INDEX 1341

FOREWORD

Whatever standards may have been used for materials research in antiquity, when fabrication was regarded more as an art than a science and tended to be shrouded in secrecy, an abrupt change occurred with the systematic discovery of the chemical elements two centuries ago by Cavendish, Priestly, Lavoisier, and their numerous successors. This revolution was enhanced by the parallel development of electrochemistry and eventually capped by the consolidating work of Mendeleyev which led to the periodic chart of the elements.

The age of materials science and technology had finally begun. This does not mean that empirical or trial and error work was abandoned as unnecessary. But rather that a new attitude had entered the field. The diligent fabricator of materials would welcome the development of new tools that could advance his or her work whether exploratory or applied. For example, electrochemistry became an intimate part of the armature of materials technology.

Fortunately, the physicist as well as the chemist were able to offer new tools. Initially these included such matters as a vast improvement of the optical microscope, the development of the analytic spectroscope, the discovery of x-ray diffraction and the invention of the electron microscope. Moreover, many other items such as isotopic tracers, laser spectroscopes and magnetic resonance equipment eventually emerged and were found useful in their turn as the science of physics and the demands for better materials evolved.

Quite apart from being used to re-evaluate the basis for the properties of materials that had long been useful, the new approaches provided much more important dividends. The ever-expanding knowledge of chemistry made it possible not only to improve upon those properties by varying composition, structure and other factors in controlled amounts, but revealed the existence of completely new materials that frequently turned out to be exceedingly useful. The mechanical properties of relatively inexpensive steels were improved by the additions of silicon, an element which had been produced first as a chemist's oddity. More complex ferrosilicon alloys revolutionized the performance of electric transformers. A hitherto all but unknown element, tungsten, provided a long-term solution in the search for a durable filament for the incandescent lamp. Eventually the chemists were to emerge with valuable families of organic polymers that replaced many natural materials.

The successes that accompanied the new approach to materials research and development stimulated an entirely new spirit of invention. What had once been dreams, such as the invention of the automobile and the airplane, were transformed into reality, in part through the modification of old materials and in part by creation of new ones. The growth in basic understanding of electromagnetic phenomena, coupled with the discovery that some materials possessed special electrical properties, encouraged the development of new equipment for power conversion and new methods of long-distance communication with the use of wired or wireless systems. In brief, the successes derived from the new approach to the development of materials had the effect of stimulating attempts to achieve practical goals which had previously seemed beyond reach. The technical base of society was being shaken to its foundations. And the end is not yet in sight.

The process of fabricating special materials for well defined practical missions, such as the development of new inventions or improving old ones, has, and continues to have, its counterpart in exploratory research that is carried out primarily to expand the range of knowledge and properties of materials of various types. Such investigations began in the field of mineralogy somewhat before the age of modern chemistry and were stimulated by the fact that many common minerals display regular cleavage planes and may exhibit unusual optical properties, such as different indices of refraction in different directions. Studies of this type became much broader and more systematic, however, once the variety of sophisticated exploratory tools provided by chemistry and physics became available. Although the groups of individuals involved in this work tended to live somewhat apart from the technologists, it was inevitable that some of their discoveries would eventually prove to be very useful. Many examples can be given. In the 1870s a young investigator who was studying the electrical properties of a group of poorly conducting metal sulfides, today classed among the family of semiconductors, noted that his specimens seemed to exhibit a different electrical conductivity when the voltage was applied in opposite directions. Careful measurements at a later date demonstrated that specially prepared specimens of silicon displayed this rectifying effect to an even more marked degree. Another investigator discovered a family of crystals that displayed surface

charges of opposite polarity when placed under unidirectional pressure, so called piezoelectricity. Natural radioactivity was discovered in a specimen of a uranium mineral whose physical properties were under study. Superconductivity was discovered incidentally in a systematic study of the electrical conductivity of simple metals close to the absolute zero of temperature. The possibility of creating a light-emitting crystal diode was suggested once wave mechanics was developed and began to be applied to advance our understanding of the properties of materials further. Actually, achievement of the device proved to be more difficult than its conception. The materials involved had to be prepared with great care.

Among the many avenues explored for the sake of obtaining new basic knowledge is that related to the influence of imperfections on the properties of materials. Some imperfections, such as those which give rise to temperature-dependent electrical conductivity in semiconductors, salts and metals could be ascribed to thermal fluctuations. Others were linked to foreign atoms which were added intentionally or occurred by accident. Still others were the result of deviations in the arrangement of atoms from that expected in ideal lattice structures. As might be expected, discoveries in this area not only clarified mysteries associated with ancient aspects of materials research, but provided tests that could have a bearing on the properties of materials being explored for novel purposes. The semiconductor industry has been an important beneficiary of this form of exploratory research since the operation of integrated circuits can be highly sensitive to imperfections.

In this connection, it should be added that the ever-increasing search for special materials that possess new or superior properties under conditions in which the sponsors of exploratory research and development and the prospective beneficiaries of the technological advance have parallel interests has made it possible for those engaged in the exploratory research to share in the funds directed toward applications. This has done much to enhance the degree of partnership between the scientist and engineer in advancing the field of materials research.

Finally, it should be emphasized again that whenever materials research has played a decisive role in advancing some aspect of technology, the advance has frequently been aided by the introduction of an increasingly sophisticated set of characterization tools that are drawn from a wide range of scientific disciplines. These tools usually remain a part of the array of test equipment.

FREDERICK SEITZ
President Emeritus, Rockefeller University
Past President, National Academy of Sciences, USA

PREFACE

Materials research is an extraordinarily broad and diverse field. It draws on the science, the technology, and the tools of a variety of scientific and engineering disciplines as it pursues research objectives spanning the very fundamental to the highly applied. Beyond the generic idea of a "material" *per se*, perhaps the single unifying element that qualifies this collection of pursuits as a field of research and study is the existence of a portfolio of characterization methods that is widely applicable irrespective of discipline or ultimate materials application. *Characterization of Materials* specifically addresses that portfolio with which researchers and educators must have working familiarity.

The immediate challenge to organizing the content for a methodological reference work is determining how best to parse the field. By far the largest number of materials researchers are focused on particular classes of materials and also perhaps on their uses. Thus a comfortable choice would have been to commission chapters accordingly. Alternatively, the objective and product of any measurement,—i.e., a materials property—could easily form a logical basis. Unfortunately, each of these approaches would have required mention of several of the measurement methods in just about every chapter. Therefore, if only to reduce redundancy, we have chosen a less intuitive taxonomy by arranging the content according to the type of measurement "probe" upon which a method relies. Thus you will find chapters focused on application of electrons, ions, x rays, heat, light, etc., to a sample as the generic thread tying several methods together. Our field is too complex for this not to be an oversimplification, and indeed some logical inconsistencies are inevitable.

We have tried to maintain the distinction between a property and a method. This is easy and clear for methods based on external independent probes such as electron beams, ion beams, neutrons, or x-rays. However many techniques rely on one and the same phenomenon for probe and property, as is the case for mechanical, electronic, and thermal methods. Many methods fall into both regimes. For example, light may be used to observe a microstructure, but may also be used to measure an optical property. From the most general viewpoint, we recognize that the properties of the measuring device and those of the specimen under study are inextricably linked. It is actually a joint property of the tool-plus-sample system that is observed. When both tool and sample each contribute their own *materials* properties—e.g., electrolyte and electrode, pin and disc, source and absorber, etc.—distinctions are blurred. Although these distinctions in principle ought not to be taken too seriously, keeping them in mind will aid in efficiently accessing content of interest in these volumes.

Frequently, the materials property sought is not what is directly measured. Rather it is deduced from direct observation of some other property or phenomenon that acts as a signature of what is of interest. These relationships take many forms. Thermal arrest, magnetic anomaly, diffraction spot intensity, relaxation rate and resistivity, to name only a few, might all serve as signatures of a phase transition and be used as "spectator" properties to determine a critical temperature. Similarly, inferred properties such as charge carrier mobility are deduced from basic electrical quantities and temperature-composition phase diagrams are deduced from observed microstructures. *Characterization of Materials*, being organized by technique, naturally places initial emphasis on the most directly measured properties, but authors have provided many application examples that illustrate the derivative properties a techniques may address.

First among our objectives is to help the researcher discriminate among alternative measurement modalities that may apply to the property under study. The field of possibilities is often very wide, and although excellent texts treating each possible method in great detail exist, identifying the most appropriate method before delving deeply into any one seems the most efficient approach. *Characterization of Materials* serves to sort the options at the outset, with individual articles affording the researcher a description of the method sufficient to understand its applicability, limitations, and relationship to competing techniques, while directing the reader to more extensive resources that fit specific measurement needs.

Whether one plans to perform such measurements oneself or whether one simply needs to gain sufficient familiarity to effectively collaborate with experts in the method, *Characterization of Materials* will be a useful reference. Although our expert authors were given great latitude to adjust their presentations to the "personalities" of their specific methods, some uniformity and circumscription of content was sought. Thus, you will find most

units organized in a similar fashion. First, an introduction serves to succinctly describe for what properties the method is useful and what alternatives may exist. Underlying physical principles of the method and practical aspects of its implementation follow. Most units will offer examples of data and their analyses as well as warnings about common problems of which one should be aware. Preparation of samples and automation of the methods are also treated as appropriate.

As implied above, the level of presentation of these volumes is intended to be intermediate between cursory overview and detailed instruction. Readers will find that, in practice, the level of coverage is also very much dictated by the character of the technique described. Many are based on quite complex concepts and devices. Others are less so, but still, of course, demand a precision of understanding and execution. What is or is not included in a presentation also depends on the technical background assumed of the reader. This obviates the need to delve into concepts that are part of rather standard technical curricula, while requiring inclusion of less common, more specialized topics.

As much as possible, we have avoided extended discussion of the science and application of the materials properties themselves, which, although very interesting and clearly the motivation for research in first place, do not generally speak to efficacy of a method or its accomplishment.

This is a *materials-oriented* volume, and as such, must overlap fields such as physics, chemistry, and engineering. There is no sharp delineation possible between a "physics" property (e.g., the band structure of a solid) and the materials consequences (e.g., conductivity, mobility, etc.) At the other extreme, it is not at all clear where a materials property such as toughness ends and an engineering property associated with performance and life-cycle begins. The very attempt to assign such concepts to only one disciplinary category serves no useful purpose. Suffice it to say, therefore, that *Characterization of Materials* has focused its coverage on a core of materials topics while trying to remain inclusive at the boundaries of the field.

Processing and fabrication are also important aspect of materials research. *Characterization of Materials* does not deal with these methods *per se* because they are not strictly measurement methods. However, here again no clear line is found and in such methods as electrochemistry, tribology, mechanical testing, and even ion-beam irradiation, where the processing can *be* the measurement, these aspects are perforce included.

The second chapter is unique in that it collects methods that are not, literally speaking, measurement methods; these articles do not follow the format found in subsequent chapters. As theory or simulation or modeling methods, they certainly serve to augment experiment. They may be a necessary corollary to an experiment to understand the result after the fact or to predict the result and thus help direct an experimental search in advance. More than this, as equipment needs of many experimental studies increase in complexity and cost, as the materials themselves become more complex and multicomponent in nature, and as computational power continues to expand, simulation of properties *will* in fact become the measurement method of choice in many cases.

Another unique chapter is the first, covering "common concepts." It collects some of the ubiquitous aspects of measurement methods that would have had to be described repeatedly and in more detail in later units. Readers may refer back to this chapter as related topics arise around specific methods, or they may use this chapter as a general tutorial. The Common Concepts chapter, however, does not and should not eliminate *all* redundancies in the remaining chapters. Expositions within individual articles attempt to be somewhat self-contained and the details as to how a common concept actually relates to a given method are bound to differ from one to the next. Although *Characterization of Materials* is directed more toward the research lab than the classroom, the focused units in conjunction with chapters one and two can serve as a useful educational tool.

The content of *Characterization of Materials* had previously appeared as *Methods in Materials Research*, a loose-leaf compilation amenable to updating. To retain the ability to keep content as up to date as possible, *Characterization of Materials* is also being published on-line where several new and expanded topics will be added over time.

ACKNOWLEDGMENTS

First we express our appreciation to the many expert authors who have contributed to *Characterization of Materials*. On the production side of the predecessor publication, *Methods in Materials Research*, we are pleased to acknowledge the work of a great many staff of the Current Protocols division of John Wiley & Sons, Inc. We also thank the previous series editors, Dr. Virginia Chanda and Dr. Alan Samuels. Republication in the present on-line and hard-bound forms owes its continuing quality to staff of the Major Reference Works group of John Wiley & Sons, Inc., most notably Dr. Jacqueline Kroschwitz and Dr. Arza Seidel.

COMMON CONCEPTS

COMMON CONCEPTS IN MATERIALS CHARACTERIZATION, INTRODUCTION

From a tutorial standpoint, one may view this chapter as a good preparatory entrance to subsequent chapters of *Characterization of Materials*. In an educational setting, the generally applicable topics of the units in this chapter can play such a role, notwithstanding that they are each quite independent without having been sequenced with any pedagogical thread in mind.

In practice, we expect that each unit of this chapter will be separately valuable to users of *Characterization of Materials* as they choose to refer to it for concepts underlying many of those exposed in units covering specific measurement methods.

Of course, not every topic covered by a unit in this chapter will be relevant to *every* measurement method covered in subsequent chapters. However, the concepts in this chapter are sufficiently common to appear repeatedly in the pursuit of materials research. It can be argued that the units treating vacuum techniques, thermometry, and sample preparation do not deal directly with the materials properties to be measured at all. Rather, they are crucial to preparation and implementation of such a measurement. It is interesting to note that the properties of materials nevertheless play absolutely crucial roles for each of these topics as they rely on materials performance to accomplish their ends.

Mass/density measurement does of course relate to a most basic materials property, but is itself more likely to be an ancillary necessity of a measurement protocol than to be the end goal of a measurement (with the important exceptions of properties related to porosity, defect density, etc.). In temperature and mass measurement, appreciating the role of standards and definitions is central to proper use of these parameters.

It is hard to think of a materials property that does not depend on the crystal structure of the materials in question. Whether the structure is a known part of the explanation of the value of another property or its determination is itself the object of the measurement, a good grounding in essentials of crystallographic groups and syntax is a common need in most measurement circumstances. A unit provided in this chapter serves that purpose well.

Several chapters in *Characterization of Materials* deal with impingement of projectiles of one kind or another on a sample, the reaction to which reflects properties of interest in the target. Describing the scattering of the projectiles is necessary in all these cases. Many concepts in such a description are similar regardless of projectile type, while the details differ greatly among ions, electrons, neutrons, and photons. Although the particle scattering unit in this chapter emphasizes the charged particle and ions in particular, the concepts are somewhat portable. A good deal of generic scattering background is provided in the chapters covering neutrons, x rays, and electrons as projectiles as well.

As *Characterization of Materials* evolves, additional common concepts will be added. However, when it seems more appropriate, such content will appear more closely tied to its primary topical chapter.

ELTON N. KAUFMANN

GENERAL VACUUM TECHNIQUES

INTRODUCTION

In this unit we discuss the procedures and equipment used to maintain a vacuum system at pressures in the range from 10^{-3} to 10^{-11} torr. Total and partial pressure gauges used in this range are also described.

Because there is a wide variety of equipment, we describe each of the various components, including details of their principles and technique of operation, as well as their recommended uses.

SI units are not used in this unit. The American Vacuum Society attempted their introduction many years ago, but the more traditional units continue to dominate in this field in North America. Our usage will be consistent with that generally found in the current literature. The following units will be used.

Pressure is given in torr. 1 torr is equivalent to 133.32 pascal (Pa).

Volume is given in liters (L), and time in seconds (s).

The flow of gas through a system, i.e., the "throughput" (Q), is given in torr-L/s.

Pumping speed (S) and conductance (C) are given in L/s.

PRINCIPLES OF VACUUM TECHNOLOGY

The most difficult step in designing and building a vacuum system is defining precisely the conditions required to fulfill the purpose at hand. Important factors to consider include:

1. The required system operating pressure and the gaseous impurities that must be avoided;
2. The frequency with which the system must be vented to the atmosphere, and the required recycling time;
3. The kind of access to the vacuum system needed for the insertion or removal of samples.

For systems operating at pressures of 10^{-6} to 10^{-7} torr, venting the system is the simplest way to gain access, but for ultrahigh vacuum (UHV), e.g., below 10^{-8} torr, the pumpdown time can be very long, and system bakeout would usually be required. A vacuum load-lock antechamber for the introduction and removal of samples may be essential in such applications.

Because it is difficult to address all of the above questions, a viable specification of system performance is often neglected, and it is all too easy to assemble a more sophisticated and expensive system than necessary, or, if budgets are low, to compromise on an inadequate system that cannot easily be upgraded.

Before any discussion of the specific components of a vacuum system, it is instructive to consider the factors that govern the ultimate, or base, pressure. The pressure can be calculated from

$$P = \frac{Q}{S} \tag{1}$$

where P is the pressure in torr, Q is the total flow, or throughput of gas, in torr-L/s, and S is the pumping speed in L/s.

The influx of gas, Q, can be a combination of a deliberate influx of process gas from an exterior source and gas originating in the system itself. With no external source, the base pressure achieved is frequently used as the principle indicator of system performance. The most important internal sources of gas are outgassing from the walls and permeation from the atmosphere, most frequently through elastomer O-rings. There may also be leaks, but these can readily be reduced to negligible levels by proper system design and construction. Vacuum pumps also contribute to background pressure, and here again careful selection and operation will minimize such problems.

The Problem of Outgassing

Of the sources of gas described above, outgassing is often the most important. With a new system, the origin of outgassing may be in the manufacture of the materials used in construction, in handling during construction, and in exposure of the system to the atmosphere. In general these sources scale with the area of the system walls, so that it is wise to minimize the surface area and to avoid porous materials in construction. For example, aluminum is an excellent choice for use in vacuum systems, but anodized aluminum has a porous oxide layer that provides an internal surface for gas adsorption many times greater than the apparent surface, making it much less suitable for use in vacuum.

The rate of outgassing in a new, unbaked system, fabricated from materials such as aluminum and stainless steel, is initially very high, on the order of 10^{-6} to 10^{-7} torr-L/s $\cdot$ cm^2 of surface area after one hour of exposure to vacuum (O'Hanlon, 1989). With continued pumping, the rate falls by one or two orders of magnitude during the first 24 hr, but thereafter drops very slowly over many months. Typically the main residual gas is water vapor. In a clean vacuum system, operating at ambient temperature and containing only a moderate number of O-rings, the lowest achievable pressure is usually 10^{-7} to mid-10^{-8} torr. The limiting factor is generally residual outgassing, not the capability of the high-vacuum pump.

The outgassing load is highest when a new system is put into service, but with steady use the sins of construction are slowly erased, and on each subsequent evacuation, the system will reach its typical base pressure more rapidly. However, water will persist as the major outgassing load. Every time a system is vented to air, the walls are exposed to moisture and one or more layers of water will adsorb virtually instantaneously. The amount adsorbed will be greatest when the relative humidity is high, increasing the time needed to reach base pressure. Water is bound by physical adsorption, a reversible process, but the binding energy of adsorption is so great that the rate of desorption is slow at ambient temperature. Physical adsorption involves van der Waal's forces, which are relatively weak. Physical adsorption should be distinguished from chemisorption, which typically involves the formation of chemical-type bonding of a gas to an atomically clean surface—for example, oxygen on a stainless steel surface. Chemisorption of gas is irreversible under all conditions normally encountered in a vacuum system. After the first few minutes of pumping, pressures are almost always in the free molecular flow regime, and when a water molecule is desorbed, it experiences only collisions with the walls, rather than with other molecules. Consequently, as it leaves the system, it is readsorbed many times, and on each occasion desorption is a slow process.

One way of accelerating the removal of adsorbed water is by purging at a pressure in the viscous flow region, using a dry gas such as nitrogen or argon. Under viscous flow conditions, the desorbed water molecules rarely reach the system walls, and readsorption is greatly reduced. A second method is to heat the system above its normal operating temperature.

Any process that reduces the adsorption of water in a vacuum system will improve the rate of pumpdown. The simplest procedure is to vent a vacuum system with a dry gas rather than with atmospheric air, and to minimize the time the system remains open following such a procedure. Dry air will work well, but it is usually more convenient to substitute nitrogen or argon.

From Equation 1, it is evident that there are two approaches to achieving a lower ultimate pressure, and hence a low impurity level, in a system. The first is to increase the effective pumping speed, and the second is to reduce the outgassing rate. There are severe limitations to the first approach. In a typical system, most of one wall of the chamber will be occupied by the connection to the high-vacuum pump; this limits the size of pump that can be used, imposing an upper limit on the achievable pumping speed. As already noted, the ultimate pressure achieved in an unbaked system having this configuration will rarely reach the mid-10^{-8} torr range. Even if one could mount a similar-sized pump on every side, the best to be expected would be a 6-fold improvement, achieving a base pressure barely into the 10^{-9} torr range, even after very long exhaust times.

It is evident that, to routinely reach pressures in the 10^{-10} torr range in a realistic period of time, a reduction in the rate of outgassing is necessary—e.g., by heating the vacuum system. Baking an entire system to 400°C for 16 hr can produce outgassing rates of 10^{-15} torr-L/s $\cdot$ cm^2 (Alpert, 1959), a reduction of 10^8 from those found after 1 hr of pumping at ambient temperature. The magnitude of this reduction shows that as large a portion as

possible of a system should be heated to obtain maximum advantage.

PRACTICAL ASPECTS OF VACUUM TECHNOLOGY

Vacuum Pumps

The operation of most vacuum systems can be divided into two regimes. The first involves pumping the system from atmosphere to a pressure at which a high-vacuum pump can be brought into operation. This is traditionally known as the rough vacuum regime and the pumps used are commonly referred to as roughing pumps. Clearly, a system that operates at an ultimate pressure within the capability of the roughing pump will require no additional pumps.

Once the system has been roughed down, a high-vacuum pump must be used to achieve lower pressures. If the high-vacuum pump is the type known as a transfer pump, such as a diffusion or turbomolecular pump, it will require the continuous support of the roughing pump in order to maintain the pressure at the exit of the high-vacuum pump at a tolerable level (in this phase of the pumping operation the function of the roughing pump has changed, and it is frequently referred to as a backing or forepump). Transfer pumps have the advantage that their capacity for continuous pumping of gas, within their operating pressure range, is limited only by their reliability. They do not accumulate gas, an important consideration where hazardous gases are involved. Note that the reliability of transfer pumping systems depends upon the satisfactory performance of two separate pumps. A second class of pumps, known collectively as capture pumps, require no further support from a roughing pump once they have started to pump. Examples of this class are cryogenic pumps and sputter-ion pumps. These types of pump have the advantage that the vacuum system is isolated from the atmosphere, so that system operation depends upon the reliability of only one pump. Their disadvantage is that they can provide only limited storage of pumped gas, and as that limit is reached, pumping will deteriorate. The effect of such a limitation is quite different for the two examples cited. A cryogenic pump can be totally regenerated by a brief purging at ambient temperature, but a sputter-ion pump requires replacement of its internal components. One aspect of the cryopump that should not be overlooked is that hazardous gases are stored, unchanged, within the pump, so that an unexpected failure of the pump can release these accumulated gases, requiring provision for their automatic safe dispersal in such an emergency.

Roughing Pumps

Two classes of roughing pumps are in use. The first type, the oil-sealed mechanical pump, is by far the most common, but because of the enormous concern in the semiconductor industry about oil contamination, a second type, the so-called "dry" pump, is now frequently used. In this context, "dry" implies the absence of volatile organics in the part of the pump that communicates with the vacuum system.

Oil-Sealed Pumps

The earliest roughing pumps used either a piston or liquid to displace the gas. The first production methods for incandescent lamps used such pumps, and the development of the oil-sealed mechanical pump by Gaede, around 1907, was driven by the need to accelerate the pumping process.

Applications. The modern versions of this pump are the most economic and convenient for achieving pressures as low as the 10^{-4} torr range. The pumps are widely used as a backing pump for both diffusion and turbomolecular pumps; in this application the backstreaming of mechanical pump oil is intercepted by the high vacuum pump, and a foreline trap is not required.

Operating Principles. The oil-sealed pump is a positive-displacement pump, of either the vane or piston type, with a compression ratio of the order of 10^5:1 (Dobrowolski, 1979). It is available as a single or two-stage pump, capable of reaching base pressures in the 10^{-2} and 10^{-4} torr range, respectively. The pump uses oil to maintain sealing, and to provide lubrication and heat transfer, particularly at the contact between the sliding vanes and the pump wall. Oil also serves to fill the significant dead space leading to the exhaust valve, essentially functioning as a hydraulic valve lifter and permitting the very high compression ratio.

The speed of such pumps is often quoted as the "free-air displacement," which is simply the volume swept by the pump rotor. In a typical two-stage pump this speed is sustained down to $\sim 1 \times 10^{-1}$ torr; below this pressure the speed decreases, reaching zero in the 10^{-5} torr range. If a pump is to sustain pressures near the bottom of its range, the required pump size must be determined from published pumping-speed performance data. It should be noted that mechanical pumps have relatively small pumping speed, at least when compared with typical high-vacuum pumps. A typical laboratory-sized pump, powered by a 1/3 hp motor, may have a speed of $\sim$3.5 cubic feet per minute (cfm), or rather less than 2 L/s, as compared to the smallest turbomolecular pump, which has a rated speed of 50 L/s.

Avoiding Oil Contamination from an Oil-Sealed Mechanical Pump. The versatility and reliability of the oil-sealed mechanical pump carries with it a serious penalty. When used improperly, contamination of the vacuum system is inevitable. These pumps are probably the most prevalent source of oil contamination in vacuum systems. The problem arises when thay are untrapped and pump a system down to its ultimate pressure, often in the free molecular flow regime. In this regime, oil molecules flow freely into the vacuum chamber. The problem can readily be avoided by careful control of the pumping procedures, but possible system or operator malfunction, leading to contamination, must be considered. For many years, it was common practice to leave a system in the standby condition evacuated only by an untrapped mechanical pump, making contamination inevitable.

Mechanical pump oil has a vapor pressure, at room temperature, in the low 10^{-5} torr range when first installed, but this rapidly deteriorates up to two orders of magnitude as the pump is operated (Holland, 1971). A pump operates at temperatures of 60°C, or higher, so the oil vapor pressure far exceeds 10^{-3} torr, and evaporation results in a substantial flux of oil into the roughing line. When a system at atmospheric pressure is connected to the mechanical pump, the initial gas flow from the vacuum chamber is in the viscous flow regime, and oil molecules are driven back to the pump by collisions with the gas being exhausted (Holland, 1971; Lewin, 1985). Provided the roughing process is terminated while the gas flow is still in the viscous flow regime, no significant contamination of the vacuum chamber will occur. The condition for viscous flow is given by the equation

$$PD \geq 0.5 \tag{2}$$

where P is the pressure in torr and D is the internal diameter of the roughing line in centimeters.

Termination of the roughing process in the viscous flow region is entirely practical when the high-vacuum pump is either a turbomolecular or modern diffusion pump (see precautions discussed under Diffusion Pumps and Turbomolecular Pumps, below). Once these pumps are in operation, they function as an effective barrier against oil migration into the system from the forepump. Hoffman (1979) has described the use of a continuous gas purge on the foreline of a diffusion-pumped system as a means of avoiding backstreaming from the forepump.

Foreline Traps. A foreline trap is a second approach to preventing oil backstreaming. If a liquid nitrogen–cooled trap is always in place between a forepump and the vacuum chamber, cleanliness is assured. But the operative word is "always." If the trap warms to ambient temperature, oil from the trap will migrate upstream, and this is much more serious if it occurs while the line is evacuated. A different class of trap uses an adsorbent for oil. Typical adsorbents are activated alumina, molecular sieve (a synthetic zeolite), a proprietary ceramic (Micromaze foreline traps; Kurt J. Lesker Co.), and metal wool. The metal wool traps have much less capacity than the other types, and unless there is evidence of their efficacy, they are best avoided. Published data show that activated alumina can trap 99% of the backstreaming oil molecules (Fulker, 1968). However, one must know when such traps should be reactivated. Unequivocal determination requires insertion of an oil-detection device, such as a mass spectrometer, on the foreline. The saturation time of a trap depends upon the rate of oil influx, which in turn depends upon the vapor pressure of oil in the pump and the conductance of the line between pump and trap. The only safe procedure is frequent reactivation of traps on a conservative schedule. Reactivation may be done by venting the system, replacing the adsorbent with a new charge, or by baking the adsorbent in a stream of dry air or inert gas to a temperature of ~300°C for several hours. Some traps can be regenerated by heating *in situ*, but only using a stream of inert gas, at a pressure in the viscous flow region, flowing from the system side of the trap to the pump (D.J. Santeler, pers. comm.). The foreline is isolated from the rest of the system and the gas flow is continued throughout the heating cycle, until the trap has cooled back to ambient temperature. An adsorbent foreline trap must be optically dense, so the oil molecules have no path past the adsorbent; commercial traps do not always fulfill this basic requirement. Where regeneration of the foreline trap has been totally neglected, acceptable performance may still be achieved simply because a diffusion pump or turbomolecular pump serves as the true "trap," intercepting the oil from the forepump.

Oil contamination can also result from improperly turning a pump off. If it is stopped and left under vacuum, oil frequently leaks slowly across the exhaust valve into the pump. When it is partially filled with oil, a hydraulic lock may prevent the pump from starting. Continued leakage will drive oil into the vacuum system itself; an interesting procedure for recovery from such a catastrophe has been described (Hoffman, 1979).

Whenever the pump is stopped, either deliberately or by power failure or other failure, automatic controls that first isolate it from the vacuum system, and then vent it to atmospheric pressure, should be used.

Most gases exhausted from a system, including oxygen and nitrogen, are readily removed from the pump oil, but some can liquify under maximum compression just before the exhaust valve opens. Such liquids mix with the oil and are more difficult to remove. They include water and solvents frequently used to clean system components. When pumping large volumes of air from a vacuum chamber, particularly during periods of high humidity (or whenever solvent residues are present), it is advantageous to use a gas-ballast feature commonly fitted to two-stage and also to some single-stage pumps. This feature admits air during the final stage of compression, raising the pressure and forcing the exhaust valve to open before the partial pressure of water has reached saturation. The ballast feature minimizes pump contamination and reduces pump-down time for a chamber exposed to humid air, although at the cost of about ten-times-poorer base pressure.

Oil-Free ("Dry") Pumps

Many different types of oil-free pumps are available. We will emphasize those that are most useful in analytical and diagnostic applications.

Diaphragm Pumps

Applications: Diaphragm pumps are increasingly used where the absence of oil is an imperative, for example, as the forepump for compound turbomolecular pumps that incorporate a molecular drag stage. The combination renders oil contamination very unlikely. Most diaphragm pumps have relatively small pumping speeds. They are adequate once the system pressure reaches the operating range of a turbomolecular pump, usually well below 10^{-2} torr, but not for rapidly roughing down a large volume. Pumps are available with speeds up to several liters per second, and base pressures from a few torr to as low as 10^{-3} torr, lower ultimate pressures being associated with the lower-speed pumps.

Operating Principles: Four diaphragm modules are often arranged in three separate pumping stages, with the lowest-pressure stage served by two modules in tandem to boost the capacity. Single modules are adequate for subsequent stages, since the gas has already been compressed to a smaller volume. Each module uses a flexible diaphragm of Viton or other elastomer, as well as inlet and outlet valves. In some pumps the modules can be arranged to provide four stages of pumping, providing a lower base pressure, but at lower pumping speed because only a single module is employed for the first stage. The major required maintenance in such pumps is replacement of the diaphragm after 10,000 to 15,000 hr of operation.

Scroll Pumps

Applications: Scroll pumps (Coffin, 1982; Hablanian, 1997) are used in some refrigeration systems, where the limited number of moving parts is reputed to provide high reliability. The most recent versions introduced for general vacuum applications have the advantages of diaphragm pumps, but with higher pumping speed. Published speeds on the order of 10 L/s and base pressures below 10^{-2} torr make this an appealing combination. Speeds decline rapidly at pressures below $\sim 2 \times 10^{-2}$ torr.

Operating Principles: Scroll pumps use two enmeshed spiral components, one fixed and the other orbiting. Successive crescent-shaped segments of gas are trapped between the two scrolls and compressed from the inlet (vacuum side) toward the exit, where they are vented to the atmosphere. A sophisticated and expensive version of this pump has long been used for processes where leaktight operation and noncontamination are essential, for example, in the nuclear industry for pumping radioactive gases. An excellent description of the characteristics of this design has been given by Coffin (1982). In this version, extremely close tolerances (10 μm) between the two scrolls minimize leakage between the high- and low-pressure ends of the scrolls. The more recent pump designs, which substitute Teflon-like seals for the close tolerances, have made the pump an affordable option for general oil-free applications. The life of the seals is reported to be in the same range as that of the diaphragm in a diaphragm pump.

Screw Compressor. Although not yet widely used, pumps based on the principle of the screw compressor, such as that used in supercharging some high-performance cars, appear to offer some interesting advantages: i.e., pumping speeds in excess of 10 L/s, direct discharge to the atmosphere, and ultimate pressures in the 10^{-3} torr range. If such pumps demonstrate high reliability in diverse applications, they constitute the closest alternative, in a single-unit "dry" pump, to the oil-sealed mechanical pump.

Molecular Drag Pump

Applications: The molecular drag pump is useful for applications requiring pressures in the 1 to 10^{-7} torr range and freedom from organic contamination. Over this range the pump permits a far higher throughput of gas, compared to a standard turbomolecular pump. It has also been used in the compound turbomolecular pump as an integral backing stage. This will be discussed in detail under Turbomolecular Pumps.

Operating Principles: The pump uses one or more drums rotating at speeds as high as 90,000 rpm inside stationary, coaxial housings. The clearance between drum and housing is ~0.3 mm. Gas is dragged in the direction of rotation by momentum transfer to the pump exit along helical grooves machined in the housing. The bearings of these devices are similar to those in turbomolecular pumps (see discussion of Turbomolecular Pumps, below). An internal motor avoids difficulties inherent in a high-speed vacuum seal. A typical pump uses two or more separate stages, arranged in series, providing a compression ratio as high as $1{:}10^7$ for air, but typically less than $1{:}10^3$ for hydrogen. It must be supported by a backing pump, often of the diaphragm type, that can maintain the forepressure below a critical value, typically 10 to 30 torr, depending upon the particular design. The much lower compression ratio for hydrogen, a characteristic shared by all turbomolecular pumps, will increase its percentage in a vacuum chamber, a factor to consider in rare cases where the presence of hydrogen affects the application.

Sorption Pumps

Applications: Sorption pumps were introduced for roughing down ultrahigh vacuum systems prior to turning on a sputter-ion pump (Welch, 1991). The pumping speed of a typical sorption pump is similar to that of a small oil-sealed mechanical pump, but they are rather awkward in application. This is of little concern in a vacuum system likely to run many months before venting to the atmosphere. Occasional inconvenience is a small price for the ultimate in contamination-free operation.

Operating Principles: A typical sorption pump is a cannister containing ~3 lb of a molecular sieve material that is cooled to liquid nitrogen temperature. Under these conditions the molecular sieve can adsorb $\sim 7.6 \times 10^4$ torr-liter of most atmospheric gases; exceptions are helium and hydrogen, which are not significantly adsorbed, and neon, which is adsorbed to a limited extent. Together, these gases, if not pumped, would leave a residual pressure in the 10^{-2} torr range. This is too high to guarantee the trouble-free start of a sputter-ion pump, but the problem is readily avoided. For example, a sorption pump connected to a vacuum chamber of ~100 L volume exhausts air to a pressure in the viscous flow region, say 5 torr, and then is valved off. The nonadsorbing gases are swept into the pump along with the adsorbed gases; the pump now contains a fraction (760–5)/760 or 99.3% of the nonadsorbable gases originally present, leaving hydrogen, helium, and neon in the low 10^{-4} torr range in the vacuum chamber. A second sorption pump on the vacuum chamber will then readily achieve a base pressure below 5×10^{-4} torr, quite adequate to start even a recalcitrant ion pump.

High-Vacuum Pumps

Four types of high-vacuum pumps are in general use: diffusion, turbomolecular, cryosorption, and sputter-ion.

Each of these classes has advantages, and also some problems, and it is vital to consider both sides for a particular application. Any of these pumps can be used for ultimate pressures in the ultrahigh vacuum region and to maintain a working chamber that is substantially free from organic contamination. The choice of system rests primarily on the ease and reliability of operation in a particular environment, and inevitably on the capital and running costs.

Diffusion Pumps

Applications: The practical diffusion pump was invented by Langmuir in 1916, and this is the most common high-vacuum pump when all vacuum applications are considered. It is far less dominant where avoidance of organic contamination is essential. Diffusion pumps are available in a wide range of sizes, with speeds of up to 50,000 L/s; for such high-speed pumping only the cryopump seriously competes.

A diffusion pump can give satisfactory service in a number of situations. One such case is in a large system in which cleanliness is not critical. Contamination problems of diffusion-pumped systems have actually been somewhat overstated. Commercial processes using highly reactive metals are routinely performed using diffusion pumps. When funds are scarce, a diffusion pump, which incurs the lowest capital cost of any of the high-vacuum alternatives, is often selected. The continuing costs of operation, however, are higher than for the other pumps, a factor not often considered.

An excellent detailed discussion of diffusion pumps is available (Hablanian, 1995).

Operating Principles: A diffusion pump normally contains three or more oil jets operating in series. It can be operated at a maximum inlet pressure of $\sim 1 \times 10^{-3}$ torr and maintains a stable pumping speed down to 10^{-10} torr or lower. As a transfer pump, the total amount of gas it can pump is limited only by its reliability, and accumulation of any hazardous gas is not a problem. However, there are a number of key requirements in maintaining its operation. First, the outlet of the pump must be kept below some maximum pressure, which can, however, be as high as the mid-10^{-1} torr range. If the pressure exceeds this limit, all oil jets in the pump collapse and the pumping stops. Consequently the forepump (often called the backing pump) must operate continuously. Other services that must be maintained without interruption include water or air cooling, electrical power to the heater, and refrigeration, if a trap is used, to prevent oil backstreaming. A major drawback of this type of pump is the number of such criteria.

The pump oil undergoes continuous thermal degradation. However, the extent of such degradation is small, and an oil charge can last for many years. Oil decomposition products have considerably higher vapor pressure than their parent molecules. Therefore modern pumps are designed to continuously purify the working fluid, ejecting decomposition products toward the forepump. In addition, any forepump oil reaching the diffusion pump has a much higher vapor pressure than the working fluid, and it too must be ejected. The purification mechanism primarily involves the oil from the pump jet, which is cooled at the pump wall and returns, by gravity, to the boiler. The cooling area extends only past the lowest pumping jet, below which returning oil is heated by conduction from the boiler, boiling off any volatile fraction, so that it flows toward the forepump. This process is greatly enhanced if the pump is fitted with an ejector jet, directed toward the foreline; the jet exhausts the volume directly over the boiler, where the decomposition fragments are vaporized. A second step to minimize the effect of oil decomposition is to design the heater and supply tubes to the jets so that the uppermost jet, i.e., that closest to the vacuum chamber, is supplied with the highest-boiling-point oil fraction. This oil, when condensed on the upper end of the pump wall, has the lowest possible vapor pressure. It is this film of oil that is a major source of backstreaming into the vacuum chamber.

The selection of the oil used is important (O'Hanlon, 1989). If minimum backstreaming is essential, one can select an oil that has a very low vapor pressure at room temperature. A polyphenyl ether, such as Santovac 5, or a silicone oil, such as DC705, would be appropriate. However, for the most oil-sensitive applications, it is wise to use a liquid nitrogen (LN2) temperature trap between pump and vacuum chamber. Any cold trap will reduce the system base pressure, primarily by pumping water vapor, but to remove oil to a partial pressure well below 10^{-11} torr it is essential that molecules make at least two collisions with surfaces at LN2 temperature. Such traps are thermally isolated from ambient temperature and only need cryogen refills every 8 hr or more. With such a trap, the vapor pressure of the pump oil is secondary, and a less expensive oil may be used.

If a pump is exposed to substantial flows of reactive gases or to oxygen, either because of a process gas flow or because the chamber must be frequently pumped down after venting to air, the chemical stability of the oil is important. Silicone oils are very resistant to oxidation, while perfluorinated oils are stable against both oxygen and many reactive gases.

When a vacuum chamber includes devices such as mass spectrometers, which depend upon maintaining uniform electrical potential on electrodes, silicone oils can be a problem, because on decomposition they may deposit insulating films on electrodes.

Operating Procedures: A vacuum chamber free from organic contamination pumped by a diffusion pump requires stringent operating procedures. While the pump is warming, high backstreaming occurs until all jets are in full operation, so the chamber must be protected during this phase, either by a LN2 trap, before the pressure falls below the viscous flow regime, or by an isolation valve.

The chamber must be roughed down to some predetermined pressure before opening to the diffusion pump. This cross-over pressure requires careful consideration. Procedures to minimize the backstreaming for the frequently used oil-sealed mechanical pump have already been discussed (see Oil-Sealed Pumps). If a trap is used, one can safely rough down the chamber to the ultimate pressure of the pump. Alternatively, backstreaming can be minimized

by limiting the exhaust to the viscous flow regime. This procedure presents a potential problem. The vacuum chamber will be left at a pressure in the 10^{-1} torr range, but sustained operation of the diffusion pump must be avoided when its inlet pressure exceeds 10^{-3} torr. Clearly, the moment the isolation valve between diffusion pump and the roughed-down vacuum chamber is opened, the pump will suffer an overload of at least two decades pressure. In this condition, the upper jet of the pump will be overwhelmed and backstreaming will rise. If the diffusion pump is operated with a LN2 trap, this backstreaming will be intercepted. But, even with an untrapped diffusion pump, the overload condition rarely lasts more than 10 to 20 s, because the pumping speed of a diffusion pump is very high, even with one inoperative jet. Consequently, the backstreaming from roughing and high-vacuum pumps remains acceptable for many applications.

Where large numbers of different operators use a system, fully automatic sequencing and safety interlocks are recommended to reduce the possibility of operator error. Diffusion pumps are best avoided if simplicity of operation is essential and freedom from organic contamination is paramount.

Turbomolecular Pumps

Applications: Turbomolecular pumps were introduced in 1958 (Becker, 1959) and were immediately hailed as the solution to all of the problems of the diffusion pump. Provided that recommended procedures are used, these pumps live up to the original high expectations.

These are reliable, general-purpose pumps requiring simple operating procedures and capable of maintaining clean vacuum down to the 10^{-10} torr range. Pumping speeds up to 10,000 L/s are available.

Operating Principles: The pump is a multistage axial compressor, operating at rotational speeds from around 20,000 to 90,000 rpm. The drive motor is mounted inside the pump housing, avoiding the shaft seal needed with an external drive. Modern power supplies sense excessive loading of the motor, as when operating at too high an inlet pressure, and reduce the motor speed to avoid overheating and possible failure. Occasional failure of the frequency control in the supply has resulted in excessive speeds and catastrophic failure of the rotor.

At high speeds, the dominant problem is maintenance of the rotational bearings. Careful balancing of the rotor is essential; in some models bearings can be replaced in the field, if rigorous cleanliness is assured, preferably in a clean environment such as a laminar-flow hood. In other designs, the pump must be returned to the manufacturer for bearing replacement and rotor rebalancing. This service factor should be considered in selecting a turbomolecular pump, since few facilities can keep a replacement pump on hand.

Several different types of bearings are common in turbomolecular pumps:

1. *Oil Lubrication*. All first-generation pumps used oil-lubricated bearings that often lasted several years in continuous operation. These pumps were mounted horizontally with the gas inlet between two sets of blades. The bearings were at the ends of the rotor shaft, on the forevacuum side. This type of pump, and the magnetically levitated designs discussed below, offer minimum vibration.

   Second-generation pumps are vertically mounted and single-ended. This is more compact, facilitating easy replacement of a diffusion pump. Many of these pumps rely on gravity return of lubrication oil to the reservoir and thus require vertical orientation. Using a wick as the oil reservoir both localizes the liquid and allows more flexible pump orientation.
2. *Grease Lubrication*: A low-vapor-pressure grease lubricant was introduced to reduce transport of oil into the vacuum chamber (Osterstrom, 1979) and to permit orientation of the pump in any direction. Grease has lower frictional loss and allows a lower-power drive motor, with consequent drop in operating temperature.
3. *Ceramic Ball Bearings*: Most bearings now use a ceramic-balls/steel-race combination; the lighter balls reduce centrifugal forces and the ceramic-to-steel interface minimizes galling. There appears to be a significant improvement in bearing life for both oil and grease lubrication systems.
4. *Magnetic Bearings*: Magnetic suspension systems have two advantages: a non-contact bearing with a potentially unlimited life, and very low vibration. First-generation pumps used electromagnetic suspension with a battery backup. When nickel-cadmium batteries were used, this backup was not continuously available; incomplete discharge before recharging cycles often reduces discharge capacity. A second generation using permanent magnets was more reliable and of lower cost. Some pumps now offer an improved electromagnetic suspension with better active balancing of the rotor on all axes. In some designs, the motor is used as a generator when power is interrupted, to assure safe shutdown of the magnetic suspension system. Magnetic bearing pumps use a second set of "touch-down" bearings for support when the pump is stationary. The bearings use a solid, low-vapor-pressure lubricant (O'Hanlon, 1989) and further protect the pump in an emergency. The life of the touch-down bearings is limited, and their replacement may be a nuisance; it is, however, preferable to replacing a shattered pump rotor and stator assembly.
5. *Combination Bearings Systems*: Some designs use combinations of different types of bearings. One example uses a permanent-magnet bearing at the high-vacuum end and an oil-lubricated bearing at the forevacuum end. A magnetic bearing does not contaminate the system and is not vulnerable to damage by aggressive gases as is a lubricated bearing. Therefore it can be located at the very end of the rotor shaft, while the oil-fed bearing is at the opposite forevacuum end. This geometry has the advantage of minimizing vibration.

Problems with Pumping Reactive Gases: Very reactive gases, common in the semiconductor industry, can result in rapid bearing failure. A purge with nonreactive gas, in the viscous flow regime, can prevent the pumped gases from contacting the bearings. To permit access to the bearing for a purge, pump designs move the upper bearing below the turbine blades, which often cantilevers the center of mass of the rotor beyond the bearings. This may have been a contributing factor to premature failure seen in some pump designs.

The turbomolecular pump shares many of the performance characteristics of the diffusion pump. In the standard construction, it cannot exhaust to atmospheric pressure, and must be backed at all times by a forepump. The critical backing pressure is generally in the 10^{-1} torr, or lower, region, and an oil-sealed mechanical pump is the most common choice. Failure to recognize the problem of oil contamination from this pump was a major factor in the problems with early applications of the turbomolecular pump. But, as with the diffusion pump, an operating turbomolecular pump prevents significant backstreaming from the forepump and its own bearings. A typical turbomolecular pump compression ratio for heavy oil molecules, $\sim 10^{12}$:1, ensures this. The key to avoiding oil contamination during evacuation is the pump reaching its operating speed as soon as is possible.

In general, turbomolecular pumps can operate continuously at pressures as high as 10^{-2} torr and maintain constant pumping speed to at least 10^{-10} torr. As the turbomolecular pump is a transfer pump, there is no accumulation of hazardous gas, and less concern with an emergency shutdown situation. The compression ratio is $\sim 10^{8}$:1 for nitrogen, but frequently below 1000:1 for hydrogen. Some first-generation pumps managed only 50:1 for hydrogen. Fortunately, the newer compound pumps, which add an integral molecular drag backing pump, often have compression ratios for hydrogen in excess of 10^{5}:1. The large difference between hydrogen (and to a lesser extent helium) and gases such as nitrogen and oxygen leaves the residual gas in the chamber enriched in the lighter species. If a low residual hydrogen pressure is an important consideration, it may be necessary to provide supplementary pumping for this gas, such as a sublimation pump or nonevaporable getter (NEG), or to use a different class of pump.

The demand for negligible organic compound contamination has led to the compound pump, comprising a standard turbomolecular stage backed by a molecular drag stage, mounted on a common shaft. Typically, a backing pressure of only 10 torr or higher, conveniently provided by an oil-free ("dry") diaphragm pump, is needed (see discussion of Oil-Free Pumps). In some versions, greased or oil-lubricated bearings are used (on the high-pressure side of the rotor); magnetic bearings are also available. Compound pumps provide an extremely low risk of oil contamination and significantly higher compression ratios for light gases.

Operation of a Turbomolecular Pump System: Freedom from organic contamination demands care during both the evacuation and venting processes. However, if a pump is contaminated with oil, the cleanup requires disassembly and the use of solvents.

The following is a recommended procedure for a system in which an untrapped oil-sealed mechanical roughing/backing pump is combined with an oil-lubricated turbomolecular pump, and an isolation valve is provided between the vacuum chamber and the turbomolecular pump.

1. *Startup*: Begin roughing down and turn on the pump as soon as is possible without overloading the drive motor. Using a modern electronically controlled supply, no delay is necessary, because the supply will adjust power to prevent overload while the pressure is high. With older power supplies, the turbomolecular pump should be started as soon as the pressure reaches a tolerable level, as given by the manufacturer, probably in the 10 torr region. A rapid startup ensures that the turbomolecular pump reaches at least 50% of the operating speed while the pressure in the foreline is still in the viscous flow regime, so that no oil backstreaming can enter the system through the turbomolecular pump.

   Before opening to the turbomolecular pump, the vacuum chamber should be roughed down using a procedure to avoid oil contamination, as was described for diffusion pump startup (see discussion above).
2. *Venting*: When the entire system is to be vented to atmospheric pressure, it is essential that the venting gas enter the turbomolecular pump at a point on the system side of any lubricated bearings in the pump. This ensures that oil liquid or vapor is swept away from the system towards the backing system. Some pumps have a vent midway along the turbine blades, while others have vents just above the upper, system-side, bearings. If neither of these vent points are available, a valve must be provided on the vacuum chamber itself. Never vent the system from a point on the foreline of the turbomolecular pump; that can flush both mechanical pump oil and turbomolecular pump oil into the turbine rotor and stator blades and the vacuum chamber. Venting is best started immediately after turning off the power to the turbomolecular pump and adjusting so the chamber pressure rises into the viscous flow region within a minute or two. Too-rapid venting exposes the turbine blades to excessive pressure in the viscous flow regime, with unnecessarily high upward force on the bearing assembly (often called the "helicopter" effect). When venting frequently, the turbomolecular pump is usually left running, isolated from the chamber, but connected to the forepump.

The major maintenance is checking the oil or grease lubrication, as recommended by the pump manufacturer, and replacing the bearings as required. The stated life of bearings is often $\sim$2 years continuous operation, though an actual life of $\geq$5 years is not uncommon. In some facilities, where multiple pumps are used in production, bearings are checked by monitoring the amplitude of the

vibration frequency associated with the bearings. A marked increase in amplitude indicates the approaching end of bearing life, and the pump is removed for maintenance.

Cryopumps

Applications: Cryopumping was first extensively used in the space program, where test chambers modeled the conditions encountered in outer space, notably that by which any gas molecule leaving the vehicle rarely returns. This required all inside surfaces of the chamber to function as a pump, and led to liquid-helium-cooled shrouds in the chambers on which gases condensed. This is very effective, but is not easily applicable to individual systems, given the expense and difficulty of handling liquid helium. However, the advent of reliable closed-cycle mechanical refrigeration systems, achieving temperatures in the 10 to 20 K range, allow reliable, contamination-free pumps, with a wide range of pumping speeds, and which are capable of maintaining pressures as low as the 10^{-10} torr range (Welch, 1991).

Cryopumps are general purpose and available with very high pumping speeds (using internally mounted cryopanels), so they work for all chamber sizes. These are capture pumps, and, once operating, are totally isolated from the atmosphere. All pumped gas is stored in the body of the pump. They must be regenerated on a regular basis, but the quantity of gas pumped before regeneration is very large for all gases that are captured by condensation. Only helium, hydrogen, and neon are not effectively condensed. They must be captured by adsorption, for which the capacity is far smaller. Indeed, if pumping any significant quantity of helium, regeneration would have to be so frequent that another type of pump should be selected. If the refrigeration fails due to a power interruption or a mechanical failure, the pumped gas will be released within minutes. All pumps are fitted with a pressure relief valve to avoid explosion, but provision must be made for the safe disposal of any hazardous gases released.

Operating Principles: A cryopump uses a closed-cycle refrigeration system with helium as the working gas. An external compressor, incorporating a heat exchanger that is usually water-cooled, supplies helium at ~300 psi to the cold head, which is mounted on the vacuum system. The helium is cooled by passing through a pair of regenerative heat exchangers in the cold head, and then allowed to expand, a process which cools the incoming gas, and in turn, cools the heat exchangers as the low-pressure gas returns to the compressor. Over a period of several hours, the system develops two cold zones, nominally 80 and 15 K. The ~80 K zone is used to cool a shroud through which gas molecules pass into its interior; water is pumped by this shroud, and it also minimizes the heat load on the second-stage array from ambient temperature radiation. Inside the shroud is an array at ~15 K, on which most other gases are condensed. The energy available to maintain the 15 K temperature is just a few watts.

The second stage should typically remain in the range 10 to 20 K, low enough to pump most common gases to well below 10^{-10} torr. In order to remove helium, hydrogen, and neon the modern cryopump incorporates a bed of charcoal, having a very large surface area, cooled by the second-stage array. This bed is so positioned that most gases are first removed by condensation, leaving only these three to be physically adsorbed.

As already noted, the total pumping capacity of a cryopump is very different for the gases that are condensed, as compared to those that are adsorbed. The capacity of a pump is frequently quoted for argon, commonly used in sputtering systems. For example, a pump with a speed of ~1000 L/s will have the capability of pumping $\sim 3 \times 10^5$ torr-liter of argon before requiring regeneration. This implies that a 200-L volume could be pumped down from a typical roughing pressure of 2.5×10^{-1} torr ~6000 times. The pumping speed of a cryopump remains constant for all gases that are condensable at 20 K, down to the 10^{-10} torr range, so long as the temperature of the second-stage array does not exceed 20 K. At this temperature the vapor pressure of nitrogen is $\sim 1 \times 10^{-11}$ torr, and that of all other condensable gases lies well below this figure.

The capacity for adsorption-pumped gases is not nearly so well defined. The capacity increases both with decreasing temperature and with the pressure of the adsorbing gas. The temperature of the second-stage array is controlled by the balance between the refrigeration capacity and generation of heat by both condensation and adsorption of gases. Of necessity, the heat input must be limited so that the second-stage array never exceeds 20 K, and this translates into a maximum permissible gas flow into the pump. The lowest temperature of operation is set by the pump design, nominally ~10 K. Consequently the capacity for adsorption of a gas such as hydrogen can vary by a factor of four or more when between these two temperature extremes. For a given flow of hydrogen, if this is the only gas being pumped, the heat input will be low, permitting a higher pumping capacity, but if a mixture of gases is involved, then the capacity for hydrogen will be reduced, simply because the equilibrium operating temperature will be higher. A second factor is the pressure of hydrogen that must be maintained in a particular process. Because the adsorption capacity is determined by this pressure, a low hydrogen pressure translates into a reduced adsorptive capacity, and therefore a shorter operating time before the pump must be regenerated. The effect of these factors is very significant for helium pumping, because the adsorption capacity for this gas is so limited. A cryopump may be quite impractical for any system in which there is a deliberate and significant inlet of helium as a process gas.

Operating Procedure: Before startup, a cryopump must first be roughed down to some recommended pressure, often $\sim 1 \times 10^{-1}$ torr. This serves two functions. First, the vacuum vessel surrounding the cold head functions as a Dewar, thermally isolating the cold zone. Second, any gas remaining must be pumped by the cold head as it cools down; because adsorption is always effective at a much higher temperature than condensation, the gas is adsorbed in the charcoal bed of the 20 K array, partially saturating it, and limiting the capacity for subsequently adsorbing helium, hydrogen, and neon. It is essential to

avoid oil contamination when roughing down, because oil vapors adsorbed on the charcoal of the second-stage array cannot be removed by regeneration and irreversibly reduce the adsorptive capacity. Once the required pressure is reached, the cryopump is isolated from the roughing line and the refrigeration system is turned on. When the temperature of the second-stage array reaches 20 K, the pump is ready for operation, and can be opened to the vacuum chamber, which has previously been roughed down to a selected cross-over pressure. This cross-over pressure can readily be calculated from the figure for the impulse gas load, specified by the manufacturer, and the volume of the chamber. The impulse load is simply the quantity of gas to which the pump can be exposed without increasing the temperature of the second-stage array above 20 K.

When the quantity of gas that has been pumped is close to the limiting capacity, the pump must be regenerated. This procedure involves isolation from the system, turning off the refrigeration unit, and warming the first- and second-stage arrays until all condensed and adsorbed gas has been removed. The most common method is to purge these gases using a warm (~60°C) dry gas, such as nitrogen, at atmospheric pressure. Internal heaters were deliberately avoided for many years, to avoid an ignition source in the event that explosive gas mixtures, such as hydrogen and oxygen, were released during regeneration. To the same end, the use of any pressure sensor having a hot surface was, and still is, avoided in the regeneration procedure. Current practice has changed, and many pumps now incorporate a means of independently heating each of the refrigerated surfaces. This provides the flexibility to heat the cold surfaces only to the extent that adsorbed or condensed gases are rapidly removed, greatly reducing the time needed to cool back to the operating temperature. Consider, for example, the case where argon is the predominant gas load. At the maximum operating temperature of 20 K, its vapor pressure is well below 10^{-11} torr, but warming to 90 K raises the vapor pressure to 760 torr, facilitating rapid removal.

In certain cases, the pumping of argon can cause a problem commonly referred to as argon hangup. This occurs after a high pressure of argon, e.g., $>1 \times 10^{-3}$ torr, has been pumped for some time. When the argon influx stops, the argon pressure remains comparatively high instead of falling to the background level. This happens when the temperature of the pump shroud is too low. At 40 K, in contrast to 80 K, argon condenses on the outer shroud instead of being pumped by the second-stage array. Evaporation from the shroud at the argon vapor pressure of 1×10^{-3} torr keeps the partial pressure high until all of the gas has desorbed. The problem arises when the refrigeration capacity is too large, for example, when several pumps are served by a single compressor and the helium supply is improperly proportioned. An internal heater to increase the shroud temperature is an easy solution.

A cryopump is an excellent general-purpose device. It can provide an extremely clean environment at base pressures in the low 10^{-10} torr range. Care must be taken to ensure that the pressure-relief valve is always operable, and to ensure that any hazardous gases are safely handled in the event of an unscheduled regeneration. There is some possibility of energetic chemical reactions during regeneration. For example, ozone, which is generated in some processes, may react with combustible materials. The use of a nonreactive purge gas will minimize hazardous conditions if the flow is sufficient to dilute the gases released during regeneration. The pump has a high capital cost and fairly high running costs for power and cooling.

Maintenance of a cryopump is normally minimal. Seals in the displacer piston in the cold head must be replaced as required (at intervals of one year or more, depending on the design); an oil-adsorber cartridge in the compressor housing requires a similar replacement schedule.

Sputter-Ion Pumps

Applications: These pumps were originally developed for ultrahigh vacuum (UHV) systems and are admirably suited to this application, especially if the system is rarely vented to atmospheric pressure. Their main advantages are as follows.

1. High reliability, because of no moving parts.
2. The ability to bake the pump up to 400°C, facilitating outgassing and rapid attainment of UHV conditions.
3. Fail-safe operation if on a leak-tight UHV system. If the power is interrupted, a moderate pressure rise will occur; the pump retains some pumping capacity by gettering. When power is restored, the base pressure is normally reestablished rapidly.
4. The pump ion current indicates the pressure in the pump itself, which is useful as a monitor of performance.

Sputter-ion pumps are not suitable for the following uses.

1. On systems with a high, sustained gas load or frequent venting to atmosphere.
2. Where a well-defined pumping speed for all gases is required. This limitation can be circumvented with a severely conductance-limited pump, so the speed is defined by conductance rather than by the characteristics of the pump itself.

Operating Principles: The operating mechanisms of sputter-ion pumps are very complex indeed (Welch, 1991). Crossed electrostatic and magnetic fields produce a confined discharge using a geometry originally devised by Penning (1937) to measure pressure in a vacuum system. A trapped cloud of electrons is produced, the density of which is highest in the 10^{-4} torr region, and falls off as the pressure decreases. High-energy ions, produced by electron collision, impact on the pump cathodes, sputtering reactive cathode material (titanium, and to a lesser extent, tantalum), which is deposited on all surfaces within line-of sight of the impact area. The pumping mechanisms include the following.

1. Chemisorption on the sputtered cathode material, which is the predominant pumping mechanism for reactive gases.

2. Burial in the cathodes, which is mainly a transient contributor to pumping. With the exception of hydrogen, the atoms remain close to the surface and are released as pumping/sputtering continues. This is the source of the "memory" effect in diode ion pumps; previously pumped species show up as minor impurities when a different gas is pumped.
3. Burial of ions back-scattered as neutrals, in all surfaces within line-of sight of the impact area. This is a crucial mechanism in the pumping of argon and other noble gases (Jepsen, 1968).
4. Dissociation of molecules by electron impact. This is the mechanism for pumping methane and other organic molecules.

The pumping speed of these pumps is variable. Typical performance curves show the pumping of a single gas under steady-state conditions. Figure 1 shows the general characteristic as a function of pressure. Note the pronounced drop with falling pressure. The original commercial pumps used anode cells the order of 1.2 cm in diameter and had very low pumping speeds even in the 10^{-9} torr range. However, newer pumps incorporate at least some larger anode cells, up to ~2.5 cm diameter, and the useful pumping speed is extended into the 10^{-11} torr range (Rutherford, 1963).

The pumping speed of hydrogen can change very significantly with conditions, falling off drastically at low pressures and increasing significantly at high pressures (Singleton, 1969, 1971; Welch, 1994). The pumped hydrogen can be released under some conditions, primarily during the startup phase of a pump. When the pressure is 10^{-3} torr or higher, the internal temperatures can readily reach 500°C (Snouse, 1971). Hydrogen is released, increasing the pressure and frequently stalling the pumpdown.

Rare gases are not chemisorbed, but are pumped by burial (Jepsen, 1968). Argon is of special importance, because it can cause problems even when pumping air. The release of argon, buried as atoms in the cathodes, sometimes causes a sudden increase in pressure of as much as three decades, followed by renewed pumping, and a concomitant drop in pressure. The unstable behavior is repeated at regular intervals, once initiated (Brubaker, 1959). This problem can be avoided in two ways.

1. By use of the "differential ion" or DI pump (Tom and James, 1969), which is a standard diode pump in which a tantalum cathode replaces one titanium cathode.
2. By use of the triode sputter-ion pump, in which a third electrode is interposed between the ends of the cylindrical anode and the pump walls. The additional electrode is maintained at a high negative potential, serving as a sputter cathode, while the anode and walls are maintained at ground potential. This pump has the additional advantage that the "memory" effect of the diode pump is almost completely suppressed.

The operating life of a sputter-ion pump is inversely proportional to the operating pressure. It terminates when the cathodes are completely sputtered through at a small area on the axis of each anode cell where the ions impact. The life therefore depends upon the thickness of the cathodes at the point of ion impact. For example, a conventional triode pump has relatively thin cathodes as compared to a diode pump, and this is reflected in the expected life at an operating pressure of 1×10^{-6} torr, i.e., 35,000 as compared to 50,000 hr.

The fringing magnetic field in older pumps can be very significant. Some newer pumps greatly reduce this problem. A vacuum chamber can be exposed to ultraviolet and x radiation, as well as ions and electrons produced by an ion pump, so appropriate electrical and optical shielding may be required.

Operating Procedures: A sputter-ion pump must be roughed down before it can be started. Sorption pumps or any other clean technique can be used. For a diode pump, a pressure in the 10^{-4} torr range is recommended, so that the Penning discharge (and associated pumping mechanisms) will be immediately established. A triode pump can safely be started at pressures about a decade higher than the diode, because the electrostatic fields are such that the walls are not subjected to ion bombardment

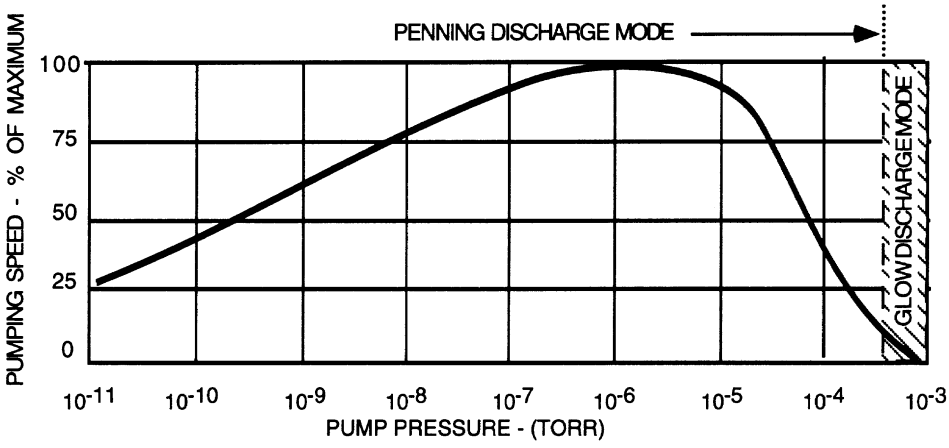

Figure 1. Schematic representation of the pumping speed of a diode sputter-ion pump as a function of pressure.

(Snouse, 1971). An additional problem develops in pumps that have operated in hydrogen or water vapor. Hydrogen accumulates in the cathodes and this gas is released when the cathode temperatures increase during startup. The higher the pressure, the greater the temperature; temperatures as high as 900°C have been measured at the center of cathodes under high gas loads (Jepsen, 1967).

An isolation valve should be used to avoid venting the pump to atmospheric pressure. The sputtered deposits on the walls of a pump adsorb gas with each venting, and the bonding of subsequently sputtered material will be reduced, eventually causing flaking of the deposits. The flakes can serve as electron emitters, sustaining localized (non-pumping) discharges and can also short out the electrodes.

Getter Pumps. Getter pumps depend upon the reaction of gases with reactive metals as a pumping mechanism; such metals were widely used in electronic vacuum tubes, being described as getters (Reimann, 1952). Production techniques for the tubes did not allow proper outgassing of tube components, and the getter completed the initial pumping on the new tube. It also provided continuous pumping for the life of the device.

Some practical getters used a "flash getter," a stable compound of barium and aluminum that could be heated, using an RF coil, once the tube had been sealed, to evaporate a mirror-like barium deposit on the tube wall. This provided a gettering surface that operated close to ambient temperature. Such films initially offer rapid pumping, but once the surface is covered, a much slower rate of pumping is sustained by diffusion into the bulk of the film. These getters are the forerunners of the modern sublimation pump.

A second type of getter used a reactive metal, such as titanium or zirconium wire, operated at elevated temperature; gases react at the metal surface to produce stable, low-vapor-pressure compounds that then diffuse into the interior, allowing a sustained reaction at the surface. These getters are the forerunners or the modern nonevaporable getter (NEG).

Sublimation pumps

Applications: Sublimation pumps are frequently used in combination with a sputter-ion pump, to provide high-speed pumping for reactive gases with a minimum investment (Welch, 1991). They are more suitable for ultrahigh vacuum applications than for handling large pumping loads. These pumps have been used in combination with turbomolecular pumps to compensate for the limited hydrogen-pumping performance of older designs. The newer, compound turbomolecular pumps avoid this need.

Operating Principles: Most sublimation pumps use a heated titanium surface to sublime a layer of atomically clean metal onto a surface, commonly the wall of a vacuum chamber. In the simplest version, a wire, commonly 85% Ti/15% Mo (McCracken and Pashley, 1966; Lawson and Woodward, 1967) is heated electrically; typical filaments deposit ~1 g before failure. It is normal to mount two or three filaments on a common flange for longer use before replacement. Alternatively, a hollow sphere of titanium is radiantly heated by an internal incandescent lamp filament, providing as much as 30 g of titanium. In either case, a temperature of ~1500°C is required to establish a useable sublimation rate. Because each square centimeter of a titanium film provides a pumping speed of several liters per second at room temperature (Harra, 1976), one can obtain large pumping speeds for reactive gases such as oxygen and nitrogen. The speed falls dramatically as the surface is covered by even one monolayer. Although the sublimation process must be repeated periodically to compensate for saturation, in an ultrahigh vacuum system the time between sublimation cycles can be many hours. With higher gas loads the sublimation cycles become more frequent, and continuous sublimation is required to achieve maximum pumping speed. A sublimator can only pump reactive gases and must always be used in combination with a pump for remaining gases, such as the rare gases and methane. Do not heat a sublimator when the pressure is too high, e.g., 10^{-3} torr; pumping will start on the heated surface, and can suppress the rate of sublimation completely. In this situation the sublimator surface becomes the only effective pump, functioning as a nonevaporable getter, and the effective speed will be very small (Kuznetsov et al., 1969).

Nonevaporable Getter Pumps (NEGs)

Applications: In vacuum systems, NEGs can provide supplementary pumping of reactive gases, being particularly effective for hydrogen, even at ambient temperature. They are most suitable for maintaining low pressures. A niche application is the removal of reactive impurities from rare gases such as argon. NEGs find wide application in maintaining low pressures in sealed-off devices, in some cases at ambient temperature (Giorgi et al., 1985; Welch, 1991).

Operating Principles: In one form of NEG, the reactive metal is carried as a thin surface layer on a supporting substrate. An example is an alloy of Zr/16%Al supported on either a soft iron or nichrome substrate. The getter is maintained at a temperature of around ~400°C, either by indirect or ohmic heating. Gases are chemisorbed at the surface and diffuse into the interior. When a getter has been exposed to the atmosphere, for example, when initially installed in a system, it must be activated by heating under vacuum to a high temperature, 600° to 800°C. This permits adsorbed gases such as nitrogen and oxygen to diffuse into the bulk. With use, the speed falls off as the near-surface getter becomes saturated, but the getter can be reactivated several times by heating. Hydrogen is evolved during reactivation; consequently reactivation is most effective when hydrogen can be pumped away. In a sealed device, however, the hydrogen is readsorbed on cooling.

A second type of getter, which has a porous structure with far higher accessible surface area, effectively pumps reactive gases at temperatures as low as ambient. In many cases, an integral heater is embedded in the getter.

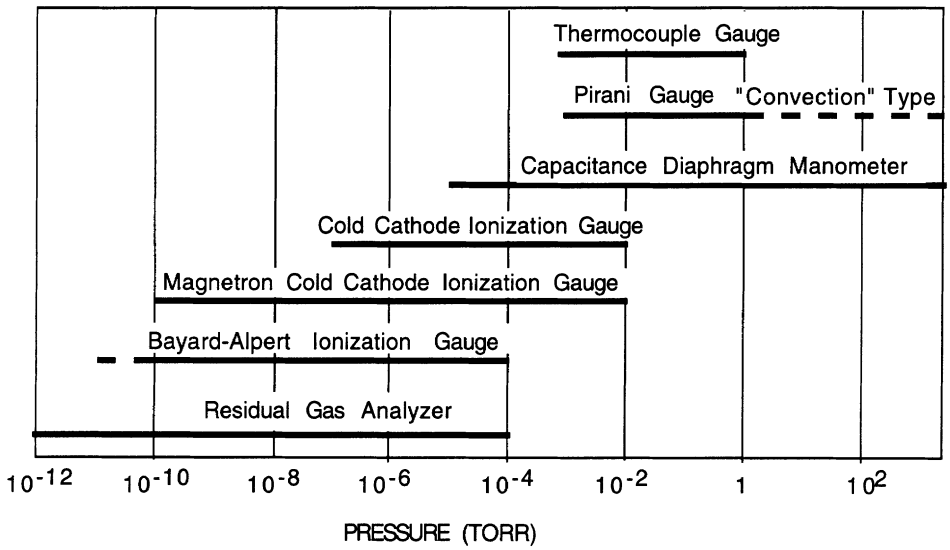

Figure 2. Approximate pressure ranges of total and partial pressure gauges. Note that only the capacitance manometer is an absolute gauge. Based, with permission, on Short Course Notes of the American Vacuum Society.

Total and Partial Pressure Measurement

Figure 2 provides a summary of the approximate range of pressure measurement for modern gauges. Note that only the capacitance diaphragm manometers are absolute gauges, having the same calibration for all gases. In all other gauges, the response depends on the specific gas or mixture of gases present, making it impossible to determine the absolute pressure without knowing gas composition.

Capacitance Diaphragm Manometers. A very wide range of gauges are available. The simplest are signal or switching devices with limited accuracy and reproducibility. The most sophisticated have the ability to measure over a range of $1{:}10^4$, with an accuracy exceeding 0.2% of reading, and a long-term stability that makes them valuable for calibration of other pressure gauges (Hyland and Shaffer, 1991). For vacuum applications, they are probably the most reliable gauge for absolute pressure measurement. The most sensitive can measure pressures from 1 torr down to the 10^{-4} torr range and can sense changes in the 10^{-5} torr range. Another advantage is that some models use stainless-steel and inconel parts, which resist corrosion and cause negligible contamination.

Operating Principles: These gauges use a thin metal, or in some cases, ceramic diaphragm, which separates two chambers, one connected to the vacuum system and the other providing the reference pressure. The reference chamber is commonly evacuated to well below the lowest pressure range of the gauge, and has a getter to maintain that pressure. The deflection of the diaphragm is measured using a very sensitive electrical capacitance bridge circuit that can detect changes of $\sim 2 \times 10^{-10}$ m. In the most sensitive gauges the device is thermostatted to avoid drifts due to temperature change; in less sensitive instruments there is no temperature control.

Operation: The bridge must be periodically zeroed by evacuating the measuring side of the diaphragm to a pressure below the lowest pressure to be measured.

Any gauge that is not thermostatically controlled should be placed in such a way as to avoid drastic temperature changes, such as periodic exposure to direct sunlight.

The simplest form of the capacitance manometer uses a capacitance electrode on both the reference and measurement sides of the diaphragm. In applications involving sources of contamination, or a radioactive gas such as tritium, this can lead to inaccuracies, and a manometer with capacitance probes only on the reference side should be used.

When a gauge is used for precision measurements, it must be corrected for the pressure differential that results when the thermostatted gauge head is operating at a different temperature than the vacuum system (Hyland and Shaffer, 1991).

Gauges Using Thermal Conductivity for the Measurement of Pressure

Applications: Thermal conductivity gauges are relatively inexpensive. Many operate in a range of $\sim 1 \times 10^{-3}$ to 20 torr. This range has been extended to atmospheric pressure in some modifications of the "traditional" gauge geometry. They are valuable for monitoring and control, for example, during the processes of roughing down from atmospheric pressure and for the cross-over from roughing pump to high-vacuum pump. Some are subject to drift over time, for example, as a result of contamination from mechanical pump oil, but others remain surprising stable under common system conditions.

Operating Principles: In most gauges, a ribbon or filament serves as the heated element. Heat loss from this element to the wall is measured either by the change in element temperature, in the thermocouple gauge, or as a change in electrical resistance, in the Pirani gauge.

Heat is lost from a heated surface in a vacuum system by energy transfer to individual gas molecules at low pressures (Peacock, 1998). This process has been used in the "traditional" types of gauges. At pressures well above 20 torr, convection currents develop. Heat loss in this mode has recently been used to extend the pressure measurement range up to atmospheric. Thermal radiation heat loss from the heated element is independent of the presence of gas, setting a lower limit to the measurement of pressure. For most practical gauges this limit is in the mid- to upper-10^{-4} torr range.

Two common sources of drift in the pressure indication are changes in ambient temperature and contamination of the heated element. The first is minimized by operating the heated element at 300°C or higher. However, this increases chemical interactions at the element, such as the decomposition of organic vapors into deposits of tars or carbon; such deposits change the thermal accommodation coefficient of gases on the element, and hence the gauge sensitivity. More satisfactory solutions to drift in the ambient temperature include a thermostatically controlled envelope temperature or a temperature-sensing element that compensates for ambient temperature changes. The problem of changes in the accommodation coefficient is reduced by using chemically stable heating elements, such as the noble metals or gold-plated tungsten.

Thermal conductivity gauges are commonly calibrated for air, and it is important to note that this changes significantly with the gas. The gauge sensitivity is higher for hydrogen and lower for argon. Thus, if the gas composition is unknown, the gauge reading may be in error by a factor of two or more.

Thermocouple Gauge. In this gauge, the element is heated at constant power, and its change in temperature, as the pressure changes, is directly measured using a thermocouple. In many geometries the thermocouple is spot welded directly at the center of the element; the additional thermal mass of the couple reduces the response time to pressure changes. In an ingenious modification, the thermocouple itself (Benson, 1957) becomes the heated element, and the response time is improved.

Pirani Gauge. In this gauge, the element is heated electrically, but the temperature is sensed by measuring its resistance. The absence of a thermocouple permits a faster time constant. A further improvement in response results if the element is maintained at constant temperature, and the power required becomes the measure of pressure.

Gauges capable of measurement over a range extending to atmospheric pressure use the Pirani principle. Those relying on convection are sensitive to gauge orientation, and the recommendation of the manufacturer must be observed if calibration is to be maintained. A second point, of great importance for safe operation, arises from the difference in gauge calibration with different gases. Such gauges have been used to control the flow of argon into a sputtering system measuring the pressure on the high-pressure side of a flow restriction. If pressure is set close to atmospheric, it is crucial to use a gauge calibrated for argon, or to apply the appropriate correction; using a gauge reading calibrated for air to adjust the argon to atmospheric results in an actual argon pressure well above one atmosphere, and the danger of explosion becomes significant.

A second technique that extends the measurement range to atmospheric pressure is drastic reduction of gauge dimensions so that the spacing between the heated element and the room temperature gauge wall is only 5 μm (Alvesteffer et al., 1995).

Ionization Gauges: Hot Cathode Type. The Bayard-Alpert gauge (Redhead et al., 1968) is the principal gauge used for accurate indication of pressure from 10^{-4} to 10^{-10} torr. Over this range, a linear relationship exists between the measured ion current and pressure. The gauge has a number of problems, but they are fairly well understood and to some extent can be avoided. Modifications of the gauge structure, such as the Redhead Extractor Gauge (Redhead et al., 1968) permit measurement into the high 10^{-13} torr region, and minimize errors due to electron-stimulated desorption (see below).

Operating Principles: In a typical Bayard-Alpert gauge configuration, shown in Figure 3A, a current of electrons, between 1 and 10 mA, from a heated cathode, is accelerated towards an anode grid by a potential of 150 V. Ions produced by electron collision are collected on an axial, fine-wire ion collector, which is maintained 30 V negative with respect to the cathode. The electron energy of 150 V is selected for the maximum ionization probability with most common gases.

The equation describing the gauge operation is

$$P = \frac{i^+}{(i^-)(K)} \tag{3}$$

where P is pressure, in torr, i^+ is the ion current, i^- is the electron current, and K, in torr^{-1}, is the gauge constant for the specific gas.

The original design of the ionization gauge, the triode gauge, shown in Figure 3B, cannot read below $\sim 1 \times 10^{-8}$ torr because of a spurious current, known as the

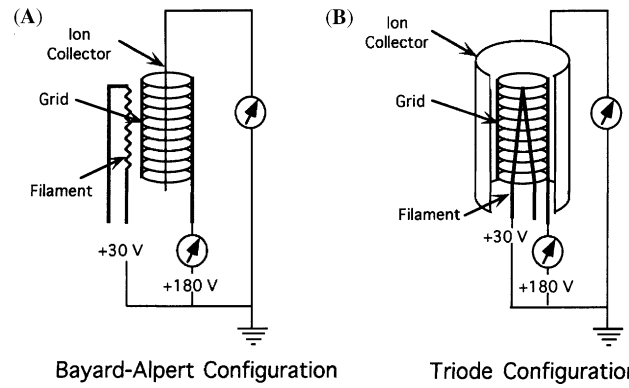

Figure 3. Comparison of the (**A**) Bayard-Alpert and (**B**) triode ion gauge geometries. Based, with permission, on Short Course Notes of the American Vacuum Society.

x-ray effect. The electron impact on the grid produces soft x rays, many of which strike the coaxial ion collector cylinder, generating a flux of photoelectrons; an electron ejected from the ion collector cannot be distinguished from an arriving ion by the current-measuring circuit. The existence of the x ray effect was first proposed by Nottingham (1947), and studies stimulated by his proposal led directly to the development of the Bayard-Alpert gauge, which simply inverted the geometry of the triode gauge. The sensitivity of the gauge is little changed from that of the triode, but the area of the ion collector, and presumably the x ray-induced spurious current, is reduced by a factor of 300, extending the usable range of the gauge to the order of 1×10^{-10} torr.

The gauge and associated electronics are normally calibrated for nitrogen gas, but, as with the thermal conductivity gauge, the sensitivity varies with gas, so the gas composition must be known for an absolute pressure reading. Gauge constants for various gases can be found in many texts (Redhead et al., 1968).

A gauge can affect the pressure in a system in three important ways.

1. An operating gauge functions as a small pump; at an electron emission of 10 mA the pumping speed is the order of 0.1 L/s. In a small system this can be a significant part of the pumping. In systems that are pumped at relatively large speeds, the gauge has negligible effect, but if the gauge is connected to the system by a long tube of small diameter, the limited conductance of the connection will result in a pressure drop, and the gauge will record a pressure lower than that in the system. For example, a gauge pumping at 0.1 L/s, connected to a chamber by a 100-cm-long, 1-cm-diameter tube, with a conductance of $\sim$0.2 L/s for air, will give a reading 33% lower than the actual chamber pressure. The solution is to connect all gauges using short and fat (i.e., high-conductance) tubes, and/or to run the gauge at a lower emission current.
2. A new gauge is a source of significant outgassing, which increases further when turned on as its temperature increases. Whenever a well-outgassed gauge is exposed to the atmosphere, gas adsorption occurs, and once again significant outgassing will result after system evacuation. This affects measurements in any part of the pressure range, but is more significant at very low pressures. Provision is made for outgassing all ionization gauges. For gauges especially suitable for pressures higher than the low 10^{-7} torr range, the grid of the gauge is a heavy non-sag tungsten or molybdenum wire that can be heated using a high-current, low-voltage supply. Temperatures of $\sim$1300°C can be achieved, but higher temperatures, desirable for UHV applications, can cause grid sagging; the radiation from the grid accelerates the outgassing of the entire gauge structure, including the envelope. The gauge remains in operation throughout the outgassing, and when the system pressure falls well below that existing before starting the outgas, the process can be terminated. For a system operating in the 10^{-7} torr range, 30 to 60 min should be adequate. The higher the operating pressure, the lower is the importance of outgassing. For pressures in the ultra-high vacuum region ($<1 \times 10^{-8}$ torr), the outgassing requirements become more rigorous, even when the system has been baked to 250°C or higher. In general, it is best to use a gauge designed for electron bombardment outgassing; the grid structure follows that of the original Bayard-Alpert design in having a thin wire grid reinforced with heavier support rods. The grid and ion collector are connected to a 500 to 1000 V supply and the electron emission is slowly increased to as high as 200 mA, achieving temperatures above 1500°C. A minimum of 60 min outgassing, using each of the two electron sources (for tungsten filament gauges), in turn, is adequate. During this procedure pressure measurements are not possible.

   After outgassing, the clean gauge will adsorb gas as it cools, and consequently the pressure will often fall significantly below its ultimate equilibrium value; it is the equilibrium value that provides a true measure of the system operation, and adequate time should be allowed for the gauge to readsorb gas and reestablish steady-state coverage. In the ultra-high vacuum region this may take an hour or more, but at higher pressure, say 10^{-6} torr, it is a transient effect.
3. The high-temperature electron emitter can interact with gases in the system in a number of ways. A tungsten filament, operating at 10 mA emission current, has a temperature on the order of 1825°C. Effects observed include the pumping of hydrogen and oxygen at speeds of 1 L/s or more; decomposition of organics, such as acetone, produce multiple fragments and can result in a substantial increase in the apparent pressure. Oxygen also reacts with trace amounts of carbon invariably present in tungsten filaments, producing carbon monoxide and carbon dioxide. To minimize such reactions, low-work-function electron emitters such as thoria-coated or thoriated tungsten and rhenium can be used, typically operating at temperatures on the order of 1450°C. An additional advantage is that the power used by a thoria-coated emitter is quite low; for example, at 10 mA emission it is $\sim$3 W for thoria-coated tungsten, as compared to $\sim$27 W for pure tungsten, so that the gauge operates at a lower overall temperature and outgassing is reduced (P.A. Redhead, pers. comm.). One disadvantage of such filaments is that the calibration stability is possibly less than that for tungsten filament gauges (Filippelli and Abbott, 1995). Additionally, thoria is radioactive and it appears possible that it will eventually be replaced by other emitters, such as yttria.

Tungsten filaments will instantaneously fail on exposure to a high pressure of air or oxygen. Where such exposure is a possibility, failure can be avoided with a rhenium filament.

A further, if minor, perturbation of an operating gauge results from greatly decreased electron emission in the presence of certain gases such as oxygen. For this reason, all gauge supplies control the electron emission by changes in temperature of the filament, typically increasing it in the presence of such gases, and consequently affecting the rate of reaction at the filament.

Electron Stimulated Desorption (ESD): The normal mechanism of gauge operation is the production of ions by electron impact on gas molecules or atoms. However, electron impact on molecules and atoms adsorbed on the grid structure results in their desorption, and a small fraction of the desorption occurs as ions, some of which will reach the ion collector. For some gases, such as oxygen on a molybdenum grid operating at low pressure, the ion desorption can actually exceed the gas-phase ion production, resulting in a large error in pressure measurement (Redhead et al., 1968). The spurious current increases with the gas coverage of the grid surface, and can be minimized by operating at a high electron-emission level, such that the rate of electron-stimulated desorption exceeds the rate of gas adsorption. Thus, one technique for detecting serious errors due to ESD is to change the electron emission. For example, an increase in current will result in a drop in the indicated pressure as the adsorption coverage is reduced. A second and more valuable technique is to use a gauge fitted with a modulator electrode, as first described by Redhead (1960). This simple procedure can clearly identify the presence of an ESD-based error and provide a more accurate reading of pressure; unfortunately, modulated gauges are not commonly available. Ultimately, low-pressure measurements are best determined using a calibrated mass spectrometer, or by a combination of a mass spectrometer and calibrated ion gauge.

Stability of Ion Gauge Calibration: The calibration of a gauge depends on the geometry of the gauge elements, including the relative positioning of the filaments and grid. For this reason, it is always desirable before calibrating a gauge to stabilize its structure by outgassing rigorously. This allows the grid structure to anneal, and, with tungsten filaments, accelerates crystal growth, which ultimately stabilizes the filament shape. In work demanding high-precision pressure measurement, comparison against a reference gauge that has a calibration traceable to the National Institutes of Standards and Technology (NIST) is essential. Clearly such a reference standard should only be used for calibration and not under conditions that are subject to the possible problems associated with use in a working environment. Recent work describes the development of a highly stable gauge structure, reportedly providing high reliability without recourse to such time-consuming calibration procedures (Arnold et al., 1994; Tilford et al., 1995).

Ionization Gauges: Cold Cathode Type. The cold cathode gauge uses a confined discharge to sustain a circulating electron current for the ionization of gases. The absence of a hot cathode provides a far more rugged gauge, the discharge requires less power, outgassing is much reduced, and the sensitivity of the gauge is high, so that simpler electronics can be used.

Based on these facts, the gauges would appear ideal substitutes for the hot-cathode type of gauge. The fact that this is not yet so where precise measurement of pressure is required is related to the history of cold cathode gauges. Some older designs of such gauges are known to exhibit serious instabilities (Lange et al., 1966). An excellent review of these gauges has been published (Peacock et al., 1991), and a recent paper (Kendall and Drubetsky, 1997) provides reassurance that instabilities should not be a major concern with modern gauges.

Operating Principles: The first widely used commercial cold cathode gauge was developed by Penning (Penning, 1937; Penning and Nienhuis, 1949). It uses an anode ring or cylinder at a potential of 2000 V placed between cathode plates at ground potential. A magnetic field of 0.15 tesla is directed along the axis of the cathode. The confined Penning discharge traps a circulating cloud of electrons, substantially at cathode potential, along the axis of the anode. The electron path lengths are very long, as compared to the hot cathode gauge, so that the pressure measuring sensitivity is very high, permitting a simple microammeter to be used for readout. The gauge is known variously as the Penning (or PIG), Philips, or simply cold cathode gauge and is widely used where a rugged gauge is required. The operating range is from 10^{-2} to 10^{-7} torr.

Note that any discharge current in the Penning and other cold cathode discharge gauges is extinguished at pressures of a few torr. When a gauge does not give a pressure indication, this means that either the pressure is below 10^{-7} torr or at many torr, a rather significant difference. Thus, it is necessary to use an additional gauge that is responsive in the blind spot of the Penning—i.e., between atmospheric pressure and 10^{-2} torr.

The Penning gauge has a number of limitations which preclude its use for the precise measurement of pressure. It is subject to some instability at the lower end of its range, because the discharge tends to extinguish. Discontinuities in the pressure indication may also occur throughout the range. Both of these characteristics were also evident in a discharge gauge that was designed to measure pressures into the 10^{-10} torr range, where discontinuities were detected throughout the entire operating range (Lange et al., 1966). These appear to result from changes between two or more modes of discharge. Note, however, that instabilities may simply indicate that the gauge is dirty.

The Penning has a higher pumping speed (up to 0.5 L/s) than a Bayard-Alpert gauge, so it is even more essential to provide a high-conductance connection between gauge and the vacuum chamber.

A number of refinements of the cold cathode gauge have been introduced by Redhead (Redhead et al., 1968), and commercial versions of these and other gauges are available for use to at least 10^{-10} torr. The discontinuities in such gauges are far less than those discussed above so that they are becoming widely used.

Mass Spectrometers. A mass spectrometer for use on vacuum systems is variously referred to as a partial

pressure analyzer (PPA), residual gas analyzer (RGA), or quad. These are indispensable for monitoring the composition of the gas in a vacuum system, for troubleshooting, and for detecting leaks. It is however a relatively difficult procedure for obtaining quantitative readings.

Magnetic Sector Mass Spectrometers: Commercial instruments were originally developed for analytical purposes but were generally too large for general application to vacuum systems. Smaller versions provided excellent performance, but the presence of a large permanent magnet or electromagnet remained a serious limitation. Such instruments are now mainly used in helium leak detectors, where a compact instrument using a small magnet is perfectly satisfactory for resolving the helium-4 peak from the only common adjacent peak, that due to hydrogen-2.

Quadrupole Mass Filter: Compact instruments are available in many versions, combined with control units that are extremely versatile (Dawson, 1995). Mass selection is accomplished through the application of a combined DC and RF electrical voltage to two pairs of quadrupole rods. The mass peaks are selected, in turn, by changing the voltage. High sensitivity is achieved using a variety of ion sources, all employing electron bombardment ionization, and by an electron-multiplier-based ion detector with a gain as high as 10^5. By adjusting the ratio of the DC and RF electrical potentials the quadrupole resolution can be changed to provide either high sensitivity to detect very low partial pressures, at the expense of the ability to completely resolve adjacent mass peaks, or low sensitivity, with more complete mass resolution.

A major problem with the quadrupole spectrometers is that not all compact versions possess the stability for quantitative applications. Very wide variations in detection sensitivity require frequent recalibration, and spurious peaks are sometimes present (Lieszkovszky et al., 1990; Tilford, 1994).

Despite such concerns, rapidly scanning the ion peaks from the gas in a system can often determine the gas composition. Interpretation is simplified by the limited number of residual gases commonly found in a system (Drinkwine and Lichtman, 1980).

VACUUM SYSTEM CONSTRUCTION AND DESIGN

Materials for Construction

Stainless steel, aluminum, copper, brass, alumina, and borosilicate glass are among the materials that have been used for the construction of vacuum envelopes. Excellent sources of information on these and other materials, including refractory metals suitable for internal electrodes and heaters, are available (Kohl, 1967; Rosebury, 1965). The present discussion will be limited to those most commonly used.

Perhaps the most common material is stainless steel, most frequently 304L. The material is available in a wide range of shapes and sizes, and is easily fabricated by heliarc welding or brazing. Brazing should be done in hydrogen or vacuum. Torch brazing with the use of a flux should be avoided, or reserved for rough vacuum applications. The flux is extremely difficult to remove, and the washing procedure leaves any holes plugged with water, so that helium leak detection is often unsuccessful. However, note that any imperfections in this and other metals tend to extend along the rolling or extrusion direction. For example, the defects in bar stock extend along the length. If a thin-walled flat disc or conical shape is machined from such stock, it will often develop holes through the wall. Construction from rolled plate or sheet stock is preferable, with cones or cylinders made by full-penetration seam welding.

Aluminum is an excellent choice for the vacuum envelope, particularly for high-atomic-radiation environments. But joining by either arc welding or brazing is exceedingly demanding.

Kovar is a material having an expansion coefficient closely matched to borosilicate glass, which is widely used in sealing windows and alumina-insulating sections for electrical feedthroughs.

Borosilicate glass remains a valid choice for construction. Although outgassing is a serious problem in an unbaked system, a bakeout to as high as 400°C reduces the outgassing so UHV conditions can readily be achieved.

High-alumina ceramic provides a high-temperature vacuum wall. It can be coated with a thin metallic film, such as titanium, and then brazed to a Kovar header to make electrical feedthroughs. Alumina stock tubing does not have close dimension tolerances. Shaping for vacuum use requires time-consuming and expensive procedures such as grinding and cavitron milling. It is useful for internal electrically insulating components, and can be used at temperatures up to at least 1800°C. In many cases where lower-temperature performance is acceptable, such components are more conveniently fabricated from either boron nitride (1650°C) or Macor (1000°C) using conventional metal-cutting techniques.

Elastomers are widely used in O-ring seals. Buna N and Viton are most commonly used. The main advantage of Viton is that it can be used up to 200°C, as compared to 80°C for Buna. The higher temperature capability is valuable for rapid degassing of the O-ring prior to installation, and also for use at an elevated temperature. Polyimide can be used as high as 300°C and is used as the sealing surface on the nose of vacuum valves intended for UHV applications, permitting a higher-temperature bakeout.

Hardware Components

Use of demountable seals allows greater flexibility in system assembly and change. Replacement of a flange-mounted component is a relatively trivial problem as compared to that where the component is brazed or welded in place. A wide variety of seals are available, but only two examples will be discussed.

O-ring Flange Seals. The O-ring seal is by far the most convenient technique for high-vacuum use. It should be generally limited to systems at pressures in the 10^{-7} torr range and higher. Figure 4A shows the geometry of a simple seal. Note that the sealing surfaces are those in contact with the two flanges. The inner surface serves only to

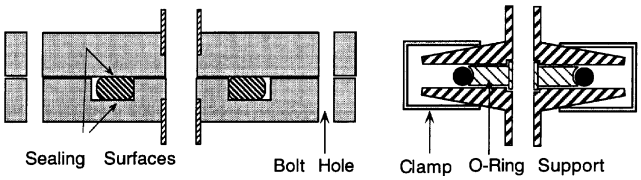

Figure 4. Simple O-ring flange (**A**) and International Standards Organization Type KF O-ring flange (**B**). Based, with permission, on Short Course Notes of the American Vacuum Society.

support the O-ring. The compressed O-ring does not completely fill the groove. The groove for vacuum use is machined so that the inside diameter fits the inside diameter of the O-ring. The pressure differential across the ring pushes the ring against the inner surface. For hydraulic applications the higher pressure is on the inside, so the groove is machined to contact the outside surface of the O-ring. Use of O-rings for moving seals is commonplace; this is acceptable for rotational motion, but is undesirable for translational motion. In the latter case, scuffing of the O-ring leads to leakage, and each inward motion of the rod transfers moisture and other atmospheric gases into the system. Many inexpensive valves use such a seal on the valve shaft, and it is the main point of failure. In some cases, a double O-ring with a grease fill between the rings is used; this is unacceptable if a clean, oil-free system is required.

Modern O-ring seal assemblies have largely standardized on the ISO KF type geometry (Fig. 4B), where the two flanges are identical. This permits flexibility in assembly, and has the great advantage that components from different manufacturers may readily be interchanged.

Acetone should never be used for cleaning O-rings for vacuum use; it permeates into the rubber, creating a long-lasting source of the solvent in the vacuum system. It is common practice to clean new O-rings by wiping with a lint-free cloth. O-rings may be lubricated with a low-vapor-pressure vacuum grease such as Apiezon M; the grease should provide a shiny surface, but no accumulation of grease. Such a film is not required to produce a leak tight seal, and is widely thought to function only as a lubricant.

All elastomers are permeable to the gases in air, and an O-ring seal is always a source of gas permeating into a vacuum system. The approximate permeation rate for air, at ambient temperature, through a Viton O-ring is 8×10^{-9} torr-L/s for each centimeter length of O-ring. This permeation load is rarely of concern in systems at pressures in the 10^{-7} torr range or higher, if the system does not include an inordinate number of such seals. But in a UHV system they become the dominant source of gas and must generally be excluded. A double O-ring geometry, with the space between the rings continuously evacuated, constitutes a useful improvement. The guard ring vacuum minimizes air permeation and minimizes the effect of leaks during motion. Such a seal extends the use of O-rings to the UHV range, and can be helpful if frequent access to the system is essential.

All-metal Flange Seals. All-metal seals were developed for UHV applications, but the simplicity and reliability of these seals finds application where the absence of leakage over a wide range of operating conditions is essential. The Conflat seal, developed by Wheeler (1963), uses a partially annealed copper gasket that is elastically deformed by capture between the knife edges on the two flanges and along the outside diameter of the gasket. Such a seal remains leak-tight at temperatures from -195° to 450°C. A new gasket should be used every time the seal is made, and the flanges pulled down metal-to-metal. For flanges with diameters above $\sim$10 in., the weight of the flange becomes excessive, and a copper-wire seal using a similar capture geometry (Wheeler, 1963) is easier to lift, if more difficult to assemble.

Vacuum Valves. The most important factor in the selection of vacuum valves is avoiding an O-ring on a sliding shaft, choosing instead a bellows seal. The bonnet of the valve is usually O-ring–sealed, except where bakeability is necessary, in which case a metal seal such as the Conflat is substituted. The nose of the valve is usually an O-ring or molded gasket of Viton, polyimide for higher temperature, or metal for the most stringent UHV applications. Sealing techniques for the a UHV valve include a knife edge nose/copper seat and a capture geometry such as silver nose/stainless steel seat (Bills and Allen, 1955).

When a valve is used between a high-vacuum pump and a vacuum chamber, high conductance is essential. This normally mandates some form of gate valve. The shaft seal is again crucial for reliable, leak-tight operation. Because of the long travel of the actuating rod, a grease-filled double O-ring has frequently been used, but evacuation would be preferable. A lever-operated drive requiring only simple rotation using an O-ring seal, or a bellows-sealed drive, provides superior performance.

Electrical Feedthroughs. Electrical feedthroughs of high reliability are readily available, from single to multiple pin, with a wide range of current and voltage ratings. Many can be brazed or welded in place, or can be obtained mounted in a flange with elastomer or metal seals. Many are compatible with high-temperature bakeout. One often overlooked point is the use of feedthroughs for thermocouples. It is common practice to terminate the thermocouple leads on the internal pins of any available feedthrough, continuing the connection on the outside of these same pins using the appropriate thermocouple compensating leads. This is acceptable if the temperature at the two ends of each pin is the same, so the EMF generated at each bimetallic connection is identical, but in opposition. Such uniformity in temperature is not the norm, and an error in the measurement of temperature is thus inevitable. Thermocouple feedthroughs with pins of the appropriate compensating metal are readily available. Alternatively, the thermocouple wires can pass through hollow pins on a feedthrough, using a brazed seal on the vacuum side of the pins.

Rotational and Translational Motion Feedthroughs. For systems operating at pressures of 10^{-7} torr and higher, O-ring seals are frequently used. They are reasonably satisfactory for rotational motion but prone to leakage in translational motion. In either case, the use of a double

O-ring, with an evacuated space between the O-rings, reduces both permeation and leakage from the atmosphere, as described above. Magnetic coupling across the vacuum wall avoids any problem of leakage and is useful where the torque is low and where precise motion is not required. If high-speed precision motion or very high torque is required, feedthroughs are available where a drive shaft passes through the wall, using a magnetic liquid seal; such seals use low-vapor-pressure liquids (polyphenylether diffusion pump fluids: see discussion of Diffusion Pumps) and are helium-leak-tight, but cannot sustain a significant bakeout. For UHV applications, bellows-sealed feedthroughs are available for precise control of both rotational and translational motion. O'Hanlon (1989) gives a detailed discussion of this.

Assembly, Processing, and Operation of Vacuum Systems

As a general rule, all parts of a vacuum system should be kept as clean as possible through fabrication and until final system assembly. This applies with equal importance if the system is to be baked. Avoid the use of sulfur-containing cutting oil in machining components; sulfur gives excellent adhesion during machining, but is difficult to remove. Rosebury (1965) provides guidance on this point.

Traditional cleaning procedures have been reviewed by Sasaki (1991). Many of these use a vapor degreaser to remove organic contamination and detergent scrubbing to remove inorganic contamination. Restrictions on the use of chlorinated solvents such as trichloroethane, and limits on the emission of volatile organics, have resulted in a switch to more environmentally acceptable procedures. Studies at the Argonne National Laboratory led to two cleaning agents which were used in the assembly of the Advanced Photon Source (Li et al., 1995; Rosenburg et al., 1994). These were a mild alkaline detergent (Almeco 18) and a citric acid-based material (Citronox). The cleaning baths were heated to 50° to 65°C and ultrasonic agitation was used. The facility operates in the low 10^{-10} torr range. Note that cleanliness was observed during all stages, so that the cleaning procedures were not required to reverse careless handling.

The initial pumpdown of a new vacuum system is always slower than expected. Outgassing will fall off with time by perhaps a factor of 10^3, and can be accelerated by increasing the temperature of the system. A bakeout to 400°C will accomplish a reduction in the outgassing rate by a factor of 10^7 in 15 hr. But to be effective, the entire system must be heated.

Once the system has been outgassed any pumpdown will be faster than the initial one as long as the system is not left open to the atmosphere for an extended period. Always vent a system to dry gas, and minimize exposure to atmosphere, even by continuing the purge of dry gas when the system is open. To the extent that the ingress of moist air is prevented, so will the subsequent pumpdown be accelerated.

Current vacuum practice for achieving ultrahigh vacuum conditions frequently involves baking to a more moderate temperature, on the order of 200°C, for a period of several days. Thereafter, samples are introduced or removed from the system by use of an intermediate vacuum entrance, the so-called load-lock system. With this technique the pressure in the main vacuum system need never rise by more than a decade or so from the operating level. If the need for ultrahigh vacuum conditions in a project is anticipated at the outset, the construction and operation of the system is not particularly difficult, but does involve a commitment to use materials and components that can be subjected to bakeout temperature without deterioration.

Design of Vacuum Systems

In any vacuum system, the pressure of interest is that in the chamber where processes occur, or where measurements are carried out, and not at the mouth of the pump. Thus, the pumping speed used to estimate the system operating pressure should be that at the exit of the vacuum chamber, not simply the speed of the pump itself. Calculation of this speed requires a knowledge of the substantial pressure drop often present in the lines connecting the pump to the chamber. In many system designs, the effective pumping speed at the chamber opening falls below 40% of the pump speed; the further the pump is located from the vacuum chamber the greater is the loss.

One can estimate system performance to avoid any serious errors in component selection. It is essential to know the conductance, C, of all components in the pumping system.

Conductance is defined by the expression

$$C = \frac{Q}{P_1 - P_2} \tag{4}$$

where C is the conductance in L/s, $(P_1 - P_2)$ is the pressure drop across the component in torr, and Q is the total throughput of gas, in torr-L/s.

The conductance of tubes with a circular cross-section can be calculated from the dimensions, although the conductance does depend upon the type of gas flow. Most high-vacuum systems operate in the molecular flow regime, which often begins to dominate once the pressure falls below 10^{-2} torr. An approximate expression for the pressure at which molecular flow becomes dominant is

$$P \geq \frac{0.01}{D} \tag{5}$$

where D is the internal diameter of the conductance element in cm and P is the pressure in torr.

In molecular flow, the conductance for air, of a long tube (where $L/D > 50$), is given by

$$C = \frac{12.1(D^3)}{L} \tag{6}$$

where L is the length in centimeters and C is in L/s.

Molecular flow occurs in virtually all high-vacuum systems. Note that the conductance in this regime is independent of pressure. The performance of pumping systems is frequently limited by practical conductance limits. For any component, conductance in the low-pressure regime is lower than in any other pressure regime, so careful design consideration is necessary.

At higher pressures ($PD \geq 0.5$) the flow becomes viscous. For long tubes, where laminar flow is fully developed ($L/D \gg 100$), the conductance is given by

$$C = \frac{(182)(P)(D^4)}{L} \tag{7}$$

As can be seen from this equation, in viscous flow, the conductance is dependent on the fourth power of the diameter, and is also dependent upon the average pressure in the tube. Because the vacuum pumps used in the higher-pressure range normally have significantly smaller pumping speeds than do those for high vacuum, the problems associated with the vacuum plumbing are much simpler. The only time that one must pay careful attention to the higher-pressure performance is when system cycling time is important, or when the entire process operates in the viscous flow regime.

When a group of components are connected in series, the net conductance of the group can be approximated by the expression

$$\frac{1}{C_{\text{total}}} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots \tag{8}$$

From this expression, it is clear that the limiting factor in the conductance of any string of components is the smallest conductance of the set. It is not possible to compensate low conductance, e.g., in a small valve, by increasing the conductance of the remaining components. This simple fact has escaped very many casual assemblers of vacuum systems.

The vacuum system shown in Figure 5 is assumed to be operating with a fixed input of gas from an external source, which dominates all other sources of gas such as outgassing or leakage. Once flow equilibrium is established, the throughput of gas, Q, will be identical at any plane drawn through the system, since the only source of gas is the external source, and the only sink for gas is the pump.

The pressure at the mouth of the pump is given by

$$P_2 = \frac{Q}{S_{\text{pump}}} \tag{9}$$

and the pressure in the chamber will be given by

$$P_1 = \frac{Q}{S_{\text{chamber}}} \tag{10}$$

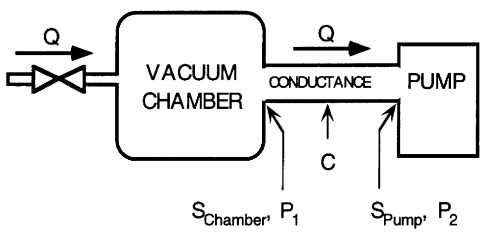

Figure 5. Pressures and pumping speeds developed by a steady throughput of gas (Q) through a vacuum chamber, conductance (C) and pump.

Combining this with Equation 4, to eliminate pressure, we have

$$\frac{1}{S_{\text{chamber}}} = \frac{1}{S_{\text{pump}}} + \frac{1}{C} \tag{11}$$

For the case where there are a series of separate components in the pumping line, the expression becomes

$$\frac{1}{S_{\text{chamber}}} = \frac{1}{S_{\text{pump}}} + \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots \tag{12}$$

The above discussion is intended only to provide an understanding of the basic principles involved and the type of calculations necessary to specify system components. It does not address the significant deviations from this simple framework that must be corrected for, in a precise calculation (O'Hanlon, 1989).

The estimation of the base pressure requires a determination of gas influx from all sources and the speed of the high-vacuum pump at the base pressure. The outgassing contributed by samples introduced into a vacuum system should not be neglected. The critical sources are outgassing and permeation. Leaks can be reduced to negligible levels using good assembly techniques. Published outgassing and permeation rates for various materials can vary by as much as a factor of two (O'Hanlon, 1989; Redhead et al., 1968; Santeler et al., 1966). Several computer programs, such as that described by Santeler (1987), are available for more precise calculation.

LEAK DETECTION IN VACUUM SYSTEMS

Before assuming that a vacuum system leaks, it is useful to consider if any other problem is present. The most important tool in such a consideration is a properly maintained log book of the operation of the system. This is particularly the case if several people or groups use a single system. If key check points in system operation are recorded weekly, or even monthly, then the task of detecting a slow change in performance is far easier.

Leaks develop in cracked braze joints, or in torch-brazed joints once the flux has finally been removed. Demountable joints leak if the sealing surfaces are badly scratched, or if a gasket has been scuffed, by allowing the flange to rotate relative to the gasket as it is compressed. Cold flow of Teflon or other gaskets slowly reduces the compression and leaks develop. These are the easy leaks to detect, since the leak path is from the atmosphere into the vacuum chamber, and a trace gas can be used for detection.

A second class of leaks arise from faulty construction techniques; they are known as virtual leaks. In all of these, a volume or void on the inside of a vacuum system communicates to that system only through a small leak path. Every time the system is vented to the atmosphere, the void fills with venting gas, then in the pumpdown this gas flows back into the chamber with a slowly decreasing throughput, as the pressure in the void falls. This extends

the system pumpdown. A simple example of such a void is a screw placed in a blind tapped hole. A space always remains at the bottom of the hole and the void is filled by gas flowing along the threads of the screw. The simplest solution is a screw with a vent hole through the body, providing rapid pumpout. Other examples include a double O-ring in which the inside O-ring is defective, and a double weld on the system wall with a defective inner weld. A mass spectrometer is required to confirm that a virtual leak is present. The pressure is recorded during a routine exhaust, and the residual gas composition is determined as the pressure is approaching equilibrium. The system is again vented using the same procedure as in the preceding vent, but the vent uses a gas that is not significant in the residual gas composition; the gas used should preferably be nonadsorbing, such as a rare gas. After a typical time at atmospheric pressure, the system is again pumped down. If gas analysis now shows significant vent gas in the residual gas composition, then a virtual leak is probably present, and one can only look for the culprit in faulty construction.

Leaks most often fall in the range of 10^{-4} to 10^{-6} torr-L/s. The traditional leak rate is expressed in atmospheric cubic centimeters per second, which is 1.3 torr-L/s. A variety of leak detectors are available with practical sensitivities varying from around 1×10^{-3} to 2×10^{-11} torr-L/s.

The simplest leak detection procedure is to slightly pressurize the system and apply a detergent solution, similar to that used by children to make soap bubbles, to the outside of the system. With a leak of $\sim 1 \times 10^{-3}$ torr-L/s, bubbles should be detectable in a few seconds. Although the lower limit of detection is at least one decade lower than this figure, successful use at this level demands considerable patience.

A similar inside-out method of detection is to use the kind of halogen leak detector commonly available for refrigeration work. The vacuum system is partially backfilled with a freon and the outside is examined using a sniffer hose connected to the detector. Leaks the order of 1×10^{-5} torr-L/s can be detected. It is important to avoid any significant drafts during the test, and the response time can be many seconds, so the sniffer must be moved quite slowly over the suspect area of the system. A far more sensitive instrument for this procedure is a dedicated helium leak detector (see below) with a sniffer hose testing a system partially back-filled with helium.

A pressure gauge on the vacuum system can be used in the search for leaks. The most productive approach applies if the system can be segmented by isolation valves. By appropriate manipulation, the section of the system containing the leak can be identified. A second technique is not so straightforward, especially in a nonbaked system. It relies on the response of ion or thermal conductivity gauges differing from gas to gas. For example, if the flow of gas through a leak is changed from air to helium by covering the suspected area with helium, then the reading of an ionization gauge will change, since the helium sensitivity is only ~16% of that for air. Unfortunately, the flow of helium through the leak is likely to be ~2.7 times that for air, assuming a molecular flow leak, which partially offsets the change in gauge sensitivity. A much greater problem is that the search for a leak is often started just after exposure to the atmosphere and pumpdown. Consequently outgassing is an ever-changing factor, decreasing with time. Thus, one must detect a relatively small decrease in a gauge reading, due to the leak, against a decreasing background pressure. This is not a simple process; the odds are greatly improved if the system has been baked out, so that outgassing is a much smaller contributor to the system pressure.

