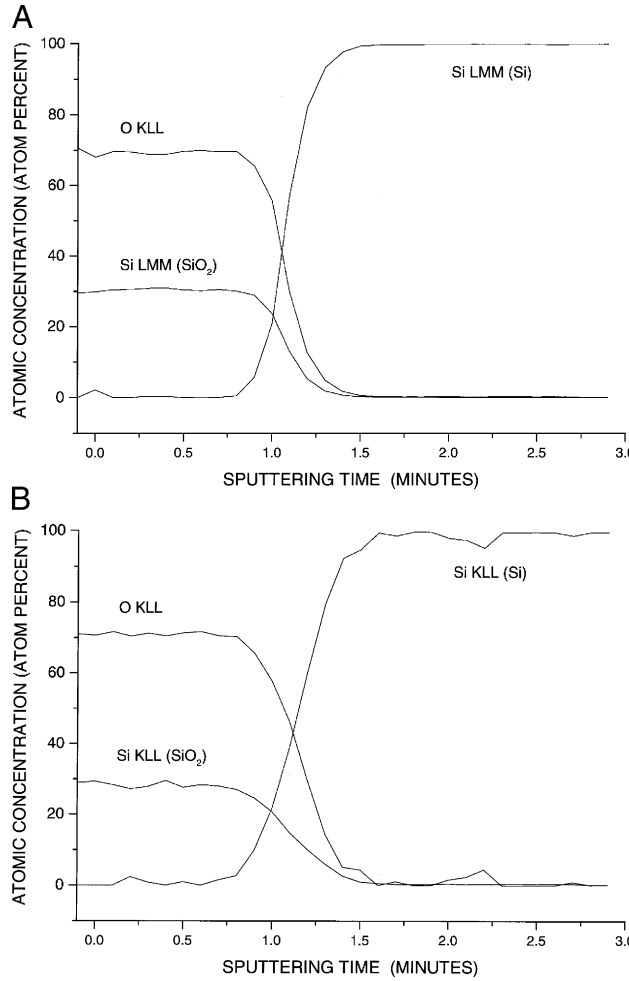

Figure 16. The sputter depth profiles of SiO_2 on Si obtained after applying linear least-squares processing to (**A**) the derivative Si LMM Auger spectra, and (**B**) the derivative Si KLL spectra to separate the Si signals from the oxide and the substrate. The concentrations were calculated using the manufacturer-supplied elemental sensitivity factors for Si and O.

involvement of valence electrons in the LMM transitions. For the KLL transitions, a well defined chemical shift occurs between the oxide and the substrate (the oxide being at lower kinetic energy), and the main peak intensity is more symmetrical in the oxide. Also present in these spectra are a few spectra from the interfacial region, but it is not obvious whether these spectra are linear combinations of the spectra from the oxide and from pure Si, or are line shapes corresponding to a different chemical state of Si. However, it can be seen that the reason for the dip in the Si KLL profile at the interface is a reduction in the peak-to-peak height of the Si KLL signal near the interface since both KLL peaks will be present side-by-side in this region, and not necessarily a decrease in Si concentration. Numerical methods such as linear least-squares fitting (Stickle and Watson, 1992) and factor analysis (Gaarenstroom, 1981) can be used to separate overlapping spectra, or the different chemical components in spectra such as in the SiO_2 on Si sputter depth profile in Figure 11. These processing programs are incorporated into numerical software packages, and have been included in some surface analysis processing software. Examples of use of the linear least-squares method to separate the two different chemical states of Si in the sputter depth profile of SiO_2 on Si are shown in Figure 16A for the derivative Si LMM and O KLL peaks, and in Figure 16B using the derivative Si KLL and O KLL peaks. Note in both examples how the Si Auger signal has been separated into the two different chemical states of Si, namely SiO_2 and pure Si, and that there is no unusual decrease in total silicon concentration at the interface, as indicated from the raw KLL data in Figure 11. The atomic concentrations were calculated using the manufacturer-supplied elemental sensitivity factors for Si and O (see discussion of Quantitative Analysis). Similar results were obtained by selecting two-component fits in factor analysis.

Quantitative Analysis

The most commonly used method for quantitative analysis of Auger spectra is that of sensitivity factors. With sensitivity factors, the atomic fractional concentration of element i, C_i, is often calculated from

$$C_i = \frac{I_i/I_i^\infty}{\sum_j I_j/I_j^\infty} \quad (2)$$

where I_i is the measured Auger intensity of element i in the unknown, I_i^∞ is the corresponding intensity from the pure element i, and the summation is over one term for each element in the unknown (remember that H and He are not detected, and are not included in this calculation). The Auger intensities should all be measured under the same experimental conditions to achieve reliable results. Sometimes, sensitivity factors are measured in the same instrument relative to a particular element such as silver, and the method is then referred to as using relative sensitivity factors. Unfortunately, most people do not measure sensitivity factors in their own instruments but rely on published values, which can differ by more than a factor of 2. Sensitivity factors between elements can vary by as much as a factor of 100 across the periodic table (Sekine et al., 1982; Childs et al., 1995).

Further improvements to Equation 2 can also be made by including corrections for atom size, electron inelastic mean free path, and electron backscatter (Seah, 1983). The atom size adjusts for density, the inelastic mean free path adjusts for the analysis depth, and backscattering adjusts for the increase in Auger intensity that occurs when energetic electrons are scattered back toward the surface and have another chance to produce Auger electrons in the atoms that are closer to the surface. In a homogeneous binary alloy of elements A and B, the atomic concentration ratio of A (C_A) to B (C_B) is then given by

$$\frac{C_A}{C_B} = F_{AB}\frac{I_A/I_A^\infty}{I_B/I_B^\infty} \quad (3)$$

where

$$F_{AB} = \left(\frac{1 + r_A(E_A)}{1 + r_B(E_A)}\right)\left(\frac{a_B}{a_A}\right)^{3/2} \quad (4)$$

and F_{AB} is nearly constant over the entire AB compositional range. $r_i(E_i)$ is the backscattering factor for element i for an electron with kinetic energy E_i, and a_i is the size of atoms in element i (Seah, 1983). These corrections are straightforward and can improve quantitative analysis, but unfortunately are rarely made.

Auger currents cannot be measured directly as they are superimposed on background currents due to secondary and backscattered electrons. Also, there is current on the low kinetic energy side of Auger peaks due to inelastic losses suffered by Auger electrons in escaping from the specimen being analyzed, and this background must be removed in the measurement. Some work has been conducted to measure the areas under Auger peaks, but this is not done routinely in quantitative analysis due to the difficulty in removing the background. Peak height measurements (direct spectra) or peak-to-peak height measurements (derivative spectra) are normally used for quantitative analysis, and each method has its own sets of sensitivity factors.

Peak height measurements are often used for Auger line scans and Auger maps, as data acquisition times can be minimized by collecting data at just two or three energy values for each element. The sloping background above the peaks should be extrapolated to the energy of the peak maximum to measure peak height, although this is not always done. This can be done using a simple algorithm if measurements are made at three energies, namely at the peak maximum, at the background just above the peak, and at a higher background energy equally spaced from the central energy. Problems in quantitative analysis for Auger line scans or maps, due to specimen topography and changes in electron backscattering coefficient, can be satisfactorily corrected in peak height data by dividing the Auger intensity by the background on the high-energy side of the peak (Prutton et al., 1983).

Peak-to-peak height measurements from derivative spectra are the most commonly used method for quantitative analysis in AES, and this is the method normally used for survey scans and for depth profiles. The peak-to-peak height method has met with a lot of success, particularly in studying metals and their alloys. The accuracy of such measurements is typically $\pm 20\%$. More accurate quantitative analysis can be achieved if standards with concentrations that are close to those of the actual specimens are used, thereby reducing errors due to variations in electron backscatter and inelastic mean free path. Large errors can occur if the standards are not measured using the same analysis equipment as for the unknown. For example, different instruments from the same manufacturer have shown a fivefold variation in the intensity ratios for high- and low-energy Auger peaks (Baer and Thomas, 1986).

Problems also arise in quantitative analysis, particularly when using peak-to-peak heights, if Auger lineshape changes occur due to a change in chemistry. For example, for oxygen adsorption on nickel, the concentration of oxygen can be in error by a factor of two if peak-to-peak height measurements are used, even though the oxygen Auger line shape changes are subtle (Hooker et al., 1976).

Improvements in quantitative analysis can be made by measuring the intensity/energy dependency of each instrument for Cu, Ag, and Au for the set of conditions normally used for analysis (e.g., different analyzer energy resolutions), and comparing the results with standard reference spectra (see NPL under Standards Sources section). This will provide the intensity response function for each experimental condition, allow accurate transferability of results between instruments, and allow the performance of a particular instrument to be monitored over time.

Standards Sources

There are several standards for AES that have been developed by national standards organizations. Standards for

depth profiling are available from the United States National Institute of Standards and Technology (NIST), and from the National Physical Laboratory (NPL) in the United Kingdom. Software for calibration of Auger electron spectrometers is available from NPL. Standard terminology, practices, and guides have been developed by the American Society for Testing and Materials (ASTM). Details are listed in the Appendix.

SAMPLE PREPARATION

Since AES is a surface-sensitive technique, the handling, preparation, mounting, and analysis of a sample is of paramount importance. For example, a fingerprint on a specimen can be sufficient contamination to mask any signal from the actual surface of interest. If the specimen has been contaminated in some way, cleaning prior to mounting might be required. Cleaning with acetone, followed by rinsing in methanol, is often used to remove soluble contaminants. It must be remembered that any solvent used for cleaning might also leave a contaminant residue. Loose contaminating particles can be removed using a jet of nitrogen gas. If the contaminant is a thin layer, it might be possible to remove the contamination by low-energy inert gas ion sputtering in the analysis chamber. Sputtering can also cause its own problems, as elements sputter at different rates and their relative concentrations at the surface can therefore change. Sample handling is described in detail in ASTM Guides E1078 and E1829 (see the Appendix).

Size limitations on specimens depend on the particular analysis chamber. Specimen diameters up to several centimeters can usually be accommodated, but height limitations are often ~1 cm when vacuum-interlocked sample insertion systems are used. Some AES systems are designed to handle 300-mm wafers. If larger samples are to be routinely studied, customized insertion systems can be designed. Samples might need to be cut from a larger piece or sectioned for analysis. If this is done, care should be exercised to minimize possible contamination. If information is needed to a depth greater than ~1 μm, samples might be sectioned or ball cratered (see discussion of Depth Profiling).

Powder-free gloves should always be used when mounting specimens, and the tools used should be clean and nonmagnetic. Samples are usually mounted on Al or stainless steel holders, and are held in place with small screws or clips. Sometimes, samples are mounted with colloidal Ag or colloidal graphite. Powders are often mounted on conducting adhesive tape.

Samples prone to outgassing can be prepumped in an auxiliary vacuum system, or in the introduction chamber, to remove volatile species. However, cross-contamination between samples might occur.

When in the analysis chamber, specimens can sometimes be prepared by fracture, cleavage, or scribing. In some cases, it may be possible to remove contaminants by heating if subsequent studies on clean surfaces are required, such as on how specific gases react with a clean surface.

Once in the analysis chamber, specimens can be moved by a manipulator and imaged with a microscope or video camera (initially) and then with the electron beam (as in an SEM), to locate the regions to be analyzed.

If samples are electrically insulating, they are sometimes mounted beneath a metal mask with a small opening or beneath a metal grid to minimize charging by placing the incident electron beam close to the metal. Tilting the sample to change the angle of incidence of the electron beam can help control charging. Changing the beam energy, reducing the beam current density, and using a low-energy electron flood gun are also effective in controlling charging.

SPECIMEN MODIFICATION

Since an energetic electron beam is used for Auger analysis, and since it is a surface-analysis technique, specimens can sometimes be modified by the beam. A manifestation of this would be that the surface composition varies with time of exposure to the beam (Pantano and Madey, 1981).

Specimen modification can occur from heating by the beam, where species might diffuse to the surface from the bulk, diffuse across the surface, or desorb from the surface. The electron beam itself can also cause desorption (e.g., fluorine desorption), it can assist the adsorption of molecules from the vacuum environment onto the surface,

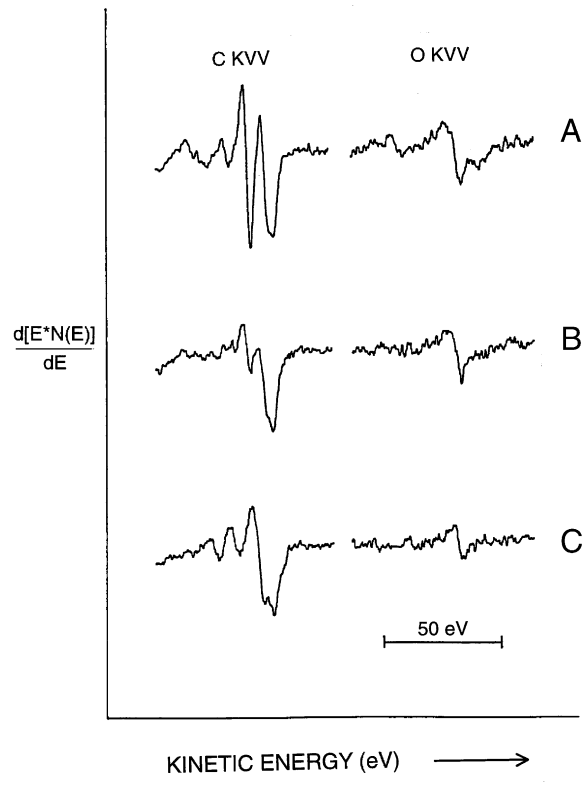

Figure 17. C and O KVV derivative Auger spectra from (**A**) CO molecularly adsorbed on Ni, (**B**) after exposure to a 1.5-keV electron beam with a current density of ~1 μA/mm^2 for 10 min, and (**C**) after exposure to the beam for 40 min.

and it can decompose species at the surface. Electron beam modification can be reduced by decreasing the beam energy, by decreasing the current density at the surface by defocusing the beam, or by rastering the beam over a certain area. If the specimen is laterally homogeneous, electron beam rastering can always be used. An example of electron beam decomposition is shown in Figure 17, where it can be seen that a low-energy beam (1 keV) with a current density of $\sim 1\ \mu A/mm^2$ produces marked changes, in a few minutes, in the C KVV and O KVV Auger spectra for CO molecularly adsorbed on Ni. In fact, some C and O is desorbed from the surface, and the remaining species are converted into nickel carbide and oxide (Hooker and Grant, 1976).

PROBLEMS

Problems in conducting an Auger analysis can occur from many sources. These include specimen modification from the electron beam and electrical charging of insulators. Problems can also be encountered in data reduction, such as peak overlap, misidentification of Auger peaks, and the possible presence of ionization loss peaks, plasmon loss peaks, and ion-excited Auger peaks in the spectra. Since ionization loss peaks, plasmon loss peaks, and ion-excited Auger peaks have not been discussed earlier, their effects on the interpretation of spectra will be discussed here.

Ionization Loss Peaks

When an electron is ejected from an atomic shell (having a binding energy E_b) by an electron from the incident beam (having a kinetic energy E_p), the energy remaining will be $(E_p - E_b)$. This remaining energy is shared between the ejected electron and the incident electron, and these electrons will also appear in the measured energy distribution, $N(E)$. This means that there will be a background of electrons in $N(E)$ from this process up to a kinetic energy of $(E_p - E_b)$, resulting in a small reduction in the intensity of $N(E)$ above this energy. This small step in $N(E)$ is sometimes observed in derivative spectra, and is called an ionization loss peak (Bishop and Riviere, 1970). Its source can be readily confirmed by changing the incident beam energy, as the feature will move in the $N(E)$ distribution by the change in beam energy (remember that Auger peaks do not change their kinetic energy when the electron beam energy is changed). These ionization loss peaks can be useful in studying surfaces, for example, where overlap of Auger peaks might make detection difficult. They can also be used to study changes in surface chemistry, as any shift in binding energy of the energy level in the atom will be reflected as a change in kinetic energy of the ionization loss peak. An example of ionization loss peaks is shown in Figure 18, for the Si L_1 and $L_{2,3}$ levels in SiO_2. In the case of conductors, ionization loss peaks might overlap plasmon loss peaks (see Plasmon Loss Peaks section), for levels with low binding energy.

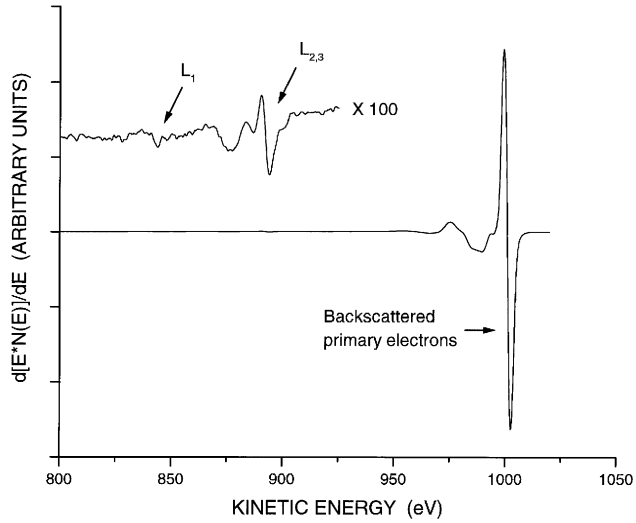

Figure 18. Ionization loss peaks in the derivative mode for the L_1 and $L_{2,3}$ levels in SiO_2. The spectrum was taken with a 100-nA, 1000-eV electron beam in <10 min. The symmetrical peak at 1000 eV is from backscattered primary electrons.

Plasmon Loss Peaks

An electron traveling through a conducting material can interact with the free electrons in the material and lose a specific amount of energy, resulting in an additional peak separated in energy by what is called the plasmon energy (Klemperer and Shepherd, 1963). Several orders of bulk plasmons can occur, and they will appear as a series of equally separated peaks of decreasing intensity on the low-kinetic-energy side of the Auger peak. Besides these bulk plasmons, the presence of the surface results in additional plasmons, called surface plasmons, that are associated with the back-scattered primary electrons and with each bulk plasmon peak. Higher-order surface plasmons are very weak and not observed directly in the loss of spectrum (Pardee et al., 1975). An example of plasmon peaks is shown in Figure 19A for 1-keV backscattered primary electrons from an Al surface, where the bulk (B) and surface (S) plasmons have energies of 15.3 and 10.3 eV, respectively. This backscattered spectrum was taken under high energy resolution, and typical Auger peaks and their corresponding plasmon loss peaks will be broader, as can be seen for the Al KLL Auger spectrum in Figure 19B. The Al $KL_1L_{2,3}$ Auger electrons near 1336 eV have their own plasmons, and the $KL_1L_{2,3}$ Auger peak also overlaps with plasmon peaks from Al $KL_{2,3}L_{2,3}$ Auger electrons, which have a peak near 1386 eV. Note that the plasmon peaks are equally spaced and decrease in intensity as they move away from the Auger peaks. Aluminum oxide would not have any plasmon peaks. The presence of plasmons will change the shape of an Auger peak, and take electrons away from the Auger peak, making quantitative analysis somewhat more difficult.

Ion-Excited Auger Peaks

Core electron levels for some elements can be ionized by low-energy (1 to 5 keV) inert gas ion bombardment,

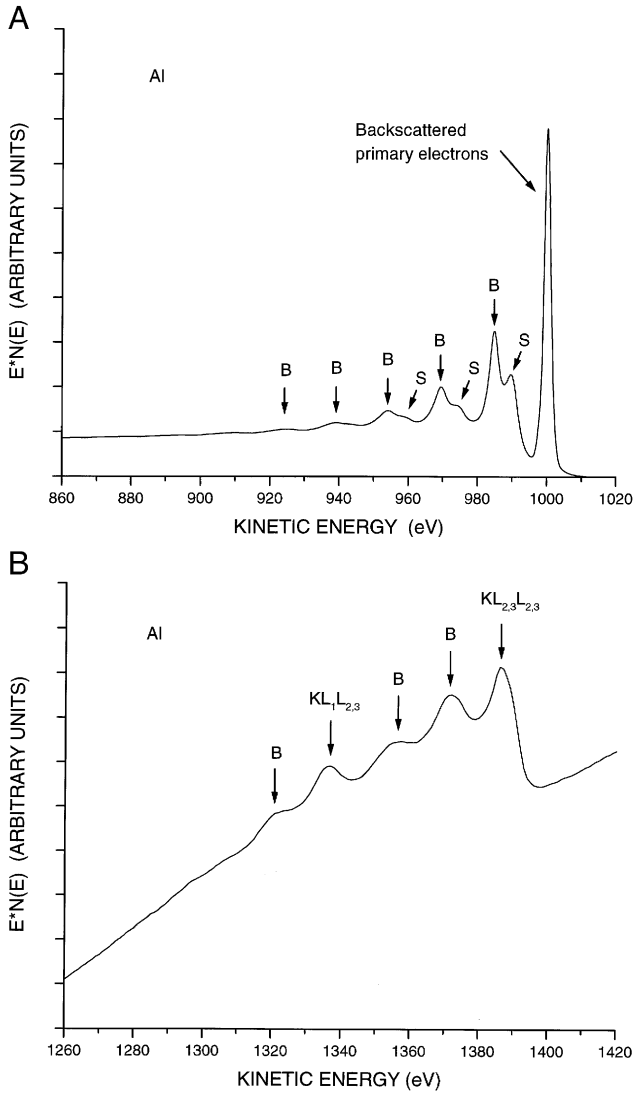

Figure 19. Plasmon peaks (bulk B, surface S) associated with (**A**) a backscattered primary electron beam at 1000 eV from Al, and (**B**) the Al $KL_1L_{2,3}$ (near 1337 eV) and $KL_{2,3}L_{2,3}$ (near 1386-eV) Auger peaks from Al obtained with a 5-keV electron beam. For Al, the bulk and surface plasmons have energies of 15.3 and 10.3 eV, respectively. The surface plasmons in (**B**) are obscured by the broad bulk plasmon peaks (reflecting the broad Auger peaks).

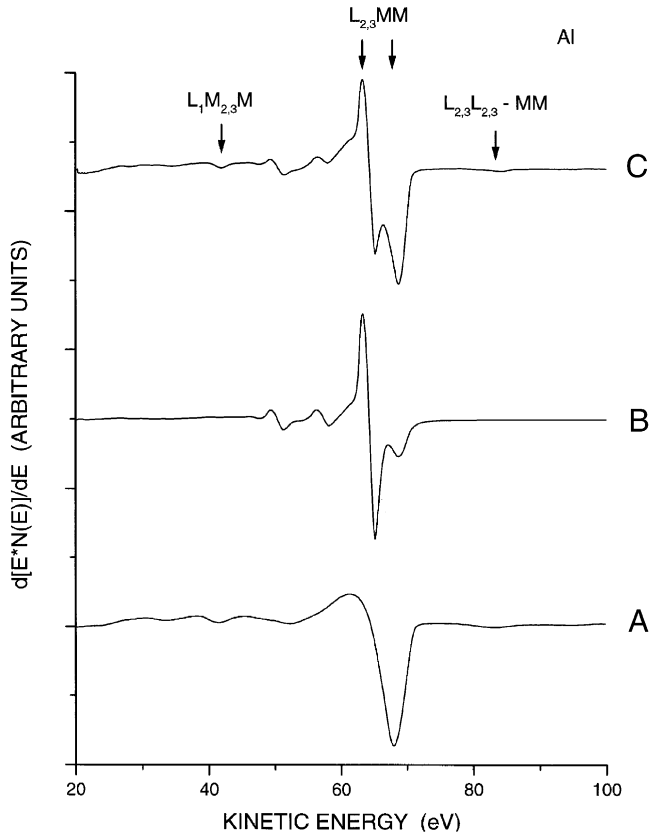

Figure 20. Derivative LMM Auger spectra, (**A**) excited by a 5-keV electron beam, (**B**) excited by a 3-keV Ar^+ ion beam, and (**C**) excited by both electron and ion beams together, as might occur in a sputter depth profile through Al.

resulting in the emission of Auger electrons from these atoms (Haas et al., 1974). Only those energy levels in an atom of the sample that can be promoted to a much lower binding energy by the incident ion during its interaction with the atom can be ionized (the relatively heavy ion cannot transfer enough energy to an electron to ionize core shell electrons). The atom is ionized in a core shell if an electron is transferred to the incident ion from a promoted core shell energy level during impact, and if it remains transferred after the collision. The ionized level then returns to its higher binding energy, and Auger electron emission can then occur. Typical levels that can be ionized by this method are the $L_{2,3}$ levels of Mg, Al, and Si, and additional Auger intensity might occur on depth profiling through layers containing these elements. The L_1 level of Mg, Al, and Si cannot be ionized, as this level is not promoted during collision with the incoming ion. During ion bombardment, Auger emission can occur from sputtered specimen ions as well as from the specimen. The spectrum produced by the ion beam will be different from that produced by an electron beam in two ways (1) the spectrum produced by ion impact will not contain all the transitions produced by electron impact, since not all levels can be promoted (e.g., the L_1 levels in these atoms), and (2) sharp, atomic-like Auger transitions will occur from sputtered ions as well (Grant et al., 1975b). A comparison of electron- and ion-excited Auger emission from Al is shown in Figure 20. The spectrum produced by electron excitation, Figure 20A, shows the main $L_{2,3}MM$ transition at 68 eV, and the $L_1L_{2,3}M$ and $L_{2,3}L_{2,3}$-MM transitions at 41 and 83 eV, respectively. The spectrum produced by Ar^+ excitation, Figure 11d.20B, shows the $L_{2,3}MM$ transition at 68 eV from the bulk Al, together with some overlapping symmetric Auger peaks from sputtered Al ions, but the $L_1L_{2,3}M$ and $L_{2,3}L_{2,3}$-MM transitions are not seen. The L_1 level is not promoted on impact with an Ar^+ ion, so the $L_1L_{2,3}M$ transition cannot occur. Also, double initial ionization of the $L_{2,3}$ level does not occur on ion impact.

Composite spectra, such as the one shown in Figure 20C, can be obtained during simultaneous electron and ion bombardment of Al. Note that the symmetric, ion-excited peaks from sputtered ions are sharper than the electron-excited peaks, and will therefore appear relatively larger in derivative spectra than in direct spectra.

ION-BEAM TECHNIQUES

INTRODUCTION

Ion Beam Analysis (IBA) involves the use of a well-defined *Beam* of energetic *Ions* for the purpose of *Analyzing* materials. In general, it is the combined attributes of the incident ions' energy, mass, and mode of interaction with the target that distinguish each of the analytic techniques described in this chapter. The range of possible ion-atom interactions that can occur in a target, and the results of that interaction that produces the detected signal, give each technique specific advantages under specific circumstances. In the units of this chapter, IBA techniques are described which utilize ion species spanning nearly the entire periodic table, ion energies which extend from several electron volts to several million electron volts, and detected signals consisting of nuclei, electrons, γ rays, x rays, optical photons, collected electrical charge, and even logic states in digital circuits.

One feature of IBA that distinguishes it from most other analytical techniques is the incredible wealth of signals that are available for detection. A simple beam of protons incident on a target offers the experimenter a "detection menu" consisting of: (1) back-scattered protons, (2) α particles formed by nuclear reactions (if the energy is high enough), (3) γ rays caused by these same reactions or Coulomb excitation, (4) x rays produced by inner atomic shell ionization followed by radiative decay, (5) secondary ions emitted by sputtering, (6) secondary electrons ionized near the surface, (7) photons produced by the ionolumenescence process, (8) electron-hole pairs collected from within biased semiconductor targets, and on and on in glutinous profusion. Of course we are not limited to just protons—one can accelerate deuterons, tritons, ^{3}He, ^{4}He, ^{6}Li, ^{7}Li, etc. Given all of the possible signals from all of the possible beams at all of the possible energies, a virtually mind-boggling range of measurements is possible. Moreover, owing to the interplay of ion, energy, and target composition combined with the capability to finely focus the beam, the experimenter can preferentially probe different regions of a sample at times in three dimensions. In the simplest of cases, for example, low-energy ions interact only with atoms that are near the surface, while high-energy ions permit measurements of the composition deep within a specimen. Thus, a modern IBA lab can usually provide a way to analyze virtually any isotope of any element, at any position, inside any sample.

The connecting thread that binds the broad range of analytical techniques presented in this chapter may not be immediately obvious, due to the widely disparate energies and ion species that are employed to probe for specific elements in specific targets. Yet, the relationships among the different IBA techniques becomes more apparent when each is plotted in a "phase space" defined by the projectile ion, energy, and the electronic and nuclear stopping powers for a specific target (i.e., the rates at which an ion loses energy in a sample due to electronic and nuclear collisions). In such a phase space of IBA techniques, shown in Figure 1, a coordinate system of projectile atomic number (specifically for H, He, C, Si, Mo and Au) is plotted versus ion energy/mass (logarithmic in E/amu) within the framework of a log-log plot of nuclear stopping power [$S(n)$] versus electronic stopping power [$S(e)$], where the stopping power units are MeV/(mg/cm^2). This plot has been generated for the "favorite son" of IBA—silicon—as the target. Aside from the qualitative rendering of the relationships among the IBA techniques, such plots also readily provide quantitative comparisons of the stopping powers of all ions across nearly all energies in a given target.

The different IBA techniques are mapped into this space by assigning each technique that region of the phase space representing its typical ion and energy parameters. Beginning with the least utilized region, i.e., that of relativistic energies, the region labeled "REL" applies to energies greater than $\sim$100 MeV/amu—approximately half the speed of light. The region labeled NRA (nuclear reaction analysis) is next. Its low energy boundary is set by the height of the Coulomb barriers for collisions between ions and Si; above this barrier, the nuclei can collide permitting the possibility of nuclear reactions. Below the Coulomb barrier is the elastic scattering region characterized by RBS (Rutherford back-scattering) for low-Z projectiles, and ERD (elastic recoil detection) for high-Z projectiles. Note that it is in this region that the electronic (and total) stopping power is maximum, and therefore the highest depth resolution IBA depth profiling is done with ions in this category. This is also the region where proton-induced x-ray emission (PIXE) is performed. The low energy boundary for this region occurs where electron screening effects become important. At still lower energies, MEIS (medium energy ion scattering) and HIBS (heavy ion back-scattering spectrometry) come into use. HIBS denotes the use of higher-Z projectiles with larger stopping powers and high sensitivity to trace elements. MEIS also takes advantage of very large stopping powers and the enormous Coulomb scattering cross-sections which tend to vary with the inverse of the projectile energy squared. Because of this, MEIS techniques also have very good depth resolution and, at times, extremely high sensitivity. We have defined this region's lower energy boundary using a velocity equal to approximately one-half the Bohr velocity. Ions with energies less than the Bohr velocity become neutralized very easily because their velocity is almost exactly matched to that of a target's outer-shell electrons which can then be easily captured by the ion. This marks the onset of the LEIS (low energy ion scattering) regime; owing to its low energy, LEIS is highly surface sensitive. When inert-gas ions are used, LEIS can provide an analysis of the outermost atomic layer in a material. Moreover, since in this regime the nuclear stopping power is a maximum, SIMS (secondary ion mass spectrometry) is performed at these energies with heavier ions that have correspondingly large sputtering yields. Finally, for ions with energies of less than 100 eV, we leave the realm of

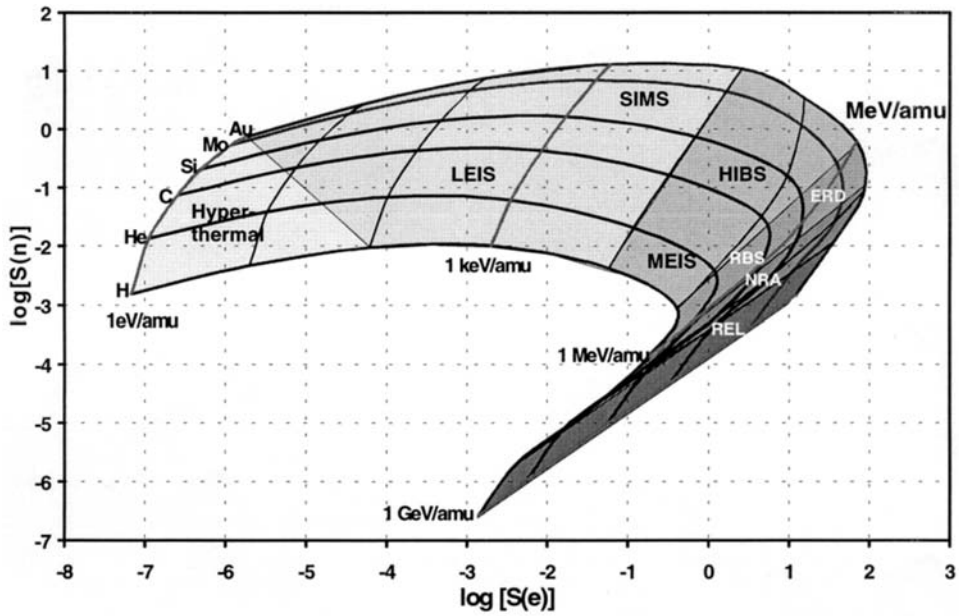

Figure 1. IBA Regimes for Si Target Incident Ions H-Au Energies from 1 eV to 1 GeV/amu.

binary collisions and enter a regime called hyperthermal, where ion-solid interactions begin to include both multibody kinematic and chemical interactions.

Common to each of the IBA techniques described in this chapter is the use of the particle accelerator—a device that the public most commonly associates with the "atom smashers" used in the early part of the 20th century to probe the structure of the atom, and later, the nucleus. Our dependence on this tool is somehow fitting given that virtually all of the techniques discussed in the following units can trace their development to the pioneering work performed by the great physicists of that era—Rutherford, Compton, Bethe, Bohr, etc. This legacy becomes apparent by simply noting that in performing any of these analyses, we are usually repeating a classic experiment, albeit with a different emphasis and better equipment, that was once performed by one of the giants of modern physics. Today's IBA techniques are the direct descendants of investigations into the nature of the atom by Lord Rutherford using back-scattered α particles, the structure of the electronic orbitals by Niels Bohr using characteristic x-ray spectra, and even the nature of stellar energy generation by Hans Bethe using the cross-sections of ion-induced nuclear reactions. When performing IBA, it is sometimes hard not to actually feel the presence of one of these legends on whose shoulders we stand.

As the reader delves into each of the following chapters, the underlying similarities in these techniques will repeatedly appear. This is not surprising, since the basis of all ion-atom scattering kinematics is contained in the simple central force problem first solved by Kepler, (and perfected for IBA purposes by Minnesota Fats and Willie Mosconi!). Likewise, in a large fraction of these techniques, the scattering cross-sections are given by the famous Rutherford equation. Thus, while it is the unique nature of the collision physics within each ion/energy regime that lends each IBA technique its particular utility for a given measurement, it is the shared traits of ion-solid interactions which unite these techniques into a single scientific field which has been the useful servant of much of today's science and technology.

KEVIN M. HORN

HIGH-ENERGY ION BEAM ANALYSIS

INTRODUCTION

It is very hard to identify the earliest application of high-energy ion beam analysis (IBA), which was a natural outgrowth of accelerator-based atomic and nuclear physics that started in the 1940s with the development of particle accelerators. In these early experiments, the composition of the target to be studied was well known, and it was the nuclear scattering or reaction cross-section that was measured. It would not be surprising if one of the very first nuclear physics pioneers turned this emphasis around and used their beams to measure the compositional uniformity of an unknown sample. Perhaps the earliest known proposal for IBA was that of E. Rubin in 1949 (Rubin, 1949, 1950) at the Stanford Research Institute, which spelled out the principle of Rutherford backscattering spectrometry (RBS). Another very early application of IBA was performed by Harald Enge at MIT (Enge et al., 1952). Enge used mega-electron-volt deuterons from one of Van de Graaff's first accelerators with a magnetic spectrometer to measure the constituents of aluminized Formvar in perhaps the earliest materials analysis application of nuclear reaction analysis (NRA). It is interesting to note that the

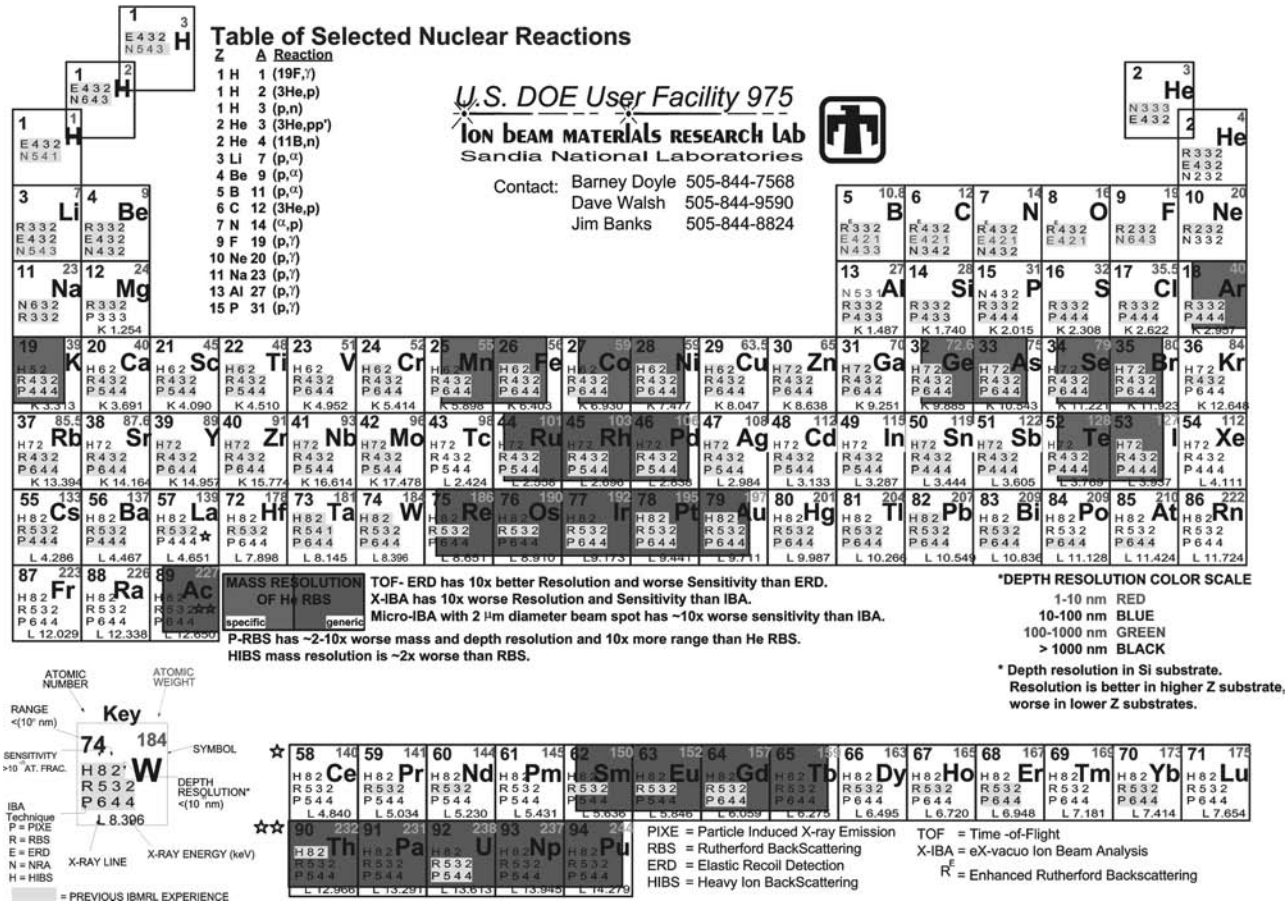

Figure 1. Ion beam analysis table of the elements.

use of magnetic spectrometers to obtain ultrahigh depth resolution is now common, and Dollinger et al. (1995) have obtained single atomic layer resolution by using an Enge Q3D magnetic spectrometer for IBA.

High-Energy IBA is generally thought to apply when the ion beam has energy greater than 0.5 MeV. There are several attributes of high-energy IBA, including (1) the ability to measure virtually any element in the periodic table, at times with isotopic specificity; (2) the ability to determine concentration as a function of depth; (3) that trace element sensitivity is not uncommon; and (4) that the technique is nondestructive with respect to the chemical makeup of the sample.

The periodic table in Figure 1 provides a convenient overview of high-energy IBA capabilities.

ION BEAM ANALYSIS PERIODIC TABLE

The purpose of the periodic table is to quickly provide information on the sensitivity, depth of analysis, and depth resolution of most modern ion beam analysis techniques in a single, easy-to-use format. One can find an interactive version of this table at: *http://www.sandia.gov/1100/1111/Elements/tablefr.htm*.

Key: Technique, Sensitivity, and Depth Resolution

The information is organized in a periodic table to facilitate its use, as most readers may have only little knowledge of IBA but will know what element they want to detect. A key to the information included in this table is found in the lower left for the element W, or tungsten. The first letter indicates the technique. The numbers that follow the technique label are logarithmic scales for sensitivity, analysis range, and depth resolution, respectively. For example (using the key), H (HIBS) can be used to measure W with a sensitivity better than 10^{-8} atomic fraction to a depth range greater than 10^2 nm. Likewise, R (RBS) can measure W with a sensitivity of 10^{-5} atomic fraction to a depth of 10^3 nm with a depth resolution better than 10^2 nm, and P (PIXE) can measure W down to 10^{-6} atomic fraction to a range and depth resolution of 10^4 nm.

This sensitivity and depth information has been calculated based on available ion-atom interaction cross-sections and assumes that (1) 100 counts are measured, (2)

the integrated incident beam current is 10 particle microcoulombs, and (3) the largest practical detector solid angles are used. These calculations ignore backgrounds and other interferences, but IBA scientists routinely use integrated incident beams of greater than 10 μC, and therefore the sensitivities cited are actually rather conservative. In many cases, actual sensitivities are an order of magnitude better. The depth resolutions listed are also very conservative and should be thought of as upper limits.

Mass Resolution

The shaded regions in the table are used to indicate the mass resolution range for He beam RBS. For the first four rows of the table (through Ar), the resolution is adequate to separate all adjacent elements except specific cases of mass interference, which are shaded (e.g., Mn and Fe cannot be separated because their mass differs by only 1 amu). For the remainder of the table, no adjacent elements are separable, and the lightly shaded "generic" mass resolution range is characteristic for an entire row of the periodic table (e.g., the shading of Ru-Rh-Pd indicates that for row 5 of the periodic table the mass resolution is not adequate to separate Ru from Pd but could separate Ru from Ag, and so on for other elements in this row).

High-energy IBA includes elastic scattering, nuclear reactions, and particle-induced X-ray emission (PIXE). We next provide brief descriptions of the techniques that fall under these headings.

ELASTIC SCATTERING (see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS)

Rutherford Backscattering Spectrometry

Rutherford backscattering spectrometry (Chu et al., 1978; Feldman and Mayer, 1986) has matured into one of the most important analytical techniques for the elemental characterization of materials and is used routinely in material science applications in many laboratories around the world. Typically, in conventional RBS, H or He ions, at mega-electron-volt energies, are elastically scattered from a nucleus in a sample and detected in a backward direction in a Si surface barrier detector. For a given detection angle, the kinematics of the elastic scattering is well known, and the energy transferred in the collision can be determined from the Rutherford theory. The scattering kinematics and the energy loss of the ion entering and leaving the sample are well understood. Therefore, the energy of the scattered ion provides information about the mass of the scattering center as well as the depth in the sample. The RBS information may provide the elemental composition and the depth distributions for single- or multi-layered samples at sensitivities as low as a few parts per million. Sensitivities are much better for heavier elements on lighter substrates, although elements with atomic numbers, Z, from 4 to 94 have been detected. Light elements in heavy matrices are much more difficult to analyze. Depth resolutions may vary from 1 to 100 nm. Analysis depth ranges are 0.1 μm to tens of micrometers, and sensitivities vary from 0.1 at. % to ~10 ppm, depending on the atomic number of the trace element.

Heavy-Ion Backscattering

Heavy-ion backscattering spectrometry (HIBS) (Doyle et al., 1989; Weller et al., 1990; Knapp and Banks, 1993) employs heavier incident ions. This increases the elastic scattering cross-section, which is proportional to $(Z_1Z_2/E)^2$, and increases the sensitivity for detection as well as the mass resolution. Here, Z_1 and E are the atomic number and energy, respectively, of the incident ion and Z_2 is the atomic number of the target atom. Because of the heavier mass of the incident ion, the depth analysis range is reduced to 0.01 to 0.1 μm while the sensitivity is increased to 0.1 to 1 ppm.

Elastic Recoil Detection Analysis

Elastic recoil detection analysis (ERDA) (L'Ecuyer et al., 1976; Doyle and Peercy, 1979; Green and Doyle, 1986; Barbour and Doyle, 1995; Dollinger et al., 1995) uses a high-energy, heavy incident ion to recoil light target elements from a sample in the forward direction. Since RBS is not suitable when $M_1 \geq M_2$, where M_1 is the mass of the incident ion and M_2 is the mass of the target element, ERDA is especially useful for light elements such as H through F. Elastic recoil detection analysis depends on the ability to distinguish between incident ions scattered in the forward direction and light recoiling atoms. Since the heavier incident ions have a larger energy loss than the lighter recoil target atoms, a thin foil is sometimes used to block the incident ions from the Si surface barrier detector. This technique may be used with a time-of-flight detector to achieve much higher depth resolution (1 nm) and even permit the separation of different isotopes of light elements. Sensitivities of 10 to 1000 ppm have been obtained. The glancing angle limits the depth analysis range to ~1 μm.

NUCLEAR REACTION ANALYSIS (see NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION)

Nuclear reaction analysis (Bird, 1989; Moore et al., 1975) and resonant nuclear reaction analysis (RNRA) (Vizkelethy, 1995) are very element specific analysis techniques in which nucleus a bombards target A resulting in a light product b and residual nucleus B, $A(a,b)B$. Nonresonant nuclear reactions (NRA) may occur when the energy of the incident nucleus is above a threshold value for the reaction. Nuclear reaction analysis allows bulk measurements of target nuclei distributed throughout a sample. The sensitivity of NRA depends upon the cross-section for the nuclear reaction. Resonant NRA may be used to depth profile the concentration of target nuclei below the surface in a sample. For both NRA and RNRA, the concentration of nuclei is then used to determine elemental concentration from isotopic compositions of the sample. Depending upon the resonant nuclear reaction employed, the technique may be used to profile from the surface to a few micrometers in depth with a resolution of a few to hundreds of nanometers. For example, commonly used

resonant nuclear reactions for H detection are $^{1}H(^{15}N,\alpha\gamma)^{12}C$ (resonance at 6.385 MeV) and $^{1}H(^{19}F,\alpha\gamma)^{16}O$ (resonance at 6.418 MeV). Depending upon the cross-section for the nuclear reaction, sensitivities may vary from 1 to 1000 ppm.

PARTICLE-INDUCED X-RAY EMISSION
(see PARTICLE-INDUCED X-RAY EMISSION)

Particle- (or equivalently proton-) induced X-Ray emission is a multielement, nondestructive analysis technique with sensitivities from major element down to parts-per-million (ppm) trace element, depending upon the elements of interest (Rickards and Ziegler, 1975; Mitchell and Ziegler, 1977; Johansson and Campbell, 1988). With PIXE, a low-atomic-number (Z_1) incident ion beam up to a few mega-electron-volts in energy bombards a sample producing atomic excitations of the elements (Z_2) present in the sample. Here, Z_2 is the atomic number of the target element. Subsequently, characteristic K, L, or M X rays are emitted from the excited elements and are counted to determine the concentrations of the trace elements. Up to 30 elements can be analyzed simultaneously.

Since, the target ionization cross-sections are proportional to Z_1^2/Z_2^4, the number of target element X rays decreases with increasing target atomic number for a given electronic shell. The target ionization cross-section increases with higher incident ion energy E until the velocity of the ion matches the orbital velocity of the electron being ionized and then decreases as $\sim 1/E$. Typically, Si(Li) detectors with Be entrance windows allow detection of elements of atomic number from 12 to 92. Windowless Si(Li) detectors allow elements down to carbon to be analyzed. Sensitivities of 1 to 100 ppm atomic (ppma) have been achieved. Analysis ranges are 1 μm to tens of micrometers.

SUMMARY

The units that follow provide the details required to select the optimum high-energy IBA technique for specific applications. The IBA periodic table in this introduction clearly portrays the interrelationships of these units.

ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS

INTRODUCTION

Composition analyses for virtually all of the elements on the periodic table can be performed through a combination of elastic ion-scattering techniques: Rutherford

backscattering spectrometry (RBS), elastic recoil detection (ERD), and enhanced-cross-section backscattering spectrometry (EBS). This unit will review the basic concepts used in elastic ion scattering for composition analysis and give examples of their use. Elastic ion scattering is also used for structure determination utilizing techniques such as ion channeling (see, e.g., Feldman et al., 1982). Composition determination using ion-beam analysis (IBA) falls into two categories: composition-depth profiling and determination of the total integrated composition of a thin region. Unknown species in a sample may be identified using elastic ion-scattering techniques, but in general, analyses involving characteristic x rays or γ rays are more accurate for determining the presence of unknown constituents. For elastic ion scattering, if the ion beam and ion energy are chosen to have sufficiently high energy loss in the sample, then a composition profile is determined as a function of depth by collecting one ion-scattering spectrum. To represent accurately the composition profile as a function of depth in the sample, an accurate knowledge of the sample's volume density is required because IBA techniques are insensitive to density. If the density of the sample is unknown, then the depth in the sample is given in terms of an areal density: depth times volume density. When the incident ion beam is very light or the ion energy very high, then the composition as a function of depth may not be resolved fully, in which case the average composition of the layer of interest is determined by integrating the signal. In this way, the number of atoms per unit area (areal density) is determined from the integrated signal. Table 1 lists typical examples of composition analyses using different elastic ion-scattering techniques with different ion beams and ion-beam energies.

The term elastic refers to the fact that the target nucleus is unchanged after the scattering event (except for kinetic energy), and therefore inelastic conversion between mass and energy or excitation of the nucleus to a higher energy state is absent. Energy and momentum are conserved, and in the center-of-mass frame of reference, the position of the center of mass remains unchanged. The term Rutherford is used to indicate that the scattering cross-section σ is predominantly a result of Coulomb scattering, and therefore σ can be described by the Rutherford formula (Rutherford, 1911). Elastic ion-scattering techniques are often thought of as nondestructive because they do not require activation of the sample, sputtering of the sample, or any other change of the sample to determine the composition of the sample. However, the ion beam does interact with the sample by breaking bonds, exciting electrons, producing phonons, and possibly creating displacements. Therefore, techniques that are sensitive to these properties (e.g., electrical and optical measurements or x-ray diffraction) should be performed prior to IBA.

Now consider a general composition analysis experiment in which a flux of particles is incident upon a sample. These particles can be electrons, ions, or photons that are scattered elastically or absorbed in the sample through energy loss of the particle. If the particle causes an electronic transition in the target atoms, then the energy of emitted radiation is characteristic of that atom and is used to identify the atom. The number of atoms in a sample is determined from knowledge of the type of interaction between the incident particle and the target atom and the probability that an interaction will occur. Each type of interaction has a different cross-section, which is the effective area for an interaction to occur between one of the incident particles and one of the target atoms. The probability for an interaction is then given by the cross-section times the areal density. This is a general description for many types of composition analysis techniques, including elastic ion scattering, and a single equation describes the quantitative composition analysis of a material: $Y = Q\sigma N\tau\Omega\eta$, where Y is the ion-scattering yield, Q is the number of incident particles, σ is the cross-section for a given process, N is the atomic density, τ is the layer thickness, Ω is the detector solid angle, and η is the detector efficiency. The yield is a measured quantity, and thus all of the details needed to determine N, the composition, reduce to a determination of the other variables in the yield equation. The rest of this unit will describe how these other variables are measured or calculated from measured

Table 1. Elastic Ion-Scattering Techniques for Typical Composition Analysis

	Energy (MeV)	θ or ϕ	Elements Analyzed	Sensitivity (at.%)	Analysis Range (μm)	Depth Resolution (μm)	Comments
He RBS	1–3.5	164	Na to U	0.001–0.1	~1.5	0.03	
H RBS[a]	1–2	164	Na to U	0.01–1.0	~10	0.08	
He ERD	2–3	164	H and D	0.1	~1 (polymers)	0.1	Non-Rutherford cross-sections
Si ERD	12–16	30	H to Li	0.05	~0.4	0.02	Range for H
	18–28		H to N	0.1	~0.4	0.03	Range for N
	28–32		H to N and O	0.2	~0.2	0.05	Range for O
He EBS	3.5	164	C	0.01	~0.5	0.03	Depth profile
	3.5		N	0.01	~0.5	0.03	Depth profile
	8.7		O	0.01	~7	0.05	Depth profile
H EBS[a]	2.5	164	O	0.1	~4	0.2	Depth profile
	4.4		S	0.1	~1		Areal density

[a] *CAUTION:* Risks possible radiation exposure to people from prompt nuclear reactions or activation of the samples. Consult your health physicist before doing high-energy proton irradiation.

quantities. In addition, IBA techniques provide depth profiles because the energy loss of the incident and scattered particles are well characterized through analytical formulas (Ziegler, 1980, 1987; Ziegler et al., 1985; Tesmer et al., 1995), and therefore the energy of these particles is described well along the path of the particles. The yield is then calculated as a function of depth in the sample because the energy at each depth in the sample is well known.

Elastic ion scattering methods using both RBS and ERD are simple and fast for quantitative elemental depth profiling in thin films (≤ 1 μm thick) for every element on the periodic table. Elastic recoil detection is often used for profiling elements with atomic number $Z \leq 8$. Sometimes enhanced-cross-section RBS is used to profile elements in the range $5 \leq Z \leq 8$, but RBS is often used for profiling elements with $Z \geq 8$. Once the system parameters are calibrated, this technique is standardless, and the spectra are turned into concentration profiles within minutes. The many attributes of RBS analysis are also shared by ERD analysis, and therefore collection of ERD spectra can be done on the same accelerator and in the same analysis chamber as RBS. The analysis of the data is fully analytical and generally independent of bonding in the sample. This is a tremendous benefit over other techniques that depend upon extensive comparison to standards and also on sputter rates that may vary from sample to sample. Finally, conventional RBS and ERD give adequate depth resolution (tens of nanometers) and sensitivity (~0.1 at.%) for many types of thin-film analyses performed in materials science. If greater depth resolution or greater sensitivity is required, then more exotic detection schemes can be used [e.g., time-of-flight (TOF) detectors, which produce a depth resolution an order-of-magnitude greater than that for conventional surface barrier detectors].

Before considering the principles of the IBA method, it is useful to place some practical limitations on the conventional use of IBA in comparison to other common materials analysis techniques. Composition analysis with approximately mega-electron-volt ions, in a rather standard IBA configuration, is less surface sensitive than techniques such as Auger electron spectroscopy (see AUGER ELECTRON SPECTROSCOPY) or x-ray photoelectron spectroscopy (XPS). Further, XPS can be used to identify changes in bonding even when the composition is not changing. For determination of the material microstructure, transmission electron microscopy (TEM) should be considered (see TRANSMISSION ELECTRON MICROSCOPY and SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING), and if local compositional analysis of regions ~10 nm in size is needed, then TEM combined with energy-dispersive x-ray spectroscopy (EDS) should be considered (see ENERGY-DISPERSIVE SPECTROMETRY). Ion beam analysis is insensitive to film density, and therefore accurate measurement of film thickness is best made by other techniques, such as ellipsometry, x-ray reflectivity, or simple step-height measurements from profilometry. Finally, for trace element analysis (ppm or less), techniques such as secondary ion mass spectroscopy (SIMS) or nuclear reaction analysis (NRA; see NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION) should be considered. In any case, thin-film composition analysis and monitoring reactions and interdiffusion of thin films are performed very effectively using RBS, ERD, and EBS, especially when complimented by the other techniques listed here.

PRINCIPLES OF THE METHOD

This unit will describe the typical IBA experiment using Si surface barrier detectors (SBDs), although several types of IBA techniques have been developed in which the detector is changed to improve the depth resolution or elemental sensitivity. Once the principles are understood for conventional IBA, these principles are extended easily for the case of specialized detectors, and the reader is referred to the literature for those cases (see, e.g., Thomas et al., 1986; Wielunski et al., 1986; Bird and Williams, 1989; Gebauer et al., 1990; Whitlow, 1990; Tesmer et al., 1995; and the Additional References for Special Detectors and Detection Schemes following the Literature Cited section). Rutherford backscattering was first done by Geiger and Marsden (1913), but this technique waited until the 1960s for wider recognition (outside the nuclear physics community) that heavy element analysis on lighter substrates could be performed using RBS (e.g., see Turkevich, 1961). One of the most useful modern IBA techniques for easy depth profiling of light elements is ERD, which was first introduced in 1976 by L'Ecuyer et al. (1976).

The physical concepts governing RBS and ERD are identical, and through the use of a computer, their spectra are easily manipulated to obtain full quantitative analyses. However, even before manipulation of the spectra to obtain a quantitative analysis, it is useful to learn to interpret the spectra in order to understand the data as it is being collected. Therefore, we will begin with a description of the concepts common to RBS and ERD, and then demonstrate how to read the spectra.

Both RBS and ERD depend on only four physical concepts: (1) the kinematic factor describes the energy transfer in an elastic two-body collision; (2) the differential scattering cross-section gives the probability for the scattering event to occur; (3) the stopping powers give the average energy loss of the projectile and scattered atoms as they traverse the sample, thereby establishing a depth scale; and (4) the energy straggling gives the statistical fluctuation in the energy loss. By applying these four physical concepts, the spectra are transformed into a quantitative concentration profile as a function of depth. The main difference in the treatment of ERD data and RBS data is in the calculation of stopping powers: the incident projectile and recoil atoms are different for ERD data, but these incident and detected ion species are the same for RBS data. As a result of the similarity of these two techniques, the analytical expressions describing the backscattering process and the elastic recoil process will be derived in parallel.

A comparison of RBS and ERD is shown in Figure 1 with ~1-MeV/amu projectiles: 1-MeV protons are used to profile Si in RBS analysis and 28-MeV Si ions are used to profile H in ERD analysis. At the top of the figure the experimental setup is shown schematically. This setup is

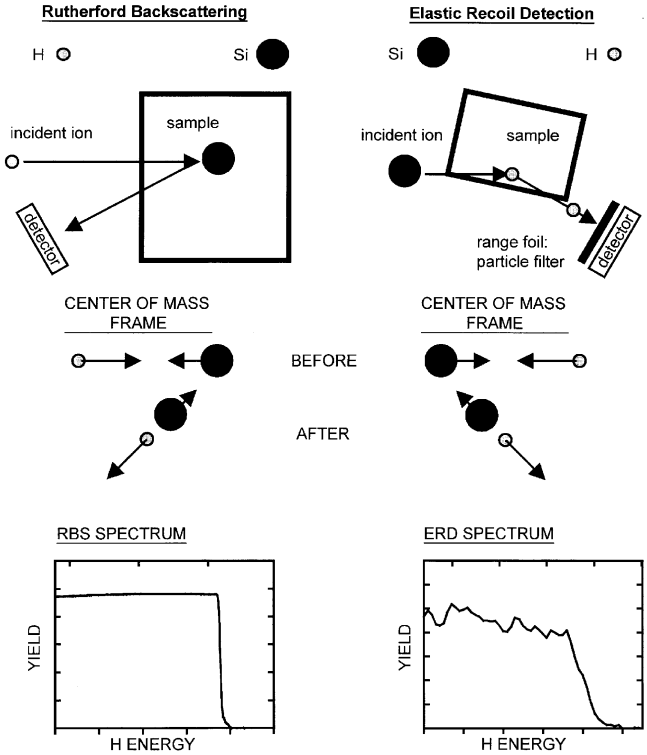

Figure 1. Schematic comparison of RBS and ERD scattering geometries in the laboratory (top) and center-of-mass (middle) frames of reference. The larger filled circle represents the Si atom and the smaller gray circle represents the H atom. In the center-of-mass frame, the scattering events for RBS and ERD are equivalent. The representative spectra for the collection of scattered H atoms for both RBS and ERD are shown at bottom.

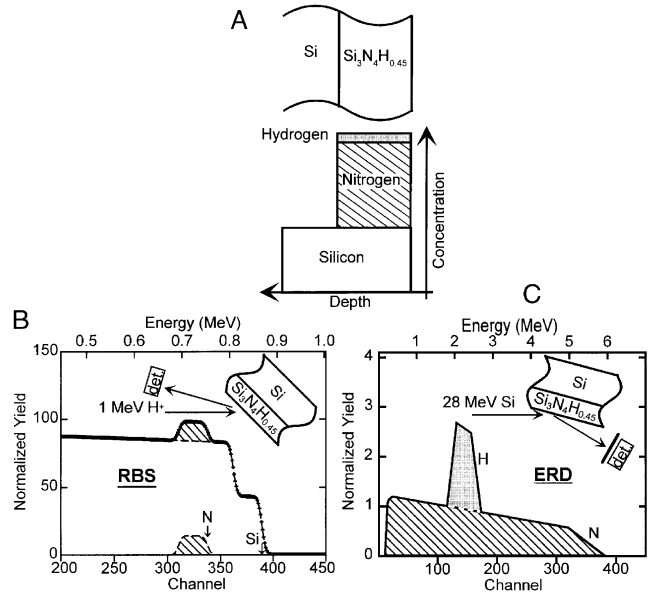

Figure 2. Collection of RBS (**B**) and ERD (**C**) spectra from a 300-nm-thick $Si_3N_4H_{0.45}$ film on Si, shown schematically (**A**), with the concentration profile shown in the middle (depth increasing to the left). The incident projectiles are 1-MeV protons for RBS and 28-MeV Si ions for ERD.

essentially the same for RBS and ERD but with the addition of a range foil for the ERD detector. In fact, RBS and ERD can be set up in the same vacuum chamber by positioning one detector in the backscattering direction and another detector with range foil in the forward-scattering position and by giving the sample holder the rotation capability to allow for grazing incidence of the projectile and exit of the recoiled atoms. The incident projectiles lose energy as they enter the sample and kinematically scatter hydrogen atoms (recoil H atoms for ERD and backscatter H atoms for RBS), and then the H atoms lose energy as they traverse the sample out to a particle detector. In both analyses, the atom entering the detector is H, but the incident ion projectiles differ. The energy loss in the range foil must be calculated when analyzing the ERD data. The differential Rutherford scattering cross-section ($d\sigma/d\Omega$) for the recoil scattering event is ~1.7 b/sr while the differential Rutherford scattering cross-section for the backscattering event is ~0.26 b/sr. The middle portion of Figure 1 schematically shows the scattering events in the center-of-mass reference frame in which RBS and ERD appear as symmetrical scattering events. The yield of H as a function of detected H energy is shown in the bottom portion of the figure for the RBS Si spectrum and the ERD H spectrum.

Both spectra in Figure 1 give the yield of detected H particles as a function of the H energy, but the important point to note is that for RBS the detected particle is the same species as the incident ion, whereas for ERD the detected particle is coming from the sample. In fact, for samples containing several light elements, many of these elements can be detected simultaneously in a single ERD spectrum. In this latter case, the detected particle energy is that for several different recoiled particles causing several overlapping ERD spectra for each detected particle. Schematically, an example is shown in Figure 2 of overlapping spectra for both RBS and ERD data representative of a 300-nm-thick Si_3N_4 layer containing 6 at.% H on a Si substrate. The elemental concentration profiles are given (Fig. 2A), one on top of the other, as stacked bars in which the height of each bar is the concentration in atomic percent and the width of the bar corresponds to depth in the sample. Simulated RBS and ERD spectra from this sample are shown in Figure 2B and C in which the signals from the different elements overlap. The signals are shaded in order to show the contributions coming from the different elements in the sample. Also, the contribution to the RBS spectrum (data points shown as plus symbols) from N alone is shown as a dashed line between channels 300 and 350. Therefore, just as for the bar graph in Figure 2A, the individual contributions to the spectra from the different elements are stacked one on top of the other. These spectra would appear on a multichannel analyzer (MCA) as the yield versus channel, and then the top energy axis is determined from an energy calibration of the channel axis. Note that a signal for H does not appear in the RBS spectrum because the incident protons are not backscattered by the H in the sample, and a signal for Si does not appear in the ERD spectrum because the Si in the sample is not scattered effectively and the incident Si is stopped in a range foil.

The height of each peak in the spectra corresponds to a concentration for that element as function of depth, which is correlated to the energy axis. The high-energy edge (front edge) of a given peak is a result of scattering from the surface of the sample and the depth scale increases to the left (decreasing energy). First, note that the front-edge position is representative of the mass of the target atom in the scattering event. For RBS, the greater the target mass, the greater is the backscattered proton energy, and therefore the increasing energy axis in this spectrum also represents increasing target mass. Similarly, the energy axis in the ERD spectrum is correlated to surface scattering for different target masses, but this correlation is made more complicated by the use of the range foil, as is discussed below, and the surface scattering for a heavy element is not always detected at a higher energy than for a lighter mass element. The surface scattering positions for each detected element are marked in the spectra of Figure 2 with the symbol for that element. The energy axis is often calibrated relative to the measured channels by using the front edge of peaks (surface scattering) for several elements present at the surface of the sample and by calculating the energy for surface scattering. Although the N has the highest concentration in this film, the height of the Si signal in the RBS spectrum and the height of the H signal in the ERD spectrum are both greater than the height of the N as a result of the difference in cross-sections and effective stopping powers relative to those for N. The height of the Si signal in the RBS spectrum below channel 350 is a result of proton scattering from Si in the substrate (100 at.% Si), and the relative decrease in the Si signal between channels 350 and 400 is a result of proton scattering from Si in the silicon nitride film with a decreased Si concentration (40 at.% Si).

The energy scale of the spectra is directly related to depth scale for each element through knowledge of the stopping power for the incident ion and the different scattered (detected) atoms. The width of the N signal in the RBS spectrum corresponds to the width of the 300-nm-thick silicon nitride film, and similarly the width of the Si signal from the $Si_3N_4H_{0.45}$ film corresponds to a depth of 300 nm. In fact, the width of these two signals are equal because the scattered particle in both cases is a proton, and therefore only one type of stopping power is involved in determining the depth scale. In contrast, the width of the N and H signals in the ERD spectrum both correspond to 300 nm of $Si_3N_4H_{0.45}$, but because the scattered particle is a H atom in one case and a N atom in the other case, two different stopping powers are involved in determining the energy-to-depth-scale conversions. Thus, each element profiled in an ERD spectrum has its own depth scale, which complicates the comparison of yields from different species as a function of depth during data collection. To accurately determine the composition-depth profiles from the RBS and ERD data, the spectra need to be separated for each element and the yield converted to atomic density N, as described under Equations for IBA (see Data Analysis and Initial Interpretation).

In contrast to RBS, where light masses produce a signal at low energies with a low yield and heavy masses produce a signal at high energies with high yield, the energy of the

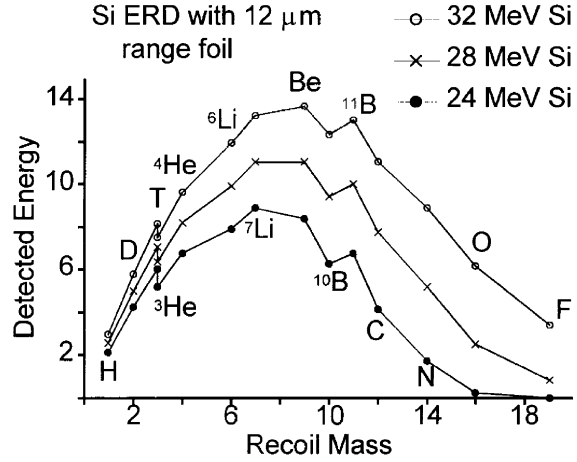

Figure 3. Detected energy calculated for recoiled atoms as a function of recoil mass for 24-, 28-, and 32-MeV Si ERD using a 12-μm Mylar range foil. For these calculations, the Si ions were incident upon the samples at an angle of 75° and the detector was at a scattering angle of 30°.

detected particle, E_d, and the yield of the ERD signals for the different masses depend strongly on the stopping power and thickness of the range foil. A heavier mass may or may not be detected at a higher energy than a light mass depending on the choice of projectile, projectile energy, type of range foil, and thickness of the range foil. Figure 3 shows E_d for recoiled atoms as a function of mass of the recoiled atom for 24-, 28-, and 32-MeV Si ion beams incident at 75° with a scattering angle of 30° and using a 12-μm Mylar range foil. If no range foil were used for these calculations, then the detected recoil energy would steadily increase with recoil mass. These curves show that the detected energy depends strongly on the increased stopping power in the range foil for the heavier recoiled atoms (amu $\geq$ 9). Mass resolution is the ability to separate in the spectra along the detected-energy axis the scattering signal from different target atoms. For surface scattering, E_d in RBS analyses depends solely on the change in kinematic scattering as a function of the target mass, whereas in ERD analyses E_d depends on the energy imparted to a recoiled atom and its stopping in the range foil. The kinematic factor K is the ratio of the scattered particle energy to the projectile energy for an elastic collision. Consequently, the selectivity for different masses in RBS analyses is determined by K, while the mass resolution in ERD analyses is determined by K and the effect of stopping in the range foil, as shown by the curves in Figure 3. For RBS the mass resolution is improved for a given ion beam by increasing the ion energy, and this is often true for ERD, but not always. For example, Figure 3 shows the ability to resolve B from He in a Si ERD spectrum is greatly improved by increasing the Si ion energy from 24 to 32 MeV, causing the difference $|E_d(B) - E_d(He)|$ to increase from 0.25 to 3.1 MeV; however, the same increase in Si ion energy causes $|E_d(He) - E_d(N)|$ to decrease from 5.1 to 0.73 MeV.

Depth resolution is the ability to separate, in the spectrum along the energy axis, the signal coming from

scattering events at different depths in the sample. Therefore, the smallest resolvable detected energy δE_d determines the smallest resolvable depth interval δx. Experimentally, the energy width δE_d is taken from the energies corresponding to 12% and 88% of full signal height for an abrupt change in sample composition (e.g., at the sample surface). An example of the difference in energy width is demonstrated in Figure 2, in which the width of the front edge (measured between the 12% and 88% yields) for the H signal is less than for the N signal in the ERD spectrum, and even though the energy-to-depth conversions for the H and N signals differ significantly, the depth resolution for the H signal is better than that for the N. The depth resolution for both RBS and ERD is improved by using lower energy projectiles or using heavier projectiles. For example, most thin-film RBS analyses are performed using ^{4}He ion beams rather than protons because of the increased depth resolution and increased cross-section. Also, ^{4}He ion beams, like beams of ^{1}H, are relatively easy to produce from simple ion sources.

The description given above for ERD analysis requires the use of a range foil in front of an SBD. However, one rare example of ERD analysis using a Si SBD without using a range foil is when a very heavy projectile is used with moderate-to-light-mass substrates. For this case, if the geometry and beam are chosen such that the recoil scattering angle ϕ is $> \sin^{-1}(M_{\text{substrate}}/M_{\text{incident ion}})$, where M is the mass of the particle, then the incident ion is not scattered into the detector and no range foil is required. This condition is particularly useful for high-depth-resolution ERD analysis with a Au ion.

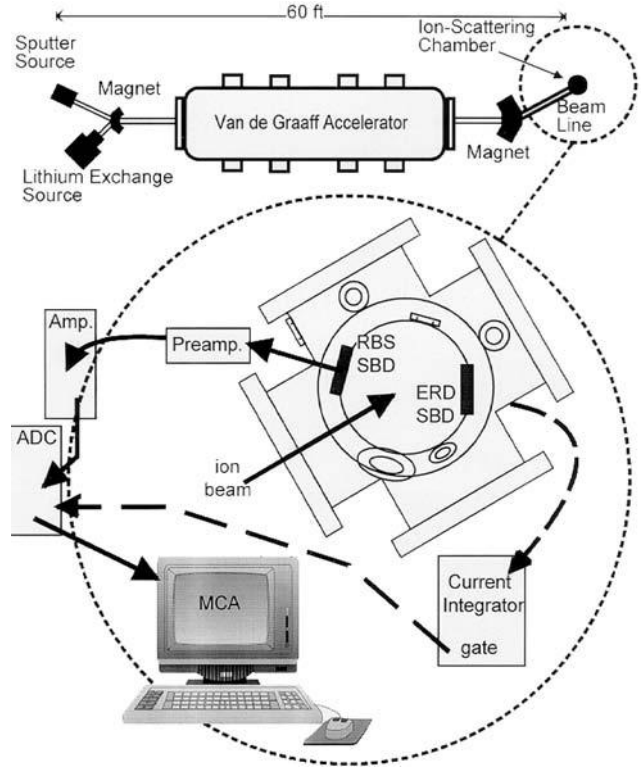

Figure 4. Typical experimental setup for RBS and ERD. Ion-beam analysis facilities are generally <100 ft in length, but this depends on the size of the accelerator being used. The expanded view, at bottom, schematically shows the ion beam scattering chamber and the electronics used to measure the target current and signal detected in an SBD (ADC = analog-to-digital converter).

PRACTICAL ASPECTS OF THE METHOD

Typical Experimental Setup

Now we describe the apparatus used in a conventional RBS or ERD experiment. Rather than give an exhaustive treatment, this discussion is intended to allow a first-time practitioner to become familiar with the purpose of different parts of the apparatus before entering the laboratory. A more detailed treatment is found in Tesmer et al. (1995), Bird and Williams (1989), Chu et al. (1978), and Mayer and Rimini (1977).

First, the ion beam is generated from a plasma or sputtered target (Fig. 4). These ions are extracted at low energy from the ion source and accelerated to millions of electron volts. A magnetic field is used to bend the ions into a specific direction along the analysis beam line (evacuated tube), and by separating the ions according to their mass-to-charge ratio for a given energy, the proper ion beam is selected for the IBA technique of interest. The ion beam is then steered onto a sample that is in an ion-scattering vacuum chamber. A variety of IBA experiments may be performed in an ion-scattering chamber, depending on sample manipulation capabilities and detector geometry. In addition, the chamber may be configured to perform *in situ* materials science experiments such as thermal treatments and gas exposures. The first variable to be determined in the yield equation is the detector solid angle Ω, which is measured with the use of a standard sample if all other parameters are known. However, most ion-scattering chambers are designed with fixed dimensions; therefore the solid angle can be calculated from simple geometry:

$$\Omega = \int_{\text{angle subtended by detector}} \sin\phi \, d\phi \, d\varepsilon \approx \frac{\text{detector area}}{z^2} \quad (1)$$

where ε is the stopping cross-section and z is the sample-to-detector distance.

The next variable to be calculated for the yield equation is Q, the number of incident projectiles, which is determined from the target current and the projectile charge. The target current may be measured either in front of the ion-scattering chamber on a rotating wheel containing slots to allow the ion beam to enter the chamber or directly from the sample of interest. In either case, care is taken to accurately measure all of the incident charge by suppressing the escape of secondary electrons from the target. One solution is to electrically isolate the scattering chamber from ground and then measure the total current on the chamber relative to ground. This technique effectively treats the entire chamber as a Faraday cup for accurate charge collection (see Chapter 12 in Tesmer et al., 1995). To ensure that low-energy secondary electrons are not

lost from the chamber in the direction of the incident beam, a suppression bias of −500 to −1000 V is applied to a wire mesh or metal aperture, which is isolated from the chamber and ground, just in front of the ion beam entrance to the chamber. The ion beam is collimated with movable slits or steered to avoid scattering from the aperture along its path to the sample. A more complete discussion of Faraday cup designs is found in Tesmer et al. (1995). The target current is then sent into a current integrator to measure the total charge incident upon the sample during the data collection, as shown in Figure 4. Generally, the amount of charge is preset on the integrator (typically to a value between 1 and 50 μC for most experiments) such that when the preset value is reached, a signal is sent to gate off the data collection. The length of time or amount of charge collected for an experiment depends on the counting statistics desired. The value needed for Q is the number of particles (not the charge), and therefore the measured charge in microcoulombs is divided by 1.6022×10^{-13} μC per ionic charge and by the ion's charge state to obtain Q (e.g., charge state 2 for He^{2+}, or 5 for Si^{5+}).

The signal measured in RBS or ERD comes from scattered atoms collected in an SBD (Fig. 4). For RBS, the backscattered beam is the same as the incident beam, while for ERD the forward-scattered beam may be composed of many atom species with mass less than that of the incident beam. Also, the incident beam may be forward scattered into the detector for ERD, and therefore a stopping foil (the range foil) is used to stop heavy species such as the incident beam from entering the detector. The number of incident projectiles that scatter into the direction of the detector is generally much greater than the number of recoiled atoms; therefore the foil is needed to prevent damage to the detector and to minimize the background signal from the primary beam.

The SBD is a reverse-biased surface barrier diode (Mayer and Lau, 1990) that contains a depletion region large enough to stop the highest energy particle to be detected. The depletion region for n-type Si is established through the application of a positive bias typically <130 V. As the detected particle traverses the depletion region, the particle loses energy, and that energy lost to electron excitation gives rise to electron-hole pair production. The electrons and holes are swept to opposite terminals of the diode and provide a pulse of current. The detected particle loses its energy quickly enough so that all of the electrons and holes created by this particle are collected in a single pulse of current. Therefore, the greater the energy of the detected particle, the more electron-hole pairs are produced, and the larger the current pulse is generated at the diode terminals. This current pulse is then sent to a charge-sensitive preamplifier to produce a signal proportional to the total charge. This signal is then sent to a spectroscopy amplifier, which outputs an approximately Gaussian signal proportional in amplitude to the size of the input pulse. The unipolar output signal from the amplifier is then sent to an analog-to-digital converter (ADC) to create a digital signal corresponding to the maximum amplitude of each pulse. A useful exercise at the beginning of each experiment is to examine on an oscilloscope the signal coming from the bipolar output of the amplifier. This signal should be examined as the bias voltage is applied to the detector in order to examine the noise reduction obtained for the optimum detector bias voltage. As the data are collected, different amplitude Gaussian peaks are seen on the oscilloscope corresponding to different energies of the detected particles. The gain of the amplifier is adjusted such that all of the most energetic particles will appear at a voltage less than the maximum input voltage for the ADC (typically 8- to 10-V maximum signal).

The digital signal coming from the ADC is recorded as a data point in a channel on an MCA in which the channel number is proportional to the amplitude of the digital signal. This creates a histogram (spectrum) of data in which the channel number represents the height of detected pulses and the yield for a given channel equals the number pulses detected for that pulse height. Each new pulse-height signal that is collected is then added to and stored in the spectrum as one additional count for that channel. This type of data acquisition is known as pulse-height analysis (PHA). Thus, the yield recorded on the MCA as a function of channel number corresponds to the yield of scattered particles with a detected energy E_d in which each channel number corresponds to a value of E_d. As mentioned above, the gate signal from the current integrator (used to measure the incident beam current) is used to turn off the ADC in order to stop the data collection. The remainder of this unit will review how the RBS and ERD spectra are converted from yield to composition and provide concrete examples.

Other Detectors and Detection Geometries

So far this unit has concentrated on conventional ERD analysis geometries, but another possible geometry for ERD is the transmission mode. For transmission ERD, the sample must be thinner than the range of the recoiled atom to be profiled. The projectile beam usually impinges on the sample at or near normal incidence, and the detector is placed at a recoil scattering angle of 0°. Additional range foils are used to stop the high-intensity projectile beam or the sample itself may be sufficient to stop the projectile. The main advantage of transmission ERD is increased sensitivity, by as much as 2 orders of magnitude, in comparison to conventional reflection geometry ERD. This increase in sensitivity stems from several factors: (1) since the analysis range scales with $\cos \Theta_1$, more material is probed with transmission ERD; (2) larger solid angles are used without significant kinematic broadening in transmission ERD since $dK/d\phi = 0$ at $\phi = 0°$ and finally, (3) the background caused by surface H is reduced considerably in the transmission mode due to smaller multiple scattering cross-sections. Wielunski et al. (1986) demonstrated a one- atom ppm sensitivity for detecting H in Ni using 4- to 6-MeV He projectiles in the transmission mode.

The scattering dynamics of ERD and RBS are quite similar, especially when viewed in the center-of-mass frame of reference. Some of these similarities are good, such as the ease of acquiring both types of spectra; but other shared aspects are actually bad, such as the built-in

mass-depth ambiguity that complicates the interpretation of both ERD and RBS energy spectra. This ambiguity results because the energy of the backscattered or recoiled ions depends both on the mass of the target atom and on the depth in the sample where the scattering occurred. Further, in the case of ERD, a mass ambiguity for scattering from the surface of a sample due to the energy loss suffered in the range foil also exists. Avoiding this ambiguity is nearly impossible in RBS because the detected ion is always the same as the incoming ion. However, in ERD, the recoil ion energy and mass are measured independently either by employing an $E - \Delta E$ particle telescope (Gebauer et al., 1990) or by combining a measurement of the ion's flight time (i.e., velocity) to that of total energy (Thomas et al., 1986; Whitlow, 1990). This latter technique is referred to as time of flight. An additional benefit of TOF techniques is that the depth resolution is improved considerably, and the use of a TOF detector is beneficial to increase depth resolution for both RBS and ERD analyses. This improvement in depth resolution results because the timing resolution involved with TOF is generally much better than the energy resolution involved with SBDs. Time-of-flight detection involves the simultaneous measurement of both the velocity and total energy of the detected atoms. The detected atom velocity is determined by measuring the time t required to pass along a preset flight path of length L, and then the detected energy is given by $E_d = ML^2/2t^2$.

DATA ANALYSIS AND INITIAL INTERPRETATION

Equations for IBA

The analytical expressions that relate the observed RBS and ERD energy spectra (the yield equation) to target atom type and concentration with depth are quite similar and will be developed here in brief. A more exhaustive treatment in the development of these equations is found in Chapters 4 and 5 of Tesmer et al. (1995), Chapter 3 of Chu et al. (1978), Brice (1973), Foti et al. (1977), and Doyle and Brice (1988). The geometries for RBS and ERD kinematic scattering in the laboratory reference frame are given in Figure 5, in which the incident beam and the directions of detection are coplanar. In this figure, for simplicity, the RBS and ERD geometries are combined, and the atom configurations before a scattering event are shown with cross-hatched circles and the atom configurations after a scattering event are shown schematically with an open circle for RBS and solid circles for ERD. However, the backscattering angle θ for RBS and forward-scattering angle ϕ for ERD are not necessarily coplanar, and the following development is made independent of that representation in the figure. The scattering angles are both measured relative to the incident beam direction. An ion beam with energy E_0, mass M_1, and atomic number Z_1 is incident onto a target atom with mass M_2 and atomic number Z_2. For RBS, the projectile is typically protons or He ions and $M_1 < M_2$, while the projectile for ERD varies widely from He ions to Au ions and $M_1 > M_2$. Through conservation of energy and momentum, the energy of the scattered atom, E_2, is related to E_0 by the kinematic factor K such that

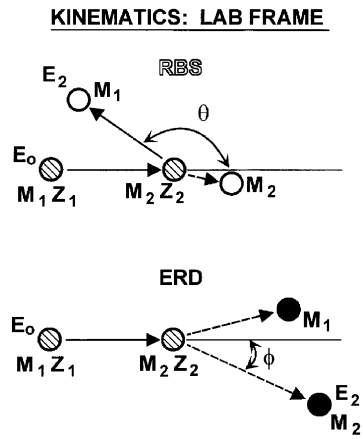

Figure 5. Schematic representation of two different elastic collision events occurring between a projectile of mass M_1, atomic number Z_1, and energy E_0 and a target of mass M_2 (atomic number Z_2) that is at rest before the collision. For RBS (open circle), the incident ion is backscattered with an energy E_2 at an angle θ measured relative to the incident beam direction. For ERD (filled circles), the target mass is recoiled forward at an angle ϕ with an energy E_2.

$$E_2 = KE_0 \tag{2}$$

and

$$K = \left(\frac{\sqrt{M_2^2 - M_1^2 \sin^2 \theta} + M_1 \cos \theta}{M_1 + M_2} \right)^2 \tag{3}$$

for RBS or

$$K = \frac{4M_1 M_2 \cos^2 \phi}{(M_1 + M_2)^2} \tag{4}$$

for ERD.

Equations 2 to 4 relate the energy before and after the scattering event, independent of depth in the sample.

The following development is based on a slab analysis in which the variables needed for the yield equation are evaluated at energies corresponding to uniform increments of depth in the sample. Figure 6 gives the geometry for the ion-scattering processes occurring at a depth x in the sample measured along the sample normal. This figure describes either the forward-scattering process using a range foil with thickness $X^{(0)}$ or the backscattering process without a range foil [$X^{(0)} = 0$]. The projectile ion beam is incident upon the sample at an angle Θ_1 measured from the surface normal to the beam direction, and the detected beam is collected in an SBD at angle Θ_2 measured from the surface normal. In an experiment, the scattering angles are fixed by the apparatus while Θ_1 and Θ_2 vary depending on the sample tilt. In Figure 6, Θ_1 and Θ_2 are coplanar and related to the scattering angle by $\theta = \pi - (\Theta_1 + \Theta_2)$ for

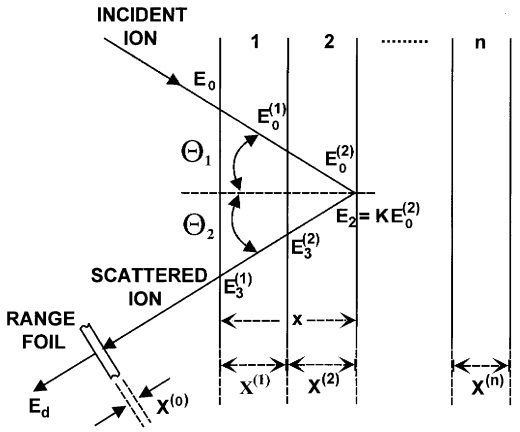

Figure 6. Schematic configuration for an elastic ion-scattering experiment used to describe either RBS or ERD analysis in which the sample is divided into n layers of thickness $X^{(n)}$) for calculations. The superscripts in parentheses refer to layer number and the subscripts on E refer to the type of atom: 0 = incident ion, 2, 3 = scattered ion. The parameters are incident ion energy E_0, incident and exit angles Θ_1 and Θ_2 (measured relative to the sample normal), the energy (E_2) of the scattered atom at depth x, the energy of the scattered atom (E_3) as it traverses the sample, and the energy detected in an SBD (E_d).

RBS or $\phi = \pi - (\Theta_1 + \Theta_2)$ for ERD [note that $\Theta_1 + \Theta_2 > \pi/2$ for ERD]; however, the formalism developed below does not require that Θ_1 be coplanar with Θ_2, and in a general experimental apparatus they may not be coplanar. The incident projectile enters the sample with energy E_0 and loses energy (dE/dx) along its path in the sample, and at a depth x the projectile has an energy $E_0^{(2)}$ just prior to a scattering event. Thus, the initial energy of the detected atom after the scattering event is $E_2 = KE_0^{(2)}$, and after traversing the sample this atom exits with energy $E_3^{(1)}$. For ERD, the recoiled atom is then incident normal to a range foil, which is assumed to be parallel to the detector surface, and this atom then loses more energy in the range foil. For either RBS or ERD, the atom is then detected with energy E_d in an SBD ($E_d = E_3^{(1)}$ for RBS).

The yield Y of detected atoms in energy channel E_d with a channel width E_d (in kilo-electron-volts perchannel) is given by

$$Y(E_d) = \frac{QN(x)\sigma(E_0^{(n)})\Omega\ \delta E_d}{\cos\ \Theta_1 dE_d/dx} \tag{5}$$

where Q is the number of incident projectiles, $N(x)$ is the atomic density of the target atom at depth x, $\sigma(E_0^{(n)})$ is the average scattering cross-section in laboratory coordinates at an energy $E_0^{(n)}$, Ω is the detector solid angle, and dx is the increment of depth at x corresponding to an increment of energy dE_d. The quantities Q, Ω, and Θ_1 are fixed by the experimental setup. A defining aperture is usually placed in front of the detector in ERD to maximize the depth resolution, which is degraded by the trajectory of the particles entering the detector at different scattering angles. Rigorously, Ω is the integral of the differential surface area element in spherical coordinates, but it is often calibrated by the yield from a standard sample (generally a H profile in ERD or a Si substrate profile in RBS). Care should be taken to avoid ion beam channeling in a crystalline sample when using the spectrum's surface edge height to calibrate a detector solid angle. Typical solid angles are $\sim$5 msr for ERD analyses and 1 msr $\leq \Omega \leq$ 10 msr for RBS analyses. To transform the yield to a concentration profile, analytical expressions for $\sigma(E_0^{(n)})$ and dE_d/dx must be determined.

First, the cross-sections for many instances are governed by Coulomb scattering, as modeled by Rutherford (1911), and expressed in the laboratory reference frame as (Marion and Young, 1968)

$$\frac{d\sigma_R(E_0^{(n)},\theta)}{d\Omega} = \left(\frac{Z_1 Z_2 e^2}{4E_0^{(n)}}\right)^2 \left(\frac{4}{\sin^4\ \theta}\right) \times \frac{\sqrt{1 - [(M_1/M_2)\sin\theta]^2} + \cos\theta)^2}{\sqrt{1 - [(M_1/M_2)\sin\theta]^2}} \tag{6}$$

for RBS and

$$\frac{d\sigma_R(E_0^{(n)},\phi)}{d\Omega} = \left(\frac{Z_1 Z_2 e^2}{4E_0^{(n)}}\right)^2 \left(\frac{4}{\cos^3\phi}\right) \frac{(M_1 + M_2)^2}{(M_2)^2} \tag{7}$$

for ERD, where $(e^2/E)^2 = 0.020731$ b for $E = 1$ MeV ($1\ b = 1 \times 10^{-24}$ cm^2). In practice, the differential cross-section is averaged over a finite volume Ω and given simply as σ_R. For those cases in which the cross-section is non-Rutherford (see Problems), the simplest solution for the thin-film approximation is to multiply the σ_R in Equations 6 and 7 by a scaling factor f in order to model the true cross-section, i.e., $\sigma = f\sigma_R$. It is important to note the functional dependencies of σ_R in Equations 6 and 7.

1. Both cross-sections are inversely proportional to the square of the projectile energy, and therefore $Y(E_d)$ increases as $(1/E_0^{(n)})^2$. Thus, the projectile energy should be decreased in order to increase the yield or sensitivity for a given element.
2. Since atomic mass is proportional to atomic number, the RBS σ_R is proportional to $(Z_1)^2$, and the ERD σ_R is $\sim (Z_1)^2$ for $M_1 \approx M_2$ and $\sim (Z_1)^4$ for $M_1 \gg M_2$. Therefore the yield for a given element is increased by using heavier projectiles.
3. The RBS σ_R is proportional to $(Z_2)^2$, and the ERD σ_R is $\sim (Z_2)^2$ for $M_1 \approx M_2$; therefore the scattering probability is greater for heavy targets than for light targets. The yield in RBS is greater for heavy targets than for light targets, but the yield in ERD also depends upon the stopping powers for the recoiled atom. For $M_1 \gg M_2$, the ERD σ_R is less dependent upon Z_2.
4. Both cross-sections are axially symmetric with respect to the incident beam direction and independent of Θ_1 and Θ_2. Thus the sample can be tilted and rotated to change the ion beam path lengths without changing the angular dependence in σ_R. For RBS,

the $(1/\sin\theta)^4$ dependence increases the yield as the backscattering angle is increased while the $\cos\Theta_1$ term in the yield equation tends to cancel the $1/\cos^3\phi$ increase in the ERD cross-section.

As described above (see Introduction), the areal density (AD) is the integrated concentration N over the layer thickness τ. From the yield Equation 5,

$$\mathrm{AD} = \int_0^\tau N(x)\,dx = \frac{\cos\Theta_1}{Q\Omega}\int_0^\tau \frac{S^{\mathrm{eff}}}{\sigma\,\delta E_\mathrm{d}} Y(E_\mathrm{d})dx = \frac{\cos\Theta_1}{Q\Omega}\int_{E_\mathrm{d}(0)}^{E_\mathrm{d}(x)} \frac{Y(E_\mathrm{d})}{\sigma}\frac{dE_\mathrm{d}}{\delta E_\mathrm{d}} \tag{8}$$

where S^{eff} is the effective stopping power $(= dE_\mathrm{d}|dx|_x)$. Equation 8 shows that the effective stopping power term is eliminated by integration when determining the areal density. In practice, the final integral of Equation 8 is evaluated as a summation; and for a surface peak, the cross-section σ_0 is evaluated at the specific energy E_0:

$$\mathrm{AD} = \frac{\cos\Theta_1}{Q\Omega\sigma_0}\sum_{\mathrm{channel}[E_\mathrm{d}(0)]}^{\mathrm{channel}[E_\mathrm{d}(x)]} Y(\mathrm{channel}) \tag{9}$$

Expressions for $\sigma(E_0^{(n)})$ and dE_d/dx are needed to convert the yield to a concentration profile, and these expressions are derived in terms of the energies $E_0^{(n)}$ and stopping powers (dE/dx) evaluated at $E_0^{(n)}$ corresponding to uniform increments of depth in the sample. A simple method to calculate the apparent energy loss in the detected beam as a function of depth is to divide the sample into a series of slabs of equal thickness, and then create a table of the corresponding energies and stopping powers for each layer or slab of the material, e.g., as shown schematically in Figure 6. The energy and depth relationships are expressed by the equations given below using the following convention for superscripts and subscripts. The subscripts refer to the atom type, except for the notation given above for the angles Θ_1 and Θ_2, and the superscripts refer to the layer of the target (1, 2, ...) or to the range foil (superscript 0). For example, the projectile energy and stopping powers are $E_0^{(n)}$ and $S_\mathrm{p}^{(n)}$, respectively; the energy for the detected atom is either $E_2^{(n)}$, or $E_3^{(n)}$ and the stopping power is $S_\mathrm{r}^{(n)}$ for recoiled atoms and $S_\mathrm{b}^{(n)}$ for backscattered atoms. The electronic energy lost by a particle as it traverses a slab containing more than one type of atom is approximated using the principle of additivity of stopping cross-sections first given by Bragg and Kleeman (1905). The stopping cross-section $\varepsilon \equiv (1/N)(dE/dx)$ is the proportionality factor between the amount of energy lost in a thin slab and the areal density of that slab. The energy loss in a material composed of several atom species is the sum of the losses for each species weighted according to the composition. This is known as Bragg's rule, and for a material with formula unit $\mathrm{A}_\alpha\mathrm{B}_\beta$,

$$\varepsilon^{\mathrm{A}_\alpha\mathrm{B}_\beta} = \alpha\varepsilon^\mathrm{A} + \beta\varepsilon^\mathrm{B} \quad \text{and} \quad S = N^{\mathrm{A}_\alpha\mathrm{B}_\beta}\varepsilon^{\mathrm{A}_\alpha\mathrm{B}_\beta} \tag{10}$$

The length of path traveled by the projectile crossing the nth slab with thickness $X^{(n)}$ is $X^{(n)}/\cos\Theta_1$, and the energy lost by the projectile is $E_0^{(n)} - E_0^{(n-1)}$. For $X^{(n)}$ sufficiently small, $S_\mathrm{p}^{(n)}$ changes little across the slab and is approximated by the value at energy $E_0^{(n-1)}$ such that:

$$E_0^{(n)} = E_0^{(n-1)} - \frac{X^{(n)}}{\cos\Theta_1}S_\mathrm{p}^{(n)}(E_0^{(n-1)} \tag{11}$$

Similarly, the energy $E_0^{(n)}$ for the detected particle as a function of depth in the sample is written in terms of a recursion relation for the energy from the previous slab boundary, or in terms of the kinematic relationship Equation 2 just after a scattering event. For an RBS scattering event occurring in slab n,

$$E_3^{(n)} = KE_0^{(n)} - \frac{X^{(n)}}{\cos\Theta_2}S_\mathrm{b}^{(n)}(KE_0^{(n)}) \tag{12}$$

and for an RBS event occurring in slab $j > n$,

$$E_3^{(n)} = E_3^{(n+1)} - \frac{X^{(n)}}{\cos\Theta_2}S_\mathrm{b}^{(n)}(E_3^{(n+1)}) \tag{13}$$

Equations 12 and 13 for ERD have a similar form and are given below (see Appendix B). In practice, the depth in the sample is related to the detected energy measured in a spectrum, and therefore the following equations relate the detected energy for the nth slab, $E_\mathrm{d}^{(n)}$, to the thickness $X^{(n)}$:

$$E_\mathrm{d}^{(n)} = K\left[E_0 - \frac{X^{(n)}}{\cos\Theta_1}\sum_{j=1}^{n} S_\mathrm{p}^{(j)}(E_0^{(j-1)})\right] - \frac{X^{(n)}}{\cos\Theta_2}\left[S_\mathrm{b}^{(n)}(KE_0^{(n)} + \sum_{j=n}^{2} S_\mathrm{b}^{(j-1)}(E_3^{(j)})\right] \tag{14}$$

for RBS and

$$E_\mathrm{d}^{(n)} = K\left[E_0 - \frac{X^{(n)}}{\cos\Theta_1}\sum_{j=1}^{n} S_\mathrm{p}^{(j)}(E_0^{(j-1)})\right] - \frac{X^{(n)}}{\cos\Theta_2}\left[S_\mathrm{r}^{(n)}(KE_0^{(n)} + \sum_{j=n}^{2} S_\mathrm{r}^{(j-1)}(E_3^{(j)})\right] - \Delta E_\mathrm{foil} \tag{15}$$

for ERD. Equations 14 and 15 are very similar with the change of notation to indicate the species of the detected atom [backscattered (b) vs. recoil (r)] and with the inclusion of stopping by the recoiled atom in the range foil for ERD calculations. The energy lost by the recoil atom in traversing the foil (ΔE_foil) should be calculated from a slab analysis of the foil containing NF slabs of thickness $\Delta x^{(0)}$ (i.e., $\mathrm{NF} = X^{(0)}/\Delta x^{(0)}$) as

$$\Delta E_\mathrm{foil} = \Delta x^{(0)}\sum_{j=1}^{\mathrm{NF}} S_\mathrm{r}^{(0)}(E_\mathrm{f}^{(j-1)}) \tag{16}$$

where the recoil atom stopping power is evaluated at the energy $E_\mathrm{f}^{(j-1)}$ before traversing the jth slab (e.g., $E_\mathrm{f}^{(0)} =$

$E_3^{(1)}$). Finally, the effective stopping power for the deleted particle at a given projectile energy, dE_d/dx, is given as

$$\left.\frac{dE_d}{dx}\right|_n = [S]_{p,b}^{(n)} \frac{S_b(E_d)}{S_b(KE_0^{(n)})} \tag{17}$$

for RBS and

$$\left.\frac{dE_d}{dx}\right|_n = [S]_{p,r}^{(n)} \prod_n \tag{18}$$

for ERD, where the energy loss factors $[S]$ corresponding to a backscattering or recoil event at energy $E_0^{(n)}$ are

$$[S]_{p,b}^{(n)} = \frac{KS_p^{(n)}(E_0^{(n)})}{\cos\Theta_1} + \frac{S_b^{(n)}(KE_0^{(n)})}{\cos\Theta_2} \tag{19}$$

for RBS and

$$[S]_{p,r}^{(n)} = \frac{KS_p^{(n)}(E_0^{(n)})}{\cos\Theta_1} + \frac{S_r^{(n)}(KE_0^{(n)})}{\cos\Theta_2} \tag{20}$$

for ERD. The product term $\prod_n$ in Equation 18 for ERD analysis is given by

$$\prod_n = \frac{S_r^{(n)}(E_3^{(n)})}{S_r^{(n)}(E_2)} \frac{S_r^{(n-1)}(E_3^{(n-q)})}{S_r^{(n-1)}(E_3^{(n)})} \cdots \frac{S_r^{(0)}(E_d)}{S_r^{(0)}(E_3^{(1)})} \tag{21}$$

which is similar to the product term $S_b(E_d)/S_b(KE_0^{(n)})$ for RBS analysis. Definitions for variables and the equations used for IBA are summarized below (see Appendices A and B).

Several methods can be followed to determine composition profiles from RBS and ERD spectra using the equations given above. In general, an iterative process is used in which the stopping powers, energies, and cross-sections for each slab layer are calculated from an estimated composition. A spectrum is simulated and compared to the data or the data are directly converted into a concentration-depth profile. Based on these results, the composition or slab thicknesses are changed and the energies, S, and σ are recalculated for another simulation or conversion of the data to a profile until a convergence between the estimated composition and results are obtained. This type of approach is used in RBS analysis programs such as RUMP (Doolittle, 1986, 1994). The method of directly converting the data to a concentration profile by scaling the data with cross-sections and dE_d/dx as a function of depth is known as spectral scaling. In this approach, a table is made containing the sample depth, $E_0^{(n)}$, $\sigma(E_0^{(n)})$, E_d, and dE_d/dx as a function of slab layer. The data are then scaled one channel at a time to produce a concentration-depth profile by interpolating between values in the table, and the energy scale is transformed to depth while the yield scale converts to concentration. The yield equation 5 is thereby converted to appear as though the cross-section and effective stopping power are constant through the sample. Analytically, the scaling is written as

$$\begin{aligned} N^{(n)}(x) &= \frac{\cos\Theta_1}{Q\Omega\,\delta E_d} \frac{dE_d/dx|_n}{\sigma_R(E_0^{(n)})} Y^{(n)}(E_d) \\ &= \frac{\cos\Theta_1}{Q\Omega\,\delta E_d} \frac{S_0^{eff}}{\sigma_0} \left[\frac{\sigma_R(E_0)}{\sigma_R(E_0^{(n)})} \frac{dE_d/dx|_n}{dE_d/dx|_0} Y^{(n)}(E_d) \right] \end{aligned} \tag{22}$$

where S_0^{eff} and σ_0 are evaluated at the incident energy E_0. The cross-section scaling factor for Rutherford cross-sections is $\sigma_R(E_0)/\sigma_R(E_0^{(n)} = [(E_0^{(n)})/E_0]^2$, and the stopping power scaling factor, $(dE_d/dx\,|_n)/(dE_d/dx\,|_0)$, is determined by interpolating from tables. Examples of spectral scaling and slab analysis of RBS and ERD spectra will be given below.

PROBLEMS

Non-Rutherford Cross-Sections

Deviations from the Rutherfordscattering cross-sections given in Equations 6 and 7 may result from Coulomb barrier penetration, which occurs most often for low-Z projectiles at high energies, or from excess screening effects, which occur most often for high-Z projectiles at low energies. At high energies, resonances occur in the backscattering cross-sections, and those resonances for which σ is enhanced relative to σ_R are useful for enhanced sensitivity of light elements with ion backscattering (EBS). These resonances occur because the incident particle has sufficient energy to penetrate the Coulomb potential barrier and probe the nuclear potential, which produces an attractive, strong, short-range force. The Coulomb potential produces a relatively weak, long-ranged repulsive force. At high energies, the projectile may penetrate into the nucleus of the target atom such that the two nuclei combine for a finite time as a single excited-state "compound nucleus." The width of a given resonance depends on the lifetime of the excited state in the compound nucleus, and for large resonance widths or energies with overlapping resonances, σ is relatively constant with energy in order to permit EBS depth profiling. Bozoian et al. (1990), Bozoian (1991a,b), and Hubbard et al. (1991) modeled the case of Coulomb barrier penetration and determined the energies E_{NR}, where the cross-sections may become non-Rutherford by 4%. In the lab reference frame their formulation of this energy is given as (Bozoian et al., 1990)

$$E_{NR}(\text{Me V}) \approx (0.12 \pm 0.01)Z_2 - (0.5 \pm 0.1) \tag{23}$$

for proton backscattering with $160^\circ < \theta(\text{lab}) < 180^\circ$,

$$E_{NR}(\text{Me V}) \approx (0.25 \pm 0.01)Z_2 + (0.4 \pm 0.2) \tag{24}$$

for ^{4}He backscattering with $160^\circ < \theta(\text{lab}) < 180^\circ$, and

$$E_{NR}(\text{Me V}) \approx \frac{-1.1934(Z_1Z_2)(M_1+M_2)}{M_1^{4/3}M_2 \ln(0.001846Z_1M_2/Z_2)} \tag{25}$$

for ERD with $\phi = 30°$. Furthermore, Andersen et al. (1980) modeled the case where screening effects cause significant deviations from the Rutherford formula, and in the laboratory reference frame for 1% screening effects (i.e., $\sigma/\sigma_R = 0.99$), the non-Rutherford energy boundary is given by

$$E_{NR}(\text{MeV/amu}) = 99 V_{LJ} \frac{M_1 + M_2}{M_1 M_2} \tag{26}$$

where

$$V_{LJ} = 48.73 Z_1 Z_2 (Z_1^{2/3} + Z_2^{2/3})^{1/2} \tag{27}$$

is the Lenz-Jensen potential in electron volts.

The use of a He ion beam for ERD analysis is nearly always in an energy range where penetration of the Coulomb barrier occurs, and the use of a Au ion beam for ERD is nearly always in an energy range where significant screening effects occur (for current IBA accelerator technology). A quick method to determine the shape of α particle and proton backscattering cross-sections at high energies is to examine the nuclear data sheet of the compound nucleus for the given nuclear reaction (see Internet Resources). As an example, the nuclear reaction $^{16}O(\alpha,\alpha)^{16}O$ for high-energy α particles backscattering from the ^{16}O nucleus creates a compound nucleus of ^{20}Ne. Figure 7 shows a portion of the data sheet (Tilley et al., 1998) for ^{20}Ne at the top and a magnified section of the $^{16}O(\alpha,\alpha)^{16}O$ cross-section at the bottom. This figure shows that sharp resonances occur at laboratory energies (in mega-electron-volts) of 2.52, 3.04, 3.08, 3.37, 3.89, 4.9, ..., and a broader resonance occurs from ~8.35 to 8.85 MeV, which is particularly useful for oxygen depth profiling. Even though the shape of the cross-section is shown here, the actual value of an enhanced cross-section should be determined from a well-characterized standard for the energy and scattering angle used in a given experiment.

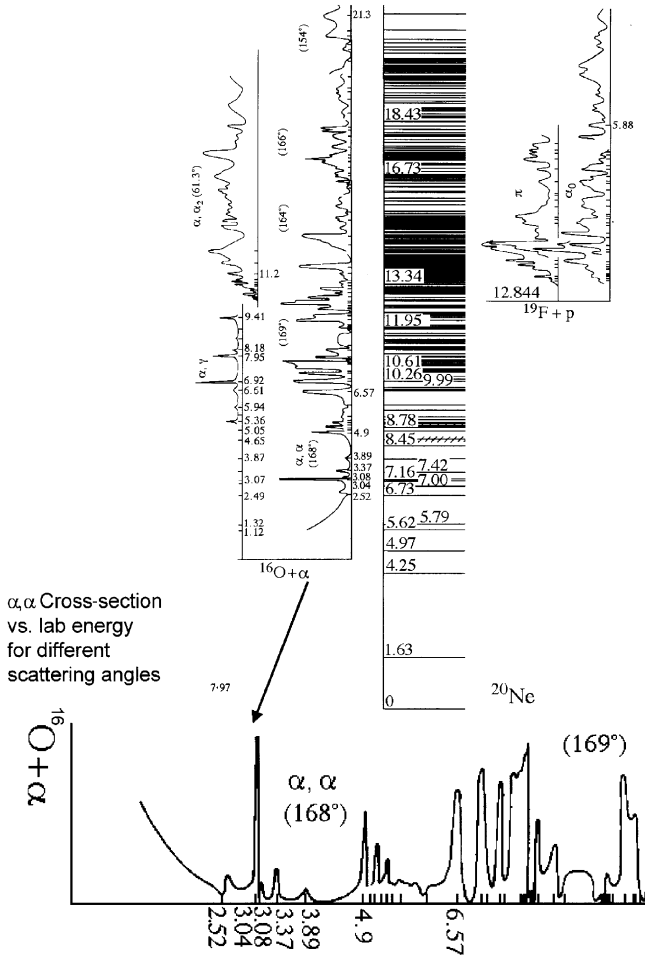

Figure 7. A portion of the nuclear data sheet for ^{20}Ne is shown at top, and a magnified view of the $^{16}O(\alpha,\alpha)^{16}O$ cross-section from this data sheet is shown at bottom.

Radiation Hazards

When the incident beam energy exceeds the Coulomb barrier of the target, nuclear reactions other than elastic scattering are possible. High-energy proton scattering can produce unwanted γ or neutron radiation exposures to workers, even along sections of the beam line away from the sample chamber. This concern is particularly significant for irradiation of light elements, but it is also important for elements such as Cu. Neutrons and γ rays are the main prompt radiation hazard while activation of the sample produces a longer lasting radiation hazard (of particular importance for high-energy proton beams). Activated samples can be easily controlled to avoid accidental radiation exposure of workers as well as satisfy regulatory agencies, but a knowledge of possible activating nuclear reactions is necessary for this purpose. Novices should seek help from a qualified radiation-health physicist to assess the hazards when using a high-energy proton beam.

Enhanced-Cross-Section Backscattering Spectrometry

Rutherford backscattering spectrometry was shown above to be highly useful for thin-film composition analysis. However, one of the disadvantages of RBS is its relative insensitivity to light elements, particularly lighter elements on heavy element substrates. Enhanced-cross-section backscattering with He ions offers sensitivity for light elements such as B, C, N, and O, and EBS with protons offers increased sensitivity for these light elements as well as even heavier elements such as S. The disadvantages of EBS as opposed to RBS is that the depth resolution for the higher energy EBS technique is generally less than that for RBS and the cross-section does not obey the Rutherford equations 6 and 7. Therefore σ_{EBS} must be calibrated from a standard. The decreased sensitivity to light elements in RBS results directly from the fact that σ_R is proportional to $(Z_1 Z_2/E)^2$. Furthermore, RBS analysis is complicated by the fact that both H and He projectiles show deviations from σ_R for light elements at relatively low energy, and in the low-energy regime where low-Z element cross-sections are still Rutherford, the depth of analysis is

rather small (<0.5 μm) and the background from heavier substrates is high.

The analytical formulas for EBS analysis are identical to those for RBS analysis with a change in the value of the cross-section. The elastic scattering cross-sections for high-energy α particles and protons were some of the first cross-sections measured with the emergence of modern particle accelerators and nuclear physics in the mid-20th century. The elements with the most useful α high-energy cross-sections are ^{11}B, ^{12}C, ^{14}N, and ^{16}O, while elements out to ^{32}S have been analyzed using high-energy proton cross-sections but with much less depth resolution. One difficulty found for EBS analysis is when the matrix contains moderate- to low-Z elements such as Si or Al, which have sharp resonances in their cross-sections, producing wild fluctuations in the backscattering signal from the matrix. These fluctuations make a determination of the light atom concentration nearly impossible, as is the case for oxygen profiling from SiO_2 or Al_2O_3 using 8.7-MeV ^4He ion EBS analysis.

EXAMPLES

Several examples are now given to demonstrate mass resolution, energy resolution, and depth of analysis for backscattering and ERD as a function of ion energy and ion species. Also, examples of how to convert spectra to composition-depth profiles for both RBS and ERD analyses are demonstrated. Figure 8 shows an RBS spectrum (+) for 2.2-MeV He^+ ions incident upon a film of $La_xSr_yCo_zO_3$ grown on a $LaAlO_3$ substrate. The spectrum is plotted from channel 15 to channel 615 similar to how it would appear when collected as data on an MCA. An MCA gives yield in counts, but for convenience the yield in Figure 8 is normalized by the number of incident particles ($Q = 20$ pμC), the solid angle ($\Omega = 6.95$ msr), and the channel energy width (3.314 keV). [Note that 20 pμC (particle micro- coulombs) is equal to $(20 \times 10^{-6}/1.602 \times 10^{-19})$ particles.] The sample was tilted 10° in order to decrease channeling in the substrate, and the detector was mounted at a scattering angle $\theta = 164°$. The top (energy) axis was determined using the surface scattering energies for O, Co, and La. These energies are given in Table 2 along with the detected energies for scattering from O, Al, and La at the film-substrate interface. Also, the surface scattering positions are marked with arrows in the figure. The Al surface energy is shown in parentheses in the table because Al is only present in the substrate, and therefore the Al edge energy is decreased from 1.224 to 1.040 MeV. The O substrate edge energy is marked in parentheses because the signal from oxygen in the substrate is small and difficult to differentiate from the background. Therefore, the O substrate energy given in Table 2 is based on the relative position of the O surface energy and the energy width of the layer as determined from the La signal.

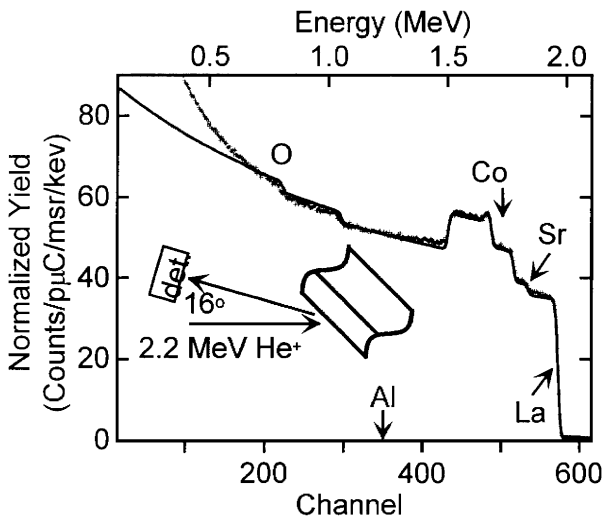

Figure 8. Backscattering spectrum (+) and simulation (solid line) obtained from 2.2-MeV He^+ ions scattered off $La_xSr_yCo_zO_3$/$LaAlO_3$ at 164° relative to the incident beam direction, with $Q = 20$ pμC, $\Omega = 6.95$ msr, $\Theta_1 = 10\circ$, and channel energy width 3.314 keV/channel.

Table 2. Energy Scale for RBS Spectrum in Figure 8

Element	Surface Scattering Energy (MeV)	Substrate Scattering Energy (MeV)
O	0.8069	(0.620)
Al	(1.224)	1.040
Co	1.685	
Sr	1.839	
La	1.965	1.780

Figure 8 shows a spectrum from a relatively simple sample, a thin film with a uniform composition (≈190 nm thick). Yet, the spectrum contains many overlapping peaks, which makes composition-depth profiling of a single element difficult because of the variation in the background signal due to the other elements in the film and the substrate. In these circumstances, a simulation of the spectrum often suffices to determine the composition of the film. A simulation of Rutherford backscattering from a $La_{0.85}Sr_{0.15}Co_{0.95}O_3$ film with an areal density of 1.6×10^{18} atoms/cm^2 is shown in this figure as a solid line using the analysis program RUMP (Doolittle, 1994). The oxygen content was determined from the reduced height of the individual metallic constituents in the film and later confirmed with greater accuracy using 8.7-MeV He^{2+} EBS. The height of the simulated substrate signal confirmed the values previously measured for Q and Ω. Deviations from the measured values occur for large dead times on the ADC or if the incident ion channels into the substrate; however, the agreement between the values given above and those determined from the simulation is better than 3%. At energies below ~0.6 MeV, the data and the simulation begin to deviate substantially as a result of multiple scattering in the substrate, which was not taken into account in the simulation. The layer thickness is given as areal density in the simulation because the exact density of the film is unknown, but if a density of 0.85×10^{23} atoms/cm^3 is assumed, then the film thickness is 188 nm. For more simple spectra in which

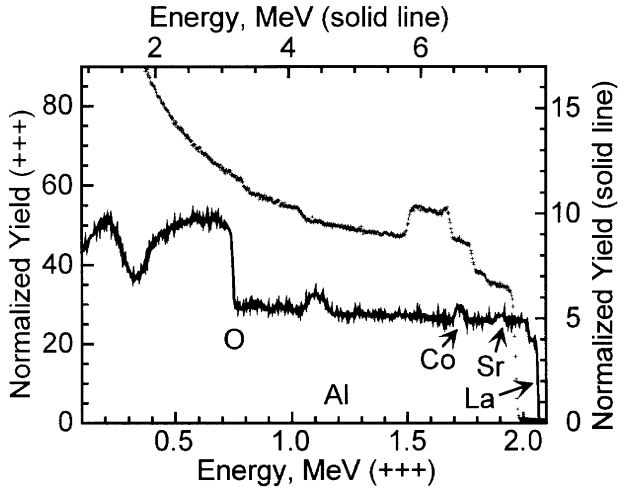

Figure 9. Spectra for backscattering off the same sample as in Figure 8. The 2.2-MeV He^+ spectra is reproduced here (+) in addition to a spectrum (solid line) obtained from 8.7-MeV He^{2+} ion scattering at 164°, with $Q = 18$ pμC, $\Omega = 6.95$ msr, $\Theta_1 = 45°$, and channel energy width 7.82 keV/channel. The left and bottom axes are for the low-energy RBS spectrum, and the right and top axes are for the high-energy EBS spectrum.

peaks of the individual elements are easily separated from a background signal, each peak is integrated to determine the areal density for that element and thus provide the relative areal densities for the composition of the layer. Also, if the ion energy were increased for analysis of this sample, then the mass resolution would increase and the individual peaks would separate in the spectrum.

A He ion energy of 8.7 MeV was used to analyze the same sample as given in Figure 8, and the spectrum is shown as a solid line in Figure 9, with the normalized yield plotted on the right axis and the energy plotted along the top axis. The parameters used for this spectrum were $Q = 18$ pμC, $\Omega = 6.95$ msr, channel energy width 7.82 keV/channel, $\Theta_1 = 45°$, and $\theta = 164°$. The sample was tilted 45° to make the apparent thickness increase for increased depth resolution. For comparison, the 2.2-MeV He^+ RBS spectrum (+) is plotted versus energy along the bottom axis and normalized yield on the left axis. To put these spectra on the same figure in a readable manner, two separate sets of axes were used because the energy and yield scales differ considerably between the spectra. In fact, it is this difference in the energy scale that gives rise to the separation of signals from different masses. The surface energies for 8.7-MeV He EBS are given in Table 3 along with the detected energies for scattering from O, Al, and La at the film-substrate interface, and the surface scattering positions for the EBS spectrum are marked with arrows in Figure 9. A comparison of the surface energies in Tables 2 and 3 show that the mass resolution, which is given by the difference in energy between surface edges, is greater for 8.7-MeV He scattering than for 2.2-MeV He scattering by a factor of 4. At the same time, the depth resolution is decreased by using a higher energy ion beam. Depth resolution δx is given by the resolution measured along the detected energy axis divided by the effective stopping power for the detected atom: $\delta x = E_d/(dE_d/dx)$. The front edges for the peaks shows that $E_d \sim 2$ times smaller for the low-energy spectrum than for the high-energy spectrum, and the effective stopping power is greater for the low-energy spectrum than for the high-energy spectrum. Thus, the depth resolution is considerably better at low energies than at high energies.