A far more productive approach is possible if a mass spectrometer is available on the system. The spectrometer is tuned to the helium-4 peak, and a small helium probe is moved around the system, taking the precautions described later in this section. The maximum sensitivity is obtained if the pumping speed of the system can be reduced by partially closing the main pumping valve to increase the pressure, but no higher than the mid-10^{-5} torr range, so that the full mass spectrometer resolution is maintained. Leaks in the 1×10^{-8} torr-L/s range should be readily detected.

The preferred method of leak detection uses a standalone helium mass spectrometer leak detector (HMSLD). Such instruments are readily available with detection limits of 2×10^{-10} torr-L/s or better. They can be routinely calibrated so the absolute size of a leak can be determined. In many machines this calibration is automatically performed at regular intervals. Given this, and the effective pumping speed, one can find, using Equation 1, whether the leak detected is the source of the observed deterioration in the system base pressure.

In an HMSLD, a small mass spectrometer tuned to detect helium is connected to a dedicated pumping system, usually a diffusion or turbomolecular pump. The system or device to be checked is connected to a separately pumped inlet system, and once a satisfactory pressure is achieved, the inlet system is connected directly to the detector and the inlet pump is valved off. In this mode, all of the gas from the test object passes directly to the helium leak detector. The test object is then probed with helium, and if a leak is detected, and is covered entirely with a helium blanket, the reading of the detector will provide an absolute indication of the leak size. In this detection mode, the pressure in the leak detector module cannot exceed $\sim 10^{-4}$ torr, which places a limit on the gas influx from the test object. If that influx exceeds some critical value, the flow of gas to the helium mass spectrometer must be restricted, and the sensitivity for detection will be reduced. This mode, of leak detection is not suitable for dirty systems, since the gas flows from the test object directly to the detector, although some protection is usually provided by interposing a liquid nitrogen cold trap.

An alternative technique using the HMSLD is the so-called counterflow mode. In this, the mass spectrometer tube is pumped by a diffusion or turbomolecular pump which is designed to be an ineffective pump for helium (and for hydrogen), while still operating at normal efficiency for all higher-molecular-weight gases. The gas from the object under test is fed to the roughing line of the mass spectrometer high-vacuum pump, where a higher pressure can be tolerated (on the order of 0.5 torr). Contaminant gases, such as hydrocarbons, as well as air, cannot reach the spectrometer tube. The sensitivity of an

HMSLD in this mode is reduced about an order of magnitude from the conventional mode, but it provides an ideal method of examining quite dirty items, such as metal drums or devices with a high outgassing load.

The procedures for helium leak detection are relatively simple. The HMSLD is connected to the test object for maximum possible pumping speed. The time constant for the buildup of a leak signal is proportional to V/S, where V is the volume of the test system and S the effective pumping speed. A small time constant allows the helium probe to be moved more rapidly over the system.

For very large systems, pumped by either a turbomolecular or diffusion pump, the response time can be improved by connecting the HMSLD to the foreline of the system, so the response is governed by the system pump rather than the relatively small pump of the HMSLD. With pumping systems that use a capture-type pump, this procedure cannot be used, so a long time constant is inevitable. In such cases, use of an HMSLD and helium sniffer to probe the outside of the system, after partially venting to helium, may be a better approach. Further, a normal helium leak check is not possible with an operating cryopump; the limited capacity for pumping helium can result in the pump serving as a low-level source of helium, confounding the test.

Rubber tubing must be avoided in the connection between system and HMSLD, since helium from a large leak will quickly permeate into the rubber and thereafter emit a steadily declining flow of helium, thus preventing use of the most sensitive detection scale. Modern leak detectors can offset such background signals, if they are relatively constant with time.

With the HMSLD operating at maximum sensitivity, a probe, such as a hypodermic needle with a very slow flow of helium, is passed along any suspected leak locations, starting at the top of the system, and avoiding drafts. Whenever a leak signal is first heard, and the presence of a leak is quite apparent, the probe is removed, allowing the signal to decay; checking is resumed, using the probe with no significant helium flow, to pinpoint the exact location of the leak. Ideally, the leak should be fixed before the probe is continued, but in practice the leak is often plugged with a piece of vacuum wax (sometimes making the subsequent repair more difficult), and the probe is completed before any repair is attempted. One option, already noted, is to blanket the leak site with helium to obtain a quantitative measure of its size, and then calculate whether this is the entire problem. This is not always the preferred procedure, because a large slug of helium can lead to a lingering background in the detector, precluding a check for further leaks at maximum detector sensitivity.

A number of points need to be made with regard to the detection of leaks:

1. Bellows should be flexed while covered with helium.
2. Leaks in water lines are often difficult to locate. If the water is drained, evaporative cooling may cause ice to plug a leak, and helium will permeate through the plug only slowly. Furthermore, the evaporating water may leave mineral deposits that plug the hole. A flow of warm gas through the line, overnight, will often open up the leak and allow helium leak detection. Where the water lines are internal to the system, the chamber must be opened so that the entire line is accessible for a normal leak check. However, once the lines can be viewed, the location of the leak is often signaled by the presence of discoloration.
3. Do not leave a helium probe near an O-ring for more than a few seconds; if too much helium goes into solution in the elastomer, the delayed permeation that develops will cause a slow flow of helium into the system, giving a background signal which will make further leak detection more difficult.
4. A system with a high background of hydrogen may produce a false signal in the HMSLD because of inadequate resolution of the helium and hydrogen peaks. A system that is used for the hydrogen isotopes deuterium or tritium will also give a false signal because of the presence of D_2 or HT, both of which have their major peaks at mass 4. In such systems an alternate probe gas such as argon must be used, together with a mass spectrometer which can be tuned to the mass 40 peak.

Finally, if a leak is found in a system, it is wise to fix it properly the first time lest it come back to haunt you!

MASS AND DENSITY MEASUREMENTS

INTRODUCTION

The precise measurement of mass is one of the more challenging measurement requirements that materials scientists must deal with. The use of electronic balances has become so widespread and routine that the accurate measurement of mass is often taken for granted. While government institutions such as the National Institutes of Standards and Technology (NIST) and state metrology offices enforce controls in the industrial and legal sectors, no such rigors generally affect the research laboratory. The process of peer review seldom makes assessments of the accuracy of an underlying measurement involved unless an egregious problem is brought to the surface by the reported results. In order to ensure reproducibility, any measurement process in a laboratory should be subjected to a rigorous and frequent calibration routine. This unit will describe the options available to the investigator for establishing and executing such a routine; it will define the underlying terms, conditions, and standards, and will suggest appropriate reporting and documenting practices. The measurement of mass, which is a fundamental measurement of the amount of material present, will constitute the bulk of the discussion. However, the measurement of derived properties, particularly density, will also be discussed, as well as some indirect techniques used particularly by materials scientists in the determination of mass and density, such as the quartz crystal microbalance for mass measurement and the analysis of diffraction data for density determination.

INDIRECT MASS MEASUREMENT TECHNIQUES

A number of differential and equivalence methods are frequently used to measure mass, or obtain an estimate of the change in mass during the course of a process or analysis. Given knowledge of the system under study, it is often possible to ascertain with reasonable accuracy the quantity of material using chemical or physical equivalence, such as the evolution of a measurable quantity of liquid or vapor by a solid upon phase transition, or the titrimetric oxidation of the material. Electroanalytical techniques can provide quantitative numbers from coulometry during an electrodeposition or electrodissolution of a solid material. Magnetometry can provide quantitative information on the amount of material when the magnetic susceptibility of the material is known.

A particularly important indirect mass measurement tool is the quartz crystal microbalance (QCM). The QCM is a piezoelectric quartz crystal routinely incorporated in vacuum deposition equipment to monitor the buildup of films. The QCM is operated at a resonance frequency that changes (shifts) as the mass of the crystal changes, providing the valuable information needed to estimate mass changes on the order of 10^{-9} to 10^{-10} g/cm^2, giving these devices a special niche in the differential mass measurement arena (Baltes et al., 1998). QCMs may also be coupled with analytical techniques such as electrochemistry or differential thermal analysis to monitor the simultaneous buildup or removal of a material under study.

DEFINITION OF MASS, WEIGHT, AND DENSITY

Mass has already been defined as a measure of the amount of material present. Clearly, there is no direct way to answer the fundamental question "what is the mass of this material?" Instead, the question must be answered by employing a tool (a balance) to compare the mass of the material to be measured to a known mass. While the SI unit of mass is the kilogram, the convention in the scientific community is to report mass or weight measurements in the metric unit that more closely yields a whole number for the amount of material being measured (e.g., grams, milligrams, or micrograms). Many laboratory balances contain "internal standards," such as metal rings of calibrated mass or an internally programmed electronic reference in the case of magnetic force compensation balances. To complicate things further, most modern electronic balances apply a set of empirically derived correction factors to the differential measurement (of the sample versus the internal standard) to display a result on the readout of the balance. This readout, of course, is what the investigator is to take on faith, and record the amount of material present

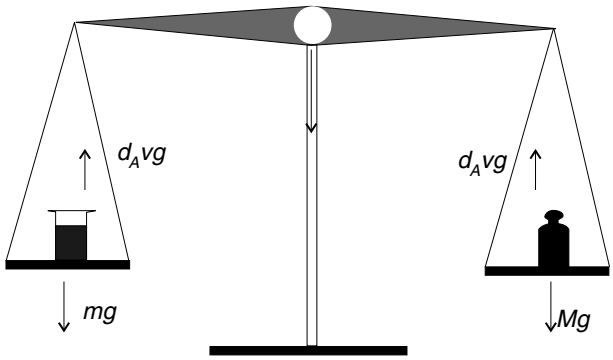

Figure 1. Schematic diagram of an equal-arm two-pan balance.

to as many decimal places as appeared on the display. In truth one must consider several concerns: what is the actual accuracy of the balance? How many of the figures in the display are significant? What are the tolerances of the internal standards? These and other relevant issues will be discussed in the sections to follow.

One type of balance does not cloak its modus operandi in internal standards and digital circuitry: the equal arm balance. A schematic diagram of an equal arm balance is shown in Figure 1. This instrument is at the origin of the term "balance," which is derived from a Latin word meaning having two pans. This elegantly simple device clearly compares the mass of the unknown to a known mass standard (see discussion of Weight Standards, below) by accurately indicating the deflection of the lever from the equilibrium state (the "balance point"). We quickly draw two observations from this arrangement. First, the lever is affected by a force, not a mass, so the balance can only operate in the presence of a gravitational field. Second, if the sample and reference mass are in a gaseous atmosphere, then each will have buoyancy characterized by the mass of the air displaced by each object. The amount of displaced air will depend on such factors as sample porosity, but for simplicity we assume here (for definition purposes) that neither the sample nor the reference mass are porous and the volume of displaced air equals the volume of the object.

We are now in a position to define the weight of an object. The weight (W) is effectively the force exerted by a mass (M) under the influence of a gravitational field, i.e., $W = Mg$, where g is the acceleration due to gravity (9.80665 m/s^2). Thus, a mass of exactly 1 g has a weight in centimeter–gram–second (cgs) units of 1 g $\times$ 980.665 cm/s^2 = 980.665 dyn, neglecting buoyancy due to atmospheric displacement. It is common to state that the object "weighs" 1 g (colloquially equating the gram to the force exerted by gravity on one gram), and to do so neglects any effect due to atmospheric buoyancy. The American Society for Testing and Materials (ASTM, 1999) further defines the force (F) exerted by a weight measured in the air as

$$F = \frac{Mg}{9.80665}\left(1 - \frac{d_A}{D}\right) \quad (1)$$

where d_A is the density of air, and D is the density of the weight (standard E4). The ASTM goes on to define a set of units to use in reporting force measurements as mass-force quantities, and presents a table of correction factors that take into account the variation of the Earth's gravitational field as a function of altitude above (or below) sea level and geographic latitude. Under this custom, forces are reported by relation to the newton, and by definition, one kilogram-force (kgf) unit is equal to 9.80665 N. The kgf unit is commonly encountered in the mechanical testing literature (see HARDNESS TESTING). It should be noted that the ASTM table considers only the changes in gravitational force and the density of dry air; i.e., the influence of humidity and temperature, for example, on the density of air is not provided. The Chemical Rubber Company's Handbook of Chemistry and Physics (Lide, 1999) tabulates the density of air as a function of these parameters. The International Committee for Weights and Measures (CIPM) provides a formula for air density for use in mass calibration. The CIPM formula accounts for temperature, pressure, humidity, and carbon dioxide concentration. The formula and description can be found in the International Organization for Legal Metrology (OIML) recommendation R 111 (OIML, 1994).

The "balance condition" in Figure 1 is met when the forces on both pans are equivalent. Taking M to be the mass of the standard, V to be the volume of the standard, m to be the mass of the sample, and v to be the volume of the sample, then the balance condition is met when $mg - d_A vg = Mg - d_A Vg$. The equation simplifies to $m - d_A v = M - d_A V$ as long as g remains constant. Taking the density of the sample to be d (equal to m/v) and that of the standard to be D (equal to M/V), it is easily shown that $m = M \times [(1 - d_A/D \div (1 - d_A/d)]$ (Kupper, 1997). This equation illustrates the dependence of a mass measurement on the air density: only when the density of the sample is identical to that of the standard (or when no atmosphere is present at all) is the measured weight representative of the sample's actual mass. To put the issue into perspective, a dry atmosphere at sea level has a density of 0.0012 g/cm^3, while that in Denver, Colorado ($\sim$1 mile above sea level) has a density of 0.00098 g/cm^3 (Kupper, 1997). If we take an extreme example, the measurement of the mass of wood (density 0.373 g/cm^3) against steel (density 8.0 g/cm^3) versus the weight of wood against a steel weight, we find that a 1 g weight of wood measured at sea level corresponds to a 1.003077 mass of wood, whereas a 1 g weight of wood measured in Denver corresponds to a 1.002511 mass of wood. The error in reporting that the weight of wood (neglecting air buoyancy) did not change would then be (1.003077 g $-$ 1.002511 g)/1 g = 0.06%, whereas the error in misreporting the mass of the wood at sea level to be 1 g would be (1.003077 g $-$ 1 g)/1.003077 g = 0.3%. It is better to assume that the variation in weight as a function of air buoyancy is negligible than to assume that the weighed amount is synonymous with the mass (Kupper, 1990).

We have not mentioned the variation in g with altitude, nor as influenced by solar and lunar tidal effects. We have already seen that g is factored out of the balance condition as long as it is held constant, so the problem will not be

encountered unless the balance is moved significantly in altitude and latitude without recalibrating. The calibration of a balance should nevertheless be validated any time it is moved to verify proper function. The effect of tidal variations on g has been determined to be of the order of 0.1 ppm (Kupper, 1997), arguably a negligible quantity considering the tolerance levels available (see discussion of Weight Standards).

Density is a derived unit defined as the mass per unit volume. Obviously, an accurate measure of both mass and volume is necessary to effect a measurement of the density. In metric units, density is typically reported in g/cm^3. A related property is the specific gravity, defined as the weight of a substance divided by the weight of an equal volume of water (the water standard is taken at 4°C, where its density is 1.000 g/cm^3). In metric units, the specific gravity has the same numerical value as the density, but is dimensionless.

In practice, density measurements of solids are made in the laboratory by taking advantage of Archimedes' principle of displacement. A fluid material, usually a liquid or gas, is used as the medium to be displaced by the material whose volume is to be measured. Precise density measurements require the material to be scrupulously clean, perhaps even degassed *in vacuo* to eliminate errors associated with adsorbed or absorbed species. The surface of the material may be porous in nature, so that a certain quantity of the displacement medium actually penetrates into the material. The resulting measured density will be intermediate between the "true" or absolute density of the material and the apparent measured density of the material containing, for example, air in its pores. Mercury is useful for the measurement of volumes of relatively smooth materials as the viscosity of liquid mercury at room temperature precludes the penetration of the liquid into pores smaller than ~5 μm at ambient pressure. On the other hand, liquid helium may be used to obtain a more faithful measurement of the absolute density, as the fluid will more completely penetrate voids in the material through pores of atomic dimension.

The true density of a material may be ascertained from the analysis of the lattice parameters obtained experimentally using diffraction techniques (see Parts X, XI, and XIII). The analysis of x-ray diffraction data elucidates the content of the unit cell in a pure crystalline material by providing lattice parameters that can yield information on vacant lattice sites versus free space in the arrangement of the unit cell. As many metallic crystals are heated, the population of vacant sites in the lattice are known to increase, resulting in a disproportionate decrease in density as the material is heated. Techniques for the measurement of true density has been reported by Feder and Nowick (1957) and by Simmons and Barluffi (1959, 1961, 1962).

WEIGHT STANDARDS

Researchers who make an effort to establish a meaningful mass measurement assurance program quickly become embroiled in a sea of acronyms and jargon. While only certain weight standards are germane to user of the precision laboratory balance, all categories of mass standards may be encountered in the literature and so we briefly list them here. In the United States, the three most common sources of weight standard classifications are NIST (formerly the National Bureau of Standards or NBS), ASTM, and the OIML. A 1954 publication of the NBS (NBS Circular 547) established seven classes of standards: J (covering denominations from 0.05 to 50 mg), M (covering 0.05 mg to 25 kg), S (covering 0.05 mg to 25 kg), S-1 (covering 0.1 mg to 50 kg), P (covering 1 mg to 1000 kg), Q (covering 1 mg to 1000 kg), and T (covering 10 mg to 1000 kg). These classifications were all replaced in 1978 by the ASTM standard E617 (ASTM, 1997), which recognizes the OIML recommendation R 111 (OIML, 1994); this standard was updated in 1997. NIST Handbook 105-1 further establishes class F, covering 1 mg to 5000 kg, primarily for the purpose of setting standards for field standards used in commerce. The ASTM standard E617 establishes eight classes (generally with tighter tolerances in the earlier classes): classes 0, 1, 2, and 3 cover the range from 1 mg to 50 kg, classes 4 and 5 cover the range from 1 mg to 5000 kg, class 6 covers 100 mg to 500 kg, and a special class, class 1.1, covers the range from 1 to 500 mg with the lowest set tolerance level (0.005 mg). The OIML R 111 establishes seven classes (also with more stringent tolerances associated with the earlier classes): E1, E2, F1, F2, and M1 cover the range from 1 mg to 50 kg, M2 covers 200 mg to 50 kg, and M3 covers 1 g to 50 kg. The ASTM classes 1 and 1.1 or OIML classes F1 and E2 are the most relevant to the precision laboratory balance. Only OIML class E1 sets stricter tolerances; this class is applied to primary calibration laboratories for establishing reference standards.

The most common material used in mass standards is stainless steel, with a density of 8.0 g/cm^3. Routine laboratory masses are often made of brass with a density of 8.4 g/cm^3. Aluminum, with a 2.7-g/cm^3 density, is often the material of choice for very small mass standards ($\leq$50 mg). The international mass standard is a 1-kg cylinder made of platinum-iridium (density 21.5 g/cm^3); this cylinder is housed in Sevres, France. Weight standard manufacturers should furnish a certificate that documents the traceability of the standard to the Sevres standard. A separate certificate may be issued that documents the calibration process for the weight, and may include a term to the effect "weights adjusted to an apparent density of 8.0 g/cm^3". These weights will have a true density that may actually be different than 8.0 g/cm^3 depending on the material used, as the specification implies that the weights have been adjusted so as to counterbalance a steel weight in an atmosphere of 0.0012 g/cm^3. In practice, variation of apparent density as a function of local atmospheric density is less than 0.1%, which is lower than the tolerances for all but the most exacting reference standards. Test procedures for weight standards are detailed in annex B of the latest OIML R 111 Committee Draft (1994). The magnetic susceptibility of steel weights, which may affect the calibration of balances based on the electromagnetic force compensation principle, is addressed in these procedures.

A few words about the selection of appropriate weight standards for a calibration routine are in order. A

fundamental consideration is the so-called 3:1 transfer ratio rule, which mandates that the error of the standard should be $<\frac{1}{3}$ the tolerance of the device being tested (ASTM, 1997). Two types of weights are typically used during a calibration routine, test weights and standard weights. Test weights are usually made of brass and have less stringent tolerances. These are useful for repetitive measurements such as those that test repeatability and off-center error (see Types of Balances). Standard weights are usually manufactured from steel and have tight, NIST-traceable tolerances. The standard weights are used to establish the accuracy of a measurement process, and must be handled with meticulous care to avoid unnecessary wear, surface contamination, and damage. Recalibration of weight standards is a somewhat nebulous issue, as no standard intervals are established. The investigator must factor in such considerations as the requirements of the particular program, historical data on the weight set, and the requirements of the measurement assurance program being used (see Mass Measurement Process Assurance).

TYPES OF BALANCES

NIST Handbook 44 (NIST, 1999) defines five classes of weighing device. Class I balances are precision laboratory weighing devices. Class II balances are used for laboratory weighing, precious metal and gem weighing, and grain testing. Class III, III L, and IIII balances are larger-capacity scales used in commerce, including everything from postal scales to highway vehicle-weighing scales. Calibration and verification procedures defined in NIST Handbook 44 have been adopted by all state metrology offices in the U.S.

Laboratory balances are chiefly available in three configurations: dual-pan equal-arm, mechanical single-pan, and top-loading. The equal arm balance is in essence that which is shown schematically in Figure 1. The single-pan balance replaces the second pan with a set of sliders, masses mounted on the lever itself, or in some cases a dial with a coiled spring that applies an adjustable and quantifiable counter-force. The most common laboratory balance is the top-loading balance. These normally employ an internal mechanism by which a series of internal masses (usually in the form of steel rings) or a system of mechanical flexures counter the applied load (Kupper, 1999). However, a spring load may be used in certain routine top-loading balances. Such concerns as changes in force constant of the spring, hysteresis in the material, etc., preclude the use of spring-loaded balances for all but the most routine measurements. On the other extreme are balances that employ electromagnetic force compensation in lieu of internal masses or mechanical flexures. These latter balances are becoming the most common laboratory balance due to their stability and durability, but it is important to note that the magnetic fields of the balance and sample may interact. Standard test methods for evaluating the performance of each of the three types of balance are set forth in ASTM standards E1270 (ASTM, 1988a; for equal-arm balances), E319 (ASTM, 1985; for mechanical single-pan balances), and E898 (ASTM, 1988b, for top-loading direct-reading balances).

A number of salient terms are defined in the ASTM standards; these terms are worth repeating here as they are often associated with the specifications that a balance manufacturer may apply to its products. The application of the principles set forth by these definitions in the establishment of a mass measurement process calibration will be summarized in the next section (see Mass Measurement Process Assurance).

Accuracy. The degree to which a measured value agrees with the true value.

Capacity. The maximum load (mass) that a balance is capable of measuring.

Linearity. The degree to which the measured values of a successive set of standard masses weighed on the balance across the entire operating range of the balance approximates a straight line. Some balances are designed to improve the linearity of a measurement by operating in two or more separately calibrated ranges. The user selects the range of operation before conducting a measurement.

Off-center Error. Any differences in the measured mass as a function of distance from the center of the balance pan.

Hysteresis. Any difference in the measured mass as a function of the history of the balance operation—e.g., a difference in measured mass when the last measured mass was larger than the present measurement versus the measurement when the prior measured mass was smaller.

Repeatability. The closeness of agreement for successive measurements of the same mass.

Reproducibility. The closeness of agreement of measured values when measurements of a given mass are repeated over a period of time (but not necessarily successively). Reproducibility may be affected by, e.g., hysteresis.

Precision. The smallest amount of mass difference that a balance is capable of resolving.

Readability. The value of the smallest mass unit that can be read from the readout without estimation. In the case of digital instruments, the smallest displayed digit does not always have a unit increment. Some balances increment the last digit by two or five, for example. Other balances incorporate a vernier or micrometer to subdivide the smallest scale division. In such cases, the smallest graduation on such devices represents the balance's readability.

Since the most common balance encountered in a research laboratory is of the electronic top-loading type, certain peculiar characteristics of this balance will be highlighted here. Balance manufacturers may refer to two categories of balance: those with versus those without internal calibration capability. In essence, an internal calibration capability indicates that a set of traceable standard masses is integrated into the mechanism of the counterbalance.

Table 1. Typical Types of Balance Available, by Capacity and Divisions

Name	Capacity (range)	Divisions Displayed
Ultramicrobalance	2 g	0.1 μg
Microbalance	3–20 g	1 μg
Semimicrobalance	30–200 g	10 μg
Macroanalytical balance	50–400 g	0.1 mg
Precision balance	100 g–30 kg	0.1 mg–1 g
Industrial balance	30–6000 kg	1 g–0.1 kg

A key choice that must be made in the selection of a balance for the laboratory is that of the operating range. A market survey of commercially available laboratory balances reveals that certain categories of balances are available. Table 1 presents common names applied to balances operating in a variety of weight measurement capacities. The choice of a balance or a set of balances to support a specific project is thus the responsibility of the investigator.

Electronically controlled balances usually include a calibration routine documented in the operation manual. Where they differ, the routine set forth in the relevant ASTM reference (E1270, E319, or E898) should be considered while the investigator identifies the control standard for the measurement process. Another consideration is the comparison of the operating range of the balance with the requirements of the measurement. An improvement in linearity and precision can be realized if the calibration routine is run over a range suitable for the measurement, rather than the entire operating range. However, the integral software of the electronics may not afford the flexibility to do such a limited function calibration. Also, the actual operation of an electronically controlled balance involves the use of a tare setting to offset such weights as that of the container used for a sample measurement. The tare offset necessitates an extended range that is frequently significantly larger than the range of weights to be measured.

MASS MEASUREMENT PROCESS ASSURANCE

An instrument is characterized by its capability to reproducibly deliver a result with a given readability. We often refer to a calibrated instrument; however, in reality there is no such thing as a calibrated balance *per se*. There are weight standards that are used to calibrate a weight measurement procedure, but that procedure can and should include everything from operator behavior patterns to systematic instrumental responses. In other words, it is the measurement process, not the balance itself that must be calibrated. The basic maxims for evaluating and calibrating a mass measurement process are easily translated to any quantitative measurement in the laboratory to which some standards should be attached for purposes of reporting, quality assurance, and reproducibility. While certain industrial, government, and even university programs have established measurement assurance programs [e.g., as required for International Standards Organization (ISO) 9000/9001 certification], the application of established standards to research laboratories is not always well defined. In general, it is the investigator who bears the responsibility for applying standards when making measurements and reporting results. Where no quality assurance programs are mandated, some laboratories may wish to institute a voluntary accreditation program. NIST operates the National Voluntary Laboratory Accreditation Program [NVLAP, telephone number (301) 975-4042] to assist such laboratories in achieving self-imposed accreditation (Harris, 1993).

The ISO Guide on the Expression of Uncertainty in Measurements (1992) identified and recommended a standardized approach for expressing the uncertainty of results. The standard was adopted by NIST and is published in NIST Technical Note 1297 (1994). The NIST publication simplifies the technical aspects of the standard. It establishes two categories of uncertainty, type A and type B. Type A uncertainty contains factors associated with random variability, and is identified solely by statistical analysis of measurement data. Type B uncertainty consists of all other sources of variability; scientific judgment alone quantifies this uncertainty type (Clark, 1994). The process uncertainty under the ISO recommendation is defined as the square root of the sum of the squares of the standard deviations due to all contributing factors. At a minimum, the process variation uncertainty should consist of the standard deviations of the mass standards used (s), the standard deviations of the measurement process (s_P), and the estimated standard deviations due to Type B uncertainty (u_B). Then, the overall process uncertainty (combined standard uncertainty) is $u_c = [(s)^2 + (s_P)^2 + (u_B)^2]^{1/2}$ (Everhart, 1995). This combined uncertainty value is multiplied by the coverage factor (usually 2) to report the expanded uncertainty (U) to the 95% (2-sigma) confidence level. NIST adopted the 2-sigma level for stating uncertainties in January 1994; uncertainty statements from NIST prior to this date were based on the 3-sigma (99%) confidence level. More detailed guidelines for the computation and expression of uncertainty, including a discussion of scatter analysis and error propagation, is provided in NIST Technical Note 1297 (1994). This document has been adopted by the CIPM, and it is available online (see Internet Resources).

J. Everhart (JTI Systems, Inc.) has proposed a process measurement assurance program that affords a powerful, systematic tool for accumulating meaningful data and insight on the uncertainties associated with a measurement procedure, and further helps to improve measurement procedures and data quality by integrating a calibration program with day-to-day measurements (Everhart, 1988). An added advantage of adopting such an approach is that procedural errors, instrument drift or malfunction, or other quality-reducing factors are more likely to be caught quickly.

The essential points of Everhart's program are summarized here.

1. Initial measurements are made by metrology specialists or experts in the measurement using a control standard to establish reference confidence limits.

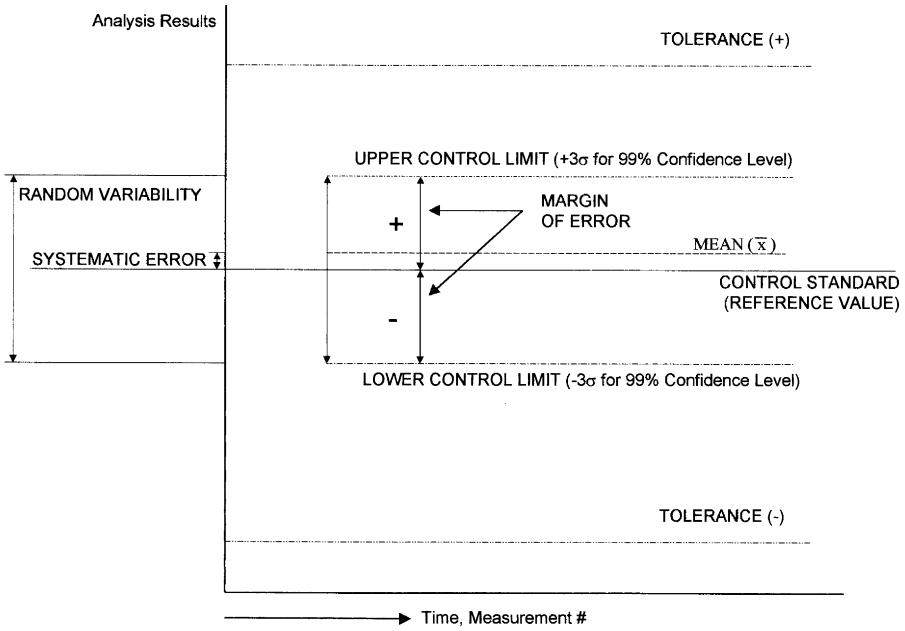

Figure 2. The process measurement assurance program control chart, identifying contributions to the errors associated with any measurement process. (After Everhart, 1988.)

2. Technicians or operators measure the control standard prior to each significant event as determined by the principal investigator (say, an experiment or even a workday).
3. Technicians or operators measure the control standard again after each significant event.
4. The data are recorded and the control measurements checked against the reference confidence limits.

The errors are analyzed and categorized as systematic (bias), random variability, and overall measurement system error. The results are plotted over time to yield a chart like that shown in Figure 2. It is clear how adopting such a discipline and monitoring the charted standard measurement data will quickly identify problems.

Essential practices to institute with any measurement assurance program are to apply an external check on the program (e.g., round robin), to have weight standards recalibrated periodically while surveillance programs are in place, and to maintain a separate calibrated weight standard, which is not used as frequently as the working standards (Harris, 1996). These practices will ensure both accuracy and traceability in the measurement process.

The knowledge of error in measurements and uncertainty estimates can immediately improve a quantitative measurement process. By establishing and implementing standards, higher-quality data and greater confidence in the measurements result. Standards established in industrial or federal settings should be applied in a research environment to improve data quality. The measurement of mass is central to the analysis of materials properties, so the importance of establishing and reporting uncertainties and confidence limits along with the measured results cannot be overstated. Accurate record keeping and data analysis can help investigators identify and correct such problems as bias, operator error, and instrument malfunctions before they do any significant harm.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the contribution of Georgia Harris of the NIST Office of Weights and Measures for providing information, resources, guidance, and direction in the preparation of this unit and for reviewing the completed manuscript for accuracy. We also wish to thank Dr. John Clark for providing extensive resources that were extremely valuable in preparing the unit.

THERMOMETRY

DEFINITION OF THERMOMETRY AND TEMPERATURE: THE CONCEPT OF TEMPERATURE

Thermometry is the science of measuring temperature, and thermometers are the instruments used to measure temperature. Temperature must be regarded as the scientific measure of "hotness" or "coldness." This unit is concerned with the measurement of temperatures in materials of interest to materials science, and the notion of temperature is thus limited in this discussion to that which applies to materials in the solid, liquid, or gas state (as opposed to the so-called temperature associated with ion

gases and plasmas, which is no longer limited to a measure of the internal kinetic energy of the constituent atoms).

A brief excursion into the history of temperature measurement will reveal that measurement of temperature actually preceded the modern definition of temperature and a temperature scale. Galileo in 1594 is usually credited with the invention of a thermometer in the form that indicated the expansion of air as the environment became hotter (Middleton, 1966). This instrument was called a thermoscope, and consisted of air trapped in a bulb by a column of liquid (Galileo used water) in a long tube attached to the bulb. It can properly be called an air thermometer when a scale is added to measure the expansion, and such an instrument was described by Telioux in 1611. Variation in atmospheric pressure would cause the thermoscope to develop different readings, as the liquid was not sealed into the tube and one surface of the liquid was open to the atmosphere.

The simple expedient of sealing the instrument so that the liquid and gas were contained in the tube really marks the invention of a glass thermometer. By making the diameter of the tube small, so that the volume of the gas was considerably reduced, the liquid dilation in these sealed instruments could be used to indicate the temperature. Such a thermometer was used by Ferdinand II, Grand Duke of Tuscany, about 1654. Fahrenheit eventually substituted mercury for the "spirits of wine" earlier used as the working liquid fluid, because mercury's thermal expansion with temperature is more nearly linear. Temperature scales were then invented using two selected fixed points—usually the ice point and the blood point or the ice point and the boiling point.

THE THERMODYNAMIC TEMPERATURE SCALE

The starting point for the thermodynamic treatment of temperature is to state that it is a property that determines in which direction energy will flow when it is in contact with another object. Heat flows from a higher-temperature object to a lower-temperature object. When two objects have the same temperature, there is no flow of heat between them and the objects are said to be in thermal equilibrium. This forms the basis of the Zeroth Law of thermodynamics. The First Law of thermodynamics stipulates that energy must be conserved during any process. The Second Law introduces the concepts of spontaneity and reversibility—for example, heat flows spontaneously from a higher-temperature system to a lower-temperature one. By considering the direction in which processes occur, the Second Law implicitly demands the passage of time, leading to the definition of entropy. Entropy, S, is defined as the thermodynamic state function of a system where $dS \geq \delta q/T$, where q is the heat and T is the temperature. When the equality holds, the process is said to be reversible, whereas the inequality holds in all known processes (i.e., all known processes occur irreversibly). It should be pointed out that dS (and hence the ratio $\delta q/T$ in a reversible process) is an exact differential, whereas δq is not. The flow of heat in an irreversible process is path dependent. The Third Law defines the absolute zero point of the thermodynamic temperature scale, and further stipulates that no process can reduce the temperature of a macroscopic system to this point. The laws of thermodynamics are defined in detail in all introductory texts on the topic of thermodynamics (e.g., Rock, 1983).

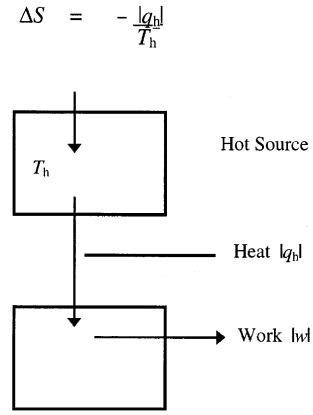

Figure 1. Change in entropy when heat is completely converted into work.

A consideration of the efficiency of heat engines leads to a definition of the thermodynamic temperature scale. A heat engine is a device that converts heat into work. Such a process of producing work in a heat engine must be spontaneous. It is necessary then that the flow of energy from the hot source to the cold sink be accompanied by an overall increase in entropy. Thus in such a hypothetical engine, heat, $|q|$, is extracted from a hot sink of temperature, T_h, and converted completely to work. This is depicted in Figure 1. The change in entropy, ΔS, is then:

$$\Delta S = \frac{-|q|}{T_h} \tag{1}$$

This value of ΔS is negative, and the process is nonspontaneous.

With the addition of a cold sink (see Fig. 2), the removal of the $|q_h|$ from the hot sink changes its entropy by

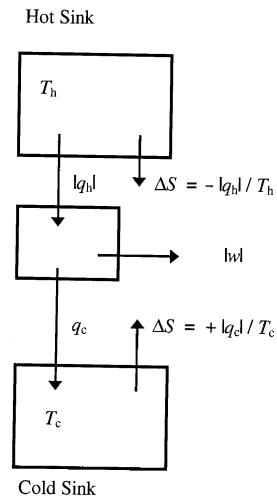

Figure 2. Change in entropy when some heat from the hot sink is converted into work and some into a cold sink.

$-|q_h|/T_h$ and the transfer of $|q_c|$ to the cold sink increases its entropy by $|q_c|/T_c$. The overall entropy change is:

$$\Delta S = \frac{-|q_h|}{T_h} + \frac{|q_c|}{T_c} \tag{2}$$

ΔS is then greater than zero if:

$$|q_c| \geq (T_c/T_h) \cdot |q_h| \tag{3}$$

and the process is spontaneous.

The maximum work of the engine can then be given by:

$$\begin{aligned} |w_{max}| &= |q_h| - |q_{c_{min}}| \\ &= |q_h| - (T_c/T_h) \cdot |q_h| \\ &= [1 - (T_c/T_h)] \cdot |q_h| \end{aligned} \tag{4}$$

The maximum possible efficiency of the engine is:

$$\varepsilon_{rev} = \frac{|w_{max}|}{|q_h|} \tag{5}$$

when by the previous relationship $\varepsilon_{rev} = 1 - (T_c/T_h)$.

If the engine is working reversibly, $\Delta S = 0$ and

$$\frac{|q_c|}{|q_h|} = \frac{T_c}{T_h} \tag{6}$$

Kelvin used this to define the thermodynamic temperature scale using the ratio of the heat withdrawn from the hot sink and the heat supplied to the cold sink. The zero in the thermodynamic temperature scale is the value of T_c at which the Carnot efficiency equals 1, and work output equals the heat supplied (see, e.g., Rock, 1983). Then for $\varepsilon_{rev} = 1$, $T = 0$.

If now a fixed point, such as the triple point of water, is chosen for convenience, and this temperature T_3 is set as 273.16 K to make the Kelvin equivalent to the currently used Celsius degree, then:

$$T_c = (|q_c|/|q_h|) \cdot T_3 \tag{7}$$

The importance of this is that the temperature is defined independent of the working substance.

The perfect-gas temperature scale is independent of the identity of the gas and is identical to the thermodynamic temperature scale. This result is due to the observation of Charles that for a sample of gas subjected to a constant low pressure, the volume, V, varied linearly with temperature whatever the identity of the gas (see, e.g., Rock, 1983; McGee, 1988).

Thus $V =$ constant $(\theta + 273.15^\circ C)$ at constant pressure, where θ denotes the temperature on the Celsius scale and $T\ (\equiv \theta + 273.15)$ is the temperature on the Kelvin, or absolute scale. The volume will approach zero on cooling at $T = -273.15^\circ C$. This is termed the absolute zero. It should be noted that it is not possible to cool real gases to zero volume because they condense to a liquid or a solid before absolute zero is reached.

DEVELOPMENT OF THE INTERNATIONAL TEMPERATURE SCALE OF 1990

In 1927, the International Conference of Weights and Measures approved the establishment of an International Temperature Scale (ITS, 1927). In 1960, the name was changed to the International Practical Temperature Scale (IPTS). Revisions of the scale took place in 1948, 1954, 1960, 1968, and 1990. Six international conferences under the title "Temperature, Its Measurement and Control in Science and Industry" were held in 1941, 1955, 1962, 1972, 1982, and 1992 (Wolfe, 1941; Herzfeld, 1955, 1962; Plumb, 1972; Billing and Quinn, 1975; Schooley, 1982, 1992). The latest revision in 1990 again changed the name of the scale to the International Temperature Scale 1990 (ITS-90).

The necessary features required by a temperature scale are (Hudson, 1982):

1. Definition;
2. Realization;
3. Transfer; and
4. Utilization.

The ITS-90 temperature scale is the best available approximation to the thermodynamic temperature scale. The following points deal with the definition and realization of the IPTS and ITS scale as they were developed over the years.

1. Fixed points are used based on thermodynamic invariant points. These are such points as freezing points and triple points of specific systems. They are classified as (a) defining (primary) and (b) secondary, depending on the system of measurement and/or the precision to which they are known.
2. The instruments used in interpolating temperatures between the fixed points are specified.
3. The equations used to calculate the intermediate temperature between each defining temperature must agree. Such equations should pass through the defining fixed points.

In given applications, use of the agreed IPTS instruments is often not practicable. It is then necessary to transfer the measurement from the IPTS and ITS method to another, more practical temperature-measuring instrument. In such a transfer, accuracy is necessarily reduced, but such transfers are required to allow utilization of the scale.

The IPTS-27 Scale

The IPTS scale as originally set out defined four temperature ranges and specified three instruments for measuring temperatures and provided an interpolating equation for each range. It should be noted that this is now called the IPTS-27 scale even though the 1927 version was called ITS, and two revisions took place before the name was changed to IPTS.

Range I: The oxygen point to the ice point (−182.97 to 0°C);

Range II: The ice point to the aluminum point (0 to 660°C);

Range III: The aluminum point to the gold point (660 to 1063.0°C);

Range IV: Above the gold point (1063.0°C and higher).

The oxygen point is defined as the temperature at which liquid and gaseous oxygen are in equilibrium, and the ice and metal points are defined as the temperature at which the solid and liquid phases of the material are in equilibrium. The platinum resistance thermometer was used for ranges I and II, the platinum versus platinum (90%)/rhodium (10%) thermocouple was used for range III, and the optical pyrometer was used for range IV. In subsequent IPTS scales (and ITS-90), these instruments are still used, but the interpolating equations and limits are modified. The IPTS-27 was based on the ice point and the steam point as true temperatures on the thermodynamic scale.

Subsequent Revision of the Temperature Scales Prior to that of 1990

In 1954, the triple point of water and the absolute zero were used as the two points defining the thermodynamic scale. This followed a proposal originally advocated by Kelvin. In 1975, the Kelvin was adopted as the standard temperature unit. The symbol T represents the thermodynamic temperature with the unit Kelvin. The Kelvin is given the symbol K, and is defined by setting the melting point of water equal to 273.15 K. In practice, for historical reasons, the relationship between T and the Celsius temperature (t) is defined as $t = T - 273.15$ K (the fixed points on the Celsius scale are water's melting point and boiling point). By definition, the degree Celsius (°C) is equal in magnitude to the Kelvin.

The IPTS-68 was amended in 1975 and a set of defining fixed points (involving hydrogen, neon, argon, oxygen, water, tin, zinc, silver, and gold) were listed.

The IPTS-68 had four ranges:

Range I: 13.8 to 273.15 K, measured using a platinum resistance thermometer. This was divided into four parts.

Part A: 13.81 to 17.042 K, determined using the triple point of equilibrium hydrogen and the boiling point of equilibrium hydrogen.

Part B: 17.042 to 54.361 K, determined using the boiling point of equilibrium hydrogen, the boiling point of neon, and the triple point of oxygen.

Part C: 54.361 to 90.188 K, determined using the triple point of oxygen and the boiling point of oxygen.

Part D: 90.188 to 273.15 K, determined using the boiling point of oxygen and the boiling point of water.

Range II: 273.15 to 903.89 K, measured using a platinum resistance thermometer, using the triple point of water, the boiling point of water, the freezing point of tin, and the freezing point of zinc.

Range III: 903.89 to 1337.58 K, measured using a platinum versus platinum (90%)/rhodium (10%) thermocouple, using the antimony point and the freezing points of silver and gold, with cross-reference to the platinum resistance thermometer at the antimony point.

Range IV: All temperatures above 1337.58 K. This is the gold point (at 1064.43°C), but no particular thermal radiation instrument is specified.

It should be noted that temperatures in range IV are defined by fundamental relationships, whereas the other three IPTS defining equations are not fundamental. It must also be stated that the IPTS-68 scale is not defined below the triple point of hydrogen (13.81 K).

The International Temperature Scale of 1990

The latest scale is the International Temperature Scale of 1990 (ITS-90). Figure 3 shows the various temperature ranges set out in ITS-90. T_{90} (meaning the temperature defined according to ITS-90) is stipulated from 0.65 K to the highest temperature using various fixed points and the helium vapor-pressure relations. In Figure 3, these "fixed points" are set out in the diagram to the nearest integer. A review has been provided by Swenson (1992). In ITS-90 an overlap exists between the major ranges for three of the four interpolation instruments, and in addition there are eight overlapping subranges. This represents a change from the IPTS-68. There are alternative definitions of the scale existing for different temperature ranges and types of interpolation instruments. Aspects of the temperature ranges and the interpolating instruments can now be discussed.

Helium Vapor Pressure (0.65 to 5 K). The helium isotopes ^{3}He and ^{4}He have normal boiling points of 3.2 K and 4.2 K respectively, and both remain liquids to $T = 0$. The helium vapor pressure–temperature relationship provides a convenient thermometer in this range.

Interpolating Gas Thermometer (3 to 24.5561 K). An interpolating constant-volume gas thermometer (1 CVGT) using ^{4}He as the gas is suggested with calibrations at three fixed points (the triple point of neon, 24.6 K; the triple point of equilibrium hydrogen, 13.8 K; and the normal boiling point of ^{4}He, 4.2 K).

Platinum Resistance Thermometer (13.8033 K to 961.78°C). It should be noted that temperatures above 0°C are typically recorded in °C and not on the absolute scale. Figure 3 indicates the fixed points and the range over which the platinum resistance thermometer can be used. Swenson (1992) gives some details regarding common practice in using this thermometer. The physical requirement for platinum thermometers that are used at high temperatures and at low temperatures are different, and no single thermometer can be used over the entire range.

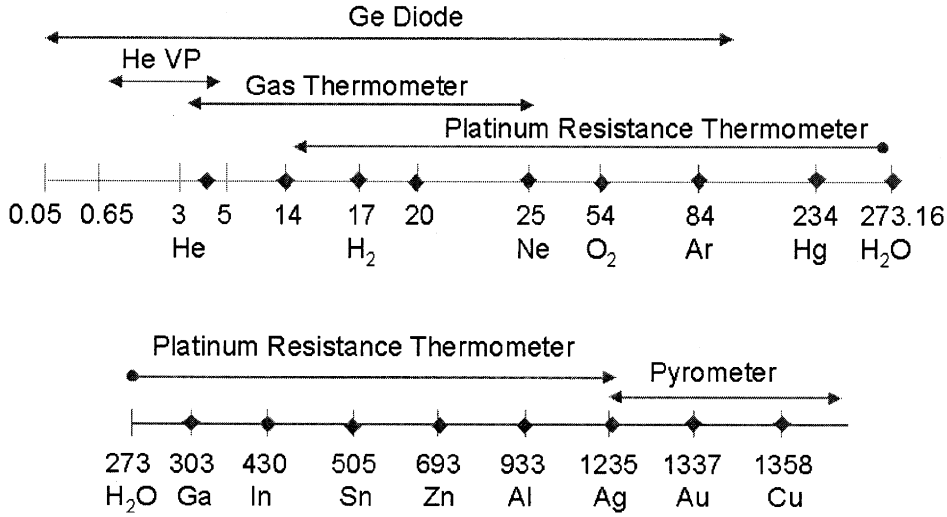

Figure 3. The International Temperature Scale of 1990 with some key temperatures noted. Ge diode range is shown for reference only; it is not defined in the ITS-90 standard. (See text for further details and explanation.)

Optical Pyrometry (above 961.78°C). In this temperature range the silver, gold, or copper freezing point can be used as reference temperatures. The silver point at 961.78°C is at the upper end of the platinum resistance scale, because have thermometers have stability problems (due to such effects as phase changes, changes in heat capacity, and degradation of welds and joints between constituent materials) above this temperature.

TEMPERATURE FIXED POINTS AND DESIRED CHARACTERISTICS OF TEMPERATURE MEASUREMENT PROBES

The Fixed Points

The ITS-90 scale utilized various "defining fixed points." These are given below in order of increasing temperature. (*Note:* all substances except ^{3}He are defined to be of natural isotopic composition.)

- The vapor point of ^{3}He between 3 and 5 K;
- The triple point of equilibrium hydrogen at 13.8033 K (equilibrium hydrogen is defined as the equilibrium concentrations of the *ortho* and *para* forms of the substance);
- An intermediate equilibrium hydrogen vapor point at ≈17 K;
- The normal boiling point of equilibrium hydrogen at ≈20.3 K;
- The triple point of neon at 24.5561 K;
- The triple point of oxygen at 54.3584 K;
- The triple point of argon at 83.8058 K;
- The triple point of mercury at 234.3156 K;
- The triple point of water at 273.16 K (0.01°C);
- The melting point of gallium at 302.9146 K (29.7646°C);
- The freezing point of indium at 429.7485 K (156.5985°C);
- The freezing point of tin at 505.078 K (231.928°C);
- The freezing point of zinc at 692.677 K (419.527°C);
- The freezing point of aluminum at 933.473 K (660.323°C);
- The freezing point of silver at 1234.93 K (961.78°C);
- The freezing point of gold at 1337.33 K (1064.18°C);
- The freezing point of copper at 1357.77 K (1084.62°C).

The reproducibility of the measurement (and/or known difficulties with the occurrence of systematic errors in measurement) dictates the property to be measured in each case on the scale. There remains, however, the question of choosing the temperature measurement probe—in other words, the best thermometer to be used. Each thermometer consists of a temperature sensing device, an interpretation and display device, and a method of connecting one to another.

The Sensing Element of a Thermometer

The desired characteristics for a sensing element always include:

1. *An Unambiguous (Monotonic) Response with Temperature*. This type of response is shown in Figure 4A. Note that the appropriate response need not be linear with temperature. Figure 4B shows an ambiguous response of the sensing property to temperature where there may be more than one temperature at which a particular value of the sensing property occurs.
2. *Sensitivity*. There must be a high sensitivity (δ) of the temperature-sensing property to temperature. Sensitivity is defined as the first derivative of the property (X) with respect to temperature: $\delta = \partial X/\partial T$.
3. *Stability*. It is necessary for the sensing element to remain stable, with the same sensitivity over a long time.

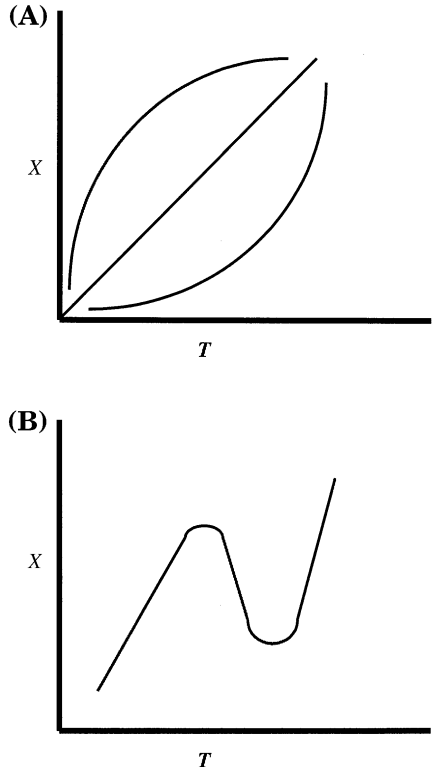

Figure 4. (**A**) An acceptable unambiguous response of temperature-sensing element (*X*) versus temperature (*T*). (**B**) An unacceptable unambiguous response of temperature-sensing element (*X*) versus temperature.

4. *Cost*. A relatively low cost (with respect to the project budget) is desirable.
5. *Range*. A wide range of temperature measurements makes for easy instrumentation.
6. *Size*. The element should be small (i.e., with respect to the sample size, to minimize heat transfer between the sample and the sensor).
7. *Heat Capacity*. A relatively small heat capacity is desirable—i.e., the amount of heat required to change the temperature of the sensor must not be too large.
8. *Response*. A rapid response is required (this is achieved in part by minimizing sensor size and heat capacity).
9. *Usable Output*. A usable output signal is required over the temperature range to be measured (i.e., one should maximize the dynamic range of the signal for optimal temperature resolution).

Naturally, all items are defined relative to the components of the system under study or the nature of the experiment being performed. It is apparent that in any single instrument, compromises must be made.

Readout Interpretation

Resolution of the temperature cannot be improved beyond that of the sensing device. Desirable features on the signal-receiving side include:

1. Sufficient sensitivity for the sensing element;
2. Stability with respect to time;
3. Automatic response to the signal;
4. Possession of data logging and archiving capabilities;
5. Low cost.

TYPES OF THERMOMETER

Liquid-Filled Thermometers

The discussion is limited to practical considerations. It should be noted, however, that the most common type of thermometer in this class is the mercury-filled glass thermometer.

Overall there are two types of liquid-filled systems:

1. Systems filled with a liquid other than mercury
2. Mercury-filled systems.

Both rely on the temperature being indicated by a change in volume. The lower range is dictated by the freezing point of the fill liquid; the upper range must be below the point at which the liquid is unstable, or where the expansion takes place in an unacceptably nonlinear fashion. The nature of the construction material is important. In many instances, the container is a glass vessel with expansion read directly from a scale. In other cases, it is a metal or ceramic holder attached to a capillary, which drives a Bourdon tube (a diaphragm or bellows device). In general organic liquids have a coefficient of expansion some 8 times that of mercury, and temperature spans for accurate work of some 10 to 25°C are dictated by the size of the container bulb for the liquid. Organic fluids are available up to 250°C, while mercury-filled systems can operate up to 650°C. Liquid-filled systems are unaffected by barometric pressure changes. Certificates of performance can generally be obtained from the instrument manufacturers.

Gas-Filled Thermometers

In vapor-pressure thermometers, the container is partially filled with a volatile liquid. Temperature at the bulb is conditioned by the fact that the interface between the liquid and the gas must be located at the point of measurement, and the container must represent the coolest point of the system. Notwithstanding the previous considerations applying to temperature scale, in practice vapor-filled systems can be operated from -40 to ~ 320°C.

A further class of gas-filled systems is one that simply relies on the expansion of a gas. Such systems are based on Charles' Law:

$$P = \frac{KT}{V} \tag{8}$$

where P is the pressure, T is the temperature (Kelvin), and V is the volume. K is a constant. The range of practical application is the widest of any filled systems. The lowest temperature is that at which the gas becomes liquid. The

highest temperature depends on the thermal stability of the gas or the construction material.

Electrical-Resistance Thermometers

A resistance thermometer is dependent upon the electrical resistance of a conducting metal changing with the temperature. In order to minimize the size of the equipment, the resistance of the wire or film should be relatively high so that the resistance can easily be measured. The change in resistance with temperature should also be large. The most common material used is a platinum wire-wound element with a resistance of $\sim$100 Ω at 0°C. Calibration standards are essential (see the previous discussion on the International Temperature Standards). Commercial manufacturers will provide such instruments together with calibration details. Thin-film platinum elements may provide an alternative design feature and are priced competitively with the more common wire-wound elements. Nickel and copper resistance elements are also commercially available.

Thermocouple Thermometers

A thermocouple is an assembly of two wires of unlike metals joined at one end where the temperature is to be measured. If the other end of one of the thermocouple wires leads to a second, similar junction that is kept at a constant reference temperature, then a temperature-dependent voltage develops called the Seebeck voltage (see, e.g., McGee, 1988). The constant-temperature junction is often kept at 0°C and is referred to as the cold junction. Tables are available of the EMF generated versus temperature when one thermocouple is kept as a cold junction at 0°C for specified metal/metal thermocouple junctions. These scales may show a nonlinear variation with temperature, so it is essential that calibration be carried out using phase transitions (i.e., melting points or solid-solid transitions). Typical thermocouple systems are summarized in Table 1.

Table 1. Some Typical Thermocouple Systems[a]

System	Use
Iron-Constantan	Used in dry reducing atmospheres up to 400°C General temperature scale: 0° to 750°C
Copper-Constantan	Used in slightly oxidizing or reducing atmospheres For low-temperature work: −200° to 50°C
Chromel-Alumel	Used only in oxidizing atmospheres Temperature range: 0° to 1250°C
Chromel-Constantan	Not to be used in atmospheres that are strongly reducing atmospheres or contain sulfur compounds Temperature range: −200° to 900°C
Platinum-Rhodium (or suitable alloys)	Can be used as components for thermocouples operating up to 1700°C

[a]Operating conditions and calibration details should always be sought from instrument manufactures.

Thermistors and Semiconductor-Based Thermometers

There are various types of semiconductor-based thermometers. Some semiconductors used for temperature measurements are called thermistors or resistive temperature detectors (RTDs). Materials can be classified as electrical conductors, semiconductors, or insulators depending on their electrical conductivity. Semiconductors have $\sim$10 to 10^6 Ω-cm resistivity. The resistivity changes with temperature, and the logarithm of the resistance plotted against reciprocal of the absolute temperature is often linear. The actual value for the thermistor can be fixed by deliberately introducing impurities. Typical materials used are oxides of nickel, manganese, copper, titanium, and other metals that are sintered at high temperatures. Most thermistors have a negative temperature coefficient, but some are available with a positive temperature coefficient. A typical thermistor with a resistance of 1200 Ω at 40°C will have a 120-Ω resistance at 110°C. This represents a decrease in resistance by a factor of about 2 for every 20°C increase in temperature, which makes it very useful for measuring very small temperature spans. Thermistors are available in a wide variety of styles, such as small beads, discs, washers, or rods, and may be encased in glass or plastic or used bare as required by their intended application. Typical temperature ranges are from −30° to 120°C, with generally a much greater sensitivity than for thermocouples. The germanium diode is an important thermistor due to its responsivity range—germanium has a well-characterized response from 0.05° to 100° Kelvin, making it well-suited to extremely low-temperature measurement applications. Germanium diodes are also employed in emissivity measurements (see the next section) due to their extremely fast response time—nanosecond time resolution has been reported (Xu et al., 1996). Ruthenium oxide RTDs are also suitable for extremely low-temperature measurement and are found in many cryostat applications.

Radiation Thermometers

Radiation incident on matter must be reflected, transmitted, or absorbed to comply with the First Law of Thermodynamics. Thus the reflectance, r, the transmittance, t, and the absorbance, a, sum to unity (the reflectance [transmittance, absorbance] is defined as the ratio of the reflected [transmitted, absorbed] intensity to the incident intensity). This forms the basis of Kirchoff's law of optics. Kirchoff recognized that if an object were a perfect absorber, then in order to conserve energy, the object must also be a perfect emitter. Such a perfect absorber/emitter is called a "black body." Kirchoff further recognized that the absorbance of a black body must equal its emittance, and that a black body would be thus characterized by a certain brightness that depends upon its temperature (Wolfe, 1998). Max Planck identified the quantized nature of the black body's emittance as a function of frequency by treating the emitted radiation as though it were the result of a linear field of oscillators with quantized energy states. Planck's famous black-body law relates the radiant

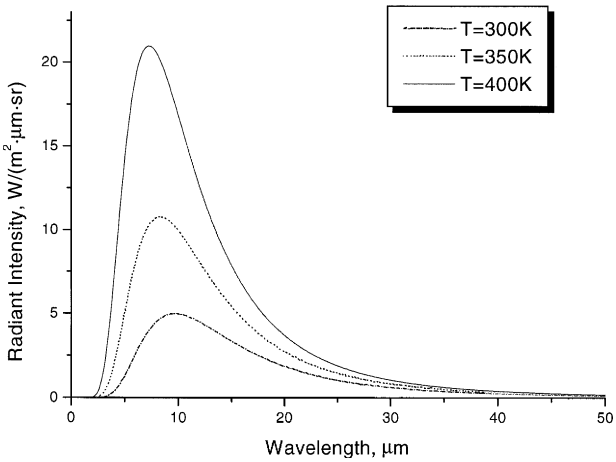

Figure 5. Spectral distribution of radiant intensity as a function of temperature.

intensity to the temperature as follows:

$$I_v = \frac{2hv^3n^2}{c^2}\frac{1}{\exp(hv/kT)-1} \tag{9}$$

where h is Planck's constant, v is the frequency, n is the refractive index of the medium into which the radiation is emitted, c is the velocity of light, k is Boltzmann's constant, and T is the absolute temperature. Planck's law is frequently expressed in terms of the wavelength of the radiation since in practice the wavelength is the measured quantity. Planck's law is then expressed as

$$I_\lambda = \frac{C_1}{\lambda^5(e^{C_2/\lambda T}-1)} \tag{10}$$

where C_1 $(= 2hc^2/n^2)$ and C_2 $(= hc/nk)$ are known as the first and second radiation constant, respectively. A plot of the Planck's law intensity at various temperatures (Fig. 5) demonstrates the principle by which radiation thermometers operate.

The radiative intensity of a black-body surface depends upon the viewing angle according to the Lambert cosine law, $I_\theta = I\cos\theta$. Using the projected area in a given direction given by $dA\cos\theta$, the radiant emission per unit of projected area, or radiance (L), for a black body is given by $L = I\cos\theta/\cos\theta = I$. For real objects, $L \neq I$ because factors such as surface shape, roughness, and composition affect the radiance. An important consequence of this is that emittance is a not an intrinsic materials property. The emissivity, emittance from a perfect material under ideal conditions (pure, atomically smooth and flat surface free of pores or oxide coatings), is a fundamental materials property defined as the ratio of the radiant flux density of the material to that of a black body under the same conditions (likewise, absorptivity and reflectivity are materials properties). Emissivity is extremely difficult to measure accurately, and emittance is often erroneously reported as emissivity in the literature (McGee, 1988). Both emittance and emissivity can be taken at a single wavelength (spectral emittance), over a range of wavelengths (partial emittance), or over all wavelengths (total emittance). It is important to properly determine the emittance of any real material being measured in order convert radiant intensity to temperature. For example, the spectral emittance of polished brass is 0.05, while that of oxidized brass is 0.61 (McGee, 1988). An important ramification of this effect is the fact that it is not generally possible to accurately measure the emissivity of polished, shiny surfaces, especially metallic ones, whose signal is dominated by reflectivity.

Radiation thermometers measure the amount of radiation (in a selected spectral band—see below) emitted by the object whose temperature is to be measured. Such radiation can be measured from a distance, so there is no need for contact between the thermometer and the object. Radiation thermometers are especially suited to the measurement of moving objects, or of objects inside vacuum or pressure vessels. The types of radiation thermometers commonly available are:

broadband thermometers
bandpass thermometers
narrow-band thermometers
ratio thermometers
optical pyrometers and
fiberoptic thermometers.

Broadband thermometers have a response from 0.3 μm optical wavelength to an upper limit of 2.5 to 20 μm, governed by the lens or window material. Bandpass thermometers have lenses or windows selected to view only nine selected portions of the spectrum. Narrow-band thermometers respond to an extremely narrow range of wavelengths. A ratio thermometer measures radiated energy in two narrow bands and calculates the ratio of intensities at the two energies. Optical pyrometers are really a special form of narrow-band thermometer, measuring radiation from a target in a narrow band of visible wavelengths centered at ~0.65 μm in the red portion of the spectrum. A fiberoptic thermometer uses a light guide to guide the radiation from the target to the detector. An important consideration is the so-called "atmospheric window" when making distance measurements. The 8- to 14-μm range is the most common region selected for optical pyrometric temperature measurement. The constituents of the atmosphere are relatively transparent in this region (that is, there are no infrared absorption bands from the most common atmospheric constituents, so no absorption or emission from the atmosphere is observed in this range).

TEMPERATURE CONTROL

It is not necessarily sufficient to measure temperature. In many fields it is also necessary to control the temperature. In an oven, a furnace, or a water bath, a constant temperature may be required. In other uses in analytical instrumentation, a more sophisticated temperature program may be required. This may take the form of a constant heating rate or may be much more complicated.

A temperature controller must:

1. receive a signal from which a temperature can be deduced;
2. compare it with the desired temperature; and
3. produce a means of correcting the actual temperature to move it towards the desired temperature.

The control action can take several forms. The simplest form is an on-off control. Power to a heater is turned on to reach a desired temperature but turned off when a certain temperature limit is reached. This cycling motion of control results in temperatures that oscillate between two set points once the desired temperature has been reached. A proportional control, in which the amount of temperature correction power depends on the magnitude of the "error" signal, provides a better system. This may be based on proportional bandwidth integral control or derivative control. The use of a dedicated computer allows observations to be set (and corrected) at desired intervals and corresponding real-time plots of temperature versus time to be obtained.

The Bureau International des Poids et Mesures (BIPM) ensures worldwide uniformity of measurements and their traceability to the Système Internationale (SI), and carries out measurement-related research. It is the proponent for the ITS-90 and the latest definitions can be found (in French and English) at *http://www.bipm.fr*.

The ITS-90 site, at *http://www.its-90.com*, also has some useful information. The text of the document is reproduced here with the permission of Metrologia (Springer-Verlag).

ACKNOWLEDGMENTS

The series editor gratefully acknowledges Christopher Meyer, of the Thermometry group of the National Institute of Standards and Technology (NIST), for discussions and clarifications concerning the ITS-90 temperature standards.

APPENDIX: TEMPERATURE-MEASUREMENT RESOURCES

Several manufacturers offer a significant level of expertise in the practical aspects of temperature measurement, and can assist researchers in the selection of the most appropriate instrument for their specific task. A noteworthy source for thermometers, thermocouples, thermistors, and pyrometers is Omega Engineering (*www.omega.com*). Omega provides a detailed catalog of products interlaced with descriptive essays of the underlying principles and practical considerations. The Mikron Instrument Company (*www.mikron.com*) manufactures an extensive line of infrared temperature measurement and calibration black-body sources. Graesby is also an excellent resource for extended-area calibration black-body sources. Inframetrics (*www. inframetrics.com*) manufactures a line of highly configurable infrared radiometers. All temperature measurement manufacturers offer calibration services with NIST-traceable certification.

Germanium and ruthenium RTDs are available from most manufacturers specializing in cryostat applications. Representative companies include Quantum Technology (*www.quantum-technology.com*) and Scientific Instruments (*www.scientificinstruments.com*). An extremely useful source for instrument interfacing (for automation and digital data acquisition) is National Instruments (*www. natinst.com*)

SYMMETRY IN CRYSTALLOGRAPHY

INTRODUCTION

The study of crystals has fascinated humanity for centuries, with motivations ranging from scientific curiosity to the belief that they had magical powers. Early crystal science was devoted to descriptive efforts, limited to measuring interfacial angles and determining optical properties. Some investigators, such as Haüy, attempted to deduce the underlying atomic structure from the external morphology. These efforts were successful in determining the symmetry operations relating crystal faces and led to the theory of point groups, the assignment of all known crystals to only seven crystal systems, and extensive compilations of axial ratios and optical indices. Roentgen's discovery of x rays and Laue's subsequent discovery of the scattering of x rays by crystals revolutionized the study of crystallography: crystal structures—i.e., the relative location of atoms in space—could now be determined unequivocally. The benefits derived from this knowledge have enhanced fundamental science, technology, and medicine ever since and have directly contributed to the welfare of human society.

This chapter is designed to introduce those with limited knowledge of space groups to a topic that many find difficult.

SYMMETRY OPERATORS

A crystalline material contains a periodic array of atoms in three dimensions, in contrast to the random arrangement of atoms in an amorphous material such as glass. The periodic repetition of a motif along a given direction in space within a fixed length t parallel to that direction constitutes the most basic symmetry operation. The motif may be a single atom, a simple molecule, or even a large, complex molecule such as a polymer or a protein. The periodic repetition in space along three noncollinear, noncoplanar vectors describes a unit parallelepiped, the unit cell, with periodically repeated lengths **a**, **b**, and **c**, the metric unit cell parameters (Fig. 1). The atomic content of this unit cell is the fundamental building block of the crystal structure. The macroscopic crystalline material results from the periodic repetition of this unit cell. The atoms within a unit cell may be related by additional symmetry operators.

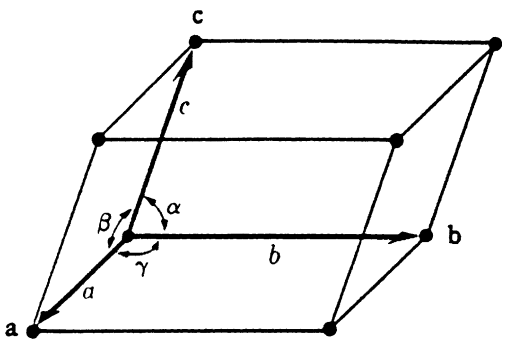

Figure 1. A unit cell.

Proper Rotation Axes

A proper rotation axis, n, repeats an object every $2\pi/n$ radians. Only 1-, 2-, 3-, 4-, and 6-fold axes are consistent with the periodic, space-filling repetition of the unit cell. In contrast, molecular symmetry axes can have any value of n. Figure 2A illustrates the appearance of space that results from the action of a proper rotation axis on a given motif. Note that a 1-fold axis—i.e., rotation by 360°—is a legitimate symmetry operation. These objects retain their handedness. The reversal of the direction of rotation will superimpose the objects without removing them from the plane perpendicular to the rotation axis. After 2π radians the rotated motif superimposes directly on the initial object. The repetition of motifs by a proper rotation axis forms congruent objects.

Improper Rotation Axes

Improper rotation axes are compound symmetry operations consisting of rotation followed by inversion or mirror reflection. Two conventions are used to designate symmetry operators. The International or Hermann-Mauguin symbols are based on rotoinversion operations, and the Schönflies notation is based on rotoreflection operations. The former is the standard in crystallography, while the latter is usually employed in molecular spectroscopy.

Consider the origin of a coordinate system, a b c, and an object located at coordinates $x\ y\ z$. Atomic coordinates are expressed as dimensionless fractions of the three-dimensional periodicities. From the origin draw a vector to every point on the object at $x\ y\ z$, extend this vector the same length through the origin in the opposite direction, and mark off this length. Thus, for every $x\ y\ z$ there will be a $-x$, $-y$, $-z$, ($\bar{x}$, $\bar{y}$, $\bar{z}$ in standard notation). This mapping creates a center of inversion or center of symmetry at the origin. The result of this operation changes the handedness of an object, and the two symmetry-related objects are enantiomorphs. Figure 3A illustrates this operator. It has the International or Hermann-Mauguin symbol $\bar{1}$ read as "one bar." This symbol can be interpreted as a 1-fold rotoinversion axis: i.e., an object is rotated 360° followed by the inversion operation. Similarly, there are $\bar{2}$, $\bar{3}$, $\bar{4}$, and $\bar{6}$ axes (Fig. 2B). Consider the $\bar{2}$ operation: a 2-fold axis perpendicular to the ac plane rotates an object 180° and immediately inverts it through the origin, defined as the point of intersection of the plane and the 2-fold axis. The two objects are related by a mirror and $\bar{2}$ is usually given the special symbol m. The object at $x\ y\ z$ is reproduced at $x\ \bar{y}\ z$ (Fig. 3B). The two objects created by inversion or mirror reflection cannot be superimposed by a proper rotation axis operation. They are related as the right hand is to the left. Such objects are known as enantiomorphs.

The Schönflies notation is based on the compound operation of rotation and reflection, and the operation is designated $\tilde{n}$ or S_n. The subscript n denotes the rotation $2\pi/n$ and S denotes the reflection operation (the German

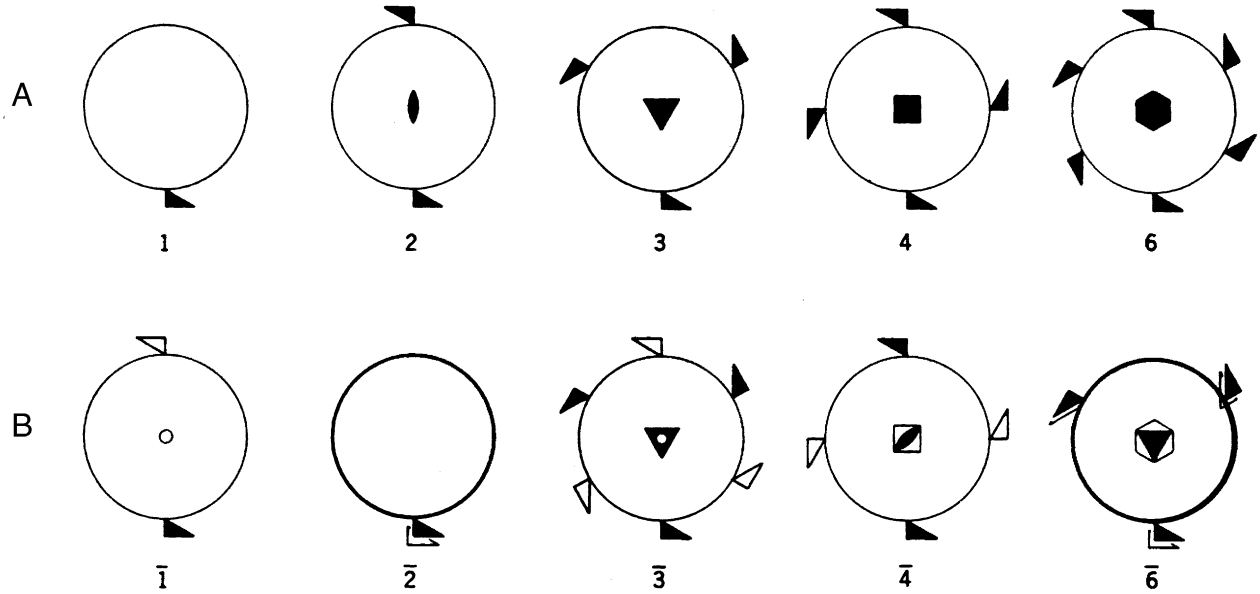

Figure 2. Symmetry of space around the five proper rotation axes giving rise to congruent objects (**A.**), and the five improper rotation axes giving rise to enantiomorphic objects (**B.**). Filled triangles are above the plane of the paper and open ones below. Courtesy of Buerger (1970).

word for mirror is *spiegel*). Consider a $\tilde{2}$ axis perpendicular to the *ac* plane that contains an object above that plane at *x y z*. Rotate the object 180° and immediately reflect it through the plane. The positional parameters of this object are $\bar{x}, \bar{y}, \bar{z}$. The point of intersection of the 2-fold rotor and the plane is an inversion point and the two objects are enantiomorphs. The special symbol i is assigned to $\tilde{2}$ or S_2, and is equivalent to $\bar{1}$ in the Hermann-Mauguin system. In this discussion only the International (Hermann-Mauguin) symbols will be used.

Screw Axes, Glide Planes

A rotation axis that is combined with translation is called a screw axis and is given the symbol n_t. The subscript t denotes the fractional translation of the periodicity

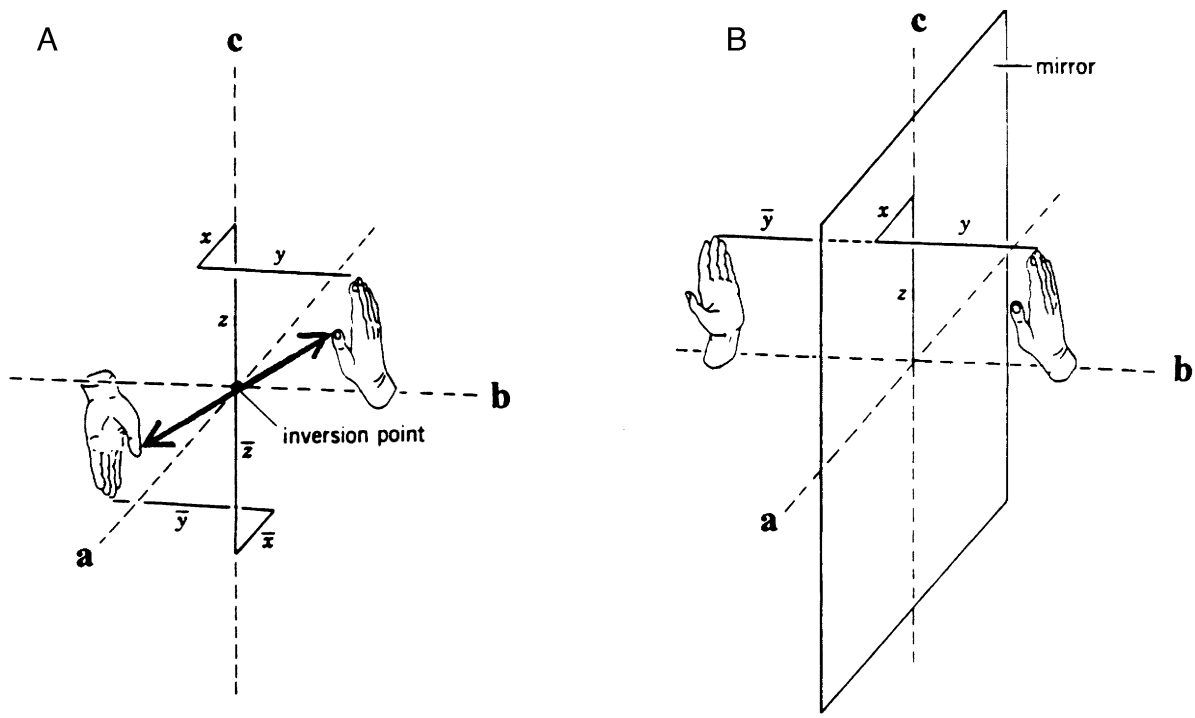

Figure 3. (**A**) A center of symmetry; (**B**) mirror reflection. Courtesy of Buerger (1970).

parallel to the rotation axis n, where $t = m/n$, $m = 1, \ldots, n-1$. Consider a 2-fold screw axis parallel to the b-axis of a coordinate system. The 2-fold rotor acts on an object by rotating it 180° and is immediately followed by a translation, $t/2$, of $\frac{1}{2}$ the b-axis periodicity. An object at $x\,y\,z$ is generated at $\bar{x}, y+\frac{1}{2}, \bar{z}$ by this 2_1 screw axis. All crystallographic symmetry operations must operate on a motif a sufficient number of times so that eventually the motif coincides with the original object. This is not the case at this juncture. This screw operation has to be repeated again, resulting in an object at x, $y+1$, z. Now the object is located one b-axis translation from the original object. Since this constitutes a periodic translation, b, the two objects are identical and the space has the proper symmetry 2_1. The possible screw axes are 2_1, 3_1, 3_2, 4_1, 4_2, 4_3, 6_1, 6_2, 6_3, 6_4, and 6_5 (Fig. 4). Note that the screw axes 3_1 and 3_2 are related as a right-handed thread is to a left-handed one. Similarly, this relationship is present for spaces exhibiting 4_1 and 4_3, 6_1 and 6_5, etc., symmetries. Note the symbols above the axes in Figure 4 that indicate the type of screw axis.

The combination of a mirror plane with translation parallel to the reflecting plane is known as a glide plane. Consider a coordinate system a b c in which the bc plane is a mirror. An object located at $x\,y\,z$ is reflected, which would

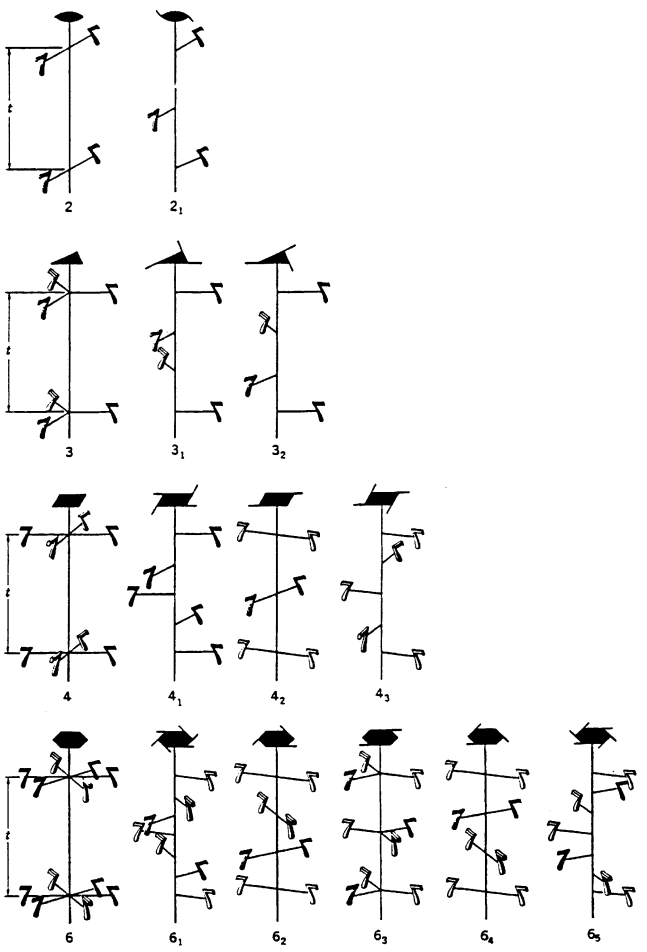

Figure 4. The eleven screw axes. The pure rotation axes are also shown. Note the symbols above the axes. Courtesy of Azaroff (1968).

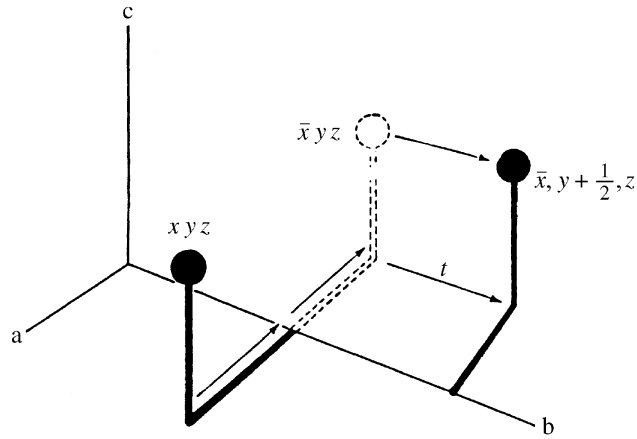

Figure 5. A b glide plane perpendicular to the a-axis.

bring it temporarily to the position $\bar{x}\,y\,z$. However, it does not remain there but is translated by $\frac{1}{2}$ of the b-axis periodicity to the point $\bar{x}, y+\frac{1}{2}, z$ (Fig. 5). This operation must be repeated to satisfy the requirement of periodicity so that the next operation brings the object to x, $y+1$, z, which is identical to the starting position but one b-axis periodicity away. Note that the first operation produces an enantiomorphic object and the second operation reverses this handedness, making it congruent with the initial object. This glide operation is designated as a b glide plane and has the symbol b. We could have moved the object parallel to the c axis by $\frac{1}{2}$ of the c-axis periodicity, as well as by the vector $\frac{1}{2}(\mathbf{b}+\mathbf{c})$. The former symmetry operator is a c glide plane, denoted by c, and the latter is an n glide plane, symbolized by n. Note that in this example an a glide plane operation is meaningless. If the glide plane is perpendicular to the b-axis, then a, c, and $n = \frac{1}{2}(\mathbf{a}+\mathbf{c})$ glide planes can exist. The extension to a glide plane perpendicular to the c-axis is obvious. One other glide operation needs to be described, the diamond glide d. It is characterized by the operation $\frac{1}{4}(\mathbf{a}+\mathbf{b})$, $\frac{1}{4}(\mathbf{a}+\mathbf{c})$, and $\frac{1}{4}(\mathbf{b}+\mathbf{c})$. The diagonal glide with translation $\frac{1}{4}(\mathbf{a}+\mathbf{b}+\mathbf{c})$ can be considered part of the diamond glide operation. All of these operations must be applied repeatedly until the last object that is generated is identical with the object at the origin but one periodicity away.

Symmetry-related positions, or equivalent positions, can be generated from geometrical considerations. However, the operations can be represented by matrices operating on a given position. In general, one can write the matrix equation

$$\mathbf{X}' = R\mathbf{X} + T$$

where $\mathbf{X}'(x'\ y'\ z')$ are the transformed coordinates, R is a rotation operator applied to $\mathbf{X}(x\ y\ z)$, and T is the translation operator. For the $\bar{1}$ operation, $x\ y\ z \Rightarrow \bar{x}\ \bar{y}\ \bar{z}$, and in matrix formulation the transformation becomes

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} \bar{1} & 0 & 0 \\ 0 & \bar{1} & 0 \\ 0 & 0 & \bar{1} \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} \qquad (1)$$

For an a glide plane perpendicular to the c-axis, $x\,y\,z \Rightarrow x+\frac{1}{2}, y, \bar{z}$, or in matrix notation

$$\begin{matrix} x' \\ y' \\ z' \end{matrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \bar{1} \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} \frac{1}{2} \\ 0 \\ 0 \end{pmatrix} \qquad (2)$$

(Hall, 1969; Burns and Glazer, 1978; Stout and Jensen, 1989; Giacovazzo et al., 1992).

POINT GROUPS

The symmetry of space about a point can be described by a collection of symmetry elements that intersect at that point. The point of intersection of the symmetry axes is the origin. The collection of crystallographic symmetry operators constitutes the 32 crystallographic point groups. The external morphology of three-dimensional crystals can be described by one of these 32 crystallographic point groups. Since they describe the interrelationship of faces on a crystal, the symmetry operators cannot contain translational components that refer to atomic-scale relations such as screw axes or glide planes. The point groups can be divided into (1) simple rotation groups and (2) higher symmetry groups. In (1), there exist only 2-fold axes or one unique symmetry axis higher than a 2-fold axis. There are 27 such point groups. In (2), no single unique axis exists but more than one n-fold axis is present, $n > 2$.

The simple rotation groups consist only of one single n-fold axis. Thus, the point groups 1, 2, 3, 4, and 6 constitute the five pure rotation groups (Fig. 2). There are four distinct, unique rotoinversion groups: $\bar{1}$, $\bar{2} = \mathrm{m}$, $\bar{3}$, $\bar{4}$, $\bar{6}$. It has been shown that $\bar{2}$ is equivalent to a mirror, m, which is perpendicular to that axis, and the standard symbol for $\bar{2}$ is m. Group $\bar{6}$ is usually labeled 3/m and is assigned to group n/m. This last symbol will be encountered frequently. It means that there is an n-fold axis parallel to a given direction, and that perpendicular to that direction a mirror plane or some other symmetry plane exists. Next are four unique point groups that contain a mirror perpendicular to the rotation axis: 2/m, $3/\mathrm{m} = \bar{6}$, 4/m, 6/m. There are four groups that contain mirrors parallel to a rotation axis: 2mm, 3m, 4mm, 6mm. An interesting change in notation has occurred. Why is 2mm and not simply 2m used, while 3m is correct? Consider the intersection of two orthogonal mirrors. It is easy to show by geometry that the line of intersection is a 2-fold axis. It is particularly easy with matrix algebra (Stout and Jensen, 1989; Giacovazzo et al., 1992). Let the ab and ac coordinate planes be orthogonal mirror planes. The line of intersection is the a-axis. The multiplication of the respective mirror matrices yields the matrix representation of the 2-fold axis parallel to the a-axis:

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \bar{1} \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \bar{1} & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \bar{1} & 0 \\ 0 & 0 & \bar{1} \end{pmatrix} \qquad (3)$$

Thus, a combination of two intersecting orthogonal mirrors yields a 2-fold axis of symmetry and similarly the combination of a 2-fold axis lying in a mirror plane produces another mirror orthogonal to it.

Let us examine 3m in a similar fashion. Let the 3-fold axis be parallel to the c-axis. A 3-fold symmetry axis demands that the a and b axes must be of equal length and at 120° to each other. Let the mirror plane contain the c-axis and the perpendicular direction to the b-axis. The respective matrices are

$$\begin{pmatrix} 0 & \bar{1} & 0 \\ 1 & \bar{1} & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 1 & \bar{1} & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} \bar{1} & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad (4)$$

and the product matrix represents a mirror plane containing the c-axis and the perpendicular direction to the a-axis. These two directions are at 60° to each other. Since 3-fold symmetry requires a mirror every 120°, this is not a new symmetry operator. In general, when n of an n-fold rotor is odd no additional symmetry operators are generated, but when n is even a new symmetry operator comes into existence.

One can combine two symmetry operators in an arbitrary manner with a third symmetry operator. Will this combination be a valid crystallographic point group? This complex problem was solved by Euler (Buerger, 1956; Azaroff, 1968; McKie and McKie, 1986). He derived the relation

$$\cos A = \frac{\cos(\beta/2)\cos(\gamma/2) + \cos(\alpha/2)}{\sin(\beta/2)\sin(\gamma/2)} \qquad (5)$$

where A is the angle between two rotation axes with rotation angles β and γ, and α is the rotation angle of the third axis. Consider the combination of two 2-fold axes with one 3-fold axis. We must determine the angle between a 2-fold and 3-fold axis and the angle between the two 2-fold axes. Let angle A be the angle between the 2-fold and 3-fold axes. Applying the formula yields $\cos A = 0$ or $A = 90°$. Similarly, let B be the angle between the two 2-fold axes. Then $\cos B = \frac{1}{2}$ and $B = 60°$. Thus, the 2-fold axes are orthogonal to the 3-fold axis and 60° to each other, consistent with 3-fold symmetry. The crystallographic point group is 32. Note again that the symbol is 32, while for a 4-fold axis combined with an orthogonal 2-fold axis the symbol is 422.

So far 17 point groups have been derived. The next 10 groups are known as the dihedral point groups. There are four point groups containing n 2-fold axes perpendicular to a principal axis: 222, 32, 422, and 622. (Note that for $n = 3$ only one unique 2-fold axis is shown.) These groups can be combined with diagonal mirrors that bisect the 2-fold axes, yielding the two additional groups $\bar{4}$ 2m and $\bar{3}$m. Four additional groups result from the addition of a mirror perpendicular to the principal axis, $\frac{2}{\mathrm{m}}\frac{2}{\mathrm{m}}\frac{2}{\mathrm{m}}$, $\bar{6}$m2, $\frac{4}{\mathrm{m}}\frac{2}{\mathrm{m}}\frac{2}{\mathrm{m}}$, and $\frac{6}{\mathrm{m}}\frac{2}{\mathrm{m}}\frac{2}{\mathrm{m}}$ making a total of 27.

We now consider the five groups that contain more than one axis of at least 3-fold symmetry: 2 3, $\bar{4}$ 3m, m$\bar{3}$, 4 3 2, and m3m. Note that the position of the 3-fold axis is in the second position of the symbols. This indicates that these point groups belong to the cubic crystal system. The stereographic projections of the 32 point groups are shown in Figure 6 (*International Union of Crystallography*, 1952).

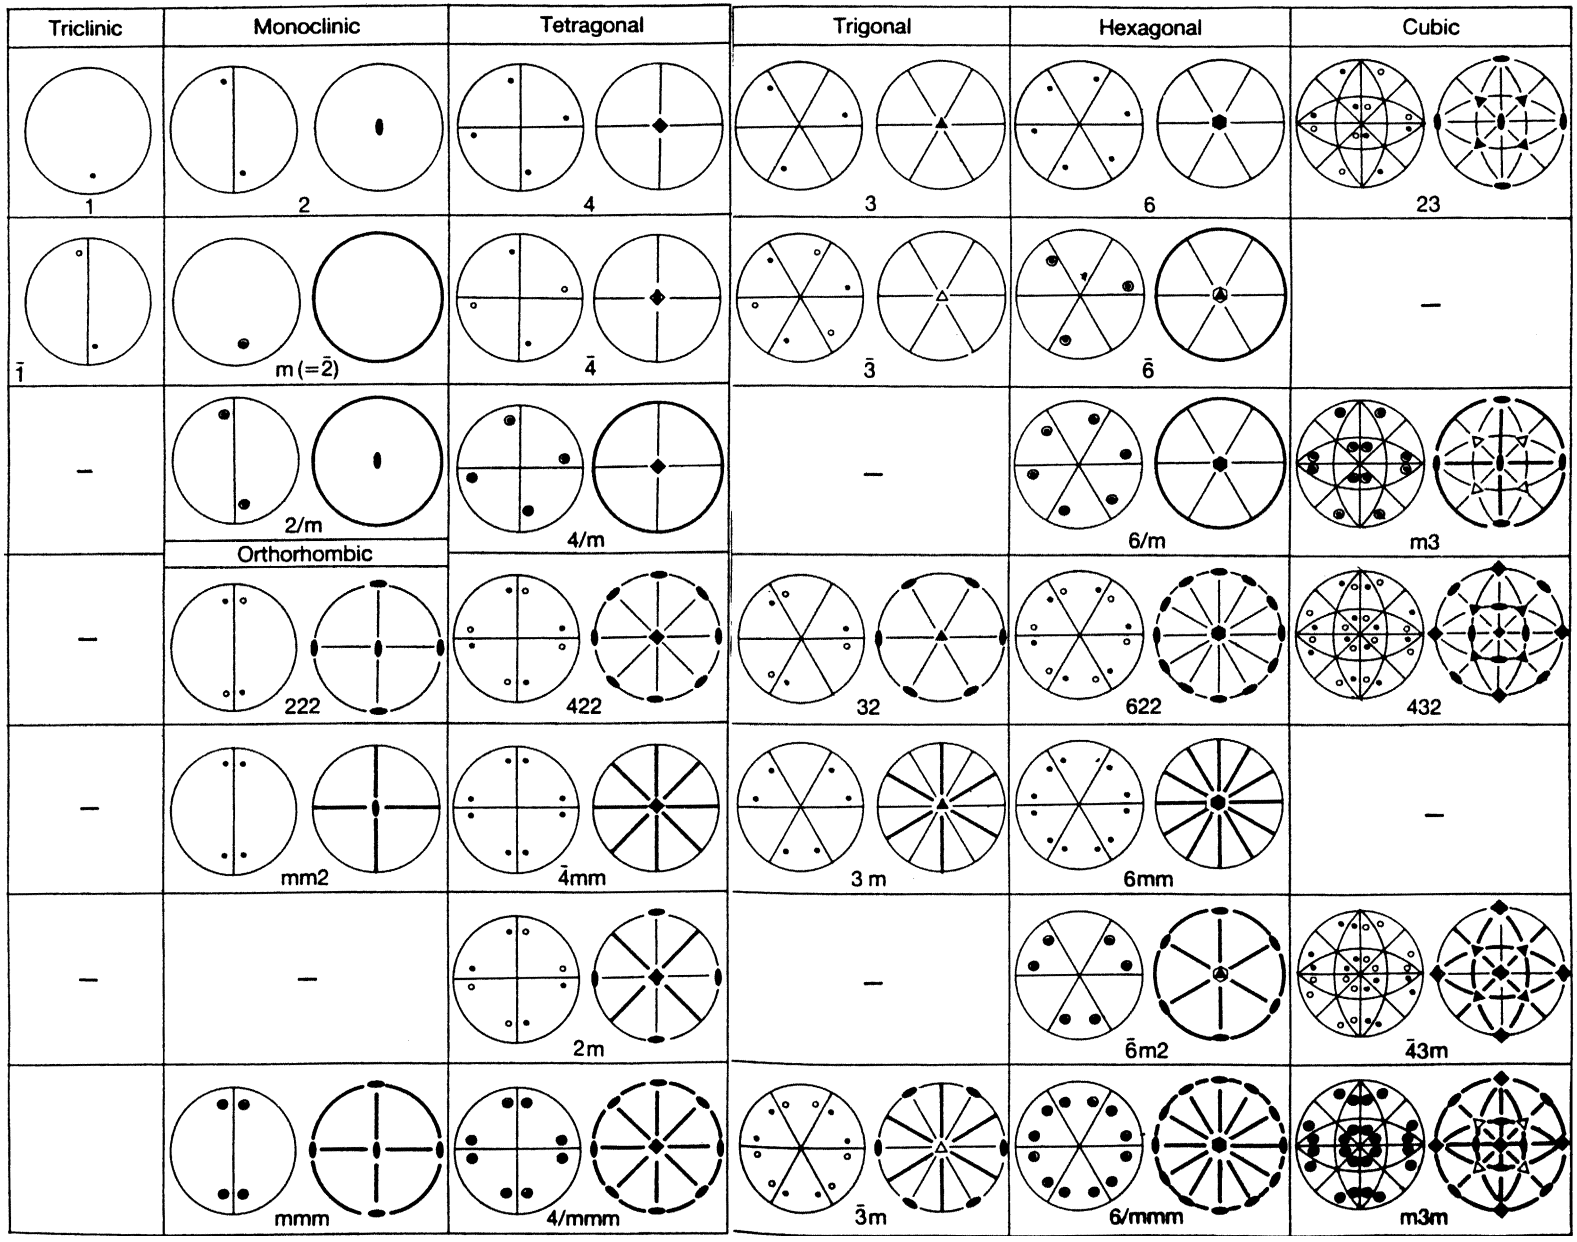

Figure 6. The stereographic projections of the 32 point groups. From the *International Tables for X-Ray Crystallography.* (International Union of Crystallography, 1952).

CRYSTAL SYSTEMS

The presence of a symmetry operator imparts a distinct appearance to a crystal. A 3-fold axis means that crystal faces around the axis must be identical every 120°. A 4-fold axis must show a 90° relationship among faces. On the basis of the appearance of crystals due to symmetry, classical crystallographers could divide them into seven groups as shown in Table 1. The symbol $\neq$ should be read as "not necessarily equal." The relationship among the metric parameters is determined by the presence of the symmetry operators among the atoms of the unit cell, but the metric parameters do not determine the crystal system. Thus, one could have a metrically cubic cell, but if only 1-fold axes are present among the atoms of the unit cell, then the crystal system is triclinic. This is the case for hexamethylbenzene, but, admittedly, this is a rare occurrence. Frequently, the rhombohedral unit cell is reoriented so that it can be described on the basis of a hexagonal unit cell (Azaroff, 1968). It can be considered a subsystem of the hexagonal system, and then one speaks of only six crystal systems.

We can now assign the various point groups to the six crystal systems. Point groups 1 and $\bar{1}$ obviously belong to the triclinic system. All point groups with only one unique 2-fold axis belong to the monoclinic system. Thus, 2, $\bar{2} = m$, and 2/m are monoclinic. Point groups like 222, mmm, etc., are orthorhombic; 32, 6, 6/mmm, etc., are hexagonal (point groups with a 3-fold axis are also labeled trigonal); 4, 4/m, 422, etc., are tetragonal; and 23, m3m, and 432, are cubic. Note the position of the 3-fold axis in the sequence of symbols for the cubic system. The distribution of the 32 point groups among the six crystal systems is shown in Figure 6. The rhombohedral and trigonal systems are not counted separately.

LATTICES

When the unit cell is translated along three periodically repeated noncoplanar, noncollinear vectors, a three-dimensional lattice of points is generated (Fig. 7). When looking at such an array one can select an infinite number of periodically repeated, noncollinear, noncoplanar vectors $\mathbf{t}_1$, $\mathbf{t}_2$, and $\mathbf{t}_3$, in three dimensions, connecting two lattice points, that will constitute the basis vectors of a unit cell for such an array. The choice of a unit cell is one of convenience, but usually the unit cell is chosen to reflect the symmetry operators present. Each lattice point at the eight corners of the unit cell is shared by eight other unit cells. Thus, a unit cell has $8 \times \frac{1}{8} = 1$ lattice point. Such a unit cell is called primitive and is given the symbol *P*. One can choose nonprimitive unit cells that will contain more than one lattice point. The array of atoms around one lattice point is identical to the same array around every other lattice point. This array of atoms may consist either of molecules or of individual atoms, as in NaCl. In the latter case the Na^+ and Cl^- atoms are actually located on lattice points. However, lattice points are usually not occupied by atoms. Confusing lattice points with atoms is a common beginners' error.

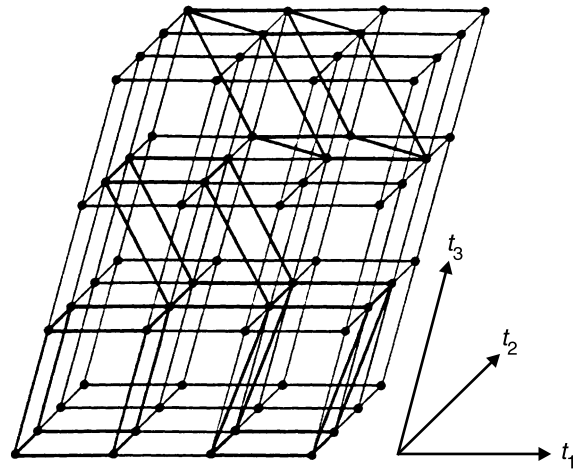

Figure 7. A point lattice with the outline of several possible unit cells.

In Table 1 the unit cells for the various crystal systems are listed with the restrictions on the parameters as a result of the presence of symmetry operators. Let the *b*-axis of a coordinate system be a 2-fold axis. The *ac* coordinate plane can have axes at any angle to each other: i.e., β can have any value. But the b-axis must be perpendicular to the *ac* plane or else the parallelogram defined by the vectors **a** and **b** will not be repeated periodically. The presence of the 2-fold axis imposes the restriction that $\alpha = \gamma = 90°$. Similarly, the presence of three 2-fold axes requires an orthogonal unit cell. Other symmetry operators impose further restrictions, as shown in Table 1.

Consider now a 2-fold *b*-axis perpendicular to a parallelogram lattice *ac*. How can this two-dimensional lattice be

Table 1. The Seven Crystal Systems

Crystal System	Minimum Symmetry	Unit Cell Parameter Relationships
Triclinic (anorthic)	Only a 1-fold axis	$a \neq b \neq c$; $\alpha \neq \beta \neq \gamma$
Monoclinic	One 2-fold axis chosen to be the unique *b*-axis, [010]	$a \neq b \neq c$; $\alpha = \gamma = 90°$, $\beta \neq 90°$
Orthorhombic	Three mutually perpendicular 2-fold axes, [100], [010], [001]	$a \neq b \neq c$; $\alpha = \beta = \gamma = 90°$
Rhombohedral[a]	One 3-fold axis parallel to the long axis of the rhomb, [111]	$a = b = c$; $\alpha = \beta = \gamma \neq 90°$
Tetragonal	One 4-fold axis parallel to the *c*-axis, [001]	$a = b \neq c$; $\alpha = \beta = \gamma = 90°$
Hexagonal[b]	One 6-fold axis parallel to the *c*-axis, [001]	$a = b \neq c$; $\alpha = \beta = 90° \gamma = 120°$
Cubic (isometric)	Four 3-fold axes parallel to the four body diagonals of a cube, [111]	$a = b = c$; $\alpha = \beta = \gamma = 90°$

[a] Usually transformed to a hexagonal unit cell.
[b] Point groups or space groups that are not rhombohedral but contain a 3-fold axis are labeled trigonal.

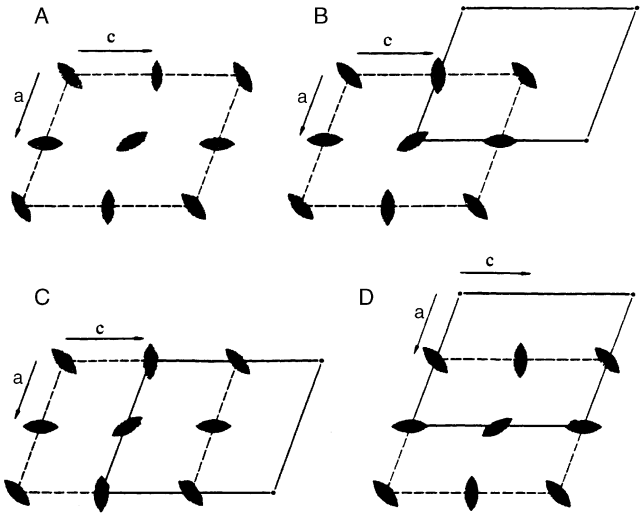

Figure 8. The stacking of parallelogram lattices in the monoclinic system. (**A**) Shifting the zero level up along the 2-fold axis located at the origin of the parallelogram. (**B**) Shifting the zero level up on the 2-fold axis at the center of the parallelogram. (**C**) Shifting the zero level up on the 2-fold axis located at $\frac{1}{2}$c. (**D**) Shifting the zero level up on the 2-fold axis located at $\frac{1}{2}$a. Courtesy of Azaroff (1968).

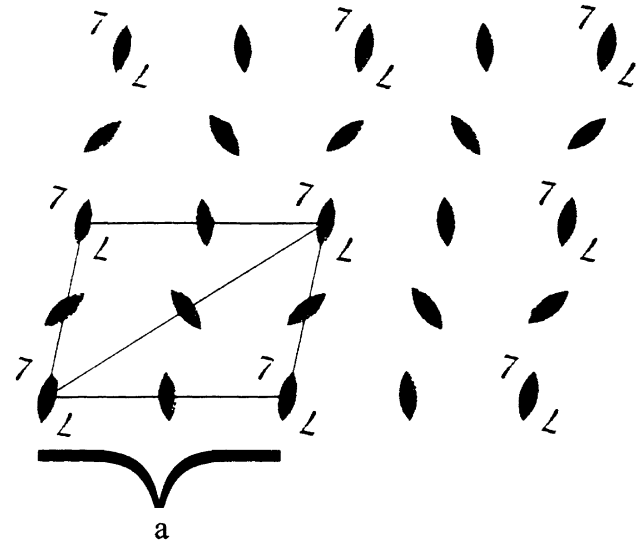

Figure 9. A periodic repetition of a 2-fold axis creates new, crystallographically independent 2-fold axes. Courtesy of Azaroff (1968).

repeated along the third dimension? It cannot be along some arbitrary direction because such a unit cell would violate the 2-fold axis. However, the plane net can be stacked along the *b*-axis at some definite interval to complete the unit cell (Fig. 8A). This symmetry operation produces a primitive cell, *P*. Is this the only possibility? When a 2-fold axis is periodically repeated in space with period **a**, then the 2-fold axis at the origin is repeated at $x = 1, 2, \ldots, n$, but such a repetition also gives rise to new 2-fold axes at $x = \frac{1}{2}, \frac{3}{2}, \ldots, z = \frac{1}{2}, \frac{3}{2}, \ldots$, etc., and along the plane diagonal (Fig. 9). Thus, there are three additional 2-fold axes and three additional stacking possibilities along the 2-fold axes located at $x = \frac{1}{2}, z = 0$; $x = 0, z = \frac{1}{2}$; and $x = \frac{1}{2}, z = \frac{1}{2}$. However, the first layer stacked along the 2-fold axis located at $x = \frac{1}{2}, z = 0$ does not result in a unit cell that incorporates the 2-fold axis. The vector from 0, 0, 0 to that lattice point is not along a 2-fold axis. The stacking sequence has to be repeated once more and now a lattice point on the second parallelogram lattice will lie above the point 0, 0, 0. The vector length from the origin to that point is the periodicity along **b**. An examination of this unit cell shows that there is a lattice point at $\frac{1}{2}, \frac{1}{2}, 0$ so that the *ab* face is centered. Such a unit cell is labeled C-face centered given the symbol C (Fig. 8D), and contains two lattice points: the origin lattice point shared among eight cells and the face-centered point shared between two cells. Stacking along the other 2-fold axes produces an A-face-centered cell given the symbol A (Fig. 8C) and a body-centered cell given the label I. (Fig. 8B). Since every direction in the monoclinic system is a 1-fold axis except for the 2-fold *b*-axis, the labeling of *a* and *c* directions in the plane perpendicular to *b* is arbitrary. Interchanging the *a* and *c* axial labels changes the A-face centering to C-face centering. By convention C-face centering is the standard orientation. Similarly, an I-centered lattice can be reoriented to a C-centered cell by drawing a diagonal in the old cell as a new axis. Thus, there are only two unique Bravais lattices in the monoclinic system, Figure 10.

The systematic investigation of the combinations of the 32 point groups with periodic translation in space generates 14 different space lattices. The 14 Bravais lattices are shown in Figure 10 (Azaroff, 1968; McKie and McKie, 1986).

Miller Indices

To explain x ray scattering from atomic arrays it is convenient to think of atoms as populating planes in the unit cell. The diffraction intensities are considered to arise from reflections of these planes. These planes are labeled by the inverse of their intercepts on the unit cell axes. If a plane intercepts the *a*-axis at $\frac{1}{2}$, the *b*-axis at $\frac{1}{2}$, and the *c*-axis at $\frac{2}{3}$ the distances of their respective periodicities, then the Miller indices are $h = 4$, $k = 4$, $l = 3$, the reciprocals cleared of fractions (Fig. 11), and the plane is denoted as (443). The round brackets enclosing the (*hkl*) indices indicate that this is a plane. Figure 11 illustrates this convention for several planes. Planes that are related by a symmetry operator such as a 4-fold axis in the tetragonal system are part of a common form. Thus, (100), (010), $(\bar{1}00)$ and $(0\bar{1}0)$ are designated by ((100)) or {100}. A direction in the unit cell—e.g., the vector from the origin 0, 0, 0 to the lattice point 1, 1, 1—is represented by square brackets as [111]. Note that the above four planes intersect in a common line, the *c*-axis or the zone axis, which is designated as [001]. A family of zone axes is indicated by angle brackets, $\langle 111 \rangle$. For the tetragonal system, this symbol denotes the symmetry-equivalent directions [111], $[\bar{1}11]$, $[1\bar{1}1]$, and

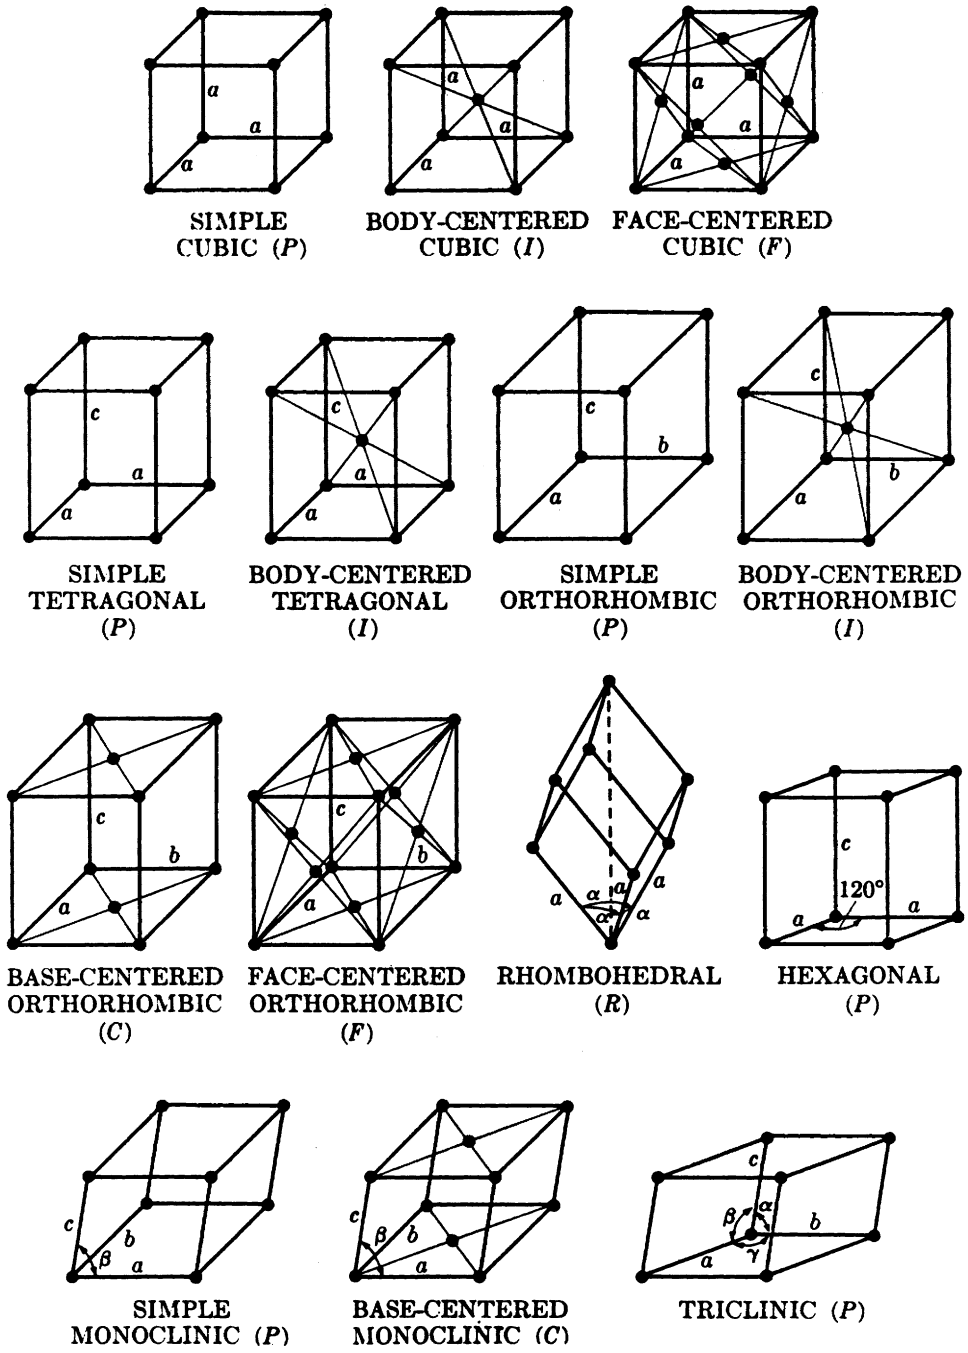

Figure 10. The 14 Bravais lattices. Courtesy of Cullity (1978).

$[\bar{1}\bar{1}1]$. The plane (hkl) and the zone axis $[uvw]$ obey the relationship $hu + kw + lz = 0$.

A complication arises in the hexagonal system. There are three equivalent a-axes due to the presence of a 3-fold or 6-fold symmetry axis perpendicular to the ab plane. If the three axes are the vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$, then $\mathbf{a}_1 + \mathbf{a}_2 = -\mathbf{a}_3$. To remove any ambiguity about which of the axes are cut by a plane, four symbols are used. They are the Miller-Bravais indices $hkil$, where $i = -(h + k)$ (Azaroff, 1968). Thus, what is ordinarily written as (111) becomes in the hexagonal system $(11\bar{2}1)$ or $(11\cdot1)$, the dot replacing the $\bar{2}$. The Miller indices for the unique directions in the unit cells of the seven crystal systems are listed in Table 1.

SPACE GROUPS

The combination of the 32 crystallographic point groups with the 14 Bravais lattices produces the 230 space groups. The atomic arrangement of every crystalline material displaying 3-dimensional periodicity can be assigned to one of

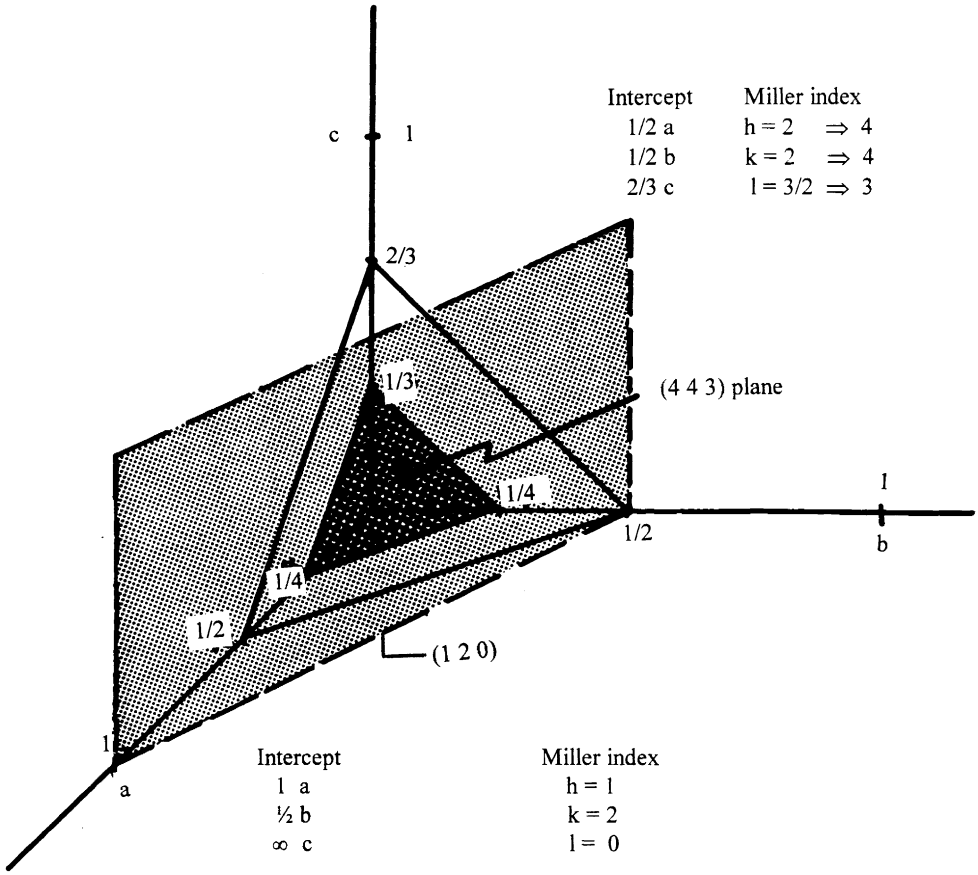

Figure 11. Miller indices of crystallographic planes.

the space groups. Consider the combination of point group 1 with a P lattice. An atom located at position $x\ y\ z$ in the unit cell is periodically repeated in all unit cells. There is only one general position $x\ y\ z$ in this unit cell. Of course, the values for $x\ y\ z$ can vary and there can be many atoms in the unit cell, but usually additional symmetry relations will not exist among them. Now consider the combination of point group $\bar{1}$ with the Bravais lattice P. Every atom at $x\ y\ z$ must have a symmetry-related atom at $\bar{x}\ \bar{y}\ \bar{z}$. Again, these positional parameters can have different values so that many atoms may be present in the unit cell. But for every atom A there must be an identical atom A′ related by a center of symmetry. The two positions are known as equivalent positions and the atom is said to be located in the general position $x\ y\ z$. If an atom is located at the special position 0, 0, 0, then no additional atom is generated. There are eight such special positions, each a center of symmetry, in the unit cell of space group $P\bar{1}$. We have just derived the first two triclinic space groups $P1$ and $P\bar{1}$. The first position in this nomenclature refers to the Bravais lattice. The second refers to a symmetry operator, in this case 1 or $\bar{1}$. The knowledge of symmetry operators relating atomic positions is very helpful when determining crystal structures. As soon as spatial positions $x\ y\ z$ of the atoms of a motif have been determined, e.g., the hand in Figure 3, then all atomic positions of the symmetry related motif(s) are known. The problem of determining all spatial parameters has been halved in the above example. The motif determined by the minimum number of atomic parameters is known as the asymmetric unit of the unit cell.

Let us investigate the combination of point group 2/m with a P Bravais lattice. The presence of one unique 2-fold axis means that this is a monoclinic crystal system and by convention the unique axis is labeled b. The 2-fold axis operating on $x\ y\ z$ generates the symmetry-related position $\bar{x}\ y\ \bar{z}$. The mirror plane perpendicular to the 2-fold axis operating on these two positions generates the additional locations $x\ \bar{y}\ z$ and $\bar{x}\ \bar{y}\ z$ for a total of four general equivalent positions. Note that the combination of 2/m gives rise to a center of symmetry. Special positions such as a location on a mirror $x\ \frac{1}{2}\ z$ permit only the 2-fold axis to produce the related equivalent position $\bar{x}\ \frac{1}{2}\ \bar{z}$. Similarly, the special position at 0, 0, 0 generates no further symmetry-related positions. A total of 14 special positions exist in space group $P2/m$. Again, the symbol shows the presence of only one 2-fold axis; therefore, the space group belongs to the monoclinic crystal system. The Bravais lattice is primitive, the 2-fold axis is parallel to the b-axis, and the mirror plane is perpendicular to the b-axis (International Union of Crystallography, 1983).

Let us consider one more example, the more complicated space group $Cmmm$ (Fig. 12). We notice that the Bravais lattice is C-face centered and that there are three mirrors. We remember that $m = \bar{2}$, so that there are essentially three 2-fold axes present. This makes the crystal system orthorhombic. The three 2-fold axes are orthogonal to

each other. We also know that the line of intersection of two orthogonal mirrors is a 2-fold axis. This space group, therefore, should have as its complete symbol $C2/m\ 2/m\ 2/m$, but the crystallographer knows that the 2-fold axes are there because they are the intersections of the three orthogonal mirrors. It is customary to omit them and write the space group as Cmmm. The three symbols after the Bravais lattice refer to the three orthogonal axes of the unit cell a, b, c. The letters m are really in the denominator so that the three mirrors are located perpendicular to the a-axis, perpendicular to the b-axis, and perpendicular to the c-axis. For the sake of consistency it is wise to consider any numeral as an axis parallel to a direction and any letter as a symmetry operator perpendicular to a direction.

C-face centering means that there is a lattice point at the position $\frac{1}{2}, \frac{1}{2}, 0$ in the unit cell. The atomic environment around any one lattice point is identical to that of any other lattice point. Therefore, as soon as the position $x\ y\ z$ is occupied there must be an identical occupant at $x+\frac{1}{2}$, $y+\frac{1}{2}$, z.

Let us now develop the general equivalent positions, or equipoints, for this space group. The symmetry-related point due to the mirror perpendicular to the a-axis operating on $x\ y\ z$ is $\bar{x}\ y\ z$. The mirror operation on these two equipoints due to the mirror perpendicular to the b-axis yields $x\ \bar{y}\ z$ and $\bar{x}\ \bar{y}\ z$. The mirror perpendicular to the c-axis operates on these four equipoints to yield $x\ y\ \bar{z}$, $\bar{x}\ y\ \bar{z}$, $x\ \bar{y}\ \bar{z}$, and $\bar{x}\ \bar{y}\ \bar{z}$. Note that this space group contains a center

of symmetry. To every one of these eight equipoints must be added $\frac{1}{2}$, $\frac{1}{2}$, 0 to take care of C-face centering. This yields a total of 16 general equipoints. When an atom is placed on one of the symmetry operators, the number of equipoints is reduced (Fig. 12A).

Clearly, once one has derived all the positions of a space group there is no point in doing it again. Figure 12 is a copy of the space group information for *C*mmm found in the *International Tables for Crystallography*, Vol. A (International Union of Crystallography, 1983). Note the diagrams in Figure 12B: they represent the changes in the space group symbols as a result of relabeling the unit cell axes. This is permitted in the orthorhombic crystal system since the *a*, *b*, and *c* axes are all 2-fold so that no label is unique. The rectangle in Figure 12B represents the *ab* plane of the unit cell. The origin is in the upper left corner with the *a*-axis pointing down and the *b*-axis pointing to the right; the *c*-axis points out of the plane of the paper. Note the symbols for the symmetry elements and their locations in the unit cell. A complete description of these symbols can be found in the *International Tables for Crystallography*, Vol. A, pages 4–10 (International Union of Crystallography, 1983). In addition to the space group information there is an extensive discussion of many crystallographic topics. No x ray diffraction laboratory should be without this volume. The determination of the space group of a crystalline material is obtained from x ray diffraction data.

Space Group Symbols

In general, space group notations consist of four symbols. The first symbol always refers to the Bravais lattice. Why, then, do we have P 1 or P 2/m? The full symbols are $P111$ and P 1 2/m 1. But in the triclinic system there is no unique direction, since every direction is a 1-fold axis of symmetry. It is therefore sufficient just to write P 1. In the monoclinic system there is only one unique direction—by convention it is the b-axis—and so only the symmetry elements related to that direction need to be specified. In the orthorhombic system there are the three unique 2-fold axes parallel to the lattice parameters a, b, and c. Thus, Pnma means that the crystal system is orthorhombic, the Bravais lattice is P, and there is an n glide plane perpendicular to the a-axis, a mirror perpendicular to the b-axis, and an a glide plane perpendicular to the c-axis. The complete symbol for this space group is $P\ 2_1/n\ 2_1/m\ 2_1/a$. Again, the 2_1 screw axes are a result of the other symmetry operators and are not expressly indicated in the standard symbol. The letter symbols are considered in the denominator and the interpretation is that the operators are perpendicular to the axes. In the tetragonal system there is the unique direction, the 4-fold c-axis. The next unique directions are the equivalent a and b axes, and the third directions are the four equivalent C-face diagonals, the $\langle 110 \rangle$ directions. The symbol $I4cm$ means that the space group is tetragonal, the Bravais lattice is body centered, there is a 4-fold axis parallel to the c-axis, there is are c glide planes perpendicular to the equivalent a and b-axes, and there are mirrors perpendicular to the C-face diagonals. Note that one can say just as well that the symmetry operators c and m are parallel to the directions.

The symbol $P\bar{3}c1$ tells us that the space group belongs to the trigonal system, primitive Bravais lattice, with a 3-fold rotoinversion axis parallel to the c-axis, and a c glide plane perpendicular to the equivalent a and b axes (or parallel to the [210] and [120] directions); the third symbol refers to the face diagonal [110]. Why the 1 in this case? It serves to distinguish this space group from the space group $P\bar{3}1c$, which is different. As before, it is part of the trigonal system. A $\bar{3}$ rotoinversion axis parallel to the c axis is present, but now the c glide plane is perpendicular to the $[1\bar{1}0]$ or parallel to the [110] directions. Since 6-fold symmetry must be maintained there are also c glide planes parallel to the a and b axes. The symbol R denotes the rhombohedral Bravais lattice, but the lattice is usually reoriented so that the unit cell is hexagonal.

The symbol $F\text{m}\bar{3}\text{m}$ full symbol $F\ 4/\text{m}\ \bar{3}\ 2/\text{m}$, tells us that this space group belongs to the cubic system (note the position of $\bar{3}$), the Bravais lattice is all faces centered, and there are mirrors perpendicular to the three equivalent a, b, and c axes, a $\bar{3}$ rotoinversion axis parallel to the four body diagonals of the cube, the $\langle 111 \rangle$ directions, and a mirror perpendicular to the six equivalent face diagonals of the cube, the $\langle 110 \rangle$ directions. In this space group additional symmetry elements are generated, such as 4-fold, 2-fold, and 2_1 axes.

Simple Example of the Use of Crystal Structure Knowledge

Of what use is knowledge of the space group for a crystalline material? The understanding of the physical and chemical properties of a material ultimately depends on the knowledge of the atomic architecture—i.e., the location of every atom in the unit cell with respect to the coordinate axes. The density of a material is $\rho = M/V$, where ρ is density, M the mass, and V the volume (see MASS AND DENSITY MEASUREMENTS). The macroscopic quantities can also be expressed in terms of the atomic content of the unit cell. The mass in the unit cell volume V is the formula weight M multiplied by the number of formula weights z in the unit cell divided by Avogadro's number N. Thus, $\rho = Mz/VN$.

Consider NaCl. It is cubic, the space group is $F\text{m}\bar{3}\text{m}$, the unit cell parameter is $a = 4.872$ Å, its density is 2.165 g/cm^3, and its formula weight is 58.44, so that $z = 4$. There are four Na and four Cl ions in the unit cell. The general position $x\ y\ z$ in space group $F\text{m}\bar{3}\text{m}$ gives rise to a total of 191 additional equivalent positions. Obviously, one cannot place an Na atom into a general position. An examination of the space group table shows that there are two special positions with four equipoints labeled $4a$, at 0, 0, 0 and $4b$, at $\frac{1}{2},\frac{1}{2},\frac{1}{2}$. Remember that F means that $x = \frac{1}{2}$, $y = \frac{1}{2}$, $z = 0$; $x = 0, y = \frac{1}{2}, z = \frac{1}{2}$; and $x = \frac{1}{2}, y = 0, z = \frac{1}{2}$ must be added to the positions. Thus, the 4 Na^+ atoms can be located at the $4a$ position and the 4 Cl^- atoms at the $4b$ position, and since the positional parameters are fixed, the crystal structure of NaCl has been determined. Of course, this is a very simple case. In general, the determination of the space group from x-ray diffraction data is the first essential step in a crystal structure determination.

CONCLUSION

It is hoped that this discussion of symmetry will ease the introduction of the novice to this admittedly arcane topic or serve as a review for those who want to extend their expertise in the area of space groups.

PARTICLE SCATTERING

INTRODUCTION

Atomic scattering lies at the heart of numerous materials-analysis techniques, especially those that employ ion beams as probes. The concepts of particle scattering apply quite generally to objects ranging in size from nucleons to billiard balls, at classical as well as relativistic energies, and for both elastic and inelastic events. This unit summarizes two fundamental topics in collision theory: kinematics, which governs energy and momentum transfer, and central-field theory, which accounts for the strength of particle interactions.

For definitions of symbols used throughout this unit, see the Appendix.

KINEMATICS

Binary Collisions

The kinematics of two-body collisions are the key to understanding atomic scattering. It is most convenient to consider such binary collisions as occurring between a moving projectile and an initially stationary target. It is sufficient here to assume only that the particles act upon each other with equal repulsive forces, described by some interaction potential. The form of the interaction potential and its effects are discussed below (see Central-Field Theory). A binary collision results in a change in the projectile's trajectory and energy after it scatters from a target atom. The collision transfers energy to the target atom, which gains energy and recoils away from its rest position. The essential parameters describing a binary collision are defined in Figure 1. These are the masses (m_1 and m_2) and the initial and final velocities (v_0, v_1, and v_2) of the projectile and target, the scattering angle (θ_s) of the projectile, and the recoiling angle (θ_r) of the target. Applying the laws of conservation of energy and momentum establishes fundamental relationships among these parameters.

Elastic Scattering and Recoiling

In an elastic collision, the total kinetic energy of the particles is unchanged. The law of energy conservation dictates that

$$E_0 = E_1 + E_2 \tag{1}$$

where $E = 1/2\,mv^2$ is a particle's kinetic energy. The law of conservation of momentum, in the directions parallel and perpendicular to the incident particle's direction, requires that

$$m_1 v_0 = m_1 v_1 \cos\theta_s + m_2 v_2 \cos\theta_r \tag{2}$$

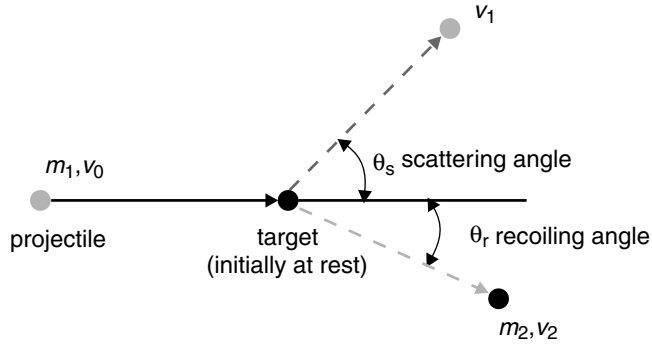

Figure 1. Binary collision diagram in a laboratory reference frame. The initial kinetic energy of the incident projectile is $E_0 = 1/2 m_1 v_0^2$. The initial kinetic energy of the target is assumed to be zero. The final kinetic energy for the scattered projectile is $E_1 = 1/2 m_1 v_1^2$, and for the recoiled particle is $E_2 = 1/2 m_2 v_2^2$. Particle energies (E) are typically expressed in units of electron volts, eV, and velocities (v) in units of m/s. The conversion between these units is $E \approx mv^2/(1.9297 \times 10^8)$, where m is the mass of the particle in amu.

for the parallel direction, and

$$0 = m_1 v_1 \sin\theta_s - m_2 v_2 \sin\theta_r \quad (3)$$

for the perpendicular direction.

Eliminating the recoil angle and target recoil velocity from the above equations yields the fundamental elastic scattering relation for projectiles:

$$2\cos\theta_s = (1+A)v_s + (1-A)/v_s \quad (4)$$

where $A = m_2/m_1$ is the target-to-projectile mass ratio and $v_s = v_1/v_0$ is the normalized final velocity of the scattered particle after the collision.

In a similar manner, eliminating the scattering angle and projectile velocity from Equations 1, 2, and 3 yields the fundamental elastic recoiling relation for targets:

$$2\cos\theta_r = (1+A)v_r \quad (5)$$

where $v_r = v_2/v_0$ is the normalized recoil velocity of the target particle.

Inelastic Scattering and Recoiling

If the internal energy of the particles changes during their interaction, the collision is inelastic. Denoting the change in internal energy by Q, the energy conservation law is stated as:

$$E_0 = E_1 + E_2 + Q \quad (6)$$

It is possible to extend the fundamental elastic scattering and recoiling relations (Equation 4 and Equation 5) to inelastic collisions in a straightforward manner. A kinematic analysis like that given above (see Elastic Scattering and Recoiling) shows the inelastic scattering relation to be:

$$2\cos\theta_s = (1+A)v_s + [1 - A(1-Q_n)]/v_s \quad (7)$$

where $Q_n = Q/E_0$ is the normalized inelastic energy factor. Comparison with Equation 4 shows that incorporating the factor Q_n accounts for the inelasticity in a collision.

When $Q > 0$, it is referred to as an inelastic energy loss; that is, some of the initial kinetic energy E_0 is converted into internal energy of the particles and the total kinetic energy of the system is reduced following the collision. Here Q_n is assumed to have a constant value that is independent of the trajectories of the collision partners, i.e., its value does not depend on θ_s. This is a simplifying assumption, which clearly breaks down if the particles do not collide ($\theta_s = 0$).

The corresponding inelastic recoiling relation is

$$2\cos\theta_r = (1+A)v_r + \frac{Q_n}{Av_r} \quad (8)$$

In this case, inelasticity adds a second term to the elastic recoiling relation (Equation 5).

A common application of the above kinematic relations is in identifying the mass of a target particle by measuring the kinetic energy loss of a scattered probe particle. For example, if the mass and initial velocity of the probe particle are known and its elastic energy loss is measured at a particular scattering angle, then the Equation 4 can be solved in terms of m_2. Or, if both the projectile and target masses are known and the collision is inelastic, Q can be found from Equation 7. A number of useful forms of the fundamental scattering and recoiling relations for both the elastic and inelastic cases are listed in the Appendix at the end of this unit (see Solutions of the Fundamental Scattering and Recoiling Relations in Terms of v, E, θ, A, and Q_n for Nonrelativistic Collisions).

A General Binary Collision Formula

It is possible to collect all the kinematic expressions of the preceding sections and cast them into a single fundamental form that applies to all nonrelativistic, mass-conserving binary collisions. This general formula in which the particles scatter or recoil through the laboratory angle θ is

$$2\cos\theta = (1+A)v_n + h/v_n \quad (9)$$

where $v_n = v/v_0$ and $h = 1 - A(1 - Q_n)$ for scattering and Q_n/A for recoiling. In the above expression, v is a particle's velocity after collision (v_1 or v_2) and the other symbols have their usual meanings. Equation 9 is the essence of binary collision kinematics.

In experimental work, the measured quantity is often the energy of the scattered or recoiled particle, E_1 or E_2. Expressing Equation 9 in terms of energy yields

$$\frac{E}{E_0} = \frac{A}{g}\left[\frac{1}{1+A}(\cos\theta \pm \sqrt{f^2 g^2 - \sin^2\theta})\right]^2 \quad (10)$$

where $f^2 = 1 - Q_n(1+A)/A$ and $g = A$ for scattering and 1 for recoiling. The positive sign is taken when $A > 1$ and both signs are taken when $A < 1$.

Scattering and Recoiling Diagrams

A helpful and instructive way to become familiar with the fundamental scattering and recoiling relations is to look at their geometric representations. The traditional approach is to plot the relations in center-of-mass coordinates, but an especially clear way of depicting these relations, particularly for materials analysis applications, is to use the laboratory frame with a properly scaled polar coordinate system. This approach will be used extensively throughout the remainder of this unit.

The fundamental scattering and recoil relations (Equation 4, Equation 5, Equation 7, and Equation 8) describe circles in polar coordinates, $(\sqrt{E}, \theta)$. The radial coordinate is taken as the square root of normalized energy (E_s or E_r) and the angular coordinate, θ, is the laboratory observation angle (θ_s or θ_r). These curves provide considerable insight into the collision kinematics. Figure 2 shows a typical elastic scattering circle. Here, $\sqrt{E}$ is $\sqrt{(E_s)}$, where $E_s = E_1/E_0$ and θ is θ_s. Note that r is simply v_s, so the circle traces out the velocity/angle relationship for scattering. Projectiles can be viewed as having initial velocity vectors

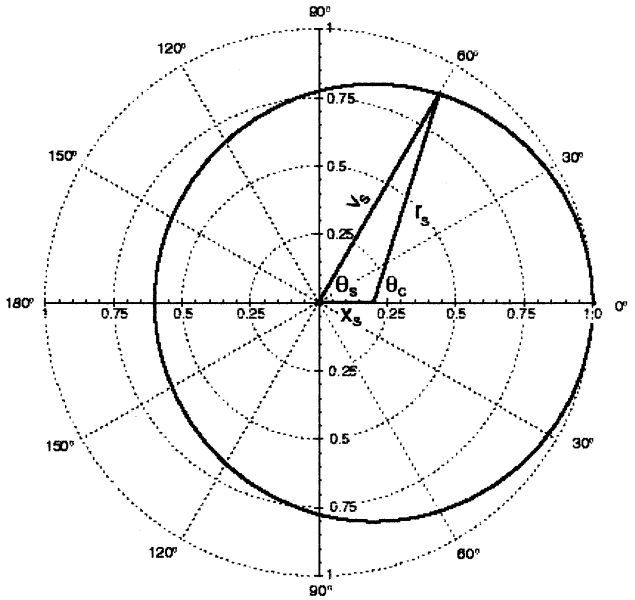

Figure 2. An elastic scattering circle plotted in polar coordinates $(\sqrt{E}, \theta)$ where E is $E_s = E_1/E_0$ and θ is the laboratory scattering angle, θ_s. The length of the line segment from the origin to a point on the circle gives the relative scattered particle velocity, v_s, at that angle. Note that $\sqrt{(E_s)} = v_s = v_1/v_0$. Scattering circles are centered at $(x_s,0^\circ)$, where $x_s = (1 + A)^{-1}$ and $A = m_2/m_1$. All elastic scattering circles pass through the point $(1,0^\circ)$. The circle shown is for the case $A = 4$. The triangle illustrates the relationships $\sin(\theta_c - \theta_s)/\sin(\theta_s) = x_s/r_s = 1/A$.

of unit magnitude traveling from left to right along the horizontal axis, striking the target at the origin, and leaving at angles and energies indicated by the scattering circle. The circle passes through the point $(1,0^\circ)$, corresponding to the situation where no collision occurs. Of course, when there is no scattering ($\theta_s = 0^\circ$), there is no change in the incident particle's energy or velocity ($E_s = 1$ and $v_s = 1$). The maximum energy loss occurs at $\theta = 180^\circ$, when a head-on collision occurs. The circle center and radius are a function of the target-to-projectile mass ratio. The center is located along the 0° direction a distance x_s from the origin, given by

$$x_s = \frac{1}{1+A} \tag{11}$$

while the radius for elastic scattering is

$$r_s = 1 - x_s = A\, x_s = \frac{A}{1+A} \tag{12}$$

For inelastic scattering, the scattering circle center is also given by Equation 11, but the radius is given by

$$r_s = fAx_s = \frac{fA}{1+A} \tag{13}$$

where f is defined as in Equation 10.

Equation 11 and Equation 12 or 13 make it easy to construct the appropriate scattering circle for any given mass ratio A. One simply uses Equation 11 to find the circle center at $(x_s,0^\circ)$ and then draws a circle of radius r_s. The resulting scattering circle can then be used to find the energy of the scattered particle at any scattering angle by drawing a line from the origin to the circle at the selected angle. The length of the line is $\sqrt{(E_s)}$.

Similarly, the polar coordinates for recoiling are $([\sqrt{(E_r)}],\theta_r)$, where $E_r = E_2/E_0$. A typical elastic recoiling circle is shown in Figure 3. The recoiling circle passes through the origin, corresponding to the case where no collision occurs and the target remains at rest. The circle center, x_r, is located at:

$$x_r = \frac{\sqrt{A}}{1+A} \tag{14}$$

and its radius is $r_r = x_r$ for elastic recoiling or

$$r_r = fx_r = \frac{f\sqrt{A}}{1+A} \tag{15}$$

for inelastic recoiling.

Recoiling circles can be readily constructed for any collision partners using the above equations. For elastic collisions ($f = 1$), the construction is trivial, as the recoiling circle radius equals its center distance.

Figure 4 shows elastic scattering and recoiling circles for a variety of mass ratio A values. Since the circles are symmetric about the horizontal (0°) direction, only semicircles are plotted (scattering curves in the upper half plane and recoiling curves in the lower quadrant). Several general properties of binary collisions are evident. First,

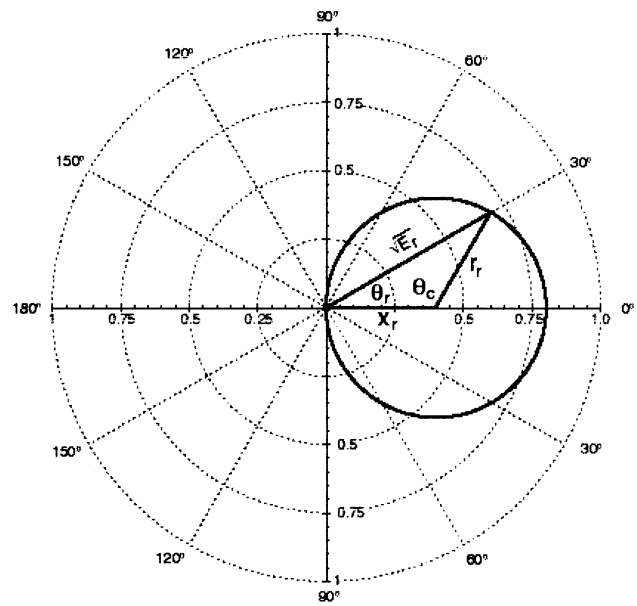

Figure 3. An elastic recoiling circle plotted in polar coordinates $(\sqrt{E},\theta)$ where E is $E_r = E_2/E_0$ and θ is the laboratory recoiling angle, θ_r. The length of the line segment from the origin to a point on the circle gives $\sqrt{(E_r)}$ at that angle. Recoiling circles are centered at $(x_r,0^\circ)$, where $x_r = \sqrt{A}/(1 + A)$. Note that $x_r = r_r$. All elastic recoiling circles pass through the origin. The circle shown is for the case $A = 4$. The triangle illustrates the relationship $\theta_r = (\pi - \theta_c)/2$.

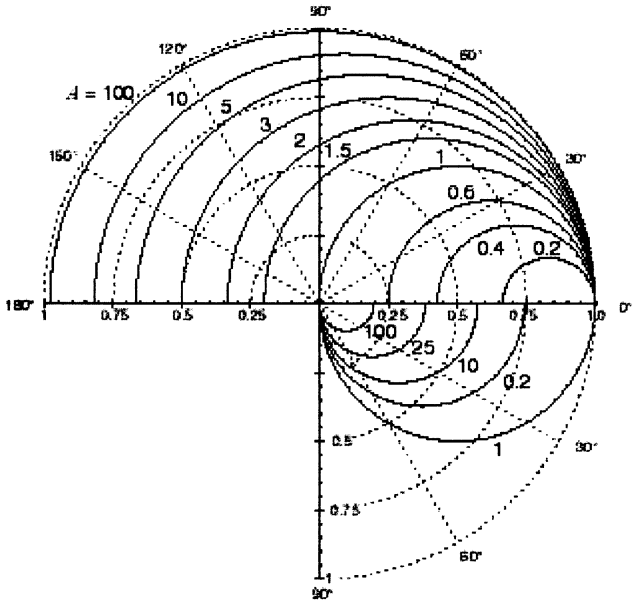

Figure 4. Elastic scattering and recoiling diagram for various values of A. For scattering, $\sqrt{(E_s)}$ versus θ_s is plotted for A values of 0.2, 0.4, 0.6, 1, 1.5, 2, 3, 5, 10, and 100 in the upper half-plane. When $A < 1$, only forward scattering is possible. For recoiling, $\sqrt{(E_r)}$ versus θ_r is plotted for A values of 0.2, 1, 10, 25, and 100 in the lower quadrant. Recoiling particles travel only in the forward direction.

for mass ratio $A > 1$ (i.e., light projectiles striking heavy targets), scattering at all angles $0^\circ < \theta_s \leq 180^\circ$ is permitted. When $A = 1$ (as in billiards, for instance) the scattering and recoil circles are the same. A head-on collision brings the projectile to rest, transferring the full projectile energy to the target. When $A < 1$ (i.e., heavy projectiles striking light targets), only forward scattering is possible and there is a limiting scattering angle, θ_{max}, which is found by drawing a tangent line from the origin to the scattering circle. The value of θ_{max} is arcsin A, because $\theta_s = r_s/x_s = A$. Note that there is a single scattering energy at each scattering angle when $A \geq 1$, but two energies are possible when $A < 1$ and $\theta_s < \theta_{max}$. This is illustrated in Figure 5. For all A, recoiling particles have only one energy and the recoiling angle $\theta_r < 90^\circ$. It is interesting to note that the recoiling circles are the same for A and A^{-1}, so it is not always possible to unambiguously identify the target mass by measuring its recoil energy. For example, using He projectiles, the energies of elastic H and O recoils at any selected recoiling angle are identical.

Center-of-Mass and Relative Coordinates

In some circumstances, such as when calculating collision cross-sections (see Central-Field Theory), it is useful to evaluate the scattering angle in the center of mass reference frame where the total momentum of the system is zero. This is an inertial reference frame with its origin located at the center of mass of the two particles. The center of mass moves in a straight line at constant velocity in the laboratory frame. The relative reference frame is also useful. It is a noninertial frame whose origin is located on the target. The relative frame is equivalent to a situation where a single particle of mass μ interacts with a fixed-point scattering center with the same potential as in the laboratory frame. In both these alternative frames of reference, the two-body collision problem reduces to a one-body problem. The relevant parameters are the reduced mass, μ, the relative energy, E_{rel}, and the center-of-mass scattering angle, θ_c. The term reduced mass originates from the fact that $\mu < m_1 + m_2$. The reduced mass is

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \tag{16}$$

and the relative energy is

$$E_{rel} = E_0\left(\frac{A}{1+A}\right) \tag{17}$$

The scattering angle θ_c is the same in the center-of-mass and relative reference frames. Scattering and recoiling circles show clearly the relationship between laboratory and center-of-mass scattering angles. In fact, the circles can readily be generated by parametric equations involving θ_c. These are simply $x = R\cos\theta_c + C$ and $y = R\sin\theta_c$, where R is the circle radius ($R = r_s$ for scattering, $R = r_r$ for recoiling) and $(C,0^\circ)$ is the location of its center ($C = x_s$ for scattering, $C = x_r$ for recoiling). Figures 2 and 3 illustrate the relationships among θ_s, θ_r, and θ_c. The relationship between θ_c and θ_s can be found by examining the triangle in Figure 2 containing θ_s and having sides of lengths x_s, r_s, and v_s. Applying the law of sines gives, for elastic scattering,

$$\tan\theta_s = \frac{\sin\theta_c}{A^{-1} + \cos\theta_c} \tag{18}$$

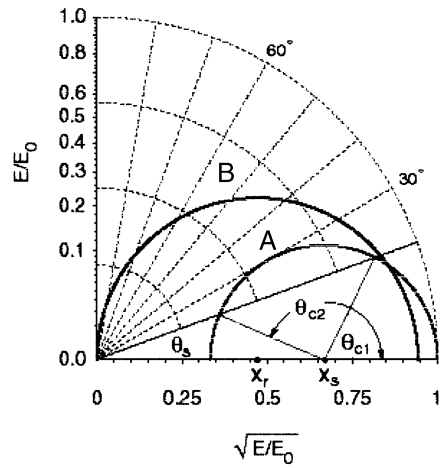

Figure 5. Elastic scattering (**A**) and recoiling (**B**) diagrams for the case $A = 1/2$. Note that in this case scattering occurs only for $\theta_s \leq 30^\circ$. In general, $\theta_s \leq \theta_{max} = \arcsin A$, when $A < 1$. Below θ_{max}, two scattered particle energies are possible at each laboratory observing angle. The relationships among θ_{c1}, θ_{c2}, and θ_s are shown at $\theta_s = 20^\circ$.

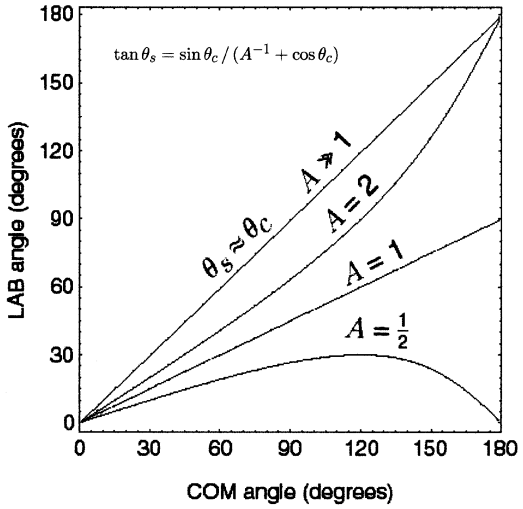

Figure 6. Correspondence between the center-of-mass scattering angle, θ_c, and the laboratory scattering angle, θ_s, for elastic collisions having various values of A: 0.5, 1, 2, and 100. For $A = 1$, $\theta_s = \theta_c/2$. For $A \gg 1$, $\theta_s \approx \theta_c$. When $A < 1$, $\theta_{max} = \arcsin A$.

Inspection of the elastic recoiling circle in Figure 3 shows that

$$\theta_r = \frac{1}{2}(\pi - \theta_c) \tag{19}$$

The relationship is apparent after noting that the triangle including θ_c and θ_r is isosceles. The various conversions between these three angles for elastic and inelastic collisions are listed in Appendix at the end of this unit (see Conversions among θ_s, θ_r, and θ_c for Nonrelativistic Collisions).

Two special cases are worth mentioning. If $A = 1$, then $\theta_c = 2\theta_s$; and as $A \to \infty$, $\theta_c \to \theta_s$. These, along with intermediate cases, are illustrated in Figure 6.

Relativistic Collisions

When the velocity of the projectile is a substantial fraction of the speed of light, relativistic effects occur. The effect most clearly seen as the projectile's velocity increases is distortion of the scattering circle into an ellipse. The relativistic parameter or Lorentz factor, γ, is defined as:

$$\gamma = (1 - \beta^2)^{-1/2} \tag{20}$$

where β, called the reduced velocity, is v_0/c and c is the speed of light. For all atomic projectiles with kinetic energies <1 MeV, γ is effectively 1. But at very high projectile velocities. γ exceeds 1, and the mass of the projectile increases to γm_0, where m_0 is the rest mass of the particle. For example, $\gamma = 1.13$ for a 100-MeV hydrogen projectile. It is when γ is appreciably greater than 1 that the scattering curve becomes elliptical. The center of the ellipse is located at the distance x_s on the horizontal axis in the scattering diagram, given by

$$x_s = \frac{1 + A\gamma}{1 + 2A\gamma + A^2} \tag{21}$$

This definition of x_s is consistent with the earlier, nonrelativistic definition since, when $\gamma = 1$, the center is as given in Equation 11. The major axis of the ellipse for elastic collisions is

$$a = \frac{A(\gamma + A)}{1 + 2A\gamma + A^2} \tag{22}$$

and the minor axis is

$$b = \frac{A}{(1 + 2A\gamma + A^2)^{1/2}} \tag{23}$$

When $\gamma = 1$,

$$a = b = r_s = \frac{A}{1 + A} \tag{24}$$

which indicates that the ellipse turns into the familiar elastic scattering circle under nonrelativistic conditions.

The foci of the ellipse are located at positions $x_s - d$ and $x_s + d$ along the horizontal axis of the scattering diagram, where d is given by

$$d = \frac{A(\gamma^2 - 1)^{1/2}}{1 + 2A\gamma + A^2} \tag{25}$$

The eccentricity of the ellipse, ε, is

$$\varepsilon = \frac{d}{a} = \frac{(\gamma^2 - 1)^{1/2}}{A + \gamma} \tag{26}$$

Examples of relativistic scattering curves are shown in Figure 7.

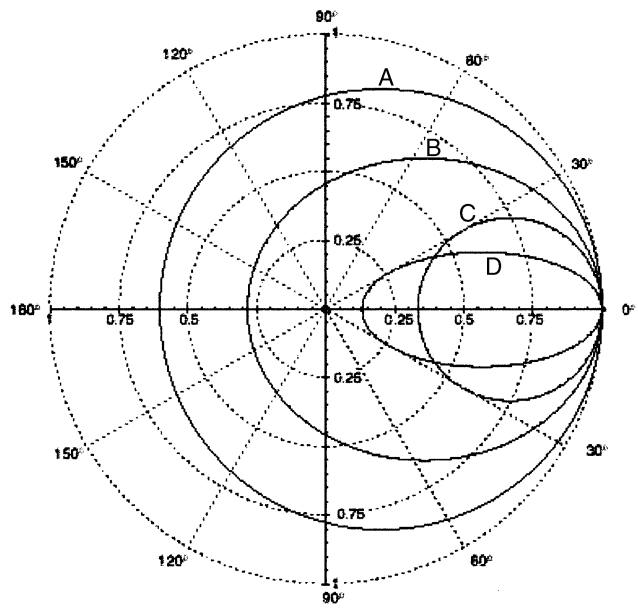

Figure 7. Classical and relativistic scattering diagrams for $A = 1/2$ and $A = 4$. (**A**) $A = 4$ and $\gamma = 1$, (**B**) $A = 4$ and $\gamma = 4.5$, (**C**) $A = 0.5$ and $\gamma = 1$, (**D**) $A = 0.5$ and $\gamma = 4.5$. Note that θ_{max} does not depend on γ.

To understand how the relativistic ellipses are related to the normal scattering circles, consider the positions of the centers. For a given $A > 1$, one finds that $x_s(e) > x_s(c)$, where $x_s(e)$ is the location of the ellipse center and $x_s(c)$ is the location of the circle center. When $A = 1$, then it is always true that $x_s(e) = x_s(c) = 1/2$. And finally, for a given $A < 1$, one finds that $x_s(e) < x_s(c)$. This last inequality has an interesting consequence. As γ increases when $A < 1$, the center of the ellipse moves towards the origin, the ellipse itself becomes more eccentric, and one finds that θ_{max} does not change. The maximum allowed scattering angle when $A < 1$ is always arcsin A. This effect is diagrammed in Figure 7.

For inelastic relativistic collisions, the center of the scattering ellipse remains unchanged from the elastic case (Equation 21). However, the major and minor axes are reduced. A practical way of plotting the ellipse is to use its parametric definition, which is $x = r_s(a)\cos\theta_c + x_s$ and $y = r_s(b)\sin\theta_c$, where

$$r_s(a) = a\sqrt{1 - Q_n/a} \tag{27}$$

and

$$r_s(b) = b\sqrt{1 - Q_n/b} \tag{28}$$

As in the nonrelativistic classical case, the relativistic scattering curves allow one to easily determine the scattered particle velocity and energy at any allowed scattering angle.

In a similar manner, the recoiling curves for relativistic particles can be stated as a straightforward extension of the classical recoiling curves.

Nuclear Reactions

Scattering and recoiling circle diagrams can also depict the kinematics of simple nuclear reactions in which the colliding particles undergo a mass change. A nuclear reaction of the form $\mathbf{A}(\mathbf{b},\mathbf{c})\mathbf{D}$ can be written as $\mathbf{A} + \mathbf{b} \rightarrow \mathbf{c} + \mathbf{D} + Q_{mass}/c^2$, where the mass difference is accounted for by Q_{mass}, usually referred to as the "Q value" for the reaction. The sign of the Q value is conventionally taken as positive for a kinetic energy-producing (exoergic) reaction and negative for a kinetic energy-driven (endoergic) reaction. It is important to distinguish between Q_{mass} and the inelastic energy factor Q introduced in Equation 6. The difference is that Q_{mass} balances the mass in the above equation for the nuclear reaction, while Q balances the kinetic energy in Equation 6. These values are of opposite sign: i.e., $Q = -Q_{mass}$. To illustrate, for an exoergic reaction ($Q_{mass} > 0$), some of the internal energy (e.g., mass) of the reactant particles is converted to kinetic energy. Hence the internal energy of the system is reduced and Q is negative in sign.

For the reaction $\mathbf{A}(\mathbf{b},\mathbf{c})\mathbf{D}$, $\mathbf{A}$ is considered to be the target nucleus, $\mathbf{b}$ the incident particle (projectile), $\mathbf{c}$ the outgoing particle, and $\mathbf{D}$ the recoil nucleus. Let $m_{\mathbf{A}}, m_{\mathbf{b}}, m_{\mathbf{c}}$, and $m_{\mathbf{D}}$ be the corresponding masses and $v_{\mathbf{b}}, v_{\mathbf{c}}$, and $v_{\mathbf{D}}$ be the corresponding velocities ($v_{\mathbf{A}}$ is assumed to be zero). We now define the mass ratios A_1 and A_2 as $A_1 = m_{\mathbf{c}}/m_{\mathbf{b}}$ and $A_2 = m_{\mathbf{D}}/m_{\mathbf{b}}$ and the velocity ratios v_{n1} and v_{n2} as $v_{n1} = v_{\mathbf{c}}/v_{\mathbf{b}}$ and $v_{n2} = v_{\mathbf{D}}/v_{\mathbf{b}}$. Note that A_2 is equivalent to the previously defined target-to-projectile mass ratio A. Applying the energy and momentum conservation laws yields the fundamental kinematic relation for particle $\mathbf{c}$, which is:

$$2\cos\theta_1 = (A_1 + A_2)v_{n1} + \frac{1 - A_2(1 - Q_n)}{A_1 v_{n1}} \tag{29}$$

where θ_1 is the emission angle of particle $\mathbf{c}$ with respect to the incident particle direction. As mentioned above, the normalized inelastic energy factor, Q_n, is Q/E_0, where E_0 is the incident particle kinetic energy. In a similar manner, the fundamental relation for particle $\mathbf{D}$ is found to be

$$2\cos\theta_2 = \frac{(A_1 + A_2)v_{n2}}{\sqrt{A_2}} + \frac{1 - A_1(1 - Q_n)}{\sqrt{A_2}v_{n2}} \tag{30}$$

where θ_2 is the emission angle of particle $\mathbf{D}$.

Equations 29 and 30 can be combined into a single expression for the energy of the products:

$$E = A_i \left[\frac{1}{A_1 + A_2}\left(\cos\theta \pm \sqrt{\cos^2\theta - \frac{(A_1 + A_2)[1 - A_j(1 - Q_n)]}{A_i}}\right)\right]^2 \tag{31}$$

where the variables are assigned according to Table 1.

Equation 31 is a generalization of Equation 10, and its symmetry with respect to the two product particles is noteworthy. The symmetry arises from the common origin of the products at the instance of the collision, at which point they are indistinguishable.

In analogy to the results discussed above (see discussion of Scattering and Recoiling Diagrams), the expressions of Equation 31 describe circles in polar coordinates $(\sqrt{E}, \theta)$. Here the circle center x_1 is given by

$$x_1 = \frac{\sqrt{A_1}}{A_1 + A_2} \tag{32}$$

and the circle center x_2 is given by

$$x_2 = \frac{\sqrt{A_2}}{A_1 + A_2} \tag{33}$$

The circle radius r_1 is

$$r_1 = x_2\sqrt{(A_1 + A_2)(1 - Q_n) - 1} \tag{34}$$

Table 1. Assignment of Variables in Equation 31

	Product Particle	
Variable	**c**	D
E	E_1/E_0	E_2/E_0
θ	q_1	θ_2
A_i	A_1	A_2
A_j	A_2	A_1

and the circle radius r_2 is

$$r_2 = x_1\sqrt{(A_1 + A_2)(1 - Q_n) - 1} \tag{35}$$

Polar ($\sqrt{E}, \theta$) diagrams can be easily constructed using these definitions. In this case, the terms light product and heavy product should be used instead of scattering and recoiling, since the reaction products originate from a compound nucleus and are distinguished only by their mass. Note that Equations 29 and 30 become equivalent to Equations 7 and 8 if no mass change occurs, since if $m_{\mathbf{b}} = m_{\mathbf{c}}$, then $A_1 = 1$. Similarly, Equations. 32 and 33 and Equations 34 and 35 are extensions of Equations. 11, 13, 14, and 16, respectively. It is also worth noting that the initial target mass, $m_{\mathbf{A}}$, does not enter into any of the kinematic expressions, since a body at rest has no kinetic energy or momentum.

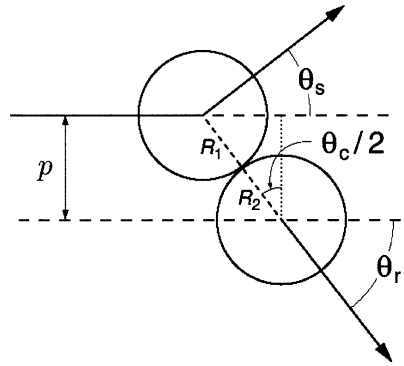

Figure 8. Geometry for hard-sphere collisions in a laboratory reference frame. The spheres have radii R_1 and R_2. The impact parameter, p, is the minimum separation distance between the particles along the projectile's path if no deflection were to occur. The example shown is for $R_1 = R_2$ and $A = 1$ at the moment of impact. From the triangle, it is apparent that $p/D = \cos(\theta_c/2)$, where $D = R_1 + R_2$.

CENTRAL-FIELD THEORY

While kinematics tells us how energy is apportioned between two colliding particles for a given scattering or recoiling angle, it tells us nothing about how the alignment between the collision partners determines their final trajectories. Central-field theory provides this information by considering the interaction potential between the particles. This section begins with a discussion of interaction potentials, then introduces the notion of an impact parameter, which leads to the formulation of the deflection function and the evaluation of collision cross-sections.

Interaction Potentials

The form of the interaction potential is of prime importance to the accurate representation of atomic scattering. The appropriate form depends on the incident kinetic energy of the projectile, E_0, and on the collision partners. When E_0 is on the order of the energy of chemical bonds ($\approx$1 eV), a potential that accounts for chemical interactions is required. Such potentials frequently consist of a repulsive term that operates at short distances and a long-range attractive term. At energies above the thermal and hyperthermal regimes (>100 eV), atomic collisions can be modeled using screened Coulomb potentials, which consider the Coulomb repulsion between nuclei attenuated by electronic screening effects. This energy regime extends up to some tens or hundreds of keV. At higher E_0, the interaction potential becomes practically Coulombic in nature and can be cast in a simple analytic form. At still higher energies, nuclear reactions can occur and must be considered. For particles with very high velocities, relativistic effects can dominate. Table 2 summarizes the potentials commonly used in various energy regimes. In the following, we will consider only central potentials, $V(r)$, which are spherically symmetric and depend only upon the distance between nuclei. In many materials-analysis applications, the energy of the interacting particles is such that pure or screened Coulomb central potentials prove highly useful.

Impact Parameters

The impact parameter is a measure of the alignment of the collision partners and is the distance of closest approach between the two particles in the absence of any forces. Its measure is the perpendicular distance between the projectile's initial direction and the parallel line passing through the target center. The impact parameter p is shown in Figure 8 for a hard-sphere binary collision. The impact parameter can be defined in a similar fashion for any binary collision; the particles can be point-like or have a physical extent. When $p = 0$, the collision is head on. For hard spheres, when p is greater than the sum of the spheres' radii, no collision occurs.

The impact parameter is similarly defined for scattering in the relative reference frame. This is illustrated in

Table 2. Interatomic Potentials Used in Various Energy Regimes[a,b]

Regime	Energy Range	Applicable Potential	Comments
Thermal	<1 eV	Attractive/repulsive	Van der Waals attraction
Hyperthermal	1–100 eV	Many body	Chemical reactions
Low	100 eV–10 keV	Screened Coulomb	Binary collisions
Medium	10 keV–1 MeV	Screened/pure Coulomb	Rutherford scattering
High	1–100 MeV	Coulomb	Nuclear reactions
Relativistic	>100 MeV	Liènard-Wiechert	Pair production

[a] Boundaries between regimes are approximate and depend on the characteristics of the collision partners.
[b] Below the Bohr electron velocity, $e^2/\hbar = 2.2 \times 10^6$ m/s, ionization and neutralization effects can be significant.

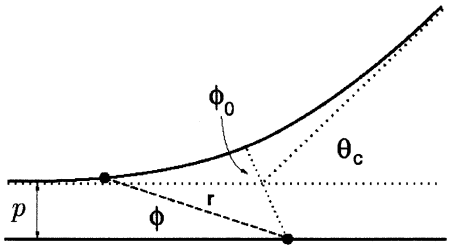

Figure 9. Geometry for scattering in the relative reference frame between a particle of mass μ and a fixed point target with a replusive force acting between them. The impact parameter p is defined as in Figure 8. The actual minimum separation distance is larger than p, and is referred to as the apsis of the collision. Also shown are the orientation angle ϕ and the separation distance r of the projectile as seen by an observer situated on the target particle. The apsis, r_0, occurs at the orientation angle ϕ_0. The relative scattering angle, shown as θ_c, is identical to the center-of-mass scattering angle. The relationship $\theta_c = |\pi - 2\phi_0|$ is apparent by summing the angles around the projectile asymptote at the apsis.

Figure 9 for a collision between two particles with a repulsive central force acting on them. For a given impact parameter, the final trajectory, as defined by θ_c, depends on the strength of the potential field. Also shown in the figure is the actual distance of closest approach, or apsis, which is larger than p for any collision involving a repulsive potential.

Shadow Cones

Knowing the interaction potential, it is straightforward, though perhaps tedious, to calculate the trajectories of a projectile and target during a collision, given the initial state of the system (coordinates and velocities). One does this by solving the equations of motion incrementally. With a sufficiently small value for the time step between calculations and a large number of time steps, the correct trajectory emerges. This is shown in Figure 10, for a representative atomic collision at a number of impact parameters. Note the appearance of a shadow cone, a region inside of which the projectile is excluded regardless of the impact parameter. Many weakly deflected projectile trajectories pass near the shadow cone boundary, leading to a flux-focusing effect. This is a general characteristic of collisions with $A > 1$.

The shape of the shadow cone depends on the incident particle energy and the interaction potential. For a pure Coulomb interaction, the shadow cone (in an axial plane) forms a parabola whose radius, $\hat{r}$ is given by $\hat{r} = 2(\hat{b}\hat{l})^{1/2}$ where $\hat{b} = Z_1 Z_2 e^2/E_0$ and $\hat{l}$ is the distance beyond the target particle. The shadow cone narrows as the energy of the incident particles increases. Approximate expressions for the shadow-cone radius can be used for screened Coulomb interaction potentials, which are useful at lower particle energies. Shadow cones can be utilized by ion-beam analysis methods to determine the surface structure of crystalline solids.

Deflection Functions

A general objective is to establish the relationship between the impact parameter and the scattering and recoiling angles. This relationship is expressed by the deflection function, which gives the center-of-mass scattering angle in terms of the impact parameter. The deflection function is of considerable practical use. It enables one to calculate collision cross-sections and thereby relate the intensity of scattering or recoiling with the interaction potential and the number of particles present in a collision system.

Deflection Function for Hard Spheres

The deflection function can be most simply illustrated for the case of hard-sphere collisions. Hard-sphere collisions have an interaction potential of the form

$$V(r) = \begin{cases} \infty & \text{when} \quad 0 \le p \le D \\ 0 & \text{when} \quad p > D \end{cases} \tag{36}$$

where D, called the collision diameter, is the sum of the projectile and target sphere radii R_1 and R_2. When p is greater than D, no collision occurs.

A diagram of a hard-sphere collision at the moment of impact is shown in Figure 8. From the geometry, it is seen that the deflection function for hard spheres is

$$\theta_c(p) = \begin{cases} 2\arccos(p/D) & \text{when} \quad 0 \le p \le D \\ 0^\circ & \text{when} \quad p > D \end{cases} \tag{37}$$

For elastic billiard ball collisions ($A = 1$), the deflection function expressed in laboratory coordinates using Equations 18 and 19 is particularly simple. For the projectile it is

$$\theta_s = \arccos(p/D) \qquad 0 \le p \le D, \quad A = 1 \tag{38}$$

and for the target

$$\theta_r = \arcsin(p/D) \qquad 0 \le p \le D \tag{39}$$

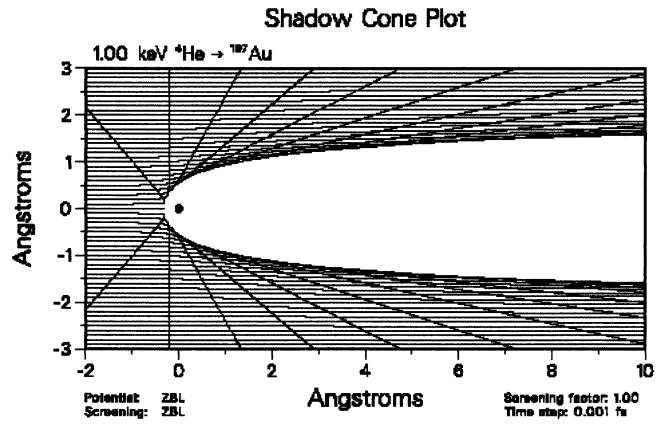

Figure 10. A two-dimensional representation of a shadow cone. The trajectories for a 1-keV ^{4}He atom scattering from a ^{197}Au target atom are shown for impact parameters ranging from +3 to −3 Å in steps of 0.1 Å. The ZBL interaction potential was used. The trajectories lie outside a parabolic shadow region. The full shadow cone is three dimensional and has rotational symmetry about its axis. Trajectories for the target atom are not shown. The dot marks the initial target position, but does not represent the size of the target nucleus, which would appear much smaller at this scale.

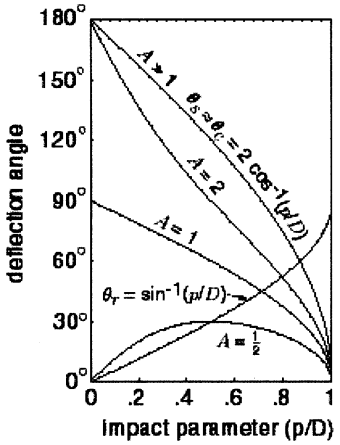

Figure 11. Deflection function for hard-sphere collisions. The center-of-mass deflection angle, θ_c is given by $2\cos^{-1}(p/D)$, where p is the impact parameter (see Fig. 8) and D is the collision diameter (sum of particle radii). The scattering angle in the laboratory frame, θ_s, is given by Equation 37 and is plotted for A values of 0.5, 1, 2, and 100. When $A = 1$, it equals $\cos^{-1}(p/D)$. At large A, it converges to the center-of-mass function. The recoiling angle in the laboratory frame, θ_r, is given by $\sin^{-1}(p/D)$ and does not depend on A.

When $A = 1$, the projectile and target trajectories after the collision are perpendicular.

For $A \neq 1$, the laboratory deflection function for the projectile is not as simple:

$$\theta_s = \arccos\left(\frac{1 - A + 2A(p/D)^2}{\sqrt{1 - 2A + A^2 + 4A(p/D)^2}}\right) \quad 0 \leq p \leq D \tag{40}$$

In the limit, as $A \to \infty$, $\theta_s \to 2\arccos(p/D)$. In contrast, the laboratory deflection function for the target recoil is independent of A and Equation 39 applies for all A. The hard-sphere deflection function is plotted in Figure 11 in both coordinate systems for selected A values.

Deflection Function for Other Central Potentials

The classical deflection function, which gives the center-of-mass scattering angle θ_c as a function of the impact parameter p, is

$$\theta_c(p) = \pi - 2p\int_{r_0}^{\infty} \frac{1}{r^2 f(r)^{1/2}}\,dr \tag{41}$$

where

$$f(r) = 1 - \frac{p^2}{r^2} - \frac{V(r)}{E_{rel}} \tag{42}$$

and $f(r_0) = 0$.

The physical meanings of the variables used in these expressions, for the case of two interacting particles, are as follows:

r: particle separation distance;

r_0: distance at closest approach (turning point or apsis);

$V(r)$: the interaction potential;

E_{rel}: kinetic energy of the particles in the center-of-mass and relative coordinate systems (relative energy).

We will examine how the deflection function can be evaluated for various central potentials. When $V(r)$ is a simple central potential, the deflection function can be evaluated analytically. For example, suppose $V(r) = k/r$, where k is a constant. If $k < 0$, then $V(r)$ represents an attractive potential, such as gravity, and the resulting deflection function is useful in celestial mechanics. For example, in Newtonian gravity, $k = -Gm_1m_2$, where G is the gravitational constant and the masses of the celestial bodies are m_1 and m_2. If $k > 0$, then $V(r)$ represents a repulsive potential, such as the Coulomb field between like-charged atomic particles. For example, in Rutherford scattering, $k = Z_1Z_2e^2$, where Z_1 and Z_2 are the atomic numbers of the nuclei and e is the unit of elementary charge. Then the deflection function is exactly given by

$$\theta_c(p) = \pi - 2\arctan\left(\frac{2pE_{rel}}{k}\right) = 2\arctan\left(\frac{k}{2pE_{rel}}\right) \tag{43}$$

Another central potential for which the deflection function can be exactly solved is the inverse square potential. In this case, $V(r) = k/r^2$, and the corresponding deflection function is:

$$\theta_c(p) = \pi\left(1 - \frac{p}{\sqrt{p^2 + k/E_{rel}}}\right) \tag{44}$$

Although the inverse square potential is not, strictly speaking, encountered in nature, it is a rough approximation to a screened Coloumb field when $k = Z_1Z_2e^2$. Realistic screened Coulomb fields decrease even more strongly with distance than the k/r^2 field.

Approximation of the Deflection Function

In cases where $V(r)$ is a more complicated function, sometimes no analytic solution for the integral exists and the function must be approximated. This is the situation for atomic scattering at intermediate energies, where the appropriate form for $V(r)$ is given by:

$$V(r) = \frac{k}{r}\Phi(r) \tag{45}$$

$F(r)$ is referred to as a screening function. This form for $V(r)$ with $k = Z_1Z_2e^2$ is the screened Coulomb potential. The constant term e^2 has a value of 14.40 eV-Å ($e^2 = c\alpha$, where $= h/2\pi$, h is Planck's constant, and α is the fine-structure constant). Although the screening function is not usually known exactly, several approximations appear to be reasonably accurate. These approximate functions have the form

$$\Phi(r) = \sum_{i=1}^{n} a_i \exp\left(\frac{-b_i r}{l}\right) \tag{46}$$

where a_i, b_i, and l are all constants. Two of the better known approximations are due to Moliére and to Ziegler, Biersack, and Littmark (ZBL). For the Moliére approximation, $n = 3$, with

$$\begin{aligned} a_1 &= 0.35 \qquad b_1 = 0.3 \\ a_2 &= 0.55 \qquad b_2 = 1.2 \\ a_3 &= 0.10 \qquad b_3 = 6.0 \end{aligned} \tag{47}$$

and

$$l = \frac{1}{4}\left[\frac{(3\pi)^2}{2}\right]^{1/3} a_0\left(Z_1^{1/2} + Z_2^{1/2}\right)^{-2/3} \tag{48}$$

where

$$a_0 = \frac{}{m_e e^2} \tag{49}$$

In the above, l is referred to as the screening length (the form shown is the Firsov screening length), a_0 is the Bohr radius, and m_e is the rest mass of the electron.

For the ZBL approximation, $n = 4$, with

$$\begin{aligned} a_1 &= 0.18175 \qquad b_1 = 3.19980 \\ a_2 &= 0.50986 \qquad b_2 = 0.94229 \\ a_3 &= 0.28022 \qquad b_3 = 0.40290 \\ a_4 &= 0.02817 \qquad b_4 = 0.20162 \end{aligned} \tag{50}$$

and

$$l = \frac{1}{4}\left[\frac{(3\pi)^2}{2}\right]^{1/3} a_0\left(Z_1^{0.23} + Z_2^{0.23}\right)^{-1} \tag{51}$$

If no analytic form for the deflection integral exists, two types of approximations are popular. In many cases, analytic approximations can be devised. Otherwise, the function can still be evaluated numerically. Gauss-Mehler quadrature (also called Gauss-Chebyshev quadrature) is useful in such situations. To apply it, the change of variable $x = r_0/r$ is made. This gives

$$\theta_c(p) = \pi - 2\hat{p}\int_0^1 \frac{1}{\sqrt{1 - (\hat{p}x)^2 - \dfrac{V}{E}}}\,dx \tag{52}$$

where $\hat{p} = p/r_0$.

The Gauss-Mehler quadrature relation is

$$\int_{-1}^{1} \frac{g(x)}{\sqrt{(1-x^2)}}\,dx \doteq \sum_{i=1}^{n} w_i g(x_i) \tag{53}$$

where $w_i = \pi/n$ and

$$x_i = \cos\left[\frac{\pi(2i-1)}{2n}\right] \tag{54}$$

Letting

$$g(x) = \hat{p}\sqrt{\frac{1-x^2}{1-(\hat{p}x)^2 - V/E}} \tag{55}$$

it can be shown that

$$\theta_c(p) \doteq \pi\left[1 - \frac{2}{n}\sum_{i=1}^{n/2} g(x_i)\right] \tag{56}$$

This is a useful approximation, as it allows the deflection function for an arbitrary central potential to be calculated to any desired degree of accuracy.

Cross-Sections

The concept of a scattering cross-section is used to relate the number of particles scattered into a particular angle to the number of incident particles. Accordingly, the scattering cross-section is $d\sigma(\theta_c) = dN/n$, where dN is the number of particles scattered per unit time between the angles θ_c and $\theta_c + d\theta_c$, and n is the incident flux of projectiles. With knowledge of the scattering cross-section, it is possible to relate, for a given incident flux, the number of scattered particles to the number of target particles. The value of scattering cross-section depends upon the interaction potential and is expressed most directly using the deflection function.

The differential cross-section for scattering into a differential solid angle $d\Omega$ is

$$\frac{d\sigma(\theta_c)}{d\Omega} = \frac{p}{\sin(\theta_c)}\left|\frac{dp}{d\theta_c}\right| \tag{57}$$

Here the solid and plane angle elements are related by $d\Omega = 2\pi \sin(\theta_c)\, d\theta_c$. Hard-sphere collisions provide a simple example. Using the hard-sphere potential (Equation 36) and deflection function (Equation 37), one obtains $d\sigma(\theta_c)/d\Omega = D^2/4$. Hard-sphere scattering is isotropic in the center-of-mass reference frame and independent of the incident energy. For the case of a Coulomb interaction potential, one obtains the Rutherford formula:

$$\frac{d\sigma(\theta_c)}{d\Omega} = \left(\frac{Z_1 Z_2 e^2}{4E_{rel}}\right)^2 \frac{1}{\sin^4(\theta_c/2)} \tag{58}$$

This formula has proven to be exceptionally useful for ion-beam analysis of materials.

For the inverse square potential (k/r^2), the differential cross-section is given by

$$\frac{d\sigma(\theta_c)}{d\Omega} = \frac{k}{E_{rel}}\frac{\pi^2(\pi - \theta_c)}{\theta_c^2(2\pi - \theta_c)^2}\frac{1}{\sin(\theta_c)} \tag{59}$$

For other potentials, numerical techniques (e.g., Equation 56) are typically used for evaluating collision cross-sections. Equivalent forms of Equation 57, such as

$$\frac{d\sigma(\theta_c)}{d\Omega} = \frac{p}{\sin(\theta_c)}\left|\frac{d\theta_c}{dp}\right|^{-1} = \frac{dp^2}{2d(\cos\theta_c)} \tag{60}$$

show that computing the cross-section can be accomplished by differentiating the deflection function or its inverse.

Cross-sections are converted to laboratory coordinates using Equations 18 and 19. This gives, for elastic collisions,

$$\frac{d\sigma(\theta_s)}{d\omega} = \frac{(1 + 2A\cos\theta_c + A^2)^{3/2}}{A^2|(A + \cos\theta_c)|}\frac{d\sigma(\theta_c)}{d\Omega} \qquad (61)$$

for scattering and

$$\frac{d\sigma(\theta_r)}{d\omega} = 4\sin\left(\frac{\theta_c}{2}\right)\frac{d\sigma(\theta_c)}{d\Omega} \qquad (62)$$

for recoiling. Here, the differential solid angle element in the laboratory reference frame, $d\omega$, is $2\pi\sin(\theta)\,d\theta$ and θ is the laboratory observing angle, θ_s or θ_r. For conversions to laboratory coordinates for inelastic collisions, see Conversions among θ_s, θ_r, and θ_c for Nonrelativistic Collisions, in the Appendix at the end of this unit.

Examples of differential cross-sections in laboratory coordinates for elastic collisions are shown in Figures 12 and 13 as a function of the laboratory observing angle. Some general observations can be made. When $A > 1$, scattering is possible at all angles (0° to 180°) and the scattering cross-sections decrease uniformly as the projectile energy and laboratory scattering angle increase. Elastic recoiling particles are emitted only in the forward direction regardless of the value of A. Recoiling cross-sections decrease as the projectile energy increases, but increase with recoiling angle. When $A < 1$, there are two branches in the scattering cross-section curve. The upper branch (i.e., the one with the larger cross-sections) results from collisions with the larger p. The two branches converge at θ_{max}.

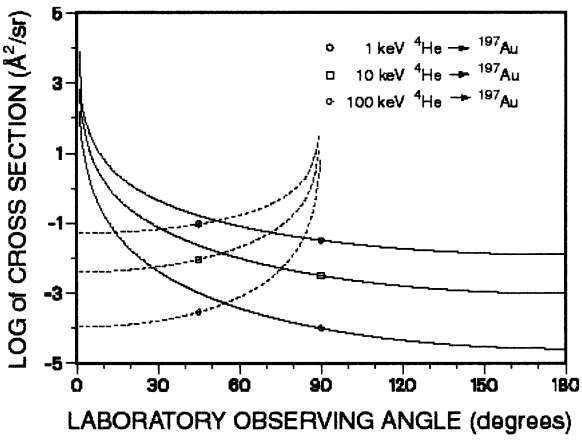

Figure 12. Differential atomic collision cross-sections in the laboratory reference frame for 1-, 10-, and 100-keV ^{4}He projectiles striking ^{197}Au target atoms as a function of the laboratory observing angle. Cross-sections are plotted for both the scattered projectiles (solid lines) and the recoils (dashed lines). The cross-sections were calculated using the ZBL screened Coulomb potential and Gauss-Mehler quadrature of the deflection function.

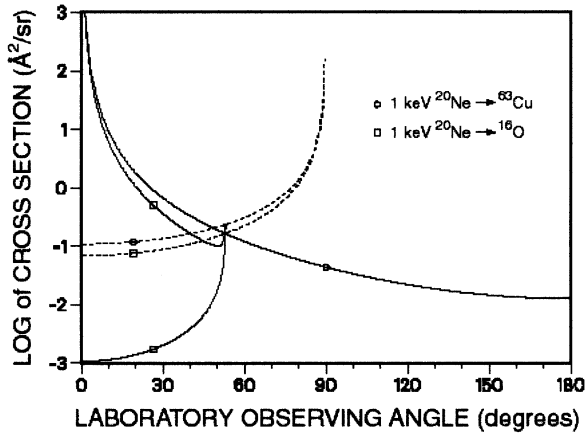

Figure 13. Differential atomic collision cross-sections in the laboratory reference frame for ^{20}Ne projectiles striking ^{63}Cu and ^{16}O target atoms calculated using ZBL interaction potential. Cross-sections are plotted for both the scattered projectiles (solid lines) and the recoils (dashed lines). The limiting angle for ^{20}Ne scattering from ^{16}O is 53.1°.

Applications to Materials Analysis

There are two general ways in which particle scattering theory is utilized in materials analysis. First, kinematics provides the connection between measurements of particle scattering parameters (velocity or energy, and angle) and the identity (mass) of the collision partners. A number of techniques analyze the energy of scattered or recoiled particles in order to deduce the elemental or isotopic identity of a substance. Second, central-field theory enables one to relate the intensity of scattering or recoiling to the amount of a substance present. When combined, kinematics and central-field theory provide exactly the tools needed to accomplish, with the proper measurements, compositional analysis of materials. This is the primary goal of many ion-beam methods, where proper selection of the analysis conditions enables a variety of extremely sensitive and accurate materials-characterization procedures to be conducted. These include elemental and isotopic composition analysis, structural analysis of ordered materials, two- and three-dimensional compositional profiles of materials, and detection of trace quantities of impurities in materials.

APPENDIX

Solutions of Fundamental Scattering and Recoiling Relations in Terms of v, E, θ, A, and Q_n for Nonrelativistic Collisions

For elastic scattering:

$$v_s = \sqrt{E_s} = \frac{\cos\theta_s \pm \sqrt{A^2 - \sin^2\theta_s}}{1+A} \tag{63}$$

$$\theta_s = \arccos\left[\frac{(1+A)v_s}{2} + \frac{1-A}{2v_s}\right] \tag{64}$$

$$A = \frac{2(1 - v_s\cos\theta_s)}{1 - v_s^2} - 1 \tag{65}$$

For inelastic scattering:

$$v_s = \sqrt{E_s} = \frac{\cos\theta_s \pm \sqrt{A^2 f^2 - \sin^2\theta_s}}{1+A} \tag{66}$$

$$\theta_s = \arccos\left[\frac{(1+A)v_s}{2} + \frac{1 - A(1-Q_n)}{2v_s}\right] \tag{67}$$

$$A = \frac{1 + v_s^2 - 2v_s\cos\theta_s}{1 - v_s^2 - Q_n} = \frac{1 + E_s - 2\sqrt{E_s}\cos\theta_s}{1 - E_s - Q_n} \tag{68}$$

$$Q_n = 1 - \frac{1 - v_s[2\cos\theta_s - (1+A)v_s]}{A} \tag{69}$$

In the above relations,

$$f^2 = 1 - \frac{1+A}{A}Q_n \tag{70}$$

and $A = m_2/m_1, v_s = v_1/v_0, E_s = E_1E_0, Q_n = Q/E_0$, and θ_s is the laboratory scattering angle as defined in Figure 1.

For elastic recoiling:

$$v_r = \sqrt{\frac{E_r}{A}} = \frac{2\cos\theta_r}{1+A} \tag{71}$$

$$\theta_r = \arccos\left[\frac{(1+A)v_r}{2}\right] \tag{72}$$

$$A = \frac{2\cos\theta_r}{v_r} - 1 \tag{73}$$

For inelastic recoiling:

$$v_r = \sqrt{\frac{E_r}{A}} = \frac{\cos\theta_r \pm \sqrt{f^2 - \sin^2\theta_r}}{1+A} \tag{74}$$

$$\theta_r = \arccos\left[\frac{(1+A)v_r}{2} + \frac{Q_n}{2Av_r}\right] \tag{75}$$

$$A = \frac{2\cos\theta_r - v_r \pm \sqrt{(2\cos\theta_r - v_r)^2 - 4Q_n}}{2v_r} = \frac{(\cos\theta_r \pm \sqrt{\cos^2\theta_r - E_r - Q_n})^2}{E_r} \tag{76}$$

$$Q_n = Av_r[2\cos\theta_r - (1+A)v_r] \tag{77}$$

In the above relations,

$$f^2 = 1 - \frac{1+A}{A}Q_n \tag{78}$$

and $A = m_2/m_1$, $v_r = v_2/v_0$, $E_r = E_2/E_0$, $Q_n = Q/E_0$, θ_r is the laboratory recoiling angle as defined in Figure 1.

Conversions among θ_s, θ_r, and θ_c for Nonrelativistic Collisions

$$\theta_s = \arctan\left[\frac{\sin 2\theta_r}{(Af)^{-1} - \cos 2\theta_r}\right] = \arctan\left[\frac{\sin\theta_c}{(Af)^{-1} + \cos\theta_c}\right] \tag{79}$$

$$\theta_r = \arctan\left[\frac{\sin\theta_c}{f^{-1} - \cos\theta_c}\right] \tag{80}$$

$$\theta_r = \frac{1}{2}(\pi - \theta_c) \quad \text{for} \quad f = 1 \tag{81}$$

$$\theta_{c_1} = \theta_s + \arcsin\left[(Af)^{-1}\sin\theta_s\right] \tag{82}$$

$$\theta_{c_2} = 2\theta_s - \theta_{c_1} + \pi \qquad \text{for} \quad \sin\theta_s < Af < 1 \tag{83}$$

$$\frac{d\sigma(\theta_s)}{d\omega} = \frac{(1 + 2Af\cos\theta_c + (A^2f^2)^{3/2}}{A^2f^2|(Af + \cos\theta_c)|}\frac{d\sigma(\theta_c)}{d\Omega} \tag{84}$$

$$\frac{d\sigma(\theta_r)}{d\omega} = \frac{(1 - 2f\cos\theta_c + f^2)^{3/2}}{f^2|\cos\theta_c - f|}\frac{d\sigma(\theta_c)}{d\Omega} \tag{85}$$

In the above relations:

$$f = \sqrt{1 - \frac{1+A}{A} Q_n} \tag{86}$$

Note that: (1) $f = 1$ for elastic collisions; (2) when $A < 1$ and $\sin \theta_s$ A, two values of θ_c are possible for each θ_s; and (3) when $A = 1$ and $f = 1$, $(\tan \theta_s)(\tan \theta_r) = 1$.

Glossary of Terms and Symbols

α	Fine-structure constant ($\approx 7.3 \times 10^{-3}$)
A	Target to projectile mass ratio (m_2/m_1)
A_1	Ratio of product **c** mass to projectile **b** ($m_{\mathbf{c}}/m_{\mathbf{b}}$)
A_2	Ratio of product **D** mass to projectile **b** mass ($m_{\mathbf{D}}/m_{\mathbf{b}}$)
a	Major axis of scattering ellipse
a_0	Bohr radius ($\approx 29 \times 10^{-11}$ m)
β	Reduced velocity (v_0/c)
b	Minor axis of scattering ellipse
c	Velocity of light ($\approx 3.0 \times 10^8$ m/s)
d	Distance from scattering ellipse center to focal point
D	Collision diameter
$d\sigma$	Scattering cross-section
ε	Eccentricity of scattering ellipse
e	Unit of elementary charge ($\approx 1.602 \times 10^{-19}$ C)
E_0	Initial kinetic energy of projectile
E_1	Final kinetic energy of scattered projectile or product **c**
E_2	Final kinetic energy of recoiled target or product **D**
E_r	Normalized energy of the recoiled target (E_2/E_0)
E_{rel}	Relative energy
E_s	Normalized energy of the scattered projectile (E_1/E_0)
γ	Relativistic parameter (Lorentz factor)
h	Planck constant (4.136×10^{-15} eV-s)
l	Screening length
μ	Reduced mass ($\mu^{-1} = m_1^{-1} + m_2^{-1}$)
m_1, $m_{\mathbf{b}}$	Mass of projectile
m_2	Mass of recoiling particle (target)
$m_{\mathbf{A}}$	Initial target mass
$m_{\mathbf{c}}$	Light product mass
$m_{\mathbf{D}}$	Heavy product mass
m_e	Electron rest mass ($\approx 9.109 \times 10^{-31}$ kg)
p	Impact parameter
ϕ	Particle orientation angle in the relative reference frame
ϕ_0	Particle orientation angle at the apsis
Φ	Electron screening function
Q	Inelastic energy factor
Q_{mass}	Energy equivalent of particle mass change (Q value)
Q_n	Normalized inelastic energy factor (Q/E_0)
r	Particle separation distance
r_0	Distance of closest approach (apsis or turning point)
r_1	Radius of product **c** circle
r_2	Radius of product **D** circle
r_r	Radius of recoiling circle or ellipse
r_s	Radius of scattering circle or ellipse
R_1	Hard sphere radius of projectile
R_2	Hard sphere radius of target
θ_1	Emission angle of product **c** particle in the laboratory frame
θ_2	Emission angle of product **D** particle in the laboratory frame
θ_c	Center-of-mass scattering angle
θ_{max}	Maximum permitted scattering angle
θ_r	Recoiling angle of target in the laboratory frame
θ_s	Scattering angle of projectile in the laboratory frame
V	Interatomic interaction potential
v_0, $v_{\mathbf{b}}$	Initial velocity of projectile
v_1	Final velocity of scattered projectile
v_2	Final velocity of recoiled target
v_c	Velocity of light product
v_D	Velocity of heavy product
v_{n1}	Normalized final velocity of product **c** particle ($v_{\mathbf{c}}/v_{\mathbf{b}}$)
v_{n2}	Normalized final velocity of product **D** particle ($v_{\mathbf{D}}/v_{\mathbf{b}}$)
v_r	Normalized final velocity of target particle (v_2/v_0)
x_1	Position of product **c** circle or ellipse center
x_2	Position of product **D** circle or ellipse center
x_r	Position of recoiling circle or ellipse center
x_s	Position of scattering circle or ellipse center
Z_1	Atomic number of projectile
Z_2	Atomic number of target

SAMPLE PREPARATION FOR METALLOGRAPHY

INTRODUCTION

Metallography, the study of metal and metallic alloy structure, began at least 150 years ago with early investigations of the science behind metalworking. According to Rhines (1968), the earliest recorded use of metallography was in 1841(Anosov, 1954). Its first systematic use can be traced to Sorby (1864). Since these early beginnings, metallography has come to play a central role in metallurgical studies—a recent (1998) search of the literature revealed over 20,000 references listing metallography as a keyword!

Metallographic sample preparation has evolved from a black art to the highly precise scientific technique it is today. Its principal objective is the preparation of artifact-free representative samples suitable for microstructural examination. The particular choice of a sample preparation procedure depends on the alloy system and also on the focus of the examination, which could include process optimization, quality assurance, alloy design, deformation studies, failure analysis, and reverse engineering. The details of how to make the most appropriate choice and perform the sample preparation are the subject of this unit.

Metallographic sample preparation is divided broadly into two stages. The aim of the first stage is to obtain a planar, specularly reflective surface, where the scale of the artifacts (e.g., scratches, smears, and surface deformation)

is smaller than that of the microstructure. This stage commonly comprises three or four steps: sectioning, mounting (optional), mechanical abrasion, and polishing. The aim of the second stage is to make the microstructure more visible by enhancing the difference between various phases and microstructural features. This is generally accomplished by selective chemical dissolution or film formation—etching. The procedures discussed in this unit are also suitable (with slight modifications) for the preparation of metal and intermetallic matrix composites as well as for semiconductors. The modifications are primarily dictated by the specific applications, e.g., the use of coupled chemical-mechanical polishing for semiconductor junctions.

The basic steps in metallographic sample preparation are straightforward, although for each step there may be several options in terms of the techniques and materials used. Also, depending on the application, one or more of the steps may be elaborated or eliminated. This unit provides guidance on choosing a suitable path for sample preparation, including advice on recognizing and correcting an unsuitable choice.

This discussion assumes access to a laboratory equipped with the requisite equipment for metallographic sample preparation. Listings of typical equipment and supplies (see Table 1) and World Wide Web addresses for major commercial suppliers (see Internet Resources) are provided for readers wishing to start or upgrade a metallography laboratory.

STRATEGIC PLANNING

Before devising a procedure for metallographic sample preparation, it is essential to define the scope and objectives of the metallographic analysis and to determine the requirements of the sample. Clearly defined objectives

Table 1. Typical Equipment and Supplies for Preparation of Metallographic Samples

Application	Items required
Sectioning	Band saw
	Consumable-abrasive cutoff saw
	Low-speed diamond saw or continous-loop wire saw
	Silicon-carbide wheels (coarse and fine grade)
	Alumina wheels (coarse and fine grade)
	Diamond saw blades or wire saw wires
	Abrasive powders for wire saw (Silicon carbide, silicon nitride, boron nitride, alumina)
	Electric-discharge cutter (optional)
Mounting	Hot mounting press
	Epoxy and hardener dispenser
	Vacuum impregnation setup (optional)
	Thermosetting resins
	Thermoplastic resins
	Castable resins
	Special conductive mounting compounds
	Edge-retention additives
	Electroless-nickel plating solutions
Mechanical abrasion and polishing	Belt sander
	Two-wheel mechanical abrasion and polishing station
	Automated polishing head (medium-volume laboratory) or automated grinding and polishing system (high-volume laboratory)
	Vibratory polisher (optional)
	Paper-backed emery and silicon-carbide grinding disks (120, 180, 240, 320, 400, and 600 grit)
	Polishing cloths (napless and with nap)
	Polishing suspensions (15-,9-,6-, and 1-μm diamond; 0.3-μm α-alumina and 0.05-μm γ-alumina; colloidal silica; colloidal magnesia; 1200- and 3200-grit emery)
	Metal and resin-bonded-diamond grinding disks (optional)
Electropolishing (optional)	Commercial electropolisher (recommended)
	Chemicals for electropolishing
Etching	Fume hood and chemical storage cabinets
	Etching chemicals
Miscellaneous	Ultrasonic cleaner
	Stir/heat plates
	Compressed air supply (filtered)
	Specimen dryer
	Multimeter
	Acetone
	Ethyl and methyl alcohol
	First aid kit
	Access to the Internet
	Material safety data sheets for all applicable chemicals
	Appropriate reference books (see Key References)

may help to avoid many frustrating and unrewarding hours of metallography.

It also important to search the literature to see if a sample preparation technique has already been developed for the application of interest. It is usually easier to fine tune an existing procedure than to develop a new one.

Defining the Objectives

Before proceeding with sample preparation, the metallographer should formulate a set of questions, the answers to which will lead to a definition of the objectives. The list below is not exhaustive, but it illustrates the level of detail required.

1. Will the sample be used only for general microstructural evaluation?
2. Will the sample be examined with an electron microscope?
3. Is the sample being prepared for reverse engineering purposes?
4. Will the sample be used to analyze the grain flow pattern that may result from deformation or solidification processing?
5. Is the procedure to be integrated into a new alloy design effort, where phase identification and quantitative microscopy will be used?
6. Is the procedure being developed for quality assurance, where a large number of similar samples will be processed on a regular basis?
7. Will the procedure be used in failure analysis, requiring special techniques for crack preservation?
8. Is there a requirement to evaluate the composition and thickness of any coating or plating?
9. Is the alloy susceptible to deformation-induced damage such as mechanical twinning?

Answers to these and other pertinent questions will indicate the information that is already available and the additional information needed to devise the sample preparation procedure. This leads to the next step, a literature survey.

Surveying the Literature

In preparing a metallographic sample, it is usually easier to fine-tune an existing procedure, particularly in the final polishing and etching steps, than to develop a new one. Moreover, the published literature on metallography is exhaustive, and for a given application there is a high probability that a sample preparation procedure has already been developed; hence, a thorough literature search is essential. References provided later in this unit will be useful for this purpose (see Key References; see Internet Resources).

PROCEDURES

The basic procedures used to prepare samples for metallographic analysis are discussed below. For more detail, see *ASM Metals Handbook, Volume 9: Metallography and Microstructures* (ASM Handbook Committee, 1985) and Vander Voort (1984).

Sectioning

The first step in sample preparation is to remove a small representative section from the bulk piece. Many techniques are available, and they are discussed below in order of increasing mechanical damage:

Cutting with a continuous-loop wire saw causes the least amount of mechanical damage to the sample. The wire may have an embedded abrasive, such as diamond, or may deliver an abrasive slurry, such as alumina, silicon carbide, and boron nitride, to the root of the cut. It is also possible to use a combination of chemical attack and abrasive slurry.

This cutting method does not generate a significant amount of heat, and it can be used with very thin components. Another important advantage is that the correct use of this technique reduces the time needed for mechanical abrasion, as it allows the metallographer to eliminate the first three abrasion steps.

The main drawback is low cutting speed. Also, the proper cutting pressure often must be determined by trial-and-error.

Electric-discharge machining is extremely useful when cutting superhard alloys but can be used with practically any alloy. The damage is typically low and occurs primarily by surface melting. However, the equipment is not commonly available. Moreover, its improper use can result in melted surface layers, microcracking, and a zone of damage several millimeters below the surface.

Cutting with a nonconsumable abrasive wheel, such as a low-speed diamond saw, is a very versatile sectioning technique that results in minimal surface deformation. It can be used for specimens containing constituents with widely differing hardnesses. However, the correct use of an abrasive wheel is a trial-and-error process, as too much pressure can cause seizing and smearing.

Cutting with a consumable abrasive wheel is especially useful when sectioning hard materials. It is important to use copious amounts of coolant. However, when cutting specimens containing constituents with widely differing hardnesses, the softer constituents are likely to undergo selective ablation, which increases the time required for the mechanical abrasion steps.

Sawing is very commonly used and yields satisfactory results in most instances. However, it generates heat, so it is necessary to use copious amounts of cooling fluid when sectioning hard alloys; failure to do so can result in localized "burns" and microstructure alterations. Also, sawing can damage delicate surface coatings and cause "peel-back." It should not be used when an analysis of coated materials or coatings is required.

Shearing is typically used for sheet materials and wires. Although it is a fast procedure, shearing causes extremely heavy deformation, which may result in artifacts. Alternative techniques should be used if possible.

Fracturing, and in particular cleavage fracturing, may be used for certain alloys when it is necessary to examine a

crystallographically specific surface. In general, fracturing is used only as a last resort.

Mounting

After sectioning, the sample may be placed on a plastic mounting material for ease of handling, automated grinding and polishing, edge retention, and selective electropolishing and etching. Several types of plastic mounting materials are available; which type should be used depends on the application and the nature of the sample.

Thermosetting molding resins (e.g., bakelite, diallyl phthalate, and compression-mounting epoxies) are used when ease of mounting is the primary consideration. Thermoplastic molding resins (e.g., methyl methacrylate, PVC, and polystyrene) are used for fragile specimens, as the molding pressure is lower for these resins than for the thermosetting ones. Castable resins (e.g., acrylics, polyesters, and epoxies) are used when good edge retention and resistance to etchants is required. Additives can be included in the castable resins to make the mounts electrically conductive for electropolishing and electron microscopy. Castable resins also facilitate vacuum impregnation, which is sometimes required for powder metallurgical and failure analysis specimens.

Mechanical Abrasion

Mechanical abrasion typically uses abrasive particles bonded to a substrate, such as waterproof paper. Typically, the abrasive paper is placed on a platen that is rotated at 150 to 300 rpm. The particles cut into the specimen surface upon contact, forming a series of "vee" grooves. Successively finer grits (smaller particle sizes) of abrasive material are used to reduce the mechanically damaged layer and produce a surface suitable for polishing. The typical sequence is 120-, 180-, 240-, 320-, 400-, and 600-grit material, corresponding approximately to particle sizes of 106, 75, 52, 34, 22, and 14 μm. The principal abrasive materials are silicon carbide, emery, and diamond.

In metallographic practice, mechanical abrasion is commonly called grinding, although there are distinctions between mechanical abrasion techniques and traditional grinding. Metallographic mechanical abrasion uses considerably lower surface speeds (between 150 and 300 rpm) and a copious amount of fluid, both for lubrication and for removing the grinding debris. Thus, frictional heating of the specimen and surface damage are significantly lower in mechanical abrasion than in conventional grinding.

In mechanical abrasion, the specimen typically is held perpendicular to the grinding platen and moved from the edge to the center. The sample is rotated 90° with each change in grit size, in order to ensure that scratches from the previous operation are completely removed. With each move to finer particle sizes, the rule of thumb is to grind for twice the time used in the previous step. Consequently, it is important to start with the finest possible grit in order to minimize the time required. The size and grinding time for the first grit depends on the sectioning technique used. For semiautomatic or automatic operations, it is best to start with the manufacturer's recommended procedures and fine-tune them as needed.

Mechanical abrasion operations can also be carried out by rubbing the specimen on a series of stationary abrasive strips arranged in increasing fineness. This method is not recommended because of the difficulty in maintaining a flat surface.

Polishing

After mechanical abrasion, a sample is polished so that the surface is specularly reflective and suitable for examination with an optical or scanning electron microscope (SEM). Metallographic polishing is carried out both mechanically and electrolytically. In some cases, where etching is unnecessary or even undesirable—for example, the study of porosity distribution, the detection of cracks, the measurement of plating or coating thickness, and microlevel compositional analysis—polishing is the final step in sample preparation.

Mechanical polishing is essentially an extension of mechanical abrasion; however, in mechanical polishing, the particles are suspended in a liquid within the fibers of a cloth, and the wheel rotation speed is between 150 and 600 rpm. Because of the manner in which the abrasive particles are suspended, less force is exerted on the sample surface, resulting in shallower grooves. The choice of polishing cloth depends on the particular application. When the specimen is particularly susceptible to mechanical damage, a cloth with high nap is preferred. On the other hand, if surface flatness is a concern (e.g., edge retention) or if problems such as second-phase "pullout" are encountered, a napless cloth is the proper choice. Note that in selected applications a high-nap cloth may be used as a "backing" for a napless cloth to provide a limited amount of cushioning and retention of polishing medium. Typically, the sample is rotated continously around the central axis of the wheel, counter to the direction of wheel rotation, and the polishing pressure is held constant until nearly the end, when it is greatly reduced for the finishing touches. The abrasive particles used are typically diamond (6 μm and 1 μm), alumina (0.5 μm and 0.03 μm), and colloidal silica and colloidal magnesia.

When very high quality samples are required, rotating-wheel polishing is usually followed by vibratory polishing. This also uses an abrasive slurry with diamond, alumina, and colloidal silica and magnesia particles. The samples, usually in weighted holders, are placed on a platen which vibrates in such a way that the samples track a circular path. This method can be adapted for chemo-mechanical polishing by adding chemicals either to attack selected constituents or to suppress selective attack.

The end result of vibratory polishing is a specularly reflective surface that is almost free of deformation caused by the previous steps in the sample preparation process. Once the procedure is optimized, vibratory polishing allows a large number of samples to be polished simultaneously with reproducibly excellent quality.

Electrolytic polishing is used on a sample after mechanical abrasion to a 400- or 600-grit finish. It too produces a specularly reflective surface that is nearly free of deformation.

Electropolishing is commonly used for alloys that are hard to prepare or particularly susceptible to deformation artifacts, such as mechanical twinning in Mg, Zr, and Bi. Electropolishing may be used when edge retention is not required or when a large number of similar samples is expected, for example, in process control and alloy development.

The use of electropolishing is not widespread, however, as it (1) has a long development time; (2) requires special equipment; (3) often requires the use of highly corrosive, poisonous, or otherwise dangerous chemicals; and (4) can cause accelerated edge attack, resulting in an enlargement of cracks and porosity, as well as preferential attack of some constituent phases.

In spite these disadvantages, electropolishing may be considered because of its processing speed; once the technique is optimized for a particular application, there is none better or faster.

In electropolishing, the sample is set up as the anode in an electrolytic cell. The cathode material depends on the alloy being polished and the electrolyte: stainless steel, graphite, copper, and aluminum are commonly used. Direct current, usually from a rectified current source, is supplied to the electrolytic cell, which is equipped with an ammeter and voltmeter to monitor electropolishing conditions.

Typically, the voltage-current characteristics of the cell are complex. After an initial rise in current, an "electropolishing plateau" is observed. This plateau results from the formation of a "polishing film," which is a stable, high-resistance viscous layer formed near the anode surface by the dissolution of metal ions. The plateau represents optimum conditions for electropolishing: at lower voltages etching takes place, while at higher voltages there is film breakdown and gas evolution.

The mechanism of electropolishing is not well understood, but is generally believed to occur in two stages: smoothing and brightening. The smoothing stage is characterized by a preferential dissolution of the ridges formed by mechanical abrasion (primarily because the resistance at the peak is lower than in the valley). This results in the formation of the viscous polishing film. The brightening phase is characterized by the elimination of extremely small ridges, on the order of 0.01 μm.

Electropolishing requires the optimization of many parameters, including electrolyte composition, cathode material, current density, bath temperature, bath agitation, anode-to-cathode distance, and anode orientation (horizontal, vertical, etc.). Other factors, such as whether the sample should be removed before or after the current is switched off, must also be considered. During the development of an electropolishing procedure, the microstructure be should first be prepared by more conventional means so that any electropolishing artifacts can be identified.

Etching

After the sample is polished, it may be etched to enhance the contrast between various constituent phases and microstructural features. Chemical, electrochemical, and physical methods are available. Contrast on as-polished surfaces may also be enhanced by nondestructive methods, such as dark-field illumination and backscattered electron imaging (see GENERAL VACCUM TECHNIQUES).

In chemical and electrochemical etching, the desired contrast can be achieved in a number of ways, depending on the technique employed. Contrast-enhancement mechanisms include selective dissolution; formation of a film, whose thickness varies with the crystallographic orientation of grains; formation of etch pits and grooves, whose orientation and density depend on grain orientation; and precipitation etching. A variety of chemical mixtures are used for selective dissolution. Heat tinting—the formation of oxide film—and anodizing both produce films that are sensitive to polarized light.

Physical etching techniques, such as ion etching and thermal etching, depend on the selective removal of atoms.

When developing a particular etching procedure, it is important to determine the "etching limit," below which some microstructural features are masked and above which parts of the microstructure may be removed due to excessive dissolution. For a given etchant, the most important factor is the etching time. Consequently, it is advisable to etch the sample in small time increments and to examine the microstructure between each step. Generally the optimum etching program is evident only after the specimen has been over-etched, so at least one polishing-etching-polishing iteration is usually necessary before a properly etched sample is obtained.

ILLUSTRATIVE EXAMPLES

The particular combination of steps used in metallographic sample preparation depends largely on the application. A thorough literature survey undertaken before beginning sample preparation will reveal techniques used in similar applications. The four examples below illustrate the development of a successful metallographic sample preparation procedure.

General Microstructural Evaluation of 4340 Steel

Samples are to be prepared for the general microstructural evaluation of 4340 steel. Fewer than three samples per day of 1-in. (2.5-cm) material are needed. The general microstructure is expected to be tempered martensite, with a bulk hardness of HRC 40 (hardness on the Rockwell C scale). An evaluation of decarburization is required, but a plating-thickness measurement is not needed.

The following sample preparation procedure is suggested, based on past experience and a survey of the metallographic literature for steel.

Sectioning. An important objective in sectioning is to avoid "burning," which can temper the martensite and cause some decarburization. Based on the hardness and required thickness in this case, sectioning is best accomplished using a 60-grit, rubber-resin-bonded alumina wheel and cutting the section while it is submerged in a coolant. The cutting pressure should be such that the 1-in. samples can be cut in 1 to 2 min.

Mounting. When mounting the sample, the aim is to retain the edge and to facilitate SEM examination. A conducting epoxy mount is suggested, using an appropriate combination of temperature, pressure, and time to ensure that the specimen-mount separation is minimized.

Mechanical Abrasion. To minimize the time needed for mechanical abrasion, a semiautomatic polishing head with a three-sample holder should be used. The wheel speed should be 150 rpm. Grinding would begin with 180-grit silicon carbide, and continue in the sequence 240, 320, 400, and 600 grit. Water should be used as a lubricant, and the sample should be rinsed between each change in grit. Rotation of the sample holder should be in the sense counter to the wheel rotation. This process takes ~35 min.

Mechanical Polishing. The objective is to produce a deformation-free and specularly reflective surface. After mechanical abrasion, the sample-holder assembly should be cleaned in an ultrasonicator. Polishing is done with medium-nap cloths, using a 6-μm diamond abrasive followed by a 1-μm diamond abrasive. The holder should be cleaned in an ultrasonicator between these two steps. A wheel speed of 300 rpm should be used and the specimen should be rotated counter to the wheel rotation. Polishing requires 10 min for the first step and 5 min for the second step. (Duration decreases because successively lighter damage from previous steps requires shorter removal times in subsequent steps.)

Etching. The aim is to reveal the structure of the tempered martensite as well as any evidence of decarburization. Etching should begin with super picral for 30 s. The sample should be examined and then etched for an additional 10 s, if required. In developing this procedure, the samples were found to be over-etched at 50 s.

Measurement of Cadmium Plating Composition and Thickness on 4340 Steel

This is an extension of the previous example. It illustrates the manner in which an existing procedure can be modified slightly to provide a quick and reliable technique for a related application.

The measurement of plating composition and thickness requires a special edge-retention treatment due to the difference in the hardness of the cadmium plating and the bulk specimen. Minor modifications are also required to the polishing procedure due to the possibility of a selective chemical attack.

Based on a literature survey and past experience, the previous sample preparation procedure was modified to accommodate a measurement of plating composition and thickness.

Sectioning. When the sample is cut with an alumina wheel, several millimeters of the cadmium plating will be damaged below the cut. Hand grinding at 120 grit will quickly reestablish a sound layer of cadmium at the surface. An alternative would be to use a diamond saw for sectioning, but this would require a significantly longer cutting time.

After sectioning and before mounting, the sample should be plated with electroless nickel. This will surround the cadmium plating with a hard layer of nickel-sulfur alloy (HRC 60) and eliminate rounding of the cadmium plating during grinding.

Polishing. A buffered solution should be used during polishing to reduce the possibility of selective galvanic attack at the steel-cadmium interface.

Etching. Etching is not required, as the examination will be more exact on an unetched surface. The evaluation, which requires both thickness and compositional measurements, is best carried out with a scanning electron microscope equipped with an energy-dispersive spectroscope (EDS, see SYMMETRY IN CRYSTALLOGRAPHY).

Microstructural Evaluation of 7075-T6 Anodized Aluminum Alloy

Samples are required for the general microstructure evaluation of the aluminum alloy 7075-T6. The bulk hardness is HRB 80 (Rockwell B scale). A single 1/2-in.-thick (1.25-cm) sample will be prepared weekly. The anodized thickness is specified as 1 to 2 μm, and a measurement is required.

The following sample preparation procedure is suggested, based on past experience and a survey of the metallographic literature for aluminum.

Sectioning. The aim is to avoid excessive deformation. Based on the hardness and because the aluminum is anodized, sectioning should be done with a low-speed diamond saw, using copious quantities of coolant. This will take ~20 min.

Mounting. The goal is to retain the edge and to facilitate SEM examination. In order the preserve the thin anodized layer, electroless nickel plating is required before mounting. The anodized surface should be first brushed with an intermediate layer of colloidal silver paint and then plated with electroless nickel for edge retention.

A conducting epoxy mount should be used, with an appropriate combination of temperature, pressure, and time to ensure that the specimen-mount separation is minimized.

Mechanical Abrasion. Manual abrasion is suggested, with water as a lubricant. The wheel should be rotated at 150 rpm, and the specimen should be held perpendicular to the platen and moved from outer edge to center of the grinding paper. Grinding should begin with 320-grit silicon carbide and continue with 400- and 600-grit paper. The sample should be rinsed between each grit and turned 90°. The time needed is ~15 min.

Mechanical Polishing. The aim is to produce a deformation-free and specularly reflective surface. After mechanical abrasion, the holder should be cleaned in an

ultrasonicator. Polishing is accomplished using medium-nap cloths, first with a 0.5-μm α-alumina abrasive and then with a 0.03-μm γ-alumina abrasive. The holder should be cleaned in an ultrasonicator between these two steps. A wheel speed of 300 rpm should be used, and the specimen should be rotated counter to the wheel rotation. Polishing requires 10 min for the first step and 5 min for the second step.

SEM Examination. The objective is to image the anodized layer in backscattered electron mode and measure its thickness. This step is best accomplished using an as-polished surface.

Etching. Etching is required to reveal the microstructure in a T6 state (solution heat treated and artificially aged). Keller's reagent (2 mL 48% HF/3 mL concentrated HCl/5 mL concentrated HNO_3/190 mL H_2O) can be used to distinguish between T4 (solution heat treated and naturally aged to a substantially stable condition) and T6 heat treatment; supplementary electrical conductivity measurements will also aid in distinguishing between T4 and T6. The microstructure should also be checked against standard sources in the literature, however.

Microstructural Evaluation of Deformed High-Purity Aluminum

A sample preparation procedure is needed for a high volume of extremely soft samples that were previously deformed and partially recrystallized. The objective is to produce samples with no artifacts and to reveal the fine substructure associated with the thermomechanical history.

There was no in-house experience and an initial survey of the metallographic literature for high-purity aluminum did not reveal a previously developed technique. A broader literature search that included Ph.D. dissertations uncovered a successful procedure (Connell, 1972). The methodology is sufficiently detailed so that only slight in-house adjustments are needed to develop a fast and highly reliable sample preparation procedure.

Sectioning. The aim is to avoid excessive deformation of the extremely soft samples. A continuous-loop wire saw should be used with a silicon-carbide abrasive slurry. The 1/4-in. (0.6-cm) section will be cut in 10 min.

Mounting. In order to avoid any microstructural recovery effects, the sample should be mounted at room temperature. An electrical contact is required for subsequent electropolishing; an epoxy mount with an embedded electrical contact could be used. Multiple epoxy mounts should be cured overnight in a cool chamber.

Mechanical Abrasion. Semiautomatic abrasion and polishing is suggested. Grinding begins with 600-grit silicon carbide, using water as lubricant. The wheel is rotated at 150 rpm, and the sample is held counter to wheel rotation and rinsed after grinding. This step takes ~5 min.

Mechanical Polishing. The objective is to produce a surface suitable for electropolishing and etching. After mechanical abrasion, and between the two polishing steps, the holder and samples should be cleaned in an ultrasonicator. Polishing is accomplished using medium-nap cloths, first with 1200- and then 3200-mesh emery in soap solution. A wheel speed of 300 rpm should be used, and the holder should be rotated counter to the wheel rotation. Mechanical polishing requires 10 min for the first step and 5 min for the second step.

Electrolytic Polishing and Etching. The aim is to reveal the microstructure without metallographic artifacts. An electrolyte containing 8.2 cm^3 HF, 4.5 g boric acid, and 250 cm^3 deionized water is suggested. A chlorine-free graphite cathode should used, with an anode-cathode spacing of 2.5 cm and low agitation. The open circuit voltage should be 20 V. The time needed for polishing is 30 to 40 s with an additional 15 to 25 s for etching.

COMMENTARY

These examples emphasize two points. The first is the importance of a conducting thorough literature search before developing a new sample preparation procedure. The second is that any attempt to categorize metallographic procedures through a series of simple steps can misrepresent the field. Instead, an attempt has been made to give the reader an overview with selected examples of various complexity. While these metallographic sample preparation procedures were written with the layman in mind, the literature and Internet sources should be useful for practicing metallographers.

COMPUTATION AND THEORETICAL METHODS

INTRODUCTION

Traditionally, the design of new materials has been driven primarily by phenomenology, with theory and computation providing only general guiding principles and, occasionally, the basis for rationalizing and understanding the fundamental principles behind known materials properties. Whereas these are undeniably important contributions to the development of new materials, the direct and systematic application of these general theoretical principles and computational techniques to the investigation of specific materials properties has been less common. However, there is general agreement within the scientific and technological community that modeling and simulation will be of critical importance to the advancement of scientific knowledge in the 21st century, becoming a fundamental pillar of modern science and engineering. In particular, we are currently at the threshold of quantitative and predictive theories of materials that promise to significantly alter the role of theory and computation in materials design. The emerging field of computational materials science is likely to become a crucial factor in almost every aspect of modern society, impacting industrial competitiveness, education, science, and engineering, and significantly accelerating the pace of technological developments.

At present, a number of physical properties, such as cohesive energies, elastic moduli, and expansion coefficients of elemental solids and intermetallic compounds, are routinely calculated from first principles, i.e., by solving the celebrated equations of quantum mechanics: either Schröedinger's equation, or its relativistic version, Dirac's equation, which provide a complete description of electrons in solids. Thus, properties can be predicted using only the atomic numbers of the constituent elements and the crystal structure of the solid as input. These achievements are a direct consequence of a mature theoretical and computational framework in solid-state physics, which, to be sure, has been in place for some time. Furthermore, the ever-increasing availability of midlevel and high-performance computing, high-bandwidth networks, and high-volume data storage and management, has pushed the development of efficient and computationally tractable algorithms to tackle increasingly more complex simulations of materials.

The first-principles computational route is, in general, more readily applicable to solids that can be idealized as having a perfect crystal structure, devoid of grain boundaries, surfaces and other imperfections. The realm of engineering materials, be it for structural, electronics, or other applications, is, however, that of "defective" solids. Defects and their control dictate the properties of real materials. There is, at present, an impressive body of work in materials simulation, which is aimed at understanding properties of real materials. These simulations rely heavily on either a phenomenological or semiempirical description of atomic interactions.

The units in this chapter of *Methods in Materials Research* have been selected to provide the reader with a suite of theoretical and computational tools, albeit at an introductory level, that begins with the microscopic description of electrons in solids and progresses towards the prediction of structural stability, phase equilibrium, and the simulation of microstructural evolution in real materials. The chapter also includes units devoted to the theoretical principles of well established characterization techniques that are best suited to provide exacting tests to the predictions emerging from computation and simulation. It is envisioned that the topics selected for publication will accurately reflect significant and fundamental developments in the field of computational materials science. Due to the nature of the discipline, this chapter is likely to evolve as new algorithms and computational methods are developed, providing not only an up-to-date overview of the field, but also an important record of its evolution.

JUAN M. SANCHEZ

INTRODUCTION TO COMPUTATION

Although the basic laws that govern the atomic interactions and dynamics in materials are conceptually simple and well understood, the remarkable complexity and variety of properties that materials display at the macroscopic level seem unpredictable and are poorly understood. Such a situation of basic well-known governing principles but complex outcomes is highly suited for a computational approach. This ultimate ambition of materials science—to predict macroscopic behavior from microscopic information (e.g., atomic composition)—has driven the impressive development of computational materials science. As is demonstrated by the number and range of articles in this volume, predicting the properties of a material from atomic interactions is by no means an easy task! In many cases it is not obvious how the fundamental laws of physics conspire with the chemical composition and structure of a material to determine a macroscopic property that may be of interest to an engineer. This is not surprising given that on the order of 10^{26} atoms may participate in an observed property. In some cases, properties are simple "averages" over the contributions of these atoms, while for other properties only extreme deviations from the mean may be important. One of the few fields in which a well-defined and justifiable procedure to go from the

atomic level to the macroscopic level exists is the equilibrium thermodynamics of homogeneous materials. In this case, all atoms "participate" in the properties of interest and the macroscopic properties are determined by fairly straightforward averages of microscopic properties. Even with this benefit, the prediction of alloy phase diagrams is still a formidable challenge, as is nicely illustrated in PREDICTION OF PHASE DIAGRAMS. Unfortunately, for many other properties (e.g., fracture), the macroscopic evolution of the material is strongly influenced by singularities in the microscopic distribution of atoms: for instance, a few atoms that surround a void or a cluster of impurity atoms. This dependence of a macroscopic property on small details of the microscopic distribution makes defining a predictive link between the microscopic and macroscopic much more difficult.

Placing some of these difficulties aside, the advantages of computational modeling for the properties that can be determined in this fashion are significant. Computational work tends to be less costly and much more flexible than experimental research. This makes it ideally suited for the initial phase of materials development, where the flexibility of switching between many different materials can be a significant advantage.