Table 3. Energy Scale for EBS Spectrum in Figure 9 (Solid Curve)

Element	Surface Scattering Energy (MeV)	Substrate Scattering Energy (MeV)
O	3.192	3.03
Al	(4.841)	4.68
Co	6.663	
Sr	7.272	
La	7.770	7.61

The high-energy ion beam with the lower stopping cross-section does afford a greater depth of analysis that is useful for thick samples. The depth of analysis can be estimated from stopping and range computer codes such as TRIM (Ziegler, 1987), and as a practical limit the maximum depth is between one-tenth and one-third the projected range. Moreover, the greatest advantage to using higher energy ion beams in an EBS analysis is demonstrated by the increased yield from O relative to La. The yield from the low-energy backscattering is considerably greater than the yield from the high-energy backscattering because of a $1/E^2$ dependence for the Rutherford cross-section. At 8.7 MeV, the He scattering from both Sr and La obeys the Rutherford formula, and therefore the yield is less than at 2.2 MeV, but the O cross-section is $22\sigma_R$ at 8.7 MeV ($\theta = 164°$, $\Omega = 6.95$ msr), and therefore the signal-to-background noise for the O signal is improved at the higher energy. The Co and Al also have non-Rutherford σ at 8.7 MeV, but $\sigma(\text{Co}) < \sigma_R(\text{Co})$ and the σ(Al) varies considerably. The rapid variation in the Al cross-section for 8.7-MeV He EBS adds uncertainty to the background below the O signal. The addition of sharp resonance background peaks below an O signal becomes much worse for Si, Al, or Al_2O_3 substrates.

A sample more complicated than the example just given can still yield a composition-depth profile as shown in the next analysis. Figure 10 is an RBS spectrum (+) collected from a thick film of Al deposited on a Si substrate in such a manner that the oxygen content in the film varies greatly with depth. A 2.8-MeV He^+ ion beam was used for this analysis to avoid sharp resonance peaks from Al or Si and to give a compromise between depth of analysis and depth resolution. Also, σ(O) was calibrated previously at this energy and for this detector geometry such that $\sigma(\text{O})/\sigma_R(\text{O}) = 1.25$. The energy scale for the spectrum in Figure 10 was calibrated from another sample such that the channel energy width is 3.11 keV/channel, $\Theta_1 = 5°$, $Q = 20$ pμC, $\Omega = 6.95$ msr, and $\theta = 164°$. The surface energies for O, Al, and Si are marked in the figure at energies 1.027, 1.558, and 1.595 MeV, respectively. To simulate this spectrum fairly well, the film was divided into six separate layers in which the thickness and composition were allowed to vary, as shown in Table 4 with the layer number

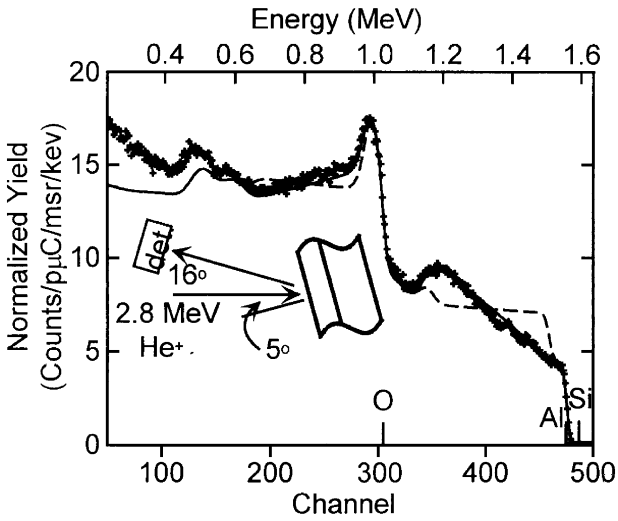

Figure 10. An RBS spectrum (+) and simulations (solid line and dashed line) for 2.8-MeV He^+ backscattering from an AlO_x/Si sample with a greatly varying oxygen content. The scattering angle is 164°, $\Theta_1 = 5°$, $Q = 20$ pμC, and $\Omega = 6.95$ msr.

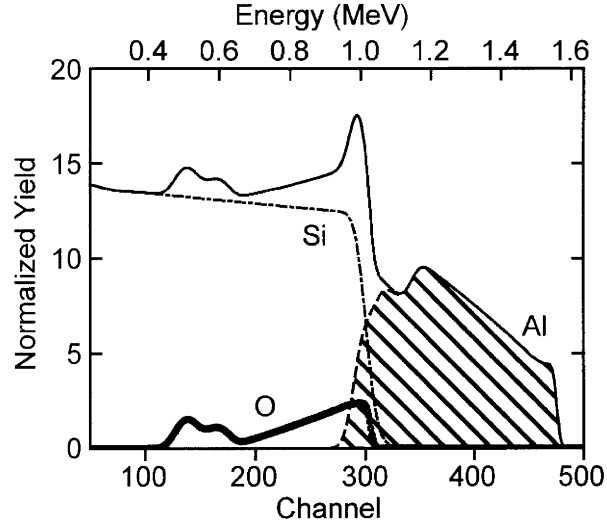

Figure 11. Simulated RBS spectrum (solid line) and the contributions to this simulation from the individual elements: Si (dash-dotted line), O (open circles), and Al (dashed line delineating the cross-hatched region). The simulation is for 2.8-MeV He^+ backscattering as described in Figure 10.

increasing in depth. Again, the thickness is given as a real density because the volume density of each layer is not known for such a complicated sample. The thicker layers were divided into two or more equal-thickness sublayers to increase the accuracy of the energy and stopping power calculations as a function of depth. Layer 2 was simulated as ten equal-thickness sublayers such that the composition across layer 2 graded linearly, as shown This simulation is presented in Figure 10 as a solid line in addition to a simulation (dashed line) assuming that layer 2 has a constant average composition $Al_{0.675}O_{0.325}$. The dashed-line simulation fits the data poorly. For such a complicated sample, the simulated sample structure in Table 4 may not be unique, but it will serve well to calculate the stopping powers and energies as a function of depth, and then the spectrum is scaled to give the composition-depth profile from the data, as demonstrated below. Further, the figure shows that the number of sample subdivisions used in the calculation is quite important, as determined from the comparison of simulations for layer 2.

The linearly graded sample simulation is given again for clarity as a solid line in Figure 11, and the individual contributions to the simulation are presented as a dash-dotted line for Si, open circles for O, and a dashed line with a cross-hatched region for Al. The contributions to the RBS spectrum from all three elements overlap in the spectral region from ~0.9 to 1.1 MeV, and this overlap produces a sharp peak at 1 MeV. The RBS signal from each element is separated from the background in the spectrum by subtracting the individual contributions to the simulation. Figures 12 and 13 show the RBS signals from the O (open circles) and the Al (+) after the simulated Si and Al (or O) signals were subtracted from the data. The solid lines are the contributions to the simulation for that element. The yields in Figures 12 and 13 were then scaled with cross-sections and stopping powers as a function of energy to give the concentration as a function of depth (in atoms per square centimeter). These scaled data are

Table 4. Sample Structure Used for Simulation in Figure 10

Layer	Thickness (10^{15} atoms/cm^2)	Composition
1	800 (with 2 sublayers)	$Al_{0.4}O_{0.6}$
2	4900 (with 10 sublayers)	Linearly graded from $Al_{0.4}O_{0.6}$ to $Al_{0.95}O_{0.05}$
3	200	$Al_{0.95}O_{0.05}$
4	1000 (with 2 sublayers)	$Al_{0.7}O_{0.3}$
5	200	$Al_{0.95}O_{0.05}$
6	1000 (with 2 sublayers)	$Al_{0.6}O_{0.4}$

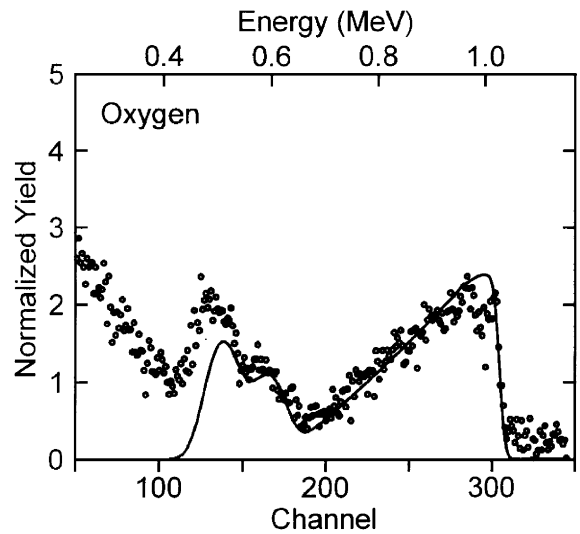

Figure 12. Oxygen signal (open circles) from the RBS spectrum of Figure 10 after the background Si and Al signals were subtracted. The simulated O signal is shown as a solid line.

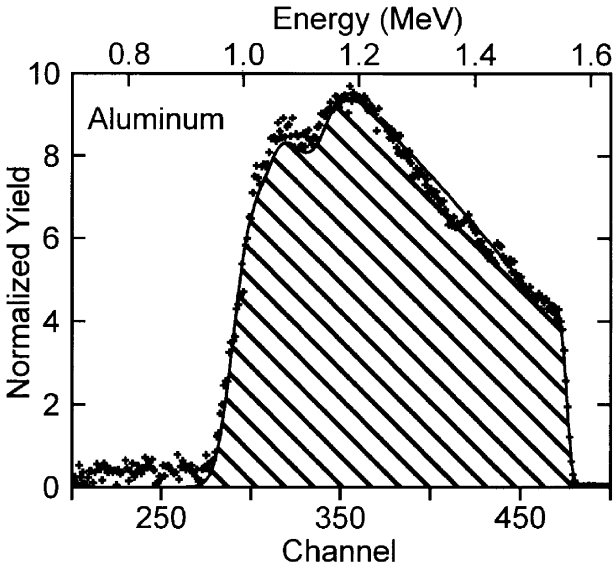

Figure 13. Aluminum signal (+) from the RBS spectrum of Figure 10, after the background Si and O signals were subtracted. The simulated Al signal is shown as a solid line delineating a cross-hatched region.

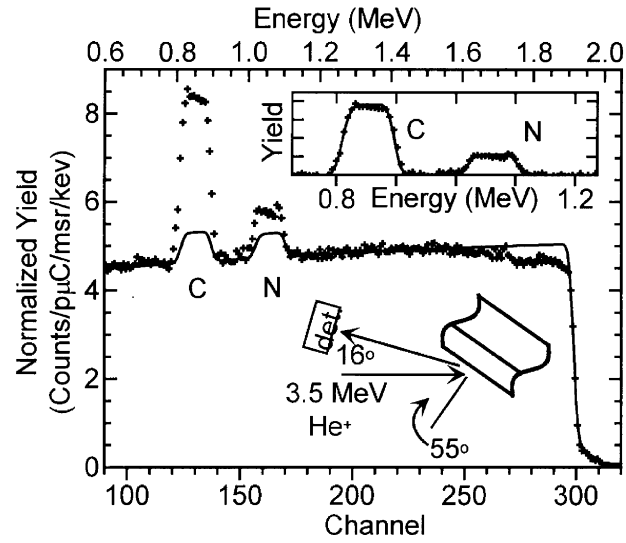

Figure 15. An RBS spectrum (+) and simulation based on Rutherford scattering (solid line) for 3.5-MeV He^+ backscattering from a CN_x/Si sample. The scattering angle is 164°, $\Theta_1 = 55°$, $Q = 20$ pμC, and $\Omega = 6.95$ msr. The inset shows the C and N signals above background overlayed by a simulation (solid line) based on enhanced scattering cross-sections ($5.6\sigma_R$ for C and $2\sigma_R$ for N).

plotted in Figure 14 with the depth (in micrometers) calculated from an assumed average volume density of 0.831×10^{23} atoms/cm^3 (about half way between Al_2O_3 and Al). Note that the depth scale is plotted with depth increasing to the right.

The previous analysis was given as an RBS example because the Al and Si cross-sections obeyed the Rutherford formula and the O cross-section was very nearly Rutherford. Still, it shows that there is no clear boundary between naming a technique as RBS or EBS, and convention allows that RBS is used as the acronym for backscattering analysis independent of the cross-section formulation. Also, σ was non-Rutherford for O at a relatively low He^+ ion energy, showing that a check is always required for the σ calibration involving He scattering from elements with $Z \leq 9$.

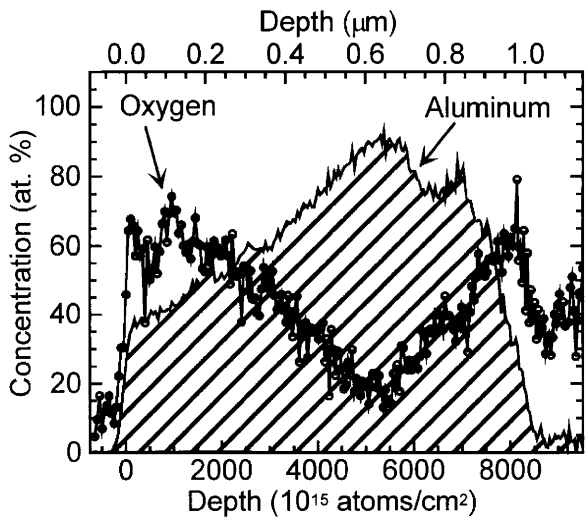

Figure 14. Oxygen (open circles) and aluminum (solid line delineating a cross-hatched region) concentration-vs.-depth profiles determined from the data given in Figures 12 and 13.

Another example of useful enhanced-scattering cross-sections is given by analysis of a CN_x film in which both the C and N cross-sections are non-Rutherford. An example of a high-energy backscattering spectrum (+) taken from a 44-nm-thick $C_{0.65}N_{0.35}$ sample deposited on a Si substrate is shown in Figure 15. The analysis beam was 3.5-MeV He^+ incident at 55° from the sample normal and $\theta = 164°$. This angle of incidence was chosen to increase the depth resolution. The surface energy for C and N are ~0.9 and 1.1 MeV, respectively. (The ERD analysis showed that the sample contains less than 2% H.)

A simulated spectrum for a film with composition $C_{0.65}N_{0.35}$ and using Rutherford cross-sections is shown in Figure 15 as a solid line. The Si cross-section is Rutherford at this energy, and thus a small amount of channeling in the Si substrate is evident in the data from channel 250 to channel 300, but channeling does not affect the height of the C and N signals because this $C_{0.65}N_{0.35}$ film is amorphous. The carbon cross-section was calibrated from a pure C film on Si, and the N cross-section was calibrated from an amorphous Si_3N_4 film on Si. The following enhancements to σ were determined for this energy and scattering geometry: carbon $\sigma = 5.6\sigma_R$, and nitrogen $\sigma = 2\sigma_R$. The C and N signals above background (+) are shown inset at the top, with the simulated signal (solid line) determined using these factors for the enhanced cross-sections. The depth resolution in these signals is 9 to 10 nm.

Great care should be taken when choosing a carbon standard. A sample that contains a considerable amount of H has a significantly different height for the C signal

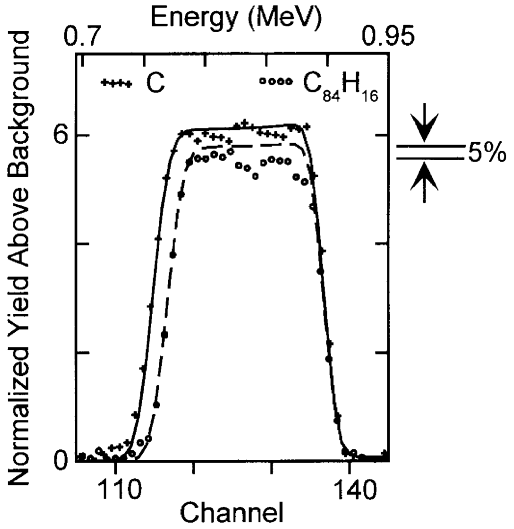

Figure 16. Carbon signal above background for RBS spectra from a pure carbon sample (+) and a $C_{84}H_{16}$ sample (open circles). The spectra were obtained using 3.5-MeV He^+ with $\theta = 164°$; $\Theta_1 = 55°$ and $\Theta = 45°$, respectively; $Q = 20$ pμC; and $\Omega = 6.95$ msr. Each spectrum (solid line and dashed line, respectively) was simulated based on the enhanced scattering cross-section given in Figure 15.

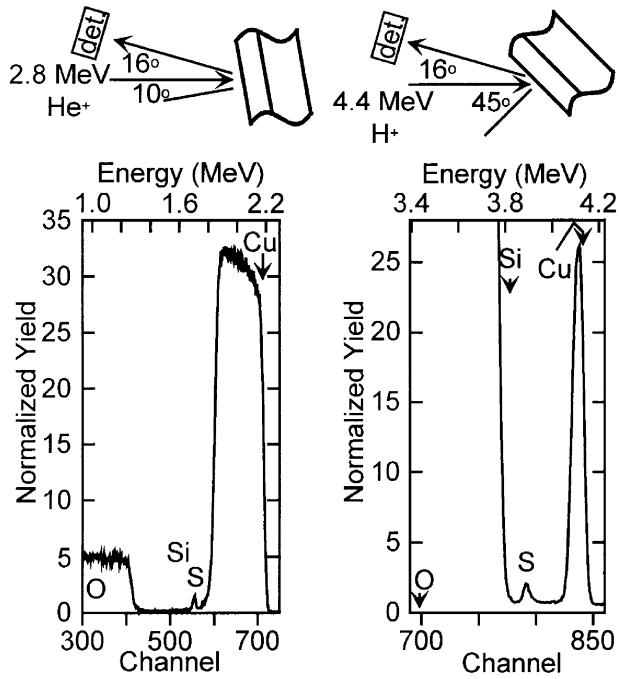

Figure 17. Helium (left) and H (right) backscattering spectra from a sulfidized Cu layer on a Si substrate. The 2.8-MeV He^+ spectrum was collected using $\theta = 164°$, $\Theta_1 = 10°$, $Q = 10$ pμC, and $\Omega = 6.95$ msr. The 4.4-MeV H^+ spectrum was collected using $\theta = 164°$, $\Theta_1 = 45°$, $Q = 10$ pμC, and $\Omega = 6.95$ msr.

than a sample that is pure C. Figure 16 shows the C signal above background for a C standard (+) containing <0.05 at.% H and for a $C_{0.84}H_{0.16}$ sample (open circle). If the $C_{0.84}H_{0.16}$ sample were used for determining σ without considering the H content, then a value of only $5\sigma_R$ would be obtained, but the low-H-content standard has a C signal that is $5.6\sigma_R$, as demonstrated by the solid line. Thus the knowledge of the H content of the standard is important to avoid errors (~10%) when calibrating the cross-section. Also, the stopping powers of C and C-H samples are often corrected for bonding effects that influence the composition analysis and thickness determination. A correction of ~5% must be applied to the simulation (dashed line) in order to obtain the proper height on the C signal from the $C_{0.84}H_{0.16}$ sample. This correction then causes an ~5% difference in the thickness of the film determined using RBS. The bonding effects on the stopping power add an increased uncertainty to the composition analysis of a CN_x film containing H because the nature of the bonding is often unknown and its effects on the stopping power are also unknown, and therefore the inherent limit to the accuracy of the composition analysis is ~5%.

An example of enhanced RBS comparing H^+ and He^+ backscattering is demonstrated by the composition analysis of sulfur on a heavy element substrate. Analysis of sulfur on Si or Al substrates is relatively easy with He^5 RBS because S is heavier than Si and Al, but analysis of a thin layer containing S on bulk Cu is more difficult. The spectra shown in Figure 17 are for 2.8-MeV He^+ and 4.4-MeV H^+ backscattering from a thin CuS_x film on a Cu layer on a Si substrate. The Θ_1 for each analysis are as indicated in the figure. For this case of He backscattering, the small S peak is just separated from the low-energy side of the Cu signal because the Cu layer was only 325 nm thick. However, a thicker Cu layer would cause the S signal to be lost on top of a large Cu background signal. Aldridge et al. (1968) examined the high-energy backscattering cross-sections for α particles incident on ^{32}S up to an energy of 17.5 MeV. The absence of enhanced cross-sections for $(alpha, \alpha)$ scattering necessitates the use of proton scattering for thick Cu substrates. Proton scattering cross-sections for the $^{32}S(p,p)^{32}S$ reaction at moderate energies are larger than σ_R (Abbandanno et al., 1973), and similar to the example given above for the $^{16}O(\alpha,\alpha)^{16}O$ reaction, a flat-top cross-section exists for the $^{32}S(p,p)^{32}S$ reaction in the energy range ≈ 4.3 to ≈ 4.5 MeV. A CdS standard was used to calibrate the sulfur cross-section for 4.4-MeV incident protons scattering at an angle of 164° such that $\sigma = 6.55\sigma_R$.

Analysis of the proton scattering S and Cu peaks in Figure 17 give the following composition in areal densities: 0.45×10^{17} S/cm^2 and 2.79×10^{18} Cu/cm^2. Although the sample was tilted to 45° relative to the incident beam in order to increase depth resolution, the sulfidized layer remained unresolved; therefore only areal densities are determined rather than a composition-depth profile. In fact, the loss of depth resolution is one of the difficulties encountered when using proton RBS rather than α RBS, as shown in this figure. Nevertheless, the enhanced S cross-section gives an enhanced yield relative to the Cu signal and good counting statistics for the areal density, yielding an uncertainty of ±10%.

Finally, focus is placed on one sample analyzed with different ion beam species and energies in order to demonstrate

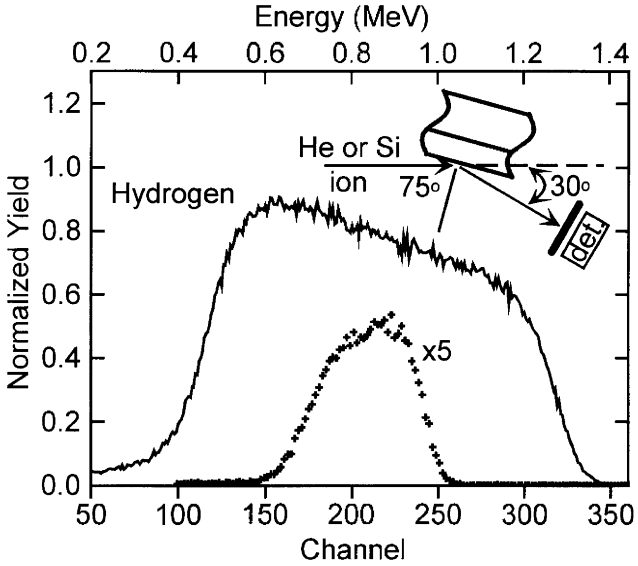

Figure 18. The ERD spectra collected from a ≈300-nm-thick Si_3N_4 layer on Si. The only detected recoil atom for these spectra is H. The 16-MeV Si ERD spectrum is shown as a solid line, and the 2.8-MeV He ERD spectrum is magnified 5 times and shown as plus symbols. For both spectra, $\phi = 30°$, $\Theta_1 = 75°$, $Q = 4$ pμC, and $\Omega = 5.26$ msr.

ERD analysis. Figure 18 shows two ERD spectra collected from the same Si_3N_4 film on a Si substrate using either 2.8-MeV He^+ ions (+) or 16-MeV Si^{3+} ions (solid line) incident at 75° relative to the sample normal. For greater visibility, the yield for the He ERD spectrum is magnified 5 times in this figure, even though the recoil cross-section for ^{4}He recoiling ^{1}H is ~2.5 times greater than Rutherford. The recoil cross-section for ^{28}Si recoiling ^{1}H is Rutherford for 16- to 30-MeV Si. Both spectra were collected at a scattering angle $\varphi = 30°$ and using a 12-μm Mylar range foil in front of the SBD. The only signal visible in these spectra arises from recoiled H atoms because all other species are either not recoiled or stopped in the range foil. This figure demonstrates that the yield and depth resolution are greatly increased by using a heavier incident projectile. Nevertheless, He ERD is often done (Green and Doyle, 1986) because either a He ion beam causes less radiation damage in the sample (e.g., polymers) or the heavy ion sources and high energies required for the heavy ion ERD are unavailable on a given accelerator.

A comparison of ERD spectra collected from this same silicon nitride sample for different incident Si ion energies is shown in Figure 19. Each spectrum was collected for $\Theta_1 = 75°$ and $\varphi = 30°$ using a 12-μm Mylar range foil. This figure shows that increasing the incident Si ion energy above 16 MeV decreases the yield for H and introduces a signal from the recoiled N that can now get through the Mylar foil. The front edges of the N and H nearly overlap for the 24-MeV Si ERD spectrum but are well separated for the 30-MeV Si ERD spectrum. As a result of recoil atom stopping in the range foil, this variation in mass resolution does not follow a simple analytical formula and is best determined by experiment or using a computer code such as SERDAP (Barbour, 1994) to determine the expected surface energies. Further, the N signal from the entire thickness of the film was observed using 30-MeV Si ERD, whereas only a portion of the N signal was observed using 24-MeV Si ERD. Thus the depth of analysis is increased by using a higher energy ion beam. The H signals are easily separated from the background signals using a linear fit of the background. These signals were then scaled by the cross-sections and stopping powers as a function of depth for the 16- and 30-MeV Si ERD spectra. The H profiles obtained from this spectral scaling, shown in Figure 20, demonstrate the increased depth

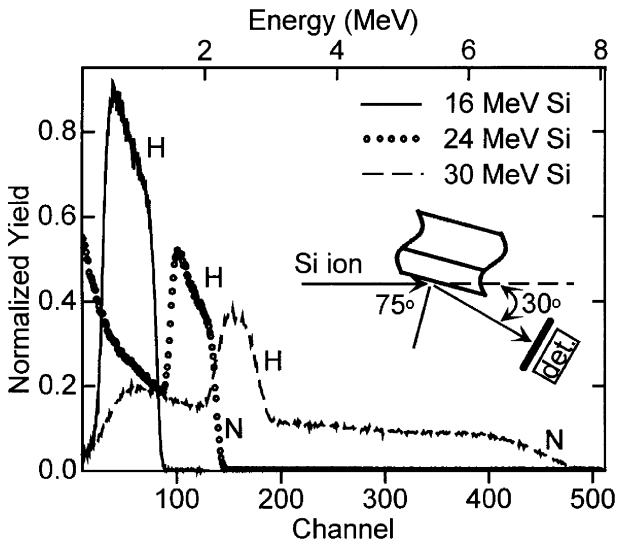

Figure 19. The ERD spectra from the same sample as in Figure 18 collected using three different ion energies: 16-MeV Si (solid line), 24-MeV Si (open circles), and 30-MeV Si (dashed line). The higher energy ERD spectra have the signal from recoiled H atoms sitting on the signal from recoiled N atoms. For all three spectra, $\phi = 30°$, $\Theta_1 = 75°$, and $\Omega = 5.26$ msr. For the 16- and 24-MeV Si spectra, $Q = 4$ pμC, whereas $Q = \Omega$ pμC for the 30-MeV spectrum.

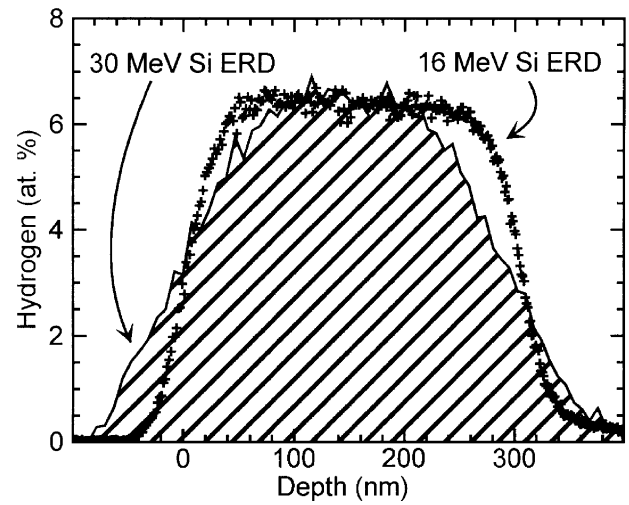

Figure 20. The H concentration-vs.-depth profiles determined from the 16-MeV Si (+) and 30-MeV Si (solid line) ERD data given in Figure 19. The N background was subtracted with a linear fit of the N signal under the H signal for the 30-MeV Si ERD data.

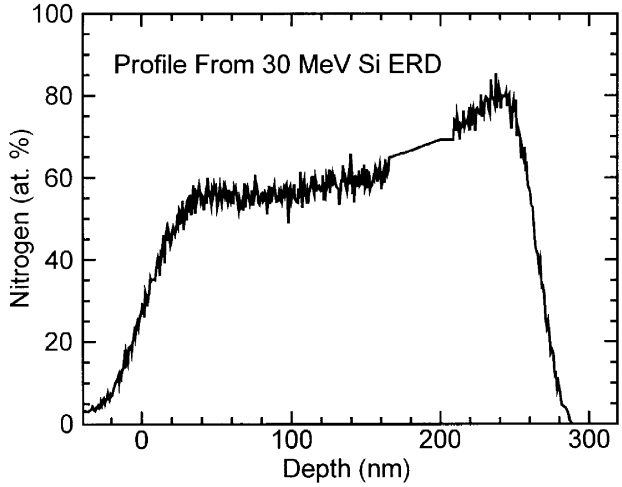

Figure 21. The N concentration-vs.-depth profile determined from the N signal for the 30-MeV Si ERD data given in Figure 19. The straight-line profile from ~160 to 210 nm has no visible statistical noise because of the linear fit used to eliminate the H signal sitting on top of the N signal.

resolution obtained with the lower energy ion beam. The depth and concentration scales were determined using the volume density of 0.903×10^{23} atoms/cm^3 for Si_3N_4.

The N profile was obtained only for the higher energy IBA and is given in Figure 21 using the same assumed volume density as in Figure 20. Comparing Figures 20 and 21 shows that the depth resolution for N is better at a given Si energy than for H as a result of the greater stopping by N than by H in the range foil. Comparison of these two figures also gives a check on the accuracy of the nitrogen stopping power in the Mylar range foil. Independently, the H and N depth profiles yield approximately the same Si_3N_4 film thickness, and therefore the stopping power used for N is acceptable. The uncertainty in the N stopping power may, however, cause inaccurate scaling of the N concentration at depth. The N profile in Figure 21 should remain constant with depth but appears to increase beyond ~160 nm. This increase may result from inaccurately calculating the N stopping power, from multiple scattering in the sample, or from a pulse-height defect effect called the nuclear deficit (i.e., some ion energy is deposited in the detector as atomic displacements rather than through the process of producing electron-hole pairs). Further work is needed to accurately determine the N stopping power in Mylar for the N energy range from 1 to 8 MeV.

APPENDIX A: GLOSSARY OF TERMS AND SYMBOLS

AD	Areal density (number of atoms per unit area)
dE/dx	Energy loss of a particle (generally as a result of electronic stopping)
dE_d/dx	Effective stopping power for the detected particle at a given projectile energy (an incremental change in E_d corresponds to an incremental change in depth, dx, at x)
dx	Increment of depth at x corresponding to an increment of energy dE_d
E_0	Energy of the incident projectile particle
E_0'	Projectile energy at a depth x'
$E_0^{(n)}$	Projectile energy incident upon slab $n+1$
$E_3^{(n)}$	Energy of the backscattered atom (or recoiled atom for ERD) as it emerges from slab n
E_d	Energy of detected particle
$E_d^{(n)}$	Detected energy for the nth slab
$E_f^{(j-1)}$	Energy in foil before recoil atom traverses the jth slab
E_{NR}	Energy where σ becomes non-Rutherford
K	Kinematic factor (ratio of the scattered particle energy to the projectile energy for an elastic collision)
L	Length of light tube
M_1	Mass of the incident projectile particle

M_2	Mass of a target atom involved in a scattering event
N	Volume density of atoms in the target
NF	Number of slabs in foil
Q	Number of incident projectiles (determined from a target current and the projectile charge)
S^{eff}	Effective stopping power
S_{p}	Projectile particle stopping power (energy loss), $= dE/dx$ projectile
S_{r} (S_{b})	Recoil (backscattered) particle stopping power (energy loss)
$[S]_{\text{p,r}}$ or $[S]_{\text{p,b}}$	Energy loss factor corresponding to a recoil (backscattering) event at energy E
t	Layer thickness; also time
V_{LJ}	Lenz-Jensen potential
x	Distance (depth) in the sample, measured along the sample normal
$X^{(0)}$	Thickness of range foil
$X^{(n)}$	Thickness of slab (sublayer) n within the sample
$Y(E_{\text{d}})$	Yield (height) of detected particles at a channel corresponding to energy E_{d}
z	Sample-to-detector distance
Z_1	Atomic number of the incident projectile particle
Z_2	Atomic number of a target atom involved in a scattering event
δE_{d}	Energy width of a channel in the multi- channel analyzer
δx	Smallest resolvable depth interval
ΔE_{foil}	Energy lost by a recoil atom in traversing the range foil
$\Delta x^{(0)}$	Incremental slab thickness for range foil containing $X^{(0)}/\Delta x^{(0)}$ slabs
ε	Stopping cross-section, $\equiv (1/N)(dE/dx)$
η	Detector efficiency
θ	Backscattering angle measured in the laboratory frame of reference
Θ_1	Incident angle, measured between the sample normal and the incident pro jectile direction
Θ_2	Detection angle, measured between the sample normal and the scattered particle direction
σ	Average differential scattering cross- section (also known as the scattering cross-section)
σ_0	Scattering cross-section of surface peak
σ_{R}	Rutherford scattering cross-section
τ	Layer thickness
ϕ	Forward (recoil) scattering angle measured in the laboratory frame of reference
Ω	Detector solid angle

APPENDIX B: RBS AND ERD EQUATIONS

Figure 22 shows equations applicable to both RBS and ERD, whereas Figure 23 shows equations applicable to either RBS or ERD. Although these analytical expressions appear complicated, their implementation through the use of a computer is simple and fast.

$$\Omega = \int_{\substack{\text{area subtended}\\ \text{by detector}}} \sin\phi \, d\phi \, d\varepsilon \approx \frac{\text{detector area}}{\text{z}^2} (\text{z} = \text{sample-to-detector distance}) \tag{1}$$

$$Y(E_{\text{d}}) = \frac{QN(x)\sigma(E_0^{(n)})\Omega\delta E_{\text{d}}}{\cos\Theta_1 \, dE_{\text{d}}/dx} \tag{5}$$

$$\text{AD} = \int_0^{\tau} N(x)(dx) = \frac{\cos\Theta_1}{Q\Omega} \int_0^{\tau} \frac{S^{\text{eff}}}{\sigma\delta E_{\text{d}}} Y(E_{\text{d}}) dx = \frac{\cos\Theta_1}{Q\Omega} \int_{E_{\text{d}}(0)}^{E_{\text{d}}(x)} \frac{Y(E_{\text{d}})}{\sigma} \frac{dE_{\text{d}}}{\delta E_{\text{d}}} \tag{8}$$

$$\text{AD} = \frac{\cos\Theta_1}{Q\Omega\sigma_0} \sum_{\text{channel}[E_{\text{d}}(0)]}^{\text{channel}[E_{\text{d}}(x)]} Y(\text{channel}) \tag{9}$$

$$\text{Bragg's rule:} \quad \varepsilon^{\text{A}}\alpha^{\text{B}}\beta = \alpha\varepsilon^{\text{A}} + \beta\varepsilon^{\text{B}} \quad \text{and} \quad S = N^{\text{A}}\alpha^{\text{B}}\beta\varepsilon^{\text{A}}\alpha^{\text{B}}\beta \tag{10}$$

$$E_0^{(n)} = E_0^{(n-1)} - \frac{X^{(n)}}{\cos\Theta_1} S_{\text{p}}^{(n)}(E_0^{(n-1)}) \tag{11}$$

$$\text{Spectral scaling:} \quad N^{(n)}(x) = \frac{\cos\Theta_1}{Q\Omega\,\delta E_{\text{d}}} \frac{dE_d/dx|_n}{\sigma_{\text{R}}(E_0^{(n)})} Y^{(n)}(E_{\text{d}}) = \frac{\cos\Theta_1}{Q\Omega\delta E_{\text{d}}} \frac{S_0^{\text{eff}}}{\sigma_0} \left[\frac{\sigma_{\text{R}}(E_0)}{\sigma_{\text{R}}(E_0^{(n)})} \frac{dE_{\text{d}}/dx|_n}{dE_{\text{d}}/dx|_0} Y^{(n)}(E_{\text{d}}) \right] \tag{22}$$

Figure 22. Equations applicable to both RBS and ERD.

NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION

INTRODUCTION

Nuclear reaction analysis (NRA) and proton- (particle-) induced gamma ray emission (PIGE) are based on the interaction of energetic (from a few hundred kilo-electron-volt to several mega-electron-volt) ions with light nuclei. Every nuclear analytical technique that uses nuclear reactions has a unique feature—isotope sensitivity. Therefore, it is insensitive to matrix effects, and there is much less interference than in methods where signals from different elements overlap. In NRA the nuclear reaction produces charged particles, while in PIGE the excited nucleus emits gamma rays. Sometimes the charged particle emission and the gamma ray emission occur simultaneously, such as in the $^{19}\mathrm{F}(\mathrm{p},\alpha\gamma)^{16}\mathrm{O}$ reaction. Both NRA and PIGE measure the concentration and depth distribution of elements in the surface layer (few micrometers) of the sample. Both techniques are limited by the available nuclear reactions. Generally, they can be used for only light elements, up to calcium. This is the basis for an important property of these methods: the nuclear reaction technique is one of the few analytical techniques that can quantitatively measure hydrogen profiles in solids. Since these techniques are sensitive to the nuclei in the sample, they are unable to provide information

about the chemical states and bonds of the elements in the sample. For the same reason they cannot provide information about the microscopic structure of the sample. Combined with channeling, NRA or PIGE can provide information about the location of the measured element in a crystalline lattice.

The sensitivity and depth resolution of these methods depend on the specific nuclear reaction. The sensitivity typically varies between 10 and 100 ppm while the depth resolution can be as good as a few nanometers or as large as hundreds of nanometers. The lateral resolution of the method depends on the size of the bombarding ion beam. Good nuclear microprobes are currently in the few-micrometer range. Also, using nuclear microprobes, an elemental/isotopic image of the sample can be recorded. Both NRA and PIGE are nondestructive, although some materials might be lattice damaged after long, high-current bombardment.

Although NRA and PIGE are quantitative, in most cases standards have to be used. Depending on the shape of the particular nuclear cross-section, nonresonant or resonant depth profiling can be used. The resonant profiling (in most cases PIGE uses resonances but there are a few charged particle reactions that have usable resonance) typically can give very good resolution, but the measurement takes much longer than in nonresonant profiling; therefore, the probability of inducing changes in the sample by the ion beam is higher.

These techniques require a particle accelerator capable of accelerating ions up to several mega-electron-volts. This limits their availability to laboratories dedicated to these methods or that have engaged in low-energy nuclear physics in the past (i.e., they have a particle accelerator that is no longer adequate for modern nuclear physics experiments because of its low energy but is quite suitable for nuclear analytical techniques).

This unit will concentrate on the specific aspects of these two nuclear analytical techniques and will not cover the details of the ion-solid interaction or the general aspects of ion beam techniques (e.g., stopping power, detection of ions). These are described in detail elsewhere in this part (see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS and MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY).

Competitive and Complementary Techniques

Practically every analytical technique that measures the concentration and depth profile of elements in the top few micrometers of a solid competes with NRA and PIGE. However, either most of these techniques are not isotope sensitive or their isotope resolution is not very good. The competing techniques can be divided into two groups: ion beam techniques and other techniques. The ion beam techniques that compete with NRA and PIGE are Rutherford backscattering spectrometry (RBS; see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS), elastic recoil detection (ERD or ERDA; see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS), proton-induced x-ray emission (PIXE; see PARTICLE-INDUCED X-RAY EMISSION), secondary ion mass spectroscopy (SIMS), medium-energy ion scattering (MEIS; see MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY), and ion scattering spectroscopy (ISS; see HEAVY-ION BACKSCATTERING SPECTROMETRY).

Rutherford backscattering spectrometry and ERD can be considered special cases of NRA in which the nuclear reaction is just an elastic scattering. The main advantage of RBS and ERD is that they are able to see almost all elements in the periodic table (with the obvious exception in RBS when the element to be detected is lighter than the bombarding ions). This can be a disadvantage when a light element has to be measured in a heavy matrix (e.g., the measurement of oxygen in tantalum by RBS). This is the typical case when NRA can solve the problem but RBS cannot. In ERD, since the forward recoiled atoms have to be mass analyzed, the measurement becomes more complicated than in NRA, requiring more sophisticated (and more expensive) instruments. The resolution and sensitivity achieved when using RBS, ERD, and NRA are on the same order, although when using very heavy ions, the sensitivity and depth resolution can be an order of magnitude better in ERD than in NRA. Using heavy ions presents other problems, but these are beyond the scope of this unit (see HEAVY-ION BACKSCATTERING SPECTROMETRY). For more discussion see Green and Doyle (1986) and Davies et al. (1995).

Proton-induced x-ray emission (see PARTICLE-INDUCED X-RAY EMISSION) can detect most elements, except H and He. Also, the detection of x rays from low-Z elements (below Na) requires a special, windowless detector. Another drawback of PIXE is that it generally cannot provide depth information.

Secondary ion mass spectroscopy can be used for most of the analyses performed in NRA, including hydrogen profiling. Its sensitivity and depth resolution are superior to those of NRA. The main advantage of NRA over SIMS is that while NRA is a nondestructive technique, SIMS depth profiling destroys the sample. Also, the depth scale with SIMS depends on accurate knowledge of sputtering rates for a specific sample.

Although MEIS and ISS can be considered competing techniques, their probing depth is much smaller (which also means much better depth resolution) than that of NRA.

Among the non–ion beam techniques, Auger electron spectroscopy (AES, see AUGER ELECTRON SPECTROSCOPY), x-ray photoelectron spectroscopy (XPS), x-ray fluorescence (XRF, see X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ANALYSIS), and neutron activation analysis (NAA) should be mentioned.

Auger electron spectroscopy and XPS not only provide concentration information but also are sensitive to the chemical states of the elements; therefore, they give information about chemical bonds. Since both methods get the information from the first few nanometers of the sample, to measure a depth profile, layers of the sample have to be removed (usually by sputtering); therefore, the sample is destroyed. X-ray fluorescence can provide concentration information about elements heavier than Na (again, it depends on the x-ray detector) but it cannot measure the depth profile. The only technique listed that has the same isotope sensitivity as NRA is NAA. However, NAA is a bulk technique and does not provide any depth information.

Most of the above-mentioned techniques are complementary techniques to NRA, and in many cases are, used concurrently with NRA. [It is quite common in ion beam analysis (IBA) laboratories for an ion-scattering chamber to have an AES or XPS spectrometer mounted on it.] The most frequent combination is RBS and NRA, since they are closely related and use the same equipment. Whereas, NRA can measure light elements in a heavy matrix but cannot see the matrix itself (at least not directly), RBS is very sensitive and has a good mass resolution for heavy elements but cannot see a small amount of some light element in a heavy matrix.

PRINCIPLES OF THE METHOD

Although NRA and PIGE are similar to other high-energy ion beam techniques (see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS and PARTICLE-INDUCED X-RAY EMISSION), here we will discuss only the principles specific to NRA and PIGE.

Both NRA and PIGE measure the prompt reaction products from nuclear reactions. The yield (number of detected particles, γ rays) provides information about the concentration of elements, and the energy of the detected charged particles provides information about the depth distribution (depth profile) of the elements. Depending on whether the reaction cross-section has a sharp resonance or not, the methods are distinguished as either resonant or nonresonant (e.g., PIGE uses only the resonant method).

When a high-energy ion beam is incident on a target, the ions slow down in the material and either undergo elastic scattering (RBS, ERDA) or induce a nuclear reaction at various depths. In a nuclear reaction, a compound nucleus is formed and almost immediately a charged particle (p, d, ^{3}He, and ^{4}He) and/or a γ photon is emitted. Many (p, α) reactions have an associated γ photon. The emitted charged particle/photon then leaves the target and is detected by an appropriate detector. The energy of the charged particle depends on the angle of the incident ion and the emitted particle, the kinetic energy of the incident particle, and the Q value of the reaction, where Q is the energy difference between the initial and final nuclear states. The energy of the emitted γ photon is determined by the energy structure of the compound nucleus (for the formulas, see Appendix). The detected number of emitted particles is proportional to the number of incident particles, the solid angle of the detector, the concentration of the atoms participating in the nuclear reaction, and the cross-section of the reaction. The charged reaction products will lose energy on their way out from the target; therefore, their energy will carry information about the depth where the nuclear reaction occurred. Since the energy of the γ photons does not change while they travel through the target, they do not provide depth information.

Nonresonant Methods

Overall Near-Surface Content. If the cross-section changes slowly in the vicinity of the E_0 bombarding energy, the absolute value of nuclei per square centimeters

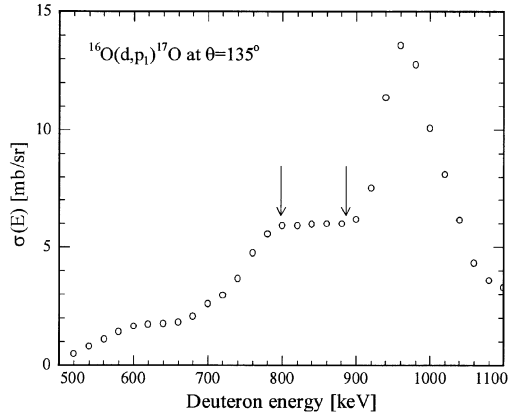

Figure 1. Cross-section of the ^{16}O(d, p$_1$)^{17}O reaction; θ is the scattering angle (Jarjis, 1979).

can be determined in thin layers independent of the concentration profile and the other components of the target. Assuming that the incident ions lose ΔE energy in the thin layer and the reaction cross-section $\sigma(E) \approx \sigma(E_0)$ for $E_0 > E > E - \Delta E$, the number of particles detected is

$$Y = \frac{Q_C \Omega \sigma(E_0) Nt}{\cos \alpha_{in}} \qquad (1)$$

where Q_C is the collected incident ion charge, is the solid angle of the detector, α_{in} is the angle between the direction of the incident beam and the surface normal of the target, and Nt is the number of nuclei per square centimeter. The spectrum of emitted particle would contain a peak with an area Y. An example of such a cross-section is shown in Figure 1. The ^{16}O(d, p$_1$)^{17}O reaction has a plateau between 800 and 900 keV, as indicated by arrows in the figure. This reaction is frequently used to determine oxygen content of thin layers or thickness of surface oxide layers up to several hundreds of nanometers.

Depth Profiling. When the thickness of the sample becomes larger and the cross-section cannot be considered constant, the spectrum becomes the convolution of the concentration profile, the energy resolution of the incident and the detected beam, and the cross-section. A typical scattering geometry is shown in Figure 2. Although the figure shows only backward geometry, forward geometry is used in certain cases as well. The depth scale can be calculated by determining the energy loss of the incident ions

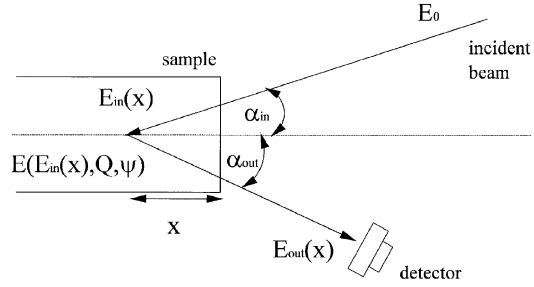

Figure 2. Typical scattering geometry used in NRA experiments.

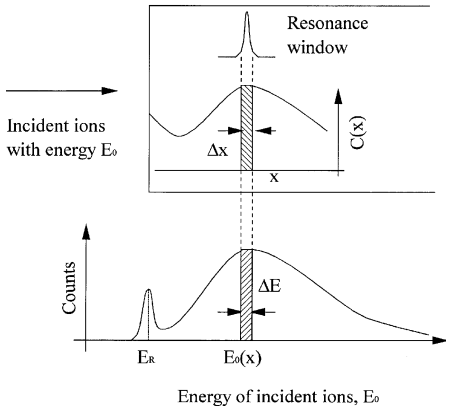

Figure 3. Principle of resonant depth profiling.

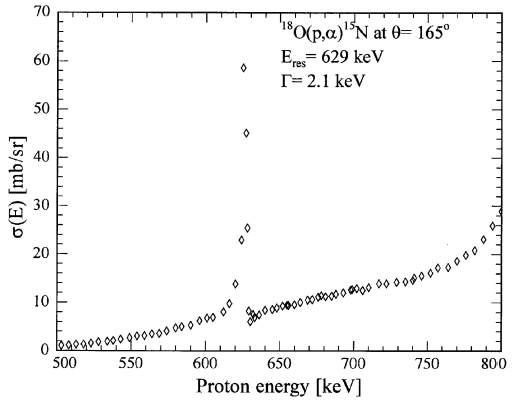

Figure 4. Cross-section of the ^{18}O(p, α)^{15}N reaction around the 629-keV resonance; θ is the scattering angle (Amsel and Samuel, 1967).

before they induce the nuclear reaction and the energy loss of the reaction product particles:

$$E_{\text{out}}(x) = E(E_{\text{in}}(x),\ Q,\ \psi) - \int_0^{x/\cos\alpha_{\text{out}}} S_{\text{out}}(E)\,dx \qquad (2)$$

$$E_{\text{in}}(x) = E_0 - \int_0^{x/\cos\alpha_{\text{in}}} S_{\text{in}}(E)\,dx \qquad (3)$$

where x is the depth at which the nuclear reaction occurs, E_0 is the energy of the incident ions, Q is the Q value of the reaction, ψ is the angle between the incident and detected beams, α_{in} and α_{out} are angles of the incident and detected beams to the surface normal of the sample, and S_{in} and S_{out} are the stopping powers of the incident ions and the reaction products. The term $E(E_{\text{in}}(x), Q, \psi)$ is the energy of the reaction product calculated from Equation 7. (Also see Fig. 7.)

In most cases, to get quantitative results, a nonlinear fit of the spectrum to a simulated spectrum is necessary (Simpson and Earwaker, 1984; Vizkelethy, 1990; Johnston, 1993). For a discussion of energy broadening, see the Appendix.

Resonant Depth Profiling

In case of sharp resonances in the cross-section, most particles/γ photons come from a very narrow region in the target that is equal to the energy-loss-related width of the resonances. As the energy of the incident beam increases, the incident ions slow to the resonance energy at deeper and deeper depth; therefore, the thin layer from which the reaction products are coming lies deeper and deeper. In this way a larger depth can be probed and a depth profile can be measured. The principle of the method is illustrated in Figure 3.

The depth x and the energy E_0 of the incident ions are related through the equation

$$E_0(x) = E_{\text{R}} + \int_0^{x/\cos\alpha_{\text{in}}} S_{\text{in}}(E)\,dx \qquad (4)$$

where E_{R} is the resonance energy. In the figure $C(x)$ is the concentration of the element to be detected. Figure 4 shows the cross-section of the ^{18}O(p, α)^{15}N reaction. The resonance at 629 keV is widely used in ^{18}O tracing experiments where oxygen movement is studied. This is an excellent example of how useful NRA and PIGE are, since these methods are sensitive to only ^{18}O and not to the other oxygen isotopes. The measured spectrum ("excitation curve") is the convolution of the concentration profile and the energy spread of the detection system. To extract the depth profile from the excitation function, we should deconvolve it with the depth-dependent energy spread or fit the excitation function to a simulation of it. The theory and simulation of narrow resonances are discussed in detail in Maurel (1980), Maurel et al. (1982), and Vickridge (1990).

PRACTICAL ASPECTS OF THE METHOD

Equipment

The primary equipment used in NRA and PIGE is an electrostatic particle accelerator, which is the source of the high-energy ion beam. The accelerators used for IBA are either Cockroft-Walton or van de Graaff type (or some slight variation of them, such as pelletron accelerators) with terminal voltage in the range of a few million volts. When higher energies are needed or heavy ions have to be accelerated, tandem accelerators are used. In general, the requirements for the accelerators used in NRA and PIGE are similar to those of any other IBA technique. In addition, to perform resonance profiling, the accelerators must have better energy resolution and stability than are necessary for RBS or ERDA and be capable of changing the beam energy easily. Usually, accelerators with slit feedback energy stabilization systems are satisfactory. Another NRA-specific requirement is needed because of the deuteron-induced nuclear reactions. When deuterons are accelerated, neutrons are generated mainly from the D(d, n) ^{3}He reaction. Therefore, if deuteron-induced nuclear reactions are used, additional shielding is necessary to protect personnel against neutrons. Many laboratories using ion beam techniques do not have this shielding.

Most NRA and PIGE measurements take place in vacuum, with the exception of a few extracted beam experiments. The required vacuum, i.e., $>10^{-3}$ Pa,

depends on the particular application; it usually ranges from 10^{-3} to 10^{-7} Pa. The main problem caused by bad vacuum is hydrocarbon layer formation on the sample under irradiation, which can interfere with the measurement. Having a load-lock system attached to the scattering chamber makes the sample changing convenient and fast.

In most cases, standard surface barrier or ion-implanted silicon particle detectors are used to detect charged particles. These detectors usually have an energy resolution around 10 to 12 keV, which is adequate for NRA. When better energy resolution is required, electrostatic or magnetic spectrometers or time-of-flight (TOF) techniques can be used.

In PIGE, NaI, BGO (bismuth germanate), Ge(Li), or HPGE (high-purity germanium) detectors are used to detect γ rays. The NaI and BGO detectors are used when high efficiency is needed (measuring low concentrations, or the cross-section is too small) using well-isolated resonances. The NaI detectors were used mainly before BGO detectors became available, but currently BGO detectors are preferred since their efficiency is higher for a given size (Kuhn et al., 1990) and have a better signal-to-background ratio. The Ge(Li) or HPGE detectors are used when there are interfering peaks in the spectrum that cannot be resolved using other detectors.

To process the signals from the detectors, standard NIM (nuclear instrument module) or CAMAC (computer-automated measurement and control) electronics modules, such as amplifiers, single-channel analyzers (SCA), and analog-to-digital converters (ADCs), are used. In most cases, the ADC is on a card in a computer or connected to a computer through some interface (e.g., GPIB, Ethernet). Therefore, the spectrum can be examined while it is being collected and the data can be evaluated immediately after the measurement.

Filtering of Unwanted Particles (NRA)

From Figure 2 it is obvious that not only the reaction products but also all the backscattered particles will reach the detector. Since the Q value of the most frequently used reactions is positive, the backscattered particle will have less energy than the reaction products; therefore, the signal from the backscattered particles will not overlap in the spectrum. [The exceptions are the (p, α) reactions with low Q value. Due to the higher stopping power of the α particles than that of the protons, the energy of an α particle coming from a deeper layer can be the same as the energy of the proton coming from another layer.] However, the cross-section of the Rutherford scattering is usually much larger than the cross-section of the nuclear reaction we want to use. Therefore, much less reaction product would be detected in a unit time than backscattered particles. Since every detection system has finite dead time, the number of backscattered particles would limit the maximum incident ion current, so the NRA measurement would take a very long time. To make the measurement time reasonable, the backscattered particles should be filtered out.

The simplest method to get rid of the backscattered particles is to use an absorber foil, since the energy of the reaction products is higher than the energy of the backscattered particles. The energy of the reaction products after the absorber foil is

$$E_{\text{abs}}(x) = E_{\text{out}}(x) - \int_0^{x_{\text{abs}}} S_{\text{abs}}(E)\,dx \qquad (5)$$

where x_{abs} and S_{abs} are the thickness and stopping power of the absorber foil and $E_{\text{out}}(x)$ is from Equation 2. Choosing an absorber foil thickness such that E_{abs} is larger than the energy range of the backscattered particles will eliminate the unwanted particles. Usually Mylar or aluminum foils are used as absorbers. The main disadvantage of the method is the poor depth resolution due the large energy spread (straggling) in the absorber foil.

There are more sophisticated methods to filter the backscattered particles. Here we briefly list them without detailed discussion:

1. Electrostatic or magnetic deflection (or the use of electrostatic or magnetic spectrometers) gives much better resolution than the absorber method but is complicated, time consuming, and expensive (spectrometers). For applications see Möller (1978), Möller et al. (1977), and Chaturvedi et al. (1990).
2. The TOF technique, a standard technique used in nuclear physics to distinguish particles, can be used to select the reaction products only. This technique requires sophisticated electronics and a two-dimensional multichannel analyzer.
3. The thin-detector technique is used when protons and α peaks overlap in a spectrum. Since the stopping power of protons is much smaller than the stopping power of α particles, the protons would lose only the fraction of their energies in a thin detector while the α particles stop completely in it. Thus the α particles will be separated from the mix. This technique uses either "dE/dx detectors," which are quite expensive, or low-resistivity detectors, with low bias voltage. Recently the use of low-resistivity detectors was studied in detail by Amsel et al. (1992).

The TOF and thin-detector techniques have the disadvantage that although they select the reaction product, the large flux of backscattered particles still reach and can damage the detector.

Energy Scanning (for Resonance Depth Profiling)

To do resonance depth profiling, the energy of the incident ion beam has to be changed in small steps. After acceleration, the ion beam goes through an analyzing magnet that selects the appropriate energy. Generally, the energy is changed by adjusting the terminal voltage and the magnetic field. Automatic energy-scanning systems have been developed using electrostatic deflection plates after the analyzing magnet by Amsel et al. (1983) and Meier and Richter (1990). Varying the voltage on these plates, the magnetic field is kept constant and the terminal voltage is changed by the slit feedback system. This

system allows energy scanning up to several hundred kilo-electron-volts.

Background, Interference, and Sensitivity

Since NRA and PIGE are both sensitive to specific isotopes, the background, interference from the sample matrix, and sensitivity, all depend on which nuclear reaction is used. When the nonresonant technique is used, the spectrum is generally background free. Interference from elements in the matrix is possible, especially in the deuteron-induced reaction case. An element-by-element discussion of the possible interferences can be found in Vizkelethy (1995) for NRA and in Hirvonen (1995) for PIGE.

In resonant depth profiling, there are two sources of background. One is natural background radiation (present only for PIGE). The effect of this background can be taken into account by careful background measurements or can be minimized by using appropriate active and passive shielding of the detector (Damjantschitsch et al., 1983; Kuhn et al., 1990; Horn and Lanford, 1990). The second background source is also present if the resonance is not an isolated resonance that sits on top of a non-resonant cross-section. In this case, the background is not constant and depends on the concentration profile of the element we want to measure. To extract a reliable depth profile from the excitation curve, a non-linear fit to a simulation is necessary.

As mentioned above, the sensitivity depends on the cross-section used and the composition of the sample. Generally the sensitivities of NRA and PIGE are on the order of 10 to 100 ppm. Lists of sensitivities for special applications can be found in Bird et al. (1974) and Hirvonen (1995).

Cross-Sections and Q values

The most important data in NRA and PIGE are the cross-sections, the Q values of the reactions, and the energy level diagrams of nuclei. The most recent compilation of Q values and energy level diagrams can be found for $A = 3$ in Tilley et al. (1987); $A = 5, \ldots, 10$ in Ajzenberg-Selove (1988); $A = 11, 12$ in Ajzenberg-Selove (1990); $A = 13, \ldots, 15$ in Ajzenberg-Selove (1991); $A = 16, 17$ in Tilley et al. (1993); f$A = 18, 19$ in Tilley et al. (1995); $A = 18, \ldots, 20$ in Ajzenberg-Selove (1987); and $A = 21, \ldots, 44$ in Endt and van der Leun (1978). Data of frequently used cross-sections can be found in Foster et al. (1995), and an extensive list of (p, γ) resonances can be found in Hirvonen and Lappalainen (1995).

The data are also available on the Internet (see Internet Resources). The energy levels are available from Lund Nuclear Data Service (LNDS) and from Triangle Universities Nuclear Laboratories (TUNL). An extensive database of nuclear cross-sections is available from the National Nuclear Data Center, NNDC) and from the T-2 Nuclear Information Services, although these serve more the needs of nuclear physicists than people working in the field of IBA. Nuclear reaction cross-sections used in IBA are available from the Sigmabase together with many (p, p) and (α,α) cross-sections.

Usage of Standards

There are two basic reasons to use standards with NRA and PIGE. First, the energy of the bombarding beam is determined by reading the generating voltmeter (GVM) of the accelerator or by reading the magnetic field of the analyzing magnet. Usually these readings are not absolute and might shift with time. Therefore, in depth profiling it is necessary to use standards to determine the energy of the resonance (with respect to the accelerator readings) and the energy spread of the beam.

Second, since the yield is proportional to the collected charge, the cross-section, and the solid angle of the detector, to make an absolute measurement, the absolute values of these three quantities must be known precisely. In most cases, these values are not available. Ion bombardment always causes secondary electron emission. Imperfect suppression of the secondary electrons falsifies the current (and therefore the collected charge) measurement. It is not easy to design a measurement setup that can measure current with high absolute precision, but high relative precision and reproducibility are easy to achieve. Also, the solid angle of the detector and the absolute cross-section are usually not known precisely. Using reference targets that compare the reference yield to the yield from the unknown sample can eliminate most of these uncertainties.

A good reference target must satisfy the following requirements: (1) have high lateral uniformity; (2) be thick enough to provide sufficient yield in reasonable time but thin enough not to cause significant change in the cross-section; (3) have a standard that is amorphous (to avoid accidental channeling); (4) be stable in air, in vacuum, and under ion bombardment; and (5) be highly reproducible.

A detailed discussion of reference targets used in nuclear microanalysis can be found in Amsel and Davies (1983).

METHOD AUTOMATION

Automation of acquisition of NRA spectra is the same as in RBS. The only task that can be automated is changing the sample. Since most of the measurements are done in high vacuum, there is a need for some mechanism to change samples without breaking the vacuum. If the scattering chamber is equipped with a load-lock mechanism, the sample change is easy and convenient and does not require automation. Without the load lock, usually large sample holders that can hold several samples are used. In this case stepping motors connected to a computer can be used to move from one sample to another.

In PIGE or resonant depth profiling, an automatic energy scanning system synchronized with data acquisition electronics is desired. Sophisticated energy scanning systems have been developed by Amsel et al. (1983) and Meier and Richter (1990). An alternative to these methods is the complete computer control of the accelerator and the analyzing magnet.

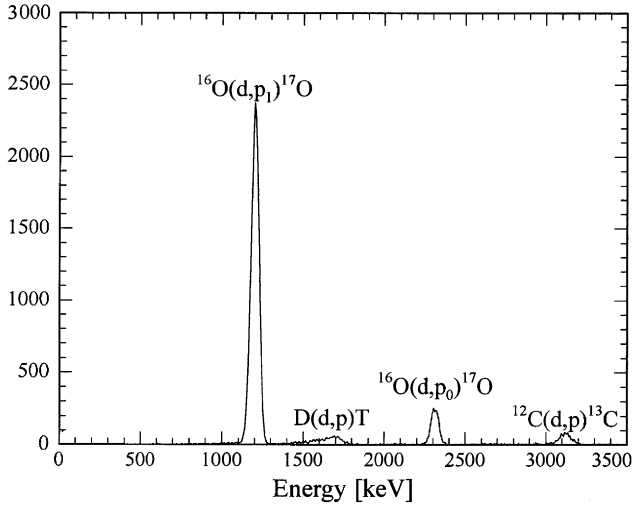

Figure 5. Measured spectrum from an 834-keV deuteron beam on 100 nm SiO_2 on Si.

DATA ANALYSIS AND INITIAL INTERPRETATION

Overall Surface Content (Film Thickness)

As mentioned above, when the cross-section can be considered flat across the thickness of the film, the overall surface content can be determined easily. Figure 5 shows a spectrum from an 834-keV deuteron beam incident on 100 nm SiO_2 on bulk Si. The ^{16}O(d, p)^{17}O reaction has two proton groups that show up as two separate peaks in the spectrum. Since the (d, p_1) cross-section has a plateau around 850 keV, we need to consider only the p_1 peak.

Using Equation 1, we can easily calculate the number of oxygen atoms per square centimeter. In most cases reference standards are used (thin Ta_2O_5 layers on Ta backing or thin SiO_2 layer on Si); therefore, the exact knowledge of the detector solid angle, cross-section, and absolute value of the collected charge is not necessary. If the reference sample contains Nt_{ref} oxygen atoms per square centimeter, the number of oxygen atoms per square centimeter in the unknown sample is

$$Nt = Nt_{\mathrm{ref}} \frac{Y}{Y_{\mathrm{ref}}} \frac{Q_{\mathrm{C}}^{\mathrm{ref}}}{Q_{\mathrm{C}}} \qquad (6)$$

where $Q_{\mathrm{C}}^{\mathrm{ref}}$ and Q_{C} are collected charges and Y_{ref} and Y are the peak areas of the p_1 protons for the reference standard and for the unknown sample, respectively. There are two peaks in the spectrum that need further explanation. The peak at higher energies is the result of the ^{12}C(d, p)^{13}C reaction from the hydrocarbon layer deposited during ion bombardment. The broad peak between the p_0 and p_1 peaks is due to the D(d, p)T reaction. Since this particular sample was used as a reference standard, during the measurements a considerable amount of deuterium had been implanted into it and is now a detectable component of the target.

Nonresonant Depth Profiling

When the cross-section cannot be considered constant, the spectrum becomes the convolution of the concentration profile with the energy broadening of the incident ions and the detected reaction particles. The interpretation is not that simple now. The energy-depth conversion can be calculated using Equations 2 and 3. If the cross-section changes only slowly, the spectrum shows the main features of the concentration profile, but this cannot be considered as quantitative analysis. To extract the concentration profile from the spectrum, the spectrum has to be simulated and the assumed concentration profile should be changed until an acceptable agreement between the simulation and the measurement is reached. Several computer programs are available that can do the simulations and fits, e.g., ANALRA (Johnston, 1993) and SENRAS (Vizkelethy, 1990). These programs are available from the Sigmabase (see Internet Resources).

Resonant Depth Profiling

In resonant depth profiling, the spectrum is usually not recorded, but the particles or γ photons are counted in an energy window. The data that carry the depth profile information is the excitation function, i.e., the number of counts vs. the incident energy. The excitation function is the convolution of the resonance cross-section, the energy profile of the incident beam as a function of depth, and the concentration profile. Qualitative features of the concentration profile can be deduced from the excitation function. Quantitative concentration profiles can be obtained by simulating the excitation function and using least-squares fitting to match it to the measured excitation functions. [More detailed discussion can be found in Hirvonen (1995).] Also, several computer programs have been developed for profiling purposes, most recently in Smulders (1986); Lappalainen (1986), and Rickards (1991). The SPACES program (Vickridge and Amsel, 1990) was developed especially for high-resolution surface studies using very narrow resonance. This program is also available from the Sigmabase.

A simple example is shown in Figure 6. In this experiment an ^{18}O profile was measured in YBaCuO using the already mentioned ^{18}O(p, α)^{15}N reaction. From the spectrum

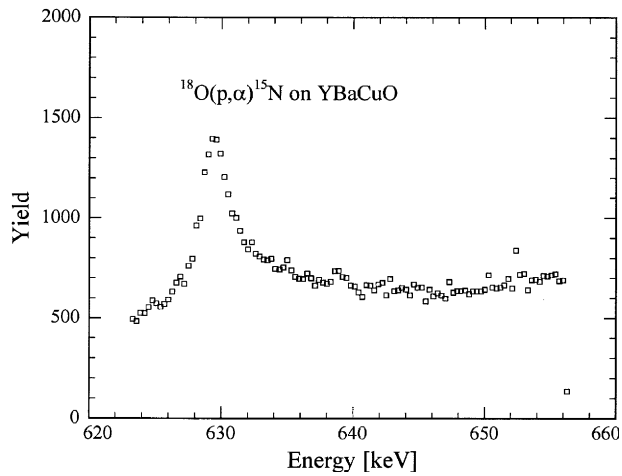

Figure 6. Excitation function of the ^{18}O(p, α)^{15}N reaction measured on an ^{18}O-enriched YBaCuO sample (Cheang-Wong, 1992).

we can deduce qualitatively that there is an ^{18}O enrichment on the surface. Using Equation 6, we can estimate the thickness of the enriched region (width of the peak divided by the stopping power of proton around the resonance energy), which is about 20 nm. Using simulation of the excitation curve and a nonlinear fit to the measured excitation function gives a 15-nm-thick layer enriched to 30% ^{18}O with 3.5% constant volume enrichment.

A recent review of the computer simulation methods in IBA can be found in Vizkelethy (1994).

SPECIMEN MODIFICATION

Although NRA and PIGE are nondestructive techniques, certain modifications to the samples can occur due to the so-called beam effect. Since a high-energy ion beam is bombarding the sample surface during the measurement, considerable heat transfer occurs. A 1-MeV ion beam with 1-$\mu A/cm^2$ current (not unusual in NRA and PIGE) means 1-W/cm^2 heat is transferred to the sample. This can be a serious problem in biological samples, and the measurement can lead to the destruction of the samples. In good heat-conducting samples, the heat does not cause a big problem, but diffusion and slight structural changes can occur. Poor heat-conducting samples will suffer local overheating that can induce considerable changes in the composition of the sample.

Apart from the heat delivered to the sample, the large measuring doses can cause considerable damage to single-crystal samples. It is especially significant in heavy-ion beams, such as ^{15}N, which is used to profile hydrogen using the $^1H(^{15}N, \alpha\gamma)^{12}C$ reaction. In this case significant hydrogen loss can occur during the analysis. Heavy ions also can cause ion beam mixing and sputtering.

To avoid these problems, the beam should be spread out over a large area on the sample if high current must be used or the current should be kept at the minimum acceptable level.

PROBLEMS

Several factors can lead to false results. Most of them can be minimized with careful design of the measurement.

A frequently encountered problem is the inability to precisely measure the current. The secondary electrons emitted from the sample can falsify the current measurement and thus measurement of the collected charge. To minimize the effect of secondary electron emission, several techniques can be used:

1. A suppression cage around the sample holder will minimize the number of escaping electrons, but it is not possible to build a perfect suppression cage. A much simpler technique is to apply positive bias to the sample, but this alternative cannot be used for every sample.
2. Isolating the scattering chamber from the rest of the beamline and allowing its use as a Faraday cup is also a good solution, but in many cases the chamber is connected electrically to other equipment that cannot be isolated.
3. There are different transmission Faraday cup designs where the current is measured not on the sample but in a separate Faraday cup that intercepts the beam in front of the sample several times per second.
4. As described above (see Practical Aspects of the Method), standards can be used to accurately measure current.

Another problem is hydrocarbon layer deposition during measurement. This can cause serious problems when narrow resonances are used for depth profiling. The incident ions will lose energy in the hydrocarbon layer that has an unknown thickness. This can lead to a false depth scale if the energy loss is significant in the hydrocarbon layer. Since the hydrocarbon layer formation is slower in higher vacuum, the best way to minimize its effect is to maintain good vacuum (see GENERAL VACCUM TECHNIQUES). Cold traps in the beamline and in the scattering chamber can significantly reduce hydrocarbon layer formation. Another way to minimize the effect of the carbon layer in case of resonance profiling (when many measurements have to be made on the same sample) is to frequently move the beam spot to a fresh area.

Interference from the elements of the matrix can be another problem. This is a potential danger in deuteron-induced reactions. Many light elements have (d, p) or (d, α) reactions, and the protons and α particles can overlap in the spectrum. Careful study of the kinematics and the choice of appropriate absorber foil thickness can solve this problem, although in certain cases the interference cannot be avoided. In PIGE, when there are interfering reactions, the use of a Ge(Li) or HPGE detector can help. The better resolution of germanium detectors allows the separation of the γ peaks from the different reactions, but at the cost of lower efficiency.

A special problem arises in single-crystal samples—accidental channeling. When the direction of the incident ions coincides with one of the main axes of the crystal, the ions are steered to these channels and the reaction yield becomes lower than it would otherwise be. (Also there is a difference between the energy loss of ions in a channel and in a random direction, which can affect the energy-to-depth conversion.) The solution is to tilt the samples to 5° to 7° with respect to the direction of the beam. (There are cases when channeling is preferred. Using NRA or PIGE combined with channeling, the lattice location of atoms can be determined.)

Electrically nonconducting samples will become charged under ion bombardment up to voltages of several kilovolts, and this can modify the beam energy. This can be especially detrimental when narrow (few hundred electron volts wide) resonances are used for depth profiling. There are several solutions to avoid surface charging: (1) A thin conducting coating (usually carbon) on the surface of the sample can reduce the charging significantly. (2) Supplying low-energy electrons from a hot filament will neutralize the accumulated positive charge on the sample surface.

A problem can arise from the careless use of the fitting programs. As in any deconvolution problem, there is usually no unique solution determined by the measured yield curve only. (One example is the fact that these deconvolutions tend to give an oscillating depth profile, which is in most cases obviously incorrect.) Extra boundary conditions and assumptions for the profile are needed to make the solution acceptable.

APPENDIX

Energy Relations in Nuclear Reactions

In a charged particle reaction, the energies of the emitted particles in the laboratory coordinate system are (see Fig. 7):

$$E_{\text{light}} = B\left(\cos\psi \pm \sqrt{\frac{D}{B} - \sin^2\psi}\right)^2 (E_0 + Q) \qquad (7)$$

$$E_{\text{heavy}} = A\left(\cos\varphi \pm \sqrt{\frac{C}{A} - \sin^2\varphi}\right)^2 (E_0 + Q) \qquad (8)$$

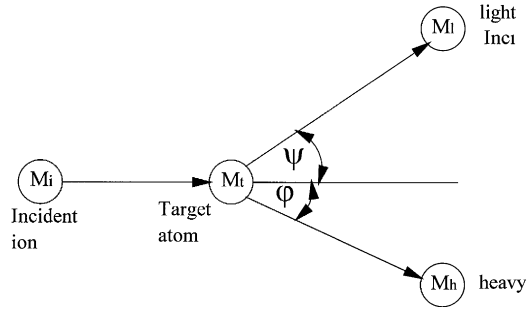

Figure 7. Reaction kinematics.

where E_0 is the energy of the incident ions; Q is the Q value of the reaction; and A, B, C, and D are given as

$$\begin{aligned} A &= \frac{M_1 M_4}{(M_1+M_2)(M_3+M_4)} \frac{E_0}{E_0+Q} \\ B &= \frac{M_1 M_3}{(M_1+M_2)(M_3+M_4)} \frac{E_0}{E_0+Q} \\ C &= \frac{M_2 M_3}{(M_1+M_2)(M_3+M_4)} \left(1 + \frac{M_1 Q}{M_2(E_0+Q)}\right) \\ D &= \frac{M_2 M_4}{(M_1+M_2)(M_3+M_4)} \left(1 + \frac{M_1 Q}{M_2(E_0+Q)}\right) \end{aligned} \qquad (9)$$

where M_1, M_2, M_3, and M_4 are the masses of the incident ion, the target nucleus, the lighter reaction product, and the heavier product, respectively.

In Equation 7 only plus signs are used unless $B > D$, in which case $\psi_{\max} = \sin^{-1}\sqrt{D/B}$, and in Equation 8 only plus signs are used unless $A > C$, in which case $\varphi_{\max} = \sin^{-1}\sqrt{C/A}$. The emitted particle then loses energy along its path until it leaves the target. The energy loss of ions inward and outward is described by Equations 8 and 9.

Energy Spread (Depth Resolution)

Equations 2 and 3 are true only on the average. Since the energy loss is a stochastic process, the ions, after passing a certain thickness, will have an energy distribution rather than a sharp energy. This phenomenon is called straggling. There are several models to describe the energy straggling; in most cases, the simplest one, Bohr straggling, is satisfactory. [One exception is the case of very narrow resonances, which is described in details in Maurel (1980) and Vickridge (1990).]

There are other factors that cause broadening of the energy in the detected spectrum. The following contribute to the energy spread of detected particles in NRA: (1) initial energy spread of the incident beam, (2) straggling of the incident ions, (3) multiple scattering, (4) geometric spread due to the finite acceptance angle of the detector and to the finite beam size, (5) straggling of the outgoing particles, (6) energy resolution of the detector, and (6) energy straggling in the absorber foil.

A detailed treatment of most of these factors can be found in Vizkelethy (1994). In PIGE and resonant depth profiling with NRA, only a few contribute to the depth resolution. Since the energy of the detected particles or γ

rays is not used to extract concentration profile information, only the initial energy spread, the straggling of the incident beam, and the resonance width determine the depth resolution. (The contribution from the multiple scattering is negligible since then normal incidence is used.)

Calculation of the Excitation Function for Resonance Depth Profiling

The excitation function at an E_0 incident energy is

$$Y(E_0) \propto \sigma(E_0) * h(E_0) * \int_0^\infty c(x) g(E_0; x)\, dx \qquad (10)$$

where $\sigma(E_0)$ is the reaction cross-section, $h(E_0)$ is the initial energy distribution of the ion beam, $c(x)$ is the concentration profile of the atoms to be detected, $g(E; x)$ is the probability that an ion loses E energy when penetrating a thickness x, and the asterisk denotes convolution. [This convolution is a very complicated calculation; for details see Maurel (1980) and Vickridge (1990).] When the resonance is not extremely narrow, the initial energy spread of the ions is not too small, and the profile is not measured very close to the surface (the energy loss is large enough that the straggling can be considered Gaussian); the function $g(E; x)$ can then be approximated with a Gaussian:

$$g(E; x) = \frac{1}{\sqrt{2\pi s^2(x)}} e^{-[E-E(x)]^2/2s^2(x)} \qquad (11)$$

where $E(x)$ is the same as $E_{\text{in}}(x)$ in Equation 3 and $s(x)$ is the root-mean-square energy straggling at x. If the resonance cross-section is given by a Breit-Wigner resonance (Blatt and Weiskopf, 1994),

$$\sigma(E_0) = \sigma_0 \frac{\Gamma^2/4}{\Gamma^2/4 + (E - E_{\text{R}})^2} \qquad (12)$$

where σ_0 is the strength, Γ is the width, and E_{R} is the energy of the resonance, then the straggling, the Doppler-broadening, and the initial energy spread can be combined into a single Gaussian with depth-dependent width. Evaluating Equation 10, the excitation function is

$$Y(E_0) \propto \int_0^\infty c(x)\sigma_0 \frac{\Gamma}{\sqrt{8}S(x)} \text{Re}\, w\left(\frac{E_0 - E_R}{\sqrt{2}S(x)} - i\frac{\Gamma}{\sqrt{8}S(x)}\right) dx \qquad (13)$$

where $\text{Re}\, w(z)$ is the real part of the complex error function and $S(x)$ the width of the combined Gaussian.

PARTICLE-INDUCED X-RAY EMISSION

INTRODUCTION

Particle-induced x-ray emission (PIXE) is an elemental analysis technique that employs a mega-electron-volt energy beam of charged particles from a small electrostatic accelerator to induce characteristic x-ray emission from the inner shells of atoms in the specimen. The accelerator can be single ended or tandem. Most PIXE work is done with 2- to 4-MeV proton beams containing currents of a few nanoamperes within a beam whose diameter is typically a few millimeters; a small amount of work with deuteron and helium beams has been reported, and use of heavier ion beams has been explored. The emitted x rays are nearly always detected in the energy-dispersive mode using a Si(Li) spectrometer. Although wavelength-dispersive x-ray spectrometry would provide superior energy resolution, its low geometric efficiency is a significant disadvantage for PIXE, in which potential specimen damage by heating limits the beam current and therefore the emitted x-ray intensity. In the proton microprobe, magnetic or electrostatic quadrupole lenses are employed to focus the beam to micrometer spot size; this makes it possible to perform micro-PIXE analysis of very small features and, also, by sweeping this microbeam along a preselected line or over an area of the specimen, to determine element distributions in one or two dimensions in a fully quantitative manner. Most proton microprobes realize a beam spot size smaller than a few micrometers at a beam current of at least 0.1 nA. In trace element analysis or imaging by micro-PIXE, the high efficiency of a Si(Li) detector, placed as close to the specimen as possible, is again mandatory for x-ray collection. To date, PIXE and micro-PIXE have most often been used to conduct trace element analysis in specimens whose major element composition is already known or has been measured by other means, such as electron microprobe analysis. However, both variants are capable of providing major element analysis for elements of atomic number down to $Z = 11$.

Competing Methods

In the absence of beam focusing, conventional PIXE is an alternative to x-ray fluorescence analysis (XRFA; see X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ANALYSIS) but requires more complex equipment. Micro-PIXE is a powerful and seamless complement to electron microprobe analysis (EPMA), a longer established microbeam x-ray emission method based on excitation by kilo-electron-volt electron beams; detection limits of a few hundred parts per million in EPMA compare with limits of a few parts per million in micro-PIXE. While the electron microprobe is ubiquitous, there are only about 50 proton microprobes around the world, but many of these can provide beam time on short notice. Conducted with the highly polarized x radiation from a synchroton storage ring equipped with insertion devices such as wigglers and undulators, XRFA now provides a strong competitor to micro-PIXE in terms of both spatial resolution (a few micrometers) and detection limits (sub−parts per million). The x-ray spectrum from an undulator is highly collimated, extremely intense, and nearly monochromatic; the exciting x-ray energy can be tuned to lie just above the absorption edge energy of the element of greatest interest, where the photoabsorption cross-section is highest, thereby optimizing the detection limit. However, there are only a handful of synchrotron facilities, and beam time is at a premium. A

much cheaper method of obtaining an x-ray microbeam is through the use of a conventional fine-focus x-ray tube and a nonimaging optical system based upon focusing capillaries (Rindby, 1993). Total-reflection XRFA (Klockenkamper et al., 1992) offers similar detection limits, but this method is restricted to very thin films deposited on a totally reflecting substrate and lacks the versatility of PIXE and XRFA as regards different specimen types. One of PIXEs merits relative to XRFA is the possibility of deploying other ion beam analysis techniques simultaneously or sequentially; these include Rutherford backscattering spectroscopy (see MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY and HEAVY-ION BACKSCATTERING SPECTROMETRY), nuclear reaction analysis (NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION), ionoluminescence, and scanning transmission ion microscopy (STIM).

Optical spectroscopy methods based on emission (AES—atomic emission spectroscopy) and absorption (AAS—atomic absorption spectroscopy) are the workhorses of trace element analysis in materials that can be reduced to liquid form or dissolved in a liquid and then atomized. The inductively coupled plasma (ICP) has become the method of choice for inducing light emission, and ICP-AES attains detection limits of 1 to 30 ng/mL of liquid; the limits referred to the original material depend on the dilution factor and typically reach down to 0.1 ppm. Interference effects among optical lines are more complex than is the case in PIXE with x-ray lines. Use of mass spectrometry (ICP-MS) reduces interferences, provides a more complete elemental coverage than ICP-AES, and has much less element-to-element variation in sensitivity than does ICP-AES; its matrix effects are less straightforward to handle than those of PIXE. Overall, PIXE is more versatile as regards specimen type and preparation than ICP-AES and ICP-MS and has the advantages of straightforward matrix correction, smoothly varying sensitivity with atomic number, and high accuracy. But for conventional bulk analysis, the highly developed optical and mass spectrometry methods will frequently be more accessible and entirely satisfactory and provide excellent detection limit without the need for an accelerator. For particular specimen types such as aerosol particulates and awkwardly shaped specimens (e.g., in archaeology) requiring nondestructive analysis, PIXE has unique advantages. The ability to handle awkwardly shaped specimens by extracting the proton beam through a thin window into the laboratory milieu is particularly valuable in archaeometric applications.

The nondestructive nature, high spatial resolution, parts per million detection limits, and high accuracy of micro-PIXE together with the simultaneous deployment of STIM and backscattering make it very competitive with other microprobe methods. It has been applied intensively in the analysis of individual mineral grains and in zoning phenomena within these, individual fly-ash particles, single biological cells, and thin tissue slices containing features such as Alzheimer's plaques (Johansson et al., 1995). Secondary ion mass spectrometry (SIMS) often provides better detection limits but is destructive. The combination of laser ablation microprobe with inductively coupled plasma (ICP) excitation and mass spectrometry offers resolution of some tens of micrometers and detection limits as low as 0.5 ppm; however, the ablation basis of this method renders matrix effects and standardization more complex than in micro-PIXE.

Detailed accounts of the fundamentals and of many applications can be found in two recent books on PIXE (Johansson and Campbell, 1988; Johansson et al., 1995), the first of which provides considerable historical perspective. The present offering is an overview, including some typical applications. The proceedings of the triennial international conferences on PIXE provide both an excellent historical picture and an account of recent developments and new applications.

PRINCIPLES OF THE METHOD

The most general relationship between element concentrations in a specimen and the intensity of detected x rays of each element is derived for the simple case of K x rays (see Appendix A). The L and M x rays may be dealt with in similar manner, with the added complexity that in these cases ionization occurs in three and five subshells, respectively, and there is the probability of vacancies being transferred by the Coster-Kronig effect to higher subshells prior to the x-ray emission occurring. In principle, Equation 6 could be used to perform standardless analysis; this would involve a complete reliance on the underlying theory and the database and on the assumed properties of the x-ray detector. At the other extreme, by employing standards that very closely mimic the major element (matrix) composition of a specimen, the PIXE analyst working on trace elements could completely avoid dependence upon theory and rely only upon calibration curves relating x-ray yield to concentration. In practice, there is much practical merit in adopting an intermediate stance. We recommend a fundamental parameter approach using the well-understood theories of the interaction of charged particle beams and photon beams with matter and of characteristic x-ray emission from inner shell vacancies but also relying on a small set of standards that need bear only limited resemblance to the specimens at hand.

In this approach the equation used to derive element concentrations from measured x-ray intensities is

$$Y(Z) = Y_1(Z) H \varepsilon_Z t_Z C_Z Q \qquad (1)$$

where $Y(Z)$ is the measured intensity of x rays in the principal line of element Z (concentration C_Z), $Y_1(Z)$ is the theoretically computed intensity per unit beam charge per unit detector solid angle per unit concentration, H is an instrumental constant that subsumes the detector solid angle and any calibration factor required to convert an indirect measurement of beam charge to units of microcoulombs, Q is the direct or indirect measure of beam charge, t_Z is the x-ray transmission fraction through any absorbers (see Practical Aspects of the Method) that are deliberately interposed between specimen and detector, and ε_Z is the detector's intrinsic efficiency. It is also straightforward to

calculate the contribution of secondary x rays fluoresced when proton-induced x rays are absorbed in the specimen and to correct for these. The various atomic physics quantities required are obtained from databases that have been developed by fitting appropriately parameterized expressions (in part based on theory and in part semiempirical) to either compilations of experimental data or theoretically generated values. The H value is determined via Equation 1 by use of appropriate standards or standard reference materials. It is implicit in the direct use of Equation 1 that the major elements have already been identified and that their concentrations are known *a priori*. This permits computation of the integrals that involve matrix effects (slowing down of the protons and attenuation of the x rays); Equation 1 then provides the trace element concentrations. However, if the x-ray lines of the major elements are observed in the spectrum, Equation 1 may be solved in an iterative manner to provide both major and trace element concentrations.

The method is fully quantitative, and its accuracy is determined in part by the accuracy of the database. The theoretically computed x-ray intensity uses ionization cross-sections and stopping powers for protons, x-ray mass attenuation coefficients, x-ray fluorescence yields and Coster-Kronig probabilities for the various subshells, and relative intensities of the lines within each x-ray series (e.g., K, L_1, ...) emitted by a given element. For ionization cross-sections, the choice is among the hydrogenic model calculations of Cohen and Harrigan (1985, 1989) or of Liu and Cipolla (1996) based on the so-called ECPSSR model of Brandt and Lapicki (1981), the equivalent but more sophisticated ECPSSR treatment of Chen and Crasemann (1985, 1989) based on self-consistent field wave functions, or experimental cross-section compilations such as those of Paul and Sacher (1989) for the K shell and Orlic et al. (1994) for the L subshells. Proton stopping powers (i.e., rate of energy loss as a function of distance traveled in an element) are usually taken from one of the various compilations of Ziegler and his colleagues, which are summarized in a report by the International Commission on Radiation Units and Measurements (1993). A variety of mass attenuation coefficient schemes ranging from theoretical to semiempirical have been used, and the XCOM database provided by the National Institute of Science and Technology (NIST; Berger and Hubbell, 1987) appears to us to be admirably suited. The relative x-ray intensities within the K and L series are invariably taken from the calculations of Scofield (1974a,b, 1975) and from fits to these by Campbell and Wang (1989), although corrections must be made for the K x rays of the elements $21 < Z < 30$ where configuration mixing effects arising from the open $3d$ subshell cause divergences; relative intensities for the M series are given by Chen and Crasemann (1984). Atomic fluorescence and Coster-Kronig probabilities may be taken from the theoretical calculations of Chen et al. (1980a,b, 1981, 1983) or from critical assessments of experimental data such as those of Krause (1979) and Bambynek (see Hubbell, 1989). Campbell and Cookson (1983) have assessed how the various uncertainties in all these quantities are transmitted into accuracy estimates for PIXE, but the best route for assessing overall accuracy remains the analysis of known reference materials.

The intrinsic efficiency of the Si(Li) x-ray detector enters Equation 1 and so must be known. This efficiency is essentially unity in the x-ray energy region between 5 and 15 keV. At higher energies ε_Z falls off because of penetration through the silicon crystal (typically 3 to 5 mm thick). At lower energies, ε_Z falls off due to attenuation in the beryllium or polymer vacuum window, the metal contact, and internal detector effects such as the escape of the primary photoelectrons and Auger electrons created in x-ray interactions with silicon atoms and loss of the secondary ionization electrons due to trapping and diffusion. The related issues of detector efficiency and resolution function (lineshape) are dealt with below (see Appendix B).

A basic assumption of the method is that the element distribution in the volume analyzed is homogeneous. The presence of subsurface inclusions, for example, would negate this assumption. Of course, micro-PIXE can be used to probe optically visible inhomogeneities such as zoning and grain boundary phenomena in minerals and to search for optically invisible inhomogeneities in, for example, air particulate deposits from cascade impactors. It can then be used to select homogeneous regions for analysis. Given (1) homogeneity and (2) knowledge of the major element concentrations, PIXE or micro-PIXE analysis is fully quantitative, with the accuracy and the detection limits determined by the type of specimen.

A great deal of PIXE work is conducted on specimens that are so thin that the proton energy is scarcely altered in traversing the specimen and there is negligible attenuation of x rays. Films of fine particulates collected from the ambient air by sampling devices are an example. In such cases, a similar approach may be taken with concentration C_Z replaced in Equation 1 by the areal density of elements in the specimen.

The main engineering advance responsible for PIXE was the advent of the Si(Li) x-ray detector in the late 1960s. Micro-PIXE was made possible by the development of high-precision magnetic quadrupole focusing lenses in the 1970s. The acceptance of PIXE and other accelerator-based ion beam techniques stimulated advances in accelerator design that have resulted in a new generation of compact, highly stable electrostatic accelerators provided primarily for ion beam analysis.

PRACTICAL ASPECTS OF THE METHOD

Most PIXE work is done with nanoampere currents of 2- to 4-MeV protons transmitted in a vacuum beam line to the specimen. However, some laboratories extract the beam into the laboratory through a thin Kapton window to deal with unwieldy or easily damaged specimens such as manuscripts or objects of art (Doyle et al., 1991).

As with EPMA, most of the technical work for the user lies in specimen preparation (see Sample Preparation). Conduct of PIXE analysis requires an expert accelerator operator to steer and focus the beam onto the specimen.

As indicated above (see Principles of the Method), the intrinsic efficiency of the Si(Li) detector as a function of

x-ray energy is an important practical aspect. This function may be determined from, e.g., the manufacturer's data on crystal thickness and the contact and window thickness. More accurate determinations of these quantities may be effected via methods outlined below (see Appendix B). The lineshape or resolution function of the detector is required (see Data Analysis and Initial Interpretation) for the interpretation of complex PIXE spectra with their many overlapping lines. Guidance in this direction is also provided below (see Appendix B).

Specimens are generally classified as thin or thick. Thin specimens are those that cause negligible reduction in the energy of the protons, and they are usually deposited on a substrate of trace-element-free polymer film; examples include microtome slices of tissue, residue from dried drops of fluid containing suspended or dissolved solids, or films of atmospheric particulate material collected by a sampling device. Thick specimens are defined as those having sufficient areal density to stop the beam within the specimen, and they may be self-supporting or may reside on a substrate. As indicated below (see Appendix A), their analysis requires full attention to the effect of the matrix in slowing down the protons and in attenuating the excited characteristic x rays. The x-ray production decreases rapidly with depth but is significant for some 10 to 30 μm. Examples of thick specimens include mineral grains, geological thin sections, metallurgical specimens, and archaeological artefacts such as jewelry, bronzes, and pottery. Specimens between these limiting cases are referred to as having intermediate thickness, and their thickness must be known if matrix effects are to be accurately handled. In early PIXE work, many intermediate specimens were treated as if they were thin; i.e., matrix effects were neglected. However, it is now customary to correct for these, using, for example, an auxiliary proton scattering or transmission measurement to determine specimen thickness and major element composition.

With specimens that stop the beam, current and charge measurements are usually accomplished very simply by having the specimen electrically insulated from the chamber and by connecting it to a charge integrator. If thick specimens are not conducting, they must be coated with a very thin layer of carbon to prevent charging; neglecting this results in periodic spark discharge, which in turn causes intense bremsstrahlung background in the x-ray spectrum. Secondary electrons are emitted from the specimen, potentially causing an error of up to 50% in beam charge determination. These electrons must be returned to the specimen by placing a suitable electrode or grid close by, at a negative potential of typically 100 V. In thin specimens, the beam is transmitted into a graphite-lined Faraday cup, also with an electron suppressor, and the charge is integrated.

Electronic dead time effects must be accounted for. After detection of an event, there is a finite processing time in the electronic system, during which any subsequent events will be lost. A dead time signal from the pulse processor may be used to gate off the charge integrator and effect the necessary correction. Alternatively, an on-demand beam deflection system may be used. Here, the proton beam passes between two plates situated about 1 m upstream of the specimen and carrying equal voltages; detection of an x ray triggers a unit that grounds one plate as rapidly as possible, thereby deflecting the beam onto a tantalum collimator. The beam is restored when electronic processing is complete, so no corrections for dead time are required. This approach has two further advantages. The first is that specimen heating effects are reduced by removing the beam when its presence is not required. The second is that pile-up of closely spaced x-ray events is substantially decreased, thereby removing undesired artefacts from the spectrum.

The finite counting rate capacity of a Si(Li) detector and its associated pulse processor and multichannel pulse height analyzer demand that unnecessary contributions in the x-ray spectrum be minimized and as much of the capacity as possible be used for the trace element x rays of interest. Most thin-specimen analyses in the atmospheric or biological science context are performed with a Mylar absorber of typically 100 to 200 μm thick employed to reduce the intense bremsstrahlung background that lies below 5 keV in the spectrum and whose intensity increases rapidly toward lower energy. With thick metallurgical, geological, or archaeological specimens, x-ray lines of major elements dominate the spectrum, making it necessary to reduce their intensities with an aluminum absorber of thickness typically 100 to 1000 μm. For example, in silicate minerals, the *K* x rays of the major elements Na, Mg, Al, and Si occupy most of the counting rate capability; an aluminum foil of thickness 100 μm reduces the intensity of these x rays to a level such that they are still present at useful intensity in the spectrum, but the x rays from trace elements of higher atomic number can now be seen, with detection limits approaching the 1-ppm level. The thickness of such filters must be accurately determined.

As a thin-specimen example, Figure 1 shows the PIXE spectrum of an air particulate standard reference material. Proton-induced x-ray emission has proven extremely powerful in aerosol analysis, and special samplers have been devised to match its capabilities (Cahill, 1995). The low detection limits facilitate urban studies with short sampling intervals in order to determine pollution patterns over a day. At the other extreme, in remote locations, robust samplers of the IMPROVE type (Eldred et al., 1990) run twice weekly for 24-h periods at sites around the world in a project aimed at assembling continental and global data on visibility and particulate composition (Eldred and Cahill, 1994). The low detection limits match PIXE perfectly with cascade impactors, where the sample is divided according to particle diameter. Figure 2 (Maenhaut et al., 1996) presents measured detection limits for two cascade impactors that are well suited to PIXE in that they create on each impaction stage a deposit of small diameter that may be totally enveloped by a proton beam of a few millimeters in diameter. Now, PIXE appears in about half of all analyses of atmospheric aerosols in the standard aerosol journals.

Figure 3 shows an example spectrum from an "almost thin" specimen where an auxiliary technique is used to determine thickness and major element composition so that matrix corrections may be applied in the data reduction. The specimen is a slice of plant tissue, and the

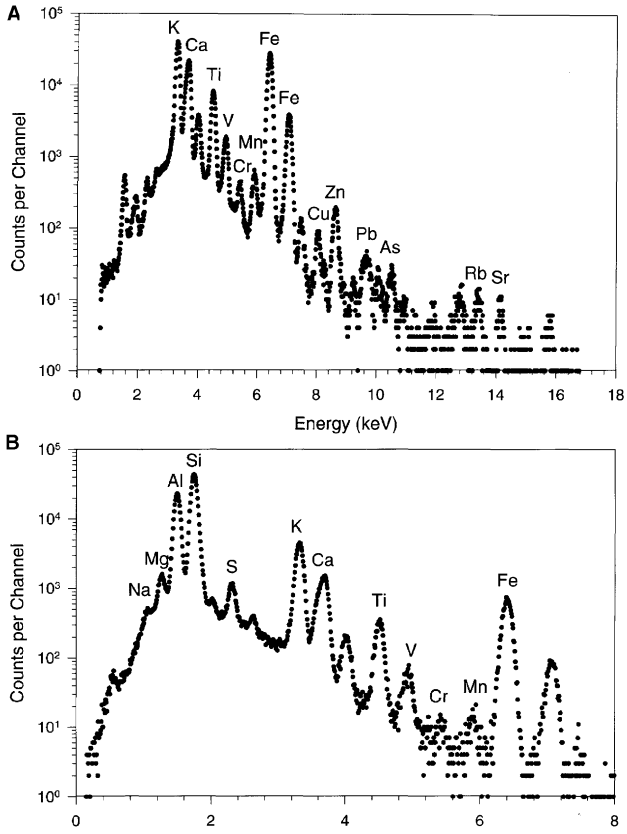

Figure 1. PIXE spectra of the BCR-128 fly ash reference standard, measured at Guelph with two x-ray detectors: **(A)** 8-μm window, no absorber; **(B)** 25-μm window, 125-μm Mylar absorber. Proton energy was 2.5 MeV.

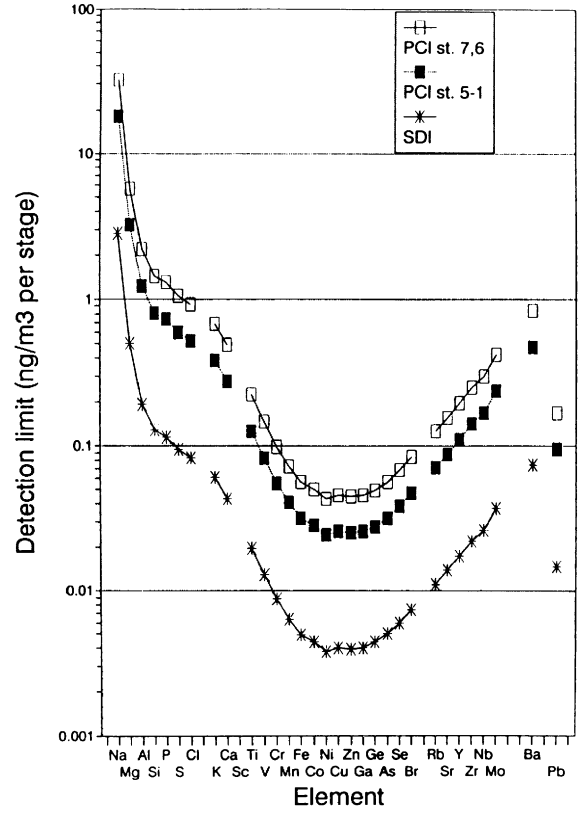

Figure 2. Detection limits for the PIXE International cascade impactor (PCI) and a small-deposit low-pressure impactor (SDI). Note that the detection limit depends upon the impactor stage. From Maenhaut et al. (1996) with permission of Elsevier Science.

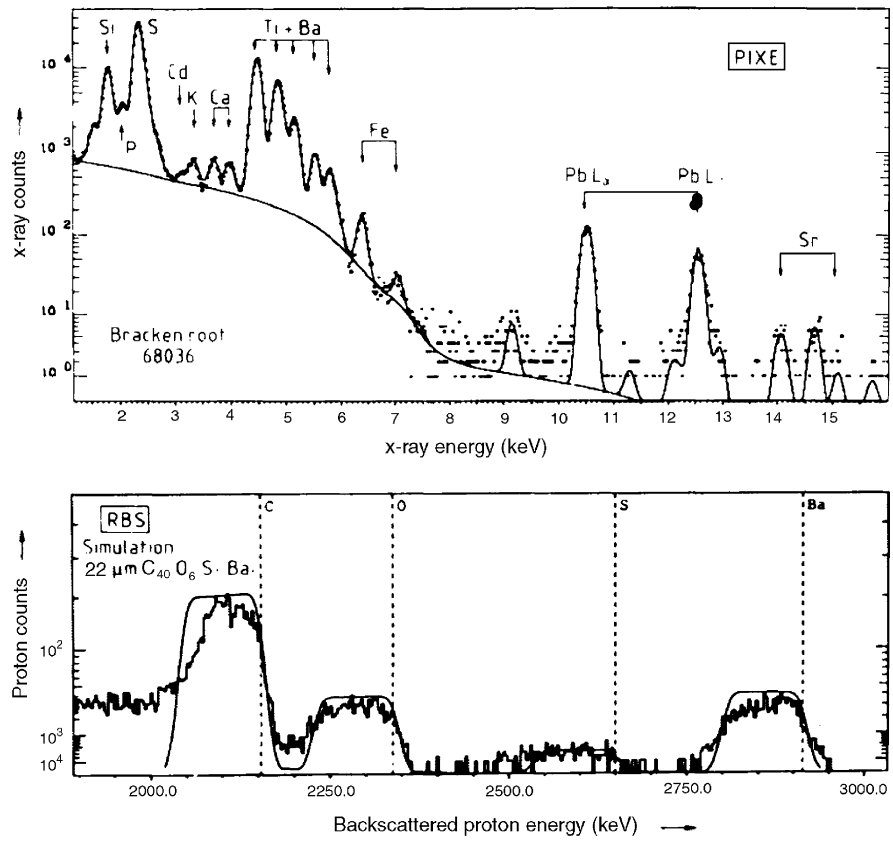

Figure 3. PIXE and proton backscattering energy spectra from a focal deposit of heavy metals in a plant root (Watt et al., 1991). Proton energy was 3 MeV. The continuous curves represent a fit (PIXE case) and a simulation (BS case). Reproduced by permission of Elsevier Science.

auxiliary technique is proton backscattering, whose results, acquired simultaneously, are in the lower panel of the figure. Many PIXE systems employ an annular silicon surface barrier detector upstream from the specimen and situated on the beam axis so that the beam passes through the annulus. This affords a detection angle close to 180° for scattered particles, which results in optimum energy resolution. This combination has proved to be a powerful means to determine major element concentrations in a large range of biological applications. Another powerful technique ancillary to micro-PIXE in the analysis of thin tissue slices is STIM. Here, a charged particle detector situated downstream from the specimen at about 15° to 25° to the beam axis records the spectrum of forward-scattered particles that reflects energy losses from both nuclear scattering and ion-electron collisions. This technique is effective in identifying structures such as individual cultured cells on a substrate, individual aerosol particles, and lesions in medical tissue. It has been used to identify neuritic plaques in brain tissue from Alzheimer's disease patients (Landsberg et al., 1992), thereby eliminating the need for immunohistochemical staining and so removing a sample preparation step that has the potential for contamination. Simultaneous recording of STIM, backscatter, and PIXE spectra and two-dimensional images has become a standard approach with biological specimens whose structure remains unaffected by preparation.

Micro-PIXE elegantly complements electron probe microanalysis in the trace element analysis of mineral grains using the same specimens and extending detection limits down to the parts per million level (Campbell and Czamanske, 1998). One major niche is the study of precious and other metals in sulfide ores. Figure 4 shows spectra of three iron-nickel sulfides (pentlandites) from a Siberian ore deposit; the large dynamic range between major elements such as iron (over 30% concentration in this case) and trace elements at tens to hundreds of parts per million concentration is typical of the earth science application area, and it necessitates use of absorbing filters (several hundred micrometers of aluminum) to depress the intensities of the intense x rays of the lighter major elements. Another important area is the study of trace elements in silicate minerals, where PIXE has aided in the development of geothermometers and fingerprinting approaches that are proving immensely powerful in, for example, assessing kimberlites for diamond potential (Griffin and Ryan, 1995).

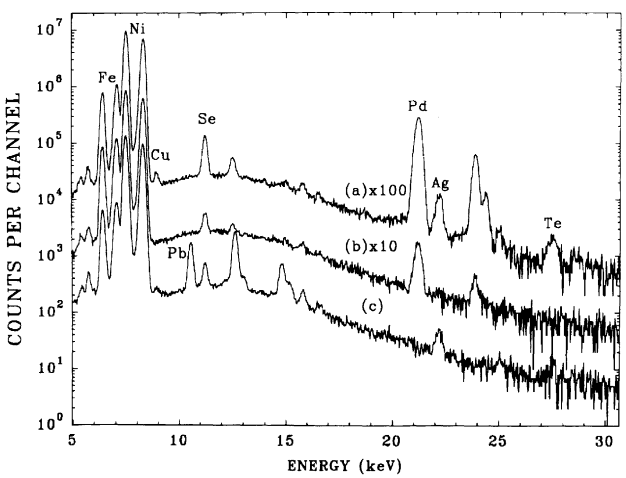

Figure 4. PIXE spectra of three Siberian pentlandites (Czamanske et al., 1992). The spectra were recorded using 3-MeV protons and an aluminum filter of 352 mm thickness. Element concentrations (in ppm) are (*a*) Se 261, Pd 2540, Ag 112, Te 54; (*b*) Se 80, Pd 132; (*c*) Se 116, Pd< 5, Ag 34, Te 36, Pb 1416.

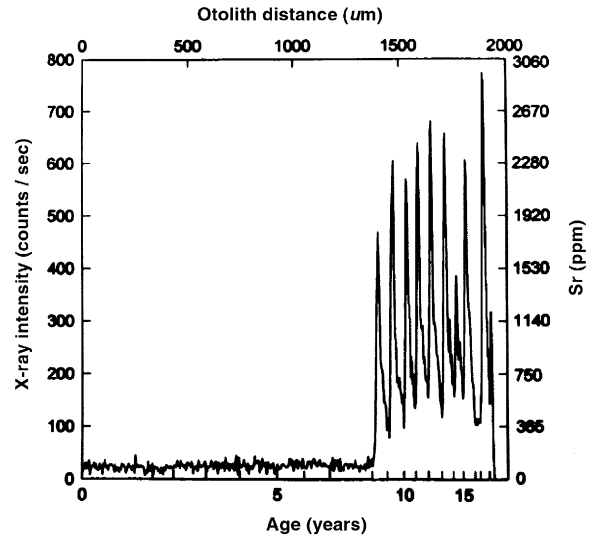

Figure 5. Strontium concentration profile in the growth zones of an otolith from an Arctic char collected from the Jayco River in the Northwest Territories of Canada (Babaluk et al., 1997). A 30-min micro-PIXE linescan was conducted using a 10 × 10-mm beam of 3-MeV protons. Reproduced by permission of the Arctic Institute of Canada.

Micro-PIXE is also widely used in trace element studies of zoned minerals, where the zoning contains information on the history of the mineral. Figure 5 shows a recently developed zoning application in calcium carbonate of biological origin—the otolith of an Arctic fish (Babaluk et al., 1997). The oscillatory behavior of Sr content in annual growth rings reflects annual migration of the fish from a freshwater lake to the open ocean, starting at age 9 years in the example shown. Micro-PIXE is now being applied in population studies for stock management.

Many more examples, including exotic ones in the fields of art and archaeometry, may be found in the book by Johansson et al. (1995). A unique example of nondestructive analysis is the use of micro-PIXE to identify use of different inks in individual letters in manuscripts. An example of a partly destructive analysis is the extraction of a very narrow core from a painting and the subsequent scanning of a microbeam along its length to identify and characterize successive paint layers.

In the absence of interfering peaks, the detection limit for an element is determined by the intensity of the continuous background on which its principal x-ray peak is superimposed in the measured spectrum. This background is due mainly to secondary electron bremsstrahlung,

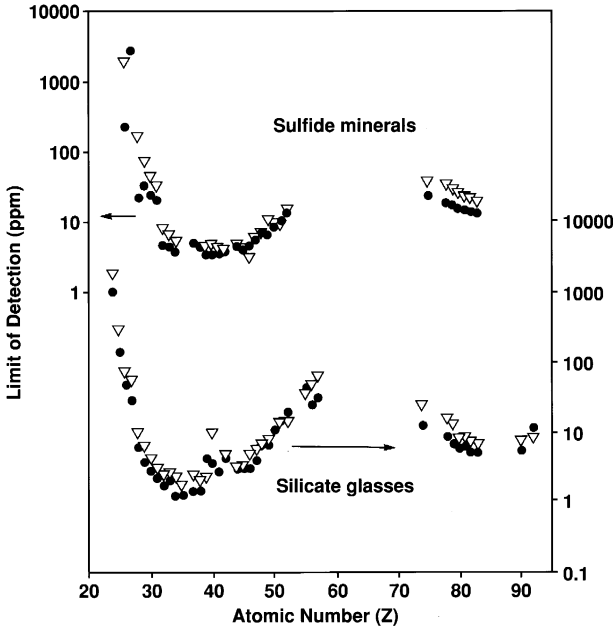

Figure 6. Micro-PIXE detection limits measured at Guelph for sulfide minerals and silicate glasses. Upper plot (left scale): triangles, pentlandites (350-μm Al filter); dots, pyrrhotite (250-mm Al filter); 10 mC of 3-MeV protons in a 5 × 10-mm spot. Lower plot (right scale): triangles, BHVO-1 basalt fused to glass; dots, rhyolitic glass RLS-158; 2.5 μC of 3-MeV protons in 5 × 10-μm spot; Al filter 250 mm.

whose intensity diminishes rapidly with increasing photon energy, but it can be augmented by gamma rays from nuclear reactions in light elements such as Na and F; these produce an essentially flat contribution to the background, visible at higher x-ray energies beyond the lower energy region where the bremsstrahlung dominates. The usual criterion is that a peak is detectable if its integrated intensity (I) exceeds a three-standard-deviation ($3\sqrt{B}$) fluctuation of the underlying background intensity (B). The desirability of a thin substrate in the case of thin specimens is obvious, since the substrate contributes only background to the spectrum. The ratio $I/3\sqrt{B}$ increases as the square root of the collected charge, suggesting that detection limits will be minimized by maximizing beam current and measuring time. Beam current is often limited by specimen damage, and measuring time may be limited by cost. Detection limits should be quoted for a given beam charge and detector geometry. The Z dependence of detection limits is U shaped, as shown in the examples of Figure 6, and this reflects the theoretical x-ray intensity expression that is included in Equation 1. For many thick specimen types, major elements contribute intense peaks and both pile-up continua and pile-up peaks to the spectrum, and these can locally worsen detection limits considerably; electronic pile-up rejection or on-demand beam deflection, which minimize such artefacts, are therefore necessary parts of a PIXE system.

The hazards of the technique are those involved with operation of any small accelerator operating with low beam currents. While radiation fields just outside the specimen chamber are very small, steps are necessary to shield radiation from beam-defining slits and from the accelerator itself. Special precautions (Doyle et al., 1991) are necessary if the beam is extracted through a window into the laboratory to analyze large or fragile specimens.

METHOD AUTOMATION

Specimen chambers usually accommodate many specimens, and computer-controlled stepping motors, either inside or outside the vacuum, are employed to expose these sequentially to the beam and to control all other aspects of data acquisition, e.g., charge measurement and selection of absorbing filter. In the case of micro-PIXE, the coordinates for each point analysis, linescan, or area map may be recorded by optical examination at the outset, permitting subsequent unsupervised data acquisition. Human intervention is only needed to break vacuum and insert new specimen loads into the analysis chamber, reevacuate, and input the parameters of the measurement (e.g., integrated charge per specimen). However, the accelerator itself is rarely automated, and a technical expert is required to steer and focus the beam prior to the analysis.

DATA ANALYSIS AND INITIAL INTERPRETATION

On the assumption that the volume sampled by the beam is homogeneous, the method is fully quantitative. Prior to analysis of measured spectra, checks are necessary to ensure that the expected detector energy resolution was maintained and that counting rate was in the proper domain.

The main step in data analysis is a nonlinear least-squares fit of a model energy-dispersive x-ray spectrum to the measured spectrum. The software requires the database mentioned earlier to describe the x-ray production process, a representation (Gaussian with corrections, as outlined below; see Appendix B) of the peaks in the energy-dispersed spectrum, and a means of dealing with continuous background; the latter may be fitted by an appropriate expression or removed by applying an appropriate algorithm prior to the least-squares fitting. Accurate knowledge of the properties of the detector and of any x-ray absorbers introduced between specimen and detector is necessary.

The quantities determined by the fit are the heights, and therefore the intensities, of the principal x-ray line of each element present in the spectrum. The intensities of all the remaining lines of each element are then set by that of the element's main line together with the relative x-ray intensity ratios provided by the database; these ratios are adjusted to reflect the effects of both absorber transmission and detector efficiency. For thick specimens, the database intensity ratios are also adjusted to reflect the effects of the matrix. This last adjustment is straightforward in a trace element determination in a known matrix; the matrix corrections to the ratios remain fixed through the iterations of the fit. The more complex case of major element measurement will be discussed below. Given the

very large number of x-ray lines present, the number of pile-up combinations can run into hundreds, and these double and triple peaks must also be modeled. A sorting process is used to eliminate pile-up combinations that are too weak to be of importance.

The final intensities provided by the fit for the principal lines of each element present are corrected for secondary fluorescence contributions, for pulse pile-up, and dead time effects (if necessary), prior to conversion to concentrations using Equation 1.

There is a linear relationship between the x-ray energy and the corresponding channel number of the peak centroid in the spectrum, and there is a linear relationship between the variance of the Gaussian peaks and the corresponding x-ray energy. The four system calibration parameters inherent in these relationships may be fixed or variable in the fitting process. The latter option has merit in that it accounts for small changes due to electronic drifts and does not require that the system be preset in any standard way.

If the major element concentrations are known *a priori*, then the second step, the conversion of these peak intensities to concentrations, is accomplished directly from Equation 1 or a variant thereof using the instrumental constant H, which is determined either using standards or from known major elements in the specimen itself. If the major elements have to be determined by the PIXE analysis, then Equation 1 has to be solved by an iterative process, starting with some estimate of concentrations and repeating the least-squares fit until consistency is achieved between the concentrations utilized and generated by Equation 1.

Various software packages are available for the above tasks (Johansson et al., 1995). They differ mainly in the databases that they adopt and in their approaches to handling the continuous background component of the spectra. The first option for the background is to add an appropriate expression to the peak model, thus describing the whole spectrum in mathematical terms, and then determine the parameter values in the background expression via the fitting process; the most common choice to describe the background has been an exponential polynomial of order up to 6 for the electron bremsstrahlung plus a linear function for the gamma ray component. The first of these two expressions must be modified to describe filter transmission and detector efficiency effects; the second needs no modification, because high-energy gamma rays are not affected by the absorbers and windows. While one particular form of expression may cope well, in an empirical sense, with a given type of specimen, there is little basis for assuming that the expressions described will be universally satisfactory. This has led to approaches that involve removing the background continuum by mathematically justifiable means. The simplest such approach, developed in the electron microprobe analogue, involves convoluting the spectrum with the "top-hat" filter shown in Figure 7. Such a convolution reduces a linear background to zero and will therefore be effective if the continuum is essentially linear within the dimensions of the filter. These dimensions are prescribed by Schamber (1977) as UW = 1 FWHM and LW = 0.5 FWHM, where FWHM is the full width at half-maximum of the resolution function at the

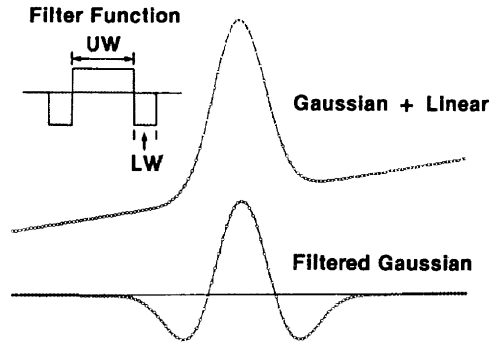

Figure 7. Top-hat filter and its effect on a Gaussian peak with linear background: UW and LW are the widths of the central and outer lobes.

x-ray energy specified. A more sophisticated multistep approach to continuum removal uses a peak-clipping algorithm to remove all peaks from the measured spectrum, and Ryan et al. (1988) have developed a version of this that is configured to cope with the very large dynamic range in peak heights that are encountered in PIXE spectra. First, the measured spectrum is smoothed by a "low-statistics digital filter" of variable width; at each channel of the spectrum this width is determined by the intensity in that channel and its vicinity. As the filter moves from a valley toward a peak, the smoothing interval is reduced to prevent the peak intensity from influencing the smoothing of the valley region. In a second step, a double-logarithmic transformation of channel content is applied, i.e.,

$$z = \ln[\ln(y + 1)] \tag{2}$$

in order to compress the dynamic range. The third step is a multipass peak clipping, in which each channel content $z(c)$ is replaced by the lesser of $z(c)$ and

$$\bar{z} = \frac{1}{2}[z(c + w) + z(c - w)] \tag{3}$$

where the scan width w is twice the FWHM corresponding to channel c. After no more than 24 passes, during which w is reduced by a factor of 2, a smooth background remains. The final step is to transform this background back through the inverse of Equation 2. The accuracy of this so-called SNIP (statistics-insensitive nonlinear peak-clipping algorithm) approach has been demonstrated in many PIXE analyses of geochemical reference materials (Ryan et al., 1990).

The VAX software package GEOPIXE (Ryan et al., 1990) is designed for thick specimens encountered in geochemistry and mineralogy and can also provide accurate elemental analysis of subsurface fluid inclusions (Ryan et al., 1995). It is installed in various micro-PIXE laboratories concerned with geochemical applications. It takes the SNIP approach to dealing with the background continuum. The widely used PC package GUPIX (Maxwell et al., 1989, 1995) deals with thin-, thick-, intermediate-, and multiple-layer specimens, employing the simple top-hat filter method to strip background. GUPIX offers the

option, useful in mineralogy, of analyzing in terms of oxides rather than elements; this enables the user to compare the sum of generated oxide concentrations to 100% and draw appropriate conclusions. GUPIX also allows the user to include one "invisible" element in the list of elements to be included in the calculation, requiring the sum of concentrations of all "visible" elements and the invisible element to sum to 100%; this can be used to determine oxygen content in oxide minerals or sulfide content in sulfide minerals when the oxygen and sulfur K x rays are not observable in the spectrum (as is usually the case). The GUPIX code can provide analysis and thickness determination of multilayer film structures, provided that the elements whose concentrations in a given layer are to be determined are not also present at unknown concentrations in any other layer. GUPIX is presently being extended to cope with analysis using deuteron and helium beams (Maxwell et al., 1997).