However, the ultimate advantage of computing methods, both in basic materials research and in applied materials design, is the level of control one has over the system under study. Whereas in an experimental situation nature is the arbiter of what can be realized, in a computational setting only creativity limits the constraints that can be forced onto a material. A computational model usually offers full and accurate control over structure, composition, and boundary conditions. This allows one to perform computational "experiments" that separate out the influence of a single factor on the property of the material. An interesting example may be taken from this author's research on lithium metal oxides for rechargeable Li batteries. These materials are crystalline oxides that can reversibly absorb and release Li ions through a mechanism called intercalation. Because they can do this at low chemical potential for Li, they are used on the cathode side of a rechargeable Li battery. In the discharge cycle of the battery, Li ions arrive at the cathode and are stored in the crystal structure of the lithium metal oxide. This process is reversed upon charging. One of the key properties of these materials is the electrochemical potential at which they intercalate Li ions, as it directly determines the battery voltage.

Figure 1A shows the potential range at which many transition metal oxides intercalate Li as a function of the number of d electrons in the metal (Ohzuku and Atsushi, 1994). While the graph indicates some upward trend of potential with the number of d electrons, this relation may be perturbed by several other parameters that change as one goes from one material to the other: many of the transition metal oxides in Figure 1A are in different crystal structures, and it is not clear to what extent these structural variations affect the intercalation potential. An added complexity in oxides comes from the small variation in average valence state of the cations, which may result in different oxygen composition, even when the

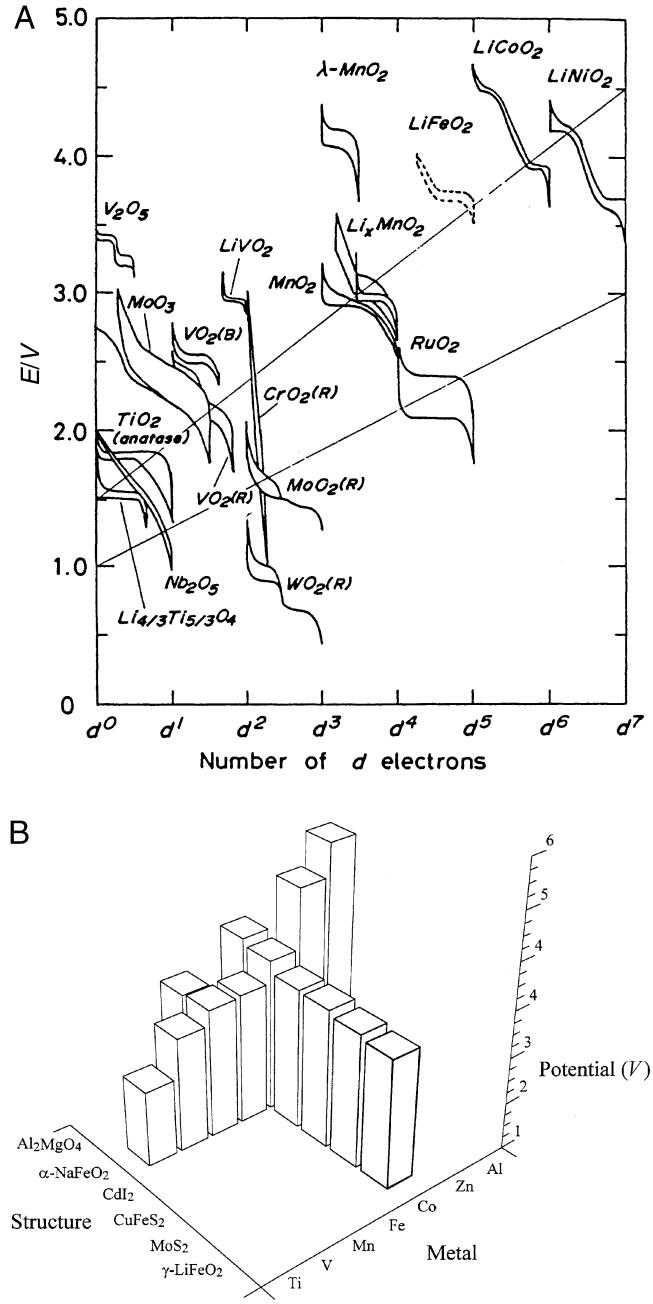

Figure 1. (**A**) Intercalation potential curves for lithium in various metal oxides as a function of the number of d electrons on the transition metal in the compound. (Taken from Ohzuku and Atsushi, 1994.) (**B**) Calculated intercalation potential for lithium in various $LiMO_2$ compounds as a function of the structure of the compound and the choice of metal M. The structures are denoted by their prototype.

chemical formula (based on conventional valences) would indicate the stoichiometry to be the same. These factors convolute the dependence of intercalation potential on the choice of transition metal, making it difficult to separate the roles of each independent factor. Computational methods are better suited to separating the influence of these different factors. Once a method for calculating the intercalation potential has been established, it can be applied to any system, in any crystal structure or oxygen

stoichiometry, whether such conditions correspond to the equilibrium structure of the material or not. By varying only one variable at a time in a calculation of the intercalation potential, a systematic study of each variable (e.g., structure, composition, stoichiometry) can be performed.

Figure 1B, the result of a series of *ab initio* calculations (Aydinol et al., 1997) clearly shows the effect of structure and metal in the oxide independently. Within the 3*d* transition metals, the effect of structure is clearly almost as large as the effect of the number of *d* electrons. Only for the non-*d* metals (Zn, Al) is the effect of metal choice dramatic. The calculation also shows that among the 3*d* metal oxides, $LiCoO_2$ in the spinel structure (Al_2MgO_4) would display the highest potential. Clearly, the advantage of the computational approach is not merely that one can predict the property of interest (in this case the intercalation potential) but also that the factors that may affect it can be controlled systematically.

Whereas the links between atomic-level phenomena and macroscopic properties form the basis for the control and predictive capabilities of computational modeling, they also constitute its disadvantages. The fact that properties must be derived from microscopic energy laws (often quantum mechanics) leads to the predictive characteristics of a method but also holds the potential for substantial errors in the result of the calculation. It is not currently possible to exactly calculate the quantum mechanical energy of a perfect crystalline array of atoms. Any errors in the description of the energetics of a system will ultimately show up in the derived macroscopic results. Many computational models are therefore still not fully quantitative. In some cases, it has not even been possible to identify an explicit link between the microscopic and macroscopic, so quantitative materials studies are not as yet possible.

The units in this chapter deal with a large variety of physical phenomena: for example, prediction of physical properties and phase equilibria, simulation of microstructural evolution, and simulation of chemical engineering processes. Readers may notice that these areas are at different stages in their evolution in applying computational modeling. The most advanced field is probably the prediction of physical properties and phase equilibria in alloys, where a well-developed formalism exists to go from the microscopic to the macroscopic. Combining quantum mechanics and statistical mechanics, a full *ab initio* theory has developed in this field to predict physical properties and phase equilibria, with no more input than the chemical construction of the system (Ducastelle, 1991; Ceder, 1993; de Fontaine, 1994; Zunger, 1994). Such a theory is predictive, and is well suited to the development and study of novel materials for which little or no experimental information is known and to the investigation of materials under extreme conditions.

In many other fields, such as in the study of microstructure or mechanical properties, computational models are still at a stage where they are mainly used to investigate the qualitative behavior of model systems and system-specific results are usually minimal or nonexistent. This lack of an *ab initio* theory reflects the very complex relation between these properties and the behavior of the constituent atoms. An example may be given from the molecular dynamics work on fracture in materials (Abraham, 1997). Typically, such fracture simulations are performed on systems with idealized interactions and under somewhat restrictive boundary conditions. At this time, the value of such modeling techniques is that they can provide complete and detailed information on a well-controlled system and thereby advance the science of fracture in general. Calculations that discern the specific details between different alloys (say Ti-6Al-4V and TiAl) are currently not possible but may be derived from schemes in which the link between the microscopic and the macroscopic is derived more heuristically (Eberhart, 1996).

Many of the mesoscale models (grain growth, film deposition) described in the papers in this chapter are also in this stage of "qualitative modeling." In many cases, however, some agreement with experiments can be obtained for suitable values of the input parameters.

One may expect that many of these computational methods will slowly evolve toward a more predictive nature as methods are linked in a systematic way.

The future of computational modeling in materials science is promising. Many of the trends that have contributed to the rapid growth of this field are likely to continue into the next decade. Figure 2 shows the exponential increase in computational speed over the last 50 years. The true situation is even better than what is depicted in Figure 2 as computer resources have also become less expensive. Over the last 15 years the ratio of computational power to price has increased by a factor of 10^4. Clearly, no other tool in material science and engineering can boast such a dramatic improvement in performance.

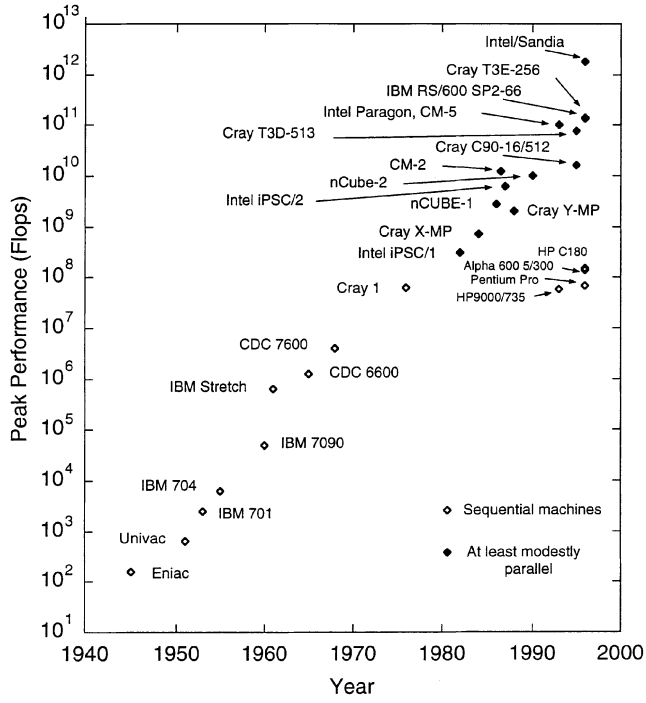

Figure 2. Peak performance of the fastest computers models built as a function of time. The performance is in floating-point operations per second (FLOPS). Data from Fox and Coddington (1993) and from manufacturers' information sheets.

However, it would be unwise to chalk up the rapid progress of computational modeling solely to the availability of cheaper and faster computers. Even more significant for the progress of this field may be the algorithmic development for simulation and quantum mechanical techniques. Highly accurate implementations of the local density approximation (LDA) to quantum mechanics [and its extension to the generalized gradient approximation (GGA)] are now widely available. They are considerably faster and much more accurate now than only a few years ago. The Car-Parrinello method and related algorithms have significantly improved the equilibration of quantum mechanical systems (Car and Parrinello, 1985; Payne et al., 1992). There is no reason to expect this trend to stop, and it is likely that the most significant advances in computational materials science will be realized through novel methods development rather than from ultra-high-performance computing.

Significant challenges remain. In many cases the accuracy of *ab initio* methods is orders of magnitude less than that of experimental methods. For example, in the calculation of phase diagrams an error of 10 meV, not large at all by *ab initio* standards, corresponds to an error of more than 100 K.

The time and size scales over which materials phenomena occur remain the most significant challenge. Although the smallest size scale in a first-principles method is always that of the atom and electron, the largest size scale at which individual features matter for a macroscopic property may be many orders of magnitude larger. For example, microstructure formation ultimately originates from atomic displacements, but the system becomes inhomogeneous on the scale of micrometers through sporadic nucleation and growth of distinct crystal orientations or phases. Whereas statistical mechanics provide guidance on how to obtain macroscopic averages for properties in homogeneous systems, there is no theory for coarse-grain (average) inhomogeneous materials. Unfortunately, most real materials are inhomogeneous.

Finally, all the power of computational materials science is worth little without a general understanding of its basic methods by all materials researchers. The rapid development of computational modeling has not been paralleled by its integration into educational curricula. Few undergraduate or even graduate programs incorporate computational methods into their curriculum, and their absence from traditional textbooks in materials science and engineering is noticeable. As a result, modeling is still a highly undervalued tool that so far has gone largely unnoticed by much of the materials science and engineering community in universities and industry. Given its potential, however, computational modeling may be expected to become an efficient and powerful research tool in materials science and engineering.

SUMMARY OF ELECTRONIC STRUCTURE METHODS

INTRODUCTION

Most physical properties of interest in the solid state are governed by the electronic structure—that is, by the Coulombic interactions of the electrons with themselves and with the nuclei. Because the nuclei are much heavier, it is usually sufficient to treat them as fixed. Under this Born-Oppenheimer approximation, the Schrödinger equation reduces to an equation of motion for the electrons in a fixed external potential, namely, the electrostatic potential of the nuclei (additional interactions, such as an external magnetic field, may be added).

Once the Schrödinger equation has been solved for a given system, many kinds of materials properties can be calculated. Ground-state properties include the cohesive energy, or heats of compound formation, elastic constants or phonon frequencies (Giannozzi and de Gironcoli, 1991), atomic and crystalline structure, defect formation energies, diffusion and catalysis barriers (Blöchl et al., 1993) and even nuclear tunneling rates (Katsnelson et al.,

1995), magnetic structure (van Schilfgaarde et al., 1996), work functions (Methfessel et al., 1992), and the dielectric response (Gonze et al., 1992). Excited-state properties are accessible as well; however, the reliability of the properties tends to degrade—or requires more sophisticated approaches—the larger the perturbing excitation.

Because of the obvious advantage in being able to calculate a wide range of materials properties, there has been an intense effort to develop general techniques that solve the Schrödinger equation from "first principles" for much of the periodic table. An exact, or nearly exact, theory of the ground state in condensed matter is immensely complicated by the correlated behavior of the electrons. Unlike Newton's equation, the Schrödinger equation is a field equation; its solution is equivalent to solving Newton's equation along all paths, not just the classical path of minimum action. For materials with wide-band or itinerant electronic motion, a one-electron picture is adequate, meaning that to a good approximation the electrons (or quasiparticles) may be treated as independent particles moving in a fixed effective external field. The effective field consists of the electrostatic interaction of electrons plus nuclei, plus an additional effective (mean-field) potential that originates in the fact that by correlating their motion, electrons can avoid each other and thereby lower their energy. The effective potential must be calculated self-consistently, such that the effective one-electron potential created from the electron density generates the same charge density through the eigenvectors of the corresponding one-electron Hamiltonian.

The other possibility is to adopt a model approach that assumes some model form for the Hamiltonian and has one or more adjustable parameters, which are typically determined by a fit to some experimental property such as the optical spectrum. Today such Hamiltonians are particularly useful in cases beyond the reach of first-principles approaches, such as calculations of systems with large numbers of atoms, or for strongly correlated materials, for which the (approximate) first-principles approaches do not adequately describe the electronic structure. In this unit, the discussion will be limited to the first-principles approaches.

Summaries of Approaches

The local-density approximation (LDA) is the "standard" solid-state technique, because of its good reliability and relative simplicity. There are many implementations and extensions of the LDA. As shown below (see discussion of The Local Density Approximation) it does a good job in predicting ground-state properties of wide-band materials where the electrons are itinerant and only weakly correlated. Its performance is not as good for narrow-band materials where the electron correlation effects are large, such as the actinide metals, or the late-period transition-metal oxides.

Hartree-Fock (HF) theory is one of the oldest approaches. Because it is much more cumbersome than the LDA, and its accuracy much worse for solids, it is used mostly in chemistry. The electrostatic interaction is called the "Hartree" term, and the Fock contribution that approximates the correlated motion of the electrons is called "exchange." For historic reasons, the additional energy beyond the HF exchange energy is often called "correlation" energy. As we show below (see discussion of Hartree-Fock Theory), the principal failing of Hartree-Fock theory stems from the fact that the potential entering into the exchange interaction should be screened out by the other electrons. For narrow-band systems, where the electrons reside in atomic-like orbitals, Hartree-Fock theory has some important advantages over the LDA. Its nonlocal exchange serves as a better starting point for more sophisticated approaches.

Configuration-interaction theory is an extension of the HF approach that attempts to solve the Schrödinger equation with high accuracy. Computationally, it is very expensive and is feasible only for small molecules with $\sim$10 atoms or fewer. Because it is only applied to solids in the context of model calculations (Grant and McMahan, 1992), it is not considered further here.

The so-called *GW* approximation may be thought of as an extension to Hartree-Fock theory, as described below (see discussion under Dielectric Screening, the Random-Phase, *GW*, and SX Approximations). The *GW* method incorporates a representation of the Green's function (G) and the Coulomb interaction (W). It is a Hartree-Fock-like theory for which the exchange interaction is properly screened. *GW* theory is computationally very demanding, but it has been quite successful in predicting, for example, bandgaps in semiconductors. To date, it has been only possible to apply the theory to optical properties, because of difficulties in reliably integrating the self-energy to obtain a total energy.

The LDA + U theory is a hybrid approach that uses the LDA for the "itinerant" part and Hartree-Fock theory for the "local" part. It has been quite successful in calculating both ground-state and excited-state properties in a number of correlated systems. One criticism of this theory is that there exists no unique prescription to renormalize the Coulomb interaction between the local orbitals, as will be described below. Thus, while the method is *ab initio*, it retains the flavor of a model approach.

The self-interaction correction (Svane and Gunnarsson, 1990) is similar to LDA + U theory, in that a subset of the orbitals (such as the *f*-shell orbitals) are partitioned off and treated in a HF-like manner. It offers a unique and well-defined functional, but tends to be less accurate than the LDA + U theory, because it does not screen the local orbitals.

The quantum Monte Carlo approach is not a mean-field approach. It is an ostensibly exact, or nearly exact, approach to determine the ground-state total energy. In practice, some approximations are needed, as described below (see discussion of Quantum Monte Carlo). The basic idea is to evaluate the Schrödinger equation by brute force, using a Monte Carlo approach. While applications to real materials so far have been limited, because of the immense computational requirements, this approach holds much promise with the advent of faster computers.

Implementation

Apart from deciding what kind of mean-field (or other) approximation to use, there remains the problem of

implementation in some kind of practical method. Many different approaches have been employed, especially for the LDA. Both the single-particle orbitals and the electron density and potential are invariably expanded in some basis set, and the various methods differ in the basis set employed. Figure 1 depicts schematically the general types of approaches commonly used. One principal distinction is whether a method employs plane waves for a basis, or atom-centered orbitals. The other primary distinction among methods is the treatment of the core. Valence electrons must be orthogonalized to the inert core states. The various methods address this by (1) replacing the core with an effective (pseudo)potential, so that the (pseudo)wave functions near the core are smooth and nodeless, or (2) by "augmenting" the wave functions near the nuclei with numerical solutions of the radial Schrödinger equation. It turns out that there is a connection between "pseudizing" or augmenting the core; some of the recently developed methods such as the Planar Augmented Wave method of Blöchl (1994), and the pseudopotential method of Vanderbilt (1990) may be thought of as a kind of hybrid of the two (Dong, 1998).

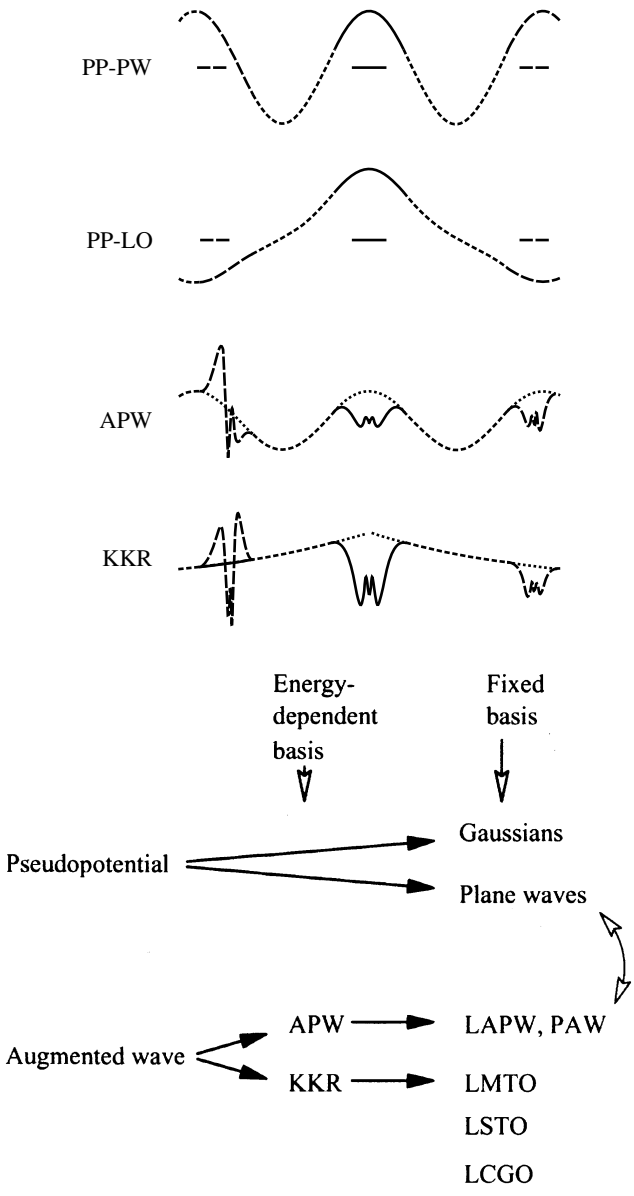

Figure 1. Illustration of different methods, as described in the text. The pseudopotential (PP) approaches can employ either plane waves (PW) or local atom-centered orbitals; similarly the augmented-wave approach employing PW becomes APW or LAPW; using atom-centered Hankel functions it is the KKR method or the method of linear muffin-tin orbitals (LMTO). The PAW (Blöchl, 1994) is a variant of the APW method, as described in the text. LMTO, LSTO and LCGO are atom-centered augmented-wave approaches with Hankel, Slater, and Gaussian orbitals, respectively, used for the envelope functions.

The augmented-wave basis sets are "intelligently" chosen in that they are tailored to solutions of the Schrödinger equation for a "muffin-tin" potential. A muffin-tin potential is flat in the interstitial region, and then spherically symmetric inside nonoverlapping spheres centered at each nucleus, and, for close-packed systems, is a fairly good representation of the true potential. But because the resulting Hamiltonian is energy dependent, both the augmented plane-wave (APW) and augmented atom-centered (Korringa, Kohn, Rostoker; KKR) methods result in a nonlinear algebraic eigenvalue problem. Andersen and Jepsen (1984 also see Andersen, 1975) showed how to linearize the augmented-wave Hamiltonian, and both the APW (now LAPW) and KKR—renamed linear muffin-tin orbitals (LMTO)—methods are vastly more efficient.

The choice of implementation introduces further approximations, though some techniques have enough machinery now to solve a given one-electron Hamiltonian nearly exactly. Today the LAPW method is regarded as the "industry standard" high-precision method, though some implementations of the LMTO method produces a corresponding accuracy, as does the plane-wave pseudopotential approach, provided the core states are sufficiently deep and enough plane waves are chosen to make the basis reasonably complete. It is not always feasible to generate a well-converged pseudopotential; for example, the high-lying *d* cores in Ga can be a little too shallow to be "pseudized" out, but are difficult to treat explicitly in the valence band using plane waves. Traditionally the augmented-wave approaches have introduced shape approximations to the potential, "spheridizing" the potential inside the augmentation spheres. This is often still done today; the approximation tends usually to be adequate for energy bands in reasonably close-packed systems, and relatively coarse total energy differences. This approximation, combined with enlarging the augmentation spheres and overlapping them so that their volume equals the unit cell volume, is known as the atomic spheres approximation (ASA). Extensions, such as retaining the correction to the spherical part of the electrostatic potential from the nonspherical part of the density (Skriver and Rosengaard, 1991) eliminate most of the errors in the ASA.

Extensions

The "standard" implementations of, for example, the LDA, generate electron eigenstates through diagonalization of the one-electron wave function. As noted before, the

one-electron potential itself must be determined self-consistently, so that the eigenstates generate the same potential that creates them.

Some information, such as the total energy and internuclear forces, can be directly calculated as a byproduct of the standard self-consistency cycle. There have been many other properties that require extensions of the "standard" approach. Linear-response techniques (Baroni et al., 1987; Savrasov et al., 1994) have proven particularly fruitful for calculation of a number of properties, such as phonon frequencies (Giannozzi and de Gironcoli, 1991), dielectric response (Gonze et al., 1992), and even alloy heats of formation (de Gironcoli et al., 1991). Linear response can also be used to calculate exchange interactions and spin-wave spectra in magnetic systems (Antropov et al., unpub. observ.). Often the LDA is used as a parameter generator for other methods. Structural energies for phase diagrams are one prime example. Another recent example is the use of precise energy band structures in GaN, where small details in the band structure are critical to how the material behaves under high-field conditions (Krishnamurthy et al., 1997).

Numerous techniques have been developed to solve the one-electron problem more efficiently, thus making it accessible to larger-scale problems. Iterative diagonalization techniques have become indispensable to the plane wave basis. Though it was not described this way in their original paper, the most important contribution from Carr and Parrinello's (1985) seminal work was their demonstration that special features of the plane-wave basis can be exploited to render a very efficient iterative diagonalization scheme. For layered systems, both the eigenstates and the Green's function (Skriver and Rosengaard, 1991) can be calculated in $O(N)$ time, with N being the number of layers (the computational effort in a straightforward diagonalization technique scales as cube of the size of the basis). Highly efficient techniques for layered systems are possible in this way. Several other general-purpose $O(N)$ methods have been proposed. A recent class of these methods computes the ground-state energy in terms of the density matrix, but not spectral information (Ordejón et al., 1995). This class of approaches has important advantages for large-scale calculations involving 100 or more atoms, and a recent implementation using the LDA has been reported (Ordejón et al., 1996); however, they are mainly useful for insulators. A Green's function approach suitable for metals has been proposed (Wang et al., 1995), and a variant of it (Abrikosov et al., 1996) has proven to be very efficient to study metallic systems with several hundred atoms.

HARTREE-FOCK THEORY

In Hartree-Fock theory, one constructs a Slater determinant of one-electron orbitals ψ_j. Such a construct makes the total wave function antisymmetric and better enables the electrons to avoid one another, which leads to a lowering of total energy. The additional lowering is reflected in the emergence of an additional effective (exchange) potential v^x (Ashcroft and Mermin, 1976). The resulting one-electron Hamiltonian has a local part from the direct electrostatic (Hartree) interaction v^H and external (nuclear) potential v^{ext}, and a nonlocal part from v^x

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + v^{\text{ext}}(\mathbf{r}) + v^H(\mathbf{r})\right]\psi_i(\mathbf{r}) + \int d^3\mathbf{r}' v^x(\mathbf{r},\mathbf{r}')\psi(\mathbf{r}') = \varepsilon_i\psi_i(\mathbf{r}) \quad (1)$$

$$v^H(\mathbf{r}) = \int \frac{e^2}{|\mathbf{r}-\mathbf{r}'|} n(\mathbf{r}') \quad (2)$$

$$v_x(\mathbf{r},\mathbf{r}') = -\sum_j \frac{e^2}{|\mathbf{r}-\mathbf{r}'|}\psi_j^*(\mathbf{r}')\psi_j(\mathbf{r}) \quad (3)$$

where e is the electronic charge and $n(\mathbf{r})$ is the electron density.

Thanks to Koopman's theorem, the change in energy from one state to another is simply the difference between the Hartree-Fock parameters ε in two states. This provides a basis to interpret the ε in solids as energy bands. In comparison to the LDA (see discussion of The Local Density Approximation), Hartree-Fock theory is much more cumbersome to implement, because of the nonlocal exchange potential $v^x(\mathbf{r},\mathbf{r}')$ which requires a convolution of v^x and ψ. Moreover, the neglect of correlations beyond the exchange renders it a much poorer approximation to the ground state than the LDA. Hartree-Fock theory also usually describes the optical properties of solids rather poorly. For example, it rather badly overestimates the bandgap in semiconductors. The Hartree-Fock gaps in Si and GaAs are both $\sim$5 eV (Hott, 1991), in comparison to the observed 1.1 and 1.5 eV, respectively.

THE LOCAL-DENSITY APPROXIMATION

The LDA actually originates in the X-α method of Slater (1951), who sought a simplifying approximation to the HF exchange potential. By assuming that the exchange varied in proportion to $n^{1/3}$, with n the electron density, the HF exchange becomes local and vastly simplifies the computational effort. Thus, as it was envisioned by Slater, the LDA is an approximation to Hartree-Fock theory, because the exact exchange is approximated by a simple functional of the density n, essentially proportional to $n^{1/3}$. Modern functionals go beyond Hartree-Fock theory because they include correlation energy as well.

Slater's X-α method was put on a firm foundation with the advent of density-functional theory (Hohenberg and Kohn, 1964). It established that the ground-state energy is strictly a functional of the total density. But the energy functional, while formally exact, is unknown. The LDA (Kohn and Sham, 1965) assumes that the exchange plus correlation part of the energy E_{xc} is a strictly local functional of the density:

$$E_{\text{xc}}[n] \approx \int d^3\mathbf{r} n(\mathbf{r})\varepsilon_{\text{xc}}[n(\mathbf{r})] \quad (4)$$

This *ansatz* leads, as in the Hartree-Fock case, to an equation of motion for electrons moving independently in

an effective field, except that now the potential is strictly local:

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + v^{\text{ext}}(\mathbf{r}) + v^H(\mathbf{r}) + v^{\text{xc}}(\mathbf{r})\right]\psi_i(\mathbf{r}) = \varepsilon_i\psi_i(\mathbf{r}) \quad (5)$$

This one-electron equation follows directly from a functional derivative of the total energy. In particular, $v^{\text{xc}}(\mathbf{r})$ is the functional derivative of E_{xc}:

$$v^{\text{xc}}(\mathbf{r}) \equiv \frac{\delta E_{\text{xc}}}{\delta n} \quad (6)$$

$$\overset{\text{LDA}}{=} \frac{\delta}{\delta n}\int d^3\mathbf{r} n(\mathbf{r})\varepsilon_{\text{xc}}[n(\mathbf{r})] \quad (7)$$

$$= \varepsilon_{\text{xc}}[n(\mathbf{r})] + n(\mathbf{r})\frac{d}{dn}\varepsilon_{\text{xc}}[n(\mathbf{r})] \quad (8)$$

Both exchange and correlation are calculated by evaluating the exact ground state for a jellium (in which the discrete nuclear charge is smeared out into a constant background). This is accomplished either by Monte Carlo techniques (Ceperley and Alder, 1980) or by an expansion in the random-phase approximation (von Barth and Hedin, 1972). When the exchange is calculated exactly, the self-interaction terms (the interaction of the electron with itself) in the exchange and direct Coulomb terms cancel exactly. Approximation of the exact exchange by a local density functional means that this is no longer so, and this is one key source of error in the LD approach. For example, near surfaces, or for molecules, the asymptotic decay of the electron potential is exponential, whereas it should decay as 1/r, where r is the distance to the nucleus. Thus, molecules are less well described in the LDA than are solids.

In Hartree-Fock theory, the opposite is the case. The self-interaction terms cancel exactly, but the operator $1/|\mathbf{r}-\mathbf{r}'|$ entering into the exchange should in effect be screened out. Thus, Hartree-Fock theory does a reasonable job in small molecules, where the screening is less important, while for solids it fails rather badly. Thus, the LDA generates much better total energies in solids than Hartree-Fock theory. Indeed, on the whole, the LDA predicts, with rather good accuracy, ground-state properties, such as crystal structures and phonon frequencies in itinerant materials and even in many correlated materials.

Gradient Corrections

Gradient corrections extend slightly the *ansatz* of the local density approximation. The idea is to assume that E_{xc} is not only a local functional of the density, but a functional of the density and its Laplacian. It turns out that the leading correction term can be obtained exactly in the limit of a small, slowly varying density, but it is divergent. To render the approach practicable, a wave-vector analysis is carried out and the divergent, low wave-vector part of the functional is cut off; these are called "generalized gradient approximations" (GGAs). Calculations using gradient corrections have produced mixed results. It was hoped that since the LDA does quite well in predicting many ground-state properties, gradient corrections would introduce the small corrections needed, particularly in systems in which the density is slowly varying. On the whole, the GGA tends to improve some properties, though not consistently so. This is probably not surprising, since the main ingredients missing in the LDA, (e.g., inexact cancellation of the self-interaction and nonlocal potentials) are also missing for gradient-corrected functionals. One of the first approximations was that of Langreth and Mehl (1981). Many of the results in the next section were produced with their functional. Some newer functionals, most notably the so-called "PBE" (named after Perdew, Burke, Enzerhof) functional (Perdew, 1997) improve results for some properties of solids, while worsening others.

Table 1. Heats of Formation, in eV, for the Hydroxyl ($OH + H_2 \rightarrow H_2O + H$), Tetrazine ($H_2C_2N_4 \rightarrow 2\,HCN + N_2$), and Vinyl Alcohol ($C_2OH_3 \rightarrow$ Acetaldehyde) Reactions, Calculated with Different Methods[a]

Method	Hydroxyl	Tetrazine	Vinyl Alcohol
HF	−0.07	−3.41	−0.54
LDA	−0.69	−1.99	−0.34
Becke	−0.44	−2.15	−0.45
PW-91	−0.64	−1.73	−0.45
QMC	−0.65	−2.65	−0.43
Expt	−0.63	—	−0.42

[a]Abbreviations: HF, Hartree-Fock; LDA, local-density approximation; Becke, GGA functional (Becke, 1993); PW-91, GGA functional (Perdew, 1997); QMC, quantum Monte Carlo. Calculations by Grossman and Mitas (1997).

One recent calculation of the heat of formation for three molecular reactions offers a detailed comparison of the HF, LDA, and GGA to (nearly) exact quantum Monte Carlo results. As shown in Table 1, all of the different mean-field approaches have approximately similar accuracy in these small molecules.

Excited-state properties, such as the energy bands in itinerant or correlated systems, are generally not improved at all with gradient corrections. Again, this is to be expected since the gradient corrections do not redress the essential ingredients missing from the LDA, namely, the cancellation of the self-interaction or a proper treatment of the nonlocal exchange.

LDA Structural Properties

Figure 2 compares predicted atomic volumes for the elemental transition metals and some *sp* bonded semiconductors to corresponding experimental values. The errors shown are typical for the LDA, underestimating the volume by ∼0% to 5% for *sp* bonded systems, by ∼0% to 10% for *d*-bonded systems with the worst agreement in the 3*d* series, and somewhat more for *f*-shell metals (not shown). The error also tends to be rather severe for the extremely soft, weakly bound alkali metals.

The crystal structure of Se and Te poses a more difficult test for the LDA. These elements form an open, low-symmetry crystal with ∼90° bond angles. The electronic structure is approximately described by pure atomic *p* orbitals linked together in one-dimensional chains, with a weak interaction between the chains. The weak

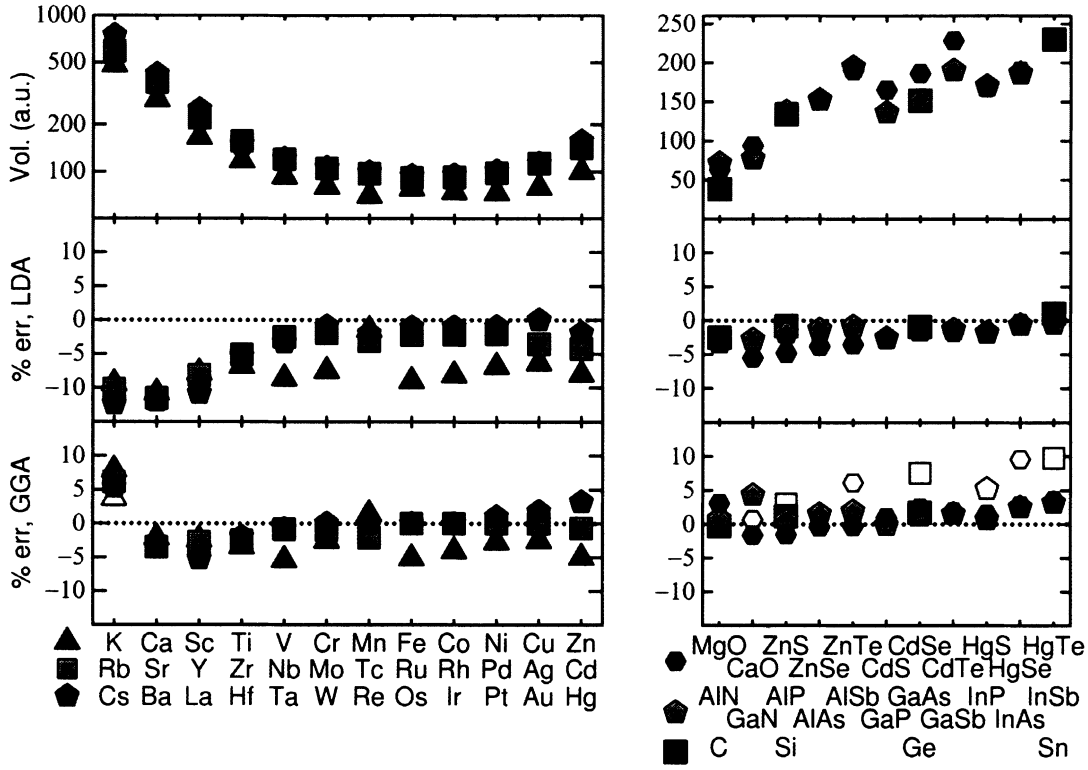

Figure 2. Unit cell volume for the elemental transition metals (left) and semiconductors (right). Left: triangles, squares, and pentagons refer to 3-, 4-, and 5-*d* metals, respectively. Right: squares, pentagons, and hexagons refer to group IV, III-V, and II-VI compounds. Upper panel: volume per unit cell; middle panel: relative error predicted by the LDA; lower panel: relative error predicted by the LDA + GGA of Langreth and Mehl (1981), except for light symbols, which are errors in the PBE functional (Perdew et al., 1996, 1997).

inter-chain interaction combined with the low symmetry and open structure make a difficult test for the local-density approximation. The crystal structure of Se and Te is hexagonal with three atoms per unit cell, and may be specified by the a and c parameters of the hexagonal cell, and one internal displacement parameter, u. Table 2 shows that the LDA predicts rather well the strong intra-chain bond length, but rather poorly reproduces the inter-chain bond length.

One of the largest effects of gradient-corrected functionals is to increase systematically and on the average improve, the equilibrium bond lengths (Fig. 2). The GGA of Langreth and Mehl (1981) significantly improves on the transition metal lattice constants; they similarly significantly improve on the predicted inter-chain bond length in Se (Table 2). In the case of the semiconductors, there is a tendency to overcorrect for the heavier elements. The newer GGA of Perdew et al. (1996, 1997) rather badly overestimates lattice constants in the heavy semiconductors.

Table 2. Crystal Structure of Se, Comparing the LDA to GGA Results (Perdew, 1991), as taken from Dal Corso and Resta (1994)[a]

	a	c	u	d_1	d_2
LDA	7.45	9.68	0.256	4.61	5.84
GGA	8.29	9.78	0.224	4.57	6.60
Expt	8.23	9.37	0.228	4.51	6.45

[a]Lattice parameters a and c are in atomic units (i.e., units of the Bohr radius a_0), as are intra-chain bond length d_1 and inter-chain bond length d_2. The parameter u is an internal displacement parameter as described in Dal Corso and Resta (1994).

LDA Heats of Formation and Cohesive Energies

One of the largest systematic errors in the LDA is the cohesive energy, i.e., the energy of formation of the crystal from the separated elements. Unlike Hartree-Fock theory, the LD functional has no variational principle that guarantees its ground-state energy is less than the true one. The LDA usually overestimates binding energies. As expected, and as Figure 3 illustrates, the errors tend to be greater for transition metals than for *sp* bonded compounds. Much of the error in the transition metals can be traced to errors in the spin multiplet structure in the atom (Jones and Gunnarsson, 1989); thus, the sudden change in the average overbinding for elements to the left of Cr and the right of Mn.

For reasons explained above, errors in the heats of formation between molecules and solid phases, or between different solid phases (Pettifor and Varma, 1979) tend to be much smaller than those of the cohesive energies. This is especially true when the formation involves atoms arranged on similar lattices. Figure 4 shows the errors typically encountered in solid-solid reactions between a

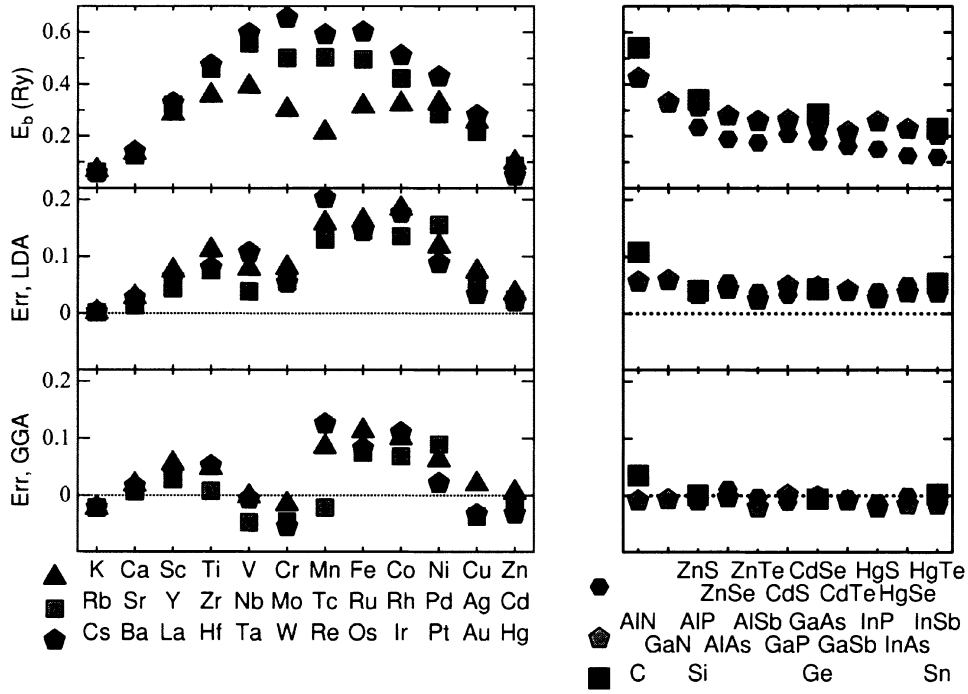

Figure 3. Heats of formation for elemental transition metals (left) and semiconductors (right). Left: triangles, squares, and pentagons refer to 3-, 4-, and 5-*d* metals, respectively. Right: squares, pentagons, and hexagons refer to group IV, III-V, and II-VI compounds. Upper panel: heat of formation per atom (Ry); middle panel: error predicted by the LDA; lower panel: error predicted by the LDA + GGA of Langreth and Mehl (1981).

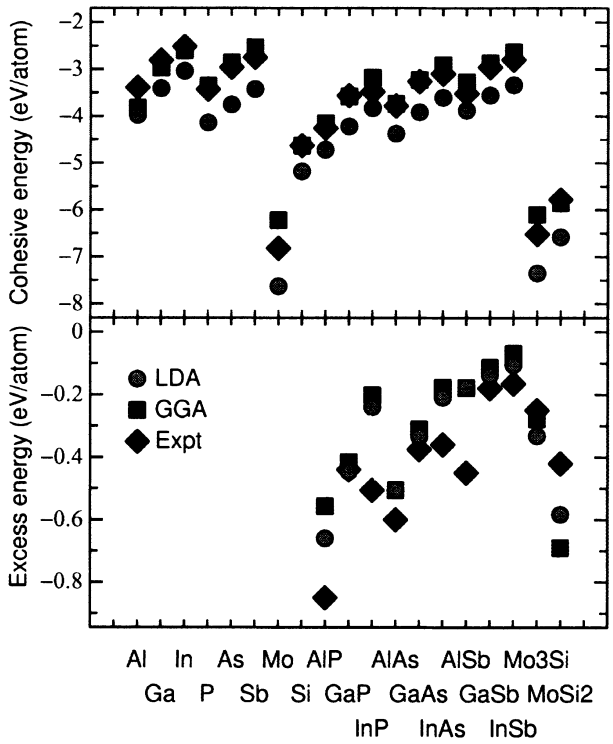

Figure 4. Cohesive energies (top), and heats of formation (bottom) of compounds from the elemental solids. The MoSi data are taken from McMahan et al. (1994). The other data were calculated by Berding and van Schilfgaarde using the FP-LMTO method (unpub. observ.).

wide range of dissimilar phases. Al is face-centered cubic (fcc), P and Si are open structures, and the other elements form a range of structures intermediate in their packing densities. This figure also encapsulates the relative merits of the LDA and GGA as predictors of binding energies. The GGA generally predicts the cohesive energies significantly better than the LDA, because the cohesive energies involve free atoms. But when solid-solid reactions are considered, the improvement disappears. Compounds of Mo and Si make an interesting test case for the GGA (McMahan et al., 1994). The LDA tends to overbind; but the GGA of Langreth and Mehl (1981) actually fares considerably worse, because the amount of overbinding is less systematic, leading to a prediction of the wrong ground state for some parts of the phase diagram. When recalculated using Perdew's PBE functional, the difficulty disappears (J. Klepis, pers. comm.).

The uncertainties are further reduced when reactions involve atoms rearranged on similar or the same crystal structures. One testimony to this is the calculation of structural energy differences of elemental transitional metals in different crystal structures. Figure 5 compares the local density hexagonal close packed–body centered cubic (hcp-bcc) and fcc-bcc energy differences in the 3-*d* transition metals, calculated nonmagnetically (Paxton et al., 1990; Skriver, 1985; Hirai, 1997). As the figure shows, there is a trend to stabilize bcc for elements with the *d* bands less than half-full, and to stabilize a close-packed structure for the late transition metals. This trend can be attributed to the two-peaked structure in the bcc *d* contribution to the density of states, which gains energy

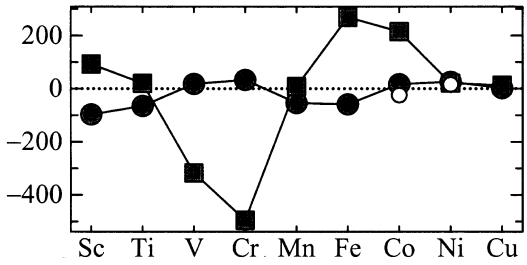

Figure 5. Hexagonal close packed–face centered cubic (hcp-fcc; circles) and body centered cubic–face centered cubic (bcc-fcc; squares) structural energy differences, in meV, for the 3-*d* transition metals, as calculated in the LDA, using the full-potential LMTO method. Original calculations are nonmagnetic (Paxton et al., 1990; Skriver, 1985); white circles are recalculations by the present author, with spin-polarization included.

when the lower (bonding) portion is filled and the upper (antibonding) portion is empty. Except for Fe (and with the mild exception of Mn, which has a complex structure with noncollinear magnetic moments and was not considered here), each structure is correctly predicted, including resolution of the experimentally observed sign of the hcp-fcc energy difference. Even when calculated magnetically, Fe is incorrectly predicted to be fcc. The GGAs of Langreth and Mehl (1981) and Perdew and Wang (Perdew, 1991) rectify this error (Bagno et al., 1989), possibly because the bcc magnetic moment, and thus the magnetic exchange energy, is overestimated for those functionals. In an early calculation of structural energy differences (Pettifor, 1970), Pettifor compared his results to inferences of the differences by Kaufman who used "judicious use of thermodynamic data and observations of phase equilibria in binary systems." Pettifor found that his calculated differences are two to three times larger than what Kaufman inferred (Paxton's newer calculations produces still larger discrepancies). There is no easy way to determine which is more correct.

Figure 6 shows some calculated heats of formation for the TiAl alloy. From the point of view of the electronic structure, the alloy potential may be thought of as a rather weak perturbation to the crystalline one, namely, a permutation of nuclear charges into different arrangements on the same lattice (and additionally some small distortions about the ideal lattice positions). The deviation from the regular solution model is properly reproduced by the LDA, but there is a tendency to overbind, which leads to an overestimate of the critical temperatures in the alloy phase diagram (Asta et al., 1992).

LDA Elastic Constants

Because of the strong volume dependence of the elastic constants, the accuracy to which LDA predicts them depends on whether they are evaluated at the observed volume or the LDA volume. Figure 7 shows both for the elemental transition metals and some *sp*-bonded compounds. Overall, the GGA of Langreth and Mehl (1981) improves on the LDA; how much improvement depends on which lattice constant one takes. The accuracy of other

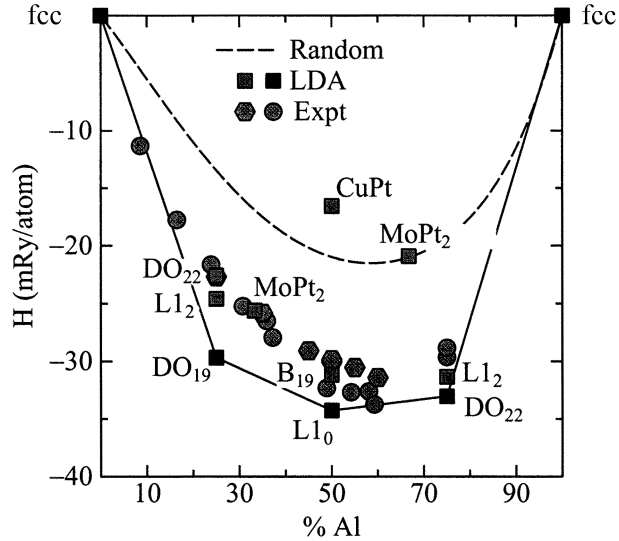

Figure 6. Heat of formation of compounds of Ti and Al from the fcc elemental states. Circles and hexagons are experimental data, taken from Kubaschewski and Dench (1955) and Kubaschewski and Heymer (1960). Light squares are heats of formation of compounds from the fcc elemental solids, as calculated from the LDA. Dark squares are the minimum-energy structures and correspond to experimentally observed phases. Dashed line is the estimated heat formation of a random alloy. Calculated values are taken from Asta et al. (1992).

elastic constants and phonon frequencies are similar (Baroni et al., 1987; Savrosov et al., 1994); typically they are predicted to within ~20% for *d*-shell metals and somewhat better than that for *sp*-bonded compounds. See Figure 8 for a comparison of c_{44}, or its hexagonal analog.

LDA Magnetic Properties

Magnetic moments in the itinerant magnets (e.g., the 3*d* transition metals) are generally well predicted by the LDA. The upper right panel of Figure 9 compares the LDA moments to experiment both at the LDA minimum-energy volume and at the observed volume. For magnetic properties, it is most sensible to fix the volume to experiment, since for the magnetic structure the nuclei may by viewed as an external potential. The classical GGA functionals of Langreth and Mehl (1981) and Perdew and Wang (Perdew, 1991) tend to overestimate the moments and worsen agreement with experiment. This is less the case with the recent PBE functional, however, as Figure 9 shows.

Cr is an interesting case because it is antiferromagnetic along the [001] direction, with a spin-density wave, as Figure 9 shows. It originates as a consequence of a nesting vector in the Cr Fermi surface (also shown in the figure), which is incommensurate with the lattice. The half-period is approximately the reciprocal of the difference in the length of the nesting vector in the figure and the half-width of the Brillouin zone. It is experimentally ~21.2 monolayers (ML) (Fawcett, 1988), corresponding to a nesting vector $q = 1.047$. Recently, Hirai (1997) calculated the

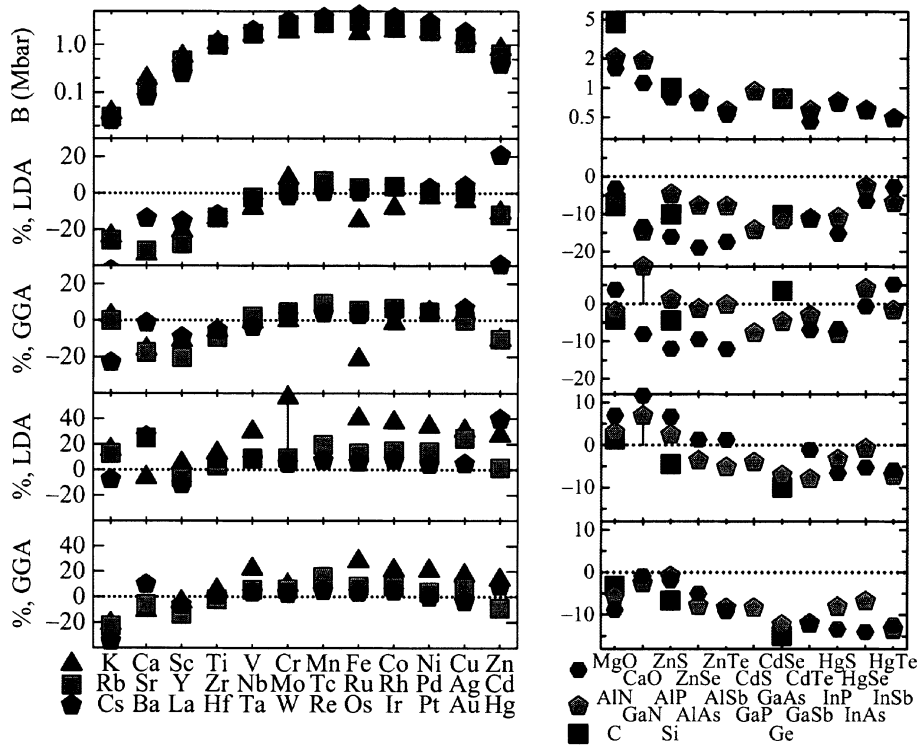

Figure 7. Bulk modulus for the elemental transition metals (left) and semiconductors (right). Left: triangles, squares, and pentagons refer, to 3-, 4-, and 5-*d* metals, respectively. Right: squares, pentagons, and hexagons refer to group IV, III-V, and II-VI compounds. Top panels: bulk modulus; second panel from top: relative error predicted by the LDA at the observed volume; third panel from top: same, but for the LDA + GGA of Langreth and Mehl (1981) except for light symbols, which are errors in the PBE functional (Perdew et al., 1996, 1997); fourth and fifth panels from top: same as the second and third panels but evaluated at the minimum-energy volume.

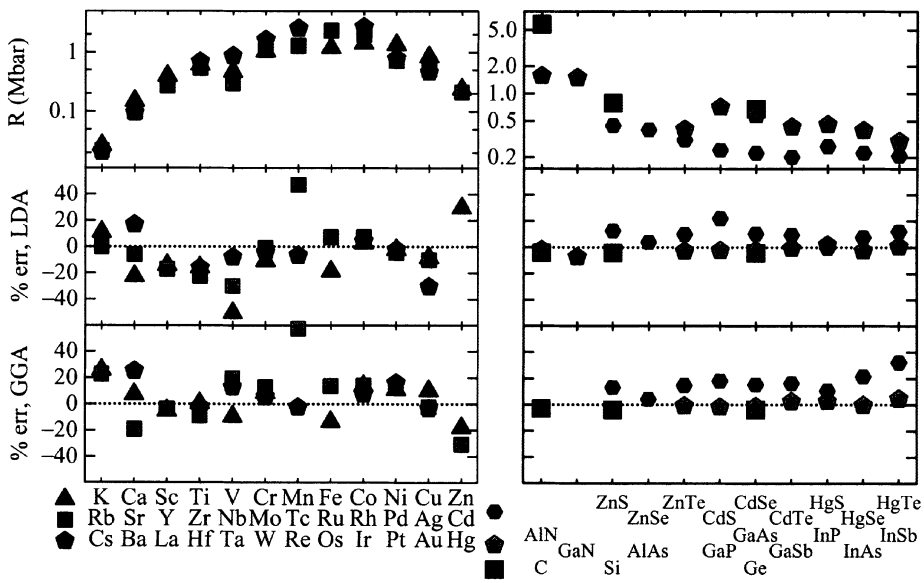

Figure 8. Elastic constant (R) for the elemental transition metals (left) and semiconductors (right), and the experimental atomic volume. For cubic structures, $R = c_{44}$. For hexagonal structures, $R = (c_{11} + 2c_{33} + c_{12}\text{-}4c_{13})/6$ and is analogous to c_{44}. Left: triangles, squares, and pentagons refer to 3-, 4-, and 5-*d* metals, respectively. Right: squares, pentagons, and hexagons refer to group IV, III-V and II-VI compounds. Upper panel: volume per unit cell; middle panel: relative error predicted by the LDA; lower panel: relative error predicted by the LDA + GGA of Langreth and Mehl (1981) except for light symbols, which are errors in the PBE functional (Perdew et al., 1996, 1997).

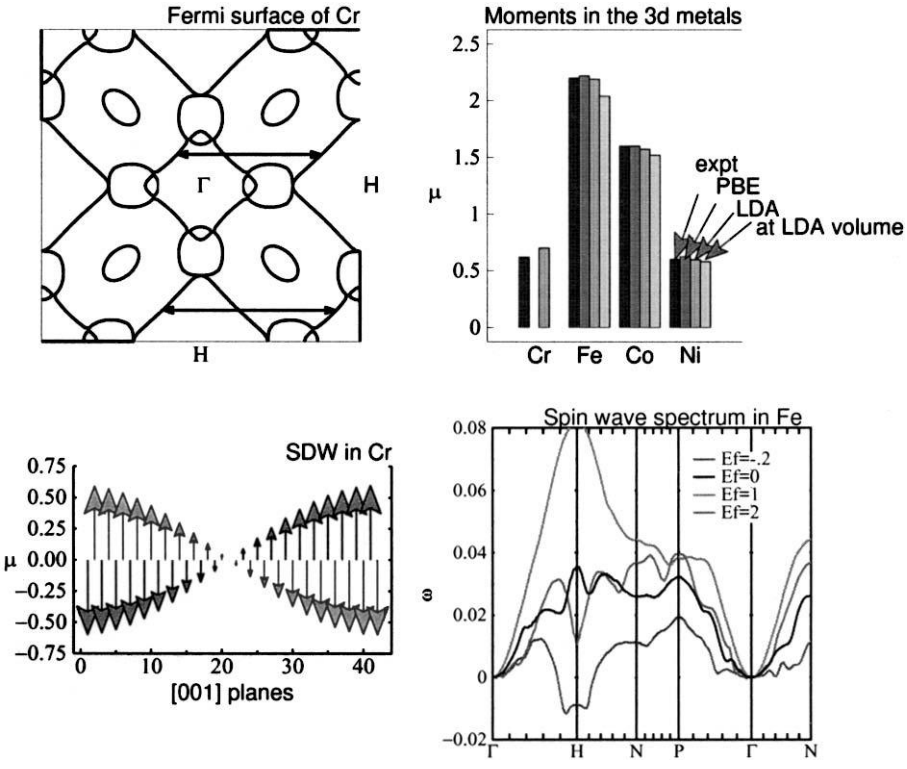

Figure 9. Upper left: LDA Fermi surface of nonmagnetic Cr. Arrows mark the nesting vectors connecting large, nearly parallel sheets in the Brillouin zone. Upper right: magnetic moments of the 3-*d* transition metals, in Bohr magnetons, calculated in the LDA at the LDA volume, at the observed volume, and using the PBE (Perdew et al., 1996, 1997) GGA at the observed volume. The Cr data is taken from Hirai (1997). Lower left: the magnetic moments in successive atomic layers along [001] in Cr, showing the antiferromagnetic spin-density wave. The observed period is ~21.2 lattice spacings. Lower right: spin-wave spectrum in Fe, in meV, calculated in the LDA (Antropov et al., unpub. observ.) for different band fillings, as discussed in the text.

period in Cr by constructing long supercells and evaluating the total energy using a layer KKR technique as a function of the cell dimensions. The calculated moment amplitude (Fig. 9) and period were both in good agreement with experiment. Hirai's calculated period was ~20.8 ML, in perhaps fortuitously good agreement with experiment. This offers an especially rigorous test of the LDA, because small inaccuracies in the Fermi surface are greatly magnified by errors in the period.

Finally, Figure 9 shows the spin-wave spectrum in Fe as calculated in the LDA using the atomic spheres approximation and a Green's function technique, plotted along high-symmetry lines in the Brillouin zone. The spin stiffness D is the curvature of ω at Γ, and is calculated to be 330 meV-A^2, in good agreement with the measured 280–310 meV-A^2. The four lines also show how the spectrum would change with different band fillings (as defined in the legend)—this is a "rigid band" approximation to alloying of Fe with Mn ($E_F < 0$) or Co ($E_F > 0$). It is seen that ω is positive everywhere for the normal Fe case (black line), and this represents a triumph for the LDA, since it demonstrates that the global ground state of bcc Fe is the ferromagnetic one. ω remains positive by shifting the Fermi level in the "Co alloy" direction, as is observed experimentally. However, changing the filling by only -0.2 eV ("Mn alloy") is sufficient to produce an instability at H, thus driving it to an antiferromagnetic structure in the [001] direction, as is experimentally observed.

Optical Properties

In the LDA, in contradistinction to Hartree-Fock theory, there is no formal justification for associating the eigenvalues ε of Equation 5 with energy bands. However, because the LDA is related to Hartree-Fock theory, it is reasonable to expect that the LDA eigenvalues ε bear a close resemblance to energy bands, and they are widely interpreted that way. There have been a few "proper" local-density calculations of energy gaps, calculated by the total energy difference of a neutral and a singly charged molecule; see, for example, Cappellini et al. (1997) for such a calculation in C_{60} and Na_4. The LDA systematically underestimates bandgaps by ~1 to 2 eV in the itinerant semiconductors; the situation dramatically worsens in more correlated materials, notably *f*-shell metals and some of the late-transition-metal oxides. In Hartree-Fock theory, the nonlocal exchange potential is too large because it neglects the ability of the host to screen out the bare Coulomb interaction $1/|\mathbf{r} - \mathbf{r}'|$. In the LDA, the nonlocal character of the interaction is simply missing. In semiconductors, the long-ranged part of this interaction should be present but screened by the dielectric constant ε_∞. Since $\varepsilon_\infty \gg 1$, the LDA does better by ignoring the nonlocal interaction altogether than does Hartree-Fock theory by putting it in unscreened.

Harrison's model of the gap underestimate provides us with a clear physical picture of the missing ingredient in the LDA and a semiquantitative estimate for the correction (Harrison, 1985). The LDA uses a fixed one-electron potential for all the energy bands; that is, the effective one-electron potential is unchanged for an electron excited across the gap. Thus, it neglects the electrostatic energy cost associated with the separation of electron and hole for such an excitation. This was modeled by Harrison by noting a Coulombic repulsion U between the local excess charge and the excited electron. An estimate of this

Coulombic repulsion U can be made from the difference between the ionization potential and electron affinity of the free atom; (Harrison, 1985) it is ~10 eV. U is screened by the surrounding medium so that an estimate for the additional energy cost, and therefore a rigid shift for the entire conduction band including a correction to the band-gap, is U/ε_∞. For a dielectric constant of 10, one obtains a constant shift to the LDA conduction bands of ~1 eV, with the correction larger for wider gap, smaller ε materials.

DIELECTRIC SCREENING, THE RANDOM-PHASE, *GW*, AND SX APPROXIMATIONS

The way in which screening affects the Coulomb interaction in the Fock exchange operator is similar to the screening of an external test charge. Let us then consider a simple model of static screening of a test charge in the random-phase approximation. Consider a lattice of points (spheres), with the electron density in equilibrium. We wish to calculate the screening response, i.e., the electron charge δ_{qj} at site j induced by the addition of a small external potential δV_i^0 at site i. Supposing the screening charge did not interact with itself—let us call this the noninteracting screening charge δq_j^0. This quantity is related to δV_j^0 by the noninteracting response function P_{ij}^0:

$$\delta q_k^0 = \sum_j P_{kj}^0 \delta V_j^0 \tag{9}$$

P_{kj}^0 can be calculated directly in first-order perturbation theory from the eigenvectors of the one-electron Schrödinger equation (see Equation 5 under discussion of The Local Density Approximation), or directly from the induced change in the Green's function, G^0, calculated from the one-electron Hamiltonian. By linearizing the Dyson's equation, one obtains an explicit representation of P_{ij}^0 in terms of G^0:

$$\delta G = G^0\, \delta V^0 G \approx G^0\, \delta V^0 G^0 \tag{10}$$

$$\delta q_{\mathrm{k}}^0 = \frac{1}{\pi}\,\mathrm{Im}\int_{-\infty}^{E_F} dz\, \delta G_{kk} \tag{11}$$

$$= \left[\frac{1}{\pi}\mathrm{Im}\sum_k \int_{-\infty}^{E_F} dz G_{kj}^0 G_{jk}^0\right]\delta V_j^0 \tag{12}$$

$$= \sum_j P_{kj}^0\, \delta V_j^0 \tag{13}$$

It is straightforward to see how the full screening proceeds in the random-phase approximation (RPA). The RPA assumes that the screening charge does not induce further correlations; that is, the potential induced by the screening charge is simply the classical electrostatic potential corresponding to the screening charge. Thus, δq_j^0 induces a new electrostatic potential δV_i^1 In the discrete lattice model we consider here, the electrostatic potential is linearly related to a collection of charges by some matrix M, i.e.,

$$\delta V_k^1 = \sum_j M_{jk}\delta q_k^0 \quad \delta V_i^1 = \sum_k M_{ik}\delta q_k^0 \tag{14}$$

If the q_k correspond to spherical charges on a discrete lattice, M_{ij} is $e^2/|\mathbf{r}_i - \mathbf{r}_j|$ (omitting the on-site term), or given periodic boundary conditions, M is the Madelung matrix (Slater, 1967). Equation 14 can be Fourier transformed, and that is typically done when the q_k are occupations of plane waves. In that case, $M_{jk} = 4\pi e^2 V^{-1}/k^2\,\delta_{jk}$.

Now δV^1 induces a corresponding additional screening charge δq_j^1, which induces another screening charge δq_j^2, and so on. The total perturbing potential is the sum of the external potential and the screening potentials, and the total screening charge is the sum of the δq^n. Carrying out the sum, one arrives at the screened charge, potential, and an explicit representation for the dielectric constant ε

$$\delta q = \sum_n \delta q^n = (1 - MP^0)^{-1} P^0\, \delta V^0 \tag{15}$$

$$\delta V = \delta V^0 + \delta V^{scr} = \sum_n \delta V^n \tag{16}$$

$$= (1 - MP^0)^{-1}\delta V^0 \tag{17}$$

$$= \varepsilon^{-1}\delta V^0 \tag{18}$$

In practical implementations for crystals with periodic boundary conditions, ε is computed in reciprocal space. The formulas above assumed a static screening, but the generalization is obvious if the screening is dynamic, that is, P^0 and ε are functions of energy.

The screened Coulomb interaction, W, proceeds just as in the screening of an external test charge. In the lattice model, the continuous variable $\mathbf{r}$ is replaced with the matrix M_{ij} connecting discrete lattice points; it is the Madelung matrix for a lattice with periodic boundary conditions. Then:

$$W_{ij}(E) = [\varepsilon^{-1}(E)M]_{ij} \tag{19}$$

The *GW* Approximation

Formally, the *GW* approximation is the first term in the series expansion of the self-energy in the screened Coulomb interaction, W. However, the series is not necessarily convergent, and in any case such a viewpoint offers little insight. It is more useful to think of the *GW* approximation as being a generalization of Hartree-Fock theory, with an energy-dependent, nonlocal screened interaction, W, replacing the bare coulomb interaction M entering into the exchange (see Equation 3). The one-electron equation may be written generally in terms of the self-energy Σ:

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + v^{\mathrm{ext}}(\mathbf{r}) + v^H(\mathbf{r})\right]\psi_i(\mathbf{r}) + \int d^3\mathbf{r}'\Sigma(\mathbf{r},\mathbf{r}';E_i)\psi(\mathbf{r}') = E_i\psi_i(\mathbf{r}) \tag{20}$$

In the *GW* approximation,

$$\Sigma^{\mathrm{GW}}(\mathbf{r},\mathbf{r}';E) = \frac{i}{2\pi}\int_{-\infty}^{\infty} d\omega e^{+i0\omega} G(\mathbf{r},\mathbf{r}';E+\omega)W(\mathbf{r},\mathbf{r}';-\omega) \tag{21}$$

The connection between *GW* theory (see Equations 20 and 21), and HF theory see Equations 1 and 3, is obvious once we make the identification of v^x with the self-energy Σ. This we can do by expressing the density matrix in terms of the Green's function:

$$\sum_j \psi_j^*(\mathbf{r}')\psi_j(\mathbf{r}) = -\frac{1}{\pi}\int_{-\infty}^{E_F} d\omega \ \mathrm{Im}\ G(\mathbf{r}', \mathbf{r}; \omega) \tag{22}$$

$$\Sigma^{\mathrm{HF}}(\mathbf{r}, \mathbf{r}'; E) = v^x(\mathbf{r}, \mathbf{r}') = -\frac{1}{\pi}\int_{-\infty}^{E_F} d\omega \ [\mathrm{Im}\ G(\mathbf{r}, \mathbf{r}'; \omega)]\ M(\mathbf{r}, \mathbf{r}') \tag{23}$$

Comparison of Equations 21 and 23 show immediately that the *GW* approximation is a Hartree-Fock-like theory, but with the bare Coulomb interaction replaced by an energy-dependent screened interaction *W*. Also, note that in HF theory, Σ is calculated from occupied states only, while in *GW* theory, the quasiparticle spectrum requires a summation over unoccupied states as well.

GW calculations proceed essentially along these lines; in practice G, ε^{-1}, W and Σ are generated in Fourier space. The LDA is used to create the starting wave functions that generate them; however, once they are made the LDA does not enter into the Hamiltonian. Usually in semiconductors ε^{-1} is calculated only for $\omega = 0$, and the ω dependence is taken from a plasmon–pole approximation. The latter is not adequate for metals (Quong and Eguiluz, 1993).

The *GW* approximation has been used with excellent results in the calculation of optical excitations, such as the calculation of energy gaps. It is difficult to say at this time precisely how accurate the *GW* approximation is in semiconductors, because only recently has a proper treatment of the semicore states been formulated (Shirley et al., 1997). Table 3 compares some excitation energies of a few semiconductors to experiment and to the LDA.

Because of the numerical difficulty in working with products of four wave functions, nearly all *GW* calculations are carried out using plane waves. There has been, however, an all-electron *GW* method developed (Aryasetiawan and Gunnarsson, 1994), in the spirit of the augmented wave. This implementation permits the *GW* calculation of narrow-band systems. One early application to Ni showed that it narrowed the valence *d* band by ~1 eV relative to the LDA, in agreement with experiment.

The *GW* approximation is structurally relatively simple; as mentioned above, it assumes a generalized HF form. It does not possess higher-order (most notably, vertex) corrections. These are needed, for example, to reproduce the multiple plasmon satellites in the photoemission of the alkali metals. Recently, Aryasetiawan and coworkers introduced a beyond-*GW* "cumulant expansion" (Aryasetiawan et al., 1996), and very recently, an *ab initio* *T*-matrix technique (Springer et al., 1998) that they needed to account for the spectra in Ni.

Usually *GW* calculations to date use the LDA to generate *G*, *W*, etc. The procedure can be made self-consistent, i.e., *G* and *W* remade with the *GW* self-energy; in fact this was essential in the highly correlated case of NiO (Aryasetiawan and Gunnarson, 1995). Recently, Holm and von Barth (1998) investigated properties of the homogeneous electron gas with a *G* and *W* calculated self-consistently, i.e., from a *GW* potential. Remarkably, they found the self-consistency worsened the optical properties with respect to experiment, though the total energy did improve. Comparison of data in Table 3 shows that the self-consistency procedure overcorrected the gap widening in the semiconductors as well.

It may be possible in principle to calculate ground-state properties in the *GW*, but this is extremely difficult in practice, and there has been no successful attempt to date for real materials. Thus, the LDA remains the "industry standard" for total-energy calculations.

[a] After Shirley et al. (1997). SX calculations are by the present author, using either the LDA *G* and *W*, or by recalculating *G* and *W* with the LDA + SX potential.

The SX Approximation

Because the calculations are very heavy and unsuited to calculations of complex systems, there have been several attempts to introduce approximations to the *GW* theory. Very recently, Rücker (unpub. observ.) introduced a generalization of the LDA functional to account for excitations (van Schilfgaarde et al., 1997). His approach, which he calls the "screened exchange" (SX) theory, differs from the usual *GW* approach in that the latter does not use the LDA at all except to generate trial wave functions needed to make the quantities such as G, ε^{-1}, and W. His scheme was implemented in the LMTO–atomic spheres approximation (LMTO-ASA; see the Appendix), and promises to be extremely efficient for the calculation of excited-state properties, with an accuracy approaching

that of the *GW* theory. The principal idea is to calculate the difference between the screened exchange and the contribution to the screened exchange from the local part of the response function. The difference in Σ may be similarly calculated:

$$\delta W = W[P^0] - W[P^{0,\mathrm{LDA}}] \tag{24}$$

$$\delta W = G\ \delta W \tag{25}$$

$$\equiv \delta v^{\mathrm{SX}} \tag{26}$$

The energy bands are generated like in *GW* theory, except that the (small) correction $\delta\Sigma$ is added to the local v^{XC}, instead of Σ being substituted for v^{XC}. The analog with *GW* theory is that

$$\Sigma(\mathbf{r}, \mathbf{r}', E) = v^{\mathrm{SX}}(\mathbf{r}, \mathbf{r}') + \delta(\mathbf{r} - \mathbf{r}')[v^{xc}(\mathbf{r}) - v^{\mathrm{sx,DFT}}(\mathbf{r})] \tag{27}$$

Although it is not essential to the theory, Rücker's implementation uses only the static response function, so that the one-electron equations have the Hartree-Fock form (see Equation 1). The theory is formulated in terms of a generalization of the LDA functional, so that the *N*-particle LDA ground state is exactly reproduced, and also the $(N+1)$-particle ground state is generated with a corresponding accuracy, provided interaction of the additional electron and the *N* particle ground state is correctly depicted by $v^{XC} + \delta\Sigma$. In some sense, Rücker's approach is a formal and more rigorous embodiment of Harrison's model. Some results using this theory are shown in Table 3 along with Shirley's results. The closest points of comparison are the *GW* calculations marked "*GW* + LDA core" and "SX"; these both use the LDA to generate the *GW* self-energy Σ. Also shown is the result of a partially self-consistent calculation, in which the *G* and *W*, Σ were remade using the LDA + SX potential. It is seen that self-consistency widens the gaps, as found by Holm and von Barth (1998) for a jellium.

LDA + *U*

As an approximation, the LDA is most successful for wide-band, itinerant electrons, and begins to fail where the assumption of a single, universal, orbital-independent potential breaks down. The LDA + *U* functional attempts to bridge the gap between the LDA and model Hamiltonian approaches that attempt to account for fluctuations in the orbital occupations. It partitions the electrons into an itinerant subsystem, which is treated in the LDA, and a subsystem of localized (*d* or *f*) orbitals. For the latter, the LDA contribution to the energy functional is subtracted out, and a Hubbard-like contribution is added. This is done in the same spirit as the SX theory described above, except that here, the LDA + *U* theory attempts to properly account for correlations between atomic-like orbitals on a single site, as opposed to the long-range interaction when the components of an electron-hole pair are infinitely separated.

A motivation for the LDA + *U* functional can already be seen in the humble H atom. The total energy of the H^+ ion is 0, the energy of the H atom is 1 Ry, and the H^- ion is barely bound; thus its total energy is also ~1 Ry. Let us assume the LDA correctly predicts these total energies (as it does in practice; the LDA binding of H is ~0.97 Ry). In the LDA, the number of electrons, *N*, is a continuous variable, and the one-electron term value is, by definition, $\varepsilon \cong \delta E/\delta N$. Drawing a parabola through these three energies, it is evident that $\varepsilon \sim 0.5$ Ry in the LDA. By interpreting ε as the energy needed to ionize H (this is the atomic analog of using energy bands in a solid for the excitation spectrum), one obtains a factor-of-two error. On the other hand, using the LDA total energy difference $E(1) - E(0) \sim 0.97$ Ry predicts the ionization of the H atom rather well. Essentially the same point was made in the discussion of Opical Properties, above. In the solid, this difficulty persists, but the error is much reduced because the other electrons that are present will screen out much of the effect, and the error will depend on the context. In semiconductors, bandgap is underestimated because the LDA misses the Coulomb repulsion associated with separating an electron-hole pair (this is almost exactly analogous to the ionization of H). The cost of separating an electron-hole pair would be <~1 Ry, except that it is reduced by the dielectric screening to ~1 Ry/10 or ~1 to 2 eV.

For narrow-band systems, there is a related difficulty. Here the problem is that as the localized orbitals change their occupations, the effective potentials on these orbitals should also change. Let us consider first a simple form of the LDA + *U* functional that corrects for the error in the atomic limit as indicated for the H atom. Consider a collection of localized *d* orbitals with occupation numbers n_i and the total number of $N_d = \sum_i n_i$. In HF theory, the Coulomb interaction between the N_d electrons is $E = UN_d(N_d - 1)/2$. It is assumed that the LDA closely approximates HF theory for this term, and so this contribution is subtracted from the LDA functional, and replaced by the occupation-dependent Hubbard term:

$$E = \frac{U}{2}\sum_{i \neq j} n_i n_j \tag{28}$$

The resulting functional (Anisimov et al., 1993) is

$$E^{\mathrm{LDA+U}} = E^{\mathrm{LDA}} + \frac{U}{2}\sum_{i \neq j} n_i n_j - \frac{U}{2}N_d(N_d - 1) \tag{29}$$

U is determined from

$$U = \frac{\partial^2 E}{\partial N_d^2} \tag{30}$$

The orbital energies are now properly occupation-dependent:

$$\varepsilon_d = \frac{\partial E}{\partial N_d} = \varepsilon_{\mathrm{LDA}} + U\left(\frac{1}{2} - n_i\right) \tag{31}$$

For a fully occupied state, $\varepsilon = \varepsilon_{\mathrm{LDA}} - U/2$, and for an unoccupied state, $\varepsilon = \varepsilon_{\mathrm{LDA}} + U/2$. It is immediately evident that this functional corrects the error in the H ionization potential. For H, $U \sim 1$ Ry, so for the neutral atom $\varepsilon = \varepsilon_{\mathrm{LDA}} - U/2 \sim -1$ Ry, while for the H^+ ion, $\varepsilon = \varepsilon_{\mathrm{LDA}} + U/2 \sim 0$.

A complete formulation of the functional must account for the exchange, and should also permit the U's to be orbital-dependent. Liechtenstein et al. (1995) generalized the functional of Anisimov to be rotationally invariant. In this formulation, the orbital occupations must be generalized to the density matrices n_{ij}:

$$E^{\mathrm{LDA}+U} = E^{\mathrm{LDA}} + \frac{1}{2}\sum_{ijkl} U_{ijkl}\, n_{ij}\, n_{kl} - E_{dc}$$

$$E_{dc} = \frac{U}{2} N_d(N_d - 1) - \frac{J}{2}[n_d^{\uparrow}(N_d^{\uparrow} - 1) + n_d^{\downarrow}(n_d^{\downarrow} - 1)] \tag{32}$$

The terms proportional to J represent the exchange contribution to the LDA energy. The up and down arrows in Equation 32 represent the relative direction of electronic spin.

One of the most problematic aspects to this functional is the determination of the U's. Calculation of U from the bare Coulomb interaction is straightforward, and correct for isolated free atom, but in the solid the screening renormalizes U by a factor of $\sim$2 to 5. Several prescriptions have been proposed to generate the screened U. Perhaps the most popular is the "constrained density-functional" approach, in which a supercell is constructed and one atom is singled out as a defect. The LDA total energy is calculated as a function of the occupation number of a given orbital (the occupation number must be constrained artificially; thus, the name "constrained density functional"), and U is obtained essentially from Equation 30 (Kanamori, 1963; Anisimov and Gunnarsson, 1991). Since U is the static limit of the screened Coulomb interaction, W, it may also be calculated with the RPA as is done in the GW approximation; see Equation 20. Very recently, W was calculated in this way for Ni (Springer and Aryasetiawan, 1998), and was found to be somewhat lower (2.2 eV) than results obtained from the constrained LDA approach (3.7 to 5.4 eV).

Results from LDA + *U*

To date, the LDA + U approach has been primarily used in rather specialized areas, to attack problems beyond the reach of the LDA, but still in an *ab initio* way. It was included in this review because it establishes a physically transparent picture of the limitations of the LDA, and a prescription for going beyond it. It seems likely that the LDA + U functional, or some close descendent, will find its way into "standard" electronic structure programs in the future, for making the small but important corrections to the LDA ground-state energies in simpler itinerant systems.

The reader is referred to an excellent review article (Anisimov et al., 1997) that provides several illustrations of the method, including a description of electronic structure of the f-shell compounds CeSb and $PrBa_2Cu_3O_7$, and some late-transition metal oxides.

Relationship between LDA + *U* and *GW* Methods

As indicated above and shown in detail in Anisimov et al. (1997), the LDA + U approach is in one sense an approximation to the GW theory, or more accurately a hybrid between the LDA and a statically screened GW for the localized orbitals. One drawback to this approach is the *ad hoc* partitioning of the electrons. The practitioner must decide which orbitals are atomic-like and need to be split off. The method has so far only been implemented in basis sets that permit partitioning the orbital occupations into the localized and itinerant states. For the materials that have been investigated so far (e.g., f-shell metals, NiO), this is not a serious problem, because which orbitals are localized is fairly obvious. The other main drawback, namely, the difficulty in determining U, does not seem to be one of principle (Springer and Aryasetiawan, 1998).

On the other hand, the LDA + U approach offers an important advantage: it is a total-energy method, and can deal with both ground-state and excited-state properties.

QUANTUM MONTE CARLO

It was noted that the Hartree-Fock approximation is inadequate for solids, and that the LDA, while faring much better, has in the LD *ansatz* an uncontrolled approximation. Quantum Monte Carlo (QMC) methods are ostensibly a way to solve the Schrödinger equation to arbitrary accuracy. Thus, there is no mean-field approximation as in the other approaches discussed here. In practice, the computational effort entailed in such calculations is formidable, and for the amount of computer time available today exact solutions are not feasible for realistic systems. The number of Monte Carlo calculations today is still limited, and for the most part confined to calculations of model systems. However, as computer power continues to increase, it is likely that such an approach will be used increasingly.

The idea is conceptually simple, and there are two most common approaches. The simplest (and approximate) is the *variational* Monte Carlo (VMC) method. A more sophisticated (and in principle, potentially exact) approach is known as the Green's function, or diffusion Monte Carlo

(GFMC) method. The reader is referred to Ceperley and Kalos (1979) and Ceperley (1999)for an introduction to both of them. In the VMC approach, some functional form for the wave function is assumed, and one simply evaluates by brute force the expectation value of the many-body Hamiltonian. Since this involves integrals over each of the many electronic degrees of freedom, Monte Carlo techniques are used to evaluate them. The assumed form of the wave functions are typically adapted from LDA or HF theory, with some extra degrees of freedom (usually a Jastrow factor; see discussion of Variational Monte Carlo, below) added to incorporate beyond-LDA effects. The free parameters are determined variationally by minimizing the energy.

This is a rapidly evolving subject, still in the relatively early stages insofar as realistic solutions of real materials are concerned. In this brief review, the main ideas are outlined, but the reader is cautioned that while they appear quite simple, there are many important details that need be mastered before these techniques can be reliably prosecuted.

Variational Monte Carlo

Given a trial wave function Ψ_T, the expectation value of any operator $O(\mathbf{R})$ of all the electron coordinates, $\mathbf{R} = r_1 r_2 r_3 \ldots$, is

$$\langle O \rangle = \frac{\int d\mathbf{R} \Psi_T^*(\mathbf{R}) O(\mathbf{R}) \Psi_T(\mathbf{R})}{\int d\mathbf{R} \Psi_T^*(\mathbf{R}) \Psi_T(\mathbf{R})} \tag{33}$$

and in particular the total energy is the expectation value of the Hamiltonian H. Because of the variational principle, it is a minimum when Ψ_T is the ground-state wave function. The variational approach typically guesses a wave function whose form can be freely chosen. In practice, assumed wave functions are of the Jastrow type (Malatesta et al., 1997), such as

$$\Psi_T = D^{\uparrow}(\mathbf{R}) D^{\downarrow}(\mathbf{R}) \exp\left[\sum_i \chi(\mathbf{r}_i) + \sum_{ij} u(\mathbf{r}_i - \mathbf{r}_j)\right] \tag{34}$$

$D^{\uparrow}(\mathbf{R})$ and $D^{\downarrow}(\mathbf{R})$ are the spin-up and spin-down Slater determinants of single-particle wave functions obtained from, for example, a Hartree-Fock or local-density calculation. χ and u are the one-body and two-body pairwise terms in the Jastrow factor, with typically 10 or 20 parameters to be determined variationally.

Integration of the expectation values of interest (usually the total energy) proceeds by integration of Equation 32 using the Metropolis algorithm (Metropolis et al., 1953), which is a powerful approach to compute integrals of many dimensions. Suppose we can generate a collection of electron configurations $\{\mathbf{R}_i\}$ such that the probability of finding configuration

$$p(\mathbf{R}_i) = \frac{|\Psi_T(\mathbf{R}_i)|^2}{\int d\mathbf{R} |\Psi_T(\mathbf{R})|^2} \tag{35}$$

Then by the central limit theorem, for such a collection of points the expectation value of any operator, in particular the Hamiltonian is

$$E = \lim_{M \to \infty} \frac{1}{M} \sum_{i=1}^{M} \psi_T^{-1}(\mathbf{R}_i) H(\mathbf{R}_i) \psi_T(\mathbf{R}_i) \tag{36}$$

How does one arrive at a collection of the $\{\mathbf{R}_i\}$ with the required probability distribution? This one obtains automatically from the Metropolis algorithm, and it is why Metropolis is so powerful. Each particle is randomly moved from an old position to a new position uniformly distributed. If $|\Psi_T(\mathbf{R}_{\text{new}})|^2 \geq |\Psi_T(\mathbf{R}_{\text{old}})|^2$, $\mathbf{R}_{\text{new}}$ is accepted.

Otherwise $\mathbf{R}_{\text{new}}$ is accepted with probability

$$\frac{|\psi_T(\mathbf{R}_{\text{new}})|^2}{|\psi_T(\mathbf{R}_{\text{old}})|^2} \tag{37}$$

Green's Function Monte Carlo

In the GFMC approach, one does not impose the form of the wave function, but it is obtained directly from the Schrödinger equation. The GFMC is one practical realization of the observation that the Schrödinger equation is a diffusion equation in imaginary time, $\tau = it$:

$$H\Psi = \frac{\partial \Psi}{\partial \tau} \tag{38}$$

As $\tau \to \infty$, Ψ evolves to the ground state. To see this, we express the formal solution of Equation 38 in terms of the eigenstates Ψ_n and eigenvalues E_n of H:

$$\Psi(\mathbf{R}, \tau) = e^{-(H + \text{const})\tau} \Psi(\mathbf{R}, 0) = \sum_n e^{-(E_n + \text{const})\tau} \Psi_n(\mathbf{R}) \tag{39}$$

Provided $\Psi(\mathbf{R}, 0)$ is not orthogonal to the ground state, and that the latter is sufficiently distinct in energy from the first excited state, only the ground state will survive as $\tau \to \infty$.

In the GFMC, Ψ is evolved from an integral form for the Schrödinger equation (Ceperley and Kalos, 1979):

$$\Psi(\mathbf{R}) = (E + \text{const}) \int d\mathbf{R}' G(\mathbf{R}, \mathbf{R}') \Psi(\mathbf{R}') \tag{40}$$

One defines a succession of functions $\Psi^{(n)}(\mathbf{R})$

$$\Psi^{(n+1)}(\mathbf{R}) = (E + \text{const}) \int d\mathbf{R}' G(\mathbf{R}, \mathbf{R}') \Psi^{(n)}(\mathbf{R}') \tag{41}$$

and the ground state emerges in the $n \to \infty$ limit.

One begins with a guess for the ground state, $\Psi^{(0)}(\{\mathbf{R}_i\})$, taken, for example, from a VMC calculation, and draws a set of configurations $\{\mathbf{R}_i\}$ randomly, with a probability distribution $\Psi^{(0)}(\mathbf{R})$. One estimates $\Psi^{(1)}(\mathbf{R}_i)$ by integrating Equation 41 for one time step using each of the $\{\mathbf{R}_i\}$ values. This procedure is repeated, with the collection $\{\mathbf{R}_i\}$ at step n drawn from the probability distribution $\Psi^{(n)}$.

The above prescription requires that G be known, which it is not. The key innovation of the method stems

from the observation that one can sample $G(\mathbf{R}, \mathbf{R}')\ \Psi^{(n)}(\mathbf{R}')$ without knowing G explicitly. The reader is referred to Ceperley and Kalos (1979) for details.

There is one very serious obstacle to the practical realization of the GFMC technique. Fermion wave functions necessarily have nodes, and it turns out that there is large cancellation in the statistical averaging between the positive and negative regions. The desired information gets drowned out in the noise after some number of iterations. This difficulty was initially resolved—and still is largely to this day, by making a fixed-node approximation. If the nodes are known, one can partition the GFMC into positive definite regions, and carry out Monte Carlo simulations in each region separately. The nodes are obtained in practice typically by an initial variational QMC calculation.

Applications of the Monte Carlo Method

To date, the vast majority of QMC calculations are carried out for model systems. There have been a few VMC calculations of realistic solids. The first "realistic" calculation was carried out by Fahy et al. (1990) on diamond; recently, nearly the same technique was used to calculate the heat of formation of BN with considerable success (Malatesta et al., 1997). One recent example, albeit for molecules, is the VMC study of heats of formation and barrier heights calculated for three small molecules; see Grossman and Mitás (1997) and Table 1.

Recent fixed-node GFMC have been reported for a number of small molecules, including dissociation energies for the first-row hydrides (LiH to FH) and some silicon hydrides (Lüchow and Anderson, 1996; Greeff and Lester, 1997), and the calculations are in agreement with experiment to within ~20 meV. Grossman and Mitás (1995) have reported a GFMC study of small Si clusters. There are few GFMC calculations in solids, largely because of finite-size effects. GFMC calculations are only possible in finite systems; solids must be approximated with small simulation cells subject to periodic boundary conditions. See Fraser et al. (1996) for a discussion of ways to accelerate convergence of errors resulting from such effects. As early as 1991, Li et al. (1991) published a VMC and GFMC study of the binding in Si. Their VMC and GFMC binding energies were 4.38 and 4.51 eV, respectively, in comparison to the LDA 5.30 eV using the Ceperley-Alder functional (Ceperley and Alder, 1980), and 5.15 eV for the von Barth-Hedin functional (von Barth and Hedin, 1972), and the experimental 4.64 eV. Rajagopal et al. (1995) have reported VMC and GFMC calculations on Ge, using a local pseudopotential for the ion cores.

From the dearth of reported results, it is clear that Monte Carlo methods are only beginning to make their way into the literature. But because the main constraint, the finite capacity of modern-day computers, is diminishing, this approach is becoming a promising prospect for the future.

SUMMARY AND OUTLOOK

This unit reviewed the status of modern electronic structure theory. It is seen that the local-density approximation, while a powerful and general purpose technique, has certain limitations. By comparing the relationships between it and other approaches, the relative strengths and weaknesses were elucidated. This also provides a motivation for reviewing the potential of the most promising of the newer, next-generation techniques.

It is not clear yet which approaches will predominate in the next decade or two. The QMC is yet in its infancy, impeded by the vast amount of computer resources it requires. But obviously, this problem will lessen in time with the advent of ever faster machines. Screened Hartree-Fock-like approaches also show much promise. They have the advantage that they are more mature and can provide physical insight more naturally than the QMC "heavy hammer." A general-purpose HF-like theory is already realized in the *GW* approximation, and some extensions of *GW* theory have been put forward. Whether a corresponding, all-purpose total-energy method will emerge is yet to be seen.

ACKNOWLEDGMENTS

The author thanks Dr. Paxton for a critical reading of the manuscript, and for pointing out Pettifor's work on the structural energy differences in the transition metals. This work was supported under Office of Naval Research contract number N00014-96-C-0183.

PREDICTION OF PHASE DIAGRAMS

A phase diagram is a graphical object, usually determined experimentally, indicating phase relationships in thermodynamic space. Usually, one coordinate axis represents temperature; the others may represent pressure, volume, concentrations of various components, and so on. This unit is concerned only with temperature-concentration diagrams, limited to binary (two-component) and ternary (three-component) systems. Since more than one component will be considered, the relevant thermodynamic systems will be alloys, by definition, of metallic, ceramic, or semiconductor materials. The emphasis here will be placed primarily on metallic alloys; oxides and semiconductors are covered more extensively elsewhere in this chapter (in SUMMARY OF ELECTRONIC STRUCTURE METHODS, BONDING IN METALS, and BINARY AND MULTICOMPONENT DIFFUSION). The topic of bonding in metals, highly pertinent to this unit as well, is discussed in BONDING IN METALS.

Phase diagrams can be classified broadly into two main categories: experimentally and theoretically determined. The object of the present unit is the theoretical determina-

tion—i.e., the calculation of phase diagrams, meaning ultimately their prediction. But calculation of phase diagrams can mean different things: there are prototype, fitted, and first-principles approaches. Prototype diagrams are calculated under the assumption that energy parameters are known *a priori* or given arbitrarily. Fitted diagrams are those whose energy parameters are fitted to known, experimentally determined diagrams or to empirical thermodynamic data. First-principles diagrams are calculated on the basis of energy parameters calculated from essentially only the knowledge of the atomic numbers of the constituents, hence by actually solving the relevant Schrödinger equation. This is the "Holy Grail" of alloy theory, an objective not yet fully attained, although recently great strides have been made in that direction.

Theory also enters in the experimental determination of phase diagrams, as these diagrams not only indicate the location in thermodynamic space of existing phases but also must conform to rigorous rules of thermodynamic equilibrium (stable or metastable). The fundamental rule of equality of chemical potentials imposes severe constraints on the graphical representation of phase diagrams, while also permitting an extraordinary variety of forms and shapes of phase diagrams to exist, even for binary systems.

That is one of the attractions of the study of phase diagrams, experimental or theoretical: their great topological diversity subject to strict thermodynamic constraints. In addition, phase diagrams provide essential information for the understanding and designing of materials, and so are of vital importance to materials scientists. For theoreticians, first-principles (or *ab initio*) calculations of phase diagrams provide enormous challenges, requiring the use of advanced techniques of quantum and statistical mechanics.

BASIC PRINCIPLES

The thermodynamics of phase equilibrium were laid down by Gibbs over 100 years ago (Gibbs, 1875–1878). His was strictly a "black-box" thermodynamics in the sense that each phase was considered as a uniform continuum whose internal structure did not have to be specified. If the black boxes were very small, then interfaces had to be considered; Gibbs treated these as well, still without having to describe their structure. The thermodynamic functions, internal energy E, enthalpy H ($= E + PV$, where P is pressure and V volume), (Helmholtz) free energy F ($= E - TS$, where T is absolute temperature and S is entropy), and Gibbs free energy G ($= H - TS = F + PV$), were assumed to be known. Unfortunately, these functions (of P, V, T, say)—even for the case of fluids or hydrostatically stressed solids, as considered here—are generally not known. Analytical functions have to be "invented" and their parameters obtained from experiment. If suitable free energy functions can be obtained, then corresponding phase diagrams can be constructed from the law of equality of chemical potentials. If, however, the functions themselves are unreliable and/or the values of the parameters not determined over a sufficiently large region of thermodynamic space, then one must resort to studying in detail the physics of the thermodynamic system under consideration, investigating its internal structure, and relating microscopic quantities to macroscopic ones by the techniques of statistical mechanics. This unit will very briefly review some of the methods used, at various stages of sophistication, to arrive at the "calculation" of phase diagrams. Space does not allow the elaboration of mathematical details, much of which may be found in the author's two *Solid State Physics* review articles (de Fontaine, 1979, 1994) and references cited therein. An historical approach is given in the author's *MRS Turnbull* lecture (de Fontaine, 1996).

Classical Approach

The condition of phase equilibrium is given by the following set of equations (Gibbs, 1875–1878):

$$\mu_I^{\alpha} = \mu_I^{\beta} = \cdots = \mu_I^{\lambda} \tag{1}$$

designating the equality of chemical potentials (μ) for component I ($= 1, \ldots, n$) in phases α, β, and γ. A convenient graphical description of Equations 1 is provided in free energy-concentration space by the common tangent rule, in binary systems, or the common tangent hyperplane in multicomponent systems. A very complete account of multicomponent phase equilibrium and its graphical interpretation can be found in Palatnik and Landau (1964) and is summarized in more readable form by Prince (1966). The reason that Equations 1 lead to a common tangent construction rather than the simple search for the minima of free energy surfaces is that the equilibria represented by those equations are constrained minima, with constraint given by

$$\sum_{I=1}^{n} x_I = 1 \tag{2}$$

where $0 \leq x_I \leq 1$ designates the concentration of component I. By the properties of the x_I values, it follows that a convenient representation of concentration space for an n-component system is that of a regular simplex in $(n - 1)$-dimensional space: a straight line segment of length 1 for binary systems, an equilateral triangle for ternaries (the so-called Gibbs triangle), a regular tetrahedron for quaternaries, and so on (Palatnik and Landau, 1964; Prince, 1966). The temperature axis is then constructed orthogonal to the simplex. The phase diagram space thus has dimensions equal to the number of (nonindependent) components. Although heroic efforts have been made in that direction (Cayron, 1960; Prince, 1966), it is clear that the full graphical representation of temperature-composition phase diagrams is practically impossible for anything beyond ternary systems and awkward even beyond binaries. One then resorts to constructing two-dimensional sections, isotherms, and isopliths (constant ratio of components).

The variance f (or number of thermodynamic degrees of freedom) of a phase region where ϕ (≥ 1) phases are in equilibrium is given by the famous Gibbs phase rule, derived from Equations 1 and 2,

$$f = n - \phi + 1 \quad \text{(at constant pressure)} \tag{3}$$

It follows from this rule that when the number of phases is equal to the number of components plus 1, the equilibrium is invariant. Thus, at a given pressure, there is only one, or a finite number, of discrete temperatures at which $n + 1$ phases may coexist. Let us say that the set of $n + 1$ phases in equilibrium is $\Sigma = \{\alpha, \beta, \ldots, \gamma\}$. Then just above the invariant temperature, a particular subset of Σ will be found in the phase diagram, and just below, a different subset.

It is simpler to illustrate these concepts with a few examples (see Figs. 1 and 2). In isobaric binary systems, three coexisting phases constitute an invariant phase equilibrium, and only two topologically distinct cases are permitted: the eutectic and peritectic type, as illustrated in Figure 1. These diagrams represent schematically regions in temperature-concentration space in a narrow temperature interval just above and just below the three-phase coexistence line. Two-phase monovariant regions ($f = 1$ in Equation 3) are represented by sets of horizontal (isothermal) lines, the tie lines (or conodes), whose extremities indicate the equilibrium concentrations of the coexisting phases at a given temperature. In the eutectic case (Fig. 1A), the high-temperature phase γ (often the liquid phase) ceases to exist just below the invariant temperature, leaving only the $\alpha + \beta$ two-phase equilibrium. In the peritectic case (Fig. 1B), a new phase, β, makes its appearance while the relative amount of $\alpha + \gamma$ two-phase material decreases. It can be seen from Figure 1 that, topologically speaking, these two cases are mirror images of each other, and there can be no other possibility. How the full-phase diagram can be continued will be shown in the next section (Mean-Field Approach) in the eutectic case calculated by means of "regular solution" free energy curves.

Ternary systems exhibit three topologically distinct possibilities: eutectic type, peritectic type, and "intermediate" (Fig. 2B, C, and D, respectively). Figure 2A shows the phase regions in a typical ternary eutectic isothermal section at a temperature somewhat higher than the four-phase invariant ($f = 0$) equilibrium $\gamma + \alpha + \beta + \gamma$. In that case, three three-phase triangles come together to form a larger triangle at the invariant temperature, just below which the γ phase disappears, leaving only the $\alpha + \beta + \gamma$ monovariant equilibrium (see Fig. 2B). For simplicity, two-phase regions with their tie lines have been omitted. As for binary systems, the peritectic case is the topological mirror image of the eutectic case: the $\alpha + \beta + \gamma$ triangle splits into three three-phase triangles, as indicated in Figure 2C. In the "intermediate" case (Fig. 2D), the invariant is no longer a triangle but a quadrilateral. Just above the invariant temperature, two triangles meet along one of the diagonals of the quadrilateral; just below, it splits into two triangles along the other diagonal.

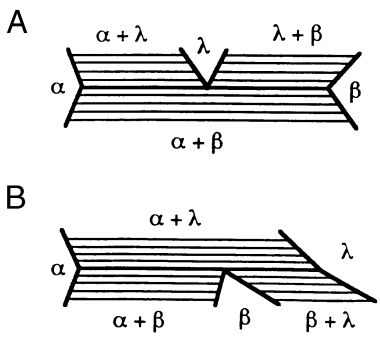

Figure 1. Binary eutectic (**A**) and peritectic (**B**) topology near the three-phase invariant equilibrium.

For quaternary systems, graphical representation is more difficult, since the possible invariant equilibria—of which there are four: eutectic type, peritectic type, and two intermediate cases—involve the merging and splitting of tetrahedra along straight lines or planes of four- or five-vertex (invariant) figures (Cayron, 1960; Prince, 1966). For even higher-component systems, full graphical representation is just about hopeless (Cayron, 1960). The Stockholm-based commercial firm Thermocalc (Jansson et al., 1993) does, however, provide software that constructs two-dimensional sections through multidimensional phase diagrams; these diagrams themselves are constructed analytically by means of Equations 1 applied to semiempirical multicomponent free energy functions.

The reason for dwelling on the universal rules of invariant equilibria is that they play a fundamental role in phase diagram determination. Regardless of the method employed—experimental or computational; prototype, fitted, or *ab initio*—these rules must be respected and often give a clue as to how certain features of the phase diagram must appear. These rules are not always respected even in published phase diagrams. They are, of course, followed in, for example, the three-volume compilation of experimentally determined binary phase diagrams published by the American Society for Metals (Mallaski, 1990).

Mean-Field Approach

The diagrams of Figures 1 and 2 are not even "prototypes"; they are schematic. The only requirements imposed are that they represent the basic types of phase equilibria in binary and ternary systems and that the free-hand-drawn phase regions obey the phase rule. For a slightly more quantitative approach, it is useful to look at the construction of a prototype binary eutectic diagram based on the simplest analytical free energy model, that of the regular solution, beginning with some useful general definitions.

Consider some extensive thermodynamic quantity, such as energy, entropy, enthalpy, or free energy F. For condensed matter, it is customary to equate the Gibbs and Helmholtz free energies. That is not to say that equilibrium will be calculated at constant volume, merely that the Gibbs free energy is evaluated at zero pressure; at reasonably low pressures, at or below atmospheric pressure, the internal states of condensed phases change very little with pressure. The total free energy of a binary solution AB for a given phase is then the sum of an "unmixed" contribution, which is the concentration-weighted average of the free energy of the pure constituents A and B, and of a mixing term that takes into account the mutual interaction of the constituents. This gives the equation

$$F = F_{\text{lin}} + F_{\text{mix}} \tag{4}$$

with

$$F_{\text{lin}} = x_{\text{A}}F_{\text{A}} + x_{\text{B}}F_{\text{B}} \tag{5}$$

where F_{lin}, known as the "linear term" because of its linear dependence on concentration, contains thermodynamic information pertaining only to the pure elements. The mixing term is the difficult one to calculate, as it also contains the important configurational entropy-of-mixing contribution. The simplest mean-field (MF) approximation regards F_{mix} as a slight deviation from the free energy of a completely random solution—i.e., one that would obtain for noninteracting particles (atoms or molecules). In the random case, the free energy is the ideal one, consisting only of the ideal free energy of mixing:

$$F_{\text{id}} = -TS_{\text{id}} \tag{6}$$

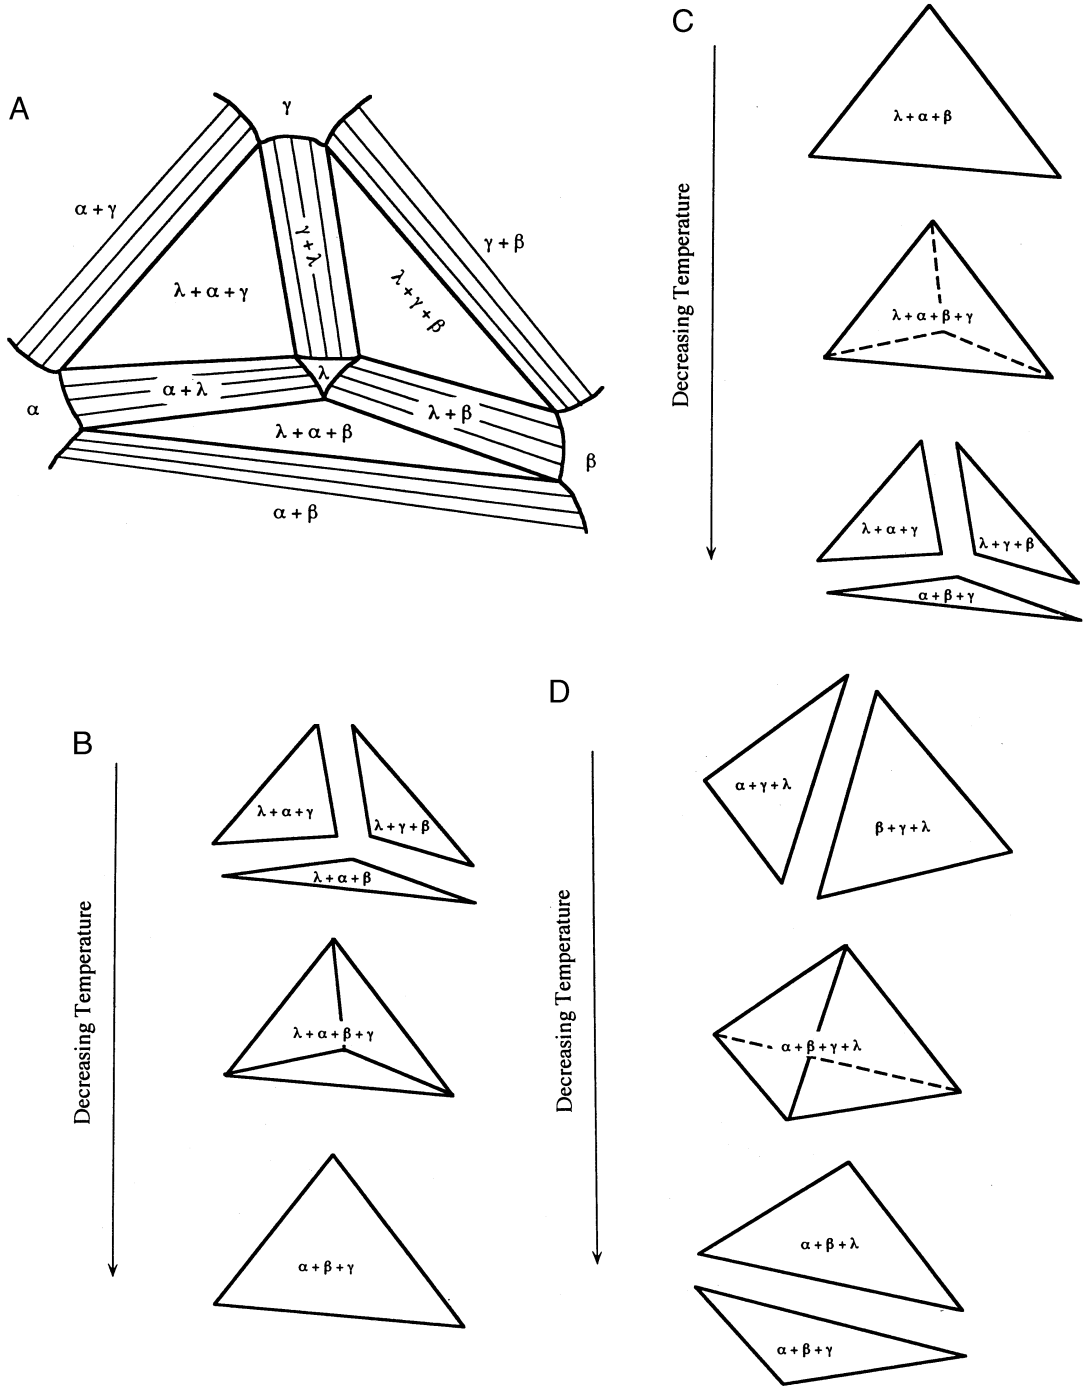

Figure 2. (**A**) Isothermal section just above the $\alpha + \beta + \gamma + \lambda$ invariant ternary eutectic temperature. (**B**) Ternary eutectic case (schematic). (**C**) Ternary peritectic case (schematic). (**D**) Ternary intermediate case (schematic).

since the energy (or enthalpy) of noninteracting particles is zero. The ideal configurational entropy of mixing per particle is given by the universal function

$$S_{\mathrm{id}} = -Nk_{\mathrm{B}}(x_{\mathrm{A}} \log x_{\mathrm{A}} + x_{\mathrm{B}} \log x_{\mathrm{B}}) \tag{7}$$

where N is the number of particles and k_{B} is Boltzmann's constant. Expression 7 is easily generalized to multicomponent systems.

What is left over in the general free energy is, by definition, the excess term, in the MF approximation taken to be a polynomial in concentration and temperature $F_{xs}(x, T)$. Here, since there is only one independent concentration because of Equation 2, one writes $x = x_{\mathrm{B}}$, the concentration of the second constituent, and $x_{\mathrm{A}} = 1 - x$ in the argument of F. In the regular solution model, the simplest formulation of the MF approximation, the simplifying assumption is also made that there is no temperature dependence of the excess entropy and the excess enthalpy depends quadratically on concentration. This gives

$$F_{xs} = x(1-x)W \tag{8}$$

where W is some generalized (concentration- and temperature-independent) interaction parameter.

For the purpose of constructing a prototype binary phase diagram in the simplest way, based on the regular solution model for the solid (σ) and liquid (λ) phases, one writes the pair of free energy expressions

$$f_\sigma = x(1-x)w_\sigma = k_{\mathrm{B}}T[x \log x + (1-x) \log (1-x)] \tag{9a}$$

and

$$f_\lambda = \Delta h - T\,\Delta s + x(1-x)w_\lambda + k_{\mathrm{B}}T[x \log x + (1-x) \log (1-x)] \tag{9b}$$

These equations are arrived at by subtracting the linear term (Equation 5) of the solid from the free energy functions of both liquid and solid (hence, the Δs in Equation 9b) and by dividing through by N, the number of particles. The lowercase letter symbols in Equations 9 indicate that all extensive thermodynamic quantities have been normalized to a single particle. The (linear) Δh term was considered to be temperature independent, and the Δs term was considered to be both temperature and concentration independent, assuming that the entropies of melting the two constituents were the same.

Free energy curves for the solid only (Equation 9a) are shown at the top portion of Figure 3 for a set of normalized temperatures ($t = k_{\mathrm{B}}T/|w|$), with $w_\sigma > 0$. The locus of common tangents, which in this case of symmetric free energy curves are horizontal, gives the miscibility gap (MG) type of phase diagram shown at the bottom portion of Figure 3. Again, tie lines are not shown in the two-phase region $\alpha + \beta$. Above the critical point ($t = 0.5$), the two phases α and β are structurally indistinguishable. Here, Δs and the constants a and b in $\Delta h = a + bx$ were fixed so that the free energy curves of the solid and liquid would intersect in a reasonable temperature interval. Within this interval, and above

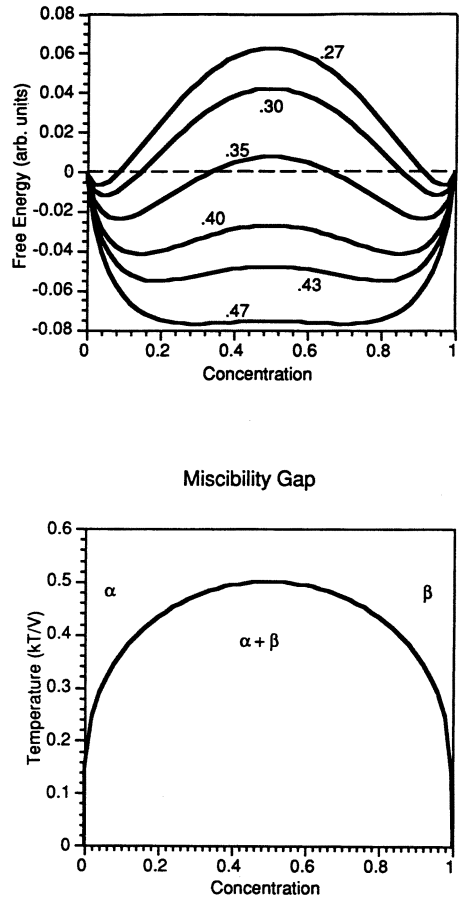

Figure 3. Regular solution free energy curves (at the indicated normalized temperatures) and resulting miscibility gap.

the eutectic ($\alpha + \beta + \gamma$) temperature, common tangency involves both free energy curves, as shown in Figure 4: the full straight-line segments are the equilibrium common tangents (filled-circle contact points) between solid (full curve) and liquid (dashed curve) free energies. For

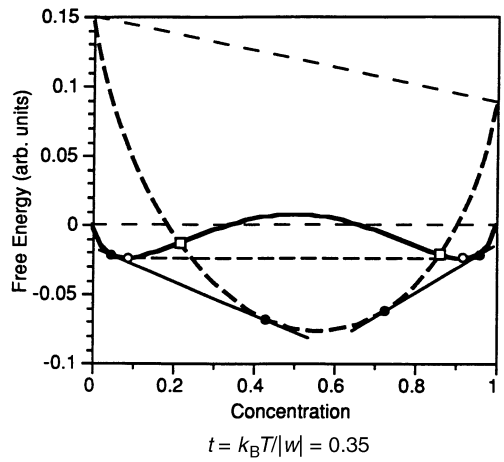

Figure 4. Free energy curves for the solid (full line) and liquid (dashed line) according to Equations 9a and 9b.

the liquid, it is assumed that $|w_\lambda| < w_\sigma$. The dashed common tangent (open circles) represents a metastable MG equilibrium above the eutectic. Open square symbols in Figure 4 mark the intersections of the two free energy curves. The loci of these intersections on a phase diagram trace out the so-called T_0 lines where the (metastable) disordered-state free energies are equal. Sets of both liquid and solid free energy curves are shown in Figure 5 for the same reduced temperatures (t) as were given in Figure 3. The phase diagram resulting from the locus of lowest common tangents (not shown) to curves such as those given in Figure 5 is shown in Figure 6. The melting points of pure A and B are, respectively, at reduced temperatures 0.47 and 0.43; the eutectic is at ~0.32.

This simple example suffices to demonstrate how phase diagrams can be generated by applying the equilibrium conditions (Equation 1) to model free energy functions. Of course, actual phase diagrams are much more complicated, but the general principles are always the same. Note that in these types of calculations the phase rule does not have to be imposed "externally"; it is built into the equilibrium conditions, and indeed follows from them. Thus, for example, the phase diagram of Figure 6 clearly belongs to the eutectic class illustrated schematically in Figure 1A. Peritectic systems are often encountered in cases where the difference of A and B melting temperatures is large with respect to the average normalized melting temperature $\bar{t}$. The general procedure outlined above may of course be extended to multicomponent systems.

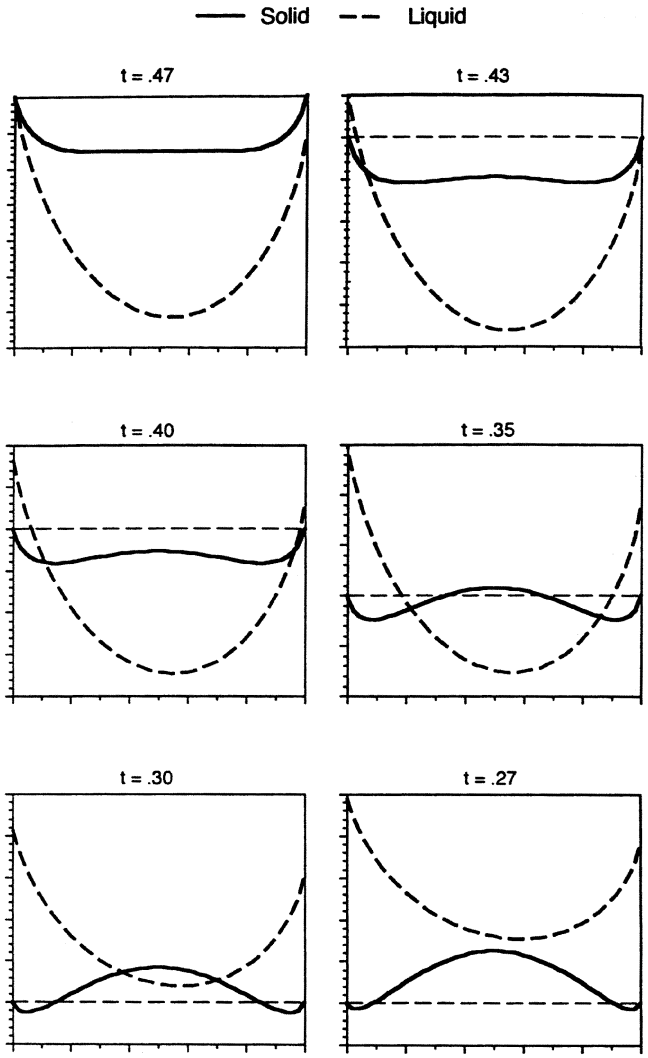

Figure 5. Free energy curves, as in Figure 4, but at the indicated reduced temperature t, generating the phase diagram of Figure 6.

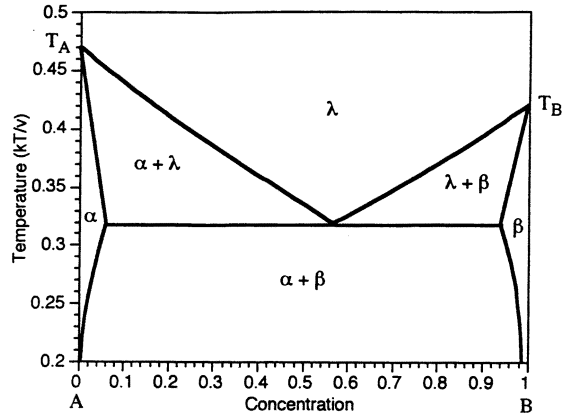

Figure 6. Eutectic phase-diagram generated from curves such as those of Figure 5.

If the interaction parameter W (Equation 8) were negative, then physically this means that unlike (A-B) near-neighbor (nn) "bonds" are favored over the average of like (A-A, B-B) "bonds." The regular solution model cannot do justice to this case, so it is necessary to introduce sublattices, one or more of which will be preferentially occupied by a certain constituent. In a sense, this atomic ordering situation is not very different from that of phase separation, illustrated in Figures 3 and 6, where the two types of atoms separate out in two distinct regions of space; here the separation is between two interpenetrating sublattices. Let there be two distinct sublattices α and β (the same notation is purposely used as in the phase separation case). The pertinent concentration variables (only the B concentration need be specified) are then x^α and x^β, which may each be written as a linear combination of x, the overall concentration of B, and η, an appropriate long-range order (LRO) parameter. In a binary "ordering" system with two sublattices, there are now two independent composition variables: x and η. In general, there is one less order parameter than there are sublattices introduced. When the ideal entropy (de Fontaine, 1979), also containing linear combinations of x and η, multiplied by $-T$ is added on, this gives so-called (generalized) Gorsky-Bragg-Williams (GBW) free energies. To construct a prototype phase diagram, possibly featuring a variety of ordered phases, it is now necessary to minimize these free energy functions with respect to the LRO parameter(s) at given x and T and then to construct common tangents.

Generalization to ordering is very important as it allows treatment of (ordered) compounds with extensive or narrow ranges of solubility. The GBW method is very convenient because it requires little in the way of computational machinery. When the GBW free energy is

expanded to second order, then Fourier transformed, it leads to the "method of concentration waves," discussed in detail elsewhere (de Fontaine, 1979; Khachaturyan, 1983), with which it is convenient to study general properties of ordering in solid solutions, particularly ordering instabilities. However, to construct fitted phase diagrams that resemble those determined experimentally, it is found that an excess free energy represented by a quadratic form will not provide enough flexibility for an adequate fit to thermodynamic data. It is then necessary to write F_{xs} as a polynomial of degree higher than the second in the relevant concentration variables: the temperature T also appears, usually in low powers.

The extension of the GBW method to include higher-degree polynomials in the excess free energy is the technique favored by the CALPHAD group (see *CALPHAD* journal published by Elsevier), a group devoted to the very useful task of collecting and assessing experimental thermodynamic data, and producing calculated phase diagrams that agree as closely as possible with experimental evidence. In a sense, what this group is doing is "thermodynamic modeling," i.e., storing thermodynamic data in the form of mathematical functions with known parameters. One may ask, if the phase diagram is already known, why calculate it? The answer is that phase diagrams have often not been obtained in their entirety, even binary ones, and that calculated free energy functions allow some extrapolation into the unknown. Also, knowing free energies explicitly allows one to extract many other useful thermodynamic functions instead of only the phase diagram itself as a graphical object. Another useful though uncertain aspect is the extrapolation of known lower-dimensional diagrams into unknown higher-dimensional ones. Finally, appropriate software can plot out two-dimensional sections through multicomponents. Such software is available commercially from Thermocalc (Jansson et al., 1993). An example of a fitted phase diagram calculated in this fashion is given below (see Examples of Applications).

It is important to note, however, that the generalizations just described—sublattices, Fourier transforms, polynomials—do not alter the degree of sophistication of the approximation, which remains decidedly MF, i.e., which replaces the averages of products (of concentrations) by products of averages. Such a procedure can give rise to certain unacceptable behavior of calculated diagrams, as explained below (see discussion of Cluster-Expansion Free Energy).

Cluster Approach

Thus far, the treatment has been restricted to a black-box approach: each phase is considered as a thermodynamic continuum, possibly in equilibrium with other phases. Even in the case of ordering, the approach is still macroscopic, each sublattice also being considered as a thermodynamic continuum, possibly interacting with other sublattices. It is not often appreciated that, even though the crystal structure is taken into consideration in setting up the GBW model, the resulting free energy function still does not contain any geometrical information. Each sublattice could be located anywhere, and such things as coordination numbers can be readily incorporated in the effective interactions W. In fact, in the "MF-plus-ideal-entropy" formulation, solids and liquids are treated in the same way: terminal solid solutions, compounds, and liquids are represented by similar black-box free energy curves, and the lowest set of common tangents are constructed at each temperature to generate the phase diagram.

With such a simple technique available, which generally produces formally satisfactory results, why go any further?

There are several reasons to perform more extensive calculations: (1) the MF method often overestimates the configurational entropy and enthalpy contributions; (2) the method often produces qualitatively incorrect results, particularly where ordering phenomena are concerned (de Fontaine, 1979); (3) short-range order (SRO) cannot be taken into account; and (4) the CALPHAD method cannot make thermodynamic predictions based on "atomistics." Hence, a much more elaborate microscopic theory is required for the purpose of calculating *ab initio* phase diagrams.

To set up such a formalism, on the atomic scale, one must first define a reference lattice or structure: face-centered cubic (fcc), body-centered cubic (bcc), or hexagonal close-packed (hcp), for example. The much more difficult case of liquids has not yet been worked out; also, for simplicity, only binary alloys (A-B) will be considered here. At each lattice site (p), define a spinlike configurational operator σ_p equal to +1 if an atom of type A is associated with it, -1 if B. At each site, also attach a (three-dimensional) vector $\mathbf{u}_p$ that describes the displacement (static or dynamic) of the atom from its ideal lattice site. For given configuration $\boldsymbol{\sigma}$ (a boldfaced $\boldsymbol{\sigma}$ indicates a vector of N $\sigma_p = \pm 1$ components, representing the given configuration in a supercell of N lattice sites), an appropriate Hamiltonian is then constructed, and the energy E is calculated at $T = P = 0$ by quantum mechanics. In principle, this program has to be carried out for a variety of supercell configurations, lattice parameters, and internal atomic displacements; then configurational averages are taken at given T and P to obtain expectation values of appropriate thermodynamic functions, in particular the free energy. Such calculations must be repeated for all competing crystalline phases, ordered or disordered, as a function of average concentration x, and lowest tangents constructed at various temperatures and (usually) at $P = 0$. As described, this task is an impossible one, so that rather drastic approximations must be introduced, such as using a variational principle instead of the correct partition function procedure to calculate the free energy and/or using a Hamiltonian based on semiempirical potentials. The first of these approximation methods—derivation of a variational method for the free energy, which is at the heart of the cluster variation method (CVM; Kikuchi, 1951)—is presented here.

The exact free energy F of a thermodynamic system is given by

$$f = -k_B T \ln Z \tag{10}$$

with partition function

$$Z = \sum_{\text{states}} e^{-E(\text{state})/k_B T} \tag{11}$$

The sum over states in Equation 11 may be partially decoupled (Ceder, 1993):

$$Z \Rightarrow \sum_{\{\sigma\}} e^{-E_{\text{stat}}(\sigma)/k_B T} \sum_{\text{dyn}} e^{-E_{\text{dyn}}(\sigma)/k_B T} \tag{12}$$

where

$$E_{\text{stat}}(\sigma) = E_{\text{repl}}(\sigma) + E_{\text{displ}}(\sigma) \tag{13}$$

represents the sum of a replacive and a displacive energy. The former is the energy that results from the rearrangements of types of atoms, still centered on their associated lattice sites; this energy contribution has also been called "ordering," "ideal," "configurational," or "chemical." The displacive energy is associated with static atomic displacements. These displacements themselves may produce volume effects, or change in the volume of the unit cell; cell-external effects, or change in the shape of the unit cell at constant volume; and cell-internal effects, or relaxation of atoms inside the unit cell away from their ideal lattice positions (Zunger, 1994). The sums over dynamical degrees of freedom may be replaced by Boltzmann factors of the type $F_{\text{dyn}}(\sigma) = E_{\text{dyn}}(\sigma) - TS_{\text{dyn}}$ to obtain finally a new partition function

$$Z = \sum_{\{\sigma\}} e^{-\Psi(\sigma)/k_B T} \tag{14}$$

with "hybrid" energy

$$\Psi(\sigma) = E_{\text{repl}}(\sigma) + E_{\text{displ}}(\sigma) + F_{\text{dyn}}(\sigma) \tag{15}$$

Even when considering the simplest case of leaving out static displacive and dynamical effects, and writing the replacive energy as a sum of nn pair interactions, this Ising model is impossible to "solve" in three dimensions: i.e., the summation in the partition function cannot be expressed in closed form. One must resort to Monte Carlo simulation or to variational solutions. To these several energies will correspond entropy contributions, particularly a configurational entropy associated with the replacive energy and a vibrational entropy associated with dynamical displacements.

Consider the configurational entropy. The idea of the CVM is to write the partition function not as a sum over all possible configurations but as a sum over selected cluster probabilities ($\mathbf{x}$) for small groups of atoms occupying the sites of 1-, 2-, 3-, 4-, many-point clusters; for example:

$$\{\mathbf{x}\} = \begin{cases} x_A, x_B & \text{points} \\ x_{AA}, x_{AB} & \text{pairs} \\ x_{AAA}, x_{AAB} & \text{triplets} \\ x_{AAAA} & \text{quads} \end{cases} \tag{16}$$

The transformation

$$Z = \sum_{\{\sigma\}} e^{-E(\sigma)/k_B T} \Rightarrow \sum_{\{\mathbf{x}\}} g(\mathbf{x}) e^{-E(\mathbf{x})/k_B T} = \sum_{\{\mathbf{x}\}} e^{-F(\mathbf{x})/k_B T} \tag{17}$$

introduces the "complexion" $g(\mathbf{x})$, or number of ways of creating configurations having the specified values of pair, triplet, ... probabilities $\mathbf{x}$. there corresponds a configurational entropy

$$S(\mathbf{x}) = k_B \log g(\mathbf{x}) \tag{18}$$

hence, a free energy $F = E - TS$, which is the one that appears in Equation 17. The optimal variational free energy is then obtained by minimizing $F(\mathbf{x})$ with respect to the selected set of cluster probabilities and subject to consistency constraints. The resulting $F(\mathbf{x}^*)$, with $\mathbf{x}^*$ being the values of the cluster probabilities at the minimum of $F(\mathbf{x})$, will be equal to or larger than the true free energy, hopefully close enough to the true free energy when an adequate set of clusters has been chosen.

Kikuchi (1951) gave the first derivation of the $g(\mathbf{x})$ factor for various cluster choices, which was followed by the more algebraic derivations of Barker (1953) and Hijmans and de Boer (1955). The simplest cluster approximation is of course that of the point, i.e., that of using only the lattice point as a cluster. The symbolic formula for the complexion in this approximation is

$$g(\mathbf{x}) = \frac{N!}{\{\bullet\}} \tag{19}$$

with the "Kikuchi symbol" (for binaries and for a single sublattice) defined by

$$\{\bullet\} = \prod_{I=A,B} (x_I N)! \tag{20}$$

The logarithm of $g(\mathbf{x})$ is required in the free energy, and it is seen, by making use of Stirling's approximation, that the entropy, calculated from Equations 19 and 20, is just the ideal entropy given in Equation 7. Thus the MF entropy is identical to the CVM point approximation.

To improve the approximation, it is necessary to go to higher clusters, pairs, triplets (triangles), quadruplets (tetrahedron, ...), and so on. Frequently used approximations for larger clusters are given in Figure 7, where the Kikuchi symbols now include pair, triplet, quadruplet, ..., cluster concentrations, as in Equation 16, instead of the simple x_I of Equation 20. The first panel (top left) shows the pair formula for the linear chain with nn interaction. This simplest of Ising models is treated exactly in this formulation. The extension of the entropy pair formula to higher-dimensional lattices is given in the top right panel, with ω being half the nn coordination number. The other formulas give better approximations; in fact, the "tetrahedron" formula is the lowest one that will treat ordering properly in fcc lattices. The octahedron-tetrahedron formula (Sanchez and de Fontaine, 1978) is more useful

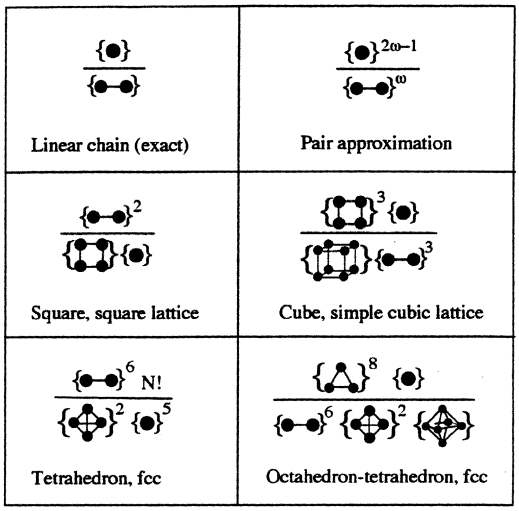

Figure 7. Various CVM approximations in the symbolic Kikuchi notation.

and more accurate for ordering on the fcc lattice because it contains next-nearest-neighbor (nnn) pairs, which are important when considering associated effective pair interactions (see below). Today, CVM entropy formulas can be derived "automatically" for arbitrary lattices and cluster schemes by computer codes based on group theory considerations. The choice of the proper cluster scheme to use is not a simple matter, although there now exist heuristic methods for selecting "good" clusters (Vul and de Fontaine, 1993; Finel, 1994).

The realization that configurational entropy in disordered systems was really a many-body thermodynamic expression led to the introduction of cluster probabilities in free energy functionals. In turn, cluster variables led to the development of a very useful cluster algebra, to be described very briefly here [see the original article (Sanchez et al., 1984) or various reviews (e.g., de Fontaine, 1994) for more details]. The basic idea was to develop complete orthonormal sets of cluster functions for expanding arbitrary functions of configurations, a sort of Fourier expansion for disordered systems. For simplicity, only binary systems will be considered here, without explicit consideration of sublattices. As will become apparent, the cluster algebra applied to the replacive (or configurational) energy leads quite naturally to a precise definition of effective cluster interactions, similar to the phenomenological w parameters of MF equations 8 and 9. With such a rigorous definition available, it will be in principle possible to calculate those parameters from "first principles," i.e., from the knowledge of only the atomic numbers of the constituents.

Any function of configuration $f(\boldsymbol{\sigma})$ can be expanded in a set of cluster functions as follows (Sanchez et al., 1984):

$$f(\sigma) = \sum_{\alpha} F_\alpha \Phi_\alpha(\sigma) \tag{21}$$

where the summation is over all clusters of lattice points (α designating a cluster of n_α points of a certain geometrical type: tetrahedron, square, ...), F_α are the expansion coefficients, and the Φ_α are suitably defined cluster functions. The cluster functions may be chosen in an infinity of ways but must form a complete set (Asta et al., 1991; Wolverton et al., 1991a; de Fontaine et al., 1994). In the binary case, the cluster functions may be chosen as products of σ variables ($= \pm 1$) over the cluster sites. The sets may even be chosen orthonormal, in which case the expansion (Equation 21) may be "inverted" to yield the cluster coefficients

$$F_\alpha = \rho_0 \sum_{\sigma} f(\sigma)\Phi_\alpha(\sigma) \equiv \langle \Phi_\alpha, f \rangle \tag{22}$$

where the summation is now over all possible 2^N configurations and ρ_0 is a suitable normalization factor. More general formulations have been given recently (Sanchez, 1993), but these simple formulas, Equations 21 and 22, will suffice to illustrate the method. Note that the formalism is exact and moreover computationally useful if series convergence is sufficiently rapid. In turn, this means that the burden and difficulty of treating disordered systems can now be carried by the determination of the cluster coefficients F_α. An analogy may be useful here: in solving linear partial differential equations, for example, one generally does not "solve" directly for the unknown function; one instead describes it by its representation in a complete set of functions, and the burden of the work is then carried by the determination of the coefficients of the expansion.

The most important application of the cluster expansion formalism is surely the calculation of the configurational energy of an alloy, though the technique can also be used to obtain such thermodynamic quantities as molar volume, vibrational entropy, and elastic moduli as a function of configuration. In particular, application of Equation 21 to the configurational energy E provides an exact expression for the expansion coefficients, called effective cluster interactions, or ECIs, V_α. In the case of pair interactions (for lattice sites p and q, say), the effective pair interaction is given by

$$V_{pq} = \tfrac{1}{4}(\bar{E}_{\mathrm{AA}} + \bar{E}_{\mathrm{BB}} - \bar{E}_{\mathrm{AB}} - \bar{E}_{\mathrm{BA}}) \tag{23}$$

where $\bar{E}_{IJ}$ ($I, J =$ A or B) is the average energy of all configurations having atom of type I at site p and of type J at q. Hence, it is seen that the V_α parameters, those required by the Ising model thermodynamics, are by no means "pair potentials," as they were often referred to in the past, but differences of energies, which can in fact be calculated. Generalizations of Equation 23 can be obtained for multiplet interactions such as V_{pqr} as a function of AAA, AAB, etc., average energies, and so on.

How, then, does one go about calculating the pair or cluster interactions in practice? One method makes use of the orthogonality property explicitly by calculating the average energies appearing in Equation 23. To be sure, not all possible configurations $\boldsymbol{\sigma}$ are summed over, as required by Equation 22, but a sampling is taken of, say, a few tens of configurations selected at random around a given IJ

pair, for instance, in a supercell of a few hundreds of atoms. Actually, there is a way to calculate directly the difference of average energies in Equation 23 without having to take small differences of large numbers, using what is called the method of direct configurational averaging, or DCA (Dreyssé et al., 1989; Wolverton et al., 1991b, 1993; Wolverton and Zunger, 1994). It is unfortunately very computer intensive and has been used thus far only in the tight binding approximation of the Hamiltonian appearing in the Schrödinger equation (see Electronic Structure Calculations section).

A convenient method of obtaining the ECIs is the structure inversion method (SIM), also known as the Connolly-Williams method after those who originally proposed the idea (Connolly and Williams, 1983). Consider a particular configuration $\boldsymbol{\sigma}_s$, for example, that of a small unit-cell ordered structure on a given lattice. Its energy can be expanded in a set of cluster functions as follows:

$$E(\sigma_s) = \sum_{r=1}^{n} m_r V_r \bar{\Phi}_r(\boldsymbol{\sigma}_s) \qquad (s = 1, 2, \ldots, q) \tag{24}$$

where $\bar{\Phi}_r(\boldsymbol{\sigma}_s)$ are cluster functions for that configuration averaged over the symmetry-equivalent positions of the cluster of type r, with m_r being a multiplicity factor equal to the number of r-clusters per lattice point. Similar equations are written down for a number (q) of other ordered structures on the same lattice. Usually, one takes $q > n$. The (rectangular) linear system (Equation 24) can then be solved by singular-value decomposition to yield the required ECIs V_r. Once these parameters have been calculated, the configurational energy of any other configuration, τ, on a supercell of arbitrary size can be calculated almost trivially:

$$E(\tau) = \sum_{s=1}^{q} C_s(\tau) E(\boldsymbol{\sigma}_s) \tag{25}$$

where the coefficients C_s may be obtained (symbolically) as

$$C_s(\tau) = \sum_{r=1}^{n} \bar{\Phi}_r^{-1}(\boldsymbol{\sigma}_s) \bar{\Phi}_r(\tau) \tag{26}$$

where $\bar{\Phi}_r^{-1}$ is the (generalized) inverse of the matrix of averaged cluster functions. The upshot of this little exercise is that, according to Equation 5, the energy of a large-unit-cell structure can be obtained as a linear combination of the energies of small-unit-cell structures, which are presumably easy to compute (e.g., by electronic structure calculation). So what about electronic structure calculations? The Electronic Structure Calculations section gives a quick overview of standard techniques in the "alloy theory" context, but before getting to that, it is worth considering the difference that the CVM already makes, compared to the MF approximation, in the calculation of a prototype "ordering" phase diagram.

Cluster Expansion Free Energy

Thermodynamic quantities are macroscopic ones, actually expectation values of microscopic ones. For the energy, for example, the expectation value $\langle E \rangle$ is needed in cluster-expanded form. This is achieved by taking the ensemble average of the general cluster expansion formula (Equation 22) to obtain, per lattice point,

$$\langle E(\boldsymbol{\sigma}) \rangle \sum_{\alpha} V_\alpha \xi_\alpha \tag{27}$$

with correlation variables defined by

$$\xi_\alpha = \langle \Phi_\alpha(\sigma) \rangle = \langle \sigma_1 \sigma_2 \ldots \sigma_{n_\alpha} \rangle \tag{28}$$

the latter equality being valid for binary systems. The entropy, already an averaged quantity, is expressed in the CVM by means of cluster probabilities $\mathbf{x}_\alpha$. These probabilities are related linearly to the correlation variables ξ_α by means of the so-called configuration matrix (Sanchez and de Fontaine, 1978), whose elements are most conveniently calculated by group theory computer codes. The required CVM free energy is obtained by combining energy (27) and entropy (18) contributions and using Stirling's approximation for the logarithm of the factorials appearing in the $g(\mathbf{x})$ expressions such as those illustrated in Figure 7, for example,

$$f \equiv f(\xi_1, \xi_2, \ldots) = \sum_r m_r V_r \xi_r - k_B T \sum_{k=1}^{K} m_k \gamma_k \times \sum_{\alpha_k} x_k(\sigma_k) \ln x_k(\sigma_k) \tag{29}$$

where the indices r and k denote sequential ordering of the clusters used in the expansion, K being the order of the largest cluster retained, and where the second summation is over all possible A/B configurations $\boldsymbol{\sigma}_k$ of cluster k. The correlations ξ_r are linearly independent variational parameters for the problem at hand, which means that the best choice for the correct free energy for the cluster approximation adopted is obtained by minimizing Equation 29 with respect to ξ_r. The γ_k coefficients in the entropy expression are the so-called Kikuchi-Barker coefficients, equal to the exponents of the Kikuchi symbols found in the symbolic formulas of Figure 7, for example. Minimization of the free energy (Equation 29) leads to systems of simultaneous algebraic equations (sometimes as many as a few hundred) in the ξ_r. This task greatly limits the size of clusters that can be handled in practice.

The CVM (Equation 29) and MF (Equation 9) free energy expressions look very different, raising the question of whether they are related to one another. They are, in the sense that the MF free energy must be the infinite-temperature limit of the CVM free energy. At high temperatures all correlations must disappear, which means that one can write the ξ_r as powers of the "point" correlations ξ_1. Since ξ_1 is equal to $2x - 1$, the energy term in Equation 29 is transformed, in the MF approximation, to a polynomial in x ($= x_B$, the average concentration of the B component). This is precisely the type of expression used by the CALPHAD group for the enthalpy, as mentioned above (see Mean-Field Approach). In the MF

limit, products of x_A and x_B must also be introduced in the cluster probabilities appearing in the configurational entropy. It is found that, for any cluster probability, the logarithmic terms in Equation 29 reduce to $n[x_A \log x_A + x_B \log x_B]$, precisely the MF (ideal) entropy term in Equation 7 multiplied by the number n of points in the cluster, thereby showing that the sum of the Kikuchi-Barker coefficients, weighted by n, must equal -1. This simple property may be used to verify the validity of a newly derived CVM entropy expression; it also shows that the type, or shape, of the clusters is irrelevant to the MF model, as only the number of points matters. This is another demonstration that the MF approximation ignores the true geometry of local atomic arrangements.

Note that, strictly speaking, the CVM is also a MF formalism, but it treats the correlations (almost) correctly for lattice distances included within the largest cluster considered in the approximation and includes SRO effects. Hence the CVM is a multisite MF model, whereas the "point" MF is a single-site model, the one previously referred to as the MF (ideal, regular solution, GBW, concentration wave, etc.) model.

It has been seen that the MF model is the same as the CVM point approximation, and the MF free energy can be derived by making the superposition ansatz, $x_{AB} \rightarrow x_A x_B$, $x_{AAB} \rightarrow x_A^2 x_B$, and so on. Of course, the point is very much simpler to handle than the "cluster" formalism. So how much is lost in terms of actual phase diagram results in going from MF to CVM? To answer that question, it is instructive to consider a very striking yet simple example, the case of ordering on the fcc lattice with only first-neighbor effective pair interactions (de Fontaine, 1979). The MF phase diagram of Figure 8A was constructed by the GBW MF approximation (Shockley, 1938), that of Figure 8B by the CVM in the tetrahedron approximation, whose symbolic formula is given in Figure 7 (de Fontaine, 1979, based on van Baal, 1973, and Kikuchi, 1974). It is seen that, even in a topological sense, the two diagrams are completely different: the GBW diagram (only half of the concentration axis is represented) shows a double second-order transition at the central composition ($x_B = 0.5$), whereas the CVM diagram shows three first-order transitions for the three ordered phases A_3B, AB_3 ($L1_2$-type ordered structure), and AB ($L1_0$). The short horizontal lines in Figure 8B are tie lines, as seen in Figure 1. The two very small three-phase regions are actually peritectic-like, topologically, as in Figure 1B.

There can be no doubt about which prototype diagram is correct, at least qualitatively: the CVM version, which in turn is very similar to the solid-state portion of the experimental Cu-Au phase diagram (Massalski, 1986; in this particular case, the first edition is to be preferred). The large discrepancy between the MF and CVM versions arises mainly from the basic geometrical figure of the fcc lattice being the nn equilateral triangle (and the associated nn tetrahedron). Such a figure leads to frustration where, as in this case, the first nn interaction favors unlike atomic pairs. This requirement can be satisfied for two of the nn pairs making up the triangle, but the third pair must necessarily be a "like" pair, hence the conflict. This frustration also lowers the transition temperature below

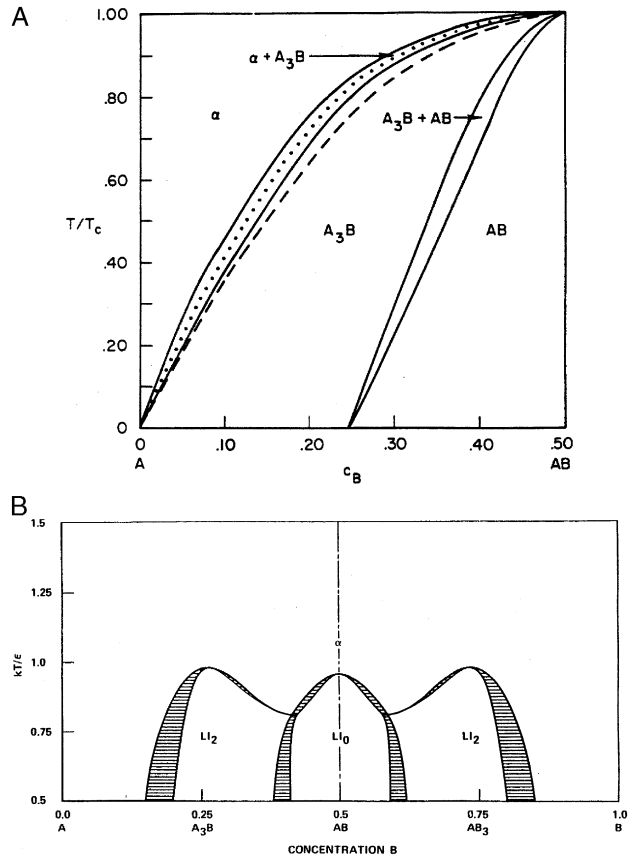

Figure 8. (**A**) Left half of fcc ordering phase diagram (full lines) with nn pair interactions in the GBW approximation; from de Fontaine (1979), according to W. Shockley (1938). Dotted and dashed lines are, respectively, loci of equality of free energies for disordered and ordered A_3B ($L1_2$) phases (so-called T_0 line) and ordering spinodal (not used in this unit). (**B**) The fcc ordering phase diagram with nn pair interactions in the CVM approximation; from de Fontaine (1979), according to C.M. van Baal (1973) and R. Kikuchi (1974).

what it would be in nonfrustrated systems. The cause of the problem with the MF approach is of course that it does not "know about" the triangle figure and the frustrated nature of its interactions. Numerically, also, the CVM configurational entropy is much more accurate than the GBW (MF), particularly if higher-cluster approximations are used.

These are not the only reasons for using the cluster approach: the cluster expansion provides a rigorous formulation for the ECI; see Equation 23 and extensions thereof. That means that the ECIs for the replacive (or strictly configurational) energy can now be considered not only as fitting parameters but also as quantities that can be rigorously calculated *ab initio*. Such atomistic computations are very difficult to perform, as they involve electronic structure calculations, but much progress has been realized in recent years, as briefly summarized in the next section.

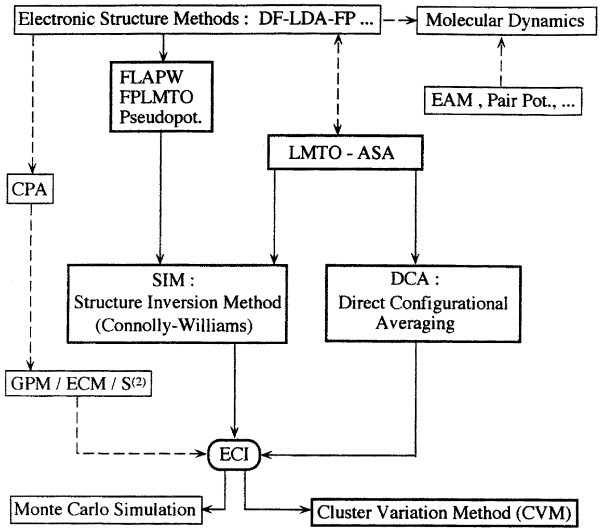

Figure 9. Flow chart for obtaining ECI from electronic structure calculations. Pot ≡ potentials.

Electronic Structure Calculations

One of most important breakthroughs in condensed-matter theory occurred in the mid-1960s with the development of the (exact) density functional theory (DFT) and its local density approximation (LDA), which provided feasible means for performing large-scale electronic structure calculations. It then took almost 20 years for practical and reliable computer codes to be developed and implemented on fast computers. Today many fully developed codes are readily accessible and run quite well on workstations, at least for moderate-size applications. Figure 9 introduces the uninitiated reader to some of the alphabet soup of electronic structure theory relevant to the subject at hand.

What the various methods have in common is solving the Schrödinger equation (sometimes the Dirac equation) in an electronically self-consistent manner in the local density approximation. The methods differ from one another in the choice of basis functions used in solving the relevant linear differential equation—augmented plane waves [(A)PW], muffin tin orbitals (MTOs), atomic orbitals in the tight binding (TB) method—generally implemented in a non-self-consistent manner. The methods also differ in the approximations used to represent the potential that an electron sees in the crystal or molecule, F or FP, designating "full potential." The symbol L designates a linearization of the eigenvalue problem, a characteristic not present in the "multiple-scattering" KKR (Korringa-Kohn-Rostocker) method. The atomic sphere approximation (ASA) is a very convenient simplification that makes the LMTO-ASA (linear muffin tin orbital in the ASA) a particularly efficient self-consistent method to use, although not as reliable in accuracy as the full-potential methods. Another distinction is that pseudopotential methods define separate "potentials" for $s, p, d, \ldots$, valence states, whereas the other self-consistent techniques are "all-electron" methods. Finally, note that plane-wave basis methods (pseudopotential, FLAPW) are the most convenient ones to use whenever forces on atoms need to be calculated. This is an important consideration as correct cohesive energies require that total energies be minimized with respect to lattice "constants" and possible local atomic displacements as well.

There is not universal agreement concerning the definition of "first-principles" calculations. To clarify the situation, let us define levels of *ab initio* character:

First level: Only the z values (atomic numbers) are needed to perform the electronic structure calculation, and electronic self-consistency is performed as part of the calculation via the density functional approach in the LDA. This is the most fundamental level; it is that of the APW, LMTO, and *ab initio* pseudopotentials. One can also use semiempirical pseudopotentials, whose parameters may be fitted partially to experimental data.

Second level: Electronic structure calculations are performed that do not feature electronic self-consistency. Then the Hamiltonian must be expressed in terms of parameters that must be introduced "from the outside." An example is the TB method, where indeed the Schrödinger equation is solved (the Hamiltonian is diagonalized, the eigenvalues summed up), and the TB parameters are calculated separately from a level 1 formulation, either from LMTO-ASA, which can give these parameters directly (hopping integrals, on-site energies) or by fitting to the electronic band structure calculated, for example, by a level 1 theory. The TB formulation is very convenient, can treat thousands of atoms, and often gives valuable band structure energies. Total energies, for which repulsive terms must be constructed by empirical means, are not straightforward to obtain. Thus, a typical level 2 approach is the combined LMTO-TB procedure.

Third level: Empirical potentials are obtained directly by fitting properties (cohesive energies, formation energies, elastic constants, lattice parameters) to experimentally measured ones or to those calculated by level 1 methods. At level 3, the "potentials" can be derived in principle from electronic structure but are in fact (partially) obtained by fitting. No attempt is made to solve the Schrödinger equation itself. Examples of such approaches are the embedded-atom method (EAM) and the TB method in the second-moment approximation (references given later).

Fourth level: Here the interatomic potentials are strictly empirical and the total energy, for example, is obtained by summing up pair energies. Molecular dynamics (MD) simulations operate with fourth- or third-level approaches, with the exception of the famous Car-Parrinello method, which performs *ab initio* molecular dynamics, combining MD with the level 1 approach.

In Figure 9, arrows emanate from electronic structure calculations, converging on the ECIs, and then lead to Monte Carlo simulation and/or the CVM, two forms of statistical thermodynamic calculations. This indicates the central role played by the ECIs in "first-principles thermodynamics." Three main paths lead to the ECIs: (a) DCA, based on the explicit application of Equations 22 and 23; (b) the SIM, based on solution of the linear system 24; and (c) methods based on the CPA (coherent potential approximation). These various techniques are described in some detail elsewhere (de Fontaine, 1994), where

original literature is also cited. Points that should be noted here are the following: (a) the DCA, requiring averaging over many configurations, has been implemented thus far only in the TB framework with TB parameters derived from the LMTO-ASA; (b) the SIM energies $E(\sigma_s)$ required in Equations 24 and 25 can be calculated in principle by any LDA method one chooses—FLAPW (Full-potential Linear APW), pseudopotentials, KKR, FPLMTO (Full-potential Linear MTO), or LMTO-ASA; and (c) the CPA, which creates an electronically self-consistent average medium possessing translational symmetry, must be "perturbed" in order to introduce short-range order through the general perturbation method (GPM) or embedded-cluster method (ECM) or $S^{(2)}$ method. The latter path (c), shown by dashed lines (meaning that it is not one trodden presently by most practitioners), must be implemented in electronic structure methods based on Green's function techniques, such as the KKR or TB methods. Another class of calculations is the very popular one of MD (also indicated in Fig. 9 by dashed arrow lines).

To summarize the procedure for doing first-principles thermodynamics, consider some paths in Figure 9. Start with an LDA electronic structure method to obtain cohesive or formation energies of a certain number of ordered structures on a given lattice; then set up a linear system as given by Equation 24 and solve it to obtain the relevant ECIs V_r. Or perform a DCA calculation, as required by Equation 22, by whatever electronic structure method appears feasible. Make sure that convergence is attained in the ECI computations; then insert these interaction parameters in an appropriate CVM free energy, minimize with respect to the correlation variables, and thereby obtain the best estimate of the free energy of the phase in question, ordered or disordered. A more complete description of the general procedure is shown in Figure 11 (see Ground-State Analysis section).

The DCA and SIM methods may appear to be quite different, but, in fact, in both cases, a certain number of configurations are being chosen: a set of random structures in the DCA, a set of small-unit-cell ordered structures in the SIM. The problem is to make sure that convergence has been attained by whatever method is used. It is clear that if all possible ordered structures within a given supercell are included, or if all possible "disordered" structures within a given cell are taken, and if the supercells are large enough, then the two methods will eventually sample the same set of structures. Which method is better in a particular case is mainly a question of convenience: the DCA generally uses small cells, the DCA large ones. The problem with the former is that certain low-symmetry configurations will be missed, and hence the description will be incomplete, which is particularly troublesome when displacements are to be taken into account. The trouble with the DCA is that it is very time consuming (to the point of being impractical) to perform first-principles calculations on large-unit-cell structures. There is no optimal panacea.

Ground-State Analysis

In the previous section, the computation of ECIs was discussed as if the only contribution to the energy was the strictly replacive one, as defined in Equations 13 and 15; yet it is clear from the latter equation that ECIs could in principle be calculated for the value of the combined function Ψ itself. For now, consider the ECIs limited to the replacive (or configurational, or Ising) energy, leaving for the next section a brief description of other contributions to the energy and free energy. In the present context, it is possible to break up the energy into different contributions. First of all it is convenient to subtract off the linear term in the total energy, according to the definition of Equation 4, applied here to E rather than to F, since only zero-temperature effects—i.e., ground-state energies—will be considered here. In Equation 4, the usual classical and MF notation was used; in the "cluster" world of the physics community it is customary to use the notation "formation energy" rather than "mixing energy," but the two are exactly the same. The symbol Δ will be used to emphasize the "difference" nature of the formation energy; it is by definition the total (replacive) energy minus the concentration-weighted average of the energies of the pure elements. This gives the following equation for binary systems:

$$F_{\text{mix}}(T=0) \equiv \Delta E_{\text{form}} = E - E_{\text{lin}} \equiv E - (x_{\text{A}}E_{\text{A}} + x_{\text{B}}E_{\text{B}}) \tag{30}$$

If the "linear" term in Equation 30 is taken as the reference state, then the formation energy can be plotted as a function of concentration for the hypothetical alloy A-B, as shown schematically in Figure 10 (de Fontaine, 1994). Three ordered structures (or compounds), of stoichiometry A_3B, AB, and AB_3, and only those, are assumed to be stable at very low temperatures, in addition to the pure elements A and B. The line linking those five structures forms the so-called convex hull (heavy polygonal line) for the system in question. The heavy dashed curve represents schematically the formation energy of the completely disordered state, i.e., the mixing energy of the hypothetical random state, the one that would have been obtained by a perfect

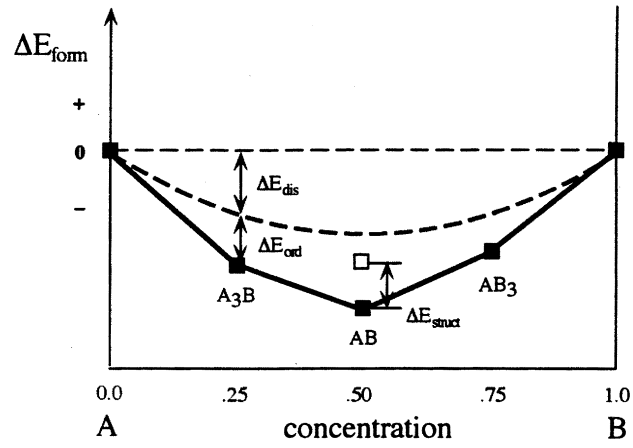

Figure 10. Schematic convex hull (full line) with equilibrium ground states (filled squares), energy of metastable state (open square), and formation energy of random state (dashed line); from de Fontaine (1994).

quench from a very high temperature state, assuming that no melting had taken place. The energy distance between the disordered energy of mixing and the convex hull is by definition the (zero-temperature) ordering energy. If other competing structures are identified, say the one whose formation energy is indicated by a square symbol in the figure, the energy difference between it and the one at the same stoichiometry (black square) is by definition the structural energy.

All the zero-temperature energies illustrated in Figure 10 can in principle be calculated by cluster expansion (CE) techniques, or, for the stoichiometric structures, by first-principles methods. The formation energy of the random state can be obtained by the cluster expansion

$$\Delta E_{\text{dis}} = \sum_{\alpha} V_{\alpha} \xi_1^{n_\alpha} \tag{31}$$

obtained from Equation 27 by replacing the correlation variable for cluster α by n_α times the point correlation ξ_1. Dissecting the energy into separate and physically meaningful contributions is useful when carrying out complex calculations.

Since the disordered-state energy in Figure 10 is a continuous curve, it necessarily follows that A and B must have the same structure and that the compounds shown can be considered as ordered superstructures, or "decorations," of the same parent structure, that of the elemental solids. But which decorations should one choose to construct the convex hull, and can one be sure that all the lowest-energy structures have been identified? Such questions are very difficult to answer in all generality; what is required is to "solve the ground-state problem". That expression can have various meanings: (1) among given structures of various stoichiometries, find the ones that lie on the true convex hull; (2) given a set of ECIs, predict the ordered structures of the parent lattice (or structure, such as hcp) that will lie on the convex hull; and (3) given a maximum range of interactions admissible, find all possible ordered ground states of the parent lattice and their domain of existence in ECI space. Problem (3) is by far the most difficult. It can be attacked by linear programming methods: the requirement that cluster concentration lie between 0 and 1 provides a set of linear constraints (via the configuration matrix, mentioned earlier) in the correlation variables, which are represented in ξ space by sets of hyperplanes. The convex polyhedral region that satisfies these constraints, i.e., the configuration polyhedron, has vertices that, in principle, have the correct ξ coordinates for the ground states sought. This method can actually predict totally new ground states, which one might never have guessed at. The problem is that sometimes the vertex determination produces ξ coordinates that do not correspond to any constructible structures—i.e., such coordinates are internally inconsistent with the requirement that the prediction will actually correspond to an actual decoration of the parent lattice. Another limitation of the method is that, in order to produce a nontrivial set of ground states, large clusters must often be used, and then the dimension of the ξ space gets too large to handle, even with the help of group theory–based computer codes (Ceder et al., 1994). Readers interested in this problem can do no better than to consult Ducastelle (1991), which also contains much useful information on the CVM, on electronic structure calculation (mostly TB based), and on the generalized perturbation method for calculating EPIs from electronic structure calculations. Another very readable coverage of ground-state problems is that given by Inden and Pitsch (1991), who also cover the derivation of multicomponent CVM equations. Accounts of the convex polyhedron method are also given in de Fontaine (1979, 1994).

Problem (2) is more tractable, since in this case the ECIs are assumed to be known, thereby determining the "objective function" of the linear programming problem. It is then possible to discover the corresponding vertex of the configurational polyhedron by use of the simplex algorithm. Problem (1) does not necessitate the knowledge or even use of the ECIs: the potentially competitive ordered structures are guessed at (in the words of Zunger, this amounts to "rounding up the usual suspects"), and direct calculations determine which of those structures will lie on the convex hull. In that case, however, the real convex hull structures may be missed altogether. Finally, it is also possible to set up a relatively large supercell and to populate it successively by all possible decoration of A and B atoms, then to calculate the energies of resulting structures by cluster expansion (Lu et al., 1991). There too, however, some optimal ordered structures may be missed, those whose unit cells will not fit exactly within the designated supercell.

Figure 11 summarizes the general method of calculating a phase diagram by cluster methods. The solution of the ground-state problem has presumably provided the correct lowest-energy ordered structures for a given parent lattice, which in turn determines the sublattices to consider. For each ordered structure, write down the CVM free energy, minimize it with respect to the configuration variables, then plot the resulting free energy curve. Now repeat these operations for another lattice, for which the required ordered states have been determined. Of course, when comparing structures on one parent lattice with another, it is necessary to know the structural energies involved, for example the difference between pure A and pure B in the fcc and bcc structures. Finally, as in the "classical" case, construct the lowest common tangents to all free energies present. Figure 11 shows schematically some ordered and disordered free energy curves at a given temperature, then at the lower panel the locus of common tangency points generating the required phase diagram, as illustrated for example in the MF approximation in Figure 5. The whole procedure is of course much more complicated than the classical or MF one, but consider what in principle is accomplished: with only the knowledge of the atomic numbers of the constituents, one will have calculated the (solid-state portion of the) phase diagram and also such useful thermodynamic quantities as the long-range, short-range order, equilibrium lattice parameters, formation and structural energies, bulk modulus (B), and metastable phase boundaries as a function of temperature and concentration. Note that calculations at a series of volumes must be performed in order to obtain quantities

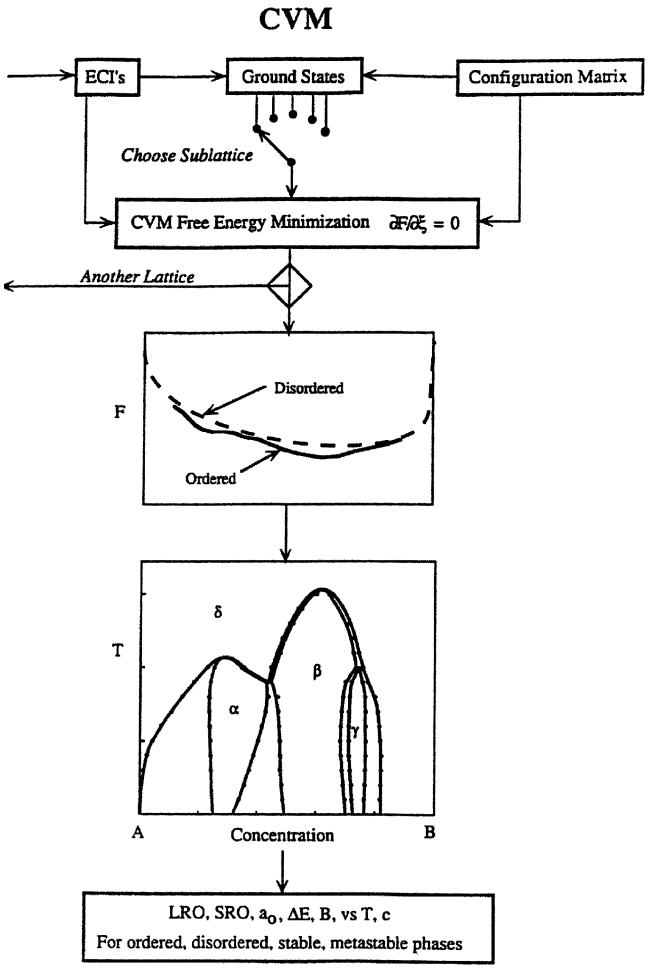

Figure 11. Flow chart for obtaining phase diagram from repeated calculations on different lattices and pertinent sublattices.

such as the equilibrium volume and the bulk modulus B. A summary of those binary and ternary systems for which the program had been at least partially completed up to 1994 was given in table form in de Fontaine (1994).

Up to now, only the strictly replacive (Ising) energy has been considered in calculating the ECIs. For simplicity, the other contributions, displacive and dynamic, that have been mentioned in previous sections have so far been left out of the picture, as indeed they often were in early calculations. It is now becoming increasingly clear that those contributions can be very large and, in case of large atomic misfit, perhaps dominant. The *ab initio* treatment of displacive interactions is a difficult topic, still being explored, and so will be summarized only briefly.

Static Displacive Interactions

In a review article, Zunger (1994) explained his views of displacive effects and stated that the only investigators who had correctly treated the whole set of phenomena, at least the static ones, were members of his group. At the time, this claim was certainly valid, indicating that far too little attention had been paid to this topic. Today, other groups have followed his lead, but the situation is still far from settled, as displacements, static and dynamic, are difficult to treat. It is useful (adopting Zunger's definitions) to examine in more detail the term E_{displ} which appears in Equations 13 and 15. From Equations 13, 15, and 30,

$$E = E_{\text{lin}} + E_{\text{stat}} = E_{\text{lin}} + \Delta E_{\text{VD}} + \Delta E_{\text{repl}} + \Delta E_{\text{def}} + \Delta E_{\text{relax}} \tag{32}$$

where E_{displ} of Equation 13 has been broken up into a volume deformation (VD) contribution, a "cell-external" deformation (ΔE_{def}), and a "cell-internal" deformation (relax). The various terms in Equation 32 are explained schematically on a simple square lattice in Figure 12 (Morgan et al., unpublished). From pure A and pure B on the same lattice but at their equilibrium volumes (the reference state E_{lin}), expand the smaller lattice parameter and contract that of the larger to a common intermediate parameter, assumed to be that of the homogeneous mixture, thus yielding the large contribution ΔE_{VD}. Now allow the atoms to rearrange at constant volume while remaining situated on the sites of the average lattice, thereby recovering energy ΔE_{repl}, discussed in the Basic Principles: Cluster Approach section under the assumption that only the "Ising energy" was contributing. Generally,

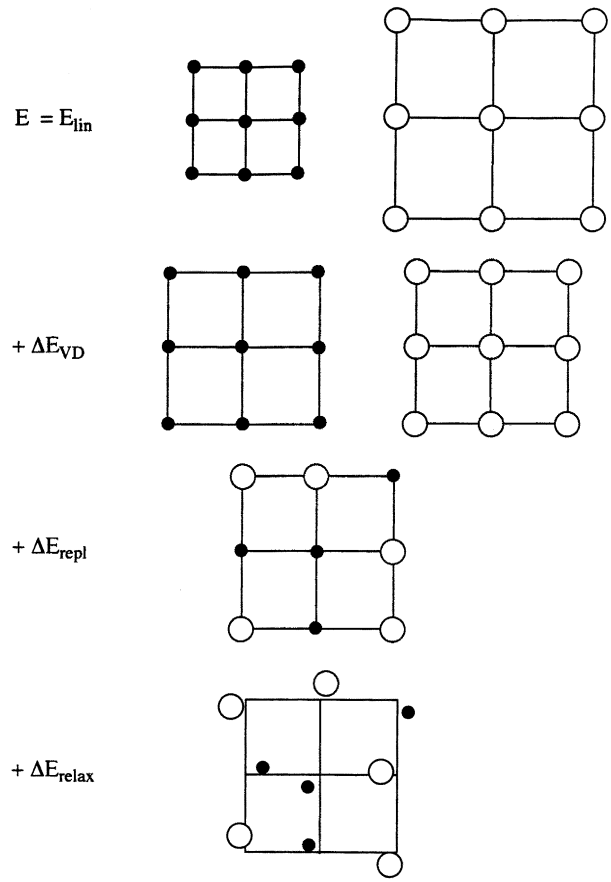

Figure 12. Schematic two-dimensional illustration of various energy contributions appearing in Equation 32; according to Morgan et al. (unpublished).

this atomic redistribution will lower the symmetry of the original states, so that the lattice parameters will extend or contract (such as c/a relaxation) and the cell angles vary at constant volume, a contribution denoted ΔE_{def} in Equation 32 but not indicated in Figure 12. Finally, the atoms may be displaced from their positions on the ideal lattice, producing a contribution denoted as ΔE_{relax}.

Equation 32 also indicates the order in which the calculations should be performed, given certain reasonable assumptions (Zunger, 1994; Morgan et al., unpublished). Actually, the cycle should be repeated until no significant atomic displacements take place. Such an iterative procedure was carried out in a strictly *ab initio* electronic structure calculation (FLMTO) by Amador et al. (1995) on the structures $L1_2$, $D0_{22}$, and $D0_{23}$ in Al_3Ti and Al_3Zr. In that case, the relaxation could be carried out without calculating forces on atoms simply by minimizing the energy, because the numbers of degrees of freedom available to atomic displacements were small. For more complicated unit cells of lower symmetry, minimizing the total energy for all possible types of displacements would be too time-consuming, so that actual atomic forces should be computed. For that, plane-wave electronic structure techniques are preferable, such as those given by FLAPW or pseudopotential codes.

Different techniques exist for calculating the various terms of Equation 32. The linear contribution E_{lin} requires only the total energies of the pure states and can generally be obtained in a straightforward way by electronic structure calculations. The volume deformation contribution is best calculated in a "classical" way, for instance by a method that Zunger has called the "ε-G" technique (Ferreira et al., 1988). If one makes the assumption that the equilibrium volume term depends essentially on the average concentration x, and not on the particular configuration $\boldsymbol{\sigma}$, then ΔE_{VD} can be generally approximated by the term $\Omega x(1-x)$, with Ω being a slowly varying function of x. The parameters of function Ω may also be obtained from electronic structure calculations (Morgan et al., unpublished). The "replacive" energy, which is the familiar "Ising" energy, can be calculated by cluster expansion techniques, as explained above, either in DCA or SIM mode. The cell-external deformation can also be obtained by electronic structure methods in which the lowest energy is sought by varying the cell parameters. Finally, various methods have been proposed to calculate the relaxation energy. One is to include the displacive and volume effects formally in the cluster expansion of the replacive term; this is done by using, as known energies $E(\sigma_s)$ in Equation 24 for the SIM, the energies of fully relaxed structures obtained from electronic structure calculations that can provide forces on atoms. This procedure can be very time consuming, as cluster expansions on relaxed structures generally converge more slowly than expansions dealing with strictly displacive effects. Also, if fairly large-unit-cell structures of low symmetry are not included in the SIM fit, the displacive effects may not get well represented. One may also define state functions (at zero kelvin) that are algebraic functions of atomic volume, c/a ratio (for hexagonal, tetragonal structures, ...), and so on, which, in a cluster expansion, will result in ECIs being functions of atomic volume, c/a ratio, etc. The resulting equilibrium energies may then be obtained by minimizing with respect to these displacive variables (Amador et al., 1995; Craievich et al., 1997). Not only energies but also free energies may thus be optimized, by minimizing the CVM free energy not only with respect to the ξ configuration variables but also with respect to volume, for instance, at various temperatures (Sluiter et al., 1989, 1990). This temperature dependence does not, however, take vibrational contributions into account (see Nonconfigurational Thermal Effects section).

Let us mention here the importance of calculating energies (or enthalpies) as a function of c/a, b/a ratios, ... at constant cell volume. It is possible, by a so-called Bain transformation, to go continuously from the fcc to the bcc structures, for example. Doing so is important not only for calculating structural energies, essential for complete phase diagram calculations, but also for ascertaining whether the higher-energy structures are metastable with respect to the ground state, or actually unstable. In the latter case, it is not permissible to use the standard CALPHAD extrapolation of phase boundaries (through extrapolation of empirical vibrational entropy functions) to obtain energy estimates of certain nonstable structures (Craievich et al., 1994). Other more general cell-external deformations have also been treated (Sob et al., 1997).

Elastic interactions, resulting from local relaxations, are characteristically long range. Hence, it is generally not feasible to use the type of cluster expansion described above (see Cluster Approach section), since very large clusters would be required in the expansion and the number of correlation variables required would be too large to handle. One successful approach is that of Zunger and collaborators (Zunger, 1994), who developed a k-space SIM with effective pair interactions calculated in Fourier space. One novelty of this approach is that the Fourier transformations feature a smoothing procedure, essential for obtaining reasonably rapid convergence; another is that of subtracting off the troublesome $k=0$ term by means of a concentration-dependent function. Previous Fourier space treatments were based on second-order expansions of the relaxation energy in terms of atomic displacements and so-called Kanzaki forces (de Fontaine, 1979; Khachaturyan, 1983)—the latter calculated by heuristic means, from the EAM (Asta and Foiles, 1996), or from an nn "spring model" (Morgan et al., unpublished).

Another option for taking static displacive effects into account is to use brute-force computer simulation techniques, such as MD or molecular statics. The difficulty here is that first-principles electronic structure methods are generally too slow to handle the millions of MD steps generally required to reach equilibrium over a sufficiently large region of space. Hence, empirical potentials, such as those provided by the EAM (Daw et al., 1993), are required. The vast literature that has grown up around these simulation techniques is too extensive to review here; furthermore, these methods are not particularly well suited to phase-diagram calculations, mainly because the average frequency for "hopping" (atomic interchange, or "replacement") is very much slower than that for atomic vibrations. Nonetheless, simulation techniques do have an

important role to play in dynamical effects, which are discussed below.

Nonconfigurational Thermal Effects

Mostly zero kelvin contributions described in the previous sections dealt only with configurational free energy. As was explained, the latter can be dealt with by the cluster variation method, which basically features a cluster expansion of the configurational entropy, Equation 29. But even there, there are difficulties: How does one handle long-range interactions, for example those coming from relaxation interactions? It has indeed been found that, in principle, all interactions needed in the energy expansion (Equation 27) must appear as clusters or subclusters of a maximal cluster appearing in the CVM configurational entropy. But, as mentioned before, the number of variables associated with large clusters increases exponentially with the number of points in the clusters: one faces a veritable "combinatorial explosion." One approximate and none-too-reliable solution is to treat the long-pair interactions by the GBW (superposition, MF) model.

A more fundamental question concerns the treatment of vibrational entropy, thermal expansion, and other excitations, such as electronic and magnetic ones. First, consider how the static and dynamic displacements can be entered in the CVM framework. Several methods have been proposed; in one of these (Kikuchi and Masuda-Jindo, 1997), the CVM free energy variables include continuous displacements, and summations are replaced by integrals. For computational reasons, though, the space is then discretized, leading to separate cluster variables at each point of the fine-mesh lattice thus introduced. Practically, this is equivalent to treating a multicomponent system with as many "components" as there are discrete points considered about each atom. Only model systems have been treated thus far, mainly containing one (real) component. In another approach, atomic positions are considered to be Gaussian distributed about their static equilibrium locations. Such is the "Gaussian CVM" of Finel (1994), which is simpler but somewhat less general than that of Kikuchi and Masuda-Jindo (1997). Again, mostly dynamic displacements have been considered thus far. One can also perform cluster expansions of the Debye temperature in a Debye-Grüneisen framework (Asta et al., 1993a) or of the average value of the logarithm of the vibrational frequencies (Garbulsky and Ceder, 1994) of selected ordered structures.

As for treating vibrational free energy along with the configurational one, it was originally considered sufficient to include a Debye-Grüneisen correction for each of the phases present (Sanchez et al., 1991). It has recently been suggested (Anthony et al., 1993; Fultz et al., 1995; Nagel et al., 1995), based on experimental evidence, that the vibrational entropy difference between ordered and disordered states could be quite large, in some cases comparable to the configurational one. This was a surprising result indeed, which perhaps could be explained away by the presence of numerous extended defects introduced by the method of preparation of the disordered phases, since in defective regions vibrational entropy would tend to be higher. Several quasiharmonic calculations were recently undertaken to test the experimental values obtained in the Ni_3Al system; one based on the Finnis-Sinclair (FS) potential (Ackland, 1994) and one based on EAM potentials (Althoff, 1977a,b). These studies gave results agreeing quite well with experimental values (Anthony et al., 1993; Fultz et al., 1995; Nagel et al., 1995) and with each other, namely, $\Delta S_{vib} = \sim 0.2k_B$ versus $0.2k_B$ to $0.3k_B$ reported experimentally. Integrated thermodynamic quantities obtained from EAM-based calculations, such as the isobaric specific heat (C_p), agree very well with available evidence for the $L1_2$ ordered phase (Kovalev et al., 1976). Figure 13 compares experimental (open circles) and calculated (curve) C_p values as a function of absolute temperature. The agreement is excellent at low temperature ranges, but the experimental points begin to deviate from the theoretical curve at ~900 K, when configurational entropy—which is not included in the present calculation—becomes important. At still higher temperatures, the quasiharmonic approximation may also introduce errors. Note that in the EAM and FS approaches, the disordered-state structures were fully relaxed (via molecular statics) and the temperature dependence of the atomic volume (by minimization of the quasiharmonic vibrational free energy) of the disordered state was fully taken into account. What is to be made of this? If the empirical potential results are valid, and so the experimental ones are as well, that means that vibrational entropy, usually neglected in the past, can play an important role in some phase diagram calculations and should be included. Still, more work is required to confirm both experimental and theoretical results.

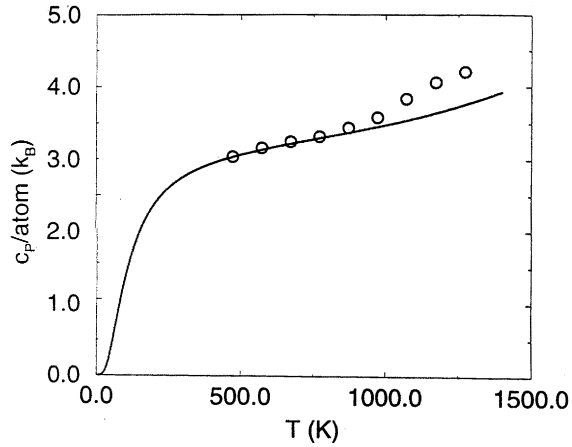

Figure 13. Isobaric specific heat as a function of temperature for ordered Ni_3Al as calculated in the quasiharmonic approximation (curve, Althoff et al., 1997a,b) and as experimentally determined (open circles, Kovalev et al., 1976).

Other contributing influences to be considered could be those of electronic and magnetic degrees of freedom. For the former, the reader should consult the paper by Wolverton and Zunger (1995). For the latter, an example of a "fitted" phase-diagram calculation with magnetic interactions will be presented in the Examples of Applications section.

EXAMPLES OF APPLICATIONS

The section on Cluster Expansion Free Energy showed a comparison between prototype fcc ordering in MF and CVM approaches. This section presents applications of various types of calculations to real systems in both fitted and first-principles schemes.

Aluminum-Nickel: Fitted, Mean-Field, and Hybrid Approaches

A very complete study of the Al-Ni phase diagram has been undertaken recently by Ansara and co-workers (1997). The authors used a CALPHAD method, in the so-called sublattice model, with parameters derived from an optimization procedure using all available experimental data, mostly from classical calorimetry but also from electromotive force (emf) measurements and mass spectrometry. Experimental phase boundary data and the assessed phase diagram are shown in Figure 14A, while the "modeled" diagram is shown in Figure 14B. The agreement is quite impressive, but of course it is meant to be so. There have also been some cluster/first-principles calculations for this system, in particular a full determination of the equilibrium phase diagram, liquid phase included, by Pasturel et al. (1992). In this work, the liquid free energy curve was obtained by CVM methods as if the liquid were an fcc crystal. This approach may sound incongruous but appears to work. In a more recent calculation for the Al-Nb alloy by these authors and co-workers (Colinet et al., 1997), the liquid-phase free energy was calculated by three different models—the MF subregular solution model, the pair CVM approximation (quasichemical), and the CVM tetrahedron—with very little difference in the results. Melting temperatures of the elements and entropies of fusion had to be taken from experimental data, as was true for the Al-Ni system. It would be unfair to compare the MF and "cluster" phase diagrams of Al-Ni because the latter was published before all the data used to construct the former were known and because the "first-principles" calculations were still more or less in their infancy at the time (1992).

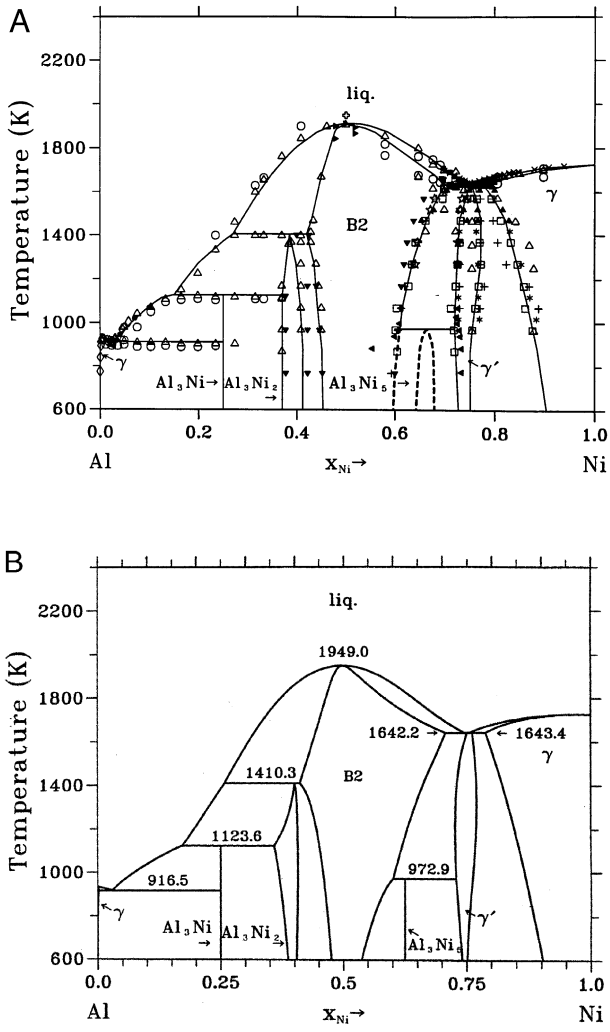

Figure 14. (**A**) Al-Ni assessed phase diagram with experimental data (various symbols; see Ansara et al., 1997, for references). (**B**) Al-Ni phase diagram modeled according to the CALPHAD method (Ansara et al., 1997).

Certainly, the MF method is by far the simpler one to use, but cannot make actual predictions from basic physical principles. Also, the physical parameters derived from an MF fit sometimes lead to unsatisfactory results. In the present Al-Ni case, the isobaric specific heat is not given accurately over a wide range of temperatures, whereas the brute-force quasiharmonic EAM calculation of the previous section gave excellent agreement with experimental data, as seen in Figure 13. Perhaps it would be more correct to refer to the CVM/*ab initio* calculations of Pasturel, Colinet, and co-workers as a hybrid method, combining electronic structure calculations, cluster expansions, and some CALPHAD-like fitting: a method that can provide theoretically valid and practically useful results.

Nickel-Platinum: Fitted, Cluster Approach

If one considers another Ni-based alloy, the Ni-Pt system, the phase diagram is quite different from those discussed in the previous section. A glance at the version of the experimental phase diagram (Fig. 15A) published in the American Society for Metals (ASM) handbook *Binary Alloy Phase Diagrams* (2nd ed.; Massalski, 1990) illustrates why it is often necessary to supplement experimental data with calculations: the Ni_3Pt and NiPt phase boundaries and the ferromagnetic transition are shown as disembodied lines, and the order/disorder Ni_3Pt (single dashed line) would suggest a second-order phase transition, which it surely is not. Consider now the cluster/fitted version—liquid phase not included: melting occurs above 1000 K in this system (Dahmani et al., 1985) of the phase diagram (Fig. 15B). The CVM tetrahedron approximation was used for the "chemical" interactions and also for magnetic interactions assumed to be nonzero only if at least two of the tetrahedron sites were occupied by Ni atoms. The chemical and magnetic interactions were obtained by fitting to recent (at the time, 1985) experimental data (Dahmani et al., 1985). It is seen that the CVM version (Fig. 15B) displays correctly three first-order transitions, and the disordering temperatures of Ni_3Pt and NiPt differ from those

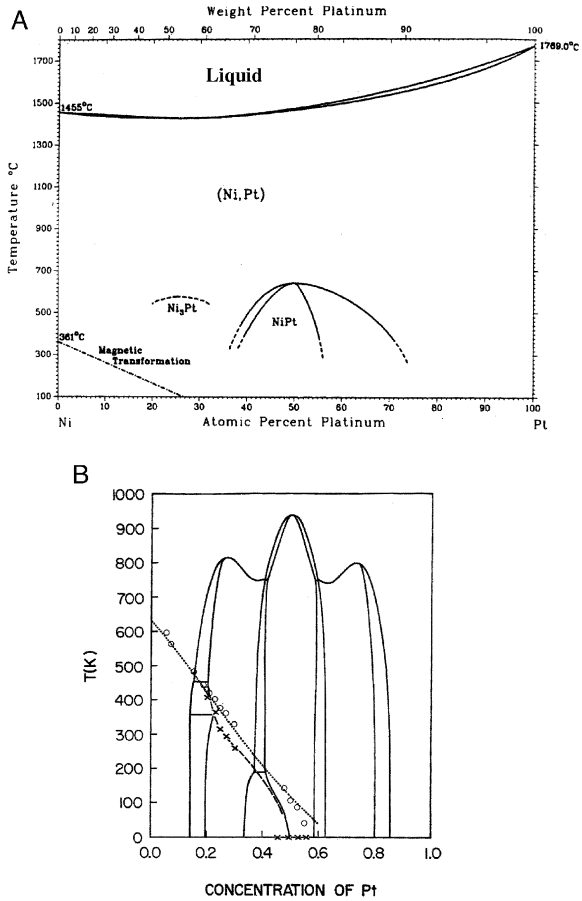

Figure 15. (**A**) Ni-Pt phase diagram according to the ASM handbook (Massalski, 1990). (**B**) Ni-Pt phase diagram calculated from a CVM free energy fitted to available experimental data (Dahmani et al., 1985).

indicated in the handbook version (Fig. 15A). It appears that the latter version, published several years after the work of Dahmani et al. (1985), is based on an older set of data; in fact the 1990 edition of the ASM handbook (Massalski, 1990) actually states that "no new data has been reported since the Hansen and Anderko phase-diagram handbook appeared in 1958!" Additionally, experimental values of the formation energies of the $L1_0$ NiPt phase were reported in 1970 by Walker and Darby (1970). The 1990 ASM handbook also fails to indicate the important perturbation of the "chemical" phase boundaries by the ferromagnetic transition, which the calculation clearly shows (Fig. 15A). There is still no unambiguous verification of the transition on the Pt-rich side of the phase diagram (platinum is expensive). Note also that a MF GBW model could not have produced the three first-order transitions expected; instead it would have given a triple second-order transition at 50% Pt, as in the MF prototype phase diagram of Figure 8A.

The solution to the three-transition problem in Ni-Pt might be to obtain the free energy parameters from electronic structure calculations, but surprises are in store there, as explained in some detail in the author's review (de Fontaine, 1994, Sect. 17). The KKR-CPA-$S^{(2)}$ calculations (Pinski et al., 1991) indicated that a 50:50 Ni-Pt solid solution would be unstable to a $\langle 100 \rangle$ concentration ordering wave, thereby presumably giving rise to an $L1_0$ ordered phase region, in agreement with experiment. However, that is true only for calculations based on what has been called the unrelaxed ΔE_{repl} energy of Equation 32. Actually, according to the Hamiltonian used in those $S^{(2)}$ calculations, the ordered $L1_0$ phase should be unstable to phase separation into Ni-rich and Pt-rich phases if relaxation were correctly taken into account, emphasizing once again that all the contributions to the energy in Equation 32 should be included. However, the $L1_0$ state is indeed the observed low-temperature state, so it might appear that the incomplete energy description was the correct one. The resolution of the paradox was provided by Lu, Wei, and Zunger (1993): The original $S^{(2)}$ Hamiltonian did not contain relativistic corrections, which are required since Pt is a heavy element. When this correction is included in a fully relaxed FLAPW calculation, the $L1_0$ phase indeed appears as the ground state in the central portion of the Ni-Pt phase diagram. Thus first-principles calculations can be helpful, but they must be performed with pertinent effects and corrections (including relativity!) taken into account—hence, the difficulty of the undertaking but also the considerable reward of deep understanding that may result.

Aluminum-Lithium: Fitted and Predicted

Aluminum-lithium alloys are strengthened by the precipitation of a metastable coherent Al_3Li phase of $L1_2$ structure (α'). Since this phase is less stable than the two-phase mixture of an fcc Al-rich solid solution (α) and a B32 bcc-based ordered structure AlLi (β), it does not appear on the experimentally determined equilibrium phase diagram (Massalski, 1986, 1990). It would therefore be useful to calculate the α/α' metastable phase boundaries and place them on the experimental phase diagram. This is what Sigli and Sanchez (1986) did using CVM free energies to fit the entire experimental phase diagram, as assessed by McAlister and reproduced here in Figure 16A from the first edition of the ASM handbook *Binary Alloy Phase Diagrams* (Massalski, 1986). Note that the newer version of the Al-Li phase diagram in the 2nd ed. of the handbook (Massalski, 1990) is incorrect (in all fairness, a correction appeared in an addendum, reproducing the older version). The CVM-fitted Al-Li phase diagram, including the metastable $L1_2$ phase region (dashed lines) and available experimental points, is shown in Figure 16B (Sigli and Sanchez, 1986). The Li-rich side of the α/α' two-phase region is shown to lie very close to the Al_3Li stoichiometry, along (as expected) with the highest disordering point, at ~825 K. A low-temperature metastable-metastable miscibility gap (because it is a metastable feature of a metastable equilibrium) is predicted to lie within the α/α' two-phase region. Note once again that the correct ordering behavior of the $L1_2$ structure by a first-order transition near $x_{\text{Li}} = 0.25$ could not have been obtained by a GBW MF model. How, then, could later authors (Khachaturyan et al., 1988) claim to have obtained a better fit to experimental points by using the method of concentration

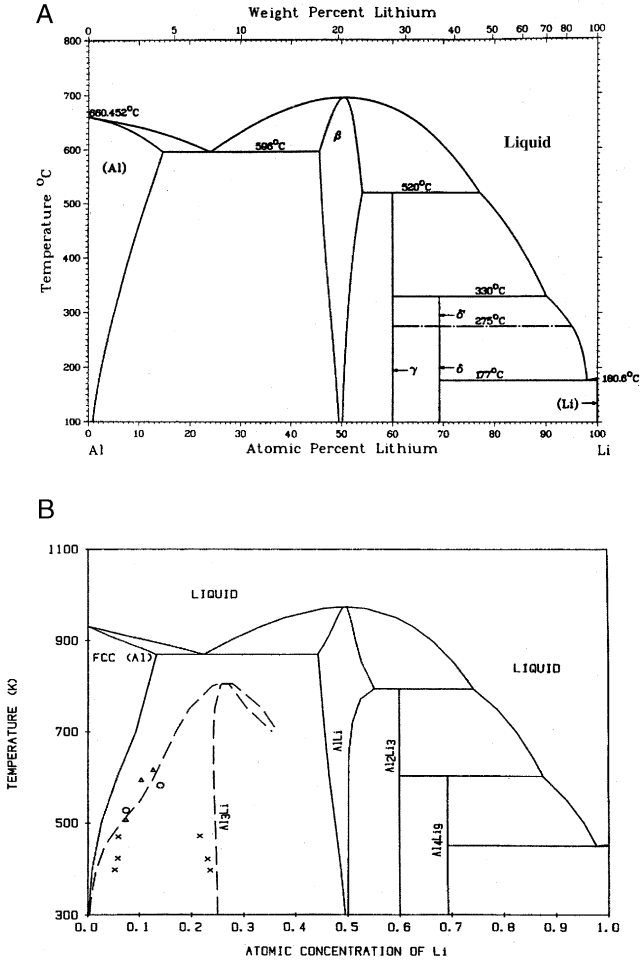

Figure 16. (**A**) Al-Li phase diagram from the first edition of the phase-diagram handbook (Massalski, 1986). (**B**) Al-Li phase diagram calculated from a CVM fit (full lines), $L1_2$ metastable phase regions (dashed lines), and corresponding experimental data (symbols; see Sigli and Sanchez, 1986).

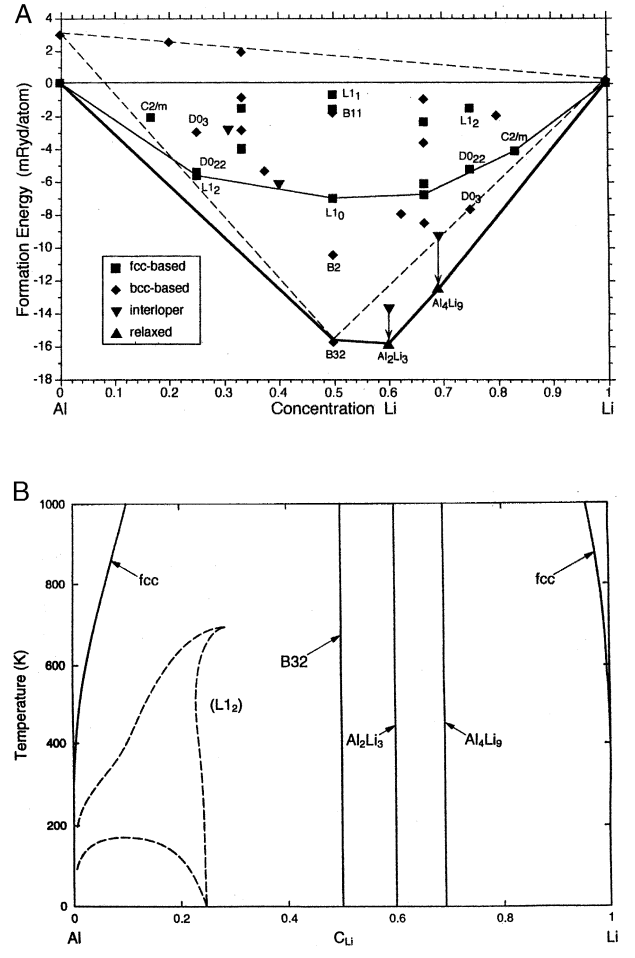

Figure 17. (**A**) Convex hull (heavy solid line) and formation energies (symbols) used in first-principles calculation of Al-Li phase diagram (from Sluiter et al., 1996). (**B**) Solid-state portion of the Al-Li phase diagram (full lines) with metastable $L1_2$ phase boundaries and metastable-metastable miscibility gap (dashed lines; Sluiter et al., 1996).

waves, which is completely equivalent to the GBW MF model? The answer is that these authors conveniently left out the high-temperature portion of their calculated phase boundaries so as not to show the inevitable outcome of their calculation, which would have incorrectly produced a triple second-order transition at concentration 0.5, as in Figure 8A.

A first-principles calculation of this system was attempted by Sluiter et al. (1989, 1990), with both fcc- and bcc-based equilibria present. The tetrahedron approximation of the CVM was used and the ECIs were obtained by structure inversion from FLAPW electronic structure calculations. The liquid free energy was taken to be that of a subregular solution model with parameters fitted to experimental data. Later (1996), the same Al-Li system was revisited by the same first author and other co-workers (Sluiter et al., 1996). This time the LMTO-ASA method was used to calculate the structures required for the SIM, and far more structures were used than previously. The calculated formation energies of structures used in the inversion are indicated in Figure 17A, an application to a real system of techniques illustrated schematically in Figure 10. All fcc-based structures are shown as filled squares, bcc based as diamonds, "interloper" structures (those that are not manifestly derived from fcc or bcc), unrelaxed and relaxed, as triangles pointing down and up, respectively. The solid thin line is the fcc-only, and the dashed thin line the bcc-only convex hull. The heavy solid line represents the overall (fcc, bcc, interloper) convex hull, its vertices being the predicted ground states for the Al-Li system. It is gratifying to see that the predicted ("rounding up the usual suspects") ground states are indeed the observed ones. The solid-state portion of the phase diagram, with free energies provided by the tetrahedron-octahedron CVM approximation (see Fig. 7), is shown in Figure 17B. The metastable α/α' ($L1_2$) phase boundaries, this time calculated completely from first principles, agree surprisingly well with those obtained by a tetrahedron CVM fit, as shown above in Figure 16B. Even the metastable MG is reproduced. Setting aside the absence of

the liquid phase, the first-principles phase diagram (no empirical parameters or fits employed) differs from the experimentally observed one (Fig. 16A) by the fact that the central B32 ordered phase has too narrow a domain of solubility. However, the calculations predict such things as the lattice parameters, bulk moduli, degree of long and short-range order as a function of temperature and concentration, and even the influence of pressure on the phase equilibria (Sluiter et al., 1996).

Other Applications

The case studies just presented are only a few among many, but should give the reader an idea of some of the difficulties encountered while attempting to gather, represent, fit, or calculate phase diagrams. Examples of other systems, up to 1994, are listed, for instance, in the author's review article (de Fontaine, 1994, Table V, Sect. 17). These have included noble metal alloys (Terakura et al., 1987; Mohri et al. 1988, 1991); Al alloys (Asta et al., 1993b,c, 1995; Asta and Johnson, 1997; Johnson and Asta, 1997); Cd-Mg (Asta et al., 1993a); Al-Ni (Sluiter et al., 1992; Turchi et al., 1991a); Cu-Zn (Turchi et al., 1991b); various ternary systems, such as Heusler-type alloys (McCormack and de Fontaine, 1996; McCormack et al., 1997); semiconductor materials (see the publications of the Zunger school); and oxides (e.g., Burton and Cohen, 1995; Ceder et al., 1995; Tepesch et al., 1995, 1996; Kohan and Ceder, 1996). In the oxide category, phase-diagram studies of the high-T_c superconductor YBCO (de Fontaine et al., 1987, 1989, 1990; Wille and de Fontaine, 1988; Ceder et al., 1991) are of special interest as the calculated oxygen-ordering phase diagram was derived by the CVM before experimental results were available and was found to agree reasonably well with available data. Material pertinent to the present unit can also be found in the proceedings of the joint NSF/CNRS Conference on Alloy Theory held in Mt. Ste. Odile, France, in October 1996 (de Fontaine and Dreyssé, 1997).

CONCLUSIONS

Knowledge of phase diagrams is absolutely essential in such fields as alloy development and processing. Yet, today, that knowledge is still incomplete: the phase diagram compilations and assessments that are available are fragmentary, often unreliable, and sometimes incorrect. It is therefore useful to have a range of theoretical models whose roles and degrees of sophistication differ widely depending on the aim of the calculation. The highest aim, of course, is that of predicting phase equilibria from the knowledge of the atomic number of the constituents, a true first-principles calculation. That goal is far from having been attained, but much progress is being realized currently. The difficulty is that so many different types of atomic/electronic interactions need to be taken into account, and the calculations are complicated and time consuming. Thus far, success along those lines belongs primarily to such quantities as heats of formation; configurational and vibrational entropies are more difficult to compute, and as a result, predictions of transition temperatures are often off by a considerable margin.

Fitting procedures can produce very accurate results, since with enough adjustable parameters, one can fit just about anything. Still, the exercise can be useful as such procedures may actually find inconsistencies in empirically derived phase diagrams, extrapolate into uncharted regions, or enable one to extract thermodynamic functions, such as free energy, from experiment using calorimetry, x-ray diffraction, electron microscopy, or other techniques. Still, one has to take care that the starting theoretical models make good physical sense. The foregoing discussion has demonstrated that GBW-type models, which produce acceptable results in the case of phase separation, cannot be used for order/disorder transformations, particularly in "frustrated" cases as encountered in the fcc lattice, without adding some rather unphysical correction terms. In these cases, the CVM, or Monte Carlo simulation, must be used. Perhaps a good compromise would be to try a combination of first-principles calculations for heats of formation supplemented by a CVM entropy plus "excess" terms fitted to available experimental data. Purists might cringe, but end users may appreciate the results. For a true understanding of physical phenomena, first-principles calculations, even if presently inaccurate regarding transition temperatures, must be carried out, but in a very complete fashion.

ACKNOWLEDGMENTS

The author thanks Jeffrey Althoff and Dane Morgan for helpful comments concerning an earlier version of the manuscript and also thanks I. Ansara, J. M. Sanchez, and M. H. F. Sluiter, who graciously provided figures. This work was supported in part by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Materials Sciences, under contract Nos. DE-AC04-94AL85000 (Sandia) and DE-AC03-76SF00098 (Berkeley).

KEY REFERENCES

Ceder, 1993. See above.

Original published text for the decoupling of configurational effects from other excitations; appeared initially in G. Ceder's Ph.D. Dissertation at U. C. Berkeley. The paper at first met with some (unjustified) hostility from traditional statistical mechanics specialists.

de Fontaine, 1979. See above.

A 200-page review of configurational thermodynamics in alloys, quite much and didactic in its approach. Written before the application of "first principles" methods to the alloy problem, and before generalized cluster techniques had been developed. Still, a useful review of earlier Bragg-Williams and concentration wave methods.

de Fontaine, 1994. See above.

Follows the 1979 review by the author; This time emphasis is placed on cluster expansion techniques and on the application of ab initio calculations. First sections may be overly general, thereby complicating the notation. Later sections are more readable, as they refer to simpler cases. Section 17 contains a useful table of published papers on the subject of CVM/ab initio calculations of binary and ternary phase diagrams, reasonably complete until 1993.

Ducastelle, 1991. See above.

"The" textbook for the field of statistical thermodynamics and electronic structure calculations (mostly tight binding and generalized perturbation method). Includes very complete description of ground-state analysis by the method of Kanamori et al. and also of the ANNNI model applied to long-period alloy superstructures.

Gibbs, 1875–1876. See above.

One of the great classics of 19th century physics, it launched a new field: that of chemical thermodynamics. Unparalleled for rigor and generality.

Inden and Pitsch, 1991. See above.

A very readable survey of the CVM method applied to phase diagram calculations. Owes much to the collaboration of A. Finel for the theoretical developments, though his name unfortunately does not appear as a co-author.

Kikuchi, 1951. See above.

The classical paper that ushered in the cluster variational method, affectionately known as "CVM" to its practitioners. Kikuchi employs a highly geometrical approach to the derivation of the CM equations. The more algebraic derivations found in later works by Ducastelle, Finel, and Sanchez (cited in this list) may be simpler to follow.

Lu et al., 1991. See above.

Fundamental paper from the "Zunger School" that recommends the Connolly-Williams method, also called the structure inversion method (SIM, in de Fontaine, 1994). That and later publications by the Zunger group correctly emphasize the major role played by elastic interactions in alloy theory calculations.

Palatnik and Landau, 1964. See above.

This little-known textbook by Russian authors (translated into English) is just about the only description of the mathematics (linear algebra, mostly) of multicomponent systems. Some of the main results given in this textbook are summarized in the book by Prince, listed below.

Prince, 1966. See above.

Excellent textbook on the classical thermodynamics of alloy phase diagram constructions, mainly for binary and ternary systems. This handsome edition contains a large number of phase diagram figures, in two colors (red and black lines), contributing greatly to clarity. Unfortunately, the book has been out of print for many years.

Sanchez et al., 1984. See above.

The original reference for the "cluster algebra" applied to alloy thermodynamics. An important paper that proves rigorously that the cluster expansion is orthogonal and complete.

Berkely, California

SIMULATION OF MICROSTRUCTURAL EVOLUTION USING THE FIELD METHOD

INTRODUCTION

Morphological pattern formation and its spatio-temporal evolution are among the most intriguing natural phenomena governed by nonlinear complex dynamics. These

phenomena form the major study subjects of many fields including biology, hydrodynamics, chemistry, optics, materials science, ecology, geology, geomorphology, and cosmology, to name a few. In materials science, the morphological pattern is referred to as microstructure, which is characterized by the size, shape, and spatial arrangement of phases, grains, orientation variants, ferroelastic/ferroelectric/ferromagnetic domains, and/or other structural defects. These structural features usually have an intermediate mesoscopic length scale in the range of nanometers to microns. Figure 1 shows several examples of microstructures observed in metals and ceramics.

Microstructure plays a critical role in determining the physical properties and mechanical behavior of materials. In fact, the use of materials as a science did not begin until human beings learned how to tailor the microstructure to modify the properties. Today the primary task of material design and manufacture is to optimize microstructures—by adjusting alloy composition and varying processing sequences—to obtain the desired properties.

Microstructural evolution is a kinetic process that involves the appearance and disappearance of various transient and metastable phases and morphologies. The optimal properties of materials are almost always associated with one of these nonequilibrium states, which is "frozen" at the application temperatures. Theoretical characterization of the transient and metastable states represents a typical nonequilibrium nonlinear and nonlocal multiparticle problem. This problem generally resists any analytical solution except in a few extremely simple cases.

With the advent of and easy access to high-speed digital computers, computer modeling is playing an increasingly important role in the fundamental understanding of the mechanisms underlying microstructural evolution. For many cases, it is now possible to simulate and predict critical microstructural features and their time evolution. In this unit, methods recently developed for simulating the formation and dynamic evolution of complex microstructural patterns will be reviewed. First, we will give a brief account of the basic features of each method, including the conventional front-tracking method (also referred to as the sharp-interface method) and the new techniques without front-tracking. Detailed description of the simulation technique and its practical application will focus on the field method since it is the one we are most familiar with and we feel it is a more flexible method with broader applications. The need to link the mesoscopic microstructural simulation with atomistic calculation as well as with macroscopic process modeling and property calculation will also be briefly discussed.

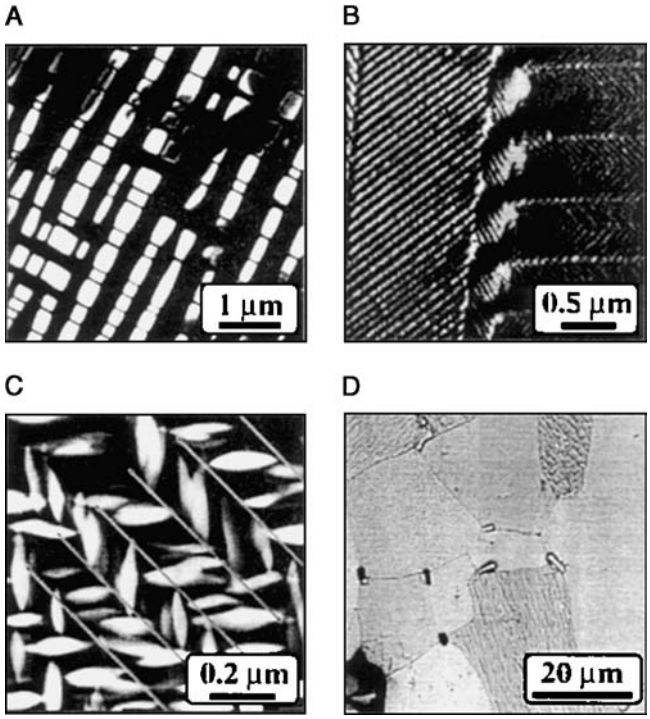

Figure 1. Examples of microstructures observed in metals and ceramics (**A**) Discontinuous rafting structure of γ' particles in Ni-Al-Mo (courtesy of M. Fahrmann). (**B**) Polytwin structure found in Cu-Au (Syutkina and Jakovleva, 1967). (**C**) Alternating band structure in Mg-PSZ (Bateman and Notis, 1992). (**D**) Polycrystalline microstructure in $SrTiO_3$-1 mol% Nb_2O_5 oxygen sensor sintered at 1550°C (Gouma et al., 1997).

Simulation Methods of Microstructural Evolution

Conventional Front-Tracking Methods. A microstructure is conventionally characterized by the geometry of interfacial boundaries between different structural components (phases, grains, etc.) that are assumed to be homogeneous up to their boundaries. The boundaries are treated as mathematical interfaces of zero thickness. The microstructural evolution is then obtained by solving the partial differential equations (PDEs) in each phase and/or domain with boundary conditions specified at the interfaces that are moving during a microstructural evolution. Such a moving-boundary or free-boundary problem is very problematic in numerical analysis and becomes extremely difficult to solve for complicated geometries. For example, the difficulties in dealing with topological changes during the microstructural evolution such as the appearance, coalescence, and disappearance of particles and domains during nucleation, growth, and coarsening processes have limited the application of the method mainly to two dimensions (2D). The extension of the calculation to 3D would introduce significant complications in both the algorithms and their implementation. In spite of these difficulties, important fundamental understanding has been developed concerning the kinetics and microstructural evolution during coarsening, strain-induced coarsening (Leo and Sekerka, 1989; Leo et al., 1990; Johnson et al., 1990; Johnson and Voorhees, 1992; Abinandanan and Johnson, 1993a,b; Thompson et al., 1994; Su and Voorhees, 1996a,b) and dendritic growth (Jou et al., 1994, 1997; Müller-Krumbhaar, 1996) by using, for example, the boundary integral method.

New Techniques Without Front Tracking. In order to take into account realistic microstructural features, novel simulation techniques at both mesoscopic and microscopic levels have been developed, which eliminate the need to track moving interfacial boundaries. Commonly used techniques include microscopic and continuum field methods, mesoscopic and atomistic Monte Carlo methods, the cellular automata method, microscopic master equations, the inhomogeneous path probability method, and molecular dynamics simulations.

Continuum Field Method (CFM). CFM (commonly referred to as the phase field method) is a phenomenological approach based on classical thermodynamic and kinetic theories (Hohenberg and Halperin, 1977; Gunton et al., 1983; Elder, 1993; Wang et al., 1996; Chen and Wang, 1996). Like conventional treatment, CFM describes microstructural evolution by PDEs. However, instead of using the geometry of interfacial boundaries, this method describes a complicated microstructure as a whole by using a set of mesoscopic field variables that are spatially continuous and time dependent. The most familiar examples of field variables are the concentration field used to characterize composition heterogeneity and the long-range order (lro) parameter fields used to characterize the structural heterogeneity (symmetry changes) in multiphase and/or polycrystalline materials. The spatio-temporal evolution of these fields, which provides all the information concerning a microstructural evolution at a mesoscopic level, can be obtained by solving the semiphenomenological dynamic equations of motion, for example, the nonlinear Cahn-Hilliard (CH) diffusion equation (Cahn, 1961, 1962) for the concentration field and the time-dependent Ginzburg-Landau (TDGL) equation (see Gunton et al., 1983 for a review) for the lro parameter fields.

CFM offers several unique features. First, it can easily describe any arbitrary morphology of a complex microstructure by using the field variables, including such details as shapes of individual particles, grains, or domains and their spatial arrangement, local curvatures of surfaces (e.g., surface groove and dihedral angle), and internal boundaries. Second, CFM can take into account various thermodynamic driving forces associated with both short- and long-range interactions, and hence allows one to explore the effects of internal and applied fields (e.g., strain, electrical, and magnetic fields) on the microstructure development. Third, CFM can simulate different phenomena such as nucleation, growth, coarsening, and applied field-induced domain switching within the same physical and mathematical formalism. Fourth, the CH diffusion equation allows a straightforward characterization of the long-range diffusion, which is the dominant process taking place (e.g., during sintering, precipitation of second-phase particles, solute segregation, etc. Fifth, the time, length, and temperature scales in the CFM are determined by the semiphenomenological constants used in the CH and TDGL equations, which in principle can be related to experimentally measured or *ab initio* calculated quantities of a particular system. Therefore, this method can be directly applied to specific material systems. Finally, it is an easy technique and its implementation in both 2D and 3D is rather straightforward. These unique features have made CFM a very attractive method in dealing with microstructural evolution in a wide range of advanced material systems. Table 1 summarizes its major recent applications (Chen and Wang, 1996).

Mesoscopic Monte Carlo (MC) and Cellular Automata (CA) Methods. MC and CA are discrete methods developed for the study of the collective behavior of a large number of elementary events. These methods are not limited to any particular physical process, and have a rich variety of applications in very different fields. The general principles of these two methods can be found in the monographs by Allen and Tildesley (1987) and Wolfram (1986). Their applications to problems related to materials science can be found in recent reviews by Satio (1997) and by Ozawa et al. (1996) for both mesoscopic and microscopic MC and in Wolfram (1984) and Lepinoux (1996) for CA.

The mesoscopic MC technique was developed by Srolovitz et al. (1983), who coarse grained the atomistic Potts model—a generalized version of the Ising model that allows more than two degenerate states—to a subgrain (particle) level for application to mesoscopic microstructural evolution, in particular grain growth in polycrystalline materials. The CA method was originally developed for simulating the formation of complicated morphological patterns during biological evolution (von Neumann, 1966; Young and Corey, 1990). Since most of the time the microscopic mechanisms of growth are unknown, CA was adopted as a trial-and-error computer experiment (i.e., by matching the simulated morphological patterns to observations) to develop a fundamental understanding of the elementary rules dominating cell duplication. The applications of CA in materials science started from work by Lepinoux and Kubin (1987) on dynamic evolution of dislocation structures and work by Hesselbarth and Göbel (1991) on grain growth during primary recrystallization.

The MC and CA methods share several common characteristics. For example, they describe mesoscopic microstructure and its evolution in a similar way. Instead of using PDEs, they map an initial microstructure on to a discrete lattice (square or triangle in 2D and cubic in 3D) with each lattice site or unit cell assigned a microstructural state (e.g., the crystallographic orientation of grains in polycrystalline materials). The interfacial boundaries are described automatically wherever the change of microstructural state takes place. The lattices are so-called coarse-grained lattices, which have a length scale much larger than the atomic scale but substantially smaller than the typical particle or domain size. Therefore, these methods can easily describe complicated morphological features defined at a mesoscopic level using the current generation of computers. The dynamic evolution of the microstructure is described by updating the microstructural state at each lattice site following either certain probabilistic procedures (in MC) or some simple deterministic transition rules (in CA). The implementation of these probabilistic procedures or deterministic rules provides certain

ways of sampling the coarse-grained phase space for the free energy minimum. Because both time and space are discrete in these methods, they are direct computational methods and have been demonstrated to be very efficient for simulating the fundamental phenomena taking place during grain growth (Srolovitz et al., 1983, 1984; Anderson et al., 1984; Gao and Thompson, 1996; Liu et al., 1996; Tikare and Cawley, 1997), recrystallization (Hesselbarth and Göbel, 1991; Holm et al., 1996), and solidification (Rappaz and Gandin, 1993; Shelton and Dunand, 1996).

However, both approaches suffer from similar limitations. First, it becomes increasingly difficult for them to take into account long-range diffusion and long-range interactions, which are the two major factors dominating microstructural evolution in many advanced material systems. Second, the choice of the coarse-grained lattice type may have a strong effect on the interfacial energy anisotropy and boundary mobility, which determine the morphology and kinetics of the microstructural evolution. Therefore, careful consideration must be given to each type of application (Holm et al., 1996). Third, the time and length scales in MC/CA simulations are measured by the number of MC/CA time steps and space increments, respectively. They do not correspond, in general, to the real time and space scales. Extra justifications have to be made in order to relate these quantities to real values (Mareschal and Lemarchand, 1996; Lepinoux, 1996; Holm et al., 1996). Some recent simulations have tried to incorporate real time and length scales by matching the simulation results to either experimental observations or constitutive relations (Rappaz and Gandin, 1993; Gao and Thompson, 1996; Saito, 1997).

Microscopic Field Model (MFM). MFM is the microscopic counterpart of CFM. Instead of using a set of mesoscopic field variables, it describes an arbitrary microstructure by a microscopic single-site occupation probability function, which describes the probability that a given lattice

site is occupied by a solute atom of a given type at a given time. The spatio-temporal evolution of the occupation probability function following the microscopic lattice-site diffusion equation (Khachaturyan, 1968, 1983) yields all the information concerning the kinetics of atomic ordering and decomposition as well as the corresponding microstructural evolution within the same physical and mathematical model (Chen and Khachaturyan, 1991a; Semenovskaya and Khachaturyan, 1991; Wang et al., 1993; Koyama et al., 1995; Poduri and Chen, 1997, 1998).

The CH and TDGL equations in CFM can be obtained from the microscopic diffusion equation in MFM by a limit transition to the continuum (Chen, 1993b; Wang et al., 1996). Both the macroscopic CH/TDGL equations and the microscopic diffusion equation are actually different forms of the phenomenological dynamic equation of motion, the Onsager equation, which simply assumes that the rate of relaxation of any nonequilibrium field toward equilibrium is proportional to the thermodynamic driving force, which is the first variational derivative of the total free energy. Therefore, both equations are valid within the same linear approximation with respect to the thermodynamic driving force.

The total free energy in MFM is usually approximated by a mean-field free energy model, which is a functional of the occupation probability function. The only input parameters in the free energy model are the interatomic interaction energies. In principle, these engeries can be determined from experiments or theoretical calculations. Therefore, MFM does not require any *a priori* assumptions on the structure of equilibrium and metastable phases that might appear along the evolution path of a nonequilibrium system. In CFM, however, one must specify the form of the free energy functional in terms of composition and long-range order parameters, and thus assume that the only permitted ordered phases during a phase transformation are those whose long-range order parameters are included in the continuum free energy model. Therefore, there is always a possibility of missing important transient or intermediate ordered phases not described by the *a priori* chosen free energy functional. Indeed, MFM has been used to predict transient or metastable phases along a phase-transformation path (Chen and Khachaturyan, 1991b, 1992).

By solving the microscopic diffusion equations in the Fourier space, MFM can also deal with interatomic interactions with very long interation ranges, such as elastic interactions (Chen et al., 1991; Semenovskaya and Khachaturyan, 1991; Wang et al., 1991a, b, 1993), Coulomb interactions (Chen and Khachaturyan, 1993; Semenovskaya et al., 1993), and magnetic and electric dipole-dipole interactions.

However, CFM is more generic and can describe larger systems. If all the equilibrium and metastable phases that may exist along a transformation path are known in advance from experiments or calculations [in fact, the free energy functional in CFM can always be fitted to the mean-field free energy model or the more accurate cluster variation method (CVM) calculations if the interatomic interaction energies for a particular system are known], CFM can be very powerful in describing morphological evolution, as we will see in more detail in the two examples given in Practical Aspects of the Method. CFM can be applied essentially to every situation in which the free energy can be written as a functional of conserved and nonconserved order parameters that do not have to be the lro parameters, whereas MFM can only be applied to describe diffusional transformations such as atomic ordering and decomposition on a fixed lattice.

Microscopic Master Equations (MEs) and Inhomogeneous Path Probability Method (PPM). A common feature of CFM and MFM is that they are both based on a free energy functional, which depends only on a local order parameter/local atomic density (in CFM) or point probabilities (in MFM). Two-point or higher-order correlations are ignored. Both CFM and MFM describe the changes of order parameters or occupation probabilities with respect to time as linearly proportional to the thermodynamic driving force. In principle, the description of kinetics by linear models is only valid when a system is not too far from equilibrium, i.e., the driving force for a given diffusional process is small. Furthermore, the proportionality constants in these models are usually assumed to be independent of the values of local order parameters or the occupation probabilities.

One way to overcome the limitations of CFM and MFM is to use inhomogeneous microscopic ME (Van Baal, 1985; Martin, 1994; Chen and Simmons, 1994; Dobretsov et al., 1995, 1996; Geng and Chen, 1994, 1996), or the inhomogeneous PPM (R. Kikuchi, pers. comm., 1996). In these methods, the kinetic equations are written with respect to one-, two-, or n-particle cluster probability distribution functions (where n is the number of particles in a given cluster), depending on the level of approximation. Rates of changes of those cluster correlation functions are proportional to the exponential of an activation energy for atomic diffusion jumps. With the input of interaction parameters, the activation energy for diffusion, and the initial microstructure, the temporal evolution of these nonequilibrium distribution functions describes the kinetics of diffusion processes such as ordering, decomposition, and coarsening, as well as the accompanying microstructural evolution. In both ME and PPM, the free energy functional does not explicitly enter into the kinetic equations of motion. High-order atomic correlations such as pair and tetrahedral correlations can be taken into account. The rate of change of an order parameter is highly nonlinear with respect to the thermodynamic driving force. The dependence of atomic diffusion or exchange on the local atomic configuration is automatically considered. Therefore, it is a substantial improvement over the continuum and microscopic field equations derived from a free energy functional in terms of describing rates of transformations. At equilibrium, both ME and PPM produce the same equilibrium states as one would calculate from the CVM at the same level of approximation.

However, if one's primary concern is in the sequence of a microstructural evolution (e.g., the appearance and disappearance of various transient and metastable structural states, rather than the absolute rate of the transformation), CFM and MFM are simpler and more powerful methods. Alternatively, as in MFM, ME and PPM can

only be applied to diffusional processes on a fixed lattice and the system sizes are limited by the total number of lattice sites that can be considered. Furthermore, it is very difficult to incorporate long-range interactions in ME and PPM. Finally, the formulation becomes very tedious and complicated as high-order probability distribution functions are included.

Atomistic Monte Carlo Method. In an atomistic MC simulation, a given morphology or microstructure is described by occupation numbers on an Ising lattice, representing the instantaneous configuration of an atomic assembly. The evolution of the occupation numbers as a function of time is determined by Metropolis types of algorithms (Allen and Tildesley, 1987). Similar to MFM and the microscopic ME, the atomistic MC may be applied to microstructural evolution during diffusional processes such as ordering transformation, phase separation, and coarsening. This method has been extensively employed in the study of phase transitions involving simple atomic exchanges on a rigid lattice in binary alloys (Bortz et al., 1974; Lebowitz et al., 1982; Binder, 1992; Fratzl and Penrose, 1995). However, there are several differences between the atomistic MC method and the kinetic equation approaches. First of all, the probability distribution functions generated by the kinetic equations are averages over a time-dependent nonequilibrium ensemble, whereas in MC, a series of snapshots of instantaneous atomic configurations along the simulated Markov chain are produced (Allen and Tildesley, 1987). Therefore, a certain averaging procedure has to be designed in the MC technique in order to obtain information about local composition or local order. Second, while the time scale is clearly defined in CFM/MFM and microscopic ME, it is rather difficult to relate the MC time steps to real time. Third, in many cases, simulations based on kinetic equations are computationally more efficient than MC, which is also the main reason why most of the equilibrium phase diagram calculations in alloys were performed using CVM instead of MC. The main disadvantage of the microscopic kinetic equations, as mentioned in the previous section, is the fact that the equations become increasingly tedious when increasingly higher-order correlations are included, whereas in MC, essentially all correlations are automatically included. Furthermore, MC is easier to implement than ME and PPM. Therefore, atomistic MC simulation remains a very popular method for modeling the diffusional transformations in alloy systems.