The above has been concerned with PIXE analysis for element concentrations in a fixed area on the specimen. In imaging applications, the beam is scanned over the specimen, and a record is built of the coordinates and channel number of each recorded x-ray event. From this record, a one- or two-dimensional image may be reconstructed using the spectrum intensity in preset "windows" to represent amounts of each element in a semiquantitative fashion. Obviously, such an approach can encounter errors due to peak overlap, but these may be dealt with by appropriate nonlinear least-squares spectrum fitting upon conclusion of the analysis. It is, however, desirable to transform observed window intensities into element concentrations in real time, updating as the data accumulate. Such a dynamic analysis method has been developed by Ryan and Jamieson (1993), and it enables on-line accumulation of PIXE maps that are inherently overlap resolved and background subtracted.

Returning now to direct analysis, standard reference materials of a similar nature to each specimen type of interest should be analyzed to demonstrate, e.g., accuracy and detection limits, which are determined in part by the measurement and in part by the fitting procedure. There are many examples of the accurate analysis of standard reference materials (SRMs). Table 1 shows the results of PIXE analysis by Maenhaut (1987) of the European Community fly-ash reference material used to simulate exposed filters from air particulate samplers. Agreement between measured and certified values is excellent, except for the elements of very low atomic number; these light elements tend to occur in larger soil-derived particles, and the data treatment used did not account for particle size effects. Table 2 summarizes a PIXE study of eight biological standard reference materials prepared for PIXE analysis by two different methods; one method (A) involved direct deposition of freeze-dried powder on the polymer substrate, and the other (D) involved Teflon bomb digestion of the powder followed by deposition and drying of aliquots. Table 3 shows micro-PIXE analyses of geochemical reference standards from three laboratories that specialize in earth science applications of micro-PIXE; these are the Commonwealth Scientific and Industrial Research Organization (CSIRO) in Australia, the University of Guelph in Canada, and the National Accelerator Center at Faure in South Africa; details of these analyses are given by Campbell and Czamanske (1998). In such studies, the accuracy of the PIXE technique is usually assessed by comparing the mean element concentrations over several replicate samples (or spots on the same sample in the micro-PIXE case). In these and other such studies, the accuracy is typically a few percent when the concentration is well above the detection limit. The matter of reproducibility or precision is discussed below (see Problems).

Table 1. Analysis by PIXE of Thin Films (BCR 128) Containing Certified Fly Ash (BCR 38)[a]

Element	Reference Value[a,b]	PIXE Value[c]	PIXE/ Reference[d]
Mg[e]	9.45 ± 0.34[f]	8.3 ± 1.1	0.88 ± 0.12
Al[e]	127.5 ± 4.9[f]	104.0 ± 1.6	0.82 ± 0.01
Si[e]	227 ± 12[f]	176.0 ± 2.1	0.78 ± 0.01
P[e]		1.60 ± 0.15	
S[e]	3.89 ± 0.13[f]	4.17 ± 0.03	1.07 ± 0.01
K[e]	34.1 ± 1.6[f]	30.6 ± 0.7	0.90 ± 0.02
Ca[e]	13.81 ± 0.63[f]	13.35 ± 0.16	0.97 ± 0.01
Ti[e]		5.07 ± 0.12	
V	334 ± 23	340 ± 2	1.02 ± 0.07
Cr	178 ± 12	161 ± 16	0.90 ± 0.09
Mn	479 ± 16	454 ± 10	0.95 ± 0.02
Fe	33.8 ± 0.7	32.9 ± 0.5	0.97 ± 0.01
Ni	194 ± 26	192 ± 8	0.99 ± 0.04
Cu	176 ± 9	169 ± 8	0.96 ± 0.05
Zn	581 ± 29	572 ± 18	0.98 ± 0.03
Ga		56.2 ± 4.5[g]	
Ge		16.3 ± 4.7[g]	
As	48.0 ± 2.3	49 ± 11[g]	1.02 ± 0.23
Br		29 ± 7[g]	
Rb		183 ± 18[g]	
Sr		187 ± 18[g]	
Zr		169 ± 23[g]	
Pb	262 ± 11	225 ± 26[g]	0.86 ± 0.10

[a] Concentrations are given in micrograms per gram unless indicated otherwise.
[b] Reference values and associated errors are for the certified fly ash (BCR 38) unless indicated otherwise.
[c] PIXE data are averages and standard deviations, based on the analysis of five thin-film samples, unless indicated otherwise.
[d] Values were obtained by dividing both the PIXE result and its associated error by the reference concentration.
[e] Concentration in millligrams per gram.
[f] Concentration and standard deviation obtained by averaging round-robin values for the fly ash.
[g] Result derived from the sum spectrum, obtained by summing the PIXE spectra of the five films analyzed; the associated error is the error from counting statistics.

SAMPLE PREPARATION

In thin-specimen work, it is straightforward to deposit thin films of powder or fluid (which is then dried) or microtome slices of biological tissue onto a polymer substrate. In aerosol specimens, the particulate material is deposited on an appropriate substrate, usually Nuclepore or Teflon filters, by the air-sampling device. Reduction of original bulk

Table 2. Comparison between Certified Values and PIXE Data[a] for 16 Elements in 8 Reference Materials

Element	Number of Certified Values	Average Absolute % Difference Relative to Certified Value[b]	
		Method A	Method D
K	7	2.1 (7)	5.7 (5)
Ca	7	6.6 (7)	51 (7)
Cr	5	[17 (4)]	[19 (4)]
Mn	7	3.3 (6)	3.1 (6)
Fe	8	5.9 (8)	3.7 (8)
Ni	2	[19 (2)]	[25 (2)]
Cu	8	5.5 (8)	3.0 (8)
Zn	6	2.3 (6)	4.0 (6)
As	6	7.8 (2)	6.2 (2)
Se	3	[0.6 (1)]	[15 (1)]
Br	1	0.7 (1)

material to a fluid or powder draws on the standard repertoire of grinding, ashing, and digestion techniques. Powdered material may be suspended in a liquid that is pipetted onto the substrate. Similarly, an aliquot of liquid containing dissolved material may be allowed to dry on the substrate. However, nonuniform deposits left from drying liquid drops may result in poorer than optimal reproducibility. The beam diameter is kept less than the specimen diameter to avoid problems of nonuniform specimen at the edges. If specimens are thin enough, there are no charging problems, but on occasion graphite coating has been necessary.

With thick specimens, a polished surface must be presented to the beam. If the specimen is an insulator, it must be carbon coated to prevent charge buildup. Geological specimens are prepared for micro-PIXE precisely as they are for electron probe microanalysis. The options are thin sections (30 to 50 μm) or multiple grains "potted" in epoxy resin.

SPECIMEN MODIFICATION

Overly large energy deposition per unit area may cause heating damage to specimens. This is observed as loss of matter from biological specimens or as crazing of mineral grains, and its avoidance is largely a matter of experience. Obviously the risk of damage increases with finer beam diameters. Volatile elements can be lost from biological materials, e.g., some compounds of sulfur, chlorine, and bromine. A guideline for tolerable beam current densities on thin biological specimens is 5 nA/mm^2 *in vacuo*

[b] Concentrations from a sum spectrum from 10 spots each having 3-μC charge.
[c] Mean concentrations from spectra of 10 spots, each having 2.5-μC charge.
[d] Concentrations from a sum spectrum from 6 spots, each having 1-μC charge.

(Maenhaut, 1990), but it is advisable to conduct tests on a particular specimen type. In geological materials, e.g., volcanic glass, mobility of sodium results in significant analytical error. Careful design is needed when analyzing certain works of art and archaeologic specimens; glass, ceramics, and paper may be discolored (Malmqvist, 1995), and the intrinsic merit of in-air PIXE analysis, which provides continuous cooling of the specimen, is obvious.

PROBLEMS

Lack of homogeneity in the volume sampled by the ion beam is a potential problem, especially in mineralogical work, where a subsurface grain may be present but invisible just under the region being analyzed or microinclusions may be present in an optically homogeneous crystallite.

Spectrum artefacts may be interpreted as element peaks by the spectrum-fitting software, leading to erroneous detection of elements that are not present. Peak tailing effects on the predominantly Gaussian response function, double and triple pile-up peaks, and escape peaks (which arise when the x-ray interaction causes creation of a silicon K x ray that escapes from the detector) must be dealt with rigorously in the code, and this requires precharacterization of the lineshape as a function of x-ray energy. Overlaps between major x-ray lines of neighboring elements can cause error, and this places demands upon the accuracy of the x-ray physics portion of the database. Inadequate description of the continuous background underlying peaks of low intensity is another source of error. As a general rule, a fitting code should be directed to fit only those elements that visual inspection suggests are contributing to the spectrum; given an extensive list of elements that is not limited by inspection, fitting codes will happily generate small concentrations that represent nothing more than minor spectral artifacts such as imperfect description of tailing.

Precision for a given specimen type is generally determined by replicate analyses that provide a standard deviation to accompany each mean concentration, as in the example of Table 3. Analysis of the same region will test the reproducibility of all aspects except the specimen itself; analysis of different spots will include any specimen inhomogeneity in the variance that is determined. Usually, if the reduced chi-squared of the fit is good, the standard deviation for a suite of replicates will be close to that expected from the counting statistics of a single measurement; if it is in excess, this constitutes evidence for sample inhomogeneity. Comparison of mean concentrations determined in this manner for standard reference materials with formally accepted or recommended concentration values provides estimates of systematic errors; these tend to derive from database errors (e.g., in x-ray attenuation coefficients or relative x-ray intensities) that affect the accuracy of the fit.

APPENDIX A: RELATIONSHIP BETWEEN X-RAY INTENSITIES AND CONCENTRATIONS

Consider the general case of a proton beam incident with energy E_0 at angle α to the specimen normal and a detector at angle Θ_{T_0} to the specimen surface; the specimen thickness is t. To an excellent approximation, the proton travels

in a straight line, its path length being $t/\cos\alpha$, and emerges from the specimen with energy E_f. The proton's energy profile (E) along its path (direction x) is given by the stopping power of the matrix S_M:

$$S_M(E) = \rho^{-1}\frac{dE}{dx} \tag{4}$$

which is the concentration-weighted sum of the stopping powers of the major (matrix) elements comprising the specimen, whose density is ρ.

We consider only K x-ray production. The treatment for L and M x rays is similar, but the existence of subshells (L_1 to L_3, M_1 to M_5) renders matters more complex. The ionization cross-section $\sigma_Z(E)$ for a constituent element Z (concentration C_Z, atomic mass A_Z) decreases along the proton path as the energy decreases.

When an ionization occurs, the probability of K x-ray emission is the fluorescence yield ω_Z, and the fraction of the K x rays appearing in the principal line ($K\alpha_1$) is b_Z. The x rays from each successive element of the path have a transmission probability $T_Z(E)$ for reaching the detector through the overlying matrix,

$$T_Z(E) = \exp\left[-\left(\frac{\mu}{\rho}\right)_{Z,M}\frac{\cos\alpha}{\sin\Theta_{To}}\int_{E_0}^{E}\frac{dE}{S_M(E)}\right] \tag{5}$$

in which the matrix mass attenuation coefficient $(\mu/\rho)_{Z,M}$ is the concentration-weighted sum of the mass attenuation coefficients $(\mu/\rho)_{Z,M}$ of the major (or matrix) elements.

Integration along the proton track gives the total x-ray intensity due to a total incident beam charge Q as

$$Y(Z) = \frac{(N_{av}/e)\omega_Z b_Z t_Z \varepsilon_Z(\Omega/4\pi)}{A_Z} Q C_Z \int_{E_0}^{E_f}\frac{\sigma_Z(E)T_Z(E)}{S_M(E)}dE \tag{6}$$

in which N_{av} is Avogadro's number, e is the electronic charge, t_Z represents the transmission of the x rays through any absorbing filter used, $\Omega/4\pi$ is the solid angle fraction subtended by the detector, and ε_Z is the detector's intrinsic efficiency.

For a thick target ($E_f = 0$), it follows that

$$Y(Z) = Y_1(Z)H\varepsilon_Z t_Z C_Z Q \tag{7}$$

where $Y_1(Z)$ is the yield computed from the PIXE database per steradian per microcoulomb per unit concentration (ppm) and H is an instrumental constant that subsumes both detector solid angle and any beam change calibration factor.

For a thin target ($E_f \sim E_0$), $T_Z(E) \sim 1$, $\sigma_Z(E)$ becomes $\sigma_Z(E_0)$, and the integral in Equation 7 reduces to $t/\cos$ a. We then have

$$Y(Z) = Y_1(Z)H\varepsilon_Z t_Z m_a(Z)Q \tag{8}$$

where $Y_1(Z)$ is the computed x-ray yield per microcoulomb per unit areal density of element Z per steradian, H is the same instrumental constant, and $m_a(Z)$ is the areal density of element Z.

Specimens of intermediate thickness and multiple-layer cases are dealt with by straightforward extensions of this formalism.

APPENDIX B: RESPONSE FUNCTION AND EFFICIENCY OF SI(LI) DETECTOR

A hypothetically perfect Si(Li) detector would provide a delta function response in the spectrum to a monoenergetic x ray. In reality, x rays have an intrinsic Lorentzian energy distribution whose width is small compared to the Gaussian broadening that arises from the statistics of charge formation and from the electronic noise. The main feature of the lineshape is therefore a Gaussian. Partial escape from the front surface of photoelectrons and Auger electrons created in the silicon causes a flat shelf extending down to low energy. Some detectors, but not all, exhibit a truncated shelf whose origin is likely due to diffusion of thermalized ionization electrons out of the front surface. Most detectors show a quasi-exponential tail that may be due in part to this out-diffusion and includes the effects of Lorentzian broadening but may also arise in part from other origins. The mathematical model for a given peak may be assembled from these features, which are shown in Figure 8. Various authors have determined the values of the parameters of these components (e.g., height, width, and truncation energy) as a function of x-ray energy by using monochromatized x rays (Campbell, 1996). PIXE analysts have recourse to an adequate, albeit less accurate, characterization by fitting PIXE spectra of pure single elements. The KMM, KLL, and KLM radiative Auger satellites present in K x-ray spectra also contribute to apparent quasi-exponential tailing features and therefore have to be allowed for in this process. An elegant method for dealing with this complication through use of multiple absorbers is given by Larsson et al. (1989).

The detectors's intrinsic efficiency, i.e., the counts in the Gaussian peak relative to the number of x-ray photons incident on the detector window, is given by

$$\varepsilon_i = \frac{(\exp[-\sum_i^4 \mu_i t_i])f_{CCE}\, f_E[1-\exp(-\mu_{Si}D)]}{(1+z/d)^2} \tag{9}$$

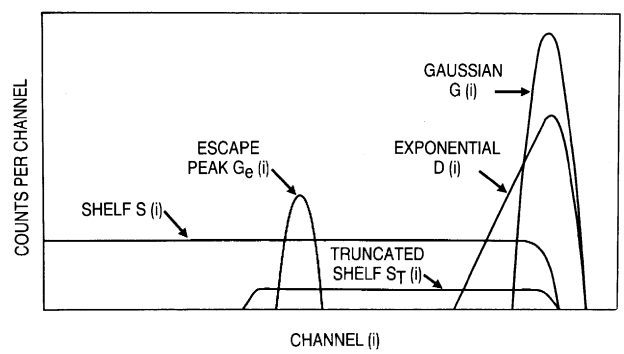

Figure 8. Typical components of the line shape of a Si(Li) detector.

where

$$z = \frac{1 - [\exp(-\mu_{Si}D)(1 + \mu_{Si}D)]}{\mu_{Si}[1 - \exp(-\mu_{Si}D)]} \quad (10)$$

and D is detector thickness, d the distance from specimen to detector surface, and μ_{Si} the linear attenuation coefficient of incident x rays in silicon. The first factor in the numerator of Equation 9 reflects x-ray attenuation in, successively, the vacuum window (beryllium or plastic), any ice layer on the cooled detector surface, the metal contact (most often gold), and any silicon dead layer that acts as a simple absorber. The second factor describes x-ray interactions that happen near the front surface of the active silicon and from which charge carriers escape via the processes described above and any others; the resulting signals fall in the shelves or the exponential features and not in the Gaussian. The factor f_E describes loss to the "escape peak," which occurs when a silicon K x ray, resulting from deexcitation after a photoelectric interaction, escapes from the crystal. The fourth factor describes penetration through the silicon. The reader will recall that the detector's solid angle was incorporated into Equation 1. That is the solid angle defined by the front surface of the silicon. Such a definition of solid angle is correct for only low-energy x rays that interact at the front of the crystal. As x-ray energy increases, the effective interaction depth is greater and the effective solid angle changes. The denominator of Equation 9 incorporates this nonnegligible effect in the intrinsic efficiency.

The detector manufacturer usually provides the thicknesses of the window, the contact, and the crystal. The presence of an ice layer is difficult to determine, but a steady decrease in efficiency at low energies betrays its presence; a detector that incorporates a heater for ice removal is advantageous. Detailed spectra measurements on pure elements are necessary to elucidate the correction for charge loss, which varies greatly among detectors. The term f_E has been determined accurately by various authors, e.g., Johansson (1982).

To determine the distance from specimen to detector crystal, one requires the distance of the crystal inside the window, which the manufacturer provides only approximately. This may be determined by recording the K x-ray spectrum from a ^{55}Fe radionuclide point source placed at accurately determined positions along the axis of the detector and invoking the inverse square law to describe its distance dependence.

The crystal thickness can be determined by constructing an efficiency curve using radionuclide point source standards and by least-squares fitting the model of Equation 9 to this curve with D as a variable. Suitable nuclides emitting x rays in the energy region 5 to 60 keV and enabling efficiency determination at accuracies of 1% to 3% are supplied by the Physikalisches-Technisches Institut in Braunschweig, Germany, and by other national laboratories charged with responsibility for standards.

RADIATION EFFECTS MICROSCOPY

INTRODUCTION

Radiation effects microscopy is a general name that includes both ion-beam-induced charge (IBIC) microscopy and single-event upset (SEU) imaging. Ion-beam-induced charge microscopy was initially developed as a means of imaging the distribution of buried *pn* junctions in microelectronic devices (Breese et al., 1992) and dislocation networks in semiconductors (Breese et al., 1993a). More recently it has found a wider range of applications, e.g., in the study of solar cells (Beckman et al., 1997), segmented silicon detectors (R.A. Bardos, pers. comm.), and chemical vapor deposition (CVD) diamond films (Manfredotti et al., 1995, 1996). Many other applications are reviewed in the literature (Breese et al., 1996), and Doyle et al. (1997) is a good source of up-to-date applications.

Ion-beam-induced charge microscopy uses a beam of mega-electron-volt light ions, mainly protons or helium, to create electron-hole pairs in semiconductor material. This energy transfer from the incident ions to the material causes them to lose energy and eventually stop in the material at a well-defined distance called the ion range. The number of these electron or hole charge carriers that are collected at a junction within the sample is measured and displayed as a function of position of the focused beam within the scanned area. This process is analogous to electron-beam-induced current (EBIC) microscopy (Leamy, 1982), which uses a focused kilo-electron-volt electron beam, and optical-beam-induced current (OBIC) microscopy (Acciarri et al., 1996), which uses a focused laser beam to study similar problems in semiconductor technology. They are also used to image dislocations and inversion layers in semiconducting materials and depletion regions in devices and to give quantitative measurements of the minority carrier diffusion length (Wu and Wittry, 1978; Chi and Gatos, 1979). A description of different EBIC imaging modes as well as more detailed accounts of the theory and technical aspects of image generation is given elsewhere (Holt et al., 1974; Leamy, 1982; Piqueras et al., 1996).

As microelectronic device features continually shrink, the amount of charge that defines the different logic levels becomes smaller. This means that the charge generated by the passage of ionizing radiation through the device is more likely to cause a change in its logic state, called a soft upset, or a SEU. This phenomenon is particularly important for satellite-based devices, which are exposed to a high flux of ionizing cosmic radiation. It is a serious problem in the design of high-density semiconductor memories (May and Woods, 1979). Much work has been done using unfocused high-energy heavy-ion beams from large tandem accelerators (Knudson and Campbell, 1983), pulsed lasers (Buchner et al., 1988), and pulsed electron beams as sources of ionizing radiation to study upset mechanisms. However, the lack of spatially resolved information led to difficulties in determining which part of the device caused the upsets. Single-event upset analyses with collimated heavy-ion beams revealed the benefits of spatially resolving the results (Geppert et al., 1991;

Nashiyama et al., 1993). This prompted the development of SEU microscopy at Sandia (Doyle et al., 1992; Horn et al., 1992; Sexton et al., 1993a). This has many similarities to IBIC, which is usually performed in conjunction with SEU microscopy to image the device components present within the area analyzed for upsets. The two techniques use almost all the same nuclear microprobe hardware and electronics. Whereas IBIC mainly uses mega-electron-volt light-ion beams for analysis, SEU analysis uses heavier ions, such as carbon or silicon, to create a plasma density of electron-hole charge carriers high enough to cause upsets (McLean and Oldham, 1982; Knudson and Campbell, 1983).

There is no displacement damage in silicon using kilo-electron-volt electrons for EBIC, and a low-power laser beam such as Ar or He-Ne used for OBIC also produces no material damage. In comparison, mega-electron-volt ions generate defects in semiconductors. This is a major drawback in IBIC and SEU imaging as it imposes a limitation on the maximum number of ions that can be used to form an image, and care must be taken that the material property that is being measured is not altered beyond what can be accounted for during data collection. The effects of ion-induced damage on the measured charge pulse height spectrum is outlined in Specimen Modification for IBIC and are more fully described by Breese et al. (1996) and for SEU analysis by Sexton et al. (1995).

A major advantage of IBIC and SEU microscopy over competing electron beam techniques is their ability to give high-spatial-resolution analysis in thick layers. This is due to the different shapes of the charge carrier generation volume of mega-electron-volt ions compared with kilo-electron-volt electrons, which are compared in Figure 1. The measured carrier generation volume is shown in the form of concentration contours. The axes are normalized to the particle range. For kilo-electron-volt electrons the generation volume is approximately spherical. The lateral extent of the generation volume can be reduced by lowering the electron beam energy, but at the expense of further decreasing the analytical depth. Because of the large lateral extent of the generation volume of the electron beam within the silicon, the high spatial resolution of the electron beam on the sample surface is degraded, so deeply buried areas cannot be imaged with high spatial resolution. For 3-MeV protons there is little lateral scattering of the proton beam in the top few micrometers, and most occurs close to the end of range, giving a teardrop-shaped carrier generation volume. If the ion range is much greater than both the depletion depth and the diffusion length of the sample (which is usually the case with mega-electron-volt protons), then carriers generated deep within the sample, where there is significant lateral scattering, will not be measured.

The main advantages of IBIC microscopy over electron and optical methods are therefore a large pentration depth and a high spatial resolution for analysis of buried features within microelectronic devices (Breese et al., 1994; Kolachina et al., 1996) or semiconductor wafers. The main advantage of SEU microscopy is its ability to give spatially resolved information on which components within microelectronic devices are responsible for changes

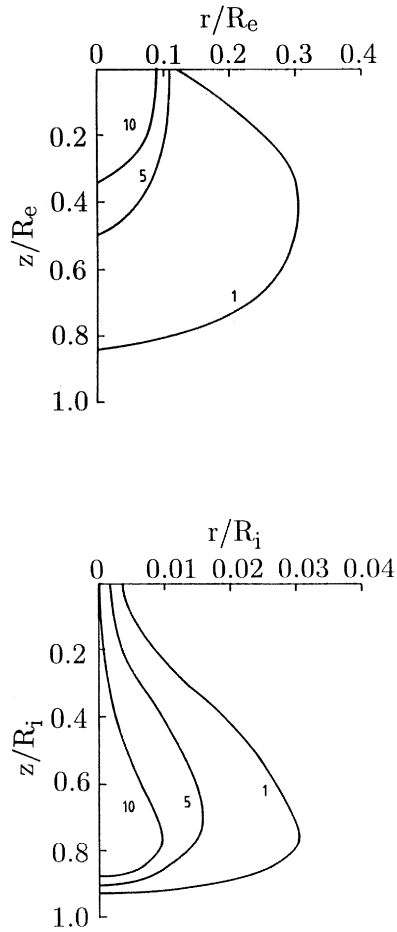

Figure 1. (**A**) Carrier generation contours for 10-keV electrons and-3 MeV protons in silicon. The lateral distance r and the depth z are plotted as fractions of (A) the electron range $R_e$and (**B**) the ion range R_i. in the device logic states due to the passage of high-energy ionizing radiation. A practical disadvantage of both forms of radiation effects microscopy is that they are only available in conjunction with nuclear microprobes located on megavolt particle accelerators (Grime and Watt, 1984; Watt and Grime, 1987; Breese et al., 1996). This makes them expensive compared with competing electron and laser beam techniques, and they are only available in laboratories that specialize in ion beam analysis, of which there are however a considerable number.

PRINCIPLES OF THE METHOD

The basic semiconductor theory relevant for IBIC and SEU imaging is reviewed here. Other sources (Sze, 1981; Kittel, 1986) are recommended for in-depth discussions of these and other theoretical aspects.

Semiconductor Theory

Ionizing radiation such as mega-electron-volt ions, kilo-electron-volt electrons, or high-frequency photons can create mobile charge carriers in semiconducting materials by transferring enough energy to the atoms to move valence electrons to the conduction band, leaving behind a positively charged hole. The average energy (E_{eh}) needed to create this electron-hole pair does not depend on the type of ionizing radiation and is constant for a given material (Klein, 1968). Charge carriers produced by ionizing radiation diffuse randomly through the semiconductor lattice, and if it contains no electric field, they become trapped and recombine until all excess carriers are removed.

If the semiconductor contains an electric field, the charge carriers are separated in the field region, and this charge flow can be measured in an external circuit. Because of the large number of charge carriers produced by individual mega-electron-volt ions, a charge pulse from each incident ion can be detected above the thermal noise level. The use of mega-electron-volt ions differs in this respect from electron and optical methods such as EBIC and OBIC, in which variations about a steady-state injection level produced by a large incident flux of ionizing radiation is detected rather than individual charge pulses, since these would not be resolved from the thermal noise of the sample.

Typical sample geometries used for IBIC microscopy are shown in Figure 2. The electric field is usually provided by *pn* junctions in microelectronic devices or by a Schottky barrier for the analysis of semiconductor wafers. Microelectronic devices typically consist of a semiconductor substrate with a patterned array of *pn* junctions at the substrate surface, which comprise the different transistors and other electronic components present (Sze, 1988). Above the semiconductor surface there are usually thick, patterned layers of insulating and metal tracks that make up the interconnecting device layers, with a thick passivation layer over the device surface. The total thickness of all the surface layers present can be up to 10 μm. As mentioned above, this is difficult to penetrate with good spatial resolution using an electron beam, and a laser beam suffers high attenuation in passing through any metallization layers, so analysis of small underlying junctions is very limited.

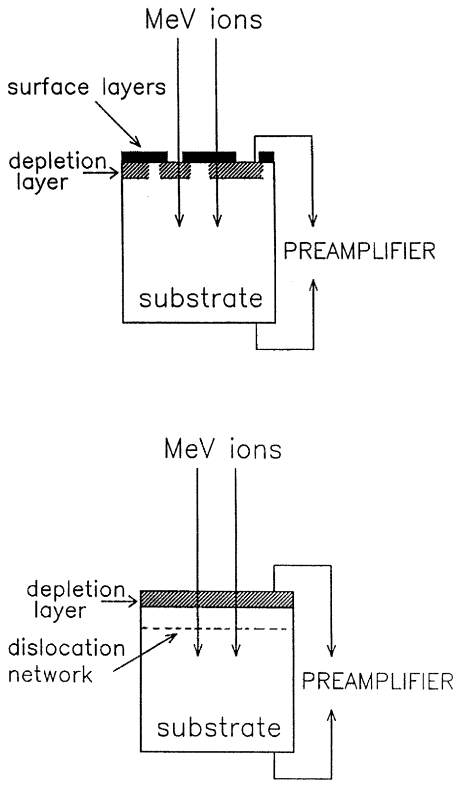

Figure 2. Schematic of geometry used for IBIC analysis of (**A**) microcircuits and (**B**) semiconductor and insulator wafers.

For both IBIC and SEU microscopy a focused beam current of ~1 fA of mega-electron-volt ions is incident on the front face of the sample, and each ion generates charge carriers along its trajectory. The number of charge carriers generated by each incident ion is measured for IBIC microscopy using a contact from the relevant depletion layer at the front face and a contact to the rear surface, each connected to a charge-sensitive preamplifier. This gives an output voltage that is amplified and measured by the data acquisition computer of the nuclear microprobe.

Quantitative Interpretation of the IBIC Pulse Height

A simple one-dimensional theory used to calculate the IBIC pulse height as a function of ion type and energy, minority carrier diffusion length, and surface and depletion layer thicknesses is described in the literature (Breese, 1993), and only a brief summary is given here. The ion-induced charge pulse height is given here in units of kilo-electron-volts. For example, a measured charge pulse height of 1 MeV from a 2-MeV ion means that half of the beam energy has generated charge carriers that contribute to the measured charge pulse height, and the other 1 MeV has been lost in passing through the surface layers or through carrier recombination within the substrate.

The total measured charge pulse height of Π kilo-electron-volts can be calculated by integrating the rate of ion electronic energy loss dE/dz between the semiconductor surface ($z = 0$) and the ion range, i.e., mean penetration depth ($z = R_i$):

$$\Pi = \int_0^{z_d} \frac{dE}{dz} dz + \int_{z_d}^{R_i} \frac{dE}{dz} \exp\left[-\frac{z - z_d}{L}\right] dz \qquad (1)$$

where L is the minority carrier diffusion length in the sample. The first term is the contribution from the charge carriers generated within the depletion region of the collecting junction, which is z_d micrometers thick. The second term is the contribution from the charge carriers diffusing to the collecting junction from the substrate. Figure 3 shows the calculated charge pulse height for protons and ^{4}He ions for different values of L, based on Equation 1. For a short diffusion length, the charge pulse height reaches a maximum value at a certain proton energy and then decreases as the proton energy is raised further. This is because at a low beam energy there is a high rate of

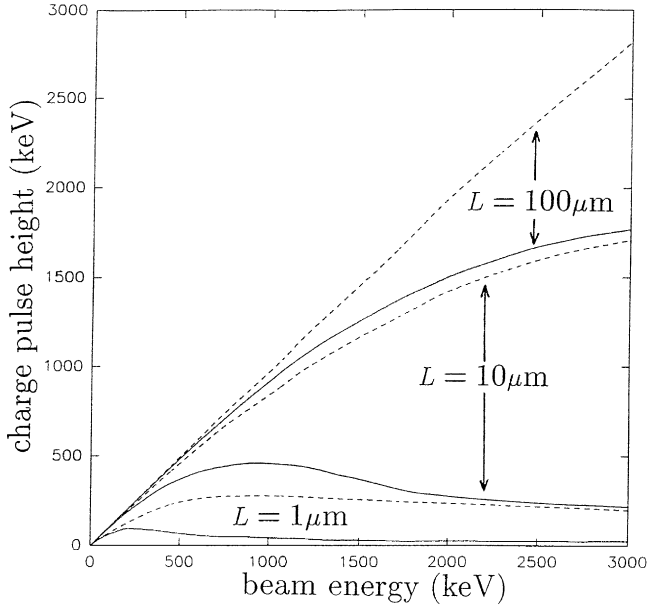

Figure 3. Variation of the charge pulse height with protons (solid lines) and ^{4}He ions (dashed lines) versus energy for diffusion lengths $L = 1$, 10, 100 μm. Courtesy of Breese et al. (1993). Copyright 1993 American Institute of Physics.

energy loss close to the surface where the generated charge carriers can be measured. As the beam energy is raised further, there is a gradual reduction in the rate of energy loss at the surface, and most carriers are generated too deep to be measured. Similar behavior is also found for kilo-electron-volt electrons (Wu and Wittry, 1978).

IBIC Topographical Contrast

It is important to know how the IBIC image contrast changes as a function of changes in surface layer thickness in order to correctly interpret the distribution of charge pulses (Breese et al., 1995). Figure 4A shows the rate of electronic energy loss with distance traveled for 2-MeV protons and 3-MeV ^{4}He ions. Since they have the same range of ~12 μm as 3-MeV ^{4}He ions, 38-keV electrons have been included, so that the charge pulse height from these different charged particles with the same range can be compared.

Figure 4B shows the charge pulse height resulting from a sample consisting of a depletion layer thickness of 1 μm and a substrate diffusion length $L = 6$ μm, with increasing surface layer thickness for the same incident charged particles. The maximum slope of the charge pulse height variation with surface layer thickness occurs close to the end of range, i.e., between 10 and 12 μm, for 3-MeV ^{4}He ions, whereas the charge pulse height for 2-MeV protons for similar thickness surface layers changes at a rate that is a hundred times slower. Thus, mega-electron-volt ^{4}He ions can produce IBIC images that are highly sensitive to device topography. In comparison, similar energy protons produce IBIC images that are almost independent of device topography, in which the contrast just depends on the distribution of the underlying *pn* junctions, as will be demonstrated in Figure 10.

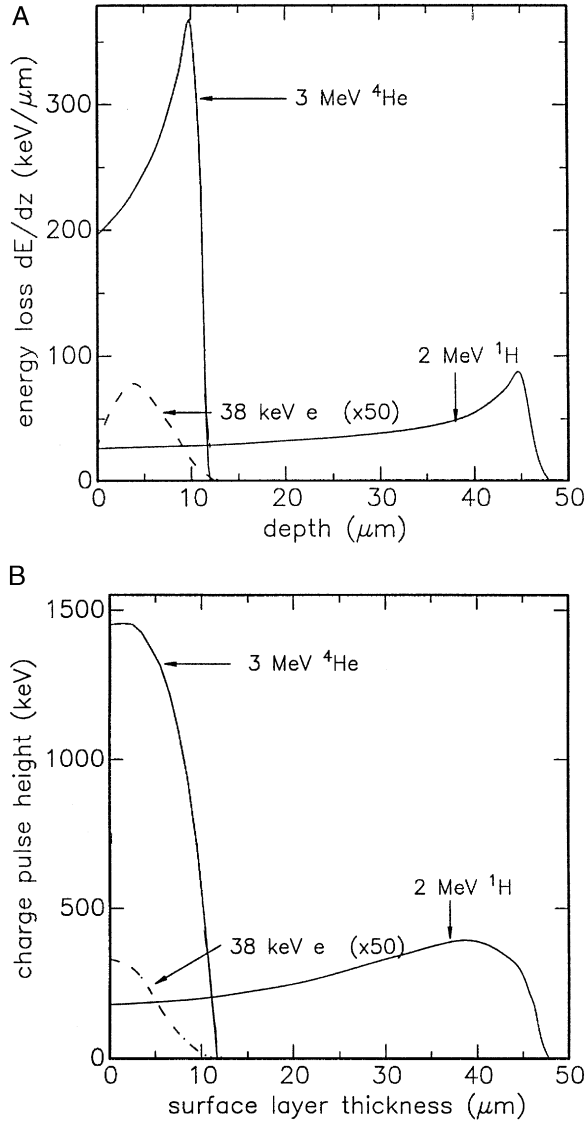

Figure 4. (**A**) Electronic energy loss with depth for 2-MeV protons, 3-MeV He ions, and 38-keV electrons (dashed line with the energy loss is multiplied by 50). (**B**) Charge pulse height resulting from a depletion layer thickness of 1 μm and a diffusion length of 6 μm as a function of increasing surface layer thickness for the same charged particles. Courtesy of Breese et al. (1995). Copyright 1995 American Institute of Physics.

The charge pulse height from 38-keV electrons is shown on the same vertical scale as for mega-electron-volt ions to compare the sensitivity of EBIC to changes in surface layer thickness (in practice, EBIC uses a steady-state large incident beam current). The maximum slope of the resultant charge pulse height variation is typically between that measured with protons and with mega-electron-volt ^{4}He ions, showing that IBIC can be made either sensitive or insensitive to topographical contrast whereas EBIC does not have this flexibility. Optical methods also lack this flexibility owing to strong attenuation by metallization layers.

This section has briefly described a basic model of ion-induced charge collection, which provides some insight into how the measured charge pulses vary with beam energy and surface layer thickness. There are two routes to obtaining better quantitative understanding for more detailed analysis and interpretation. First, better analytical models of ion-induced charge diffusion and collection are being developed (Donolato et al., 1996; Nipoti et al., 1998). These take into account two-dimensional lateral charge diffusion effects, which should result in better quantitative understanding of how the proximity of *pn* junctions, grain boundaries, and dislocations affect IBIC image contrast. The second route to acquiring a better insight into charge collection mechanisms is with detailed computer simulations. These seem to be the best path to a quantitative understanding of three-dimensional charge collection for use with IBIC and SEU microscopy, as described above.

SEU Microscopy

The passage of a high-energy, heavy ion through a semiconductor can produce a region with a very high density of excess charge carriers along the ion path because of the ion's high rate of electronic energy loss. The dense plasma created around heavy ions is a reasonable experimental analogy for the passage of strongly ionizing cosmic radiation passing through device memories in satellite-based microelectronic devices, which is why this has become an important research area. If the carrier density reaches a critical level, then enough charge might be collected at a sensitive device junction to change the device logic state, causing a corruption of the information stored, i.e., a SEU has occurred. Figure 5 gives a schematic of the SEU imaging process within a nuclear microprobe. A focused heavy-ion beam is scanned over the chip, and the information stored within the device is sampled at each beam position within the scanned area, so that an image can be constructed showing the upset probability at each location.

If a heavy ion passes through a depletion region of a device memory (Fig. 6), the resultant dense plasma formation can distort its shape, giving rise to the phenomenon of charge funneling (McLean and Oldham, 1982). The carrier density can reach up to 10^{20} cm^{-3} along the path of a heavy ion, which is much greater than the typical device substrate doping density. As a consequence, the junction depletion layer in the vicinity of the ion path is quickly neutralized, and the high electric field in the junction is screened by electrons being drawn off at the electrode. The electric field associated with the junction is reduced in size and becomes elongated in the direction of the ion path, and Figure 6C shows the distorted equipotential line associated with this effect. The effect of this charge funnel is to give a much larger measured charge pulse than would otherwise occur by charge drift and diffusion alone. The charge is also much more localized around the

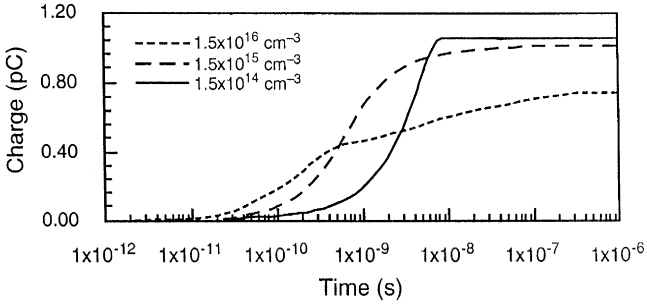

Figure 7. Simulated charge transients generated by a 100-MeV Fe ion in three n^+/p silicon diodes with substrate doping densities shown in the top left. Courtesy of Dodd et al. (1994).

struck junction, as less charge diffuses away to be absorbed by other junctions, resulting in a much increased susceptibility of the device to SEUs.

Charge-funneling effects are also important to IBIC as well as for SEU analysis because they should be taken into account when calculating the charge pulse height due to heavy ions if the ionization carrier density is much greater than the substrate density. Sophisticated two- and three-dimensional computer codes (Dodd et al., 1994; Dodd, 1996) can be used to model the effects of SEU and charge-funneling effects in order to gain a detailed understanding of the basic mechanisms that can upset devices and to distinguish funneling from the effects of charge drift and diffusion.

An example is a heavily doped (5×10^{20} cm^{-3}) n^+ diffusion in a p-type silicon substrate with different doping concentrations (Dodd et al., 1994). The passage of a 100-MeV Fe ion through this system was modeled to investigate under what conditions it could upset the device. Figure 7 shows the simulated charge collection transients from one quadrant of the symmetrical device area for three different substrate doping densities. The total measured amount of charge decreases with increasing substrate doping density, because it is less likely that significant additional amounts of charge will be collected via the funneling effect. For the lightly doped substrates, nearly all the charge carriers are collected by a charge-funneling process, so there is little extra charge to be collected by diffusion after the funnel collapses ~10 ns after the passage of the ion through the device. For the more heavily doped substrate of 1.5×10^{16}cm^{-3}, the funnel collapses 400 ps after ion impact, leaving a considerable fraction of charge carriers free to diffuse through the device. Some carriers diffuse to the collecting junction and others recombine, so less charge is measured in total.

Further Advances

An interesting development that should further enhance the capabilities of IBIC and SEU analysis is the production of time-resolved, or transient, IBIC images. Presently being developed by the Sandia microprobe group (Schone, 1998), this enables those charge components from the depletion region and from the substrate to be measured directly, being distinguished by their different charge collection time scales. The ion-induced transient response is measured with a timing resolution of tens of picoseconds, as has already been done with unfocused ion beams (Wagner et al., 1988). The experimental procedure is to store the digitized ion-induced current transient along with the (x,y) position coordinates of the beam. From the stored data, the shape of the current transient can be studied as a function of position as well as time, enabling direct measurements of the critical charge needed to cause SEUs. These also help to test numerical three-dimensional simulations of charge diffusion and charge funneling.

A similar system has been built by the Melbourne microprobe group (Laird et al., 1999). The installation of a cold stage on this system capable of cooling samples to liquid helium temperature should enable transient IBIC pulses to be studied as a function of temperature, in a similar manner to deep level transient spectroscopy; see DEEP-LEVEL TRANSIENT SPECTROSCOPY (Lang, 1974).

PRACTICAL ASPECTS OF THE METHOD

The basic layout used for IBIC analysis of microcircuits and Schottky barrier samples is shown in Figure 2. The IBIC pulses are measured using standard charged particle detection electronics, similar to those used for other ion beam analysis techniques. Each pulse is fed to a low-noise charge-sensitive preamplifier whose output voltage is proportional to the measured number of carriers generated by individual ions.

Charge-sensitive preamplifiers are ideal for use in IBIC experiments because they integrate the induced charge on a feedback capacitor. A charge-sensitive preamplifier typically has an open-loop gain of $\sim 10^4$ so that it appears as a large capacitance to the sample, rendering the gain insensitive to changes in the sample capacitance. Details of preamplifier design, pulse shaping, and methods of noise reduction are described in many texts (e.g., Bertolini and Coche, 1968; England, 1974). The preamplifier output voltage V_o, is given as

$$V_o = \frac{1000\Pi e}{E_{eh}C} \tag{2}$$

where Π is the measured charge pulse height in kiloelectron-volts, given by Equation 1. With a feedback capacitance $C = 1$ pF, a typical preamplifier output pulse size is 44 mV per mega-electron-volts of energy of the incident ion. The small output pulses from the preamplifier are fed into an amplifier, which gives an output voltage of ~1 V. This is then fed into the data acquisition computer and an image is generated showing either variations in the average measured charge pulse height or the intensity of counts from different "windows" of the spectrum at each pixel within the scanned area.

A beam current of ~1 fA (i.e., ~6000 ions/s) is typically used for both IBIC and SEU microscopy since the maximum data acquisition rate available with most nuclear microprobes is less than 10 kHz. To produce a focused spot containing such a small current, a much larger beam current of 100 pA is first focused in a conventional

manner (Breese et al., 1996). The object and divergence slits are then closed until the remaining current is a few thousand ions per second, as measured by a semiconductor detector placed in the path of the ion beam. This procedure ensures that the sample is not irradiated with a high ion dose prior to analysis. The sample is then moved onto the beam axis, and a large-area IBIC image is used to identify and position the region of interest. With SEU analysis, damage effects are even more critical since heavier ions are used. Therefore, initial sample positioning with SEU microscopy is also best carried out using IBIC with light ions, since they will cause much less damage prior to SEU analysis.

IBIC Examples

A typical IBIC charge pulse height spectrum measured from a 300 × 300 μm^2 area of an extended programmable read-only-memory (EPROM) chip using a focused 3-MeV proton beam is shown in Figure 8. The charge pulses in this case are up to five times larger than the thermal noise level, which occupies the lower end of the spectrum. The lower input threshold of the amplifier should be raised to a level such that very few noise pulses are measured or else the high noise level will saturate the data acquisition system and the ion-induced charge pulses will not be measured. However, if the threshold is raised too far, then the smallest charge pulses will not be measured, demonstrating the problem of a poor signal-to-noise ratio, which must always be borne in mind in IBIC experiments. This may also influence the choice of incident ion used for the IBIC analysis, since heavier ions usually give larger charge pulses (see Fig. 4).

In this example the device is an *n*-type metal-oxide-semiconductor (NMOS) memory chip. The area analyzed contains two output driver field effect transistors and also two transistors comprising the input buffer. The metallization consists of a 1-μm-thick layer of Al(1% Si). Over the surface of the device is an ∼1.5-μm-thick SiO_2 passivation layer, with a total surface layer thickness up to 4 μm. Figure 9 shows three IBIC images of this 300 × 300 μm^2 area, but with different preamplifier connections and device pin voltages in each case. In each case, spectra similar to that shown in Figure 8 are measured, and IBIC images showing the average charge pulse height at each pixel are produced. The differing contrasts are explained in detail elsewhere (Breese et al., 1992), but they demonstrate here that IBIC can generate images showing the different distributions of active components buried several micrometers beneath the surface of the functioning device.

Figure 10 shows IBIC images of the central region of Figure 9c with the device under the same operating conditions. Figure 10 shows a 75 × 75 μm^2 image generated using 3-MeV protons and a 40 × 40 μm^2 image generated with 2.3-MeV ^{4}He ions. Figure 10b shows strong topographical contrast where the circles along the lengths of the horizontally running metallized source and drain regions can be seen. These are not visible in Figure 10a, which only shows IBIC contrast due to the layout of the underlying

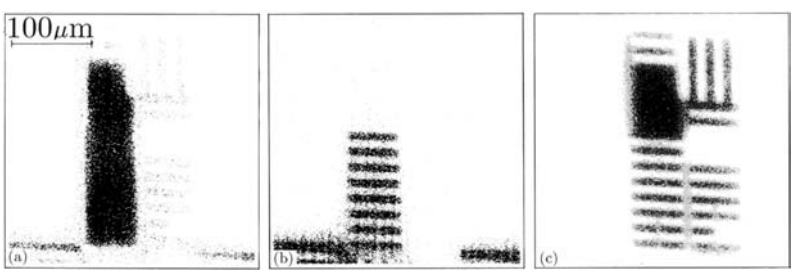

Figure 9. Three 300 × 300 μm^2 IBIC images of the same device area. The preamplifier connections are (**A**) between the supply voltage pin, with $V_{cc} = +5$ V and ground. The output driver voltage $V_{o=+5}$ V, and the data pin is not connected here. (**B**) Same as (A) except the data pin is now also connected to a different preamplifier. (**C**) Measured between the data pin and ground but with other transistors on.

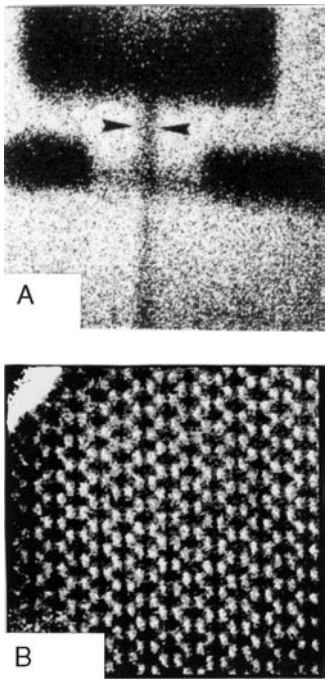

Figure 11. (**A**) $20 \times 20\ \mu m^2$ IBIC image of a GaAs device, between the *p*- and *n*-type contacts. A 0.8-μm-wide depletion region is indicated. pn junctions. This demonstrates the insensitivity of IBIC to device topography using mega-electron-volt protons, as calculated in Figure 4B. The maximum signal-to-noise level in Figure 10b is ~50, whereas in the proton IBIC images of this same area it was ~5, so in this case the use of heavier ions has greatly increased the pulse sizes.

Other IBIC Examples

An IBIC image of a GaAs high-electron-mobility transistor is shown in Figure 11a. The surface of the device was patterned using a focused Be^+ ion beam, which formed *p*-type material and resulted in the formation of a field effect transistor with a very narrow gate depletion region that was confined both laterally and in depth. The IBIC images were generated using contacts between the *p*- and *n*-type material, with a 10-μm-thick Al foil placed between the focused 3-MeV protons and the device surface. On the IBIC image, a 0.8-μm-wide depletion region is indicated by arrows; this high spatial resolution resulted from the low lateral straggling of mega-electron-volt protons through thick surface layers.

Figure 11b shows an IBIC image of a $65 \times 65\ \mu m^2$ area of the memory array in a 4-Mbit dynamic random-access memory (DRAM) device. Smaller charge pulses were measured from the light-colored honeycomb structure of 1-μm-wide trench cells that comprise parts of the individual memory cells. To prepare a sample suitable for IBIC microscopy, all the device surface layers were removed using hydrofluoric acid, leaving just the *p*-type substrate and the *n*-doped trench walls. Electrical contacts were then produced by depositing a thin gold layer onto the back surface to form an ohmic contact and a thin aluminum layer onto the front surface to form a Schottky contact in the geometry shown in Figure 2B. This device also formed part of an IBIC study of methods of compensating for the effects of beam-induced damage in IBIC images, as described by Breese et al. (1993b).

DATA ANALYSIS AND INTERPRETATION

SEU analysis of SRAMs

An example of the SEU analysis of radiation-hardened static random-access memory (SRAM) devices is given here. An SEU image generated using a low-intensity beam of 24-MeV Si^{6+} ions scanning over a $40 \times 40\ \mu m^2$ area of the device is shown in Figure 12a, and the schematic of the device layout within this area is shown in Figure 12b. The SEU image was produced by interrogating the device logic state as a function of irradiation with the focused ion beam at each pixel within the scanned area. The SEU image shows variations in the upset probability within this area as darker shading at the center and lighter shading toward the edges of the upset-generating region.

An IBIC image of the same area generated using 2.4-MeV ^4He ions is shown in Figure 12c. The ion impact locations that give rise to upsets within this scanned area can now be directly identified by comparing the SEU and IBIC images with the device layout. In this case, the upset

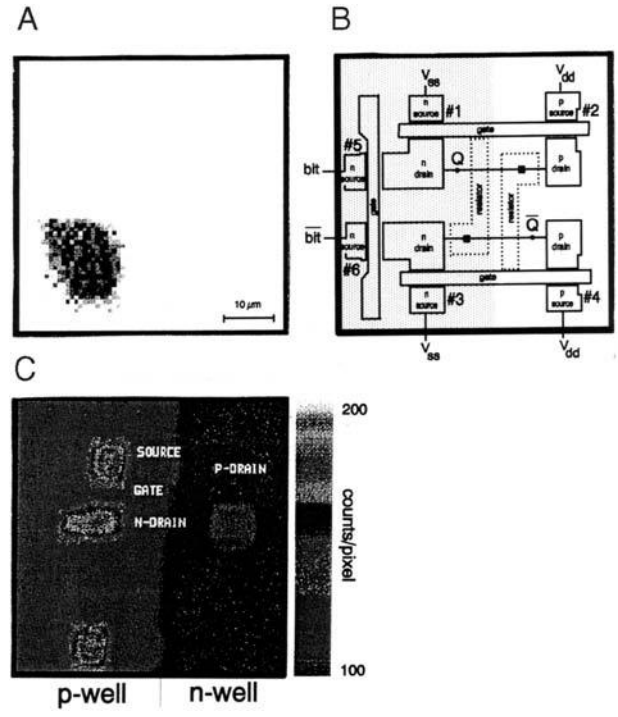

Figure 12. (**A**) $40 \times 40\ \mu m^2$ SEU image of the SRAM device. (**B**) Schematic of the device layout in this area and (**C**) IBIC image from the same area. Courtesy of Horn et al. (1993). Figure 13. SEU images of an SRAM memory cell showing the logic state dependence: (**A**) with logic 1 initially stored in the memory cell and (**B**) with logic state 0 initially stored. Courtesy of Horn et al. (1993).

area was localized around an *n*-channel transistor drain. In the IBIC image, a large charge pulse was measured from the *n* drains within the *p* well of the device. Within the *p* well, a large charge pulse was also measured from the *n* source, but from the SEU image this is shown to be insensitive to upsets. There is a weaker region of charge collection within the *n*-well region on the right of the IBIC image, corresponding to a *p* drain. A detailed explanation of the observed IBIC image contrast in terms of the device layout is given in the literature (Horn et al., 1993; Sexton et al., 1993b), where the behavior observed in the SEU image was correlated with the observed IBIC contrast. It was postulated that regions of larger than expected charge pulses could arise from a "shunt" effect (Kreskovsky and Grubin, 1986) caused by the high ion-induced carrier density along the ion path.

Single-event upset microscopy also gives the opportunity to measure logic-state-dependent upsets. Figure 13 shows an SEU image from the same SRAM device structure for each of two different initial logic states. As can be seen, the upsets occur in different positions, and the sensitive volume is of a different shape and size, depending on the initial value stored. This observation is typical of the additional information to be gained by the ability to spatially resolve the locations of SEUs.

SPECIMEN MODIFICATION

The main damage mechanism of mega-elextron-volt ions in semiconductors is the creation of vacancy/interstitial pairs, called Frenkel defects. This is caused by direct collisions between the incident ions and the lattice nuclei, in which a sufficient amount of energy is imparted to the nucleus to displace it from its lattice site. Their primary effect for IBIC and SEU microscopy is a reduction in the minority carrier diffusion length, because the defects act as trapping and recombination centers. Since many charge pulses should ideally be measured at each pixel to reduce the statistical noise in IBIC and SEU images, ion-induced damage is a major drawback as it limits the beam dose, which can be used to produce an image before the image contrast greatly changes.

Prior to the development of IBIC, it was demonstrated that a nuclear microprobe could be used to spatially resolve ion beam damaged areas in a *pn* junction by measuring the charge pulses from the focused beam (Angell et al., 1989). Since the subsequent development of IBIC as an analytical technique, the effects of ion-induced damage and methods of compensating for its effects have been studied extensively (Breese et al., 1993b, 1995).

A study into the observed damage occurring during SEU analysis (Sexton et al., 1995) investigated whether the observed damage effects with heavy ions were due to the ionizing energy loss component, i.e., to possible charge buildup in insulating layers, or the nonionizing component, i.e., to displacement effects. Devices were irradiated with X-rays to model the effects of ionizing radiation, and it was found that no significant changes were observed in subsequent SEU behavior. In comparison, identical devices irradiated with large doses of 30-MeV copper ions underwent significant changes in SEU behavior after a certain dose, with more components becoming sensitive to upsets with cumulative beam dose. It was postulated that this was due to a reduction of the critical charge threshold for upset produced by beam damage effects of the nonionizing component of the energy loss.

Using the same simple theory to characterize charge collection as described in Principles of the Method, a rough guide to the behavior of IBIC pulses with cumulative beam dose can be derived. The calculated rate of charge pulse height reduction for different energy protons and α-particles is shown in Figure 14. In brief, the charge pulse height reduces with cumulative beam dose because of a reduction in the minority carrier diffusion length. The reduction is faster for heavier ions because they introduce more defects and thus decrease the diffusion length more rapidly.

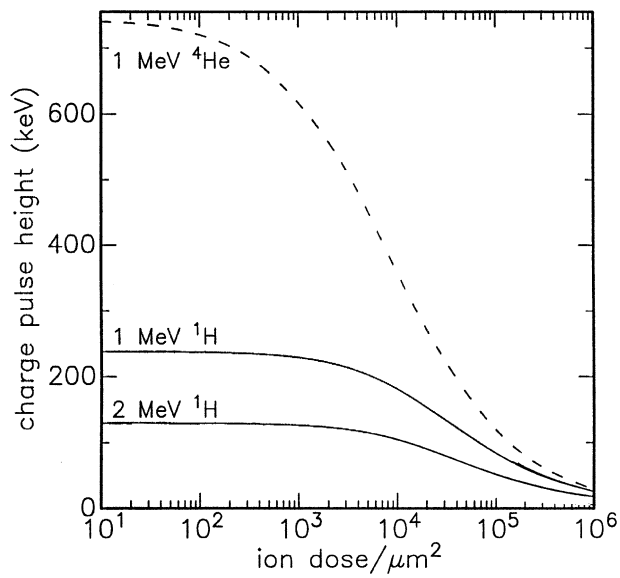

Figure 14. Calculated charge pulse height with cumulative ion irradiation with 1- and 2-MeV protons (solid lines) and 1-MeV ^{4}He ions (dashed lines). An initial diffusion length of 5 μm is assumed. Except where indicated, reprinted from Breese (1993) with permission. Copyright 1993 American Institute of Physics.

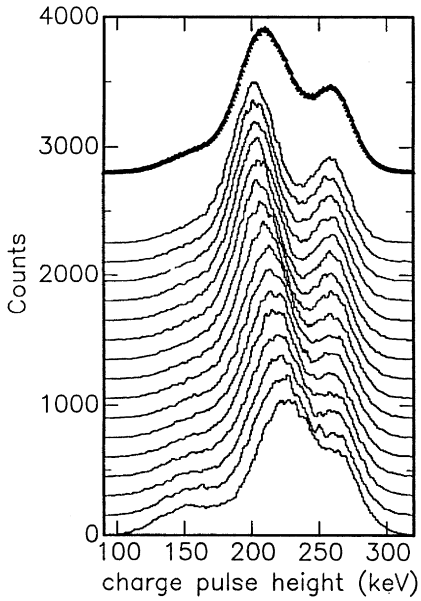

Figure 15. Charge pulse height spectra from a 80×80 μm^2 area produced using 2-MeV ^4He ions. The measured charge pulse height spectra with cumulative sequential dose increments of 9 ions/μm^2 are offset vertically by a fixed arbitrary amount for clarity. The uppermost spectrum is the cumulative spectrum from which the sequential spectra were extracted. Reprinted from Breese et al. (1995) with permission. Copyright 1995 American Institute of Physics.

Therefore, although heavier ions give a larger measured IBIC pulse than similar energy light ions, this advantage might be outweighed by the more rapid rate of damage. This is another consideration when choosing the optimum type of ion for use in IBIC or SEU analysis.

The best type of data acquisition system to use for IBIC and SEU microscopy is an event-by-event system (O'Brien et al., 1993), which stores the measured charge pulses along with their position coordinates for subsequent processing and analysis. The specific advantage of this is that the measured charge pulse height data set can be sliced into sequential dose increments so that the evolution of the charge pulse height spectrum and image contrast from different parts of the scanned area can be examined with the cumulative ion dose.

Figure 15 shows the IBIC pulse height spectra from a 80×80 μm^2 area of a different microelectronic device. Here 2-MeV ^4He ions are used, and the resultant spectrum is shown at the start of data collection and also after fixed sequential dose increments. It can be seen that different parts of the charge pulse height spectrum behave in different ways; the left-hand peak decreases in size with increasing beam dose, whereas the right-hand peak remains the same size. The explanation for this type of behavior is given below. Here it suffices to say that even though the charge pulse height in adjacent pixels may vary differently with cumulative ion dose, i.e., the contrast may change, the charge pulses can still be used to generate an IBIC image when an event-by-event acquisition system is used.

Minimizing the Effects of Ion-Induced Damage

Ion-induced damage of the semiconductor substrate decreases the measured amount of charge because the increased recombination of the slowly diffusing charge carriers causes a reduction in the carrier diffusion length, as described below. The mechanism by which the amount of charge measured from the depletion region reduces with ion-induced damage is more complex. Charge carriers generated in the depletion region have a much lower recombination probability than those generated in the substrate because of the associated electric field. This accelerates the carriers in opposite directions and reduces the probability of them becoming trapped and recombining at any defects present.

Figure 16 shows a schematic of the final locations of ions with a fixed energy penetrating through an increasingly thick surface layer into a narrow depletion region and then into the substrate. For a thin surface layer, the ions penetrate deep into the substrate, and most of the measured charge is due to carriers diffusing from the substrate to the collecting junction. Since the distribution of the nonionizing energy loss along the ion trajectory follows a similar trend as the electronic energy loss, most of the defects are created in the substrate, where they have a large effect on the measured charge pulse height. For a thicker surface layer, all the ions may be stopped in the depletion layer at the semiconductor surface. The maximum defect generation rate also occurs here, where they have a much smaller effect on the measured charge pulse height since charge carriers are much less likely to be trapped here. For a still thicker surface layer (*c*), most of the ions are stopped in the surface layers and only a few penetrate into the depletion region. If the ion does not

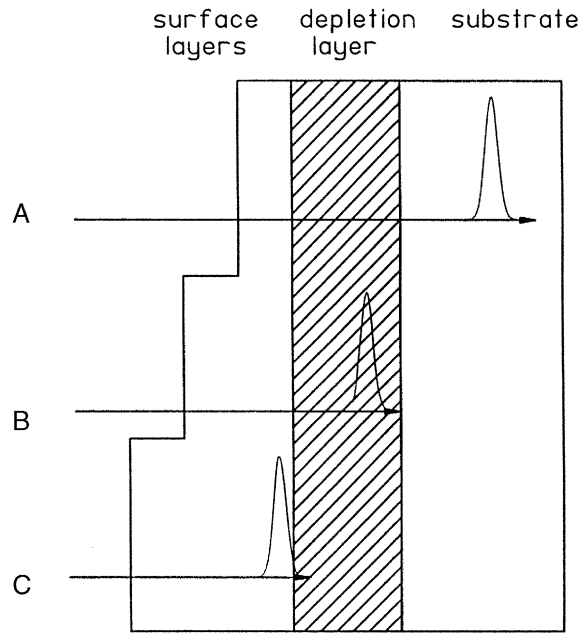

Figure 16. Schematic showing the locations of the end-of-range defects (approximated as Gaussian distributions) for increasing surface layer thicknesses from (**A**) to (**C**).

generate enough charge carriers to be measured above the noise level, then it will not be detected.

The different behavior of the two charge peaks in Figure 15 is due to the effect shown in Figure 16. The left-hand peak is due to ions that penetrate into the substrate and so reduces in height rapidly, whereas the right-hand peak is due to ions that are stopped in depletion regions present.

PROBLEMS

Two experimental problems commonly encountered during IBIC experiments are difficulties in producing measurable charge pulses and the associated large noise level present from the microelectronic device or semiconductor wafer.

Absence of Observed Charge Pulses

It is important to test the electrical contacts to the IBIC or SEU sample before irradiating them in the microprobe. Otherwise there is a high probability of unintentionally damaging the sample by mistaking the absence of measured IBIC pulses for the absence of a beam irradiating it. First the sample's sensitivity to light should be checked by measuring the current flowing through it. Light generates charge carriers in a similar manner to ions, so on most types of samples there should be a large increase in the measured current with light shining on them. Next the sample in the shielded microprobe chamber should be connected and a determination made as to whether the noise level measured with an oscilloscope (with the chamber lights off) is small enough to resolve charge pulses. Excessively large noise level might be due to poor barrier preparation or wrong connections to the microelectronic device. A further wise step is to check that charge pulses generated by α-particles from a test source can be resolved from the noise level. If not, then the use of heavier ions to produce larger charge pulses should be considered. Also, the amplifier polarity should be set so as to give positive pulses into the data acquisition system—a commonly made mistake.

Methods of Noise Reduction

If the noise level in an SEU or IBIC sample is too high, then it is difficult to sufficiently resolve the pulses. Great care must therefore be taken to reduce the noise level as much as possible before the start of data collection.

The noise level typically encountered with IBIC and SEU samples is $\sim$1 mV at the preamplifier output for microcircuit devices. Noise in charge-sensitive preamplifiers has three main sources: the input field effect transistor, the input capacitance, and the preamplifier resistance. The noise contribution from the input capacitance increases at a typical rate of 15 to 20 eV/pF, so any excess capacitance should be removed. Leads between the preamplifier and the sample should be as short as possible since the capacitance increases with lead length, and ideally the preamplifier should be mounted inside the target chamber to be as close as possible to the sample. For IBIC analysis of semiconductor wafers, the area of the Schottky barrier or the number of pins connected to the preamplifier should be as small as possible to minimize the total active area, as this reduces the capacitance. The leads should be well screened, and the sample should be isolated from earth loops, circulating currents, and radio frequency pickup from other components of the microprobe electronics. For SEU analysis, which typically requires a larger number of feedthroughs and connections to the device in the microprobe chamber in order to check its logic state after every incident ion, it is even more important that no external noise is introduced that might affect the device.

The noise level in the measured charge pulse height spectrum also depends on the amplifier time constant. A typical value of 1 μs is frequently used for the best signal-to-noise ratio. The optimum value depends on both the current flowing in the sample and its capacitance. Decreasing the time constant too much can decrease the measured charge pulse height because not all the trapped carriers may have detrapped, so it may be necessary to make a compromise between the best signal-to-noise ratio and quantifying the diffusion length from the measured charge pulse height. Once all excess input capacitance to the preamplifier has been eliminated, the remaining measured noise level is dominated by thermal generation of charge carriers. Cooling the material reduces the thermally generated noise level. The charge pulse height spectra measured from Schottky barriers for IBIC microscopy have been very noisy to date, because large-area barriers have been used in order to manually attach a thin wire to the front surface using silver paint. Since both the capacitance and the thermally generated noise contributions increase with the barrier area, this should ideally be as small as possible.

TRACE ELEMENT ACCELERATOR MASS SPECTROMETRY

INTRODUCTION

Accelerator mass spectrometry (AMS; Jull et al., 1997) is a relatively new analytical technique that is being used in over 40 laboratories worldwide for the measurements of cosmogenic long-lived radioisotopes, as a tracer in biomedical applications, and for trace element analysis of stable isotopes. The use of particle accelerators, along with mass spectrometric methods, has allowed low-concentration measurements of small-volume samples. The use of AMS to directly count ions, rather than measure radiation from slow radioactive decay processes in larger samples, has resulted in sensitivities of one part in 10^{15} (Elmore and Phillips, 1987; Jull et al., 1997). The ions are accelerated to mega-electron-volt energies and can be detected with 100% efficiency in particle detectors. The improved sensitivities and smaller sample sizes have resulted in a wide variety of applications in anthropology, archaeology, astrophysics, biomedical sciences, climatology, ecology, geology, glaciology, hydrology, materials science, nuclear physics, oceanography, sedimentology, terrestrial studies, and volcanology, among others (Jull et al., 1997). Accelerator mass spectrometry has opened new areas of research in the characterization of trace elements in materials.

This unit will focus on the technique of trace element accelerator mass spectrometry (TEAMS) and its applications in the analysis of stable isotopes in materials. This technique has been labeled by different groups as TEAMS (McDaniel et al., 1992; Datar et al., 1996, 1997a,b; Grabowski et al., 1997; McDaniel et al., 1998a,b), accelerator secondary-ion mass spectrometry (SIMS; Purser et al., 1979; Anthony et al., 1994a,b; Ender et al., 1997a,b,c,d), secondary-ion accelerator mass spectrometry (SIAMS; Ender et al., 1997a,b; Massonet et al., 1997), super-SIMS (Anthony et al., 1986), atomic mass spectrometry (Anthony et al., 1990b; McDaniel et al., 1990a), AMS (Anthony et al., 1985; Wilson et al., 1997b), and microbeam AMS (Sie and Suter, 1994; Sie et al., 1997a,c; Niklaus et al., 1997; Sie et al., 1999).

Trace element AMS for stable isotopes is very similar to SIMS, which is one of the most sensitive techniques for determination of elemental composition in materials. As with SIMS, TEAMS is a destructive technique that may be used in a static mode for bulk measurements of elemental composition or may be used in a dynamic mode to profile elemental composition as a function of depth in the material. As with SIMS, TEAMS employs a positively charged, primary-ion beam at energies of 3 to 30 keV to sputter secondary ions, atoms, and molecules from the surface or near surface of a material. Of course, most of the particles sputtered from the surface are electrically neutral and cannot be analyzed at all unless one uses a laser or some other means to ionize the neutrals, e.g., sputter-initiated resonance ionization spectrometry (SIRIS). With SIMS, either positive or negative secondary ions may be extracted from the surface through a few kilovolts and then magnetically analyzed to determine composition. This is an advantage because some atoms more readily form positive ions while others more readily form negative ions (Wilson et al., 1989). A disadvantage of SIMS is that both atomic and molecular ions are produced and, in many cases, the molecular mass is nearly the same as the atomic mass of interest. For example, ^{30}SiH has the same nominal mass as ^{31}P. Operating SIMS in a high-mass-resolution mode can reduce the molecular interferences by reducing the slit openings into the magnetic spectrometer, but this is at the cost of reduced signal strength and therefore reduced sensitivity (Wilson et al., 1989).

Trace element AMS employs a tandem electrostatic accelerator with the center terminal at a positive potential. The secondary ions from the sample, which are injected into the tandem accelerator, must be negatively charged to be accelerated to the terminal. At the terminal, the atomic and molecular secondary ions from the sample are stripped of a number of electrons in a gas or foil stripper. The electron stripping causes molecular break-up through a Coulomb explosion into elemental ions, which are then accelerated to higher energy and exit the accelerator. If the diatomic or triatomic molecular ion is stripped to a 3^+ or greater charge state, almost all molecules break up into elemental constituents (Weathers et al., 1991). With TEAMS, the resulting atomic ions, which are in a number of different charge states with correspondingly different energies, are extracted from the high-energy end of the tandem accelerator. The atomic ions are then magnetically analyzed for momentum/charge (mv/q) and electrostatically analyzed for energy/charge (E/q), which together give mass/charge (m/q) discrimination. Here, m is the mass, ν is the velocity, E is the kinetic energy, and q is the charge of the ion. To eliminate atomic interferences from possible break-up fragments that have the same m/q (e.g., $^{28}Si^{2+}$ from Si_2 break-up vs. $^{56}Fe^{4+}$), the total energy of the ion is measured in a surface barrier detector or ionization chamber.

Sensitivities for TEAMS measurements vary for different elements. These sensitivities depend on (1) the ability to form a negative atomic ion or a negatively charged molecule that can be accelerated to the terminal and then broken apart; (2) the charge state used for the measurements since the charge state ($\geq 3^+$) must be chosen to remove molecular interferences; and (3) transmission of the ion from the sample through the accelerator and beamlines to the detector. By calibrating the secondary-ion yield against reference standards and by measuring the depth of the sputtered crater, a quantified depth profile can be obtained. The sensitivity or detection limit depends on the amount or volume of material available to analyze. The sensitivity can be much better for bulk measurements, where the element of interest is uniformly dispersed throughout the material. Then, the sample can be run almost indefinitely until good statistics have been obtained. Typically, sensitivities of 0.1 part per billion (ppb) can be obtained in the depth-profiling mode (McDaniel et al., 1998a,b; Datar et al., 2000) and 5 parts per trillion (ppt) in the bulk analysis mode. Theoretical sensitivities of 1 ppt are expected under ideal conditions. Because sensitivities are so high, it is sometimes difficult to obtain suitable reference standards.

Complementary, Competitive, and Alternative Methods

There are a number of complementary trace analysis techniques of lower sensitivity and lower cost than TEAMS. The logical choice for TEAMS measurements is as a complement to other measurements provided by photon, electron, proton, or heavier ions. Depending upon the concentrations of the trace elements of interest in the sample, one may want to use one of the lower cost methods which can have sensitivities from major-element down to sub-ppb. Since TEAMS can be used for both bulk and depth-profiling measurements, some of the techniques discussed below are primarily for bulk analysis [inductively coupled plasma mass spectrometry and neutron activation analysis (ICPMS, NAA)], and others may be used for depth profile analysis (SIMS, SIRIS). Other competitive techniques that involve high-energy ion beam analysis (IBA) are described in the section introduction (HIGH-ENERGY ION BEAM ANALYSIS).

Secondary-Ion Mass Spectrometry. A complementary, alternative method to TEAMS, and one of the most powerful techniques for the characterization of materials, is SIMS (Benninghoven et al., 1987; Wilson et al., 1989; Lu, 1997; Gillen et al., 1998). In fact, the front end of TEAMS is like a SIMS system. In the next few paragraphs, the operating principles and analytical capabilities of SIMS are reviewed both as an introduction to TEAMS and as a competitive and complementary technique. An excellent SIMS tutorial is provided at the web site of Charles Evans and Associates: http://www.cea.com/tutorial.htm.

With SIMS, a positive primary-ion beam, which can be O_2^+, O^+, Cs^+, Ar^+, Xe^+, Ga^+, or any number of other species, typically 3 to 30 keV in energy, sputters secondary ions from the surface of a material. The bombarding primary ion produces atomic and molecular secondary ions and neutrals of the sample material, resputtered primary ions, and electrons and photons. Typically, O_2^+ is used if the secondary ions are more likely to be electropositive, and Cs^+ is typically used if the secondary ions are more likely to be electronegative. The choice of sputter ion can cause a change in secondary-ion yield of several orders of magnitude. Some elements do not form negative ions (e.g., N, Mg, Mn, Zn, Cd, Hg, and the noble gases), and many elements form negative ions very weakly. Of course, most of the particles sputtered from the surface are electrically neutral and cannot be analyzed at all unless one uses a laser or some other means to ionize the neutrals. Sputter-initiated resonance ionization spectrometry is such a method. The small fraction that are ionized depend strongly upon the matrix from which they are sputtered. The sputtering process is not just with the surface layer but consists of the implantation of the primary species into the sample at depths of 1 to 10 nm and the removal of the atoms or molecules from the surface by the energy loss of the primary ion through cascade collisions. Typical sputter rates in SIMS vary between 0.5 and 5 nm/s and depend upon beam intensity, sample material, and crystal orientation. The secondary ions, which are extracted through a potential of a few kilovolts and mass analyzed, are representative of the composition of the sample being analyzed. The sputter yield is the ratio of the number of atoms sputtered to the number of primary ions impinging on the sample and can range from 5 to 15. An advantage of SIMS is that secondary-ion yields can be measured over a dynamic range from matrix atoms to ppb.

The SIMS detection limits for most trace element are 1×10^{12} to 1×10^{16} atoms/cm^3. Factors that affect sensitivity and detection limits are ionization efficiencies or relative sensitivity factors (RSFs; Wilson et al., 1989); dark currents from electron multiplier detectors, which limits the minimum count rate; vacuum system elements and elements from SIMS components, which produce background counts; and mass interferences. Because both atomic and molecular ions are sputtered from the surface and analyzed with SIMS, the detection sensitivity for some elements is limited by molecular interferences. For example, in Si, ^{56}Fe is masked by $(^{28}Si)_2$; ^{31}P is masked by ^{30}SiH, $^{29}SiH_2$, and $^{28}SiH_3$; and ^{32}S is masked by $(^{16}O)_2$, among others. However, the molecular species do allow chemical information to be extracted from a sample in some cases.

The SIMS instruments may use magnetic sector, radio frequency (RF) quadrupole, or time-of-flight (TOF) mass analyzers. The secondary ions must also be energy analyzed. The magnetic sector mass analyzer separates the secondary ions by their momentum/charge (mv/q). Because of the high extraction voltage used for secondary ions, magnetic sector analyzers have high mass transmission. Magnetic sector analyzers may be used in a high-mass-resolution mode to separate molecular masses that interfere with an atomic mass of interest. This is usually accomplished at the expense of signal strength and therefore reduced sensitivity. RF quadrupole mass analyzers are smaller, more compact, and easier to use. A mass spectrum is produced by applying RF and direct current electric fields to a quadrupole rod assembly. Quadrupole SIMS instruments have loss of transmission and mass resolution

with increasing mass and also cannot operate in a high-mass-resolution mode. The TOF mass analyzers, which are used with pulsed secondary-ion beams, have high transmission and mass resolution. TOF-SIMS provides excellent surface sensitivity, and many commercial instruments couple this with submicrometer primary optics for analysis.

The SIMS data may be taken in either a bulk analysis or a depth-profiling mode. Bulk analysis allows scanning of the mass spectrometer while a sample is being sputtered away. Bulk analysis may also provide greater sensitivity since a larger volume of material is available for analysis. Bulk measurements are mainly useful for uniformly doped impurities or for surface analysis. Depth profiling allows the concentration of impurities to be determined as a function of depth beneath the surface. One or more masses are monitored as the mass spectrometer is sequentially switched. For the mass of interest, the detector signal comes from increasingly greater depths in the sample. Accurate depth profiles require uniform bombardment of the sample analysis area (i.e., a flat bottom crater) with no contribution from the crater walls, adjacent sample surfaces, or nearby instrument surfaces. Usually the primary-ion beam, which may range in size from 1 μm to hundreds of micrometers, is rastered over a region of the sample. Only data from the center part of the scan are retained for analysis to reduce contributions from crater walls.

Secondary-ion yields for elements can vary by many orders of magnitude for a given material or matrix and even from matrix to matrix. It is therefore difficult to quantify SIMS results without using calibration standards. Wilson et al. (1989) have provided tables of RSFs for many elements for both O_2^+ and Cs^+ bombardment of different substrate materials, which help quantify SIMS data.

Sputter-Initiated Resonance Ionization Spectrometry. Sputter-initiated resonance ionization spectrometry is a relatively young and powerful method for selectively ionizing and analyzing materials (Winograd et al., 1982; Pellin et al., 1987, 1990; Bigelow et al., 1999, 2001). As with TEAMS and SIMS, SIRIS also removes atoms and molecules from a sample by sputtering with ions at kiloelectron-volt energies. Again, the majority of the sputtered atoms and molecules are neutral and only a small fraction is ionized. This fraction depends strongly upon the matrix of the material. TEAMS and SIMS mass analyze this ionized fraction. SIRIS uses lasers to ionize the much larger sputtered neutral fraction for a particular species with essentially 100% efficiency and then detects the post-ionized atoms. With SIRIS, two or more lasers are used to first resonantly excite an atom and then ionize it from the excited state. By suitably tuning the lasers, only one atomic species is ionized at a time. Therefore, even without subsequent mass analysis, SIRIS is highly selective and efficient. The yield ratio of atoms detected to atoms sputtered can approach 0.1, which may be several orders of magnitude better than SIMS or TEAMS. The SIRIS technique has been demonstrated to have bulk detection limits as low as 100 ppt (Pellin et al., 1990). Because ≅80% of the sputtered atoms originate from the surface monolayer of the sample and ≅95% from the top two surface monolayers (Hubbard et al., 1989), SIRIS has excellent surface sensitivity. Because of the high useful yield, measurements may be made while sputtering sub-monolayer target thicknesses, making SIRIS essentially nondestructive. However, SIRIS may also be used to measure atoms below the surface if the primary-ion beam is allowed to sputter the sample for a longer time. One limitation of SIRIS is that it is very element specific, and multielement work may require several laser schemes.

Neutron Activation Analysis. Other mature methods that are readily available and provide rapid and economical, multielement, ppb-level detection of trace elements include NAA (Kruger, 1971). While NAA has excellent sensitivity in some cases (e.g., ^{197}Au in Si), the sensitivity of NAA is limited by the neutron capture cross sections, which vary from element to element. In addition, NAA may be primarily useful for Si since irradiation of other compound semiconductor materials like GaAs and HgCdTe will produce higher background radiation from the additional substrate elements.

Inductively Coupled Plasma Mass Spectrometry. Inductively coupled plasma mass spectrometry is a sensitive bulk materials analysis technique (10^{14} atoms/cm^3 or 10 ppb; Houk, 1986; Baumann and Pavel, 1989). Essentially the entire sample is vaporized, and the resulting plasma is analyzed by mass spectrometry. However, there may be a concern about incomplete elemental dissolution and contamination during sample preparation.

Neutron Activation–Accelerator Mass Spectrometry. Neutron activation (NA) followed by AMS has been used to study light impurities in Si (Elmore et al., 1989; Gove et al., 1990). Neutron activation is used to produce long-lived radioisotopes, which generally have lower concentrations in the environment. After activation, AMS can provide more sensitive background-free measurements of the neutron activation products.

For example, neutron activation to convert stable ^{35}Cl to the long-lived radioisotope ^{36}Cl followed by conventional AMS has been used to study both the diffusion of Cl in Si (Datar et al., 1995) and the impurity Cl concentration in Si. This gets around the problem of having to ensure source cleanliness since the ambient ^{36}Cl has an abundance ratio of 10^{-15} vis-à-vis stable Cl. This was especially useful in the Rochester measurements (Datar et al., 1995) since the ion source used for the measurements was heavily contaminated with stable Cl. This technique can be used in principle for any isotope that produces a suitable, relatively long lived isotope by thermal neutron activation. The sensitivity of the measurement can be increased by increasing the total thermal neutron flux incident on the samples.

Choosing the Proper Technique. From the above discussion, the basic criteria for choosing TEAMS over other techniques should be based upon the need to determine elemental concentrations in a sample for those elements

that need high sensitivity or have a molecular interference. Because of the cost and difficulty of a TEAMS measurement, TEAMS should not be used for all elements if the element can be analyzed by an alternative and less expensive method such as Rutherford backscattering spectrometry (RBS; see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS), particle-induced X-ray emission (PIXE; see PARTICLE-INDUCED X-RAY EMISSION), or nuclear reaction analysis (NRA; see NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION). In some cases, chemical information may be needed for a sample, and SIMS would be more useful. For some elements, molecular interferences are not a problem, and SIMS would be easier and less expensive. In addition, for low-mass-resolution applications, SIMS may give lower detection limits due to higher ionization rates with O_2^+ primary-ion bombardment.

PRINCIPLES OF THE METHOD

The Trace Element Accelerator Mass Spectrometry Facility

The TEAMS facility consists of three main components: (1) the ultraclean ion source for the generation of negative secondary ions from a material by primary-ion sputtering, much like in SIMS; (2) the tandem accelerator, which accelerates the secondary ions to mega-electron-volt energies and strips electrons to remove molecular interferences; and (3) the detector system, which includes the high-energy beam transport line with magnetic and electrostatic analysis, and the particle total energy detection system. Different laboratories around the world are employing a number of different approaches to TEAMS, and attempts will be made to contrast these different approaches in this unit. However, the following description of TEAMS will be primarily the University of North Texas (UNT) facility.

Ultraclean Ion Source for Negatively Charged Secondary-Ion Generation

The ion source is designed to produce secondary ions from the sample while minimizing contaminant ions produced from the ion source hardware and from previous samples. The ion source is discussed in detail under Practical Aspects of the Method.

Secondary-Ion Acceleration and Electron-Stripping System

With the sample biased at -13 kV, the negatively charged secondary ions are extracted from the chamber at the energy of 13 keV and passed through a 45° electrostatic analyzer (ESA). The ESA discriminates against energy/charge (E/q) with $E/\Delta E = 75$ for a 2-mm slit width. The ESA passes all masses originating from the sample surface that have the correct extraction energy. Secondary ions originating from other surfaces in the ion source chamber are prevented from being passed down the extraction beamline and into the tandem accelerator. Since the negative ion yield is at most 1% to 2%, a typical secondary-ion beam after the ESA due to 900 nA of 23-keV Cs^+ (10 keV from Cs oven plus 13 keV from negative sample bias) is

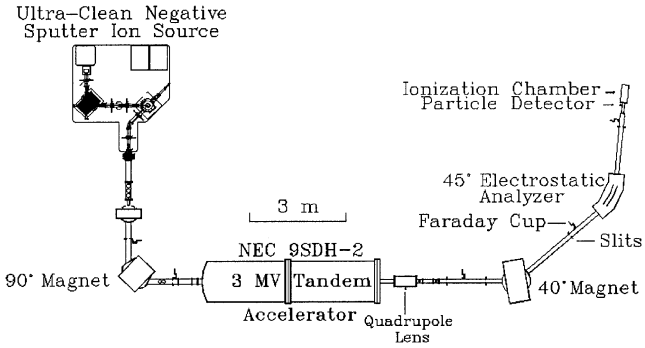

Figure 1. The TEAMS facility in the Ion Beam Modification and Analysis Laboratory at the University of North Texas.

≅50 to 60 nA of ^{28}Si through a 2-mm slit opening. After the ESA, the negative ion beam is passed through a 90° dipole magnet and momentum/charge analyzed (mv/q) with $m/\Delta m = 500$ for a 2-mm slit width. A mass scan after the 90° magnet would be equivalent to a SIMS analysis and would include molecular as well as atomic negative ions. After the 90° magnet, the ^{28}Si secondary-ion beam is ≅12 to 15 nA. Figure 1 shows the TEAMS system at UNT.

The 13-keV negative ions are injected into the tandem accelerator and accelerated to the terminal, which typically is operated at 1.7 MV for TEAMS. For an ion with charge 1^-, injection voltage $U = 13$ kV, and terminal voltage $V = 1.7$ MV, the ion energy is given by

$$E = e(U + V) \tag{1}$$

The higher energy negative ions (1.713 MeV) are then efficiently stripped of one or more electrons in the terminal by an N_2 gas or carbon foil stripper. The gas or foil stripper is sufficiently thick to produce atomic and molecular ions in a distribution of positive charge states q (Betz, 1972; Wiebert et al., 1994). All of the charge states produced will be accelerated again from the terminal down the high-energy side of the tandem accelerator, producing a number of different energy ions. The 1^+ ions will gain another 1.7 MeV of energy; the 2^+ ions will gain another 3.4 MeV of energy, and so on for each subsequent charge state q. The mass m of the ion exiting the accelerator may be less than the mass m_0 of the ion injected (if dissociation occurs in the terminal) or equal to the injected mass if no dissociation occurs. The total energy of the ion of mass m after the accelerator is given by

$$E = e(m/m_0)(U + V) + eqV \tag{2}$$

where the first term is the residual energy from the dissociated ion in the terminal and the second term is the post-stripping energy. This energy neglects the energy loss of the ion in the stripper gas, which can vary from 0.1 keV for H to 7.0 keV for Si and must be taken into account in subsequent analysis (Arrale et al., 1991). The N_2 gas pressure may be used to optimize the production of the charge state of interest. For 1.7 MV terminal voltage, the most populated charge state is 3^+ for masses in the range

from 20 to 60 amu. The charge state chosen after acceleration and for further analysis depends upon possible interferences with other m/q ions, mainly from matrix elements in the sample and upon the charge state needed for molecular break-up. Molecules in a 1^+ or 2^+ charge state will still exist and will be accelerated to the higher energies. There are several molecules that are known to be at least metastable in a 3^+ charge state. While most of these molecular ions are larger clusters or organic molecules (Burdick et al., 1986; Saunders, 1989), a few are relatively small trimers CS_2 and CSe_2 and the dimer S_2 (Morvay and Cornides, 1984). The small dimers B_2 and AlO have been observed to remain in a 3^+ metastable state for many microseconds, enough time to travel all the way from the terminal to the detector (Weathers et al., 1991; Kim et al., 1995). Normally, ions in a 3^+ charge state are chosen to ensure that there are no molecular interferences. Occasionally, for some elements, a charge state of 4^+ or 5^+ might be more desirable. The rule of thumb is that m/q should be a noninteger.

For elements that do not form negative ions or do so very poorly, the sensitivity for atomic detection would be very low or zero. However, for these cases, a negative molecular ion may be injected into the tandem accelerator of the form $(MX)^{1-}$, where M is the matrix atom or some other atom present in the sample (e.g., Si) and X is the impurity atom of interest. After accelerating the molecule to the terminal and breaking it apart by electron stripping, the atomic fragment of interest, X^{q+}, may be analyzed, where q is the charge state of the ion. Therefore, essentially, any element in the periodic table may be analyzed by the TEAMS technique. Indeed, the sensitivity for detection of each element depends upon a number of things, such as negative ion formation probability, matrix composition, sample contamination, surface oxidation or covering, charge state chosen, and transmission through the accelerator.

High-Energy Beam Transport, Analysis, and Detection System

After acceleration to mega-electron-volt energies and break-up of molecular interferences, the total ion beam in all charge states is 20 to 30 nA of ^{28}Si. The atomic ions in the chosen charge state are selected by magnetic analysis at 40° and by electrostatic analysis at 45°, as seen in Figure 1. After the magnetic and electrostatic analysis, the $^{28}Si^{3+}$ beam is ≅6 nA and ≅5 nA, respectively. The magnetic rigidity is given by $Br_b = mv/q$ with $m/\Delta m \cong 300$ for a 2-mm slit width, and the electrostatic rigidity is given by $\mathcal{E}r_e = 2E/q$ with $E/\Delta E \cong 250$. Here, B and $\mathcal{E}$ are the magnetic and electric field strengths, respectively, and r_b and r_e are the radii of curvature in the magnetic and electric fields, respectively. Combining these two analyses gives m/q. To eliminate atomic interferences from possible break-up fragments that have the same m/q (e.g., $^{28}Si^{2+}$ from the break-up of Si_2 and $^{56}Fe^{4+}$), the total energy of the ion is measured in a surface barrier detector or ionization chamber.

For bulk measurements of uniformly distributed impurities or dopants, the beam spot may be spread out to ~2 mm in diameter to increase count rate and the sample may be counted for longer time periods. For depth-profiling measurements, only data collected from the center ≅12% of the rastered area (plus the width of the sputter beam) are gated into the pulse height analyzer. Data from the remaining ≅88% of the rastered area, which includes the secondary ions sputtered from the crater wall, are discarded. It is still possible and even likely that some of the material comprising the ≅88% could be resputtered back onto the sample center ≅12% region, producing a contamination of the sample and reduced sensitivity.

The TEAMS system is automated and under computer control. The software to operate and control the TEAMS system is a combination of in-house and LabView programs at UNT. The software allows magnetic and electrostatic analyzers to scan mv/q and E/q, respectively, to a precision of 1:10,000 and to make either bulk or depth-profiling measurements. The magnetic and electrostatic analyzers are calibrated by analyzing known masses, usually from different matrix elements or molecules. Both atomic and molecular ions and atomic fragments are typically used for calibrating a wide range of magnetic (mv/q) and electric (E/q) rigidities. The software also operates Faraday cups, viewers, detectors, quadrupoles, steerers, and beam attentuators. Transmission through the entire TEAMS system is ≅1% to 8%.

Future Possible Advances in TEAMS

Future possible advances in TEAMS include the development of a tandem accelerator specially designed to directly couple to a SIMS source (with suitably modified injection optics) and the possible development of an efficient charge exchange canal to enable conversion of positive ions to negative ions. The Naval Research Laboratory (NRL) group (Grabowski et al., 1997) is constructing a TEAMS system by attaching a SIMS instrument to a tandem accelerator. Future improvements would include a submicrometer primary-ion beam and a means for secondary electron imaging of features on a sample. The Australia group (Sie et al., 1998) and the Zurich group (Ender et al., 1997c) have already developed microbeam TEAMS systems. Also on the horizon are other techniques to increase ionization probabilities such as laser postionization of neutrals sputtered from a sample (e.g., SIRIS; Winograd et al., 1982; Pellin et al., 1987, 1990; Bigelow et al., 1999, 2001). For some applications, the truly atomic aspects of TEAMS may be used to advantage, for example, in profiles through layered films.

PRACTICAL ASPECTS OF THE METHOD

The uniqueness of TEAMS is that it combines the two techniques of AMS and SIMS and can thereby be used to measure very low levels of stable isotopes of almost any element in a variety of different matrices corresponding to different materials (Rucklidge et al., 1981, 1982; Wilson et al., 1991, 1997a,b; Ender et al., 1997a-c; Massonet et al., 1997; McDaniel et al., 1998a,b; Datar et al., 2000). TEAMS has the capability to achieve ppt detection limits for some

elements in Si, which is considerably better than SIMS. TEAMS analysis is similar to SIMS. Perhaps, the largest benefit of TEAMS results from the passage of the secondary ions through a tandem accelerator where electrons are stripped from the molecular ion, resulting in a Coulomb explosion of the molecule into its elemental components. With TEAMS, after molecular break-up, magnetic (mv/q), electrostatic (E/q), and total energy (E) analyses are performed that uniquely identify the elemental ion. The mega-electron-volt energies of the secondary ions allow nuclear physics particle detectors to be used with essentially 100% detection efficiency because of the reduction in detector noise and scattered particles. The sensitivity of TEAMS is reduced because only one charge state ion is analyzed from the distribution of charge states produced during the electron-stripping process in the tandem accelerator. Since the most dominant charge state is usually chosen for analysis, the reduction in sensitivity is usually by only a factor of 3. The current depth-profiling detection limits at UNT of $\cong$0.1 ppb atomic are primarily due to ion source contamination and suboptimal secondary-ion transmission through the accelerator and analysis system (McDaniel et al., 1998a,b). Removal of source contamination and improvements in system transmission should allow ppt-level detection of stable elements in the depth-profiling mode. Bulk detection limits are lower because more material is available to analyze just by counting longer. Other TEAMS facilities around the world have similar detection limits (see section on existing TEAMS facilities in operation or under construction below).

The TEAMS technique can be used to easily discriminate against molecular interferences. However, it cannot easily discriminate against isobaric interferences, since at relatively low energies the ionization chamber detector cannot provide significant dE/dx information. Thus, in the case of more than one isotope with possible isobaric interferences, the isotope without any interferences should be chosen for analysis.

Ultraclean Ion Source Design Details

The ion source is designed to reduce sample contamination from elements in the ion source hardware and from chemically similar elements in the Cs and cross-contamination from other or previously analyzed samples (commonly called source memory effects). To reduce sample contamination, ion source components exposed to the primary-ion beam may be coated with ultraclean Si or some other pure material. The ion optics should be designed to reduce scattering onto the sample (Kirchhoff et al., 1994). The primary-ion beam is Cs^+, which readily provides electrons for the production of negatively charged atomic and molecular ions. The Cs^+ may be produced by a surface ionization ion source with an energy spread of approximately $kT = 0.1$ eV, where $k = 1.38 \times 10^{-23}$ JK^{-1} is the Boltzmann constant, and T is the temperature in K. For nominal energies of 10 keV incident upon the sample, the fractional energy spread is approximately $\Delta E/E = 10^{-5}$. The sample is held at a negative bias of 11 to 30 kV to allow the secondary ion produced to have enough energy to be injected into the accelerator and transmitted through the entire

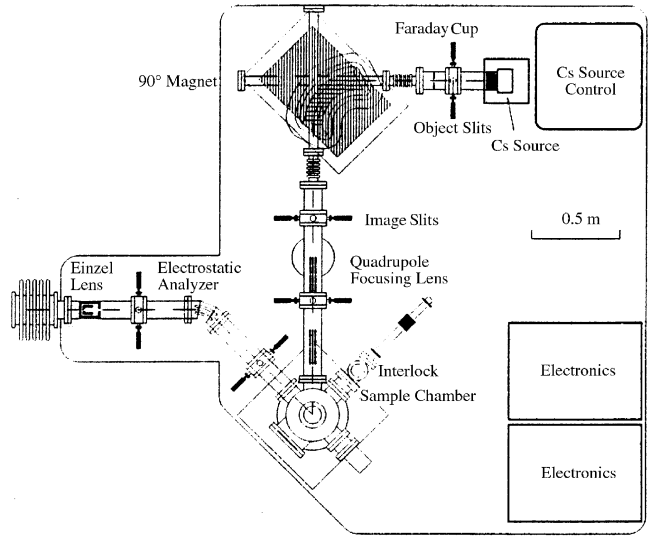

Figure 2. The TEAMS ultraclean negative sputter ion source. Shown are the Cs oven, the 90° magnet for preanalysis of the Cs sputter beam, sample chamber with sample load interlock, and 45° electrostatic analyzer in the secondary-ion beamline. Not shown are the eight Einzel focusing lenses, the six octupole steerers, and Cs beam scanner, which are electrostatic and therefore mass independent. Also, not shown is the aperture plate with laser drilled holes from 2 mm down to 0.2 mm, which allows the beam object size to be varied for microbeam production. Because of the many components for focusing and steering the primary Cs beam and the secondary ions from the sample, the entire source is under computer control at the source and in the control room.

TEAMS system. The lower sample bias allows better depth resolution in the sample. For the sample biased at -13 kV, the total primary-ion impact energy is 23 keV. While the Cs^+ ion beam may be very monoenergetic, it is not very pure. The primary Cs^+ ion beam should also be magnetically preanalyzed (mv/q) before striking the sample to reduce contamination of the sample (Kirchhoff et al., 1994). The ion source is normally capable of depth profiling with a microbeam primary ion as well as bulk impurity measurements in materials. For depth profiling, the last optical element before the sample is usually used to raster the primary-ion microbeam over a selected region of the sample. Secondary-ion data are then accumulated only from the center (12% to 20%) region of the crater sputtered by the primary ion to reduce wall contributions. It is necessary to have a microscope in the sample chamber to observe and monitor the beam spot on the sample.

Figure 2 shows the main components of the ultraclean ion source developed at the Ion Beam Modification and Analysis Laboratory (IBMAL) at the UNT (Kirchhoff et al., 1994). The intensity of the ion source is determined by the brightness of the primary Cs source, which is a UNT-modified, model 133 Cs source available from HVEC-Europa. The modifications are in the extraction and focusing optics and steering fields and have resulted in an increase in source brightness. Using computer control and optimization algorithms, the output parameters of the source can be rapidly optimized. The maximum half-angle of divergence of the Cs beam from the source was measured to be $\sim$9 mrad. The laboratory

emittance of the source was determined to be $\cong 7 \times 10^{-4}$ π-cm-mrad. For the 10-keV Cs ions, this corresponds to a normalized emittance of $\cong 7 \times 10^{-5}$ π-cm-mrad $(\text{MeV})^{1/2}$. This parameter indicates that, in the absence of aberrations, the theoretical spot size, without significant current loss, is ≅40 μm in diameter. In reality, the smallest spot size attained thus far at UNT is ≅60 μm in diameter. The use of reducing apertures can further reduce the spot size at the expense of intensity. This beam spot is continuously variable up to ≅2 mm in diameter for use in bulk analysis. Sie et al. (1998) and Ender et al. (1997c) have developed primary-ion microbeams that are on the order of 1 μm to a few micrometers in diameter.

The 10-keV Cs^+ ion beam is magnetically analyzed with a double-focusing 90° electromagnet to remove other alkali metals and Mo and Fe. These elements are produced from the components in the Cs and the ion gun. The ion source magnetic spectrometer helps to remove ambiguity and chance of contamination. Therefore, the Cs beam striking the sample is ^{133}Cs. Contamination has been shown to be well below 1 ppt after magnetic filtering.

Following the magnetic spectrometer, the primary ions enter an electrostatic zoom lens column that forms an intense microprobe. For depth-profiling measurements, the Cs^+ is scanned across the sample in a spiral digital meander pattern. The sample region scanned is ~1 mm × 1 mm in area and is divided into a 128 × 128 pixel integrated image, which is regenerated for each frame. The scanning system is digitally controlled from a digital input-output (I/O) card resident in a personal computer. Because of the number of active focusing and steering elements in the primary-ion beamline and the secondary-ion beamline, the ion source operation components are under computer control.

A microbeam may be formed from the momentum-analyzed ^{133}Cs ion beam with a combination of two quadrupole/octupole quadruplets. The first quadrupole is presently designed to produce a stigmatic image with a magnification $M_{Q1} = -1/50$ or less. This demagnification is followed by a long-working-distance quadrupole/octupole quadruplet objective to produce an elliptical spot at near-unity magnification in the vertical direction and a magnification of ~0.707 in the horizontal direction. Therefore, when the beam impinges on the sample surface at near 45°, the spot will appear almost circular. In practice, the strong horizontal electric field between the extraction plate and the sample bends the primary beam so that the angle of impact is ≅25° for ≅ −20-keV sample bias. The final optical element in the primary column of the ion source is a two-stage, eight-electrode dipole element that produces a translation of the beam of ±4 mm without introducing any variation in the angle of impact upon the sample. This feature is important when sputtering a uniformly deep crater for depth profiling. The dipole element scans the ion beam in a raster pattern. By correlating electronically the position of the primary-ion beam spot and the detection of the secondary ion at the other end of the apparatus, one can build an image of impurities distributed across the surface of the sample. The lateral resolution of the image, however, is limited by the beam spot size, which is presently ≅60 μm at the UNT facility. By acquiring the secondary ions versus time and knowing the rate at which the ion beam erodes the surface of the sample, one can build a profile of the impurity distribution versus depth. Therefore, in principle, a three-dimensional impurity map is possible. The limitation of available impurity ions in a sputtered volume will set a lower limit on the size of the beam spot for a given concentration of impurity atom. For example, for a typical Cs sputtering rate of ~2 Å/s (2×10^{-4} μm/s) and a 100 × 100 μm analyzed area, the sample volume of 2 μm^3 would contain 10^{11} Si atoms. One impurity atom detected in 1 s in this volume would correspond to a sensitivity of 10^{-11}, or 10 ppt. Higher impurity concentrations would require a smaller sample volume while lower impurity concentrations would require a larger sample volume.

Because of the developments in SIMS instruments that allow for a primary-ion microbeam and secondary electron imaging of a sample, some laboratories are using existing SIMS instruments to inject into the tandem accelerator and analysis system for the TEAMS facility (e.g., Grabowski et al., 1997). To improve the depth resolution of the data, the primary-ion energy and the sample bias should be as low as possible, while the sample bias should still be high enough to ensure adequate transmission through the remainder of the accelerator and beam transport system.

Secondary electron images permit accurate and rapid positioning of the primary Cs^+ ion beam on the sample. The sample is also viewed by a long-working-distance microscope with a field of view equal to the sample size (≅3 mm) and a resolution of a few micrometers. A remote high-resolution TV monitor views the optical image. The position of the sample is adjusted by a four-axis manipulator (x-y-z-θ) to allow three translations and one rotation about the secondary ion axis which is perpendicular to the sample surface.

Throughout the ion source, all first surfaces, which can be "seen" by the primary or secondary ions, are Si. The use of ultrapure and ultraclean Si on the first surfaces of the focusing and steering lenses, slits, Faraday cups, and apertures reduces the contamination of the sample from ion-wall scattering. These specialized components may be fabricated from relatively inexpensive materials (Kirchhoff et al., 1994). To further reduce sample contamination, the vacuum system is all metal sealed and has a base pressure, without baking, of $\cong 2 \times 10^{-9}$ torr. The sample holder, which will hold up to 19 individual samples 3 mm in diameter, is admitted and removed from the sample chamber via a sample interlock and manipulator. Samples are positioned on the sample holder and prepared for analysis in a class 100, portable clean room.

For samples that are insulating, a charge compensation system is required. This may be an electron gun that sprays electrons upon the sample to reduce sample charging in much the same way as with a standard SIMS instrument.

Calibration of TEAMS Magnetic and Electrostatic Analyzers

With TEAMS, in most cases, one is attempting to measure a trace quantity of an impurity element in a matrix, as

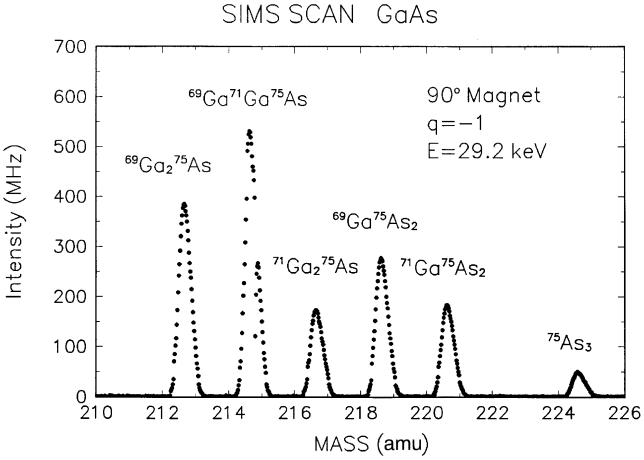

Figure 3. SIMS mass scan of the 90° preinjection magnet showing the characteristic signature spectrum of the trimer molecules formed in a charge state $q = 1^-$ from a GaAs matrix sample in the ion source. The peak heights are related to the natural abundances of the ^{69}Ga (60.1%) and ^{71}Ga (39.9%) isotopes. For each mass in the spectrum, a magnetic rigidity Br_b is determined, which is used to build a calibration file for the mass 212- to 225-amu region. Atomic and molecular ions of different masses are used for other mass regions.

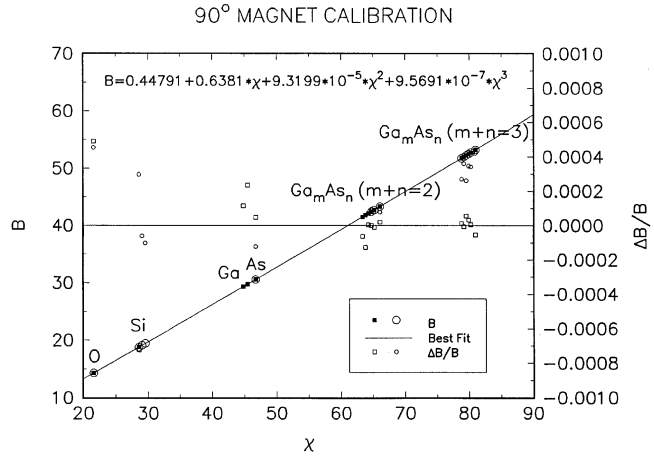

Figure 4. Graph of the 90° preinjection magnet calibration file showing magnetic field strength B versus $\chi_B = Br_b = mv/q$, the magnetic rigidity, which is dependent on the m, E, and q of the analyzed ion. The calibration file was determined from spectra like the one shown in Figure 3. The right-hand axis is a measure of the goodness of fit, the residual $\Delta B/B$, and is less than 0.0006 for all χ. The calculated fit, which is given at the top of the graph, is interpolated to find magnetic field strengths for other masses.

either a bulk elemental mass scan or an elemental depth profile of one or two elements. The small concentration of the impurity element requires that the TEAMS magnetic and electric fields used for analysis be precisely calibrated. The TEAMS system is calibrated by measuring mass scans of elements of known concentrations, i.e., the elements of the matrix for the sample being measured. Figure 3 shows a characteristic signature spectrum of the trimers (e.g., $(^{69}Ga^{71}Ga^{75}As)^{1-}$) that occurs with the 90° preinjection magnet mass scan of a GaAs sample. The calibrations are run sequentially through the 90° preinjection magnet, the 40° postacceleration magnet, and the 45° ESA for a fixed terminal voltage. A calibration file is constructed for each magnet, and the ESA from the isotopic mass and the magnetic ($\chi_B = Br_b = mv/q$) or electrostatic ($\chi_\mathcal{E} = \mathcal{E}r_e = 2E/q$) rigidity. Atomic and molecular ions as well as dissociated ions may be used for calibration. After the calibration files have been constructed, cubic polynomial fits to the data for each magnet were found to be necessary while a straight-line fit was found to be sufficient for the ESA. Figure 4 shows a representative calibration for the 90° preinjection magnet. The 40° postacceleration magnet (HVEC) is similarly calibrated. The electrostatic voltage for the ESA is plotted versus the electrostatic rigidity, $\chi_\mathcal{E} = \mathcal{E}r_e = 2E/q$, for different known masses. The calculated fits are interpolated to set magnetic and electric field strengths for future mass analyses. The secondary ions from the sample are analyzed through the entire spectrometer under computer control. A calibration precision of 0.001 in $\Delta B/B$ and 0.002 in $\Delta V/V$ is required for preservation of isotopic ratios, which is the true test of an accurate calibration of the system. For example, for elements with more than one stable isotope, the stable isotopes should appear in the correct proportions in a mass scan, as shown in Figure 3.

Existing TEAMS Facilities in Operation or Under Construction

The characteristics of a number of TEAMS facilities are discussed below. The information was provided to the author by personnel from the different TEAMS laboratories. (See the Internet Resources for contact information.)

Paul Scherrer Institute (PSI)/ETH Zurich Accelerator SIMS Laboratory. The PSI/ETH tandem accelerator facility serves as a national and international center for AMS. This very sensitive method is currently the leading technique for the detection of long-lived radionuclides such as ^{10}Be, ^{14}C, ^{26}Al, ^{36}Cl, and ^{129}I at isotopic ratios between 10^{-10} and 10^{-15}. These isotopes are intensively studied as natural tracers in earth sciences and in climate history research. In addition to radionuclide AMS, the PSI/ETH Zurich laboratory is actively involved in TEAMS research.

The TEAMS facility in Zurich includes a sputter chamber with an ideal extraction of secondary ions into the already existing beamline of the AMS facility in Zurich. At the same time, the chamber design keeps the contamination due to sputtering of secondary ions in the vicinity of the sample as low as possible. This was achieved with the extraction geometry shown in Figure 5.

The finely focused Cs^+ primary-ion beam is produced with a commercial Cs431 SIMS ion source from ATOMIKA in Munich, Germany (Wittmaack, 1995). It can produce beam currents from 0.2 to 800 nA with corresponding beam spot sizes of 1 to 150 μm. The Cs beam is analyzed with an $E \times B$ filter and sent through a 1° electrostatic deflector to remove impurities and neutral components and to keep contamination from the primary beam as low as possible. Also, the primary beam can be scanned over the sample to perform imaging of trace elements on the sample surface.

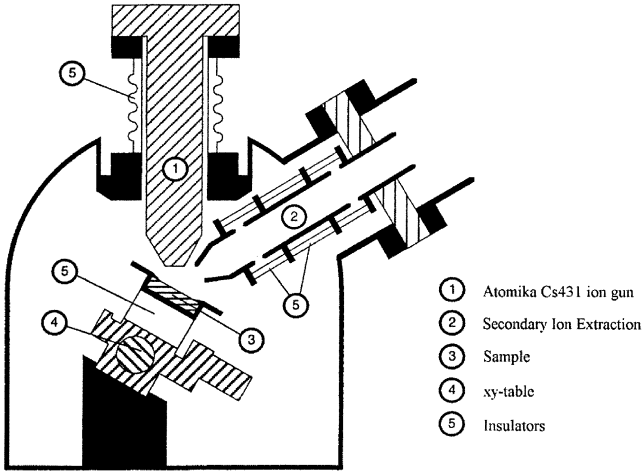

Figure 5. Schematic cross section through the TEAMS-sputtering chamber at the AMS facility in Zurich.

Using specific extraction voltages on the electrodes in the vicinity of the sample, the positive secondary ions are kept on the sample as much as possible and negative ions are extracted as much as possible so that they cannot be accelerated toward electrodes and produce tertiary ions and neutrals that would contaminate the sample. However, since this process cannot be suppressed completely, all the electrodes of the source have been coated with a 20-μm-thick layer of gold so that contamination of the sample due to the sputtering processes is kept low for all elements except gold (Döbeli et al., 1994; Ender et al., 1997a–c).

The extracted negative ions are deflected into the main beamline of the AMS facility and analyzed as in routine measurements. The EN6-Van de Graaff tandem accelerator is usually run at a terminal voltage of 5 MV, and a two-electrode gas ionization detector is used for the separation of isobaric interferences (Ender, 1997).

The facility has been tested with respect to detection limits, imaging, and depth profiling on trace elements in Si wafers. Table 1 and Figure 6 show a summary of the results for the TEAMS facility in Zurich for the bulk detection of trace elements in Si (Ender et al., 1997d).

Ongoing projects on the TEAMS facility are the measurement of isotopic ratios of trace elements in sedimen-

Table 1. Bulk Detection Limits for Trace Elements in Si Measured at PSI-ETH Zurich[a]

Element	Atomic Ratio	Atomic Density (atoms/cm^3)
B	1×10^{-10}	5×10^{12}
Al	7×10^{-11}	3.5×10^{12}
P	2×10^{-10}	1×10^{13}
Fe	2×10^{-9}	1×10^{14}
Ni	2×10^{-9}	1×10^{14}
Cu	2×10^{-9}	1×10^{14}
As	9×10^{-12}	4.5×10^{11}
Sb	2×10^{-10}	1×10^{13}

[a] The bulk detection limits are given as atomic ratios of trace element to Si and as atomic densities.

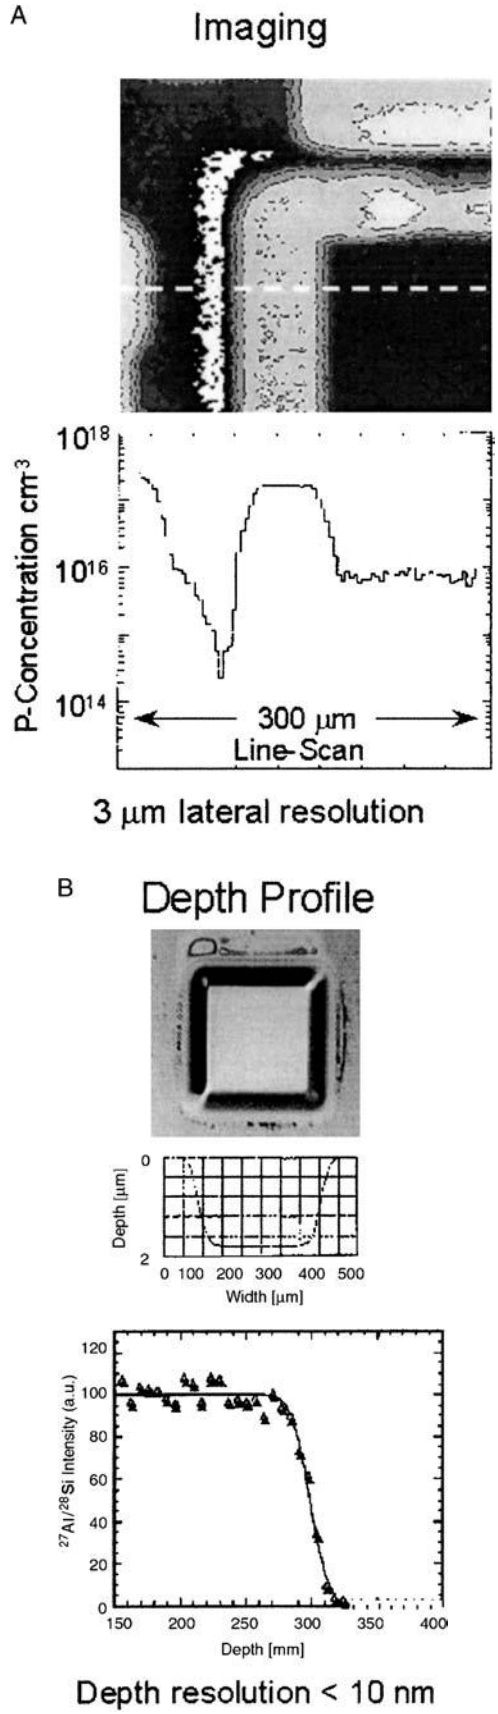

Figure 6. (**A**) Lateral resolution and (**B**) depth resolution of the TEAMS facility in Zurich.

tary layers and extraterrestrial matter with the goal to solve problems in geology and nuclear astrophysics. The main interest lies in the measurement of the heavy platinum group elements (PGEs). With the finely focused Cs beam, one can measure samples as small as ~200 ng. This also might have potential for the analysis of radioisotopes (Maden et al., 1999, 2000).

University of Toronto IsoTrace Laboratory. The University of Toronto is well known as one of the first laboratories to do radionuclide AMS. The existing AMS facility has also been used for a number of years for *in situ* TEAMS measurements of Au, Ag, and PGEs in mineral grains and meteorites (Rucklidge et al., 1981, 1982; Wilson et al., 1990; Rucklidge et al., 1990a,b; Kilius et al., 1990; Wilson et al., 1995; Rucklidge et al., 1992; Wilson et al., 1997a–c; Wilson, 1998; Sharara et al., 1999; Litherland et al., 2000, 2001). The "heavy-element" program developed at IsoTrace had its beginnings in the fertile period of collaborative research at the University of Rochester, circa 1977 to 1981, which saw trial analyses of PGEs such as Ir and Pt in pressed, powdered targets of rock and mineral samples using a broad-beam Cs^+ source on the tandem accelerator. Further development at IsoTrace was slow but sped up in the late 1980s with the evolution of a multitarget sample-mount format that involved the drilling of small (4-mm-wide) cylindrical "minicores" of samples and reference materials that were then mounted in sets of 12 in a 25-mm circular holder and polished to a fine finish, permitting mineralogical or metallographic tests prior to analysis. It should be noted that the sample chamber and 25 × 25-mm micrometer-resolution stage came first, in 1984, to combine unrestrained three-dimensional mobility and adequate sample-viewing optics, essential features for analysis of targets such as rocks. Rocks are almost always heterogeneous mixtures of one or more mineral species of variable shapes and grain sizes. The initial work conducted on the new stage was again of the pressed-powder variety, but the move to solid targets promoted a spate of measurements and rapid progress from circa 1989 to 1997, as summarized below. The principal limitations of the technology (aside from questions of cost and availability) that have thus far restricted adoption of these methods are perceived to be (1) the need to use conducting targets, whereas common rock-forming minerals are mostly good insulators, and (2) the broad Cs^+ beam size (maximum range may be 250 to 1500 μm, but commonly ~1000 μm), which limits application to relatively coarse grained samples. If any group succeeds in going beyond these constraints, which are common to ^{14}C-oriented accelerator laboratories, the next question will probably return to quantitation and the development of reference materials. In the course of this work, IsoTrace has addressed this by fabricating "fire assay" beads based on dissolution of well-characterized samples into a conducting nickel sulfide matrix.

Possible applications of TEAMS are almost limitless if the questions of surface charge build-up and spatial resolution can be addressed at a facility with a flexible analytical repertoire. Analytical capability evolved at IsoTrace due to the efforts of the late Linas Kilius and the other laboratory staff but did not exist in the very first incarnation of the laboratory, a straightforward ^{14}C system. Although test measurements were made on semiconductors, most trace element data at IsoTrace have involved conducting minerals and metals in rocks, meteorites, and archaeological artifacts. In addition, a large majority of the measurements have centered on just eight elements, the precious metals, namely Au and Ag, and the six PGEs (Pt, Ir, and Rh, which form negative ions readily, and Pd, Ru, and Os, for which sensitivity is significantly lower). Typical bulk detection levels achieved in short (e.g., 10 to 200 s) counting times are given in Table 2. Approximately 40 elements have been the subject of basic research at IsoTrace (see the short essay on heavy element research on the web page), but the precious metals have dominated the applications work.

Table 2. Standard Bulk Detection Levels (±30%) for Some Trace Elements for Analysis Times Less Than 200 s at the University of Toronto[a]

Element	Bulk Detection Level (ppb)	Atoms/cm^3
Ru	4	1.2×10^{14}
Rh	0.5	1.5×10^{13}
Pd	4	1.1×10^{14}
Ag	0.05	1.4×10^{12}
Os	20	3.2×10^{14}
Ir	0.25	3.9×10^{12}
Pt	0.1	1.5×10^{12}
Au	0.005	8×10^{10}

[a] If required, lower detection levels can be obtained with increased analysis time, limited by the availability of material.

It is important to note that in-house research has emphasized the importance of collecting TEAMS data as part of a broad spectrum of research on a topic. This ideally includes collection of samples in the field, classic petrographic (microscopic) studies, and sometimes whole-rock analyses of bulk samples plus collection of mineral-chemical data for major to trace elements using a full range of methods—some combination of electron, proton, and ion microprobe analyses as well as the broad-beam TEAMS.

The PGEs and Au typically behave as siderophile or chalcophile (iron- or sulfur-loving) metals, present at low-ppb levels or below in the earth's crust but at much higher levels in many meteorites and (by inference) in the cores of the differentiated terrestrial planets. A factor of roughly 1000 is necessary to enrich typical crystal rocks from ppb levels to the ppm grades, which constitute ore in most hard-rock gold and platinum mines today. The TEAMS of precious metals has largely been directed to the following materials: common Fe-Cu-Ni-As sulfides, Fe-Ti-Cr oxides, copper (both natural native copper and refined metal), and the common Fe-Ni-Co metal phases in iron meteorites and graphite. These materials have been analyzes in three broad contexts:

1. Distribution of the metals among coexisting ore minerals in various classes of mineral deposit. All the precious metals may occur both in concentrated form (rare minerals such as Au, $PtAS_2$, and PdSb)

and "invisibly" within the crystal structures of common ore minerals at levels from <1 ppb to 100 ppm or more—much more in the case of Ag.

2. Chemistry of iron meteorites, where the PGE and Au must occur dispersed among a generally small number of reduced phases: Ni-Fe alloys, phosphides, carbides, FeS, and graphite.
3. Provenance of archaeological metals. Thus, smelted Cu of European derivation has been shown by instrumental neutron activation analysis (INAA), AMS, and humble petrographic methods to be distinct from the purer native copper recovered for perhaps seven millennia by the inhabitants of the Great Lakes region. As with natural materials, samples must be characterized by context and microscopic properties prior to analyses, which may include ^{14}C dating of suitable components.

In terms of trace element work, the most important research at IsoTrace since 1997 has been method and equipment development by graduate students (see web site). In the geological context, the work of Ilia Tomski and Jonathan Doupé promises to broaden the range of available analytical strategies, while Jenny Krestow's project addresses the fundamental problem of analyzing insulating targets, including common minerals such as olivine and quartz.

Technical University Munich Secondary Ion AMS Facility. The Munich Tandem Accelerator Laboratory at the Technical University Munich, Garching, Germany, has developed a radionuclide AMS facility and has recently developed an ultraclean ion source for stable isotope impurities (Massonet et al., 1997).

At the Munich accelerator laboratory an ultraclean injector has been built that is used for SIAMS. It utilizes a magnetically analyzed Cs sputter beam and a large-volume ultrahigh vacuum target chamber. In the first stage apertures, electrodes, and target shielding were made of copper; in the second stage these parts were gold plated; and in the third stage the target aperture and the target shielding were made of high-purity Si. In the third stage, the best results were obtained. See, e.g., Fe and Cu in Table 3. The other elements were measured with copper- or gold-plated parts. The work was the doctoral thesis of Stefan Massonet (Massonet, 1998). Currently the AMS system is being used for the measurement of depth profiles. Table 3 presents bulk detection limits for trace elements in Si.

Table 3. Bulk Detection Limits for Trace Elements in Si Measured with the UltraClean Injector at the Munich Accelerator Laboratory with SIAMS[a]

Element	Atomic Ratio	Atomic Density (atoms/cm^3)
B	1.1×10^{-10}	5.5×10^{12}
N	8.2×10^{-8}	4.1×10^{16}

[b] Target aperture and target shielding made of high-purity Si.

CSIRO Heavy Ion Analytical Facility (HIAF), Sydney, Australia. Another specialized TEAMS system is the AUSTRALIS (AMS for Ultra Sensitive Trace Element and Isotopic Studies) system, a microbeam TEAMS system that utilizes a 3-MV Tandetron at CSIRO HIAF, Sydney, Australia (Sie and Suter, 1994; Sie et al., 1997a–c, 1998, 1999; Sie et al., 2000a,b, 2001). Commissioned in 1997, the system is aimed at enabling *in situ* microanalysis of geological samples for radiogenic and stable isotope data free from molecular and isobaric interferences. The microbeam ion source, developed from a HICONEX source, produces a 30-μm-diameter Cs^+ beam routinely and includes a high-magnification sample viewing system in the reflected geometry, facilitating sample positioning and tuning of the primary beam. In measurements of Pb and S isotopes, high-precision isotope ratios of better than 1:1000 have been achieved for geochronological applications. The high precision is made possible by a fast bouncing system at both the low- and high-energy ends to counter the effect of instabilities in the ion source and beam transport system. Measurements were conducted at a terminal voltage of 1.5 to 2 MV. Lead isotopes are measured as Pb^{4+} ions from PbS^- injected ions. Sulfur isotopes are measured as S^{2+} or S^{3+} ions from injected S^- ions. The trace element detection capability is demonstrated in measurements of precious metals, the PGEs, and Au from an assortment of geological and meteoritic samples. Detection sensitivity as low as sub-ppb has been obtained for Au in sulfides, which will be of great benefit in studies of ore deposit mineralogy and mineral processing. The Australia group has also demonstrated the facility for Os isotope measurements in meteorite samples, opening up the possibility of widespread use of the Re-Os system in exploration programs.

Naval Research Laboratory TEAMS Facility. One of the most ambitious programs is at the NRL, Washington, DC (Grabowski et al., 1997). A large portion of the novel TEAMS facility at the NRL is now installed. When completed, this facility will provide for parallel mass analysis over a broad mass range for conducting and insulating samples and offer 10 μm lateral image resolution, depth

profiling, and sensitivity down to tens of ppt of trace impurities. The facility will use a modified commercial SIMS system as the source of secondary ions to provide these capabilities. This ion source is being installed. After the ion source, the facility uses a Pretzel magnet (Knies et al., 1997a) to act as a unique recombinator to simultaneously transmit from 1 to 200 amu ions but attenuate intense matrix-related beams. Following acceleration, a single charge state is selected by a 3° electrostatic bend; then the selected ions are electrostatically analyzed for energy/charge (E/q) by a 2.2-m-radius, 30° spherical ESA with $E/\Delta E \cong 800$. Finally, a split-pole mass spectrograph with a 1.5-m-long focal plane provides parallel analysis over a broad mass range ($m_{max}/m_{min} = 8$) with high mass resolution ($m/\Delta m \cong 2500$). Micro-channel-plate-based position-sensitive detector modules are used to populate the focal plane.

Currently, vacuum and beam optics hardware are in place, and testing is underway with a multicathode ion source in place of the SIMS ion source. This more intense source simplifies diagnostic testing and initial research efforts. All twelve position-sensitive detector modules for the focal plane of the spectrograph have been received, and their testing is progressing well. Programmatically, the NRL is actively involved in the study of gas hydrates present under the ocean floor, which includes plans to analyze cycling between various carbon pools present there. Since ^{14}C analysis is an important part of this work, the TEAMS facility has been modified to include a switching ESA to choose between the new multicathode ion source and the SIMS ion source for injection into the Pretzel magnet. It is anticipated that operations can be easily switched between standard radioisotope AMS and TEAMS efforts. Preliminary ^{14}C analysis is currently underway.

University of North Texas Ion Beam Modification and Analysis Laboratory TEAMS Facility. The UNT TEAMS facility has been described in detail in other parts of this unit and will only be briefly summarized here. The UNT TEAMS facility is a dedicated trace element AMS that is part of the IBMAL.

The facility is characterized by an ultraclean ion source with magnetic (mv/q) analysis of the primary Cs^+ sputter beam to remove contaminants. The Cs^+ beam may be raster scanned over the sample for depth-profiling measurements with a spot size of 60 to 90 μm or enlarged to ~2 mm diameter for bulk impurity measurements. The samples are analyzed in a high-vacuum chamber with all components that could be hit by the beam coated with ultrapure Si to reduce sample contamination. The secondary ions extracted from the sample are electrostatically analyzed at 45°, magnetically analyzed at 90°, and injected into the 3-MV National Electrostatics tandem accelerators. After the accelerator, the energetic secondary ions are magnetically analyzed at 40° and electrostatically analyzed at 45°. The secondary ions are detected in a Faraday cup for matrix ions and in a surface barrier detector or ionization chamber for trace impurity ions.

The TEAMS system has been used mainly to demonstrate depth-profiling capability for a number of trace elemental species in a variety of semiconductor materials, e.g., Si, GeSi, GaAs, GaN, and SiC (Datar et al., 1997a,b; McDaniel et al., 1998a,b; Datar et al., 2000). This is noteworthy because depth profile measurements are the primary concern of the semiconductor industry. Depth profile measurements can also be compared directly with SIMS results.

Table 4. Detection Limits in Si in Depth-Profiling Mode at the University of North Texas[a]

Element	Matrix	Depth-Profiling Detection Limits (atoms/cm^3)
B	Si	4×10^{14}
F	Si	2×10^{13}
P	Si	3×10^{13}
Ni	Si	1×10^{14}
Cu	Si	2×10^{14}
Zn	Si	1×10^{15}
As	Si	2×10^{14}
Mo	Si	1×10^{15}
Sb	Si	1×10^{15}
Se	Si	1×10^{12}
As	Ge_xSi_{1-x}	1×10^{15}

[a] The depth window is ~50 Å.

The TEAMS facility can be operated in a bulk analysis mode or depth-profiling mode. The bulk analysis mode is generally more sensitive, since one can count the impurity ions for a longer time. In the depth-profiling mode, there is a limited amount of material available at a particular sputtering depth. Table 4 gives the detection limits in Si in the depth-profiling mode in atoms per cubic centimeter.

Engineering Advances That Made TEAMS Possible

Some of the advances that made TEAMS feasible include voltage-stable tandem accelerators, specially designed low-contamination ion sources, the use of all-electrostatic focusing and steering elements, double-focusing spherical electrostatic energy analyzers, the development of fast-switching magnet power supplies, the development of nuclear detectors for mega-electron-volt energy ions. The operation and voltage control of tandem accelerators allows the production of energetic ions with less energy uncertainty, thereby enabling magnetic and electrostatic analysis.

Historical Evolution of TEAMS

Accelerator mass spectrometry was first used by Alvarez and Cornog (1939a,b) to measure natural abundances of ^3He. It was reincarnated when Muller (1977) suggested that a cyclotron could be used for detection of ^{14}C, ^{10}Be, and other long-lived radioisotopes. Independently in 1977, the University of Rochester group (Purser et al., 1977) demonstrated that AMS could be used to separate ^{14}C from the isobar ^{14}N because of the instability of the $^{14}N^-$ ion. Later, Nelson et al. (1977) at McMaster University and Bennett et al. (1977) at the University of Rochester reported accelerator measurements of natural ^{14}C.

Purser et al. (1979) reported that accelerator SIMS is a very promising technique for the detection of trace elements in ultrapure materials. A lot of the early work

done at Rochester and Toronto concentrated on the *in situ* TEAMS measurements of PGEs, Au, and Ag in mineralogical and geological samples (Rucklidge et al., 1981, 1982). Since then, the Toronto group has continued this TEAMS research in mineral grains and meteorites (Wilson et al., 1997a,b). The Rochester group measured quantitative TEAMS depth profiles of N and Cl in semiconductor-grade Si wafers (Elmore et al., 1989; Gove et al., 1990).

Anthony and Thomas (1983) first suggested the use of AMS for the detection of stable isotopes present as contaminants or impurity dopants in ultrapure semiconductor materials. Preliminary measurements were made on the carbon-dating AMS facility at the University of Arizona (Anthony et al., 1985, 1986). Anthony and Donahue (1987) showed that AMS could help provide solutions for semiconductor problems. Following this lead, a TEAMS system dedicated to broad-band stable isotope measurements over the entire range of the periodic table was designed and constructed at IBMAL at the UNT in collaboration with Texas Instruments (Anthony et al., 1989, 1990a,b, 1991, 1994a,b; Matteson et al., 1989, 1990; McDaniel et al., 1990a,b, 1992, 1993, 1994, 1995, 1998a,b; Kirchhoff et al., 1994; Datar et al., 1996, 1997a,b, 2000; Zhao et al., 1997). Other groups soon followed with modifications of existing radionuclide AMS facilities to perform stable isotope measurements at PSI/ETH Zurich (Döbeli et al., 1994; Ender, 1997; Ender et al., 1997a-d) and the Technical University Munich (Massonet et al., 1997) or construction of new facilities at CSIRO in Australia (Sie and Suter, 1994; Niklaus et al., 1997; Sie et al., 1997a–c) and at the NRL (Grabowski et al., 1997; Knies et al., 1997a,b).

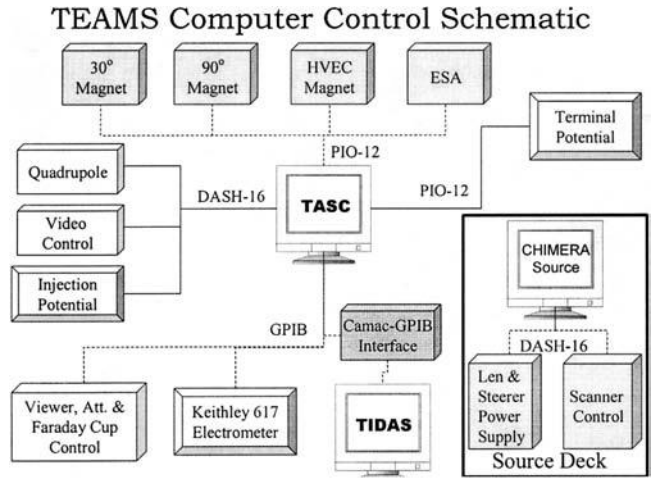

Figure 7. Block diagram of the TEAMS computer control and data acquisition system at UNT. The ion source, accelerator, and data acquisition system are controlled by three personal computers. The tandem accelerator system control (TASC) computer controls the magnets, electrostatic analyzer, quadrupole, terminal potential, ion source injection potential, viewers, Faraday cups, and attenuators and is connected to the CAMAC modular data-handling system crate through a GPIB interface. The TI data acquisition system (TIDAS) is connected to a CAMAC crate through a GPIB interface. Detector signals from either the ionization chamber or Si particle detector are passed into the CAMAC crate amplifier and stored in the TIDAS. The voltages (or currents) for the ion source Cs source bias, 90° magnet, eight Einzel lenses, six *x-y* steerers, Cs beam scanner, sample bias, extraction bias, and 45° ESA are controlled by the ion source computer, which can be operated in the accelerator control room or at the source.

METHOD AUTOMATION

Due to the extreme complexity of the ion source at UNT, computer control is essential for steering and focusing all elements in both primary- and secondary-ion beamlines. By systematically varying the control voltage and measuring the beam current, the optimum control voltage can be determined for each parameter. Ideally, if all beamlines are properly aligned, the steering voltages should be zero. Practically, as long as the steering voltages are near zero, near-optimum tuning can be assumed. The accelerator, beamline, and analyzing elements are also under computer control and can be set to the appropriate settings by keyboard entry. Figure 7 shows a block diagram of the computer control and data acquisition system at UNT.

For depth profile measurements, one simply clicks on the depth profile icon. A pop-up menu enables one to enter all the necessary parameters, and the computer automatically acquires the raw depth profile data. The operator determines the endpoint and stops data acquisition. The raw data are stored in a file of the operator's choice. Sample changes have to be done manually. The measurement should not be left unattended. For bulk measurements, the computer control program is also used, except that the entries in the pop-up menu are different. Due to the unique nature of the computer control system, most software was initially developed in-house and later converted to a LabView-based system.

DATA ANALYSIS AND INITIAL INTERPRETATION

Bulk Impurity Measurements

For bulk measurements, where a constant, very low level concentration is to be measured, the acquisition time can be increased and the tuning can be done on each sample and not just the blank, to increase transmission. Furthermore, if a standard sample with a constant low-level impurity doping is available, additional fine tuning of the TEAMS system can be done, leading to enhanced impurity transmission with a corresponding increase in sensitivity. This procedure is essentially the same as radioisotope AMS measurements, where following the use of a stable isotope as a pilot beam, the final fine tuning is done using a known standard. Bulk analysis measurements are identical to that used for isotope ratio measurements in AMS. The matrix ion count rate is measured briefly as a current, while the impurity count rate is measured for a longer time in a particle detector or ionization chamber. The time difference is because there are fewer impurity ions compared to matrix ions. By repeatedly cycling between the two measurements, good statistics can be obtained for both matrix

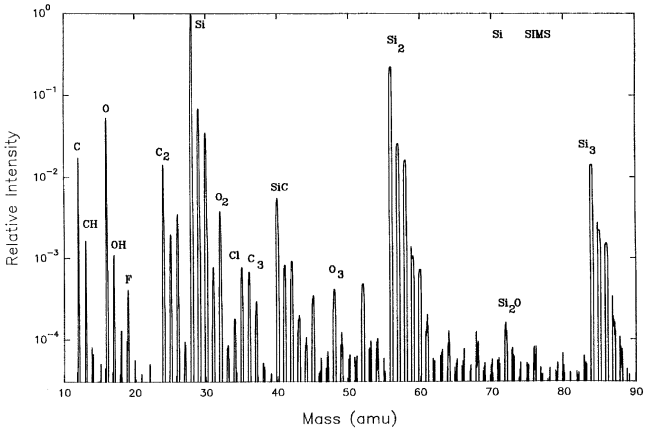

Figure 8. Bulk analysis SIMS mass scan of a heavily contaminated Si sample. All peak intensities are relative to the ^{28}Si peak, which is set equal to 1.0.

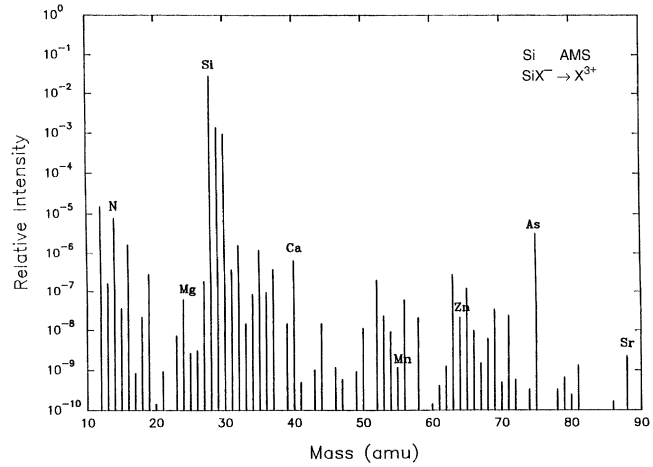

Figure 10. Bulk analysis TEAMS mass scan of the same sample similar to Figure 9, except a molecular mass was chosen to accelerate to the terminal of the accelerator. The signals have been normalized to the ^{28}Si signal in Figure 9 for direct comparison.

and impurity ions. Elmore et al. (1984) has given a detailed exposition of the technique.

The TEAMS bulk measurements can also provide a quick mass scan of elements present in a sample in much the same way as SIMS, except the molecular interferences can be suppressed. For example, Figures 8 to 10 show representative bulk analysis mass scans of a heavily contaminated Si sample over an extended mass range of 10 to 90 amu. All isotopic relative intensities are normalized to the ^{28}Si peak, which is set equal to 1.0 in Figures 8 and 9. The pre-tandem-acceleration analysis shown in Figure 8 represents a conventional negative ion SIMS spectrum with contributions to many mass regions from molecular ions. The atomic and molecular ions are extracted from the sample, pass out of the ion source chamber through the 45° electrostatic analyzer and the 90° magnetic spectrometer, and are measured as a current in a Faraday cup, as shown in Figure 1. Detection before the accelerator is limited to current measurements because of the high currents, but molecular ions are still present. For example, some of the molecular ion interferences shown in the SIMS mass scan in Figure 8 are given in Table 5 with their intensity relative to $^{28}Si^-$. In many cases the molecular ion intensity is much greater than an atomic ion at the same mass.

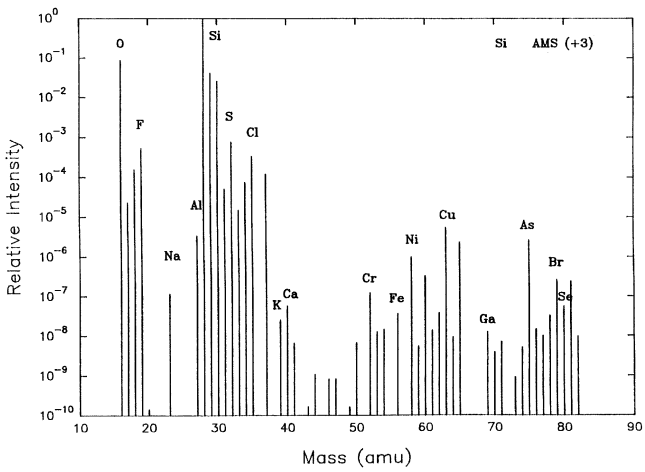

Figure 9. Bulk analysis TEAMS mass scan of the same sample as in Figure 8. All peak intensities are relative to ^{28}Si, which is set equal to 1.0.

Figure 9 is a TEAMS bulk analysis mass scan of the same Si sample after passage through the tandem accelerator and high-energy magnetic (mv/q) and electrostatic (E/q) analysis with charge state $q = 3^+$ and total energy (E) detection. The relative intensities of the isotopes shown are normalized to the intensity of the $^{28}Si^{3+}$ peak, which is set equal to 1.0. Most of the lower intensity measurements shown require direct ion counting in a particle detector as opposed to higher intensity current measurements. Counting time was 5 s per mass interval for all measurements or ~400 s for the entire mass scan. Since all isotopic ions analyzed were in a $q = 3^+$ charge state, interfering molecular ions have been rejected by breaking up the molecules in the terminal of the accelerator. In addition to removal of the molecular interferences, detection of ions in high-energy particle detectors has removed detector background noise as well as most m/q interferences. Signals from break-up products that still exhibit m/q interferences at masses 36, 42, 45, 48, 51, 57, and 84 are not shown in Figure 9. Elements with zero electron affinity (e.g., Mg, Mn, Zn) will not form negative ions, and the TEAMS mass scan does not show any signal for these masses. As seen by comparison of the relative intensities in Figures 8 and 9 and Table 5, the molecular interferences are reduced, in some cases, by many orders of magnitude. For example, the relative intensity of $(^{28}Si)_2$ at mass 56 (^{56}Fe) is reduced by almost seven orders of magnitude in the TEAMS data compared to the SIMS data. The $^{28}Si^{12}C$ at mass 40 (^{40}Ca) is reduced by almost five orders of magnitude in the TEAMS data compared to the SIMS data. The molecular peaks $(^{29}Si)_2$, $^{29}Si^{28}Si^{1}H$, etc. at mass 58 (^{58}Ni) are reduced by over four orders of magnitude in the TEAMS data compared to the SIMS data.

Table 5. Molecular Ion Impurities in SIMS Mass Scan in Figure 8.1 Relative to $^{28}Si^-$ Intensity and Atomic Ion Intensities from TEAMS Mass Scan in Figure 9 Relative to $^{28}Si^{3+}$ Intensity[a]

Molecular Ion	Mass (amu)	Intensity/$^{28}Si^-$ (Figure 8)	Intensity/$^{28}Si^{3+}$ (Figure 9)	Elemental Ion
$^{16}O^1H$	17	1.2×10^{-3}	3.0×10^{-5}	^{17}O
$(^{12}C)_2$	24	1.6×10^{-2}	$<10^{-10}$	^{24}Mg
$^{30}Si^1H$	31	7.0×10^{-4}	7.0×10^{-5}	^{31}P
$(^{16}O)_2$	32	4.0×10^{-3}	9.0×10^{-4}	^{32}S
$^{28}Si^{12}C$	40	6.0×10^{-3}	7.0×10^{-8}	^{40}Ca
$^{24}Mg^{28}Si$, etc	52	5.0×10^{-4}	1.3×10^{-7}	^{52}Cr
$(^{28}Si)_2$	56	2.5×10^{-1}	4.0×10^{-8}	^{56}Fe
$^{28}Si^{29}Si^1H$, $^{29}Si_2$, etc.	58	2.0×10^{-2}	1.0×10^{-6}	^{58}Ni
$^{28}SiO_2$, $^{30}Si_2$, etc.	60	7.0×10^{-4}	4.0×10^{-7}	^{60}Ni
$(^{28}Si)_2{}^{16}O$	72	1.8×10^{-4}	$<10^{-10}$	^{72}Ge

[a] Break-up of the molecular interferences reduces the intensities by orders of magnitude in many cases.

Because of the removal of the molecular interferences in the TEAMS data, the correct isotopic abundances are found for O, Si, Cl, Ni, and Cu, which indicates that calibration of the magnetic and electrostatic analyzers is correct.

Even though all the molecular ions are dissociated in the stripping canal of the tandem accelerator, there still may be some m/q interferences. During a mass scan, the preacceleration magnet is tuned for a charge state $q = 1^-$, while the postacceleration magnet is tuned for the charge state of interest, which is $q = 3^+$ for Figure 9. Even though direct molecular interferences are removed, molecular fragments may still cause an ambiguity. For example, $((^{12}C)_n)^-$ molecules can be produced from the vacuum system during the sputtering process (as seen in Figure 8). Any $((^{12}C)_3)^-$ molecular ions will dissociate after stripping but will result in a large production of $^{12}C^+$ ions. The $^{12}C^+$ ions at mass 12 have the same m/q as the atomic ions at mass 36 (e.g., $^{36}S^{3+}$) and therefore will pass into the final total energy detector. The $^{12}C^-$ ions created during the sputtering process will not be an interference for mass 36 because it will not pass through the preacceleration magnet. Even though the total energy spectroscopy will separate the peaks, the tails from high levels of ^{12}C may lead to saturation of the detector and incorrect results. Several of the masses with known interferences described above (36, 42, 45, 48, 51, 57, and 84) are not included in the mass scan in Figure 9. These interferences can be removed by analyzing a different charge state and therefore a different m/q.

Some elements do not form negative ions directly, e.g., N, Mg, Mn, and Zn. In these cases, molecular ions of the form SiX-, where X represents the element of interest, are injected into the accelerator. The break-up products X^{3+} are accelerated down the high-energy side of the accelerator, magnetically and electrostatically analyzed, and detected in the total energy detector. Figure 10 shows such a TEAMS spectrum in which the intensity of each signal has been normalized to the maximum ^{28}Si signal in Figure 9 for direct comparison. Several ions that were not detectable in the TEAMS mass scan in Figure 9 are now measured in the correct isotopic abundances, e.g., N, Mg, Mn, and Zn. Signals from break-up products at masses 36, 42, 45, 48, 51, 57, and 84 are not removed in Figure 10.

Data Analysis for Bulk Measurements

This procedure for bulk analysis provides a relative normalization of the impurity element to the amount of matrix element present in the sample, which is well known. Of course, this procedure does not account for the differences in negative ion formation probabilities of different elements or molecules or charge state fractionation of the ion in the terminal of the accelerator. In fact, some elements will not form a negative ion at all (e.g., N, Mg, Mn, Zn). For these elements that do not form a negative ion, in almost all cases, a molecule with this element can be found that will form a negative ion, therefore allowing analysis of essentially every element in the periodic table. A distribution of charge states is produced during electron stripping in the terminal of the accelerator. Because the magnetic (mv/q) and electrostatic (E/q) analyses pass only one charge state from this distribution, only a fraction of the original ions from the sample are analyzed and detected. Fortunately, the $q = 3^+$ charge state most used in the analysis is the most populated for masses in the range of ~30 to 60 amu when stripped at an energy of ~1.5 to 3 MeV. In addition, this procedure requires that the Cs sputter beam be constant over the length of the mass scan and that the calibration of the magnetic and electrostatic analyzers be accurate over the mass range of the scan. The calibration is normally checked before and after the measurement, as discussed earlier with Figure 3, by running a mass scan of the masses present for the matrix elements to see the characteristic signature spectrum.

Mass scans over a range of masses are useful to confirm isotopic natural abundances of an element of interest as well as to check for interferences that may be present at a particular mass. In the TEAMS analysis beamline, the UNT facility has a pneumatically controlled Faraday cup followed by a Si charged particle detector that may be inserted into the beam or withdrawn and then an ionization chamber. For a mass scan as shown in Figure 9 or 10,

the magnetic and electrostatic fields are set to the correct values to pass the initial mass of interest with the Faraday cup in the beam path. If the current measured in the Faraday cup for that mass is below a preset value, the Faraday cup is removed from the beam path and the ions of that mass are detected in the Si detector or ionization chamber for a preset time. If not, then the mass is measured as a current in the Faraday cup as Coulombs per second and converted to particles per second, taking into account the charge state of the ion. After completing the preset measuring time, the magnetic and electrostatic fields are incremented to the next mass of interest, and a measurement is made for that mass, and so on for the entire mass range of interest. Usually the time of measurement is of the order of a few seconds for each mass value. Counting for a longer time period can reduce the minimum background count and therefore improve the detection limit. For example, for a 5-s count at each mass value, the minimum detectable count rate is 1 count in 5 s or 0.2 counts/s (cps). For a 100-s count at each mass value, the minimum detectable count rate is 1 count in 100 s or 0.01 cps, which is 20 times more sensitive.

Depth-Profiling Impurity Measurements

To measure a depth profile of Cu in Si, for example, the key parameter is the terminal voltage on the accelerator. The terminal voltage should be chosen such that the most abundant charge state for Cu is 3^+ or higher. There is some flexibility in the choice of impurity ion species injected into the accelerator. For some elements, the ion MX^-, where M is a matrix atom and X is an impurity atom, is more prolific than the ion X^-. As far as possible, then the most prolific negative ion should be chosen. The RSF tables in Wilson et al. (1989) provide a good guide to the best possible negative ion to be injected. Care must be exercised in the choice of the positive charge state selected for postaccelerator analysis to avoid m/q degeneracies with the matrix ion(s) since it can swamp the detector. For example, during ^{58}Ni measurements, charge state 4^+ has the same m/q as $^{29}Si^{2+}$ and the Ni signal can be swamped in the detector by the tail of the Si signal, even though they are at different energies. The m/q interferences from nonmatrix species can be separated by energy in the detector, as the count rate is usually not very high. If the impurity concentration to be measured is high as for a dopant, then a less abundant charge state can be chosen to avoid swamping the detector. However, in the rest of the present discussion, it will be assumed that one is interested in only measuring very low concentration levels, which is the strength of TEAMS.

As previously mentioned, the nuclear-type particle detector has essentially zero dark current because the ion is at mega-electron-volt energies. Thus, the lowest counting rate of the detector is determined by the acquisition time for that particular data point in the depth profile, which in turn is determined by the volume of the available material. For example, with a sputtering rate of 2 Å/s, an acquisition time of 20 s implies that the measurement represents an average concentration for a slice of material 40 Å thick. The lowest measurable concentration in 20 s is 0.05 cps (one count in the 20 s). By increasing the acquisition time to 50 s, the lowest measured concentration now corresponds to 0.02 cps, but now it represents an average over 100 Å. However, one must remember that the sputtering process in the ion source causes depth profile broadening due to the penetration of the Cs ions into the sample. This effect is of the order of 100 Å (Vandervorst and Shepherd, 1987). Therefore, the Cs penetration depth limits the ultimate depth sensitivity.

For the example of a Cu depth profile in a Si sample, the experimental parameters were as follows:

Sample bias: 11.17 keV. The lower the sample bias, the better, as it reduces the Cs penetration depth (Vandervorst and Shepherd, 1987).

Secondary ions injected into the tandem accelerator: $^{63}Cu^-$, $^{28}Si^-$.

Terminal voltage: 1.7 MV.

Ions transported to the end of the beamline: 6.8 MeV $^{63}Cu^{3+}$, 6.8 MeV $^{28}Si^{3+}$.

Cu ions were measured in an ionization chamber with an acquisition time of 20 s, and Si ion current was measured in a Faraday cup just in front of the detector.

The tuning was done using a nominally blank pure Si sample. The focusing and steering elements were adjusted to get maximum $^{28}Si^{3+}$ current in the final Faraday cup. It was assumed that the analyzing elements (the magnets and the electrostatic analyzer) were already calibrated. This calibration is periodically checked. For depth profile measurements, one has to specify the isotopes to be measured along with the charge states and the acquisition time. In the case of m/q interferences, the total energy gate width in the ionization chamber has to be specified also. Typically, in depth profile measurements, one sequentially cycles between a matrix ion count rate measurement and an impurity isotope count rate measurement. Switching the system between different masses involves dead time since the magnets cannot be switched instantaneously. By suitable choice of matrix charge state, this dead time can be reduced. The matrix ion count rate measurement serves as a basis for normalization of unknown depth profiles to standard implanted depth profiles as well as serving as a check on system stability (very much similar to both AMS and SIMS).

Before measuring an unknown depth profile, a standard implant is measured. Thus, for the Cu profile, after the blank measurement, an implanted standard was measured. This serves as an additional check on the measurement process. Finally, the unknown sample was measured with exactly the same parameters as the standard implant. Figure 11 shows an example of a Cu impurity depth profile measurement for a 10-keV, 1×10^{16} atoms/cm^2 As-implanted Si wafer. The Cu concentration decreases from the surface but then shows an unexpected peak around 0.1 μm into the wafer before finally tailing off at a concentration level of 4×10^{14} atoms/cm^3, which is a factor of 6 lower than the SIMS measurement. A nominally blank sample of Si is run after measurements of an unknown sample to get an estimate of cross-contamination from other samples and also to make sure that running the unknown sample has not contaminated the source.

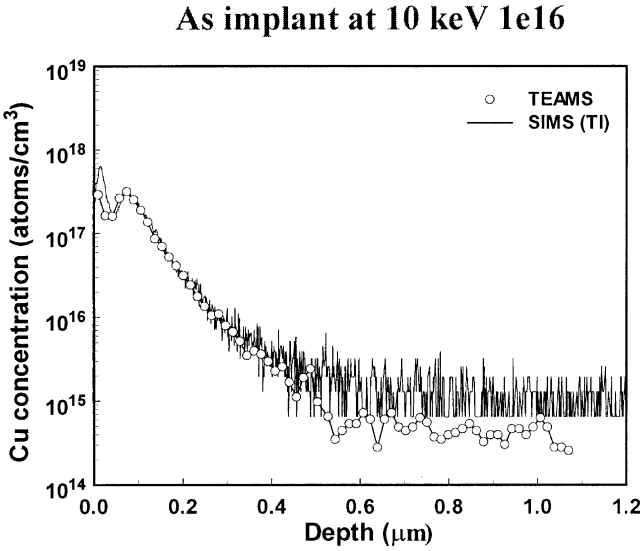

Figure 11. TEAMS Cu impurity depth profile in a 10-keV, 1×10^{16} atoms/cm^2 ^{75}As implant in Si. Also shown is a SIMS depth profile for comparison. The TEAMS and SIMS profiles are in good agreement until the SIMS detection limit is reached at ~0.4 μm in depth. After 0.4 μm, TEAMS is about a factor of 6 more sensitive than the SIMS measurements.

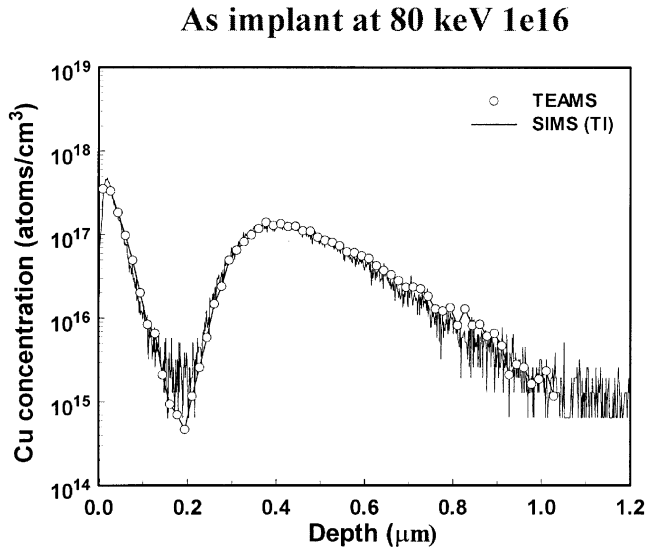

Figure 13. TEAMS Cu impurity depth profile in an 80-keV, 1×10^{16} atoms/cm^2 ^{75}As implant in Si. Also shown is a SIMS depth profile for comparison. The TEAMS and SIMS profiles are in good agreement. TEAMS can be seen to be more sensitive than the SIMS measurements in the dip in the spectrum at ~0.2 μm.

Figures 12 and 13 show TEAMS Cu impurity concentrations as a function of depth in As-implanted Si wafers. Figure 12 shows an impurity Cu depth profile for a 40-keV, 1×10^{16} atoms/cm^2 As implant. Figure 13 shows an impurity Cu depth profile for an 80-keV, 1×10^{16} atoms/cm^2 As implant. The Cu concentrations in both spectra decrease from the surface peak but then increase again to form a deeper secondary peak. The depth of the secondary peak scales with the As implant energy. SIMS measurements were done later to confirm the TEAMS data. The SIMS depth profile data are overlaid on the TEAMS data and the agreement is excellent. During data acquisition, both isotopes of Cu were measured with TEAMS, and the isotope ratios were found to be in agreement with their natural abundances. This is an indication that the Cu was not implanted along with the As and that the two Cu isotopes were not implanted separately. Only one mass can be implanted at a time.

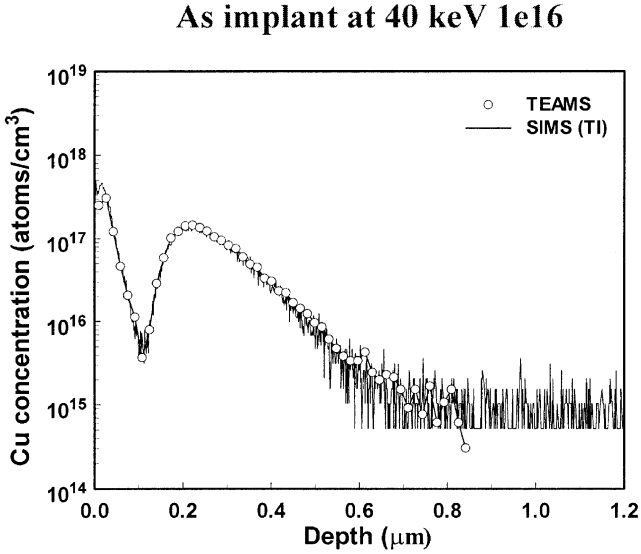

Figure 12. TEAMS Cu impurity depth profile in a 40-keV, 1×10^{16} atoms/cm^2 ^{75}As implant in Si. Also shown is a SIMS depth profile for comparison. The TEAMS and SIMS profiles are in good agreement until the SIMS detection limit for Cu is reached.

Data Analysis for Depth-Profiling Measurements

The raw data are measurements of count rate versus time. After analysis, the samples are removed from the ion source and the crater depths are measured with a surface profilometer. The measured depth gives a straightforward time-to-depth conversion assuming a constant sputtering rate, which is monitored via the matrix ion count rate. The count rate data are normalized to concentration (atoms per cubic centimeter). Normalization can be accomplished by scaling the peak count rate of the standard implant to the known concentration as well as by integrating the area under the standard profile and obtaining a yield factor. These methods are independent of each other. They have been described in detail by Wilson et al. (1989), Datar (1994), and Datar et al. (1997a, 1997b). The section on calibration of data acquisition below also has a sample demonstration of data normalization for an implant standard sample. The final depth profile is achieved by multiplying both axes of the raw data plot with the respective normalization factors. Typically, after a series of unknowns, another standard is run with the unknowns being sandwiched between standard samples. The final data are referred to the standards and the nominal blank. A nominally blank sample is run after measurements of an

unknown sample to get an estimate of cross-contamination from other samples and to make sure that running the unknown sample has not contaminated the source. Float-zone Si is a good blank sample.

Standard samples for depth-profiling measurements are implanted samples with known doses and known energies. However, any sample where the depth profile is known beforehand can be used as a standard. For bulk measurements, standard samples should be uniformly doped with the impurity of interest. Standards may be cross-checked in a number of TEAMS laboratories.

Interpretation of the Data. The final depth profile has exactly as much information as a SIMS profile, and in general, data interpretation has to take into account the same factors. Due to the extreme sensitivity, accuracy can only be compared to a known standard. Absolute measurements without reference to a standard are not possible. Also, for bulk measurements, one can only refer the data to a known standard in a manner similar to conventional AMS.

Calibration of Data Acquisition. Assuming a constant sputtering rate (checked by monitoring the Cs current before and after the measurement as well as by periodically measuring the matrix element current during the measurement), the time-to-depth conversion is simply done by measuring the depth of the crater after measurement using a profilometer. Converting the count rate to concentration is more involved. The SIMS RSFs cannot be used due to charge state fractionation as well as possible variations in transmission efficiency. In due course, TEAMS RSFs can be developed that take into account these factors as well. At present, calibration is done using implant standards. Assuming the depth profile is measured to exhaustion, the ratio of the integrated area under the depth profile to the implant dose gives the "yield" of the system. This information is used to normalize the unknown profile. The yield factor can also be used to normalize bulk impurity concentration measurements in the absence of uniformly doped standards. The concentration normalization factor (CNF) is given by Datar (1994) as

$$\mathrm{CNF} = \frac{\text{implanted dose (atoms / cm}^2\text{)}}{\text{area under profile} \times \text{sputtering rate (cm/s)}} \quad (3)$$

Then, the concentration at a given depth is given by

$$\text{Concentration} = \text{cps} \times \mathrm{CNF} \quad (4)$$

For example, Figure 14A shows a raw depth profile for a 100-keV, 2×10^{14} atoms/cm^2, ^{60}Ni implant in Si. The total number of Ni ions measured (obtained by integrating the area under the cps versus the time profile) was 4.287×10^6. The sputtering rate (obtained by measuring the depth of the crater after the measurement) was 2.6 Å/s. Since the implanted dose was 2×10^{14} atoms/cm^2,

$$\mathrm{CNF} = \frac{2 \times 10^{14}\ \text{atoms/cm}^2}{4.287 \times 10^6\ \text{atoms} \times 2.6 \times 10^{-8}\ \text{cm/s)}} = 1.82 \times 10^{15}\ \text{s/cm}^3 \quad (5)$$

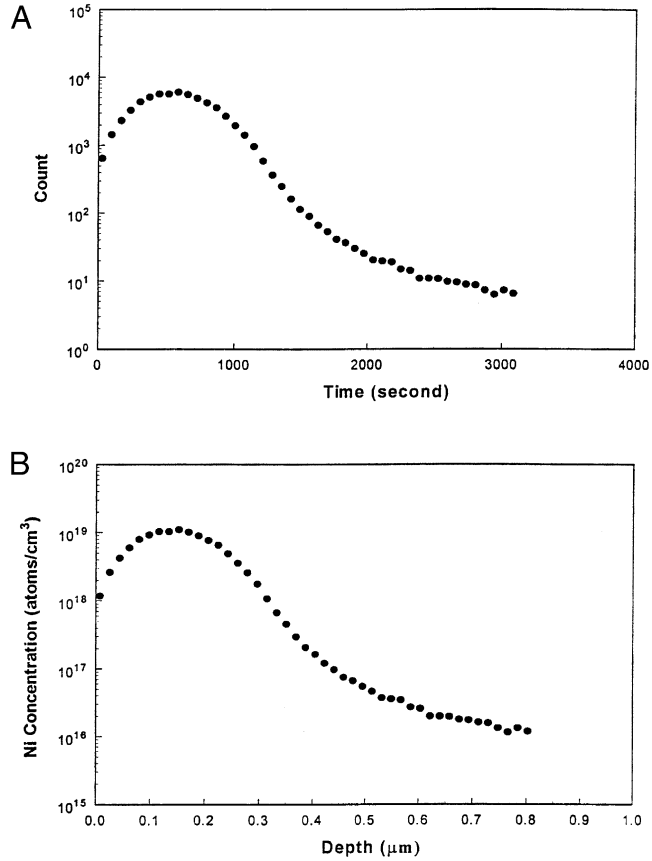

Figure 14. (**A**) Measured depth profile for a 100-keV, 2×10^{14} atoms/cm^2, ^{60}Ni implant in Si. (**B**) Normalized depth profile for Figure 14A showing concentration versus depth.

This means that a count rate of 1 cps corresponds to a concentration of 1.82×10^{15} atoms/cm^3. The detection limit is the least count multiplied by the normalization factor. Figure 14B shows the normalized depth profile as concentration (atoms per cubic centimeter) versus depth (micrometers). The two graphs are identical; just the x and y axes have been renormalized.

For the unknown sample, which has been run under the same conditions, the count rate numbers can be multiplied by the CNF to convert the depth profile into a concentration profile. Thus, the normalization is critically dependent upon the use of implant standards for depth profile measurements. For bulk measurements, an even better standard would be samples with known constant impurity levels. But basically, as in radioisotope AMS, the final numbers should always be referred to the standard used.

SAMPLE PREPARATION

Extreme care has to be taken during sample preparation to avoid surface particulate impurities. For depth profile measurements, it is desirable that the sample be flat and at least somewhat conductive. Typically, a TEAMS sample is a small square at least 4×4 mm. The samples are

loaded into the sample holder in a class 100 clean room. Care is taken to ensure that different kinds of samples do not come in contact with each other, essentially the same procedures as with SIMS.

SPECIMEN MODIFICATION

Trace element AMS is a destructive technique, and the samples cannot be reused for other measurements. In addition, the sputtering process itself affects the depth distribution of the impurity being measured due to ion beam mixing. Here, the sputtering ion actually drives the impurity further into the sample. This effect is more pronounced for higher Cs impact energies and causes depth profile broadening. This is the primary reason to attempt to use the lowest Cs impact energy possible that allows good transmission through the accelerator and analysis beamline. At UNT, the Cs impact energy is the sum of the 10 keV from the Cs oven and the energy from the negative sample bias, which has been operated as high as 30 kV, for a total impact energy of 40 keV. Recently, the sample bias has been reduced to 11 kV, which makes the Cs impact energy 21 keV, without significant loss of transmission through the entire system. The ranges of 21- and 40-keV Cs ions in Si are ~178 Å and ~266 Å, respectively. Therefore, 40-keV Cs ions penetrate Si ~1.5 times as far as 21-keV Cs ions.

PROBLEMS

Accidental contamination from particulates, elements in the vacuum system, and from sputtering neighboring samples is a hazard. Running samples in order from low concentration to high concentration if approximate concentration levels are known can minimize contamination. Sometimes, due to improper sample positioning, the transmission is unusually low. The matrix ion current measurement is usually a good indicator of this problem.

In general, sample positioning with respect to the extraction optics is the most critical factor affecting the reproducibility of the data. The ion source at UNT is being modified to improve the reproducibility in sample positioning.

Destroying a particle detector is possible by placing too much ion current on it due to unexpected matrix-based signal. Use of an ionization chamber for tune-up and initial measurements essentially solves this problem. The surface barrier particle detector can then be used to make higher resolution measurements.

A long measurement can take as long as an hour. Accelerator terminal voltage drift has to be monitored since this can affect transmission. Once again, periodically running standard samples or measuring matrix currents can be used to monitor the terminal voltage.

Over time, the analyzing magnet calibrations may change and will have to be recalibrated. Periodic measurements of known samples are the best safeguard against erroneous readings due to a number of different effects.

ACKNOWLEDGMENTS

The author would like to acknowledge the many funding sources that were required for the development of the TEAMS facility in the Ion Beam Modification and Analysis Laboratory (IBMAL) at the University of North Texas (UNT), including the State of Texas Coordinating Board Advanced Technology Program, the University of North Texas, Texas Instruments (TI), the Office of Naval Research, the National Science Foundation, and the Robert A. Welch Foundation. The TEAMS system at UNT would not have been possible without the technical support of Mark Anthony, Roy Beavers, and Tommy Bennett at TI.

The author would like to thank the many colleagues that have worked with him over the years on the design and development of the TEAMS system at UNT. Jerry Duggan, Sam Matteson, Duncan Weathers, Dwight Maxson, Jimmy Cobb, and Bobby Turner of UNT have been involved with the TEAMS development from the beginning. Graduate students and postdoctoral research scientists that have worked long and hard on TEAMS include Danny Marble, Joe Kirchhoff, György Vizkelethy, Sameer Datar, Yong-Dal Kim, Zhiyong Zhao, Steve Renfrow, Elaine Roth, Eugene Reznik, Baonian Guo, Karim Arrale, and David Gressett.

The author has benefited from many discussions with numerous people around the world that are experts in this field, including Soey Sie, Martin Suter, Ken Grabowski, Graham Hubler, David Knies, Barney Doyle, Ken Purser, Drew Evans, David Elmore, Harry Gove, Liam Kieser, Graham Wilson, Eckehart Nolte, Colin Maden, Hans-Arno Synal, John Vogel, Jay Davis, Doug Donahue, and Greg Norton. I especially thank Sameer Datar, who helped write parts of this unit and for his critical reading, and my wife Linda McDaniel for grammatical corrections. I particularly want to thank Mark Anthony for his belief in this project, for his continued support over the past few years, and for reading and commenting on the manuscript.

APPENDIX A: GLOSSARY OF TERMS

AMS	Accelerator mass spectrometry
Charge state	The amount of charge on an ion. Usually refers to positive ions since only singly charged negative ions have been observed. Obviously, the maximum charge state of an elemental ion corresponds to its atomic number.
Class-100 clean room	A room with atmospheric particulate concentration of particles greater than 0.5 μm diameter not exceeding 100 particles/ft^3 (or 3500 particles/m^3)
CNF	Concentration normalization factor
cps	Counts per second
Depth profile	Plot of elemental concentration as a function of depth from the surface
Detection limit	Lowest meaningful concentration level that can be measured
ICPMS	Inductively coupled plasma mass spectrometry
Ionization chamber	An instrument used to measure the energy of a particle. It is basically a parallel-plate capacitor filled with a gas. Energetic particles entering the chamber lose energy by ionizing the gas. The amount of ionization produced is proportional to the energy. It is a very sensitive instrument capable of detecting single particles.
ion source	Produces ions for injection into accelerator
INAA	Instrumental neutron activation analysis
NAA	Neutron activation analysis
NA-AMS	Neutron activation followed by acceler- ator mass spectroscopy
NRA	Nuclear reaction analysis
PGEs	Platinum group elements (Ru, Rh, Pd, Os, Ir, Pt)
PIXE	Particle-induced X-Ray emission
ppb	parts per billion ($1/10^9$)
ppm	parts per million ($1/10^6$)
ppt	parts per trillion ($1/10^{12}$)
Primary ion	Ion incident on sample surface that sputters the sample. Typically for TEAMS it is Cs^+.
RBS	Rutherford backscattering spectroscopy
RSFs	Relative sensitivity factors
Secondary ion	Ion sputtered from the sample by the primary ion. Can be positive or negative. Neutral atoms or molecules can also be sputtered from the sample surface.
Sensitivity	Lowest measurable concentration or detection limit in atoms per cubic centimeters
SIMS	Secondary-ion mass spectrometry
SIRIS	Sputter-initiated resonance ionization spectrometry
Solid-state or surface barrier	A semiconductor detector that works in a manner similar to an ionization

detector	chamber but is substantially more compact. Energetic particles incident on the detector create electron-hole pairs in the depletion region of a p-n junction. The electrons and holes are swept off in opposite directions by an applied electric field, constituting a current pulse that generates a signal. The signal strength is roughly proportional to the energy of the incident particles.
Tandem accelerator	Electrostatic accelerator based on the Van De Graaff principle, with a high positive potential at the center terminal. The center terminal is charged to a high potential by charges carried from ground by a belt or a chain. The accelerating column is enclosed in a pressure vessel filled with SF_6 or other insulating gases.
TEAMS	Trace element accelerator mass spectrometry or trace element atomic mass spectrometry
TOF-SIMS	Time of flight–secondary ion mass spectrometry

APPENDIX B: INSTRUMENT SPECIFICATIONS AND SUPPLIERS

1. Cs gun: General Ionex, model 133 surface ionization Cs source. This gun is no longer made. Very similar guns are sold by Peabody Scientific, Atomika.
2. Cs analyzing magnet: Made by Magnecoil, Peabody, MA. Supplied by National Electrostatics Corp.
3. Cs Analyzing Magnet Power supply, TCR 20T125: Made by Electronic Measurements.
4. Sample chamber: Made to specification by Huntington Mechanical Laboratories, 1040 L'Avenida, Mountain View, CA 94043. Chamber features four-axis manipulator and load-lock for sample changing.
5. Electron flood gun for charge compensation; model EFG-8 with EGPS-8 power supply: Kimball Physics, 311 Kimball Hill Rd. Wilton NH, 03086.
6. 45° secondary-ion electrostatic analyzer: In-house fabrication.
7. 90° analyzing magnet: Supplied by National Electrostatics Corp.
8. 3MV, electrostatic, tandem pelletron accelerator, model 9SDH-2: Part of the accelerator beamline, supplied by National Electrostatics Corp., 7540 Graber Rd. Box 620310, Middleton, WI 53562-0310.
9. 40° bending magnet: HVEE Europa BV PO Box 99, 3800 AB Amersfoort, The Netherlands. Mass-Energy product $(mE/q^2) \sim 60$.
10. 45° double-focusing spherical electrostatic analyzer: In-house fabrication.
11. Si surface-barrier particle detector: Ortec, 801 S. Illinois Ave., Oak Ridge, Tenn. 37831-0895.
12. Total energy detector ionization chamber: In-house development.
13. Data acquisition and control software: Developed in-house using LabWindows and LabView 4.1 (National Instruments) for PCs using a CAMAC crate with a GPIB interface.

INTRODUCTION TO MEDIUM-ENERGY ION BEAM ANALYSIS

INTRODUCTION

The earliest applications of ion beam techniques for materials analysis, typified by the work of Tollestrup et al. (1949), were carried out with mega-electron-volt beams in the course of basic research in nuclear physics, and the mega-electron-volt beam techniques (described in Section 12a of this chapter) still form the indispensable core of the subject. In the broadest sense, the importance of these techniques lies in the fact that the information they yield depends upon nuclear properties and interactions and is, therefore, relatively insensitive to perturbation by local properties such as the chemical environment and electronic structure. The relevant nuclear physics and scattering theory are well known experimentally and often theoretically, and in consequence, important parameters such as interaction cross-sections are known from first principles (PARTICLE SCATTERING). This is in sharp contrast to the situation for some other important techniques (e.g., secondary ion mass spectrometry) where the fundamental measurement interactions may be very vulnerable to the unique idiosyncrasies of a specimen. It is essential to stress the unity of ion beam analysis even as one seeks to differentiate the relatively newer medium-energy techniques from their more mature high-energy predecessors.

First it is important to understand what is meant by "medium energy." There are two answers, one historical and one based upon the physics of scattering. Physically, ion beam techniques may be termed medium energy if the energy of the beam is low enough that the deviation of the scattering cross-section from the unscreened Rutherford value is greater than ~1%. In addition, the energy must be high enough to assume both that the beam interacts with the target by binary elastic collisions (except when it is traveling in a channeling direction) and that most backscattered particles remain ionized. (The latter constraint differentiates medium- from low-energy

ion scattering, where it is assumed that the ionized component of backscattered particles is strongly correlated with scattering events at the specimen's surface.) For practical purposes, medium energy encompasses ion beam energies from a few tens of to a few hundreds of kilo-electron-volts, and even a bit higher for heavy ions being used in forward-recoil work. Below this range, ion scattering becomes increasingly surface specific. Above it lies the full range of conventional elastic scattering and nuclear reaction analysis.

Historically, medium energy has been defined by technology. The field of ion beam analysis owes its ubiquity, if not its existence, to a single device, the silicon surface-barrier particle detector (see the review by McKenzie, 1979, and references therein). A surface-barrier detector is essentially a large-area Schottky-barrier diode. It has approximately unit efficiency for detecting particle radiation, produces an output signal that is highly linear with the energy of the particle striking it, and is remarkably inexpensive to produce and operate. Along with the lead pencil and the digital compact disk, it is an example of a technology that, from its inception, was so elegant in design, so well suited to its purpose, and so demonstrably superior in function and economics to competitive alternatives that it at once revolutionized a field of activity. However, surface-barrier detectors experience diminished relative energy resolution when used for α particle radiation below $\sim$500 keV. As a result, for years almost all ion beam analysis has been conducted using projectiles with energy greater than this.

At the low end of the energy scale, a technique called low-energy ion scattering (known both by the acronym LEIS and, in early literature, as ISS, for ion surface scattering) was used to study surface structure. Typically, this work was done by pulsing the accelerator beam and using an electron multiplier with exposed cathode to detect scattered ions. Formidable technical problems with producing adequately short beam pulses, as well as other fundamental issues, placed a practical upper limit on this technique of 20 to 30 keV. Thus, the historic range of medium energy began above LEIS and ranged up to the domain of the surface-barrier detector.

As is the case for high-energy ion beam analysis, most of the tools needed for medium-energy ion beam analysis have been developed and perfected for nuclear research and are widely available commercially. This is notably not the case for spectrometers, which still fall largely in the class of research instrumentation and are available, but less readily so.

The units that follow describe some medium-energy ion beam analytical techniques that are optimized for different problems. Time-of-flight medium-energy backscattering and forward-recoil spectrometry, described in MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY, are quite similar to the high-energy techniques of Section 12a but offer increased depth resolution, sensitivity, and surface specificity at the expense of total analyzable depth and ease of use. Forward-recoil measurement of hydrogen at medium energies can be particularly effective, especially when it is important to measure hydrogen and other light elements simultaneously.

Heavy-ion backscattering spectrometry, described in HEAVY-ION BACKSCATTERING SPECTROMETRY, is a variant of time-of-flight backscattering that is optimized for the highest possible sensitivity, specifically for the measurement of ultra-low-level metallic contaminants on device-grade Si wafer surfaces. Along with total-reflection x-ray fluorescence spectrometry, it is the definitive method currently available for this measurement.

Medium-energy ion scattering, which uses a toroidal electrostatic spectrometer to analyze both energy and angle of scattered particles, is the oldest of the medium-energy techniques and is a definitive method for the precise lattice location of surface atoms by a detailed analysis of channeling and blocking.

If you are reading this, you are probably trying to decide if a medium-energy ion beam technique is right for your problem. If you have not done so, you should first familiarize yourself with the general principles of ion scattering in PARTICLE SCATTERING. If you can solve your problem with one of the high-energy techniques described in Section 12a, then you should probably do so. Medium-energy techniques are appropriate for specialized problems and circumstances as described in the pages that follow.

MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY

INTRODUCTION

Medium-energy backscattering spectrometry is a variation of Rutherford backscattering spectrometry (RBS) (ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS) using ions with energies ranging from a few tens to a few hundreds of kilo-electron-volts. The ion beam, frequently He^+, is directed onto a specimen and the number of backscattered ions per incident ion is measured as a function of scattered-ion energy at one or more angles relative to the beam direction. The fundamental physical process being used is that of a binary collision between the nuclei of an ion in the beam and a near-stationary atom in the target. In such a collision, the energy of the backscattered ion is determined uniquely by its original energy, the scattering angle (which is the angle between the ion's trajectories before and after the collision), and the ratio of the masses. Consequently, a measurement of the energy of a backscattered ion at a specific angle may be used to infer the mass

of the target atom with which it collided. The number of backscattered ions is proportional to the collision cross-section and the total number of available scattering centers. Since collision cross-sections are known *a priori* in this energy range, the number of backscattered ions with a given energy is a direct measure of the number of atoms of the corresponding mass in the target.

The method achieves additional richness as the result of a second physical phenomenon, the gradual loss of kinetic energy through collisions as an ion penetrates through matter. This is measured by stopping power (also called linear energy transfer), which is the average energy lost, typically in electron volts per unit of length (measured in atoms per square centimeter) of trajectory in the target. If an ion passes through the surface of a specimen and experiences a collision at some depth within it, it will lose energy on both the inward and outward legs of its trajectory. Consequently, a second factor controlling the energy of backscattered ions is the depth within the target at which the collision occurs. As a result, it is usually possible to extract quantitative information about the distribution of specific species within the near-surface region of the specimen. There are a number of excellent reviews of ion penetration in the literature that include both theoretical background and algorithms for computing stopping power (Ziegler et al., 1985; Rauhala, 1995; Nastasi et al., 1996). For the purposes of this unit, it is sufficient to note that for medium-energy ions the stopping power is dominated by collisions between the nucleus of the projectile and the electrons of the target, so-called electronic stopping, which results in relatively uniform loss of energy with minimal angular divergence of the beam. Widely accepted semiempirical procedures are available for computing electronic stopping power.

Additional information can often be derived from backscattering spectra for specimens that are crystalline or multilayer structures with some crystalline and other amorphous layers by exploiting the phenomenon of particle channeling (Feldman et al., 1982; Swanson, 1995). At medium energies, the angular widths of particle channels, which vary as the inverse square root of particle energy, are of the general order of a degree. This can be exploited through precise control of target orientation in order to obtain information about target crystallinity or additional information about target structure or to deliberately suppress scattering from one region of a specimen in order to emphasize that from another. Channels are so wide at medium energies that accidental channeling occurs frequently and can adversely affect the precision of measurements.

Backscattering spectrometry is most formidable for the analysis of higher atomic mass constituents of a sample, because the spectral features attributable to lower-atomic-mass surface constituents such as carbon or oxygen will occur at the same energy as features attributable to higher-atomic-mass constituents such as silicon located more deeply in the sample. Thus, a heavier substrate produces a background that complicates the analysis of light elements on the surface. Forward-recoil spectrometry, particularly when done by time of flight, addresses this situation.

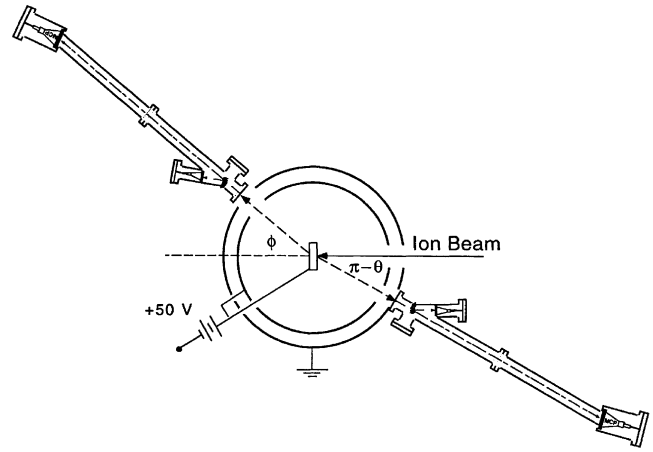

Figure 1. Schematic of the vacuum chamber of a medium-energy ion scattering apparatus showing the target, a forward-scattering and backscattering spectrometer, and their relative orientations with respect to the incident ion beam. The target is biased at +50 V and is situated in a large Faraday cup.

Forward-recoil and backscattering spectrometry, as the names imply, differ primarily in the geometry of the basic ion beam–target collision (Fig. 1). In medium-energy forward-recoil spectrometry, in the laboratory the detector of scattered ions is located at a direction that is typically $\sim 30^\circ$ with respect to the original direction of the ion beam. In binary collisions between beam ions and atoms of the target, the latter are forbidden from having laboratory scattering angles exceeding 90°, so that the features of backscattering spectra are all attributable to scattered ions from the beam. In forward-recoil spectrometry, both target and beam species are present. The optimum situation for light-element detection is achieved by a combination of time-of-flight spectrometry and the use of a beam projectile with higher atomic mass than the target elements of interest. When a heavy projectile strikes a light target, the latter moves away at a speed that, in the laboratory, can be nearly twice that of the former. As a result, at the fixed angle of the detector, of the common light elements hydrogen will be moving most swiftly, followed by carbon, nitrogen, and so on. By measuring the time that these particles require to traverse a fixed distance, they may be sorted by element in a spectrum devoid of the background that would be present in either a backscattering spectrum (where hydrogen would be unobservable) or a forward-recoil measurement using an energy-dispersive detector. Medium-energy forward-recoil spectrometry is among the most sensitive techniques available for the quantitative measurement of surface hydrogen, particularly when it is important to measure other light elements, such as carbon, nitrogen, or oxygen, simultaneously.

Particle detection technology is an extremely important issue in medium-energy ion beam analysis. The remainder of this unit will focus on time-of-flight spectrometry optimized for high-resolution measurements. Other methods, including magnetic and electrostatic spectrometers, pulsed-beam accelerator systems, and time-of-flight spectrometry optimized for other measurements, will be discussed

briefly (see Complementary and Alternative Techniques, below), along with several other methods for depth profiling, trace-element identification, and hydrogen measurement. Throughout, special attention will be paid to the relationship between medium-energy backscattering and conventional high-energy RBS.

Complementary and Alternative Techniques

Time-of-flight medium-energy backscattering is a variation of conventional (high-energy) RBS that has been optimized for high-resolution depth profiling of the first few tens of nanometers of the surface of multilayer planar structures. When devising an ion beam analytical strategy for a specific specimen, it is best to determine first if high-energy (≈2-MeV) backscattering will provide satisfactory information. If it will, then considerations of cost, availability, and ease of interpretation of the data all argue that it should be used. Medium-energy backscattering should be considered if the region of interest is within a few tens of nanometers of the surface and if the depth resolution of conventional RBS appears to be inadequate. Medium-energy backscattering can routinely achieve near-surface depth resolutions better by about a factor of 4 than high-energy RBS with a surface-barrier detector. For the special case of profiling oxygen in SiO_2 films on Si, one should also consider medium-energy proton scattering using a toroidal electrostatic analyzer.

In general, it is always best to use an ion beam technique for elemental depth profiling, if one is available. This is because absolute cross-sections are known, and therefore measurements are quantitative, and because ion beam techniques typically look at the specimen in depth. An alternative procedure is to combine a highly surface-specific technique with the gradual erosion of the specimen by either chemical erosion or sputtering. Examples would include secondary ion mass spectrometry (SIMS) and sputter Auger profiling (see AUGER ELECTRON SPECTROSCOPY). SIMS is extremely sensitive to trace elements. When it is performed in conjunction with slow near-threshold sputtering of a sample, it is termed "static" and can be used for elemental depth profiling by observing secondary ion yields as a function of duration of erosion. This procedure can produce excellent depth profiles of many elements simultaneously, but like all variations of SIMS, absolute values are not readily obtained. In sputter Auger electron spectrometry, one or more specific Auger lines are monitored as a function of erosion. Both static SIMS and sputter Auger require an independent measurement of erosion to assign an absolute depth scale. With ion beam techniques, the depth scale follows from a knowledge of the stopping power.

Medium-energy forward-recoil spectrometry is particularly well suited to measure surface hydrocarbons, especially when they are on metallic or other high-atomic-mass substrates. Alternative techniques include high-energy forward recoil (Barbour and Doyle, 1995; Tirira et al., 1996) and, for specific cases such as hydrogen, nuclear reaction analysis. At mega-electron-volt energies, forward-recoil spectrometry has been carried out both by time-of-flight spectrometry and by the use of surface-barrier detectors in conjunction with thin foils that function essentially as filters to reject forward-scattered beam ions (Barbour and Doyle, 1995). Whenever possible, all forward recoil, regardless of beam energy, should be carried out using time-of-flight techniques. This is because velocity and not energy is the appropriate natural parameter for dispersive analysis. Medium-energy forward-recoil spectrometry should be considered when very high sensitivity is a goal of the experiment. It may also be appropriate when a specimen is very fragile and must receive the minimum possible radiation dose consistent with analysis. Since damage cross-sections often vary as E_0^{-1} while scattering cross-sections vary as E_0^{-2}, the lowest energy suitable for analysis is optimum. Medium-energy forward-recoil measurements can be made on thin organic foils with as few as 10^{11} total ions striking the target (Arps and Weller, 1995).

The preferred method for hydrogen measurement on and near the surfaces of materials is by nuclear resonant reaction analysis using $^1H(^{15}N, \alpha\gamma)^{12}C$ or $^1H(^{19}F, \alpha\gamma)^{16}O$ (PARTICLE-INDUCED X-RAY EMISSION). However, neither of these methods is capable of simultaneously returning information about other components of the specimen. Medium-energy forward-recoil spectrometry provides information about all low-atomic-mass constituents at once and, therefore, can be used in situations where the picture obtained by nuclear reaction analysis is incomplete. Medium-energy forward-recoil spectrometry has been shown to be capable of achieving a depth resolution and sensitivity for hydrogen of ~6 nm and $10^{13}\,cm^{-2}$, respectively (Arps and Weller, 1996). SIMS is also used successfully for hydrogen measurement, but is not as predictable as nuclear reaction or forward-recoil analysis because the cross-section for secondary hydrogen ion production is a function of the state of the surface and is not well known.

PRINCIPLES OF THE METHOD

The definitive treatment of backscattering spectrometry is the book by Chu et al. (1978). The subject has been reviewed recently by Leavitt et al. (1995) and also in ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS of this work, which describes conventional mega-electron-volt methods. What follows is a brief review of the basic principles of backscattering spectrometry with particular emphasis on those aspects in which medium-energy techniques differ from their high-energy counterparts. Additional material specific to forward-recoil spectrometry is also provided. The basic geometry of a medium-energy backscattering experiment with a time-of-flight spectrometer is shown in Figure 1.

When a particle with energy E_0 and mass M_1 strikes a stationary target particle with mass $M_2 > M_1$ and is observed to be scattered by an angle θ in the laboratory, then the energy of the scattered particle will be

$$E_1 = K \cdot E_0 = E_0 \left(\frac{\{x \cdot \cos(\theta) + [1 - x^2 \sin^2(\theta)]^{1/2}\}^2}{(1 + x^2)^2} \right) \quad (1)$$

where $x \equiv M_1/M_2$. This expression defines the kinematic factor K, which relates the incident energy of a particle to its energy after the collision. This is the fundamental relationship by which the mass M_2 of a surface constituent is obtained from the measured backscattered energy E_1.

When an ion beam is normally incident on a surface covered by a thin layer of thickness t, the observed number of backscattering events Y_i attributable to the ith constituent is given by the relationship

$$Y_i = \eta(K \cdot E_0) \cdot Q \cdot (N_i \cdot t) \cdot \Omega \cdot \sigma_i(E_0, \theta) \qquad (2)$$

where N_i is the density of the ith component in atoms per cubic centimeter, Q is the total number of incident projectiles, Ω is the solid angle of the spectrometer, and σ_i is the differential cross-section for the collision (PARTICLE SCATTERING). Strictly speaking, one should integrate the cross-section over the solid angle subtended by the detector, but in practice the solid angle is usually so small that the approximation of Equation 2 is satisfactory. The remaining term, $\eta(K \cdot E_0)$, is the spectrometer quantum efficiency, which is the probability that a particle incident upon the detector will result in a measurable event (Weller et al., 1994). The efficiency is a function of the energy of the backscattered particle and, implicitly, of the particle species. The presence of the efficiency term in Equation 2 is one of the features that distinguishes medium-energy backscattering from its higher-energy analog. At mega-electron-volt energies, the particle detector of choice is the silicon surface barrier detector. The quantum efficiency of surface barrier detectors is so near unity that it is almost universally ignored, and linearity of the output signal with particle energy is also assumed (Lennard et al., 1986). As a result, $N_i t$ can be directly inferred from a measurement of Y_i, Q, and Ω, the latter being, at least in principle, a simple exercise in geometry. This, of course, supposes a knowledge of σ_i, but this is known from theory for mega-electron-volt scattering to be the Rutherford cross-section, given in the laboratory reference frame (Darwin, 1914; Chu et al., 1978) by

$$\sigma_R(E_0, \theta) = \left(\frac{Z_1 Z_2 e^2}{2E_0}\right)^2 \left(\frac{\{\cos(\theta) + [1 - x^2 \sin^2(\theta)]^{1/2}\}^2}{\sin^4(\theta)[1 - x^2 \sin^2(\theta)]^{1/2}}\right) \qquad (3)$$

Here Z_1 and Z_2 are the atomic numbers of the projectile and the ith target constituent, respectively, and e^2 is the square of the electron's charge, which may be conveniently expressed as 1.44 eV·nm.

In medium-energy work, both the unit efficiency and Rutherford cross-section approximations fail, adding significantly to the complexity of interpreting medium-energy backscattering data. It is perhaps some consolation, however, that they only appear as a product $\eta \cdot \sigma$ (see Equation 2) and therefore can be treated as a single entity. Discussion of the efficiency will be postponed until after the discussion of the general features of a time-of-flight spectrometer (see Practical Aspects of the Method, Spectrometer Efficiency). The scattering cross-section will be considered first.

A general rule for the range of validity of the Rutherford cross-section has been given by Davies et al. (1995). They assert that the above expression should be within ±4% between the limits of $0.03 Z_1 \cdot {Z_2}^2$ keV and $0.3 Z_1 \cdot {Z_2}^{2/3}$ MeV. Above this limit, nuclear reactions begin to occur. Below it, in the range of medium-energy collisions, the presence of electrons significantly screens the collision. For the common case of a He^+ particle beam, the lower threshold for silicon, $Z_2 = 14$, is ~ 12 keV, while for gold, $Z_2 = 79$, it is ~370 keV. The departure of the cross-section from the Rutherford value at low energies has been studied extensively (L'Ecuyer et al., 1979, and references therein) and found to be well described by the Lenz-Jensen (Andersen et al., 1980) screened Coulomb potential. For reference purposes, algorithms have been developed (Mendenhall and Weller, 1991) that are sufficiently accurate and efficient to permit the classical cross-section for this potential to be computed in real time. However, in view of the uncertainty in the spectrometer efficiency, the following simple expression for the ratio of the screened to the Rutherford cross-section proposed by Andersen et al. (1980), which is typically accurate to a few percent, is recommended for most practical calculations:

$$\frac{\sigma}{\sigma_R} = \left(1 + \frac{48.73 Z_1 Z_2 (1 + x)(Z_1^{2/3} + Z_2^{2/3})^{1/2}}{E_0(\text{eV})}\right)^{-1} \qquad (4)$$

where, as indicated, E_0 is expressed in electron volts, and the mass ratio x has been defined above. Figure 2A shows the ratio of the Lenz-Jensen screened cross-section to the Rutherford cross-section for He^+ ions on Si, Cu, and Au. Figure 2B, which shows a comparison of the approximation of Equation 4 with the exact Lenz-Jensen cross-section for the extreme case of He^+ on gold, serves to illustrate the quality of the approximation.

Figure 3 presents a graph of the stopping power of He^+ ions in Si, Cu, and Au in the range of Rutherford and medium-energy backscattering. As described above, stopping power is the physical phenomenon that gives backscattering spectrometry its depth-profiling ability. From this graph alone, one would conclude that, because the stopping power is smaller, medium-energy depth profiles would, in principle, contain less information. However, the loss in intrinsic depth differentiation is more than made up by the gains in spectrometer resolution made possible by exchanging a surface barrier detector for a time-of-flight spectrometer.

Backscattering data consist of spectra made by producing a histogram of the number of backscattered particles observed within energy bins of equal width. Figures 4A–D contain computer-simulated backscattering spectra as they would be observed with a surface barrier detector (Figs. 4A–C, E_0 equals 2 MeV, 1 MeV, and 500 keV, respectively) and a time-of-flight spectrometer (Fig. 4D, $E_0 = 250$ keV). In all cases the specimen is assumed to be a device-grade silicon wafer covered with 20 nm of SiO_2 (density 2.22 g/cm^3), 10 nm of $TiN_{0.8}$ (molecular density same as stoichiometric TiN), 15 nm of TiN (density 4.94 g/cm^3), and a trace contamination of W on the surface with an areal density of 4×10^{14} cm^{-2}. In all cases, the He^+

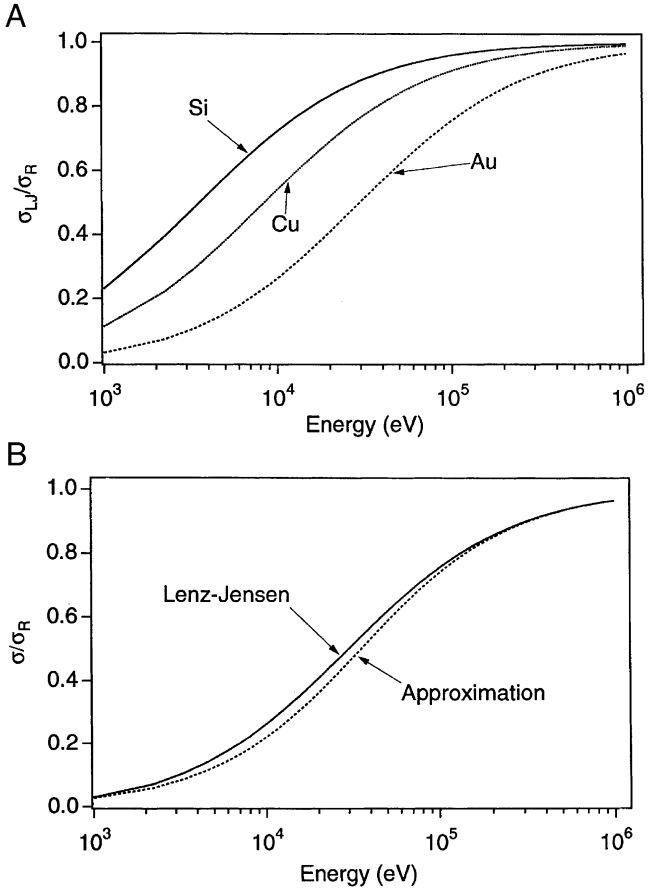

Figure 2. Medium-energy scattering cross-sections. (**A**) The ratio of the Lenz-Jensen cross-section to the Rutherford cross-section, as a function of energy, for He^+ scattering from several target nuclei at a laboratory angle of 150°. (**B**) A comparison of the ratio of the Lenz-Jensen cross-section to the Rutherford cross-section and the approximation to this ratio suggested by Andersen et al. (1980). The approximation is given here as Equation 4. The comparison is for He^+ scattering from Au at 150° in the laboratory.

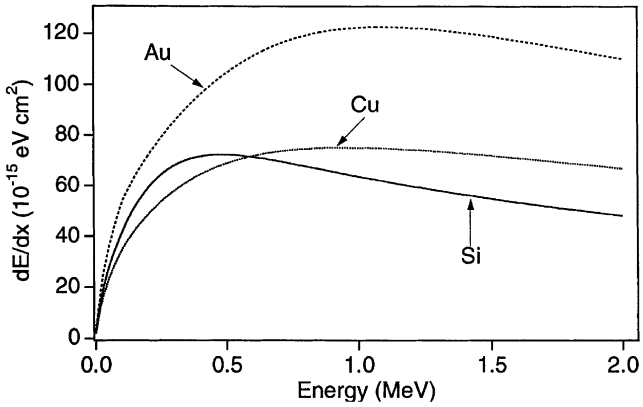

Figure 3. The stopping power of He ions in Si, Cu, and Au as a function of energy. These were computed as described in Ziegler et al. (1985).

beam is incident normally on the surface and the scattering angle is 150°. The amount of deposited charge is 100 μC and the solid angle of both detectors is 1 msr. Both spectrometers are assumed to have unit efficiency as a function of energy. The resolution of the surface barrier detector is taken to be 13 keV, which is typical of commercial devices when new. The resolution of the medium-energy system is more complicated since it is energy dependent, but it has been taken to be the experimentally determined resolution of a typical time-of-flight spectrometer, expressed in the energy domain. For the simulation, all isotopes of all the elements present have been included explicitly, as has energy straggling, using the results of Yang et al. (1991). Stopping power has been computed using the methods of Ziegler et al. (1985) and cross-sections using the algorithms of Mendenhall and Weller (1991). It is assumed that the spectra have been taken in such a way that channeling is not significant. In practice, this is probably best accomplished by aligning the beam a few degrees from a known channel or by rotating the target continuously during the measurement. The plots have been scaled vertically to mimic data taken with a multichannel analyzer adjusted for a conversion gain of 1 keV per channel for the surface barrier spectra and 250 eV per channel for the time-of-flight spectrum. The effects of counting statistics have been omitted for clarity. These figures help to illustrate graphically the relative merits of mega-electron-volt and kilo-electron-volt backscattering.

The small isolated peak at the right of each of the spectra shown in Figures 4A–D is attributable to the trace contamination of W on the sample surface. To quantify the surface concentration, one would simply use Equation 2 with the total yield taken as the integrated number of counts comprising the peak. Because the W is not distributed in depth but instead is concentrated on the surface, the width of the peak is a measure of the system resolution. For the surface barrier spectra this energy resolution is approximately constant as a function of energy. For the time-of-flight spectrum the resolution is poorer at larger energies. For the spectra of Figures 4A and B the large isolated peak is attributable to Ti, and its width is also narrow. However, it shows some broadening relative to the W peak. In Figure 4C it is clearly apparent that the Ti peak has width, but no structure is visible. In all these spectra, the total Ti can be easily measured by the same procedure used for quantifying W.

The pronounced step feature near the center of the spectra of Figures 4A–D is attributable to silicon in the SiO_2 layer and in the silicon substrate, and is referred to as the silicon edge. Because this target is thick, the silicon signal occupies the full range of the spectrum below (to the left of) the edge. Notice the two small peaks visible above the silicon background in Figure 4A. These are attributable to nitrogen and oxygen, with the oxygen peak being at higher energy. For beam energies of 1 and 2 MeV these are fully resolved, but at 0.5 MeV, the surface barrier detector is unable to separate these peaks.

The spectrum of Figure 4D shows the view of the specimen, again omitting statistical fluctuations, that would be obtained by time-of-flight medium-energy backscattering. (See Practical Aspects of the Method for a method to derive an energy spectrum from raw time-of-flight data.) The

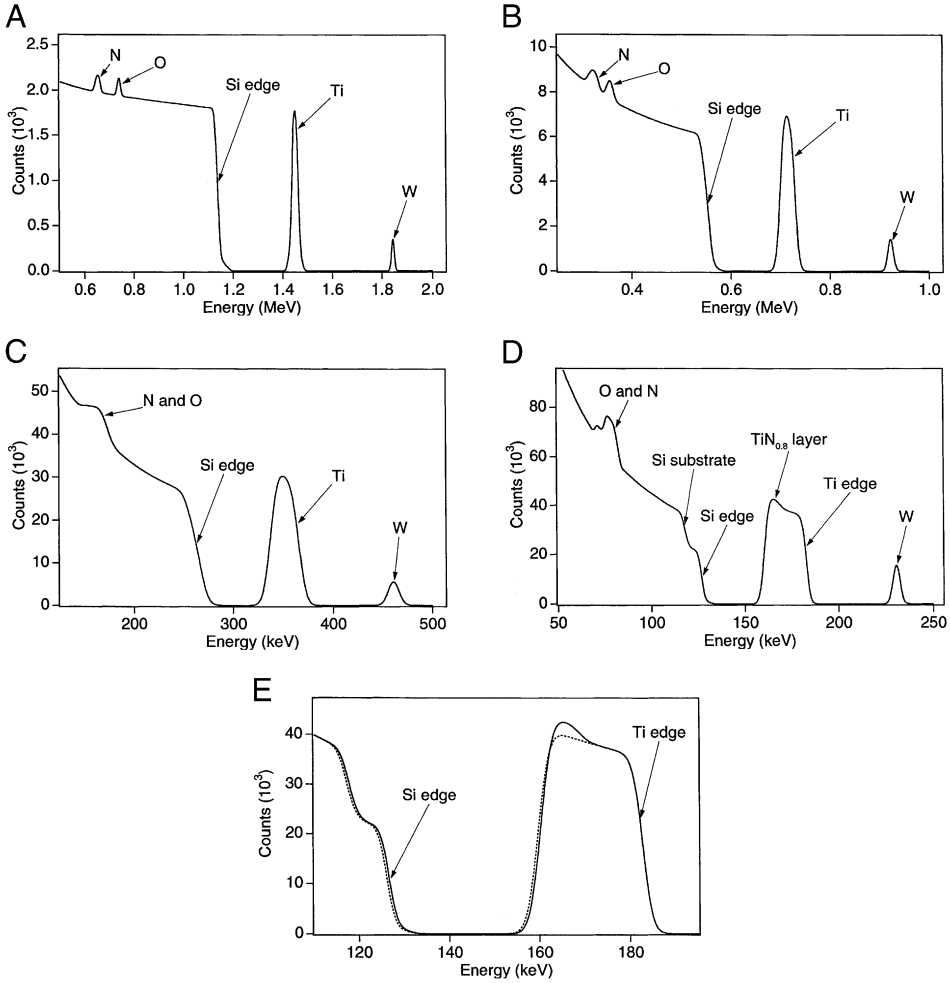

Figure 4. A computer simulation comparing backscattering at various energies using a surface barrier detector (**A–C**) and a time-of-flight spectrometer (**D–E**). The target is a TiN film, with a nitrogen-deficient region, on SiO_2 on Si. There is a trace of W contamination on the surface. (**E**) An expanded view of the Ti peak from (**D**) along with the result (dotted line) that would be expected from a fully stoichiometric TiN film, demonstrating that the nitrogen-deficient region is clearly discernible.

important points to notice are that the Ti peak now clearly contains structure to the extent that it is higher on the left than the right side, and that the silicon edge now contains definite evidence of a step. From these observations alone, it is possible to conclude that the TiN layer does not have uniform composition and that the oxygen is associated with silicon in the form of an SiO_2 film whose thickness can be inferred from the spectrum. This additional insight has been achieved at the expense of the loss of resolution of the nitrogen and oxygen features, which are now fully merged. This is demonstrated clearly in Figure 4E, which compares the Ti peak with a portion partially depleted in N against a simulation of the same target with a single stoichiometric layer of TiN 25 nm thick.

The method of inferring the stoichiometry of a thin film from backscattering data is the same for both medium-energy and high-energy backscattering and is described at length by Chu et al. (1978) and by Leavitt et al. (1995) as well as in ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS. Similarly, procedures have been devised to infer depth profiles from measured backscattering data. It is important to emphasize, however, that the problem of inverting a backscattering spectrum to produce a target structure does not, in general, have a unique solution and is further complicated by statistical fluctuations in the data, small- and large-angle multiple scattering of the beam and scattered ions, channeling, uncertainties in density, and the surface topography of the specimen, in addition to factors such as energy straggling and measurement resolution, which have been simulated in Figures 4A–E.

It is generally true that the more *a priori* knowledge that one has about a specimen, the more precisely one can infer its structure. For example, in the semiconductor industry, where fabricating thin-film structures is the *sine qua non* of integrated circuit manufacture, engineers ordinarily know the order and approximate composition of individual layers in a multilayer thin-film structure. In this case, it is possible, working from approximate starting values, to use a simulation procedure such as the one used to produce Figures 4A–E in a closed-loop algorithm to find the values of parameters such as film thickness and composition that provide the best fit to measured data in the sense of χ^2 minimization or some other measure of goodness of fit. For mega-electron-volt data there are computer algorithms in the published literature to implement such procedures (Doolittle, 1984, 1985, 1990) as well as proprietary computer programs available from commercial

sources (e.g., Strathman, 1990). (See Leavitt et al., 1995, for a more complete list of published simulation algorithms.) However, as of this writing, these have not yet been adapted to explicitly handle medium-energy backscattering. The general problem of inversion of backscattering spectra continues to be an area of active research as the advance of computer power continues to widen the range of methods that can be undertaken practically. The goal of this research, which is to extract all statistically significant information contained in backscattering spectra, is still elusive, although important progress is being made (Barradas et al., 1997).

PRACTICAL ASPECTS OF THE METHOD

The previous section discussed issues relating to medium-energy ion scattering for the most part without reference to any specific spectrometric technique. This is appropriate because there are a number of methods, including electrostatic and magnetic spectrometers, pulsed-beam and foil-based time-of-flight spectrometers, and even cryogenic solid-state detectors, by which the experiments can be performed, and novel variations frequently appear in the literature. Each method has advantages and disadvantages and continues to benefit from time to time by advances in technology. The choice of which method to use is not abstract, but is closely related to the nature of the problem at hand. The discussion in this section will be restricted to a particular style of foil-based time-of-flight spectrometer that has a straightforward design and an attractive set of operating characteristics. Foil-based time-of-flight spectrometers were originally introduced for heavy-ion spectrometry in nuclear physics (see Pfeffer et al., 1973, and Betts, 1979, and references therein) and later adapted for backscattering spectrometry using mega-electron-volt heavy ions (Chevarier et al., 1981). They were first applied to medium-energy ion beam analysis by Mendenhall and Weller (1989, 1990). Several time-of-flight configurations have been reviewed critically by Whitlow (1990).

Time-of-Flight Spectrometry

An energy-dispersive particle spectrometer such as a silicon surface-barrier detector functions by converting the energy of a kinetic particle to an approximately proportional quantity of electric charge. A time-of-flight spectrometer functions by measuring the time that it takes for a particle to traverse a fixed distance. This requires two signals representing a "start" and a "stop" that are associated with, but possibly offset by a fixed time from, the beginning and end of the traversal. In time-of-flight spectrometry, the issue is how best to obtain a start signal, since a stop signal can always be produced by simply collecting the particle in any of several detectors. In pulsed-beam time of flight, the start signal is derived by knowing that all ions of the beam arrive at the target in a narrow pulse. In foil-based time of flight, a very thin foil, usually of carbon, is placed at the beginning of the measured flight path. This foil is so thin that an ion hitting it passes through with minimal loss of energy and perturbation of its trajectory.

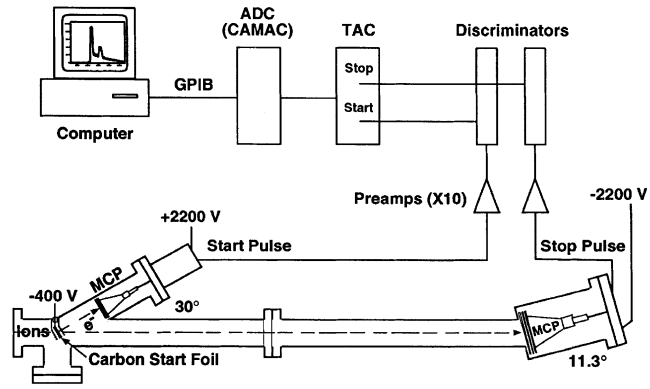

Figure 5. Principal components of a medium-energy time-of-flight spectrometer system. This system is computer controlled and CAMAC based (Weller, 1995a). The angle of the stop detector is chosen to optimize resolution as described in the text.

As it exits the foil, the ion produces secondary electrons with significant (but not unit) probability, and these are accelerated away and detected to produce a start signal. A time-of-flight spectrometer of this type is shown in Figure 5.

Spectrometer Efficiency

The characteristics of the spectrometer enter into the determination of the concentrations of constituents via the energy-dependent efficiency term η in Equation 2. It is possible to understand the physical origin of this efficiency by considering individually the mechanisms by which events may be lost. For example, while the perturbation of the trajectory by the start foil is small, it is not zero, and a predictable number of events will be lost because small-angle multiple scattering deflects some particles enough to miss the stop detector (see Fig. 5). Similarly, since the production of a start pulse requires secondary electrons, and since the production of secondary electrons is inherently statistical, there will be instances in which a particle will pass through the start foil without creating a start pulse. Additional processes that may disrupt the normal sequence of events in the spectrometer include scattering of ions or electrons from various meshes, the intrinsic dead area on the surface of microchannel plates, and the statistical nature of the development of pulses in these detectors. The cumulative effect of these various events has been summarized in a model of time-of-flight spectrometer performance that is, in principle, capable of predicting the energy-dependent performance of a time-of-flight spectrometer from first principles (Weller et al., 1994). However, because many input parameters to the model, such as secondary electron emission yields, are highly variable and dependent upon vacuum conditions and age and composition of the components, among other things, the model is best used in conjunction with measurements of efficiency, so that these parameters need not be known *a priori*. This semiempirical approach is demonstrated in Figure 6, which uses experimentally determined parameters along with the equations of Weller et al. (1994) to obtain efficiency curves

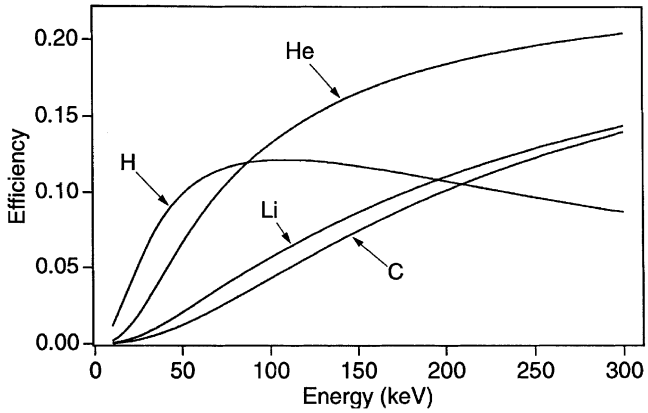

Figure 6. The efficiency of the time-of-flight spectrometer shown in Figure 5 for hydrogen, helium, and carbon ions as a function of energy, computed using empirical parameters in conjunction with the formalism described by Weller et al. (1994).

for a time-of-flight spectrometer like that shown in Figure 5. Note that the curve for H, unlike the others, has a maximum in the region of interest. This is attributable to the dependence of the secondary electron yield on electronic stopping power. It is important to emphasize that the efficiency of a spectrometer for a given ion is a property of the measuring device and not of the target being measured. Thus, while it is necessary to use a standard for the initial calibration of the instrument, it is not necessary to employ standards that mimic the properties of individual targets in order to achieve quantitative results. In this sense, the method is to be contrasted with SIMS, where the characteristics of a surface may have a strong impact on the relative intensities of the signals from various surface constituents.

Sensitivity

In general, elastic scattering spectrometries are more sensitive at lower incident beam energies, all other things being equal, because the collision cross-section decreases with increasing energy (see Equation 3). Thus, medium-energy backscattering and forward-recoil spectrometry enjoy an intrinsic advantage of as much as two orders of magnitude when compared with their high-energy counterparts. However, a portion of this is forfeited in practice because of the efficiency of the spectrometer, as discussed in the previous paragraph. See HEAVY-ION BACKSCATTERING SPECTROMETRY for a discussion of a system that has been optimized for extremely high sensitivity.

The trace-element sensitivity of medium-energy backscattering is limited by two factors, the gradual sputter removal of the constituent of interest and multiple scattering of the beam within the target. If, instead of scattering once at an angle θ in order to enter the spectrometer, a particle scatters twice at an angle $\theta/2$, then its energy will be considerably higher. Ordinarily, these multiple collisions (including all possible pairs of events that sum to an angle θ) are sufficiently rare that they are ignored in analyzing backscattering data. However, for heavy trace elements such as, for example, iron on silicon, multiple scattering in the silicon substrate can lead to the production of counts in the region of the iron peak that is kinematically forbidden to binary collisions with individual substrate atoms. These counts constitute a background that limits the signal-to-noise ratio of true iron counts. This multiple-scattering background, which has been studied extensively by Brice (1992), is most significant for heavy-ion backscattering (HEAVY-ION BACKSCATTERING SPECTROMETRY).

For light-ion backscattering, as for example with He^+, the predominant factor controlling sensitivity is sputtering (Weller, 1993). Sputtering, the erosion of a material by ion impacts, typically results in from 10^{-3} to as many as 10 or more surface atoms being removed for each ion impact (Yamamura and Tawara, 1996). In the absence of sputtering, a trace-element backscattering measurement could proceed until all atoms of the element of interest are involved in a collision. With sputtering, it is convenient to define the sensitivity by the constraint that the fractional amount of the trace element removed is equal to the fractional uncertainty that is acceptable in the final answer. The only difficulty with this is that the *a priori* sputtering yields of trace elements in a foreign host are not well known (Pedersen et al., 1996), so that plausible assumptions about these yields must be made. Doing so results in the following formula for the minimum areal concentration ρ of a surface constituent that can be measured with a fractional uncertainty ε (Weller, 1993):

$$\rho = \frac{1 + \sqrt{1 + 8\varepsilon^2 B}}{2\varepsilon^3} \cdot \frac{Y_s}{\rho_s A_s \Omega \sigma \eta} \tag{5}$$

where A_s is the area of the target that is irradiated by the beam and B is the number of background counts in the region of the spectrum that contains valid counts. The quantities σ and η are the cross-section and spectrometer efficiency, respectively, and Ω is the spectrometer's solid angle. This expression is based upon the assumption that the probability P that a beam ion removes a target atom is related to the (dimensionless) sputtering yield of the substrate Y_s through the relation

$$P \approx Y_s \cdot \frac{\rho}{\rho_s} \tag{6}$$

where ρ_s is taken to be the areal density of substrate atoms in the region from which sputtered particles are drawn. This is typically the first two or three atomic layers of the target (Dumke et al., 1983). Equation 6 expresses the assumption that trace elements are sputtered randomly from the surface with a probability equal to their fractional representation in the volume from which sputtered particles can emerge. Estimates of sputtering yields may be obtained using the equations or tables of Yamamura and Tawara (1996). For trace quantities of copper on silicon analyzed by He^+ with a general-purpose spectrometer like that shown in Figure 5, Equation 6 predicts a sensitivity of $\sim 10^{11}$ cm^{-2} in the absence of background ($B = 0$). However, achieving this figure would require exceptionally long measuring times. For trace elements with concentrations below $\sim 10^{13}$ cm^{-2}, a system optimized

for sensitivity should be used (HEAVY-ION BACKSCATTERING SPECTROMETRY).

Resolution

The energy resolution of a spectrometer is important because it is a direct measure of the depth resolution of backscattering spectrometry. It is important to emphasize, however, that resolution is not a unique concept. Most often, in analogy to the Rayleigh criterion familiar from optics, two isolated peaks in a backscattering spectrum are said to be resolved when their separation is equal to the full width at half-maximum (FWHM) of the peaks. In this case, any additional separation results in an observable bimodal structure. This definition certainly captures the essence of the physics for cases, such as superlattices, where the objective is to discern changes in the concentration of an element as a function of depth. However, there is another closely related concept, that of layer thickness, for which this definition of resolution results in an unduly pessimistic estimate of the quality of the data. In this second type of measurement, one is typically interested in small variations in the thickness of a layer rather than in the details of its structure. Essentially, the problem is that of locating the edge of a spectral feature, which is approximately equivalent to locating the centroid of an isolated peak. This can typically be done with an uncertainty of $\approx$10% of a standard deviation, σ, of the peak, as compared with the FWHM, which is 2.35σ. Thus, it is possible to measure thickness variations that are more than an order of magnitude smaller than the standard definition of resolution would suggest. There is no contradiction here, simply an inconsistency in what exactly is meant by "resolution." In the paragraphs that follow, the usual Rayleigh concept will be adopted, with the understanding that it may not be appropriate in all circumstances.

If δE is the uncertainty (FWHM) from all sources in the measurement of a backscattered particle's energy, then the corresponding uncertainty in depth of the target atom is (Chu et al., 1978)

$$\delta x = \frac{\delta E}{[S]} \tag{7}$$

where the denominator is known as the energy loss or stopping power factor and is given by

$$[S] = \left[K\left(\frac{dE}{dx}\right)_{\text{in}} \cdot \frac{1}{\cos(\theta_1)} + \left(\frac{dE}{dx}\right)_{\text{out}} \cdot \frac{1}{\cos(\theta_2)}\right] \tag{8}$$

Here K is the kinematic factor defined above, dE/dx is the stopping power, and θ_1 and θ_2 are angles made with the target surface normal by the inward and outward trajectories of the particle, respectively (Leavitt et al., 1995). As a particle penetrates a target, the uncertainty in its energy grows as a result of straggling, which is the intrinsic uncertainty associated with the statistics of energy loss (Yang et al., 1991). Thus, depth resolution is always best at the surface of a target, where it is limited by the uncertainty of the beam energy E_0 and the properties of the spectrometer.

Three primary design characteristics govern the resolution of a time-of-flight spectrometer such as is shown in Figure 5: minor differences in the length of the flight paths of different ions, straggling in the carbon start foil, and nonuniformity of the foil either in thickness or density. Of these, foil nonuniformity is the most serious (McDonald et al., 1999). An additional variation due to the natural kinematic broadening associated with the variation of θ across the finite acceptance solid angle of the spectrometer is also significant (Equation 1), as is a charge-exchange process that produces small parasitic features offset from the true value by plus or minus the value of the start foil bias, or $\sim$300 eV (Weller et al., 1996).

The velocity of a 100-keV He^+ ion is $\approx$2.2 mm/ns. As a result, it is necessary to design a spectrometer so that most trajectories differ by no more than a millimeter or so. This is the reason for the relative angles between the start and stop detectors in Figure 5. If all ions entered the spectrometer along parallel trajectories, then the offset angles measured from the spectrometer axis should be equal. However, for particles emerging from a point source, there is another angle that produces minimum path length dispersion, which is dependent upon the distance between the target and the start foil and the length of the drift section. Interestingly, a further adjustment of this angle conveys an advantage unique to time-of-flight methods. Ions with larger scattering angles move more slowly as a result of the natural variation of the kinematic factor K with angle (Equation 1). As a result, it is possible to adjust the relative angles of the start and stop detectors to minimize kinematic dispersion from the finite solid angle of the spectrometer. This adjustment, although it amounts to only about a degree, produces a clear improvement in performance for the ion for which it is optimized (Weller et al., 1996).

Considering fundamental physical processes such as straggling and limitations imposed by geometry, time-of-flight spectrometers like that shown in Figure 5 should have a resolution of $<$1%, or perhaps 1 keV for a 150-keV ion (McDonald et al., 1999). With favorable target orientation (see Equation 8), this should produce a depth resolution of $\approx$1 nm at the target surface. This is approximately a factor of 2 better than has been achieved in the laboratory because of the microscopic roughness of available carbon start foils, but still somewhat inferior to results obtainable in proton backscattering using high-resolution electrostatic analyzers. It compares quite favorably with results obtained using surface barrier detectors simply because of the improved resolution (Williams and Möller, 1978).

Instrumentation

The electronic instrumentation needed to implement a time-of-flight system is standard (Weller, 1995a) and available from commercial vendors. The essential components are the start and stop detectors, timing discriminators, and time-to-amplitude or time-to-digital converters. The fundamental, active, particle-detecting elements in time-of-flight spectrometers are microchannel plates (Fig. 5). These are high-density arrays of microscopic, continuous-dynode electron multipliers fabricated in millimeter-thick glass wafers (Wiza, 1979). New microchannel

plates operated at rated bias can produce pulses that are a significant fraction of a volt. However, they are so fast that most general-purpose oscilloscopes cannot display them.

With proper signal-handling techniques (Weller, 1995a, and references cited therein), it should be possible to couple the start and stop pulses directly to timing discriminators, whose function it is to produce uniform time markers that are insensitive to pulse amplitude. However, in practice, it may be necessary to add a stage of voltage amplification between the microchannel plates and timing discriminators. Amplifiers with bandwidth of at least 1 GHz are needed for this purpose. The timing discriminator outputs are used as the definitive start and stop signals are fed to a timing module.

Two styles of timing modules are in common use. One, called a time-to-amplitude converter (TAC), produces an output pulse whose height is proportional to the time difference between the start and stop signal. This is very convenient because the resulting linear pulse may be directly substituted for the amplified and shaped output of a surface-barrier detector. In a system of this type, the pulse from the TAC goes to a multichannel pulse-height analyzer that completes the analysis by producing a histogram of the number of pulses as a function of amplitude. This scheme may sound laboriously indirect, but it is capable of achieving resolutions of ≈50 ps when configured for medium-energy scattering and, until very recently, was clearly superior to directly counting ticks of a clock (Porat, 1973). The alternative time-to-digital converter (TDC) scheme in its purist form does, indeed, directly count the ticks of a clock between the start and stop signals. In this approach, the number of clock ticks is used as a pointer into a memory bank (a histogramming memory) and one count is recorded for each valid interval measurement. With countable clock frequencies now in the tens of gigahertz, producing correspondingly high resolution, this method is a practical alternative to time-to-amplitude conversion. However, it is worth noting that, at the time of this writing, commercial modules called TDCs are often, in reality, TACs and pulse analog-to-digital converters packaged as a unit.

Examples

Figures 7A–C show the result of measuring an SiO_2 thin film nominally 13.9 nm thick grown on crystalline Si by medium-energy backscattering using a beam of 270-keV He^+ ions. Figure 7A shows the raw time-of-flight spectrum as accumulated. In Figure 7B, this spectrum has been transformed to the energy domain using the procedure described below. Figure 7C contains the final version of this spectrum, which has been corrected for the efficiency of the spectrometer. These data were taken with the specimen oriented so that the beam is aligned with the ⟨110⟩ direction of the crystalline Si. This causes the number of counts from the bulk Si region to be suppressed, while Si and O counts from the amorphous SiO_2 layer are unaffected. An analysis of the oxygen peak reveals that the oxide is ~13.1 nm thick, in good agreement with the nominal thickness. The analysis of the Si peak is more complicated because it contains constituents from both the SiO_2 layer and the first few layers of the crystalline Si. This channeling surface peak is discussed by Feldman et al. (1982) and Swanson (1995).

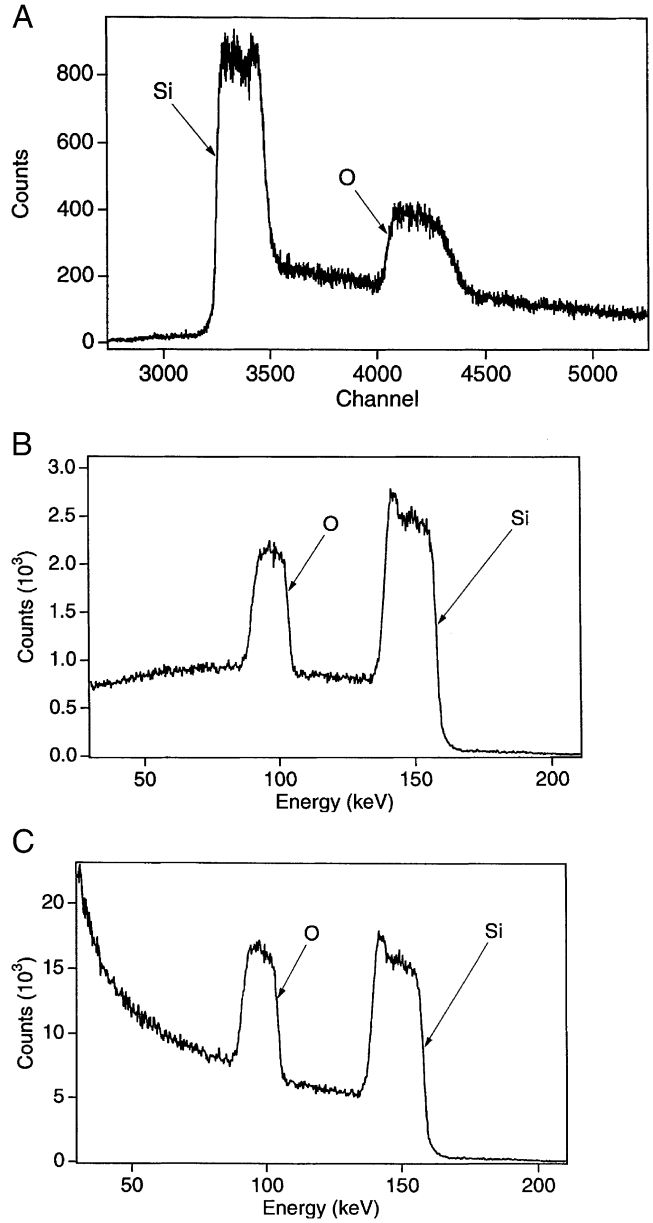

Figure 7. Time-of-flight medium-energy backscattering spectrum of a 13-nm SiO_2 film on Si. The ion beam was He^+ at 270 keV. The beam is channeled in the ⟨110⟩ direction of the Si substrate in order to accentuate the Si and O in the amorphous oxide layer. The scattering angle was 150°. (**A**) Raw data showing number of counts versus channel in the multichannel analyzer. Each channel has a width of 122 ps. (**B**) The data rendered in the energy domain using the transformation described in the text. (**C**) The energy spectrum corrected for spectrometer efficiency using the efficiency function plotted in Figure 6. Note in each case, but particularly in the energy spectra, that the channeling surface peak attributable to the first few atomic layers of Si in the substrate is clearly visible on the low-energy side of the Si spectral feature.

Figure 8 shows the result of measuring the surface of an Si wafer, as delivered by the vendor, for hydrocarbon

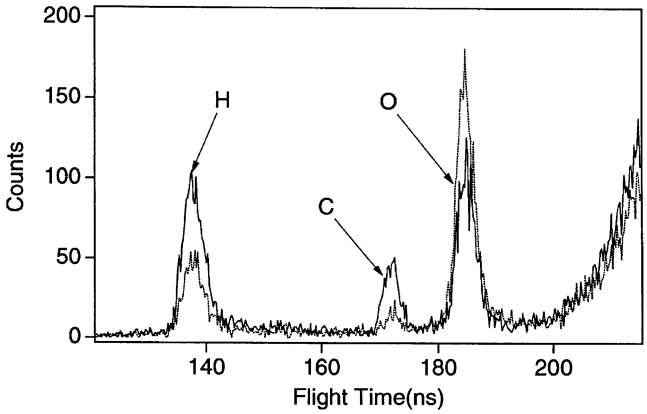

Figure 8. Time-of-flight forward-recoil spectrum of Si wafer showing surface H, C, and O before and after cleaning with ozone. The solid line is the spectrum of the as-delivered wafer. The spectrum shown as a dotted line was made after cleaning. The ozone exposure removed H and C but increased the thickness of the surface SiO_2 layer as indicated by the increased O signal. The ion beam was Ar^{3+} at 810 keV.

contamination using medium-energy forward-recoil spectrometry. The beam was 810 keV Ar^{3+}. The spectrum reveals three distinct peaks that are attributable to surface H, C, and O. While the hydrogen could have been measured by, for example, nuclear reaction analysis (Lanford, 1995; also see NUCLEAR REACTION ANALYSIS AND PROTON-INDUCED GAMMA RAY EMISSION), and the oxygen separately by backscattering, this measurement has revealed both in a way that makes it straightforward to determine the relative areal densities of the three constituents simultaneously.

Safety Considerations

Medium-energy backscattering spectrometry poses no special laboratory safety hazards. General safety considerations are the same as for most classes of surface analytical equipment. The most serious concern is shock hazard from any of several high-voltage sources that are needed to carry out the experiments. Ion beam irradiation by kilo-electron-volt ions is essentially nondestructive for most targets and produces no lingering effect to alter the intrinsic toxicity of a specimen. Particle accelerators used in the technique are often capable of producing x rays, especially when operated improperly, and must therefore be supported by appropriate radiation safety staff under the laws of the jurisdiction in which they are located.

A subtle safety issue in this regard is less well known. When a highly insulating material such as silica is irradiated with kilo-electron-volt ions, the surface can become charged to many tens of kilovolts. Eventually, the surface will break down electrically and a significant spark will occur in the vacuum chamber. These sparks are easily capable of producing measurable pulses of x rays that may sometimes even be observed outside the vacuum system, especially through windows. Although it is quite unlikely that this source would ever generate enough x rays to be an issue for personal safety, it could affect the results of radiation surveys and might also impact the need for shielding or placement of the target chamber in the laboratory.

METHOD AUTOMATION

In principle, the acquisition of backscattering spectra may be highly automated. A full range of NIM and CAMAC modular electronics is available commercially, and multichannel pulse-height analysis is now usually done by computer (Weller, 1995b). Specialized equipment, such as goniometers for channeling studies, may easily be synchronized with data collection under computer control. However, medium-energy backscattering is still a specialized technique, and production-scale systems are not available as they are for conventional mega-electron-volt Rutherford backscattering.

The analysis of backscattering data is, in general, not highly automated, at least not in the sense of, for example, gamma ray spectroscopy, where peak search-and-fit algorithms have been developed that are capable of nearly independently extracting the identity and intensity of all the gamma rays in a spectrum. Although algorithms have existed for many years to assist in the reduction of backscattering data (Doolittle, 1984, 1985, 1990) and new methods continue to be explored that further reduce the need for operator intervention (Barradas et al., 1997), human judgment still plays a role in most ion scattering data analysis. These principles are discussed next (see Data Analysis and Interpretation), along with considerations that are specific to the handling of medium-energy ion scattering data.

DATA ANALYSIS AND INTERPRETATION

Backscattering Data

The steps for analyzing time-of-flight medium-energy backscattering data are, in order, to convert the spectrum from the time to the energy domain, to apply a correction for the efficiency of the spectrometer as a function of energy, and finally to extract information on elemental concentrations and depth profiles using techniques identical to those used for high-energy Rutherford backscattering spectra. In the final stage, it is essential to use cross-sections and stopping powers that are appropriate for the energy range.

The process of converting a time-of-flight spectrum to an equivalent representation in the energy domain is often called rebinning, since it represents a sorting of collected counts from equal-width time bins to equal-width energy bins. Both time-of-flight and energy spectra are essentially differential quantities, since they are histograms of the number of events whose defining parameter, time or energy, falls within a given narrow range defined by a single channel. Thus, to convert from a time-domain spectrum $P_t(t)$ to an equivalent energy-domain spectrum $P_E(E)$ requires use of the fundamental relationship

$$P_E(E) = P_t(t(E))\left|\frac{dt(E)}{dE}\right| \tag{9}$$

where t is the flight time that corresponds with backscattered energy E, and the parameters are related through the mass M_1 of the backscattered particle and the drift length d of the spectrometer by

$$E = \frac{1}{2} M_1 \left(\frac{d}{t}\right)^2 \tag{10}$$

Although Equation 9 can be used directly in order to perform the conversion, it is not the preferred method. A more direct procedure is to use the integral form of this equation:

$$\int_0^E P_E(E')dE' = \int_{t(T)}^{\infty} P_t(t')dt' \tag{11}$$

To apply Equation 11, first it is necessary to create an integral time spectrum by iteratively summing adjacent channels of the time-of-flight spectrum from the longest flight time (rightmost, highest array index) to the shortest. This can be accomplished on an array in place. At the $N-1$ channel of an N-channel spectrum, the value of channel $N-1$ is added to the value of channel N and the sum is put in location $N-1$. This is repeated with N replaced by $N-1$ iteratively until N is zero. This is the integral time spectrum. To obtain an integral energy spectrum, an array is created and each location is filled with the value of the integral time spectrum at the time corresponding to the various equally spaced energies. It will, of course, rarely be the case that an energy and corresponding time value both fall exactly on channel boundaries in their respective spectra, so normally one must interpolate linearly between two values in the integral time spectrum to obtain the energy value. After the integral energy spectrum has been created, the process must be inverted by subtracting adjacent channels to recover a differential energy spectrum. This too can be done on an array in place. This conversion from a time to an energy spectrum has the virtue that it very accurately preserves total numbers of counts through the transformation and is very economical to compute.

It is important to issue a caution at this point. It is generally assumed in the analysis of ion scattering data that the variance associated with each channel of a multichannel spectrum is the Poisson value, that is, that the variance equals the number of counts and *the uncertainties of adjacent channels are uncorrelated*. This is true in raw time-of-flight spectra but may not be true in the corresponding rebinned energy spectra. The problem lies with the widths of the channels. For proper statistics, the width of time channels must be less than the time-equivalent width of the highest-energy channel in the energy spectrum. If this condition fails, then it is clear from the above description of rebinning that, in the high-energy region of the spectrum, channel values will be created by extracting two or more energy values by interpolation between the same two points in the integral time spectrum. This introduces strong correlation into adjacent channel values and changes the statistical character of the data. It is good practice to choose the width of time bins so that, even at the highest energies of interest, each energy bin corresponds to two or more time bins. In this way, the statistics of rebinned time-of-flight spectra will be practically equivalent to those of energy spectra that have been measured directly by an energy-dispersive spectrometer.

After time-of-flight spectra have been rebinned to the energy domain, they should be corrected for spectrometer efficiency as described above (see Practical Aspects of the Method, Spectrometer Efficiency). This consists of a straightforward channel-by-channel multiplication of the energy spectrum by a value appropriate to the ion and energy. It is important to emphasize again that this correction is completely independent of the specimen and only a function of spectrometer characteristics. As such, it does not introduce sample-to-sample variation. It does, however, change the statistics of the spectrum, since in any given channel statistical uncertainly is based upon the actual number of measured counts and not the corrected number of counts. Strictly speaking, one should also include at this point an estimate of error produced by the correction itself. With careful measurements, however, this can be made quite small. Also, the efficiency correction produces its greatest effect in the lower-energy portion of the spectrum, where its impact on the appearance of a spectrum is large but where there are seldom features of quantitative interest.

After rebinning and efficiency correction, time-of-flight spectra, along with their associated arrays of variances, may be treated with the tools and techniques that have been developed for elastic scattering spectrometry with energy-dispersive spectrometers (ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS).

Forward-Recoil Data

The rebinning process described above is of limited usefulness for one-dimensional forward-recoil data. Since forward-recoil spectra contain events attributable to different species, it is only possible to do rebinning of a one-dimensional spectrum sensibly in a spectral region known to contain only one species of ion, such as hydrogen or carbon. Furthermore, in forward recoil, time is the proper distinguishing characteristic, the one with the greatest power of differentiation of species. Thus, with the exception of near-surface hydrogen profiling, one-dimensional forward-recoil spectra should be used directly to infer properties of the specimen.

The mass of surface constituents can be identified by their energy E_2, computed using Equation 10, along with the recoil kinematic factor K_R:

$$E_2 = K_R \cdot E_0 = \frac{4M_1M_2}{(M_1+M_2)^2}\cos^2(\phi) \tag{12}$$

where ϕ is the angle of the recoil measured with respect to the initial beam direction. Absolute concentrations of low-atomic-mass surface constituents can be computed directly using Equation 2 along with spectrometer efficiencies, the peak areas (total counts), and the forward-recoil cross-section σ_r, given here in terms of the center-of-mass scattering angle $\theta_c = \pi - 2\phi$ and center-of-mass cross-section

$\sigma_c(\theta_c)$ by a standard kinematic transformation (e.g., Weller, 1995b):

$$\sigma_r(\phi) = 4\sigma_c[\theta_c(\phi)]\cos(\phi) = 4\sigma_c(\pi - 2\phi)\cos(\phi) \qquad (13)$$

Most previous research on forward-recoil spectrometry has used high-energy ions and surface-barrier detectors in conjunction with range foils. These are self-supporting thin films placed between the specimen and the detector to act as filters to the passage of certain ions. Procedures have been developed to analyze these data (Barbour and Doyle, 1995) but are of limited applicability for medium-energy time-of-flight work.

The most advanced technology for forward-recoil spectrometry combines time-of-flight with energy spectrometry in an experiment in which both parameters are measured for each event (Tirira et al., 1996). This gives rise to two-dimensional histograms with distinct spectral features that correspond to specific elements. This method works best for heavy ions with energies of many (often tens of) mega-electron-volts, and as a result, application of this method has been limited to a relatively small number of laboratories. Multiparameter forward-recoil spectrometry at medium energies has not been well studied.

PROBLEMS

The definitive enumeration of the myriad of ways that ion scattering measurements can go astray has been compiled by Davies et al. (1995) and should be read by all serious students and practitioners of the field. Issues important for medium-energy time-of-flight work are emphasized here.

For quantitative measurements, it is essential to be able to integrate the beam charge accurately, since it is the measure of the total number of incident ions (Equation 2). This is done with a specially designed charge-collection structure known as a Faraday cup (England, 1974; Davies et al., 1995). Nature confounds the casual designer of a Faraday cup with a dizzying array of processes that complicate what would seem to be a straightforward measurement task. Currents used in time-of-flight medium-energy ion beam analysis range from a maximum of a few tens of nanoamperes, when analyzing for trace elements on a low-atomic-mass substrate, to <1 nA for forward-recoil measurements of hydrogen. Making a 1% measurement in the latter case could be compromised by a mere millivolt of stray voltage (or instrumental offset) across a resistance of 100 MΩ. More likely to cause trouble, however, are processes intrinsic to ion beam experiments such as secondary electron emission at the target or ion beam neutralization through charge exchange with the residual vacuum. With a good design and careful attention to detail (Davies et al., 1995), charge integration at the level of 5% should be easily achieved.