Molecular Dynamics Simulations. Since microstructure evolution is realized through the movement of individual atoms, atomistic simulation techniques such as the atomistic molecular dynamics (MD) approach should, in principle, provide more direct and accurate descriptions by solving Newton's equations of motion for each atom in the system. Unfortunately, such a brute force approach is still not feasible computationally when applied to studying overall mesoscale microstructural evolution. For example, even with the use of state-of-the-art parallel computers, MD simulations cannot describe dynamic processes exceeding nanoseconds in systems containing several million atoms. In microstructural evolution, however, many morphological patterns are measured in submicrons and beyond, and the transport phenomena that produce them may occur in minutes and hours. Therefore, it is unlikely that the advancements in computer technology will make such length and time scales accessible by atomistic simulations in the near future.

However, the insight into microscopic mechanisms obtained from MD simulations provides critical information needed for coarser scale simulations. For example, the semiphenomenological thermodynamic and kinetic coefficients in CFM and the fundamental transition rules in MC and CA simulations can be obtained from the atomistic simulations. On the other hand, for some localized problems of microstructural evolution (such as the atomic rearrangement near a crack tip and within a grain boundary, deposition of thin films, sintering of nanoparticles, and so on), atomistic simulations have been very successful (Abraham, 1996; Gumbsch, 1996; Sutton, 1996; Zeng et al., 1998; Zhu and Averback, 1996; Vashista et al., 1997). The readers should refer to the corresponding units (see, e.g., PREDICTION OF PHASE DIAGRAMS) of this volume for details.

In concluding this section, we must emphasize that each method has its own advantages and limitations. One should make the best use of these methods for the problems that he is solving. For complicated problems, one may use more than one method to utilize the complementary characteristics of each of them.

PRINCIPLES OF THE METHOD

CFM is a mesoscopic technique that solves systems of coupled nonlinear partial differential equations of a set of coarse-grained field variables. The solution provides spatio-temporal evolution of the field variables from which detailed information can be obtained on the sizes and shapes of individual particles/domains and their spatial arrangements at each time moment during the microstructural evolution. By subsequent statistical analysis of the simulation results, more quantitative microstructural information such as average particle size and size distribution as well as constitutive relations characterizing the time evolution of these properties can be obtained. These results may serve as valuable input for macroscopic process modeling and property calculations. However, no structural information at an atomic level (e.g., the atomic arrangements of each constituent phase/domain and their boundaries) can be obtained by this method. On the other hand, it is still too computationally intensive at present to use CFM to directly simulate microstructural evolution during an entire material process such as metal forming or casting. Also, the question of what kinds of microstructure provide the optimal properties cannot be answered by the microstructure simulation itself. To answer this question we need to integrate the microstructure simulation with property calculations. Both process modeling and property calculation belong to the domain of macroscopic simulation, which is characterized by the use of constitutive equations. Typical macroscopic simulation techniques include the finite element method (FEM) for

solids and the finite difference method (FDM) for fluids. The generic relationships between simulation techniques at different length and time scales will be discussed in Future Trends, below.

Theoretical Basis of CFM

The principles of CFM are based on the classical thermodynamic and kinetic theories. For example, total free energy reduction is the driving force for the microstructural evolution, and the atomic and interface mobility determines the rate of the evolution. The total free energy reduction during microstructural evolution usually consists of one or several of the following: reduction in bulk chemical free energy; decrease of surface and interfacial energies; relaxation of elastic strain energy; reduction in electrostatic/magnetostatic energies; and relaxation of energies associated with an external field such as applied stress, electrical, or magnetic field. Under the action of these forces, different structural components (phases/domains) will rearrange themselves, through either diffusion or interface controlled kinetics, into new configurations with lower energies. Typical events include nucleation (or continuous separation) of new phases and/or domains and subsequent growth and coarsening of the resulting multiphase/multidomain heterogeneous microstructure.

Coarse-Grained Approximation. According to statistical mechanics, the free energy of a system is determined by all the possible microstates characterized by the electronic, vibrational, and occupational degrees of freedom of the constituent atoms. Because it is still impossible at present to sample all these microscopic degrees of freedom, a coarse-grained approximation is usually employed in the existing simulation techniques where a free energy functional is required. The basic idea of coarse graining is to reduce the $\sim 10^{23}$ microscopic degrees of freedom to a level that can be handled by the current generation of computers. In this approach, the microscopic degrees of freedom are separated into "fast" and "slow" variables and the computational models are built on the slow ones. The remaining fast degrees of freedom are then incorporated into a so-called coarse-grained free energy. Familiar examples of the fast degrees of freedom are (a) the occupation number at a given lattice site in a solid solution that fluctuates rapidly and (b) the magnetic spin at a given site in ferromagnetics that flip rapidly. The corresponding slow variables in the two systems will be the concentration and magnetization, respectively. These variables are actually the statistical averages over the fast degrees of freedom. Therefore, the slow variables are a small set of mesoscopic variables whose dynamic evolution is slow compared to the microscopic degrees of freedom, and whose spatial variation is over a length scale much larger than the interatomic distance. After such a coarse graining, the $\sim 10^{23}$ microscopic degrees of freedom are replaced by a much smaller number of mesoscopic variables whose spatio-temporal evolution can be described by the semiphenomenological dynamic equations of motion. On the other hand, these slow variables are the quantities that are routinely measured experimentally, and hence the calculation results can be directly compared with experimental observations.

Under the coarse-grained approximation, computer simulation of microstructural evolution using the field method is reduced to the following four major steps:

1. Find the proper slow variables for the particular microstructural features under consideration.
2. Formulate the coarse-grained free energy, F_{cg}, as a function of the chosen slow variables following the symmetry and basic thermodynamic behavior of the system.
3. Fit the phenomenological coefficients in F_{cg} to experimental data or more fundamental calculations.
4. Set up appropriate initial and/or boundary conditions and numerically solve the field kinetic equations (PDEs).

The solution will yield the spatio-temporal evolution of the field variables that describes every detail of the microstructure evolution at a mesoscopic level. The computer programming in both 2D and 3D is rather straightforward; the following diagram summarizes the main steps involved in a computer simulation (Fig. 2).

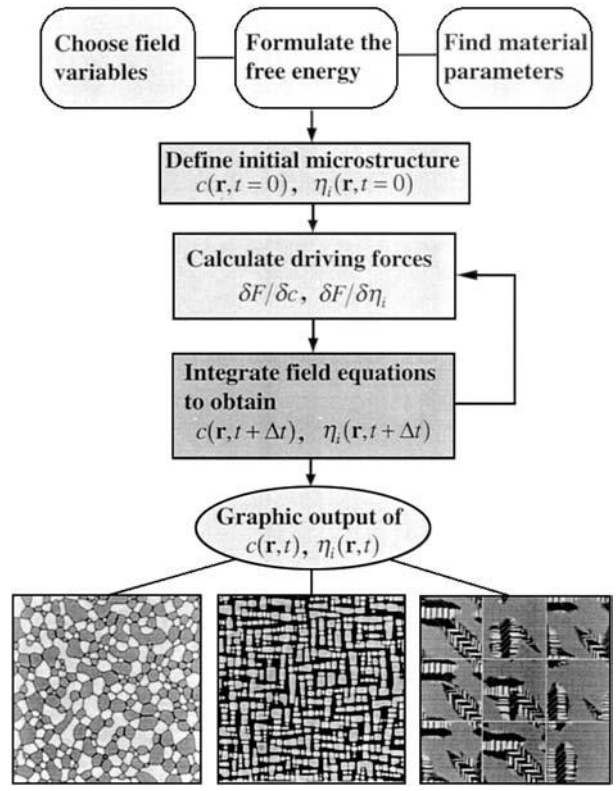

Figure 2. The basic procedures of CFM.

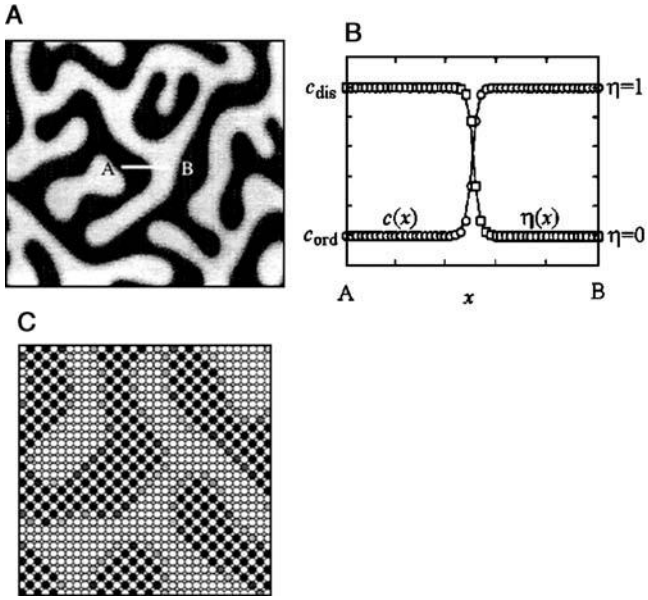

Figure 3. Typical 2D contour plot of concentration field (**A**) 1D plot of concentration and lro parameter profiles across an interface (**B**), and a plot of the occupation probability function (**C**) for a two-phase mixture of ordered and discarded phases.

Selection of Slow Variables. The mesoscopic slow variables used in CFM are defined as spatially continuous and time-dependent field variables. As already mentioned, the most commonly used field variables are the concentration field, $c(\mathbf{r}, t)$ (where $\mathbf{r}$ is the spatial coordinate), which describes compositional inhomogeneity and the lro parameter field, $\eta(\mathbf{r}, t)$, which describes structural inhomogeneity. Figure 3 shows the typical 2D contour plots (Fig. 3A) and one-dimensional (1D) profiles (Fig. 3B) of these fields for a two-phase alloy where the coexisting phases have not only different compositions but different crystal symmetry as well. To illustrate the coarse graining scheme, the atomic structure described by a microscopic field variable, $n(\mathbf{r}, t)$, the occupation probability function of a solute atom at a given lattice site, is also presented (Fig. 3C).

The selection of field variables for a particular system is a fundamental question that has to be answered first. In principle, the number of variables selected should be just enough to describe the major characteristics of an evolving microstructure (e.g., grains and grain boundaries in a polycrystalline material, second-phase particles of two-phase alloys, orientation variants in a martensitic crystal, and electric/magnetic domains in ferroelectrics and ferromagnetics). Worked examples can be found in Table 1. Detailed procedures for the selection of field variables for a particular application can be found in the examples presented in Practical Aspects of the Method.

Diffuse-Interface Nature. From Figure 3B, one may notice that the field variables $c(\mathbf{r}, t)$ and $\eta(\mathbf{r}, t)$ are continuous across the interfaces between different phases or structural domains, even though they have very large gradients in these regions. For this reason, CFM is also referred to as a diffuse interface approach. However, mesoscopic simulation techniques [e.g., the conventional sharp interface approach, the discrete lattice approach (MC and CA), or the diffuse interface CFM] ignore atomic details, and hence give no direct information on the atomic arrangement of different phases and interfacial boundaries. Therefore, they cannot give an accurate description of the thickness of interfacial boundaries. In the front tracking method, for example, the thickness of the boundary is zero. In MC, the boundary is defined as the regions between adjacent lattice sites of different microstructural states. Therefore, the thickness of the boundary is roughly equal to the lattice parameter of the coarse-grained lattice. In CFM, the boundary thickness is also commensurate with the mesh size of the numerical algorithm used for solving the PDEs (~3 to 5 mesh grids).

Formulation of the Coarse-Grained Free Energy. Formulation of the nonequilibrium coarse-grained free energy as a functional of the chosen field variables is central to CFM because the free energy defines the thermodynamic behavior of a system. The minimization of the free energy along a transformation path yields the transient, metastable, and equilibrium states of the field variables, which in turn define the corresponding microstructural states. All the energies that are microstructure dependent, such as those mentioned earlier, have to be properly incorporated. These energies fall roughly into two distinctive categories: the ones associated with short-range interatomic interactions (e.g., the bulk chemical free energy and interfacial energy) and the ones resulting from long-range interactions (e.g., the elastic energy and electrostatic energy). These energies play quite different roles in driving the microstructural evolution.

Bulk Chemical Free Energy. Associated with the short-range interatomic interactions (e.g., bonding between atoms), the bulk chemical free energy determines the number of phases present and their relative amounts at equilibrium. Its minimization gives the information that is found in an equilibrium phase diagram. For a mixture of equilibrium phases, the total chemical free energy is morphology independent, i.e., it does not depend on the size, shape, and spatial arrangement of coexisting phases and/or domains. It simply follows the Gibbs additive principle and depends only on the volume fraction of each phase. In the field approach, the bulk chemical free energy is described by a local free energy density function, f, which can be approximated by a Landau-type of polynomial expansion with respect to the field variables. The specific form of the polynomial is usually obtained from general symmetry and stability considerations that do not require reference to the atomic details (Izyumov and Syromyatnikov, 1990). For an isostructural spinodal decomposition, for example, the simplest polynomial providing a double-well structure of the f-c diagram for a miscibility gap (Fig. 4) can be formulated as

$$f(c) = -\frac{1}{2}A_1(c - c_\alpha)^2 + \frac{1}{4}A_2(c - c_\beta)^4 \qquad (1)$$

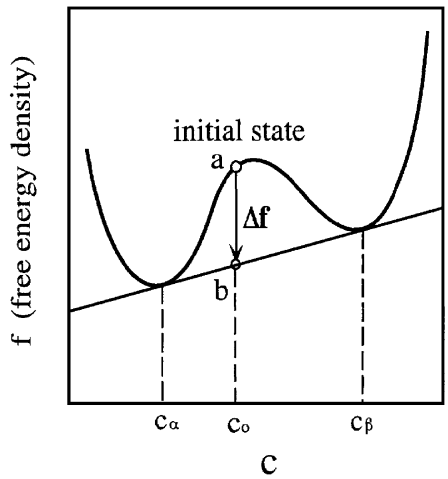

Figure 4. A schematic free energy vs. composition plot for spinodal decomposition.

where A_1, A_2, c_α, and c_β are positive constants. In general, the phenomenological expansion coefficients A_1 and A_2 are functions of temperature and their temperature dependence determines the specific thermodynamic behavior of the system. For example, A_1 should be negative when the temperatures are above the miscibility gap.

If an alloy is quenched from its homogenization temperature within a single-phase field in the phase diagram into a two-phase field, the free energy of the initial homogeneous single-phase, which is characterized by $c(\mathbf{r}, t) = c_0$, is given by point a in the free energy curve in Figure 4. If the alloy decomposes into a two-phase mixture of compositions c_α and c_β, the free energy is given by point b, which corresponds to the minimum free energy at the given composition. The bulk chemical free energy reduction (per unit volume) is the free energy difference at the two points a and b, i.e., Δf, which is the driving force for the decomposition.

Interfacial Energy. The interfacial energy is an excess free energy associated with the compositional and/or structural inhomogeneities occurring at interfaces. It is part of the chemical free energy and can be introduced into the coarse-grained free energy by adding a gradient term (or gradient terms for complex systems where more than one field variable is required) to the bulk free energy (Rowlinson, 1979; Ornstein and Zernicke, 1918; Landau, 1937a, b; Cahn and Hilliard, 1958), for example,

$$F_{\text{chem}} = \int_V \left[f(c) + \frac{1}{2}\kappa_C (\nabla c)^2 \right] dV \qquad (2)$$

where F_{chem} is the total chemical free energy, κ_C is the gradient energy coefficient, which, in principle, depends on both temperature and composition and can be expressed in terms of interatomic interaction energies (Cahn and Hilliard, 1958; Khachaturyan, 1983), (∇) is the gradient operator, and V is the system volume. The second term in the bracket of the integrand in Equation (2) is referred to as the gradient energy term. Please note that the gradient energy, (volume integral of the gradient) is not the interfacial energy. The interfacial energy by definition is the total excess free energy associated with inhomogeneities at interfaces and is given by (Cahn and Hilliard, 1958)

$$\sigma_{\text{int}} = \int_{c_\alpha}^{C_\beta} \sqrt{2\kappa_C [f(c) - f_0(c)]}\, dc \qquad (3)$$

where $f_0(c)$ is the equilibrium free energy density of a two-phase mixture. It is represented by the common tangent line through c_α and c_β in Figure 4. Therefore, the gradient energy is only part of the interfacial energy.

Elastic Energy. Microstructural evolution in solids usually involves crystal lattice rearrangement, which leads to a lattice mismatch between the coexisting phases/domains. If the interphase boundaries are coherent, i.e., the lattice planes are continuous across the boundaries, elastic strain fields will be generated in the vicinity of the boundaries to eliminate the lattice discontinuity. The elastic interaction associated with the strain fields has an infinite long-range asymptote decaying as $1/r^3$, where r is the separation distance between two interacting finite elements of the coexisting phases/domains. Accordingly, the elastic energy arising from such a long-range interaction is very different from the bulk chemical free energy and the interfacial energy, which are associated with the short-range interactions. For example, the bulk chemical free energy depends only on the volume fraction of each phase, and the interfacial energy depends only on the total interfacial area, while the elastic energy depends on both the volume and the morphology of the coexisting phases. The contribution of elastic energy to the total free energy results in a very special situation where the total bulk free energy becomes morphology dependent. In this case, the shape, size, orientation, and spatial arrangement of phases/domains become internal thermodynamic parameters similar to concentration and lro parameter profiles. Their equilibrium values are determined by minimizing the total free energy. Therefore, elastic energy relaxation is a key driving force dominating the microstructural evolution in coherent systems. It is responsible for the formation of various collective mesoscopic domain structures.

The elasticity theory for calculating the elastic energy of an arbitrary microstructure was proposed about 30 years ago by Khachaturyan (1967, 1983) and Khachaturyan and Shatalov (1969) using a sharp-interface description and a shape function to characterize a microstructure. It has been reformulated for the diffuse-interface description using a composition field, $c(\mathbf{r}, t)$, if the strain is predominantly caused by the concentration heterogeneity (Wang et al., 1991a,b, 1993; Chen et al., 1991; Onuki, 1989a,b), or lro parameter fields, $\eta_p^2(\mathbf{r}, t)$ (where p represents the pth orientation variant of the product phase), if the strain is mainly caused by the structural heterogeneity (Chen et al., 1992; Wang et al., 1993; Fan and Chen, 1995a; Wang et al., 1995). The elastic energy

has a closed form in Fourier space in terms of concentration or lro parameter fields,

$$E_{\text{el}} = \frac{1}{2}\int \frac{d^3k}{(2\pi)^3} B(\mathbf{e})\,|\tilde{c}(\mathbf{k})|^2 \tag{4}$$

$$E_{\text{el}} = \frac{1}{2}\sum_{pq}\int \frac{d^3k}{(2\pi)^3} B_{pq}(\mathbf{e})\{\eta_p^2(\mathbf{r},t)\}_{\mathbf{k}}\{\eta_q^2(\mathbf{r},t)\}_{\mathbf{k}}^{*} \tag{5}$$

where $\mathbf{e} = \mathbf{k}/k$ is a unit vector in reciprocal space, $\tilde{c}(\mathbf{k})$ and $\{\eta_p^2(\mathbf{r},t)\}_{\mathbf{k}}$ are the Fourier transforms of $c(\mathbf{r}, t)$ and $\eta_p^2(\mathbf{r},t)$, respectively, and $\{\eta_q^2(\mathbf{r},t)\}_{\mathbf{k}}^{*}$ is the complex conjugate of $\{\eta_q^2(\mathbf{r},t)\}_{\mathbf{k}}$. The sign $\int$ in Equations 4 and 5 means that a volume of $(2\pi)^3/V$ about $\mathbf{k} = 0$ is excluded from the integration.

$$B(\mathbf{e}) = c_{ijkl}\varepsilon_{ij}^0\varepsilon_{kl}^0 - e_i\sigma_{ij}^0\Omega_{jk}(\mathbf{e})\sigma_{kl}^0 e_l \tag{6}$$

$$B_{pq}(\mathbf{e}) = c_{ijkl}\varepsilon_{ij}^0(p)\varepsilon_{kl}^0(q) - e_i\sigma_{ij}^0(p)\Omega_{jk}(\mathbf{e})\sigma_{kl}^0(q)e_l \tag{7}$$

where e_i is the ith component of vector $\mathbf{e}$, c_{ijkl} is the elastic modulus tensor, ε_{ij}^0 and $\varepsilon_{ij}^0(p)$ are the stress-free transformation strain transforming the parent phase into the product phase, and the pth orientation variant of the product phase, respectively, $\sigma_{ij}^0(p) = c_{ijkl}\varepsilon_{kl}^0(p)$ and $\Omega_{ij}(\mathbf{e})$ is a Green function tensor, which is inverse to the tensor $\Omega(\mathbf{e})_{ij}^{-1} = c_{ijkl}e_k e_l$. In Equations 6 and 7, repeated indices imply summation.

The effect of elastic strain on coherent microstructural evolution can be simply included into the field formalism by adding the elastic energy (Equation 4 or 5) into the total coarse-grained free energy, F_{cg}. The function $B(\mathbf{e})$ in Equation 4 or $B_{pq}(\mathbf{e})$ in Equation 5 characterizes the elastic properties and crystallography of the phase transformation of a system through the Green function $\Omega_{ij}(\mathbf{e})$ and the coefficients σ_{ij}^0 and $\sigma_{ij}^0(p)$, respectively, while all the information concerning the morphology of the mesoscopic microstructure enters in the field variables $c(\mathbf{r}, t)$ and $\eta_p(\mathbf{r},t)$. It should be noted that Equations 4 and 5 are derived for homogeneous modulus cases where the coexisting phases are assumed to have the same elastic constants. Modulus misfit may also have an important effect on the microstructural evolution of coherent precipitates (Onuki and Nishimori, 1991; Lee, 1996a; Jou et al., 1997), particularly when an external stress field is applied (Lee, 1996b; Li and Chen 1997a). This effect can also be incorporated in the field approach (Li and Chen, 1997a) by utilizing the elastic energy equation of an inhomogeneous solid formulated by Khachaturyan et al. (1995).

Energies Associated with External Fields. Microstructures will, in general, respond to external fields. For example, ferroelastic, ferroelectric, or ferromagnetic domain walls will move under externally applied stress, electric, or magnetic fields, respectively. Therefore, one can tailor a microstructure by applying external fields. Practical examples include stress aging of superalloys to produce rafting structures (e.g., Tien and Copley, 1971) and thermomagnetic aging to produce highly anisotropic microstructures for permanent magnetic materials (e.g., Cowley et al., 1986). The driving force due to an external field can be incorporated into the field model by including a coupling term between an internal field and an applied field in the coarse-grained free energy: i.e.,

$$F_{\text{coup}} = -\int_V xY\,dV \tag{8}$$

where x represents an internal field such as a local strain field, a local electrical polarization field, or a local magnetic moment field, and Y represents the corresponding applied stress, electric, and magnetic field. The internal field can either be a field variable itself, chosen to represent a microstructure in the field model, or it can be represented by a field variable (Li and Chen, 1997a, b, 1998a, b). If the applied field is homogeneous, the coupling potential energy becomes

$$F_{\text{coup}} = -V\bar{x}Y \tag{9}$$

where $\bar{x}$ is the average value of the internal field over the entire system volume, V.

If a system is homogeneous in terms of its elastic properties and its dielectric and magnetic susceptibilities, this coupling term is the only contribution to the total driving force produced by the applied fields. However, the problem becomes much more complicated if the properties of the material are inhomogeneous. For example, for an elastically inhomogeneous material, such as a two-phase solid of which each phase has a different elastic modulus, an applied field will produce a different elastic deformation within each phase. Consequently, an applied stress field will cause a lattice mismatch in addition to the lattice mismatch due to their stress-free lattice parameter differences. In general, the contribution from external fields to the total driving force for an inhomogeneous material has to be computed numerically for a given microstructure. However, for systems with very small inhomogeneity, as shown by Khachaturyan et al. (1995) for the case of elastic inhomogeneity, the problem can be solved analytically using the effective medium approximation, and the contribution from externally applied stress fields can be directly incorporated into the field model, as will be shown later in one of the examples given in Practical Aspects of the Method.

The Field Kinetic Equations. In most systems, the microstructure evolution involves both compositional and structural changes. Therefore, we generally need two types of field variables, conserved and nonconserved, to fully define a microstructure. The most familiar example of a conserved field variable is the concentration field. It is conserved in a sense that its volume integral is a constant equal to the total number of solute atoms. An example of a nonconserved field is the lro parameter field, which describes the distinction between the symmetry of different phases or the crystallographic orientation between different structural domains of the same phase. Although the lro parameter does not enter explicitly into the equilibrium thermodynamics that are determined solely by the dependence of the free energy on compositions, it may not be

ignored in microstructure modeling. The reason is that it is the evolution of the lro parameter toward equilibrium that describes the crystal lattice rearrangement, atomic ordering, and, in particular, the metastable and transient structural states.

The temporal evolution of the concentration field is governed by a generalized diffusion equation that is usually referred to as the Cahn-Hillaird equation (Cahn, 1961, 1962):

$$\frac{\partial c(\mathbf{r},t)}{\partial t} = -\nabla \bullet \mathbf{J} \tag{10}$$

where $\mathbf{J} = -M\nabla\mu$ is the flux of solute atoms, M is the diffusion mobility, and

$$\mu = \frac{\delta F_{\mathrm{cg}}}{\delta c} = \frac{\delta F_{\mathrm{chem}}}{\delta c} + \frac{\delta F_{\mathrm{elast}}}{\delta c} + \cdots \tag{11}$$

is the chemical potential. The temporal evolution of the lro parameter field is described by a relaxation equation, often called the time-dependent Ginzburg-Landau (TDGL) equation or the Allen-Cahn equation,

$$\frac{\partial \eta(\mathbf{r},t)}{\partial t} = -L\frac{\delta F_{\mathrm{cg}}}{\partial \eta(\mathbf{r},t)} \tag{12}$$

where L is the relaxation constant. Various forms of the field kinetic equations can be found in Gunton et al. (1983). Equations 10 and 12 are coupled through the total coarse-grained free energy, F_{cg}. With random thermal noise terms added, both types of equations become stochastic and their applications to studying critical dynamics have been extensively discussed (Hohenberg and Halperin, 1977; Gunton et al., 1983).

PRACTICAL ASPECTS OF THE METHOD

In the above formulation, simulating microstructural evolution using CFM has been reduced to finding solutions of the field kinetic equations Equations 10 and/or 12 under conditions corresponding to either a prototype model system or a real system. The major input parameters include the kinetic coefficients in the kinetic equations and the expansion coefficients and phenomenological constants in the free energy equations. These parameters are listed in Table 2.

Because of its simplicity, generality, and flexibility, CFM has found a rich variety of applications in very different material systems in the past two decades. For example, by choosing different field variables, the same formalism has been adapted to study solidification in both single- and two-phase materials; grain growth in single-phase materials; coupled grain growth and Ostward ripening in two-phase composites; solid- and liquid-state sintering; and various solid-state phase transformations in metals and ceramics including superalloys, martensitic alloys, transformation toughened ceramics, ferroelectrics, and superconductors (see Table 1 for a summary and references). Later in this section we present a few typical examples to illustrate how to formulate a realistic CFM for a particular application.

Table 2. Major Input Parameters of CFM

Input Coefficients in CFM	Fitting Properties
M, L—The kinetic coefficients in Equations 11 and 13	In general, they can be fitted to atomic diffusion and grain/interfacial boundary mobility data
$A_i (i = 1, 2, \ldots)$—The polynomial expansion coefficient in free energy Equation 1	These parameters can be fitted to the typical free energy vs. concentration curve (and also free energy vs. lro parameter curves for ordering systems), which can be obtained from either the CALPHAD[a] program or CVM[b,c] calculations
κ_C—The gradient coefficients in Equation 2	It can be fitted to available interfacial energy data
c_{ijkl} and ε_0—Elastic constants and lattice misfit	Experimental data are available for many systems

Microstructural Evolution of Coherent Ordered Precipitates

Precipitation hardening by small dispersed particles of an ordered intermetallic phase is the major strengthening mechanism for many advanced engineering materials including high-temperature and ultralightweight alloys that are critical to the aerospace and automobile industries. The Ni-based superalloys are typical prototype examples. In these alloys, the ordered intermetallic γ'-Ni_3X $L1_2$ phase precipitates out from the compositionally disordered γ face-centered cubic (fcc) parent phase. Experimental studies have revealed a rich variety of interesting morphological patterns of γ', which play a critical role in determining the mechanical behavior of the material. Well-known examples include rafting structures and split patterns.

A typical example of the discontinuous rafting structure (chains of cuboid particles) formed in a Ni-based superalloy during isothermal aging can be found in Figure 1A, where the ordered particles (bright shades) formed via homogeneous nucleation are coherently embedded in the disordered parent phase matrix (dark shades). They have cuboidal shapes and are very well aligned along the elastically soft $\langle 100 \rangle$ directions. These ordered particles distinguish themselves from the disordered matrix by differences in composition, crystal symmetry, and lattice parameters. In addition, they also distinguish themselves from each other by the relative positions of the origin of their sublattices with respect to the origin of their parent phase lattice, which divides them into four distinctive types of ordered domains called antiphase domains (APDs). When these APDs impinge on each other during

growth and coarsening, a particular structural defect called an antiphase domain boundary (APB) is produced. The energy associated with APBs is usually much higher than the interfacial energy.

The complication associated with the combined effect of ordering and coherency strain in this system has made the microstructure simulation a difficult challenge. For example, all of these structural features have to be considered in a realistic model because they all contribute to the microstructural evolution.

The composition and structure changes associated with the $L1_2$ ordering can be described by the concentration field, $c(\mathbf{r}, t)$, and the lro parameter field, $\eta(\mathbf{r}, t)$, respectively. According to the concentration wave representation of atomic ordering (Khachaturyan, 1978), the lro parameters represent the amplitudes of the concentration waves that generate the atomic ordering. Since the $L1_2$ ordering is generated by superposition of three concentration waves along the three cubic directions in reciprocal space, we need three lro parameters to define the $L1_2$ structure. The combination of the three lro parameters will automatically characterize the four types of APDs and three types of APBs associated with the $L1_2$ ordering. The concentration field plus the three lro parameter fields will fully define the system at a mesoscopic level.

After selecting the field variables, the next step is to formulate the coarse-grained free energy as a functional of these fields. A general form of the polynomial approximation of the bulk chemical free energy can be written as a Taylor expansion series

$$\begin{aligned} f(c,\eta_1,\eta_2,\eta_3) = f_0(c,T) &+ \sum_{p=1}^{3} A_p(c,T)\eta_p \\ &+ \frac{1}{2}\sum_{p,q=1}^{3} A_{pq}(c,T)\eta_p\eta_q \\ &+ \frac{1}{3}\sum_{p,q,r=1}^{3} A_{pqr}(c,T)\eta_p\eta_q\eta_r \\ &+ \frac{1}{4}\sum_{p,q,r,s=1} A_{pqrs}(c,T)\eta_p\eta_q\eta_r\eta_s + \cdots \end{aligned} \tag{13}$$

where $A_p(c,T)$ to $A_{pqrs}(c,T)$ are the expansion coefficients. The free energy $f(c,\eta_1,\eta_2,\eta_3)$, must be invariant with respect to the symmetry operations of an fcc lattice. This requirement drastically simplifies the polynomial. For example, it reduces Equation 13 to the following (Wang et al., 1998):

$$\begin{aligned} f(c,\eta_1,\eta_2,\eta_3) = f_0(c,T) &+ \frac{1}{2}A_2(c,T)(\eta_1^2+\eta_2^2+\eta_3^2) \\ &+ \frac{1}{3}A_3(c,T)\eta_1\eta_2\eta_3 + \frac{1}{4}A_4(c,T)(\eta_1^4+\eta_2^4+\eta_3^4) \\ &+ \frac{1}{4}A_4'(c,T)(\eta_1^2+\eta_2^2+\eta_3^2)^2 + \cdots \end{aligned} \tag{14}$$

According to Equation 14, the minimum energy state is always 4-fold degenerate with respect to the lro parameters. For example, there are four sets of lro parameters that correspond to the free energy extremum, i.e.,

$$\begin{aligned} (\eta_1,\eta_2,\eta_3) = (\eta_0,\eta_0,\eta_0)(\eta_0,-\eta_0,-\eta_0),(-\eta_0,\eta_0,-\eta_0), \\ (-\eta_0,-\eta_0,\eta_0) \end{aligned} \tag{15}$$

where η_0 is the equilibrium lro parameter. These parameters satisfy the following extremum condition

$$\frac{\partial f(c,\eta_1,\eta_2,\eta_3)}{\partial \eta_p} = 0 \tag{16}$$

where $p = 1, 2, 3$. The four sets of lro parameters given in Equation 16 describe the four energetically and structurally equivalent APDs of the $L1_2$ ordered phase. Such a free energy polynomial for the $L1_2$ ordering was first obtained by Lifshitz (1941, 1944) using the theory of irreducible representation of space groups. Similar formulations were also used by Lai (1990), Braun et al. (1996), and Li and Chen (1997a).

The total chemical free energy with the contributions from both concentration and lro parameter inhomogeneities can be formulated by adding the gradient terms. A general form can be written as

$$\begin{aligned} F = \int_V \Big\{ &\frac{1}{2}\kappa_C[\nabla_C(\mathbf{r},t)]^2 + \frac{1}{2}\sum_{p=1}^{3}\kappa_{ij}(p)\nabla_i\eta_p(\mathbf{r},t)\nabla_j\eta_p(\mathbf{r},t) \\ &+ f(c,\eta_1,\eta_2,\eta_3)\Big\} dV \end{aligned} \tag{17}$$

where κ_C and $\kappa_{ij}(p)$ are the gradient energy coefficients and V is the total volume of the system. Different from Equation 2, additional gradient terms of lro parameters are included in Equation 18, which contribute to both interfacial and APB energies as a result of the structural inhomogeneity at these boundaries. These gradient terms introduce correlation between the compositions at neighboring points and also between the lro parameters at these points. In general, the gradient coefficients κ_C and $\kappa_{ij}(p)$ can be determined by fitting the calculated interfacial and APB energies to experimental data for a given system. Next, we present the simplest procedures to fit the polynomial approximation of Equation 14 to experimental data of a particular system.

In principle, with a sufficient number of the polynomial expansion coefficients as fitting parameters, the free energy can always be described with the desired accuracy. For the sake of simplicity, we approximate the free energy density $f(c,\eta_1,\eta_2,\eta_3)$ by a fourth-order polynomial. In this case, the expression of the free energy (Equation 14) for a single-ordered domain with $\eta_1 = \eta_2 = \eta_3 = \eta$ becomes

$$\begin{aligned} f(c,\eta) = &\frac{1}{2}B_1(c-c_1)^2 + \frac{1}{2}B_2(c_2-c)\eta^2 \\ &- \frac{1}{3}B_3\eta^3 + \frac{1}{4}B_4\eta^4 \end{aligned} \tag{18}$$

where

$$\frac{1}{2}B_1(c-c_1)^2 = f_0(c,T_0) \tag{19}$$

$$\frac{1}{2}B_2(c_2-c) = \frac{3}{2}A_2(c,T_0) \tag{20}$$

$$B_3 = -A_3(c,T_0) \tag{21}$$

$$\frac{1}{4}B_4 = \frac{3}{4}A_4(c,T_0) + \frac{9}{4}A_4'(c,T_0) \tag{22}$$

T_0 is the isothermal aging temperature and B_1, B_2, B_3, B_4, c_1, and c_2 are positive constants. The first requirement for the polynomial approximation in Equation 18 is that the signs of the coefficients should be determined in such a way that they provide a global minimum of $f(c,\eta_1,\eta_2,\eta_3)$ at the four sets of lro parameters given in Equation 15. In this case, minimization of the free energy will produce all four possible antiphase domains.

Minimizing $f(c,\eta)$ with respect to η gives the equilibrium value of the lro parameter $\eta = \eta_0(c)$. Substituting $\eta = \eta_0(c)$ into Equation 18 yields $f[c,\eta_0(c)]$, which becomes a function of c only. A generic plot of the *f-c* curve, which is typical for an fcc + $L1_2$ two-phase region in systems like Ni-Al superalloys, is shown in Figure 5. This plot differs from the plot for isostructural decomposition shown in Figure 4 in having two branches. One branch describes the ordered phase and the other describes the disordered phase. Their common tangent determines the equilibrium compositions of the ordered and disordered phases. The simplest way to find the coefficients in Equation 18 is to fit the polynomial to the *f-c* curves shown in Figure 5. If we assume that the equilibrium compositions of γ and γ' phases at $T_0 = 1270$ K are $c_\gamma = 0.125$ and $c_{\gamma'} = 0.24$ (Okamoto, 1993), the lro parameter for the ordered phase is $\eta_{\gamma'} = 0.99$, and the typical driving force of the transformation $|\Delta f| = f(c^*)$ [where c^* is the composition at which the γ and γ' phase have the same free energy (Fig. 5)] is unity, then the coefficients in Equation 19 will have the values $B_1 = 905.387$, $B_2 = 211.611$, $B_3 = 165.031$, $B_4 = 135.637$, $c_1 = 0.125$, and $c_2 = 0.383$, where B_1 to B_4 are measured in units of $|\Delta f|$. The *f-c* diagram produced by this set of parameters is identical to the one shown in Figure 5.

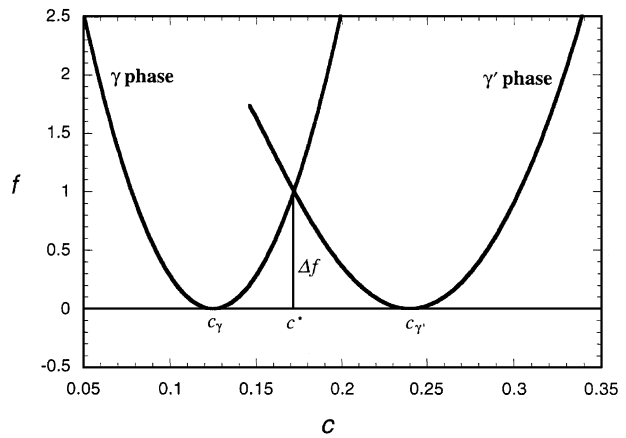

Figure 5. A typical free energy vs. composition plot for a γ/γ' two-phase Ni-Al alloy. The parameter f is presented in a reduced unit.

Note that the above fitting procedure is only semiquantitative because it fits only three characteristic points: the equilibrium compositions c_γ and $c_{\gamma'}$ and the typical driving force $|\Delta f|$ (whose absolute value will be determined below). More accurate fitting can be obtained if more data are available from either calculations or experiments.

In Ni-Al, the lattice parameters of the ordered and disordered phases depend on their compositions only. The strain energy of such a coherent system is then given by Equation 4. It is a functional of the concentration profile $c(\mathbf{r})$ only. The following experimental data have been used in the elastic energy calculation: lattice misfit between γ'/γ phases: $\varepsilon_0 = (a_{\gamma'} - a_\gamma)/a_\gamma \approx 0.0056$ (Miyazaki et al., 1982); elastic constants: $c_{11} = 2.31$, $c_{12} = 1.49$, $c_{44} = 1.17 \times 10^{12}$ erg/cm^3 (Pottenbohm et al., 1983). The typical elastic energy to bulk chemical free energy ratio, $\mu = (c_{11}+c_{12})^2\varepsilon_0^2/|\Delta f|c_{11}$, has been chosen to be 1600 in the simulation, which yields a typical driving force $|\Delta f| = 1.85 \times 10^7$ erg/cm^3.

As with any numerical simulation, it is more convenient to work with dimensionless quantities. If we divide both sides of Equations 10 and 12 by the product $L|\Delta f|$ and introduce a length unit l to the increment of the simulation grid to identify the spatial scale of the microstructure described by the solutions of these equations, we can present all the dimensional quantities entering the equations in the following dimensionless forms:

$$\tau = L|\Delta f|t, \quad \rho = x/l, \quad \varphi_1 = \frac{\kappa_C}{|\Delta f|l^2}, \quad \varphi_2 = \frac{\kappa}{|\Delta f|l^2}, \quad M^* = \frac{M}{Ll^2} \tag{23}$$

where $\tau, \rho, \varphi_1, \varphi_2$ and M^* are the dimensionless time, and length, and gradient energy coefficients and the diffusion mobility, respectively. For simplicity, the tensor coefficient $\kappa_{ij}(p)$ in Equation 17 has been assumed to be $\kappa_{ij}(p) = \kappa\delta_{ij}$ (where δ_{ij} is the Kronecker delta symbol), which is equivalent to assuming an isotropic APB energy. The following numerical values have been used in the simulation: $\varphi_1 = -50.0, \varphi_2 = 5.0, M^* = 0.4$. The value of φ_1 could be positive or negative for systems undergoing ordering, depending on the atomic interaction energies. Here φ_1 is assigned a negative value. By fitting the calculated interfacial energy between γ and γ', $\sigma_{\text{siml}} = \sigma^*_{\text{siml}}|\Delta f|l$ ($\sigma^*_{\text{siml}} = 4.608$ is the calculated dimensionless interfacial energy), to the experimental value, $\sigma_{\text{exp}} = 14.2$ erg/cm^3 (Ardell, 1968), we can find the length unit l of our numerical grid: $l = 16.7$ Å. The simulation result that we will show below is obtained for a 2D system with 512×512 grid points. Therefore, the size of the system is $512l = 8550$ Å. The time scale in the simulation can also be determined if we know the experimental data or calculated values of the kinetic coefficient L or M for the system considered.

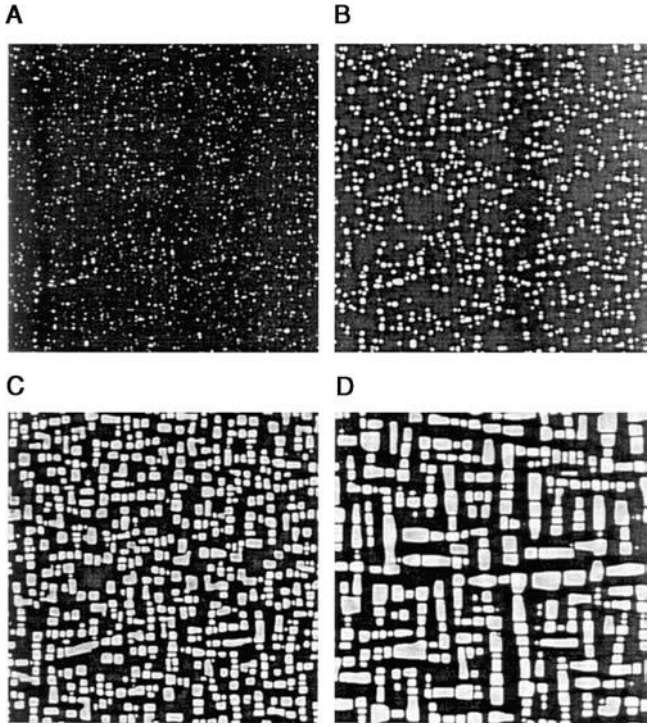

Figure 6. Microstructural evolution of γ' precipitates in Ni-Al obtained by CFM for a 2D system. (**A**) $\tau = 0.5$, (**B**) $\tau = 2$, (**C**) $\tau = 10$, (**D**) $\tau = 100$, where τ is a reduced time.

Since the model is able to describe both ordering and long-range elastic interaction and the material parameters have been fitted to experimental data, numerical solutions of the coupled field kinetic equations, Equations 10 and 12 should be able to reproduce the major characteristics of the microstructural development. Figure 6 shows a typical example of the simulated microstructural evolution for an alloy with 40% (volume fraction) of the ordered phase, where the microstructure is presented through shades of gray in accordance with the concentration field, $c(\mathbf{r}, t)$. The higher the value of $c(\mathbf{r}, t)$, the brighter the shade. The simulation was started from an initial state corresponding to a homogeneous supersaturated solid solution characterized by $c(\mathbf{r},t,0) = \bar{c}, \eta_1(\mathbf{r},t,0) = \eta_2(\mathbf{r},t,0) = \eta_3(\mathbf{r},t,0) = 0$, where $\bar{c}$ is the average composition of the alloy. The nucleation process of the transformation was simulated by the random noise terms added to the field kinetic equations, Equations 10 and 12. Because of the stochastic nature of the noise terms, the four types of ordered domains generated by the $L1_2$ ordering are randomly distributed and have comparable populations.

The microstructure predicted in Figure 6D shows a remarkable agreement with experimental observations (e.g., Fig. 1A), even though the simulation results were obtained for a 2D system. The major morphological features of γ' precipitates observed in the experiments—for example, both the cuboidal shapes of the particles and the discontinuous rafting structures (discrete cuboid particles aligned along the elastically soft directions)—have been reproduced. However, if any of the structural features of the system mentioned earlier (such as the crystal lattice misfit or the ordered nature of the precipitates) is not included, none of these features appear (see Wang et al., 1998, for details).

This example shows that CFM is able to capture the main characteristics of the microstructural evolution of misfitting ordered precipitates involving four types of ordered domains during all three stages of precipitation (e.g., nucleation, growth, and coarsening). Furthermore, it is rather straightforward to include the effect of applied stress in the homogeneous modulus approximation (Li and Chen, 1997a, b) and in cases where the modulus inhomogeneity is small (Khachaturyan et al., 1995; Li and Chen, 1997a). Roughly speaking, an applied stress produces two effects. One is an additional lattice mismatch due to the difference in the elastic constants of the precipitates and the matrix (e.g., the elastic inhomogeneity),

$$\Delta\varepsilon \sim \frac{\Delta\lambda}{\bar{\lambda}^2}\sigma^a \tag{24}$$

where $\Delta\varepsilon$ is the additional mismatch strain caused by the applied stress, $\Delta\lambda$ is the modulus difference between precipitates and matrix, $\bar{\lambda}$ is the average modulus of the two-phase solid, and σ^a is the magnitude of the applied stress. The other is a coupling potential energy,

$$\begin{aligned} F_{\text{coup}} &= -\int_V \bar{\varepsilon}\sigma^a \, d^3r \\ &\sim -V\sum_p \omega_p \varepsilon(p)\sigma^a \end{aligned} \tag{25}$$

where $\bar{\varepsilon}$ is the homogeneous strain and ω_p is the volume fraction of the precipitates.

For an elastically homogeneous system, the coupling potential energy term is the only contribution that can affect the microstructure of a two-phase material. For the γ' precipitates in the Ni-based superalloys discussed above, both γ and γ' are cubic, and thus the lattice misfit is dilatational. The γ' morphology can be affected by applied stresses only when the elastic modulus is inhomogeneous. According to Khachaturyan et al. (1995), if the difference between elastic constants of the precipitates and the matrix is small, the elastic energy of a coherent microstructure can be calculated by (1) replacing the elastic constant in the Green's function tenor, $\Omega_{ij}(e)$, with the average value

$$\bar{c}_{ijkl} = c^*_{ijkl}\omega + c_{ijkl}(1-\omega) \tag{26}$$

where c^*_{ijkl} and c_{ijkl} are the elastic constants of precipitates and the matrix, respectively; and by (2) replacing σ^0_{ij} in Equation 6 with

$$\sigma^*_{ij} = \bar{c}_{ijkl}\varepsilon^0_{kl} - \Delta c_{ijkl}\bar{\varepsilon}_{kl} \tag{27}$$

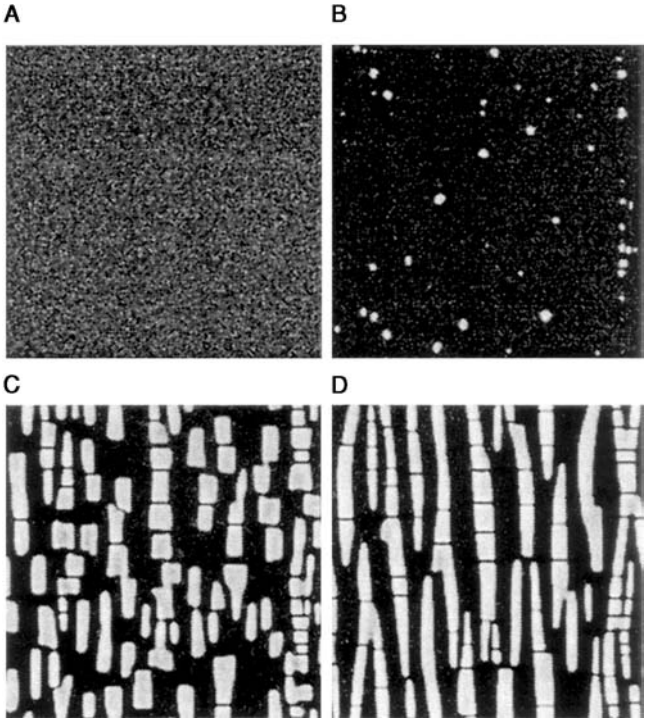

Figure 7. Microstructural evolution during precipitation of γ' particles in γ matrix under a vertically applied tensile strain. (**A**) $\tau = 100$, (**B**) $\tau = 300$, (**C**) $\tau = 1500$, (**D**) $\tau = 5000$, where τ is a reduced time.

where $\bar{\varepsilon}_{ij}$ is the homogeneous strain and $\Delta c_{ijkl} = c^*_{ijkl} - c_{ijkl}$. When the system is under a constant strain constraint, the homogeneous strain, $\bar{\epsilon}_{ij}$, is the applied strain. In this case, $bar\epsilon_{ij} = \bar{\epsilon}ij^a = \bar{S}_{ijkl}\bar{\sigma}^a_{kl}$, where $\bar{\epsilon}^a_{ij}$ is the constraint strain caused by initially applied stress $\bar{\sigma}^a_{kl}$. The parameter $\bar{S}_{ijkl}$ is the average fourth-rank compliance tensor. Figure 7 shows an example of the simulated microstructural evolution during precipitation of the γ' phase from a γ matrix under a constant tensile strain along the vertical direction (Li and Chen, 1997a). In the simulation, the kinetic equations were discretized using 256×256 square grids, and essentially the same thermodynamic model was employed as described above for the precipitation of γ' ordered particles from a γ matrix without an externally applied stress. The elastic constants of γ' and γ employed are (in units of 10^{10} ergs/cm^3) $C^*_{11} = 16.66$, $C^*_{12} = 10.65$, $C^*_{44} = 9.92$, and $C_{11} = 11.24$, $C_{12} = 6.27$, and $C_{44} = 5.69$, respectively. The magnitude of the initially applied stress is 4×10^8 ergs/cm^3 ($= 40$ MPa). It can been seen in Figure 7 that γ' precipitates were elongated along the applied tensile strain direction and formed a raft-like microstructure. Comparing this finding to the results obtained in the previous case (Fig. 6D), where the rafts are equally oriented along the elastically soft directions ([10] and [01] in the 2D system considered), the rafts in the presence of an external field are oriented uniaxially. In principle, one could use the same model to predict the effect of composition, phase volume fraction, stress state, and magnitude on the directional coarsening (or rafting) behavior.

Microstructural Evolution During Diffusion-Controlled Grain Growth

Controlling grain growth, and hence the grain size, is a critical issue for the processing and application of polycrystalline materials. One of the effective methods of controlling grain growth is the development of multiphase composites or duplex microstructures. An important example is the Al_2O_3-ZrO_2 two-phase composite, which has been extensively studied because of its toughening and superplastic behaviors (for a review, see Harmer et al., 1992). Coarsening of such a two-phase microstructure is driven by the reduction in the total grain and interphase boundary energy. It involves two quite different but simultaneous processes: grain growth through grain boundary migration and Ostwald ripening via long-range diffusion.

To model such a process, one can describe an arbitrary two-phase polycrystalline microstructure using the following set of field variables (Chen and Fan, 1996; Fan and Chen, 1997c, d, e),

$$\eta^\alpha_1(\mathbf{r},t), \eta^\alpha_2(\mathbf{r},t), \ldots, \eta^\alpha_p(\mathbf{r},t), \eta^\beta_1(\mathbf{r},t), \eta^\beta_2(\mathbf{r},t), \ldots, \eta^\beta_q(\mathbf{r},t), c(\mathbf{r},t) \tag{28}$$

where $\eta^\alpha_i (i = 1, \ldots, p)$ and $\eta^\beta_j (j = 1, \ldots, q)$ are called orientation field variables, with each representing grains of a given crystallographic orientation of a given phase. Those variables change continuously in space and assume continuous values ranging from -1.0 to 1.0. For example, a value of 1.0 for $\eta^\alpha_1(\mathbf{r},t)$, with values for all the other orientation variables 0.0 at $\mathbf{r}$, means that the material at position ($\mathbf{r}$, t) belongs to a α grain with the crystallographic orientation labeled as 1. Within the grain boundary region between two α grains with orientation 1 and 2, $\eta^\alpha_1(\mathbf{r},t)$ and $\eta^\alpha_2(\mathbf{r},t)$ will have absolute values intermediate between 0.0 and 1.0. The composition field is $c(\mathbf{r},t)$, which takes the value of c_α within an α grain and c_β within a β grain. The parameter $c(\mathbf{r},t)$ has intermediate values between c_α and c_β across an α/β interphase boundary.

The total free energy of such a two-phase system, F_{cg}, can be written as

$$F_{cg} = \int \Bigg[f_0(c(\mathbf{r},t), \eta^\alpha_1(\mathbf{r},t), \eta^\alpha_2(\mathbf{r},t), \ldots, \eta^\alpha_p(\mathbf{r},t), \eta^\beta_1(\mathbf{r},t), \eta^\beta_2(\mathbf{r},t), \ldots, \eta^\beta_q(\mathbf{r},t) + \frac{\kappa_c}{2}\left(\nabla c(\mathbf{r},t)\right)^2 + \sum_{i=1}^{p} \frac{\kappa^\alpha_i}{2}\left(\nabla \eta^\alpha_i(\mathbf{r},t)\right)^2 + \sum_{i=1}^{q} \frac{\kappa^\beta_i}{2}\left(\nabla \eta^\beta_i(\mathbf{r},t)\right)^2 \Bigg] d^3r \tag{29}$$

where f_0 is the local free energy density, κ_C, κ^α_i, and κ^β_i are the gradient energy coefficients for the composition field and orientation fields, and p and q represent the number of orientation field variables for α and β. The cross-gradient energy terms have been ignored for simplicity. In order to simulate the coupled grain growth and Ostwald ripening for a given system, the free energy density

function f_0 should have the following characteristics: (1) if the values of all the orientation field variables are zero, it describes the dependence of the free energy of the liquid phase on composition; (2) the free energy density as a function of composition in a given α-phase grain is obtained by minimizing f_0 with respect to the orientation field variable corresponding to that grain under the condition that all other orientation field variables are zero; (3) the free energy density as a function of composition of a given β phase grain may be obtained in a similar way. Therefore, all the phenomenological parameters in the free energy model, in principle, may be fixed using the information about the free energies of the liquid, solid α phase, and solid β phase.

Other main requirements for f_0 is that it has p degenerate minima with equal depth located at $(\eta_1^\alpha, \eta_2^\alpha, \ldots, \eta_p^\alpha) = (1,0,\ldots,0),(0,1,\ldots,0),\ldots,(0,0,\ldots,1)$in p-dimension orientation space at the equilibrium concentration c_α, and that it have q degenerate minima located at $(\eta_1^\beta, \eta_2^\beta, \ldots, \eta_q^\beta) = (1,0,\ldots,0),(0,1,\ldots,0),\ldots,(0,0,\ldots,1)$ at c_β. These requirements ensure that each point in space can only belong to one crystallographic orientation of a given phase.

Once the free energy density is obtained, the gradient energy coefficients can be fitted to the grain boundary energies of α and β as well as the α/β boundary energy by numerically solving Equations 10 and 12. The kinetic coefficients, in principle, can be fitted to grain boundary mobility and atomic diffusion data.

It should be emphasized that unless one is interested in phase transformations between α and β, the exact form of the free energy density function may not be very important in modeling microstructural evolution during coarsening of a two-phase solid. The reason is that the driving force for grain growth is the reduction in total grain and interphase boundary energy. Other important parameters are the diffusion coefficients and boundary mobilities. In other words, we assume that the values of the grain and interphase boundary energies together with the kinetic coefficients completely control the kinetics of microstructural evolution, irrespective of the form of the free energy density function.

Below we show an example of investigating the micostructural evolution and the grain growth kinetics in the Al_2O_3-ZrO_2 system using the continuum field model. It was reported (Chen and Xue, 1990) that the ratio of grain boundary energy in Al_2O_3 (denoted as α phase) to the interphase boundary energy between Al_2O_3 and ZrO_2 is $R_\alpha = \sigma^\alpha_{\text{alu}}/\sigma^{\alpha\beta}_{\text{int}} = 1.4$, and the ratio of grain boundary energy in ZrO_2 (denoted as β phase) to the interphase boundary energy is $R_\beta = \sigma^\beta_{\text{zir}}/\sigma^{\alpha\beta}_{\text{int}} = 0.97$. The gradient coefficients and phenomenological parameters in the free energy density function are fitted to reproduce these experimentally determined ratios. The following assumptions are made in the simulation: the grain boundary energies and the interphase boundary energy are isotropic, the grain boundary mobility is isotropic, and the chemical diffusion coefficient is the same in both phases. The systems of CH and TDGL equations are solved using the finite difference in space and explicit Euler method in time (Press et al., 1992).

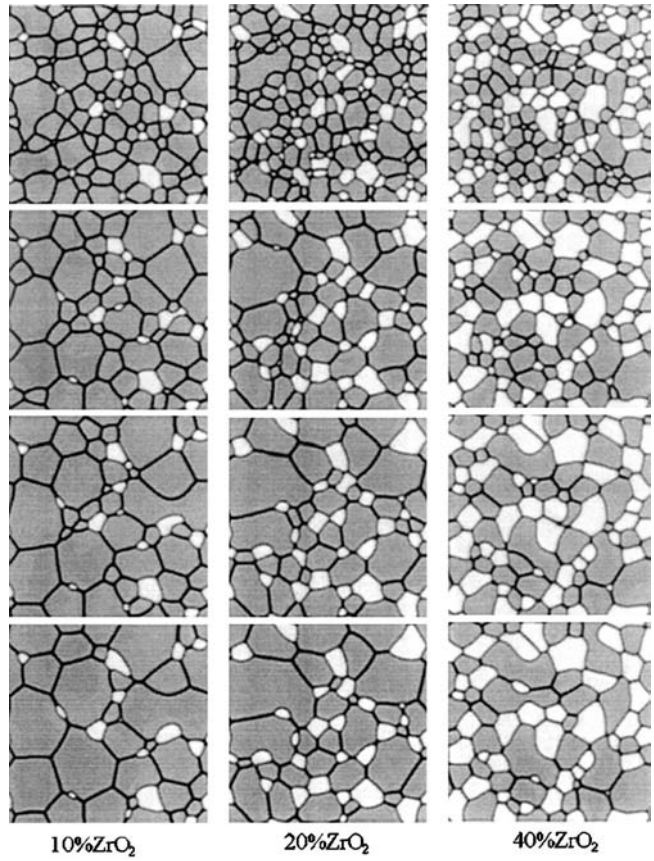

Figure 8. The temporal microstructural evolution in ZrO_2-Al_2O_3 two-phase solids with volume fraction of 10%, 20%, and 40% ZrO_2.

Examples of microstructures with 10%, 20%, and 40% volume fraction of ZrO_2 are shown in Figure 8. The computer simulations were carried out in two dimensions with 256×256 points and with periodic boundary conditions applied along both directions. Bright regions will be β grains (ZrO_2), gray regions are α grains (Al_2O_3), and the dark lines are grain or interphase boundaries. The total number of orientation field variables $(p + q)$ is 30. The initial microstructures were generated from fine grain structures produced by a normal grain growth simulation, and then by randomly assigning all the grains to either α or β according to the desired volume fractions. The simulated microstructures agree very well with those observed experimentally (Lange and Hirlinger, 1987; French et al., 1990; Alexander et al., 1994). More importantly, the main features of coupled grain growth and Ostwald ripening, as observed experimentally, are predicted by the computer simulations (for details, see Fan and Chen, 1997e).

One can obtain all the kinetic data and size distributions with the temporal microstructural evolution. For example, we showed that for both phases, the average size $(R)_t$ as a function of time (t) follows the growth-power law $R_t^m - R_0^m = kt$, with $m = 3$, which is independent of the volume fraction of the second phase, indicating that the coarsening is always controlled by the long-range diffusion process in two-phase solids (Fan and Chen, 1997e). The predicted volume fraction dependence of the kinetic

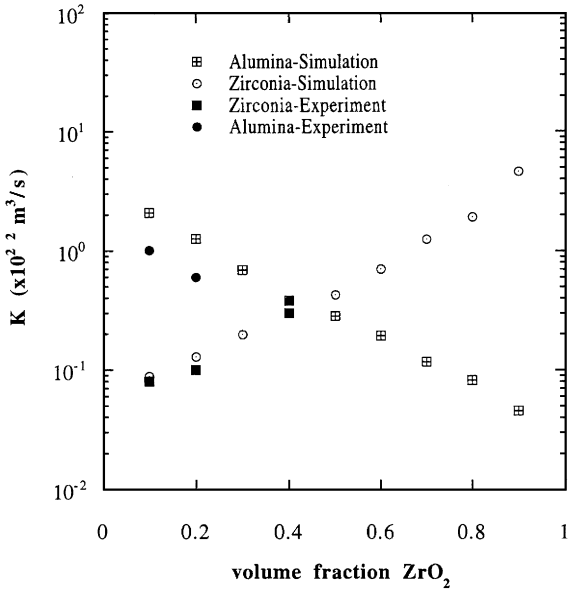

Figure 9. Comparison of simulation and experiments on the dependence of kinetic coefficient k in each phase on volume fraction of ZrO_2 in (Al_2O_3-ZrO_2). (Adopted from Alexander et al., 1994.)

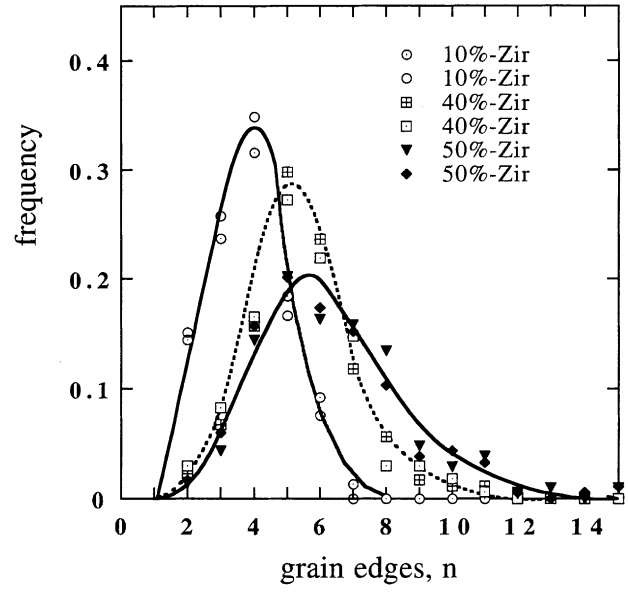

Figure 11. The effect of volume fraction on the topological distributions of ZrO_2 (β) Phase in Al_2O_3-ZrO_2 systems.

coefficients is compared with experimental results in the Ce-doped Al_2O_3-ZrO_2 (CeZTA) system (Alexander et al., 1994) in Figure 9. In Figure 9, the kinetic coefficients were normalized with the experimental values for CeZTA at 40% ZrO_2 (Alexander et al., 1994).

One type of distribution that we can obtain from the simulated microstructures is the topological distribution that is a plot of the frequency of grains with a certain number of sides. The topological distributions for the α and β phases in the 10% ZrO_2 system are compared in Figure 10. It can be seen that the second phase (10% ZrO_2) has much narrower distributions and the peaks have shifted to the four-sided grain while the distributions for the matrix phase (90% Al_2O_3) are much wider with the peaks still at the six-sided grains. The effect of volume fractions on topological distributions of the ZrO_2 phase is summarized in Figure 11. It shows that, as the volume fraction of ZrO_2 increases, topological distributions become wider and peak frequencies lower; this is accompanied by a shift of the peak position from four- to five-sided grains. Similar dependence of topological distributions on volume fractions were observed experimentally on 2D cross-sections of 3D microstructures in the Al_2O_3-ZrO_2 two-phase composites (Alexander, 1995).

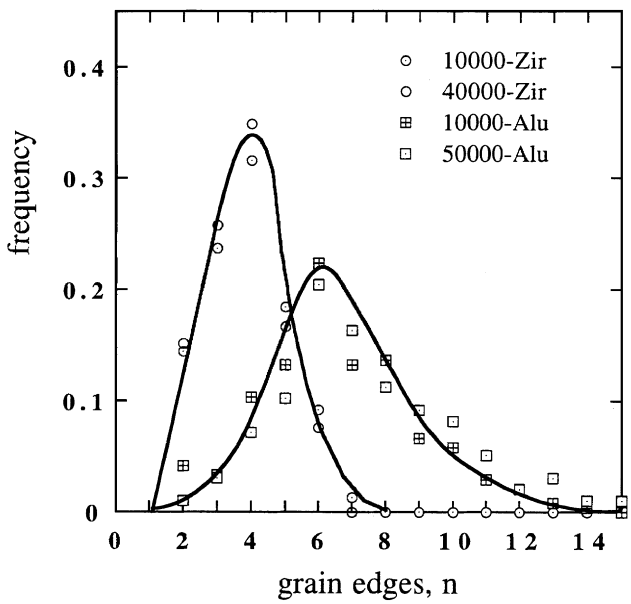

Figure 10. The comparison of topological distributions between Al_2O_3 (α) phase and ZrO_2 (β) Phase in 10% ZrO_2 + 90% Al_2O_3 system. The numbers in the legend represent the time steps.

FUTURE TRENDS

Though process modeling has enjoyed great success in the past years and many commercial software packages are currently available, simulating microstructural evolution is still at its infant stage. It significantly lags behind process modeling. To our knowledge, no commercial software programs are available to process design engineers. Most of the current effort focuses on model development, algorithm improvement, and analyses of fundamental problems. Much more effort is needed toward the development of commercial computational tools that are able to provide optimized processing conditions for desired microstructures. This task is very challenging and the following aspects should be properly addressed.

Links Between Microstructure Modeling and Atomistic Simulations, Continuum Process Modeling, and Property Calculation

One of the greatest challenges associated with materials research is that the fundamental phenomena that

determine the properties and performance of materials take place over a wide range of length and time scales, from microscopic through mesoscopic to macroscopic. As already mentioned, microstructure is defined by mesoscopic features and the CFM discussed in this unit is accordingly a mesoscopic technique. At present, no single simulation method can cover the full range of the three scales. Therefore, integrating simulation techniques across different length and time scales is the key to success in computational characterization of the generic processing/structure/property/performance relationship in material design. The mesoscopic simulation technique of microstructural evolution plays a critical role. It forms a bridge between the atomic-level fundamental calculation and the macroscopic semiempirical process and performance modeling. First of all, fundamental material properties obtained from the atomistic calculations, such as thermodynamic and transport properties, interfacial and grain boundary energies, elastic constants, and crystal structures and lattice parameters of equilibrium and metastable phases, provide valuable input for the mesoscopic microstructural simulations. The output of the mesoscopic simulations (e.g., the detailed microstructural evolution in the form of constitutive relations) can then serve as important input for the macroscopic modeling. Integrating simulations across different length scales and especially time scales is critical to the future virtual prototyping of industrial manufacturing processes, and it will remain the greatest challenge in the next decade for computational materials science (see, e.g., Kirchner et al., 1996; Tadmore et al., 1996; Cleri et al., 1998; Broughton and Rudd, 1998).

More Efficient Numerical Algorithms

From the examples presented above, one can see that simulating the microstructural evolution in various material systems using the field method has been reduced to finding solutions of the corresponding field kinetic equations with all the relevant thermodynamic driving forces incorporated and with the phenomenological parameters fitted to the observed or calculated values. Since the field equations are, in general, nonlinear coupled integral-differential equations, their solution is quite computationally intensive. For example, the typical microstructure evolution shown in Figure 6, obtained with 512×512 uniform grid points using the simple forward Euler technique for numerical integration, takes about 2 h of CPU time and 40 MB of memory of the Cray-C90 supercomputer at the Pittsburg Supercomputing Center. A typical 3D simulation of martensitic transformation using $64 \times 64 \times 64$ uniform grid points (Wang and Khachaturyan, 1997) requires about 2 h of CPU time and 48 MB of memory. Therefore, development of faster and less memory-demanding algorithms and techniques plays a critical role in practical applications of the method.

The most frequently used numerical algorithm in CFM is the finite difference method. For periodic boundary conditions, the fast Fourier transform algorithm (also called spectral method) has also been used, particularly in systems with long-range interactions. In this case, the Fourier transform converts the integral-deferential equations into algebraic equations. In reciprocal space, the simple forward Euler differencing technique can be employed for the numerical solution of the equations. It is a single-step explicit scheme allowing explicit calculation of quantities at time step $t + \Delta t$ in terms of only quantities known at time step t. The major advantages of this single-step explicit algorithm is that it takes little storage, requires a minimal number of Fourier transforms, and executes quickly because it is fully vectorizable (vectorizing a loop will speed up execution by roughly a factor of 10). The disadvantage is that it is only first-order accurate in Δt. In particular, when the field equations are solved in real space the stability with respect to mesh size, numerical noise, and time step could be a major problem. Therefore, more accurate methods are strongly recommended. The time steps allowed in the single-step forward Euler method in reciprocal space fall basically in the range of 0.1 to 0.001 (in reduced units).

Recently, Chen and Shen (1998) proposed a semi-implicit Fourier-spectral method for solving the field equations. For a single TDGL equation, it is demonstrated that for a prescribed accuracy of 0.5% in both the equilibrium profile of an order parameter and the interface velocity, the semi-implicit Fourier-spectral method is $\sim$200 and 900 times more efficient than the explicit Euler finite-difference scheme in 2D and 3D, respectively. For a single CH equation describing the strain-dominated microstructural evolution, the time step that one can use in the first-order semi-implicit Fourier-spectral method is about 400 to 500 times larger than the explicit Fourier-spectral method for the same accuracy.

In principle, the semi-implicit schemes can also be efficiently applied to the TDGL and CH equations with Dirichlet, Neumann, or mixed boundary conditions by using the fast Legendre- or Chebyshev-spectral methods developed (Shen, 1994, 1995) for second- and fourth-order equations. However, the semi-implicit scheme also has its limitations. It is most efficient when applied to problems whose principal elliptic operators have constant coefficients, although problems with variable coefficients can be treated with slightly less efficiency by an iterative procedure (Shen, 1994) or a collocation approach (see, e.g., Canuto et al., 1987). Also, since the proposed method uses a uniform grid for the spatial variables, it may be difficult to resolve extremely sharp interfaces with a moderate number of grid points. In this case, an adaptive spectral method may become more appropriate (see, e.g., Bayliss et al., 1990).

There are two generic features of microstructure evolution that can be utilized to improve the efficiency of CFM simulations. First, the linear dimensions of typical microstructure features such as average particle or domain size keep increasing in time. Second, the compositional and structural heterogeneities of an evolving microstructure usually assume significant values only at interphase or grain boundaries, particularly for coarsening, solidification, and grain growth. Therefore, an ideal numerical algorithm for solving the field kinetic equations should have the potential of generating (1) uniform-mesh grids that change scales in time and (2) adaptive nonuniform grids

that change scales in space, with the finest grids on the interfacial boundaries. The former will make it possible to capture structures and patterns developing at increasingly coarser length scales and the latter will allow us to simulate larger systems. Such adaptive algorithms are under active development. For example, Provatas et al. (1998) recently developed an adaptive grid algorithm to solve the field equations applied to solidification by using adaptive refinement of a finite element grid. They showed that, in two dimensions, solution time will scale linearly with the system size, rather than quadratically as one would expect in a uniform mesh. This finding allows one to solve the field model in much larger systems and for longer simulation times. However, such an adaptive method is generally much more complicated to implement than the uniform grid. In addition, if the spatial scale is only a few times larger than the interfacial width, such an adaptive scheme may not be advantageous over the uniform grid. It seems that the parallel processing techniques developed in massive MD simulations (see, e.g., Vashista et al., 1997) are more attractive in the development of more efficient CFM codes.

PROBLEMS

The accuracy of time and spatial discretization of the kinetic field equations may have a significant effect on the interfacial energy anisotropy and boundary mobility. A common error that could result from a rough discretization of space in the field method is the so-called dynamic frozen result (the microstructure stops to evolve with time artificially). Therefore, careful consideration must be given to a particular type of application, particularly when quantitative information on the absolute growth and coarsening rate of a microstructure is desired. Validation of the growth and coarsening kinetics of CFM simulations against known analytical solutions is strongly recommended. Recently, Bösch et al. (1995) proposed a new algorithm to overcome these problems by randomly rotating and shifting the coarse-grained lattice.

ACKNOWLEDGMENTS

The authors gratefully acknowledge support from the National Science Foundation under Career Award DMR9703044 (YW) and under grant number DMR 96-33719 (LQC) as well as from the Office of Naval Research under grant number N00014-95-1-0577 (LQC). We would also like to thank Bruce Patton for his comments on the manuscript and Depanwita Banerjee and Yuhui Liu for their help in preparing some of the micrographes.

BONDING IN METALS

INTRODUCTION

The conditions controlling alloy phase formation have been of concern for a long time, even in the period prior to the advent of the first computer-based electronic structure calculations in the 1950s. In those days, the role of such factors as atomic size and valence were considered, and significant insight was gained, associated with names such as Hume-Rothery. In recent times, electronic structure calculations have yielded the total energies of systems, and hence the heats of formation of competing real and hypothetical phases. Doing this accurately has become of increasing importance as the groups capable of thermodynamic measurements have dwindled in number.

This unit will concentrate on the alloys of the transition metals and will consider both the old and the new (for some early views of non-transition metal alloying, see Hume-Rothery, 1936). In the first part, we will inspect some of the ideas concerning metallic bonding that derive from the early days. Many of these ideas are still applicable and offer insights into alloy phase behavior that are computationally cheaper, and in some cases rather different, from those obtainable from detailed computation. In the second part, we will turn to the present-day total-energy calculations. Comparisons between theoretical and experimental heats of formation will not be made, because the spreads between experimental heats and their computed

counterparts are not altogether satisfying for metallic systems. Instead, the factors controlling the accuracy of the computational methods and the precision with which they are carried out will be inspected. All too often, consideration of computational costs leads to results that are less precisely defined than is needed. The discussion in the two sections necessarily reflects the biases and preoccupations of the authors.

FACTORS AFFECTING PHASE FORMATION

Bonding-Antibonding and Friedel's *d*-Band Energetics

If two electronic states in an atom, molecule, or solid are allowed by symmetry to mix, they will. This hybridization will lead to a "bonding" level lying lower in energy than the original unhybridized pair plus an "antibonding" level lying above. If only the bonding level is occupied, the system gains by the energy lowering. If, on the other hand, both are occupied, there is no gain to be had since the center of gravity of the energy of the pair is the same before and after hybridization. Friedel (1969) applied this observation to the d-band bonding of the transition metals by considering the ten d-electron states of a transition metal atom broadening into a d band due to interactions with neighboring atoms in an elemental metal. He presumed that the result was a rectangular density of states with its center of gravity at the original atomic level. With one d state per atom, the lowest tenth of the density of states would be occupied, and adding another d electron would necessarily result in less gain in band-broadening energy since it would have to lie higher in the density of states. Once the d bands are half-filled, there are only antibonding levels to be occupied and the band-broadening energy must drop, that energy being

$$E_{d\,\mathrm{band}} \propto n(10-n)W \tag{1}$$

where n is the d-electron count and W the bandwidth. This expression does quite well—i.e., the maximum cohesion (and the maximum melting temperatures) does occur in the middle of the transition metal rows. This trend has consequences for alloying because the heat of formation of an A_xB_{1-x} alloy involves the competition between the energy of the alloy and those of the elemental solids, i.e.,

$$\Delta H = E[A_xB_{1-x}] - xE[A] - (1-x)E[B] \tag{2}$$

If either A or B resides in the middle of a transition metal row, those atoms have the most to lose, and hence the alloy the least to gain, upon alloy formation.

Crystal Structures of the Transition Metals

Sorting out the structures of either the transition metals or the main group elements is best done by recourse to electronic structure calculations. In a classic paper, Pettifor (1970) did tight-binding calculations that correctly yielded the hcp→ bcc→hcp→fcc sequence that occurs as one traverses the transition metal rows, if one neglects the magnetism of the 3d elements (where hcp signifies hexagonal close-packed, bcc is body-centered cubic, and fcc is face-centered cubic). The situation is perhaps better described by Figure 1.

The Topologically Close-Packed Phases

While it is common to think of the metallic systems as forming in the fcc, bcc, and hcp structures, many other crystalline structures occur. An important class is the abovementioned Frank-Kasper phases. Consider packing atoms of equal size starting with a pair lying on a bond line and then adding other atoms at equal bond lengths lying on its equator. Adding two such atoms leads to a tetrahedron formed by the four atoms; adding others leads to additional tetrahedra sharing the bond line as a common edge. The number of regular tetrahedra that can be packed with a common edge (q_{tetra}) is nonintegral.

$$q_{\mathrm{tetra}} = \frac{2\pi}{\cos^{-1}(1/3)} = 5.104299\ldots \tag{3}$$

Thus, geometric factors frustrate the topological close packing associated with having an integral number of such neighbors common to a bond line. Frank and Kasper (1958, 1959) introduced a construct for crystalline structures that adjusts to this frustration. The construct involves four species of atomic environments and, having some relation to the above ideal tetrahedral packing, the resulting structures are known as tcp phases. The first environment is the 12-fold icosahedral environment where the atom at the center shares $q = 5$ common nearest

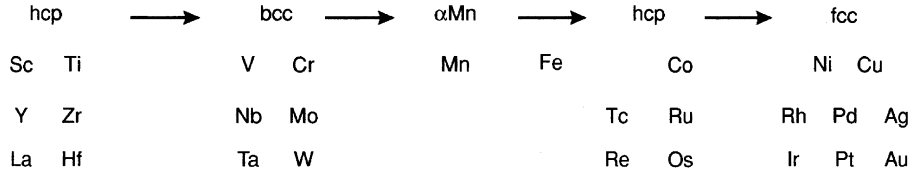

Figure 1. Crystalline structures of the transition metals as a function of d-band filling. αMn has a structure closely related to the topologically close-packed (tcp)– or Frank-Kasper (1958, 1959)–type phases and forms because of its magnetism; otherwise it would have the hcp structure. Similarly, Co would be fcc if it were not for its magnetism. Ferromagnetic iron is bcc and as a nonmagnetic metal would be hcp.

neighbors with each of the 12 neighbors. The other three environments are 14-, 15-, and 16-fold coordinated, each with twelve $q = 5$ neighbor bond lines plus two, three, and four neighbors, respectively, sharing $q = 6$ common nearest neighbors. Nelson (1983) has pointed out that the $q = 6$ bond lines may be viewed as $-72°$ rotations or disclinations leading to an average common nearest neighbor count that is close in value to q_{tetra}. Hence, the introduction of disclinations has caused a relaxation of the geometric frustration leading to a class of tcp phases that have, on average, tetrahedral packing. This involves nonplanar arrays of atomic sites of differing size. The nonplanarity encourages the systems to be nonductile. If compound formation is not too strong, transition metal alloys tend to form in structures determined by their average d-electron count—i.e., the same sequence, hcp → bcc → tcp → hcp → fcc, is found for the elements. For example, in the Mo-Ir system the four classes of structures, bcc → fcc, are traversed as a function of Ir concentration. One consequence of this is the occurrence of half-filled d-band alloys having high melting temperatures that are brittle tcp phases—i.e., high-temperature, mechanically unfavorable phases. The tcp phases that enter this sequence tend to have higher coordinated sites in the majority and include the Cr_3Si, A15 (the structure associated with the highest of the low-T_c superconductors), and the σCrFe structure. Other tcp phases where the larger atoms are in the minority tend to be line compounds and do not fall in the above sequence. These include the Laves phases and a number of structures in which the rare earth 3d hard magnets form. There are also closely related phases, such as αMn (Watson and Bennett, 1985), that involve other atomic environments in addition to the four Frank-Kasper building blocks. In fact, αMn itself may be viewed as an alloy, not between elements of differing atomic number, but instead between atoms of differing magnetic moment and hence of differing atomic size. There are also some hard magnet structures, closely related to the Laves phase, that involve building blocks other than the four of Frank and Kasper.

Bonding-Antibonding Effects

When considering stronger compound formation between transition metals, such as that involving one element at the beginning and another at the end of the transition metal rows, there are strong deviations from having the maximum heats of formation at 50:50 alloy composition. This skewing can be seen in the phase diagrams by drawing a line between the melting temperatures of the elemental metals and inspecting the deviations from that line for the compounds in between. This can be understood (Watson et al., 1989) in terms of the filling of "bonding" levels, while leaving the "antibonding" unfilled, but with unequal numbers of the two. Essential to this is that the centers of gravity of the d bands intrinsic to the two elements be separated. In general, the d levels of the elements to the left in the transition metal rows lie higher in energy, so that this condition is met. The consequences of this are seen in Figure 2, where the calculated total densities of states for observed phases of Pd_3Ti and PdTi are plotted

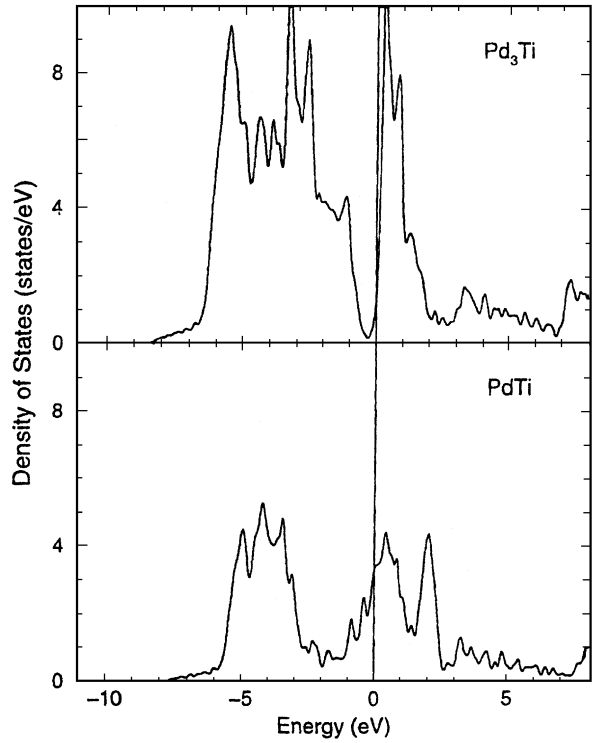

Figure 2. Calculated densities of states for Pd_3Ti (Cu_3Au structure) and PdTi (CsCl structure), which are the observed phases of the Pd-Ti system as obtained by the authors of this unit. The zeroes of the energy coordinate are the Fermi energies of the system. Some of the bumpiness of the plots is due to the finite sets of **k**-points (165 and 405 special points for the two structures), which suffice for determining the total energies of the systems.

(the densities of states in the upper plot are higher because there are twice the number of atoms in the crystal unit cell). The lower energy peak in each plot is Pd 4d in origin, while the higher energy peak is Ti 3d. However, there is substantial hybridization of the other atom's d and non-d character into the peaks. In the case of 1:1 PdTi, accommodation of the Pd-plus-Ti charge requires filling the low-lying "bonding" peak plus part of the antibonding. Going on to 3:1, all but a few states are accommodated by the bonding peak alone, resulting in a stabler alloy; the heat of formation (measured per atom or per mole-atom) is calculated to be some 50% greater than that for the 1:1. Hence, the phase diagram is significantly skewed. Because of the hybridization, very little site-to-site charge transfer is associated with this band filling—i.e., emptying the Ti peaks does not deplete the Ti sites of charge by much, if at all. Note that the alloy concentration at which the bonding peak is filled and the antibonding peak remains empty depends on the d counts of the two constituents. Thus, Ti alloyed with Rh would have this bonding extreme closer to 1:1, while for Ru, which averaged with Ti has half-filled d bands, the bonding peak filling occurs at 1:1.

When alloying a transition metal with a main group element such as Al there is only one set of d bands and the situation is different. Elemental Al has free electronlike bands, but this is not the case when alloyed with a transition metal where several factors are at play, including

hybridization with the transition metal and a separate narrowing of the *s*- and *p*-band character intrinsic to Al, since the Al atoms are more dilute and further apart. One consequence of this is that the *s*-like wave function character at the Al sites is concentrated in a peak deep in the conduction bands and contributes to the bonding to the extent that transition metal hybridization has contributed to this isolation. In contrast, the Al *p* character hybridizes with the transition metal wave function character throughout the bands, although it occurs most strongly deep in the transition metal *d* bands, thus again introducing a contribution to the bonding energy of the alloy. Also, if the transition metal *d* bands have a hollow in their density of states, hybridization, particularly with the Al *p*, tends to deepen and more sharply define the hollow. Occasionally this even leads to compounds that are insulators, such as Al_2Ru.

Size Effects

Another factor important to compound formation is the relative sizes of the constituent elements. Substitutional alloying is increasingly inhibited as the difference in size of the constituents is increased, since differences in size introduce local strains. Size is equally important to ordered phases. Consider the CsCl structure, common to many 1:1 intermetallic phases, which consists of a bcc lattice with one constituent occupying the cube centers and the other the cube corners. All of the fourteen first and second nearest neighbors are chemically important in the bcc lattice, which for the CsCl structure involves eight closest unlike and six slightly more removed like neighbors. Having eight closest unlike neighbors favors phase formation if the two constituents bond favorably. However, if the constituents differ markedly in size, and if the second-neighbor distance is favorable for bonding between like atoms of one constituent, it is unfavorable for the other. As a result, the large 4*d* and 5*d* members of the Sc and Ti columns do not form in the CsCl structure with other transition metals; instead the alloys are often found in structures such as the CrB structure, which has seven, rather than eight, unlike near neighbors and again six somewhat more distant like near neighbors among the large constituent atoms. In the case of the smaller atoms, the situation is different; there are but four like neighbors, two of which are at closer distances than the unlike neighbors, and thus this structure better accommodates atoms of measurably different size than does that of CsCl. Another bcc-based structure is the antiphase Heusler BiF_3 structure. Many ternaries such as N_2MA (where N and M are transition metals and A is Al, Ga, or In) form this structure, in which N atoms are placed at the cube corners, while the A and M atoms are placed in the cube centers but alternate along the *x*, *y*, and *z* directions. Important to the occurrence of these phases is that the A and the M not be too different in size.

Size is also important in the tcp phases. Those appearing in the abovementioned transition metal alloy sequences normally involve the 12-, 14-, and 15-fold Frank-Kasper sites. Their occurrence and some significant range of stoichiometries are favored (Watson and Bennett, 1984) if the larger atoms are in a range of 20% to 40% larger in elemental volume than the smaller constituent. In contrast, the Laves structures involve 12- and 16-fold sites, and these only occur if the large atoms have elemental volumes that are at least 30% greater than the small; in some cases the difference is a factor of 3. These size mismatches imply little or no deviation from strict stoichiometry in the Laves phases.

The role of size as a factor in controlling phase formation has been recognized for many years and still other examples could be mentioned. Size clearly has impact on the energetics of present-day electronic structure calculations, but its impact is often not transparent in the calculated results.

Charge Transfer and Electronegativities

In addition to size and valence (*d*-band filling) effects, a third factor long considered essential to compound formation is charge transfer. Although presumably heavily screened in metallic systems, charge transfer is normally attributed to the difference in electronegativities (i.e., the propensity of one element to attract valence electron charge from another element) of the constituent elements. Roughly speaking, there are as many electronegativity scales as there are workers who have considered the issue. One classic definition is that of Mulliken (Mulliken, 1935; Watson et al., 1983), where the electronegativity is taken to be the average ionization energy and electron affinity of the free ion. The question arises whether the behavior of the free atom is characteristic of the atom in a solid. One alternative choice for solids is to measure the heights of the elemental chemical potentials—i.e., their Fermi levels—with respect to each other inside a common crystalline environment or, barring this, to assign the elemental work functions to be their electronegativities (e.g., Gordy and Thomas, 1956). Miedema has employed such a metallurgist's scale, somewhat adjusted, in his effective Hamiltonian for the heats of formation of compounds (de Boer et al., 1988), where the square of the difference in electronegativities is the dominant binding term in the resultant heat. The results are at best semiquantitative and, as often as not, they get the direction of the abovementioned distortion of heats with concentration in the wrong direction. Nevertheless, these types of models represent a "best buy" when one compares quality of results to computational effort. Present-day electronic structure calculations provide much better estimates of heats of formation, but with vastly greater effort.

The difference in the electronegativities of two constituents in a compound may or may not provide some measure of the "transfer" of charge from one site to another. Different reasonably defined electronegativity scales will not even agree as to the direction of the transfer, but more serious are questions associated with defining such transfer in a crystal when given experimental data or the results of an electronic structure calculation. Some measurements, such as those of hyperfine effects or of chemically induced core or valence level shifts in photoemission, are complicated by more than one contribution to a shift. Even given a detailed charge density map from calculation

or from x-ray diffraction, there remain problems of attribution: one must first choose what part of the crystal is to be attributed to which atomic site and then the conclusions concerning any net transfer of charge will be a figment of that choice (e.g., assigning equal site volumes to atoms of patently different size does not make sense). Even if atomic cells can be satisfactorily chosen for some system, problems remain. As quantum chemists have known for years, the charge at a site is best understood as arising from three contributions: the charge intrinsic to the site, the tails of charge associated with neighboring atoms (the "medium" in which the atom finds itself), and an overlap charge (Watson et al., 1991). The overlap charge is often on the order of one electron's worth. Granted that the net charge transfer in a metallic system is small, the attribution of this overlap charge determines any statement concerning the charge at, and intrinsic to, a site. In the case of gold-alkali systems, computations indicate (Watson and Weinert, 1994) that while it is reasonable to assign the alkalis as being positively charged, their sites actually are negatively charged due to Au and overlap charge lapping into the site.

There are yet other complications to any consideration of "charge transfer." As noted earlier, hybridization in and out of d bands intrinsic to some particular transition metal involves the wave function character of other constituents of the alloy in question. This affects the on-site d-electron count. In alloys of Ni, Pd, or Pt with other transition metals or main group elements, for example, depletion by hybridization of the d count in their already filled d-band levels is accompanied by a filling of the unoccupied levels, resulting in the metals becoming noble metal-like with little net change in the charge intrinsic to the site. In the case of the noble metals, and particularly Cu and Au, whose d levels lie closer to the Fermi level, the filled d bands are actively involved in hybridization with other alloy constituents, resulting in a depletion of d-electron count that is screened by a charge of non-d character (Watson et al., 1971). One can argue as to how much this has to do with the simple view of "electronegativity." However, subtle shifts in charge occur on alloying, and depending on how one takes their measure, one can have them agree or disagree in their direction with some electronegativity scale.

Wave Function Character of Varying *l*

Usually, valence electrons of more than one l (orbital angular momentum quantum number) are involved in the chemistry of an atom's compound formation. For the transition and noble metals, it is the d and the non-d s-p electrons that are active, while for the light actinides there are f-band electrons at play as well. For the main group elements, there are s and p valence states and while the p may dominate in semiconductor compound formation, the s do play a role (Simons and Bloch, 1973; St. John and Bloch, 1974). In the case of the Au metal alloying cited above, Mössbauer isomer shifts, which sample changes in s-like contact charge density, detected charge flow onto Au sites, whereas photoelectron core-level shifts indicated deeper potentials and hence apparent charge transfer off Au sites. The Au $5d$ are more compact than the $6s$-$6p$, and any change in d count has approximately twice the effect on the potential as changes in the non-d counts (this is the same for the transition metals as well). As a result, the Au alloy photoemission shifts detected the d depletion due to hybridization into the d bands, while the isomer shift detected an increase in non-d charge. Neither experiment alone indicated the direction of any net charge transfer. Often the sign of transition metal core-level shifts upon alloying is indicative (Weinert and Watson, 1995) of the sign of the change in d-electron count, although this is less likely for atoms at the surface of a solid (Weinert and Watson, 1995). Because of the presence of charge of differing l, if the d count of one transition metal decreases upon alloying with another, this does not imply that the d count on the other site increases; in fact, as often as not, the d count increases or decreases at the two sites simultaneously. There can be subtle effects in simple metals as well. For example, it has long been recognized that Ca has unoccupied $3d$ levels not far above its Fermi level that hybridize during alloying. Clearly, having valence electrons of more than one l is important to alloy formation.

Loose Ends

A number of other matters will not be attended to in this unit. There are, e.g., other physical parameters that might be considered. When considering size for metallic systems, the atomic volume or radius appears to be appropriate. However, for semiconductor compounds, another measure of size appears to be relevant (Simons and Bloch, 1973; St. John and Bloch, 1974), namely, the size of the atomic cores in a pseudopotential description. Of course, the various parameters are not unrelated to one another, and the more such sets that are accumulated, the greater may be the linearities in any scheme employing them. Given such sets of parameters, there has been a substantial literature of so-called structural maps that employ the averages (as in d-band filling) and differences (as in sizes) as coordinates and in which the occurrence of compounds in some set of structures is plotted. This is a cheap way to search for possible new phases and to weed out suspect ones. As databases increase in size and availability, such mappings, employing multivariant analyses, will likely continue. These matters will not be discussed here.

WARNINGS AND PITFALLS

Electronic structure calculations have been surprisingly successful in reproducing and predicting physical properties of alloys. Because of this success, it is easy to be lulled into a false sense of security regarding the capabilities of these types of calculations. A critical examination of reported calculations must consider issues of both precision and accuracy. While these two terms are often used interchangeably, we draw a distinction between them.

We use the word "accuracy" to describe the ability to calculate, on an absolute scale, the physical properties of a system. The accuracy is limited by the physical effects,

which are included in the model used to describe the actual physical situation. "Precision," on the other hand, relates to how well one does solve a given model or set of equations. Thus, a very precise solution to a poor model will still have poor accuracy. Conversely, it is possible to get an answer in excellent agreement with experiment by inaccurately solving a poor model, but the predictive power of such a model would be questionable at best.

Issues Relating to Accuracy

The electronic structure problem for a real solid is a many-body problem with on the order of 10^{23} particles, all interacting via the Coulomb potential. The main difficulty in solving the many-body problem is not simply the large number of particles, but rather that they are interacting. Even solving the few-electron problem is nontrivial, although recently Monte Carlo techniques have been used to generate accurate wave functions for some atoms and small molecules where on the order of 10 electrons have been involved.

The H_2 molecule already demonstrates one of the most important conceptual problems in electronic structure theory, namely, the distinction between the band theory (molecular orbital) and the correlated-electron (Heitler-London) points of view. In the molecular orbital theory, the wave function is constructed in terms of Slater determinants of one-particle wave functions appropriate to the systems; for H_2, the single-particle wave functions are $\{\phi_a + \phi_b\}/\sqrt{2}$, where ϕ_a is a hydrogen-like function centered around the nucleus at R_a. This choice of single-particle wave functions means that the many-body wave function $\Psi(1,2)$ will have terms such as $\phi_a(1)\phi_a(2)$, i.e., there is a significant probability that both electrons will be on the same site. When there is significant overlap between the atomic wave functions, this behavior is what is expected; however, as the nuclei are separated, these terms remain and hence the H_2 molecule does not dissociate correctly. The Heitler-London approximation corrects this problem by simply neglecting those terms that would put two electrons on a single site. This additional Coulomb correlation is equivalent to including an additional large repulsive potential U between electrons on the same site within a molecular orbital picture, and is important in "localized" systems.

The simple band picture is roughly valid when the band width W (a measure of the overlap) is much larger than U; likewise the Heitler-London highly correlated picture is valid when U is much greater than W. It is important to realize that few, if any, systems are completely in one or the other limit and that many of the systems of current interest, such as the high-T_c superconductors, have $W \sim U$. Which limit is a better starting point in a practical calculation depends on the system, but it is naive, as well as incorrect, to claim that band theory methods are inapplicable to correlated systems. Conversely, the limitations in the treatment of correlations should always be kept in mind.

Most modern electronic structure calculations are based on density functional theory (Kohn and Sham, 1965). The basic idea, which is discussed in more detail elsewhere in this unit (SUMMARY OF ELECTRONIC STRUCTURE METHODS), is that the total energy (and related properties) of a many-electron system is a unique functional of the electron density, $n(r)$, and the external potential. In the standard Kohn-Sham construct, the many-body problem is reduced to a set of coupled one-particle equations. This procedure generates a mean-field approach, in which the effective one-particle potentials include not only the classical Hartree (electrostatic) and electron-ion potentials but also the so-called "exchange-correlation" potential. It is this exchange-correlation functional that contains the information about the many-body problem, including all the correlations discussed above.

While density functional theory is in principle correct, the true exchange-correlation functional is not known. Thus, to perform any calculations, approximations must be made. The most common approximation is the local density approximation (LDA), in which the exchange-correlation energy is given by

$$E_{xc} = \int dr\, n(r)\varepsilon_{xc}(r) \tag{4}$$

where $\varepsilon_{xc}(r)$ is the exchange-correlation energy of the homogeneous electron gas of density n. While this approximation seems rather radical, it has been surprisingly successful. This success can be traced in part to several properties: (1) the Coulomb potential between electrons is included correctly in a mean-field way and (2) the regions where the density is rapidly changing are either near the nucleus, where the electron-ion Coulomb potential is dominant, or in tail regions of atoms, where the density is small and will give only small exchange-correlation contributions to the total energy.

Although the LDA works rather well, there are several notable defects, including generally overestimated cohesive energies and underestimated lattice constants relative to experiment. A number of modifications to the exchange-correlation potential have been suggested. The various generalized gradient approximations (GGAs; Perdew et al., 1996, and references cited therein) include the effect of gradients of the density to the exchange-correlation potential, improving the cohesive energies in particular. The GGA treatment of magnetism also seems to be somewhat superior: the GGA correctly predicts the ferromagnetic bcc state to be most stable (Bagano et al., 1989; Singh et al., 1991; Asada and Terakura, 1992). This difference is apparently due in part to the larger magnetic site energy (Bagano et al., 1989) in the GGA than in the LDA; this increased magnetic site energy may also help resolve a discrepancy (R.E. Watson and M. Weinert, pers. comm.) in the heats of formation of nonmagnetic Fe compounds compared to experiment. Although the GGA seems promising, there are also some difficulties. The lattice constants for many systems, including a number of semiconductors, seem to be overestimated in the GGA, and consequently, magnetic moments are also often overestimated. Furthermore, proper introduction of gradient terms generally requires a substantial computational increase in the fast Fourier transform meshes in order to properly describe the potential terms arising from the density gradients.

Other correlations can be included by way of additional effective potentials. For example, the correlations associated with the on-site Coulomb repulsion characterized by U in the Heitler-London picture can be modeled by a local effective potential. Whether or not these various additional potentials can be derived rigorously is still an open question, and presently they are introduced mainly in an *ad hoc* fashion.

Given a density functional approximation to the electronic structure, there are still a number of other important issues that will limit the accuracy of the results. First, the quantum nature of the nuclei is generally ignored and the ions simply provide an external electrostatic potential as far as the electrons are concerned. The justification of the Born-Oppenheimer approximation is that the masses of the nuclei are several orders of magnitude larger than those of the electrons. For low-Z atoms such as hydrogen, zero-point effects may be important in some cases. These effects are especially of concern in so-called "first-principles molecular dynamics" calculations, since the semiclassical approximation used for the ions limits the range of validity to temperatures such that k_bT is significantly higher than the zero-point energies.

In making comparisons between calculations and experiments, the idealized nature of the calculational models must be kept in mind. Generally, for bulk systems, an infinite periodic system is assumed. Real systems are finite in extent and have surfaces. For many bulk properties, the effect of surfaces may be neglected, even though the electronic structure at surfaces is strongly modified from the bulk. Additionally, real materials are not perfectly ordered but have defects, both intrinsic and thermally activated. The theoretical study of these effects is an active area of research in its own right.

The results of electronic structure calculations are often compared to spectroscopic measurements, such as photoemission experiments. First, the eigenvalues obtained from a density functional calculation are not directly related to real (quasi) particles but are formally the Lagrange multipliers that ensure the orthogonality of the auxiliary one-particle functions. Thus, the comparison of calculated eigenvalues and experimental data is not formally sanctioned. This view justifies any errors, but is not particularly useful if one wants to make comparisons with experiments. In fact, experience has shown that such comparisons are often quite useful. Even if one were to assume that the eigenvalues correspond to real particles, it is important to realize that the calculations and the experiments are not describing the same situation. The band theory calculations are generally for the ground-state situation, whereas the experiments inherently measure excited-state properties. Thus, a standard band calculation will not describe satellites or other spectral features that result from strong final-state effects. The calculations, however, can provide a starting point for more detailed calculations that include such effects explicitly.

While the issues that have been discussed above are general effects that may affect the accuracy of the predictions, another class of issues is how particular effects—spin-orbit, spin-polarization, orbital effects, and multiplets—are described. These effects are often ignored or included in some approximation. Here, we will briefly discuss some aspects that should be kept in mind.

As is well known from elementary quantum mechanics, the spin-orbit interaction in a single-particle system can be related to dV/dr, where V is the (effective) potential. Since the density functional equations are effectively single-particle equations, this is also the form used in most calculations. However, for a many-electron atom, it is known (Blume and Watson, 1962, 1963) that the spin-orbit operator includes a two-electron piece and hence cannot be reduced to simply dV/dr. While the usual manner of including spin-orbit is not ideal, neglecting it altogether for heavy elements may be too drastic an approximation, especially if there are states near the Fermi level that will be split.

Magnetic effects are important in a large class of materials. A long-standing discussion has revolved around the question of whether itinerant models of magnetism can describe systems that are normally treated in a localized model. The exchange-correlation potential appropriate for magnetic systems is even less well known than that for nonmagnetic systems. Nevertheless, there have been notable successes in describing the magnetism of Ni and Fe, including the prediction of enhanced moments at surfaces.

Within band theory, these magnetic systems are most often treated by means of spin-polarized calculations, where different potentials and different orbitals are obtained for electrons of differing spin. A fundamental question arises in that the total spin of the system S is not a good quantum number in spin-polarized band theory calculations. Instead, S_z is the quantity that is determined. Furthermore, in most formulations the spin direction is uncoupled from the lattice; only by including the spin-orbit interaction can anisotropies be determined. Because of these various factors, results obtained for magnetic systems can be problematic. Of particular concern are those systems in which different types of magnetic interactions are competing, such as antiferromagnetic systems with several types of atoms. As yet, no general and practical formulation applicable to all systems exists, but a number of different approaches for specific cases have been considered.

While in most solids orbital effects are quenched, for some systems (such as Co and the actinides), the orbital moment may be substantial. The treatment of orbital effects until now has been based in an *ad hoc* manner on an approximation to the Racah formalism for atomic multiplet effects. The form generally used is strictly only valid (e.g., Watson et al., 1994) for the configuration with maximal spin, a condition that is not met for the metallic systems of interest here. However, even with these limitations, many computed orbital effects appear to be qualitatively in agreement with experiment. The extent to which this is accidental remains to be seen.

Finally, in systems that are localized in some sense, atomic multipletlike structure may be seen. Clearly, multiplets are closely related to both spin polarization and orbital effects. The standard LDA or GGA potentials cannot describe these effects correctly; they are simply beyond the physics that is built in, since multiplets have both total

spin and orbital momenta as good quantum numbers. In atomic Hartree-Fock theory, where the symmetries of multiplets are correctly obeyed, there is a subtle interplay between aspherical direct Coulomb and aspherical exchange terms. Different members of a multiplet have different balances of these contributions, leading to the same total energy despite different charge and spin densities. Moreover, many of the states are multideterminantal, whereas the Kohn-Sham states are effectively single-determinantal wave functions. An interesting point to note (e.g., Watson et al., 1994) is that for a given atomic configuration, there may be states belonging to different multiplets, of differing energy (with different S and L) that have identical charge and spin densities. An example of this in the d^4 configuration is the ^{5}D, $M_L = 1$, $M_S = 0$, which is constructed from six determinants—the ^{3}H, $M_L = 5$, $M_S = 0$, which is constructed from two determinants; and the ^{1}I, $M_L = 5, M_S = 0$, which is also constructed from two determinants. All three have identical charge and spin densities (and share a common M_S value), and thus both LDA- and GGA-like approximations will incorrectly yield the same total energies for these states. The existence of these states shows that the true exchange-correlation potential must depend on more than simply the charge and magnetization densities, perhaps also the current density. Until these issues are properly resolved, an *ad hoc* patch, which would be an improvement on the above-mentioned approximation for orbital effects, might be to replace the aspherical LDA (GGA) exchange-correlation contributions to the potential at a magnetic atomic site by an explicit estimate of the Hartree-Fock aspherical exchange terms (screened to crudely account for correlation), but the cost would be the necessity to carry electron wave function as well as density information during the course of a calculation.

Issues Relating to Precision

The majority of first-principles electronic structure calculations are done within the density functional framework, in particular either the LDA or the GGA. Once one has chosen such a model to describe the electronic structure, the ultimate accuracy has been established, but the precision of the solution will depend on a number of technical issues. In this section, we will address some of them.

There are literally orders-of-magnitude differences in computational cost depending on the approximations made. For understanding some properties, the simplest calculations may be completely adequate, but it should be clear that "precise" calculations will require detailed attention to the various approximations. One of the difficulties is that often the only way to show that a given approximation is adequate is to show that it agrees with a more rigorous calculation without that approximation.

First Principles Versus Tight Binding. The first distinction is between "first-principles" calculations and various parameterized models, such as tight binding. In a tight-binding scheme, the important interactions and matrix elements are parameterized based on some model systems, either experimental or theoretical, and these are then used to calculate the electronic structure of other systems. The advantage is that these methods are extremely fast, and for well-tested systems such as silicon and carbon, the results appear to be quite reliable. The main difficulties are related to those cases where the local environments are so different that the parameterizations are no longer adequate, including the case in which several different atomic species are present. In this case, the interactions among the different atoms may be strongly modified from the reference systems. Generating good tight-binding parameterizations is a nontrivial undertaking and involves a certain amount of art as well as science.

First-principles methods, on the other hand, start with the basic set of density functional equations and then must decide how to best solve them. In principle, once the nuclear charges and positions (and other external potentials) are given, the problem is well defined and there should be a density functional "answer." In practice, there are many different techniques, the choice of which is a matter of personal taste.

Self-Consistency. In density functional theory, the basic idea is to determine the minimum of the total energy with respect to the density. In the Kohn-Sham procedure, this minimization is cast into the form of a self-consistency condition on the density and potential. In both the Kohn-Sham procedure and a direct minimization, the precision of the result is related to the quality of the density. Depending on the properties of interest, the requirements can vary. The total energy is one of the least sensitive, since errors are second order in δn. However, when comparing the total energies of different systems, these second-order differences may be of the same scale as the desired answer. If one needs accurate single-particle wave functions in order to predict the quantity of interest, then there are more stringent requirements on self-consistency since the errors are first order. Decreasing δn requires more computer time, hence there is always some tradeoff between precision and practical considerations. In making these decisions, it is crucial to know what level of uncertainty one is willing to accept beforehand and to be prepared to monitor it.

All-Electron Versus Pseudopotential Methods. While self-consistency in some form is common to all methods, a major division exists between all-electron and pseudopotential methods. In all-electron methods, as the name implies, all the valence and core electrons are treated explicitly, although the core electrons may be treated in a slightly different fashion than the valence electrons. In this case, the electrostatic and exchange-correlation effects of all the electrons are explicitly included, even though the core electrons are not expected to take part in the chemical bonding. Because the core electrons are so strongly bound, the total energy is dominated by the contributions from the core. In the pseudopotential methods, these core electrons are replaced by an additional potential that attempts to mimic the effect of the core electrons on the valence state in the important bonding region of the solid. Here the calculated total energy is

significantly smaller in magnitude since the core electrons are not treated explicitly. In addition, the valence wave functions have been replaced by pseudo–wave functions that are significantly smoother than the all-electron wave functions in the core region. An important feature of pseudopotentials is the arbitrariness/freedom in the definition of the pseudopotentials that can be used to optimize them for different problems. While there are a number of advantages to pseudopotentials, including simplicity of computer codes, it must be emphasized that they are still an approximation to the all-electron result; furthermore, the large magnitude of the all-electron total energy does not cause any inherent problems.

Generating a pseudopotential that is transferable, i.e., that can be used in many different situations, is both nontrivial and an art; in an all-electron method, this question of transferability simply does not exist. The details of the pseudopotential generation scheme can affect both their convergence and the applicability. For example, near the beginning of the transition metal rows, the core cutoff radii are of necessity rather large, but strong compound formation may cause the atoms to have particularly close approaches. In such cases, it may be difficult to internally monitor the transferability of the pseudopotential, and one is left with making comparisons to all-electron calculations as the only reliable check. These comparisons between all-electron and pseudopotential results need to be done on the same systems. In fact, we have found in the Zr-Al system (Alatalo et al., 1998) that seemingly small changes in the construction of the pseudopotentials can cause qualitative differences in the relative stability of different phases. While this case may be rather extreme, it does provide a cautionary note.

Basis Sets. One of the major factors determining the precision of a calculation is the basis set used, both its type and its convergence properties. The physically most appealing is the linear combination of atomic orbitals (LCAOs). In this method, the basis functions are atomic orbitals centered at the atoms. From a simple chemical point of view, one would expect to need only nine functions ($1s$, $3p$, $5d$) per transition metal atom. While such calculations give an intuitive picture of the bonding, the general experience has been that significantly more basis functions per atom are needed, including higher l orbitals, in order to describe the changes in the wave functions due to bonding. One further related difficulty is that straightforwardly including more and more excited atomic orbitals is generally not the most efficient approach: it does not guarantee that the basis set is converging at a reasonable rate.

For systemic improvement of the basis set, plane waves are wonderful because they are a complete set with well-known convergence properties. It is equally important that plane waves have analytical properties that make the formulas generally quite simple. The disadvantage is that, in order to describe the sharp structure in the atomic core wave functions and in the nuclear-electron Coulomb interaction, exceedingly large numbers of plane waves are required. Pseudopotentials, because there are no core electrons and the very small wavelength structures in the valence wave functions have been removed, are ideally suited for use with plane-wave basis sets. However, even with pseudopotentials, the convergence of the total energy and wave functions with respect to the plane-wave cutoff must be monitored closely to ensure that the basis sets used are adequate, especially if different systems are to be compared. In addition, the convergence of the plane-wave energy cutoff may be rather slow, depending on both the particular atoms and the form of the pseudopotential used.

To treat the all-electron problem, another class of methods besides the LCAOs is used. In the augmented methods, the basis functions around a nucleus are given in terms of numerical solutions to the radial Schrödinger equation using the actual potential. Various methods exist that differ in the form of the functions to be matched to in the interstitial region: plane waves [e.g., various augmented plane wave (APW) and linear APW (LAPW) methods], r^{-l} (LMTOs), Slater-type orbitals (LASTOs), and Bessel/Hankel functions (KKR-type). The advantage of these methods is that in the core region where the wave functions are changing rapidly, the correct functions are used, ensuring that, e.g., cusp conditions are satisfied. These methods have several different cutoffs that can affect the precision of the methods. First, there is the spherical partial-wave cutoff l and the number of different functions inside the sphere that are used for each l. Second, the choice and number of tail functions are important. The tail functions should be flexible enough to describe the shape of the actual wave functions in that region. Again, plane waves (tails) have an advantage in that they span the interstitial well and the basis can be systematically improved. Typically, the number of augmented functions needed to achieve convergence is smaller than in pseudopotential methods, since the small-wavelength structure in the wave functions is described by numerical solutions to the corresponding Schrödinger equation.