With good charge integration, the efficiency of the time-of-flight spectrometer can be measured. The simplest approach is to obtain a target with a known areal density of a heavy trace element such as gold at the surface and to measure this target with different incident beam energies so that the range of backscattered energies covers the range of interest in general measurements. The effectiveness of this approach is dependent upon the accuracy of beam-current integration. The quality of the measurement can be improved by using a target with two isolated peaks that are well separated in energy. The beam energy is then raised or lowered in such a way that, through successive runs, the low-energy peak moves to the position formerly occupied by the high-energy peak, or the reverse. This maintains an internal check of charge integration and provides data to normalize from run to run. In this way, a curve of spectrometer efficiency as a function of energy can be produced from the calculated cross-section and reliably interpolated between measured points, using either a semiempirical model (Weller et al., 1994) or convenient analytic functions of energy. Since spectrometer efficiency must be measured for every ion to achieve the highest-accuracy results, it is sufficient to use the approximate screened cross-section given by Equation 4.

At medium energies, the critical angles for channeling in crystalline targets are very large (Swanson, 1995). This can be of very great help in suppressing background counts so that, for example, the oxygen content of a thin oxide on Si can be measured more accurately (Fig. 7C). However, accidental channeling can distort a spectrum and create a misleading impression about the structure of the sample. It is good practice to make critical measurements at several angles in order to be able to check for this kind of distortion. It is even better to continuously rotate the sample during a measurement to approximate the appearance of an amorphous target.

Another effect that varies strongly with target orientation is loss of resolution due to surface roughness. Ion scattering measurements at all energies work best on planar targets. Moreover, depth resolution can be enhanced by tilting the target so that ion trajectories, and consequently energy loss, are maximized in layers of interest. Detailed studies by Williams and Möller (1978) suggest that for 2-MeV ions the best depth resolution can be obtained using grazing incidence and exit angles of 5° to 10°. However, at these extreme angles, even minor surface imperfections can produce large variations in the cumulative energy loss of ions on different trajectories. For this reason, discretion should be exercised when using target angle to enhance resolution, and under normal circumstances, trajectories closer than <15° to the plane of the target should be used with considerable caution. It is possible to obtain ~2-nm resolution using conventional RBS with grazing exit-angle geometry provided the target surface is (atomically) smooth. Similar resolution can be obtained using medium-energy backscattering without the need for grazing exit angles.

Finally, it is important to keep in mind that the beam that is striking the target may not be what it is thought to be. This is because most accelerators use magnets to select a specific beam from the many that are produced by the ion source. The relevant parameter, known as magnetic rigidity, is $(2M \cdot E/q^2)^{1/2}$, where M, E, and q are, respectively, the mass, energy, and charge of the ions in the beam. In medium-energy accelerators, E is almost

always equal to $q \cdot V$, where V is the accelerating voltage, so that any time two ions have the same M/q, they cannot be distinguished. The most important case for medium-energy backscattering is that of He^{2+} and H_2^+. The omnipresence of the hydrogen molecular ion makes the use of doubly charged helium, to obtain higher energies, a dangerous proposition. This mass interference taken together with the difficulty of producing He^{2+} in the first place argues strongly against the use of this ion for routine analytical work.

ACKNOWLEDGMENTS

The author would like to thank Kyle McDonald and Len C. Feldman for helpful comments during the preparation of this unit. The primary support for the development of time-of-flight medium-energy ion beam analysis has been provided by the U.S. Army Research Office under contracts DAAL 03-92-G-0037, DAAH 04-94-G-0148, and DAAH 04-95-1-0565.

HEAVY-ION BACKSCATTERING SPECTROMETRY

INTRODUCTION

Heavy-ion backscattering spectrometry (HIBS) is a new technique for nondestructively analyzing ultratrace levels of impurities on the surface of very pure substrates. Although any high-Z contaminant ($Z \geq 18$) on a pure low-Z substrate can be measured, recent practical applications for HIBS have focused on measuring contaminants found on silicon wafers used in semiconductor manufacturing. Therefore, discussions of HIBS will focus in this area. The technique is based on the same principles described elsewhere (see ELASTIC ION SCATTERING FOR COMPOSITION ANALYSIS and MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY) for high-energy Rutherford backscattering spectrometry (RBS) and medium-energy ion backscattering spectrometry. The approach was invented and patented at Sandia National Laboratories and led to the construction of a HIBS User Facility, built in collaboration with SEMATECH member companies and Vanderbilt University. The facility was opened in June 1995 for use by U.S. industry, national laboratories, and universities in conducting contamination studies and is located at Sandia.

The motivation for HIBS is to detect metallic contamination at levels significantly below those that can be detected by RBS or medium-energy ion backscattering, both of which have a limit of $\sim 1 \times 10^{13}$ atoms/cm^2 for near-surface impurities. By the year 2001, as reported in the National Technology Roadmap for Semiconductors

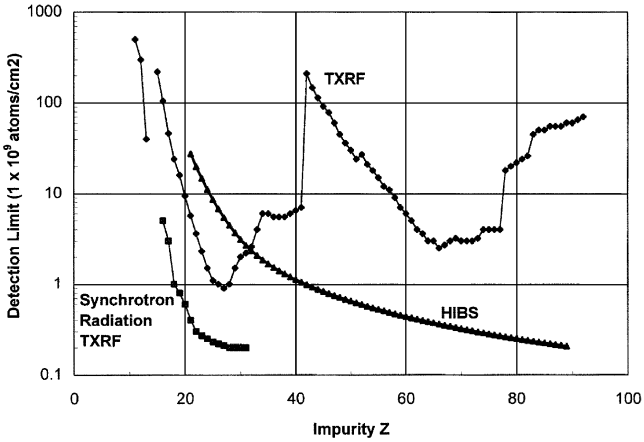

Figure 1. HIBS vs. total-reflection x-ray fluorescence (TXRF) detection limits on pure silicon. TXRF limits are shown using traditional x-ray and newer synchrotron radiation sources.

(Semiconductor Industry Association, 1997), contamination control in the microelectronics industry will require tools that can measure $\sim 1 \times 10^{10}$ atoms/cm^2 for transition metals in starting material. A sensitivity curve, shown in Figure 1, demonstrates how HIBS meets this requirement on silicon. The detection limit for well-separated elements on a clean Si surface ranges from $\sim 6 \times 10^9$ atoms/cm^2 for Fe to $\sim 3 \times 10^8$ atoms/cm^2 for Au, without the use of vapor phase decomposition (VPD) to preconcentrate the impurities. Using VPD would improve the sensitivity by at least an order of magnitude.

The HIBS technique can be illustrated by following the ion trajectory shown in Figure 2. An 120-keV C^+ ion beam is typically used, with the beam focused onto an $\sim$3-mm^2 spot at the sample surface. The relatively large beam spot size, which reduces sputtering and sample heating, allows the use of a higher beam current ($\sim$20 nA). Ion beam effects such as sputtering, sample heating, and ion beam enhanced diffusion are discussed later. It should be noted that sputtering, although limiting the ultimate sensitivity of HIBS, is not as serious a limitation as once thought (Pedersen et al., 1996). Carbon ions backscattered from the sample are collected by a time-of-flight detector array having a large solid angle maximized for high sensitivity. The screening foil in each detector has a thickness chosen to filter out carbon ions scattered from the substrate but to pass ions scattered from heavier atoms, such as impurities on the surface. Measuring the yield versus flight time of the backscattered carbon ions allows both the mass and areal density of the near-surface impurities to be determined from basic physical backscattering concepts.

Other surface analysis techniques for detection of trace element contamination are briefly discussed next, with the strengths and weaknesses of each compared to those of HIBS. A detailed discussion of the basic theoretical and practical aspects of HIBS will then be provided.

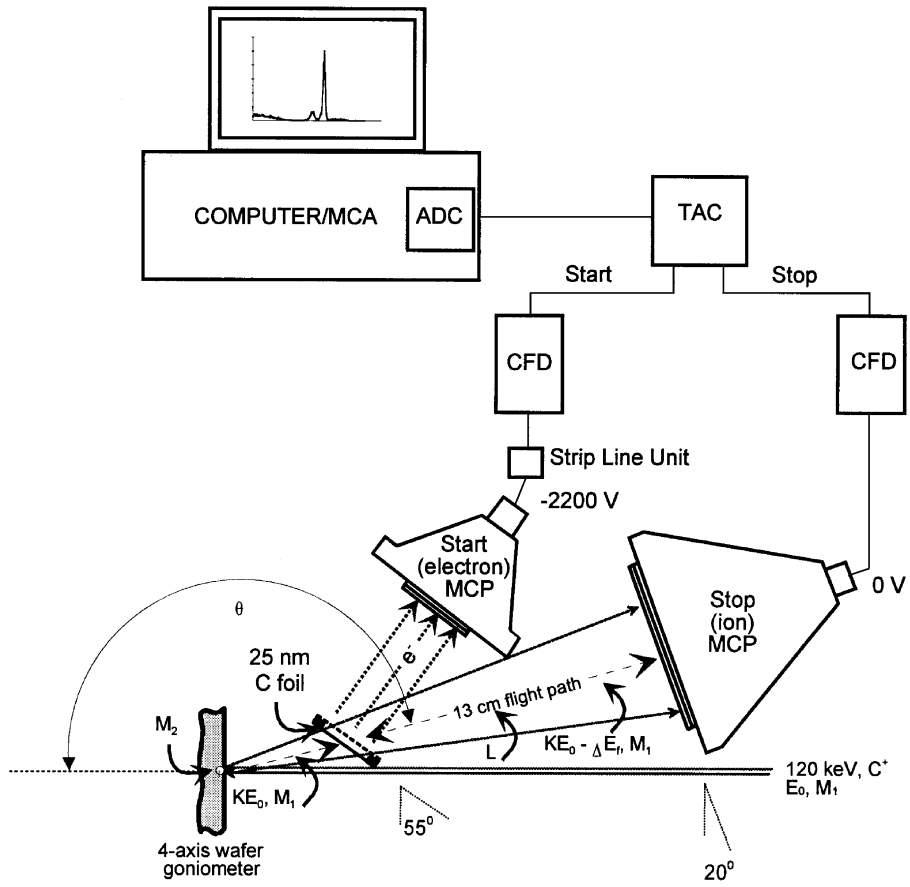

Figure 2. Typical HIBS time-of-flight detector with associated data acquisition instrumentation. Backscattering kinematics are also illustrated.

Competitive, Complementary, and Alternative Techniques

A number of other techniques for trace element analysis are available, with total-reflection x-ray fluorescence (TXRF) and secondary-ion mass spectroscopy (SIMS) being the most widely used. All the techniques differ from HIBS in one very important aspect: they require standard samples for quantitative analysis. Since HIBS is a standardless measurement, one of its primary applications is to calibrate standard samples for use by the other analysis techniques. Another difference is that all but TXRF are destructive; that is, the sample may not be reused or subjected to an alternative analysis in the same area. The HIBS technique is nondestructive for further wafer analysis, but the wafer cannot be returned to production without further processing.

Total-reflection x-ray fluorescence using traditional x-ray sources is both a competitive and a complementary technique. Recently, a version of TXRF using synchrotron radiation has been introduced with the potential for higher sensitivity to many elements than can be achieved with any other method. Neither HIBS nor TXRF require sample preparation, and both provide spatial information about the impurities on the test sample. For an accurate measurement, TXRF requires an optically flat surface, such as the front side of a wafer, whereas HIBS can also measure rough surfaces, such as the backside of a wafer. Typically, TXRF is used to measure only the transition metals, with an anode change required to measure high-Z metals, while HIBS surveys all elements with $Z \geq 18$ in a single experiment. As shown in Figure 1, TXRF has relatively poor sensitivity for high-Z metallic contamination ($Z > 30$), so HIBS complements TXRF for measuring high-Z contamination. On the other hand, TXRF, using traditional x-ray sources, has better mass resolution than HIBS and is used extensively by the semiconductor industry, being the tool of choice when measuring production wafers. Mass resolution in HIBS ranges from ~2 amu for Fe to ~20 amu for Pb, but its survey capability and accuracy make it an excellent tool for precise quantification of known contaminants. The analysis depth for TXRF is ~5 nm on an unpatterned bare silicon wafer or SiO_2, whereas HIBS measures contamination in samples to a depth of ~10 nm. Even when measuring the same wafer for the concentration of contaminants, TXRF instruments may report widely varying areal densities. Because of its high accuracy and standardless configuration, HIBS has been used to nondestructively verify the areal density of contamination on TXRF standards and calibrate TXRF tools (Werho et al., 1997; Banks et al., 1998). High concentrations of one element can cause interference in detecting other elements, for both TXRF and HIBS. The TXRF instruments have been highly developed, providing automated wafer exchange, data acquisition, and analysis. The HIBS system at Sandia is partially automated, but it requires up to 90 min per point when analyzing for $\sim 1 \times 10^9$ atoms/cm^2 levels, while TXRF measurements take ~15 min per point for the same level.

Secondary-ion mass spectrometry has been used for many years and is a valuable tool for many problems. Based on the sputter erosion of the surface being analyzed, SIMS is inherently a depth profiling technique with good bulk sensitivity (<1 ppm). However, its sensitivity to a thin surface contaminant is not as good as other techniques and its sensitivity to various elements can vary by orders of magnitude in the same substrate. Even the sensitivity for a single element varies with different substrates.

Destructive alternative techniques such as inductively coupled plasma mass spectroscopy (ICP-MS), graphite furnace atomic absorption mass spectroscopy (GFAA-MS), glow discharge mass spectroscopy (GD-MS), and a variation of TXRF called microsample x-ray analysis (MXA) are used to measure contamination, mostly in liquids, to the ppt level. They can be used, indirectly, to measure surface contamination by concentrating the elements through dissolution of the sample surface using VPD. The VPD technique exposes the surface of a wafer to an acidic HF vapor for a set time, and then the etched products are collected by a droplet of ultraclean deionized water rolled around the surface. Finally, the liquid droplet is analyzed by one of the above techniques. The droplet can also be placed on a separate clean low-Z film and allowed to dry for x-ray analysis (or HIBS). Collection efficiencies between 95% and 99% have been reported using the VPD process, except for Cu, for which it is ~20%. There is some concern about the use of this technique as wafer sizes increase. All the techniques using VPD are labor intensive; however, automated VPD equipment has recently been introduced and could increase throughput. The availability of these techniques and their exceptional sensitivity, ranging to 1×10^8 atoms/cm^2, make them competitive.

PRINCIPLES OF THE METHOD

The four principles of traditional RBS on which HIBS is based (see MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY) are (1) the kinematic factor K, which describes the energy transfer between a projectile and target nucleus in an elastic collision; (2) the scattering cross-section σ, defined as the probability of a scattering event occurring; (3) the stopping cross-section ε, which determines the energy loss of a projectile as it undergoes interactions with target nuclei and electrons; and (4) the energy straggling Ω_{Bohr}, i.e., a statistical fluctuation in the energy loss of a projectile.

The yield equation $Y = Q\sigma N t \Omega_D \eta$ gives the yield of backscattered particles as a function of the number of ions (Q) hitting the target layer, the atomic density (N) and thickness (t) of the layer, and the probability (σ) of the projectile ions being backscattered from the layer into a detector with a finite solid angle (Ω_{D}) and detection efficiency (η).

It follows from the yield equation that if the factors Q, σ, Ω_{D}, and η are increased, then the corresponding yield increase allows for the detection of increasingly lower areal densities, where the areal density is the product of the target atomic density and thickness, Nt, normally expressed in atoms per square centimeter. Detection of increasingly lower areal densities is commonly referred to as increasing the sensitivity.

Although HIBS is based on the same fundamental concepts as RBS and medium-energy ion backscattering, the emphasis is placed on maximizing sensitivity to trace elements on the surface of a lower Z substrate. This increased sensitivity is accomplished in two ways. First, since the backscattering cross-section (σ) scales as Z^2/E^2, where Z and E are the atomic number and energy of the analysis beam, the HIBS scattering yield from all elements is dramatically increased by using a high-Z analysis beam with a relatively low energy, such as C^+ at 120 keV.

Of course, this increase in yield also increases the backscattering from the substrate, so a means of eliminating the ions scattered from substrate atoms is needed. This is accomplished by the second, key aspect of the technique: a screening foil incorporated in the design of the time-of-flight detectors eliminates essentially all ions backscattered from the substrate while still allowing those backscattered from heavy impurities on the surface to be detected. The foil is already required in the time-of-flight detector for producing a start pulse for the timing. By making the foil somewhat thicker than required, only ions backscattered with energies above a given threshold are passed through the foil to the second part of the detector, thus eliminating most of the ions backscattered from the substrate (such as silicon), which would otherwise comprise an overwhelmingly large background in the spectrum. It should be noted that simply using electronic discrimination of this background cannot be used because the microchannel plates would have to process the recoiled ions from substrate atoms, saturating the detectors.

Some ions scattered from the substrate will still be passed through the foil because of straggling in the foil and multiple small-angle scattering in the substrate, so further improvements can be made by use of ion channeling. When allowed by the sample configuration, aligning the analyzing ion beam with the crystalline channels in the substrate will further reduce the residual background from the substrate, helping to increase sensitivity.

Further improvements in sensitivity are obtained in HIBS by using multiple time-of-flight detectors, each with a large solid angle (Ω_D), and a relatively large ($\sim$3-mm^2) beam spot. The large beam allows higher beam current and longer counting time, increasing the number of projectile ions (Q) while minimizing sputter erosion of the sample. Although the efficiency of each time-of-flight detector is lower than that of the surface barrier detector (SBD) commonly used in RBS measurements, the gain in mass resolution offsets the lower efficiency. Another advantage of an ion beam analysis such as HIBS is that measurement of areal density of surface impurities on a target is largely insensitive to chemical bonding or electronic configuration in the target (Feldman and Mayer, 1986; Ziegler and Manoyan, 1988).

Depth information about the sample is contained in the energy loss of the projectile ion and can be extracted using the known stopping cross-section (ε), with straggling (Ω_{Bohr}) limiting the resolution of this depth information. The energy loss is due to two mechanisms: projectile interactions with electrons in the target, referred to as electronic stopping, and small angle scattering with target atoms, called nuclear stopping. Since HIBS uses a low-energy beam of carbon ions, depth information is limited to very near the surface, and thus the technique is generally not useful for depth profiling.

Basic Theory

The fundamentals of HIBS are based on the four basic physical concepts of traditional RBS, as previously noted and found in several excellent reference books (e.g., Chu et al., 1978; Feldman and Mayer, 1986; Tesmer et al., 1995). These references discuss RBS fundamentals using a He ion beam and an SBD to obtain a yield-versus-energy spectrum. Early HIBS experiments also used an SBD (Knapp et al., 1994a). However, limitations of the SBD, discussed later, caused its discontinued use. The HIBS technique now uses the carbon foil-based time-of-flight detection scheme, which is described in the literature (Chevarier et al., 1981; Mendenhall and Weller, 1989; Dobeli et al., 1991; Knapp et al., 1994b; Anz et al., 1995).

The four basic Rutherford backscattering physical concepts are kinematic factor, scattering cross-section, stopping cross-section, and straggling, with the information gained being that of mass identity, atomic composition, depth, and the limits to mass and depth resolution, respectively. Equations based on these concepts allow analysis of the raw HIBS backscattering data.

Referring to Figure 2, when a projectile ion with initial energy E_0 and mass M_1 undergoes a simple elastic collision with a stationary atom M_2 at the surface of the substrate, the backscatter energy E_1 at an angle θ in the laboratory frame of reference can be determined from the kinematic factor, defined as $K \equiv E_1/E_0$, where $M_2 > M_1$. Thus the backscatter energy is

$$E_1 = KE_0 = E_0\left[\frac{\{x\cos(\theta) + [1 - x^2\sin^2(\theta)]^{1/2}\}}{1+x}\right]^2 \quad (1)$$

where $x \equiv M_1/M_2$. Note that the backscattered particle energy E_1 is only dependent on the initial energy E_0, the ratio of the projectile and target masses, M_1/M_2, and the laboratory scattering angle θ. After backscattering, the particle energy can also be described by the product of its mass and velocity, $E_1 = \frac{1}{2}M_1V_1^2$, where the projectile velocity can be found from $V_1 = L/\tau$ by measuring the time τ to travel the fixed path length L the ion traverses in the detector. These basic equations allow a determination of the mass of the atom from which the ion was backscattered, which is the general principle on which the time-of-flight technique is based.

The carbon projectile loses energy when penetrating and exiting the target and when passing through the carbon foil. Carbon ions that are not immediately backscattered from surface contaminant atoms penetrate the surface of the target, lose a finite amount of energy, are backscattered, and then lose more energy on their exit path, with the total energy loss denoted as ΔE_s. Many of the ions, of course, are not backscattered and come to rest in the sample. (The probability of backscattering, or the scattering cross-section, will be discussed later.) The backscattered ions are collimated, to reduce stray ion

scattering, and then pass through the carbon foil, losing additional energy ΔE_f. Most energetic ions that pass through the carbon foil eject electrons that are accelerated into the start microchannel plate (MCP) and create a start timing pulse τ_0. As described earlier, the cumulative energy losses occur through electronic and nuclear stopping, with the losses used to advantage by stopping most projectile ions scattered from the substrate in the carbon foil, reducing unnecessary counts from these scattering events. However, due to straggling in the foil and multiple scattering in the substrate, the ions backscattered from silicon can never be eliminated completely.

Energy lost in a layer can be calculated from the stopping power of the material in the layer. This loss is given as $\Delta E_s = [\varepsilon]Nt$, where $[\varepsilon]$ is the stopping cross-section factor, N is the atomic density of the layer, and t is the thickness of the layer. The stopping cross-section is defined as $\varepsilon \equiv (1/N)(dE/dx)$, where dE/dx is the stopping power or change in energy per unit distance. The stopping cross-section typically has units expressed as eV/10^{15} atoms/cm^2. The stopping cross-section factor is given by the formula (Chu et al., 1978)

$$[\varepsilon] = \left[\frac{K}{\cos\theta_1}\varepsilon_{in} + \frac{1}{\cos\theta_2}\varepsilon_{out}\right] \tag{2}$$

where θ_1 and θ_2 are the angles that the projectile ion makes with respect to the surface normal as it enters and leaves the target and ε_{in} and ε_{out} are the stopping cross-sections along the inward and outward paths of the projectile ion, respectively. Although the low-energy carbon projectile ions lose a small amount of energy while penetrating and exiting the target, the loss is neglected in HIBS analyses because the surface energy loss KE_0 is approximately equal to the total loss ΔE_s.

The energy of the ions escaping the substrate or the carbon foil exhibits a statistical energy distribution referred to as straggling. This straggling limits both the energy (and therefore the time) and mass resolution of the system. Straggling is commonly described using Bohr's equation,

$$\Omega^2_{Bohr} = 4\pi Z_1^2 e^4 N Z_2 t \tag{3}$$

which shows that for a projectile ion with atomic number Z_1 passing through a layer with atomic density N, atomic number Z_2, and thickness t, the projectile ion energy straggling (Ω_{Bohr}) increases with the square root of the foil electron areal density, NZ_2t. Straggling exhibits a projectile ion velocity dependence, not shown in Bohr's equation, and therefore, modified versions of Bohr's theory are now used (Lindhard and Scharff, 1953; Bonderup and Hvelplund, 1971; Chu, 1976; and Besenbacher et al., 1980). It should be noted that no theory exists for slow heavy ions in a light matrix. Bohr's equation predicts a symmetrical Gaussian distribution of energy equal to $2.355\,\Omega_{Bohr}$ at full width at half-maximum (FWHM) due to projectile ion interactions with electrons in the foil. For most backscattering spectra, straggling appears as the integral of the Gaussian distribution and is described by a complementary error function. Empirically, this is seen as a slope in the backscattered energy edge for each target mass, with the energy distribution of $2.355\Omega_{Bohr}$ at FWHM corresponding to the 12% to 88% range of the slope.

After the ion traverses the start foil and produces the start timing signal, it continues its flight until being stopped by the ion MCP, where it produces a stop signal τ_{stop}. After signal processing, a time-to-amplitude converter is used to give a digital pulse, with a height proportional to the time difference between the start and stop timing signal, $\tau_{stop} - \tau_0$. These signals are binned in a multichannel analyzer, giving a yield-versus-time spectrum. The yield for the ith element, Y_i, is dependent on several factors, according to the equation

$$Y_i = \eta(KE_0 - \Delta E_f)Q(N_i t)\Omega_D \sigma_i(E_0, \theta) \tag{4}$$

where $\eta(KE_0 - \Delta E_f)$ is the efficiency of the detector at the energy of the projectile ion after passing through the foil, Q is the total number of projectiles hitting the target, N_i is the atomic density in atoms per cubic centimeter of the ith contaminant element, t is the thickness of the contaminant layer, Ω_D is the detector solid angle, and $\sigma_i(E_0, \theta)$ is the screened cross-section for the collision with the ith element. Determining the yield is complicated by the energy dependence of the detector efficiency and the reduction of the scattering cross-section due to electron screening as discussed in detail by elsewhere (see MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY). However, the yield can be determined with reasonable accuracy by a computer analysis algorithm, described later. The screened scattering cross-section (Anderson et al., 1980) is given in the equation

$$\sigma_i = \sigma_R\left(1 + \frac{0.04873\,Z_1 Z_2 (Z_1^{2/3} Z_2^{2/3})^{1/2}(1+x)}{E_0}\right)^{-1} \tag{5}$$

where E_0 is the initial projectile ion energy, Z_1 and Z_2 are the projectile and the ith target element atomic numbers, respectively, and $x \equiv M_1/M_2$. This value differs by only a few percent from the more precise Lenz-Jensen screened cross-section (see MEDIUM-ENERGY BACKSCATTERING AND FORWARD-RECOIL SPECTROMETRY). The Rutherford cross-section σ_R in the laboratory frame of reference is given (Darwin, 1914; Chu et al., 1978) as

$$\sigma_R(E_0, \theta) = \left(\frac{Z_1 Z_2 e^2}{2E_0}\right)^2 \left(\frac{\{\cos(\theta) + [1 - x^2\sin^2(\theta)]^{1/2}\}^2}{\sin^4(\theta)[1 - x^2\sin^2(\theta)]^{1/2}}\right) \tag{6}$$

where E_0, Z_1, Z_2, and x are described in Equation 5, θ is the laboratory angle through which the projectile ion is scattered, and e^2 is the square of the electron's charge, which may be expressed as 1.4398×10^{-10} keV·cm.

PRACTICAL ASPECTS OF THE METHOD

The first HIBS experiments used an SBD. However, limitations of the SBD (e.g., low count rate leading to pulse

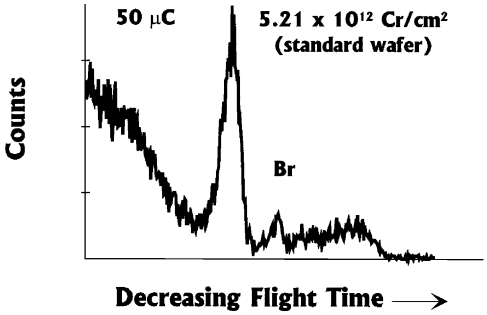

Figure 3. An important use of HIBS is to calibrate other trace element analysis tools. The HIBS measurements on Cr (above), Fe, and Ni contamination standard wafers were used to calibrate TXRF instruments at Motorola.

pileup, degraded energy resolution due to electronic noise, and radiation damage from high-Z ions) warranted changing to a time-of-flight detection scheme using a carbon foil. Since the time-of-flight HIBS detectors give a yield-versus-flight-time spectrum, it looks similar to one acquired by RBS, with spectra showing increasing mass numbers to the right (this assumes that flight time is shown decreasing to the right). Typical spectra can be seen in Figure 3 and Figure 4. Portions of the spectra in Figure 4 show the physical phenomena that limit the mass resolution and sensitivity of the time-of-flight technique.

Time-of-Flight Spectrometer

A schematic of the time-of-flight spectrometer used in HIBS is shown in Figure 2 and consists of a collimator, a thin carbon foil (~25 nm) placed in the path of the backscattered carbon projectiles, an electron accelerating grid, and two MCPs. Secondary electrons are produced when the projectile passes through the foil, with the number ejected based on statistics. These electrons are then accelerated by the grid into the first MCP to provide a start timing pulse. As discussed previously, the foil also serves as a filter to eliminate most of the carbon ions scattered from the substrate, suppressing the substrate background. Carbon ions that pass through the foil continue their flight until being stopped by the second MCP, where they produce a stop timing pulse.

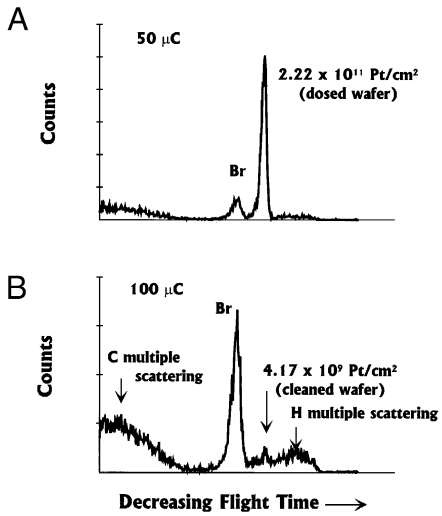

Figure 4. Another important use of HIBS is for contamination-free semiconductor manufacturing research. Texas Instruments used HIBS analyses to determine the dose of Pt contaminant on a wafer (**A**) and to show the efficacy of a HNO_3:HF (95:5) mix to clean the wafer (**B**). Scales for (**A**) and (**B**) are identical. Spectra background (**B**) is due to multiple scattering of the C analysis beam in the Si substrate and H recoiled from the wafer's surface.

Sensitivity and Mass Resolution

A number of factors influence the detection limits and mass resolution that can be achieved with HIBS: detector efficiency, choice of beam species and energy, sputtering, and background due to multiple scattering and random coincidences (Knapp et al., 1996). The detection limits can be reduced in a number of ways: increasing the solid angle by using multiple detectors, using a larger beam spot, channeling the incident beam along a crystal axis of the substrate, and matching the choice of beam to the screening foil thickness. All of these were incorporated in the design of the HIBS system at Sandia. Of course, sputtering of the sample surface by the analysis beam is the ultimate limit to the statistics that can be obtained, and hence the sensitivity. Beam effects due to sample heating are considered negligible. Sputtering and ion beam–enhanced diffusion can be potential problems when measuring surface contaminants in a metal-silicon system because erosion and diffusion can cause a decrease in the backscattering signal. If it is suspected that sputtering or beam-enhanced diffusion might be a problem, the areal density as a function of beam flux can be measured to determine if the problem exists and, if it does, extract the starting areal density. A study using a large N^+ ion flux to measure metallic surface contaminants (Fe, Cu, Mo, W, and Au on silicon) showed that sputtering is not a significant limitation to the sensitivity of HIBS for these elements and that diffusion was limited to <10 nm (Pedersen et al., 1996).

We define the detection limit as $DL = 2 \times (\text{background})^{0.5} \times (\text{calibrationfactor})$ where the background is taken under the full width of the peak for the element of interest. A number of alternative definitions could be used, and many are discussed by Currie (1960). Heavy-ion backscattering spectrometry cannot be considered to have a "well-known blank" (a sample with no contaminants, to be measured as a background), since we have found that no Si wafer is completely free of heavy-element contamination at levels HIBS can detect. However, since the peaks due to contaminants in a spectrum are generally surrounded on each side by wide regions of well-defined background, the background under the peaks can be fit fairly well and its standard deviation reduced to a low level. In this case, the criteria of Currie (1960) would be $DL = 1.64 \times (\text{background})^{0.5} \times (\text{calibrationfactor})$, or 18% lower than our definition.

The efficiency of the MCPs for detecting electrons, ions, and neutral particles in the sub-100-keV energy range is not well known, nor is the electron-producing efficiency of the carbon screening foil. The MCPs also have a count

rate limitation that may in turn limit the amount of beam current that can be used. Straggling in the foil is also an important effect, dominating the observed time resolution and limiting the mass resolution that can be achieved, through broadening of the peak widths. The mass resolution of the Sandia HIBS system, with its present 5-$\mu g/cm^2$ carbon foil, is about 1 amu for Ti-V, 3 amu for Cu-Zn, and 18 to 20 amu for the heaviest elements. That is, for elements near Cu, two peaks of equal magnitude can be separated if the masses of the two elements differ by 3 amu or more.

Scattering in the foil is also a serious consideration for the detector sensitivity, since it results in some ions exiting at angles that do not intercept the ion MCP, reducing the effective solid angle of the detector. This effect is stronger at lower energy, offsetting the gains in overall sensitivity that can be obtained by going to lower beam energy. The problem has been illustrated by TRIM (a code applied to the transport of ions in matter; Ziegler and Biersack, 1995) calculations of the distribution of trajectories of N particles passing through a foil at two different energies. The percentage of particles that remain in the acceptance angle of the ion MCP is much lower at low energy: the simulation shows 85% of the 160-keV particles reach the MCP, but only 22% do so at 40 keV.

The effect of foil scattering will vary with beam species and energy and of course will be different for different foil thicknesses. For a given foil, measurements of the detector efficiency will show that some ions are detected more efficiently than others, primarily because of the relative amounts of foil scattering, but also due to details of electron production efficiency and MCP detection efficiency. An analytical model of the efficiency of time-of-flight ion detectors of this general configuration has been developed elsewhere (Weller et al., 1994).

Background in the spectra is the major limit to the sensitivity that can be achieved. We have found that background can come from several sources: scattering of ions and electrons around the chamber, scattering from the substrate "leaking" through the foil, and beam contamination posing major problems. The first problem can be minimized by proper containment of the beam and shielding of the detectors from unwanted ions and electrons. The second problem is due not just to straggling in the foil but also to multiple scattering of the ion beam in the substrate: for a very low number of incoming ions, multiple scattering events can steer the ions back out of the substrate with higher than expected energy, making the particles indistinguishable from those scattered from heavy atoms on the surface. This low-level background cannot be eliminated, but it can be minimized by channeling of the analysis beam.

While using N^+ and O^+ ion beams for HIBS analysis, we also identified beam contamination by NH_2 and CH_2 and forward scattering of H as sources of background in the Sandia HIBS system, often at such low levels that they had remained unnoticed in an earlier HIBS system with less sensitivity. To minimize beam contamination problems, we settled on a C^+ beam for all high-sensitivity measurements. Using the Sandia HIBS system with three detectors and 25-nm foils, we have observed background levels implying detection limits to impurities on Si ranging monotonically from $\sim 6 \times 10^9$ atoms/cm^2 for Fe to $\sim 3 \times 10^8$ atoms/cm^2 for Au.

Instrumentation

Figre 2 shows a typical time-of-flight detector and associated instrumentation used for HIBS measurements. The detector and instruments are commercially available and consist of MCP assemblies for the start and stop MCPs, a strip line unit for the start MCP, constant fraction discriminators (CFDs), a time-to-amplitude converter (TAC), an analog-to-digital converter (ADC) board, and a multichannel analyzer (MCA). The start MCP uses a 20-mm-diameter chevron and the stop MCP uses a 40-mm-diameter chevron. Since HIBS uses three time-of-flight detectors to maximize the detector solid angle, three each of the units mentioned above are needed, with the exception of the CFDs and MCA. Two CFDs (with quad inputs) can be used to process all start and stop timing signals, and the MCA has the capability of processing data from all three detectors. The strip line unit is used to block the -2200-V output level of the electron MCP and allow the timing signal to pass while providing impedance matching to reduce signal reflections. A fast oscilloscope (bandwidth $\geq$ 400 MHz) is needed to monitor the timing pulse outputs from the MCP assemblies and to set up the CFDs.

A CFD that provides a zero-crossing timing pulse output for use by the TAC module gives better time resolution than the leading-edge type. A short coaxial cable, whose length is determined experimentally, must be used to set the zero-crossover point and adjust the CFD walk, which can be labor intensive. At least one manufacturer (Ortec) has recently offered a picosecond timing discriminator that does not require this cable but processes only one signal.

Recent advances in MCP assembly technology (Galileo) have resulted in low-profile versions being made available, with a tenfold height reduction, which could allow a more compact HIBS system to be designed. This new generation of MCPs has an extended dynamic range, a higher gain, a shorter output pulse width, and lower noise. These features could allow a higher count rate, greater efficiency, and better mass resolution. These low-profile MCPs also have integral resistor biasing of the plates and feature a quick-change module for replacement of the plates, reducing both installation and maintenance time.

A small 200-keV accelerator (Peabody Scientific, model PS-250) using a Duoplasmatron gas source is used to obtain the C^+ projectile ions measured by the HIBS instrumentation described above. However, implanters or other accelerators with good energy stability ($\sim$250 eV), a high-resolution mass analyzing magnet ($\leq$0.5 amu), and other features similar to the Peabody accelerator would also work well.

Examples

Measurements by two major semiconductor manufacturers, Motorola and Texas Instruments, serve as examples of using HIBS to solve integrated circuit manufacturing

problems. Motorola has used the HIBS facility to help solve problems in the calibration of TXRF instruments (Werho et al., 1997; Banks et al., 1998). The TXRF instruments are used for detecting trace levels of transition metals introduced by semiconductor processing procedures and equipment. These instruments are typically calibrated using the manufacturer's calibration data. This independent calibration has led to inaccuracies and a resulting lack of interchangeability in TXRF data. To illustrate the problem caused by independent calibration, the average error in measuring the same contamination standard wafers by different laboratory sites during a round robin conducted at Motorola showed errors in excess of 350%. To solve this problem, HIBS was used to nondestructively verify the areal density of a contaminant on commercially obtained contamination standard wafers used to calibrate these instruments. Figure 3 shows a typical spectrum taken on a Cr standard wafer. The HIBS values measured on this Cr-contaminated wafer, as well as other standard wafers contaminated with Fe and Ni, generally verified the vendor's value to within $\pm 10\%$. The HIBS data were then used to create a universal sensitivity factor curve for recalibration of the TXRF instruments used in the study. This recalibration generally reduced the error between TXRF instruments to $< \pm 10\%$. Using this universal method for calibrating TXRF instruments has led to improved quality control during integrated circuit (IC) manufacturing. The calibration method has international applicability, since the lack of interchangeability of data between TXRF instruments is a problem that has been reported worldwide (Hockett et al., 1992).

Texas Instruments has used HIBS technology to evaluate the handling and processing of new materials that can be used in the manufacture of ultralarge-scale integrated (ULSI) dynamic random-access memories (DRAMs). Texas Instruments used the HIBS facility at Sandia National Laboratories in the development of cleaning processes for the removal of high-Z metallic contamination (Banks et al., 1998). To decrease the size of capacitors used in ULSI DRAMs, Texas Instruments has been studying the use of a high-k dielectric (where k is the relative dielectric constant), barium-strontium-titanate (BST) between platinum electrodes (Pt/BST/Pt). Because of the concern over cross-contamination of wafers and processing tools with these materials, several questions needed to be answered, including how effective their present cleaning methods were at removing these heavy metals. To begin answering this question, wafers were uniformly dosed with the contaminants and the areal density was measured. The wafers were then subjected to various cleaning methods, the results of one of which is shown in Figure 4, and measured again. This comparison shows the efficacy of the cleaning process and demonstrates the excellent sensitivity of HIBS.

Safety Considerations

The two primary safety hazards associated with HIBS measurements are exposure to (1) high voltage and (2) x radiation. These hazards are mitigated through the use of stringent safeguards. A physical barrier must be set up around the accelerator with an appropriate door interlock used to disconnect power to the high-voltage supply in the event that high voltage is inadvertently left on when attempting to enter the accelerator enclosure. In addition, it is a good practice to use a radiation monitor interlocked with the high-voltage supply, shutting the supply off when radiation above acceptable limits is detected. Another feature that should be incorporated in the accelerator enclosure design is to provide an OSHA-approved grounding rod for discharging high voltages that might exist on various isolated accelerator components. The accelerator should always be grounded before conducting maintenance or repairs. Finally, easily accessible panic switches should be located both inside and outside an enclosure, providing for emergency shutdown of the accelerator. All applicable regulations of local, regional, and national authorities should be adhered to for installation and operation of the accelerator. General radiological guidelines for conducting ion beam measurements and a listing of regulating agencies can be found in Tesmer et al. (1995).

METHOD AUTOMATION

Sample positioning and data collection in HIBS can be semiautomated so that little operator intervention is needed during data acquisition, with the operator only needing to make minor adjustments of the ion accelerator parameters. In the HIBS system at Sandia, motor control hardware and software using the IEEE-488 protocol are used in conjunction with Microsoft Visual Basic® to control a four-axis sample goniometer. This control is needed so that a wafer (or sample) may be positioned at precise x and y coordinates and also allow channeling. The software automatically converts x and y coordinates (given in millimeters) into polar coordinates for translation by the stepping motors. To mimic the spot size of TXRF instruments, HIBS steps the beam spot ($\sim$3 mm^2) around in a $\sim$1-cm^2 pattern. This allows direct comparison of the areal density collected and reported by TXRF instruments to that of HIBS. This large pattern also further reduces the sputtering of contaminants being measured.

The raw time-of-flight data are collected by three ADC boards installed in a personal computer, with the three spectra being processed by a commercially available MCA software package (Oxford) that interfaces with the boards. Data are normally acquired until a preset amount of charge has been collected on a sample. An automated beam stop incorporated into the beam line blocks the beam after reaching a preset condition. With this minimal degree of automation, data collection can proceed while data are being analyzed.

DATA ANALYSIS AND INITIAL INTERPRETATION

The HIBS data analysis provides information about the identity and concentration of heavy-metal surface impurities on very pure substrates. Computer algorithms, derived from fundamental equations and discussed below,

are used to determine areal density and mass for a given peak in the time-of-flight spectrum. It should be noted that this spectrum is the sum of three separate but simultaneously acquired spectra from the HIBS detectors. Spectra manipulation, such as shifting and scaling prior to the analysis, is not discussed. However, this spectra manipulation and subsequent analysis have been semi-automated with software written in Microsoft Visual Basic®. Copies of the program, called HIBWIN© (Knapp, 1995), can be obtained by contacting the author at Sandia National Laboratories.

Areal Density

To find the areal density, Equation 4 can be used. To use this equation, however, the detector efficiency η, which is a function of the backscattered ion energy, must be determined empirically (Weller, 1993). For the HIBS system at Sandia, a standard target consisting of three elements, Fe, Ag, and Pt, evaporated onto a clean silicon substrate is used to determine η. The concentration of each element is approximately one monolayer so that standard RBS can be used to calibrate the standard. Using Equation 4, it follows that the areal density of an unknown element i can be found from

$$Y_i = \eta(KE_0 - \Delta E_f)Q(N_i t)\Omega_D \sigma_i(E_0, \theta) \tag{7}$$

and for a known standard,

$$Y_s = \eta(KE_0 - \Delta E_f)Q(N_s t)\Omega_D \sigma_s(E_0, \theta) \tag{8}$$

so that, solved simultaneously, the two equations give

$$N_i t = \frac{Y_i}{Q\sigma_i(E_0, \theta)} f \tag{9}$$

where f is the factor $1/(a + bE + cE^2)$. The coefficients of this second-order polynomial equation are determined from the known areal densities (from RBS measurements) and HIBS yields for Fe, Ag, and Pt measured on the standard by substituting them into the equation

$$N_n t = \frac{Y_n}{Q\sigma_n(E_0, \theta)}(a + bE_n + cE_n^2) \tag{10}$$

where $n = 1, 2, 3$ for Fe, Ag, and Pt, respectively. The values needed for the energy E_n of the carbon particle after scattering from the standard elements and passing through the range foil can be approximated from the equation (Doyle et al., 1989)

$$E_n = [KE_0^{(1-a)} - C_1]^{1/(1-a)} \tag{11}$$

where $n = 1, 2, 3$ and the terms K and E_0 have been described. The exponential terms $1 - a$ and $1/(1 - a)$ allow a fit of the E-versus-mass curve, and C_1 is an energy constant proportional to the thickness of the carbon foil. Once the unknown coefficients, exponential, and constant terms from Equations 10 and 11 are found, subsequent areal densities for other elements are easily determined.

Background and Sensitivity

From the previous discussion on HIBS sensitivity, it follows that the sensitivity is found by substituting $2\sqrt{\text{Bkg}}$ for the yield in Equation 9. The value of the background is found by performing a fit to the spectral background using the equation

$$y = de[-a(x - c_2)]^m + be[-a(x - c_1)]^m \tag{12}$$

The variable d is found from the average height of the spectral background in the high-velocity (fast-time) part of the spectrum and b from the average height in the slow-time portion of the spectrum. A best fit to the background is obtained in the software by the user inputting a value for m and setting four markers at strategic locations on the spectral background to define the variables d and b as well as the exponential terms involving c_1 and c_2.

Mass

When performing the areal density calibration, as discussed above, the flight times for a carbon ion backscattered from the standard masses Fe, Ag, and Pt can also be determined by using the beam energy E_n after passing through the foil, calculated from Equation 11 and using $V_n = (L/\tau_n)$. The velocity is found from

$$V_n = \left(\frac{2E_n(\text{keV})}{M_1(\text{amu})}k\right)^{1/2} \tag{13}$$

where E_n and M_1 were previously described and $k = 9.648 \times 10^{14}$ for units of centimeters per second, $L = 13$ cm, and n is 1, 2, 3 for Fe, Ag, and Pt, respectively. Knowing the time-to-amplitude converter time range, the number of channels in a spectrum, and the calculated flight times from the standard masses allows calibration of the time/channel. The peak channel position for each standard element is found by calculating the peak median (counts on either side of the peak are equal). The calibration is then used for subsequent time-to-mass conversions.

SAMPLE PREPARATION

The HIBS measurements require no sample preparation; however, special precautions should be taken to prevent any extraneous contamination. Unpacking and insertion of samples for HIBS analyses into the chamber loadlock should be done in at least a class 10 environment. The loadlock is required to prevent damaging the thin foils used by the HIBS detectors. A small footprint class 10 minienvironment is ideal for space-limited laboratories and only requires wearing clean room gloves and a laboratory coat. Samples or wafers should only be handled with low-Z tweezers or a wafer wand.

PROBLEMS

There are four main areas where the potential for misapplication or interpretive errors might occur when using the

HIBS technique. First, HIBS is an ultratrace element surface analytical technique, with the depth of analysis being ~10 nm. Use for analysis of samples with impurities extending well below the surface is difficult. Other techniques more suited for trace element depth profiling, such as SIMS, are discussed under Competitive, Complementary, and Alternative Techniques, above. Second, HIBS mass resolution is relatively poor and mass dependent, as compared to TXRF and other techniques, with HIBS mass resolution ranging from ~2 amu for Fe to ~20 amu for Pb. This can lead to interpretive errors, for example, in assigning a mass to a single high-Z peak or overlapping peaks that are close in mass, as discussed under Sensitivity and Mass Resolution, above. Also, as with other techniques, high concentrations of one element can interfere in the detection of other elements. Third, sputtering and ion beam-enhanced diffusion can be potential problems when measuring surface comtaminants in a metal-silicon system because erosion and diffusion can cause a decrease in the backscattering signal and reduced sensitivity. However, these effects do not appear to be a significant problem for the HIBS technique (Pedersen et al., 1996). If it is suspected that sputtering or beam-enhanced diffusion might be a problem, the areal density as a function of beam flux can be measured to determine if the problem exists and, if it does, extract the starting areal density. Fourth, background in the spectra is a major limit to the sensitivity that can be achieved with the HIBS technique, which ranges from $\sim 6 \times 10^9$ atoms/cm^2 for Fe to $\sim 3 \times 10^8$ atoms/cm^2 for Au when measured on very pure substrates. Careful design eliminates many factors contributing to this background, as discussed under Sensitivity and Mass Resolution, above. However, multiple scattering of the ion beam in the sample and forward scattering of H on the sample surface cannot be entirely eliminated. Multiple scattering is greatly reduced by channeling of the analysis beam, leaving H scattered by the ion beam into the detectors as a problem. This is discussed in more detail under Sensitivity and Mass Resolution and is shown in the spectrum of Figure 4B. The analysis software used for HIBS, discussed above (see Data Analysis and Initial Interpretation), was written to minimize errors introduced by background.

ACKNOWLEDGMENTS

The authors would like to thank B. L. Doyle for initiating the HIBS concept and providing technical oversight during the research and development phases of HIBS. Sandia National Laboratories is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the U.S. Department of Energy under contract no. DE-AC04-94AL85000.

NEUTRON TECHNIQUES

INTRODUCTION

This part and its supplements explore the wide range of applications of elastic and inelastic neutron scattering to the study of materials. Neutron scattering provides information complementary to several other techniques found in this volume. Perhaps most closely related are the x-ray scattering methods described in X-RAY TECHNIQUES. The utility of both x-ray and neutron scattering methods in investigations of atomic scale structure arises from the close match of the wavelength of these probes to typical interatomic distances (a few Angstroms). The differences between these two techniques bear some further discussion.

The absorption of neutrons by most elemental species is generally quite weak, while the x-ray absorption cross-sections, at typical energies (around 8 keV), are much larger. Therefore, neutron scattering measurements probe bulk properties of the system while x-rays generally sample only the first few microns of the bulk. The principal x-ray scattering interaction in materials involves the atomic electrons, so the scattering power for x rays is proportional to the electron density and, therefore, scales with the atomic number, Z, of elements in the sample. Neutron scattering lengths, on the other hand, do not exhibit any simple scaling relationship with Z and can vary significantly between neighboring elements in the periodic table. For this reason, neutron and x-ray diffraction measurements are often combined to provide elemental contrast in complicated systems.

The principal neutron scattering interactions involve both the nuclei of constituent elements and the magnetic moment of the outer electrons. Indeed, the cross-section for scattering from magnetic electrons is of the same order as scattering from the nuclei, so this technique is of great utility in studying magnetic structures of magnetic materials. Indeed, neutron scattering is generally the probe of choice for the determination of magnetic structure and microscopic investigations of magnetic properties of materials.

Finally, thermal neutron energies are typically on the order of a few meV to tens of meV, an energy scale that is comparable to many important elementary excitations in solids. Inelastic neutron scattering measures the gain or loss in energy of the scattered neutron as compared to the incident neutron energy. The energy loss or gain corresponds to energy transferred to or from the system in the form of excitations. Therefore inelastic neutron scattering has become a critical probe of elementary excitations including phonon and magnon dispersion in solids.

Facilities for neutron scattering are found at both nuclear reactors and, more recently, at accelerator-based spallation neutron sources. The steady flux at thermal energies at reactor sources is well-suited to instruments such as triple-axis spectrometers, which can probe elementary excitations at a particular point in reciprocal space. Spallation sources are, by design, best suited to time-of-flight studies of inelastic scattering because of the inherent time structure of the source.

NEUTRON POWDER DIFFRACTION

INTRODUCTION

Historical Aspects of the Method

The first powder diffraction studies on simple materials such as iron metal using x rays were done independently by Debye and Scherrer (1916) in Germany and by Hull (1917) in the United States. For a long time x-ray powder diffraction was primarily used for qualitative purposes such as phase identification and the assessment of crystallinity. The earliest structure determinations using only powder diffraction data was demonstrated when Zachariasen (1949) solved the structures of α- and β-UF_5 by an intuitive trial-and-error approach. An important subsequent step was taken when Zachariasen and Ellinger (1963) solved the monoclinic structure of β-plutonium using manual direct-method procedures (see X-RAY POWDER DIFFRACTION). The use of neutrons for such powder diffraction work has advanced significantly over the past 50 years.

The first neutron powder diffractometer was built at Argonne National Laboratory in 1945 (Zinn, 1947). The first generation of neutron powder diffractometers were subsequently built almost simultaneously by Wollan and Shull (1948) at Oakridge National Laboratory, Hurst and co-workers (1950) at Chalk River, Canada, and Bacon et al. (1950) at Harwell, England. They were the prototype of the so-called constant-wavelength angle-dispersive two-axis diffractometer whose basic features have not changed over the last 50 years. What has changed and is largely responsible for the rapid development of neutron powder diffraction was the increased flux of neutrons made available by the controlled fission processes of uranium. The highest neutron fluxes at a nuclear research reactor source can be found at the Institute Laue-Langevin (ILL) in Grenoble, France, with its 60-MW high-flux reactor (HFR). High-flux neutron sources allow the use of tighter neutron beam collimation and larger "take-off" angles, thereby increasing the resolution of diffraction experiments by reducing the line widths of Bragg reflections. Today, the required mechanical precision to move a massive detector bank is routinely somewhere between 0.01° and 0.02° in 2θ. The size and type of the detector also have undergone dramatic changes. Instead of the BF_3 counters used in the early days, today either position-sensitive detectors based on microstrip technology (Convert et al., 1997) or multicounter arrays typically with up to 64 individual ^3He counters are state-of-the-art. And last but not least, improvements in large,vertically focusing monochromators

with a reproducible aniso-tropic mosaic microstructure yielding well-defined spectral peak shapes have allowed the potential of high-resolution neutron powder diffraction to be fully developed (Axe et al., 1994).

Investigations of the magnetic susceptibility of materials such as MnO led to the concept of antiferromagnetism proposed by Néel (1932). The first experimental proof of this concept was provided by the powder neutron scattering experiments of Shull and Smart (1949). They demonstrated that, by cooling below the transition temperature, new Bragg diffraction peaks ("magnetic peaks") appeared that arise because the magnetic unit cell is twice the size of the "chemical" unit cell.

The seminal achievement of Rietveld in the late 1960s opened the door for refinements of neutron and x-ray powder diffraction patterns of complex structures with up to 50 atoms in the asymmetric unit cell (Rietveld, 1967, 1969). In the early 1970s Rietveld refinements were still performed predominantly to refine neutron powder diffraction data due to the simpler peak shape of the Bragg reflections. More complex peak shapes were developed subsequently for x-ray and especially synchrotron powder diffraction data. Since then, the attempt to solve more and more complex structures from powder diffraction data alone (*ab initio*) by using and adapting the tools developed for single-crystal crystallography was pursued by a steadily growing community of powder diffraction users. Today, structure solution and refinement are no longer the exclusive domain of single-crystal diffraction. The availability of highly collimated monochromatic neutron and x-ray beams, the development of the neutron time-of-flight powder diffraction technique used at neutron spallation sources, and the advances in instrumentation and computational methods make it possible to tackle the problems of *ab initio* structure determination in an almost routine and systematic manner (Cheetham, 1986; Cheetham and Wilkinson, 1992; see KINEMATIC DIFFRACTION OF X RAYS and DYNAMICAL DIFFRACTION). In fact, powder diffraction is the only tool capable of obtaining crystallographic information from samples such as catalytically active zeolites and low- and high-temperature phases where single crystals are simply not available. At the same time, information concerning the mesoscopic properties of materials such as texture, particle size, and stacking faults can also be obtained. The continuing efforts made in unraveling the structural details of superconducting oxides and the recently discovered oxides exhibiting colossal magnetoresistance have demonstrated the indisputable usefulness of high-resolution neutron powder diffraction. Modern powder diffraction using neutrons, x rays, and synchrotron x-ray radiation has developed from a qualitative method some 20 years ago to a quantitative method now used to detect new phases and determine their atomic, magnetic, and mesoscopic structure as well as their volume fractions if they are present in a mixture.

Neutron powder diffraction is a complementary technique to x-ray powder diffraction and electron diffraction. The greater penetration depth of neutrons, the fact that the neutron-nucleus interaction is a point scattering process implying no variation of the nuclear scattering length with scattering angle, the independence of the scattering cross-section from the number of electrons (Z) of an element, and therefore the stronger interaction of neutrons with "light" elements such as oxygen and hydrogen, and its isotope specificity as well as its interaction with unpaired electrons ("magnetic scattering") make neutrons a unique and indispensable probe for structural condensed matter physics and chemistry. However, x-ray powder diffraction and, in particular, synchrotron x-ray powder diffraction can investigate samples many thousand times smaller and have an intrinsic resolution at least one order of magnitude better than the best neutron powder diffractometer. A major drawback for neutron scattering is that it can presently only be done at large facilities (research reactors and spallation sources), whereas laboratory-based x-ray scattering equipment provides the same flux much more conveniently. Current governmental policies will not permit the construction or upgrade of present-day research reactor sources in the United States. The future of U.S. neutron scattering therefore relies solely on accelerator-based spallation sources. Electron diffraction is a very powerful tool to obtain both real and reciprocal space images of minute amounts of powders. In combination with other supplementary techniques such as solid-state nuclear magnetic resonance (NMR), which allows, e.g., the determination of Wyckoff multiplicities and interatomic distances by exploiting the nuclear Overhauser effect (NOE), physicists, chemists, and materials scientists have a powerful arsenal to elucidate condensed matter structures.

PRINCIPLES OF THE METHOD

The Neutron—A Different Kind of Probe

Independent of the specific interaction probes such as electrons, x rays, neutrons, or positrons have with matter, there is a general formalism for scattering phenomena upon which we will rely in the following. We distinguish two types of scattering. In elastic scattering, the probing particle is deflected without energy loss or gain. In inelastic scattering, the probing particle loses or gains energy. This energy gain or loss is called energy transfer. In both cases the probe is scattered by an angle 2θ and the scattering event is defined by the scattering vector $\mathbf{Q} = \mathbf{K}' - \mathbf{K}$ (Bragg's law), where $\mathbf{K}$ and $\mathbf{K}'$ are the wave vectors before and after diffraction. In the elastic case, $\mathbf{Q} = 4\pi \sin \theta/\lambda$, with λ being the wavelength. The scattering vector $\mathbf{Q}$ multiplied by $h/2\pi$ is called the momentum transfer, where h is Planck's constant. If the probing particles interact with the scattering centers in such a way that the scattered waves have a phase relationship with each other, the case is referred to as coherent scattering and interference is possible between scattered waves with different amplitudes and phases. Diffraction or Bragg scattering is the simplest form of coherent scattering. If the probes interact in an independent, random-phase-related manner among the different scattering centers, the case is referred to as incoherent scattering. No interference is possible in the incoherent scattering case. The intensities rather than

the amplitudes originating from the different scattering centers only add up. This may simply increase the background of a diffraction experiment or be used to provide information about a specific scattering species at different times and positions.

The neutron is an invaluable probe for condensed matter research. When neutrons interact elastically with matter, there are important differences from x rays.

Neutrons do not primarily interact with the electrons but with the nuclei of atoms. Due to the short range of nuclear forces, the size of these scattering centers are on the order of 10^5 times smaller than the distances between them. The nucleus is effectively a point scatterer, and the neutron is therefore scattered isotropicially. The interaction potential is a delta function, called Fermi's pseudopotential, and can be expressed as

$$V(r) = \frac{2\pi h^2}{m} b\delta(r) \tag{1}$$

h being Planck's constant and m the mass of the neutron. The Fermi length or scattering length b has the dimension of a length and is often given in femtometers. It can be expressed using the Breit-Wigner (1936) equation

$$b = R - \frac{\Gamma}{2kE_r} \tag{2}$$

where R is the nuclear radius, k the Boltzman constant, E_r a resonant energy for the neutron-nucleus system, and Γ the width of the nuclear energy level.

In contrast, x rays are not scattered isotropically since the size of the "electron cloud" is comparable to the wavelengths used to probe them. As a result, one observes a decrease of the atomic form factor and therefore of the Bragg intensities at high scattering angles. In the case of neutrons, however, the scattering length b is constant at all scattering angles. The interaction of the neutron with the nucleus is weak, especially when compared to electrons involved in very strong electrostatic potential interactions or x rays interacting via their electromagnetic radiation field with electrons. The energy of a 1-Å-wavelength neutron is 82 meV, whereas the energy of a 1-Å x-ray photon is 12 keV. A 0.037-Å electron has an energy of 100 keV. An often-neglected experimental consequence of this weak neutron-nucleus interaction is that neutrons have a very high penetration depth into matter, typically on the order of centimeters. Neutrons are a true bulk probe. The penetration depth of x rays (typically 0.5 mm) and electrons (typically 100 Å) is low enough that one has to take into consideration the possibility of near-surface effects, especially when the sample contains high-Z atoms, Z being the atomic number. The linear absorption coefficients in Al for neutrons and x rays both with a wavelength of 1.79 Å (i.e., comparable to a lattice spacing) are 0.014 and 212 cm^{-1}, respectively. In other words, the intensity of the neutron beam is reduced by half after going through roughly 50 cm of Al, whereas for x rays, it is already halved after going through 0.003 cm. This is why, from an experimentalist's point of view, sample environments (e.g., cryostats, magnets, pressure cells) are a lot easier to engineer and use in neutron than in x-ray scattering experiments. However, even with the highest currently available neutron fluxes, one will only be able to work with monochromatic beams that have fluxes of only $\sim 10^8$ neutrons/cm^2/s impinging on the sample. This is equivalent to what an ordinary sealed x-ray tube generates. Typical fluxes at synchrotron sources are more than 6 orders of magnitude higher. As a result of this intrinsically low flux, the typical neutron powder diffraction experiment requires gram quantities of material in order to obtain data with good statistics within a reasonable amount of time. This is in marked contrast to conventional and synchrotron x-ray powder diffraction experiments where milligram quantities are sufficient.

Another important difference from x rays is that the interaction of the neutron with the nucleus does not vary systematically with the atomic number Z. Thus, in certain cases, low-Z elements such as deuterium ($Z = 1$, $b = 6.671$ fm) or oxygen ($Z = 8$, $b = 5.80$ fm) interact more strongly with neutrons than do high-Z elements such as Ce ($Z = 58$, $b = 4.84$ fm) or W ($Z = 74$, $b = 4.86$ fm). In oxides, the scattering contribution of the oxygen to the Bragg reflections is in general higher with neutrons than with x rays, especially when high-Z cations are present. This is of tremendous advantage when investigating oxide structures, where the subtleties of oxygen displacements and tilts of oxygen coordination polyhedra are structural signatures of materials with significantly different physical properties. This oxygen-sensitive scattering power combined with the fact that there is no "fall-off" of the scattering length at high scattering angles when scattering neutrons led to the enormous number of neutron powder diffraction studies performed over the last decades on oxides and in particular the high-temperature cuprate superconductors.

Furthermore, even neighboring elements can have very different scattering lengths such as Mn ($Z = 25$, $b = -3.73$ fm), Fe ($Z = 26$, $b = 9.45$ fm), and Co ($Z = 27$, $b = 2.5$ fm). Without the need to perform x-ray diffraction experiments at various wavelengths and to use anomalous dispersion to distinguish between Mn and Fe or between Fe and Co, one neutron measurement can establish a particular cation distribution. This is very important when investigating the magnetic properties in solid solutions of, e.g., $Fe_{3-x}Co_xO_4$ oxides with the spinell structure. The distribution of Fe and Co among the tetrahedral and octahedral sites of the oxide structure determines the magnetism in these compounds.

In another illustrative example, the compound $NaMnFeF_6$ can be described as an ordered distribution of Na^+, Mn^{2+}, and Fe^{3+} cations located in the hexagonal close-packed (hcp) lattice of fluorine. X rays have no problem distinguishing between Na^+ and the Mn^{2+} or Fe^{3+} sites. However, there are two possible ordering schemes for Mn and Fe in the space group P321 where there are three Wyckoff positions available for these metals: 1a, 2d, and 3f. The difference between the model where Mn is located in 3f and Fe in 1a and 2d and the model where Fe is located in 3f and Mn in 1a and 2d is striking. This remarkable difference between the two models for the cation distribution is shown in Figure 1.

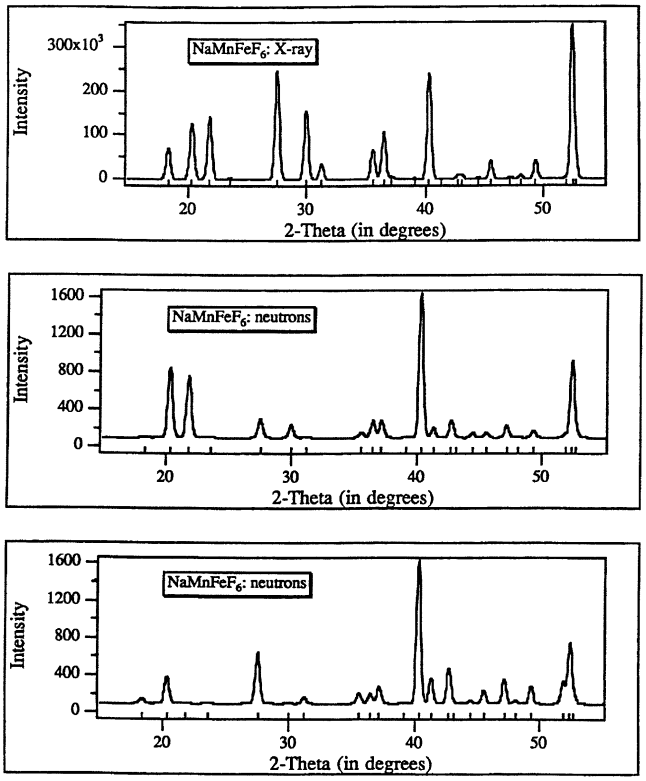

Figure 1. Powder diffraction pattern of $NaMnFeF_6$ calculated for two different ordering models. Top: X-ray diffraction pattern: cation ordering is not distinguishable since Fe^{3+} and Mn^{2+} have the same form factor far from the absorption edge. Middle: Neutron powder diffraction pattern calculated with Mn in 3*f* and Fe in 1*a* and 2*d*. Bottom: Neutron powder diffraction pattern calculated with Mn in 1*a* and 2*d* and Fe in 3*f*.

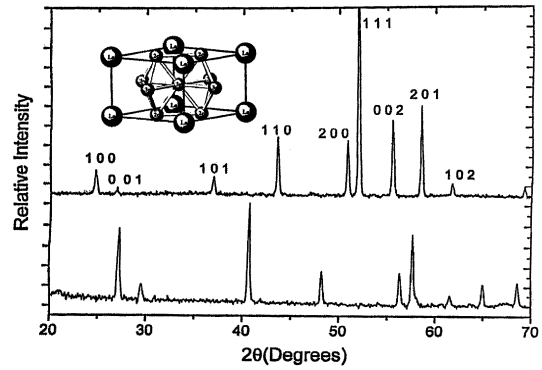

Figure 2. Neutron powder diffraction pattern of $LaNi_{3.55}Co_{0.75}Al_{0.3}Mn_{0.4}$ ($\lambda = 1.9$ Å) and $La(^{58}Ni_{0.376}\ ^{62}Ni_{.0.623})_{3.55}Co_{0.75}Al_{0.3}Mn_{0.4}$ ($\lambda = 2.1$ Å).

The neutron-nucleus interaction depends on the atomic number Z as well as on the atomic weight. Isotopes, which have the same Z but different weight, can vary substantially in their neutron scattering length. The neutron-nucleus interaction also allows for a negative scattering length b (e.g., H, Mn, ^{62}Ni, ^{48}Ti). This corresponds to a phase change of p radians during the scattering process.

Exploiting these last two properties of the neutron-nucleus interaction allows contrast variation experiments to be done by altering the scattering length b of a given atomic species by isotope substitution. The most known example is hydrogen ($b = -3.74$ fm) and deuterium ($b = 6.674$ fm). Varying the ratio of, e.g., H_2O/D_2O changes the "visibility" of water in diffraction experiments. This technique is extensively used in small-angle neutron scattering (SANS). In general, neutron powder diffraction experiments are performed with deuterated samples due to the large incoherent scattering of hydrogen. However, if only small amounts of hydrogen are present, hydrogenated samples can be used, as will be discussed below.

In certain favorable cases the net elastic scattering contribution of certain elements can be reduced to zero by varying the isotopic ratios within the sample: Ni has three isotopes with positive scattering lengths and one with a negative scattering length (^{58}Ni, $b = 14.4$ fm; ^{60}Ni, $b = 2.8$ fm; ^{61}Ni, $b = 7.60$ fm; and ^{62}Ni, $b = -8.7$ fm); Ti has two isotopes, namely, ^{48}Ti with $b = -6.08$ fm and ^{50}Ti with $b = 6.18$ fm. Certain members of intermetallic alloys with the AB_5 structure are replacing the cadmium electrode in nickel cadmium batteries due to their benign environmental impact and high-energy density. The AB_5 structure contains planes of A and B cations in the basal plane and only B cations in the midplane, as shown in the inset of Figure 2. To reduce corrosion and thus enhance the cycle life of the battery while maintaining good energy storage capacity, commercial electrodes have the stoichiometry $LaNi_{3.55}Co_{0.75}Mn_{0.4}Al_{0.3}$. However, due to the high cost of cobalt, current research efforts are focused on reducing its amount to make the battery economically competitive. It is therefore important to know the location of the cobalt within the alloy. When using metals with isotopes present in their natural abundance, the scattering is dominated by nickel, and only very little stems from cobalt since nickel has a scattering length of 10.3 fm, which is four times higher than that of cobalt ($b = 2.5$ fm). If, however, one makes an alloy using a mixture of the isotopes ^{58}Ni and ^{62}Ni in the respective proportions 37.6% to 62.3%, the picture changes dramatically; nickel no longer contributes to the Bragg scattering, and cobalt dominates the scattering from the B_5 sublattice. The tremendous changes in the diffraction pattern are shown in Figure 2, where the first nine Bragg reflections of an alloy containing metals with a natural isotopic abundance are compared to one containing the zero-scattering "isotopic alloy" $^{58}Ni_{0.376}\ ^{62}Ni_{0.623}$. Rietveld refinements of this data set together with data of samples with natural isotope abundance revealed that cobalt prefers to be located in the midplane and not in the basal plane of this structure.

Another important application of neutron scattering is possible because neutrons have a magnetic moment of $1.9132\mu_n$ that can interact via dipole-dipole interactions with the magnetic moments of unpaired electrons. The magnitudes of magnetic and nuclear scattering are of the same order of magnitude, but now the unpaired electron density can no longer be approximated as a point scatterer, as is done for the nucleus. Magnetic scattering of neutrons is not isotropic, and angle-dependent form factors similar

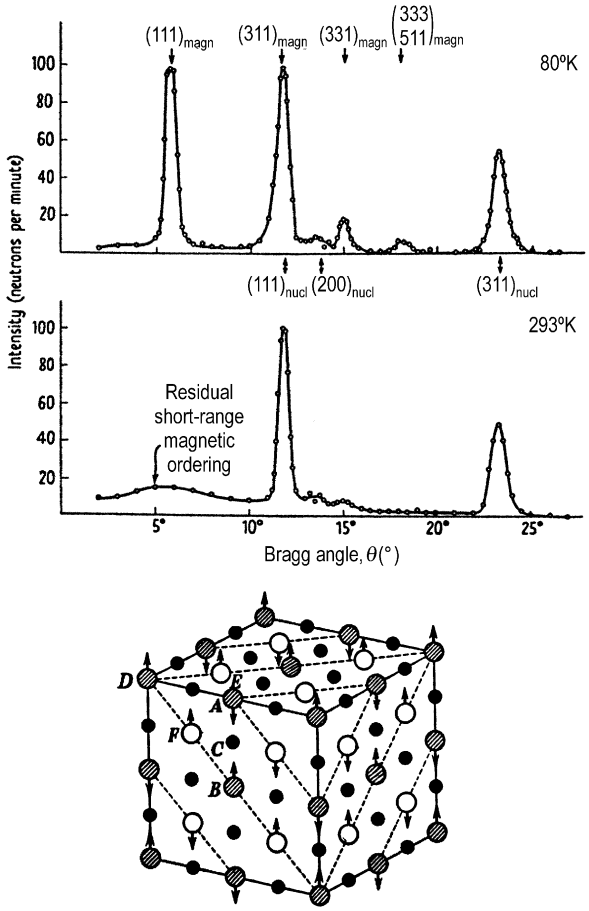

Figure 3. Neutron powder diffraction pattern of MnO at 80 and 293 K. The low-temperature pattern reveals extra antiferromagnetic reflections that can be indexed within a magnetic unit cell twice the size of the chemical unit cell. The magnetic unit cell below the Curie point is shown as an inset.

to the ones in x-ray scattering are observed (see MAGNETIC NEUTRON SCATTERING).

As mentioned above, the theory of antiferromagnetism was developed by Néel (1932), but it took 17 years until neutron powder diffraction provided its first experimental proof. Shull and Smart (1949) measured the neutron powder diffraction pattern of MnO at 80 and 293 K, which is below and above its antiferromagnetic phase transition at 120 K. As shown in Figure 3, the pattern at 80 K revealed the appearance of additional diffraction peaks, which could only be accounted for by a doubling of the "chemical" cell of MnO. The first reflection is thus the 111 of the "magnetic" unit cell. Subsequent experiments by Shull et al. (1951) revealed that the intensity of this peak decreases and becomes zero as one approaches the phase transition. This was the first observation of magnetic Bragg scattering, and the observed magnetic intensities were compared with model calculations provided by Néel (1948). The model has a magnetic unit cell made up of eight chemical unit cells. These four sublattices are arranged so that they have sheets of atoms with their spin pointing in the same direction parallel to (111) planes. These sheets of ferromagnetically coupled spins are coupled antiferromagnetically along (111). This antiferromagntic coupling between second nearest neighbors is achieved via a superexchange mediated by the oxygen. This was postulated by Kramers (1934). Figure 3 depicts the magnetic unit cell. A model that gives equally good agreement with the intensities of the magnetic Bragg reflections is one where the magnetic moments of the neighboring atoms in the individual sublattices vary randomly from crystallite to crystallite; in other words, the sublattices are not coupled. If the sublattices are coupled, the structure is no longer cubic but rhombohedral. This was confirmed by low-temperature x-ray measurements by Tombs and Rooksby (1950)—a historical first to illustrate the valuable complementary use of x-ray and neutron scattering. In the rhombohedral symmetry, the four pairs of reflections that make up the {111} magnetic Bragg reflections are no longer equivalent. Only the (111) and $(-1-1-1)$ planes will give rise to magnetic intensities. The $(-11-1)$ plane has as many atoms with their magnetic moment pointing in one way as in the opposite and thus will contribute no magnetic intensity to the {111} reflection. The orientation of the magnetic moment parallel to the [100] axis is not arbitrary. If one calculates the intensity of the {111} magnetic Bragg reflection with the magnetic moments perpendicular to (111), no magnetic intensity results since only the perpendicular component of the magnetic moment with respect to the scattering vector contributes to magnetic Bragg scattering. If one would align the magnetic moments along the (111) sheets, an exceedingly strong magnetic intensity results. That distinction between these various models is a direct consequence of the reduction of symmetry from cubic to rhombohedral.

The neutron also has a spin angular momentum of $\frac{1}{2}$. One can separate neutrons into beams of spin-up and spin-down neutrons having equal moments of $\pm\frac{1}{2}\hbar$ (where $\hbar = h/2\pi$), respectively. This is done by, e.g., using the (111) reflection of the Heusler alloy Cu_2MnAl, whose nuclear and magnetic scattering contributions compensate each other exactly for one of the two spin states. These neutrons are referred to as polarized neutrons and can be used to distinguish between nuclear and magnetic scattering since only the perpendicular component of the atomic magnetic moment with respect to the scattering vector will contribute to magnetic scattering. Polarized neutron scattering is severely hampered and has difficulties to live up to its potential since the available present-day sources are all too weak to provide high-flux polarized neutron beams using current techniques: polarized neutron scattering is currently a truly signal-limited technique. Further details concerning this neutron diffraction technique are found in Williams (1988).

PRACTICAL ASPECTS OF THE METHOD

The Angle-Dispersive Constant-Wavelength Diffractometer

This is the most familiar experimental set-up for neutron powder diffraction experiments and resembles the standard laboratory-based x-ray powder diffractometer. In a

nuclear reactor, neutrons are created by controlled fission of ^{235}U. Neutrons released by nuclear fission have a kinetic energy of ~5 MeV. A so-called moderator made in most cases of either H_2O or D_2O surrounds the reactor core. Its purpose is to "slow down" the neutrons via inelastic neutron-proton or neutron-deuterium collisions. Using the wave-particle formalism and de Broglie's equation $\lambda = h/mv$, with v being the velocity, the energy of a neutron can be expressed as

$$E(\text{meV}) = 0.08617T = 5.227v^2 = \frac{81.81}{\lambda^2} \qquad (3)$$

where the temperature of the moderator T is in kelvins, the velocity ν is in kilometers per second, and the wavelength λ is in angstroms. If water is used ($T = 300$ K), the mean wavelength is 1.78 Å and the neutrons have an energy of 25.8 meV. This moderation process is rather imperfect and results in a broad distribution of wavelengths available for experiments. If the moderator is sufficiently thick, the neutrons will have a Maxwellian energy distribution, their average kinetic energy being $\frac{3}{2}kT$, where k is the Boltzmann constant. If one selects a monochromatic beam with a certain wavelength resolution $\Delta\lambda/\lambda$ by using a single-crystal monochromator and the scattering angle 2θ is varied by stepping the detector, then the measurement mode is referred to as angle dispersive. The reflectivity of a perfect single crystal is low due to the small angular misalignment of the mosaic blocks—the so-called mosaic spread. In neutron powder diffraction, germanium is the natural choice for monochromation, especially since it has the diamond structure in which lattice planes whose Miller indices (hkl) are all odd are systematically absent. Therefore, λ/2 contamination will not occur from Bragg scattering. However, the mosaic spread has to be increased to make monochromators that can provide a reasonable flux. Recently, a significant advancement was reported by Axe et al. (1994). Instead of "squashing" single crystals, thin wafers are plastically deformed and then reassembled into composites. The reproducible creation of a spatially homogeneous but anisotropic mosaic spread led to a well-defined neutron energy profile and symmetrical spectral peak shapes, which are crucial for high-resolution neutron powder diffraction. The angle at which the neutrons are reflected off their flight path by the monochromator toward the sample is called the take-off angle. The higher this take-off angle, the better the angular resolution $\Delta d/d$ will be. Differentiating Bragg's law, one obtains

$$\frac{\Delta\lambda}{\lambda} = \frac{\Delta d}{d} + \Delta\theta \cot\theta \qquad (4)$$

The resolution is given by

$$\frac{\Delta d}{d} = \Delta\theta \cot\theta \qquad (5)$$

with $\Delta\theta$ being the mosaic spread of the monochromator reflecting at an angle θ, the take-off angle. To obtain a high angular resolution (small $\Delta d/d$), a large take-off angle has to be chosen. However, the intensity also depends on $\Delta/\lambda\lambda$ and will thus decrease as the take-off angle is increased. This is why only in high-flux reactors can the gain in resolution be afforded without paying the penalty of unreasonably small fluxes at the samples (resulting in prohibitive long counting times) in order to achieve good signal-to-noise ratios. The resolution of an angle-dispersive set-up depends on the narrow band $\Delta/\lambda\lambda$ selected by the monochromator and is further enhanced by using Soller collimators before the monochromator and detector and optionally between the monochromator and sample. Soller collimators (Soller, 1924) consist of a number of thin sheets bound together to form a series of long and narrow channels. These sheets are painted with a neutron-absorbing paint containing gadolinium to absorb diverging neutrons. The resolution of an angle-dispersive neutron powder diffractometer is further discussed in Appendix A.

Time-of-Flight Diffractometers

For didactic reasons, most arguments and examples that follow will be made using the constant-wavelength or angle-dispersive diffractometers found at research reactors. However, there is another type of neutron source, the spallation source and associated with it a second type of diffractometer, the time-of-flight diffractometer. The spallation source relies on a process whereby highly accelerated particles such as protons with energies of ~800-MeV impact on a target made of uranium or lead. Thereby neutrons are "kicked out" of the nuclei. The experimental requirements for diffraction at a spallation source are different. The time structure of the neutron beam created by the proton beam on the target is exploited in these measurements. In the time-of-flight experiment the detector is located at a fixed value of 2θ while the sample is irradiated by a pulsed, "white" neutron beam containing a very large wavelength distribution $\Delta/\lambda\lambda$. All wavelengths created in the spallation process are then moderated and impinge onto the sample without being selected by a monochromator. A coarse wavelength selection is achieved by placing choppers in the beam. These are rotating discs of neutron-absorbing material with an opening cut into it. By varying the speed, one can select neutrons with different speeds and therefore energies and wavelengths. For a given reflection, the Bragg condition $\lambda = 2d \sin\theta$ is satisfied at a specific wavelength. This wavelength can be determined by measuring the time it takes the neutron to reach the detector after hitting the sample. The resolution of a time-of-flight powder diffractometer is given by

$$\frac{\Delta Q}{Q} = \left[\left(\frac{\Delta t}{t}\right)^2 + \left(\frac{\Delta L}{L}\right)^2 + \left(\frac{\cot\theta}{\Delta\theta}\right)^2\right]^{1/2} \qquad (6)$$

where t is the time of flight of the neutrons and Δt its uncertainty mainly due to the uncertainty in the moderation time, L the flight path length and ΔL its uncertainty due to a finite target and moderator size. The angle θ is the scattering angle and $\Delta\theta$ is the angle subtended at the source by the active area of the detector. From this equa-

tion, one can deduce that the highest resolution is obtained using a long flight path L and a detector close to $\theta = 90^\circ$, referred to as the backscattering position. As an example, the high-resolution neutron powder diffractometer located at the spallation source ISIS at the Rutherford Laboratory in the United Kingdom has a 96-m-long flight path and a detector in the backscattering position. If one would use only a detector array covering a small angular range close to the backscattering position, the largest d spacing using a neutron pulse with a wavelength distribution $\lambda_1 < \lambda < \lambda_2$ that could be observed would be $\lambda_2/2$. At the $2\theta = 90^\circ$ position, a d spacing of $\lambda_2\sqrt{2}$ can be observed. One has to keep this in mind because the observation of high d spacings is of crucial importance for the determination and refinement of magnetic structures as well as for indexing unknown structures. Each time neutrons are created in a spallation process, typically every 20 ms, a complete diffraction pattern is collected. Successive pulses have to be accumulated to improve the signal-to-noise ratio. The resolution curve of a time-of-flight diffractometer is almost constant with scattering angle 2θ. Thus, minute lattice constant deviations can be resolved from high-order reflections without suffering the instrumental broadening that angle-dispersive instruments suffer beyond the minimum at the take-off angle (see Appendix A). A disadvantage of time-of-flight neutron powder diffraction is that wavelength-dependent corrections for the incident intensity, absorption, extinction, and detector efficiencies have to be made and the peak shape is highly asymmetrical. Despite these tedious corrections, sophisticated software packages exist and the time-of-flight method is used as routinely as the angle-dispersive procedure. It appears that in the future new neutron sources will probably be spallation sources rather than reactors. Time-of-flight neutron powder data have been used to determine structures from powder data alone (Cheetham, 1986). David et al. (1993) used high-resolution time-of-flight neutron powder diffraction data collected as the spallation source ISIS to study in detail the structure of the soccer ball–shaped molecule C_{60} as a function of temperature. Subtle aspects of an orientational glass transition and precursor effects of the order-disorder transition at 260 K were observed. Detailed analysis revealed that, despite the lower precision when compared to single-crystal measurements and the resulting larger errors, time-of-flight neutron powder diffraction data can be used to reproduce all the essential details found in a single-crystal synchrotron radiation experiment. This illustrates the remarkable amount of information that can be extracted using state-of-the-art neutron time-of-flight data and data analysis.

SAMPLE PREPARATION

Samples should resemble as much as possible an ideal random powder consisting of particles with sizes between 1 and 5 μm. The size distribution should be as smooth and Gaussian as possible. If larger crystallites dominate the sample, the measured intensities will have severe and nonsystematic deviations from the "true" values based on crystallography. The intensities of certain d spacings are then no longer evenly distributed on the Debye-Scherrer cones but rather are clustered in spots depending on the orientation of the bigger crystallites. There are no corrections that can be applied to these type of nonrandom samples. If too small particles are present, line-broadening effects will occur that can be corrected for (see The particle size effect). The minute amount of sample present in the beam and the highly collimated x-ray beam in a synchrotron x-ray powder diffraction experiment will exacerbate problems with nonrandomness. If the nonrandomness is systematic, as in samples with preferred orientation, it can be corrected for in Rietveld refinements. Recently, Wessels et al. (1999) used preferred orientation to solve structures from powder data alone. In neutron powder diffraction experiments, the larger size of the beam, its larger divergence, and the required gram quantities of sample to obtain useful signal-to-noise ratios within reasonable time result in a better sampling and averaging of the powder sample. Therefore, fewer problems with nonrandomness are encountered. If, however, a low-temperature structure of a compound is investigated that is a liquid or a gas at room temperature, it is advisable to cool and reheat the sample several times in order to obtain a "good" powder sample. The cooling time might become a crucial parameter since cooling too slow might result in crystallites that are too large, and therefore not all crystallite orientations will be equally represented.

DATA ANALYSIS AND INITIAL INTERPRETATION

Positions of the Bragg Reflections

For constant-wavelength diffractometers the d spacings of a crystalline sample are obtained from the measured angular position 2θ using Bragg's law:

$$\lambda = 2d \sin\theta \tag{7}$$

In a time-of-flight neutron powder diffractometer, the d spacings can be obtained by converting the time-of-flight t via

$$d = \frac{ht}{2mL \sin\theta} \tag{8}$$

where the detectors are located so that $L \sin\theta$ is a constant and m is the mass of the neutron.

The obtained d spacings allow the determination of the lattice constants with an accuracy of a few hundredths of angstroms in the case of neutrons. This accuracy is crucial when attempting to use lattice constants to determine phases in mixtures, index unknown phases, or determine thermal expansion coefficients and residual stress in materials. Accurate d spacings can only be obtained by carefully aligning the diffractometer, thus minimizing systematic errors (zero shift of the detector in 2θ), and using the proper peak shape when fitting the diffraction peaks. An adequate correction to the asymmetry due to axial divergence is especially important (see Peak Asymmetry Due to Axial Divergence). Figure 4 shows a diffraction pattern

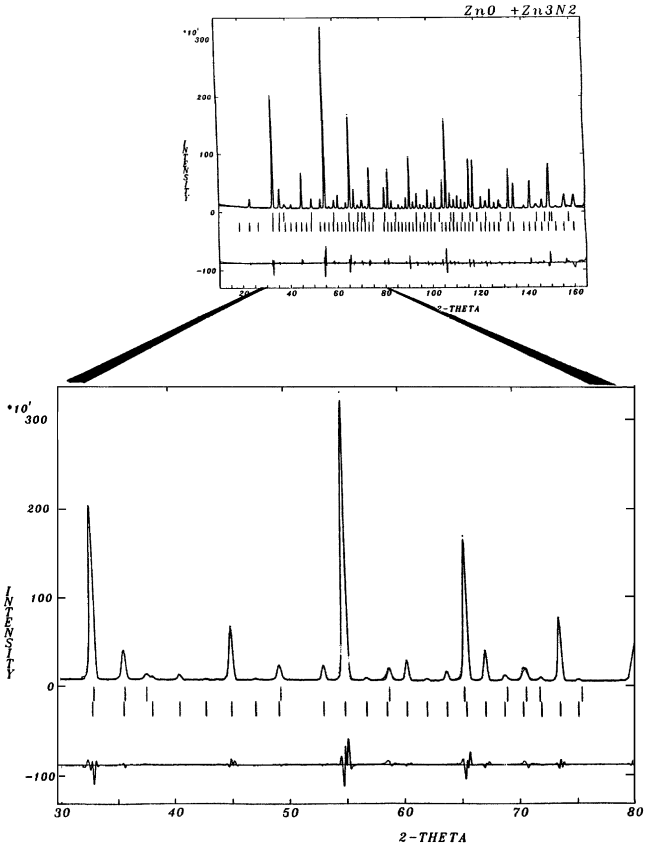

Figure 4. Neutron powder diffraction pattern of Zn_3N_2 containing ZnO as an impurity. The first row of tick marks below the pattern indicates the position of the Bragg reflections stemming from Zn_3N_2 [$a = b = 3.255(1)$ Å, $c = 5.2112(1)$ Å, space group $P63mc$], the second from cubic ZnO [$a = 9.7839(2)$ Å, space group $I\alpha3$].

of a sample of Zn_3N_2 that contains ZnO as an impurity phase. It is apparent that due to the superposition of the Bragg reflections of these two phases, only a high angular resolution allows the separation of these two phases.

The Peak Shape

The diffraction profile function or peak shape describes the intensity distribution about the Bragg position 2θ. Ultimately, the width of Bragg reflections is determined by the Darwin width. For an ideal crystal, Darwin (1914) found that the width of a reflection depends only on the structure factor and the number of interfering d spacings. Its finite width is due to the weakening of the primary beam inside the crystal due to multiple Bragg reflection—also called primary extinction. In addition to the Darwin width, various effects broaden the diffraction lines. The most commonly used quantifier for the width of a reflection is the full width at half-maximum (FWHM). The experimentally observed peak shape in the case of a constant-wavelength diffractometer is the result of the convolution of two components: (1) the optical characteristics of a diffractometer such as the wavelength distribution $\Delta\lambda/\lambda$ diffracted off the monochromator at a given take-off angle θ_m and the various collimators (see Appendix A) and (2) the actual physical contributions of the sample to the profile.

Instrumental Contributions to the Peak Shape

The resolution of a constant-wavelength neutron powder diffractometer can be calculated according to a theory first developed by Caglioti et al. (1958). The most important result of this simple theory is that the neutron peak shapes are to a very good first approximation Gaussian:

$$\Omega(2\theta) = \frac{2}{\mathrm{FWHM}}\left(\frac{\ln 2}{\pi}\right)^{1/2} \exp\left(\frac{-4 \ln 2(2\theta - 2\theta_0)^2}{\mathrm{FWHM}^2}\right) \quad (9)$$

The intensity distribution $\Omega(2\theta)$ about their Bragg position $2\theta_0$ is fully described by the FWHM. This is a very good approximation for low- and medium-resolution neutron powder diffractometers, and the rapid development of the Rietveld method was largely due to this simple mathematical description of the peak shape. For high-resolution neutron powder diffraction data and especially laboratory-based and synchrotron x-ray powder diffraction data, more sophisticated peak shapes had to be developed. In general, the resolution curve of a neutron powder diffractometer that describes the angular variation of the FWHM of the Bragg reflections can be given according to Cagliotti et al. as a simple expression (see Appendix A):

$$\mathrm{FWHM}^2 = U \tan^2\theta + V \tan\theta + W \quad (10)$$

However, there are significant deviations from this simple description that are especially apparent in high-resolution neutron powder diffraction.

Peak Asymmetry Due to Axial Divergence

An adequate peak-shape function is of utmost importance in the analysis of crystalline structures when using the Rietveld profile refinement technique. This is especially true for the low-angle region of a constant-wavelength high-resolution neutron powder diffraction pattern where severe asymmetries due to axial divergence occur. The appropriate asymmetry correction in these low-angle 2θ regions might determine success or failure when using, e.g., auto-indexing routines to determine the unit-cell dimensions of unknown structures. With a nondivergent point source and a truly randomized powder, the radiation scattered at a given Bragg reflection will lie on the surface of a Debye-Scherrer cone with semiangle 2θ. The detector itself lies on the surface of a cylinder with its axis parallel to the 2θ axis of the diffractometer. The intersection of the Debye-Scherrer cone with the detector cylinder is an ellipse. The center of this ellipse is at 0° for Bragg reflections with $2\theta < 90^\circ$ and at 180° for reflections with a $2\theta > 90^\circ$. The further from 90°, the more the ellipticity will increase. As Figure 5 shows, this departure leads to a peak asymmetry because diffracted neutrons from the ends of the intercepted part of the Debye-Scherrer cone will hit the detector on the side of the peak closer to the center of the ellipse first. This is known as axial divergence. Increasing the height of the detector and the size of

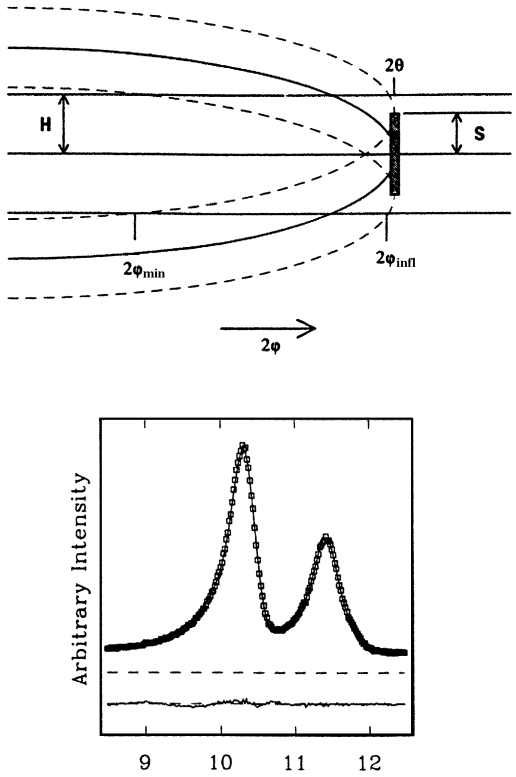

Figure 5. Band of intensity, diffracted by a sample with height $2S$, as seen by a detector with opening $2H$ and a detector angle 2φ moving in the detector cylinder. For angles below $2\varphi_{min}$, no intensity is detected. For angles between $2\varphi_{infl}$ and 2θ, the entire sample can be seen by the detector. Observed and calculated profiles are for neutron powder diffraction peaks of a zeolite sample measured at the instrument HRNPD at Brookhaven National Laboratory.

the sample will lead to greater counting rates and shorter measurement times—an important factor for high-resolution neutron powder diffraction due to the intrinsically weaker sources available in neutron scattering, as discussed earlier. However, these combined measures to increase the counting rates will also increase the asymmetry. The integrated intensities of affected reflections are biased since a larger part of the Debye-Scherrer ring is collected at lower angles. Rietveld (1969) introduced a refineable asymmetry factor providing a purely empirical correction. A widespread and commonly used empirical correction is the split–Pearson VII function described by Brown and Edmonds (1980) and Toraya (1986). Another approach is to take into account the essential optical features of the diffraction optics to correct for the asymmetry. Cooper and Sayer (1975) introduced an asymmetry correction for neutron powder diffraction based on the calculation of the resolution function in reciprocal space. However, this correction was not widely used due to the difficulties of deriving asymmetric profile functions from the source, sample, and detector contribution. Howard (1982) used the approach of Eastabrook (1952) and applied it to neutron diffraction with a point source and sample as well as a finite detector height. The correction term contains one variable parameter depending on the ratio of the detector height to the distance between sample and detector. This is currently incorporated into the Rietveld refinement programs LHPM (Hill and Howard, 1987), DBW (Wiles and Young, 1981), and older versions of GSAS (Larson and Von Dreele, 1990) and works quite well for the predominantly Gaussian peak shapes occurring in neutron powder diffraction. A more rigorous approach was advanced by van Laar and Yelon (1984). Their correction includes a finite sample size and detector height when the latter is bigger and a weight function takes into account edge effects when the detector first intercepts the Debye-Scherrer cone up to the point where it "sees" the whole sample. Finger et al. (1994) generalized the van Laar and Yelon approach, and it is currently encoded in the latest versions of GSAS. The latest generation of high-resolution neutron powder diffractometers has benefited tremendously from this correction. These diffractometers use large, vertically focusing monochromators and have detector apertures with axial divergences of several degrees. The asymmetry of low-angle peaks from materials with large unit cells such as zeolites can be described without using any free parameters.

Mesoscopic Properties Influencing the Peak Shape

When using a "real" diffractometer, the measured resolution will always be worse than the design specifications. Besides neutron optical effects stemming from nonideal collimators and monochromators that degrade the flux and resolution, there are so-called mesoscopic properties of the sample that influence the peak shape. It is important to account for these structural variations at length scales of tens to thousands of angstroms in high-resolution neutron powder diffraction data sets. We will mainly concentrate on four of them: the particle size effect, microstrain, extinction, and stacking faults.

The Particle Size Effect. The particle size effect is due to coherent diffraction emanating from finite domain sizes within the grains of a powder. Kinematical diffraction theory assumes an infinite lattice. In this case, the Bragg reflections are δ functions. The smaller the particle from which diffraction emanates, the more this δ function will be "smeared out." The broadening of all points in reciprocal space is uniform. Using Bragg's law, one can derive that

$$\frac{\Delta d}{d^2} = -\frac{\Delta\theta}{\tan\theta} = -\frac{\Delta(2\theta)\cos\theta}{\lambda} \tag{11}$$

This reveals that particle size broadening $\Delta(2\theta)$ varies with $1/\cos\theta$ in 2θ space. Analysis of size broadening is often performed using the Scherrer equation:

$$\Delta(2\theta) = \frac{K\lambda}{A\cos\theta} \tag{12}$$

where A is the thickness of the coherently diffracting domain and K is a dimensionless crystal shape constant close to unity, which is also referred to as the Scherrer constant.

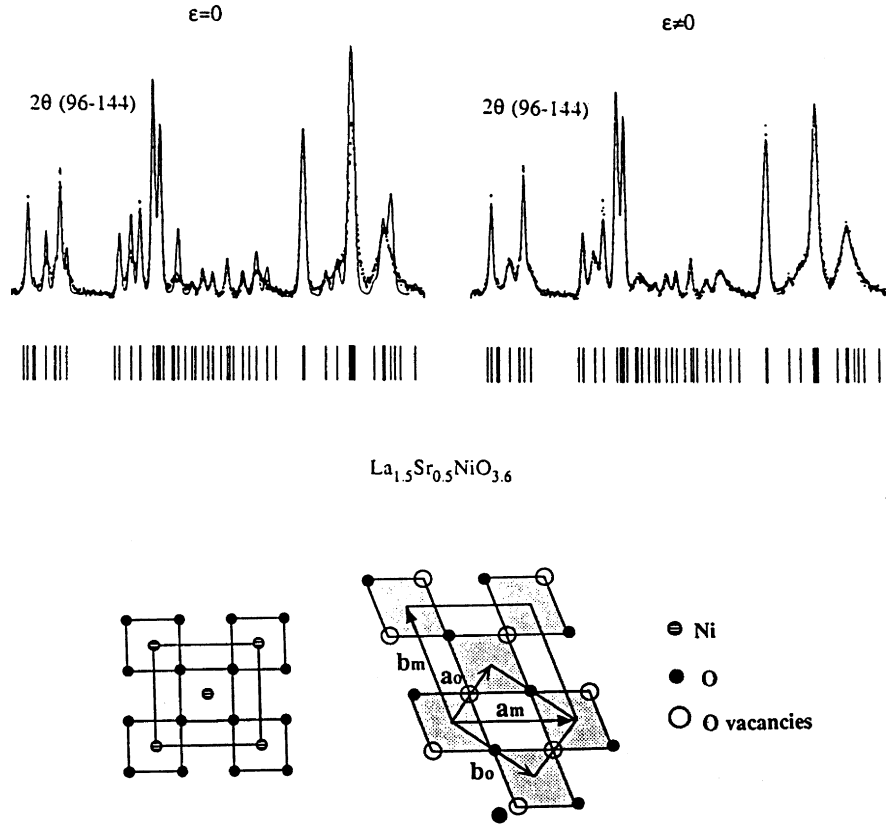

Figure 6. Portions of the neutron powder diffraction pattern of $La_{1.5}Sr_{0.5}NiO_{3.6}$ showing the effect of microstrain due to the partial ordering of the oxygen vacancies as depicted in the lower part.The fit depicted in the left part does not take microstrain into account.

Microstrain Broadening. Microstrain ε is due to a local variation $\Delta d/d$ of the average d spacing. These variations can be due to external stresses leading to anisotropic strain in the crystallites, lattice defects, or local compositional fluctuations described by a constant $\varepsilon = \Delta d/d$. In contrast to particle size broadening, the effect of strain varies in reciprocal space. Differentiating Bragg's law with respect to the diffraction angle θ, one obtains

$$\mathrm{d}\theta = -\tan\theta \frac{\mathrm{d}d_{hkl}}{d_{hkl}} \tag{13}$$

In this case, we have the compositional fluctuations as constant and not the size A, and therefore

$$\Delta\theta = -\tan\theta \frac{\Delta d}{d} \tag{14}$$

This term is no longer wavelength dependent. Therefore, if we change wavelength, the width of a line (corrected for instrumental contribution!) should not vary in the case of only microstrain broadening. The variations in d spacings $\Delta \mathrm{d}/d$ manifest themselves in a broadening of the diffraction line centered at 2θ:

$$\Delta(2\theta) = -2\varepsilon\tan\theta \tag{15}$$

These two mesoscopic properties of materials, particle size and strain, are increasingly studied due to their important consequences for the physical properties of materials such as resistivity, magnetism, and the occurrence of phase transitions. Medarde and Rodriguez-Carvajal (1997) investigated the oxygen vacancy ordering in $La_{2-x}Sr_xNiO_{4-\delta}(0 \leq x \leq 0.5)$. In La_2NiO_4, the crystallographic structure is locally orthorhombic. However, the local fluctuations are correlated in such a way that their macroscopic average is tetragonal. This is due to the stress induced by the size mismatch between NiO_2 and La_2O_2 layers. The (hhl) reflections are narrow, whereas the $(h0l)$ and $(0kl)$ reflections reveal an increasing broadening with increasing values of h and k (Rodriguez-Carvajal et al., 1991). When substituting La^{3+} by Sr^{2+}, the broadening diminishes since the size mismatch between the NiO_2 and $(La,Sr)_2O_2$ layers is reduced. Above a critical $x \sim; 0.135$, the oxygen vacancies order and give rise to an extra broadening of reflections. This microstrain created by ordered oxygen vacancies along the orthorhombic a axis corresponds to ~1.7% of its total length. Figure 6 shows two Rietveld refinements of $La_{1.5}Sr_{0.5}NiO_{3.6}$, one of them refining a model for the microstrain, the other assuming no microstrain.

Microstrain and particle size effects can be separated by their q dependency when both are present in a material. There are various techniques to extract these types of mesoscopic properties from powder diffraction data. The most commonly used is based on the Williamson-Hall plot. Combining the Scherrer equation with the equation describing microstrain broadening leads to

$$\mathrm{FWHM}_{corr}\frac{\cos\theta}{\lambda} = \frac{1}{A} + \frac{C\varepsilon\sin\theta}{\lambda} \tag{16}$$

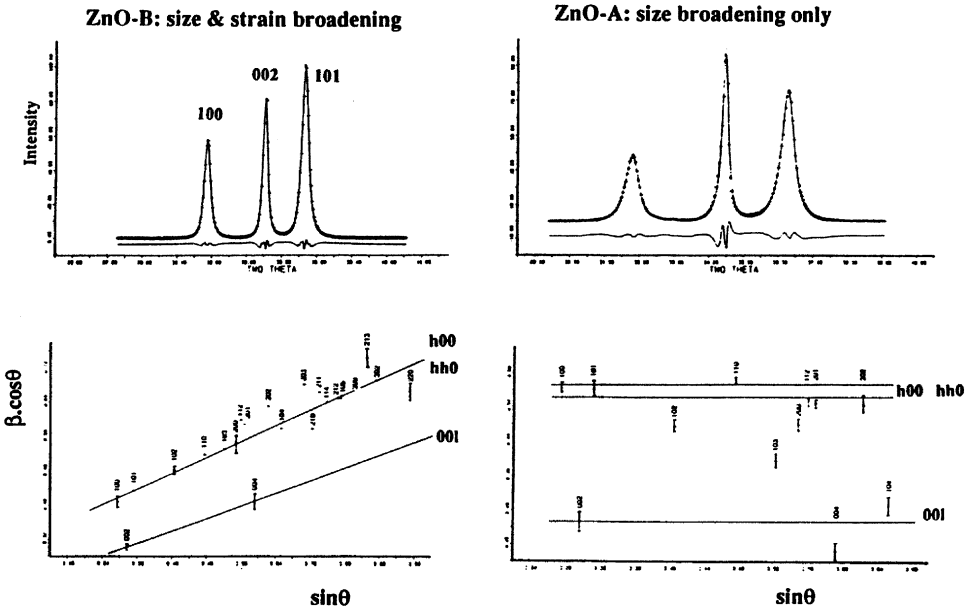

Figure 7. Williamson-Hall plots for two samples of ZnO prepared in different conditions: sample A is strain free but made of small ansiotropic crystallites. Sample B reveals both particle size and microstrain effect. (Adapted from Langford and Louër 1986.)

where $\mathrm{FWHM}_{\mathrm{corr}}$ is corrected for instrumental resolution and C varies with ε and the FWHM. The Scherrer constant K is assumed to be unity. When plotting $\mathrm{FWHM}_{\mathrm{corr}} \cos\theta$ of Bragg reflections versus $\sin\theta$, one can extract the domain size A as the y intercept and ε from the slope. Both T and ε can be anisotropic. One can therefore determine the crystalline shape and the direction of microstrain in crystallites. Figure 7 compares two samples of ZnO, one of them revealing broadening due to particle sizes, the other where both a broadening due to particle size and strain occur. The Williamson-Hall plots for both cases show how powerful this simple analysis can be.

Extinction is defined as the reduction of the ideal kinematical intensity due to depletion of the primary beam and rescattering of the diffracted beam. Sabine et al. (1988) demonstrated that in time-of-flight neutron powder diffraction primary extinction can be substantial when highly crystalline samples are measured. The extinction coefficient E is a function of the scattering angle and can be expressed as

$$E = E_{\mathrm{L}} \cos^2\theta + E_{\mathrm{B}} \sin^2\theta \tag{17}$$

$$E_{\mathrm{L}} = 1 - \frac{x}{2} + \frac{x^2}{4} - \frac{5x^3}{48} + \frac{7x^4}{192} \tag{18}$$

$$E_{\mathrm{B}} = \frac{1}{(1+x)^{1/2}} \tag{19}$$

$$x = (KN_{\mathrm{c}}\lambda FD)^2 \tag{20}$$

Here, D is a refinable parameter and K a shape factor that is unity for a cube and $\frac{3}{4}$ for a sphere of diameter D; N_{c} is the number of unit cells, F the structure factor, and λ the wavelength.

Stacking Faults. Due to the high angular resolutions achievable with modern synchrotron and neutron powder diffractometers, stacking faults are more and more noticeable. The diffracted intensity from a sample containing stacking disorder is the weighted incoherent sum of diffraction pattern emanating from each crystallite orientation and defect arrangement. Any single stacking fault can be included into the calculations in a rather straightforward fashion, but the number of permutations of stacking faults increases the computational effort substantially. Stacking faults were originally discovered in cold-worked metals. They represent disorder in the stacking sequence of layers along a particular direction. In the face-centered cubic (fcc) structure layers of atoms can be seen stacking along the [111] direction, whereas in the hcp structure the layers stack along [001]. The possible atomic layer positions in the hcp lattice is ABABAB... along [001], and in the fcc lattice it is ABCABCABCABC... along [111]. A so-called deformation fault occurs in the fcc structure when the sequence ABCABCABC is altered to, e.g., ABCA**C**ABCA This deformation fault corresponds to a shift of all layers after the fault (bold **C**) to the right. A twin fault in the fcc structure is represented by a sequence change from ABCABCABC to ABCA**B**ACBA. The stacking sequence is reversed to the left and right of the fault. Twin faults in fcc structures along [111] lead to diffraction line broadening, whereas deformation faults lead to line broadening as well as line positional shifts. This can be understood in a simple qualitative picture: if one writes down three possible deformation fault sequences and compares them to the original sequence, one observes that all A, B, and C layers following the fault (in bold) are now closer to the original A^* layer than in the unfaulted fcc sequence:

A^* B C A **C** A
A^* B C A B **A**
A^* B C **B** C A
A^* B C A B C

This change of the translational periodicity leads to a broadening due to local variations and a peak shift. If one does the same for possible twin-fault structures, one observes that the A, B, and C layers following the fault

(in bold) are shifted forward or backward or remain in the same sequence position as the unfaulted fcc sequence, leading only to an increased dispersion along c resulting in peak broadening:

A* B C A **B** A
A* B C **A** C B
A* B C A B **C**
A* B C A B C

An exemplary study by Berliner and Werner (1986) showed that the structure of lithium at 20 K has a so-called 9R structure with the nine-layer repeating sequence ABCBCACAB, which is highly faulted below 20 K. Their stacking fault analysis revealed deformation stacking-fault probabilities of 7%.

Wilson (1942, 1943) developed a difference equation method, where the probability of the occurrence of a given layer is related to the probability that it occurred in previous layers. Hendricks and Teller (1942) generalized this approach by using correlation probability matrices including effects of the nearest-neighbor layer-layer correlations and different stacking vectors.

Cowley (1976a,b, 1981) came up with another approach by analyzing single-layer terms in the Patterson function and separating intensity contributions into "no-fault" terms, which were summed as geometric series, and "fault" terms, which were summed explicitly. This led to quicker convergence in low-fault cases. Recently, Treacy et al. (1991) implemented a general recursion algorithm to calculate the diffraction pattern with coherent planar faults. Their DIFFaX program is rather easy to apply to even complex structures such as zeolite beta (Newsam et al., 1988) and intergrowths.

Delmas and Tessier (1997) correlated the broadening observed in $Ni(OH)_2$ to stacking faults. The occurrence of fcc domains in the hcp of oxygen can be related to the electrochemical behavior of this material used as electrodes in batteries and explains unexpected Raman bands. The work by Roessli et al. (1993) emphasizes the fact that when diffracting with neutrons magnetic stacking faults can also occur. In their low-temperature measurements of $HoBa_2Cu_3O_7$, the magnetic superstructure reflections show remarkably different widths and shapes: asymmetric, e.g., $0, \frac{1}{2}, \frac{1}{2}$; broad but symmetric, $0, \frac{1}{2}, \frac{3}{2}$; and narrow and resolution limited, $1, \frac{1}{2}, \frac{1}{2}$. They can be explained by an interplay of the q dependence of the magnetic form factor and finite magnetic correlations on the order of 30 Å along the c axis. The latter is the equivalent to magnetic stacking faults along the c axis.

The Rietveld Method

The Rietveld method makes use of the fact that the peak shapes of Bragg reflections can be described analytically and the variation of their widths (FWHM) with the scattering angle 2θ can be expressed as a convolution of optical characteristics depending on the diffractometer (take-off angle of the monochromator and collimation) and sample-related effects such as strain and particle size broadening effects, as discussed above.

This allows least-squares refinements of crystal structure parameters without explicitly extracting structure factors or integrated intensities. For details with respect to reliability factors and estimated standard deviations, see Appendices A and B. Less frequently, one finds studies relying on a two-stage approach where individual intensities are extracted (Jansen et al., 1988).

The Rietveld algorithm fits the observed diffraction pattern using as variables the optical characteristics and the structural parameters. A function

$$M = \sum w_i (y_i - y_{c,i})^2 \qquad (21)$$

is minimized, where $w_i = 1/\sigma_i^2$ is the weight assigned to an individually measured intensity y_i at step i, σ is the variance assigned to the observation y_i, and $y_{c,i}$ is the calculated intensity at step i. The calculated intensities $y_{c,i}$ are obtained by adding the contributions stemming from the contributions of the overlapping Bragg reflections to the background $y_{b,i}$:

$$y_{c,i} = y_{b,i} + \sum_i s_\phi \sum j_{\phi k} \mathrm{Lp}_{\phi k} O_{\phi k} |F_{\phi k}|^2 \Omega_{i\phi k} \qquad (22)$$

The first sum adds all the various contributions from different phases ϕ; the second sum adds all contributions from different reflections k. The scale factor S_ϕ is proportional to the volume fraction of the phase, $j_{\phi k}$ is the multiplicity of the kth reflection, $\mathrm{Lp}_{\phi k}$ is the Lorentz factor, $O_{\phi k}$ is a factor describing any mesoscopic effects (particle size, strain, preferred orientation), $F_{\phi k}$ is the nuclear and magnetic structure factor including the displacement contributions, and $\Omega_{i\phi k}$ describes the peak profile function of reflection k. A well-defined and symmetrical peak profile function that can be parameterized by a small number of variables and whose 2θ dependency can be described by Cagliotti et al. (1958) equation or similar functions is advantageous. It will result in fewer correlations between the so-called machine parameters and the structural parameters (positional coordinates and displacement parameters). A not well-defined peak shape leads to "unstable" least-squares refinements and larger errors of the refined structural parameters. The density of reflections increases tremendously with increasing 2θ, and the quality of the Rietveld fit relies on the separation of close d spacings at higher scattering angles. This separation will benefit from the highest resolution available at high scattering angles and a well-understood peak shape. Furthermore, as shown above, certain mesoscopic effects manifest themselves as deviations of the peak shape at high scattering angles.

Quantitative Phase Analysis

In the absence of severe absorption, the intensity diffracted by a crystalline phase is proportional to the amount of irradiated material. The Rietveld method can be used to extract the structures and volume fractions of individual phases when phase mixtures are present (Hill and Howard, 1987; Bish and Howard, 1988). One just has to sum over the contributions of all phases present represented by their individual scale factor proportional to the volume fraction of the phase. When measuring in

the Debye-Scherrer geometry, the scale factor for each phase is proportional to

$$a_j \propto \frac{m_j}{(ZMV_c)_j} \tag{23}$$

with M being the mass per formula unit of the phase, Z the number of formula units per unit cell, and V_c the volume of the unit cell. By constraining the sum of the weight fractions to unity, one can determine the relative weight of any component of a mixture. This is an implicit constraint since one assumes no amorphous phase to be present. Adding an internal standard to the sample allows determination of absolute weight fractions. Even in severe overlap one can determine the weight fractions of phase mixtures. The high-resolution neutron powder diffraction pattern of the Zn_3N_2 and ZnO mixture depicted in Figure 4 was refined as a two-phase mixture revealing that the sample contains 10% ZnO as an impurity phase. Any refinements that did not take into account ZnO resulted in poor fits and unreliable Zn_3N_2 parameters.

Partial Structure Determination

In many structural investigations using neutron powder diffraction, a large portion of the crystallographic structure is already known but the location of a few atoms remains elusive. When solving and refining structures using x-ray powder diffraction data, often low-Z elements cannot be located with high enough precision and accuracy. Then neutron powder diffraction becomes essential to fully determine and understand the structure. This is the case when hydrogen or lithium is present as extra framework atoms in zeolites or silicates (Paulus et al., 1990; Vogt et al., 1990). The location of organic molecules in zeolites opened up an important application for neutron powder diffraction. In such cases the known fragment of the structure is refined against the diffraction data using the Rietveld refinement technique, and a difference Fourier map based on the difference between experimentally observed and calculated structure factors of the known fragment using the calculated phases is constructed:

$$\Delta(hkl) = |F_{obs}(hkl)| - |F_{calc}(hkl)| \tag{24}$$

This map will in many cases reveal the positions of the missing atoms as peaks. Rotella et al. (1982) used this approach to locate the deuterium atoms in $DTaWO_6$. In certain cases even nondeuterated samples can be investigated: Harrison et al. (1995) measured the neutron powder diffraction pattern of $(NH_4)_2(WO_3)_3SeO_3$ and using difference Fourier techniques were able to determine the four hydrogen atoms as negative peaks (due to their negative scattering length). One hydrogen reveals larger displacement parameters than the other three. Examining the structure revealed that this was the only hydrogen not involved in hydrogen bonding. The interpretation of difference Fourier maps is not always as straightforward as described above due to noise introduced by series termination errors (Prince, 1994). An alternative to locate atoms, especially extra framework cations in zeolites, is the maximum-entropy technique (Papoular and Cox, 1995). This technique is based on Bayesian analysis and the use of entropy maximization in crystallography (Bricogne, 1991). The use in powder diffraction was pioneered by Antoniadis et al. (1990).

Ab Initio Structure Determination from Power Data

The development of high-resolution neutron powder diffractometers with their high angular 2θ resolution resulted in a dramatic reduction of peak overlap in the neutron powder diffraction pattern. Although solving structures from powder diffraction data alone is by no means as straightforward as when using single-crystal diffraction data, more and more structures of important materials are determined this way. Many times a combination of electron, x-ray, and neutron diffraction is used. The complexities of structures being solved is impressive: Morris et al. (1992) solved and refined the structure of $Ga_2(HPO_3)_3 \cdot 4H_2O$, a novel framework structure with 29 atoms in the asymmetric unit cell and 171 structural parameters by combining the use of synchrotron x-ray and neutron powder diffraction data. From high-resolution neutron powder diffraction data alone, Buttrey et al. (1994) determined the structure of the high-temperature polymorph of Bi_2MoO_6. This monoclinic structure has 36 atoms in the asymmetric unit cell and was refined using 146 structural parameters. In another structure determination using synchrotron x-ray and neutron powder diffraction data, Morris et al. (1994) solved the structure of $La_3Ti_5Al_{15}O_{37}$ with 60 atoms in the asymmetric unit and 183 structural parameters. The successive steps of such an *ab initio* structure determination are presented in the following paragraphs.

Indexing. Before intensities can be extracted, one has to determine the unit cell and space group. Using single peak-fitting routines, individual d spacings are determined. It is very important in this step that systematic errors are eliminated as much as possible. In neutron powder diffraction data, the two most serious errors that will determine success or failure when indexing are (1) the low-angle asymmetry due to axial divergence (see above) and (2) the zero-point shift of the detector. One way to determine the zero point of the detector is to mix the sample with a known standard such as silicon and thus "sacrifice" a certain amount of material for indexing purposes. Another approach is to determine the zero-point shift in a separate experiment with a known standard since the mechanical reproducibility is in general $<0.01^\circ$ with state-of-the-art equipment such as absolute encoders. If possible, one should also attempt to use larger wavelengths, if available, since the peak overlap will be further reduced in 2θ, as can be seen from Bragg's law. However, any wavelength with $\lambda/2$ components should be avoided. Any presence of even minute impurity phases will make the task of indexing the powder pattern more difficult and in many cases impossible, especially when dealing with low-symmetry structures. The pattern of the Zn_3N_2-ZnO mixture shown in Figure 4 shows the effect an impurity phase would have. Peak splitting and slight shoulders

in the low-angle 2θ region could lead to the wrong assumption that the structure actually has a lower symmetry. The significant better angular resolution of synchrotron x-ray powder diffraction data due to almost ten times smaller FWHMs can be of great help if one runs into problems with large unit cells and low-symmetry space groups. Once reliable d spacings have been extracted, several computer programs for indexing are available. They are based on various strategies ranging from trial and error, deductive determination, and semiexhaustive to exhaustive search algorithms. Certain programs work better for low-symmetry space groups, others for high-symmetry ones. An overview of these techniques is given by Shirley (1984). In general, indexing programs will give the user more than one solution each associated with a certain quality factor value. The most common quality factor used is M_{20} and is defined as

$$M_{20} = \frac{Q_{\text{calc}}^{\max}}{2N_{\text{calc}}\langle\delta\rangle} \tag{25}$$

using the first 20 peak positions where $Q = 1/(d_{hkl})^2$, N_{calc} is the number of potentially observable calculated lines up to the last indexed line, and $\langle\delta\rangle$ is the absolute mean difference in Q between experimental and calculated peak positions. As a general rule of thumb, any solution with an $M_{20} < 10$ is suspicious, whereas solutions with $M_{20} > 20$ are generally correct. Another common "quality factor" is F_N:

$$F_N = \frac{N}{\langle|\Delta(2\theta)|\rangle N_{\text{possible}}} \tag{26}$$

In this case, N_{possible} is the number of possible peak positions out to the Nth observed peak.

The most popular autoindexing programs are ITO (Visser, 1969), TREOR (Werner et al., 1985), and DIVCOL (Louër and Vargas, 1982).

The space group can be determined the "old fashioned" way by comparing the various extinction rules listed, e.g., in the International Tables (IUC, 1992). Certain program suites provide little search routines for this purpose (e.g., Byrom and Lucas, 1991).

The Extraction of Individual Structure Factors. Once the cell parameters and the space group are known, a full cell-constrained profile refinement can be performed. The individual intensities are treated as variables together with the unit cell parameters, the zero-point shift, and other "machine parameters" such as the U, V, and W coefficients (Appendix A), the asymmetry parameter, and any other parameters describing the peak shape. Cell-constrained refinements were first proposed by Pawley (1981). However, in the original procedure all peaks that occurred within a given angular range were generated from the starting cell parameters and then their intensities were refined in a least-squares procedure together with the machine parameters and the cell constants. These led to large correlations among the parameters and ill conditioning of the least-squares fit, often resulting in divergence. The use of the individual intensities in the least-squares refinement resulted in enormous normal equations and the major cause of instabilities (see Basics of Crystallographic Refinements). A computationally more stable algorithm was proposed by J.C. Taylor and first implemented by LeBail et al. (1988). The integrated intensities of the individual reflections are not used in the least-squares process but are instead calculated by iteration starting from crudely estimated intensities. However, due to this iterative process, the errors assigned to the individual intensities are no longer correct in the sense that they represent the counting statistics. These are crucial for the subsequent step in an *ab initio* structure determination. Therefore, according to Pawley, a cell-constrained refinement should be used as a last step to obtain correct errors. Furthermore, the errors of completely overlapping reflection should be assigned with the method derived by David (1987).

Structure Solution. All known standard structure solution techniques can be applied (Christensen et al., 1985, 1989; Cheetham, 1986; Cheetham and Wilkinson, 1991). Often trial-and-error attempts based on a good knowledge of crystal chemistry are successful. The two main methods are Patterson methods and direct methods. Patterson methods are based on the use of the autocorrelation function:

$$P(x,y,z) = \frac{1}{V^2}\sum\sum\sum F_{hkl}^2 \cos 2\pi(hx + ky + lz) \tag{27}$$

They are easy to calculate but often difficult to interpret since they represent interatomic vectors rather than atomic positions. If heavy scatterers are present, they will dominate the Patterson maps. Therefore, the success rate with x-ray data sets is higher than with neutron data sets, where the scattering power is in general more equally distributed among the atoms. Structures are frequently solved more easily using direct methods based on probabilistic relations between intensities and phases of the structure factors when neutron data are available. Other less-frequently used approaches to solve structures from powder diffraction only are (1) the MEDIC algorithm based on Patterson map deconvolution (Rius and Miravitles, 1988), (2) methods based on statistical mechanics such as simulated annealing using the R factor as a cost function (Semenovskaya et al., 1985), (3) image reconstruction techniques (Johnson and Davide, 1987), (4) the increasingly popular maximum-entropy approach (David, 1990, Gilmore et al., 1993), and (5) a recently very promising genetic algorithm for fitting trial structures against measured powder diffraction data (Shankland et al., 1997).

Time-Dependent Neutron Powder Diffraction

The combination of powerful neutron sources and the development of fast detectors allows diffraction experiments to be recorded within a few minutes and in some cases even in a few seconds. We can thus observe rapid changes. With the new high-intensity diffractometer D20

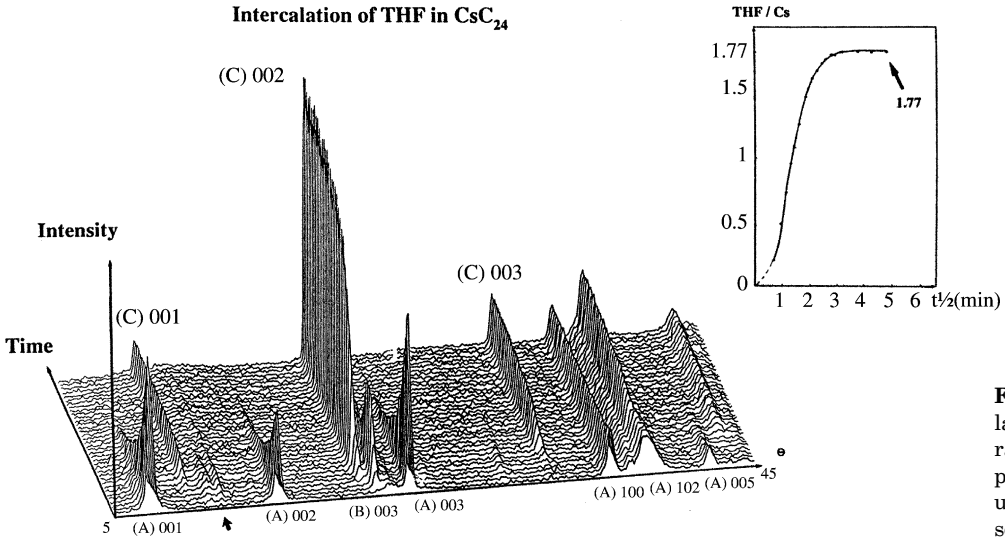

Figure 8. Evolution of the intercalation of deuterated tetrahydrofuran in CsC_{24} with time: a transient phase with a life time of a few minutes as indicated by arrow can be seen.

at the ILL (Convert et al., 1997) and the GEM project at the spallation source ISIS in the United Kingdom, neutron powder diffraction will open up the "time domain" for chemists and material scientists in an unprecedented manner. The temporal information gained during a chemical or physical process can be very important and opens up the study of chemical reactions by identifying intermediate crystalline species as well as the study of phase transformations in general. The notion of a static chemical structure "frozen in space" is being replaced by the dynamics of an evolving system. Time-dependent diffraction experiments are performed by externally perturbing a sample and then monitoring the relaxation of this sample back toward equilibrium. The time it takes to perform a single measurement will be shorter than the relaxation time of the process. The external perturbation can be temperature, pressure, magnetic, or electric field. It can be applied once or in a cyclic fashion. Two distinctions can be made with respect to the observed processes: First, in nonreversible processes time dependence is monitored by recording data sequentially. Second, in reversible processes the relaxation time of the process can be much shorter than the time it takes to record a pattern with good statistics. In such an experiment the perturbation time is divided into different time slices, and the data are recorded and accumulated over many cycles. Reversible processes in the range of 10 ms were observed using a special variable-time-delay electronics at the D20 prototype by Convert et al. (1990).

The use of position-sensitive detectors (PSDs) in thermal neutron scattering (Convert and Forsyth, 1983) in the late 1970s triggered these investigations. The low-resolution high-intensity diffractometer D1B at the ILL was increasingly being used by chemists and material scientists to identify intermediate and transient crystalline species during chemical reactions and phase transformations. Pannetier (1986, 1988) performed the groundbreaking work in this field. Besides qualitative studies, time-dependent studies allow in a quantitative way the determination of the kinetic laws governing the transformations. This is done by measuring the volume fraction of each phase as a function of time. By monitoring the normalized intensities of a few strong reflections, one can determine a time-dependent volume fraction $\alpha(t) = I(t) - I(0)/I(\infty) - I(0)$ for an appearing and $\alpha(t) = I(\infty) - I(t)/I(\infty) - I(0)$ for a disappearing phase. The temporal evolution of α can be described in very simple terms of nucleation and growth (Christian, 1975) using the so-called Avrami-Erofeev equation: $a(t) = 1 - \exp[-k_T(t)^n]$, where the exponent n is a constant related to the dimensionality of nucleation and growth [$3 \leq n \leq 4$ for a three-dimensional (3D) process] and $k_T(t)$ the kinetic constant of the reaction depending on the temperature.

Examples in this field are the pressure-induced NaCl-to-CsCl type structural transformation in RbI (Yamada et al., 1984) and the solid-gas reaction of tetrahydrofuran (THF) vapor with the second-stage graphite intercalation compound CsC_{24}. The latter reaction takes place over a few hours at room temperature. The temporal evolution of this chemical system is shown in Figure 8. Goldman et al. (1988) identified the distinct steps in this reaction: CsC_{24} vanishes rapidly as an intermediate $CsC_{24}(THF)_x$ with $x \approx 1$ evolves. This intermediate phase, indicated by the arrow in Figure 8, has a lifetime on the order of minutes until the final first-stage intermediate $CsC_{24}(THF)_{\sim 1.8}$ appears. There were no indications from the bulk properties that this structural intermediate exists.

Neutron powder diffraction studies, combined with the unique capabilities of neutrons to alter the scattering lengths by the right mixture of isotopes, was shown earlier to be a very powerful tool, especially in site-disordered alloys. In time-dependent studies, this can be used as a "marker" for the specific element during transformations, as the following example illustrates: the discovery of quasicrystalline Al-Mn alloys with long-range icosahedral symmetry (Schechtman et al., 1984) led to many intriguing questions. One of them was what happens when these quasicrystals transform to "normal" crystalline alloys? Substituting part of the Mn ($b_{coh} = -3.73$ fm) with various amounts of Fe ($b_{coh} = 9.54$ fm) allows again the formation

of a "zero-scattering" composition, namely $Mn_{0.72}Fe_{0.28}$ in the transition metal sublattice. Comparing $Al_{85}Si(Mn_{0.72}Fe_{0.28})_{14}$ with $Al_{85}SiMn_{14}$ revealed diffuse scattering at the onset of crystallization of the latter but not in the case of the zero-scattering alloy. It appears that the transformation is an order-disorder transition involving the transition metal sublattice and not the Al subnetwork (Pannetier et al., 1987).

Another increasingly popular time-dependent structural investigation is the *in situ* electrochemical experiment. Using electrochemical cells directly in the neutron beam, Latoche et al. (1992) investigated the structural changes taking place in a $LaNi_{4.5}Al_{0.5}Dx$ electrode during charge and discharge. Phases with out-of-equilibrium cell parameters were observed and related to the charge-discharge rate. In the near future more and more studies using high-intensity neutron powder diffractometers to probe the time dependency of chemical processes will become feasible due to new and powerful machines currently under construction or close to completion.

PROBLEMS

Basics of Crystallographic Refinements

An increasing sophistication in data collection and correction procedures for absorption, extinction, preferred orientation, strain, particle size, and asymmetry due to axial divergence has substantially enhanced the quality of data available nowadays from modern neutron powder diffractometers. However, the misuse of Rietveld refinement programs, perhaps through failure to grasp the principles, sometimes leads to poor refinements of high-quality data. With increasing complexity (large unit cell, low symmetry) of the investigated structures, the need to use restraints and constraints in the refinement to limit parameter space and achieve convergence is becoming increasingly important. The following is an attempt to shed some light onto the mystery of modern refinement strategies.

Any structural refinement program for x-ray, neutron, or electron diffraction data obtained from gases, liquids, or powder or single crystal will provide a model for the pattern of electron or nuclear density describing the atomic structure. We have well-established and proven theories of the interaction of x rays, neutrons (mainly kinematical scattering), and electrons (dynamical scattering) with the electrons (in the case of x rays and electrons) and nuclei (in the case of neutrons) of the investigated matter. Given high-quality observations of scattering amplitudes and estimates of phases, we can compute electron or nuclear density by using a 3D Fourier summation of structure factors. Crystallography is about defining and refining these models.

Detailed references for a full mathematical background of least-squares techniques can be found in Press (1986) and Prince (1994). Here is the "poor man's version":

We have a mathematical expression for Y_c (calculated intensities) as a function of variables x_i (positional and displacement parameters) whose values we wish to determine. We have experimental values Y_0 from our diffraction experiment. Expanding Y_c as a Taylor series in x_i, we determine shifts δx zthat will be applied to the initial values of x to improve Y_c, thus minimizing the difference between Y_0 and Y_c:

$$Y_{\text{old}} + \left(\frac{\partial Y}{\partial x_1}\right)\delta x_1 + \left(\frac{\partial Y}{\partial x_2}\right)\delta x_2 \cdots = Y_{\text{new}} \tag{28}$$

By minimizing,

$$Y_0 - Y_c = \sum \left(\frac{\partial Y}{\partial x_i}\right)\delta x_i \tag{29}$$

we express all individual equations in matrices as

$$\mathbf{A}\,\delta x = \mathbf{y} \tag{30}$$

Multiplying both sides by $\mathbf{A}'$, the transpose of $\mathbf{A}$, we obtain the so-called normal equations:

$$\mathbf{H}\,\delta x = \mathbf{A}'\mathbf{y} = \mathbf{r} \tag{31}$$

The normal matrix $\mathbf{H}$ is square and made up of terms $h_{ij} = \Sigma(\partial Y_m/\partial x_i)\,(\partial Y_m/\partial x_j)$ and $\mathbf{r}$ is a vector of terms

$$r_i = \sum \left(\frac{\partial y_m}{\partial x_i}\right)(Y_{\text{obs}} - Y_{\text{calc}}) \tag{32}$$

Solving these equations for δx leads to

$$\delta x = \mathbf{H}^{-1}\mathbf{r} \tag{33}$$

As is standard practice in crystallography, the least-squares errors, the estimated standard deviations, are obtained from the diagonal elements of the variance-covariance matrix and the goodness-of-fit index S:

$$\sigma_i = S_{\text{wp}} A^{-1/2} \tag{34}$$

with $S_{\text{wp}} = [\sum w_i (y_{i,\text{obs}} - y_{i,\text{calc}})^2/(N_0 - N_{\text{par}})^2]^{1/2}$, where N_0 is the number of profile points and N_{par} the number of parameters used. Prince (1981) has criticized this procedure. A recent summary of this highly controversial and statistically unsound procedure is given by Post and Bish (1989). The underlying assumption that a proper weighting scheme is being used is questionable. As a "rule of thumb," the calculated estimated standard deviations tend to underestimate the "true" error by a factor of 2 to 3 for positional parameters and even more in the case of displacement parameters and site occupancies (see Appendix C).

The most used refinement algorithm is a weighted least-squares algorithm that minimizes χ^2. For more details on statistics, see Prince (1994). This assumes that the distribution of the random variable is due to counting statistics and is Gaussian. If the errors of the observations are independent and normally distributed, one obtains the correct estimates of the parameters. If this is no longer true due to, e.g., low counting statistics, other better suited methods should be used. In this case, a Poisson distribution might better represent the experimental errors and

the maximum-likelihood method used (Antoniadis et al., 1990). Currently, one Rietveld program (FULLPROF) has this option incorporated. With good counting statistics, maximum-likelihood and minimum-χ^2 methods give the same results. The maximum-likelihood method is an iteratively reweighted least-squares fit. The weights are determined by the fit. This is in marked difference to the weighted least-squares fit where the weights determine the fit.

Constraints

Constraints and restraints are both assumptions made about the solutions to crystallographic problems. In the case of a restraint, the solution is more tightly restrained to satisfy the assumption the greater our confidence is in the assumption. When using a constraint, we insist that this assumption is obeyed. In the early literature (Rollet, 1965), restraints were often referred to as "slack constraints." We can subdivide constraints into explicit and implicit constraints. Implicit constraints are implied to be without appreciable errors, and our model will be implicitly constrained by the fact that we are using these corrections and assumptions. Examples of implicit constraints are the corrections for Lorentz polarization, absorption corrections, the scattering lengths used in neutron diffraction, and the form factors used in x-ray or magnetic neutron scattering. The assumption that no significant amorphous phase is present in a phase mixture is also an implicit constraint when refining multiphase mixtures and attempting to determine weight fractions. Any errors in these implicit constraints will lead to errors in the final model that are not accounted for by the estimated standard deviations of the refined parameters. In neutron powder diffraction refinements, these considerations are generally applicable to refinements where the choice of form factors will crucially influence the refined magnetic moment, or for instance an incorrect absorption correction will bias the nonharmonic expansion of the anisotropic displacement parameters. To extract physically meaningful information from displacement parameters, one has to deal with implicit constraints in an appropriate manner. Explicit constraints are choices we make in the course of a refinement. The peak shape is an important but often overlooked one. The choice of space groups is an obvious one. In many refinements, it is difficult to decide if a structure is better described in a high-symmetry space group than in a lower symmetry space group with more variables that are highly correlated and lead to an unstable refinement. One solution to this problem is to refine in the lower space group but apply symmetry constraints between certain atoms related by pseudomirror planes. Using the same parameters but assigning opposite signs to the two atoms will achieve this. Coupling the parameters of these atom pairs leads to only one pair of least-squares parameters, thus reducing correlations and leading to a well-converging refinement. Thus, although the structure is described in a lower symmetry space group, the use of explicit constraints introduces symmetry elements from a higher symmetry space group. Another "classical" pitfall in refinements is the need to impose a constraint when describing the model in certain space groups where the origin is not fixed by symmetry such as $P1$, Pc, and $P2$. If there is no fixed origin, the normal matrix will be singular. The solution is to fix a certain atom. This is done by not refining, e.g., the z coordinate in space group $P2$. However, this position will not have an estimated standard deviation and all estimated standard deviations of the z components of the other atoms will therefore be biased. Using the variance-covariance matrix is the appropriate way to extract the correct estimated standard deviations in such a case (Prince, 1994). Another problem often occurring is site disorder. This can be the case of two different atomic species occupying or partially occupying the same site. In both cases, the total occupancy can be an explicit constraint. Many problems in refinements are concerned with the displacement parameters. They are often loosely referred to as "temperature factors." The question arises if a given atom has an isotropic or anisotropic displacement parameter. This choice will influence the bond distances to the neighboring atoms. Sometimes, even anisotropic displacement parameters are not the solution to the problem. One might have to describe rigid units of the structure by using a TLS model (Prince, 1994). The T stands for translation, the L for libration, and the S for screw movement of the rigid group. The right choice of the rigid unit and explicit constraints (e.g., all translational components of the fragments are the same) is crucial and will influence the final R factors (see Appendix B). Often, rigid-body constraints are used to lead the refinement in the right direction. Certain structural coordination polyhedra such as octahedra or tetrahedra are initially constrained to a rigid unit with an "ideal" geometry. The individual atomic parameters are replaced by a total of six parameters, three defining a rotation, three a translation. The significant reduction of parameters from $3n$ to 6 for n atoms reduces the complexity of the normal matrix substantially and generally leads to a smoother refinement. In the initial states of an attempt to solve the structure of SF_6, Cockcroft and Firch (1988) applied such chemical constraints to preserve the SF_6 octahedra in refinements against high-resolution neutron powder diffraction data. This resulted in a smooth convergence to a model, which was then the starting model for further refinements.

Restraints

Restraints, or "slack or soft constraints" as they are referred to in the older literature (Waser, 1963; Rollet, 1965), are ways of influencing the refinement by introducing other observables Y_{obs}. These new observables are then subject to the same mathematical treatment as the "real" experimental observables (intensities). They are added into the normal matrix and the $\mathbf{r}$ vector. Additional variables can be as simple as a dummy atom needed to restrain planarity in a benzene molecule, a nonbonding restraint to avoid overly unphysical distances during the refinement, or the restraints with respect to refining combined x-ray and neutron diffraction data sets. It is important to consider the weights applied to these supplemental observations or subsidiary conditions, as they are also sometimes called, when refining with restraints. If there

are only few restraints, then we can assign a desired estimated standard deviation to them and scale them to the weighted residual for the intensities (Rollet, 1965). The most widely used restraint is the bond restraint:

$$(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2 = d^2 \qquad (35)$$

The value for d is generally taken from the literature. Six parameters are coupled. In the refinement $d^2 = \Delta x' \mathbf{G} \Delta x$, with $\mathbf{G}$ being the metric tensor. Differentiating leads to

$$\frac{\partial d}{\partial x_1} = \frac{g_{11}\Delta x + g_{12}\Delta y + g_{13}\Delta z}{d} \qquad (36)$$

and

$$\frac{\partial d}{\partial x_2} = \frac{g_{11}\Delta x + g_{12}\Delta y + g_{13}\Delta z}{d} \qquad (37)$$

However, note that the position within the unit cell is not fixed. If used alone, this will lead to a singular matrix. For fairly rigid units, this type of constraint is quite appropriate since the assigned estimated standard deviation is symmetric. When trying to mimic, for example, van der Waals interactions, one might want to use an "asymmetric" estimated standard deviation. Using a "penalty function" can achieve this by calculating an energy using a van der Waals potential involving the restraints. This takes into account the fact that when dealing with van der Waals interactions, you accept longer but not shorter interactions as physically sensible.

KEY REFERENCES

Bish, D. L. and Post, J. E. 1989. Modern Powder Diffraction, Reviews in Mineralogy, Vol. 20. The Mineralogical Society of America, Washington, D.C.

Covers neutron powder diffraction as well as x-ray and synchrotron powder diffraction. Contains valuable information with respect to experimental procedures and data analysis.

Young, R. A. 1993. The Rietveld Method. International Union of Crystallography. Oxford University Press, New York.

Provides an excellent introduction to modern Rietveld refinement techniques and neutron powder diffraction using pulsed sources and reactor-based instruments. The 15 parts are written by acknowledged researchers who cover the field in theoretical as well as practical aspects. Highly recommended.

APPENDIX A: OPTICS OF A CONSTANT WAVELENGTH DIFFRACTOMETER

The Cagliotti coefficients U, V, and W are functions of the collimators α_1, α_2, and α_3, of the mosaic spread β of the monochromator crystals and the monochromator scattering angle ("take-off" angle) θ_m:

$$\mathrm{FWHM} = (U\tan^2\theta + V\tan\theta + W)^{1/2} \tag{38}$$

where

$$U = \frac{4(\alpha_1^2\alpha_2^2 + \alpha_1^2\beta^2 + \alpha_2^2\beta^2)}{\tan 2\theta_m(\alpha_1^2 + \alpha_2^2 + 4\beta^2)} \tag{39}$$

$$V = -\frac{4\alpha_2^2(\alpha_1^2 + 2\beta^2)}{\tan\theta_m(\alpha_1^2 + \alpha_2^2 + 4\beta^2)} \tag{40}$$

$$W = \frac{\alpha_1^2\alpha_2^2 + \alpha_1^2\alpha_3^2 + \alpha_2^2\alpha_3^2 + 4\beta^2(\alpha_2^2 + \alpha_3^2)}{\alpha_1^2 + \alpha_2^2 + 4\beta^2} \tag{41}$$

and with a minimum of the FWHM at

$$\left(W - \frac{V^2}{4U}\right)^{1/2} \tag{42}$$

Here, α_1, α_2, α_3 are the beam divergences of the in-pile, monochromator-sample, and sample-detector collimators, respectively. This FWHM can be rewritten as

$$\mathrm{FWHM} = \frac{N}{(\alpha_1^2 + \alpha_2^2 + 4\beta^2)^{1/2}} \tag{43}$$

where

$$N = \left(\frac{\alpha_1^2\alpha_2^2 + \alpha_1^2\alpha_3^2 + \alpha_2^2\alpha_3^2 + 4\beta^2(\alpha_2^2 + \alpha_3^2)}{(\alpha_1^2 + \alpha_2^2 + 4\beta^2) - 4a\alpha_2^2(\alpha_1^2 + 2\beta^2) + 4a^2(\alpha_1^2\alpha_2^2 + \alpha_1^2\beta^2 + \alpha_2^2\beta^2}\right)^{1/2} \tag{44}$$

$$a = \frac{\tan\theta}{\tan\theta_m} \tag{45}$$

θ, being the Bragg angle. An important result is that the FWHM decreases with N and N becomes smaller the closer θ is to the take-off angle θ_m. The best resolution of a neutron powder diffractometer will be near the take-off position. After the take-off position, the FWHM increases considerably. For high-resolution purposes, one will attempt to use a take-off angle as high as possible. The diffractometer D2B at the ILL has a θ_m of 135°, and the HRNPD at Brookhaven National Laboratory has a θ_m of 120°.

APPENDIX B: RELIABILITY FACTORS

One of the most debated areas of Rietveld refinement is of the the so-called reliability factors, often called "R factors," which assess the quality of the model with respect to the data. In a least-squares refinement, one minimizes R. Therefore, the choice of R is nontrivial. The two most-used R factors in a Rietveld refinement are the profile R factor R_p and the weighted profile R factor R_{wp}:

$$R_p = \frac{\sum |y_i - y_{i,\mathrm{calc}}|}{\sum y_i} \tag{46}$$

$$R_{wp} = \left(\frac{m}{\sum w_i y_I^2}\right)^{1/2} \tag{47}$$

where $M = \Sigma w_i (y_i - y_{i,\mathrm{calc}})^2$ is the actual function the refinement routine is minimizing and $w_i = 1/\sigma_i^2$ the weight assigned to the observed intensity y_i at step i, σ_i being the variance of observation y_i and $y_{i,\mathrm{calc}}$ the calculated intensity at the ith step of the pattern. Another important R factor is

$$R_{\mathrm{Bragg}} = \frac{\sum |I_i - I_{i,\mathrm{calc}}|}{\sum I_i} \tag{48}$$

which is a reliability factor commonly used in refinements of integrated intensity data. The term I_i is the integrated intensities at point i.

The best R factor to judge the agreement between experimental data and the structural model is R_{Bragg}. However, R_{Bragg} is deduced with the help of a model and is therefore biased in favor of the model. This is different when using model-free structure refinement techniques such as maximum-entropy techniques. The R_{Bragg} is also rather insensitive to inadequate modeling of the peak shape and the presence of peaks stemming from other phases. This is not the case with R_{wp}, which depends very much on how well the profile function used describes the peak shape, especially the low-angle asymmetry correction. Therefore, R_{wp} is less sensitive to the structural parameters than R_{Bragg}. Another problem with R_{wp} is that it can be misleadingly small if the refined background is high since it is easier to get a good fit of a slowly varying background than of the Bragg reflections that contain the structural information. This is an important consideration when measuring materials containing hydrogen, since the incoherent scattering will raise the background. Even minute residual hydrogen in deuterated compounds or materials synthesized from hydrogen-containing precursors will result in a higher background.

Other R factors are

$$\chi^2 = \frac{M}{N - P + C} \tag{49}$$

$$R_e = \frac{R_{wp}}{\sqrt{\chi^2}} \tag{50}$$

where N, P, and C are the numbers of data points, refined parameters, and constraints, respectively.

The frequently encountered Durbin-Watson statistic parameters d and Q (Hill and Flack, 1987) measure the correlation between adjacent residuals:

$$d = \frac{\sum [w_i (y_i - y_{i,\mathrm{calc}}) - w_{i-1}(y_{i-1} - y_{i-1,\mathrm{calc}})]^2}{\sum w_1^2 (y_i - y_{i,\mathrm{calc}})^2} \tag{51}$$

Serial correlation is tested at the 99.9% confidence level by comparing d to Q:

$$Q = 2\left(\frac{N-1}{N-P} - \frac{3.0902}{(N+2)^{1/2}}\right) \tag{52}$$

If $d < Q$, there is a positive serial correlation, which means successive residuals will have the same sign. If $Q < d < 4 - Q$, there is no correlation between neighboring points, and if $d > 4 - Q$, there is a negative correlation. The ideal value for d is 2.00. If the calculated and observed profile functions do not match well, there will be a strong correlation of the residuals of neighboring points and the Durbin-Watson d value will be far from 2.00.

APPENDIX C: ESTIMATED STANDARD DEVIATIONS

The question of what is an independent observation N is not only for purists, the reason being that N is used to calculate the estimated standard deviation (esd):

$$\mathrm{esd}_i = \left(\frac{M_{ii}^{-1} \sum w_i (y_i - y_{i,\mathrm{calc}})^2}{N - P + C}\right)^{1/2} \tag{53}$$

where M_{ii}^{-1} is the diagonal in the inverted least-squares matrix, P the number of refined variables, and C the total number of constraints. In Rietveld refinements one uses the number of points measured and not the number of individual reflections I_{hkl} as in single-crystal refinements. The estimated standard deviations are not the probable experimental error; rather they are the minimal possible probable error arising from random errors alone. There are certain systematic errors (e.g., peak shape, background) that arise from implicit constraints that are not considered in the estimated standard deviations. In other words, the experimental reproducibility will only then reflect the estimated standard deviations when the random errors ("counting statistics") are the dominant errors.

Berar and Lelann (1991) showed that the underestimation of the estimated standard deviations is due to serial correlations as assessed by the Durbin-Watson statistics and modified the summation to adjust the estimated standard deviations. An important problem arises when reflections completely overlap and therefore the error associated with the individual intensity has to be assigned. Using a probabilistic method, David (1987) derived a method to deal with these cases.

APPENDIX D: COMPUTER PROGRAMS FOR RIETVELD ANALYSIS

The best source for up-to-date Rietveld refinements programs and other useful programs for powder diffraction are available on the Commission for Powder Diffraction's homepage *www.za.iucr.org/iucr-top/comm/cpd/rietveld.html*. This site provides access to new and updated program versions and should be consulted by anyone looking for powder diffraction–related software.

The first Rietveld refinement code was written in ALGOL by H. M. Rietveld (1969). Hewat (1973) modified the code and converted it to FORTRAN. PROF, as it became known, was the standard program in the early days to analyze neutron powder pattern. A further offspring of the original Rietveld program was MPROF, which featured a modification to incorporate two phase refinements (Bendall et al., 1983).

GSAS Generalized Structure Analysis System, written by Allen C. Larson and Robert B. von Dreele, LANSCE, MS-H805, Los Alamos National Laboratory, Los Alamos, NM 87545. This is one of the most used Rietveld refinement programs in the world, even though, as its name implies, it is a multipurpose program suite. It runs under OPENVMS/VAX, OPENVW/ALPHA, Silicon Graphics IRIX, Ultrix, HPUX, and DOS. This program allows the refinement of fixed wavelength as well as time-of-flight data. It furthermore allows the combined refinement of various powder and single- crystal data sets as well as neutron and x-ray diffraction data and has all the "mesoscopic" features incorporated such as particle size and microstrain as well as a recently added feature for the refinement of texture using spherical harmonics.

Website: *http://www.mist.lansce.lanl.gov*
Author: *vondreele@lanl.gov*

FULLPROF Written by Juan Rodriguez-Carvajal (unpublished). It is also originally based on DBW3.2 but incorporates, among many extensions, the capability to refine microstrain and particle size in a generalized manner. It runs on Vax machines under VMS, on Suns, IBM Riscs, HP Unix, and Silicon Graphics as well as PCs. This program is especially useful for refining magnetic structures. The formula for the magnetic structure factor and its derivatives with respect to the parameters was programmed in a general fashion. The Fourier coefficients can be given either as standard crystallographic or spherical components. The program generates satellite reflections of up to 24 propagation vectors per phase and refines their components in reciprocal lattice units (Rodriguez-Carvajal, 1993). This program allows the user to perform many nonstandard refinements because of user-supplied executables that can be linked to the FULLPROF library. FULLPROF also allows refinements using the maximum-likelihood technique.

Author: *bah@atom.ansto.gov.au* (Brett Hunter)

RIETAN Written by F. Izumi. The program runs on a UNIX platform. It is also a modern Rietveld refinement program that allows the refinement of incommensurate structures as well as superstructures. Furthermore, it also allows the choice of least-squares algorithms (Gauss-Newton, modified Marquardt, and conjugate direction) at the beginning of each refinement cycle, which is very helpful to assure smoother convergence especially in the early stages of a refinement.

Author: *izumi@nirim.go.ip*

XRS-82 Written by C. Baerlocher (1986). It is based on the X-Ray 72 system. This code is particularly interesting for scientist working on the structures of zeolites since it has elaborate constraints and restraints with various stereochemical aspects as well as a learned profile function (Baerlocher, 1993).

PROFIL Written by J. K. Cockcroft. It is a modern Rietveld refinement that was not based on any older versions of code but written completely from scratch. It is a very fast and easy-to-use program resembling SHELX in the way its free format input file is constructed. The output files are very detailed and contain very useful crystallographic information, such as conversion of the various displacement parameters, distances, and angles with estimated standard deviations, correlation matrices, and resolution curves converted in FWHM versus 2θ. This is a program suited for the nonspecialist. It allows the focus to remain on crystallography. Various output files feed into other programs. It also contains a full-profile-refinements option based on LeBails algorithm, which generates input files for use in SHELX-82 direct methods and Patterson techniques.

It should be pointed out that refining neutron powder diffraction data with different Rietveld refinement programs leads to differences that sometimes exceed the determined errors. This was shown by Woodward et al. (1995) when comparing the results of refinements of the same data sets of triclinic and monoclinic WO_3 using the three Rietveld refinement programs GSAS, Rietan, and

PROFIL. Subtle differences in peak shapes, the different low-angle asymmetry corrections for axial divergence, the way the background is accounted for, and the way errors are calculated lead to these discrepancies. In another study, Hill (1992) reported on the results of a Rietveld round robin. The main conclusion was again that the refinement of neutron data showed a rather narrow distribution for the coordinates and anisotropic displacement parameters about the single-crystal values and that the errors are substantially smaller than those of interrefinement variations.

SINGLE-CRYSTAL NEUTRON DIFFRACTION

INTRODUCTION

Single-crystal neutron diffraction measures the elastic Bragg reflection intensities from crystals of a material, the structure of which is the subject of investigation. A single crystal is placed in a beam of neutrons produced at a nuclear reactor or at a proton accelerator-based spallation source. Single-crystal diffraction measurements are commonly made at thermal neutron beam energies, which correspond to neutron wavelengths in the neighborhood of 1 Å. For high-resolution studies requiring shorter wavelengths (~0.3 to 0.8 Å), a pulsed spallation source, or a high-temperature moderator (a "hot source") at a reactor may be used. When complex structures with large unit-cells are under investigation, as is the case in structural biology, a cryogenic-temperature moderator (a "cold source") may be employed to obtain longer neutron wavelengths (~4 to 10 Å). A monochromatic beam technique is generally used at reactors, which normally operate as continuous wave (CW) neutron sources. At spallation sources, which normally are pulsed, a time-of-flight Laue method with a broad range of neutron wavelengths is generally used, and the neutron wavelength is determined from the time-of-flight for neutrons to reach the detector. The type of moderator is again generally optimized for the particular application, in a manner similar to what is the common practice at reactors.

A single-crystal neutron diffraction analysis will determine the crystal structure of the material, typically including its unit cell and space group, the positions of the atomic nuclei and their mean-square displacements, and relevant lattice site occupancies. Because the neutron possesses a magnetic moment, the magnetic structure of the material can be determined as well from the magnetic contribution to the Bragg intensities (see MAGNETIC NEUTRON SCATTERING).

Instruments for single-crystal diffraction (single-crystal diffractometers or SCDs) are generally available among the facilities at the major neutron-scattering centers. Beam time on many of these instruments is available through a proposal mechanism. For a listing of neutron SCD instruments and their corresponding facility contacts, see Table 1.

Complementary and Related Techniques

A number of techniques give information on crystal structure complementary to that provided by single-crystal neutron diffraction. Some of the most important of these are listed below along with brief descriptions. For additional information on these techniques, and their advantages and disadvantages, see the corresponding chapters of *Characterization of Materials* in which they are described. It is worth noting that neutron diffraction is a very expensive proposition, first of all involving the often demanding and time-consuming preparation of large, high-quality crystals (at least 1 mm^3 in volume). Then it is generally necessary to travel to a neutron scattering research center to perform the measurements, which typically require from several days to several weeks. One therefore should be certain that neutron diffraction is the technique of choice for solving the problem at hand—otherwise one of the complementary methods should be considered first.

Single-crystal x-ray diffraction is the method most directly complementary to single-crystal neutron diffraction. The chief difference between the two methods is that, while neutron diffraction images the nuclear scattering density in the crystal, x-ray diffraction images the electron-density distribution. Neutron diffraction therefore has important advantages in studies where hydrogen or other light atoms must be located, or where isotopic substitutions may be of interest, and of course for magnetic structures as well. Magnetic structures can also be studied using x-rays, although there the effect is much smaller, so that synchrotron radiation is generally required. In the special case where the x-ray energy is close to an absorption edge of a magnetic center in the sample, resonance enhancement of the magnetic scattering can produce effects comparable in magnitude to those observed with neutrons. X-ray and neutron diffraction measurements can be combined to good effect in studies seeking detailed information about the valence electron-density distribution in a material, particularly when hydrogen is present (Coppens, 1997).

Powder neutron (NEUTRON POWDER DIFFRACTION) and powder x-ray (X-RAY POWDER DIFFRACTION) diffraction are also powerful techniques for determining crystal structure. For many important classes of materials single crystals may be difficult or even impossible to obtain. Powder diffraction methods have the advantage of wide applicability and generally allow for much more rapid data collection than do single-crystal methods. This makes powder methods ideal for studies of materials over ranges of temperature and pressure, for example, in studies investigating phase transitions, and for in situ real-time studies. The chief disadvantage of powder methods stems from the more limited amount of information obtained in the diffraction pattern, which generally places an upper limit on the complexity of structures that can be satisfactorily treated. Progress in this regard continues at a rapid

pace, however, so that structures with on the order of 100 independent atoms in the crystallographic asymmetric unit may now be considered as suitable candidates for powder studies. Recently, powder-diffraction studies of proteins have even been undertaken, fitting highly constrained structure models to the data (Von Dreele, 1999). Both powder and single-crystal x-ray techniques have been enormously enhanced by the availability of synchrotron x-ray sources, with their high-intensity beams. At the third-generation synchrotron sources, x-ray intensities may be as much as nine or ten orders of magnitude larger than for the most currently available intense neutron beams.

Electron diffraction (Section 11c) is another complementary technique for crystal-structure determination—particularly when studying surfaces and interfaces, where low-energy electron diffraction (LOW-ENERGY ELECTRON DIFFRACTION) is especially powerful, or when only microcrystals are available. Progress in dynamical computations that take multiple scattering into account (n-beam dynamical diffraction computations) is extending the power of electron diffraction for the solution and refinement of crystal structures.

Nuclear magnetic resonance (NUCLEAR MAGNETIC RESONANCE IMAGING) is also a valuable technique for investigating the structure of materials. To cite just one application, high-field solid-state NMR can yield accurate distances between hydrogen atoms and—particularly in materials with high thermal motion or disorder—results may sometimes be more reliable than for comparable interatomic distances obtained from neutron diffraction.

Scope of This Unit

This unit outlines the basic principles of single-crystal neutron diffraction and provides examples to illustrate the range of materials that can be studied. Sufficient practical details are included, it is hoped, to help a non-expert get started with the technique and locate an appropriate neutron diffraction facility. A listing of the instruments that are available at various neutron sources is included in Table 1.

For readers desiring additional background, the classic monograph by Bacon (1975) provides an excellent starting point. Wilson (1999) has recently published an overview that includes a comprehensive survey of neutron diffraction results on molecular materials. For those wishing to investigate the subject in more detail, Marshall and Lovesey (1971) provide an exhaustive theoretical treatment of all aspects of neutron scattering.

PRINCIPLES OF THE METHOD

Single-crystal neutron diffraction measures elastic, coherent scattering, i.e., the Bragg reflection intensities (see X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS). Although the measurements and their interpretation are generally quite straightforward, and amount to a standard crystal-structure analysis analogous to what is done with x rays, neutron structure determinations are still relatively uncommon. This is so because of the limited number of neutron crystallography facilities and the need to obtain large samples in order to observe adequate reflection intensities (see Complementary and Related Techniques). Thus, for example, the contents of a recent release of the Cambridge Structural Database of organic and organometallic crystal structures (Allen and Kennard, 1993) consist of less than 1% neutron-determined structures (the overwhelming majority of the remaining 99% are x-ray-determined structures).

Basic Theory of Single-Crystal Neutron Diffraction

The nuclear scattering density in a crystal may be expressed in terms of the neutron structure factors, $F(h,k,l)$, by the familiar relationship

$$\rho(x,y,z) = \Sigma F(h,k,l)\exp\{-2\pi i(hx+ky+lz)\} \qquad (1)$$

where the Fourier summation (Equation 1) runs over the Miller indices h,k,l, and the coordinates x,y,z are expressed in terms of fractions of the unit-cell translations **a**, **b**, **c**. The nuclear scattering density is simply the atomic probability density at any point multiplied by the corresponding neutron scattering amplitude.

As noted above, neutrons are scattered by the atomic nuclei in a crystal, while x-rays are scattered by the electrons. Because the nuclear radius is $\sim 10^4$ times smaller than the neutron wavelengths that are used in diffraction, the neutron scattering amplitude is a constant independent of the momentum transfer, $Q = 4\pi(\sin\theta/\lambda)$. For x rays, on the other hand, the scattering amplitude, also called the scattering factor or form factor, falls off with increasing Q due to destructive interference of the scattering from different regions of the electron-density cloud. Each isotope has a unique neutron scattering amplitude, but these values lie within the same order of magnitude across the entire periodic table, as illustrated in Figure 1. For x-rays, the scattering amplitude increases with the atomic number of atoms, so that diffraction is dominated by contributions from the high-Z atoms. For this reason, neutron diffraction has important advantages in studies where hydrogen or other light atoms must be located, or

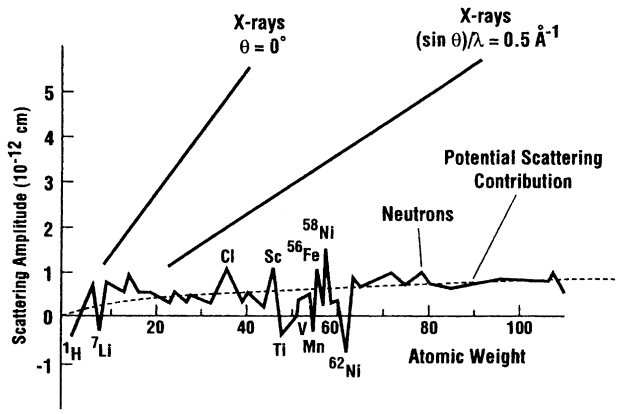

Figure 1. Neutron scattering amplitudes as a function of atomic weight. Adapted from Bacon (1975).

where isotopic substitutions may be of interest, as has been mentioned earlier. Further, because neutron diffraction images the nuclear scattering density in the crystal, it provides an unbiased estimate of the mean nuclear position. X-ray diffraction studies generally assume that the nucleus is located at the centroid of its electron-density cloud. This can be a poor assumption, e.g., where hydrogen atoms form covalent bonds. For example, C-H bond distances determined by x-ray diffraction are systematically shortened by ~0.1 Å due to the effects of bonding on the hydrogen 1*s* electron-density distribution.

It is, of course, not possible to obtain the scattering-density function $\rho(x,y,z)$ directly from the observed diffraction intensities, because of the crystallographic phase problem. In practice, an initial estimate of the neutron structure factor phases is usually obtained from a prior x-ray diffraction study. Probabilistic direct methods of phase determination developed for x-ray structure determination have, however, also been shown to work in the neutron case, e.g., for organic and organometallic crystals (Broach et al., 1979). Direct methods seem to work in practice in spite of the existence of negative scattering density whenever hydrogen is present, which actually contradicts one of the underlying assumptions of direct methods. Phase-determination methods based on anomalous dispersion can also be applied in neutron diffraction for special cases involving crystals that contain one of a handful of highly absorbing elements, including Li, B, Cd, Sm, and Gd (see, e.g., Koetzle and Hamilton, 1975, and references cited therein).

Neutron structure analysis and refinement generally utilizes standard kinematical diffraction theory. According to kinematical theory (see KINEMATIC DIFFRACTION OF X RAYS), the Bragg reflection intensity $I(h,k,l)$ is given by the relationship

$$I(h,k,l) \propto (i_o k\lambda^2 V_c/V^2)|F(h,k,l)|^2 \qquad (2)$$

where i_o is the incident neutron flux, V_c is the crystal volume, V is the unit-cell volume, and $|F(h,k,l)|^2$ is the squared structure factor. The relationship in Equation 2 holds for the monochromatic beam case. For the Laue case, i_o is a function of λ reflecting the neutron flux spectrum incident on the sample. Equation 2 omits the Lorenz term, which must be introduced to correct for the geometrical effect caused by scanning reflections to obtain integrated Bragg intensities.

The structure factor is

$$F(h,k,l) = \Sigma a_i b_i \exp(-W_i)\exp\{2\pi i(hx+ky+lz)\} \qquad (3)$$

where a_i is the atomic site occupancy, b_i is the neutron scattering amplitude, and W_i is the Debye-Waller factor, and the summation in Equation 3 runs over n atoms in the crystallographic unit cell.

From Equations 2 and 3, it is apparent that the diffracted intensity will fall off as the unit-cell volume increases. In order to achieve sufficient diffracted intensity, it is therefore necessary to grow larger single crystals for materials with larger unit cells. The use of longer neutron wavelengths is also highly desirable in this case, e.g., by performing the experiment at an instrument located on a cold moderator beamline.

The Debye-Waller factor W_i takes into account the reduction in diffracted intensity from interference produced by smearing of the scattering density due to thermal motion in the sample. Equation 4 is the isotropic approximation

$$W_i = \exp\{-U_i Q^2/2\} = \exp\{-8\pi^2 U_i(\sin^2\theta/\lambda^2)\} \qquad (4)$$

where U_i is the atomic mean-square displacement (adp). It is often the practice to introduce an anisotropic harmonic model in which second-order tensors are employed to describe the adps. In that case, the Debye-Waller factor is given by

$$\begin{aligned} W_i = \exp\{-2\pi^2(&U_{11}a^{*2}h^2 + U_{22}b^{*2}k^2 \\ &+ U_{33}c^{*2}l^2 + 2U_{12}\boldsymbol{a}^*\bullet\boldsymbol{b}^*hk + 2U_{13}\boldsymbol{a}^*\bullet\boldsymbol{c}^*hl \\ &+ 2U_{23}\boldsymbol{b}^*\bullet\boldsymbol{c}^*kl \end{aligned} \qquad (5)$$

where $\boldsymbol{a}^*$, $\boldsymbol{b}^*$, and $\boldsymbol{c}^*$ are reciprocal lattice vectors. Higher-order tensor descriptions may be used to model anharmonic effects.

Neutron diffraction is often the method of choice in studies aimed at a precise description of thermal motion and/or disorder because it is easier to determine the Debye-Waller factor in the neutron case where the atomic scattering amplitude is a constant independent of Q (see above), and there is therefore minimal correlation between the Debye-Waller factor and the site occupancy. In contrast, the x-ray atomic form factor may assume a Q dependence quite similar to that of the Debye-Waller factor, leading to high correlations in the least-squares minimization approach to structure refinement.

That the neutron scattering amplitude is independent of Q confers an additional advantage not always well appreciated. When diffraction measurements are made at cryogenic temperatures, thereby lowering the adp parameters, neutron Bragg intensities will exhibit a much reduced fall-off with Q compared to the x-ray case. This results in substantially improved precision in the atomic positions.

The standard kinematical theory outlined above ignores the effects of absorption and extinction in real crystals. Absorption is often quite minimal except in the case of crystals that contain hydrogen, where the effective absorption due to hydrogen incoherent scattering can be quite appreciable. The measured neutron intensities can be corrected for absorption using the method of Gaussian integration (Busing and Levy, 1957) or by employing an analytical technique in which the crystal is described in terms of Vornoi polyhedra (Templeton and Templeton, 1973).

The use of large crystals often requires that extinction corrections be included during neutron structure refinement to obtain a satisfactory fit to the strong reflections. A number of formalisms have been developed for this purpose. Perhaps the most widely used is that of Becker and Coppens (1975), which in its most general implementation treats both primary and secondary extinction.

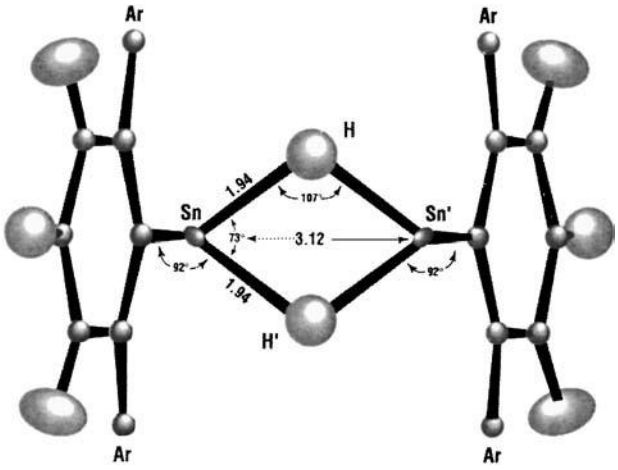

Figure 2. The molecular structure of a tin(II) hydride complex determined by a neutron diffraction study on IPNS SCD at 20 K (Koetzle et al., 2001). Estimated standard deviations in bond distances and angles are less than 0.01 Å and 0.1°, respectively.

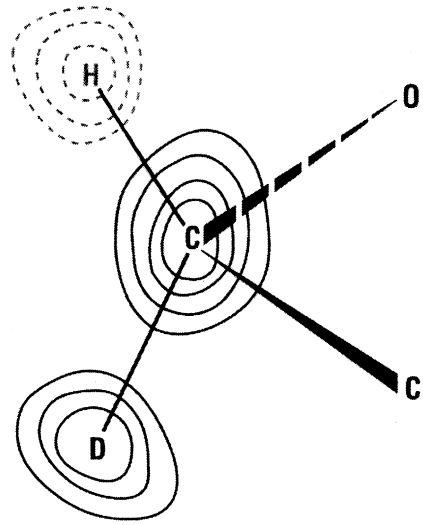

Figure 3. Contoured neutron Fourier map for (+)-neopentyl-1-d-alcohol (S) with positive nuclear scattering density at C and D shown as solid contours and negative nuclear scattering density at H shown as dashed contours (Yuan et al., 1994).

PRACTICAL ASPECTS OF THE METHOD

The initial applications of single-crystal neutron diffraction to the study of molecular structure were carried out at first generation research reactors around 1950. For additional information in this regard, see, e.g., the studies of KHF_2 (Peterson and Levy, 1952) and ice (Peterson and Levy, 1953, 1957) at Oak Ridge National Laboratory and the study of KH_2PO_4 (KDP) at Harwell (Bacon and Pease, 1953, 1955). KDP was also studied independently at about the same time at Oak Ridge (Peterson et al., 1953, 1954). These studies provided an important demonstration of the advantages of neutron diffraction for determining the positions of hydrogen atoms and for studying hydrogen bonding.

Single-crystal methods are being employed at modern reactor and spallation neutron sources to study the structures of a broad range of materials. For example, the tin hydride complex shown in Figure 2 was investigated (Koetzle et al., 2001) using the SCD spectrometer at the Intense Pulsed Neutron Source (IPNS) at Argonne National Laboratory. Collection of Bragg intensity data at a temperature of 20 K for this triclinic crystal with 111 independent atoms, unit-cell volume $V = 1986$ Å^3, and crystal volume $V_c = 15$ mm^3 required 11 days on SCD. Low-temperature studies of this quality allow full, unconstrained refinement of the structure model incorporating anisotropic Debye-Waller factors and readily yield metal-hydrogen bond distances with a precision of better than 0.01 Å. The amount of beam time used by this experiment is quite representative at present at IPNS for this type of organometallic crystal.

Figure 3 shows an application of Fourier methods to single-crystal neutron diffraction data obtained at the Brookhaven National Laboratory High Flux Beam Reactor (HFBR; note that the HFBR neutron source ceased operation in 1999). In this site-specific isotope labeling study of a chiral organic alcohol (Yuan et al., 1994), the neutron Fourier map readily gives the location of the deuterium label that was introduced in an enzymatic hydrogenation reaction.

Figure 4 shows the results of a study of the variation with temperature of the anharmonic thermal motion in the cubic form of ZnS (zincblende; Moss et al., 1980,

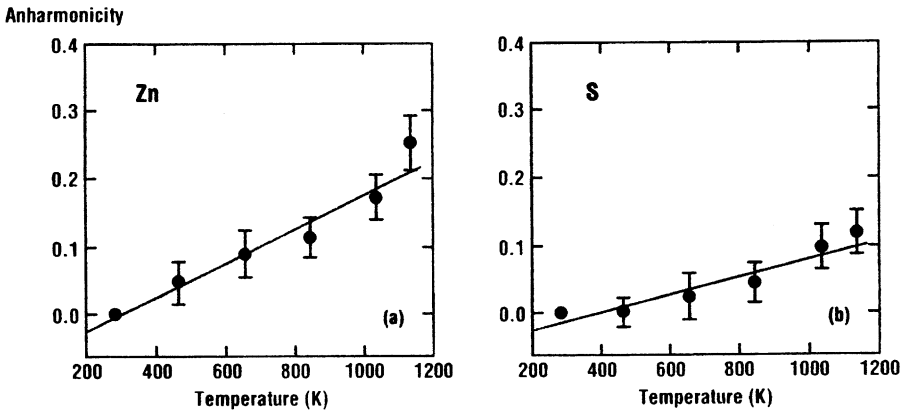

Figure 4. Anharmonicity of atomic displacements in zincblende (ZnS; m.p. 1973 K; cubic phase) as a function of temperature (Moss et al., 1980, 1983).

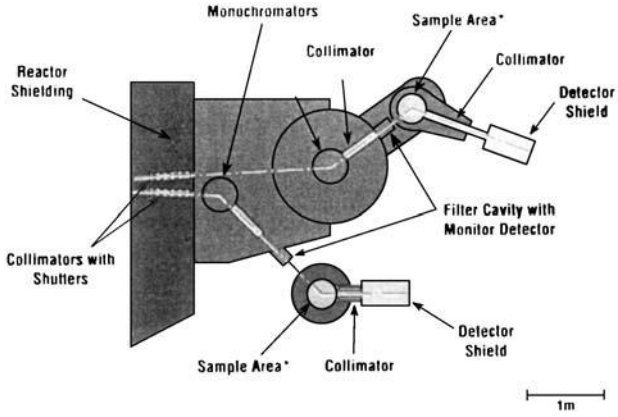

Figure 5. Schematic plan of the SCD spectrometers formerly installed at the dual thermal beam port H6 at the Brookhaven High-Flux Beam Reactor (HFBR).

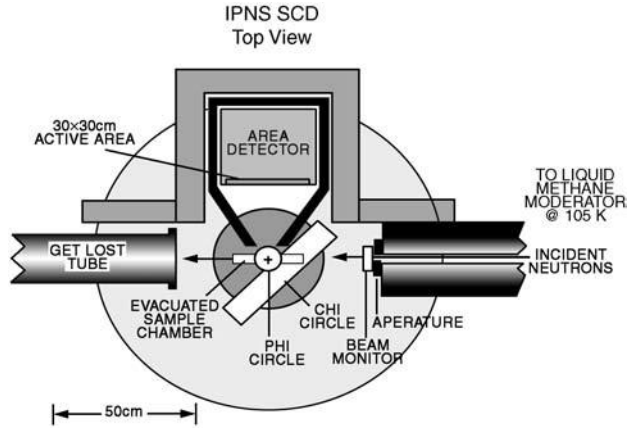

Figure 6. Schematic plan of the SCD spectrometer installed on a liquid methane moderator at the Argonne Intense Pulsed Neutron Source (IPNS).

1983). This high-resolution study, also carried out on one of the single-crystal diffractometers at the HFBR, used a relatively short neutron wavelength of 0.83 Å and successfully modeled the higher-order contributions to the Debye-Waller factor for a zincblende sample drawn from the collections of the Smithsonian Institution, Washington, D.C.

Neutron Sources and Instrumentation

As mentioned earlier, neutron sources fall into two categories: nuclear reactors, which normally operate as CW neutron sources, and spallation sources, which normally are pulsed. A pulsed nuclear reactor (IBR-30) operates at the Frank Laboratory of Nuclear physics in Dubna, Russia, and a CW spallation source (SINQ) operates at the Paul Scherer Institute in Villigen, Switzerland. A listing of neutron scattering centers offering single-crystal diffraction facilities that will host users from other organizations is given in Table 1.

Figure 5 schematically illustrates a representative SCD set-up at a reactor. Using this facility, which was formerly installed on a dual thermal beam port at the HFBR at Brookhaven, neutron beams in the wavelength range 0.8 to 1.7 Å could be extracted using a variety of monochromator crystals. Common choices for monochromators include Be, Si, Ge, Cu, and pyrolitic graphite. The incident beam horizontal divergence could be selected to match the mosaic spread of the sample using a Soller slit collimator, and a circular aperture was employed to limit the beam diameter to approximately twice the dimensions of the sample to minimize the background. Samples were mounted on one of the two four-circle diffractometers with Eulerian cradles that provided for full orientation control. The samples were generally centered in the incident beam using the observed setting angles for an azimuthal reflection. This enabled a precise centering to be carried out with the sample inside a cryostat or other specialized environment. Integrated Bragg intensities were recorded by scanning the samples in steps about the vertical (ω) axis, counting for a preset incident-beam monitor count to correct for any variation in the incident neutron flux from the reactor over time. The addition of position-sensitive area detectors has significantly enhanced the performance of many of the SCDs currently in operation at reactors (see discussion of Detectors, below). In particular, the recent emergence of neutron imaging-plate detectors and the development of improved glass scintillation detectors have been important advances.

Figure 6 is a schematic view of the SCD at Argonne's IPNS, which serves as an illustration of an instrument at a spallation neutron source. This diffractometer (Schultz, 1987), which is installed at a beam port on a liquid methane cryogenic moderator, operates by the time-of-flight Laue method (see X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS). The full spectrum of neutrons from the moderator is allowed to impinge on the sample, and the wavelength is determined by the time-of-flight required for neutrons to reach the detector, i.e., $\lambda = ht/ml$, where h is Planck's constant, t is the neutron time-of-flight, m is the neutron mass, and l is the source-to-detector distance.

The Eulerian cradle mount is used to orient the sample for a series of intensity data collection histograms, recording t and the position for each neutron arriving at the area detector. Counts are accumulated for a preset number of accelerator pulses. The IPNS proton accelerator operates at 30 Hz and a proton beam power of 7 kW. A depleted uranium spallation target is employed at present. With the geometry shown in Figure 6, a complete hemisphere of reciprocal space can be explored while collecting a total of 45 data histograms. In contrast to monochromatic beam methods, where the sample must be rotated to scan through Bragg reflections in order to obtain integrated intensities, in the Laue method the sample is held stationary while counting is in progress. This significantly simplifies the experiment and may be of particular advantage, for example, when a special sample environment is required or when carrying out rapid reciprocal-lattice surveys, e.g., while searching for phase transitions over a range of temperature and/or pressure.

In general, each neutron scattering center has developed its own instrumentation, and the design of each SCD spectrometer is unique in its details. From the prospective experimenter's point of view, however, most SCDs probably will look quite similar in the sense that they will feature an Eulerian cradle sample mount that offers the possibility of deploying cryostats, furnaces, pressure cells, etc., to obtain a wide range of sample environments. As was mentioned earlier, a successful experiment requires production of a large, well-formed single crystal. Generally, the minimum satisfactory sample size falls in the range 1 to 10 mm^3, with larger samples required for larger unit cells. These large samples are required because even at the current most powerful spallation neutron source, the 180 kW ISIS at the Rutherford Appleton Laboratory in the U.K., or at the most powerful high-flux reactor sources, the 58 MW High Flux Reactor (HFR) at the Institut Laue-Langevin in Grenoble, France, and the 85 MW High Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory in the U.S.A., the neutron flux on sample at the SCDs is several orders of magnitude reduced compared to the flux from a conventional, sealed-tube laboratory x-ray source.

Bent crystal focusing monochromators (see, e.g., Tanaka et al., 1999b, 2000) have been installed at a number of reactor SCD instruments. Significant intensity enhancement has been achieved in this way, in some cases approaching one order of magnitude.

Detectors

The first generation of SCD instruments at reactors utilized single-channel gas proportional counters filled with BF_3 or ^3He. These detectors capture neutrons by the reactions $^{10}B + {}^1n = {}^7Li + {}^4He + 2.8$ MeV, and $^3He + {}^1n = {}^1H + {}^3H + 0.76$ MeV, respectively. The thermal neutron capture cross-section of ^3He is $\sim$1.5 times that of ^{10}B, and for this reason ^3He counters are usually lighter and smaller than BF_3 counters.

Modern neutron SCD instruments generally include two-dimensional position-sensitive detectors, allowing for parallel data collection. Area detectors are, in any event, required for the time-of-flight Laue instruments at pulsed spallation sources. Neutron position-sensitive detectors are of three types: gas-filled proportional counters, generally using ^3He; scintillation counters, such as the ^6Li-glass detector on the SCD at IPNS (see Fig. 6); and imaging-plate detectors, which utilize a Gd converter. Neutron imaging plates (Niimura et al., 1994, Tazaki et al., 1999) have the important advantage of being flexible, which facilitates covering a large solid angle. Powerful new SCDs utilizing imaging plates and oscillation/Weissenberg geometry have been developed since 1990 (LADI, Wilkinson and Lehmann, 1991; Cipriani et al., 1995; BIX, Tanaka et al, 1999a). Imaging plates are integrating detectors and are therefore, unfortunately, not suitable for use on time-of-flight Laue instruments.

Future Outlook

The application of neutron scattering in general, including single-crystal diffraction, has always been constrained by the limited number of research facilities available. With the advent of the 2 MW Spallation Neutron Source (SNS), now under construction at Oak Ridge and scheduled to begin operation in 2006, the neutron scattering community will have at its disposal a state-of-the-art facility of unprecedented power and intensity, with approximately an order of magnitude increase over the power currently delivered by ISIS. Planning for major new spallation facilities is at an advanced stage in Europe, with the European Spallation Source (ESS) project, and also in Japan (JHF project). The SNS is expected to make possible a broad range of new SCD applications. For example, it should be possible to do the following.

1. Use much smaller single crystals, perhaps approaching normal x-ray sized samples ($\sim$0.01 mm^3 in volume), which will greatly expand the range of materials that can be investigated.
2. Obtain complete SCD data sets in minutes, as opposed to the days or weeks that are presently required. This should enable the study of many interesting processes in real time. To cite just one example of interest, it should be possible to investigate solid-state photochemical reactions where the mechanisms can be probed by following site-specific isotope labels (Ohgo et al., 1996, 1997).
3. Carry out extensive parametric studies, including investigating materials over a broad range of temperatures and pressures, which, in practice, at existing facilities, can only be done conveniently with powders. This would be extremely important for many materials applications, e.g., to understand the response of hydrogen-bonded ferroelectric, ferroelastic, and nonlinear optical (NLO) materials to temperature and pressure changes.

A critical challenge facing the neutron scattering community is how to replace the facilities at the current generation of research reactors. The majority of these facilities were commissioned in the 1950s and 1960s, and some are nearing the end of their projected lifetimes. Two new research reactor facilities are currently under development, at Garching, Germany, where the 20 MW FRM-II is scheduled to be operational in 2002, and at ANSTO, Lucas Heights, Australia, where a 20-MW replacement for the HIFAR reactor is scheduled to be completed in 2005.

DATA ANALYSIS AND INITIAL INTERPRETATION

As discussed above (see Principles of the Method), initial values of the neutron structure factor phases are usually calculated based on a structure model obtained from a prior x-ray diffraction study. Although the neutron phases can be obtained by direct methods (see above), the x-ray study provides an efficient structure solution and serves the important dual purpose of allowing a check for problems, such as twinning, that might make it difficult to obtain a high-quality neutron structure. Most neutron

scattering facilities strongly recommend that prospective SCD users have an x-ray structure of their material in hand before embarking on their neutron measurements.

Each SCD instrument generally provides its users with its own specially adapted suite of programs to handle data reduction, i.e., for Bragg peak indexing, integration of peak intensities, absorption correction, and merging of equivalent reflections. For Laue data, equivalent reflections are generally not merged, since they may be collected at different neutron wavelengths and their extinction corrections may therefore differ one from another. For information on data reduction software, the reader should consult the facility websites listed in Table 1. These websites generally identify the responsible instrument scientists who can advise prospective users on what to expect.

Refinement of neutron structures may be carried out with a standard crystallographic program package. Program systems in common use at neutron scattering centers include GSAS (*http://www.ncnr.nist.gov/programs/crystallography/software/gsas.html*; Larson and Von Dreele, 2000) and SHELX (*http://shelx.uni-ac.gwdg.de/SHELX/*; Sheldrick, 1997).

SAMPLE PREPARATION

As has been noted above, single-crystal neutron diffraction requires a large, high-quality crystal, generally at least 1 mm^3 in volume. There usually is no need for the crystal to be deuterated. This contrasts with the situation for neutron powder diffraction (see NEEUTRON POWDER DIFFRACTION), where gram-quantities of sample generally are required, and the material must be completely deuterated to avoid prohibitively high background from incoherent scattering of hydrogen. Single-crystal samples are normally mounted on an aluminum or vanadium pin with a suitable adhesive. Vanadium is sometimes used to reduce the background because of its extremely small neutron scattering amplitude. Aluminum will usually suffice, however, so long as the diameter of the pin is substantially smaller than that of the crystal. The personnel responsible for the facility's SCD instrument can advise as to the proper type of pin to use. Often the most suitable course is to bring unmounted samples to the neutron scattering center and to use the local laboratory facilities for final sample preparation.

Provision for on-site sample-handling facilities is frequently an important factor to consider when choosing a neutron scattering center. For example, prospective users with air-sensitive samples will want to be certain that facilities exist for handling and mounting their crystals under an inert atmosphere. The availability of well-equipped conventional laboratory facilities adjacent to the neutron source can critically affect the outcome of an experiment.

PROBLEMS

The most common reason for failure of a single-crystal neutron diffraction experiment is poor crystal quality. Ideally, smaller crystals from the same crystallization batch as the neutron samples will be examined first by x-ray diffraction, to assure their quality and to ascertain that the crystals scatter to adequate resolution (in Q). Optical examination of the samples under a polarizing microscope frequently may help to reject twinned specimens and agglomerates.

Once a neutron sample has been chosen, a careful assessment should be made of its mosaic spread along the principal crystal axes. At reactor instruments, this is usually done using ω scans, while at spallation-source instruments it is accomplished by examining preliminary data histograms that are collected to determine the sample orientation. A crystal with noticeably split diffraction profiles often will give unsatisfactory results. It is also important to avoid overlap in neighboring reflections that may result in high mosaic spreads, i.e., greater than about 2° in ω, particularly for crystals with large unit cells.

For proper estimation of intensities, it is critical that position-sensitive detectors be calibrated to remove effects of nonuniform response and to estimate detector dead-time losses, if any. At spallation-source instruments, the detector calibration must include allowance for the wavelength dependence of detector efficiency. Detector calibrations generally will have been carried out by the instrument scientist, placing an incoherent scatterer such as a vanadium rod in the sample position, and the resulting corrections will be applied automatically during data reduction.

Background corrections are also important, especially when data are acquired using a position-sensitive detector. A very successful and widely used technique that employs a variable background mask adjusted to maximize $I/\sigma(I)$, where I is the integrated intensity and $\sigma(I)$ its estimated standard deviation (Lehmann and Larsen, 1974), has been adapted to treat such data.

As noted above, the ideal kinematical expression for the Bragg reflection intensity given in Equation 2 ignores the effects of absorption and extinction that are present in real crystals. In particular, extinction is often important in neutron diffraction because of the requirement for large, well-formed crystals. Zachariasen (1967) gave an early treatment of extinction. Coppens and Hamilton (1970) extended the Zachariasen formalism to treat crystals with anisotropic extinction. Becker and Coppens (1974a,b, 1975) made further improvements, while Thornley and Nelmes (1974) treated the case of highly anisotropic extinction. For single-crystal neutron studies, it is important to have access to a crystallographic least-squares structure refinement program that allows for extinction. This should not pose a serious problem, however, since many modern refinement programs include the popular Becker-Coppens extinction formalism. When extinction is particularly severe, high correlations may occur in the least-squares refinement between extinction parameters and some of the adps, or more uncommonly even with the atomic positions. In these cases, special care should be taken, e.g., by employing restraints or damping factors, and by carefully testing the various extinction models to determine which one best fits the observed intensity data.

An absorption correction should always be applied to the observed Bragg intensities before attempting to treat

extinction in the least-squares refinement. It is preferable to measure the crystal, and index its faces, before beginning data collection. In practice, however, many samples are approximated as spheres, e.g., when the material is air-sensitive and therefore difficult to measure. Fortunately, absorption is usually quite modest for neutrons and actually rarely exceeds around 50%. An exception might be for crystals containing highly absorbing elements such as Li, B, Cd, Sm, and Gd, where it also may be important to include anomalous dispersion corrections. For many samples, however, the majority of the absorption will result from the reduction in the effective incident-beam intensity due to incoherent scattering of hydrogen. Howard et al. (1987) have determined the wavelength dependence of the hydrogen incoherent scattering cross-section, which is needed for proper absorption correction of time-of-flight Laue data from spallation sources.

PHONON STUDIES

INTRODUCTION

Until the beginning of this century, the models used to understand the properties of solids were based on the assumption that atomic nuclei are fixed at their equilibrium positions. These models have been very successful in explaining many of the low-temperature properties of solids, and especially those of metals, whose properties are determined to a large extent by the behavior of the conduction electrons. Many well-known properties of solids (such as sound propagation, specific heat, thermal expansion, conductivity, melting, and superconductivity), however, cannot be explained without considering the vibrational motion of the nuclei around their equilibrium positions. The study of lattice dynamics—or of phonons, which are the quanta of the vibrational field in a solid—was initiated by the seminal papers of Einstein (1907, 1911), Debye (1912), and Born and von Kármán (1912, 1913). Initially, most of the theoretical and experimental studies were devoted to the study of phonons in crystalline solids, as the name lattice dynamics implies. At present, the field encompasses the study of the dynamical properties of solids with defects, surfaces, and amorphous solids. It is impossible in a single unit to present even a brief overview of this field. The discussion that follows will therefore be limited to a brief outline of the neutron scattering techniques used for the study of phonons in crystalline solids. Additional information can be found in many books devoted to this subject (see Bibliography). Particularly useful is the four-volume book *Dynamical Properties of Solids* edited by Horton and Maradudin (1974), and several parts in *Neutron Scattering*, Vol. 23 of *Methods of Experimental Physics*, edited by Sköld and Price (1986).

Indirect information about the lattice dynamical properties of solids can be obtained from a variety of macroscopic measurements. For instance, in some cases, the phonon contribution to the specific heat or resistivity can be easily separated from other contributions and can provide important information about the lattice dynamical properties of a solid. In addition, measurements of sound velocities are particularly useful, since they provide the slopes of the acoustic phonon branches. Since such macroscopic measurements are relatively easy and inexpensive to make in a modern materials science laboratory, they should, in principle, be performed before one undertakes a detailed phonon study by spectroscopic techniques.

Direct measurement of the frequencies of long-wavelength optical phonons can be obtained by Raman scattering and infrared spectroscopy (Cardona, 1975–1991; Burstein, 1967). These experiments provide essential information for solids containing several atoms per unit cell and should be performed, if possible, before one undertakes a time-consuming and expensive detailed neutron scattering study. Also, for simple solids, information about the phonon dispersion curves can be obtained from x-ray diffuse scattering experiments.

Presently, the most powerful technique for the study of phonons is the inelastic scattering of thermal neutrons. The technique directly determines the dispersion relation, that is, the relationship between the frequency and propagation vector of the phonons. Its power was demonstrated by Brockhouse and Stewart (1955), who, following a suggestion put forward by Placzek and Van Hove (1954), measured the dispersion relation of aluminum.

PRINCIPLES OF THE METHOD

Given the potential seen by the nuclei of a solid, the description of their motion is reduced to the study of the oscillations of a system of particles around their equilibrium positions, which is a well-known problem in mechanics. The basic problem here is to determine the potential seen by the nuclei. If we assume that the electrons follow nuclear motion adiabatically, the effective potential $\phi(R)$ seen by the nuclei is written as,

$$\phi(R) = V(R) + V_e(R) \tag{1}$$

where R collectively denotes the nuclear positions, $V(R)$ is the nuclear interaction energy, and $V_e(R)$ is the average electronic energy determined with the nuclei fixed at R.

For a given potential, the motion of the nuclei can be immediately determined if we assume that the displacements of the nuclei from their equilibrium positions are small compared to their separation (the harmonic approximation). This approximation is very good, except for solids consisting of light nuclei, such as solid ^{4}He. If the harmonic approximation is valid, it is well known from mechanics that any nuclear motion can be considered as a superposition of a number of monochromatic waves, the normal vibrational modes or characteristic vibrations of the system. For a system containing N nuclei, the number of normal modes is $3N - 6$, the number of vibrational degrees of freedom of the system; for a solid $3N - 6 \cong 3N$, since the number of nuclei in this case is very large. The frequencies of the normal modes are obtained by diagonalizing the force constant matrix, a relatively simple problem in the case of a molecule. In an amorphous solid, one is faced with the formidable problem of diagonalizing a $3N \times 3N$ matrix. With present advances in computer technology, such direct diagonalizations are becoming possible and play an increasingly important role in the study of the vibrational properties of amorphous solids.

The translational symmetry of crystalline solids considerably simplifies the determination of the frequencies of their normal modes. In this case, the problem is reduced to the determination of the motion of the atoms contained in a unit cell. The normal modes are propagating vibrational waves with the propagation wave vector $\mathbf{q}$ determined by the crystal geometry. If the unit cell contains r nuclei, their frequencies $\omega_j(\mathbf{q})$ are obtained by diagonalizing a $3r \times 3r$ force constant matrix, which is a more tractable problem than the one encountered in amorphous solids. The relation

$$\omega = \omega_j(\mathbf{q}) \qquad (j = 1, 2, \ldots, 3r) \tag{2}$$

between the frequency and wave vector is called the dispersion relation. It consists of $3r$ branches labeled by the index j. Among these branches, there are three acoustic branches whose frequencies approach zero at the long-wavelength limit ($\mathbf{q} \to 0$). In this limit, the dispersion of the acoustic branches is linear, $\omega = \nu_j \mathbf{q}$, where ν_j is the appropriate sound velocity in the solid and the propagating vibrational waves in the solid are simply sound waves. The remaining $3r - 3$ branches tend to a finite frequency as $\mathbf{q} \to 0$ and are called optic branches, since some of these vibrational modes interact with light. For each wave vector of a branch, the motion of the nuclei in the cell is determined by solving the equations of motion. The pattern of motion in the cell is specified by the polarization vectors $\mathbf{e}_d^j(\mathbf{q})(d = 1, 2, \ldots, r)$, which provide the direction of motion of the nuclei in the cell. A vibrational mode is called longitudinal or transverse if the polarization vectors are parallel and perpendicular, respectively, to the propagation vector $\mathbf{q}$. The allowed values of the propagation vector $\mathbf{q}$ are determined by the boundary conditions on the surface of the crystal. The bulk properties of the crystal are not influenced by the specific form of the boundary conditions. For convenience, periodic boundary conditions are usually adopted. Because of the periodicity of the crystal, all physically distinct values of $\mathbf{q}$ can be obtained by restricting the allowed values of $\mathbf{q}$ in one of the primitive cells of the reciprocal lattice. Actually, instead of the primitive cell of the reciprocal lattice, it is more convenient to use the first Brillouin zone, which is the volume enclosed by planes that are the perpendicular bisectors of the lines joining a reciprocal lattice point to its neighboring points.

In the classical description outlined above, any nuclear motion can be considered as the superposition of propagating waves with various propagation vectors and polarizations. The analogy with the classical description of the electromagnetic field should be noted. As in the case of the electromagnetic field, the quantum description is easily obtained. In the harmonic approximation, the motions of the nuclei can be decoupled by a canonical transformation to normal coordinates. By this transformation, the nuclear Hamiltonian is reduced to a sum of Hamiltonians corresponding to independent harmonic oscillators, and the quantization of the vibrational field is reduced to that of the harmonic oscillator. Thus, instead of the classical wave description, we have the quantum description in terms of quanta, called phonons, that propagate through the lattice with definite energy and momentum. The energy $E_j(\mathbf{q})$ and momentum $\mathbf{p}$ of the phonon are

related to the frequency and wave vector of the corresponding vibrational wave by the well-known relations

$$E_j(\mathbf{q}) = \hbar\omega_j(\mathbf{q}) \qquad \mathbf{p} = \hbar\mathbf{q} \tag{3}$$

where $\hbar = h/2\pi$ is Planck's constant.

The free motion of noninteracting phonons corresponds to the free propagation of the monochromatic waves in the harmonic approximation. The phonons have finite lifetimes, however, since anharmonic interaction as well as interaction with other elementary excitations in the solid are always present. At thermal equilibrium, brought about by the above mentioned interactions, the average number of phonons, n_j, is given by the Bose-Einstein relation

$$n_j = \frac{1}{\exp(E_j/k_{\mathrm{B}}T) - 1} \tag{4}$$

where k_{B} is Boltzmann's constant.

Notice that at high temperatures ($E_j/k_{\mathrm{B}}T \ll 1$) the number of phonons is proportional to the temperature and inversely proportional to their energy.

From the measured phonon frequencies, one can evaluate the frequency distribution or phonon spectrum, which can be used to calculate the thermodynamic properties of the solid, such as the lattice specific heat. The frequency distribution, $Z(\omega)$, is defined so that $Z(\omega)\Delta\,\omega$ is the fraction of vibrational frequencies in the interval between ω and $\omega + \Delta\omega$.

$$Z(\omega) = \frac{1}{3N}\sum_{j,\mathbf{q}} \delta[\omega - \omega_j(\mathbf{q})] \tag{5}$$

where δ is Dirac's delta function.

As mentioned earlier, the most detailed information about the lattice dynamical properties of solids is obtained by studying the scattering of thermal neutrons by a crystalline specimen of solid. This is because the energy and wave vector of thermal neutrons are of the same order as those of the normal vibrations in a solid.

The scattering cross-section consists of an incoherent and a coherent part. The most detailed information about the lattice dynamical properties of the solid is obtained by measuring the coherent one-phonon inelastic neutron scattering cross-section from a single crystal. In such studies, incoherent and multiphonon processes are of importance only because their contribution to the background scattering may complicate observation of the one-phonon coherent processes.

The coherent cross-section for scattering of the neutron to a final state characterized by a wave vector $\mathbf{k}_1$ (and energy $E_1 = \hbar k_1/2m$) due to the creation or annihilation of a single phonon of frequency $\omega_j(\mathbf{q})$ is essentially (see, e.g., Chapter 1 of Sköld and Price, 1986) given by

$$\frac{k_1}{k_0}\frac{\left[n_j(\mathbf{q}) + \frac{1}{2} \pm \frac{1}{2}\right]}{\omega_j(\mathbf{q})}|F(\mathbf{Q})|^2\delta[E_1 - E_0 \pm \hbar\omega_j(\mathbf{q})]\delta(\mathbf{Q} \mp \mathbf{q} - \tau) \tag{6}$$

In this equation,

$$\mathbf{Q} = \mathbf{k}_0 - \mathbf{k}_1 \tag{7}$$

is the scattering vector; $[n_j(\mathbf{q}) + \frac{1}{2} \pm \frac{1}{2}]$ is the population factor with $n_j(\mathbf{q})$ given by Equation 4, the upper and lower signs correspond to phonon creation and phonon annihilation, respectively; the delta functions assure conservation of energy and momentum in the scattering process

$$\mathbf{Q} = \mathbf{q} + \tau \qquad E_1 - E_0 = \mp\hbar\omega_j(\mathbf{q}) \tag{8}$$

and the inelastic structure factor $F(\mathbf{Q})$ is defined by

$$F(\mathbf{Q})\sum_d M_d^{-1/2} b_d \mathbf{e}_d^j(\mathbf{q}) \cdot \mathbf{Q} e^{i\mathbf{Q}\cdot\mathbf{d}} e^{-W_d} \tag{9}$$

with the sum extending over the atoms of the unit cell. In this equation, M_d is the mass of the dth atom in the unit cell, b_d its coherent neutron scattering length, $\mathbf{d}$ its position vector, and e^{-W_d} the Debye-Waller factor.

PRACTICAL ASPECTS OF THE METHOD

The study of the coherent one-phonon inelastic neutron scattering from a single crystal is the most powerful technique for detailed investigation of the lattice dynamics of crystalline solids. Simple inspection of the coherent one-phonon neutron scattering cross-section (Equation 6) provides valuable information for the practical implementation of the technique.

The cross-section is inversely proportional to the phonon frequency and proportional to the population factor ($n_j + \frac{1}{2} \pm \frac{1}{2}$). Thus, for the low-lying modes ($\hbar\omega/kT < 1$), the intensity is inversely proportional to the square of the phonon frequency. The population factor is n_j for processes with neutron energy gain (phonon annihilation) and $(n_j + 1)$ for processes with neutron energy loss (phonon creation). Since $n_j(\mathbf{q})$ rapidly decreases with increasing $\hbar\omega/kT$, experiments with neutron energy loss are generally preferred. The k_1/k_0 factor in the cross-section, which favors energy-gain processes, cannot outweigh the gain in intensity due to the population factor for the energy-loss processes. Measurements with neutron energy gain, however, can be very useful in checking, whenever necessary, the results obtained by energy-loss measurements. Also, in experiments using neutrons of very low-incident energies (e.g., 5 meV), one is restricted in most cases to the observation of energy-gain processes. It should also be noted that because of the population factor, the intensity of the observed neutron groups usually increases with increasing sample temperature. Actually, for the low-lying modes [$(\hbar\omega/kT) \ll 1$], the intensity of the neutron groups is proportional to the sample temperature. Because of this gain in intensity with increasing temperature, most detailed studies of the dispersion curves have been performed at room or higher temperatures. The decrease in the Debye-Waller factor e^{-2W} with increasing temperature, with few exceptions, only moderates the increase of the intensity with increasing temperature. At high temperatures,

however, the increase in background scattering and the changes in the shape and width of the observed neutron groups, resulting from anharmonic effects, may considerably complicate the measurements.

The intensity of a neutron group corresponding to a certain mode depends on the crystal structure of the material through the square of the inelastic structure factor. It can be seen that there are definite advantages to performing the measurements, whenever possible, in mirror symmetry planes—such as the (110) and (001) planes in the case of cubic crystals. In fact, if the neutron scattering vector **Q** lies in a mirror plane, in principle no one-phonon scattering can be observed from modes polarized perpendicularly to the mirror plane. This considerably simplifies the task of identifying the modes with polarization vectors lying in the plane. In addition, the frequencies and polarization vectors of these modes vary slowly in the vicinity of and perpendicular to the mirror plane. As a result, the vertical collimation of the incident and scattered neutron beams can usually be much more relaxed than the horizontal collimation, thus obtaining more intensity without any significant loss in the accuracy of the measurements. The polarization dependence of the inelastic structure factor is exploited in practice to differentiate between various normal modes and to adopt the best experimental arrangement for their detection. For instance, if in a certain direction the modes are by symmetry purely longitudinal or transverse, the experimental configuration can be arranged so that the intensity is maximized for either the longitudinal or the transverse modes.

To illustrate these elementary considerations, let us consider the simple case of a monatomic face-centered cubic (fcc) structure like Cu. In this case, the modes along the [100], [110], and [111] directions are, by symmetry, purely longitudinal or transverse. Also, by symmetry, the transverse branches along the [100] and [111] directions are degenerate. The transverse branches along the [110] direction, on the other hand, are not degenerate and usually are denoted by T_2 (polarization parallel to the cube edge) and T_1 (polarization parallel to a face diagonal). Most of the measurements of the dispersion curves in these directions can be obtained by studying the scattering in the (110) mirror plane of the crystal. With the crystal in this orientation, all the longitudinal branches, the transverse branches along [111] and [100], and the T_2 [110] branch can be obtained. Typical scattering geometries for the detection of longitudinal and transverse [100] modes in the $(1\bar{1}0)$ scattering plane are indicated in Figure 1. The T_1 (110) branch can be observed by measurements in the (100) plane of the crystal. With the crystal in this orientation, measurements can be made along the [1ξ0] direction as well. These modes, usually designated Λ and Π, are not purely longitudinal or transverse. The dispersion curves of Cu are given in Figure 2. Notice that the measurements along the [110] direction were extended beyond the zone boundary to point X, where the L[110] branch is degenerate with T[100] and T_2[110] is degenerate with the L[100].

In simple cases, such as that of Cu, the symmetry of the structure determines the polarization vectors in high-symmetry directions and allows selection of the proper experimental arrangements. In more complicated structures with unit cells containing several atoms, planning of experiments is difficult, if not impossible, without some prior knowledge regarding the inelastic structure factor. In these cases, one proceeds by adopting a Born–von Kármán model with forces extending to a couple of nearest neighbors. By assigning reasonable values to the force constants (using, e.g., information available about the lattice dynamics of the system, such as measured values of the elastic constants), the structure factors can be evaluated. These calculated inelastic structure factors can then be used to plan the experimental measurements. As soon as some data have been obtained, the force constants can be readjusted, and a more realistic set of intensities can be calculated to serve as a guide for the selection of experimental conditions.

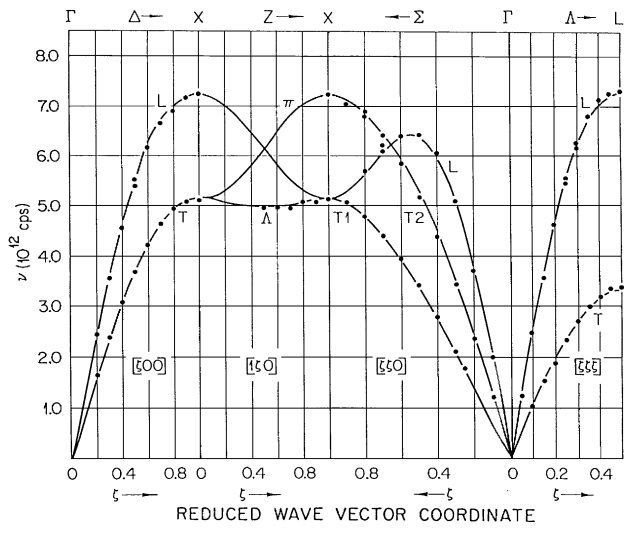

Figure 2. The molecular structure of a tin(II) hydride complex determined by a neutron diffraction study on IPNS SCD at 20 K (Koetzle et al., 2001). Estimated standard deviations in bond distances and angles are less than 0.01 Å and 0.1°, respectively.

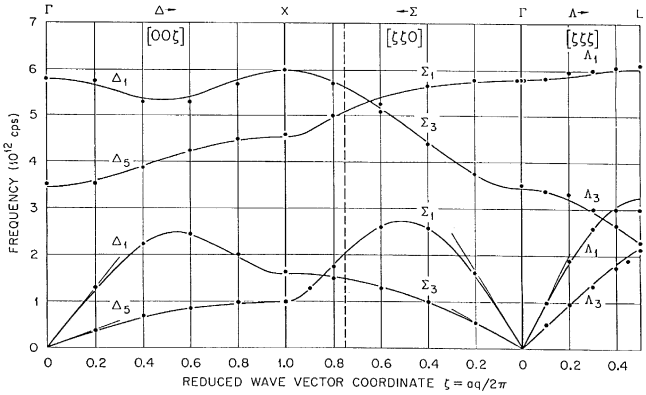

Figure 3. Contoured neutron Fourier map for (+)-neopentyl-1-d-alcohol (S) with positive nuclear scattering density at C and D shown as solid contours and negative nuclear scattering density at H shown as dashed contours (Yuan et al., 1994).

To illustrate this point, let us consider AgCl, which is a slightly more complicated case than that of Cu. This ionic crystal has the sodium chloride structure, and the Bragg intensities with even and odd Miller indices are proportional, respectively, to $(b_{Ag} + b_{Cl})^2$ (strong reflections) and $(b_{Ag} - b_{Cl})^2$ (weak reflections). By symmetry, the high-symmetry-direction branches are purely longitudinal or transverse. At Γ, the two atoms in the unit cell move in phaseand out of phase, respectively, for the acoustic and optical branches. It is easily seen by using Equation 9 that, close to Γ, measurements for the acoustic and optical branches should be performed around strong and weak reflections, respectively—a rule of thumb applicable to systems with two atoms per unit cell. This simple rule is only valid close to the zone center, however. In this particular experiment, the measurements away from Γ were planned using shell-model calculations of the inelastic structure factor. The measured dispersion curves of AgCl are given in Figure 3. Notice the similarity of the acoustic branches to those of the fcc structure, in particular the degeneracies at the point *X*.

The inelastic structure factor, and therefore the intensity, increases as Q^2, although this increase is moderated at large Q values by the Debye-Waller factor. This decrease of the Debye-Waller factor is not usually significant. The case of quantum crystals, such as ^{4}He, is a notable exception. In these crystals, the displacements of the atoms from their equilibrium positions are so large that the decrease with increasing Q of the Debye-Waller factor makes the observation of phonons impossible except around a few reflections with relatively small Miller indices. Thus, with some exceptions, such as the case of ^{4}He mentioned above, the measurements must be performed around reflections with large Miller indices.

Once the experimental conditions have been defined, following the general principles just outlined, the intensity of the observed neutron groups is determined by the intensity of the neutron source and the resolution of the instrument. Since the intensities vary inversely as a relatively high power (~4) of the overall resolution of the instrument, one must adopt a compromise between high resolution and reasonable intensity. With the neutron fluxes available in present-day sources, the energy resolution for a typical experiment is of the order of 1%, a relatively poor resolution compared to those ordinarily obtained in light-scattering experiments. There are essentially two methods allowing the determination of the neutron energy with such precision: (1) Bragg scattering from a single crystal (used as monochromator or analyzer) and (2) measuring the time of flight of the neutrons, chopped into pulses, over a known distance. A large number of instruments have been designed utilizing the first, the second, or a combination of these methods.

The choice of a particular instrument depends on the type of problem to be investigated. For single crystals, the region of interest in $(\mathbf{Q}\omega)$ space is considerably reduced by the symmetry of the crystal. Most of the relevant information regarding the lattice dynamics can be obtained by measuring a relatively small number of phonon frequencies at points or along lines of high symmetry of reciprocal space. For this type of experiment, one needs to perform a variety of rather specific scans in $(\mathbf{Q}\omega)$ space. It is generally accepted that, for these types of measurements, the triple-axis spectrometer has a definite advantage over other instruments. For incoherent scattering experiments, on the other hand, time-of-flight instruments are more convenient. These instruments are also preferred in coherent scattering experiments involving the measurement of a large number of frequencies in a relatively extended region of $(\mathbf{Q}\omega)$ space (as, e.g., in amorphous solids and complex compounds with a very large primitive unit cell).

The arguments presented here are mainly valid for instruments installed at nuclear reactors. Time-of-flight instruments are, of course, the natural machines to use with a pulsed source. Several time-of-flight machines, such as the multianalyzer crystal instrument and the constant-Q spectrometer, are presently being used at pulsed sources for coherent inelastic scattering experiments. Of these instruments, only the multianalyzer crystal instrument can reach the versatility of the triple-axis spectrometers (operating at continuous neutron sources) for coherent neutron scattering studies. Since the various instruments and their characteristics are described in detail in recent reviews (Dolling, 1974; Windsor, 1981, 1986), we present here only a few remarks regarding the use of the triple-axis spectrometer.

Triple-Axis Spectrometry

The design of present-day triple-axis spectrometers has changed little from that originally proposed by Brockhouse (1961). A schematic diagram of such an instrument is shown in Figure 4. A monochromatic beam of neutrons, obtained by Bragg reflection (through an angle $2\theta_M$) from a monochromator crystal, is scattered by the sample (through an angle ϕ) and the energy of this scattered beam is determined by Bragg scattering (through an angle $2\theta_A$) from an analyzer crystal. The orientation of the sample is defined by the angle χ between a certain crystal axis and the incident beam. The overall resolution of the instruments is governed by the collimators C_1, C_2, C_3, and C_4

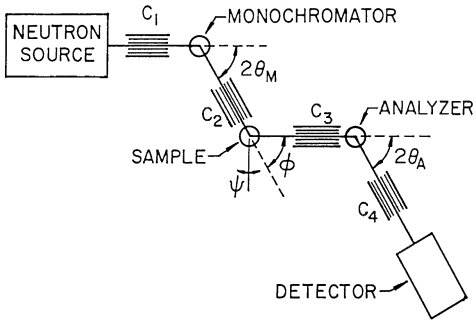

Figure 4. Anharmonicity of atomic displacements in zincblende (ZnS; m.p. 1973 K; cubic phase) as a function of temperature (Moss et al., 1980, 1983).

and the mosaic spreads of the crystals (monochromator, analyzer, and sample).

In some designs, no collimator (C_1) between the source and the monochromating crystal is used, since the natural collimation of the incident beam due to the relatively large distance between source and monochromator may be sufficient for most practical applications. Some horizontal collimation, however, is desirable, especially if it is easily adjustable, since it provides additional flexibility and reduces the overall background (for most experiments, a horizontal collimation before the monochromator between 40′ and 1° is sufficient). Since the distances between the sample and, respectively, the monochromator and the analyzer crystal are relatively short, it is necessary to introduce collimators (C_2, C_3) in order to restrict the horizontal divergence of the neutrons incident on and scattered from the specimen. In typical experiments, the horizontal collimation of the incident and scattered beam is 10′ to 40′. In most experiments no collimator (C_4) is used between the analyzer and the counter; a coarse (40′ to 2°) horizontal collimation can, however, reduce background if this is a serious problem in the measurements. Since most of the measurements in coherent neutron scattering experiments are performed in mirror planes, usually no vertical collimation is necessary. If, however, it is suspected that in a particular experiment scattering by modes off the horizontal scattering plane has been observed, the experiment should be repeated with some vertical collimation.

A low-sensitivity counter (usually a ^{235}U fission chamber) is placed before the sample to monitor the flux of neutrons incident on the sample. This monitor counter is normally used to control the counting times, so that no corrections are necessary for any changes in the incident neutron flux during the experiment. A second monitor counter is usually placed after the sample to detect Bragg scattering from the specimen, which may give rise to a spurious neutron group by incoherent scattering from the analyzer crystal. The signal counter is usually a high-efficiency (80% to 90%) $^{10}BF_3$ gas detector. Recently, the more compact ^3He gas detectors have replaced the $^{10}BF_3$ counters in several installations.

The intensity obtained in an experiment depends critically on the monochromator and analyzer crystals used in the spectrometer. In principle, the nuclei of the material used for a good monochromator (or analyzer) should have negligible absorption and incoherent scattering and fairly large coherent scattering cross-sections. Unfortunately, it is not always possible to obtain large single crystals of sufficient mosaic spread to obtain high reflectivity for all materials with favorable neutron characteristics. There are many methods of improving the reflectivities and other characteristics of the crystals used as monochromators (or analyzers), the most common being the mechanical distortion of the crystal at room or high temperatures. For details on this subject, we refer to the review by Freund (1976). The most useful monochromator (and analyzer) at present is pyrolytic graphite, which is ordered only along the c axis. In typical experiments, the (002) reflection of pyrolytic graphite is used at energies below ~50 meV. At higher energies the Bragg scattering angles become quite small [because of the relatively large lattice constant ($c = 6.71$ Å) of pyrolytic graphite]. This results in relatively poor energy resolution (since from Bragg's law $\Delta E = 2E \cot\theta_M \Delta\theta_M$). In addition, at these higher energies, the reflectivity decreases because of the scattering by parasitic reflections. Thus, at higher energies Be [usually reflecting from the (002) planes] is often used as a monochromator and/or analyzer in typical experiments. In practice, it is highly desirable to have many good monochromator crystals available in order to optimize intensity and resolution in a particular experiment. In most neutron scattering research centers, pyrolytic graphite as well as Be and (distorted) Ge crystals are available to be used as monochromators (or analyzers).

One of the most important advantages of the triple-axis spectrometer is its versatility. Highly specific scans along selected lines of the ($\mathbf{Q}\omega$) space can be performed under various experimental conditions, since both the neutron energy and the instrumental resolution can be easily adjusted during the experiments. There are several modes of operation. Irrespective of the mode of operation, however, the experiment determines ω as a function of $\mathbf{Q}$ (or $\mathbf{q}$). In the experimental plane, the energy and momentum conservation conditions determine the three unknowns, ω and the two components of $\mathbf{Q}$ along two axes in the scattering plane. Since in a crystal spectrometer there are four independently variable parameters (E_0, E_1, ϕ, and ψ), there are evidently a large number of ways in which to perform an experimental scan. Usually E_1 or E_0 is kept fixed during a particular scan.

The triple-axis spectrometer can, like a time-of-flight machine, be operated in the so-called conventional mode. In this mode $\mathbf{k}_0$ (and E_0) remain fixed, and the energies of the neutrons scattered at a fixed angle are analyzed by changing the setting of the analyzer crystal. As the magnitude (but not the direction) of $\mathbf{k}_1$ (and E_1) is varied, the extremity of the scattering vector moves through reciprocal space causing $\mathbf{q}$ to change, and neutron groups are observed if the energy and momentum conservation conditions are fulfilled. The disadvantage of this method is that it cannot be used to determine phonon frequencies at specified values of the wave vector $\mathbf{q}$, except by interpolation between values obtained in a series of experiments.

To determine the phonon frequencies at preselected values of $\mathbf{q}$, the constant-$\mathbf{Q}$ method is used. The ease

with which measurements with constant $\mathbf{Q}$ (and $\mathbf{q}$) can be performed with a triple-axis spectrometer is one of its main advantages over time-of-flight methods. The principle of this method, first introduced by Brockhouse (1960, 1961), is very simple. The choice of $\mathbf{q}$ and the reciprocal lattice point around which the scan is to be performed fix the components, say Q_x, Q_y, of the vector $\mathbf{Q}$, which is to remain constant during the scan. For instance, by assuming that E_1 is to be kept constant during the scan, a range of values for E_0 (or equivalently, $2\ \theta_M$) is chosen using a guess for the energy of the phonon. For each of these values of E_0, the appropriate values of ϕ and ψ are obtained from the momentum conservation conditions. If a neutron group is observed in the scan, its center will determine the frequency of a phonon with propagation vector $\mathbf{q}$. Similarly, the constant-$\mathbf{Q}$ scan can be performed keeping the incident neutron energy E_0 fixed. In most cases it is preferable to keep E_1 fixed, since in a constant-E_0 scan the variation in the sensitivity of the analyzer spectrometer as the scattered neutron energy varies during the scan can distort the observed neutron groups. In a constant-E_1 scan, no correction is needed for the k_1/k_0 factor in the cross- section since k_1 is fixed and k_0 is canceled by the $1/\nu_0$ sensitivity of the monitor counter. Another important advantage of the constant-$\mathbf{Q}$ method is that integrated intensities can be obtained and interpreted more easily than with other methods. This can be easily seen by momentarily neglecting the finite resolution of the instrument. The theoretical intensity is then obtained by simply integrating the theoretical cross-section over the phonon modes observed during an experimental scan. This matter is not trivial (Waller and Fröman, 1952), since E_0, E_1, k_0, and k_1, which appear in the delta functions, are related. For a general scan, the result of the integration is to multiply the expression preceding the delta functions by $|\mathrm{J}_j|^{-1}$, where the Jacobian J_j depends on the slope of the dispersion curve under study. This dependence on the slope of the branch being studied complicates the analysis of the measured intensities. For a constant-$\mathbf{Q}$ scan, on the other hand, $\omega_j(\mathbf{q})$ is independent of the energy transfer, since $\mathbf{q}$ is constant, and the integration is trivial, $\mathrm{J}_j = 1$.

In addition to the conventional and constant-$\mathbf{Q}$ scans, a variety of other scans can be programmed with a triple-axis spectrometer. One of the most useful is the constant-energy-transfer scan. In this type of scan, E_0 and E_1 are kept fixed and the angles ϕ and ψ are varied so that the measurement is performed with constant energy transfer along a predetermined line in reciprocal space. This type of scan is preferred over a constant-$\mathbf{Q}$ scan for very steep dispersion curves or whenever there is a sharp dip in a dispersion curve—as, e.g., in the study of the longitudinal phonon frequencies in the vicinity of $\mathbf{q} = \frac{2}{3}[111]$ of some body-centered cubic (bcc) metals.

Finally, a few comments should be made regarding the resolution of a triple-axis spectrometer and its focusing properties. Assume that the instrument has been set to detect neutrons scattered by the sample with momentum transfer $\mathbf{Q}_0$ and energy transfer $\hbar\omega_0$. Because of the finite collimation of the neutron beams and the finite mosaic spreads of the crystals (monochromator, analyzer, and sample), there is also a finite probability for the instrument to detect neutrons experiencing momentum transfer $\mathbf{Q}$ and energy transfer $\hbar\omega$ differing from $\mathbf{Q}_0$ and $\hbar\omega_0$ by $\Delta\mathbf{Q}$ and $\hbar\Delta\omega$, respectively. This probability is usually denoted by $R(\mathbf{Q} - \mathbf{Q}_0, \omega - \omega_0)$ and defines the resolution or transmission function of the instrument. The intensity observed for a particular setting of the spectrometer $(\mathbf{Q}_0, \omega_0)$ is then simply the convolution of the one-phonon coherent scattering cross-section with the resolution function around $\mathbf{Q}_0, \omega_0$:

$$I(\mathbf{Q}_0, \omega_0) = \int R(\mathbf{Q} - \mathbf{Q}_0, \omega - \omega_0)\sigma(\mathbf{Q}, \omega)d\mathbf{Q}\,d\omega \qquad (10)$$

The course of any particular scan can then be visualized as the stepwise motion of the resolution function through the dispersion surface. If one assumes that the transmission functions of the collimators and single crystals (monochromator, analyzer, and sample) are Gaussian distributions, a relatively simple analytical expression for the resolution of the instrument can be obtained (Cooper and Nathans, 1967; Mller et al., 1970),

$$R(\mathbf{Q} - \mathbf{Q}_0, \omega - \omega_0) = R_0 \exp\left\{-\frac{1}{2}\sum_{k,l=1}^{4} M_{kl}x_k x_l\right\} \qquad (11)$$

where $x_i = \Delta Q_i (i = 1, 2, 3)$, $x_4 = \Delta\omega$, and R_0 and M_{kl} are rather complicated expressions specified by the collimations and the mosaic spreads of the crystals. In writing this expression, x_1 was taken along $\mathbf{Q}_0$, and x_3 was vertical. The surface over which $R = R_0/2$ is represented by

$$\sum_{k,l=1}^{4} M_{kl}x_k x_l = 1.386 \qquad (12)$$

and is referred to as the resolution ellipsoid. Since the experiment is performed in a plane that is usually horizontal, in practically all cases, one is only concerned with the three-dimensional ellipsoid in the $\Delta Q_| = \Delta Q_\parallel, \Delta Q_2 = \Delta Q_\perp, \Delta\omega$ space (where $\Delta Q_\parallel$ and $\Delta Q_\perp$ denote the components of $\Delta\mathbf{Q}$ parallel and perpendicular to $\mathbf{Q}_0$, respectively). Typically, the resolution ellipsoid is quite elongated along $\Delta\omega$, and it is more elongated along $\Delta Q_\parallel$ than along $\Delta Q_\perp$. The elongated nature of the resolution ellipsoid is responsible for the focusing characteristics of the spectrometer: the width of the observed neutron groups will depend on the orientation of the long axes of the ellipsoid with respect to the dispersion surface. Clearly (see Fig. 5), the sharpest neutron group will be obtained if the experimental configuration is such that the long axis of the resolution ellipsoid is parallel to the dispersion surface. Because of the shape of the ellipsoid, focusing effects are more pronounced for transverse acoustic phonons (with $\Delta_q\omega$ perpendicular to $\mathbf{Q}_0$) than for longitudinal phonons (with $\Delta_q\omega$ parallel to $\mathbf{Q}_0$). In the experiments, the transverse phonons are always measured with a focused configuration. Sometimes, it may also be useful to measure longitudinal phonons not in a purely longitudinal configuration ($\mathbf{Q} \| \mathbf{q}$) but in a configuration favorable for focusing. To determine the focused configuration for a given

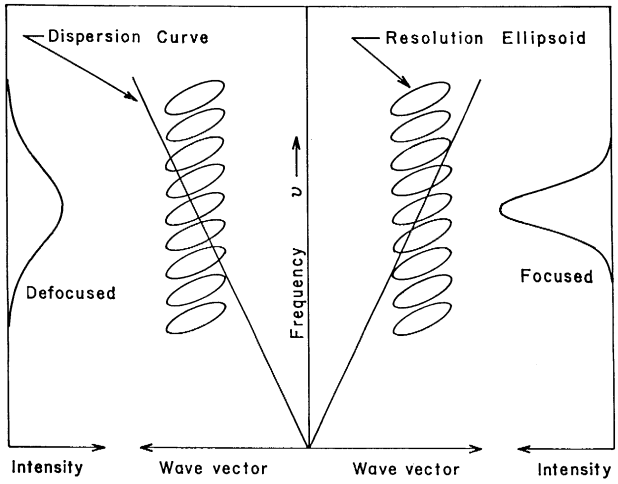

Figure 5. Schematic plan of the SCD spectrometers formerly installed at the dual thermal beam port H6 at the Brookhaven High-Flux Beam Reactor (HFBR).

instrument, one usually measures the neutron groups corresponding to a low-lying transverse acoustic phonon with **Q** taken, in the clockwise and counterclockwise sense, respectively, from a selected reciprocal lattice point. The sharpest of the two neutron groups (see Fig. 6) indicates which of the two configurations is focused, and thus establishes in which direction (clockwise or counterclockwise) from a reciprocal point the propagation vector of a transverse phonon (with ω increasing with increasing $\mathbf{q}$) should be taken to exploit focusing.

Computer programs for the evaluation of the resolution function are available in all neutron scattering centers. In many studies (e.g., the determination of intrinsic phonon widths), such detailed calculations of the resolution function are essential. For the planning of most experiments, however, simple estimates of the resolution are sufficient since they provide the information needed for the proper choice of the instrumental parameters. The contribution to the energy resolution of the spectrometer of each collimator and crystal involved can be evaluated, and an estimate of the overall energy resolution can be obtained by taking the square root of the sum of the squares of these contributions. Each contribution, $\Delta\omega$, to the energy resolution is obtained (Stedman and Nilsson, 1966), from

$$\Delta\omega = \Delta\mathbf{k} \cdot \left[\frac{\hbar}{m}\mathbf{k} - \nabla_q \omega(\mathbf{q})\right] \tag{13}$$

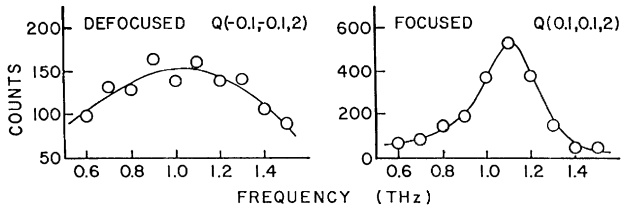

Figure 6. Schematic plan of the SCD spectrometer installed on a liquid methane moderator at the Argonne Intense Pulsed Neutron Source (IPNS).

In this equation, $\mathbf{k}$ stands for the average neutron wave vectors ($\mathbf{k}_0$ for the incident or $\mathbf{k}$, or the scattered beam) and $\Delta\mathbf{k}$ for the spread around these average values introduced by the collimators and finite mosaic spreads of the monochromator and analyzer crystal. To be more specific, let us assume that the monochromator is set to reflect neutrons of wave vector $\mathbf{k}_0$. As a result of the finite collimation α of the beam and the mosaic width β of the monochromator, the distribution of incident neutron wave vectors around $\mathbf{k}_0$ has a width $\Delta\mathbf{k}_0 = \Delta\mathbf{k}_{0c} + \Delta\mathbf{k}_{0\eta}$ (where $\Delta\mathbf{k}_{0c}$ from the collimation and $\Delta\mathbf{k}_{0\eta}$ from the mosaic width of the monochromator). It is easily shown, using Bragg's law, that $\Delta\mathbf{k}_{0c}(|\Delta\mathbf{k}_{0c}| = \alpha k_0 \theta_M)$ is parallel to the reflecting planes of the monochromator, whereas $\Delta\mathbf{k}_{0\eta}(|\Delta\mathbf{k}_{0\eta}| = \beta k_0 \cot\theta_M)$ is along $\mathbf{k}_0$. Notice that the distribution has a pronounced elongation along $\Delta\mathbf{k}_{0c}$, since $|\Delta\mathbf{k}_{0c}|/|\Delta\mathbf{k}_{0\eta}|$ is typically between 2.5 and 5, a feature alluded to earlier in this section. It can be seen from Equation 13 that to minimize this contribution to the energy resolution, the experimental arrangement should be such that the vector $[(\hbar\mathbf{k}_0/m) - \nabla_q\omega]$ is approximately normal to the monochromator reflecting planes, and this is the focusing condition at the monochromator. When this condition is approximately satisfied, the spread of incident energy around E_0 due to the distribution of incident wave vectors (first term in the right-hand side of Equation 13) approximately matches the spread in ω (second term of Equation 13) brought about by the spread in $\mathbf{q}$ due to Δk_0. Similar considerations apply to the scattered beam. In particular, the configuration of the analyzer spectrometer can be chosen to satisfy the focusing condition: $[(\hbar\mathbf{k}_0/m) - \nabla_q\omega]$ parallel to the normal to the analyzer reflecting planes. By using such simple considerations, the optimum focusing configuration can be adopted and a reasonable estimate of the resolution of the instrument can be obtained. The resolution widths calculated by this simple method are accurate to within $\sim$15%, which is sufficient for typical experiments.

METHOD AUTOMATION

Presently, all neutron scattering spectrometers used for the study of phonons are computer operated. By simple commands, the user can direct the instrument to perform any given scan or a series of scans with different parameters. Of course, software limits must be set so that the spectrometer does not assume a configuration incompatible with the experimental setup. In a triple-axis spectrometer, it is recommended to use limit-switches, in addition to the software limits, to restrict the motion of the monochromator drum, counter, and sample table within the limits set by a particular experimental setup. This is particularly important if the sample is in a cryostat, dilution refrigerator, or superconducting magnet.

In practically all neutron scattering spectrometers, the data can be printed and/or displayed graphically. In addition, in most spectrometers the user can perform a preliminary analysis of the collected data by using the computer programs available at the instrument site.

DATA ANALYSIS

Over the last 35 years, considerable progress has been made toward understanding of the connection between phonon measurements and the crystalline and electronic structure of solids. Until the pioneering work of Toya (1958), on the dispersion curves of Na, the measured dispersion curves of solids were analyzed in terms of simple phenomenological models based on the Born–von Kármán formalism.

As mentioned earlier, the vibration frequencies of a crystalline solid, in the harmonic approximation, are determined by a $3r \times 3r$ force constant (or dynamical) matrix, which depends on the forces between the nuclei. In a Born–von Kármán model, only forces extending to a few nearest neighbors are introduced. The number of independent force constants one needs to introduce is considerably reduced by the crystal symmetry and the requirement of translational and rotational invariance of the solid as a whole. The force constants introduced are considered as adjustable parameters to be determined by fitting to the experimental data. With few exceptions, however, Born–von Kármán models with a few adjustable parameters cannot adequately describe the measured dispersion curves. This is because of the different ways with which the electrons screen and modify the internuclear Coulomb forces in the various classes of materials. By making reasonable assumptions about the response of the electronic medium, however, a large number of phenomenological models have been advanced to explain the lattice dynamical properties of various classes of solids. A detailed description of these phenomenological models can be found in many books (Born and Huang, 1954; Bilz and Kress, 1979; Hardy and Karo, 1979; Brüesch, 1982; Venkataraman et al., 1975; Horton and Maradudin, 1974) and review articles (Hardy, 1974; Cochran, 1971; Sinha, 1973).

Phenomenological models are extremely useful since they can be used to calculate the phonon density of states and the lattice specific heat. Also, they are used to calculate the inelastic structure factors that are invaluable in planning experimental measurement of the dispersion curves of solids containing several atoms per unit cell. The main drawback of phenomenological models is that in most cases the parameters introduced to characterize the electronic response to the nuclear motion have no clear physical interpretation. In many cases, it is difficult, if not impossible, to understand how the results are related to the detailed electronic structure of materials, as provided by energy-band calculations.

Following the work of Toya (1958) on the dispersion curves of Na, the lattice dynamics of simple metals was developed within the framework of the pseudopotential theory of metals (Harrison, 1966; Heine, 1968; Cohen and Heine, 1968; Heine and Weaire, 1968). For most of the other classes of materials, however, it was impossible until the mid-1970s to relate the measured dispersion curves to the electronic properties of the materials. Progress in computational techniques has presently made possible first-principles calculations. The most direct approach describes the electronic response to the nuclear motion by a dielectric matrix (or electronic susceptibility). In practical applications, however, one is faced with the problem of inverting this dielectric matrix, a rather formidable problem. Because of this problem, only few calculations have been performed to date with this direct (or inversion) method.

Various methods have been proposed to overcome the computational problems of the dielectric function formalism of the general theory. The basic idea is to separate the band structure contribution to the dynamical matrix. One of the most commonly used methods is that put forward by Varma and Weber (1977, 1979). In this approach, the dynamical matrix is reduced to

$$D = D_{\mathrm{sr}} + D_2 \tag{14}$$

where D_{sr} is determined by relatively short-range forces and D_2 is the main band structure contribution. In practical applications the only calculation needed is that of D_2, since D_{sr} is parametrized by using short-range force constants. Many phonon anomalies observed in the dispersion curves of metals have been explained by this method.

Finally, it should be emphasized that presently it is possible to evaluate phonon frequencies directly and to compare them with the experimental results. These *ab initio* or frozen phonon calculations (Chadi and Martin, 1976; Wendel and Martin, 1978, 1979; Yin and Cohen, 1980; Kunc and Martin, 1981; Harmon et al., 1981; Yin and Cohen, 1982; Kunc and Martin, 1982; Ho et al., 1982) are particularly powerful in relating observed phonon anomalies in the dispersion curves to the electronic properties of the solid. To illustrate the principle of the method, consider a perfect (monatomic) crystal and another obtained from the first by displacing the atoms to the positions they assume instantaneously in the presence of a lattice wave of wave vector $\mathbf{q}$ and frequency $\omega(\mathbf{q})$. Clearly, the second lattice is obtained from the perfect lattice by displacing the atoms, at the equilibrium positions $\mathbf{l}$ by

$$\Delta\mathbf{R}_l = \mathbf{u}_0 \cos(\mathbf{q} \cdot \mathbf{l}) \tag{15}$$

where $\mathbf{u}_0$ defines the amplitude and direction of the displacement. The energy difference per atom, ΔE, between the two lattices is simply the potential energy per atom for the "frozen" phonon mode,

$$\Delta E = \frac{1}{N}\sum_l \frac{1}{2} M\omega^2(\mathbf{q})|\delta\mathbf{R}_l|^2 \tag{16}$$

which can be written as

$$\Delta E = \frac{1}{2} M\omega^2(\mathbf{q})\left[\frac{1}{N}|\mathbf{u}_0|^2 \sum_l \cos^2(\mathbf{q} \cdot \mathbf{l})\right] \tag{17}$$

For a zone boundary phonon [$\mathbf{q} = (\tau/2)$], the expression in brackets is simply $|\mathbf{u}_0|^2$, whereas for arbitrary $\mathbf{q}$, it is $\frac{1}{2}|\mathbf{u}_0|^2$. To obtain the phonon frequency, the energy difference ΔE is evaluated as a function of the displacement $|\mathbf{u}_0|$ by calculating the total energies of the distorted and

perfect crystal. The phonon frequency is then obtained from the curvature of the energy-difference versus displacement curve.

The method is used to obtain frequencies of phonon modes with wave vector $\mathbf{q}$ such that $n\mathbf{q} = \tau$ (where n is an integer), since only in this case is the distorted crystal also periodic (with a larger real-space cell), and its total energy can be calculated by the same techniques as those used to obtain the total energy of the perfect crystal. The computational times increase, of course, as the number of atoms in the larger cell of the distorted crystal increases. Accurate calculations of total energies for crystal structures with 10 to 15 atoms per cell are presently feasible.

Frozen phonon calculations have been performed for simple metals and semiconductors, as well as transition metals. In general, the agreement between calculated and experimentally determined frequencies is excellent. In a slightly different approach (Kunc and Martin, 1982; Yin and Cohen, 1982), the phonon dispersion curves along high symmetry directions can be obtained by calculating the force constants between atomic layers perpendicular to the direction of wave propagation. In these calculations, a supercell containing a sufficient number of layers is adopted and the interlayer force constants are obtained from the Hellmann-Feynman forces acting on individual atomic layers when a certain layer is displaced along the direction of wave propagation.

Probably the most appealing aspect of this method is that it provides not only phonon frequencies, but also additional information for comparison with the experimental results: lattice constants, bulk moduli, and elastic constants (obtained by subjecting the perfect crystal to a homogeneous deformation). Also, by studying the departure from a parabola of the energy versus displacement curves, one can obtain information about anharmonic effects. In addition, extra minima in the energy versus displacement curves may indicate instability of the lattice toward a certain phase transformation. It should be pointed out, however, that the calculations are valid essentially at $T = 0$, a fact that is sometimes overlooked in comparing the calculations to the experimental results.

In practice, the analysis and interpretation of the results is facilitated considerably if good quality data are collected. Given a sample of good quality this can be achieved by minimizing the background, optimizing the resolution, and adopting sufficient counting times for satisfactory counting statistics. The phonon frequencies, obtained by fitting the phonon peaks, are assigned to the various branches using Born–von Kármán model calculations. The dispersion curves are then fitted to those given by various theoretical or phenomenological models. A preliminary analysis of the results can be made as the experiment is in progress by making use of the programs available in practically all neutron scattering facilities.

SAMPLE PREPARATION

A few remarks should be made regarding the samples used for phonon measurements. From the expression of the inelastic structure factor, it is evident that light elements with relatively large coherent cross-sections are favored for coherent inelastic scattering experiments. Actually, the small mass of ^{4}He made possible the measurements of the dispersion curves of this quantum crystal. If the incoherent cross-section that contributes to the background is not sufficiently small, it may also complicate the measurements. In such cases the use of single isotopes, as in materials containing Ni, can be very helpful. The use of appropriate isotopes may actually be essential if the material to be studied has a significant neutron absorption cross-section (much larger than $\sim$100 b). For instance, the use of nonabsorbing isotopes made possible the study of the dispersion curves of Cd (Chernyshov et al., 1979; Dorner et al., 1981). In such extreme cases, however, one must seriously examine the possibility of obtaining the desired information by an x-ray diffuse scattering experiment instead (see X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS). For instance, such measurements have been performed on V, which, because of its low coherent scattering length (0.05×10^{-12} cm), is difficult to study with standard coherent inelastic scattering techniques.

For coherent neutron scattering experiments, it is almost essential to have a single-crystal specimen whose size is dictated by the material properties and the intensity of the neutron source. For most materials, information about lattice dynamics can be obtained in a high-flux source on samples as small as 0.05 cm^3. In general, for detailed studies, one needs specimens of the order of 1 cm^3 or larger. If it is available, a single crystal of high perfection (mosaic spread 0.2° should be used. In high-temperature or -pressure experiments, as well as in studies where the sample is brought through a phase transformation, however, the experimentalist may have little, if any, control of the mosaic spread of the sample. In such cases, measurements may have to be performed on crystals with mosaic spreads as large as 5°. Difficulties arising from loss in experimental resolution and Bragg-phonon scattering processes in such cases are discussed in the Problems section.

When possible, high-purity samples should be used, since impurities as well as defects increase the background scattering. It should be noted, however, that impurity contents as high as 1000 ppm have, in most cases, very little effect on the dispersion curves of the material being studied. Significant hydrogen content, on the other hand, can complicate the experiments considerably. In addition to its large incoherent cross-section, which considerably increases the background, hydrogen can precipitate as a hydride at a certain temperature and cause a large increase in the mosaic of the sample. This is particularly troublesome in studies of lattice dynamics as a function of temperature.

As mentioned earlier, most of the detailed coherent neutron scattering studies have been performed on single-crystal specimens. Recently, however, it has been demonstrated (Buchenau et al., 1981) that considerable information about the lattice dynamics of materials can be obtained by studies of the coherent neutron scattering by polycrystalline samples. In the case of Ca, the dispersion curves obtained by this technique were found to be in good agreement with measurements performed on

single-crystal specimens (Stassis et al., 1983). For materials for which relatively large single crystals are not available, study of the coherent scattering by a polycrystalline sample may prove to be extremely valuable.