The authors of this unit have employed a number of different calculational schemes, including the full-potential LAPW (FLAPW) (Wimmer et al., 1981; Weinert et al., 1982) and LASTO (Fernando et al., 1989) methods. The LASTO method, which uses Slater-type orbitals (STOs) as tail functions in the interstitial region, has been used to estimate heats of formation of transition metal alloys in a diverse set of well-packed and ill-packed compound crystal structures. Using a single s-, p-, and d-like set of STOs is inadequate for any serious estimate of compound heats of formation. Generally, $2s$, $2p$, $2d$, and an f-like STO were employed for a transition metal element when searching for the compound's optimum lattice volume, c/a, b/a, and any internal atomic coordinates not controlled by symmetry. Once this was done, a final calculation was performed with an additional d plus a g-like STO (clearly the same basis must be employed when determining the reference energy of the elemental metal). Usually, the effect on the calculated heat of formation was measurably < 0.01 eV/atom, but occasionally this difference was larger. These basis functions were only employed in the interstitial region, but nevertheless any claim of a computational precision of, say, 0.01 eV/atom required a substantial basis for such metallic transition metal compounds.

There are lessons to be learned from this experience for other schemes relying on localized basis functions and/or small basis sets such as the LMTO and LCAO methods.

Full Potentials. Over the years a number of different approximations have been made to the shape of the potential. In one simple picture, a solid can be thought of as being composed of spherical atoms. To a first approximation, this view is correct. However, the bonding will cause deviations and the charge will build up between the atoms. The charge density and the potential thus have rather complicated shapes in general. Schemes that account for these shapes are normally termed "full potential." Depending on the form of the basis functions and other details of the computational technique, accounting for the detailed shape of the potential throughout space may be costly and difficult.

A common approximation is the muffin-tin approximation, in which the potential in the spheres around the atoms is spherical and in the interstitial region it is flat. This form is a direct realization of the simple picture of a solid given above, and is not unreasonable for metallic bonding of close-packed systems. A variant of this approximation is the atomic-sphere approximation (ASA), in which the complications of dealing with the interstitial region are avoided by eliminating the interstices completely; in order to conserve the crystal volume, the spheres are increased in size. In the ASA, the spheres are thus of necessity overlapping. While these approximations are not too unreasonable for some systems, care must be exercised when comparing heats of formation of different structures, especially ones that are less well packed.

In a pure plane-wave method, the density and potential will again be given in terms of a plane-wave expansion. Even the Coulomb potential is easy to describe in this basis; for this reason, plane-wave (pseudopotential) methods are generally full potential to begin with. For the other methods, the solution of the Poisson equation becomes more problematic since either there are different representations in different regions of space or the site-centered representation is not well adapted to the long-range nonlocal nature of the Coulomb potential. Although this aspect of the problem can be dealt with, the largest computational cost of including the full potential is in including the nonspherical contributions consistently in the Hamiltonian.

Many of the present-day augmented methods, starting with the FLAPW method, include a full-potential description. However, even within methods that claim full potentials, there are differences. For example, the FLAPW method solves the Poisson equation correctly for the complete density described by different representations in different regions of space. On the other hand, certain "full-potential" LMTO methods solve for the nonspherical terms in the spheres but then extrapolate these results in order to obtain the potential in the interstitial. Even with this approximation, the results are significantly better than LMTO-ASA.

At this time, it can be argued that a calculation of a heat of formation or almost any other observable should not be deemed "precise" if it does not involve a full-potential treatment.

Brillouin Zone Sampling. In solving the electronic structure of an ordered solid, one is effectively considering a crystal of N unit cells with periodic boundary conditions. By making use of translational symmetry, one can reduce the problem to finding the electronic structure at N **k**-points in the Brillouin zone. Thus, there is an exact 1:1 correspondence between the effective crystal size and the number of **k**-points. If there are additional rotational (or time-reversal) symmetries, then the number of **k**-points that must be calculated is reduced. Note that using **k**-points to increase the effective crystal size always has linear scaling. Because the figure of merit is the effective crystal size, using large unit cells (but small numbers of **k**-points) to model real systems may be both inefficient and unreliable in describing the large-crystal limit. As a simple example, the electronic structure of a monoatomic fcc metal calculated using only 60 special **k**-points in the irreducible wedge is identical to that calculated using a supercell with 2048 atoms and the single Γ **k**-point. While this effective crystal size (number of **k**-points) is marginal for many purposes, a supercell of 2048 atoms is still not routinely done.

The number of **k**-points needed for a given system will depend on a number of factors. For filled-band systems such as semiconductors and insulators, fewer points will be needed. For metallic systems, enough **k**-points to adequately describe the Fermi surface and any structure in the density of states nearby are needed. Although tricks such as using very large temperature broadenings can be useful in reaching self-consistency, they cannot mimic structures in the density of states that are not included because of a poor sampling of the Brillouin zone. When comparisons are to be made between different structures, it is necessary that tests regarding the convergence in the number of **k**-points be made for each of the structures.

Besides the number of **k**-points that are used, it is important to use properly symmetrized **k**-points. A surprisingly common error in published papers is that only the **k**-points in the irreducible wedge appropriate for a high-symmetry (typically cubic) system is used, even when the irreducible wedge that should be used is larger because the overall symmetry has been reduced. Depending on the system, the effects of this type of error may not be so large that the results are blatantly wrong but may still be of significance.

Structural Relaxations. For simple systems, reliable experimental data exist for the structural parameters. For more complicated structures, however, there is often little, if any, data. Furthermore, LDA (or GGA) calculations do not exactly reproduce the experimental lattice constants or volumes, although they are reasonably good. The energies associated with these differences in lattice constants may be relatively small, on the order of a few hundredths of an electron volt per atom, but these energies may be significant when comparing the heats of formation of competing phases, both at the same and at different concentrations. For complicated structures, the internal structural parameters are even less well known experimentally, but they may have a relatively large effect on the heats of formation (the energies related to variations

of the internal parameters are on the scale of optical phonon modes).

To calculate consistent numbers for properties such as heats of formation, the total energy should be minimized with respect to both external (e.g., lattice constants) and internal structural parameters. Often the various parameters are coupled, making a search for the minimum rather time-consuming, although the use of forces and stresses are helpful. Furthermore, while the changes in the heats may be small, it is necessary to do the minimization in order to find out how close the initial guess was to the minimum.

Final Cautions

There is by now a large body of work suggesting that modern electronic structure theory is able to reliably predict many properties of materials, often to within the accuracy that can be obtained experimentally. In spite of this success, the underlying assumptions, both physical and technical, of the models used should always be kept in mind. In assessing the quality and applicability of a calculation, both accuracy and precision must be considered. Not all physical systems can be described using band theory, but the results of a band theory may still provide a good starting point or input to other theories. Even when the applicability of band theory is in question, a band calculation may give insights into the additional physics that needs to be included.

Technical issues, i.e., precision, are easier to quantify. In practice there are trade-offs between precision and computational cost. For many purposes, simpler methods with various approximations may be perfectly adequate. Unfortunately, often it is only possible to assess the effect of an approximation by (partially) removing it. Technical issues that we have found to be important in studies of heats of formation of metallic systems, regardless of the specific method used, include the flexibility of the basis set, adequate Brillouin zone sampling, and a full-potential description. Although the computational costs are relatively high, especially when the convergence checks are included, this effort is justified by the increased confidence in both the numerical results and the physics that is extracted from the numbers.

Over the years there has been a concern with the accuracy of the approximations employed. Too often, arguments concerning relative accuracies of, say, LDA versus GGA, for some particular purpose, have been mired in the inadequate precision of some of the computed results being compared. Verifying the precision of a result can easily increase the computational cost by one or more orders of magnitude but, on occasion, is essential. When the increased precision is not needed, simple economics dictates that it be avoided.

CONCLUSIONS

In this unit, we have attempted to address two issues associated with our understanding of alloy phase behavior. The first is the simple metallurgical modeling of the kind associated with Hume-Rothery's name (although many workers have been involved over the years). This modeling has involved parameters such as valence (d-band filling), size, and electronegativity. As we have attempted to indicate, partial contact can be made with present-day electronic structure theory. The ideas of Hume-Rothery, Friedel, and others concerning the role of d-band filling in alloy phase formation has an immediate association with the densities of states, such as those shown for Pd-Ti in Figure 2. In contrast, the relative sizes of alloy constituents are often essential to what phases are formed, but the role of size (except as manifested in a calculated total energy) is generally not transparent in band theory results. The third parameter, electronegativity, attempts to summarize complex bonding trends in a single parameter. Modern-day computation and experiment have shed light on these complexities. For the alloys at hand, "charge transfer" involves band hybridization of charge components of various l, of band filling, and of charge intrinsic to neighboring atoms overlapping onto the atom in question. All of these effects cannot be incorporated easily into a single numbered scale. Despite this, scanning for trends in phase behavior in terms of such parameters is more economical than doing vast arrays of electronic structure calculations in search of hitherto unobserved stable and metastable phases, and has a role in metallurgy to this day.

The second matter, which overlaps other units in this chapter, deals with the issues of accuracy and precision in band theory calculations and, in particular, their relevance to estimates of heats of formation. Too often, published results have not been calculated to the precision that a reader might reasonably presume or need.

BINARY AND MULTICOMPONENT DIFFUSION

INTRODUCTION

Diffusion is intimately related to the irreversible process of mixing. Almost two centuries ago it was observed for the first time that gases tend to mix, no matter how carefully stirring and convection are avoided. A similar tendency was later also observed in liquids. Already in 1820 Faraday and Stodart made alloys by mixing of metal powders and subsequent annealing. The scientific study of diffusion processes in solid metals started with the measurements of Au diffusion in Pb by Roberts-Austen (1896). The early development was discussed by, for example, Mehl (1936) during a seminar on atom movements (ASM, 1951) in Chicago. The more recent theoretical development concentrated on multicomponent effects, and extensive discussions can be found in the textbooks by Adda and Philibert (1966) and Kirkaldy and Young (1987).

Diffusion processes play an important role during all processing and usage of materials at elevated temperatures. Most materials are based on a major component and usually several alloy elements that may all be important for the performance of the materials, i.e., the materials are multicomponent systems. In this unit, we shall present the theoretical basis for analyzing diffusion processes in multicomponent solid metals. However, despite their limited practical applicability, for pedagogical reasons we shall also discuss binary systems.

We shall present the famous Fick's law and mention its relation to other linear laws such as Fourier's and Ohm's laws. We shall formulate a general linear law and introduce the concept of mobility. A special section is devoted to the choice of frame of reference and how this leads to the various diffusion coefficients, e.g., individual diffusion coefficients, chemical diffusion, tracer diffusion, and self-diffusion.

We shall then turn to the general multicomponent for mulation, i.e., the Fick-Onsager law, and extend the discussion on the frames of reference to the multicomponent systems.

In a multicomponent system with n components, $n - 1$ concentration variables may be varied independently, and

the concentration of one of the components has to be chosen as a dependent variable. This choice is arbitrary, but it is often convenient to choose one of the major components as the dependent component and sometimes it is even necessary to change the choice of dependent component. Then, a new set of diffusion coefficients have to be calculated from the old set. This is discussed in the section Change of Dependent Concentration Variable.

The diffusion coefficients, often called diffusivities, express the linear relation between diffusive flux and concentration gradients. However, from a strict thermodynamic point of view, concentration gradients are not forces because real forces are gradients of some potential, e.g., electrical potential or chemical potential, and concentration is not a true potential. The kinetic coefficients relating flux to gradients in chemical potential are called mobilities. In a system with n components, $n(n-1)$ diffusion coefficients are needed to give a full representation of the diffusion behavior whereas there are only n independent mobilities, one for each diffusing component. This means that the diffusivities are not independent, and experimental data should thus be stored as mobilities rather than as diffusivities. For binary systems it does not matter whether diffusivities or mobilities are stored, but for ternary systems there are six diffusivities and only three mobilities. For higher-order systems the difference becomes larger, and in practice it is impossible to construct a database based on experimentally measured diffusivities. A database should thus be based upon mobilities and a method to calculate the diffusivities whenever needed. A method to represent experimental information in terms of mobilities for diffusion in multicomponent interstitial and substitutional metallic systems is presented, and the temperature and concentration dependences of the mobilities are discussed. The influence of magnetic and chemical order will be discussed.

In this unit we shall not discuss the mathematical solution of diffusion problems. There is a rich literature on analytical solutions of heat flow and diffusion problems; see, e.g., the well-known texts by Carslaw and Jaeger (1946/1959), Jost (1952), and Crank (1956). It must be emphasized that the analytical solutions are usually less applicable to practical calculations because they cannot take into account realistic conditions, e.g., the concentration dependence of the diffusivities and more complex boundary conditions. In binary systems it may sometimes be reasonable to approximate the diffusion coefficient as constant and obtain satisfactory results with analytical solutions. In multicomponent systems the so-called off-diagonal diffusivities are strong functions of concentration and may be approximated as constant only when the concentration differences are small. For multicomponent systems, it is thus necessary to use numerical methods based on finite differences (FDM) or finite elements (FEM).

THE LINEAR LAWS

Fick's Law

The formal basis for the diffusion theory was laid by the German physiologist Adolf Fick, who presented his theoretical analysis in 1855. For an isothermal, isobaric, one-phase binary system with diffusion of a species B in one direction z, Fick's famous law reads

$$J_{\mathrm{B}} = -D_{\mathrm{B}} \frac{\partial c_{\mathrm{B}}}{\partial z} \tag{1}$$

where J_{B} is the flux of B, i.e., the amount of B that passes per unit time and unit area through a plane perpendicular to the z axis, and c_{B} is the concentration of B, i.e., the amount of B per unit volume. Fick's law thus states that the flux is proportional to the concentration gradient, and D_{B} is the proportionality constant called the diffusivity or the diffusion coefficient of B and has the dimension length squared over time. Sometimes it is called the diffusion constant, but this term should be avoided since D is not a constant at all. For instance, its variation with temperature is very important. It is usually represented by the following mathematical expression, the so-called Arrhenius relation:

$$D = D_0 \exp\left(\frac{-Q}{RT}\right) \tag{2}$$

where Q is the activation energy for diffusion, D_0 is the frequency factor, R is the gas constant, and T is the absolute temperature.

The flux J must be measured in a way analogous to the way used for the concentration c. If J is measured in moles per unit area and time, c must be in moles per volume. If J is measured in mass per unit area and time, c must be measured in mass per volume. Notice that the concentration in Fick's law must never be expressed as mass percent or mole fraction. When the primary data are in percent or fraction, they must be transformed. We thus obtain, e.g.,

$$c_{\mathrm{B}}\left(\frac{\mathrm{mol\,B}}{m^3}\right) = \frac{x_{\mathrm{B}}}{V_m}\left(\frac{\mathrm{mol\,B/mol}}{m^3/\mathrm{mol}}\right) \tag{3}$$

and

$$dc_{\mathrm{B}} = \left(1 - \frac{d\ln V_m}{d\ln x_{\mathrm{B}}}\right)\frac{dx_{\mathrm{B}}}{V_m} \tag{4}$$

where V_m is the molar volume and x_{B} the mole fraction. We can thus write Fick's law in the form

$$J_{\mathrm{B}} = -\frac{D^x_{\mathrm{B}}}{V_m}\frac{\partial x_{\mathrm{B}}}{\partial z} \tag{5}$$

where $D^x_{\mathrm{B}} = (1 - d\ln V_m/d\ln x_{\mathrm{B}})D_{\mathrm{B}}$. It may often be justified to approximate D^x_{B} with D_{B}, and in the following we shall adopt this approximation and drop the superscript x.

Experimental data usually indicate that the diffusion coefficient varies with concentration. With D evaluated experimentally as a function of concentration, Fick's law may be applied for practical calculations and yields precise results. Although such a concentration dependence certainly makes it more difficult to find analytical solutions to diffusion, it is easily handled by numerical methods on

the computer. However, it must be emphasized that the diffusivity is not allowed to vary with the concentration gradient.

There are many physical phenomena that obey the same type of linear law, e.g., Fourier's law for heat conduction and Ohm's law for electrical conduction.

General Formulation

Fick's law for diffusion can be brought into a more fundamental form by introducing the appropriate thermodynamic potential, i.e., the chemical potential μ_B, instead of the concentration. Assuming that $\mu_B = \mu_B(c_B)$,

$$J_B = -D_B \frac{\partial c_B}{\partial z} = -L_B \frac{\partial \mu_B}{\partial z} = -L_B \frac{d\mu_B}{dc_B} \frac{\partial c_B}{\partial z} \tag{6}$$

i.e.,

$$D_B = L_B \frac{d\mu_B}{dc_B} \tag{7}$$

where L_B is a kinetic quantity playing the same role as the heat conductivity in Fourier's law and the electric conductivity in Ohm's law. Noting that a potential gradient is a force, we may thus state all such laws in the same form: Flux is proportional to force. This is quite different from the situation of Newtonian mechanics, which states that the action of a force on a body causes the body to accelerate with an acceleration proportional to the force. However, if the body moves through a media with friction, a linear relation between velocity and force is observed after a transient time.

Note that for ideal or dilute solutions we have

$$\mu_B = \mu_B^0 + RT \ln x_B = \mu_B^0 + RT \ln(c_B V_m) \tag{8}$$

and we find for the case when V_m may be approximated as constant that

$$D_B = \frac{RT}{x_B} V_m L_B \tag{9}$$

Mobility

From a more fundamental point of view we may understand that Fick's law should be based on $\partial\mu_B/\partial z$, which is the force that acts on the B atoms in the z direction. One should thus expect a "current density" that is proportional to this force and also to the number of B atoms that feel this force, i.e., the number of B atoms per volume, $c_B = x_B/V_m$. The constant of proportionality that results from such a consideration may be regarded as the mobility of B. This quantity is usually denoted by M_B and is defined by

$$J_B = -M_B \frac{x_B}{V_m} \frac{\partial \mu_B}{\partial z} \tag{10}$$

By comparison, we find $M_B x_B/V_m = L_B$, and thus

$$D_B = M_B \frac{x_B}{V_m} \frac{d\mu_B}{dc_B} \tag{11}$$

For dilute or ideal solutions we find

$$D_B = M_B RT \tag{12}$$

This relation was initially derived by Einstein. At this stage we may notice that Equation 10 has important consequences if we want to predict how the diffusion of B is affected when one more element is added to the system. When element C is added to a binary A-B alloy, we have $\mu_B = \mu_B(c_B, c_C)$, and consequently

$$\begin{aligned} J_B &= -M_B c_B \frac{\partial \mu_B}{\partial z} = -M_B c_B \left(\frac{\partial \mu_B}{\partial c_B} \frac{\partial c_B}{\partial z} + \frac{\partial \mu_B}{\partial c_C} \frac{\partial c_C}{\partial z} \right) \\ &= -D_{BB} \frac{\partial c_B}{\partial z} - D_{BC} \frac{\partial c_C}{\partial z} \end{aligned} \tag{13}$$

i.e., we find that the diffusion of B not only depends on the concentration gradient of B itself but also on the concentration gradient of C. Thus the diffusion of B is described by two diffusion coefficients:

$$D_{BB} = M_B c_B \frac{\partial \mu_B}{\partial c_B} \tag{14}$$

$$D_{BC} = M_B c_B \frac{\partial \mu_B}{\partial c_C} \tag{15}$$

To describe the diffusion of both B and C, we would thus need at least four diffusion coefficients.

DIFFERENT FRAMES OF REFERENCE AND THEIR DIFFUSION COEFFICIENTS

Number-Fixed Frame of Reference

The form of Fick's law depends to some degree upon how one defines the position of a certain point, i.e., the frame of reference. One method is to count the number of moles on each side of the point of interest and to require that these numbers stay constant. For a binary system this method will automatically lead to

$$J_A + J_B = 0 \tag{16}$$

if J_A and J_B are expressed in moles. This particular frame of reference is usually called the number-fixed frame of reference. If we now apply Fick's law, we shall find

$$-\frac{D_A}{V_m} \frac{\partial x_A}{\partial z} = J_A = -J_B = \frac{D_B}{V_m} \frac{\partial x_B}{\partial z} \tag{17}$$

Because $\partial x_A/\partial z = -\partial x_B/\partial z$, we must have $D_A = D_B$. The above method to define the frame of reference is thus equivalent to assuming that $D_A = D_B$. In a binary system we can thus only evaluate one diffusion coefficient if the number-fixed frame of reference is used. This diffusion

coefficient describes how rapidly concentration gradients are leveled out, i.e., the mixing of A and B, and is called the "chemical diffusion coefficient" or the "interdiffusion coefficient."

Volume-Fixed Frame of Reference

Rather than count the number of moles flowing in each direction, one could look at the volume and define a frame of reference from the condition that there would be no net flow of volume, i.e.,

$$J_A V_A + J_B V_B = 0 \tag{18}$$

where V_A and V_B are the partial molar volumes of A and B, respectively. This frame of reference is called the volume-fixed frame of reference. Also in this frame of reference it is possible to evaluate only one diffusion coefficient in a binary system.

Lattice-Fixed Frame of Reference

Another method of defining the position of a point is to place inert markers in the system at the points of interest. One could then measure the flux of A and B atoms relative to the markers. It is then possible that more A atoms will diffuse in one direction than will B atoms in the opposite direction. In that case one must work with different diffusion coefficients D_A and D_B. Using this method, we may thus evaluate individual diffusion coefficients for A and B. Sometimes the term "intrinsic diffusion coefficients" is used. Since the inert markers are regarded as fixed to the crystalline lattice, this frame of reference is called the lattice-fixed frame of reference.

Suppose that it is possible to evaluate the fluxes for A and B individually in a binary system, i.e., the lattice-fixed frame of reference. In this case, we may apply Fick's law for each of the two components:

$$J_A = -\frac{D_A}{V_m}\frac{\partial x_A}{\partial z} \tag{19}$$

$$J_B = -\frac{D_B}{V_m}\frac{\partial x_B}{\partial z} \tag{20}$$

The individual, or intrinsic, diffusion coefficients D_A and D_B usually have different values. It is convenient in a binary system to choose one independent concentration and eliminate the other one. From $\partial x_A/\partial z = -\partial x_B/\partial z$, we obtain

$$J_A = D_A \frac{1}{V_m}\frac{\partial x_B}{\partial z} = -D_{AB}^{A}\frac{1}{V_m}\frac{\partial x_B}{\partial z} \tag{21}$$

$$J_B = -D_B \frac{1}{V_m}\frac{\partial x_B}{\partial z} = -D_{BB}^{A}\frac{1}{V_m}\frac{\partial x_B}{\partial z} \tag{22}$$

where we have introduced the notation D_{AB}^{A} and D_{BB}^{A} as the diffusion coefficients for A and B, respectively, with respect to the concentration gradient of B when the concentration of A has been chosen as the dependent variable. Observe that

$$D_{AB}^{A} = -D_A \tag{23}$$

$$D_{BB}^{A} = D_B \tag{24}$$

Transformation between Different Frames of Reference

We may transform between two arbitrary frames of reference by means of the relations

$$J'_A = J_A - \frac{\vartheta}{V_m}x_A \tag{25}$$

$$J'_B = J_B - \frac{\vartheta}{V_m}x_B \tag{26}$$

where the primed frame of reference moves with the migration rate ϑ relative the unprimed frame of reference. Summation of Equations 25 and 26 yields

$$J'_A + J'_B = J_A + J_B - \frac{\vartheta}{V_m} \tag{27}$$

We shall now apply Equation 27 to derive a relation between the individual diffusion coefficients and the interdiffusion coefficient. Evidently, if the unprimed frame of reference corresponds to the case where J_A and J_B are evaluated individually and the primed to $J'_A + J'_B = 0$, we have

$$\frac{\vartheta}{V_m} = J_A + J_B \tag{28}$$

Here, ϑ is called the Kirkendall shift velocity because it was first observed by Kirkendall and his student Smigelskas that the markers appeared to move in a specimen as a result of the diffusion (Smigelskas and Kirkendall, 1947).

Introducing the mole fraction of A, x_A, as the dependent concentration variable and combining Equations 21 through 28, we obtain

$$J'_B = -\left[(1-x_B)D_{BB}^{A} - x_B D_{AB}^{A}\right]\frac{1}{V_m}\frac{\partial x_B}{\partial z} \tag{29}$$

We may thus define

$$D_{BB}^{A'} = \left[(1-x_B)D_{BB}^{A} - x_B D_{AB}^{A}\right] \tag{30}$$

which is essentially a relation first derived by Darken (1948). The interdiffusion coefficient is often denoted $\tilde{D}_{AB}$. However, we shall not use this notation because it is not suitable for extension to multicomponent systems.

We may introduce different frames of reference by the generalized relation

$$a_A J_A + a_B J_B = 0 \tag{31}$$

Table 1. Diffusion Coefficients and Frames of Reference in Binary Systems

1. Fick's law

x_A dependent variable	x_B dependent variable	relations (Eq. 59)
$J_B = -\frac{D^A_{BB}}{V_m}\frac{\partial x_B}{\partial z}$	$J_B = -\frac{D^B_{BA}}{V_m}\frac{\partial x_A}{\partial z}$	$D^A_{BB} = -D^B_{BA}$
$J_A = -\frac{D^A_{AB}}{V_m}\frac{\partial x_B}{\partial z}$	$J_A = -\frac{D^B_{AA}}{V_m}\frac{\partial x_A}{\partial z}$	$D^A_{AB} = -D^B_{AA}$

2. Frames of reference
   (a) Lattice fixed: J_A and J_B independent $\rightarrow$ D^A_{BB} and D^A_{AB} independent, two individual or intrinsic diffusion coefficients.
   Kirkendall shift velocity: $\vartheta = -(D^A_{BB} + D^A_{AB})\frac{\partial x_B}{\partial z}$
   (b) Number fixed:
   $J_{A'} + J_{B'} = 0 \rightarrow D^{A'}_{BB} = -D^{A'}_{AB} \qquad D^{A'}_{BB} = [(1 - x_B)D^A_{BB} - x_B D^A_{AB}]$
   One chemical diffusion coefficient or interdiffusion coefficient

For example, if A is a substitutional atom and B is an interstitial solute, it is convenient to choose a frame of reference where $a_A = 1$, $a_B = 0$. In this frame of reference there is no flow of substitutional atoms. They merely constitute a background for the interstitial atoms. Table 1 provides a summary of some relations in differing frames of reference.

The Kirkendall Effect and Vacancy Wind

We may observe a Kirkendall effect whenever the atoms move with different velocities relative to the lattice, i.e., when their individual diffusion coefficients differ. However, such a behavior is incompatible with the so-called place interchange theory, which was predominant before the experiments of Smigelskas and Kirkendall (1947). This theory was based on the idea that diffusion takes place by direct interchange between the atoms. In fact, the observation that different elements may diffuse with different rates is strong evidence for the vacancy mechanism, i.e., diffusion takes place by atoms jumping to neighboring vacant sites. The lattice-fixed frame of reference would then be regarded as a number-fixed frame of reference if the vacancies are considered as an extra component. We may then introduce a vacancy flux J_{Va} by the relation

$$J_A + J_B + J_{Va} = 0 \tag{32}$$

and we find that

$$J_{Va} = -\frac{\vartheta}{V_m} \tag{33}$$

The above discussion not only is an algebraic exercise but also has some important physical implications. The flux of vacancies is a real physical phenomenon manifested in the Kirkendall effect and is frequently referred to as the vacancy wind. Vacancies would be consumed or produced at internal sources such as grain boundaries. However, under certain conditions very high supersaturations of vacancies will be built up and pores may form, resulting in so-called Kirkendall porosity. This may cause severe problems when heat treating joints of dissimilar materials because the mechanical properties will deteriorate.

It is thus clear that by the chemical diffusion coefficient we may evaluate how rapidly the components mix but will have no information about the Kirkendall effect or the risk for pore formation. To predict the Kirkendall effect, we would need to know the individual diffusion coefficients.

Tracer Diffusion and Self-diffusion

Consider a binary alloy A-B. One could measure the diffusion of B by adding some radioactive B, a so-called tracer of B. The radioactive atoms would then diffuse into the inactive alloy and mix with the inactive B atoms there. The rate of diffusion depends upon the concentration gradient of the radioactive B atoms, $\partial c^*_B/\partial z$. We denote the corresponding diffusion constant by D^*_B and the mobility by M^*_B. Since the tracer is added in very low amounts, it may be considered as a dilute solution and Equation 12 holds; i.e., we have

$$D^*_B = M^*_B RT \tag{34}$$

From a chemical point of view, the radioactive B atoms are almost identical to the inactive B atoms, and their mobilities should be very similar:

$$M^*_B = M_B \tag{35}$$

We thus obtain with high accuracy

$$D_B = \frac{D^*_B}{RT}\frac{x_B}{V_m}\frac{d\mu_B}{dc_B} \tag{36}$$

It must be noted that these two diffusion constants have different character. Here, the diffusion coefficient D^*_B describes how the radioactive and inactive B atoms mix with each other and is called the tracer diffusion coefficient. If the experiment is performed by adding the tracer to pure B, D^*_B will describe the diffusion of the inactive B atoms as well as the radioactive ones. It is justified to

assume that the same amount of inactive B atoms will flow in the opposite direction to the flow of the radioactive B atoms. Thus, in pure B, D_B^* concerns self-diffusion and is called the "self-diffusion coefficient." More generally we may denote the intrinsic diffusion of B in pure B as the self-diffusion of B.

DIFFUSION IN MULTICOMPONENT ALLOYS: FICK-ONSAGER LAW

For diffusion in multicomponent solutions, a first attempt of representing the experimental data may be based on the assumption that Fick's law is valid for each diffusing substance k, i.e.,

$$J_k = -D_k \frac{\partial c_k}{\partial z} \tag{37}$$

The diffusivities D_k may then be evaluated by taking the ratio between the flux and concentration gradient of k. However, when analyzing experimental data, it is found, even in rather simple systems, that this procedure results in diffusivities that also depend on the concentration gradients. This would make Fick's law useless for all practical purposes, and a different multicomponent formulation must be found. This problem was first solved by Onsager (1945), who suggested the following multicomponent extension of Fick's law:

$$J_k = -\sum_{j}^{n-1} D_{kj} \frac{\partial c_j}{\partial z} \tag{38}$$

We can rewrite this equation if instead we introduce the chemical potential of the various species μ_k and assume that the μ_k are unique functions of the composition. Introducing a set of parameters L_{kj}, we may write

$$J_k = -\sum_i L_{ki} \frac{\partial \mu_i}{\partial z} = -\sum_i \sum_j L_{ki} \frac{\partial \mu_i}{\partial c_j} \frac{\partial c_j}{\partial z} \tag{39}$$

and may thus identify

$$D_{kj} = \sum_i L_{ki} \frac{\partial \mu_i}{\partial c_j} \tag{40}$$

Onsager's extension of Fick's law includes the possibility that the concentration gradient of one species may cause another species to diffuse. A well-known experimental demonstration of this effect was given by Darken (1949), who studied a welded joint between two steels with initially similar carbon contents but quite different silicon contents. The welded joint was heat treated at a high temperature for some time and then examined. Silicon is substitutionally dissolved and diffuses very slowly despite the strong concentration gradient. Carbon, which was initially homogeneously distributed, dissolves interstitially and diffuses much faster from the silicon-rich to the silicon-poor side. In a thin region, the carbon diffusion is actually opposite to what is expected from Fick's law in its original formulation, so-called up-hill diffusion.

Equation 10 may be regarded as a special case of Equation 40 if we assume that it applies also in multicomponent systems:

$$J_k = -M_k \frac{x_k}{V_m} \frac{\partial \mu_k}{\partial z} \tag{41}$$

Onsager went one step further and suggested the general formulation

$$J_k = -\sum L_{ki} X_i \tag{42}$$

where J_k stands for any type of flux, e.g., diffusion of a species, heat, or electric charge, and X_i is a force, e.g., a gradient of chemical potential, temperature, or electric potential. The off-diagonal elements of the matrix of phenomenological coefficients L_{ki} represent coupling effects, e.g., diffusion caused by a temperature gradient, the "Soret effect," or heat flow caused by a concentration gradient, the "Dufour effect." Moreover, Onsager (1931) showed that the matrix L_{ki} is symmetric if certain requirements are fulfilled, i.e.,

$$L_{ki} = L_{ik} \tag{43}$$

In 1968 Onsager was given the Nobel Prize for the above relations, usually called the Onsager reciprocity relations.

FRAMES OF REFERENCE IN MULTICOMPONENT DIFFUSION

The previous discussion on transformation between different frames of reference is easily extended to systems with n components. In general, a frame of reference is defined by the relation

$$\sum_{k=1}^{n} a_k J'_k = 0 \tag{44}$$

and the transformation between two frames of reference is given by

$$J'_k = J_k - \frac{\vartheta}{V_m} x_k \qquad (k = 1, \ldots, n) \tag{45}$$

where the primed frame of reference moves with the migration rate ϑ relative to the unprimed frame of reference. Multiplying each equation with a_k and summing $k = 1, \ldots, n$ yield

$$\sum_{k=1}^{n} a_k J'_k = \sum_{k=1}^{n} a_k J_k - \frac{\vartheta}{V_m} \sum_{k=1}^{n} a_k x_k \tag{46}$$

Combination of Equations 44 and 46 yields

$$\frac{\vartheta}{V_m} = \sum_{k=1}^{n} \frac{a_k J_k}{a_m} \tag{47}$$

where we have introduced $a_m = \sum_{k=1}^{n} a_k x_k$. Equation 45 then becomes

$$J'_k = J_k - \frac{x_k}{a_m}\sum_{i=1}^{n} a_i J_i$$
$$= \sum_{i=1}^{n}\left(\delta_{ik} - \frac{x_k a_i}{a_m}\right) J_i \qquad (k = 1, \ldots, n) \qquad (48)$$

where the Kronecker delta $\delta_{ik} = 1$ when $i = k$ and $\delta_{ik} = 0$ otherwise.

If the diffusion coefficients are known in the unprimed frame of reference and we have arbitrarily chosen the concentration of component n as the dependent concentration, i.e.,

$$J_k = -\frac{1}{V_m}\sum_{j=1}^{n-1} D_{kj}^{n} \frac{\partial x_j}{\partial z} \qquad (49)$$

we may directly express the diffusivities in the primed framed of reference by the use of Equation 47 and obtain

$$D_{kj}^{n'} = \sum_{i=1}^{n}\left(\delta_{ik} - \frac{x_k a_i}{a_m}\right) D_{ij}^{n} \qquad (50)$$

It should be noticed that Equations 48 and 50 are valid regardless of the initial frame of reference. In other words, the final result does not depend on whether one transforms directly from, for example, the lattice-fixed frame of reference to the number-fixed frame of reference or if one first transforms to the volume-fixed frame of reference and subsequently from the volume-fixed frame of reference to the number-fixed frame of reference.

By inserting Equation 42 in Equation 48, we find a similar expression for the phenomenological coefficients of Equation 42:

$$L'_{kj} = \sum_{i=1}^{n}\left(\delta_{ik} - \frac{x_k a_i}{a_m}\right) L_{ij} \qquad (51)$$

As a demonstration, the transformations from the lattice-fixed frame of reference to the number-fixed frame of reference in a ternary system A-B-C are given as

$$D_{\mathrm{BB}}^{\mathrm{A}'} = \left[(1 - x_{\mathrm{B}}) D_{\mathrm{BB}}^{\mathrm{A}} - x_{\mathrm{B}} D_{\mathrm{AB}}^{\mathrm{A}} - x_{\mathrm{B}} D_{\mathrm{CB}}^{\mathrm{A}}\right]$$
$$D_{\mathrm{BC}}^{\mathrm{A}'} = \left[x_{\mathrm{B}}(1 - x_{\mathrm{B}}) D_{\mathrm{BC}}^{\mathrm{A}} - x_{\mathrm{B}} D_{\mathrm{AC}}^{\mathrm{A}} - x_{\mathrm{B}} D_{\mathrm{CC}}^{\mathrm{A}}\right]$$
$$D_{\mathrm{CB}}^{\mathrm{A}'} = \left[x_{\mathrm{C}}(1 - x_{\mathrm{C}}) D_{\mathrm{CC}}^{\mathrm{A}} - x_{\mathrm{C}} D_{\mathrm{AB}}^{\mathrm{A}} - x_{\mathrm{C}} D_{\mathrm{BB}}^{\mathrm{A}}\right]$$
$$D_{\mathrm{CC}}^{\mathrm{A}'} = \left[(1 - x_{\mathrm{C}}) D_{\mathrm{CC}}^{\mathrm{A}} - x_{\mathrm{C}} D_{\mathrm{AC}}^{\mathrm{A}} - x_{\mathrm{C}} D_{\mathrm{CC}}^{\mathrm{A}}\right] \qquad (52)$$

For a system with n components, we thus need $(n-1) \times (n-1)$ diffusion coefficients to obtain a general description of how the concentration differences evolve in time. Moreover, since the diffusion coefficients usually are functions not only of temperature but also of composition, it is almost impossible to obtain a complete description of a real system by experimental investigations alone, and a powerful method to interpolate and extrapolate the information is needed. This will be discussed under Modeling Diffusion in Substitutional and Interstitial Metallic Systems. However, both the $(n-1)n$ individual diffusion coefficients and the $(n-1)(n-1)$ interdiffusion coefficients can be calculated from n mobilities (see Equation 41) provided that the thermodynamic properties of the system are known.

CHANGE OF DEPENDENT CONCENTRATION VARIABLE

In practical calculations it is often convenient to change the dependent concentration variable. If the diffusion coefficients are known with one choice of dependent concentration variable, it then becomes necessary to recalculate them all. In a binary system the problem is trivial because $\partial x_{\mathrm{A}}/\partial z = -\partial x_{\mathrm{B}}/\partial z$ and a change in dependent concentration variable simply means a change in sign of the diffusion coefficients, i.e.,

$$D_{\mathrm{AB}}^{\mathrm{A}} = -D_{\mathrm{AA}}^{\mathrm{B}} \qquad (53)$$

$$D_{\mathrm{BB}}^{\mathrm{A}} = -D_{\mathrm{BA}}^{\mathrm{B}} \qquad (54)$$

In the general case we may derive a series of transformations as

$$J_k = -\frac{1}{V_m}\sum_{j=1}^{n} D_{kj}^{l} \frac{\partial x_j}{\partial z} \qquad (55)$$

Observe that we may perform the summation over all components if we postulate that

$$D_{kl}^{l} = 0 \qquad (56)$$

Since $\partial x_l/\partial z = -\sum_{j \neq l} \partial x_j/\partial z$, we may change from x_l to x_i as dependent concentration variable by rewriting Equation 55:

$$J_k = -\frac{1}{V_m}\sum_{j=1}^{n} (D_{kj}^{l} - D_{ki}^{l}) \frac{\partial x_j}{\partial z} \qquad (57)$$

i.e., we have

$$J_k = -\frac{1}{V_m}\sum_{j=1}^{n} D_{kj}^{i} \frac{\partial x_j}{\partial z} \qquad (58)$$

and we may identify the new set of diffusion coefficients as

$$D_{kj}^{i} = D_{kj}^{l} - D_{ki}^{l} \qquad (59)$$

It is then immediately clear that $D_{ki}^{i} = 0$, i.e., Equation 56 that was postulated must hold. We may further conclude that the binary transformation rules are obtained as special cases. Note that Equation 89 holds irrespective of the frame of reference used because it is a trivial mathematical consequence on the interdependence of the concentration variables.

MODELING DIFFUSION IN SUBSTITUTIONAL AND INTERSTITIAL METALLIC SYSTEMS

Frame of Reference and Concentration Variables

In cases where we have both interstitial and substitutional solutes, it is convenient to define a number-fixed frame of reference with respect to the substitutional atoms. In a system (A, B)(C, Va), where A and B are substitutionally dissolved atoms, C is interstitially dissolved, and Va denotes vacant interstitial sites, we define a number-fixed frame of reference from $J_A + J_B = 0$. To be consistent, we should then not use the mole fraction x as the concentration variable but rather the fraction u defined by

$$\begin{aligned} u_B &= \frac{x_B}{x_A + x_B} = \frac{x_B}{1 - x_C} \qquad u_A = 1 - u_B \\ u_C &= \frac{x_C}{x_A + x_B} = \frac{x_C}{1 - x_C} \end{aligned} \tag{60}$$

The fraction u is related to the concentration c by

$$c_k = \frac{x_k}{V_m} = \frac{u_k(1 - x_C)}{V_m} = \frac{u_k}{V_S} \tag{61}$$

where $V_S = V_m/(1 - x_C)$ is the molar volume counted per mole of substitutional atom and is usually more constant than the ordinary molar volume. If we approximate it as constant, we obtain

$$\frac{\partial c_k}{\partial z} = \frac{1}{V_S}\frac{\partial u_k}{\partial z} \tag{62}$$

Mobilities and Diffusivities

We shall now discuss how experimental data on diffusion may be represented in terms of simple models. As already mentioned, the experimental evidence suggests that diffusion in solid metals occurs mainly by thermally activated atoms jumping to nearby vacant lattice sites. In a random mixture of the various kinds of atoms $k = 1, 2, \ldots, n$ and vacant sites, the probability that an atom k is nearest neighbor with a vacant site is given by the product $y_k y_{Va}$, where y_k is the fraction of lattice sites occupied by k and y_{Va} the fraction of vacant lattice sites.

From absolute reaction rate theory, we may derive that the fluxes in the lattice-fixed frame of reference are given by

$$J_k = -y_k y_{Va}\frac{\Omega_{kVa}}{V_S}\left[\frac{\partial \mu_k}{\partial z} - \frac{\partial \mu_{Va}}{\partial z}\right] \tag{63}$$

where Ω_{kVa} represents how rapidly k jumps to a nearby vacant site. Assuming that we everywhere have thermodynamic equilibrium, at least locally, $\mu_{Va} = 0$, and thus Equation 63 becomes

$$J_k = -y_k y_{Va}\frac{\Omega_{kVa}}{V_S}\frac{\partial \mu_k}{\partial z} \tag{64}$$

The fraction of vacant substitutional lattice sites is usually quite small, and it is convenient to introduce the mobility $M_k = y_{Va}\Omega_{kVa}$. However, the fraction of vacant interstitial site is usually quite high, and if k is an interstitial solute, it is more convenient to set $M_k = \Omega_{kVA}$. Introducing $c_k = u_k/V_S$ and $u_k \cong y_k$, we have

$$J_k = -c_k M_k \frac{\partial \mu_k}{\partial z} = -L_{kk}\frac{\partial \mu_k}{\partial z} \tag{65}$$

if k is substitutional and

$$J_k = -c_k y_{Va} M_k \frac{\partial \mu_k}{\partial z} = -L_{kk}\frac{\partial \mu_k}{\partial z} \tag{66}$$

if k is interstitial. (The double index kk does not mean summation in Equations 65 and 66.)

When the thermodynamic properties are established, i.e., when the chemical potentials μ_i are known as functions of composition, Equation 40 may be used to derive a relation between mobilities and the diffusivities in the lattice-fixed frame of reference. Choosing component n as the dependent component and using u fractions as concentration variables, i.e., the functions $\mu_i(u_1, u_2, \ldots, u_{n-1})$, we obtain, for the intrinsic diffusivities,

$$D^n_{kj} = u_k M_k \frac{\partial \mu_k}{\partial u_j} \tag{67}$$

if k is substitutional and

$$D^n_{kj} = u_k y_{Va} M_k \frac{\partial \mu_k}{\partial u_j} \tag{68}$$

if k is interstitial.

One may change to a number-fixed frame of reference with respect to the substitutional atoms defined by

$$\sum_{k \in s} J'_k = 0 \tag{69}$$

where $k \in s$ indicates that the summation is performed over the substitutional fluxes only. Equation 50 yields

$$D^{n'}_{kj} = u_k M_k \frac{\partial \mu_k}{\partial u_j} - u_k \sum_{i \in s}^{n} u_i M_i \frac{\partial \mu_i}{\partial u_j} \tag{70}$$

when k is substitutional and

$$D^{n'}_{kj} = u_k y_{Va} M_k \frac{\partial \mu_k}{\partial u_j} - u_k \sum_{i \in s}^{n} u_i M_i \frac{\partial \mu_i}{\partial u_j} \tag{71}$$

when k is interstitial.

If we need to change the dependent concentration variable by means of Equation 59, it should be observed that we can never choose an interstitial component as the dependent one. From the definition of the u fractions, it is evident that the u fractions of the interstitial components are independent, whereas for the substitutional components we have

$$\sum_{k \in s} u_k = 1 \tag{72}$$

We thus obtain

$$D^i_{kj} = D^l_{kj} - D^l_{ki} \tag{73}$$

when j is substitutional and

$$D^i_{kj} = D^l_{kj} \tag{74}$$

when j is interstitial.

If the thermodynamic properties, the functions $\mu_i(u_1, u_2, \ldots, u_{n-1})$, are known, we may use Equations 67 to 74 to extract mobilities from experimental data on all the various diffusion coefficients. For example, if the tracer diffusion coefficient D^*_k is known, we have

$$M_k = \frac{D^*_k}{RT} \tag{75}$$

Temperature and Concentration Dependence of Mobilities

From absolute reaction rate arguments, we expect that the mobility obeys the following type of temperature dependence:

$$M_k = \frac{1}{RT}\nu\delta^2 \exp\left(-\frac{\Delta G^*_k}{RT}\right) \tag{76}$$

where ν is the atomic vibrational frequency of the order of magnitude 10^{13} s^{-1}; δ is the jump distance and of the same order of magnitude as the interatomic spacing, i.e., a few angstroms; and ΔG^*_k is the Gibbs energy activation barrier and may be divided into an enthalpy and an entropy part, i.e., $\Delta G^*_k = \Delta H^*_k - \Delta S^*_k T$. We may thus write Equation 76 as

$$M_k = \frac{1}{RT}\nu\delta^2 \exp\left(\frac{\Delta S^*_k}{R}\right)\exp\left(\frac{-\Delta H^*_k}{RT}\right) \tag{77}$$

If ΔH^*_k and ΔS^*_k are temperature independent, one obtains the Arrhenius expression

$$M_k = \frac{1}{RT} M^0_k \exp\left(-\frac{Q_k}{RT}\right) \tag{78}$$

where Q_k is the activation energy and $M^0_k = \nu\delta^2 \exp(\Delta S^*_k/R)$ is a preexponential factor. The experimental information may thus be represented by an activation energy and a preexponential factor for each component. In general, the experimental information suggests that both these quantities depend on composition. For example, the mobility of a Ni atom in pure Ni will generally differ from the mobility of a Ni atom in pure Al.

It seems reasonable that the entropy part of ΔG^*_k should obey the same type of concentration dependence as the enthalpy part. However, the division of ΔG^*_k into enthalpy and entropy parts is never trivial and cannot be made from the experimental temperature dependence of the mobility unless the quantity $\nu\delta^2$ is known, which is seldom the case. To avoid any difficulty arising from the division into enthalpy and entropy parts, it is suggested that the quantity $RT\ \ln(RTM_k)$ rather than M^0_k and Q_k should be expanded as a function of composition, i.e., the function

$$\begin{aligned} RT\ln(RTM_k) &= RT\ln(\nu\delta^2) - (\Delta H^*_k - \Delta S^*_k T) \\ &= RT\ln(M^0_k) - Q_k \end{aligned} \tag{79}$$

The above function may then be expanded by means of polynomials of the composition, i.e., for a substitutional solution we write

$$RT\ln(RTM_k) = \Phi_k = \sum_i x_i {}^0\Phi_{ki} + \sum_i \sum_{j>i} x_i x_j \Phi_{kij} \tag{80}$$

where ${}^0\Phi_{ki}$ is $RT\ln(RTM_k)$ in pure i in the structure under consideration. The function Φ_{kij} represents the deviation from a linear interpolation between the endpoint values; ${}^0\Phi_{ki}$ and Φ_{kij} may be arbitrary functions of temperature but linear functions correspond to the Arrhenius relation. For example, in a binary A-B alloy we write

$$RT\ln(RTM_A) = x_A {}^0\Phi_{AA} + x_B {}^0\Phi_{AB} + x_A x_B \Phi_{AAB} \tag{81}$$

$$RT\ln(RTM_B) = x_A {}^0\Phi_{BA} + x_B {}^0\Phi_{BB} + x_A x_B \Phi_{BAB} \tag{82}$$

It should be observed that the four parameters of the type ${}^0\Phi_{AA}$ may be directly evaluated if the self-diffusivities and the diffusivities in the dilute solution limits are known because then Equation 75 applies and we may write ${}^0\Phi_{AA} = RT\ln(D_A^{\text{in pure A}})$ and $\Phi_{AB} = RT\ \ln(D_A^{\text{in pure B}})$ and similar equations for the mobility of B.

In the general case, the experimental information shows that the parameters Φ_{kij} will vary with composition and may be represented by the so-called Redlich-Kister polynomial

$$\Phi_{kij} = \sum_{r=0}^{m} {}^r\Phi_{kij}(x_i - x_j)^r \tag{83}$$

For substitutional and interstitial alloys, the u fraction is introduced and Equation 80 is modified into

$$RT\ln(RTM_k) = \Phi_k = \sum_i \sum_j u_i u_j \left(\frac{1}{c}\right) {}^0\Phi_{kij} + \cdots \tag{84}$$

where i stands for substitutional elements and j for interstitials and c denotes the number of interstitial sites per substitutional site. The parameter ${}^0\Phi_{kij}$ stands for the value of $RT\ln(RTM_k)$ in the hypothetical case when there is only i on the substitutional sublattice and all the interstitial sites are occupied by j. Thus we have ${}^0\Phi_{ki} = {}^0\Phi_{ki\text{Va}}$.

Effect of Magnetic Order

The experimental information shows that ferromagnetic ordering below the Curie temperature lowers the mobility M_k by a factor $\Gamma^{\text{mag}}_k < 1$. This yields a strong deviation from the Arrhenius behavior. One may include the possibility of a temperature-dependent activation energy by the general definition

$$Q_k = -R\frac{\partial \ln(RTM_k)}{\partial(1/T)} \tag{85}$$

It is then found that there is a drastic increase in the activation energy in the temperature range around the Curie temperature T_C and the ferromagnetic state below T_C has a higher activation energy than the paramagnetic state at high temperatures. It is suggested (Jönsson, 1992) that this effect is taken into account by an extra term $RT \ln \Gamma_k^{mag}$ in Equation 79, i.e.,

$$RT \ln(RTM_k) = RT \ln(M_k^{0para}) - Q_k^{para} + RT \ln \Gamma_k^{mag} \quad (86)$$

The superscript para means that the preexponential factor and the activation energy are taken from the paramagnetic state. The magnetic contribution is then given by

$$RT \ln \Gamma_k^{mag} = (6RT - Q_k^{para})\alpha\xi \quad (87)$$

For body-centered cubic (bcc) alloys $\alpha = 0.3$, but for face-centered cubic (fcc) alloys the effect of the transition is small and $\alpha = 0$. The state of magnetic order at the temperature T under consideration is represented by ξ, which is unity in the fully magnetic state at low temperatures and zero in the paramagnetic state. It is defined as

$$\xi = \frac{\Delta H_T^{mag}}{\Delta H_0^{mag}} \quad (88)$$

where $\Delta H_T^{mag} = \int_T^\infty c_P^{mag} dT$ and c_P^{mag} is the magnetic contribution to the heat capacity.

Diffusion in B2 Intermetallics and Effect of Chemical Order

Tracer Diffusion and Mobility. Chemical order is defined as any deviation from a disordered mixture of atoms on a crystalline lattice. Like the state of magnetic order, the state of chemical order has a strong effect on diffusion. Most experimental studies are on intermetallics with the B2 structure, which may be regarded as two interwoven simple-cubic sublattices. At sufficiently high temperatures there is no long-range order and the two sublattices are equivalent; this structure is called A2, i.e., the normal bcc structure. Upon cooling, the long-range order onsets at a critical temperature, i.e., there is a second-order transition to the B2 state. Most of the experimental observations concern tracer diffusion in binary A2-B2 alloys, and the effect of chemical ordering is then very similar to that of magnetic ordering; see, e.g., the first studies on β-brass by Kuper et al. (1956). Close to the critical temperature there is a drastic increase in the activation energy defined as $Q_k = -R\,\partial(\ln D_k^*)/\partial(1/T)$, and in the ordered state it is substantially higher than in the disordered state. In practice, this means that the tracer diffusion and the corresponding mobility are drastically decreased by ordering.

In the theoretical analysis of diffusion in partially ordered systems, it is common, as in the case of disordered systems, to adopt the local equilibrium hypothesis. This means that both the vacancy concentration and the state of order are governed by the thermodynamic equilibrium for the composition and temperature under consideration. For a binary A-B system with A2-B2 ordering, Girifalco (1964) found that the ordering effect may be represented by the expression

$$Q_k = Q_k^{dis}(1 + \alpha_k s^2) \quad (89)$$

where $k =$ A or B, and Q_k^{dis} is the activation energy for tracer diffusion in the disordered state at high temperatures, α_k may be regarded as an adjustable parameter, and s is the long-range order parameter. For A2-B2, ordering s is defined as $y'_B - y''_B$, where y'_B and y''_B are the B occupancy on the first and second sublattices, respectively. For the stoichiometric composition $x_B = \frac{1}{2}$, it may be written as $s = 2y'_B - 1$.

The experimental verification of Equation 89 indicates that there is essentially no change in diffusion mechanism as the ordering onsets but a vacancy mechanism would also prevail in the partially ordered state. However, the details on the atomic level may be more complex. It has been argued that after a B atom has completed its jump to a neighboring vacant site, it is on the wrong sublattice; an antisite defect has been created. There is thus a deviation from the local equilibrium that must be restored in some way. A number of mechanisms involving several consecutive jumps have been suggested; see the review by Mehrer (1996). However, it should be noted that thermodynamic equilibrium is a statistical concept and does not necessarily apply to each individual atomic jump. For each B atom jumping to the wrong sublattice there may be, on average, a B atom jumping to the right sublattice, and as a whole the equilibrium is not affected.

In multicomponent alloys, several order parameters are needed, and Equation 89 does not apply. Using the site fractions y'_A, y'_B, y''_A, and y''_B and noting that they are interrelated by means of $y'_A + y'_B = 1$, $y''_A + y''_B = 1$, and $y'_B + y''_B = 2x_B$, i.e., there is only one independent variable, we have

$$\left[y'_A y''_B + y'_B y''_A - 2x_A x_B\right] = \frac{1}{2}s^2 \quad (90)$$

and Equation 89 may be recast into

$$Q_k = Q_k^{dis} + \Delta Q_k^{order}[y'_A y''_B + y'_B y''_A - 2x_A x_B] \quad (91)$$

where $\Delta Q_k^{order} + 2Q_k^{dis}\alpha_k$. It then seems natural to apply the following multicomponent generalization of Equations 89 and 91:

$$Q_k = Q_k^{dis} + \sum_i \sum_{i \neq j} \Delta Q_{kij}^{order}[y'_i y''_j - x_i x_j] \quad (92)$$

As already mentioned, there is no indication of an essential change in diffusion mechanism due to ordering, and Equation 64 is expected to hold also in the partially ordered case. We may thus directly add the effect of ordering to Equation 80:

$$RT \ln(RTM_k) = \Phi_k = \sum_i x_i{}^0\Phi_{ki} + \sum_i \sum_{j>i} x_i x_j \Phi_{kij} + \sum_i \sum_{i \neq j} \Delta Q_{kij}^{order}[y'_i y'_j - x_i x_j] \quad (93)$$

When Equation 93 is used, the site fractions, i.e., the state of order, must be obtained in some way, e.g., from experimental data or from a thermodynamic calculation.

Interdiffusion. As already mentioned, the experimental observations show that ordering decreases the mobility, i.e., diffusion becomes slower. This effect is also seen in the experimental data on interdiffusion, which shows that the interdiffusion coefficient decreases as ordering increases. In addition, there is a particularly strong effect at the critical temperature or composition where order onsets. This drastic drop in diffusivity may be understood from the thermodynamic factors $\partial\mu_k/\partial\mu_j$ in Equation 70. For the case of a binary substitutional system A-B, we may apply the Gibbs-Duhem equation, and Equation 70 may be recast into

$$D_{BB}^{A'} = [x_A M_B + x_B M_A] x_B \frac{\partial \mu_B}{\partial x_B} \qquad (94)$$

The derivative $\partial\mu_B/\partial x_B$ reflects the curvature of the Gibbs energy as a function of composition and drops to much lower values as the critical temperature or composition is passed and ordering onsets. In principle, the change is discontinuous but short-range order tends to smooth the behavior. The quantity $x_B\,\partial\mu_B/\partial x_B$ exhibits a maximum at the equiatomic composition and thus opposes the effect of the mobility, which has a minimum when there is a maximum degree of order. It should be noted that although M_A and M_B usually have their minima close to the equiatomic composition, the quantity $[x_A M_B + x_B M_A]$ generally does not except in the special case when the two mobilities are equal. This is in agreement with experimental observations showing that the minimum in the interdiffusion coefficient is displaced from the equiatomic composition in NiAl (Shankar and Seigle, 1978).

CONCLUSIONS: EXAMPLES OF APPLICATIONS

In this unit, we have discussed some general features of the theory of multicomponent diffusion. In particular, we have emphasized equations that are useful when applying diffusion data in practical calculations. In simple binary solutions, it may be appropriate to evaluate the diffusion coefficients needed as functions of temperature and composition and represent them by any type of mathematical functions, e.g., polynomials. When analyzing experimental data in higher order systems, where the number of diffusion coefficients increases drastically, this approach becomes very complicated and should be avoided. Instead, a method based on individual mobilities and the thermodynamic properties of the system has been suggested. A suitable code would then contain the following parts: (1) numerical solution of the set of coupled diffusion equations, (2) thermodynamic calculation of Gibbs energy and all derivatives needed, (3) calculation of diffusion coefficients from mobilities and thermodynamics, (4) a thermodynamic database, and (5) a mobility database.

This method has been developed by the present author and his group and has been implemented in the code DICTRA (Ågren, 1992). This code has been applied to many practical problems [see, e.g., the work on composite steels by Helander and Ågren (1997)] and is now commercially available from Thermo-Calc AB (www.thermo-calc.se).

MOLECULAR-DYNAMICS SIMULATION OF SURFACE PHENOMENA

INTRODUCTION

Molecular-dynamics (MD) simulation is a well-developed numerical technique that involves the use of a suitable algorithm to solve the classical equations of motion for atoms interacting with a known interatomic potential. This method has been used for several decades now to illustrate and understand the temperature and pressure dependencies of dynamical phenomena in liquids, solids, and liquid-solid interfaces. Extensive details of this technique and its applications can be found in Allen and Tildesley (1987) and references therein.

MD simulation techniques are also well suited for studying surface phenomena, as they provide a qualitative understanding of surface structure and dynamics. This unit considers the use of MD techniques to better understand surface disorder and premelting. Specifically, it examines the temperature dependence of structure and vibrational dynamics at surfaces of face-centered cubic (fcc) metals—mainly Ag, Cu, and Ni. It also makes contact with results from other theoretical and experimental methods.

While the emphasis in this chapter is on metal surfaces, the MD technique has been applied over the years to a wide variety of surfaces including those of semiconductors, insulators, alloys, glasses, and simple or binary liquids. A full review of the pros and cons of the method as applied to these very interesting systems is beyond the scope of this chapter. However, it is worth pointing out that the success of the classical MD simulation depends to a large extent on the exactness with which the forces acting on the ion cores can be determined. On semiconductor and insulator surfaces, the success of *ab initio* molecular dynamics simulations has made them more suitable for such calulations, rather than classical MD simulations.

Understanding Surface Behavior

The interface with vacuum makes the surface of a solid very different from the material in the bulk. In the bulk, periodic arrangement of atoms in all directions is the norm, but at the surface such symmetry is absent in the direction normal to the surface plane. This broken symmetry is responsible for a range of striking features. Quantized modes, such as phonons, magnons, plasmons, and polaritons, have surface counterparts that are localized in the surface layers—i.e., the maximum amplitude of these excitations lies in the top few layers.

A knowledge of the distinguishing features of surface excitations provides information about the nature of the bonds between atoms at the surface and about how these bonds differ from those in the bulk. The presence of the surface may lead to a rearrangement or reassignment of bonds between atoms, to changes in the local electronic density of states, to readjustments of the electronic structure, and to characteristic hybridizations between atomic orbitals that are quite distinct from those in the bulk solid.

The surface-induced properties in turn may produce changes in the atomic arrangement, the reactivity, and the dynamics of the surface atoms. Two types of changes in the atomic geometry are possible: an inward or outward shift of the ionic positions in the surface layers, called surface relaxation, or a rearrangement of ionic positions in the surface layer, called surface reconstruction. Certain metallic and semiconductor surfaces show striking reconstruction and appreciable relaxation, while others may not exhibit a pronounced effect. Well-known examples of surface reconstruction include the 2×1 reconstruction of Si(100), consisting of buckled dimers (Yang et al., 1983); the "missing row" reconstruction of the (110) surface of metals, such as Pt, Ir, and Au (Chan et al., 1980; Binnig et al., 1983; Kellogg, 1985); and the "herringbone" reconstruction of Au(111) (Perdereau et al., 1974; Barth et al., 1990).

The rule of thumb is that the more open the surface, the more the propensity to reconstruct or relax; however, not all open surfaces reconstruct. The elemental composition of the surface may be a determining factor in such structural transitions. On some solid surfaces, structural changes may be initiated by an absorbed overlayer or other external agent (Onuferko et al., 1979; Coulman et al. 1990; Sandy et al., 1992).

Whether a surface relaxes or reconstructs, the observed features of surface vibrational modes demonstrate changes in the force fields in the surface region (Lehwald et al., 1983). The changes in surface force fields are sensitive to the details of surface geometry, atomic coordination, and elemental composition. They also reflect the modification of the electronic structure at surfaces, and subsequently of the chemical reactivity of surfaces. A good deal of research on understanding the structural electronic properties and the dynamics at solid surfaces is linked to the need to comprehend technologically important processes, such as catalysis and corrosion.

Also, in material science and in nanotechnology, a comprehensive understanding of the characteristics of solid surfaces at the microscopic level is critical for purposes such as the production of good-quality thin films that are grown epitaxially on a substrate. Although technological developments in automation and robotics have made the industrial production of thin films and wafers routine, the quality of films at the nanometer level is still not guaranteed.

To control film defects, such as the presence of voids, cracks, and roughness, on the nanometer scale, it is neces-

sary to understand atomic processes including sticking, attachment, detachment, and diffusion of atoms, vacancies, and clusters. Although these processes relate directly to the mobility and the dynamics of atoms impinging on the solid surface (the substrate), the substrate itself is an active participant in these phenomena. For example, in epitaxial growth, whether the film is smooth or rough depends on whether the growth process is layer-by-layer or in the form of three-dimensional clusters. This, in turn, is controlled by the relative magnitudes of the diffusion coefficients for the motion of adatoms, dimers, and atomic clusters and vacancies on flat terraces and along steps, kinks, and other defects generally found on surfaces. Thus, to understand the atomistic details of thin film growth, we need to also develop an understanding of the temperature-dependent behavior of solid surfaces.

Surface Behavior Varies with Temperature

The diffusion coefficients, as well as the structure, dynamics, and stability of the surface, vary with surface temperature. At low temperatures the surface is relatively stable and the mobility of atoms, clusters, and vacancies is limited. At high temperatures, increased mobility may allow better control over growth processes, but it may also cause the surface to disorder. The distinction between low and high temperatures depends on the material, the surface orientation, and the presence of defects such as steps and kinks.

Systematic studies of the structure and dynamics of flat, stepped, and kinked surfaces have shown that the onset of enhanced anharmonic vibrations leads not just to surface disordering (Lapujoulade, 1994) but to several other striking phenomena, whose characteristics depend on the metal, the geometry, and the surface atomic coordination. As disordering continues with increasing temperature, there comes a stage at which certain surfaces undergo a structural phase transition called roughening (van Biejeren and Nolden, 1987). With further increase in temperature, some surfaces premelt before the bulk melting temperature is reached (Frenken and van der Veen, 1985).

Existence of surface roughening has been confirmed by experimental studies of the temperature variation of the surface structure of several elements: Cu(110) (Zeppenfeld et al., 1989; Bracco, 1994), Ag(110) (Held et al., 1987; Bracco et al., 1993), and Pb(110) (Heyraud and Metois, 1987; Yang et al., 1989), as well as several stepped metallic surfaces (Conrad and Engel, 1994). Surface premelting has so far been confirmed only on two metallic surfaces: Pb(110) (Frenken and van der Veen, 1985) and Al(110) (Dosch et al., 1991). Additionally, anomalous thermal behavior has been observed in diffraction measurements of Ni(100) (Cao and Conrad, 1990a), Ni(110) (Cao and Conrad, 1990b) and Cu(100) (Armand et al., 1987).

Computer-simulation studies using molecular-dynamics (MD) techniques provide a qualitative understanding of the processes by which these surfaces disorder and premelt (Stoltze, et al., 1989; Barnett and Landman, 1991; Loisel et al., 1991; Yang and Rahman, 1991; Yang et al., 1991; Hakkinen and Manninen, 1992; Beaudet et al., 1993; Toh et al., 1994). One MD study demonstrated the appearance of the roughening transition on Ag(110) (Rahman et al., 1997). Interestingly, certain other surfaces, such as Pb(111), have been reported to superheat, i.e., maintain their structural order even beyond the bulk melting temperature (Herman and Elsayed-Ali, 1992).

Experimental and theoretical studies of metal surfaces have revealed trends in the temperature dependence of structural order and how this relationship varies with the bulk melting temperature of the solid. Geometric and orientational effects may also play an important role in determining the temperature at which disorder sets in. Less close-packed surfaces, or surfaces with regularly spaced steps and terraces, called vicinal surfaces, may undergo structural transformations at temperatures lower than those observed for their flat counterparts. There are, of course, exceptions to this trend, and surface geometry alone is not a good indicator of temperature-driven transformations at solid surfaces. Regardless, the propensity of a surface to disorder, roughen, or premelt is ultimately related to the strength and extent of the anharmonicity of the interatomic bonds at the surface.

Experimental and theoretical investigations in the past two decades have revealed a variety of intriguing phenomena at metal surfaces. An understanding of these phenomena is important for both fundamental and technological reasons: it provides insight about the temperature dependence of the chemical bond between atoms in regions of reduced symmetry, and it aids in the pursuit of novel materials with controlled thermal behavior.

Molecular Dynamics and Surface Phenomena

Simply speaking, the studies of surface phenomena may be classified into studies of surface structure and studies of surface dynamics. Studies of surface structure imply a knowledge of the equilibrium positions of atoms corresponding to a specific surface temperature. As mentioned above, one concern is surface relaxation, in which the spacings between atoms in the topmost layers at their 0 K equilibrium configuration may be different from that in the bulk-terminated positions. To explore thermal expansion at the surface, this interlayer separation is examined as a function of the surface temperature. Studies of surface structure also include examination of quantities like surface stress and surface energetics: surface energy (the energy needed to create the surface) and activation barriers (the energy needed to move an atom from one position to another).

In surface dynamics, the focus is on atomic vibrations about equilibrium positions. This involves investigation of surface phonon frequencies and their dispersion, mean-square atomic vibrational amplitudes, and vibrational densities of states. At temperatures for which the harmonic approximation is valid and phonons are eigenstates of the system, knowledge of the vibrational density of states provides information on the thermodynamic properties of surfaces: for example, free energy, entropy, and heat capacity. At higher temperatures, anharmonic contributions to the interatomic potential become important; they manifest themselves in thermal expansion, in the

softening of phonon frequencies, in the broadening of phonon line-widths, and in a nonlinear variation of atomic vibrational amplitudes and mean-square displacements with respect to temperature.

In the above description we have omitted mention of some other intriguing structural and dynamical properties of solid surfaces, e.g., that of a roughening transition (van Biejeren and Nolden, 1987) on metal surfaces, or a deroughening transition on amorphous metal surfaces (Ballone and Rubini, 1996), which have also been examined by the MD technique. Amorphous metal surfaces are striking, as they provide a cross-over between liquidlike and solidlike behavior in structural, dynamical, and thermodynamical properties near the glass transition. Another surface system of potential interest here is that of alloys that exhibit peculiarities in surface segregation. These surfaces offer challenges to the application of MD simulations because of the delicate balances in the detailed description of the system necessary to mimic experimental observations.

The discussion below summarizes a few other simulation and theoretical methods that are used to explore structure and dynamics at metal surfaces, and provides details of some molecular-dynamics studies.

Related Theoretical Techniques

The accessibility of high-powered computers, together with the development of simulation techniques that mimic realistic systems, have led in recent years to a flurry of studies of the structure and dynamics at metal surfaces. Theoretical techniques range from those based on first-principles electronic-structure calculations to those utilizing empirical or semiempirical model potentials.

A variety of first-principles or *ab initio* calculations are familiar to physicists and chemists. Studies of the structure and dynamics of surfaces are generally based on density functional theory in the local density approximation (Kohn and Sham, 1965). In this method, quantum mechanical equations are solved for electrons in the presence of ion cores. Calculations are performed to determine the forces that would act on the ion cores to relax them to their minimum energy equilibrium position, corresponding to 0 K. Quantities such as surface relaxation, stress, surface energy, and vibrational dynamics are then obtained with the ion cores at the minimum energy equilibrium configuration. These calculations are very reliable and provide insight into electronic and structural changes at surfaces. Accompanied by lattice-dynamics methods, these *ab initio* techniques have been successful in accurately predicting the frequencies of surface vibrational modes and their displacement patterns. However, this approach is computationally very demanding and the extension of the method to calculate properties of solids at finite temperatures is still prohibitive. Readers are referred to a review article (Bohnen and Ho, 1993) for further details and a summary of results.

First-principles electronic-structure calculations have been enhanced in recent years (Payne et al., 1992) by the introduction of new schemes (Car and Parrinello, 1985) for obtaining solutions to the Kohn-Sham equations for the total energy of the system. In an extension of the *ab initio* techniques, classical equations of motion are solved for the ion cores with forces obtained from the self-consistent solutions to the electronic-structure calculations. This is the so-called first-principles molecular-dynamics method. Ideally, the forces responsible for the motion of the ion cores in a solid are evaluated at each step in the calculation from solutions to the Hamiltonian for the valence electrons. Since there are no adjustable parameters in the theory, this approach has good predictive power and is very useful for exploring the structure and dynamics at any solid surface. However, several technical obstacles have generally limited its applicability to metallic systems. Until improved *ab initio* methods become feasible for use in studies of the dynamics and structure of systems with length and time scales in the nano regime, finite temperature studies of metal surfaces will have to rely on model interaction potentials.

Studies of structure and dynamics using model, many-body interaction potentials are performed either through a combination of energy minimization and lattice-dynamics techniques, as in the case of first-principles calculations, or through classical molecular-dynamics simulations. The lattice-dynamics method has the advantage that once the dynamical force constant matrix is extracted from the interaction potential, calculation of the vibrational properties is straightforward. The method's main drawback is in the use of the harmonic or the quasi-harmonic approximation, which restricts its applicability to temperatures of roughly one-half the bulk melting temperature. Nevertheless, the method provides a reasonable way to analyze experimental data on surface phonons (Nelson et al., 1989; Yang et al., 1991; Kara et al., 1997a). Moreover, it provides a theoretical framework for calculating the temperature dependence of the diffusion coefficient for adatom and vacancy motion along selected paths on surfaces (Kürpick et al., 1997). These calculations agree qualitatively with experimental results. Also, this theoretical approach allows a linkage to be established between the calculated thermodynamic properties of vicinal surfaces (Durukanoglu et al., 1997) and the local atomic coordination and environment.

The lattice dynamical approach, being quasi-analytic, provides a good grasp of the physics of systems and insights into the fundamental processes underlying the observed surface phenomena. It also provides measures for testing results of molecular-dynamics simulations for surface dynamics at low temperatures.

PRINCIPLES AND PRACTICE OF MD TECHNIQUES

Unprecedented developments in computer and computational technology in the past two decades have provided a new avenue for examining the characteristics of systems. Computer simulations now routinely supplement purely theoretical and experimental modes of investigation by providing access to information in regimes inaccessible otherwise. The main idea behind MD simulations is to mimic real-life situations on the computer. After preparing a sample system and determining the fundamental forces

that are responsible for the microscopic interactions in the system, the system is first equilibrated to the temperature of interest. Next, the system is allowed to evolve in time through time steps of magnitude relevant to the characteristics of interest. The goal is to collect substantial statistics of the system over a reasonable time interval, so as to provide reliable average values of the quantities of interest. Just as in experiments, the larger the gathered statistics, the smaller is the effect of random noise. The statistics that emerge at the end of an MD simulation consist of the phase space (positions and velocities) description of the system at each time step. Suitable correlation functions and other averaged quantities are then calculated to provide information on the structural and dynamical properties of the system.

For the simulation of surface phenomena, MD cells consisting of a few thousand atoms arranged in several (ten to twenty) layers are sufficient. Some other analytical applications—for example, the study of the propagation of cracks in solids—may use classical MD simulations with millions of atoms in the cell (Zhou et al., 1997). The minimum size of the cell depends very much on the nature of the dynamical property of interest. In studying surface phenomena, periodic boundary conditions are applied in the two directions parallel to the surface while no such constraint is imposed in the direction normal to it. For the results presented here, Nordsieck's algorithm with a time step of 10^{-15} s is used to solve Newton's equations for all the atoms in the MD cell.

For any desired temperature, a preliminary simulation for the bulk system (in this case, 256 particles arranged in an fcc lattice with periodic boundary conditions applied in all three directions) is carried out under conditions of constant temperature and constant pressure (NPT) to obtain the lattice constant at that temperature. A system with a particular surface crystallographic orientation is then generated using the bulk-terminated positions. Under conditions of constant volume and constant temperature (NVT), this surface system is equilibrated to the desired temperature, usually obtained in simulations of ~10 to 20 ps, although longer runs are necessary at temperatures close to a transition. Next, the system is isolated from its surroundings and allowed to evolve in a much longer run, anywhere from hundreds of picoseconds to tens of nanoseconds, while its total energy remains constant (a microcanonical or NVE ensemble). The output of the MD simulation is the phase space information of the system—i.e., the positions and velocities of all atoms at every time step. Statistics on the positions and velocities of the atoms are recorded. All information about the structural properties and the dynamics of the system is obtained from appropriate correlation functions, calculated from recorded atomic positions and velocities.

An essential ingredient of the above technique is the interatomic interaction potentials that provide the forces with which atoms move. Semiempirical potentials based on the embedded-atom method (EAM; Foiles et al., 1986) have been used. These are many-body potentials, and therefore do not suffer from the unrealistic constraints that pair-potentials would impose on the elastic constants and energetics of the system.

For the six fcc metals (Ni, Pd, Pt, Cu, Ag, and Au) and their intermetallics, the simulations using many-body potentials reproduce many of the observed characteristics of the bulk metal (Daw et al., 1993). More importantly, the sensitivity of these interaction potentials to the local atomic coordination makes them suitable for use in examining the structural properties and dynamics of the surfaces of these metals. The EAM is one of a genre of realistic many-body potentials methods that have become available in the past 15 years (Finnis and Sinclair, 1984; Jacobsen et al., 1987; Ercolessi et al, 1988).

The choice of the EAM to derive interatomic potentials introduces some ambiguity into the calculated values of physical properties, but this is to be expected as these are all model potentials with a set of adjustable parameters. Whether a particular choice of interatomic potentials is capable of characterizing the temperature-dependent properties of the metallic surface under consideration can only be ascertained by performing a variety of tests and comparing the results to what is already known experimentally and theoretically. The discussion below summarizes some of the essentials of these potentials; the original papers provide further details.

The EAM potentials are based on the concept that the solid is assembled atom by atom and the energy required to embed an atom in a homogeneous electron background depends only on the electron density at that particular site. The total internal energy of a solid can thus be written as in Equation 1:

$$E_{\text{tot}} = \sum_i F_i(\rho_{h,i}) + \frac{1}{2}\sum_{i,j} \phi_{ij}(R_{ij}) \tag{1}$$

$$\rho_{h,i} = \sum_{j \neq i} f_j(R_{ij}) \tag{2}$$

where $\rho_{h,i}$ is the electron density at atom i due to all other (host) atoms, f_j is the electron density of atom j as a function of distance from its center, R_{ij} is the distance between atoms i and j, F_i is the energy required to embed atom i into the homogeneous electron density due to all other atoms, and ϕ_{ij} is a short-range pair potential representing an electrostatic core-core repulsion.

In Equation 2 a simplifying assumption connects the host electron density to a superposition of atomic charge densities. It makes the local charge densities dependent on the local atomic coordination. It is not clear *a priori* how realistic this assumption is, particularly in regions near a surface or interface. However, with the assumption, the calculations turn out to be about as computer intensive as those based on simple pair potentials. Another assumption implicit in the above equations is that the background electron density is a constant. Even with these two approximations, it is not yet feasible to obtain the embedding energy from first principles. These functions are obtained from a fit to a large number of experimentally observed properties, such as the lattice constants, the elastic constants, heats of sublimation, vacancy formation energies, and bcc-fcc energy differences.

DATA ANALYSIS AND INTERPRETATION

Structure and Dynamics at Room Temperature

To demonstrate some results of MD simulations, the three low-Miller-index surfaces (100), (110), and (111) of fcc solids are considered. The top layer geometry and the associated two-dimensional Brillouin zones and crystallographic axes are displayed in Figure 1. The z axis is in each case normal to the surface plane. This section presents MD results for the structure and dynamics of these surfaces for Ag, Cu, and Ni at room temperature.

As anharmonic effects are small at room temperature, the MD results can be compared with available results from other calculations, most of which are based on the harmonic approximation in solids. Room temperature also provides a good opportunity to compare MD results with a variety of experimental data that are commonly taken at room temperature. In addition, at room temperature quantum effects are not expected to be important. The discussion below begins by exploring anisotropy in the mean-square vibrational amplitudes at the (100), (110), and (111) surfaces. This is followed by an examination of the interlayer relaxations at these surfaces.

Mean-Square Vibrational Amplitudes. The mean-square vibrational amplitudes of the surface and the bulk atoms are calculated using Equation 3:

$$\langle u_{j\alpha}^2 \rangle = \frac{1}{N_j} \sum_{i=1}^{N_j} \langle [r_{i\alpha}(t) - \langle r_{i\alpha}(t-\tau) \rangle \tau]^2 \rangle \qquad (3)$$

where the left-hand side represents the Cartesian component α of the mean-square vibrational amplitudes of atoms in layer j, and $r_{i\alpha}$ the instantaneous position of atom i along α. The terms in brackets, $\langle \ldots \rangle$, are time averages with τ as a time interval. These calculated vibrational amplitudes provide useful information for the analysis of structural data on surfaces. Without the direct information provided by MD simulations, values for surface vibrational amplitudes are estimated from an assigned surface Debye temperature—an *ad hoc* notion in itself.

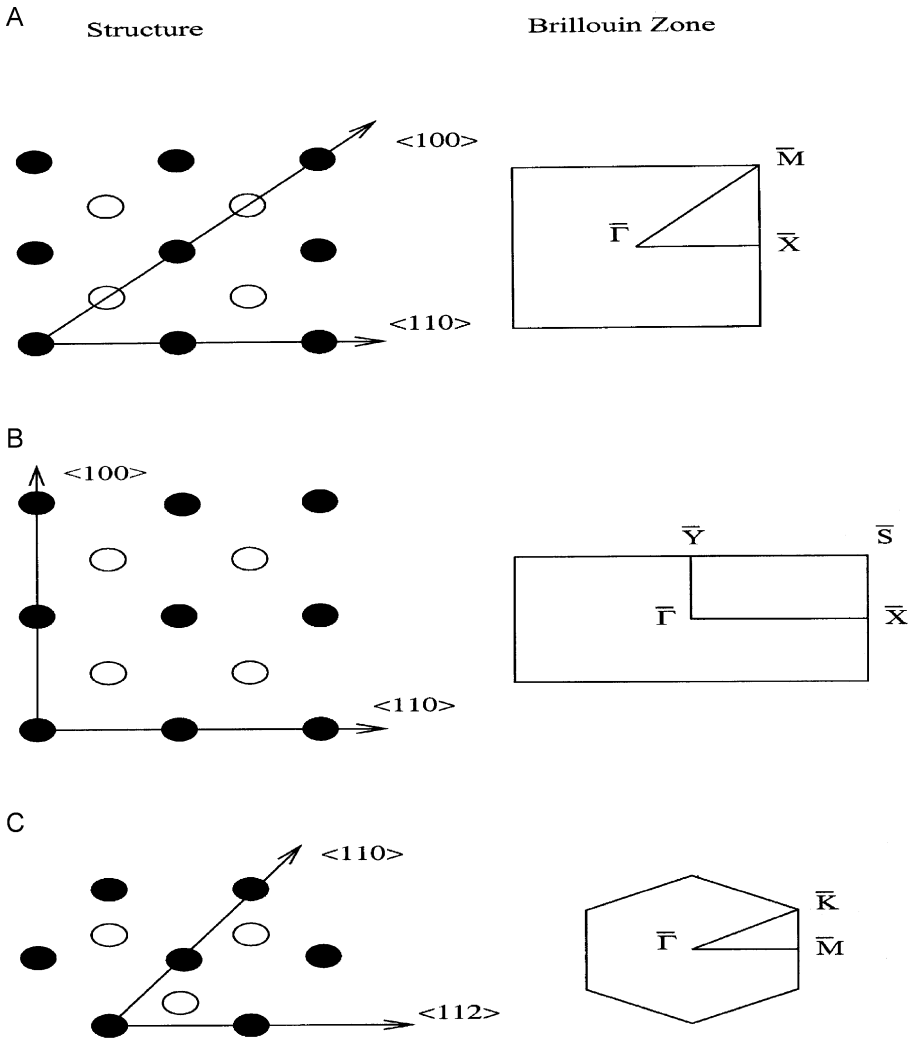

Figure 1. The structure, crystallographics directions, and surface Brillouin zone for the (**A**) (100), (**B**) (110), and (**C**) (111), surfaces of fcc crystals.

Table 1. Simulated Mean-square Displacements in Units of 10^{-2} A^2 at 300 K

	$\langle u_x^2 \rangle$	$\langle u_y^2 \rangle$	$\langle u_z^2 \rangle$
Ag(100)	1.38	1.38	1.52
Cu(100)	1.3	1.3	1.28
Ni(100)	0.7	0.7	0.81
Ag(110)	1.43	1.95	1.86
Cu(110)	1.13	1.95	1.31
Ni(110)	0.73	1.13	0.86
Ag(111)	1.10	1.17	1.59
Cu(111)	0.95	0.95	1.27
Ni(111)	0.55	0.58	0.94
Ag(bulk)	0.8	0.8	0.8
Cu(bulk)	0.7	0.7	0.7
Ni(bulk)	0.39	0.39	0.39

A few comments about mean-square vibrational amplitudes provide some background to the significance of this measurement. In the bulk metal, the mean-square vibrational amplitudes, $\langle u_{j\alpha}^2 \rangle$, have to be isotropic. However, at the surface, there is no reason to expect this to be the case. In fact, there are indications that the mean-square vibrational amplitudes of the surface atoms are anisotropic. Although experimental data for the in-plane vibrational amplitudes are difficult to extract, anisotropy has been observed in some cases. Moreover, as the force constants between atoms at the surface are generally different from those in the bulk, and as this deviation does not follow a simple pattern, it is intriguing to see if there is a universal relationship between surface vibrational amplitudes and those of an atom in the bulk. In view of these questions, it is also interesting to examine the values obtained from MD simulations for the three surfaces of Ag, Cu, and Ni at 300 K. These are summarized in Table 1.

The main message from Table 1 is that the vibrational amplitude normal to the surface (out of plane) in most cases is not larger than the in-plane vibrational amplitudes. This finding contradicts expectations from earlier calculations that did not take into account the deviations in surface force constants from bulk values (Clark et al., 1965). For the more open (110) surface, the amplitude in the $\langle 001 \rangle$ direction is larger than that in the other two directions. On the (100) surface, the amplitudes are almost isotropic, but on the closed-packed (111) surface, the out-of-plane amplitude is the largest. In each case, the surface amplitude is larger than that in the bulk, but the ratio depends on the metal and the crystallographic orientation of the surface.

It has not been possible to compare quantitatively the MD results with experimental data, mainly because of the uncertainties in the extraction of these numbers. Qualitatively, there is agreement with the results on Ag(100) (Moraboit et al., 1969) and Ni(100) (Cao and Conrad, 1990a), where the vibrational amplitudes are found to be isotropic. For Cu(100), though, the in-plane amplitude is reported to be larger than the out-of-plane amplitude by 30% (Jiang et al., 1991), while the MD results indicate that they are isotropic. On Ag(111), the MD results imply that the out-of-plane amplitude is larger, but experimental data suggest that it is isotropic (Jones et al., 1966). As the techniques are further refined and more experimental data become available for these surfaces, a direct comparison with the values in Table 1 could provide further insight into vibrational amplitudes on metal surfaces.

Interlayer Relaxation. Simulations of interlayer relaxation for the (100), (111), and (110) surfaces of Ag, Cu, and Ni using EAM potentials are found to be in reasonable agreement with experimental data, except for Ni(110) and Cu(110), for which the EAM underestimates the values. A problem with these comparisons, particularly for the (110) surface, is the wide range of experimental values obtained by various techniques. Different types of EAM potentials and other semiempirical potentials also yield a range of values for the interlayer relaxation. The reader is referred to the article by Bohnen and Ho (1993) for a comparison of the values obtained by various experimental and theoretical techniques.

Table 2 displays the values of the interlayer relaxations obtained in MD simulations at 300 K. In general, these values are reasonable and in line with those extracted from experimental data. For Cu(110), results available from first principles calculations show an inward relaxation of 9.2% (Rodach et al., 1993), compared to 4.73% in the MD simulations. This discrepancy is not surprising given the rudimentary nature of the EAM potentials. However, despite this discrepancy with interlayer relaxation, the MD-calculated values of the surface phonon frequencies are in very good agreement with experimental data and also with available first-principles calculations (Yang and Rahman 1991; Yang et al., 1991).

Structure and Dynamics at Higher Temperatures

This section discusses the role of anharmonic effects as reflected in the following: surface phonon frequency shifts and line-width broadening; mean-square vibrational amplitudes of the atoms; thermal expansion; and the onset of surface disordering. It also considers the appearance of premelting as the surface is heated to the bulk melting temperature.

Surface Phonons of Metals. When the MD/EAM approach is used, the surface phonon dispersion is in reasonable agreement with experimental data for most modes on

Table 2. Simulated Interlayer Relaxation at 300 K in Å[a]

Surface	d_{bulk}	d_{12}	$(d_{12} - d_{\text{bulk}})/d_{\text{bulk}}$
Ag(100)	2.057	2.021	−1.75%
Cu(100)	1.817	1.795	−1.21%
Ni(100)	1.76	1.755	−0.30%
Ag(110)	1.448	1.391	−3.94%
Cu(110)	1.285	1.224	−4.73%
Ni(110)	1.245	1.211	−2.70%
Ag(111)	2.376	2.345	−1.27%
Cu(111)	2.095	2.071	−1.11%
Ni(111)	2.04	2.038	−0.15%

[a] Here, d_{bulk} and d_{12} are the interlayer spacing in the bulk and between the top two layers, respectively.

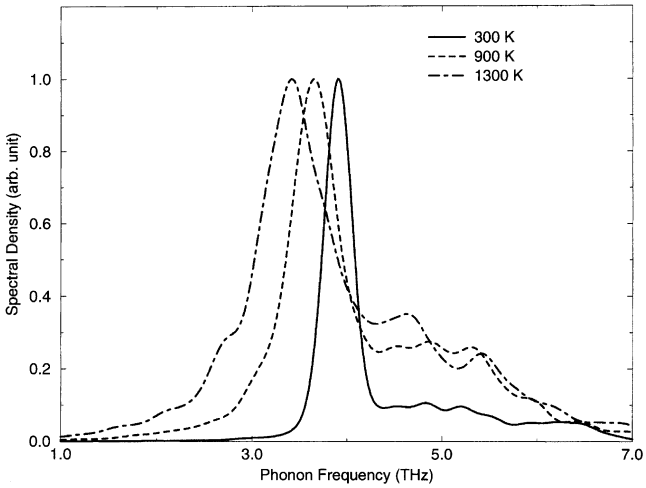

Figure 2. Phonon spectral densities representing the shear vertical mode at $\bar{M}$ on Ni(111) at three different temperatures (from Al-Rawi and Rahman, in press).

the (100), (110), and (111) surfaces of Ag, Cu, and Ni. In MD simulations, the phonon spectral densities in the one-phonon approximation can be obtained from Equation 4 (Hansen and Klein, 1976; Wang et al., 1988):

$$\rho_{j\alpha\alpha}(\vec{Q}_{||\tau}) = \int e^{i\omega t}\left[\sum_{i=1}^{N_j} e^{i\vec{Q}_{||}\vec{R}_i^{\alpha}}\langle v_i^{\alpha}(t)v_0^{\alpha}(0)\rangle\right]dt \qquad (4)$$

with

$$\langle v_2^{\alpha}(t)v_i^{\alpha}(0)\rangle = \frac{1}{MN_j}\sum_{m=1}^{M}\sum_{j=1}^{N_j} v_{i+j}^{\alpha}(t+z_m)v_i^{\alpha}(\tau_m)$$

where $\rho_{j\alpha\alpha}$ is the spectral density for the displacements along the direction $\alpha(=x,y,z)$ of the atoms in layer j, N_j is the number of atoms in layer j, $\vec{Q}_{||}$ is the two dimensional wave-vector parallel to the surface, and R_i^0 is the equilibrium position of atom i whose velocity is $\vec{v}_i$ and M is the number of MD steps.

Figure 2 shows the phonon spectral densities arising from the displacement of the atoms in the first layer with wave-vectors corresponding to $\bar{M}$ point in the Brillouin zone (see Fig. 1) for Ni(111). The spectral density for the shear vertical mode (the Rayleigh wave) is plotted for three different surface temperatures. The softening of the phonon frequency and the broadening of the line width with increasing temperatures attest to the presence of anharmonic effects (Maradudin and Fein, 1962). Such shifts in the frequency of a vibrational mode and the broadening of its line width also have been found for Cu(110) and Ag(110), both experimentally (Baddorf and Plummer, 1991; Bracco et al., 1996) and in MD simulations (Yang and Rahman, 1991; Rahman and Tian, 1993).

Mean-Square Atomic Displacements. The temperature dependence of the mean-square displacements of the top three layers of Ni(110), Ag(110), and Cu(110) shows very

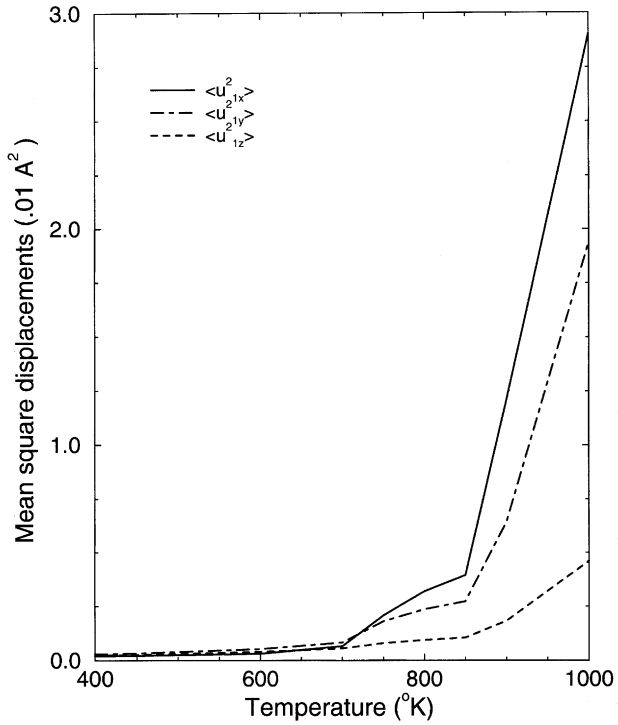

Figure 3. Mean-square displacement of top layer Ag(110) atoms (taken from Rahman et al., 1997).

similar behavior. In general, for the top layer atoms of the (110) surface, the amplitude along the y axis (the $\langle 001\rangle$ direction, perpendicular to the close-packed rows) is the largest at low temperatures. The in-plane amplitudes continue to increase with rising temperature; $\langle u_{1y}^2\rangle$ dominates until adatoms and vacancies are created. Beyond this point, $\langle u_{1x}^2\rangle$ becomes larger than $\langle u_{1y}^2\rangle$, indicating a preference for the adatoms to diffuse along the close-packed rows (Rahman et al., 1997). Figure 3 shows this behavior for the topmost atoms of Ag(110). Above 700 K, large anharmonic effects come into play, and adatoms and vacancies appear on the surface, causing the in-plane mean-square displacements to increase abruptly. Figure 3 also shows that the out-of-plane vibrational amplitude does not increase as rapidly as the in-plane amplitudes, indicating that interlayer diffusion is not as dominant as intralayer diffusion at medium temperatures.

The temperature variation of the mean-square displacements is a good indicator of the strength of anharmonic effects. For a harmonic system, $\langle u^2\rangle$ varies linearly with temperature. Hence, the slope of $\langle u^2\rangle/T$ can serve as a measure of anharmonicity. Figure 4 shows $\langle u^2\rangle/T$. This is plotted so that the relative anharmonicity in the three directions for the topmost atoms of Ag(110) can be examined over the range of 300 to 700 K. Once again, on the (110) surface, the $\langle 001\rangle$ direction is the most anharmonic and the vertical direction is the least so. The slight dip for $\langle u_{1z}^2\rangle$ at 450 K is due to statistical errors in the simulation results. The anharmonicity is largest along the y axis, at lower temperatures.

In experimental studies, such as those with low-energy electron diffraction (LOW-ENERGY ELECTRON DIFFRACTION), the

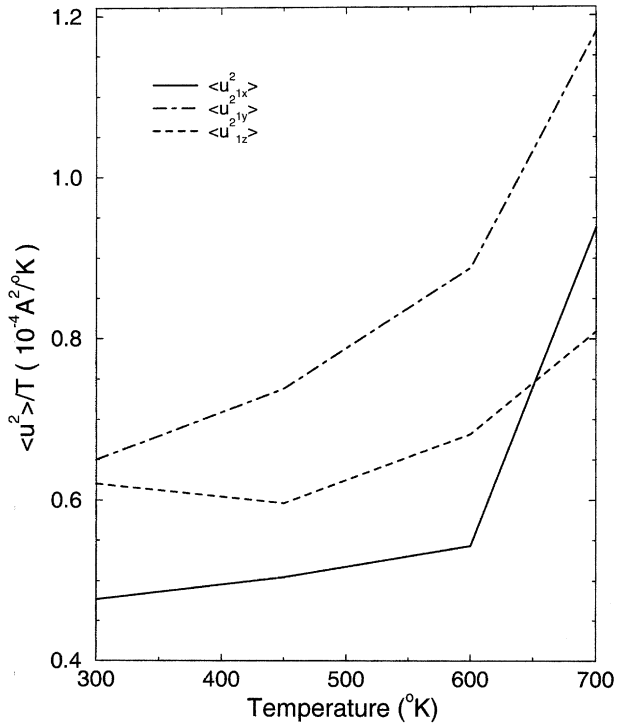

Figure 4. Anharmonicity in mean-square vibrational amplitudes for top layer atoms of Ag(110) (taken from Rahman et al., 1997).

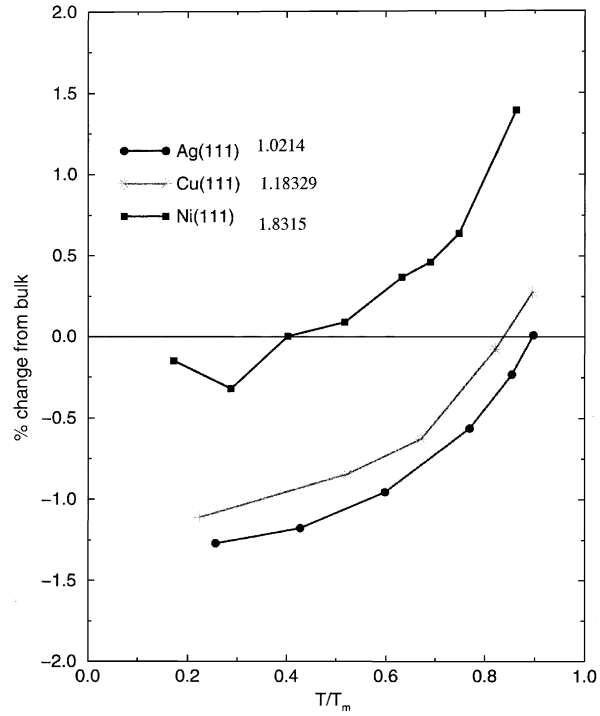

Figure 5. Thermal expansion of Ag(111), Cu(111), and Ni(111). From Al-Rawi and Rahman (in press). Here, T_m is the bulk melting temperature.

intensities of the diffracted beams are most sensitive to the vibrational amplitudes perpendicular to the surface (through the Debye-Waller factor). For several surfaces, the intensity of the beam appears to attenuate dramatically beginning at a specific temperature (Cao and Conrad, 1990a,b).

On both Cu(110) and Cu(100) surfaces, previous studies indicate the onset of enhanced anharmonic behavior at 600 K (Yang and Rahman, 1991; Yang et al., 1991). For Ag(110) the increment is more gradual, and there is already an onset of anharmonic effects at ~450 K. More detailed examination of the MD results show that adatoms and vacancies begin to appear at ~750 K on Ag(110) (Rahman et al., 1997) and ~850 K on Cu(110) (Yang and Rahman, 1991). However, the (100) and (111) surfaces of these metals do not display the appearance of a significant number of adatom/vacancy pairs. Instead, long-range order is maintained up to almost the bulk melting temperature (Yang et al., 1991; Hakkinen and Manninen, 1992; Al-Rawi et al., 2000).

A comparative experimental study of the onset of surface disordering on Cu(100) and Cu(110) using helium-atomic-beam diffraction (Gorse and Lapujoulade, 1985) adds credibility to the conclusions from MD simulations. This experimental work shows that although Cu(100) maintains its surface order until 1273 K (the bulk melting temperature), Cu(110) begins to disorder at ~500 K.

Surface Thermal Expansion. The molecular-dynamics technique is ideally suited to the examination of thermal expansion at surfaces, as it takes into account the full extent of anharmonicity of the interaction potentials. In the direction normal to the surface, the atoms are free to move and establish new equilibrium interlayer separation, although within each layer atoms occupy equilibrium positions as dictated by the bulk lattice constant for that temperature. Here again, the more open (110) surfaces of fcc metals show a propensity for appreciable surface thermal expansion over a given temperature range. For example, temperature-dependent interlayer relaxation on Ag(110) shows a dramatic change, from −4% at 300 K to + 4% at 900 K (Rahman and Tian, 1993). A similar increment (10% over the temperature range 300 to 1700 K) was found for Ni(110) in MD simulations (Beaudet et al., 1993) and also experimentally (Cao and Conrad, 1990b).

Results from MD simulations for the thermal expansion of the (111) surface indicate behavior very similar to that in the bulk. Figure 5 plots surface thermal expansion for Ag(111), Cu(111), and Ni(111) over a broad range of temperatures. Although all interlayer spacings expand with increasing temperature, that between the surface layers of Ag(111) and Cu(111) hardly reaches the bulk value even at very high temperatures. This result is different from those for the (110) surfaces of the same metals. Some experimental data also differ from the results presented in Figure 5 for Ag(111) and Cu(111). This is a point of ongoing discussion: ion-scattering experiments report a 10% increment over bulk thermal expansion at between 700 K and 1150 K (Statiris et al., 1994) for Ag(111), while very recent x-ray scattering data (Botez et al., in press)

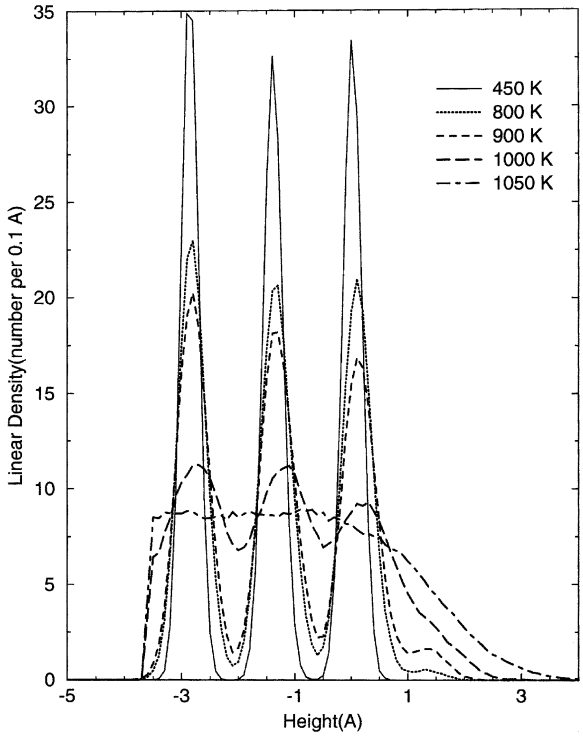

Figure 6. Time-averaged linear density of atoms initially in the top three layers of Ag(110).

and MD simulations do not display this sudden expansion at elevated temperature (Lewis, 1994; Kara et al., 1997b).

Temperature Variation of Layer Density. As the surface temperature rises, the number of adatoms and vacancies on the (110) surface increases and the surface begins to disorder. This tendency continues until there is no order maintained in the surface layers. In the case of Ag(110), the quasi-liquid-like phase occurs at ~1000 K. One measure of this premelting, the layer density for the atoms in the top three layers, is plotted in Figure 6.

At 450 K, the atoms are located in the first, second, and third layers. At ~800 K the situation is much the same, except that some of the atoms have moved to the top to form adatoms. The effect is more pronounced at 900 K, and is dramatic at 1000 K: the three peaks are very broad, with a number of atoms floating on top. At 1050 K, the three layers are submerged into one broad distribution. At this temperature, the atoms in the top three layers are diffusing freely over the entire extent of the MD cell. This is called premelting. The bulk melting temperature of Ag calculated with an EAM potential is 1170 K (Foiles et al., 1986).

The calculated structure factor for the system also indicates a sudden decrease in the layer-by-layer order. Surface melting is also defined by a sharp decline of the in-plane orientational order, at the characteristic temperature (Rahman et al., 1997; Toh et al., 1994). In contrast to the (110) surface, the (111) surface of the same metals do not appear to premelt (Al-Rawi and Rahman, in press), and vacancies and adatom pairs do not appear until close to the melting temperature.

PROBLEMS

MD simulations of surface phenomena provide valuable information on the temperature dependence of surface structure and dynamics. Such data may be difficult to obtain with other theoretical techniques. However, the MD method has limitations that may make its application questionable in some circumstances.

First, the MD technique is based on classical equations of motion, and therefore, it cannot be applied in cases where quantum effects are bound to play a significant role. Secondly, the method is not self-consistent. Model interaction potentials need to be provided as input to any calculation. The predictive power of the method is thus tied to the accuracy with which the chosen interaction potentials describe reality.

Thirdly, in order to depict phenomena at the ionic level, the time steps in MD simulations have to be quite a bit smaller than atomic vibrational frequencies ($\sim 10^{-13}$ s). Thus, an enormously large number of MD time steps are needed to obtain a one-to-one correspondence with events observed in the laboratory. Typically, MD simulations are performed in the nanosecond time scale and these results are extrapolated to provide information about events occurring in the microsecond and millisecond regime in the laboratory. Related to the limitation on time scale is the limitation on length scale. At best, MD simulations can be extended to millions of atoms in the MD cell. This is still a very small number compared to that in a real sample. Efforts are underway to extend the time scales in MD simulations by applying methods like the accelerated MD (Voter, 1997).

There is also a price to be paid for periodic boundary conditions that are imposed to remove edge effects from MD simulations. (These arise from the finite size of the MD cell.) Phenomena that change the geometry and shape of the MD cell, such as surface reconstruction, need extra effort and become more time consuming and elaborate.

Finally, to properly simulate any event, enough statistics have to be collected. This requires running the program a large number of times with new initial conditions. Even with these precautions it may not be possible to record all events that take place in a real system. Rare events are, naturally, the most problematic for MD simulations.

ACKNOWLEDGMENTS

This is work was supported in part by the National Science Foundation and the Kansas Center for Advanced Scientific Computing. Computations were performed on the Convex Exemplar multiprocessor supported in part by the NSF under grants No. DMR-9413513, and CDA-9724289. Many thanks to my co-workers A. Al-Rawi, A. Kara, Z. Tian, and L. Yang for their hard work, whose results form the basis of this unit.

SIMULATION OF CHEMICAL VAPOR DEPOSITION PROCESSES

INTRODUCTION

Chemical vapor deposition (CVD) processes constitute an important technology for the manufacturing of thin solid films. Applications include semiconducting, conducting, and insulating films in the integrated circuit industry, superconducting thin films, antireflection and spectrally selective coatings on optical components, and anticorrosion and antiwear layers on mechanical tools and equipment. Compared to other deposition techniques, such as sputtering, sublimation, and evaporation, CVD is very versatile and offers good control of film structure and composition, excellent uniformity, and sufficiently high growth rates. Perhaps the most important advantage of CVD over other deposition techniques is its capability for conformal deposition—i.e., the capability of depositing films of uniform thickness on highly irregularly shaped surfaces.

In CVD processes a thin film is deposited from the gas phase through chemical reactions at the surface. Reactive gases are introduced into the controlled environment of a reactor chamber in which the substrates on which deposition takes place are positioned. Depending on the process conditions, reactions may take place in the gas phase, leading to the creation of gaseous intermediates. The energy required to drive the chemical reactions can be supplied thermally by heating the gas in the reactor (thermal CVD), but also by supplying photons in the form of, e.g., laser light to the gas (photo CVD), or through the application of an electrical discharge (plasma CVD or plasma enhanced CVD). The reactive gas species fed into the reactor and the reactive intermediates created in the gas phase diffuse toward and adsorb onto the solid surface. Here, solid-catalyzed reactions lead to the growth of the desired film. CVD processes are reviewed in several books and survey papers (e.g., Bryant, 1977; Bunshah, 1982; Dapkus, 1982; Hess et al., 1985; Jensen, 1987; Sherman, 1987; Vossen and Kern, 1991; Jensen et al., 1991; Pierson, 1992; Granneman, 1993; Hitchman and Jensen, 1993; Kodas and Hampden-Smith, 1994; Rees, 1996; Jones and O'Brien, 1997).

The application of new materials, the desire to coat and reinforce new ceramic and fibrous materials, and the tremendous increase in complexity and performance of semiconductor and similar products employing thin films

are leading to the need to develop new CVD processes and to ever increasing demands on the performance of processes and equipment. This performance is determined by the interacting influences of hydrodynamics and chemical kinetics in the reactor chamber, which in turn are determined by process conditions and reactor geometry. It is generally felt that the development of novel reactors and processes can be greatly improved if simulation is used to support the design and optimization phase.

In the last decades, various sophisticated mathematical models have been developed, which relate process characteristics to operating conditions and reactor geometry (Heritage, 1995; Jensen, 1987; Meyyappan, 1995a). When based on fundamental laws of chemistry and physics, rather than empirical relations, such models can provide a scientific basis for design, development, and optimization of CVD equipment and processes. This may lead to a reduction of time and money spent on the development of prototypes and to better reactors and processes. Besides, mathematical CVD models may also provide fundamental insights into the underlying physicochemical processes and may be of help in the interpretation of experimental data.

PRINCIPLES OF THE METHOD

In CVD, physical and chemical processes take place at greatly differing length scales. Such processes as adsorption, chemical reactions, and nucleation take place at the microscopic (i.e., molecular) scale. These phenomena determine film characteristics such as adhesion, morphology, and purity. At the mesoscopic (i.e., micrometer) scale, free molecular flow and Knudsen diffusion phenomena in small surface structures determine the conformality of the deposition. At the macroscopic (i.e., reactor) scale, gas flow, heat transfer, and species diffusion determine process characteristics such as film uniformity and reactant consumption.

Ideally, a CVD model consists of a set of mathematical equations describing the relevant macroscopic, mesoscopic, and microscopic physicochemical processes in the reactor, and relating these phenomena to microscopic, mesoscopic, and macroscopic properties of the deposited films.

The first step is the description of the processes taking place at the substrate surface. A surface chemistry model describes how reactions between free sites, adsorbed species, and gaseous species close to the surface lead to the growth of a solid film and the creation of reaction products. In order to model these surface processes, the macroscopic distribution of the gas temperatures and species concentrations at the substrate surface must be known. Concentration distributions near the surface will generally differ from the inlet conditions and depend on the hydrodynamics and transport phenomena in the reactor chamber. Therefore, the core of a CVD model is formed by a transport phenomena model, consisting of a set of partial differential equations with appropriate boundary conditions describing the gas flow and the transport of energy and species in the reactor at the macroscopic scale, complemented by a thermal radiation model, describing the radiative heat exchange between the reactor walls. A gas phase chemistry model gives the reaction paths and rate constants for the homogeneous reactions, which influence the species concentration distribution through the production/destruction of chemical species. Often, plasma discharges are used in addition to thermal heating in order to activate the chemical reactions. In such a case, the gas phase transport and chemistry models must be extended with a plasma model. The properties of the gas mixture appearing in the transport model can be predicted based on the kinetic theory of gases. Finally, the macroscopic distributions of gas temperatures and concentrations at the substrate surface serve as boundary conditions for free molecular flow models, predicting the mesoscopic distribution of species within small surface structures and pores.

The abovementioned constituent parts of a CVD simulation model are briefly described in the following subsections. Within this unit, it is impossible to present all details needed for successfully setting up CVD simulations. However, an attempt is made to give a general impression of the basic ideas and approaches in CVD modeling, and of its capabilities and limitations. Many references to available literature are provided that will assist the interested reader in further study of the subject.

Surface Chemistry

Any CVD model must incorporate some form of surface chemistry. However, very limited information is usually available on CVD surface processes. Therefore, simple lumped chemistry models are widely used, assuming one single overall deposition reaction. In certain epitaxial processes operated at atmospheric pressure and high temperature, the rate of this overall reaction is very fast compared to convection and diffusion in the gas phase: the deposition is transport limited. In that case, useful predictions on deposition rates and uniformity can be obtained by simply setting the overall reaction rate to infinity (Wahl, 1977; Moffat and Jensen, 1986; Holstein et al., 1989; Fotiadis, 1990; Kleijn and Hoogendoorn, 1991). When the deposition rate is kinetically limited by the surface reaction, however, some expression for the overall rate constant as a function of species concentrations and temperature is needed. Such lumped reaction models have been published for CVD of, e.g., polycrystalline silicon (Jensen and Graves, 1983; Roenigk and Jensen, 1985; Peev et al., 1990a; Hopfmann et al., 1991), silicon nitride (Roenigk and Jensen, 1987; Peev et al., 1990b), silicon oxide (Kalindindi and Desu, 1990), silicon carbide (Koh and Woo, 1990), and gallium arsenide (Jansen et al., 1991).