SPECIMEN MODIFICATION

In general, the scattering of thermal neutrons is a nondestructive experimental technique. However, after irradiation practically all samples become to some extent radioactive. It is therefore important before performing an experiment to estimate the activity of the samples after irradiation and to avoid, if possible, the use of elements that upon irradiation become long-lived radioactive isotopes. After the experiment is completed, users are required to have the samples checked by the institutional radiation safety office (Health Physics). In many cases the sample is stored for several days or weeks to allow its activity to decay to admissible levels before it is shipped to the user.

PROBLEMS

Collection of data on a triple-axis spectrometer is complicated by the observation of peaks arising from higher-order contamination. If a monochromator is set to reflect neutrons of energy E_0 from the (hkl) plane, it is also set to reflect in the same direction neutrons of energy $n^2 E_0$ from the $(nh\ nk\ nl)$ plane. Similarly, if the analyzer is set to reflect neutrons of energy E_1, it will also reflect in the direction of the counter neutrons of energy $m^2 E_1$. It is easily seen that, as a result, various spurious neutron groups may be observed. One of the most common is due to the elastic incoherent scattering by the sample, in the direction of the analyzer, of the nth-order component of the incident beam. Clearly, if n and m are such that $n^2 E_0 = m^2 E_1 = m^2(E_0 \pm \hbar\omega)$, a spurious neutron group will be observed that could be attributed to the creation (or annihilation) of a phonon of energy $\hbar\omega$. If such a problem is suspected, one can repeat the measurement using a sufficiently high E_1 (or E_0) so that this process is not energetically possible for any values of n and m. Quite generally, by measurements at different energies one can avoid ambiguities arising from spurious neutron groups due to higher-order contamination. This problem is serious, however, in studies of complex systems, and various methods are used to minimize it.

The simplest method to deal with the problem of order contamination is to choose the incident energy close to the maximum of the reactor spectrum so that the higher-order contamination in the incident beam arises from the low-flux region of the spectrum. In most experiments, however, one needs lower energies for better energy resolution. It is, therefore, highly desirable to decrease the flux of higher-energy neutrons incident on the monochromator crystal. This can be achieved by placing a single crystal of high perfection before the monochromator. The choice of the best filter for this purpose is restricted by the difficulty of obtaining large, highly perfect, single crystals of the desired material. Quartz, silicon, and sapphire have been used with considerable success. Of these, silicon and quartz are used at liquid nitrogen temperatures and have similar characteristics. Sapphire seems to be more effective and can be used at room temperature without significant loss of efficiency. Note that mechanical velocity selectors and curved neutron guides can also be used for the same purpose. For instance, an S-shaped neutron guide is installed between the cold source and the IN-12 triple-axis spectrometer of the high flux reactor at the Institut Laue-Langevin.

Even when the higher-energy neutron flux incident on the monochromator has been minimized as described above, additional discrimination of the higher-order contamination is desirable in a large number of experiments. This is usually achieved by using appropriate filters. Pyrolitic graphite is probably the most useful, and it is used routinely in typical experiments. It is particularly efficient in a narrow energy range around 13.7 and 14.7 meV. Pyrolitic graphite filters are also quite efficient at 30.5 and 42 meV. The filter, typically several inches thick, is oriented so that the c axis is along the beam and is positioned in front of either the analyzer or the sample (depending on whether the experiment is performed at fixed scattered or incident neutron energy). For experiments at low energies ($\leq$5 meV), polycrystalline filters such as Be are frequently used. In this case, one exploits the fact that no coherent elastic scattering occurs if the neutron wavelength exceeds twice the largest spacing between planes in the material. Finally, it should be mentioned that one can eliminate a specific higher-order contamination by appropriate choice of the analyzer or monochromator. For instance, one of the most troublesome processes is the incoherent elastic scattering by the sample of the primary beam, in the direction of the analyzer, followed by second-order scattering from the analyzer $(n = 1, m = 2)$. This process can be eliminated by using Ge (or Si) reflecting from the (111) planes as analyzer, since for all practical purposes the (222) reflection is forbidden for diamond-structure crystals.

Since we discussed in some detail how to deal with the spurious neutron groups arising from higher-order contamination, it is appropriate now to mention three other processes that may introduce similar problems. The first process, alluded to earlier in this section, involves Bragg scattering of the primary incident beam (of energy E_0) by the sample in the direction of the scattered beam followed by incoherent scattering by the analyzer in the direction of the counter. In the second process, neutrons with energy E_1 in the incident beam may be Bragg reflected from the sample and then from the analyzer into the detector. In both cases, a relatively high count rate will be observed in the second monitor, which is placed behind the sample. The problem is then easily eliminated by a slight change of experimental conditions. The third case involves a double-scattering process in the sample: coherent one-phonon scattering followed or preceded by Bragg scattering. This process is particularly troublesome since it gives rise to neutron groups corresponding to modes that in principle should not be observed under the experimental conditions of the measurement. For instance, quite often one observes in a longitudinal scan, neutron groups corresponding

to transverse modes. In principle, this problem can be practically eliminated by using a single crystal of small mosaic spread. In experiments with crystals of large mosaic spreads (as is often the case in high-pressure or -temperature studies), this double-scattering process can complicate the measurements considerably.

Finally, it should be mentioned that radiation damage of the sample is not usually a problem because the sample is exposed to the relatively low intensity and low energy beam reflected by the monochrometer. A notable exception is the cast of some classes of biological materials.

MAGNETIC NEUTRON SCATTERING

INTRODUCTION

The neutron is a spin-$\frac{1}{2}$ particle that carries a magnetic dipole moment of -1.913 nuclear magnetons. Magnetic neutron scattering then originates from the interaction of the neutron's spin with the unpaired electrons in the sample, either through the dipole moment associated with an electron's spin or via the orbital motion of the electron. The strength of this magnetic dipole-dipole interaction is comparable to the neutron-nuclear interaction, and thus there are magnetic cross-sections that are analogous to the nuclear ones, which reveal the structure and dynamics of materials over wide ranges of length scale and energy. Magnetic neutron scattering plays a central role in determining and understanding the microscopic properties of a vast variety of magnetic systems—from the fundamental nature, symmetry, and dynamics of magnetically ordered materials—to the elucidation of the magnetic characteristics essential in technological applications.

One traditional role of magnetic neutron scattering has been the measurement of magnetic Bragg intensities in the magnetically ordered regime. Such measurements can be used to determine the spatial arrangement and directions of the atomic magnetic moments, the atomic magnetization density of the individual atoms in the material, and the value of the ordered moments as a function of thermodynamic parameters such as temperature, pressure, and applied magnetic field. These types of measurements can be carried out on single crystals, powders, thin films, and artificially grown multilayers, and often the information collected can be obtained by no other experimental technique. For magnetic phenomena that occur over length scales that are large compared to atomic distances, the technique of magnetic small angle neutron scattering (SANS) can be applied, in analogy to structural SANS. This is an ideal technique to explore domain structures, long wavelength oscillatory magnetic states, vortex structures in superconductors, and other spatial variations of the magnetization density on length scales from 1 to 1000 nm. Another specialized technique is neutron reflectometry, which can be used to investigate the magnetization profile in the near-surface regime of single crystals, as well as the magnetization density of thin films and multilayers, in analogy with structural reflectometry techniques. This particular technique has enjoyed dramatic growth during the last decade due to the rapid advancement of atomic deposition capabilities.

Neutrons can also scatter inelastically, to reveal the magnetic fluctuation spectrum of a material over wide ranges of energy ($\sim 10^{-8} - 1$ eV) and over the entire Brillouin zone. Neutron scattering plays a truly unique role in that it is the only technique that can directly determine the complete magnetic excitation spectrum, whether it is in the form of the dispersion relations for spin wave excitations, wave vector and energy dependence of critical fluctuations, crystal field excitations, magnetic excitons, or moment fluctuations. In the present overview we will discuss some of these possibilities.

Competitive and Related Techniques

Much of the information that can be obtained from neutron scattering, such as ordering temperatures and ferromagnetic moments, can and should be compared with magnetic measurements of quantities such as specific heat, susceptibility, and magnetization (Magnetism and magnetic measurements). Indeed it is often highly desirable to have measurements available from these traditional techniques before undertaking the neutron measurements, as a way of both characterizing the particular specimen being used and to be able to focus the neutron data collection to the range of temperature, applied field, etc., of central interest. Thus these complementary measurements are highly desirable.

For magnetic diffraction, the technique that is directly competitive is magnetic x-ray scattering. The x-ray magnetic cross-sections are typically $\sim 10^{-6}$ of those of charge scattering, but with the high fluxes available from synchrotron sources x-ray scattering from these cross-sections is readily observable. The information that can be obtained is also complementary to neutrons in that neutrons scatter from the total magnetization in the system, whether it originates from spin or orbital motions, while for x rays

the spin and orbital contributions can be distinguished. X rays also have the advantage that the wavelength can be tuned to an electronic resonance, which can increase the cross-section by as much as $\sim 10^4$, and thus it can be an element-specific technique. However, the limited number of resonances available restricts the materials that can be investigated, while the high absorption cross-sections and the generally more stringent experimental needs and specimen requirements are disadvantages. Each x-ray photon also carries $\sim 10^6$ times the energy that a neutron carries, and the combination of this with the brightness of a synchrotron source can cause rather dramatic changes in the physical or chemical properties of the sample during the investigation. Neutrons are a much gentler probe, but the low flux relative to synchrotron sources also means that larger samples are generally needed. Both techniques must be carried out at centralized facilities. Magnetic x-ray diffraction is a relatively young technique, though, and its use is expected to grow as the technique develops and matures. However, neutron scattering generally will continue to be the technique of choice when investigating new materials.

For the investigation of spin dynamics, there are a number of experimental techniques that can provide important information. Mössbauer spectroscopy (MÖSSBAUER SPECTROMETRY), muon spin precession, and perturbed angular correlation of nuclear radiation measurements can reveal characteristic time scales, as well as information about the site symmetry of the magnetism and the ordered moment as a function of temperature. Raman and infrared (IR) spectroscopy can reveal information about the long-wavelength (Brillouin zone–center) excitations (RAMAN SPECTROSCOPY OF SOLIDS), and the magnon density of states via two-magnon processes. Microwave absorption can determine the spin wave excitation spectrum at very long wavelengths (small wave vectors $\mathbf{q}$), while nuclear magnetic resonance (NUCLEAR MAGNETIC RESONANCE IMAGING) can give important information about relaxation rates. However, none of these techniques can explore the full range of dynamics that neutrons can, and in this regard there is no competitive experimental technique for measurements of the spin dynamics.

PRINCIPLES OF THE METHOD

Magnetic Diffraction

The cross-section for magnetic Bragg scattering (Bacon, 1975) is given by

$$I_{\mathrm{M}}(\mathbf{g}) = C\left(\frac{\gamma e^2}{2mc^2}\right)^2 \mathbf{M}_{\mathrm{g}} A(\theta_{\mathrm{B}}) |F_{\mathrm{M}}(\mathbf{g})|^2 \qquad (1)$$

where I_{M} is the integrated intensity for the magnetic Bragg reflection located at the reciprocal lattice vector, $\mathbf{g}$, the neutron-electron coupling constant enclosed in large parentheses evaluates as -0.27×10^{-12} cm, C is an instrumental constant that includes the resolution of the measurement, $A(\theta_{\mathrm{B}})$ is an angular factor that depends on the method of measurement (e.g., sample angular rotation, or $\theta : 2\theta$ scan), and $\mathbf{M}_{\mathrm{g}}$ is the multiplicity of the reflection (for a powder sample). The magnetic structure factor $F_{\mathrm{M}}(\mathbf{g})$ is given in the general case (Blume, 1961) by

$$F_{\mathrm{M}}(\mathbf{g}) = \sum_{j=1}^{N} e^{ig\cdot\mathbf{r}_j} \hat{\mathbf{g}} \times [\mathbf{M}_j(\mathbf{g}) \times \hat{\mathbf{g}}] e^{-W_j} \qquad (2)$$

where $\hat{\mathbf{g}}$ is a unit vector in the direction of the reciprocal lattice vector $\mathbf{g}$, $M_j(\mathbf{g})$ is the vector form factor of the jth ion located at $\mathbf{r}_j$ in the unit cell, W_j is the Debye-Waller factor (see MÖSSBAUER SPECTROMETRY) that accounts for the thermal vibrations of the jth ion, and the sum is over all (magnetic) atoms in the unit cell. The triple cross product originates from the vector nature of the dipole-dipole interaction of the neutron with the electron. A quantitative calculation of $M_j(\mathbf{g})$ in the general case involves evaluating matrix elements of the form $\langle \pm | 2\boldsymbol{S} e^{i\mathbf{g}\bullet\mathbf{R}} + \boldsymbol{O} | \pm \rangle$, where $\boldsymbol{S}$ is the (magnetic) spin operator, $\boldsymbol{O}$ is the symmetrized orbital operator introduced by Trammell (1953), and $|\pm\rangle$ represents the angular momentum state. This can be quite a complicated angular-momentum computation involving all the electron orbitals in the unit cell. However, usually the atomic spin density is *collinear*, by which we mean that at each point in the spatial extent of the electron's probability distribution, the *direction* of the atomic magnetization density is the same. In this case, the direction of $M_j(\mathbf{g})$ does not depend on $\mathbf{g}$, and the form factor is just a scalar function, $f(\mathbf{g})$, which is simply related to the Fourier transform of the magnetization density. The free-ion form factors have been tabulated for essentially all the elements. If one is familiar with x-ray diffraction, then it is helpful to note that the magnetic form factor for neutron scattering is analogous to the form factor for charge scattering of x rays, except that for x rays it corresponds to the Fourier transform of the total charge density of all the electrons, while in the magnetic neutron case it is the transform of the "magnetic" electrons, which are the electrons whose spins are unpaired. Recalling that a Fourier transform inverts the relative size of objects, the magnetic form factor typically decreases much more rapidly with $\mathbf{g}$ than for the case of x-ray charge scattering, since the unpaired electrons are usually the outermost ones of the ion. This dependence of the scattering intensity on $f(\mathbf{g})$ is a convenient way to distinguish magnetic cross-sections from nuclear cross-sections, where the equivalent of the form factor is just a constant (the nuclear coherent scattering amplitude b).

If, in addition to the magnetization density being collinear, the magnetic moments in the ordered state point along a unique direction (i.e., the magnetic structure is a ferromagnet, or a simple $+-+-$ type antiferromagnet), then the square of the magnetic structure factor simplifies to

$$|F_{\mathrm{M}}(\mathbf{g})|^2 = \langle 1 - (\hat{\mathbf{g}} \bullet \hat{\boldsymbol{\eta}})^2 \rangle \left| \sum_j \eta_j \langle \mu_j^z \rangle f_j(\mathbf{g}) e^{-W_j} e^{i\mathbf{g}\bullet\mathbf{r}_j} \right|^2 \qquad (3)$$

where $\hat{\boldsymbol{\eta}}$ denotes the (common) direction of the ordered moments and η_j the sign of the moment (± 1), $\langle \mu_j^2 \rangle$ is the

average value of the ordered moment in thermodynamic equilibrium at (T, H, P, ...), and the orientation factor $\langle 1-(\hat{\mathbf{g}}\bullet\hat{\boldsymbol{\eta}})^2\rangle$ represents an average over all possible domains. If the magnetic moments are the same type, then this expression further simplifies to

$$|F_{\mathrm{M}}(\mathbf{g})|^2 = \langle 1-(\hat{\mathbf{g}}\bullet\hat{\boldsymbol{\eta}})^2\rangle\langle\mu^z\rangle^2 f^2(\mathbf{g})e^{-2W_j}\left|\sum_j \eta_j e^{i\mathbf{g}\bullet\mathbf{r}_j}\right|^2 \quad (4)$$

We see from these expressions that neutrons can be used to determine several important quantities: the location of magnetic atoms in the unit cell and the spatial distribution of their magnetic electrons, as well as the dependence of $\langle\mu^z\rangle$ on temperature, field, pressure, or other thermodynamic variables, which is directly related to the order parameter for the phase transition (e.g., the sublattice magnetization). Often the preferred magnetic axis, $\hat{\boldsymbol{\eta}}$, can also be determined from the relative intensities. Finally, the scattering can be put on an absolute scale by internal comparison with the nuclear Bragg intensities I_{N} from the same sample, given by

$$I_{\mathrm{N}}(\mathbf{g}) = CM_{\mathbf{g}}A(\theta_{\mathrm{B}})|F_{\mathrm{N}}(\mathbf{g})|^2 \quad (5)$$

with

$$|F_{\mathrm{N}}(\mathbf{g})|^2 = \left|\sum_j b_j e^{-W_j}e^{i\mathbf{g}\bullet\mathbf{r}_j}\right|^2 \quad (6)$$

Here b_j is the coherent nuclear scattering amplitude for the jth atom in the unit cell, and the sum is over all atoms in the unit cell. Often the nuclear structure is known accurately and F_{N} can be calculated, whereby the saturated value of the magnetic moment can be obtained.

Subtraction Technique

There are several ways that magnetic Bragg scattering can be distinguished from the nuclear scattering from the structure. Above the magnetic ordering temperature, all the Bragg peaks are nuclear in origin, while as the temperature drops below the ordering temperature the intensities of the magnetic Bragg peaks rapidly develop, and for unpolarized neutrons the nuclear and magnetic intensities simply add. If these new Bragg peaks occur at positions that are distinct from the nuclear reflections, then it is straightforward to distinguish magnetic from nuclear scattering. In the case of a ferromagnet, however, or for some antiferromagnets that contain two or more magnetic atoms in the chemical unit cell, these Bragg peaks can occur at the same position. One standard technique for identifying the magnetic Bragg scattering is to make one diffraction measurement in the paramagnetic state well above the ordering temperature, and another in the ordered state at the lowest temperature possible, and then subtract the two sets of data. In the paramagnetic state, the (free ion) diffuse magnetic scattering is given (Bacon, 1975) by

$$I_{\mathrm{Para}} = \frac{2}{3}C\left(\frac{\gamma e^2}{2mc^2}\right)^2 \mu_{\mathrm{eff}}^2 f(\mathbf{Q})^2 \quad (7)$$

where μ_{eff} is the effective magnetic moment $\{= g[J(J+1)]^{1/2}$ for a free ion$\}$. This is a magnetic incoherent cross-section, and the only angular dependence is through the magnetic form factor $f(\mathbf{Q})$. Hence this scattering looks like "back-ground." There is a sum rule on the magnetic scattering in the system, though, and in the ordered state most of this diffuse scattering shifts into the coherent magnetic Bragg peaks. A subtraction of the high-temperature data (Equation 7) from the data obtained at low temperature (Equation 1) will then yield the magnetic Bragg peaks, on top of a deficit (negative) of scattering away from the Bragg peaks due to the disappearance of the diffuse paramagnetic scattering in the ordered state. On the other hand, usually none of the nuclear cross-sections change significantly with temperature, and hence drop out in the subtraction. A related subtraction technique is to apply a large magnetic field in the paramagnetic state, to induce a net (ferromagnetic-like) moment. The zero-field (nuclear) diffraction pattern can then be subtracted from the high-field pattern to obtain the induced-moment diffraction pattern.

Polarized Beam Technique

When the neutron spins that impinges on a sample has a well-defined polarization state, then the nuclear and magnetic scatterin that originates from the sample interferes *coherently*, in contrast to being separate cross-sections like Equations 1 and 5, where magnetic and nuclear intensities just add. A simple example is provided by the magnetic and nuclear scattering from elemental iron, which has the body-centered cubic (bcc) structure and a (saturated) ferromagnetic moment of $2.2\mu_{\mathrm{B}}$ at low temperature. It is convenient to define the magnetic scattering amplitude p (Bacon, 1975) as

$$p = \left(\frac{\gamma e^2}{2mc^2}\right)\langle\mu\rangle f(\mathbf{g}) \quad (8)$$

and then the structure factor for the scattering of polarized neutrons is given by

$$F(\mathbf{g}) = (b\pm p)e^{-W_j}(1+e^{i\pi(h+k+l)}) \quad (9)$$

where the $\pm$ indicates the two polarization states of the incident neutrons. The phase factor in parentheses originates from the sum over the unit cell, which in this case is just two identical atoms located at the origin (0,0,0) and the body-centered position (1/2,1/2,1/2), and (hkl) are Miller indices (SYMMETRY IN CRYSTALLOGRAPHY). This gives the familiar selection rule that for a bcc lattice $h+k+l$ must be an even integer for Bragg reflection to occur. The smallest nonzero reciprocal lattice vector is then the (1,1,0), and for this reflection ($\mathbf{g} = 3.10$ Å^{-1}) the magnetic scattering amplitude is as follows:

$$p = (0.27 \times 10^{-12}\ \text{cm})(2.2)(0.59) = 0.35 \times 10^{-12}\ \text{cm} \quad (10)$$

The coherent nuclear scattering amplitude for iron is $b = 0.945 \times 10^{-12}$ cm and is independent of the Bragg reflection. The flipping ratio R is defined as the ratio of the intensities for the two neutron polarizations; for this reflection we have

$$R = \left(\frac{0.945 + 0.35}{0.945 - 0.35}\right)^2 = 4.74 \quad (11)$$

Note that, for a different Bragg reflection, the only quantity that changes is $f(\mathbf{g})$, so that a measurement of the flipping ratio at a series of Bragg peaks (hkl) can be used to make precision determinations of the magnetic form factor, and thus by Fourier transform the spatial distribution of the atomic magnetization density. It also should be noted that if $b \approx p$, then the flipping ratio will be very large, and this is in fact one of the standard methods employed to produce a polarized neutron beam in the first place.

In the more general situation when the magnetic structure is not a simple ferromagnet, polarized beam diffraction measurements with polarization analysis of the scattered neutrons must be used to establish unambiguously which peaks are magnetic, which are nuclear, and more generally to separate the magnetic and nuclear scattering at Bragg positions where there are both nuclear and magnetic contributions. The polarization analysis technique as applied to this problem is in principle straightforward; complete details can be found elsewhere (Moon et al., 1969; Williams, 1988). Nuclear coherent Bragg scattering never causes a reversal, or spin-flip, of the neutron spin direction upon scattering. Thus the nuclear peaks will only be observed in the non-spin-flip scattering geometry. We denote this configuration as $(+\ +)$, where the neutron is incident with up spin, and remains in the up state after scattering. Non-spin-flip scattering also occurs if the incident neutron is in the down state, and remains in the down state after scattering [denoted $(-\ -)$]. The magnetic cross-sections, on the other hand, depend on the relative orientation of the neutron polarization $\mathbf{P}$ and the reciprocal lattice vector $\mathbf{g}$. In the configuration where $\mathbf{P} \perp \mathbf{g}$, half the magnetic Bragg scattering involves a reversal of the neutron spin [denoted by $(-\ +)$ or $(+\ -)$], and half does not. Thus, for the case of a purely magnetic reflection the spin-flip $(-\ +)$ and non-spin-flip $(+\ +)$ intensities should be equal in intensity. For the case where $\mathbf{P} \parallel \mathbf{g}$, all the magnetic scattering is spin-flip. Hence for a pure magnetic Bragg reflection the spin-flip scattering should be twice as strong as for the $\mathbf{P} \perp \mathbf{g}$ configuration, while ideally no non-spin-flip scattering will be observed. The analysis of these cross-sections can be used to unambiguously identify nuclear from magnetic Bragg scattering.

Inelastic Scattering

Magnetic inelastic scattering plays a unique role in determining the spin dynamics in magnetic systems, as it is the only probe that can directly measure the complete magnetic excitation spectrum. Typical examples are spin wave dispersion relations, critical fluctuations, crystal field excitations, and moment/valence fluctuations.

As an example, consider identical spins S on a simple cubic lattice, with a coupling given by $-JS_i \cdot S_j$ where J is the (Heisenberg) exchange interaction between neighbors separated by the distance a. The collective excitations for such an ensemble of spins are magnons (or loosely termed "spin waves"). If we have $J > 0$ so that the lowest energy configuration is where the spins are parallel (a ferromagnet), then the magnon dispersion along the edge of the cube (the [100] direction) is given by $E(q) = 8JS[\sin^2(qa/2)]$. At each wave vector $\mathbf{q}$, the magnon energy is different, and a neutron can interact with the system of spins and either create a magnon at $(\mathbf{q}, E)$, with a concomitant change of momentum and loss of energy of the neutron, or conversely destroy a magnon with a gain in energy. The observed change in momentum and energy for the neutron can then be used to map out the magnon dispersion relation. Neutron scattering is particularly well suited for such inelastic scattering studies since neutrons typically have energies that are comparable to the energies of excitations in the solid, and therefore the neutron energy changes are large and easily measured. The dispersion relations can then be measured over the entire Brillouin zone (see, e.g., Lovesey, 1984).

Additional information about the nature of the excitations can be obtained by polarized inelastic neutron scattering techniques, which are finding increasing use. Spin wave scattering is represented by the raising and lowering operators $S\pm = S_x \pm iS_y$, which cause a reversal of the neutron spin when the magnon is created or destroyed. These "spin-flip" cross-sections are denoted by $(+\ -)$ and $(-\ +)$. If the neutron polarization $\mathbf{P}$ is parallel to the momentum transfer $\mathbf{Q}$, $\mathbf{P} \parallel \mathbf{Q}$, then spin angular momentum is conserved (as there is no orbital contribution in this case). In this experimental geometry, we can only create a spin wave in the $(-\ +)$ configuration, which at the same time causes the total magnetization of the sample to decrease by one unit ($1\mu_B$). Alternatively, we can destroy a spin wave only in the $(+\ -)$ configuration, while increasing the magnetization by one unit. This gives us a unique way to unambiguously identify the spin wave scattering, and polarized beam techniques in general can be used to distinguish magnetic from nuclear scattering in a manner similar to the case of Bragg scattering.

Finally, we note that the magnetic Bragg scattering is comparable in strength to overall magnetic inelastic scattering. However, all the Bragg scattering is located at a single point in reciprocal space, while the inelastic scattering is distributed throughout the (three-dimensional) Brillouin zone. Hence, when actually making inelastic measurements to determine the dispersion of the excitations, one can only observe a small portion of the dispersion surface at any one time, and thus the observed inelastic scattering is typically two to three orders of magnitude less intense than the Bragg peaks. Consequently these are much more time-consuming measurements, and larger samples are needed to offset the reduction in intensity. Of course, a successful determination of the dispersion relations yields a complete determination of the fundamental atomic interactions in the solid.

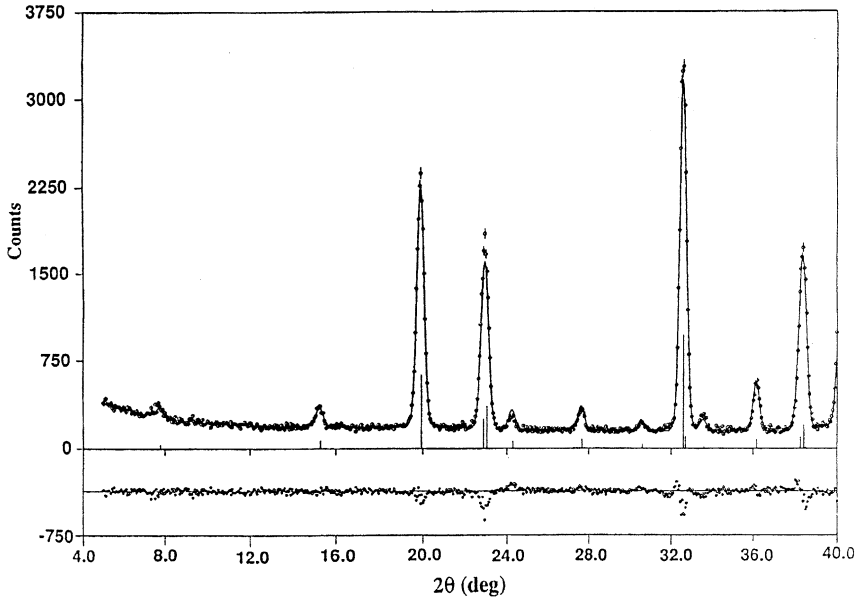

Figure 1. Calculated (solid curve) and observed intensities at room temperature for a powder of antiferromagnetically ordered $YBa_2Fe_3O_8$. The differences between calculated and observed are shown at the bottom. (Huang et al., 1992.)

PRACTICAL ASPECTS OF THE METHOD

Diffraction

As an example of Bragg scattering, a portion of the powder diffraction pattern from a sample of $YBa_2Fe_3O_8$ is shown in Figure 1 (Huang et al., 1992). The solid curve is a Rietveld refinement (Young, 1993) of both the antiferromagnetic and crystallographic structure for the sample. From this type of data, we can determine the full crystal structure; lattice parameters, atomic positions in the unit cell, site occupancies, etc. We can also determine the magnetic structure and value of the ordered moment. The results of the analysis are shown in Figure 2; the crystal structure is identical to the structure for the $YBa_2Cu_3O_7$ high-T_C cuprate superconductor, with the Fe replacing the Cu, and the magnetic structure is also the same as has been observed for the Cu spins in the oxygen-reduced ($YBa_2Cu_3O_6$) semiconducting material.

Experimentally, we can recognize the magnetic scattering by several characteristics. First, it should be temperature-dependent, and the Bragg peaks will vanish above the ordering temperature. Figure 3 shows the temperature dependence of the intensity of the peak at a scattering angle of 19.5° in Figure 1. The data clearly reveal a phase transition at the Néel temperature for $YBa_2Fe_3O_8$ of 650 K (Natali Sora et al., 1994); the Néel temperature is where long-range antiparallel order of the spins first occurs. Above the antiferromagnetic phase transition, this peak completely disappears, indicating that it is a purely magnetic Bragg peak. A second characteristic is that the magnetic intensities become weak at high scattering angles (not shown), as $f(\mathbf{g})$ typically falls off strongly with increasing angle. A third, more elegant, technique is to use polarized neutrons. The polarization technique can be used at any temperature, and for any material, regardless of whether or not it has a crystallographic distortion (e.g., via magnetoelastic interactions) associated with the magnetic transition. It is more involved and time-consuming experimentally, but yields an unambiguous identification and separation of magnetic and nuclear Bragg peaks.

First consider the case where $\mathbf{P} \parallel \mathbf{g}$, which is generally achieved by having a horizontal magnetic field, which must also be oriented along the scattering vector. In this geometry, all the magnetic scattering is spin-flip, while the nuclear scattering is always non-spin-flip. Hence for a magnetic Bragg peak the spin-flip scattering should be twice as strong as for the $\mathbf{P} \perp \mathbf{g}$ configuration (vertical

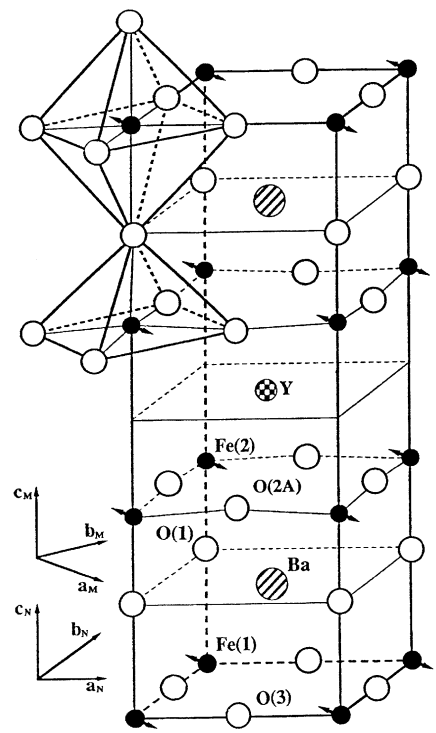

Figure 2. Crystal and magnetic structure for $YBa_2Fe_3O_8$ deduced from the data of Figure 1. (Huang et al., 1992.)

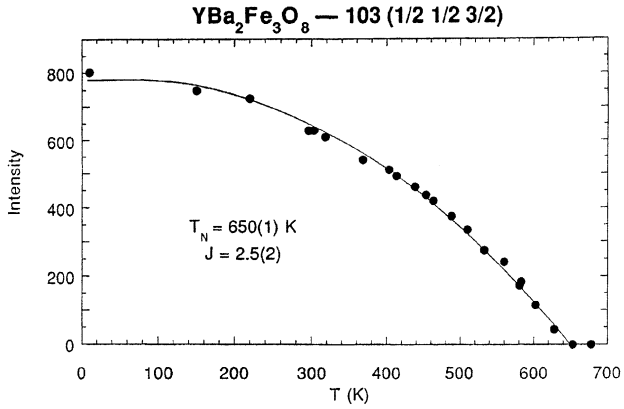

Figure 3. Temperature dependence of the intensity of the magnetic reflection found at a scattering angle of 19.5° in Figure 1. The Néel temper ature is 650 K. (Natali et al., 1994.)

field), while the nuclear scattering is non-spin-flip scattering and independent of the orientation of **P** and **g**. Figure 4 shows the polarized beam results for the same two peaks, at scattering angles (for this wavelength) of 30° and 35°; these correspond to the peaks at 19.5° and 23° in Figure 1. The top section of the figure shows the data for the $\mathbf{P} \perp \mathbf{g}$ configuration. The peak at 30° has the identical intensity for both spin-flip and non-spin-flip scattering, and hence we conclude that this scattering is purely magnetic in origin, as inferred from Figure 3. The peak at 35°, on the other hand, has strong intensity for (+ +), while the intensity for (− +) is smaller by a factor of 1/11, the instrumental flipping ratio in this measurement. Hence, ideally there would be no spin-flip scattering, and this peak is identified as a pure nuclear reflection. The center row shows the same peaks for the $\mathbf{P} \parallel \mathbf{g}$ configuration, while the bottom row shows the subtraction of the $\mathbf{P} \perp \mathbf{g}$ spin-flip scattering from the $\mathbf{P} \parallel \mathbf{g}$ spin-flip scattering. In this subtraction procedure, instrumental background, as well as all nuclear scattering cross-sections, cancel, isolating the magnetic scattering. We see that there is magnetic intensity only for the low angle position, while no intensity survives the subtraction at the 35° peak position. These data unambiguously establish that the 30° peak is purely magnetic, while the 35° peak is purely nuclear. This simple example demonstrates how the technique works; obviously it would play a much more critical role in cases where it is not clear from other means what is the origin of the peaks, such as in regimes where the magnetic and nuclear peaks overlap, or in situations where the magnetic transition is accompanied by a structural distortion. If needed, a complete "magnetic diffraction pattern" can be obtained and analyzed with these polarization techniques.

In cases where there is no significant coupling of the magnetic and lattice systems, on the other hand, the subtraction technique can also be used to obtain the magnetic diffraction pattern (see, e.g., Zhang et al., 1990). This technique is especially useful for low-temperature magnetic phase transitions where the Debye-Waller effects can be

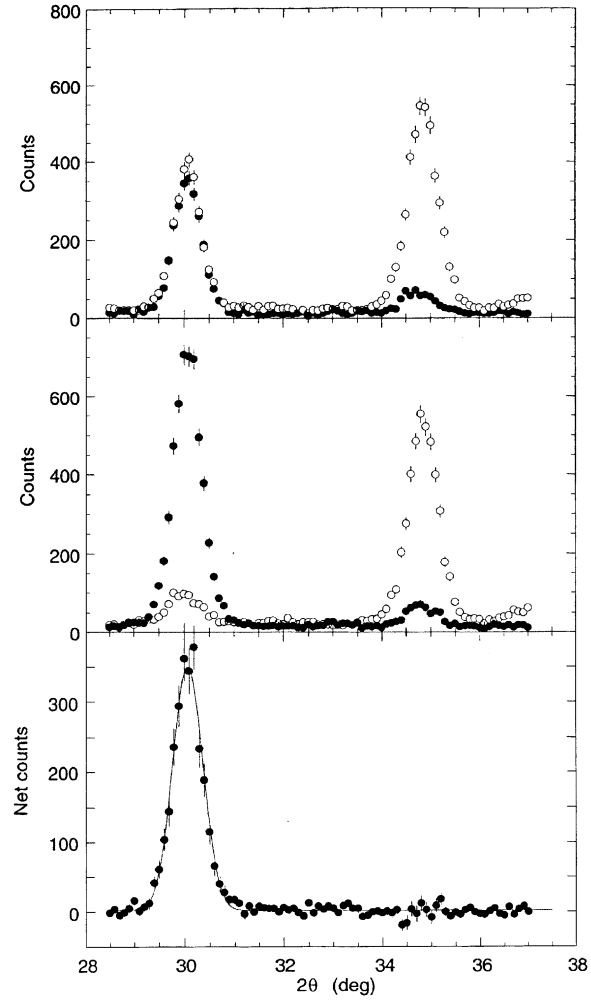

Figure 4. Polarized neutron scattering. The top portion of the figure is for $\mathbf{P} \perp \mathbf{g}$, where the open circles show the non-spin-flip scattering and the filled circles are the observed scattering in the spin-flip configuration. The low angle peak has equal intensity for both cross-sections, and thus is identified as a pure magnetic reflection, while the ratio of the (++) to (−+) scattering for the high-angle peak is 11, the instrumental flipping ratio. Hence this is a pure nuclear reflection. The center portion of the figure is for $\mathbf{P} \perp \mathbf{g}$ and the bottom portion is the subtraction of the $\mathbf{P} \perp \mathbf{g}$ spin-flip scattering from the data for $\mathbf{P} \parallel \mathbf{g}$. Note that in the subtraction procedure all background and nuclear cross-sections cancel, isolating the magnetic scattering. (Huang et al., 1992.)

safely neglected. Figure 5 shows the diffraction patterns for $Tm_2Fe_3Si_5$, which is an antiferromagnetic material that becomes superconducting under pressure (Gotaas et al., 1987). The top part of the figure shows the diffraction pattern obtained above the antiferromagnetic ordering temperature of 1.1 K, where just the nuclear Bragg peaks are observed. The middle portion of the figure shows the low-temperature diffraction pattern in the ordered state, which contains both magnetic and nuclear Bragg peaks, and the bottom portion shows the subtraction, which gives the magnetic diffraction pattern.

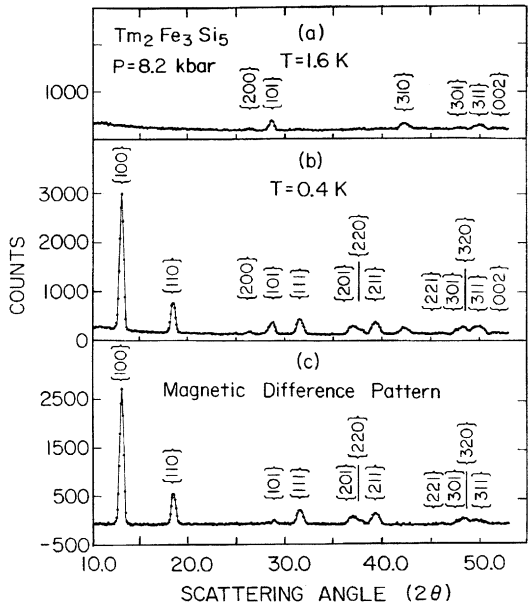

Figure 5. Diffraction patterns for the antiferromagnetic superconductor $Tm_2Fe_3Si_5$. The top part of the figure shows the nuclear diffraction pattern obtained above the antiferromagnetic ordering temperature of 1.1 K, the middle portion of the figure shows the low-temperature diffraction pattern in the ordered state, and the bottom portion shows the subtraction of the two, which gives the magnetic diffraction pattern. (Gotaas et al., 1987.)

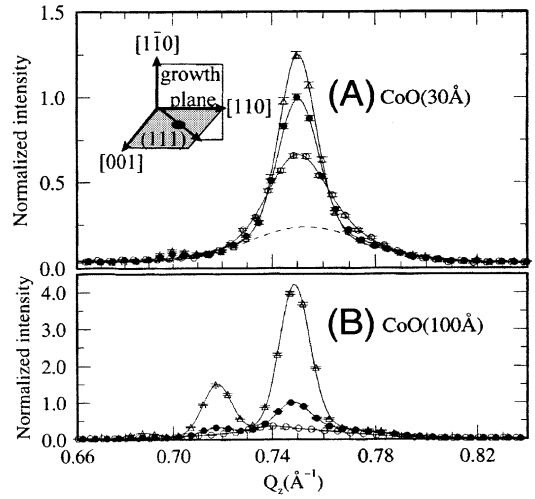

Figure 7. Neutron diffraction scans of the (111) reflection along the [001] growth axis direction (scattering vector $\mathbf{Q}_z$) for (**A**) $[Fe_3O_4$/(100 Å)CoO(30 Å)$]_{50}$ and (**B**) $[Fe_3O_4$/(100 Å)CoO(100 Å)$]_{50}$ superlattices, taken at 78 K in zero applied field. The closed circles, open circles, and triangles indicate data taken after zero-field cooling (initial state), field cooling with an applied field ($H = 14$ kOe) in the [110] direction, and field cooling with an applied field in the [110] direction, respectively. The inset illustrates the scattering geometry. The dashed lines indicate the temperature-and field-independent Fe_3O_4 component (Ijiri et al., 1998).

Another example of magnetic Bragg diffraction is shown in Figure 6. Here we show the temperature dependence of the intensity of an antiferromagnetic Bragg peak on a single crystal of the high-T_C superconductor ($T_C \approx 92$ K) $ErBa_2Cu_3O_7$ (Lynn et al., 1989). The magnetic interactions of the Er moments in this material are highly anisotropic, and this system turns out to be an ideal two-dimensional (2D) (planar) Ising antiferromagnet; the solid curve is Onsager's exact solution to the $S = \frac{1}{2}$, 2D Ising model (Onsager, 1944), and we see that it provides an excellent representation of the experimental data.

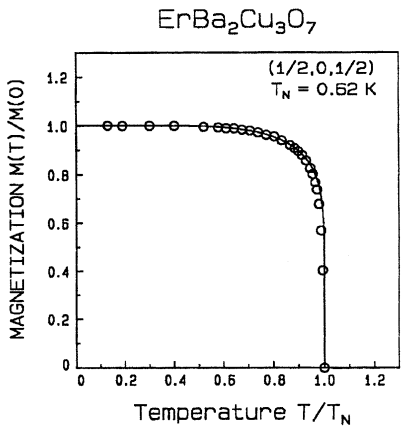

Figure 6. Temperature dependence of the sublattice magnetization for the Er spins in superconducting $ErBa_2Cu_3O_7$, measured on a single crystal weighing 31 mg. The solid curve is Onsager's exact theory for the 2D, $S = \frac{1}{2}$, Ising model (Lynn et al., 1989).

A final diffraction example is shown in Figure 7, where the data for two Fe_3O_4/CoO superlattices are shown (Ijiri et al., 1998). The superlattices consist of 50 repeats of 100-Å thick layers of magnetite, which is ferrimagnetic, and either 30- or 100-Å thick layers of the antiferromagnet CoO. The superlattices were grown epitaxially on single-crystal MgO substrates, and thus these may be regarded as single-crystal samples. These scans are along the growth direction (Q_z), and show the changes in the magnetic scattering that occur when the sample is cooled in an applied field, versus zero-field cooling. These data, together with polarized beam data taken on the same samples, have elucidated the origin of the technologically important exchange biasing effect that occurs in these magnetic superlattices.

It is interesting to compare the type and quality of data that are represented by these three examples. The powder diffraction technique is quite straightforward, both to obtain and analyze the data. In this case, typical sample sizes are ~1–20 g, and important and detailed information can be readily obtained with such sample sizes in a few hours of spectrometer time, depending on the particulars of the problem. The temperature dependence of the order parameter in $ErBa_2Cu_3O_7$, on the other hand, was obtained on a single crystal weighing only 31 mg. Note that the statistical quality of the data is much better than for the powder sample, even though the sample is more than 2 orders of magnitude smaller; this is because it is a single crystal and all the scattering is directed into a single peak, rather than scattering into a powder-diffraction ring. The final example was for Fe_3O_4/CoO

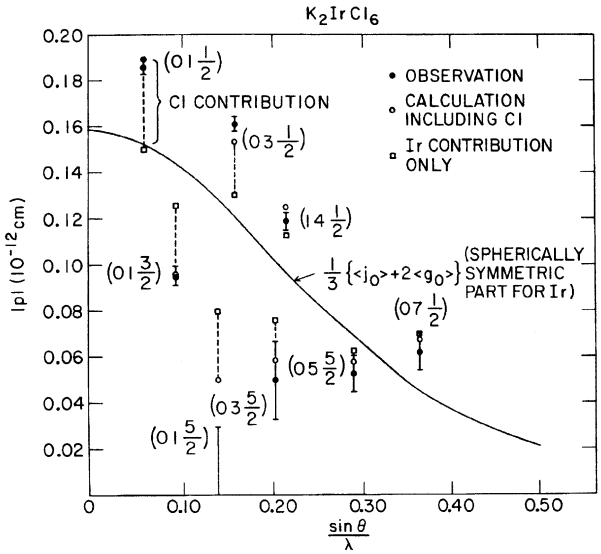

Figure 8. Comparison of the observed and calculated magnetic form factor for the cubic K_2IrCl_6 system, showing the enormous directional anisotropy along the spin direction ([001] direction) compared with perpendicular to the spin direction. The contribution of the Cl moments along the spin direction, arising from the covalent bonding, is also indicated; no net moment is transferred to the Cl ions that are perpendicular to the spin direction. (Lynn et al., 1976.)

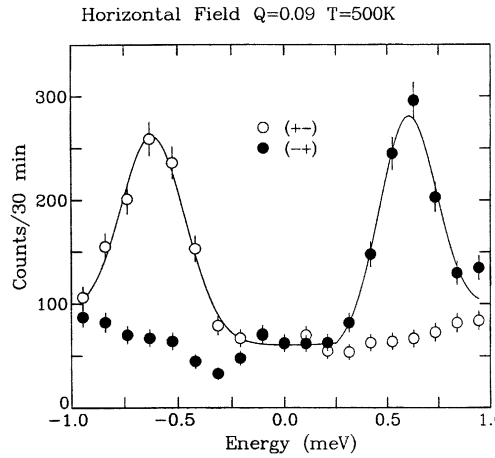

Figure 9. Spin-flip scattering observed for the amorphous Invar $Fe_{86}B_{14}$ isotropic ferromagnetic system in the $\mathbf{P} \parallel \mathbf{Q}$ configuration. Spin waves are observed for neutron energy gain ($E < 0$) in the $(+-)$ cross-section, and for neutron energy loss ($E > 0$) in the $(-+)$ configuration. (Lynn et al., 1993.)

superlattices, where the weight of the superlattices that contribute to the scattering is ~1 mg. Thus it is clear that interesting and successful diffraction experiments can be carried out on quite small samples.

The final example in this section addresses the measurement of a magnetic form factor, in the cubic antiferromagnetic K_2IrCl_6. The Ir ions occupy a face-centered cubic (fcc) lattice, and the *5d* electrons carry a magnetic moment that is covalently bonded to the six Cl ions located octahedrally around each Ir ion. One of the interesting properties of this system is that there is charge transfer from the Ir equally onto the six Cl ions. A net spin transfer, however, only occurs for the two Cl ions along the direction in which the Ir spin points. This separation of spin and charge degrees of freedom leads to a very unusual form factor that is highly anisotropic, as shown in Figure 8 (Lynn et al., 1976). Note the rapid decrease in the form factor as one proceeds along the (*c* axis) spin direction, from the (0,1,1/2), to the (0,1,3/2), then to the (0,1,5/2) Bragg peak, which in fact has an unobservable intensity. In this example, ~30% of the total moment is transferred onto the Cl ions, which is why these covalency effects are so large in this compound. It should be noted that, in principle, x-ray scattering should be able to detect the charge transferred onto the (six) Cl ions as well, but this is much more difficult to observe because it is a very small fraction of the total charge. In the magnetic case, in contrast, it is a large percentage effect and has a different symmetry than the lattice, which makes the covalent effects much easier to observe and interpret.

Inelastic Scattering

There are many types of magnetic excitations and fluctuations that can be measured with neutron scattering techniques, such as magnons, critical fluctuations, crystal field excitations, magnetic excitons, and moment/valence fluctuations. To illustrate the basic technique, consider an isotropic ferromagnet at sufficiently long wavelengths (small q). The spin wave dispersion relation is given by $E_{sw} = D(T)q^2$, where D is the spin wave "stiffness" constant. The general form of the spin wave dispersion relation is the same for all isotropic ferromagnets, a requirement of the (assumed) perfect rotational symmetry of the magnetic system, while the numerical value of D depends on the details of the magnetic interactions and the nature of the magnetism. One example of a prototypical isotropic ferromagnet is amorphous $Fe_{86}B_{14}$. Figure 9 shows an example of polarized beam inelastic neutron scattering data taken on this system (Lynn et al., 1993). These data were taken with the neutron polarization $\mathbf{P}$ parallel to the momentum transfer $\mathbf{Q}(\mathbf{P} \parallel \mathbf{Q})$, where we should be able to create a spin wave only in the $(-+)$ configuration, or destroy a spin wave only in the $(+-)$ configuration. This is precisely what we see in the data—for the $(-+)$ configuration the spin waves can only be observed for neutron energy loss scattering ($E > 0$), while for the $(+-)$ configuration, spin waves can only be observed in neutron energy gain ($E < 0$). This behavior of the scattering uniquely identifies these excitations as spin waves.

Data like these can be used to measure the renormalization of the spin waves as a function of temperature, as well as to determine the lifetimes as a function of wave vector and temperature. An example of the renormalization of the "stiffness" constant D for the magnetoresistive oxide $Tl_2Mn_2O_7$ is shown in Figure 10 (Lynn et al., 1998). Here, the wave vector dependence of the dispersion relation has been determined at a series of q's, and the stiffness parameter is extracted from the data. The variation in the stiffness parameter is then plotted, and indicates a

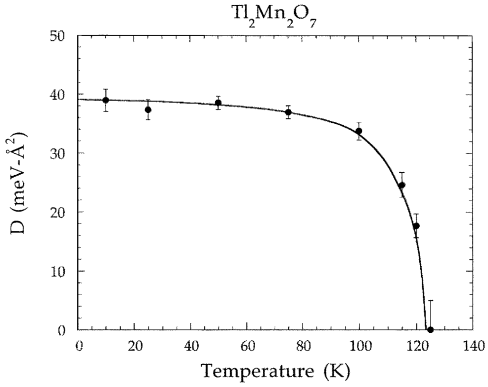

Figure 10. Temperature dependence of the spin wave stiffness $D(T)$ in the magnetoresistive $Tl_2Mn_2O_7$ pyrochlore, showing that the spin waves renormalize as the ferromagnetic transition is approached. (Lynn et al., 1998.) Below T_C the material is a metal, while above T_C it exhibits insulator behavior.

smooth variation with a ferromagnetic transition temperature of 123 K. These measurements can then be compared directly with theoretical calculations. They can also be compared with other experimental observations, such as magnetization measurements, whose variation with temperature originates from spin wave excitations.

Finally, these types of measurements can be extended all the way to the zone boundary on single crystals. Figure 11 shows an example of the spin wave dispersion relation for the ferromagnet $La_{0.85}Sr_{0.15}MnO_3$, a system that undergoes a metal-insulator transition that is associated with the transition to ferromagnetic order (Vasiliu-Doloc et al., 1998). The top part of the figure shows the dispersion relation for the spin wave energy along two high-symmetry directions, and the solid curves are fits to a simple nearest-neighbor spin-coupling model. The overall trend of the data is in reasonable agreement with the model, although there are some clear discrepancies as well, indicating that a more sophisticated model will be needed in order to obtain quantitative agreement. In addition to the spin wave energies, though, information about the intrinsic lifetimes can also be determined, and these linewidths are shown in the bottom part of the figure for both symmetry directions. In the simplest type of model, no intrinsic spin wave linewidths at all would be expected at low temperatures, while we see here that the observed linewidths are very large and highly anisotropic, indicating that an itinerant-electron type of model is more appropriate for this system.

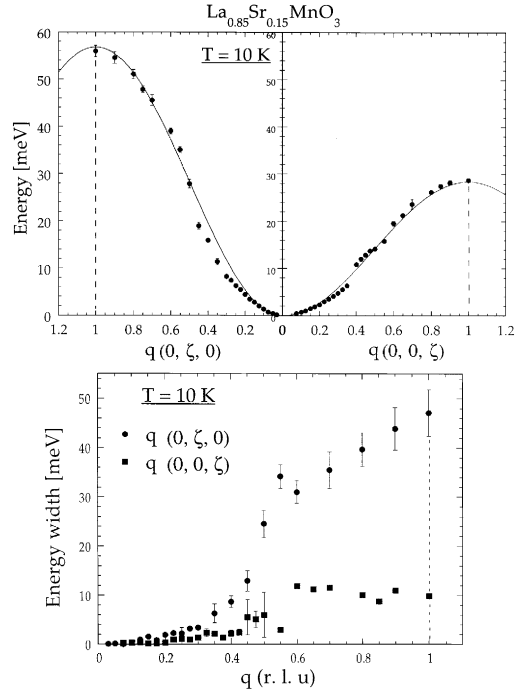

Figure 11. Ground state spin wave dispersion along the (0,1,0) and (0,0,1) directions measured to the zone boundary for the magnetoresistive manganite $La_{0.85}Sr_{0.15}MnO_3$. The solid curves are a fit to the dispersion relation for a simple Heisenberg exchange model. The bottom part of the figure shows the intrinsic linewidths of the excitations. In the standard models, intrinsic linewidths are expected only at elevated temperatures. The large observed linewidths demonstrate the qualitative inadequacies of these models. (Vasiliu-Doloc et al., 1998.)

METHOD AUTOMATION

Neutrons for materials research are produced by one of two processes; fission of U^{235} in a nuclear reactor, or by the spallation process where high energy protons from an accelerator impact on a heavy-metal target like W and explode the nuclei. Both techniques produce high-energy (MeV) neutrons, which are then thermalized or sub-thermalized in a moderator (such as heavy water) to produce a Maxwellian spectrum of thermal or cold neutrons, with energies in the meV range. Thus all neutron scattering instrumentation is located at centralized national facilities, and each facility generally has a wide variety of instrumentation that has been designed and constructed for the specific facility, and is maintained and scheduled by facility scientists. Generally, any of these instruments can be used to observe magnetic scattering, and with the number and diversity of spectrometers in operation it is not practical to review the instrumentation here; the interested user should contact one of the facilities directly. The facilities themselves operate for periods of weeks at a time continuously, and hence, since the early days of neutron scattering all the data collection has been accomplished by automated computer control.

SAMPLE PREPARATION

As a general rule, there is no particular preparation that is required for the sample, in the sense that there is no need, for example, to polish the surface, cleave it under high vacuum, or perform similar procedures. Neutrons are a deeply penetrating bulk probe, and hence generally do not interact with the surface. There are two exceptions to this rule. One is when utilizing polarized neutrons in the investigation of systems with a net magnetization, where a rough surface can cause the variations in the local

magnetic field that depolarize the neutrons. In such cases, the surface may need to be polished. The second case is for neutron reflectometry, where small-angle mirror reflection is used to directly explore the magnetization profile of the surface and interfacial layers. In this case, the samples need to be optically flat over the full size of the sample (typically 1 to 10 cm^2), and of course the quality of the film in terms of, e.g., surface roughness and epitaxial quality becomes part of the investigation.

For magnetic single crystal diffraction, typical sample sizes should be no more than a few mm^3 in order to avoid primary and secondary extinction effects; if the sample is too large, extinction will always limit the accuracy of the data obtained. Since the magnetic Bragg intensity is proportional to the square of the ordered moment, any extinction effects will depend on the value of $\langle \mu_z \rangle$ at a particular temperature and field, while the ideal size of the sample can vary by three to four orders of magnitude, depending on the value of the saturation moment.

Powder diffraction requires gram-sized samples, generally in the range of 1 to 20 g. The statistical quality of the data that can be obtained is directly related to the size, so in principle there is a direct trade-off between sample size and the time required to collect a set of diffraction data at a particular temperature or magnetic field. Sample sizes smaller than 1 g can also be measured, but since the neutron facilities are heavily oversubscribed, in practice a smaller sample size translates into fewer data sets, so an adequate-sized sample is highly desirable.

The cross-sections for inelastic scattering are typically two to three orders of magnitude smaller than elastic cross-sections, and therefore crystals for inelastic scattering typically must be correspondingly larger in comparison with single-crystal diffraction. Consequently, for both powder diffraction and inelastic scattering, the general rule is the bigger the sample the better the data. The exception is if one or more of the elements in a material has a substantial nuclear absorption cross-section, in which case the optimal size of the sample is then determined by the inverse of this absorption length. The absorption cross-sections are generally directly proportional to the wavelength of the neutrons being employed for a particular measurement, and the optimal sample size then depends on the details of the spectrometer and the neutron wavelength(s). For the absorption cross-sections of all the elements, see Internet Resources. In some cases, particular isotopes can be substituted to avoid some large absorption cross-sections, but generally these are expensive and/or are only available in limited quantity. Therefore isotopic substitution can be employed only for a few isotopes that are relatively inexpensive, such as deuterium or boron, or in scientifically compelling cases where the cost can be justified.

DATA ANALYSIS AND INITIAL INTERPRETATION

One of the powers of neutron scattering is that it is a very versatile tool and can be used to probe a wide variety of magnetic systems over enormous ranges of length scale ($\sim$0.1 to 10000 Å) and dynamical energy ($\sim$10 neV to 1 eV). The instrumentation to provide these measurement capabilities is equally diverse, but data analysis software is generally provided for each instrument to perform the initial interpretation of the data. Moreover, the technique is usually sufficiently fundamental and the interpretation sufficiently straightforward that the initial data analysis is often all that is needed.

PROBLEMS

Neutron scattering is a very powerful technique, but in general it is a flux-limited, and this usually requires a careful tradeoff between instrumental resolution and signal. There can also be unwanted cross-sections that appear and contaminate the data, and so one must of course exercise care in collecting the data and be vigilant in its interpretation. If a time-of-flight spectrometer is being employed, for example, there may be frame overlap problems that can mix the fastest neutrons with the slowest, and give potentially spurious results. Similarly, if the spectrometer employs one or more single crystals to monochromate or analyze the neutron energies, then the crystal can reflect higher-order wavelengths [since Bragg's law is $n\lambda = 2d\sin(\theta)$] which can give spurious peaks. Sometimes these can be suppressed with the use of filters, but more generally it is necessary to vary the spectrometer conditions and retake the data in order to identify genuine cross-sections from spurious ones. This identification process can consume considerable beam time.

Another problem can be encountered in identifying the magnetic Bragg scattering in powders using the subtraction technique. If the temperature is sufficiently low, the nuclear spins may begin to align with the electronic spins, particularly if there is a large hyperfine field. Significant polarization can occur at temperatures of a few degrees kelvin and lower, and the nuclear polarization can be confused with electronic magnetic ordering. Another problem can be encountered if the temperature dependence of the Debye-Waller factor is significant, or if there is a structural distortion associated with the magnetic transition, such as through a magnetoelastic interaction. In this case, the nuclear intensities will not be identical, and thus will not cancel correctly in the subtraction. It is up to the experimenter to decide if this is a problem, within the statistical precision of the data. A problem can also occur if there is a significant thermal expansion, where the diffraction peaks shift position with temperature. By significant, we mean that the shift is noticeable in comparison with the instrumental resolution employed. Again it is up to the experimenter to decide if this is a problem. In both these latter cases, though, a full refinement of the combined magnetic and nuclear structures in the ordered phase can be carried out. Alternatively, polarized beam techniques can be employed to unambiguously separate the magnetic and nuclear cross-sections. Finally, if one uses the subtraction technique in the method where a field is applied, the field can cause the powder particles to reorient if there is substantial crystalline magnetic anisotropy in the sample. This preferred orientation will remain when the field is removed, and will be evident in the nuclear peak intensities, but must be taken into account.

Finally, we remark about the use of polarized neutrons. Highly polarized neutron beams can be produced by single-crystal diffraction from a few special magnetic materials, from magnetic mirrors, or from transmission of the beam through a few specific nuclei where the absorption cross-section is strongly spin dependent. The choices are limited, and consequently most spectrometers are not equipped with polarization capability. For instruments that do have a polarized beam option, generally one has to sacrifice instrumental performance in terms of both resolution and intensity. Polarization techniques are then typically not used for many problems in a routine manner, but rather are usually used to answer some specific question or make an unambiguous identification of a cross-section, most often after measurements have already been carried out with unpolarized neutrons.

ACKNOWLEDGMENTS

I would like to thank my colleagues, Julie Borchers, Qing Huang, Yumi Ijiri, Nick Rosov, Tony Santoro, and Lida Vasiliu-Doloc, for their assistance in the preparation of this unit.

There are vast numbers of studies in the literature on various aspects presented here. The specific examples used for illustrative purposes were chosen primarily for the author's convenience in obtaining the figures, and his familiarity with the work.

x-ray magnetic circular dichroism (XMCD), 957–959
Benzoic acid, combustion calorimetry, 372
Bessel function, small-angle scattering (SAS), 220–221

Bethe approximation
energy-dispersive spectrometry (EDS), standardless analysis, 1148–1149
ion beam analysis (IBA), 1176
multiple-beam diffraction, 239
Bethe-Slater curve, ferromagnetism, 525–526
Bias conditions, deep level transient spectroscopy (DLTS), semiconductor materials, 421–422
Bidimensional rotating frame NQRI, emergence of, 787–788
Bilayer materials, angle-resolved x-ray photoelectron spectroscopy (ARXPS), 987–988
Bimolecular reaction rates, chemical vapor deposition (CVD) model, gas-phase chemistry, 169
Binary collisions, particle scattering, 51
general formula, 52
Binary/multicomponent diffusion
applications, 155
dependent concentration variable, 151
frames of reference and diffusion coefficients, 147–150
Kirkendall effect and vacancy wind, 149
lattice-fixed frame of reference, 148
multicomponent alloys, 150–151
number-fixed frame of reference, 147–148
tracer diffusion and self-diffusion, 149–150
transformation between, 148–149
volume-fixed frame of reference, 148
linear laws, 146–147
Fick's law, 146–147
mobility, 147
multicomponent alloys
Fick-Onsager law, 150
frames of reference, 150–151
research background, 145–146
substitutional and interstitial metallic systems, 152–155
B2 intermetallics, chemical order, 154–155
frame of reference and concentration variables, 152
interdiffusion, 155
magnetic order, 153–154
mobilities and diffusivities, 152–153
temperature and concentration dependence of mobilities, 153
Binary phase information, differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 368
Binding energy
Auger electron spectroscopy (AES), 1159–1160
x-ray photoelectron spectroscopy (XPS)
chemical state information, 986
final-state effects, 975–976
B2 intermetallics, binary/multicomponent diffusion, 154–155
Biological materials
scanning electrochemical microscopy (SECM), 644
scanning tunneling microscopy (STM) analysis, 1115
Biot-Savart law, electromagnet structure and properties, 499–500
Bipolar junction transistors (BJTs), characterization
basic principles, 467–469
competitive and complementary techniques, 466–467
limitations of, 471
measurement equipment sources and selection criteria, 471
protocols and procedures, 469–470
research background, 466–467
sample preparation, 470–471

Bipolar magnetic field gradient, magnetic resonance imaging (MRI), flow imaging sequence, 769–770
Bipotentiostat instrumentation, scanning electrochemical microscopy (SECM), 642–643
Birefringent polarizer, ellipsometry, 738
Bitter pattern imaging, magnetic domain structure measurements, 545–547
Black-body law, radiation thermometer, 36–37
"Bleach-out" effect, nuclear quadrupole resonance (NQR), spin relaxation, 780
Bloch wave vector
  diffuse intensities, metal alloys, first-principles calcuations, electronic structure, 265–266
  dynamical diffraction, 228
  scanning transmission electron microscopy (STEM)
    dynamical diffraction, 1101–1103
    strain contrast imaging, 1106–1108
  solid-solution alloy magnetism, 183–184
Bode plots
  corrosion quantification, electrochemical impedance spectroscopy (EIS), 599–603
  semiconductor-liquid interfaces, differential capacitance measurements, 617–619
Body-centered cubic (bcc) cells
  iron (Fe) magnetism
    local moment fluctuation, 187–188
    Mössbauer spectroscopy, 828–830
  x-ray diffraction, structure-factor calculations, 209
Bohr magnetons
  magnetic fields, 496
  magnetic moments, atomic and ionic magnetism, local moment origins, 513–515
  paramagnetism, 493–494
  transition metal magnetic ground state, itinerant magnetism at zero temperature, 182–183
Bohr velocity, ion beam analysis (IBA), 1175–1176
Boltzmann constant
  chemical vapor deposition (CVD) model
    gas-phase chemistry, 169
    kinetic theory, 171
  liquid surface x-ray diffraction, simple liquids, 1040–1041
  phonon analysis, 1318
  pn junction characterization, 467–468
  thermal diffuse scattering (TDS), 213
Boltzmann distribution function
  Hall effect, semiconductor materials, 412
  quantum paramagnetiic response, 521–522
  semiconductor-liquid interface, dark current-potential characteristics, 607
Bond distances
  diffuse scattering techniques, 885
  single-crystal x-ray structure determination, 861–863
Bonding-antibonding
  Friedel's *d*-band energetics, 135
  metal alloys, transition metals, 136–137
Bonding principles
  metal alloys
    limits and pitfalls, 138–144
      accuracy limits, 139–141
      all-electron *vs.* pseudopotential methods, 141–142
      basis sets, 142–143
      first principles *vs.* tight binding, 141
      full potentials, 143
      precision issues, 141–144
      self-consistency, 141
      structural relaxations, 143–144
    phase formation, 135–138
      bonding-antibonding effects, 136–137
      charge transfer and electronegativities, 137–138
      Friedel's *d*-band energetics, 135
      size effects, 137
      topologically close-packed phases, 135–136
      transition metal crystal structures, 135
      wave function character, 138
    research background, 134–135
  surface phenomena, molecular dynamics (MD) simulation, 156–157
  x-ray photoelectron spectroscopy (XPS), initial-state effects, 976–978
Boonton 72B meter, capacitance-voltage (C-V) characterization, 460–461
Borie-Sparks (BS) technique, diffuse scattering techniques, 886–889
  data interpretation, 895–897
Born approximation
  distorted-wave Born approximation
    grazing-incidence diffraction (GID), 244–245
    surface x-ray diffraction measurements, 1011
  liquid surface x-ray diffraction
    non-specular scattering, 1033–1034
    reflectivity measurements, 1032–1033
  multiple-beam diffraction, second-order approximation, 238–240
Born-Oppenheimer approximation
  electronic structure computational analysis, 74–75
  metal alloy bonding, accuracy calculations, 140–141
Born-von Kármán model, phonon analysis, 1319–1323
  data analysis, 1324–1325
Borosilicate glass, vacuum system construction, 17
Boundary conditions
  dynamical diffraction, basic principles, 229
  impulsive stimulated thermal scattering (ISTS) analysis, 754–756
  multiple-beam diffraction, NBEAM theory, 238
  two-beam diffraction
    diffracted intensities, 233
    dispersion surface, 230–231
Bound excitons, photoluminescence (PL) spectroscopy, 682
Boxcar technique, deep level transient spectroscopy (DLTS), semiconductor materials, 424–425
Bragg-Brentano diffractometer, x-ray powder diffraction, 838–839
Bragg-Fresnel optics, x-ray microprobes, 946–947
Bragg reflection principles
  diffuse intensities, metal alloys, atomic short-range ordering (ASRO) principles, 257
  diffuse scattering techniques
    intensity computations, 901–904
    research background, 882–884
  dynamical diffraction
    applications, 225
    multiple Bragg diffraction studies, 225–226
  grazing-incidence diffraction (GID), 241–242
    inclined geometry, 243
  ion-beam analysis (IBA), ERD/RBS equations, 1188–1189
  liquid surface x-ray diffraction, instrumetation criteria, 1037–1038
  local atomic order, 214–217
  magnetic neutron scattering
    diffraction techniques, 1332–1335
    inelastic scattering, 1331
    magnetic diffraction, 1329–1330
    polarized beam technique, 1330–1331
    subtraction technque, 1330
  magnetic x-ray scattering
    data analysis and interpretation, 934–935
    resonant antiferromagnetic scattering, 931–932
    surface magnetic scattering, 932–933
  multiple-beam diffraction, basic principles, 236–237
  neutron powder diffraction
    angle-dispersive constant-wavelength diffractometer, 1290
    microstrain broadening, 1294–1296
    particle size effect, 1293–1294
    peak shape, 1292
    positional analysis, 1291–1292
    probe configuration, 1286–1289
    time-of-flight diffractomer, 1290–1291
  nonresonant magnetic x-ray scattering, 920–921
  phonon analysis, 1320
  scanning transmission electron microscopy (STEM)
    incoherent scattering, 1099–1101
    phase-contrast illumination, 1094–1097
  single-crystal neutron diffraction
    instrumentation criteria, 1312–1313
    protocols, 1311–1313
    research background, 1307–1309
  small-angle scattering (SAS), 219–222
  surface/interface x-ray diffraction, 218–219
  surface x-ray diffraction
    crystallographic alignment, 1014–1015
    error detection, 1018–1019
  thermal diffuse scattering (TDS), 211–214
  transmission electron microscopy (TEM)
    Ewald sphere construction, 1066–1067
    extinction distances, 1068
    Kikuchi line origin and scattering, 1075–1076
    selected-area diffraction (SAD), 1072–1073
    structure and shape factor analysis, 1065–1066
  two-beam diffraction
    boundary conditions and Snell's law, 230–231
    Darwin width, 232
    diffracted intensities, 234–235
    diffracted wave properties, 229–230
    dispersion equation solution, 233
    hyperboloid sheets, 230
    wave field amplitude ratios, 230
    x-ray birefringence, 232–233
    x-ray standing wave (XWS) diffraction, 232, 235–236
  x-ray absorption fine structure (XAFS) spectroscopy, energy resolution, 877
  x-ray diffraction, 209
  X-ray microdiffraction analysis, 945
  x-ray powder diffraction, 837–838
    crystal lattice and space group determination, 840
    data analysis and interpretation, 839–840
    error detection, 843
    integrated intensities, 840
Brale indenter, Rockwell hardness values, 323
Bravais lattices
  diffuse intensities, metal alloys, concentration waves, 258–260
  Raman active vibrational modes, 709–710, 720–721
  single-crystal x-ray structure determination, crystal symmetry, 854–856
  space groups, 46–50
  transmission electron microscopy (TEM), structure and shape factor analysis, 1065–1066
Breakdown behavior, *pn* junction characterization, 469

Breit-Wigner equation, neutron powder diffraction, probe configuration, 1287–1289
Bremsstrahlung ischromat spectroscopy (BIS)
  ultraviolet photoelectron spectroscopy (UPS) and, 723
  x-ray photoelectron spectroscopy (XPS), 979–980
Brewster angle microscopy (BAM)
  carrier lifetime measurement, free carrier absorption (FCA), 441
  liquid surfaces and monomolecular layers, 1028
  liquid surface x-ray diffraction
    Langmuir monolayers, 1043
    p-polarized x-ray beam, 1047
Bright-field imaging
  reflected-light optical microscopy, 676–680
  transmission electron microscopy (TEM)
    complementary dark-field and selected-area diffraction (SAD), 1082–1084
    deviation vector and parameter, 1068
    protocols and procedures, 1069–1071
    thickness modification, deviation parameter, 1081–1082
Brillouin zone dimension
  diffuse intensities, metal alloys, concentration waves, first-principles calcuations, electronic structure, 265–266
  magnetic neutron scattering, inelastic scattering, 1331
  magnetotransport in metal alloys, magnetic field behavior, 563–565
  metal alloy bonding, precision calculations, 143
  quantum paramagnetiic response, 521–522
  ultraviolet photoelectron spectroscopy (UPS), energy band dispersion, 725
Brinell hardness testing
  automated methods, 319
  basic principles, 317–318
  data analysis and interpretation, 319–320
  hardness values, 317–318, 323
  limitations and errors, 322
  procedures and protocols, 318–319
  research background, 316–317
  sample preparation, 320
  specimen modification, 320–321
Brittle fracture, fracture toughness testing
  load-displacement curves, 304
  Weibull distribution, 311
Broadband radiation thermometer, operating principles, 37
Bulk analysis
  secondary ion mass spectrometry (SIMS) and, 1237
  trace element accelerator mass spectrometry (TEAMS)
    data analysis protocols, 1249–1250
    impurity measurements, 1247–1249
Bulk capacitance measurements, electrochemical photocapacitance spectroscopy (EPS), semiconductor materials, 624
Bulk chemical free energy
  coherent ordered precipitates, microstructural evolution, 123
  metal alloy bonding, accuracy calculations, 140–141
  microstructural evolution, 119–120
Bulk crystals, surface x-ray diffraction, 1008–1009
Bulk measurements
  automation, 404
  basic principles, 403
  limitations, 405
  protocols and procedures, 403–404
  sample preparation, 404–405
  semiconductor materials, Hall effect, 416–417
Burger's vector
  stress-strain analysis, yield-point phenomena, 283–284
  transmission electron microscopy (TEM), defect analysis, 1085
Burial pumping, sputter-ion pump, 11
Butler-Volmer equation, corrosion quantification, Tafel technique, 593–596

Cadmium plating, metallographic analysis, measurement on 4340 steel, 67
Cagliotti coefficients, neutron powder diffraction, constant wavelength diffractometer, 1304–1305
Cahn-Hilliard (CH) diffusion equation
  continuum field method (CFM), 114
    diffusion-controlled grain growth, 127–128
    interfacial energy, 120
    numerical algorithms, 129–130
  microscopic field model (MFM), 116
  microstructural evolution, field kinetics, 122
Calibration protocols
  combustion calorimetry, 379
  differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 366–367
  diffuse scattering techniques, absolute calibration, measured intensities, 894
  electron paramagnetic resonance (EPR), 797
  energy-dispersive spectrometry (EDS), 1156
  gas analysis, simultaneous thermogravimetry (TG)-differential thermal analysis (TG-DTA), 393
  hot cathode ionization gauges, 16
  magnetometry, 536
  mass measurement process assurance, 28–29
  trace element accelerator mass spectrometry (TEAMS)
    data acquisition, 1252
    magnetic/electrostatic analyzer calibration, 1241–1242
  transmission electron microscopy (TEM), 1088–1089
  x-ray absorption fine structure (XAFS) spectroscopy, 877
Calorimetric bomb apparatus, combustion calorimetry, 375–377
Calorimetry. *See* Combustion calorimetry
CALPHAD group
  diffuse intensities, metal alloys, basic principles, 254
  Phase diagram predictions
    aluminum-lithium analysis, 108–110
    aluminum-nickel analysis, 107
    basic principles, 91
    cluster approach, 91–92, 96–99
    cluster expansion free energy, 99–101
    electronic structure calculations, 101–102
    ground-state analysis, 102–104
    mean-field approach, 92–96
    nickel-platinum analysis, 107–108
    nonconfigurational thermal effects, 106–107
    research background, 90–91
    static displacive interactions, 104–106
Camera equation, transmission electron microscopy (TEM), selected-area diffraction (SAD), 1072–1073
Cantilever magnetometer, principles and applications, 535
Capacitance diaphragm manometers, applications and operating principles, 13
Capacitance meters, capacitance-voltage (C-V) characterization
  limitations of, 463–464
  selection criteria, 460–461
Capacitance-voltage (C-V) characterization
  pn junctions, 467
  research background, 401
  semiconductors
    basic principles, 457–458
    data analysis, 462–463
    electrochemical profiling, 462
    instrument limitations, 463–464
    mercury probe contacts, 461–462
    profiling equipment, 460–461
    protocols and procedures, 458–460
    research background, 456–457
    sample preparation, 463
    trapping effects, 464–465
Capillary tube electrodes, scanning electrochemical microscopy (SECM), 648–659
Carbon materials, Raman spectroscopy of solids, 712–713
Carnot efficiency, thermodynamic temperature scale, 32
Carrier decay transient extraction, carrier lifetime measurement, free carrier absorption (FCA), 441
Carrier deficit, carrier lifetime measurement, 428–429
Carrier lifetime measurement
  characterization techniques, 433–435
    device related techniques, 435
    diffusuion-length-based methods, 434–435
    optical techniques, 434
  cyclotron resonance (CR), 805–806
  free carrier absorption, 438–444
    automated methods, 441
    basic principles, 438–440
    carrier decay transient, 441
    computer interfacing, 441
    data analysis and interpretation, 441–442
    depth profiling, sample cross-sectioning, 443
    detection electronics, 440–441
    geometrical considerations, 441
    lifetime analysis, 441–442
    lifetime depth profiling, 441
    lifetime mapping, 441–442
    limitations, 443–444
    probe laser selection, 440
    processed wafers, metal and highly doped layer removal, 443
    pump laser selection, 440
    sample preparation, 442–443
    virgin wafers, surface passivation, 442–443
  generation lifetime, 431
  photoconductivity, 444–450
    basic principles, 444
    data analysis, 446–447
    high-frequency range, automation, 445–446
    limitations, 449–450
    microwave PC decay, 447–449
    radio frequency PC decay, 449
    sample preparation, 447
    standard PC decay method, 444–445
  photoluminescence, 450–453
    automated procedures, 451–452
    data analysis and interpretation, 452–453
    deep level luminescence, 450–451
    limitations, 453
    near-band-gap emission, 450
    photon recycling, 451
    shallow impurity emission, 450
  physical quantities, 433
  recombination mechanisms, 429–431
  selection criteria, characterization methods, 453–454
  steady-state, modulated, and transient methods, 435–438
    data interpretation problems, 437
    limitations, 437–438
    modulation-type method, 436
    pulsed-type methods, 437–438

Carrier lifetime measurement (*Continued*)
quasi-steady-state-type method, 436–437
surface recombination and diffusion, 432–433
theoretical background, 401, 427–429
trapping techniques, 431–432
Cartesian coordinates, Raman active vibrational modes, 710
Case hardening, microindentation hardness testing, 318
Catalyst analysis, thermogravimetric (TG) analysis, gas-solid reactions, 356
Cathode burial, sputter-ion pump, 11
Cathode-ray tubes (CRT), scanning electron microscopy (SEM), 1052–1053
Cathodoluminescence (CL) technique, *pn* junction characterization, 466–467
Cauchy's inequality, single-crystal x-ray structure determination, direct method computation, 865–868
Cavity resonators, microwave measurement techniques, 409
Cellular automata (CA) method, microstructural evolution, 114–115
Center-of-mass reference frame
forward-recoil spectrometry, data interpretation, 1270–1271
particle scattering, kinematics, 54–55
Central-field theory, particle scattering, 57–61
cross-sections, 60–61
deflection functions, 58–60
approximation, 59–60
central potentials, 59
hard spheres, 58–59
impact parameter, 57–58
interaction potentials, 57
materials analysis, 61
shadow cones, 58
Central potentials, particle scattering, central-field theory, 57
deflection function, 59
Ceramic materials
turbomolecular pumps, 7
x-ray photoelectron spectroscopy (XPS), 988–989
CFD-ACE, chemical vapor deposition (CVD) model, hydrodynamics, 174
Cgs magnetic units
general principles, 492–493
magnetic vacuum permeability, 511
Chain of elementary reactions, chemical vapor deposition (CVD) model, gas-phase chemistry, 168–169
Channeling approximation, scanning transmission electron microscopy (STEM), dynamical diffraction, 1102–1103
Channel plate arrays, x-ray photoelectron spectroscopy (XPS), 982–983
Channeltrons, x-ray photoelectron spectroscopy (XPS), 982–983
Character table, vibrational Raman spectroscopy, group theoretical analysis, 718
Charge-balance equation (CBE), semiconductor materials, Hall effect, 412, 416
Charge correlation effects, diffuse intensities, metal alloys
concentration waves, first-principles calcuations, electronic structure, 266
hybriziation in NiPt alloys and, 266–268
Charge-coupled device (CCD)
low-energy electron diffraction (LEED), instrumentation and automation, 1126–1127
photoluminescence (PL) spectroscopy, 684
Raman spectroscopy of solids, dispersed radiation measurment, 707–708
single-crystal x-ray structure determination
basic principles, 850
detector components, 859–860
transmission electron microscopy (TEM)
automation, 1080
phase-contrast imaging, 1096–1097
Charged particle micropobes, x-ray microprobes, 940–941
Charge-funneling effects, ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1228
Charge transfer
cyclic voltammetry, nonreversible charge-transfer reaactions, 583–584
metal alloy bonding, 137–138
semiconductor-liquid interface
photoelectrochemistry, thermodynamics, 606–607
time-resolved photoluminescence spectroscopy (TRPL), 630–631
Charpy V-Notch impact testing, fracture toughness testing, 302
Chemically modified electrodes (CMEs), electrochemical profiling, 579–580
Chemical order
diffuse intensities, metal alloys, magnetic effects and, 268
diffuse scattering techniques
basic principles, 884–885
research background, 882–884
substitutional and interstitial metallic systems, 154–155
Chemical polishing, ellipsometry, surface preparations, 741–742
Chemical shift imaging (CSI)
Auger electron spectroscopy (AES), 1162–1163
nuclear magnetic resonance
basic principles, 764–765
imaging sequence, 770
x-ray photoelectron spectroscopy (XPS)
applications, 986
initial-state effects, 976–978
reference spectra, 996–998
research background, 970–972
Chemical thinning, transmission electron microscopy (TEM), sample preparation, 1086
Chemical vapor deposition (CVD), simulation models
basic components, 167–173
free molecular transport, 169–170
gas-phase chemistry, 168–169
hydrodynamics, 170–172
kinetic theory, 172
plasma physics, 170
radiation, 172–173
surface chemistry, 167–168
limitations, 175–176
research background, 166–167
software applications
free molecular transport, 174
gas-phase chemistry, 173
hydrodynamics, 174
kinetic theory, 175
plasma physics, 174
radiation, 175
surface chemistry, 173
Chemisorption, sputter-ion pump, 10–11
CHEMKIN software, chemical vapor deposition (CVD) models
limitations, 175–176
surface chemistry, 173
Chromatic aberration
optical microscopy, 669–670
transmission electron microscopy (TEM), lens defects and resolution, 1078
Chromatograpy, evolved gas analysis (EGA) and, 396–397
Circular dichroism. *See* X-ray magnetic circular dichroism
Circularly polarized x-ray (CPX) sources, x-ray magnetic circular dichroism (XMCD), 957–959
figure of merit, 969–970
Classical mechanics
magnetic x-ray scattering, 919–920
Raman spectroscopy of solids, electromagnetic radiation, 699–701
resonant scattering analysis, 906–907
surface magneto-optic Kerr effect (SMOKE), 570–571
Classical phase equilibrium, phase diagram predictions, 91–92
Clausius-Mosotti equation, electric field gradient, nuclear couplings, nuclear quadrupole resonance (NQR), 777
Cleaning procedures, vacuum systems, 19
Cllip-on gage, mechanical testing, extensometers, 285

Cluster magnetism, spin glass materials, 516–517
Cluster variational method (CVM)
diffuse intensities, metal alloys, 255
concentration waves, multicomponent alloys, 259–260
mean-field theory and, 262–263
phase diagram prediction
nickel-platinum alloys, 107–108
nonconfigurational thermal effects, 106–107
phase diagram predictions, 96–99
free energy calculations, 99–100
Cmmm space group, crystallography, 47–50
Coarse-grained approximation, continuum field method (CFM), 118
Coarse-grained free energy formulation, microstructural evolution, 119
Coaxial probes, microwave measurement techniques, 409
Cobalt alloys
magnetism, magnetocrystalline anisotropy energy (MAE), 193
magnetocrystalline anisotropy energy (MAE), Co-Pt alloys, 199–200
paramagnetism, first-principles calculations, 189
Cobalt/copper superlattices, surface magneto-optic Kerr effect (SMOKE), 573–574
Cockroft-Walton particle accelerator, nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), 1203–1204
Coherence analysis
low-energy electron diffraction (LEED), estimation techniques, 1134
Mössbauer spectroscopy, 824–825
phonon analysis, neutron scattering, 1325–1326
scanning transmission electron microscopy (STEM)
phase-contrast imaging *vs.*, 1093–1097
research background, 1091–1092
strain contrast imaging, 1106–1108
Coherent ordered precipitates, microstructural evolution, 122–126
Coherent potential approximation (CPA)
diffuse intensities, metal alloys
concentration waves, first-principles calcuations, electronic structure, 264–266
hybridization in NiPt alloys, charge correlation effects, 267–268
metal alloy magnetism, magnetocrystalline anisotropy energy (MAE), 192–193
solid-solution alloy magnetism, 183–184
Cohesive energies, local density approximation (LDA), 79–81

Cold cathode ionization gauge, operating principles, 16
Collective magnetism, magnetic moments, 515
Collision diameter, particle scattering, deflection functions, hard spheres, 58–59
Combination bearings systems, turbomolecular pumps, 7
Combustion calorimetry
  commercial sources, 383
  data analysis and interpretation, 380–381
  limitations, 381–382
  protocols and procedures, 375–380
    analytical chemistry and, 377–378
    calibration protocols, 379
    experimental protocols, 377
    measurement protocols, 378–379
    non-oxygen gases, 380
    standard state corrections, 379–380
  research background, 373–374
  sample preparation, 381
  thermodynamic principles, 374–375
Combustion energy computation, combustion calorimetry, enthalpies of formation computation *vs.,* 380–381
Compact-tension (CT) specimens, fracture toughness testing
  crack extension measurement, 309–311
  load-displacement curve measurement, 308
  sample preparation, 311–312
  stress intensity and J-integral calculations, 314–315
Compensator, ellipsometry, 738
Compliance calculations, fracture toughness testing, 315
Compton scattering
  diffuse scattering techniques, inelastic scattering background removal, 891–893
  x-ray absorption fine-structure (XAFS) spectroscopy, 875–877
  x-ray microfluorescence, 942
Computational analysis. *See also* specific computational techniques, e.g. Schrödinger equation

closed/core shell diamagnetism, dipole moments, atomic origin, 512
Diaphragm pumps
applications, 4
operating principles, 5
Dichroic signal, x-ray magnetic circular dichroism (XMCD), 953–955
basic theory, 955–957
data analysis, 963–964
Dielectric constants, ellipsometry, 737
Dielectric screening, electronic structure analysis, 84–87
Dielectric tensor, surface magneto-optic Kerr effect (SMOKE), 570–571
Difference equations, neutron powder diffraction, stacking faults, 1296
Differential capacitance measurements, semiconductor-liquid interfaces, 616–619
Differential cross-section, particle scattering, central-field theory, 60
Differential interference contrast (DIC), reflected-light optical microscopy, 679–680
Differential ion pump, operating principles, 11
Differential scanning calorimetry (DSC). *See also* Simultaneous thermogravimetry (TG)-differential thermal analysis/differential scanning calorimetry (TG-DTA/DSC)
automated procedures, 370
basic principles, 363–366
data analysis and interpretation, 370–371
defined, 337–339
limitations, 372
protocols and procedures, 366–370
applications, 367–370
calibration, 366–367
instrumentation, 367
zero-line optimization, 366
research background, 362–363
sample preparation, 371
specimen modification, 371–372
thermal analysis, 339
thermogravimetric (TG) analysis, 346
Differential scattering cross-sections, ion-beam analysis (IBA), 1181–1184
Differential thermal analysis (DTA). *See also* Simultaneous thermogravimetry (TG)-differential thermal analysis (TG-DTA)
automated procedures, 370
basic principles, 363–366
data analysis and interpretation, 370–371
defined, 337–339
limitations, 372
protocols and procedures, 366–370
applications, 367–370
calibration, 366–367
instrumentation, 367
zero-line optimization, 366
research background, 362–363
sample preparation, 371
simultaneous techniques for gas analysis, research background, 392–393
specimen modification, 371–372
thermogravimetric (TG) analysis, 346
Diffraction techniques. *See also* specific techniques, e.g. X-ray diffraction
defined, 207
density definition and, 26
diffuse scattering and, 884
magnetic neutron scattering, 1332–1335
Mössbauer spectroscopy, 824–825
transmission electron microscopy (TEM)
bright-field/dark-field imaging, 1070–1071
lattice defect diffraction contrast, 1068–1069
pattern indexing, 1073–1074
Diffractometer components
liquid surface x-ray diffraction, instrumetation criteria, 1037–1038
neutron powder diffraction
angle-dispersive constant-wavelength diffractometer, 1289–1290
time-of-flight diffractomer, 1290–1291
surface x-ray diffraction, 1009–1010
alignment protocols, 1020–1021
angle calculations, 1021
five-circle diffractometer, 1013–1014
Diffuse intensities
metal alloys
atomic short-range ordering (ASRO)
principles, 256
concentration waves
density-functional approach, 260–262
first-principles, electronic-structure calculations, 263–266
multicomponent alloys, 257–260
mean-field results, 262
mean-field theory, improvement on, 262–267
pair-correlation functions, 256–257
sum rules and mean-field errors, 257
competitive and related techniques, 254–255
computational principles, 252–254
data analysis and interpretation, 266–273
Cu_2NiZn ordering wave polarization, 270–271
CuPt van Hove singularities, electronic topological transitions, 271–273
magnetic coupling and chemical order, 268
multicomponent alloys, 268–270
Ni-Pt hybridization and charge correlation, 266–268
temperature-dependent shift, ASRO peaks, 273
high-temperature experiments, effective interactions, 255–256
two-beam diffraction
boundary condition, 233
Bragg case, 234–235
integrated intensities, 235
Laue case, 233–234
Diffuse-interface approach, microstructural evolution, 119
Diffuse scattering techniques
intensity computations, 886–889
absolute calibration, measured intensities, 894
derivation protocols, 901–904
liquid surface x-ray diffraction
non-specular scattering, 1038–1039
simple liquids, 1041
surface x-ray scattering, 1016
x-ray and neutron diffuse scattering
applications, 889–894
automation, 897–898
bond distances, 885
chemical order, 884–885
comparisons, 884
competitive and related techniques, 883–884
crystalling solid solutions, 885–889
data analysis and interpretation, 894–896
diffuse x-ray scattering techniques, 889–890
inelastic scattering background removal, 890–893
limitations, 898–899
measured intensity calibration, 894
protocols and procedures, 884–889
recovered static displacements, 896–897
research background, 882–884
resonant scattering terms, 893–894
sample preparation, 898
Diffusion coefficients
binary/multicomponent diffusion, 146
multicomponent diffusion, frames of reference, 150–151
substitutional and interstitial metallic systems, 152–153
Diffusion-controlled grain growth, microstructural evolution, 126–128
Diffusion imaging sequence, magnetic resonance imaging (MRI), 769
Diffusion length
carrier lifetime measurement
free carrier absorption (FCA), limitations of, 443–444
methods based on, 434–435
surface recombination and diffusion, 432–433
semiconductor materials, semiconductor-liquid interfaces, 614–616
Diffusion potential, capacitance-voltage (C-V) characterization, *p-n* junctions, 457–458
Diffusion processes, binary/multicomponent diffusion
applications, 155
dependent concentration variable, 151
frames of reference and diffusion coefficients, 147–150
linear laws, 146–147
multicomponent alloys
Fick-Onsager law, 150
frames of reference, 150–151
research background, 145–146
substitutional and interstitial metallic systems, 152–155
Diffusion pumps
applications, 6
operating principles and procedures, 6–7
Dimagnetism, principles of, 511
Dimensionless quantitates, coherent ordered precipitates, microstructural evolution, 124–126
Dimer-adatom-stacking fault (DAS) model, surface x-ray diffraction, silicon surface example, 1017–1018
Diode structures, characterization
basic principles, 467–469

competitive and complementary techniques, 466–467
limitations of, 471
measurement equipment sources and selection criteria, 471
protocols and procedures, 469–470
research background, 466–467
sample preparation, 470–471
Dipole magnetic moments
atomic origin, 512–515
closed/core shell diamagnetism, 512
coupling theories, 519–527
antiferromagnetism, 524
ferrimagnetism, 524–525
ferromagnetism, 522–524
Heisenberg model and exchange interactions, 525–526
helimagnetism, 526–527
paragmagnetism, classical and quantum theories, 519–522
local atomic moments
collective magnetism, 515
ionic magnetism, 513–515
neutron powder diffraction, 1288–1289
nuclear quadrupole resonance (NQR), nuclear moments, 775–776
Dirac equation
computational analysis, applications, 71
Mössbauer effect, 819–820
Mössbauer spectroscopy, hyperfine magnetic field (HMF), 823–824
Dirac's delta function, phonon analysis, 1318
Direct configurational averaging (DCA), phase diagram prediction
cluster variation, 99
electronic structure, 101–102
ground-state analysis, 102–104
Direct detection procedures, nuclear quadrupole resonance (NQR), 780–781
Direct methods
single-crystal x-ray structure determination, 860–861
computations, 865–868
surface x-ray diffraction measurements, crystallographic refinement, 1018
x-ray absorption spectroscopy, 870
Discrete Fourier transform (DFT), thermal diffusivity, laser flash technique, 388–389
Disk-shaped electrodes, scanning electrochemical microscopy (SECM), 648–659
Disordered local moment (DLM)
face-centered cubic (fcc) iron, moment alignment *vs.* moment formation, 193–195
metal alloy magnetism
first-principles calculations, 188–189
gold-rich AuFe alloys, atomic short range order (ASRO), 198–199
iron-vanadium alloys, 196–198
local exchange splitting, 189–190
local moment fluctuation, 187–188
Disordered states, x-ray absorption fine structure (XAFS) spectroscopy, 872–873
Dispersed radiation measurment, Raman spectroscopy of solids, 707–708
Dispersion corrections
transmission electron microscopy (TEM), sample preparation, 1087
x-ray diffraction, scattering power and length, 210
Dispersion equation, two-beam diffraction, solution, 233
Dispersion surface
dynamical diffraction, basic principles, 228–229
two-beam diffraction, 230–231
boundary conditions and Snell's law, 230–231
hyperboloid sheets, 230
Poynting vector and energy flow, 231
wave field amplitude ratios, 230
Dispersive transmission measurement, x-ray absorption fine structure (XAFS) spectroscopy, 875–877
Displacement principle
density definition and, 26
diffuse scattering techniques
diffuse intensity computations, 902–904
static displacement recovery, 897–898
Distorted-wave Born approximation (DWBA)
grazing-incidence diffraction (GID), 244–245
liquid surface x-ray diffraction, non-specular scattering, 1034–1036
surface x-ray diffraction measurements, grazing incidence, 1011
Documentation protocols
in thermal analysis, 340–341
thermogravimetry (TG), 361–362
tribological testing, 333
Doniach-Sunjic peak shape, x-ray photoelectron spectroscopy (XPS), 1006
Donor-acceptor transitions, photoluminescence (PL) spectroscopy, 683
Doping dependence, carrier lifetime measurement, 431
Double-beam spectrometer, ultraviolet/visible absorption (UV-VIS) spectroscopy, 692–693
Double-counting corrections, diffuse intensities, metal alloys, concentration waves, first-principles calcuations, electronic structure, 264–266
Double-crystal monochromator
liquid surface x-ray diffraction, error detection, 1044–1045
surface x-ray diffraction, beamline alignment, 1019–1020
Double-resonance experiments
electron-nuclear double resonance (ENDOR), 796
nuclear quadrupole resonance (NQR), frequency-swept Fourier-transform spectrometers, 780–781
Double sum techniques, diffuse intensity computations, 902–904
Dougle-critical-angle phenomenon, grazing-incidence diffraction (GID), 243
DPC microscopy, magnetic domain structure measurements, Lorentz transmission electron microscopy, 551–552
Drive stiffness, tribological and wear testing, 328–329
Drude model, cyclotron resonance (CR), 806–807
Drude-Sommerfeld "free electron" model, magnetotransport in metal alloys, 562–563
Dry gases, vacuum system principles, outgassing, 2–3
Dufour effect, chemical vapor deposition (CVD) model, hydrodynamics, 171
"Dummy" orientation matrix (DOM), surface x-ray diffraction
crystallographic alignment, 1014–1015
protocols, 1026
Dynamical diffraction
applications, 225–226
Bragg reflections, 225–226
crystals and multilayers, 225
defect topology, 225
grazing-incidence diffraction, 226
internal field-dependent phenomena, 225
basic principles, 227–229
boundary conditions, 229
dispersion surface, 228–229
fundamental equations, 227–228
internal fields, 229
grazing incidence diffraction (GID), 241–246
distorted-wave Born approximation, 244–245
evanescent wave, 242
expanded distorted-wave approximation, 245–246
inclinded geometry, 243
multlayers and superlattices, 242–243
specular reflectivity, 241–242
literature sources, 226–227
multiple-beam diffraction, 236–241
basic principles, 236–237
NBEAM theory, 237–238
boundary conditions, 238
D-field component eigenequation, 237
eigenequation matrix, 237–238
intensity computations, 238
numerical solution strategy, 238
phase information, 240
polarization density matrix, 241
polarization mixing, 240
second-order Born approximation, 238–240
standing waves, 240
three-beam interactions, 240
scanning transmission electron microscopy (STEM), Z-contrast imaging, 1101–1103
theoretical background, 224–225
two-beam diffraction, 229–236
anomalous transmission, 231–232
Darwin width, 232
diffuse intensities
boundary condition, 233
Bragg case, 234–235
integrated intensities, 235
Laue case, 233–234
dispersion equation solution, 233
dispersion surface properties, 230–231
boundary conditions, Snell's law, 230–231
hyperboloid sheets, 230
Poynting vector and energy flow, 231
wave field amplitude ratios, 230
Pendellösung, 231
standing waves, 235–236
x-ray birefringence, 232–233
x-ray standing waves (XSWs), 232
Dynamical processes, nuclear quadrupole resonance (NQR), 790
Dynamic random-access memory (DRAM) device
heavy-ion backscattering spectrometry (HIBS)
ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1230
Dynamic stability conditions, superconducting magnets, 502
Dynamic thermomechanometry, defined, 339

Echo-planar imaging sequence, magnetic resonance imaging (MRI), 768–769
ECPSSR model, particle-induced x-ray emission (PIXE), 1212
Eddy-current measurements, non-contact techniques, 407–408
Effective cluster interactions (ECIs)
diffuse intensities, metal alloys, 255
high-temperature experiments, 255–256
mean-field results, 263
phase diagram prediction, ground-state analysis, 102–104
phase diagram predictions, cluster variational method (CVM), 98–99
Effective drift diffusion model, chemical vapor deposition (CVD), plasma physics, 170
Effectively probed volume, carrier lifetime measurement, free carrier absorption (FCA), probe selection criteria, 440
Effective mass approximation (EMA), cyclotron resonance (CR), 806
quantum mechanics, 808

Eigenequations
  dynamical diffraction, boundary conditions, 229
  multiple-beam diffraction
    D-field components, 237
    matrix form, 237–238
Elastic collision
  particle scattering, 51–52
    diagrams, 52–54
  phase diagram prediction, static displacive interactions, 105–106
Elastic constants
  impulsive stimulated thermal scattering (ISTS), 745–746
  local density approximation (LDA), 81–82
Elastic energy, microstructural evolution, 120–121
Elastic ion scattering
  composition analysis
    applications, 1191–1197
    basic concepts, 1181–1184
    detector criteria and detection geometries, 1185–1186
    equations, 1186–1189
    experimental protocols, 1184–1186
    limitations, 1189–1191
    nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE) and, 1201–1202
    research background, 1179–1181
  Rutherford backscattering spectroscopy (RBS), 1178
Elastic properties
  impulsive stimulated thermal scattering (ISTS) analysis, 747–749
  tension testing, 279
Elastic recoil detection analysis (ERDA)
  composition analysis
    applications, 1191–1197
    basic concepts, 1181–1184
    detector criteria and detection geometries, 1185–1186
    equations, 1186–1189, 1199–1200
    experimental protocols, 1184–1186
    limitations, 1189–1191
    research background, 1179–1181
  elastic scattering, 1178
  nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE), 1201–1202
Elastomers, O-ring seals, 17
Electrical and electronic measurements
  bulk measurements, 403–405
  conductivity measurement, 401–403
  microwave techniques, 408–410
  non-contact methods, 407–408
  research background, 401
  surface measurements, 405–406
Electrical feedthroughs, vacuum systems, 18
Electrical interference, thermogravimetric (TG) analysis, mass measurement errors and, 357–358
Electrical-resistance thermometer, operating principles, 36
Electrical resistivity, magnetotransport in metal alloys
  magnetic field behavior, 563–565
  research applications, 559
  transport equations, 560–561
  zero field behavior, 561–563
Electrical transport measurements, superconductors
  automation of, 480–481
  bath temperature fluctuations, 486–487
  competitive and related techniques, 472–473
  contact materials, 474
  cooling options and procedures, 478–479
  critical current criteria, 474–475
  current-carring area for critical current to current density, 476
  current contact length, 477

Fermi energy level
  band theory of magnetism, 516
  capacitance-voltage (C-V) characterization, trapping measurements, 465
  pn junction characterization, 467–468
  scanning tunneling microscopy (STM), 1113–1114
  semiconductor-liquid interface, photoelectrochemistry, thermodynamics, 606
  transition metal magnetic ground state, itinerant magnetism at zero temperature, 182–183
  ultraviolet photoelectron spectroscopy (UPS)
    automation, 731–732
    electronic phase transitions, 727
    energy band dispersion, 727
    full width at half maximum values, 730
    photoemission *vs.* inverse photoemission, 722–723
Fermi filling factor, diffuse intensities, metal alloys, concentration waves, first-principles calcuations, electronic structure, 265–266
Fermi's golden rule
  resonant scattering analysis, 908–909
  x-ray absorption fine structure (XAFS) spectroscopy, single-scattering picture, 870–872
Fermi's pseudopotential, neutron powder diffraction, probe configuration, 1287–1289
Fermi-surface nesting
  electronic topological transitions, van Hove singularities in CuPt, 272–273
  multicomponent alloys, 268–270
Ferrimagnetism, principles and equations, 524–525
Ferroelectric materials, microbeam analysis, strain distribution, 948–949
Ferromagnetism
  basic principles, 494–495
  collective magnetism as, 515
  magnetic x-ray scattering, 924–925
    nonresonant scattering, 930
    resonant scattering, 932
  mean-field theory, 522–524
  permanent magnets, 497–499
  ultraviolet photoelectron spectroscopy (UPS), energy band dispersion, 725, 727
Feynman-Peierls' inequality, metal alloy magnetism
  atomic short range order (ASRO), 190–191
  first-principles calculations, 188–189
Fiberoptic thermometer, operating principles, 37
Fick-Onsager law, binary/multicomponent diffusion, 150
Fick's law
  binary/multicomponent diffusion
    basic equations, 146–147
    Fick-Onsager extension, 150
    general formulation, 147
    mobility, 147
    number-fixed frame of reference, 147–148
  chemical vapor deposition (CVD) model, hydrodynamics, 171
  semiconductor-liquid interface, laser spot scanning (LSS), 626–628
Field cooling, superconductor magnetization, 518–519
Field cycling methods, nuclear quadrupole resonance (NQR)
  indirect detection, 781
  spatially resolved imaging, 788–789
Field-dependent diffraction, dynamical diffraction, applications, 225
Field-effect transistor (FET), energy-dispersive spectrometry (EDS), 1137–1140
Field emission electron guns (FESEMs)
  applications, 1057
  scanning electron microscopy (SEM)
    instrumentation criteria, 1054
    resolution parameters, 1053
    selection criteria, 1061
Field factor, electromagnet structure and properties, 499–500
Field ion microscopy (FIM)
  diffuse scattering techniques, comparisons, 884
  transmission electron microscopy (TEM) and, 1064
Field kinetic equations, microstructural evolution, 121–122
Field simulation. *See also* Continuum field method (CFM)

microstructural evolution, 113–117
atomistic Monte Carlo method, 117
cellular automata (CA) method, 114–115
continuum field method (CFM), 114–115
conventional front-tracking, 113–114
inhomogeneous path probability method (PPM), 116–117
mesoscopic Monte Carlo method, 114–115
microscopic field model, 115–116
microscopic master equations, 116–117
molecular dynamics (MD), 117
Figure of merit
ultraviolet photoelectron spectroscopy (UPS) light sources, 734–735
x-ray magnetic circular dichroism (XMCD), circularly polarized x-ray sources, 969–970
Film properties
chemical vapor deposition (CVD) models, limitations, 175–176
electrochemical quartz crystal microbalance (EQCM), 657–658
impulsive stimulated thermal scattering (ISTS), 744–746, 745–746
applications, 749–752
automation, 753
competitive and related techniques, 744–746
data analysis and interpretation, 753–757
limitations, 757–758
procedures and protocols, 746–749
research background, 744–746
sample preparation and specimen modification, 757
ion-beam analysis (IBA), ERD/RBS techniques, 1192–1197
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE), 1206
particle-induced x-ray emission (PIXE), 1213–1216
single-crystal x-ray structure determination, 859–860
surface phenomena, molecular dynamics (MD) simulation, 156–157
Filtering procedures, x-ray absorption fine structure (XAFS) spectroscopy, 878–879
Final-state effects, x-ray photoelectron spectroscopy (XPS), 974–976
Finite difference equation, continuum field method (CFM), 129–130
Finitei-pulse-time effect, thermal diffusivity, laser flash technique, 388–389
First Law of thermodynamics
combustion calorimetry and principles of, 374–375
radiation thermometer, 36–37
thermal analysis and principles of, 341–343
thermodynamic temperature scale, 31–32
First-principles calculations
diffuse intensities, metal alloys
basic principles, 254
concentration waves
density-functional theory (DFT), 260–262
electronic-structure calculations, 263–266
energy-dispersive spectrometry (EDS), standardless analysis, 1148–1149
metal alloy bonding, precision measurements, 141
metal alloy magnetism, 188–189
limitations, 201
paramagnetic Fe, Ni, and Co, 189
molecular dynamics (MD) simulation, surface phenomena, 158
Fitted-standards standardless analysis, energy-dispersive spectrometry (EDS), 1149–1150
Five-circle diffractometer, surface x-ray diffraction, 1013–1014
angle calculations, 1021
Fixed spin moment (FSM) calculations, transition metal magnetic ground state, itinerant magnetism at zero temperature, 183
Fixture size and properties, fracture toughness testing, 312–313
Flash diffusivity measurements, thermal diffusivity, laser flash technique, 390
Flash getter pump, applications, 12
Flat-band potential measurements, semiconductor-liquid interface, 628–630
Flow imaging sequence, magnetic resonance imaging (MRI), 769–770
Fluctuating Local Band (FLB) theory, metal alloy magnetism, local moment fluctuation, 187–188
FLUENT software, chemical vapor deposition (CVD) model, hydrodynamics, 174
Fluorescence microscopy
energy-dispersive spectrometry (EDS), matrix corrections, 1145
liquid surfaces and monomolecular layers, 1028
x-ray absorption fine-structure (XAFS) spectroscopy
basic principles, 875–877
errors, 879
x-ray magnetic circular dichroism (XMCD), 961–962
x-ray microfluorescence analysis, 942–945
automation, 949
background signals, 944
characteristic radiation, 942–943
data analysis, 950
detector criteria, 944
error detection, 950–951
fluorescence yields, 942
micro XAFS, 943
penetration depth, 943–944
photoabsorption cross-sections, 943
sample preparation, 949–950
x-ray microprobe
protocols and procedures, 941–942
research background, 939–941
Fluorescence yield, energy-dispersive spectrometry (EDS), standardless analysis, 1148
Flux density, permanent magnets, 497–499
Flux-gate magnetometer, magnetic field measurements, 506
Flux magnetometers
flux-integrating magnetometer, 533
properties of, 533–534
Flux sources, permanent magnets as, 499
Flying spot technique, carrier lifetime measurement, diffusion-length-based methods, 435
Focused ion beam (FIB) thinning, transmission electron microscopy (TEM), sample preparation, 1086–1087
Force field changes, surface phenomena, molecular dynamics (MD) simulation, 156–157
Force magnetometers, principles and applications, 534–535
Foreline traps, oil-sealed pumps, 4
Forward-recoil spectrometry
applications, 1268–1269
automation, 1269
backscattering data, 1269–1270
basic principles, 1261–1265
complementary and alternative techniques, 1261
data analysis and interpretation, 1269–1271
protocols for, 1270–1271
forward-recoil data, 1270–1271
instrumentation criteria, 1267–1268
limitations, 1271–1272
research background, 1259–1261
resolution, 1267
safety issues, 1269
sensitivity parameters, 1266–1267
spectrometer efficiency, 1265–1266
time-of-flight spectrometry (TOS), 1265
Foucault microscopy, magnetic domain structure measurements, Lorentz transmission electron microscopy, 551–552
FOURC software, resonant scattering, experimental design, 914
Fourier transform infrared (FTIR) spectrometry
gas analysis, 398
simultaneous techniques for gas analysis, research background, 393
Fourier transform magneto-spectroscopy (FTMS), cyclotron resonance (CR)
basic principles, 808–812
data analysis and interpretation, 813–814
error detection, 814–815
Fourier transform Raman spectroscopy (FTRS), principles and protocols, 708–709
Fourier transforms
chemical vapor deposition (CVD) model, radiation, 172–173
dynamical diffraction, 228
liquid surface x-ray diffraction, non-specular scattering, 1035–1036
low-energy electron diffraction (LEED), quantitative measurement, 1125
magnetic neutron scattering, 1329–1330
magnetic resonance imaging (MRI), 765–767
metal alloy magnetism, atomic short range order (ASRO), 191
Mössbauer effect, momentum space representation, 819–820
nuclear quadrupole resonance (NQR), data analysis and interpretation, 789
scanning transmission electron microscopy (STEM), probe configuration, 1098
single-crystal x-ray structure determination, direct method computation, 866–868
small-angle scattering (SAS), two-phase model, 220
x-ray absorption fine structure (XAFS) spectroscopy
data analysis and interpretation, 878–879
single scattering picture, 871–872
x-ray diffraction, crystal structure, 208–209
X-ray microdiffraction analysis, 944–945
Four-point bulk measurement
basic principles, 403
conductivity measurements, 402
protocols and procedures, 403–404
superconductors, electrical transport measurement, 473–474
Four-point probing, conductivity measurements, 402
Fracture toughness testing
basic principles, 302–307
crack driving force *(G),* 304–305
crack extension measurement, 308
crack tip opening displacement (CTOD) (δ), 307
data analysis and interpretation
sample preparation, 311–312

    field kinetic equations, 121–122
    interfacial energy, 120
    slow variable selection, 119
  microstructural evolution, diffusion-controlled grain growth, 126–128
  phase diagram predictions, cluster variational method (CVM), 96–99, 99–100
Free excess carriers, carrier lifetime measurement, 438–439
Free induction decay (FID). *See also* Pseudo free induction decay
  magnetic resonance imaging (MRI), 765–767
  nuclear magnetic resonance, 765
  nuclear quadrupole resonance (NQR), data analysis and interpretation, 789
  nutation nuclear resonance spectroscopy, 784
Free molecular transport, chemical vapor deposition (CVD) model
  basic components, 169–170
  software tools, 174
Free-space radiation, microwave measurement techniques, 409
Free-to-bound transitions, photoluminescence (PL) spectroscopy, 683
Frequency-swept continuous wave detection, nuclear quadrupole resonance (NQR), 780–781
Frequency-swept Fourier-transform spectrometers, nuclear quadrupole resonance (NQR), 780–781
Fresnel microscope, magnetic domain structure measurements, Lorentz transmission electron microscopy, 551–552
Fresnel reflection coefficients
  ellipsometry
    reflecting surfaces, 736–737
    relative phase/amplitude calculations, 739–740
  grazing-incidence diffraction (GID), 241–242
    distorted-wave Born approximation (DWBA), 244–245
  liquid surface x-ray diffraction
    non-specular scattering, 1034–1036
    reflectivity measurements, 1029–1031
      multiple stepwise and continuous interfaces, 1031–1033
  surface magnetic scattering, 933–934
Friction, high-strain-rate testing, 299
Friction coefficient, tribological and wear testing, 325–326
  drive stiffness and, 328–329
  equipment and measurement techniques, 326–327
Friction tests, tribological and wear testing
  categories and classification, 328–329
  data analysis and interpretation, 334–335
Friedel's law
  d-band energetics, bonding-antibonding, 135
  single-crystal x-ray structure determination, 854
    crystal symmetry, 854–856
Fringe field sensors, magnetic field measurements, 506
Front-tracking simulation, microstructural evolution, 113–114
Frozen phonon calculations, phonon analysis, 1324–1325
Full potentials, metal alloy bonding, precision calculations, 143
FULLPROF software, neutron powder diffraction, Rietveld refinements, 1306
Full width at half-maximum (FWHM)
  diffuse scattering techniques, inelastic scattering background removal, 891–893
  energy-dispersive spectrometry (EDS), 1137–1140
  heavy-ion backscattering spectrometry (HIBS), 1277
  medium-energy backscattering, 1267
  neutron powder diffraction
    constant wavelength diffractometer, 1303–1304
    instrumentation criteria, 1292
    microstrain broadening, 1294–1295
    peak shapes, 1292
    Rietveld refinements, 1296
  particle-induced x-ray emission (PIXE) analysis, 1217–1218
  Raman spectroscopy of solids, 710–712
  ultraviolet photoelectron spectroscopy (UPS), 730
  x-ray microprobes, tapered capillary devices, 945
  x-ray photoelectron spectroscopy (XPS), 989
    background subtraction, 990–991
    peak position, 992, 1005
  x-ray powder diffraction, 837–838
Furnace windings, thermogravimetric (TG) analysis, 348–349

GaAs structures, capacitance-voltage (C-V) characterization, 462–463
Galvani potential, corrosion quantification, Tafel technique, 593–596
Gamma ray emission, Mössbauer effect, 818–820
Gärtner equation, semiconductor-liquid interfaces, diffusion length, 614–616
Gas analysis
  combustion calorimetry, 380
  simultaneous techniques for
    automated testing, 399
    benefits and limitations, 393–394
    chemical and physical methods, 398–399
    commercial TG-DTA equipment, 394–395
    evolved gas analysis and chromatography, 396–397
    gas and volatile product collection, 398
    infrared spectrometery, 397–398
    limitations, 399
    mass spectroscopy for thermal degradation and, 395–396
    research background, 392–393
    TG-DTA principles, 393
  thermal analysis with, 339
  time-resolved x-ray powder diffraction, 845–847
Gas chromatography (GC), simultaneous techniques for gas analysis, research background, 393
Gas density detector, evolved gas analysis (EGA) and chromatography, 397
Gas-filled thermometer, operating principles, 35–36
Gas flow, superconductors, electrical transport measurements, 478
Gas-liquid chromatography (GLC), evolved gas analysis (EGA) and, 397
Gas permeation, O-ring seals, 18
Gas-phase chemistry, chemical vapor deposition (CVD) model
  basic components, 168–169
  software tools, 173
Gas-sensing membrane electrodes, evolved gas detection (EGD), 399
Gas-solid reactions, thermogravimetric (TG) analysis, 355–356
Gaussian distribution
  liquid surface x-ray diffraction, simple liquids, 1040–1041
  x-ray absorption fine structure (XAFS) spectroscopy, 873
Gaussian peak shapes, x-ray photoelectron spectroscopy (XPS), 1005–1007
Gauss-Mehlaer quadrature, particle scattering, central-field theory, deflection function, 60
Gebhart absorption-factor method, chemical vapor deposition (CVD) model, radiation, 173
Gelfand-Levitan-Marchenko (GLM) method, liquid surface x-ray diffraction, scattering length density (SLD) analysis, 1039–1043
Generalized gradient approximations (GGAs)
  local density approximation (LDA), 78–79
    heats for formation and cohesive energies, 80–81
    structural properties, 78–79
  metal alloy bonding, accuracy calculations, 139–141
  metal alloy magnetism, 185–186
General-purpose interface bus (GPIB), thermomagnetic analysis, 541–544
Generation/collection (GC) mode, scanning electrochemical microscopy (SECM)

basic principles, 641–642
error detection, 647–648
properties and principles, 636–637
Generation lifetime, carrier lifetime measurement, 431
Geometrical issues, carrier lifetime measurement, free carrier absorption (FCA), 441
GEOPIXE software, particle-induced x-ray emission (PIXE) analysis, 1217–1218
Georgopoulos/Cohen (GC) technique, diffuse scattering techniques, 887–889
data interpretation, 896–897
Getter pumps
classification, 12
nonevaporable getter pumps (NEGs), 12
G-factor, resistive magnets, power-field relations, 503
Gibbs additive principle, continuum field method (CFM), bulk chemical free energy, 119–120
Gibbs energy activation barrier, substitutional and interstitial metallic systems, temperature and concentration dependence, 153
Gibbs free energy
combustion calorimetry, 371–372
phase diagram predictions, mean-field approximation, 92–96
thermal analysis and principles of, 342–343
Gibbs grand potential, metal alloy paramagnetism, finite temperatures, 186–187
Gibbs phase rule, phase diagram predictions, 91–92
Gibbs triangle, diffuse intensities, metal alloys
concentration waves, multicomponent alloys, 259–260
multicomponent alloys, Fermi-surface nesting and van Hove singularities, 269–270
Glass transition temperatures, differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 368–369
Glide planes, symmetry operators, 40–42
Glow discharge mass spectrosscopy (GD0MS), heavy-ion backscattering spectrometry (HIBS) and, 1275
Gold impurities, deep level transient spectroscopy (DLTS), semiconductor materials, 419
Gold-rich AuFe alloys
atomic short range order (ASRO), 198–199
diffuse intensities, metal alloys, magnetic coupling and chemical order, 268
Gorsky-Bragg-Williams (GBW) free energies
diffuse intensities, metal alloys, mean-field results, 262
phase diagram predictions
cluster variational method (CVM), 99–100
mean-field approximation, 95–96
Gradient corrections, local density approximation (LDA), 78–79
Gradient energy term, interfacial energy, 120
Gradient-recalled echo sequence, magnetic resonance imaging (MRI), 768
Grain growth, microstructural evolution, diffusion-controlled grain growth, 126–128
Graphite furnace atomic absorption mass spectroscopy (GFAA-MS), heavy-ion backscattering spectrometry (HIBS) and, 1275
Grating criteria, spectrometers/monochromators, Raman spectroscopy of solids, 706–707
Grazing-incidence diffraction (GID), 241–246
applications, 226
distorted-wave Born approximation, 244–245
evanescent wave, 242
expanded distorted-wave approximation, 245–246
inclinded geometry, 243
liquid surface x-ray diffraction
alkane surface crystallization, 1043
components, 1038–1039
error sources, 1044–1045

Heating rate
gas analysis, simultaneous thermogravimetry (TG)-differential thermal analysis (TG-DTA), 394
thermogravimetric (TG) analysis, 351–352
Heating-rate curves, defined, 338
Heat loss, thermal diffusivity, laser flash technique, 388–389
Heats of formation, local density approximation (LDA), 79–81
Heat transfer relations
chemical vapor deposition (CVD) model, radiation, 172–173
differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 368–369
thermal diffusivity, laser flash technique, 385–386
thermogravimetric (TG) analysis, 350–352
Heavy-atom model, single-crystal x-ray structure determination, 860–861
computational techniques, 868–869

Heavy-ion backscattering spectrometry (HIBS)
applications, 1279–1280
automation, 1280
basic principles, 1275–1277
competitive, complementary, and alternative strategies, 1275
data analysis and interpretation, 1280–1281
areal density, 1281
background and sensitivity, 1281
mass measurements, 1281
elastic scattering, 1178
instrumentation criteria, 1277–1280
sensitivity and mass resolution, 1278–1279
limitations, 1281–1282
research background, 1273–1275
safety protocols, 1280
sample preparation, 1281
Heavy product, particle scattering, nuclear reactions, 57
Heisenberg-Dirac Hamiltonian, metal alloy magnetism, 180
Heisenberg exchange theory
collective magnetism, 515
ferromagnetism, 525–526
surface magneto-optic Kerr effect (SMOKE), 571
Heitler-London series, metal alloy bonding, accuracy calculations, 139–141
Helicopter effect, turbomolecular pumps, venting protocols, 8
Helimagnetism, principles and equations, 526–527
Helium gases, cryopump operation, 9–10
Helium mass spectrometer leak detector (HMSLD), leak detection, vacuum systems, 21–22
Helium vapor pressure, ITS-90 standard, 33
Helmholtz free energy
Landau magnetic phase transition theory, 529–530
semiconductor-liquid interfaces, differential capacitance measurements, 617–619
Hemi-spherical analysis, ultraviolet photoelectron spectroscopy (UPS), 729
Hemispherical sector analyzer (HSA), x-ray photoelectron spectroscopy (XPS), 980–982
Hermann-Mauguin symmetry operator
improper rotation axis, 39–40
single-crystal x-ray structure determination, crystal symmetry, 855–856
Heterodyne detection, impulsive stimulated thermal scattering (ISTS), 749
Heterogeneous broadening, nuclear quadrupole resonance (NQR), 790
Heterojunction bipolar transistors (HBTs), characterization
basic principles, 467–469
competitive and complementary techniques, 466–467
limitations of, 471
measurement equipment sources and selection criteria, 471
protocols and procedures, 469–470
research background, 466–467
sample preparation, 470–471
High-alumina ceramics, vacuum system construction, 17
High-energy beam transport, analysis, and detection, trace element accelerator mass spectrometry (TEAMS), 1239
High energy electron diffraction, transmission electron microscopy (TEM), deviation vector and parameter, 1068
High-energy ion beam analysis (IBA)
elastic recoil detection analysis (ERDA), 1178
heavy-ion backscattering, 1178
nuclear reaction analysis (NRA), 1178–1179
particle-induced x-ray emission, 1179
periodic table, 1177–1178
research background, 1176–1177
Rutherford backscattering spectrometry, 1178
Higher-order contamination, phonon analysis, 1326–1327
High-field sensors, magnetic field measurements, 506–510
Hall effect sensors, 506–508
magnetoresistive sensors, 508–509
nuclear magnetic resonance (NMR), 509–510
search coils, 509
High-frequency ranges
carrier lifetime measurement, automated photoconductivity (PC), 445–446
electron paramagnetic resonance (EPR), continuous-wave (CW) experiments, 795–796
High level injection, carrier lifetime measurement, 428–429
Highly doped layers, carrier lifetime measurement, metal/highly doped layer removal, free carrier absorption (FCA), 443
High-pressure magnetometry, principles and applications, 535
High-resolution spectrum, x-ray photoelectron spectroscopy (XPS), 974–978
appearance criteria, 993–994
final-state effects, 974–976
initial-state effects, 976–978
silicon example, 997–998
High-resolution transmission electron microscopy (HRTEM)
astigmatism, 1079
basic principles, 1064
bright-field/dark-field imaging, 1071
data analysis, 1081
sample preparation, 1108
scanning transmission electron microscopy (STEM) *vs.,* 1090–1092
phase-contrast imaging, 1096–1097
High-strain-rate testing
basic principles, 290–292
data analysis and interpretation, 296–298
limitations, 299–300
method automation, 296
protocols for, 292–296
stress-state equilibrium, 294–295
temperature effects, 295–296
sample preparation, 298
specimen modification, 298–299
theoretical background, 288–290
High-temperature electron emitter, hot cathode ionization gauges, 15
High-temperature superconductors (HTSs)
electrical transport measurement
applications, 472
contact materials, 474
current-carrying area, 476
current sharing with other materials, 474
current supply, 476–477
powder-in-tube HTSs, sample quality issues, 486
magnetic measurements *vs.,* 473
superconducting magnets, 500–502
High-temperature testing, stress-strain analysis, 286
High-vacuum pumps, classification, 6–12
cryopumps, 9–10
diffusion pumps, 6–7
getter pumps, 12
nonevaporable getter pumps (NEGs), 12
sputter-ion pumps, 10–12
sublimation pumps, 12
turbomolecular pumps, 7–9
Holographic imaging, magnetic domain structure measurements, 554–555
Holographic notch filter (HNF), Raman spectroscopy of solids, optics properties, 706
Homogeneous materials
carrier lifetime measurement, 428–429
thermal diffusivity, laser flash technique, 391–392
Honl corrections, x-ray diffraction, 210
Hooke's law, elastic deformation, 281
Hopkinson bar technique
design specifications for, 292–294
high-strain-rate testing
historical background, 289
protocols for, 292–296
stress-state equilibrium, 294–295
temperature effects, 295–296
tensile/torsional variants, 289–290
Hot cathode ionization gauges
calibration stability, 16
electron stimulated desorption (ESD), 15–16
operating principles, 14–15
Hot corrosion, electrochemical impedance spectroscopy (EIS), 601–603
Hot zone schematics, thermogravimetric (TG) analysis, 348–349
Hund's rules
magnetic moments, 512
atomic and ionic magnetism, local moment origins, 513–515
metal alloy magnetism, 180–181
electronic structure, 184–185
Hybridization, diffuse intensities, metal alloys, charge correlation effects, NiPt alloys, 266–268
Hybrid magnets, structure and properties, 503–504
Hydraulic-driven mechanical testing system, fracture toughness testing, load-displacement curve measurement, 307–308
Hydrocarbon layer deposition, nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE) and, error detection, 1207–1208
Hydrodynamics, chemical vapor deposition (CVD) model
basic components, 170–171
software tools, 174
Hyperboloid sheets, two-beam diffraction, dispersion surface, 230
Hyperfine interactions, Mössbauer spectroscopy
body-centered cubic (bcc) iron solutes, 828–830
data analysis and interpretation, 831–832
magnetic field splitting, 823–824
overview, 820–821
Hysteresis loop
magnetism principles, 494–495
permanent magnets, 497–499
surface magneto-optic Kerr effect (SMOKE), 569–570
experimental protocols, 571–572

Ice accumulation, energy-dispersive spectrometry (EDS), 1155
Ideal diode equation, *pn* junction characterization, 467–468
Ideality factor, *pn* junction characterization, 470
Ignition systems, combustion calorimetry, 376–377
Illuminated semiconductor-liquid interface
J-E equations, 608–609
monochromatic illumination, 610
polychromatic illumination, 610–611
Illumination modes, reflected-light optical microscopy, 676–680

Image-analysis measurement, hardness test equipment, automated reading, 319
Image-enhancement techniques, reflected-light optical microscopy, 676–680
Image formation protocols
  scanning electron microscopy (SEM), 1052–1053
    quality control, 1059–1060
    selection criteria, 1061, 1063
  scanning tunneling microscopy (STM), 1114
Imaging plate systems, single-crystal x-ray structure determination, 860
Impact parameters
  particle scattering, central-field theory, 57–58
  wear testing protocols, 331
Impedance analysis, electrochemical quartz crystal microbalance (EQCM), 655–657
Impingement of projectiles, materials characterization, 1
Impulse response, scanning electrochemical microscopy (SECM), feedback mode, 639–640
Impulsive stimulated thermal scattering (ISTS)
  applications, 749–752
  automation, 753
  competitive and related techniques, 744–746
  data analysis and interpretation, 753–757
  limitations, 757–758
  procedures and protocols, 746–749
  research background, 744–746
  sample preparation and specimen modification, 757
  vendor information, 759
Impurity measurements, trace element accelerator mass spectrometry (TEAMS)
  bulk analysis, 1247–1249
  depth-profiling techniques, 1250–1251
Inclined geometry, grazing-incidence diffraction (GID), 243
Incoherent imaging, scanning transmission electron microscopy (STEM)
  phase-contrast illumination *vs.*, 1094–1097
  probe configuration, 1098
  research background, 1091–1092
  scattering devices, 1098–1101
  weakly scattering objects, 1111
Indexing procedures
  low-energy electron diffraction (LEED), qualitative analysis, 1122–1124
  neutron powder diffraction, 1297–1298
  transmission electron microscopy (TEM)
    diffraction pattern indexing, 1073–1074
    Kikuchi line indexing, 1076–1077
Indirect detection techniques, nuclear quadrupole resonance (NQR), field cycling methods, 781
Indirect mass measurement techniques, basic principles, 24
Indirect structural technique, x-ray absorption spectroscopy, 870
Induced currents, magnetic field effects and applications, 496
Inductively coupled plasma (ICP) mass spectrometry
  heavy-ion backscattering spectrometry (HIBS) and, 1275
  particle-induced x-ray emission (PIXE), 1211
  trace element accelerator mass spectrometry (TEAMS) and, 1237
Inelastic scattering
  diffuse scattering subtraction, 890–893
  magnetic neutron scattering
    basic principles, 1331
    data analysis, 1335–1336
  particle scattering, 52
    diagrams, 52–54
  x-ray photoelectron spectroscopy (XPS), survey spectrum, 974
Inertia, high-strain-rate testing, 299
Inert/reactive atmosphere, thermogravimetric (TG) analysis, 354–355
Infrared absorption spectroscopy (IRAS), solids analysis, *vs.* Raman spectroscopy, 699
Infrared (IR) spectrometry
  gas analysis and, 397–398
  magnetic neutron scattering and, 1321
Inhomogeneity
  Hall effect, semiconductor materials, 417
  x-ray photoelectron spectroscopy (XPS), initial-state effects, 978
Inhomogeneous path probability method (PPM), microstructural evolution, 116–117
Initial-state effects, x-ray photoelectron spectroscopy (XPS), 976–978
In situ analysis
  time-dependent neutron powder diffraction, 1300
  transmission electron microscopy (TEM), specimen modification, 1088
Instrumentation criteria
  capacitance-voltage (C-V) characterization, 463–464
  combustion calorimetry, 375–377
  differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 367
    selection criteria, 373
  electrochemical quartz crystal microbalance (EQCM), 658–659
    automated procedures, 659–660
  gas analysis, simultaneous thermogravimetry (TG)-differential thermal analysis (TG-DTA), sample holder criteria, 394
  heavy-ion backscattering spectrometry (HIBS), 1279
  impulsive stimulated thermal scattering (ISTS), 749–752
  ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1228–1230
  liquid surface x-ray diffraction, 1036–1038
  low-energy electron diffraction (LEED), 1125–1126
  magnetic x-ray scattering, 934–935
  medium-energy backscattering, 1267–1268
  neutron powder diffraction, peak shape, 1292
  nuclear magnetic resonance, 770–771
  nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), 1203–1204
  optical microscopy, 668–671
  phonon analysis, triple-axis spectrometry, 1320–1323
  resonant scattering, 912–913
  scanning electrochemical microscopy (SECM), 642–643
  scanning electron microscopy (SEM), basic components, 1053–1057
  scanning transmission electron microscopy (STEM), sources, 1111
  single-crystal neutron diffraction, 1312–1313
  single-crystal x-ray structure determination, 859–860
  single event upset (SEU) microscopy, 1227–1228
  superconductors, electrical transport measurements, 476–477, 479–480
  surface x-ray diffraction, 1011–1015
    crystallographic alignment, 1014–1015
    five-circle diffractometer, 1013–1014
    laser alignment, 1014
    sample manipulator, 1012–1013
    vacuum system, 1011–1012
  thermal diffusivity, laser flash technique, 385–386
  trace element accelerator mass spectrometry (TEAMS), 1258
  ultraviolet photoelectron spectroscopy (UPS), 733
  x-ray magnetic circular dichroism (XMCD), 957–962
    circularly polarized sources, 957–959
    detector devicees, 959
    measurement optics, 959–962
  x-ray photoelectron spectroscopy (XPS), 978–983
    analyzers, 980–982
    detectors, 982
    electron detection, 982–983
    maintenance, 983
    sources, 978–980
Instrumentation errors, hardness testing, 322
Instrumented indentation testing, basic principles, 317
Integrated intensity
  magnetic x-ray scattering, nonresonant antiferromagnetic scattering, 929–930
  small-angle scattering (SAS), 222
  two-beam diffraction, 235
  x-ray powder diffraction, Bragg peaks, 840
Integrated vertical Hall sensor, magnetic field measurements, 507–508
Intensity computations
  Auger electron spectroscopy (AES), 1167–1168
  diffuse scattering techniques, 886–889
    absolute calibration, measured intensities, 894
    derivation protocols, 901–904
  low-energy electron diffraction (LEED), quantitative measurement, 1124–1125
  multiple-beam diffraction, NBEAM theory, 238
  particle-induced x-ray emission (PIXE), 1216–1217
    x-ray intensities and concentrations, 1221–1222
  surface x-ray diffraction, crystal truncation rods (CTR), 1009
Intensity-measuring ellipsometer, automation, 739
Interaction potentials
  molecular dynamics (MD) simulation, surface phenomena, 159
  particle scattering, central-field theory, 57
Interdiffusion, substitutional and interstitial metallic systems, 155
Interfacial energy, microstructural evolution, 120
Interference effects
  nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE), 1205
  surface/interface x-ray diffraction, crystal truncation rods (CTR), 219
  x-ray absorption fine structure (XAFS) spectroscopy, single scattering picture, 871–872
  x-ray diffraction
    crystal structure, 208–209
    single-crystal x-ray structure determination, 851–858
Interlayer surface relaxation, molecular dynamics (MD) simulation, room temperature structure and dynamics, 161
Internal fields, dynamical diffraction, basic principles, 229
Internal magnetic field, ferromagnetism, 522–524
International Organization for Legal Metrology (OILM), weight standards, 26–27
International symmetry operators, improper rotation axis, 39–40
International temperature scales (ITS)
  IPTS-27 scale, 32–33
  IPTS-68 scale, 33
  ITS-90, 33

Interparticle interference, small-angle scattering (SAS), 222
Interplanar spacing, transmission electron microscopy (TEM), diffraction pattern indexing, 1073–1074
Interpolating gas thermometer, ITS-90 standard, 33
Inverse heating-rate curves, defined, 338
Inverse modeling, impulsive stimulated thermal scattering (ISTS), 753–754
Inverse photoemission, ultraviolet photoelectron spectroscopy (UPS)
  vs. photoemission, 722–723
  valence electron characterization, 723–724
Inverse photoemission (IPES), metal alloy magnetism, local exchange splitting, 189–190
Ion beam analysis (IBA)
  accelerator mass spectrometry, 1235
  elastic ion scattering for composition analysis
    applications, 1191–1197
    basic concepts, 1181–1184
    detector criteria and detection geometries, 1185–1186
    equations, 1186–1189
    experimental protocols, 1184–1186
    limitations, 1189–1191
    research background, 1179–1181
  forward-recoil spectrometry
    applications, 1268–1269
    automation, 1269
    backscattering data, 1269–1270
    basic principles, 1261–1265
    complementary and alternative techniques, 1261
    data analysis and interpretation, 1269–1271
    forward-recoil data, 1270–1271
    instrumentation criteria, 1267–1268
    limitations, 1271–1272
    research background, 1259–1261
    resolution, 1267
    safety issues, 1269
    sensitivity parameters, 1266–1267
    spectrometer efficiency, 1265–1266
    time-of-flight spectrometry (TOS), 1265
  heavy-ion backscattering spectrometry (HIBS)
    applications, 1279–1280
    automation, 1280
    basic principles, 1275–1277
    competitive, complementary, and alternative strategies, 1275
    data analysis and interpretation, 1280–1281
      areal density, 1281
      background and sensitivity, 1281
      mass measurements, 1281
    instrumentation criteria, 1277–1280
      sensitivity and mass resolution, 1278–1279
    limitations, 1281–1282
    research background, 1273–1275
    safety protocols, 1280
    sample preparation, 1281
  high-energy ion beam analysis (IBA)
    elastic recoil detection analysis (ERDA), 1178
    heavy-ion backscattering, 1178
    nuclear reaction analysis (NRA), 1178–1179
    particle-induced x-ray emission, 1179
    periodic table, 1177–1178
    research background, 1176–1177
    Rutherford backscattering spectrometry, 1178
  medium-energy backscattering
    applications, 1268–1269
    automation, 1269
    backscattering data, 1269–1270
    basic principles, 1261–1265
    complementary and alternative techniques, 1261
    data analysis and interpretation, 1269–1271
    forward-recoil data, 1270–1271
    instrumentation criteria, 1267–1268
    limitations, 1271–1272
    research background, 1258–1259, 1259–1261
    resolution, 1267
    safety issues, 1269
    sensitivity parameters, 1266–1267
    spectrometer efficiency, 1265–1266
    time-of-flight spectrometry (TOS), 1265
  nuclear reaction analysis (NRA)
    automation, 1205–1206
    background, interference, and sensitivity, 1205
    cross-sections and Q values, 1205
    data analysis, 1206–1207
    energy relations, 1209
    energy scanning, resonance depth profiling, 1204–1205
    energy spread, 1209–1210
    instrumentation criteria, 1203–1204
    limitations, 1207–1208
    nonresonant methods, 1202–1203
    research background, 1200–1202
    resonant depth profiling, 1203
    specimen modification, 1207
    standards, 1205
    unwanted particle filtering, 1204
  particle-induced x-ray emission (PIXE)
    automation, 1216
    basic principles, 1211–1212
    competing methods, 1210–1211
    data analysis, 1216–1218
    limitations, 1220
    protocols and techniques, 1213–1216
    research background, 1210–1211
    sample preparation, 1218–1219
    specimen modification, 1219–1220
  proton-induced gamma ray emission (PIGE)
    automation, 1205–1206
    background, interference, and sensitivity, 1205
    cross-sections and Q values, 1205
    data analysis, 1206–1207
    energy relations, 1209
    energy scanning, resonance depth profiling, 1204–1205
    energy spread, 1209–1210
    instrumentation criteria, 1203–1204
    limitations, 1207–1208
    nonresonant methods, 1202–1203
    research background, 1200–1202
    resonant depth profiling, 1203
    specimen modification, 1207
    standards, 1205
    unwanted particle filtering, 1204
  radiation effects microscopy
    basic principles, 1224–1228
    instrumentation criteria, 1128–1230
    ion-induced damage, 1232–1233
    limitations, 1233
    quantitative analysis, pulse height interpretations, 1225–1226
    research background, 1223–1224
    semiconductor materials, 1225
    SEU microscopy, 1227–1228
      static random-access memory (SRAM), 1230–1231
    specimen modification, 1231–1232
    topographical contrast, 1226–1227
  research background, 1175–1176
  trace element accelerator mass spectrometry (TEAMS)
    automation, 1247
    bulk analysis
      impurity measurements, 1247–1249
      measurement data, 1249–1250
    complementary, competitive and alternative methods, 1236–1238
      inductively coupled plasma mass spectrometry, 1237
      neutron activation-accelerator mass spectrometry (NAAMS), 1237
      neutron activation analysis (NAA), 1237
      secondary-ion mass spectrometry (SIMS), 1236–1237
      selection criteria, 1237–1238
      sputter-initiated resonance ionization spectrometry (SIRIS), 1237
    data analysis and interpretation, 1247–1252
      calibration of data, 1252
    depth-profiling
      data analysis, 1251–1252
      impurity measurements, 1250–1251
    facilities profiles, 1242–1246
      CSIRO Heavy Ion Analytical Facility (HIAF), 1245
      Naval Research Laboratory, 1245–1246
      Paul Scherrer Institute (PSI)/ETH Zurich Accelerator SIMS Laboratory, 1242–1244
      Technical University Munich Secondary Ion AMS Facility, 1245
      University of North Texas Ion Beam Modification and Analysis Laboratory, 1246
      University of Toronto IsoTrace Laboratory, 1244–1245
    facility requirements, 1238
    future applications, 1239
    high-energy beam transport, analysis, and detection, 1239
    historical evolution, 1246–1247
    impurity measurements
      bulk analysis, 1247–1249
      depth-profiling, 1250–1251
    instrumentation criteria, 1239–1247
      magnetic and electrostatic analyzer calibration, 1241–1242
      ultraclean ion source design, 1240–1241
    instrumentation specifications and suppliers, 1258
    limitations, 1253
    research background, 1235–1238
    sample preparation, 1252–1253
    secondary-ion acceleration and electron-stripping system, 1238–1239
    specimen modification, 1253
    ultraclean ion sources, negatively charged secondary-ion generation, 1238
Ion-beam-induced charge (IBIC) microscopy
  basic principles, 1224–1228
  instrumentation criteria, 1128–1230
  ion-induced damage, 1232–1233
  limitations, 1233
  quantitative analysis, pulse height interpretations, 1225–1226
  research background, 1223–1224
  semiconductor materials, 1225
  SEU microscopy, 1227–1228
    static random-access memory (SRAM), 1230–1231
  specimen modification, 1231–1232
  topographical contrast, 1226–1227
Ion burial, sputter-ion pump, 11
Ion excitation
  Auger electron spectroscopy (AES), peak error detection, 1171–1173
  energy-dispersive spectrometry (EDS), 1136
Ionic magnetism, local moment origins, 513–515
Ionic migration, energy-dispersive spectrometry (EDS), specimen modification, 1152–1153

Ion-induced damage, ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1232–1233
Ionization cross-section, energy-dispersive spectrometry (EDS), standardless analysis, 1148
Ionization gauges
  cold cathode type, 16
  hot cathode type
    calibration stability, 16
    electron stimulated desorption (ESD), 15–16
    operating principles, 14–15
Ionization loss peaks, Auger electron spectroscopy (AES), error detection, 1171
Ion milling, transmission electron microscopy (TEM), sample preparation, 1086–1087
Ion pumps, surface x-ray diffraction, 1011–1012
Ion scattering spectroscopy (ISS), Auger electron spectroscopy (AES) *vs.,* 1158–1159
Iron (Fe) alloys. *See also* Nickel-iron alloys
  magnetism
    atomic short range order (ASRO), 191
      gold-rich AuFe alloys, 198–199
    magnetocrystalline anisotropy energy (MAE), 193
    moment formation and bonding, FeV alloys, 196
  Mössbauer spectroscopy, body-centered cubic (bcc) solutes, 828–830
  paramagnetism, first-principles calculations, 189
Irreversibility field (H_{irr}), superconductors, electrical transport measurement
  applications, 472
  extrapolation, 475
  magnetic measurement *vs.,* 473
Ising energy, phase diagram prediction, static displacive interactions, 104–106
Isobaric mass change determination, defined, 338
Isolation valves, sputter-ion pump, 12
Isomers, combustion calorimetry, 377–378
Isomer shift, Mössbauer spectroscopy
  basic principles, 821–822
  hyperfine interactions, 820–821
Isothermal method, thermogravimetric (TG) analysis, kinetic theory, 352–354
Isotropic materials, reflected-light optical microscopy, 678–680
Itinerant magnetism, transition metal magnetic ground state, zero temperature, 181–183

J-E equations, semiconductor-liquid interface
  concentration overpotentials, 611–612
  illuminated cases, 608–609
  kinetic properties, 631–633
  series resistance overpotentials, 612
J-integral approach, fracture toughness testing
  basic principles, 306–307
  crack extension measurement, 311
  research background, 302
  sample preparation, 312
  SENB and CT speciments, 314–315
  unstable fractures, 309
Johnson noise, scanning tunneling microscopy (STM), 1113–1114
Joint leaks, vacuum systems, 20
Junction capacitance transient, deep level transient spectroscopy (DLTS), semiconductor materials, 421–423
Junction diodes, deep level transient spectroscopy (DLTS), semiconductor materials, 420
Junction field-effect transistors (JFETs), characterization
  basic principles, 467–469
  competitive and complementary techniques, 466–467
  limitations of, 471
  measurement equipment sources and selection criteria, 471
  protocols and procedures, 469–470
  research background, 466–467
  sample preparation, 470–471

Katharometer, evolved gas analysis (EGA) and chromatography, 396–397
Keating model, surface x-ray diffraction measurements, crystallographic refinement, 1018
Keithley-590 capacitance meter, capacitance-voltage (C-V) characterization, 460–461
Kelvin-Onsager relations, magnetotransport in metal alloys, 560–561
Kelvin relations, magnetotransport in metal alloys, basic principles, 560
Kerr effect magnetometry
  magnetic domain structure measurements, magneto-optic imaging, 547–549
  principles and applications, 535–536
  surface magneto-optic Kerr effect (SMOKE)
    automation, 573
    classical theory, 570–571
    data analysis and interpretation, 573–574
    limitations, 575
    multilayer formalism, 571
    phenomenologica origins, 570
    protocols and procedures, 571–573
    quantum theory, ferromagnetism, 571
    research background, 569–570
    sample preparation, 575
Kikuchi-Barker coefficients, phase diagram predictions, cluster variational method (CVM), 99–100
Kikuchi lines
  scanning transmission electron microscopy (STEM), instrumentation criteria, 1104–1105
  transmission electron microscopy (TEM)
    deviation vector and parameter, 1067–1068
      defect contrast, 1085
      specimen orientation, 1075–1078
        deviation parameters, 1077–1078
        electron diffuse scattering, 1075
        indexing protocols, 1076–1077
        line origins, 1075–1076
Kinematic theory
  diffuse scattering techniques, crystal structure, 885–889
  dynamical diffraction, theoretical background, 224–225
  ion beam analysis (IBA), 1176
  ion-beam analysis (IBA), elastic two-body collision, 1181–1184
  liquid surface x-ray diffraction, reflectivity measurements, 1032–1033
  particle scattering, 51–57
    binary collisions, 51
    center-of-mass and relative coordinates, 54–55
    elastic scattering and recoiling, 51–52
    inelastic scattering and recoiling, 52
    nuclear reactions, 56–57
    relativistic collisions, 55–56
    scattering/recoiling diagrams, 52–54
  single-crystal neutron diffraction and, 1310–1311
  transmission electron microscopy (TEM)
    deviation vector and parameter, 1068
    structure and shape factor analysis, 1065–1066
  x-ray diffraction
    crystalline material, 208–209
    lattice defects, 210
    local atomic arrangement - short-range ordering, 214–217
    research background, 206
    scattering principles, 206–208
    small-angle scattering (SAS), 219–222
      cylinders, 220–221
      ellipsoids, 220
      Guinier approximation, 221
      integrated intensity, 222
      interparticle interference, 222
      K=0 extrapolation, 221
      porod approximation, 221–222
      size distribution, 222
      spheres, 220
      two-phase model, 220
    structure factor, 209–210
    surface/interface diffraction, 217–219
      crystal truncation rods, 219
      two-dimensional diffraction rods, 218–219
    thermal diffuse scattering (TDS), 210–214
Kinetic energy
  Auger electron spectroscopy (AES), 1159–1160
  chemical vapor deposition (CVD) model
    basic components, 171
    software tools, 175
  electrochemical photocapacitance spectroscopy (EPS), semiconductor materials, 625
  low-energy electron diffraction (LEED), quantitative analysis, 1129–1131
  semiconductor-liquid interface
    steady-state J-E data, 631–633
    time-resolved photoluminescence spectroscopy (TRPL), 630–631
  thermal analysis and, 343
  thermogravimetric (TG) analysis, applications, 352–354
  ultraviolet photoelectron spectroscopy (UPS), photoemission process, 726–727
  x-ray photoelectron spectroscopy (XPS), 971–972
    analyzer criteria, 981–982
    background subtraction, 990–991
Kirchoff's law of optics, radiation thermometer, 36–37
Kirkendall effect, binary/multicomponent diffusion, vacancy wind and, 149
Kirkendall shift velocity, binary/multicomponent diffusion, frames of reference, transition between, 148–149
Kirkpatrick-Baez (KB) mirrors, x-ray microprobes, 946
KLM line markers, energy-dispersive spectrometry (EDS), qualitative analysis, 1142–1143
Knock-on damage, transmission electron microscopy (TEM), metal specimen modification, 1088
Knoop hardness testing
  automated methods, 319
  basic principles, 317–318
  data analysis and interpretation, 319–320
  hardness values, 317–318, 323
  limitations and errors, 322
  procedures and protocols, 318–319
  research background, 316–317
  sample preparation, 320
  specimen modification, 320–321
Knudsen diffusion coefficient, chemical vapor deposition (CVD) model, free molecular transport, 169–170
Knudsen effect
  combustion calorimetry, 371–372
  thermogravimetric (TG) analysis, instrumentation and apparatus, 349–350

Kohn-Sham equation
diffuse intensities, metal alloys, concentration waves, density-functional theory (DFT), 260–262
metal alloy bonding
accuracy calculations, 139–141
precision measurements, self-consistency, 141
metal alloy magnetism
competitive and related techniques, 185–186
magnetocrystalline anisotropy energy (MAE), 192–193
solid-solution alloy magnetism, 183–184
transition metal magnetic ground state, itinerant magnetism at zero temperature, 182–183
Koopman's theorem, electronic structure analysis, Hartree-Fock (HF) theory, 77
Korringa-Kohn-Rostocker (KKR) method
band theory of magnetism, layer Korringa Kohn Rostoker (LKKR) technique, 516
diffuse intensities, metal alloys
concentration waves, first-principles calcuations, electronic structure, 264–266
hybridization in NiPt alloys, charge correlation effects, 267–268
metal alloy magnetism, magnetocrystalline anisotropy energy (MAE), 192–193
phase diagram prediction, electronic structure, 101–102
solid-solution alloy magnetism, 183–184
Kossel cones, transmission electron microscopy (TEM), Kikuchi line indexing, 1076–1077
Kovar, vacuum system construction, 17
k-points, metal alloy bonding, precision calculations, Brillouin zone sampling, 143
Kramers-Kronig relation, resonant scattering analysis, 907
Krivoglaz-Clapp-Moss formula, diffuse intensities, metal alloys
concentration waves, density-functional theory (DFT), 260–262
mean-field results, 262–263
Kronecker delta function, 209
Kruschov equation, wear testing, 334

Laboratory balances, applications, 27
Lambert cosine law, radiation thermometer, 37
Lamb modes
impulsive stimulated thermal scattering (ISTS), 754–755
Mössbauer effect, 818–820
Landau levels, cyclotron resonance (CR), 805–806
quantum mechanics, 808
Landau-Lifshitz equation, resonant scattering analysis, 909–910
Landau theory, magnetic phase transitions, 529–530
thermomagnetic analysis, 544
Lande *g* factor, local moment origins, 514–515
Langevin function
diagmagnetism, dipole moments, atomic origin, 512
ferromagnetism, 524
paramagnetism, classical and quantum theories, 520–522
superparamagnetism, 522
Langmuir monolayers, liquid surface x-ray diffraction
data analysis, 1041–1043
grazing incidence and rod scans, 1036
Lanthanum hexaboride electron guns
Auger electron spectroscopy (AES), 1160–1161
scanning electron microscopy (SEM)
instrumentation criteria, 1054
selection criteria, 1061
Laplace equation
magnetotransport in metal alloys, 560–561
thermal diffusivity, laser flash technique, 388–389
Larmor frequency
closed/core shell diamagnetism, dipole moments, atomic origin, 512
nuclear magnetic resonance, 764–765
nuclear quadrupole resonance (NQR), Zeeman-perturbed NRS (ZNRS), 782–783
Laser components
impulsive stimulated thermal scattering (ISTS), 750–752
photoluminescence (PL) spectroscopy, 684
Raman spectroscopy of solids, radiation sources, 705
surface x-ray diffraction, alignment protocols, 1014
ultraviolet/visible absorption (UV-VIS) spectroscopy, 690
Laser flash technique, thermal diffusivity
automation of, 387
basic principles, 384–385
data analysis and interpretation, 387–389
limitations, 390
protocols and procedures, 385–387
research background, 383–384
sample preparation, 389
specimen modification, 389–390
Laser magneto-spectroscopy (LMS), cyclotron resonance (CR)
basic principles, 808–812
data analysis and interpretation, 813–814
error detection, 814–815
far-infrared (FIR) sources, 810–812
Laser spot scanning (LSS), semiconductor-liquid interface, photoelectrochemistry, 626–628
Lattice-fixed frame of reference
binary/multicomponent diffusion, 148
substitutional and interstitial metallic systems, 152
Lattice systems. *See also* Reciprocal lattices
conductivity measurements, research background, 401–403
crystallography, 44–46
Miller indices, 45–46
deep level transient spectroscopy (DLTS), 419
defects, x-ray diffraction, 210
density definition and, 26
local atomic arrangment - short-range ordering, 214–217
metal alloy magnetism, atomic short range order (ASRO), 191
molecular dynamics (MD) simulation, surface phenomena, 158–159
phonon analysis, basic principles, 1317–1318
Raman active vibrational modes, 709–710, 720–721
single-crystal x-ray structure determination, crystal symmetry, 854–856
thermal diffuse scattering (TDS), 212–214
transition metal magnetic ground state, itinerant magnetism at zero temperature, 183
transmission electron microscopy (TEM), defect diffraction contrast, 1068–1069
ultraviolet photoelectron spectroscopy (UPS), 730
x-ray powder diffraction, crystal lattice determination, 840
Laue conditions
diffuse scattering techniques, 887–889
low-energy electron diffraction (LEED), 1122
single-crystal neutron diffraction, instrumentation criteria, 1312–1313
single-crystal x-ray structure determination, 853
protocols and procedures, 858–860
two-beam diffraction
anomalous transmission, 231–232
diffracted intensities, 233–234
hyperboloid sheets, 230
Pendellösung, 231
x-ray standing wave (XWS) diffraction, 232
x-ray diffraction
crystal structure, 208–209
local atomic correlation, 215–217
Layer density, surface phenomena, molecular dynamics (MD) simulation, temperature variation, 164
Layer Korringa Kohn Rostoker (LKKR) technique, band theory of magnetism, 516
Lead zirconium titanate film, impulsive stimulated thermal scattering (ISTS), 751–752
Leak detection, vacuum systems, 20–22
Least-squares computation
energy-dispersive spectrometry (EDS), peak overlap deconvolution, multiple linear least squares (MLLS) method, 1144–1145
neutron powder diffraction
refinement algorithms, 1300–1301
Rietveld refinements, 1296
single-crystal x-ray structure determination, crystal structure refinements, 857–858
thermal diffusivity, laser flash technique, 389
L edges
resonant scattering
angular dependent tensors L=2, 916
L=2 measurements, 910–911
L=4 measurements, 911–912
x-ray absorption fine structure (XAFS) spectroscopy, 873
Lennard-Jones parameters, chemical vapor deposition (CVD) model, kinetic theory, 171
Lens defects and resolution
optical microscopy, 669
scanning electron microscopy (SEM), 1054
transmission electron microscopy (TEM), 1078–1080
aperture diffraction, 1078
astigmatism, 1079
chromatic aberration, 1078
resolution protocols, 1079–1080
spherical aberration, 1078
Lenz-Jensen potential, ion-beam analysis (IBA), non-Rutherford cross-sections, 1190
Lenz's law of electromagnetism
diamagnetism, 494
closed/core shell diamagnetism, dipole moments, atomic origin, 512
superconductor magnetization, 518–519
Level-crossing double resonance NQR nutation spectroscopy, 785
LHPM program, neutron powder diffraction
axial divergence peak asymmetry, 1293
Rietveld refinements, 1306
Lifetime analysis
carrier lifetime measurement, free carrier absorption (FCA), 441–442
x-ray photoelectron spectroscopy (XPS), 973–974
Lifetime characterization. *See* Carrier lifetime measurement
Lifetime depth profiling, carrier lifetime measurement, free carrier absorption (FCA), 441
Lifetime mapping, carrier lifetime measurement, free carrier absorption (FCA), 441–442
Light-emitting diodes (LEDs)
carrier lifetime measurement, photoluminescence (PL), 451–452
deep level transient spectroscopy (DLTS), semiconductor materials, 419

Light-ion backscattering, medium-energy backscattering, trace-element sensitivity, 1266–1267
Light leakage, energy-dispersive spectrometry (EDS), 1154–1155
Light product, particle scattering, nuclear reactions, 57
Light scattering, Raman spectroscopy of solids, semiclassical physics, 701–702
Light sources
  ellipsometry, 738
  ultraviolet photoelectron spectroscopy (UPS), 728–729
Linear combination of atomic orbitals (LCAOs), metal alloy bonding, precision calculations, 142–143
Linear dependence, carrier lifetime measurement, free carrier absorption (FCA), 438–439
Linear elastic fracture mechanics (LEFM)
  fracture toughness testing
    crack tip opening displacement (CTOD) (δ), 307
    stress intensity factor *(K),* 306
  fracture-toughness testing, 302
    basic principles, 303
Linear laws, binary/multicomponent diffusion, 146–147
Linearly variable differential transformer (LVDT), stress-strain analysis, low-temperature testing, 286
Linear muffin tin orbital method (LMTO), electronic topological transitions, van Hove singularities in CuPt, 272–273
Linear polarization, corrosion quantification, 596–599
Line scans, Auger electron spectroscopy (AES), 1163–1164
Lineshape analysis, surface x-ray diffraction, 1019
Liouville's theorem, ultraviolet photoelectron spectroscopy (UPS), figure of merit light sources, 734–735
Liquid alkanes, liquid surface x-ray diffraction, surface crystallization, 1043
Liquid-filled thermometer, operating principles, 35
Liquid metals, liquid surface x-ray diffraction, 1043
Liquid nitrogen (LN2) temperature trap, diffusion pump, 6–7
Liquid surfaces, x-ray diffraction
  basic principles, 1028–1036
  competitive and related techniques, 1028
  data analysis and interpretation, 1039–1043
    Langmuir monolayers, 1041–1043
    liquid alkane crystallization, 1043
    liquid metals, 1043
    simple liquids, 1040–1041
  non-specular scattering
    GID, diffuse scattering, and rod scans, 1038–1039
    reflectivity measurements, 1033
  p-polarized x-ray beam configuration, 1047
  reflectivity, 1029–1036
    Born approximation, 1033–1034
    distorted-wave Born approximation, 1034–1036

Molecular beam epitaxy (MBE)
low-energy electron diffraction (LEED), 1121
surface magneto-optic Kerr effect (SMOKE), superlattice structures, 573–574
Molecular dissociation
microstructural evolution, 117
sputter-ion pump, 11
Molecular drag pump, application and operation, 5
Molecular dynamics (MD) simulation
electronic structure analysis, phase diagram prediction, 101–102
phase diagram prediction, static displacive interactions, 105–106
surface phenomena
data analysis and interpretation, 160–164
higher-temperature dynamics, 161–162
interlayer relaxation, 161
layer density and temperature variation, 164
mean-square atomic displacement, 162–163
metal surface phonons, 161–162
room temperature structure and dynamics, 160–161
thermal expansion, 163–164
limitations, 164
principles and practices, 158–159
related theoretical techniques, 158
research background, 156
surface behavior, 156–157
temperature effects on surface behavior, 157
Molecular flow, vacuum system design, 19
Molecular orbitals, ultraviolet photoelectron spectroscopy (UPS), 727–728
Molecular point group, group theoretical analysis, vibrational Raman spectroscopy, 703–704
Moliére approximation, particle scattering, central-field theory, deflection function, 60
Moment formation
metal alloy magnetism, 180
FeV alloys, 196
local moment fluctuation, 187–188
nickel-iron alloys, atomic long and short range order (ASRO), 195–196
metal alloy paramagnetism, finite temperatures, 187
Momentum matching, low-energy electron diffraction (LEED), sample preparation, 1131–1132
Momentum space representation, Mössbauer effect, 819–820
Monochromatic illumination, semiconductor-liquid interface, 610
Monochromators. *See* Spectrometers/monochromators
Monomolecular layers, x-ray diffraction
basic principles, 1028–1036
competitive and related techniques, 1028
data analysis and interpretation, 1039–1043
Langmuir monolayers, 1041–1043
liquid alkane crystallization, 1043
liquid metals, 1043
simple liquids, 1040–1041
non-specular scattering
GID, diffuse scattering, and rod scans, 1038–1039
reflectivity measurements, 1033
p-polarized x-ray beam configuration, 1047
reflectivity, 1029–1036
Born approximation, 1033–1034
distorted-wave Born approximation, 1034–1036
Fresnel reflectivity, 1029–1031
grazing incidence diffraction and rod scans, 1036
instrumentation, 1036–1038
multiple stepwise and continuous interfaces, 1031–1033
non-specular scattering, 1033
research background, 1027–1028
specimen modification, 1043–1045
Monotonic heating, thermal diffusivity, laser flash technique, 386–387
Monte Carlo simulation
chemical vapor deposition (CVD) model
free molecular transport, 170
radiation, 173
diffuse intensities, metal alloys
concentration waves, multicomponent alloys, 259–260
effective cluster interactions (ECIs), 255–256
energy-dispersive spectrometry (EDS), standardless analysis, backscatter loss correction, 1149
scanning electron microscopy (SEM), signal generation, 1050–1052
Mössbauer effect, basic properties, 818–820
Mössbauer spectroscopy
basic properties, 761–762
bcc iron alloy solutes, 828–830
coherence and diffraction, 824–825
crystal defects and small particles, 830–831
data analysis and interpretation, 831–832
diffuse scattering techniques, comparisons, 883–884
electric quadrupole splitting, 822–823
hyperfine interactions, 820–821
magnetic field splitting, 823–824
isomer shift, 821–822
magnetic neutron scattering and, 1321
Mössbauer effect, 818–820
nuclear excitation, 817–818
phase analysis, 827–828
phonons, 824
radioisotope sources, 825–826
recoil-free fraction, 821
relaxation phenomena, 824
research background, 816–817
sample preparation, 832
single-crystal x-ray structure determniation, 851
synchrotron sources, 826–827
valence and spin determination, 827
Mott detector, ultraviolet photoelectron spectroscopy (UPS), 729
Mott-Schottky plots
electrochemical photocapacitance spectroscopy (EPS), surface capacitance measurements, 625
semiconductor-liquid interface
differential capacitance measurements, 617–619
flat-band potential measurements, 628–629
Mounting procedures, metallographic analysis
7075-T6 anodized aluminum alloy, 68
deformed high-purity aluminum, 69
sample preparation, 66
4340 steel, 67

Muffin-tin approximation
linear muffin tin orbital method (LMTO), electronic topological transitions, van Hove singularities in CuPt, 272–273
metal alloy bonding, precision calculations, 143
Multichannel analyzer (MCA)
energy-dispersive spectrometry (EDS), 1137–1140
heavy-ion backscattering spectrometry (HIBS), 1279
ion-beam analysis (IBA), 1182–1184
ERD/RBS examples, 1191–1197
surface x-ray diffraction
basic principles, 1010
crystallographic alignment, 1014–1015
Multicomponent alloys
concentration waves, 257–260
diffuse intensities, Fermi-surface nesting, and van Hove singularities, 268–270
Multilayer structures
dynamical diffraction, applications, 225
grazing-incidence diffraction (GID), 242–243
surface magneto-optic Kerr effect (SMOKE), 571
Multiphonon mechanism, carrier lifetime measurement, 429
Multiple-beam diffraction, 236–241
basic principles, 236–237
literature sources, 226
NBEAM theory, 237–238
boundary conditions, 238
D-field component eigenequation, 237
eigenequation matrix, 237–238
intensity computations, 238
numerical solution strategy, 238
phase information, 240
polarization density matrix, 241
polarization mixing, 240
second-order Born approximation, 238–240
standing waves, 240
three-beam interactions, 240
Multiple linear least squares (MLLS) method, energy-dispersive spectrometry (EDS), peak overlap deconvolution, 1144–1146
Multiple scattering
magnetic x-ray scattering
error detection, 935
nonresonant scattering, 929–930
x-ray absorption fine structure (XAFS) spectroscopy, 873–874
Multiple-specimen measurement technique, fracture toughness testing, crack extension measurement, 308
Multiple stepwise interfaces, liquid surface x-ray diffraction, reflectivity measurements, 1031–1033
Multiplet structures
metal alloy bonding, accuracy calculations, 140–141
x-ray photoelectron spectroscopy (XPS), final-state effects, 976
Multiple-wavelength anomalous diffraction (MAD), resonant scattering, 905
Multipole contributions, resonant scattering analysis, 909–910
Muon spin resonance, basic principles, 762–763

Nanotechnology, surface phenomena, molecular dynamics (MD) simulation, 156–157
Narrow-band thermometer, operating principles, 37
National Institutes of Standards and Technology (NIST), weight standards, 26–27
Natural oxide films, electrochemical dissolution, ellipsometric measurement, 742
Naval Research Laboratory, trace element accelerator mass spectrometry (TEAMS) research at, 1245–1246
NBEAM theory, multiple-beam diffraction, 237–238
boundary conditions, 238
D-field component eigenequation, 237
eigenequation matrix, 237–238
intensity computations, 238
numerical solution strategy, 238
Near-band-gap emission, carrier lifetime measurement, photoluminescence (PL), 450
Near-edge x-ray absorption fine structure (NEXAFS) spectroscopy. *See also* X-ray absorption near-edge structure (XANES) spectroscopy
micro-XAFS, 943
ultraviolet photoelectron spectroscopy (UPS) and, 726
Near-field regime, scanning tunneling microscopy (STM), 1112–1113
Near-field scanning optical microscopy (NSOM)
magnetic domain structure measurements, 548–549
pn junction characterization, 467
Near-surface effects
magnetic x-ray scattering errors, 936
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE) and, 1202
Necking phenomenon
nonuniform plastic deformation, 282
stress-strain analysis, 280–281
Neel temperature, antiferromagnetism, 524
Nernst equation
cyclic voltammetry
quasireversible reaction, 583
totally reversible reaction, 582–583
semiconductor-liquid interface, photoelectrochemistry, thermodynamics, 605–606
Nernst-Ettingshausen effect, magnetotransport in metal alloys, transport equations, 561
Net magnetization, nuclear magnetic resonance, 765
Neutron activation-accelerator mass spectrometry, trace element accelerator mass spectrometry (TEAMS) and, 1237
Neutron activation analysis (NAA)
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE) and, 1201–1202
trace element accelerator mass spectrometry (TEAMS) and, 1237
Neutron diffuse scattering
applications, 889–894
automation, 897–898
bond distances, 885
chemical order, 884–885
comparisons, 884
competitive and related techniques, 883–884
crystalling solid solutions, 885–889
data analysis and interpretation, 894–896
diffuse x-ray scattering techniques, 889–890
inelastic scattering background removal, 890–893
limitations, 898–899
magnetic diffuse scattering, 904–905
magnetic x-ray scattering, comparisons, 918–919
measured intensity calibration, 894
protocols and procedures, 884–889
recovered static displacements, 896–897
research background, 882–884
resonant scattering terms, 893–894
sample preparation, 898
Neutron powder diffraction
angle-dispersive constant-wavelength diffractometer, 1289–1290
constant wavelength diffractometer wavelength, 1304–1305
constraints, 1301
crystallographic refinements, 1300–1301
data analysis, 1291–1300
ab initio structure determination, 1297–1298
axial divergence and peak asymmetry, 1292–1293
Bragg reflection positions, 1291–1292
indexing techniques, 1297–1298
particle structure determination, 1297
peak shape, 1292
quantitative phase analysis, 1296–1297
structure factor extraction, 1298
structure solution, 1298
estimated standard deviations, 1305–1306
limitations, 1300–1302
mesoscopic properties, 1293–1296
microstrain broadening, 1294–1295
particle size effect, 1293–1294
stacking faults, 1295–1296
probe characteristics, 1286–1289
reliability factors, 1305
research background, 1285–1286
restraints, 1301–1302
Rietveld analysis
protocols, 1296
software programs, 1306–1307
sample preparation, 1291
single-crystal neutron diffraction and, 1307–1309
single-crystal x-ray structure determination, 850–851
time-dependent neutron powder diffraction, 1298–1300
time-of-flight diffractometers, 1290–1291
x-ray diffraction *vs.*, 836
Neutron sources, single-crystal neutron diffraction, 1312–1313
Neutron techniques
magnetic neutron scattering
automation, 1336
data analysis, 1337
diffraction applications, 1332–1335
inelastic scattering
basic principles, 1331
protocols for, 1335–1336
limitations, 1337–1338
magnetic diffraction, 1329–1330
polarized beam technique, 1330–1331
research background, 1328–1329
sample preparation, 1336–1337
subtraction techniques, 1330
neutron powder diffraction
angle-dispersive constant-wavelength diffractometer, 1289–1290
constant wavelength diffractometer wavelength, 1304–1305
constraints, 1301
crystallographic refinements, 1300–1301
data analysis, 1291–1300
ab initio structure determination, 1297–1298
axial divergence and peak asymmetry, 1292–1293
Bragg reflection positions, 1291–1292
indexing techniques, 1297–1298
particle structure determination, 1297
peak shape, 1292
quantitative phase analysis, 1296–1297
structure factor extraction, 1298
structure solution, 1298
estimated standard deviations, 1305–1306

limitations, 1300–1302
mesoscopic properties, 1293–1296
microstrain broadening, 1294–1295
particle size effect, 1293–1294
stacking faults, 1295–1296
probe characteristics, 1286–1289
reliability factors, 1305
research background, 1285–1286
restraints, 1301–1302
Rietveld analysis
protocols, 1296
software programs, 1306–1307

triple-axis spectrometry, 1320–1323
limitations, 1326–1327
research background, 1316–1317
sample preparation, 1325–1326
specimen modification, 1326
research background, 1285
single-crystal neutron diffraction
applications, 1311–1312
data analysis and interpretation, 1313–1314
neutron sources and instrumentation, 1312–1313
research background, 1307–1309
sample preparation, 1314–1315
theoretical background, 1309–1311
Newton-Raphson algorithm, diffuse intensities, metal alloys, mean-field theory and, 263
Newton's equations, molecular dynamics (MD) simulation, surface phenomena, 159
Newton's law of cooling, combustion calorimetry, 379
Nickel-iron alloys, atomic short range order (ASRO), energetics and electronic origins, 193–196
Nickel-platinum alloys
diffuse intensities, hybriziation in NiPt alloys, charge correlation effects, 266–268
magnetism
first-principles calculations, 189
paramagnetism, 189
magnetocrystalline anisotropy energy (MAE), 193
phase diagram predictions, cluster variational method (CVM), 107–108
Nonconfigurational thermal effects, phase diagram prediction, 106–107
Nonconsumable abrasive wheel cutting, metallographic analysis, sample preparation, 65
Non-contact measurements
basic principles, 407
protocols and procedures, 407–408
Nonevaporable getter pumps (NEGs), applications, operating principles, 12
Nonlinearity, fracture toughness testing
load-displacement curves, 303–304
stable crack mechanics, 309–311
Nonlinear least-squares analysis, thermal diffusivity, laser flash technique, 389
Nonlinear optical effects, cyclotron resonance (CR), far-infrared (FIR) radiation sources, 809
Nonohmic contacts, Hall effect, semiconductor materials, 417
Nonrelativistic collisions, particle scattering conversions, 62–63
fundamental and recoiling relations, 62
Nonresonant depth-profiling, nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE) and
basic principles, 1202
data analysis, 1206
Nonresonant magnetic x-ray scattering
antiferromagnets, 928–930
ferromagnets, 930
research background, 918–919
theoretical concepts, 920–921
Nonreversible charge-transfer reaactions, cyclic voltammetry, 583–584
Non-Rutherford cross-sections, ion-beam analysis (IBA)
ERD/RBS techniques, 1191–1197
error detection, 1189–1190
Non-specular scattering, liquid surface x-ray diffraction
GID, diffuse scattering, and rod scans, 1038–1039
measurement protocols, 1033–1036
Nonuniform detection efficiency, energy-dispersive spectrometry (EDS), 1139–1140
Nonuniform laser beam, thermal diffusivity, laser flash technique, 390
Nonuniform plastic deformation, stress-strain analysis, 282
Nordsieck's algorithm, molecular dynamics (MD) simulation, surface phenomena, 159
Normalization procedures, x-ray absorption fine structure (XAFS) spectroscopy, 878–879
Notch filter
microbeam analysis, 948
Raman spectroscopy of solids, optics properties, 705–706
Notch-toughness testing
research background, 302
sample preparation, 312
n-type metal-oxide semiconductor (NMOS), ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1229–1230
Nuclear couplings, nuclear quadrupole resonance (NQR), 776–777
Nuclear excitation, Mössbauer spectroscopy, 817–818
Nuclear magnetic resonance (NMR)
applications, 767–771
back-projection imaging sequence, 768
basic principles, 762–763
chemical shift imaging sequence, 770
data analysis and interpretation, 771
diffusion imaging sequence, 769
echo-planar imaging sequence, 768–769
flow imaging sequence, 769–770
gradient recalled echo sequence, 768
instrumentation setup and tuning, 770–771
limitations, 772
magnetic field effects, 496
measurement principles, 509–510
magnetic neutron scattering and, 1321
sample preparation, 772
single-crystal neutron diffraction and, 1309
solid-state imaging, 770
spin-echo sequence, 768
superconducting magnets, 500–502
theoretical background, 763–765
three-dimensional imaging, 770
Nuclear moments, nuclear quadrupole resonance (NQR), 775–776
Nuclear quadrupole resonance (NQR)
data analysis and interpretation, 789
direct detection techniques, spectrometer criteria, 780–781
dynamics limitations, 790
first-order Zeeman perturbation and line shapes, 779
heterogeneous broadening, 790
indirect detection, field cycling methods, 781
nuclear couplings, 776–777
nuclear magnetic resonance (NMR), comparisons, 761–762
nuclear moments, 775–776
one-dimensional Fourier transform NQR, 781–782
research background, 775
sensitivity problems, 789
spatially resolved NQR, 785–789
field cycling methods, 788–789
magnetic field gradient method, 785–786

light sources, 728–729
limitations, 733
photoemission process, 726–727
photoemission *vs.* inverse photoemission, 722–723
physical relations, 730
sample preparation, 732–733
sensitivity limits, 730–731
surface states, 727
valence electron characterization, 723–724
ultraviolet/visible absorption (UV-VIS) spectroscopy
applications, 692
array detector spectrometer, 693
automation, 693
common components, 692
competitive and related techniques, 690
dual-beam spectrometer, 692–693
limitations, 696
materials characterization, 691–692, 694–695
materials properties, 689
qualitative/quantitative analysis, 689–690
quantitative analysis, 690–691, 693–694
research background, 688–689
sample preparation, 693, 695
single-beam spectrometer, 692
specimen modification, 695–696
Optically-detected resonance (ODR) spectroscopy, cyclotron resonance (CR), 812–813
Optical microscopy
adjustment protocols, 671–674
basic components, 668–671
reflected-light optical microscopy
illumination modes and image-enhancement techniques, 676–680
limitations, 680–681
procedures and protocols, 675–680
research background, 674–675
sample preparation, 680
research background, 667–668
Optical parametric oscillation (OPO), cyclotron resonance (CR), far-infrared (FIR) radiation sources, 809
Optical properties
ellipsometric measurement, 740–741
local density approximation (LDA), 83–84
scanning electron microscopy (SEM), 1054
quality control, 1059–1060
x-ray magnetic circular dichroism (XMCD), 959–962
x-ray microprobes, 945–947
Optical pyrometry
ITS-90 standard, 33
operating principles, 37
Optical reciprocity theorem, grazing-incidence diffraction (GID), distorted-wave Born approximation (DWBA), 244–245

Optical techniques, carrier lifetime measurement, 434
Optics properties, Raman spectroscopy of solids, 705–706
Optimization protocols, energy-dispersive spectrometry (EDS), 1140–1141
Orbital angular momentum number, metal alloy bonding, wave function variation, 138
Orbital effects
  metal alloy bonding, accuracy calculations, 140–141
  x-ray magnetic circular dichroism (XMCD), 953–955
Orientation matrices, surface x-ray diffraction
  crystallographic alignment, 1014–1015
  protocols, 1026
O-ring seals
  configuration, 17–18
  elastomer materials for, 17
  rotational/translation motion feedthroughs, 18–19
Ornstein-Zernicke equation
  diffuse intensities, metal alloys, concentration waves, density-functional theory (DFT), 261–262
  metal alloy magnetism, atomic short range order (ASRO), 190–191
ORTEP program, single-crystal x-ray structure determination, 861–864
Outgassing
  Auger electron spectroscopy (AES), sample preparation, 1170
  hot cathode ionization gauges, 15
  vacuum system principles, 2–3
    pumpdown procedures, 19
  x-ray photoelectron spectroscopy (XPS), sample preparation, 998–999
Overcorrelation, diffuse intensities, metal alloys, mean-field results, 262
Overpotentials, semiconductor materials, J-E behavior, 611–612
  series resistance, 612
Oxidative mechanisms, tribological and wear testing, 324–325
Oxides, scanning tunneling microscopy (STM) analysis, 1115
Oxygen purity, combustion calorimetry, 377–378
  error detection and, 381–382

Pair correlations
  diffuse intensities, metal alloys
    atomic short-range ordering (ASRO) principles, 256–257
    basic definitions, 252–254
  diffuse scattering techniques, 888–889
Palladium tips, scanning tunneling microscopy (STM), 1114
Parabolic rate law, corrosion quantification, electrochemical impedance spectroscopy (EIS), 600–603
Parallel frequencies, electrochemical quartz crystal microbalance (EQCM), 660
Parallel geometry, carrier lifetime measurement, free carrier absorption (FCA), 439440
Paramagnetism
  classical and quantum theories, 519–522
  electron paramagnetic resonance (EPR), theoretical background, 793
  metal alloys, finite temperatures, 186–187
  nuclear magnetic resonance data analysis, 771–772
  principles of, 511–512
  spin glass materials, cluster magnetism of, 516–517
  theory and principles, 493–494
Parratt formalism, liquid surface x-ray diffraction, reflectivity measurements, 1031
Partial differential equations (PDEs), front-tracking simulation, microstructural evolution, 113–114
Partial pressure analyzer (PPA), applications, 16
Particle accelerator
  ion beam analysis (IBA), 1176
  nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), 1203–1204
Particle detection, medium-energy backscattering, 1260–1261
Particle erosion, wear testing and, 329–330
Particle filtering, nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), 1204
Particle-induced x-ray emission (PIXE)
  automation, 1216
  basic principles, 1211–1212
  competing methods, 1210–1211
  data analysis, 1216–1218
  limitations, 1220
  protocols and techniques, 1213–1216
  research background, 1179, 1210–1211
  sample preparation, 1218–1219
  specimen modification, 1219–1220
Particle scattering
  central-field theory, 57–61
    cross-sections, 60–61
    deflection functions, 58–61
      approximation, 59–60
      central potentials, 59
      hard spheres, 58–59
    impact parameter, 57–58
    interaction potentials, 57
    materials analysis, 61
    shadow cones, 58
  kinematics, 51–57
    binary collisions, 51
    center-of-mass and relative coordinates, 54–55
    elastic scattering and recoiling, 51–52
    inelastic scattering and recoiling, 52
    nuclear reactions, 56–57
    relativistic collisions, 55–56
    scattering/recoiling diagrams, 52–54
  nonrelativistic collisions
    conversions, 62–63
    fundamental and recoiling relations, 62
  research background, 51
Particle size distribution
  Mössbauer spectroscopy, 830–831
  neutron powder diffraction, 1293–1294
  small-angle scattering (SAS), 222
  thermogravimetric (TG) analysis, 357
Particle structure determination, neutron powder diffraction, 1297
Passive film deposition, corrosion quantification, Tafel technique, 596
Patterson mapping
  neutron powder diffraction
    stacking faults, 1296
    structure factor relationships, 1298
  single-crystal x-ray structure determination, 858–859
    heavy-atom computation, 868–869
  x-ray powder diffraction, candidate atom position search, 840–841
Pauli exclusion principle, metal alloy magnetism, 180
Pauli paramagnetism
  band theory of magnetism, 516
  defined, 493–494
  local moment origins, 513–515
Paul Scherrer Institute (PSI)/ETH Zurich Accelerator SIMS Laboratory, trace element accelerator mass spectrometry (TEAMS) research at, 1242–1244
PBE functionals, local density approximation (LDA), gradient corrections, 78
Peak current measurement, cyclic voltammetry, 587
Peak height measurments
  Auger electron spectroscopy (AES), 1169
  ion-beam analysis (IBA), 1183–1184
Peak identification
  Auger electron spectroscopy (AES), 1162
    ion excitation, 1171–1173
  energy-dispersive spectrometry (EDS), deconvolution protocols, 1144–1145
  x-ray photoelectron spectroscopy (XPS), 991–992
    reference spectra, 996–998
PEAK integration software, surface x-ray diffraction, data analysis, 1024–1025
Peak position, x-ray photoelectron spectroscopy (XPS), 992
Peak shape, neutron powder diffraction, mesoscopic properties, 1293–1296
  microstrain broadening, 1294–1295
  particle size effect, 1293–1294
  stacking faults, 1295–1296
Peak shapes
  neutron powder diffraction, 1292
    axial divergence asymmetry, 1292–1293
    instrumental contributions, 1292
  x-ray photoelectron spectroscopy (XPS), classification, 1004–1007
Peltier heat, magnetotransport in metal alloys
  basic principles, 560
  transport equations, 561
Pendellösung period, two-beam diffraction, 231
  diffracted intensities, 234
Pendry's *R* factor, low-energy electron diffraction (LEED), quantitative analysis, 1130–1131
Penetration depth, x-ray microfluorescence, 943–944
Penning ionization gauge (PIG), operating principles, 16
Periodic boundary conditions, molecular dynamics (MD) simulation, surface phenomena, 158–159
  limitations from, 164
Periodic heat flow, thermal diffusivity, laser flash technique, 383–384
Periodic table, ion beam analysis (IBA), 1177–1178
Permanent magnets
  applications, 496
  structures and properties, 497–499
Permittivity parameters
  microwave measurement techniques, 409
    cavity resonators, 409–410
    coaxial probes, 409
  surface x-ray diffraction, defined, 1028–1029
Perpendicular geometry, carrier lifetime measurement, free carrier absorption (FCA), 439–440
Phase-contrast imaging
  reflected-light optical microscopy, 679–680
  scanning transmission electron microscopy (STEM)
    coherence analysis, 1093–1097
    dynamical diffraction, 1101–1103
    research background, 1092
Phase diagrams, predictions
  aluminum-lithium analysis, 108–110
  aluminum-nickel analysis, 107
  basic principles, 91
  cluster approach, 91–92, 96–99
  cluster expansion free energy, 99–101
  electronic structure calculations, 101–102

Phase diagrams, predictions (*Continued*)
ground-state analysis, 102–104
mean-field approach, 92–96
nickel-platinum analysis, 107–108
nonconfigurational thermal effects, 106–107
research background, 90–91
static displacive interactions, 104–106
Phase equilibrium, basic principles, 91–92
Phase field method. *See also* Continuum field method (CFM)
Phase formation
metal alloy bonding, 135–138
bonding-antibonding effects, 136–137
charge transfer and electronegativities, 137–138
Friedel's *d*-band energetics, 135
size effects, 137
topologically close-packed phases, 135–136
transition metal crystal structures, 135
wave function character, 138
multiple-beam diffraction, 240
Phase retarders, x-ray magnetic circular dichroism (XMCD), 958–959
Phase shifts
low-energy electron diffraction (LEED), 1125
Mössbauer spectroscopy, 827–828
Raman spectroscopy of solids, 711–712
scanning transmission electron microscopy (STEM), research background, 1092
x-ray absorption fine structure (XAFS) spectroscopy, single scattering picture, 871–872
Phenomenological models, phonon analysis, 1324–1325
PHOENICS-CVD, chemical vapor deposition (CVD) model, hydrodynamics, 174
Phonons
magnetotransport in metal alloys, 562–563
Mössbauer spectroscopy, 824
neutron analysis
automation, 1323
basic principles, 1317–1318
data analysis, 1324–1325
instrumentation and applications, 1318–1323
triple-axis spectrometry, 1320–1323
limitations, 1326–1327
research background, 1316–1317
sample preparation, 1325–1326
specimen modification, 1326
photoluminescence (PL) spectroscopy, replicas, 682–683
spectral densities, metal surfaces, molecular dynamics (MD) simulation, 161–162
thermal diffuse scattering (TDS), 212–214
Photoabsorption, x-ray microfluorescence
basic principles, 942
cross-sections, 943
Photoconductivity (PC)
carrier lifetime measurement, 444–450
basic principles, 444
data analysis, 446–447
high-frequency range, automation, 445–446
limitations, 449–450
microwave PC decay, 447–449
optical techniques, 434
radio frequency PC decay, 449
research background, 428
sample preparation, 447
standard PC decay method, 444–445
steady-state methods, 435–438
cyclotron resonance (CR), 812
Photocurrent density-potential behavior, semiconductor-liquid junctions, 609
Photocurrent/photovoltage measurements, semiconductor materials, 605–613
charge transfer at equilibrium, 606–607
electrochemical cell design, 609–610
J-E equations, 608–609
concentration overpotentials, 611–612
series resistance overpotentials, 612
raw current-potential data, 611
sample preparation, 612–613
semiconductor-liquid interface, 610–611
current density-potential properties, 607–608
dark current-potential characteristics, 607
thermodynamics, 605–606
Photodiode array (PDA), Raman spectroscopy of solids, dispersed radiation measurment, 707–708
Photoelectrochemistry, semiconductor materials
electrochemical photocapacitance spectroscopy, 623–626
photocurrent/photovoltage measurements, 605–613
charge transfer at equilibrium, 606–607
electrochemical cell design, 609–610
J-E equations, 608–609
concentration overpotentials, 611–612
series resistance overpotentials, 612
raw current-potential data, 611
sample preparation, 612–613
semiconductor-liquid interface, 610–611
current density-potential properties, 607–608
dark current-potential characteristics, 607
junction thermodynamics, 605–606
research background, 605
semiconductor-liquid interface
band gap measurement, 613–614
differential capacitance measurements, 616–619
diffusion length, 614–616
flat-band potential measurements, 628–630
J-E data, kinetic analysis, 631–632
laser spot scanning, 626–628
photocurrent/photovoltage measurements, 610–611
current density-potential properties, 607–608
dark current-potential characteristics, 607
junction thermodynamics, 605–606
transient decay dynamics, 619–622
surface recombiation velocity, time-resolved microwave conductivity, 622–623
time-resolved photoluminescence spectroscopy, interfacial charge transfer kinetics, 630–631
Photoelectromagnetic (PEM) effect, carrier lifetime measurement, steady-state methods, 436
Photoelectron detectors, x-ray photoelectron spectroscopy (XPS), 982–983
Photoemission
angle-resolved x-ray photoelectron spectroscopy (ARXPS), 987–988
metal alloy magnetism, local exchange splitting, 189–190
ultraviolet photoelectron spectroscopy (UPS)
automation, 731–732
vs. inverse photoemission, 722–723
limitations, 733
process, 726–727
valence electron characterization, 723–724
x-ray photoelectron spectroscopy (XPS), 971–972
survey spectrum, 973–974
Photoluminescence (PL) spectroscopy
alloy broadening, 682
automation, 686
band-to-band recombination, 684
bound excitons, 682
carrier lifetime measurement, 450–453
automated procedures, 451–452
data analysis and interpretation, 452–453
deep level luminescence, 450–451
limitations, 453
near-band-gap emission, 450
photon recycling, 451
research background, 428
shallow impurity emission, 450
steady-state methods, 436
defect-level transitions, 683–684
donor-acceptor and free-to-bound transitions, 683
excitons and exciton-polaritons, 682
experimental protocols, 684–865
limitations, 686
low-temperature PL spectra
band interpretation, 686–687
crystal characterization, 685–686
phonon replicas, 682–683
research background, 681–682
room-temperature PL plating, 686
curve-fitting, 686
sample preparation, 686
specimen modification, 686
Photometric ellipsometry, defined, 735
Photomultiplier tubes (PMTs)
magnetic x-ray scattering, detector criteria, 927–928
photoluminescence (PL) spectroscopy, 684
Raman spectroscopy of solids, dispersed radiation measurment, 707–708
semiconductor-liquid interfaces, transient decay dynamics, 621–622
Photon energy
energy-dispersive spectrometry (EDS), 1136, 1137–1140
ultraviolet photoelectron spectroscopy (UPS), 728–729
light sources, 728–729
wavelength parameters, 730
Photon recycling, carrier lifetime measurement, photoluminescence (PL), 451
Physical quantities, carrier lifetime measurement, 433
Pick-up loops, superconductors, electrical transport measurements, signal-to-noise ratio, 483–484
Piezo-birefringent elements, polarization-modulation ellipsometer, 739
Piezoelectric behavior, electrochemical quartz crystal microbalance (EQCM), 653–654
Pirani gauge, applications and operation, 14
Placement effects, Hall effect, semiconductor materials, 417
Planar devices
magnetic x-ray scattering, beamline properties, 927
x-ray magnetic circular dichroism (XMCD), 958–959
Planck's constant
chemical vapor deposition (CVD) model, gas-phase chemistry, 169
deep level transient spectroscopy (DLTS), semiconductor materials, 421
neutron powder diffraction, probe configuration, 1286–1289
phonon analysis, 1318
radiation thermometer, 36–37
Plane wave approach
electronic structure analysis, 76
phase diagram prediction, 101–102
metal alloy bonding, precision calculations, 142–143
Plasma physics
chemical vapor deposition (CVD) model
basic components, 170

software tools, 174
ion beam analysis (IBA), ERD/RBS techniques, 1184–1186
Plasmon loss
Auger electron spectroscopy (AES), error detection, 1171

standards, 1205
unwanted particle filtering, 1204
Proton scattering, ion-beam analysis (IBA), ERD/RBS examples, 1195–1197
Pseudo free induction decay, rotating frame NQR imaging, 786–788
Pseudopotential approach
electronic structure analysis, 75
metal alloy bonding
precision measurements, self-consistency, 141–142
semiconductor compounds, 138
phonon analysis, 1324–1325
Pulsed Fourier transform NMR
basic principles, 765
electron paramagnetic resonance (EPR), 796
Pulsed magnetic fields, laboratory settings, 505
Pulsed MOS capacitance technique
carrier lifetime measurement, 431, 435
Pulsed step measurements, superconductors, electrical transport measurements, current ramp rate, 479
Pulsed-type measurement techniques, carrier lifetime measurement, 436–438
Pulse height measurements, ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1225–1226
Pulse laser
impulsive stimulated thermal scattering (ISTS), 750–752
thermal diffusivity, laser flash technique, 385–386
Pulse magnets
cyclotron resonance (CR), laser magneto-spectroscopy (LMS), 811–812
structure and properties, 504–505
Pulse nclear magnetic resonance (NMR), magnetic field measurements, 510
Pump beam photons, carrier lifetime measurement, free carrier absorption (FCA), 439
Pumpdown procedures, vacuum systems, 19
Pumping speed
sputter-ion pump, 11
vacuum system principles, outgassing, 2–3
Pump lasers, carrier lifetime measurement, free carrier absorption (FCA), selection criteria, 440
Purity of materials, differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 367–368
Quadrupolar moments
Mössbauer spectroscopy, electric quadrupole splitting, 822–823
nuclear quadrupole resonance (NQR), 776
resonant magnetic x-ray scattering, 922–924
Quadrupole mass filter, applications and operating principles, 17
Qualitative analysis
Auger electron spectroscopy (AES), 1161–1162
energy-dispersive spectrometry (EDS), 1141–1143
low-energy electron diffraction (LEED)
basic principles, 1122–1124
data analysis, 1127–1128
mass measurement process assurance, 28–29
ultraviolet/visible absorption (UV-VIS) spectroscopy, comptetitive and related techniques, 689–690
Quantitative analysis
Auger electron spectroscopy (AES), 1169
differential thermal analysis, defined, 363
energy-dispersive spectrometry (EDS), 1143
standardless analysis, 1147–1148
accuracy testing, 1150
applications, 1151
first-principles standardless analysis, 1148–1149
fitted-standards standardless analysis, 1149–1150
ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, pulse height interpretation, 1225–1226
low-energy electron diffraction (LEED)
basic principles, 1124–1125
data analysis, 1128–1131
medium-energy backscattering, 1271–1272
neutron powder diffraction, 1296–1297
Raman spectroscopy of solids, 713
ultraviolet/visible absorption (UV-VIS) spectroscopy
comptetitive and related techniques, 689–690
interpretation, 693–694
procedures and protocols, 690–691
x-ray powder diffraction, phase analysis, 842, 844–845
Quantum mechanics
cyclotron resonance (CR), 808
low-energy electron diffraction (LEED), quantitative analysis, 1129–1131
resonant scattering analysis, 908–909
surface magneto-optic Kerr effect (SMOKE), 571
Quantum Monte Carlo (QMC), electronic structure analysis, 75
basic principles, 87–89
Quantum paramagnetiic response, principles and equations, 521–522
Quarter wave plates, magnetic x-ray scattering, beamline properties, 927
Quartz crystal microbalance (QCM)
basic principles, 24
electrochemical analysis
automation, 659–660
basic principles, 653–658
data analysis and interpretation, 660
equivalent circuit, 654–655
film and solution effects, 657–658
impedance analysis, 655–657
instrumentation criteria, 648–659
limitations, 661
quartz crystal properties, 659
research background, 653
sample preparation, 660–661
series and parallel frequency, 660
specimen modification, 661
Quasi-Fermi levels, carrier lifetime measurement, trapping, 431–432
Quasireversible reaction, cyclic voltammetry, 583
Quasi-steady-state-type measurement technique, carrier lifetime measurement, 436–437
Quench detection
electrical transport measurements, superconductors, 480–481
superconducting magnets, 501
Q values
heavy-ion backscattering spectrometry (HIBS), 1275–1276
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE), cross-sections and, 1205
nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), particle filtering, 1204

Radiation effects microscopy
basic principles, 1224–1228
instrumentation criteria, 1128–1230
ion-induced damage, 1232–1233
limitations, 1233
quantitative analysis, pulse height interpretations, 1225–1226
research background, 1223–1224
semiconductor materials, 1225
SEU microscopy, 1227–1228
static random-access memory (SRAM), 1230–1231
specimen modification, 1231–1232
topographical contrast, 1226–1227
Radiation sources
chemical vapor deposition (CVD) model
basic components, 172–173
software tools, 175
energy-dispersive spectrometry (EDS), stray radiation, 1155
ion-beam analysis (IBA), hazardous exposure, 1190
liquid surface x-ray diffraction, damage from, 1044–1045
Raman spectroscopy of solids, 704–705
x-ray microfluorescence, 942–943
Radiation thermometer, operating principles, 36–37
Radiative process, carrier lifetime measurement, 430
Radiofrequency (RF)
magnetic resonance imaging (MRI), 765–767
nuclear quadrupole resonance (NQR), research background, 775
PC-decay, carrier lifetime measurement
optical techniques, 434
principles and procedures, 449
Radiofrequency (RF) quadrupole analyzer, secondary ion mass spectrometry (SIMS) and, 1236–1237
Radioisotope sources, Mössbauer spectroscopy, 825–826
Radiolysis, transmission electron microscopy (TEM), polymer specimen modification, 1088
Radius of gyration, small-angle scattering (SAS), 221
Raman active vibrational modes
aluminum crystals, 709–710
solids, 720–721
Raman spectroscopy of solids
competitive and related techniques, 699
data analysis and interpretation, 709–713
active vibrational modes, aluminum compounds, 709–710
carbon structure, 712–713
crystal structures, 710–712
dispersed radiation measurement, 707–708
electromagnetic radiation, classical physics, 699–701

Fourier transform Raman spectroscopy, 708–709
group theoretical analysis, vibrational Raman spectroscopy, 702–704
character tables, 718
point groups and matrix representation, symmetry operations, 717–718
vibrational modes of solids, 720–722
vibrational selection rules, 716–720
light scattering, semiclassical physics, 701–702
limitations, 713–714
magnetic neutron scattering and, 1321
optical alignment, 706
optics, 705–706
polarization, 708
quantitative analysis, 713
radiation sources, 704–705
research background, 698–699
spectrometer components, 706–707
theoretical principles, 699–700
Random noise, superconductors, electrical transport measurements, signal-to-noise ratio, 485
Random-phase approximation (RPA), electronic structure analysis, 84–87
Rapid-scan FT spectrometry, cyclotron resonance (CR), 810
Rare earth ions, atomic/ionic magnetism, ground-state multiplets, 514–515
Ratio thermometer, operating principles, 37
Rayleigh scattering
impulsive stimulated thermal scattering (ISTS) analysis, 754–755
Raman spectroscopy of solids, optics properties, 705–706
scanning transmission electron microscopy (STEM)
incoherent scattering, 1099–1101
phase-contrast illumination, 1094–1097
transmission electron microscopy (TEM), aperture diffraction, 1078
R-curve behavior, fracture toughness testing, 302
crack driving force *(G),* 305
sample preparation, 311–312
Reaction onset temperatures, differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 368–369
Reaction rate mode, scanning electrochemical microscopy (SECM), 640–641
Reaction reversibility. *See* Reversible reactions
Reactive gases
cryopump, 9–10
turbomolecular pumps, bearing failure and, 8
"Reactive sticking coefficient" concept, chemical vapor deposition (CVD) model, surface chemistry, 168
Readout interpretation
magnetic resonance imaging (MRI), readout gradient, 768
thermometry, 35
Rear-face temperature rise, thermal diffusivity, laser flash technique, 384–385

phonon analysis, basic principles, 1317–1318
surface x-ray scattering, mapping protocols, 1016
transmission electron microscopy (TEM)
deviation vector and parameter, 1067–1068
diffraction pattern indexing, 1073–1074
tilting specimens and electron beams, 1071
x-ray diffraction, crystal structure, 209
Recoil-free fraction, Mössbauer spectroscopy, 821
Recoiling, particle scattering
diagrams, 52–54
elastic recoiling, 51–52
inelastic recoiling, 52
nonrelativistic collisions, 62
Recombination mechanisms
carrier lifetime measurement, 429–431
limitations, 438
photoluminescence (PL), 452–453
surface recombination and diffusion, 432–433
photoluminescence (PL) spectroscopy, band-to-band recombination, 684
pn junction characterization, 468–469
Rectangular resonator, electron paramagnetic resonance (EPR), continuous-wave (CW) experiments, 794–795
Redhead Extractor gauge, operating principles, 14–15
Redox potentials, semiconductor-liquid interface, current density-potential properties, 607–608
Reduced mass, particle scattering, kinematics, 54
Reference electrodes, semiconductor electrochemical cell design, photocurrent/photovoltage measurements, 610
Reference materials, tribological testing, 333
Refinement algorithms, neutron powder diffraction, 1300–1301
Reflected-light optical microscopy
basic principles, 667
illumination modes and image-enhancement techniques, 676–680
limitations, 680–681
procedures and protocols, 675–680
research background, 674–675
sample preparation, 680
Reflection high-energy electron diffraction (RHEED)
low-energy electron diffraction (LEED), comparisons, 1121
surface magneto-optic Kerr effect (SMOKE), 573–574
surface x-ray diffraction and, 1007–1008
ultraviolet photoelectron spectroscopy (UPS), sample preparation, 732–733
Reflection polarimetry. *See* Ellipsometry
Reflectivity
ellipsometry, 735–737
defined, 737
liquid surface x-ray diffraction, 1029–1036
Born approximation, 1033–1034
distorted-wave Born approximation, 1034–1036
error sources, 1044–1045
Fresnel reflectivity, 1029–1031
grazing incidence diffraction and rod scans, 1036
instrumentation, 1036–1038
multiple stepwise and continuous interfaces, 1031–1033
non-specular scattering, 1033–1036
simple liquids, 1040–1041
surface x-ray diffraction, 1015–1016
Refractive lenses, x-ray microprobes, 946
REITAN program, neutron powder diffraction, Rietveld refinements, 1306
Relative amplitude
ellipsometric measurement
angle of incidence errors, 742
basic principles, 735
optical properties, 740–741
polarizer/analyzer readings, 739–740
ellipsometry, reflecting surfaces, 736–737
Relative coordinates, particle scattering, kinematics, 54–55
Relative energy, particle scattering, kinematics, 54
Relative phase, ellipsometric measurement
angle of incidence errors, 742
basic principles, 735
optical properties, 740–741
polarizer/analyzer readings, 739–740
reflecting surfaces, 736–737
Relative sensitivity factors (RSFs), secondary ion mass spectrometry (SIMS) and, 1236–1237
Relativistic collisions, particle scattering, kinematics, 55–56
Relaxation measurements
Mössbauer spectroscopy, 824
non-contact techniques, 408
x-ray photoelectron spectroscopy (XPS), final-state effects, 975–976
Relaxation time approximation (RTA), semiconductor materials, Hall effect, 412
interpretation, 416
Reliability factors
low-energy electron diffraction (LEED), quantitative analysis, 1130–1131
neutron powder diffraction, 1305
Renninger peaks, multiple-beam diffraction, 236–237
Renormalized forward scattering (RFS), low-energy electron diffraction (LEED), 1135
Repeated-cycle deformation, tribological and wear testing, 324–325
Replication process, transmission electron microscopy (TEM), sample preparation, 1087
Residual gas analyzer (RGA), applications, 16
Resistive magnets, structure and properties, 502–504
hybrid magnets, 503–504
power-field relations, 502–503
Resistivity. *See* Conductivity measurements; Electrical resistivity

Snell's law
dynamical diffraction, boundary conditions, 229
ellipsometry, reflecting surfaces, 736–737
liquid surface x-ray diffraction, reflectivity measurements, 1029–1031
two-beam diffraction, dispersion surface, 230–231
Software tools
chemical vapor deposition (CVD) models
free molecular transport, 174
gas-phase chemistry, 173
hydrodynamics, 174
kinetic theory, 175
limitations of, 175–176
plasma physics, 174
radiation, 175
surface chemistry, 173
diffuse scattering techniques, 898–899
electrical transport measurements, superconductors, 480–481
electron paramagnetic resonance (EPR), 798
Mössbauer spectroscopy, 831–832
neutron powder diffraction
axial divergence peak asymmetry, 1293
indexing procedures, 1298
Rietveld refinements, 1306–1307
particle-induced x-ray emission (PIXE) analysis, 1217–1218
phonon analysis, triple-axis spectrometry, 1320–1323
scanning electrochemical microscopy (SECM), 642–643
single-crystal x-ray structure determination, 858–860
superconductors, electrical transport measurement, data analysis, 482
surface x-ray diffraction
crystal truncation rod (CTR) profiles, 1015
data analysis, 1024–1025
lineshape analysis, 1019
Solenoids, electromagnet structure and properties, 499–500
Solids analysis
Raman spectroscopy
competitive and related techniques, 699
data analysis and interpretation, 709–713
active vibrational modes, aluminum compounds, 709–710
carbon structure, 712–713
crystal structures, 710–712
dispersed radiation measurement, 707–708
electromagnetic radiation, classical physics, 699–701
Fourier transform Raman spectroscopy, 708–709

group theoretical analysis, vibrational Raman spectroscopy, 702–704
character tables, 718
point groups and matrix representation, symmetry operations, 717–718
vibrational modes of solids, 720–722
vibrational selection rules, 716–720
light scattering, semiclassical physics, 701–702
limitations, 713–714
optical alignment, 706
optics, 705–706
polarization, 708
quantitative analysis, 713
radiation sources, 704–705
research background, 698–699
spectrometer components, 706–707
theoretical principles, 699–700
ultraviolet photoelectron spectroscopy (UPS), energy band dispersion, 727
x-ray photoelectron spectroscopy (XPS), research background, 970–972
Solid-solid reactions, thermogravimetric (TG) analysis, 356
Solid-solution alloys, magnetism, 183–184
Solid-state detectors, fluorescence analysis, 944
Solid-state imaging
nuclear magnetic resonance, 770
single-crystal x-ray structure determination, 851
Solution resistance
corrosion quantification, Tafel technique, 596
electrochemical quartz crystal microbalance (EQCM), 657–658
Soret effect, chemical vapor deposition (CVD) model, hydrodynamics, 171
Sorption pump, application and operation, 5
Source-to-specimen distance, x-ray diffraction, 206
Space groups
crystallography, 46–50
single-crystal x-ray structure determination, crystal symmetry, 855–856
x-ray powder diffraction, crystal lattice determination, 840
Spatially resolved nuclear quadruople resonance
basic principles, 785–789
field cycling methods, 788–789
magnetic field gradient method, 785–786
rotating frame NQR imiaging, 786–788
temperature, stress, and pressure imaging, 788
Specimen geometry
fracture toughness testing
load-displacement curves, 304
stress intensity factor *(K),* 306
stress-strain analysis, 285
thermogravimetric (TG) analysis, 351–352
transmission electron microscopy (TEM), deviation parameter, 1077–1078
Specimen modification
Auger electron spectroscopy (AES)
alignment protocols, 1161
basic principles, 1170–1171
cyclic voltammetry, 590
differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 371–372
electrochemical quartz crystal microbalance (EQCM), 661
electron paramagnetic resonance (EPR), 799–800
energy-dispersive spectrometry (EDS), 1152–1153
position protocols, 1156
fracture toughness testing, alignment, 312–313
high-strain-rate testing, 298–299
impulsive stimulated thermal scattering (ISTS) analysis, 757
ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1231–1232
liquid surface x-ray diffraction, 1043–1045
low-energy electron diffraction (LEED), 1132
magnetic domain structure measurements
Lorentz transmission electron microscopy, 552
magneto-optic imaging, 548–549
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE) and, 1207
particle-induced x-ray emission (PIXE)
error detection, 1219–1220
protocols, 1212–1216
phonon analysis, 1326
photoluminescence (PL) spectroscopy, 687
scanning electrochemical microscopy (SECM), 644–645
scanning electron microscopy (SEM), 1059
scanning transmission electron microscopy (STEM), 1108
single-crystal x-ray structure determination, 863
superconductors, electrical transport measurement, 483
thermal diffusivity, laser flash technique, 389
trace element accelerator mass spectrometry (TEAMS), 1253
transmission electron microscopy (TEM)
basic principles, 1087–1088
thickness modification, deviation parameter, 1081–1082
tribological testing, 332–333
ultraviolet/visible absorption (UV-VIS) spectroscopy, 695–696
x-ray absorption fine structure (XAFS) spectroscopy, 880
x-ray photoelectron spectroscopy (XPS), 999
Specimen-to-detector distance, x-ray diffraction, 206
Spectral resolution
Auger electron spectroscopy (AES), 1161
nuclear quadrupole resonance (NQR), data analysis and interpretation, 789
Spectroelectrochemical quartz crystal microbalance (SEQCM), instrumentation criteria, 659
Spectrometers/monochromators
diffuse scattering techniques, 894–987
electron spectrometers, ultraviolet photoelectron spectroscopy (UPS), 729
alignment protocols, 729–730
automation, 731–732
liquid surface x-ray diffraction, instrumetation criteria, 1036–1038
magnetic x-ray scattering, 925, 927–928
medium-energy backscattering, efficiency protocols, 1265–1266
nuclear quadrupole resonance (NQR), direct detection techniques, 780–781
phonon analysis, triple-axis spectrometry, 1320–1323
photoluminescence (PL) spectroscopy, 684
Raman spectroscopy of solids, criteria for, 706–707
surface x-ray diffraction, beamline alignment, 1019–1020
ultraviolet/visible absorption (UV-VIS) spectroscopy, components, 692
x-ray absorption fine structure (XAFS) spectroscopy
detection methods, 875–877
glitches, 877–878
x-ray magnetic circular dichroism (XMCD), 959–962
glitches, 966
Spectrum channel width and number, energy-dispersive spectrometry (EDS), measurement protocols, 1156
Spectrum distortion, energy-dispersive spectrometry (EDS), 1140
Spectrum subtraction, Auger electron spectroscopy (AES), 1167–1168
SPECT software
diffuse scattering techniques, 898–899
x-ray microfluorescence/microdiffraction, 949
Specular reflectivity
grazing-incidence diffraction (GID), 241–242
distorted-wave Born approximation (DWBA), 244–245
liquid surface x-ray diffraction, measurement protocols, 1028–1033
surface x-ray diffraction, crystal truncation rod (CTR) profiles, 1015–1016
Spheres, small-angle scattering (SAS), 220
Spherical aberration, transmission electron microscopy (TEM), lens defects and resolution, 1078
Spherical sector analysis, Auger electron spectroscopy (AES), 1160–1161
"SPICE" models, chemical vapor deposition (CVD), plasma physics, 170
Spin density functional theory (SDFT)
metal alloy magnetism
atomic short range order (ASRO), 190–191
competitive and related techniques, 185–186
first-principles calculations, 188–189
limitations, 200–201
transition metal magnetic ground state, itinerant magnetism at zero temperature, 181–183
Spin determination, Mössbauer spectroscopy, 827
Spin-echo sequence, magnetic resonance imaging (MRI)
basic principles, 768
theoretical background, 767
Spin 1 energy level, nuclear quadrupole resonance (NQR), 777–778
Spin 3/2 energy level, nuclear quadrupole resonance (NQR), 778
Spin 5/2 energy level, nuclear quadrupole resonance (NQR), 778
Spin glass materials, cluster magnetism, 516–517
Spin-lattice relaxation, nuclear magnetic resonance, 764–765
Spin moments
nuclear quadrupole resonance (NQR), 776
x-ray magnetic circular dichroism (XMCD), 953–955
Spin-orbit interaction
metal alloy bonding, accuracy calculations, 140–141
surface magneto-optic Kerr effect (SMOKE), 571
x-ray photoelectron spectroscopy (XPS), 973–974
Spin packets, nuclear magnetic resonance, 764–765
Spin-polarization effects, metal alloy bonding, accuracy calculations, 140–141
Spin polarized low-energy electron microscopy (SPLEEM), magnetic domain structure measurements, 556–557
Spin-polarized photoemission (SPPE) measurements, x-ray magnetic circular dichroism (XMCD) comparison, 955
Spin properties, nuclear magnetic resonance theory, 763–765
Spin relaxation, nuclear quadrupole resonance (NQR), 779–780
Spin-spin coupling, nuclear magnetic resonance, 764–765

Split Hopkinson pressure bar technique, high-strain-rate testing, 290
automation procedures, 296
data analysis and interpretation, 297–298
limitations, 299–300
sample preparation, 298
specimen modification, 298–299
stress-state equilibrium, 294–295
temperature effects, 295–296
Split-Pearson VII function, neutron powder diffraction, axial divergence peak asymmetry, 1293
Spontaneous magnetization
collective magnetism, 515
ferromagnetism, 523–524
Spot profile analysis LEED (SPA-LEED)
instrumentation criteria, 1126–1127
surface x-ray diffraction and, 1008
Spot profile analysis RHEED (SPA-RHEED), surface x-ray diffraction and, 1008
Spurious signaling
nuclear quadrupole resonance (NQR), 789–790
phonon analysis, 1326–1327
Sputter-initiated resonance ionization spectrometry (SIRIS)
secondary ion mass spectrometry (SIMS) and, 1236–1237
trace element accelerator mass spectrometry (TEAMS) and, 1235, 1237
Sputter-ion pump
applications, 10
operating principles and procedures, 10–12
Sputter profiling
angle-resolved x-ray photoelectron spectroscopy (ARXPS), 986–988
Auger electron spectroscopy (AES), depth-profile analysis, 1165–1167
ion beam analysis (IBA), ERD/RBS techniques, 1184–1186
Stability/reactivity, thermogravimetric (TG) analysis, 355
Stable crack mechanics, fracture toughness testing, 309–311
Stacking faults, neutron powder diffraction, 1295–1296
Stainless steel
vacuum system construction, 17
weight standards, 26–27
Staircase step measurements, superconductors, electrical transport measurements, current ramp rate, 479
Standardless analysis, energy-dispersive spectrometry (EDS), 1147–1148
accuracy testing, 1150
applications, 1151
first-principles standardless analysis, 1148–1149
fitted-standards standardless analysis, 1149–1150
Standard reference material
Auger electron spectroscopy (AES), sources, 1169–1170, 1174
energy-dispersive spectrometry (EDS), matrix corrections, 1146–1147
particle-induced x-ray emission (PIXE) analysis, 1218
Standards
mass measurement process assurance, 28–29
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE), 10205
in thermal analysis, 340
weight, 26–27
Standard state corrections, combustion calorimetry, 379–380
Standing waves
multiple-beam diffraction, 240
two-beam diffraction, 235–236
Startup procedures, turbomolecular pumps, 8
Static displacive interactions
diffuse scattering techniques, recovered displacements, 897–898
phase diagram prediction, 104–106
Static indentation hardness testing
applications and nomenclature, 318–319
automated methods, 319
basic principles, 317–318
data analysis and interpretation, 319–320
limitations and errors, 322
procedures and protocols, 318–319
research background, 316–317
sample preparation, 320
specimen modification, 320–321
Static magnetic field, nuclear magnetic resonance, instrumentation and tuning, 770–771
Static random-access memory (SRAM) devices, ion-beam-induced charge (IBIC)/single event upset (SEU) microscopy, 1230–1231
Statistics-insensitive nonlinear peak-clipping (SNIP) algorithm, particle-induced x-ray emission (PIXE) analysis, 1217–1218
"Steady-state" carrier profile, carrier lifetime measurement, surface recombination and diffusion, 432–433
Steady-state techniques, carrier lifetime measurement, 435–438
data interpretation issues, 437
limitations of, 437–438
quasi-steady-state-type method, 436–437
Steel samples, metallographic analysis, 4340 steel
cadmium plating composition and thickness, 68
microstructural evaluation, 67–68
Sternheimer effect, nuclear quadrupole resonance (NQR), 777
Stoichiometry, combustion calorimetry, 378
Stokes-Poincaré parameters, multiple-beam diffraction, polarization density matrix, 241
Stokes Raman scattering, Raman spectroscopy of solids, semiclassical physics, 701–702
Stoner enhancement factor, band theory of magnetism, 516
Stoner theory
band theory of magnetism, 515–516
Landau magnetic phase transition, 529–530
Stoner-Wohlfarth theory, transition metal magnetic ground state, itinerant magnetism at zero temperature, 181–183
Stopping power, energy-dispersive spectrometry (EDS), standardless analysis, 1148–1149
Strain contrast imaging, scanning transmission electron microscopy (STEM), data interpretation, 1106–1108
Strain distribution, microbeam analysis
ferroelectric sample, 948–949
tensile loading, 948
Strain-gauge measurements, high-strain-rate testing, 300
Strain rate
fracture toughness testing, crack driving force *(G),* 305
stress-strain analysis, 283
Stress field, fracture toughness testing, sharp crack, 314
Stress intensity factor *(K),* fracture toughness testing
basic principles, 305–306
defined, 302
SENB and CT speciments, 314–315
stable crack mechanics, 309–311
two-dimensional representation, 303
unstable fractures, 309
Stress measurements
impulsive stimulated thermal scattering (ISTS), 745–746
nuclear quadrupole resonance spectroscopy, 788
Stress-state equilibrium, high-strain-rate testing, 294–295
Stress-strain analysis
data analysis and interpretation, 287–288
elastic deformation, 281
fracture toughness testing, crack driving force *(G),* 304–305
high-strain-rate testing, Hopkinson bar technique, 290–292
mechanical testing, 280–282
curve form variables, 282–283
definitions, 281–282
material and microstructure, 283
temperature and strain rate, 283
yield-point phenomena, 283–284
Stretched exponentials, carrier lifetime measurement, 432
Structural phase transformation, thermomagnetic analysis, 542–544
Structural relaxation, metal alloy bonding, precision calculations, 143–144
Structure-factor calculations, x-ray diffraction
crystal structure, 208–209
principles and examples, 209–210
Structure factor relationships
neutron powder diffraction
individual extraction, 1298
solution techniques, 1298
resonant scattering, 909–910
tensor structure factors, 916
single-crystal neutron diffraction and, 1309–1311
single-crystal x-ray structure determination, 852–853
direct method computation, 866–868
surface x-ray diffraction, 1010–1011
error detection, 1018–1019
transmission electron microscopy (TEM) analysis, 1065–1066
x-ray powder diffraction, 845
detail analysis, 847–848
Structure inversion method (SIM), phase diagram predictions, cluster variational method (CVM), 99
Sublimation pumps
applications, 12
operating principles, 12
surface x-ray diffraction, 1011–1012
Substitutional and interstitial metallic systems, binary/multicomponent diffusion, 152–155
B2 intermetallics, chemical order, 154–155
frame of reference and concentration variables, 152
interdiffusion, 155
magnetic order, 153–154
mobilities and diffusivities, 152–153
temperature and concentration dependence of mobilities, 153
Substrate generation/tip collection (SG/TC), scanning electrochemical microscopy (SECM), 641–642
Subtraction technique, magnetic neutron scattering, 1330
error detection, 1337–1338
Sum peaks, energy-dispersive spectrometry (EDS), 1139
qualitative analysis, 1142–1143
Sum rules
diffuse intensities, metal alloys, atomic short-range ordering (ASRO) principles, 257

x-ray magnetic circular dichroism (XMCD), 956–957
data analysis, 964
error detection, 966
Super-Borrmann effect, multiple-beam standing waves, 240
Super command format, surface x-ray diffraction, 1025–1026
Superconducting magnets
changing fields stability and losses, 501–502
protection, 501
quench and training, 501
structure and properties, 500–502
Superconducting quantum interference device (SQUID)
magnetometry
automation of, 537
components, 532
principles and applications, 534
nuclear quadrupole resonance (NQR)
detector criteria, 781
nuclear moments, 776
thermomagnetic analysis, 540–544
Superconductors
diamagnetism, 494
electrical transport measurements
automation of, 480–481
bath temperature fluctuations, 486–487
competitive and related techniques, 472–473
contact materials, 474
cooling options and procedures, 478–479
critical current criteria, 474–475
current-carrying area for critical current to current density, 476
current contact length, 477
current ramp rate and shape, 479
current supply, 476–477
current transfer and transfer length, 475–477
data analysis and interpretation, 481–482
electromagnetic phenomena, 479
essential theory
current sharing, 474
four-point measurement, 473–474
Ohm's law, 474
power law transitions, 474
generic protocol, 480
instrumentation and data acquisition, 479–480
lead shortening, 486
magnetic field strength extrapolation and irreversibility field, 475
maximum measurement current determination, 479
probe thermal contraction, 486
research background, 472–473
sample handling/damage, 486
sample heating and continuous-current measurements, 486
sample holding and soldering/making contacts, 478
sample preparation, 482–483
sample quality, 487
sample shape, 477
self-field effects, 487
signal-to-noise ratio parameters, 483–486
current supply noise, 486
grounding, 485
integration period, 486
pick-up loops, 483–484
random noise and signal spikes, 485–486
thermal electromotive forces, 484–485
specimen modification, 483
thermal cycling, 487
troubleshooting, 480
voltage tap placement, 477
voltmeter properties, 477
zero voltage definition, 474
magnetization, 517–519
permanent magnets in, 496
Superlattice structures
grazing-incidence diffraction (GID), 242–243
magnetic neutron scattering, diffraction, 1334–1335
surface magneto-optic Kerr effect (SMOKE), 573–574
Superparamagnetism, principles of, 522
Surface analysis
Auger electron spectroscopy (AES), 1158–1159
automation, 406
basic principles, 405–406
limitations, 406
nuclear reaction analysis (NRA) and proton-induced gamma ray emission (PIGE), film thickness, 1206
protocols and procedures, 406
Surface barrier detectors (SBDs)
heavy-ion backscattering spectrometry (HIBS), 1276
ion-beam analysis (IBA) experiments, 1181–1184
ERD/RBS techniques, 1185–1186
medium-energy backscattering, backscattering techniques, 1262–1265
Surface capacitance measurements, electrochemical photocapacitance spectroscopy (EPS), semiconductor materials, 624–625
Surface degradation, electrochemical photocapacitance spectroscopy (EPS), semiconductor materials, 626
Surface extended x-ray absorption fine structure (EXAFS) analysis, low-energy electron diffraction (LEED), 1121
Surface magnetic scattering, protocols and procedures, 932–934
Surface magnetometry, principles and applications, 535–536
Surface magneto-optic Kerr effect (SMOKE)
automation, 573
classical theory, 570–571
data analysis and interpretation, 573–574
limitations, 575
medium-boundary and medium-propagation matrices, 576–577
multilayer formalism, 571
phenomenologica origins, 570
protocols and procedures, 571–573
quantum theory, ferromagnetism, 571
research background, 569–570
sample preparation, 575
ultrathin limit, 577
Surface photovoltage (SPV) technique, carrier lifetime measurement, diffusion-length-based methods, 435
Surface preparation
carrier lifetime measurement
passivation, free carrier absorption (FCA), 442–443
recombination and diffusion, 432–433
chemical vapor deposition (CVD) model
basic components, 167–168
software tools, 173
ellipsometry
polishing protocols, 741–742
reflecting surfaces, 735–737
molecular dynamics (MD) simulation
data analysis and interpretation, 160–164
higher-temperature dynamics, 161–162
interlayer relaxation, 161
layer density and temperature variation, 164
mean-square atomic displacement, 162–163
metal surface phonons, 161–162
room temperature structure and dynamics, 160–161
thermal expansion, 163–164
limitations, 164
principles and practices, 158–159
related theoretical techniques, 158
research background, 156
surface behavior, 156–157
temperature effects on surface behavior, 157
pn junction characterization, 468
surface/interface x-ray diffraction, 217–219
crystal truncation rods, 219
two-dimensional diffraction rods, 218–219
ultraviolet photoelectron spectroscopy (UPS), 727
sample preparation, 732–733
Surface recombination capture coefficient, electrochemical photocapacitance spectroscopy (EPS), semiconductor materials, 625
Surface recombination velocity
carrier lifetime measurements, time-resolved microwave conductivity, 622–623
semiconductor-liquid interfaces, transient decay dynamics, 620–622
Surface reconstruction, molecular dynamics (MD) simulation, 156–157
Surface relaxation, molecular dynamics (MD) simulation, 156–157
Surface roughness
angle-resolved x-ray photoelectron spectroscopy (ARXPS), 988
liquid surface x-ray diffraction, reflectivity measurements, 1033
surface x-ray scattering, 1016
temperature effects, molecular dynamics (MD) simulation, 157
Surface x-ray diffraction
angle calculations, 1021
basic principles, 1008–1011
crystallographic measurements, 1010–1011
grazing incidence, 1011
measurement instrumentation, 1009–1010
surface properties, 1008–1009
beamline alignment, 1019–1020
competitive and related strategies, 1007–1008
data analysis and interpretation, 1015–1018
crystal truncation rod (CTR) profiles, 1015
diffuse scattering, 1016
grazing incidence measurements, 1016–1017
reciprocal lattice mapping, 1016
reflectivity, 1015–1016
silicon surface analysis, 1017–1018
software programs, 1024–1025
diffractometer alignment, 1020–1021
instrumentation criteria, 1011–1015
crystallographic alignment, 1014–1015
five-circle diffractometer, 1013–1014
laser alignment, 1014
sample manipulator, 1012–1013
vacuum system, 1011–1012
limitations, 1018–1019
liquid surfaces
basic principles, 1028–1036
competitive and related techniques, 1028
data analysis and interpretation, 1039–1043
Langmuir monolayers, 1041–1043
liquid alkane crystallization, 1043
liquid metals, 1043
simple liquids, 1040–1041
non-specular scattering
GID, diffuse scattering, and rod scans, 1038–1039
reflectivity measurements, 1033

Surface x-ray diffraction (*Continued*)
p-polarized x-ray beam configuration, 1047
reflectivity, 1029–1036
Born approximation, 1033–1034
distorted-wave Born approximation, 1034–1036
Fresnel reflectivity, 1029–1031
grazing incidence diffraction and rod scans, 1036
instrumentation, 1036–1038
multiple stepwise and continuous interfaces, 1031–1033
non-specular scattering, 1033
research background, 1027–1028
specimen modification, 1043–1045
research background, 1007–1008
scan categories, 1027
super command format, 1025–1026
ultrahigh-vacuum (UHV) systems
bakeout procedure, 1023–1024
basic principles, 1011–1012
load-lock procedure, 1023
protocols and procedures, 1022–1024
venting procedures, 1023
Survey spectrum
Auger electron spectroscopy (AES), 1163–1164
x-ray photoelectron spectroscopy (XPS), 972–974
analyzer criteria, 981–982
post-processing of, 1000–1001
SX approximation, electronic structure analysis, 85–86
Symbols, in thermal analysis, 339–340
Symmetry analysis
crystallography, 39–42
improper rotation axes, 39–40
proper rotation axes, 39
screw axes and glide planes, 40–42
in crystallography, 39
resonant scattering, 906
resonant scattering analysis, 909–910
single-crystal x-ray structure determination, crystal symmetry, 854–856
surface x-ray diffraction, error detection, 1019
transmission electron microscopy (TEM), diffraction pattern indexing, 1073–1074
vibrational Raman spectroscopy
group theoretical analysis, 718–720
matrix representations, 717–720
Synchrotron radiation
diffuse scattering techniques, 882–884
magnetic x-ray scattering
beamline properties, 925–927
hardware criteria, 925–926
Mössbauer spectroscopy, radiation sources, 826–827
surface x-ray diffraction, diffractometer components, 1009–1010
ultraviolet photoelectron spectroscopy (UPS), 728–729
commercial sources, 734
x-ray absorption fine structure (XAFS) spectroscopy, 877
x-ray photoelectron spectroscopy (XPS), 980
x-ray powder diffraction, 839

Tafel technique
corrosion quantification, 593–596
limitations, 596
linear polarization, 596–599
protocols and procedures, 594–596
cyclic voltammetry, quasireversible reaction, 583
Tapered capillary devices, x-ray microprobes, 945
Taylor expansion series
coherent ordered precipitates, microstructural evolution, 123
small-angle scattering (SAS), 221
thermal diffuse scattering (TDS), 211–214
Taylor rod impact test, high-strain-rate testing, 290
Technical University Munich Secondary Ion AMS Facility, trace element accelerator mass spectrometry (TEAMS) research at, 1245
Temperature cross-sensitivity, Hall effect sensors, 508
Temperature-dependent Hall (TDH) measurements, semiconductor materials, 414–416
Temperature factors, neutron powder diffraction, 1301
Temperature gradients, thermogravimetric (TG) analysis, 350–352
Temperature measurement
binary/multicomponent diffusion, substitutional and interstitial metallic systems, 153
combustion calorimetry, 378–379
control of, 37–38
corrosion quantification, electrochemical impedance spectroscopy (EIS), 600–603
defined, 30–31
differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 367–368
fixed points, ITS-90 standard, 34
gas analysis, simultaneous thermogravimetry (TG)-differential thermal analysis (TG-DTA), 394
high-strain-rate testing, 295–296

Ultraclean ion sources, trace element accelerator mass spectrometry (TEAMS)
  design criteria, 1239–1240
  negatively charged secondary ion generation, 1238
Ultrahigh-vacuum (UHV) systems
  all-metal flange seals, 18
  assembly, processing and operation, 19
  basic principles, 1–2
  bellows-sealed feedthroughs, 19
  construction materials, 17
  hot cathode ionization gauges, 15
  low-energy electron diffraction (LEED), comparisons, 1121
  O-ring seals, limits of, 18
  scanning tunneling microscopy (STM), 1117
  sputter-ion pump, 10–11
  surface magneto-optic Kerr effect (SMOKE), 573
  surface x-ray diffraction
    bakeout procedure, 1023–1024
    basic principles, 1011–1012
    load-lock procedure, 1023
    protocols and procedures, 1022–1024
    venting procedures, 1023
  valve construction, 18
  x-ray absorption fine structure (XAFS), 876–877
  x-ray photoelectron spectroscopy (XPS)
    instrumentation, 978–983
    research background, 970–972
Ultralarge-scale integrated circuits, heavy-ion backscattering spectrometry (HIBS), 1280
Ultra microbalances, thermogravimetric (TG) analysis, 347–350
Ultramicroelectrode (UME), scanning electrochemical microscopy (SECM)
  feedback mode, 638–640
  properties and applications, 636
Ultramicrotomy, transmission electron microscopy (TEM), sample preparation, 1087
Ultrasonic microhardness testing, basic principles, 316
Ultrathin limit, surface magneto-optic Kerr effect (SMOKE), 577
Ultraviolet photoelectron spectroscopy (UPS)
  alignment procedures, 729–730
  atoms and molecules, 727–728
  automation, 731
  competitive and related techniques, 725–726
  data analysis and interpretation, 731–732
  electronic phase transitions, 727
  electron spectrometers, 729
  energy band dispersion, 723–725
    solid materials, 727
  light sources, 728–729
    figure of merit, 734–735
  limitations, 733
  photoemission process, 726–727
  photoemission *vs.* inverse photoemission, 722–723
  physical relations, 730
  sample preparation, 732–733
  sensitivity limits, 730–731
  surface states, 727
  synchrotron light sources, 734
  valence electron characterization, 723–724
  x-ray photoelectron spectroscopy (XPS), comparisons, 971
Ultraviolet/visible absorption (UV-VIS) spectroscopy
  applications, 692
  array detector spectrometer, 693
  automation, 693
  common components, 692
  competitive and related techniques, 690
  dual-beam spectrometer, 692–693
  limitations, 696
  materials characterization, 691–692, 694–695
  materials properties, 689
  qualitative/quantitative analysis, 689–690
  quantitative analysis, 690–691, 693–694
  research background, 688–689
  sample preparation, 693, 695
  single-beam spectrometer, 692
  specimen modification, 695–696
Uncertainty principle
  diffuse scattering techniques, 887–889
  resonance spectroscopies, 761–762
  x-ray photoelectron spectroscopy (XPS), composition analysis, 994–996
Uniaxial flow stress, static indentation hardness testing, 317
Uniform plastic deformation, stress-strain analysis, 282
Units (magnetism), general principles, 492–493
Universal gas constant, corrosion quantification, Tafel technique, 593–596
University of North Texas Ion Beam Modification and Analysis Laboratory, trace element accelerator mass spectrometry (TEAMS) research at, 1246
University of Toronto IsoTrace Laboratory, trace element accelerator mass spectrometry (TEAMS) at, 1244–1245
Unloading compliance technique, fracture toughness testing, crack extension measurement, 308
Unstable crack growth, fracture toughness testing, load-displacement behavior, 304–305
Unstable fractures, fracture toughness testing, 308–309

Upper critical field strength (H_{c2}), superconductors
electrical transport measurements, extrapolation, 475
magnetic measurements, 473
magnetization, 519
superconductors-to-normal (S/N) transition, electrical transport measurement, estimation protocols, 482

Vacancy wind, binary/multicomponent diffusion, Kirkendall effect, 149
Vacuum systems
basic principles, 1–3
outgassing, 2–3
leak detection, 20–22
load-lock antechamber, basic principles, 1–2
nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), 1203–1204
pumps
surface x-ray diffraction, 1011–1012
technological principles, 3
scanning electron microscopy (SEM), 1061
scanning transmission electron microscopy (STEM), error detection, 1108
standards and units, 1
surface x-ray diffraction, basic properties, 1011–1012
system construction and design
assembly, processing and operation, 19
design criteria, 19–20
hardware components, 17–19
materials, 17
technological principles
cryopumps, 9–10
diffusion pumps, 6–7
getter pumps, 12
high-vacuum pumps, 5–6
nonevaporable getter pumps (NEGs), 12
oil-free (dry) pumps, 4–5
oil-sealed pumps, 3–4
roughing pumps, 3
scroll pumps, 5
sorption pumps, 5
sputter-ion pumps, 10–12
sublimation pumps, 12
thermal conductivity gauges for pressure measurement, 13–17
total/partial pressure measurement, 13
turbomolecular pumps, 7–9
vacuum pumps, 3
ultraviolet photoelectron spectroscopy (UPS), automation, 731–732
Valence bands, x-ray photoelectron spectroscopy (XPS), 973–974
Valence electron characterization
Mössbauer spectroscopy, 827
ultraviolet photoelectron spectroscopy (UPS), 723–724
Valence potential, x-ray photoelectron spectroscopy (XPS), initial-state effects, 977–978
Valves, vacuum systems, 18
Van de Graaff particle accelerator, nuclear reaction analysis (NRA)/proton-induced gamma ray emission (PIGE), 1203–1204
Van der Pauw method
conductivity measurements, 402
Hall effect, semiconductor materials, relaxation time approximation (RTA), 413
semiconductor materials, Hall effect, automated apparatus, 414
surface measurements, 406
Van der Waals forces
liquid surface x-ray diffraction, simple liquids, 1040–1041
neutron powder diffraction, 1302
vacuum system principles, outgassing, 2–3
Van Hove singularities, diffuse intensities, metal alloys
copper-platinum alloys, 271–273
multicomponent alloys, 268–270
Van't Hoff equation
differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 368
thermal analysis and principles of, 342–343
Vapor phase deposition (VPD), heavy-ion backscattering spectrometry (HIBS), 1274
Vapor phase epitaxy (VPE) reactor, capacitance-voltage (C-V) characterization, 462–463
Variability in test results, tribological and wear testing, 335
Variable frequency Hewlett-Packard meters, capacitance-voltage (C-V) characterization, 460–461
Variable-pressure scanning electron microscopy (SEM)
basic principles, 1056–1057
specimen modification, 1059
Variational Monte Carlo (VMC), electronic structure analysis, 88–89
Venting protocols
surface x-ray diffraction, ultrahigh-vacuum (UHV) systems, 1023
turbomolecular pumps, 8
Vertical illuminators, reflected-light optical microscopy, 675–676
Vibrating-coil magnetometer (VCM), principles and applications, 535
Vibrating-sample magnetometer (VSM)
automation, 537
properts and applications, 533–534
thermomagnetic analysis, 540–544
Vibrational Raman spectroscopy, group theoretical analysis, 702–704
character tables, 718
point groups and matrix representation, symmetry operations, 717–718
vibrational modes of solids, 720–722
vibrational selection rules, 716–720
Vibrational selection rules, group theoretical analysis, 716–717
symmetry operators, 718–720
Vibrational spectra, group theoretical analysis, 717–720
Vickers hardness testing
automated methods, 319
basic principles, 317–318
data analysis and interpretation, 319–320
hardness values, 317–318, 323
limitations and errors, 322
procedures and protocols, 318–319
research background, 316–317
sample preparation, 320
specimen modification, 320–321
Virgin wafers, carrier lifetime measurement, free carrier absorption (FCA), 442–443
Virtual leaks, vacuum systems, 20–22
Viscous flow
oil-sealed pumps, oil contamination, avoidance, 4
vacuum system design, 20
Voigt function, x-ray photoelectron spectroscopy (XPS), peak shape, 1006
Volatile products
energy-dispersive spectrometry (EDS), loss mechanisms, 1153
gas analysis and, 398
Voltage spikes, superconductors, electrical transport measurements, signal-to-noise ratio, 485
Voltage tap, superconductors, electrical transport measurements, placement protocols, 477
Voltmeter properties, superconductors, electrical transport measurements, 477
Volume deformation (VD), phase diagram prediction, static displacive interactions, 104–106
Volume-fixed frame of reference, binary/multicomponent diffusion, 148
Vortex melting transition, superconductor magnetization, 519

Warren-Cowley order parameter
diffuse intensities, metal alloys
atomic short-range ordering (ASRO) principles, pair correlations, 257
basic definitions, 252–254
concentration waves, density-functional theory (DFT), 261–262
copper-nickel-zinc alloys, 269–270
effective cluster interactions (ECIs), 255–256
diffuse scattering techniques, 886–889
protocols and procedures, 889–894
x-ray diffraction, local atomic correlation, 215–217
Wave equations, high-strain-rate testing, Hopkinson bar technique, 290–292
Wave field amplitude ratios, two-beam diffraction, dispersion surface, 230
Wave function character
metal alloy bonding, 138
ultraviolet photoelectron spectroscopy (UPS), photoemission process, 726–727
Waveguide mode velocities, impulsive stimulated thermal scattering (ISTS) analysis, 756–757
Wave-length-dispersive x-ray spectrometry (WDS), energy-dispersive spectrometry (EDS), matrix corrections, 1145–1147
Wavelength properties
fluorescence analysis, dispersive spectrometers, 944
impulsive stimulated thermal scattering (ISTS), 746–749
Wave measurements, thermal diffusivity, laser flash technique *vs.,* 383–384
Weak-beam dark-field (WBDF) imaging, transmission electron microscopy (TEM), 1071
Weak scattering sources
magnetic x-ray scattering, 935
scanning transmission electron microscopy (STEM), incoherent imaging, weakly scattering objects, 1111
Wear coefficients, tribological and wear testing, 326–327
Wear curves, wear testing protocols, 330–331
Wear-rate-*vs.*-usage curve, wear testing protocols, 331
Wear testing
acceleration, 333
automation of, 333–334
basic principles, 317, 324–326
classification of, 324–325
control factors, 332–333
data analysis and interpretation, 334
equipment and measurement techniques, 326–327
friction coefficients, 326
friction testing, 328–329
general procedures, 326
limitations, 335

research background, 324
results analysis, 333
sample preparation, 335
techniques and procedures, 329–332
test categories, 327–328
wear coefficients, 326–327
Weight
definitions, 24–26
standards for, 26–27
Weilbull distribution, fracture toughness testing, brittle materials, 311
Weiss molecular field constant
ferromagnetism, 523–524
surface magneto-optic Kerr effect (SMOKE), 571
Wigner-Eckart theorem, resonant scattering analysis, 909–910
Williamson-Hall plot, neutron powder diffraction, microstrain broadening, 1294–1295
Wollaston prism, reflected-light optical microscopy, 679–680
Wood notation, low-energy electron diffraction (LEED), qualitative analysis, 1123–1124
Working distance, optical microscopy, 670
Working electrode, cyclic voltammetry, 585–586

X-band frequencies, electron paramagnetic resonance (EPR), continuous-wave (CW) experiments, rectangular resonator, 794–795
XCOM database, particle-induced x-ray emission (PIXE), 1212
X-ray absorption, energy-dispersive spectrometry (EDS), matrix corrections, 1145
X-ray absorption fine structure (XAFS) spectroscopy
automation, 878
data analysis and interpretation, 878–879
detection methods, 875–877
energy calibration, 877
energy resolution, 877
harmonic content, 877
limitations, 880
micro-XAFS, fluorescence analysis, 943
monochromator glitches, 877–878
related structures, 870
research background, 869–870
sample preparation, 879–880
simple picture components, 872–874
disorder, 872–873

      object function retrieval, 1105–1106
      strain contrast, 1106–1108
    dynamical diffraction, 1101–1103
    incoherent scattering, 1098–1101
      weakly scattered objects, 1111
    limitations, 1108
    manufacturing sources, 1111
    probe formation, 1097–1098
    protocols and procedures, 1104–1105
    research background, 1090–1093
    sample preparation, 1108
    specimen modification, 1108
  transmission electron microscopy (TEM), 1063–1064
Zeeman effects
  nuclear quadrupole resonance (NQR), perturbation and line shapes, 779
  splitting
    Pauli paramagnetism, 493–494
    quantum paramagnetiic response, 521–522
Zeeman-perturbed NRS (ZNRS), nuclear quadrupole resonance (NQR), basic principles, 782–783
Zero field cooling (ZFC), superconductor magnetization, 518–519
Zero-line optimization, differential thermal analysis (DTA)/differential scanning calorimetry (DSC), 366
Zero magnetic field
  magnetotransport in metal alloys, 561–563
  nuclear quadrupole resonance (NQR)
    energy levels, 777–779
      higher spin nuclei, 779
      spin 1 levels, 777–778
      spin 3/2 levels, 778
      spin 5/2 levels, 778–779
    two-dimensional zero-field NQR, 782–785
      exchange NQR spectroscopy, 785
      level-crossing double resonance NQR nutation spectroscopy, 785
      nutation NRS, 783–784
      Zeeman-perturbed NRS (ZNRS), 782–783
Zeroth Law of Thermodynamics, thermodynamic temperature scale, 31–32
Zero voltage definition, superconductors, electrical transport measurement, 474
Zinc alloys. *See also* Copper-nickel-zinc alloys
  x-ray diffraction, structure-factor calculations, 209
Zone plates, x-ray microprobes, 945–946