In order to arrive at such a lumped deposition model, a surface reaction mechanism can be proposed, consisting of several elementary steps. As an example, for the process of chemical vapor deposition of tungsten from tungsten hexafluoride and hydrogen [overall reaction: $WF_6(g) + 3H_2(g) \rightarrow W(\text{solid}) + 6HF(g)$] the following mechanism can be proposed:

1. $WF_6(g) + s \leftrightarrow WF_6\ (s)$
2. $WF_6(s) + 5s \leftrightarrow W(\text{solid}) + 6F(s)$

3. $H_2(g) + 2s \leftrightarrow 2H(s)$
4. $H(s) + F(s) \leftrightarrow HF(s) + s$
5. $HF(s) \leftrightarrow HF(g) + s$ (1)

where (g) denotes a gaseous species, (s) an adsorbed species, and s a free surface site. Then, one of the steps is considered to be rate limiting, leading to a rate expression of the form

$$R^s = R^s(P_1, \ldots, P_N, T_s) \tag{2}$$

relating the deposition rate R^s to the partial pressures P_i of the gas species and the surface temperature T_s. When, e.g., in the above example, the desorption of HF (step 5) is considered to be rate limiting, the growth rate can be shown to depend on the H_2 and WF_6 gas concentrations as (Kleijn, 1995)

$$R^s = \frac{c_1[H_2]^{1/2}[WF_6]^{1/6}}{1 + c_2[WF_6]^{1/6}} \tag{3}$$

The expressions in brackets represent the gas concentrations. Finally, the validity of the mechanism is judged through comparison of predicted and experimental trends in the growth rate as a function of species pressures. Thus, it can be concluded that Equation 3 compares favorably with experiments in which a 0.5 order in H_2 and a 0 to 0.2 order in WF_6 is found. The constants c_1 and c_2 are parameters, which can be fitted to experimental growth rates as a function of temperature.

An alternative approach is the so-called "reactive sticking coefficient" concept for the rate of a reaction like A(g) → B(solid) + C(g). The sticking coefficient γ_A with 0 $0 \leq \gamma_A \leq 1$) is defined as the fraction of molecules of A that are incorporated into the film upon collision with the surface. For the deposition rate we now find (Motz and Wise, 1960):

$$R^s = \frac{\gamma_A}{1 - \gamma_A/2} \times \frac{P_A}{(2\pi M_A R T_S)^{1/2}} \tag{4}$$

with M_A the molar mass of species A, P_A its partial pressure, and T_S the surface temperature. The value of γ_A (with $0 \leq \gamma_A \leq 1$) has to be fitted to experimental data again.

Lumped reaction mechanisms are unlikely to hold for strongly differing process conditions, and do not provide insight into the role of intermediate species and reactions. More fundamental approaches to surface chemistry modeling, based on chains of elementary reaction steps at the surface and theoretically predicted reaction rates, applying techniques based on bond dissociation enthalpies and transition state theory, are just beginning to emerge. The prediction of reaction paths and rate constants for heterogeneous reactions is considerably more difficult than for gas-phase reactions. Although clearly not as mature as gas-phase kinetics modeling, impressive progress in the field of surface reaction modeling has been made in the last few years (Arora and Pollard, 1991; Wang and Pollard, 1994), and detailed surface reaction models have been published for CVD of, e.g., epitaxial silicon (Coltrin et al., 1989; Giunta et al., 1990a), polycrystalline silicon (Kleijn, 1991), silicon oxide (Giunta et al., 1990b), silicon carbide (Allendorf and Kee, 1991), tungsten (Arora and Pollard, 1991; Wang and Pollard, 1993; Wang and Pollard, 1995), gallium arsenide (Tirtowidjojo and Pollard, 1988; Mountziaris and Jensen, 1991; Masi et al., 1992; Mountziaris et al., 1993), cadmium telluride (Liu et al., 1992), and diamond (Frenklach and Wang, 1991; Meeks et al., 1992; Okkerse et al., 1997).

Gas-Phase Chemistry

A gas-phase chemistry model should state the relevant reaction pathways and rate constants for the homogeneous reactions. The often applied semiempirical approach assumes a small number of participating species and a simple overall reaction mechanism in which rate expressions are fitted to experimental data. This approach can be useful in order to optimize reactor designs and process conditions, but is likely to lose its validity outside the range of process conditions for which the rate expressions have been fitted. Also, it does not provide information on the role of intermediate species and reactions.

A more fundamental approach is based on setting up a chain of elementary reactions. A large system of all plausible species and elementary reactions is constructed. Typically, such a system consists of hundreds of species and reactions. Then, in a second step, sensitivity analysis is used to eliminate reaction pathways that do not contribute significantly to the deposition process, thus reducing the system to a manageable size. Since experimental data are generally not available in the literature, reaction rates are estimated by using tools such as statistical thermodynamics, bond dissociation enthalpies, and transition-state theory and Rice-Rampsberger-Kassel-Marcus (RRKM) theory. For a detailed description of these techniques the reader is referred to standard textbooks (e.g., Slater, 1959; Robinson and Holbrook, 1972; Benson, 1976; Laidler, 1987; Steinfeld et al., 1989). Also, computational chemistry techniques (Clark, 1985; Simka et al., 1996; Melius et al., 1997) allowing for the computation of heats of formation, bond dissociation enthalpies, transition state structures, and activation energies are now being used to model CVD chemical reactions. Thus, detailed gas-phase reaction models have been published for CVD of, e.g., epitaxial silicon (Coltrin et al., 1989; Giunta et al., 1990a), polycrystalline silicon (Kleijn, 1991), silicon oxide (Giunta et al., 1990b), silicon carbide (Allendorf and Kee, 1991), tungsten (Arora and Pollard, 1991; Wang and Pollard, 1993; Wang and Pollard, 1995), gallium arsenide (Tirtowidjojo and Pollard, 1988; Mountziaris and Jensen, 1991; Masi et al., 1992; Mountziaris et al., 1993), cadmium telluride (Liu et al., 1992), and diamond (Frenklach and Wang, 1991; Meeks et al., 1992; Okkerse et al., 1997).

The chain of elementary reactions in the gas phase mechanism will consist of unimolecular reactions of the general form A → C + D, and bimolecular reactions of the general form A + B → C + D. Their forward reaction rates are k[A] and k[A][B], respectively, with k the reaction rate constant and [A] and [B] the concentrations, respectively, of species A and B.

Generally, the temperature dependence of a reaction rate constant k(T) can be expressed accurately by a (modified) Arrhenius expression:

$$k(T) = AT^{\beta}\exp\left(\frac{-E}{RT}\right) \tag{5}$$

where T is the absolute temperature, A is a pre-exponential factor, E is the activation energy, and β is an exponent accounting for possible nonideal Arrhenius behavior. At the high temperatures and low pressures used in many CVD processes, unimolecular reactions may be in the so-called pressure fall-off regime, in which the rate constants may exhibit significant pressure dependencies. This is described by defining a low-pressure and a high-pressure rate constant according to Equations 6 and 7, respectively:

$$k_0(T) = A_0T^{\beta_0}\exp\left(\frac{-E_0}{RT}\right) \tag{6}$$

$$k_\infty(T) = A_\infty T^{\beta_\infty}\exp\left(\frac{-E_\infty}{RT}\right) \tag{7}$$

combined to a pressure dependent rate constant:

$$k(P,T) = \frac{k_0(T)k_\infty(T)P}{k_\infty(T) + k_0(T)P}F_{\text{corr}}(P,T) \tag{8}$$

where T, A, E, and β have the same meaning as in Equation 5, and the subscripts zero and infinity refer to the low-pressure and high-pressure limits, respectively. In its simplest form, $F_{\text{corr}} = 1$, but more accurate correction functions have been proposed (Gilbert et al., 1983; Kee et al., 1989). The correction function $F_{\text{corr}}(P,T)$ can be predicted from RRKM theory (Robinson and Holbrook, 1972; Forst, 1973; Roenigk et al., 1987; Moffat et al., 1991a). Computer programs with the necessary algorithms are available as public domain software (e.g., Hase and Bunker, 1973).

For the prediction of bimolecular reaction rates, transition-state theory can be applied (Benson, 1976; Steinfeld et al., 1989). According to this theory, the rate constant, k, for the bimolecular reaction:

$$A + B \rightarrow X^{\ddagger} \rightarrow C \tag{9}$$

(where $X^{\ddagger}$ is the transition state) is given by:

$$k = L^{\ddagger}\frac{k_BT}{h}\frac{Q^{\ddagger}}{Q_AQ_B}\exp\left(-\frac{E_0}{k_BT}\right) \tag{10}$$

where k_B is Boltzmann's constant and h is Planck's constant. The calculation of the partition functions $Q^{\ddagger}$, Q_A, and Q_B, and the activation energy E_0, requires knowledge of the structure and vibrational frequencies of the reactants and the intermediates. Parameters for the transition state are especially hard to obtain experimentally and are usually estimated from experimental frequency factors and activation energies of similar reactions, using empirical thermochemical rules (Benson, 1976). More recently, computational (quantum) chemistry methods (Stewart, 1983; Dewar et al., 1984; Clark, 1985; Hehre et al., 1986; Melius et al., 1997; also see Practical Aspects of the Method for information about software from Biosym Technologies) have been used to obtain more precise and direct information about transition state parameters (e.g., Ho et al., 1985, 1986; Ho and Melius, 1990; Allendorf and Melius, 1992; Zachariah and Tsang, 1995; Simka et al., 1996).

The forward and reverse reaction rates of a reversible reaction are related through thermodynamic constraints. Therefore, in a self-consistent chemistry model only the forward (or reverse) rate constant should be predicted or taken from experiments. The reverse (or forward) rate constant must then be obtained from thermodynamic constraints. When $\Delta G^0(T)$ is the standard Gibbs energy change of a reaction at standard pressure, P^0, its equilibrium constant is given by:

$$K_{\text{eq}}(T) = \exp\left(-\frac{\Delta G^0(T)}{RT}\right) \tag{11}$$

and the forward and reverse rate constants k_f and k_r are related as:

$$k_r(P,T) = \frac{k_f(P,T)}{K_{\text{eq}}(T)}\left(\frac{RT}{P^0}\right)^{\Delta\nu} \tag{12}$$

where $\Delta\nu$ is the net molar change of the reaction.

Free Molecular Transport

When depositing films on structured surfaces (e.g., a porous material or the structured surface of a wafer in IC manufacturing), the morphology and conformality of the film is determined by the meso-scale behavior of gas molecules inside these structures. At atmospheric pressure, mean free path lengths of gas molecules are of the order of 0.1 μm. At the low pressures applied in many CVD processes (down to 10 Pa), the mean free path may be as large as 1 mm. As a result, the gas behavior inside small surface structures cannot be described with continuum models, and a molecular approach must be used, based on approximate solutions to the Boltzmann equation. The main focus in meso-scale CVD modeling has been on the prediction of the conformality of deposited films. A good review can be found in Granneman (1993).

A first approach has been to model CVD in small cylindrical holes as a Knudsen diffusion and heterogeneous reaction process (Raupp and Cale, 1989; Chatterjee and McConica, 1990; Hasper et al., 1991; Schmitz and Hasper, 1993). This approach is based on a one-dimensional pseudocontinuum mass balance equation for the species concentration c along the depth z of a hole with diameter r:

$$\pi r^2 D_K\frac{\partial^2 c}{\partial z^2} = 2\pi r R(c) \tag{13}$$

The Knudsen diffusion coefficient (D_K) is proportional to the diameter of the hole (Knudsen, 1934):

$$D_K = \frac{2}{3}r\left(\frac{8RT}{\pi M}\right)^{1/2} \tag{14}$$

In this equation, M represents the molar mass of the species. For zero order reaction kinetics [deposition rate $R(c) \neq f(c)$] the equations can be solved analytically. For non-zero order kinetics they must be solved numerically (Hasper et al., 1991). The great advantages of this approach are its simplicity and the fact that it can easily be extended to include both the free molecular, transition, and continuum regimes. An important disadvantage is that the approach can be used for simple geometries only.

A more fundamental approach is the use of Monte Carlo techniques (Cooke and Harris, 1989; Ikegawa and Kobayashi, 1989; Rey et al., 1991; Kersch and Morokoff, 1995). The method can easily be extended to include phenomena such as complex gas and surface chemistry, specular reflection of particles from the walls, surface diffusion (Wulu et al., 1991), and three-dimensional effects (Coronell and Jensen, 1993). The method can in principle be applied to the free molecular, transition, and near-continuum regimes, but extension to the continuum regime is prohibited by computational demands. Surface smoothing techniques and the simulation of a large number of molecules are necessary to avoid (nonphysical) local thickness variations.

A third approach is the so-called "ballistic transport reaction" model (Cale and Raupp, 1990a,b; Cale et al., 1990, 1991), which has been implemented in the EVOLVE code (see Practical Aspects of the Method). The method makes use of the analogy between diffuse reflection and absorption of photons on gray surfaces, and the scattering and adsorption of reactive molecules on the walls of the hole. The approach seems to be very successful in the prediction of film profiles in complex two- and three-dimensional geometries. It is much more flexible than the Knudsen diffusion type models and has a more sound theoretical foundation. Compared to Monte Carlo methods, the ballistic method seems to be very efficient, requiring much less computational effort. Its main limitation is probably that the method is limited to the free molecular regime and cannot be extended to the transition or continuum flow regimes.

An important issue is the coupling between macro-scale and meso-scale phenomena (Gobbert et al., 1996; Hebb and Jensen, 1996; Rodgers and Jensen, 1998). On the one hand, the boundary conditions for meso-scale models are determined by the local macro-scale gas species concentrations. On the other hand, the meso-scale phenomena determine the boundary conditions for the macro-scale model.

Plasma

The modeling of plasma-based CVD chemistry is inherently more complex than the modeling of comparable neutral gas processes. The low-temperature, partially ionized discharges are characterized by a number of interacting effects, e.g., plasma generation of active species, plasma power deposition, and loss mechanisms and surface processes at the substrates and walls (Brinkmann et al., 1995b; Meyyappan, 1995b). The strong nonequilibrium in a plasma implies that equilibrium chemistry does not apply. In addition it causes a variety of spatio-temporal inhomogeneities. Nevertheless, important progress is being made in developing adequate mathematical models for low-pressure gas discharges. A detailed treatment of plasma modeling is beyond the scope of this unit, and the reader is referred to review texts (Chapman, 1980; Birdsall and Langdon, 1985; Boenig, 1988; Graves, 1989; Kline and Kushner, 1989; Brinkmann et al., 1995b; Meyyappan, 1995b).

Various degrees of complexity can be distinguished in plasma modeling: On the one hand, engineering-oriented, so-called "SPICE" models, are conceptually simple, but include various degrees of approximation and empirical information and are only able to provide qualitative results. On the other hand, so-called particle-in-cell (PIC)/Monte Carlo collision models (Hockney and Eastwood, 1981; Birdsall and Langdon, 1985; Birdsall, 1991) are closely related to the fundamental Boltzmann equation, and are suited to investigate basic principles of discharge operation. However, they require considerable computational resources, and in practice their use is limited to one-dimensional simulations only. This also applies to so-called "fluid-dynamical" models (Park et al., 1989; Gogolides and Sawin, 1992), in which the plasma is described in terms of its macroscopic variables. This results in a relatively simple set of partial differential equations with appropriate boundary conditions for, e.g., the electron density and temperature, the ion density and average velocity, and the electrical field potential. However, these equations are numerically stiff, due to the large differences in relevant time scales which have to be resolved, which makes computations expensive.

As an intermediate approach between the above two extremes, Brinkmann and co-workers (Brinkmann et al., 1995b) have proposed the so-called effective drift diffusion model for low-pressure RF plasmas as found in plasma enhanced CVD. This regime has been shown to be physically equivalent to fluid-dynamical models, with differences in predicted plasma properties of $<10\%$. However, compared to fluid-dynamical models, savings in CPU time of 1 to 2 orders of magnitude are obtained, allowing for the application in two- and three-dimensional equipment simulation (Brinkmann et al., 1995a).

Hydrodynamics

In the macro-scale modeling of the gas flow in the reactor, the gas is usually treated as a continuum. This assumption is valid when the mean free path length of the molecules is much smaller than a characteristic dimension of the reactor geometry, i.e., in general for pressures >100 Pa and typical dimensions >1 cm. Furthermore, the gas is treated as an ideal gas and the flow is assumed to be laminar, the Reynolds number being well below values at which turbulence might be expected.

In CVD we have to deal with multicomponent gas mixtures. The composition of an N-component gas mixture can be described in terms of the dimensionless mass fractions ω_i of its constituents, which sum up to unity:

$$\sum_{i=1}^{N} \omega_i = 1 \qquad (15)$$

Their diffusive fluxes can be expressed as mass fluxes $\vec{j}_i$ with respect to the mass-averaged velocity $\vec{v}$:

$$\vec{j}_i = \rho\omega_i(\vec{v}_i - \vec{v}) \tag{16}$$

The transport of momentum, heat, and chemical species is described by a set of coupled partial differential equations (Bird et al., 1960; Kleijn and Werner, 1993; Kleijn, 1995; Kleijn and Kuijlaars, 1995). The conservation of mass is given by the continuity equation:

$$\frac{\partial\rho}{\partial t} = -\nabla\cdot(\rho\vec{v}) \tag{17}$$

where ρ is the gas density and t the time. The conservation of momentum is given for Newtonian fluids by:

$$\frac{\partial\rho\vec{v}}{\partial t} = -\nabla\cdot(\rho\vec{v}\vec{v}) + \nabla\cdot\{\mu[\nabla\vec{v} + (\nabla\vec{v})^{\dagger}] - \frac{2}{3}\mu(\nabla\cdot\vec{v})\mathbf{I}\} - \nabla p + \rho\vec{g} \tag{18}$$

where μ is viscosity, $\mathbf{I}$ the unity tensor, p is the pressure, and $\vec{g}$ the gravity vector. The transport of thermal energy can be expressed in terms of temperature T. Apart from convection, conduction, and pressure terms, its transport equation comprises a term denoting the Dufour effect (transport of heat due to concentration gradients), a term representing the transport of enthalpy through diffusion of gas species, and a term representing production of thermal energy through chemical reactions, as follows:

$$c_p\frac{\partial\rho T}{\partial t} = -c_p\nabla\cdot(\rho\vec{v}T) + \nabla\cdot(\lambda\nabla T) + \frac{DP}{Dt} + \underbrace{\nabla\cdot\left(RT\sum_{i=1}^{N}\frac{D_i^T}{M_i}\nabla(\ln x_i)\right)}_{\text{Dufour}} \underbrace{-\sum_{i=1}^{N}\vec{j}_i\cdot\nabla\frac{H_i}{M_i}}_{\text{inter-diffusion}} \underbrace{-\sum_{i=1}^{N}\sum_{k=1}^{K}H_i\nu_{ik}R_k^g}_{\text{heat of reaction}} \tag{19}$$

where c_p is the specific heat, λ the thermal conductivity, P pressure, x_i is the mole fraction of gas i, D_i^T its thermal diffusion coefficient, H_i its enthalpy, $\vec{j}_i$ its diffusive mass flux, ν_{ik} its stoichiometric coefficient in reaction k, M_i its molar mass, and R_k^g the net reaction rate of reaction k. The transport equation for the ith gas species is given by:

$$\frac{\partial\rho\omega_i}{\partial t} = \underbrace{-\nabla\cdot(\rho\vec{v}\omega_i)}_{\text{convection}} - \underbrace{\nabla\cdot\vec{j}_i}_{\text{diffusion}} + \underbrace{M_i\sum_{k=1}^{K}\nu_{ik}R_k^g}_{\text{reaction}} \tag{20}$$

where $\vec{j}_i$ represents the diffusive mass flux of species i. In an N-component gas mixture, there are $N-1$ independent species equations of the type of Equation 20, since the mass fraction must sum up to unity (see Eq. 15).

Two phenomena of minor importance in many other processes may be specifically prominent in CVD, i.e., multicomponent effects and thermal diffusion (Soret effect). The most commonly applied theory for modeling gas diffusion is Fick's Law, which, however, is valid for isothermal, binary mixtures only. In the rigorous kinetic theory of N-component gas mixtures, the following expression for the diffusive mass flux vector is found (Hirschfelder et al., 1967),

$$\frac{M}{\rho}\sum_{j=1,j\neq i}^{N}\frac{\omega_i\vec{j}_j - \omega_j\vec{j}_i}{M_j\mathcal{D}_{ij}} = \nabla\omega_i + \omega_i\frac{\nabla M}{M} - \nabla(\ln T)\frac{M}{\rho}\sum_{j=1,j\neq i}^{N}\frac{\omega_i D_j^T - \omega_j D_i^T}{M_j\mathcal{D}_{ij}} \tag{21}$$

where M is the average molar mass, $\mathcal{D}_{ij}$ is the binary diffusion coefficient of a gas pair and D_i^T is the thermal diffusion coefficient of a gas species. In general, $D_i^T > 0$ for large, heavy molecules (which therefore are driven toward cold zones in the reactor), $D_i^T < 0$ for small, light molecules (which therefore are driven toward hot zones in the reactor), and $\Sigma D_i^T = 0$. Equation 21 can be rewritten by separating the diffusive mass flux vector $\vec{j}_i$ into a flux driven by concentration gradients $\vec{j}_i^C$ and a flux driven by temperature gradients $\vec{j}_i^T$:

$$\vec{j}_i = \vec{j}_i^C + \vec{j}_i^T \tag{22}$$

with

$$\frac{M}{\rho}\sum_{j=1}^{N}\frac{\omega_i\vec{j}_j^C - \omega_j\vec{j}_i^C}{M_j\mathcal{D}_{ij}} = \nabla\omega_i + \omega_i\frac{\nabla M}{M} \tag{23}$$

and

$$\vec{j}_i^T = -D_i^T\nabla(\ln T) \tag{24}$$

Equation 23 relates the N diffusive mass flux vectors $\vec{j}_i^C$ to the N mass fractions and mass fraction gradients. In many numerical schemes however, it is desirable that the species transport equation (Eq. 20) contains a gradient-driven "Fickian" diffusion term. This can be obtained by rewriting Equation 23 as:

$$\vec{j}_i^C = \underbrace{-\rho D_i^{SM}\nabla\omega_i}_{\text{Fick term}} - \underbrace{\rho\omega_i D_i^{SM}\frac{\nabla m}{m}}_{\text{multi-component 1}} + \underbrace{m\omega_i D_i^{SM}\sum_{j=1,j\neq i}\frac{\vec{j}_j^C}{M_j\mathcal{D}_{ij}}}_{\text{multi-component 2}} \tag{25}$$

and defining a diffusion coefficient D_i^{SM}:

$$D_i^{SM} = \left(\sum_{j=1,j\neq i}^{N}\frac{x_i}{\mathcal{D}_{ij}}\right)^{-1} \tag{26}$$

The divergence of the last two terms in Equation 25 is treated as a source term. Within an iterative solution scheme, the unknown diffusive fluxes $\vec{j}_j^C$ can be taken from a previous iteration.

The above transport equations are supplemented with the usual boundary conditions in the inlets and outlets

and at the nonreacting walls. On reacting walls there will be a net gaseous mass production which leads to a velocity component normal to the wafer surface:

$$\vec{n} \cdot (\rho \vec{v}) = \sum_i M_i \sum_l \sigma_{il} R_l^s \tag{27}$$

where $\vec{n}$ is the outward-directed unity vector normal to the surface, ρ is the local density of the gas mixture, R_l^s the rate of the lth surface reaction and σ_{il} the stoichiometric coefficient of species i in this reaction. The net total mass flux of the ith species normal to the wafer surface equals its net mass production:

$$\vec{n} \cdot (\rho \omega_i \vec{v} + \vec{j_i}) = M_i \sum_l \sigma_{il} R_l^s \tag{28}$$

Kinetic Theory

The modeling of transport phenomena and chemical reactions in CVD processes requires knowledge of the thermochemical properties (specific heat, heat of formation, and entropy) and transport properties (viscosity, thermal conductivity, and diffusivities) of the gas mixture in the reactor chamber.

Thermochemical properties of gases as a function of temperature can be found in various publications (Svehla, 1962; Coltrin et al., 1986, 1989; Giunta et al., 1990a,b; Arora and Pollard, 1991) and databases (Gordon and McBride, 1971; Barin and Knacke, 1977; Barin et al., 1977; Stull and Prophet, 1982; Wagman et al., 1982; Kee et al., 1990). In the absence of experimental data, thermochemical properties may be obtained from ab initio molecular structure calculations (Melius et al., 1997).

Only for the most common gases can transport properties be found in the literature (Maitland and Smith, 1972; l'Air Liquide, 1976; Weast, 1984). The transport properties of less common gas species may be calculated from kinetic theory (Svehla, 1962; Hirschfelder et al., 1967; Reid et al., 1987; Kleijn and Werner, 1993; Kleijn, 1995; Kleijn and Kuijlaars, 1995). Assumptions have to be made for the form of the intermolecular potential energy function $\phi(r)$. For nonpolar molecules, the most commonly used intermolecular potential energy function is the Lennard-Jones potential:

$$\phi(r) = 4\varepsilon \left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} \right] \tag{29}$$

where r is the distance between the molecules, σ the collision diameter of the molecules, and ε their maximum energy of attraction. Lennard-Jones parameters for many CVD gases can be found in Svehla (1962), Coltrin et al. (1986), Coltrin et al. (1989), Arora and Pollard (1991), and Kee et al. (1991), or can be estimated from properties of the gas at the critical point or at the boiling point (Bird et al., 1960):

$$\frac{\varepsilon}{k_B} = 0.77 T_c \quad \text{or} \quad \frac{\varepsilon}{k_B} = 1.15 T_b \tag{30}$$

$$\sigma = 0.841 V_c \quad \text{or} \quad \sigma = 2.44 \frac{T_c}{P_c} \quad \text{or} \quad \sigma = 1.166 V_{b,l} \tag{31}$$

where T_c and T_b are the critical temperature and normal boiling point temperature (K), P_c is the critical pressure (atm), V_c and $V_{b,l}$ are the molar volume at the critical point and the liquid molar volume at the normal boiling point ($cm^3\ mol^{-1}$), and k_B is the Boltzmann constant. For most CVD gases, only rough estimates of Lennard-Jones parameters are available. Together with inaccuracies in the assumptions made in kinetic theory, this leads to an accuracy of predicted transport properties of typically 10% to 25%. When the transport properties of its constituent gas species are known, the properties of a gas mixture can be calculated from semiempirical mixture rules (Reid et al., 1987; Kleijn and Werner, 1993; Kleijn, 1995; Kleijn and Kuijlaars, 1995). The inaccuracy in predicted mixture properties may well be as large as 50%.

Radiation

CVD reactor walls, windows, and substrates adopt a certain temperature profile as a result of their conjugate heat exchange. These temperature profiles may have a large influence on the deposition process. This is even more true for lamp-heated reactors, such as rapid thermal CVD (RTCVD) reactors, in which the energy bookkeeping of the reactor system is mainly determined by radiative heat exchange.

The transient temperature distribution in solid parts of the reactor is described by the Fourier equation (Bird et al., 1960):

$$\rho_s c_{p,s} \frac{\partial T}{\partial t} = \nabla \cdot (\lambda_s \nabla T_s) + q''' \tag{32}$$

where q''' is the heat-production rate in the solid material, e.g., due to inductive heating, ρ_s, $c_{p,s}$, λ_s, and T_s are the solid density, specific heat, thermal conductivity, and temperature. The boundary conditions at the solid-gas interfaces take the form:

$$\vec{n} \cdot (\lambda_s \nabla T_s) = q''_{\text{conv}} + q''_{\text{rad}} \tag{33}$$

where q''_{conv} and q''_{rad} are the convective and radiative heat fluxes to the solid and $\vec{n}$ is the outward directed unity vector normal to the surface. For the interface between a solid and the reactor gases (the temperature distribution of which is known) we have:

$$q''_{\text{conv}} = -\vec{n} \cdot (\lambda_g \nabla T_g) \tag{34}$$

where λ_g and T_g are the thermal conductivity and temperature of the reactor gases. Usually, we do not have detailed information on the temperature distribution outside the reactor. Therefore, we have to use heat transfer relations like:

$$q''_{\text{conv}} = \alpha_{\text{conv}} (T_s - T_{\text{ambient}}) \tag{35}$$

to model the convective heat losses to the ambient, where α_{conv} is a heat-transfer coefficient.

The most challenging part of heat-transfer modeling is the radiative heat exchange inside the reactor chamber,

which is complicated by the complex geometry, the spectral and temperature dependence of the optical properties (Ordal et al., 1985; Palik, 1985), and the occurrence of specular reflections. An extensive treatment of all these aspects of the modeling of radiative heat exchange can be found, e.g., in Siegel and Howell (1992), Kersch and Morokoff (1995), Kersch (1995a), or Kersch (1995b).

An approach that can be used if the radiating surfaces are diffuse-gray (i.e., their absorptivity and emissivity are independent of direction and wavelength) is the so-called Gebhart absorption-factor method (Gebhart, 1958, 1971). The reactor walls are divided into small surface elements, across which a uniform temperature is assumed. Exchange factors G_{ij} between pairs $i - j$ of surface elements are evaluated, which are determined by geometrical line-of-sight factors and optical properties. The net radiative heat transfer to surface element j now equals:

$$q''_{rad,j} = \frac{1}{A_j} \sum_i G_{ij} \varepsilon_i \sigma_B T_i^4 A_i - \varepsilon_j \sigma_B T_j^4 \qquad (36)$$

where ε is the emissivity, σ_B the Stefan-Boltzmann constant, and A the surface area of the element.

In order to incorporate further refinements, such as wavelength, temperature and directional dependence of the optical properties, and specular reflections, Monte Carlo methods (Howell, 1968) are more powerful than the Gebhart method. The emissive power is partitioned into a large number of rays of energy leaving each surface, which are traced through the reactor as they are being reflected, transmitted, or absorbed at various surfaces. By choosing the random distribution functions of the emission direction and the wavelength for each ray appropriately, the total emissive properties from the surface may be approximated. By averaging over a large number of rays, the total heat exchange fluxes may be computed (Coronell and Jensen, 1994; Kersch and Morokoff, 1995; Kersch, 1995a,b).

PRACTICAL ASPECTS OF THE METHOD

In the previous section, the seven main aspects of CVD simulation (i.e., surface chemistry, gas-phase chemistry, free molecular flow, plasma physics, hydrodynamics, kinetic theory, and thermal radiation) have been discussed (see Principles of the Method). An ideal CVD simulation tool should integrate models for all these aspects of CVD. Such a comprehensive tool is not available yet. However, powerful software tools for each of these aspects can be obtained commercially, and some CVD simulation software combines several over the necessary models.

Surface Chemistry

For modeling surface processes at the interface between a solid and a reactive gas, the SURFACE CHEMKIN package (available from Reaction Design; also see Coltrin et al., 1991a,b) is undoubtedly the most flexible and powerful tool available at present. It is a suite of FORTRAN codes allowing for easily setting up surface reaction simulations. It defines a formalism for describing surface processes between various gaseous, adsorbed, and solid bulk species and performs bookkeeping on concentrations of all these species. In combination with the SURFACE PSR (Moffat et al., 1991b), SPIN (Coltrin et al., 1993a) and CRESLAF (Coltrin et al., 1993b) codes (all programs available from Reaction Design), it can be used to model the surface reactions in a perfectly stirred tank reactor, a rotating disk reactor, or a developing boundary layer flow along a reacting surface. Simple problems can be run on a personal computer in a few minutes; more complex problems may take dozens of minutes on a powerful workstation.

No models or software are available for routinely predicting surface reaction kinetics. In fact, this is as yet probably the most difficult and unsolved issue in CVD modeling. Surface reaction kinetics are estimated based on bond dissociation enthalpies, transition state theory, and analogies with similar gas phase reactions; the success of this approach largely depends on the skills and expertise of the chemist performing the analysis.

Gas-Phase Chemistry

Similarly, for modeling gas-phase reactions, the CHEMKIN package (available from Reaction Design; also see Kee et al., 1989) is the *de facto* standard modeling tool. It is a suite of FORTRAN codes allowing for easily setting up reactive gas flow problems, which computes production/destruction rates and performs bookkeeping on concentrations of gas species. In combination with the CHEMKIN THERMODYNAMIC DATABASE (Reaction Design) it allows for the self-consistent evaluation of species thermochemical data and reverse reaction rates. In combination with the SURFACE PSR (Moffat et al., 1991a), SPIN (Coltrin et al., 1993a), and CRESLAF (Coltrin et al., 1993b) codes (all programs available from Reaction Design) it can be used to model reactive flows in a perfectly stirred tank reactor, a rotating disk reactor, or a developing boundary layer flow, and it can be used together with SURFACE CHEMKIN (Reaction Design) to simulate problems with both gas and surface reactions. Simple problems can be run on a personal computer in a few minutes; more complex problems may take dozens of minutes on a powerful workstation.

Various proprietary and shareware software programs are available for predicting gas phase rate constants by means of theoretical chemical kinetics (Hase and Bunker, 1973) and for evaluating molecular and transition state structures and electronic energies (available from Biosym Technologies and Gaussian Inc.). These programs, especially the latter, require significant computing power. Once the possible reaction paths have been identified and reaction rates have been estimated, sensitivity analysis with, e.g., the SENKIN package (available from Reaction Design, also see Lutz et al., 1993) can be used to eliminate insignificant reactions and species. As in surface chemistry, setting up a reaction model that can confidently be used in predicting gas phase chemistry is still far from trivial, and the success largely depends on the skills and expertise of the chemist performing the analysis.

Free Molecular Transport

As described in the previous section (see Principles of the Method) the "ballistic transport-reaction" model is probably the most powerful and flexible approach to modeling free molecular gas transport and chemical reactions inside very small surface structures (i.e., much smaller than the gas molecules' mean free path length). This approach has been implemented in the EVOLVE code. EVOLVE 4.1a is a low-pressure transport, deposition, and etch-process simulator developed by T.S. Cale at Arizona State University, Tempe, Ariz., and Motorola Inc., with support from the Semiconductor Research Corporation, The National Science Foundation, and Motorola, Inc. It allows for the prediction of the evolution of film profiles and composition inside small two-dimensional and three-dimensional holes of complex geometry as functions of operating conditions, and requires only moderate computing power, provided by a personal computer. A Monte Carlo model for microscopic film growth has been integrated into the computational fluid dynamics (CFD) code CFD-ACE (available from CFDRC).

Plasma Physics

The modeling of plasma physics and chemistry in CVD is probably not yet mature enough to be done routinely by nonexperts. Relatively powerful and user-friendly continuum plasma simulation tools have been incorporated into some tailored CFD codes, such as Phoenics-CVD from Cham, Ltd. and CFDPLASMA (ICP) from CFDRC. They allow for two- and three-dimensional plasma modeling on powerful workstations at typical CPU times of several hours. However, the accurate modeling of plasma properties requires considerable expert knowledge. This is even more true for the relation between plasma physics and plasma enhanced chemical reaction rates.

Hydrodynamics

General purpose CFD packages for the simulation of multi-dimensional fluid flow have become available in the last two decades. These codes have mostly been based on either the finite volume method (Patankar, 1980; Minkowycz et al., 1988) or the finite element method (Taylor and Hughes, 1981; Zienkiewicz and Taylor, 1989). Generally, these packages offer easy grid generation for complex two-dimensional and three-dimensional geometries, a large variety of physical models (including models for gas radiation, flow in porous media, turbulent flow, two-phase flow, non-Newtonian liquids, etc.), integrated graphical post-processing, and menu-driven user-interfaces allowing the packages to be used without detailed knowledge of fluid dynamics and computational techniques. Obviously, CFD packages are powerful tools for CVD hydrodynamics modeling. It should, however, be realized that they have not been developed specifically for CVD modeling. As a result: (1) the input data must be formulated in a way that is not very compatible with common CVD practice; (2) many features are included that are not needed for CVD modeling, which makes the packages bulky and slow; (3) the numerical solvers are generally not very well suited for the solution of the stiff equations typical of CVD chemistry; (4) some output that is of specific interest in CVD modeling is not provided routinely; and (5) the codes do not include modeling features that are needed for accurate CVD modeling, such as gas species thermodynamic and transport property databases, solids thermal and optical property databases, chemical reaction mechanism and rate constants databases, gas mixture property calculation from kinetic theory, multicomponent ordinary and thermal diffusion, multiple chemical species in the gas phase and at the surface, multiple chemical reactions in the gas phase and at the surface, plasma physics and plasma chemistry models, and non-gray, non-diffuse wall-to-wall radiation models. The modifications required to include these features in general-purpose fluid dynamics codes are not trivial, especially when the source codes are not available. Nevertheless, promising results in the modeling of CVD reactors have been obtained with general purpose CFD codes.

A few CFD codes have been specially tailored for CVD reactor scale simulations including the following.

PHOENICS-CVD (Phoenics-CVD, 1997), a finite-volume CVD simulation tool based on the PHOENICS flow simulator by Cham Ltd. (developed under EC-ESPRIT project 7161). It includes databases for thermal and optical solid properties and thermodynamic and transport gas properties (CHEMKIN-format), models for multicomponent (thermal) diffusion, kinetic theory models for gas properties, multireaction gas-phase and surface chemistry capabilities, the effective drift diffusion plasma model and an advanced wall-to-wall thermal radiation model, including spectral dependent optical properties, semitransparent media and specular reflection. Its modeling capabilities and examples of its applications have been described in Heritage (1995).

CFD-ACE, a finite-volume CFD simulation tool by CFD Research Corporation. It includes models for multicomponent (thermal) diffusion, efficient algorithms for stiff multistep gas and surface chemistry, a wall-to-wall thermal radiation model (both gray and non-gray) including semitransparent media, and integrated Monte Carlo models for free molecular flow phenomena inside small structures. The code can be coupled to CFD-PLASMA to perform plasma CVD simulations.

FLUENT, a finite-volume CFD simulation tool by Fluent Inc. It includes models for multicomponent (thermal) diffusion, kinetic theory models for gas properties, and (limited) multistep gas-phase chemistry and simple surface chemistry.

These codes have been available for a relatively short time now and are still continuously evolving. They allow for the two-dimensional modeling of gas flow with simple chemistry on powerful personal computers in minutes. For three-dimensional simulations and simulations including, e.g., plasma, complex chemistry, or radiation effects, a powerful workstation is needed, and CPU times may be several hours. Potential users should compare the capabilities, flexibility, and user-friendliness of the codes to their own needs.

Kinetic Theory

Kinetic gas theory models for predicting transport properties of multicomponent gas mixtures have been incorporated into the PHOENICS-CVD, CVD-ACE, and FLUENT flow simulation codes. The CHEMKIN suite of codes contains a library of routines as well as databases (Kee et al., 1990) for evaluating transport properties of multicomponent gas mixture as well.

Thermal Radiation

Wall-to-wall thermal radiation models, including essential features for CVD modeling such as spectrally dependent (non-gray) optical properties, semitransparent media (e.g., quartz) and specular reflection, on, e.g., polished metal surfaces, have been incorporated in the PHOENICS-CVD and CFD-ACE flow simulation codes. In addition many stand-alone thermal radiation simulators are available, e.g., ANSYS (from Swanson Analysis Systems).

PROBLEMS

CVD simulation is a powerful tool in reactor design and process optimization. With commercially available CFD software, rather straightforward and reliable hydrodynamic modeling studies can be performed, which give valuable information on, e.g., flow recirculations, dead zones, and other important reactor design issues. Thermal radiation simulations can also be performed relatively easily, and they provide detailed insight in design parameters such as heating uniformities and peak thermal load.

However, as soon as one wishes to perform a comprehensive CVD simulation to predict issues such as film deposition rate and uniformity, conformality, and purity, several problems arise.

The first problem is that every available numerical simulation code to be used for CVD simulation has some limitations or drawbacks. The most powerful and tailored CVD simulation models—i.e., the CHEMKIN suite from Reaction Design—allows for the hydrodynamic simulation of highly idealized and simplified flow systems only, and does not include models for thermal radiation and molecular behavior in small structures. CFD codes (even the ones that have been tailored for CVD modeling, such as PHOENICS-CVD, CFD-ACE, and FLUENT) have limitations with respect to modeling stiff multi-reaction chemistry. The coupling to molecular flow models (if any) is only one-way, and incorporated plasma models have a limited range of validity and require specialist knowledge. The simulation of complex three-dimensional reactor geometries with detailed chemistry, plasma and/or radiation can be very cumbersome, and may require long CPU times.

A second and perhaps even more important problem is the lack of detailed, reliable, and validated chemistry models. Models have been proposed for some important CVD processes (see Principles of the Method), but their testing and validation has been rather limited. Also, the "translation" of published models to the input format required by various software is error-prone. In fact, the unknown chemistry of many processes is the most important bottle-neck in CVD simulation.

The CHEMKIN codes come with detailed chemistry models (including rate constants) for a range of processes. To a lesser extent, detailed chemistry models for some CVD processes have been incorporated in the databases of PHOENICS-CVD as well.

Lumped chemistry models should be used with the greatest care, since they are unlikely to hold for process conditions different from those for which they have been developed, and it is sometimes even doubtful whether they can be used in a different reactor than that for which they have been tested. Even detailed chemistry models based on elementary processes have a limited range of validity, and the use of these models in a different pressure regime is especially dangerous. Without fitting, their accuracy in predicting growth rates may well be off by 100%. The use of theoretical tools for predicting rate constants in the gas phase requires specialized knowledge and is not completely straightforward. This is even more the case for surface reaction kinetics, where theoretical tools are just beginning to be developed.

A third problem is the lack of accurate input data, such as Lennard-Jones parameters for gas property prediction, thermal and optical solid properties (especially for coated surfaces), and plasma characteristics. Some scattered information and databases containing relevant parameters are available, but almost every modeler setting up CVD simulations for a new process will find that important data are lacking.

Furthermore, the coupling between the macro-scale (hydrodynamics, plasma, and radiation) parts of CVD simulations and meso-scale models for molecular flow and deposition in small surface structures is difficult (Jensen et al., 1996; Gobbert et al., 1997), and this, in particular, is what one is interested in for most CVD modeling.

Finally, CVD modeling does not, at present, predict film structure, morphology, or adhesion. It does not predict mechanical, optical, or electrical film properties. It does not lead to the invention of new processes or the prediction of successful precursors. It does not predict optimal reactor configurations or processing conditions (although it can be used in evaluating the process performance as a function of reactor configuration and processing conditions). It does not generally lead to quantitatively correct growth rate or step coverage predictions without some fitting aided by prior experimental knowledge of the deposition kinetics.

However, in spite of all these limitations, carefully setup CVD simulations can provide reactor designers and process developers with a wealth of information, as shown in many studies (Kleijn, 1995). CVD simulations predict general trends in the process characteristics and deposition properties in relation to process conditions and reactor geometry and can provide fundamental insight into the relative importance of various phenomena. As such, it can be an important tool in process optimization and reactor design, pointing out bottlenecks in the design and issues that need to be studied more carefully. All of this leads to more efficient, faster, and less expensive process design, in which less trial and error is involved. Thus,

successful attempts have been made in using simulation, for example, to optimize hydrodynamic reactor design and eliminate flow recirculations (Evans and Greif, 1987; Visser et al., 1989; Fotiadis et al., 1990), to predict and optimize deposition rate and uniformity (Jensen and Graves, 1983; Kleijn and Hoogendoorn, 1991; Biber et al., 1992), to optimize temperature uniformity (Badgwell et al., 1994; Kersch and Morokoff, 1995), to scale up existing reactors to large wafer diameters (Badgwell et al., 1992), to optimize process operation and processing conditions with respect to deposition conformality (Hasper et al., 1991; Kristof et al., 1997), to predict the influence of processing conditions on doping rates (Masi et al., 1992), to evaluate loading effects on selective deposition rates (Holleman et al., 1993), and to study the influence of operating conditions on self-limiting effects (Leusink et al., 1992) and selectivity loss (Werner et al., 1992; Kuijlaars, 1996).

The success of these exercises largely depends on the skills and experience of the modeler. Generally, all available CVD simulation software leads to erroneous results when used by careless or inexperienced modelers.

MAGNETISM IN ALLOYS

INTRODUCTION

The human race has used magnetic materials for well over 2000 years. Today, magnetic materials power the world, for they are at the heart of energy conversion devices, such as generators, transformers, and motors, and are major components in automobiles. Furthermore, these materials will be important components in the energy-efficient vehicles of tomorrow. More recently, besides the obvious advances in semiconductors, the computer revolution has been fueled by advances in magnetic storage devices, and will continue to be affected by the development of new multicomponent high-coercivity magnetic alloys and multilayer coatings. Many magnetic materials are important for some of their other properties which are superficially unrelated to their magnetism. Iron steels and iron-nickel (so-called "Invar", or volume INVARiant) alloys are two important examples from a long list. Thus, to understand a wide range of materials, the origins of magnetism, as well as the interplay with alloying, must be uncovered. A quantum-mechanical description of the electrons in the solid is needed for such understanding, so as to describe, on an equal footing and without bias, as many key microscopic factors as possible. Additionally, many aspects, such as magnetic anisotropy and hence permanent magnetism, need the full power of relativistic quantum electrodynamics to expose their underpinnings.

From Atoms to Solids

Experiments on atomic spectra, and the resulting highly abundant data, led to several empirical rules which we now know as Hund's rules. These rules describe the filling of the atomic orbitals with electrons as the atomic number is changed. Electrons occupy the orbitals in a shell in such a way as to maximize both the total spin and the total angular momentum. In the transition metals and their alloys, the orbital angular momentum is almost "quenched;" thus the spin Hund's rule is the most important. The quantum mechanical reasons behind this rule are neatly summarized as a combination of the Pauli exclusion principle and the electron-electron (Coulomb) repulsion. These two effects lead to the so-called "exchange" interaction, which forces electrons with the same spin states to occupy states with different spatial distribution, i.e., with different angular momentum quantum numbers. Thus the exchange interaction has its origins in minimizing the Coulomb energy locally—i.e., the intrasite Coulomb energy—while satisfying the other constraints of quantum mechanics. As we will show later in this unit, this minimization in crystalline metals can result in a competition between intrasite (local) and intersite (extended) effects—i.e. kinetic energy stemming from the curvature of the wave functions. When the overlaps between the orbitals are small, the intrasite effects dominate, and magnetic moments can form. When the overlaps are large, electrons hop from site to site in the lattice at such a rate that a local moment cannot be sustained. Most of the existing solids are characterized in terms of this latter picture. Only in a few places in the periodic table does the former picture closely reflect reality. We will explore one of these places here, namely the 3*d* transition metals.

In the 3*d* transition metals, the states that are derived from the 3*d* and 4*s* atomic levels are primarily responsible for a metal's physical properties. The 4*s* states, being more spatially extended (higher principal quantum number), determine the metal's overall size and its compressibility. The 3*d* states are more (but not totally) localized and give rise to a metal's magnetic behavior. Since the 3*d* states are not totally localized, the electrons are considered to be mobile giving rise to the name "itinerant" magnetism for such cases.

At this point, we want to emphasize that moment formation and the alignment of these moments with each other have different origins. For example, magnetism plays an important role in the stability of stainless steel, FeNiCr. Although it is not ferromagnetic (having zero net magnetization), the moments on its individual constituents have not disappeared; they are simply not aligned. Moments may exist on the atomic scale, but they might not point in the same direction, even at near-zero temperatures. The mechanisms that are responsible for the moments and for their alignment depend on different aspects of the electronic structure. The former effect depends on the gross features, while the latter depends on very detailed structure of the electronic states.

The itinerant nature of the electrons makes magnetism and related properties difficult to model in transition metal alloys. On the other hand, in magnetic insulators the exchange interactions causing magnetism can be represented rather simply. Electrons are appropriately associated with particular atomic sites so that "spin" operators can be specified and the famous Heisenberg-Dirac Hamiltonian can then be used to describe the behavior of these systems. The Hamiltonian takes the following form,

$$H = -\sum_{ij} J_{ij} \hat{S}_i \cdot \hat{S}_j \qquad (1)$$

in which J_{ij} is an "exchange" integral, measuring the size of the electrostatic and exchange interaction and $\hat{S}_i$ is the spin vector on site i. In metallic systems, it is not possible to allocate the itinerant electrons in this way and such pairwise intersite interactions cannot be easily identified. In such metallic systems, magnetism is a complicated many-electron effect to which Hund's rules contribute. Many have labored with significant effort over a long period to understand and describe it.

One common approach involves a mapping of this problem onto one involving independent electrons moving in the fields set up by all the other electrons. It is this aspect that gives rise to the spin-polarized band structure, an often used basis to explain the properties of metallic magnets. However, this picture is not always sufficient. Herring (1966), among others, noted that certain components of metallic magnetism can also be discussed using concepts of localized spins which are, strictly speaking, only relevant to magnetic insulators. Later on in this unit, we discuss how the two pictures have been

combined to explain the temperature dependence of the magnetic properties of bulk transition metals and their alloys.

In certain metals, such as stainless steel, magnetism is subtly connected with other properties via the behavior of the spin-polarized electronic structure. Dramatic examples are those materials which show a small thermal expansion coefficient below the Curie temperature, T_c, a large forced expansion in volume when an external magnetic field is applied, a sharp decrease of spontaneous magnetization and of the Curie temperature when pressure is applied, and large changes in the elastic constants as the temperature is lowered through T_c. These are the famous "Invar" materials, so called because these properties were first found to occur in the fcc alloys Fe-Ni (65% Fe), Fe-Pd, and Fe-Pt (Wassermann, 1991). The compositional order of an alloy is often intricately linked with its magnetic state, and this can also reveal physically interesting and technologically important new phenomena. Indeed, some alloys, such as $Ni_{75}Fe_{25}$, develop directional chemical order when annealed in a magnetic field (Chikazurin and Graham, 1969). Magnetic short-range correlations above T_c, and the magnetic order below, weaken and alter the chemical ordering in iron-rich Fe-Al alloys, so that a ferromagnetic $Fe_{80}Al_{20}$ alloy forms a DO_3 ordered structure at low temperatures, whereas paramagnetic $Fe_{75}Al_{25}$ forms a B2 ordered phase at comparatively higher temperatures (Stephens, 1985; McKamey et al., 1991; Massalski et al., 1990; Staunton et al., 1997). The magnetic properties of many alloys are sensitive to the local environment. For example, ordered Ni-Pt (50%) is an anti-ferromagnetic alloy (Kuentzler, 1980), whereas its disordered counterpart is ferromagnetic (MAGNETIC MOMENT AND MAGNETIZATION, MAGNETIC NEUTRON SCATTERING). The main part of this unit is devoted to a discussion of the basis underlying such magneto-compositional effects.

Since the fundamental electrostatic exchange interactions are isotropic, and do not couple the direction of magnetization to any spatial direction, they fail to give a basis for a description of magnetic anisotropic effects which lie at the root of technologically important magnetic properties, including domain wall structure, linear magnetostriction, and permanent magnetic properties in general. A description of these effects requires a relativistic treatment of the electrons' motions. A section of this unit is assigned to this aspect as it touches the properties of transition metal alloys.

PRINCIPLES OF THE METHOD

The Ground State of Magnetic Transition Metals: Itinerant Magnetism at Zero Temperature

Hohenberg and Kohn (1964) proved a remarkable theorem stating that the ground state energy of an interacting many-electron system is a unique functional of the electron density $n(\mathbf{r})$. This functional is a minimum when evaluated at the true ground-state density $n_o(\mathbf{r})$. Later Kohn and Sham (1965) extended various aspects of this theorem, providing a basis for practical applications of the density functional theory. In particular, they derived a set of single-particle equations which could include all the effects of the correlations between the electrons in the system. These theorems provided the basis of the modern theory of the electronic structure of solids.

In the spirit of Hartree and Fock, these ideas form a scheme for calculating the ground-state electron density by considering each electron as moving in an effective potential due to all the others. This potential is not easy to construct, since all the many-body quantum-mechanical effects have to be included. As such, approximate forms of the potential must be generated.

The theorems and methods of the density functional (DF) formalism were soon generalized (von Barth and Hedin, 1972; Rajagopal and Callaway, 1973) to include the freedom of having different densities for each of the two spin quantum numbers. Thus the energy becomes a functional of the particle density, $n(\mathbf{r})$, and the local magnetic density, $\mathbf{m}(\mathbf{r})$. The former is sum of the spin densities, the latter, the difference. Each electron can now be pictured as moving in an effective magnetic field, $\mathbf{B}(\mathbf{r})$, as well as a potential, $V(\mathbf{r})$, generated by the other electrons. This spin density functional theory (SDFT) is important in systems where spin-dependent properties play an important role, and provides the basis for the spin-polarized electronic structure mentioned in the introduction. The proofs of the basic theorems are provided in the originals and in the many formal developments since then (Lieb, 1983; Driezler and da Providencia, 1985).

The many-body effects of the complicated quantum-mechanical problem are hidden in the exchange-correlation functional $E_{xc}[n(\mathbf{r}), \mathbf{m}(\mathbf{r})]$. The exact solution is intractable; thus some sort of approximation must be made. The local approximation (LSDA) is the most widely used, where the energy (and corresponding potential) is taken from the uniformly spin-polarized homogeneous electron gas (see SUMMARY OF ELECTRONIC STRUCTURE METHODS and PREDICTION OF PHASE DIAGRAMS). Point by point, the functional is set equal to the exchange and correlation energies of a homogeneously polarized electron gas, ε_{xc}, with the density and magnetization taken to be the local values, $E_{xc}[n(\mathbf{r}), \mathbf{m}(\mathbf{r})] = \int \varepsilon_{xc}[n(\mathbf{r}), \mathbf{m}(\mathbf{r})]\, n(\mathbf{r})\, d\mathbf{r}$ (von Barth and Hedin, 1972; Hedin and Lundqvist, 1971; Gunnarsson and Lundqvist, 1976; Ceperley and Alder, 1980; Vosko et al., 1980).

Since the "landmark" papers on Fe and Ni by Callaway and Wang (1977), it has been established that spin-polarized band theory, within this Spin Density Functional formalism (see reviews by Rajagopal, 1980; Kohn and Vashishta, 1982; Driezler and da Providencia, 1985; Jones and Gunnarsson, 1989) provides a reliable quantitative description of magnetic properties of transition metal systems at low temperatures (Gunnarsson, 1976; Moruzzi et al., 1978; Koelling, 1981). In this modern version of the Stoner-Wohlfarth theory (Stoner, 1939; Wohlfarth, 1953), the magnetic moments are assumed to originate predominately from itinerant d electrons. The exchange interaction, as defined above, correlates the spins on a site, thus creating a local moment. In a ferromagnetic metal, these moments are aligned so that the systems possess a finite magnetization per site (see GENERATION AND MEASUREMENT OF MAGNETIC FIELDS, MAGNETIC MOMENT AND MAGNETIZATION,

and THEORY OF MAGNETIC PHASE TRANSITIONS). This theory provides a basis for the observed non-integer moments as well as the underlying many-electron nature of magnetic moment formation at $T = 0$ K.

Within the approximations inherent in LSDA, electronic structure (band theory) calculations for the pure crystalline state are routinely performed. Although most include some sort of shape approximation for the charge density and potentials, these calculations give a good representation of the electronic density of states (DOS) of these metals. To calculate the total energy to a precision of less than a few milli–electron volts and to reveal fine details of the charge and moment density, the shape approximation must be eliminated. Better agreement with experiment is found when using extensions of the LSDA. Nonetheless, the LSDA calculations are important in that the ground-state properties of the elements are reproduced to a remarkable degree of accuracy. In the following, we look at a typical LSDA calculation for bcc iron and fcc nickel.

Band theory calculations for bcc iron have been done for decades, with the results of Moruzzi et al. (1978) being the first of the more accurate LSDA calculations. The figure on p. 170 of their book (see Literature Cited) shows the electronic density of states (DOS) as a function of the energy. The density of states for the two spins are almost (but not quite) simply rigidly shifted. As typical of bcc structures, the d band has two major peaks. The Fermi energy resides in the top of d bands for the spins that are in the majority, and in the trough between the uppermost peaks. The iron moment extracted from this first-principles calculation is 2.2 Bohr magnetons per atom, which is in good agreement with experiment. Further refinements, such as adding the spin-orbit contributions, eliminating the shape approximation of the charge densities and potentials, and modifying the exchange-correlation function, push the calculations into better agreement with experiment. The equilibrium volume determined within LSDA is more delicate, with the errors being $\sim$3% about twice the amount for the typical nonmagnetic transition metal. The total energy of the ferromagnetic bcc phase was also found to be close to that of the nonmagnetic fcc phase, and only when improvements to the LSDA were incorporated did the calculations correctly find the former phase the more stable.

On the whole, the calculated properties for nickel are reproduced to about the same degree of accuracy. As seen in the plot of the DOS on p. 178 of Moruzzi et al. (1978), the Fermi energy lies above the top of the majority-spin d bands, but in the large peak in the minority-spin d bands. The width of the d band has been a matter of a great deal of scrutiny over the years, since the width as measured in photoemission experiments is much smaller than that extracted from band-theory calculations. It is now realized that the experiments measure the energy of various excited states of the metal, whereas the LSDA remains a good theory of the ground state. A more comprehensive theory of the photoemission process has resulted in a better, but by no means complete, agreement with experiment. The magnetic moment, a ground state quantity extracted from such calculations, comes out to be $\sim$0.6 Bohr magnetons per atom, close to the experimental measurements. The equilibrium volume and other such quantities are in good agreement with experiment, i.e., on the same order as for iron.

In both cases, the electronic bands, which result from the solution of the one-electron Kohn-Sham Schrödinger equations, are nearly rigidly exchange split. This rigid shift is in accord with the simple picture of Stoner-Wohlfarth theory which was based on a simple Hubbard model with a single tight-binding d band treated in the Hartree-Fock approximation. The model Hamiltonian is

$$\hat{H} = \sum_{ij,\sigma} (\varepsilon_0^\sigma \delta_{ij} + t_{ij}^\sigma) a_{i,\sigma}^\dagger a_{j,\sigma} + \frac{I}{2} \sum_{i,\sigma} a_{i,\sigma}^\dagger a_{i,\sigma} a_{i,-\sigma}^\dagger a_{i,-\sigma} \qquad (2)$$

in which $a_{i,\sigma}$ and $a_{i,\sigma}^\dagger$ are respectively the creation and annihilation operators, ε_0^σ a site energy (with spin index σ), t_{ij} a hopping parameter, inversely related to the d-band width, and I the many-body Hubbard parameter representing the intrasite Coulomb interactions. And within the Hartree-Fock approximation, a pair of operators is replaced by their average value, $\langle \ldots \rangle$, i.e., their quantum mechanical expectation value. In particular, $a_{i,\sigma}^\dagger \; a_{i,\sigma} a_{i,-\sigma}^\dagger a_{i,-\sigma} \approx a_{i\cdot\sigma}^\dagger a_{i,\sigma} \langle a_{i,-\sigma}^\dagger a_{i,-\sigma} \rangle$, where $\langle a_{i,-\sigma}^\dagger a_{i,-\sigma} \rangle = 1/2\,(\bar{n}_i - \mu_i \sigma)$. On each site, the average particle numbers are $\bar{n}_i = \bar{n}_{i,+1} + \bar{n}_{i,-1}$ and the moments are $\bar{\mu}_i = \bar{n}_{i,+1} - \bar{n}_{i,-1}$. Thus the Hartree-Fock Hamiltonian is given by

$$\hat{H} = \sum_{ij,\sigma} \left[\left(\varepsilon_0^\sigma + \frac{1}{2} I \bar{n}_i - \frac{1}{2} I \bar{\mu}_i \right) \delta_{ij} + t_{ij}^\sigma \right] a_{i,\sigma}^\dagger a_{j,\sigma} \qquad (3)$$

where $\bar{n}_i$ is the number of electrons on site i and $\bar{\mu}_i$ the magnetization. The terms $I\bar{n}_i/2$ and $I\bar{\mu}_i/2$ are the effective potential and magnetic fields, respectively. The main omission of this approximation is the neglect of the spin-flip particle-hole excitations and the associated correlations.

This rigidly exchange-split band-structure picture is actually valid only for the special cases of the elemental ferromagnetic transition metals Fe, Ni, and Co, in which the d bands are nearly filled, i.e., towards the end of the $3d$ transition metal series. Some of the effects which are to be extracted from the electronic structure of the alloys can be gauged within the framework of simple, single-d-band, tight-binding models. In the middle of the series, the metals Cr and Mn are anti-ferromagnetic; those at the end, Fe, Ni, and Co are ferromagnetic. This trend can be understood from a band-filling point of view. It has been shown (e.g. Heine and Samson, 1983) that the exchange-splitting in a nearly filled tight-binding d band lowers the system's energy and hence promotes ferromagnetism. On the other hand, the imposition of an exchange field that alternates in sign from site to site in the crystal lattice lowers the energy of the system with a half-filled d band, and hence drives anti-ferromagnetism. In the alloy analogy, almost-filled bands lead to phase separation, i.e., $k = 0$ ordering; half-filled bands lead to ordering with a zone-boundary wavevector. This latter case is the analog of antiferromagnetism. Although the electronic structure of SDF theory, which provides such good quantitative estimates of magnetic properties of metals when compared to the experimentally measured values, is somewhat more complicated than this; the gross features can be usefully discussed in this manner.

Another aspect from the calculations of pure magnetic metals—which have been reviewed comprehensively by Moruzzi and Marcus (1993), for example—that will prove topical for the discussion of 3*d* metallic alloys, is the variation of the magnetic properties of the 3*d* metals as the crystal lattice spacing is altered. Moruzzi et al. (1986) have carried out a systematic study of this phenomenon with their "fixed spin moment" (FSM) scheme. The most striking example is iron on an fcc lattice (Bagayoko and Callaway, 1983). The total energy of fcc Fe is found to have a global minimum for the nonmagnetic state and a lattice spacing of 6.5 atomic units (a.u.) or 3.44 Å. However, for an increased lattice spacing of 6.86 a.u. or 3.63 Å, the energy is minimized for a ferromagnetic state, with a magnetization per site, $\bar{\mu} \approx 1\mu_B$ (Bohr magneton). With a marginal expansion of the lattice from this point, the ferromagnetic state strengthens with $\bar{\mu} \approx 2.4\,\mu_B$. These trends have also been found by LMTO calculations for non-collinear magnetic structures (Mryasov et al., 1992). There is a hint, therefore, that the magnetic properties of fcc iron alloys are likely to be connected to the alloy's equilibrium lattice spacing and vice versa. Moreover these properties are sensitive to both thermal expansion and applied pressure. This apparently is the origin of the "low spin–high spin" picture frequently cited in the many discussions of iron Invar alloys (Wassermann, 1991). In their review article, Moruzzi and Marcus (1993) have also summarized calculations on other 3*d* metals noting similar connections between magnetic structure and lattice spacing. As the lattice spacing is increased beyond the equilibrium value, the electronic bands narrow, and thus the magnetic tendencies are enhanced. More discussion on this aspect is included with respect to Fe-Ni alloys, below.

We now consider methods used to calculate the spin-polarized electronic structure of the ferromagnetic 3*d* transition metals when they are alloyed with other metallic components. Later we will see the effects on the magnetic properties of these materials where, once again, the rigidly split band structure picture is an inappropriate starting point.

Solid-Solution Alloys

The self-consistent Korringa-Kohn-Rostoker coherent-potential approximation (KKR-CPA; Stocks et al., 1978; Stocks and Winter, 1982; Johnson et al., 1990) is a mean-field adaptation of the LSDA to systems with substitutional disorder, such as, solid-solution alloys, and this has been discussed in COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS. To describe the theory, we begin by recalling what the SDFT-LDA means for random alloys. The straightforward but computationally intractable track along which one could proceed involves solving the usual self-consistent Kohn-Sham single-electron equations for all configurations, and averaging the relevant expectation values over the appropriate ensemble of configurations to obtain the desired observables. To be specific, we introduce an occupation variable, ξ_i, which takes on the value 1 or 0; 1 if there is an A atom at the lattice site i, or 0 if the site is occupied by a B atom. To specify a configuration, we must then assign a value to these variables ξ_i at each site. Each configuration can be fully described by a set of these variables $\{\xi_i\}$. For an atom of type α on site k, the potential and magnetic field that enter the Kohn-Sham equations are not independent of its surroundings and depend on all the occupation variables, i.e., $V_{k,\alpha}(\mathbf{r}, \{\xi_i\})$, $\mathbf{B}_{k,\alpha}(\mathbf{r},\{\xi_i\})$. To find the ensemble average of an observable, for each configuration, we must first solve (self-consistently) the Kohn-Sham equations. Then for each configuration, we are able to calculate the relevant quantity. Finally, by summing these results, weighted by the correct probability factor, we find the required ensemble average.

It is impossible to implement all of the above sequence of calculations as described, and the KKR-CPA was invented to circumvent these computational difficulties. The first premise of this approach is that the occupation of a site, by an A atom or a B atom, is independent of the occupants of any other site. This means that we neglect short-range order for the purposes of calculating the electronic structure and approximate the solid solution by a random substitutional alloy. A second premise is that we can invert the order of solving the Kohn-Sham equations and averaging over atomic configurations, i.e., find a set of Kohn-Sham equations that describe an appropriate "average" medium. The first step is to replace, in the spirit of a mean-field theory, the local potential function $V_{k,\alpha}(\mathbf{r},\{\xi_i\})$ and magnetic field $\mathbf{B}_{k,\alpha}(\mathbf{r},\{\xi_i\})$ with $V_{k,\alpha}(\mathbf{r})$ and $\mathbf{B}_{k,\alpha}(\mathbf{r})$, the average over all the occupation variables except the one referring to the site k, at which the occupying atom is known to be of type α. The motion of an electron, on the average, through a lattice of these potentials and magnetic fields randomly distributed with the probability c that a site is occupied by an A atom, and 1-c by a B atom, is obtained from the solution of the Kohn-Sham equations using the CPA (Soven, 1967). Here, a lattice of identical effective potentials and magnetic fields is constructed such that the motion of an electron through this ordered array closely resembles the motion of an electron, on the average, through the disordered alloy. The CPA determines the effective medium by insisting that the substitution of a single site of the CPA lattice by either an A or a B atom produces no further scattering of the electron on the average. It is then possible to develop a spin density functional theory and calculational scheme in which the partially averaged electronic densities, $n_A(\mathbf{r})$ and $n_B(\mathbf{r})$, and the magnetization densities $\mu_A(\mathbf{r})$, $\mu_B(\mathbf{r})$, associated with the A and B sites respectively, total energies, and other equilibrium quantities are evaluated (Stocks and Winter, 1982; Johnson et al., 1986, 1990; Johnson and Pinski, 1993).

The data from both x-ray and neutron scattering in solid solutions show the existence of Bragg peaks which define an underlying "average" lattice (see Chapters 10 and 13). This symmetry is evident in the average electronic structure given by the CPA. The Bloch wave vector is still a useful quantum number, but the average Bloch states also have a finite lifetime as a consequence of the disorder. Probably the strongest evidence for accuracy of the calculated electron lifetimes (and velocities) are the results for the residual resistivity of Ag-Pd alloys (Butler and Stocks, 1984; Swihart et al., 1986).

The electron movement through the lattice can be described using multiple-scattering theory, a Green's-function method, which is sometimes called the Korringa-Kohn-Rostoker (KKR) method. In this merger of multiple scattering theory with the coherent potential approximation (CPA), the ensemble-averaged Green's function is calculated, its poles defining the averaged energy eigenvalue spectrum. For systems without disorder, such energy eigenvalues can be labeled by a Bloch wavevector, **k**, are real, and thus can be related to states with a definite momentum and have infinite lifetimes. The KKR-CPA method provides a solution for the averaged electronic Green's function in the presence of a random placement of potentials, corresponding to the random occupation of the lattice sites. The poles now occur at complex values, **k** is usually still a useful quantum number but in the presence of this disorder, (discrete) translation symmetry is not perfect, and electrons in these states are scattered as they traverse the lattice. The useful result of the KKR-CPA method is that it provides a configurationally averaged Green function, from which the ensemble average of various observables can be calculated (Faulkner and Stocks, 1980).

Recently, super-cell versions of approximate ensemble-averaging are being explored due to advances in computers and algorithms (Faulkner et al., 1997). However, strictly speaking, such averaging is limited by the size of the cell and the shape approximation for the potentials and charge density. Several interesting results have been obtained from such an approach (Abrikosov et al., 1995; Faulkner et al., 1998). Neither the single-site CPA and the super-cell approach are exact; they give comple mentary information about the electronic structure in alloys.

Alloy Electronic Structure and Slater-Pauling Curves

Before the reasons for the loss of the conventional Stoner picture of rigidly exchange-split bands can be laid out, we describe some typical features of the electronic structure of alloys. A great deal has been written on this subject, which demonstrates clearly how these features are also connected with the phase stability of the system. An insight into this subject can be gained from many books and articles (Johnson et al., 1987; Pettifor, 1995; Ducastelle, 1991; Györffy et al., 1989; Connolly and Williams, 1983; Zunger, 1994; Staunton et al., 1994).

Consider two elemental d-electron densities of states, each with approximate width W and one centered at energy ε_A, the other at ε_B, related to atomic-like d-energy levels. If $(\varepsilon_A - \varepsilon_B) \gg W$ then the alloy's densities of states will be "split band" in nature (Stocks et al., 1978) and, in Pettifor's language, an ionic bond is established as charge flows from the A atoms to the B atoms in order to equilibrate the chemical potentials. The virtual bound states associated with impurities in metals are rough examples of split band behavior. On the other hand, if $(\varepsilon_{A\ -\ \varepsilon B}) \ll W$, then the alloy's electronic structure can be categorized as "common-band"-like. Large-scale hybridization now forms between states associated with the A and B atoms. Each site in the alloy is nearly charge-neutral as an individual ion is efficiently screened by the metallic response function of the alloy (Ziman, 1964). Of course, the actual interpretation of the detailed electronic structure involving many bands is often a complicated mixture of these two models.

In either case, half-filling of the bands lowers the total energy of the system as compared to the phase-separated case (Heine and Samson, 1983; Pettifor, 1995; Ducastelle, 1991), and an ordered alloy will form at low temperatures. When magnetism is added to the problem, an extra ingredient, namely the difference between the exchange field associated with each type of atomic species, is added. For majority spin electrons, a rough measure of the degree of "split-band" or "common-band" nature of the density of states is governed by $(\varepsilon_A^{\uparrow} - \varepsilon_B^{\uparrow})/W$ and a similar measure $(\varepsilon_A^{\downarrow} - \varepsilon_B^{\downarrow}/W$ for the minority spin electrons. If the exchange fields differ to any large extent, then for electrons of one spin-polarization, the bands are common-band-like while for the others a "split-band" label may be more appropriate. The outcome is a spin-polarized electronic structure that cannot be described by a rigid exchange splitting.

Hund's rules dictate that it is frequently energetically favorable for the majority-spin d states to be fully occupied. In many cases, at the cost of a small charge transfer, this is accomplished. Nickel-rich nickel-iron alloys provide such examples (Staunton et al., 1987) as shown in Figure 1. A schematic energy level diagram is shown in Figure 2.

One of the first tasks of theories or explanations based on electronic structure calculations is to provide a simple explanation of why the average magnetic moments per atom of so many alloys, M, fall on the famous Slater-Pauling curve, when plotted against the alloys' valence electron per atom ratio. The usual Slater-Pauling curve for 3d row (Chikazumi, 1964) consists of two straight lines. The plot rises from the beginning of the 3d row, abruptly changes the sign of its gradient and then drops smoothly to zero at the end of the row. There are some important groups of compounds and alloys whose parameters do not fall on this line, but, for these systems also, there appears to be some simple pattern.

For those ferromagnetic alloys of late transition metals characterized by completely filled majority spin d states, it is easy to see why they are located on the negative-gradient straight line. The magnetization per atom, $M = N_{\uparrow} - N_{\downarrow}$, where $N_{\uparrow(\downarrow)}$, describes the occupation of the majority (minority) spin states which can be trivially re-expressed in terms of the number of electrons per atom Z, so that $M = 2N_{\uparrow} - Z$. The occupation of the s and p states changes very little across the 3d row, and thus $M = 2N_{d\uparrow} - Z + 2N_{sp\uparrow}$, which gives $M = 10 - Z + 2N_{sp\uparrow}$.

Many other systems, most commonly bcc based alloys, are not strong ferromagnets in this sense of filled majority spin d bands, but possess a similar attribute. The chemical potential (or Fermi energy at T = 0 K) is pinned in a deep valley in the minority spin density of states (Johnson et al., 1987; Kubler, 1984). Pure bcc iron itself is a case in point, the chemical potential sitting in a trough in the minority spin density of states (Moruzzi et al., 1978, p. 170). Figure 1B shows another example in an iron-rich, iron-vanadium alloy. The other major segment of the Slater-Pauling curve of a positive-gradient straight line can be explained by

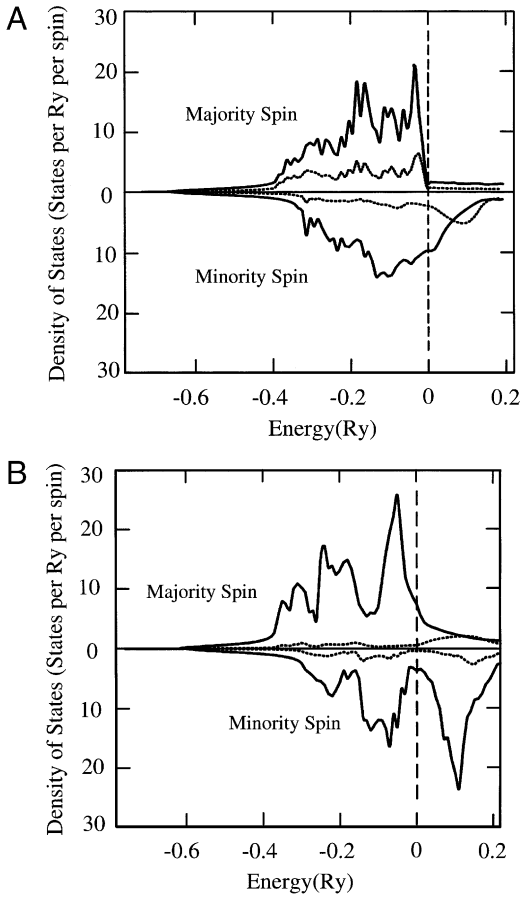

Figure 1. (**A**) The electronic density of states for ferromagnetic $Ni_{75}Fe_{25}$. The upper half displays the density of states for the majority-spin electrons, the lower half, for the minority-spin electrons. Note, in the lower half, the axis for the abscissa is inverted. These curves were calculated within the SCF-KKR-CPA, see Johnson et al. (1987). (**B**) The electronic density of states for ferromagnetic $Fe_{87}V_{13}$. The upper half displays the density of states for the majority-spin electrons; the lower half, for the minority-spin electrons. Note, in the lower half, the axis for the abscissa is inverted. These curves were calculated within the SCF-KKR-CPA (see Johnson et al., 1987).

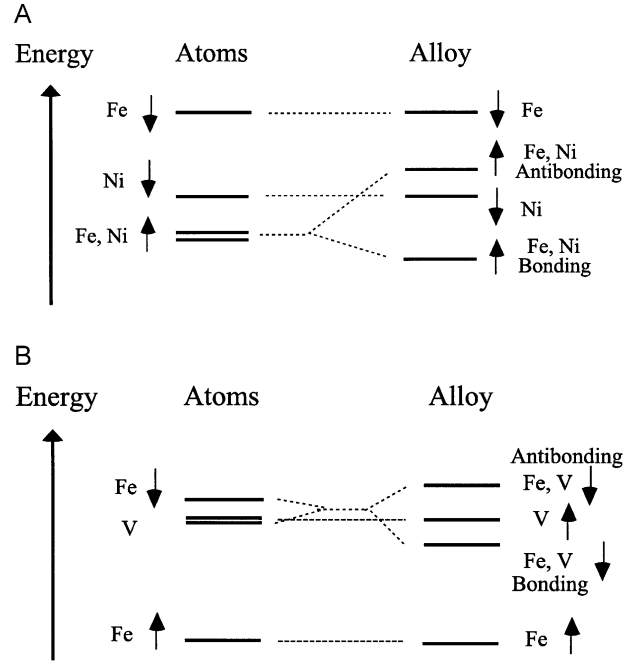

Figure 2. (**A**) Schematic energy level diagram for Ni-Fe alloys. (**B**) Schematic energy level diagram for Fe-V Alloys.

using this feature of the electronic structure. The pinning of the chemical potential in a trough of the minority spin d density of states constrains $N_{d\downarrow}$ to be fixed in all these alloys to be roughly three. In this circumstance the magnetization per atom $M = Z - 2N_{d\downarrow} - 2N_{sp\downarrow} = Z - 6 - 2N_{sp\downarrow}$. Further discussion on this topic is given by Malozemoff et al. (1984), Williams et al. (1984), Kubler (1984), Gubanov et al. (1992), and others. Later in this unit, to illustrate some of the remarks made, we will describe electronic structure calculations of three compositionally disordered alloys together with the ramifications for understanding of their properties.

Competitive and Related Techniques: Beyond the Local Spin-Density Approximation

Over the past few years, improved approximations for E_{xc} have been developed which maintain all the best features of the local approximation. A stimulus has been the work of Langreth and Mehl (1981, 1983), who supplied corrections to the local approximation in terms of the gradient of the density. Hu and Langreth (1986) have specified a spin-polarized generalization. Perdew and co-workers (Perdew and Yue, 1986; Wang and Perdew, 1991) contributed several improvements by ensuring that the generalized gradient approximation (GGA) functional satisfies some relevant sum rules. Calculations of the ground state properties of ferromagnetic iron and nickel were carried out (Bagno et al., 1989; Singh et al., 1991; Haglund, 1993) and compared to LSDA values. The theoretically estimated lattice constants from these calculations are slightly larger and are therefore more in line with the experimental values. When the GGA is used instead of LSDA, one removes a major embarrassment for LSDA calculations, namely that paramagnetic bcc iron is no longer energetically stable over ferromagnetic bcc iron. Further applications of the SDFT-GGA include one on the magnetic and cohesive properties of manganese in various crystal structures (Asada and Terakura, 1993) and another on the electronic and magnetic structure of the ordered B2 FeCo alloy (Liu and Singh, 1992). In addition, Perdew et al. (1992) have presented a comprehensive study of the GGA for a range of systems and have also given a review of the GGA (Perdew et al., 1996; Ernzerhof et al., 1996).

Notwithstanding the remarks made above, SDF theory within the local spin-density approximation (LSDA) provides a good quantitative description of the low-temperature properties of magnetic materials containing simple and transition metals, which are the main interests of this unit, and the Kohn-Sham electronic structure also gives a reasonable description of the quasi-particle

spectral properties of these systems. But it is not nearly so successful in its treatment of systems where some states are fairly localized, such as many rare-earth systems (Brooks and Johansson, 1993) and Mott insulators. Much work is currently being carried out to address the shortcomings found for these fascinating materials. Anisimov et al. (1997) noted that in exact density functional theory, the derivative of the total energy with respect to number of electrons, $\partial E/\partial N$, should have discontinuities at integral values of N, and that therefore the effective one-electron potential of the Kohn-Sham equations should also possess appropriate discontinuities. They therefore added an orbital-dependent correction to the usual LDA potentials and achieved an adequate description of the photoemission spectrum of NiO. As an example of other work in this area, Severin et al. (1993) have carried out self-consistent electronic structure calculations of rare-earth(R)-Co_2 and R-Co_2H_4 compounds within the LDA but in which the effect of the localized open $4f$ shell associated with the rare-earth atoms on the conduction band was treated by constraining the number of $4f$ electrons to be fixed. Brooks et al. (1997) have extended this work and have described crystal field quasiparticle excitations in rare earth compounds and extracted parameters for effective spin Hamiltonians. Another related approach to this constrained LSDA theory is the so-called "LSDA + U" method (Anisimov et al., 1997) which is also used to account for the orbital dependence of the Coulomb and exchange interactions in strongly correlated electronic materials.

It has been recognized for some time that some of the shortcomings of the LDA in describing the ground state properties of some strongly correlated systems may be due to an unphysical interaction of an electron with itself (Jones and Gunnarsson, 1989). If the exact form of the exchange-correlation functional $E_{\rm xc}$ were known, this self-interaction would be exactly canceled. In the LDA, this cancellation is not perfect. Several efforts improve cancellation by incorporating this self-interaction correction (SIC; Perdew and Zunger, 1981; Pederson et al., 1985). Using a cluster technique, Svane and Gunnarsson (1990) applied the SIC to transition metal oxides where the LDA is known to be particularly defective and where the GGA does not bring any significant improvements. They found that this new approach corrected some of the major discrepancies. Similar improvements were noted by Szotek et al. (1993) in an LMTO implementation in which the occupied and unoccupied states were split by a large on-site Coulomb interaction. For Bloch states extending throughout the crystal, the SIC is small and the LDA is adequate. However, for localized states the SIC becomes significant. SIC calculations have been carried out for the parent compound of the high T_c superconducting ceramic, La_2CuO_4 (Temmerman et al., 1993) and have been used to explain the γ-α transition in the strongly correlated metal, cerium (Szotek et al., 1994; Svane, 1994; Beiden et al., 1997).

Spin Density Functional Theory within the local exchange and correlation approximation also has some serious shortcomings when straightforwardly extended to finite temperatures and applied to itinerant magnetic materials of all types. In the following section, we discuss ways in which improvements to the theory have been made.

Magnetism at Finite Temperatures: The Paramagnetic State

As long ago as 1965, Mermin (1965) published the formal structure of a finite temperature density functional theory. Once again, a many-electron system in an external potential, $V^{\rm ext}$, and external magnetic field, $\mathbf{B}^{\rm ext}$, described by the (non-relativistic) Hamiltonian is considered. Mermin proved that, in the grand canonical ensemble at a given temperature T and chemical potential ν, the equilibrium particle $n(\mathbf{r})$ and magnetization $\mathbf{m}(\mathbf{r})$ densities are determined by the external potential and magnetic field. The correct equilibrium particle and magnetization densities minimize the Gibbs grand potential, Ω

$$\Omega = \int V^{\rm ext}(\mathbf{r}) n(\mathbf{r})\, d\mathbf{r} - \int \mathbf{B}^{\rm ext}(\mathbf{r}) \cdot \mathbf{m}(\mathbf{r})\, d\mathbf{r} + \frac{e^2}{2}\int\int \frac{n(\mathbf{r}) n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}\, d\mathbf{r}' + G[n,\mathbf{m}] - \nu \int n(\mathbf{r})\, d\mathbf{r} \quad (4)$$

where G is a unique functional of charge and magnetization densities at a given T and ν. The variational principle now states that Ω is a minimum for the equilibrium, n and $\mathbf{m}$. The function G can be written as

$$G[n,\mathbf{m}] = T_{\rm s}[n,\mathbf{m}] - TS_{\rm s}[n,\mathbf{m}] + \Omega_{\rm xc}[n,\mathbf{m}] \quad (5)$$

with $T_{\rm s}$ and $S_{\rm s}$ being respectively the kinetic energy and entropy of a system of noninteracting electrons with densities n, $\mathbf{m}$, at a temperature T. The exchange and correlation contribution to the Gibbs free energy is $\Omega_{\rm xc}$. The minimum principle can be shown to be identical to the corresponding equation for a system of noninteracting electrons moving in an effective potential $\tilde{V}$

$$\tilde{V}[n,\mathbf{m}] = \left(V^{\rm ext} + e^2\int \frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\, d\mathbf{r}' + \frac{\delta\,\Omega_{\rm xc}}{\delta\, n(r)}\right)\tilde{1} + \left(\frac{\delta\,\Omega_{\rm xc}}{\delta \mathbf{m}(\mathbf{r})} - \mathbf{B}^{\rm ext}\right)\cdot\tilde{\sigma} \quad (6)$$

which satsify the following set of equations

$$\left(-\frac{\hbar^2}{2m}\tilde{1}\,\vec{\nabla}^2 + \tilde{V}\right)\varphi_i(\mathbf{r}) = \varepsilon_i \phi_i(\mathbf{r}) \quad (7)$$

$$n(\mathbf{r}) = \sum_i f(\varepsilon_i - \nu)\, tr\,[\phi_i^*(\mathbf{r})\phi_i(\mathbf{r})] \quad (8)$$

$$\mathbf{m}(\mathbf{r}) = \sum_i f(\varepsilon_i - \nu)\, tr\,[\phi_i^*(\mathbf{r})\tilde{\sigma}\phi_i(\mathbf{r})] \quad (9)$$

where $f(\varepsilon - \nu)$ is the Fermi-Dirac function. Rewriting Ω as

$$\Omega = -\sum_i f(\varepsilon_i - \nu) N(\varepsilon_i) - \frac{e^2}{2}\int\int \frac{n(\mathbf{r}) n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}\, d\mathbf{r}' + \Omega_{\rm xc} - \int d\mathbf{r}\left(\frac{\delta\Omega_{\rm xc}}{\delta n(\mathbf{r})} n(\mathbf{r}) + \frac{\delta\Omega_{\rm xc}}{\delta \mathbf{m}(\mathbf{r})}\cdot\mathbf{m}(\mathbf{r})\right) \quad (10)$$

involves a sum over effective single particle states and where *tr* represents the trace over the components of the Dirac spinors which in turn are represented by $\phi_i(\mathbf{r})$, its conjugate transpose being $\phi_i^*(\mathbf{r})$. The nonmagnetic part of the potential is diagonal in this spinor space, being propor-

tional to the 2×2 unit matrix, $\tilde{1}$. The Pauli spin matrices $\tilde{\sigma}$ provide the coupling between the components of the spinors, and thus to the spin orbit terms in the Hamiltonian. Formally, the exchange-correlation part of the Gibbs free energy can be expressed in terms of spin-dependent pair correlation functions (Rajagopal, 1980), specifically

$$\Omega_{\mathrm{xc}}[n,\mathbf{m}] = \frac{e^2}{2}\int_0^1 d\lambda \int\int \sum_{\sigma,\sigma'} \frac{n_\sigma(\mathbf{r}) n_{\sigma'}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} g_\lambda(\sigma,\sigma';\mathbf{r},\mathbf{r}')\, d\mathbf{r}\, d\mathbf{r}' \tag{11}$$

The next logical step in the implementation of this theory is to form the finite temperature extension of the local approximation (LDA) in terms of the exchange-correlation part of the Gibbs free energy of a homogeneous electron gas. This assumption, however, severely underestimates the effects of the thermally induced spin-wave excitations. The calculated Curie temperatures are much too high (Gunnarsson, 1976), local moments do not exist in the paramagnetic state, and the uniform static paramagnetic susceptibility does not follow a Curie-Weiss behavior as seen in many metallic systems.

Part of the pair correlation function $g_\lambda(\sigma,\sigma';r,r')$ is related by the fluctuation-dissipation theorem to the magnetic susceptibilities that contain the information about these excitations. These spin fluctuations interact with each other as temperature is increased. Ω_{xc} should deviate significantly from the local approximation, and, as a consequence, the form of the effective single-electron states are modified. Over the past decade or so, many attempts have been made to model the effects of the spin fluctuations while maintaining the spin-polarized single-electron basis, and hence describe the properties of magnetic metals at finite temperatures. Evidently, the straightforward extension of spin-polarized band theory to finite temperatures misses the dominant thermal fluctuation of the magnetization and the thermally averaged magnetization, **M**, can only vanish along with the "exchange-splitting" of the electronic bands (which is destroyed by particle-hole, "Stoner" excitations across the Fermi surface). An important piece of this neglected component can be pictured as orientational fluctuations of "local moments," which are the magnetizations within each unit cell of the underlying crystalline lattice and are set up by the collective behavior of all the electrons. At low temperatures, these effects have their origins in the transverse part of the magnetic susceptibility. Another related ingredient involves the fluctuations in the magnitudes of these "moments," and concomitant charge fluctuations, which are connected with the longitudinal magnetic response at low temperatures. The magnetization **M** now vanishes as the disorder of the "local moments" grows. From this broad consensus (Moriya, 1981), several approaches exist which only differ according to the aspects of the fluctuations deemed to be the most important for the materials which are studied.

Competitive and Related Techniques: Fluctuating "Local Moments"

Some fifteen years ago, work on the ferromagnetic $3d$ transition metals—Fe, Co, and Ni—could be roughly partitioned into two categories. In the main, the Stoner excitations were neglected and the orientations of the "local moments," which were assumed to have fixed magnitudes independent of their orientational environment, corresponded to the degrees of freedom over which one thermally averaged. Firstly, the picture of the Fluctuating Local Band (FLB) theory was constructed (Korenman et al., 1977a,b,c; Capellman, 1977; Korenman, 1985), which included a large amount of short-range magnetic order in the paramagnetic phase. Large spatial regions contained many atoms, each with their own moment. These moments had sizes equivalent to the magnetization per site in the ferromagnetic state at $T = 0$ K and were assumed to be nearly aligned so that their orientations vary gradually. In such a state, the usual spin-polarized band theory can be applied and the consequence of the gradual change to the orientations could be added perturbatively. Quasi-elastic neutron scattering experiments (Ziebeck et al., 1983) on the paramagnetic phases of Fe and Ni, later reproduced by Shirane et al. (1986), were given a simple though not uncontroversial (Edwards, 1984) interpretation of this picture. In the case of inelastic neutron scattering, however, even the basic observations were controversial, let alone their interpretations in terms of "spin-waves" above T_c which may be present in such a model. Realistic calculations (Wang et al., 1982) in which the magnetic and electronic structures are mutually consistent are difficult to perform. Consequently, examining the full implications of the FLB picture and systematic improvements to it has not made much headway.

The second type of approach is labeled the "disordered local moment" (DLM) picture (Hubbard, 1979; Hasegawa, 1979; Edwards, 1982; Liu, 1978). Here, the local moment entities associated with each lattice site are commonly assumed (at the outset) to fluctuate independently with an apparent total absence of magnetic short-range order (SRO). Early work was based on the Hubbard Hamiltonian. The procedure had the advantage of being fairly straightforward and more specific than in the case of FLB theory. Many calculations were performed which gave a reasonable description of experimental data. Its drawbacks were its simple parameter-dependent basis and the fact that it could not provide a realistic description of the electronic structure, which must support the important magnetic fluctuations. The dominant mechanisms therefore might not be correctly identified. Furthermore, it is difficult to improve this approach systematically.

Much work has focused on the paramagnetic state of body-centered cubic iron. It is generally agreed that "local moments" exist in this material for all temperatures, although the relevance of a Heisenberg Hamiltonian to a description of their behavior has been debated in depth. For suitable limits, both the FLB and DLM approaches can be cast into a form from which an effective classical Heisenberg Hamiltonian can be extracted

$$-\sum_{ij} J_{ij}\hat{e}_i \cdot \hat{e}_j \tag{12}$$

The "exchange interaction" parameters J_{ij} are specified in terms of the electronic structure owing to the itinerant

nature of the electrons in this metal. In the former FLB model, the lattice Fourier transform of the J_{ij}'s

$$L(\mathbf{q}) = \sum_{ij} J_{ij}(\exp(i\mathbf{q}\cdot\mathbf{R}_{ij}) - 1) \tag{13}$$

is equal to $Av\mathbf{q}^2$, where v is the unit cell volume and A is the Bloch wall stiffness, itself proportional to the spin wave stiffness constant D (Wang et al., 1982). Unfortunately the J_{ij}'s determined from this approach turn out to be too short-ranged to be consistent with the initial assumption of substantial magnetic SRO above T_c.

In the DLM model for iron, the interactions, J_{ij}'s, can be obtained from consideration of the energy of an interacting electron system in which the local moments are constrained to be oriented along directions $\hat{e}_i$ and $\hat{e}_j$ on sites i and j, averaging over all the possible orientations on the other sites (Oguchi et al., 1983; Györffy et al., 1985), albeit in some approximate way. The J_{ij}'s calculated in this way are suitably short-ranged and a mutual consistency between the electronic and magnetic structures can be achieved.

A scenario between these two limiting cases has been proposed (Heine and Joynt, 1988; Samson, 1989). This was also motivated by the apparent substantial magnetic SRO above T_c in Fe and Ni, deduced from neutron scattering data, and emphasized how the orientational magnetic disorder involves a balance in the free energy between energy and entropy. This balance is delicate, and it was shown that it is possible for the system to disorder on a scale coarser than the atomic spacing and for the magnetic and electronic structures. The length scale is, however, not as large as that initially proposed by the FLB theory.

"First-Principles" Theories

These pictures can be put onto a "first-principles" basis by grafting the effects of these orientational spin fluctuations onto SDF theory (Györffy et al., 1985; Staunton et al., 1985; Staunton and Györffy, 1992). This is achieved by making the assumption that it is possible to identify and to separate fast and slow motions. On a time scale long in comparison with an electronic hopping time but short when compared with a typical spin fluctuation time, the spin orientations of the electrons leaving a site are sufficiently correlated with those arriving so that a non-zero magnetization exists when the appropriate quantity is averaged on this time scale. These are the "local moments" which can change their orientations $\{\hat{e}_i\}$ slowly with respect to the time scale, whereas their magnitudes $\{\mu_i(\{\hat{e}_j\})\}$ fluctuate rapidly. Note that, in principle, the magnitude of a moment on a site depends on its orientational environment.

The standard SDF theory for studying electrons in spin-polarized metals can be adapted to describe the states of the system for each orientational configuration $\{\hat{e}_i\}$ in a similar way as in the case of noncollinear magnetic systems (Uhl et al., 1992; Sandratskii and Kubler, 1993; Sandratskii, 1998). Such a description holds the possibility to yield the magnitudes of the local moments $\mu_k = \mu_k(\{\hat{e}_j\})$ and the electronic Grand Potential for the constrained system $\Omega(\{\hat{e}_i\})$. In the implementation of this theory, the moments for bcc Fe and fictitious bcc Co are fairly independent of their orientational environment, whereas for those in fcc Fe, Co, and Ni, the moments are further away from being local quantities.

The long time averages can be replaced by ensemble averages with the Gibbsian measure $P(\{\hat{e}_j\}) = e^{-\beta\Omega(\{\hat{e}_j\})}/Z$, where the partition function is

$$Z = \prod_i \int d\hat{e}_i e^{-\beta\Omega(\{\hat{e}_j\})} \tag{14}$$

where β is the inverse of $k_B T$ with Boltzmann's constant k_B. The thermodynamic free energy, which accounts for the entropy associated with the orientational fluctuations as well as creation of electron-hole pairs, is given by $F = -k_B T \ln Z$. The role of a classical "spin" (local moment) Hamiltonian, albeit a highly complicated one, is played by $\Omega(\{\hat{e}_i\})$.

By choosing a suitable reference "spin" Hamiltonian $\Omega(\{\hat{e}_i\})$ and expanding about it using the Feynman-Peierls' inequality (Feynman, 1955), an approximation to the free energy is obtained

$$F \leq F_0 + \langle \Omega - \Omega_0 \rangle_0 = \tilde{F}$$

with

$$F_0 = -k_B T \ln\left[\prod_i \int d\hat{e}_i e^{-\beta\Omega_0(\{\hat{e}_i\})}\right] \tag{15}$$

and

$$\langle X \rangle_0 = \frac{\prod_i \int d\hat{e}_i X e^{-\beta\Omega_0}}{\prod_i \int d\hat{e}_i e^{-\beta\Omega_0}} = \prod_i \int d\hat{e}_i P_0(\{\hat{e}_i\}) X(\{\hat{e}_i\}) \tag{16}$$

With Ω_0 expressed as

$$\Omega_0 = \sum_i \omega_i^{(1)}(\hat{e}_i) + \sum_{i\neq j} \omega_{ij}^{(2)}(\hat{e}_i, \hat{e}_j) + \cdots \tag{17}$$

a scheme is set up that can in principle be systematically improved. Minimizing $\tilde{F}$ to obtain the best estimate of the free energy gives $\omega_i^{(1)}$, $\omega_{ij}^{(2)}$ etc., as expressions involving restricted averages of $\Omega(\{\hat{e}_i\})$ over the orientational configurations.

A mean-field-type theory, which turns out to be equivalent to a "first principles" formulation of the DLM picture, is established by taking the first term only in the equation above. Although the SCF-KKR-CPA method (Stocks et al., 1978; Stocks and Winter, 1982; Johnson et al. 1990) was developed originally for coping with compositional disorder in alloys, using it in explicit calculations for bcc Fe and fcc Ni gave some interesting results. The average magnitude of the local moments, $\langle \mu_i(\{\hat{e}_j\}) \rangle_{\hat{e}_i} = \mu_i(\hat{e}_i) = \bar{\mu}$, in the paramagnetic phase of iron was $1.91\mu_B$. (The total magnetization is zero since $\langle \mu_i(\{\hat{e}_j\}) \rangle = 0$. This value is roughly the same magnitude as the magnetization per atom in

the low temperature ferromagnetic state. The uniform, paramagnetic susceptibility, $\chi(T)$, followed a Curie-Weiss dependence upon temperature as observed experimentally, and the estimate of the Curie temperature T_c was found to be 1280 K, also comparing well with the experimental value of 1040 K. In nickel, however, $\bar{\mu}$ was found to be zero and the theory reduced to the conventional LDA version of the Stoner model with all its shortcomings.

This mean field DLM picture of the paramagnetic state was improved by including the effects of correlations between the local moments to some extent. This was achieved by incorporating the consequences of Onsager cavity fields into the theory (Brout and Thomas, 1967; Staunton and Györffy, 1992). The Curie temperature T_c for Fe is shifted downward to 1015 K and the theory gives a reasonable description of neutron scattering data (Staunton and Györffy, 1992). This approach has also been generalized to alloys (Ling et al., 1994a,b). A first application to the paramagnetic phase of the "spin-glass" alloy $Cu_{85}Mn_{15}$ revealed exponentially damped oscillatory magnetic interactions in agreement with extensive neutron scattering data and was also able to determine the underlying electronic mechanisms. An earlier application to fcc Fe showed how the magnetic correlations change from anti-ferromagnetic to ferromagnetic as the lattice is expanded (Pinski et al., 1986). This study complemented total energy calculations for fcc Fe for both ferromagnetic and antiferromagnetic states at absolute zero for a range of lattice spacings (Moruzzi and Marcus, 1993).

For nickel, the theory has the form of the static, high-temperature limit of Murata and Doniach (1972), Moriya (1979), and Lonzarich and Taillefer (1985), as well as others, to describe itinerant ferromagnets. Nickel is still described in terms of exchange-split spin-polarized bands which converge as T_c is approached but where the spin fluctuations have drastically renormalized the exchange interaction and lowered T_c from ~3000 K (Gunnarsson, 1976) to 450 K. The neglect of the dynamical aspects of these spin fluctuations has led to a slight overestimation of this renormalization, but $\chi(T)$ again shows Curie-Weiss behavior as found experimentally, and an adequate description of neutron scattering data is also provided (Staunton and Györffy, 1992). Moreover, recent inverse photoemission measurements (von der Linden et al., 1993) have confirmed the collapse of the "exchange-splitting" of the electronic bands of nickel as the temperature is raised towards the Curie temperature in accord with this Stoner-like picture, although spin-resolved, resonant photoemission measurements (Kakizaki et al., 1994) indicate the presence of spin fluctuations.

The above approach is parameter-free, being set up in the confines of SDF theory, and represents a fairly well defined stage of approximation. But there are still some obvious shortcomings in this work (as exemplified by the discrepancy between the theoretically determined and experimentally measured Curie constants). It is worth highlighting the key omission, the neglect of the dynamical effects of the spin fluctuations, as emphasized by Moriya (1981) and others.

Competitive and Related Technique for a "First-Principles" Treatment of the Paramagnetic States of Fe, Ni, and Co

Uhl and Kubler (1996) have also set up an *ab initio* approach for dealing with the thermally induced spin fluctuations, and they also treat these excitations classically. They calculate total energies of systems constrained to have spin-spiral $\{\hat{e}_i\}$ configurations with a range of different propagation vectors $\mathbf{q}$ of the spiral, polar angles θ, and spiral magnetization magnitudes μ using the non-collinear fixed spin moment method. A fit of the energies to an expression involving $\mathbf{q}$, θ, and μ is then made. The Feynman-Peierls inequality is also used where a quadratic form is used for the "reference Hamiltonian," H_0. Stoner particle-hole excitations are neglected. The functional integrations involved in the description of the statistical mechanics of the magnetic fluctuations then reduce to Gaussian integrals. Similar results to Staunton and Györffy (1992) have been obtained for bcc Fe and for fcc Ni. Uhl and Kubler (1997) have also studied Co and have recently generalized the theory to describe magnetovolume effects. Face-centered cubic Fe and Mn have been studied alongside the "Invar" ordered alloy, Fe_3Pt.

One way of assessing the scope of validity of these sorts of *ab initio* theoretical approaches, and the severity of the approximations employed, is to compare their underlying electronic bases with suitable spectroscopic measurements.

"Local Exchange Splitting"

An early prediction from a "first principles" implementation of the DLM picture was that a "local-exchange" splitting should be evident in the electronic structure of the paramagnetic state of bcc iron (Györffy et al., 1983; Staunton et al., 1985). Moreover, the magnitude of this splitting was expected to vary sharply as a function of wave-vector and energy. At some wave-vectors, if the "bands" did not vary much as a function of energy, the local exchange splitting would be roughly of the same size as the rigid exchange splitting of the electronic bands of the ferromagnetic state, whereas at other points where the "bands" have greater dispersion, the splitting would vanish entirely. This local exchange-splitting is responsible for local moments.

Photoemission (PES) experiments (Kisker et al., 1984, 1985) and inverse photoemission (IPES) experiments (Kirschner et al., 1984) observed these qualitative features. The experiments essentially focused on the electronic structure around the Γ and H points for a range of energies. Both the Γ'_{25} and Γ'_{12} states were interpreted as being exchange-split, whereas the H'_{25} state was not, although all were broadened by the magnetic disorder. Among the DLM calculations of the electronic structure for several wave-vectors and energies (Staunton et al., 1985), those for the Γ and H points showed the Γ'_{12} state as split and both the Γ'_{25} and H'_{25} states to be substantially broadened by the local moment disorder, but not locally exchange split. Haines et al. (1985, 1986) used a tight-binding model to describe the electronic structure, and employed the recursion method to average over various orientational configurations. They concluded that a

modest degree of SRO is compatible with spectroscopic measurements of the Γ'_{25} d state in paramagnetic iron. More extensive spectroscopic data on the paramagnetic states of the ferromagnetic transition metals would be invaluable in developing the theoretical work on the important spin fluctuations in these systems.

As emphasized in the introduction to this unit, the state of magnetic order in an alloy can have a profound effect upon various other properties of the system. In the next subsection we discuss its consequence upon the alloy's compositional order.

Interrelation of Magnetism and Atomic Short Range Order

A challenging problem to study in metallic alloys is the interplay between compositional order and magnetism and the dependence of magnetic properties on the local chemical environment. Magnetism is frequently connected to the overall compositional ordering, as well as the local environment, in a subtle and complicated way. For example, there is an intriguing link between magnetic and compositional ordering in nickel-rich Ni-Fe alloys. $Ni_{75}Fe_{25}$ is paramagnetic at high temperatures; it becomes ferromagnetic at ~900 K, and then, at at temperature just 100 K cooler, it chemically orders into the Ni_3Fe $L1_2$ phase. The Fe-Al phase diagram shows that, if cooled from the melt, paramagnetic $Fe_{80}Al_{20}$ forms a solid solution (Massalski et al., 1990). The alloy then becomes ferromagnetic upon further cooling to 935 K, and then forms an apparent DO_3 phase at ~670 K. An alloy with just 5% more aluminum orders instead into a B2 phase directly from the paramagnetic state at roughly 1000 K, before ordering into a DO_3 phase at lower temperatures. In this subsection, we examine this interrelation between magnetism and compositional order. It is necessary to deal with the statistical mechanics of thermally induced compositional fluctuations to carry out this task. COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS has described this in some detail (see also Györffy and Stocks, 1983; Györffy et al., 1989; Staunton et al., 1994; Ling et al., 1994b), so here we will simply recall the salient features and show how magnetic effects are incorporated.

A first step is to construct (formally) the grand potential for a system of interacting electrons moving in the field of a particular distribution of nuclei on a crystal lattice of an A_cB_{1-c} alloy using SDF theory. (The nuclear diffusion times are very long compared with those associated with the electrons' movements and thus the compositional and electronic degrees of freedom decouple.) For a site i of the lattice, the variable ξ_i is set to unity if the site is occupied by an A atom and zero if a B atom is located on it. In other words, an Ising variable is specified. A configuration of nuclei is denoted $\{\xi_i\}$ and the associated electronic grand potential is expressed as $\Omega(\{\xi_i\})$. Averaging over the compositional fluctuations with measure

$$P(\{\xi_i\}) = \frac{\exp(-\beta\Omega(\{\xi_i\}))}{\prod_i \sum_{\xi_i} \exp(-\beta\Omega(\{\xi_i\}))} \tag{18}$$

gives an expression for the free energy of the system at temperature T

$$F(\{\xi_i\}) = -k_B T \ln\left[\prod_i \sum_{\xi_i} \exp(-\beta\Omega\{\xi_i\})\right] \tag{19}$$

In essence, $\Omega(\{\xi_i\})$ can be viewed as a complicated concentration-fluctuation Hamiltonian determined by the electronic "glue" of the system. To proceed, some reasonable approximation needs to be made (see review provided in COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS. A course of action, which is analogous with our theory of spin fluctuations in metals at finite T, is to expand about a suitable reference Hamiltonian Ω_0 and to make use of the Feynman-Peierls inequality (Feynman, 1955). A mean field theory is set up with the choice

$$\Omega_0 = \sum_i V_i^{\text{eff}} \cdot \xi_i \tag{20}$$

in which $V_i^{\text{eff}} = \langle\Omega\rangle^0_{Ai} - \langle\Omega\rangle^0_{Bi}$ where $\langle\Omega\rangle^0_{A(B)i}$ is the Grand Potential averaged over all configurations with the restriction that an A(B) nucleus is positioned on the site i. These partial averages are, in principle, accessible from the SCF-KKR-CPA framework and indeed this mean field picture has a satisfying correspondence with the single-site nature of the coherent potential approximation to the treatment of the electronic behavior. Hence at a temperature T, the chance of finding an A atom on a site i is given by

$$c_i = \frac{\exp(-\beta(V_i^{\text{eff}} - \nu))}{(1 + \exp(-\beta(V_i^{\text{eff}} - \nu))} \tag{21}$$

where ν is the chemical potential difference which preserves the relative numbers of A and B atoms overall.

Formally, the probability of occupation can vary from site to site, but it is only the case of a homogeneous probability distribution $c_i = c$ (the overall concentration) that can be tackled in practice. By setting up a response theory, however, and using the fluctuation-dissipation theorem, it is possible to write an expression for the compositional correlation function and to investigate the system's tendency to order or phase segregate.

If a field, which couples to the occupation variables $\{\xi_i\}$ and varies from site-to-site, is applied to the high temperature homogeneously disordered system, it induces an inhomogeneous concentration distribution $\{c + \delta c_i\}$. As a result, the electronic charge rearranges itself (Staunton et al., 1994; Treglia et al., 1978) and, for those alloys which are magnetic in the compositionally disordered state, the magnetization density also changes, i.e. $\{\delta\mu_i^{\text{A}}\}$, $\{\delta\mu_i^{\text{B}}\}$. A theory for the compositional correlation function has been developed in terms of the SCF-KKR-CPA framework (Györffy and Stocks, 1983) and is discussed at length in COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS. In reciprocal "concentration-wave" vector space (Khachaturyan, 1983), this has the Ornstein-Zernicke form

$$\alpha(\mathbf{q}) = \frac{\beta c(1-c)}{(1 - \beta c(1-c)S^{(2)}(\mathbf{q}))} \tag{22}$$

in which the Onsager cavity fields have been incorporated (Brout and Thomas, 1967; Staunton and Györffy, 1992;

Staunton et al., 1994) ensuring that the site-diagonal part of the fluctuation dissipation theorem is satisfied. The key quantity $S^{(2)}(\mathbf{q})$ is the direct correlation function and is determined by the electronic structure of the disordered alloy.

In this way, an alloy's tendency to order depends crucially on the magnetic state of the system and upon whether or not the electronic structure is spin-polarized. If the system is paramagnetic, then the presence of "local moments" and the resulting "local exchange splitting" will have consequences. In the next section, we describe three case studies where we show the extent to which an alloy's compositional structure is dependent on whether the underlying electronic structure is "globally" or "locally" spin-polarized, i.e., whether the system is quenched from a ferromagnetic or paramagnetic state. We look at nickel-iron alloys, including those in the "Invar" concentration range, iron-rich Fe-V alloys, and finally gold-rich AuFe alloys.

The value of $\mathbf{q}$ for which $S^{(2)}(q)$, the direct correlation function, has its greatest value signifies the wavevector for the static concentration wave to which the system is unstable at a low enough temperature. For example, if this occurs at $q = 0$, phase segregation is indicated, whilst for a $A_{75}B_{25}$ alloy a maximum value at $\mathbf{q} = (1, 0, 0)$ points to an $L1_2(Cu_3Au)$ ordered phase at low temperatures. An important part of $S^{(2)}(\mathbf{q})$ derives from an electronic state filling effect and ties in neatly with the notion that half-filled bands promote ordered structures whilst nearly filled or nearly empty states are compatible with systems that cluster when cooled (Ducastelle, 1991; Heine and Samson, 1983). This propensity can be totally different depending on whether the electronic structure is spin-polarized or not, and hence whether the compositionally disordered state is ferromagnetic or paramagnetic as is the case for nickel-rich $Ni_{75}Fe_{25}$, for example (Staunton et al., 1987). The remarks made earlier in this unit about bonding in alloys and spin-polarization are clearly relevant here. For example, majority spin electrons in strongly ferromagnetic alloys like $Ni_{75}Fe_{25}$, which completely occupy the majority spin d states "see" very little difference between the two types of atomic site (Fig. 2) and hence contribute little to $S^{(2)}(\mathbf{q})$ and it is the filling of the minority-spin states which determine the eventual compositional structure. A contrasting picture describes those alloys, usually bcc-based, in which the Fermi energy is pinned in a valley in the minority density of states (Fig. 2, panel B) and where the ordering tendency is largely governed by the majority-spin electronic structure (Staunton et al., 1990).

For a ferromagnetic alloy, an expression for the lattice Fourier transform of the magneto-compositional cross-correlation function $\vartheta_{ik} = \langle \mu_i \xi_k \rangle - \langle \mu_i \rangle \langle \xi_k \rangle$ can be written down and evaluated (Staunton et al., 1990; Ling et al., 1995a). Its lattice Fourier transform turns out to be a simple product involving the compositional correlation function, $\vartheta(\mathbf{q}) = \alpha(\mathbf{q})\gamma(\mathbf{q})$, so that ϑ_{ik} is a convolution of $\gamma_{ik} = \delta\langle \mu_i \rangle / \delta c_k$ and α_{kj}. The quantity γ_{ik} has components

$$\gamma_{ik} = (\mu^{\mathrm{A}} - \mu^{\mathrm{B}})\delta_{ik} + c\frac{\delta \mu_i^{\mathrm{A}}}{\delta c_k} + (1-c)\frac{\delta \mu_i^{\mathrm{B}}}{\delta c_k} \qquad (23)$$

The last two quantities, $\delta\mu_i^{\mathrm{A}}/\delta c_k$ and $\delta\mu_i^{\mathrm{B}}/\delta c_k$, can also be evaluated in terms of the spin-polarized electronic structure of the disordered alloy. They describe the changes to the magnetic moment μ_i on a site i in the lattice occupied by either an A or a B atom when the probability of occupation is altered on another site k. In other words, γ_{ik} quantifies the chemical environment effect on the sizes of the magnetic moments. We studied the dependence of the magnetic moments on their local environments in FeV and FeCr alloys in detail from this framework (Ling et al., 1995a). If the application of a small external magnetic field is considered along the direction of the magnetization, expressions dependent upon the electronic structure for the magnetic correlation function can be similarly found. These are related to the static longitudinal susceptibility $\chi(\mathbf{q})$.

The quantities $\alpha(\mathbf{q})$, $\vartheta(\mathbf{q})$, and $\chi(\mathbf{q})$ can be straightforwardly compared with information obtained from x-ray (Krivoglaz, 1969; also see Chapter 10, section b) and neutron scattering (Lovesey, 1984; also see MAGNETIC NEUTRON SCATTERING), nuclear magnetic resonance (NUCLEAR MAGNETIC RESONANCE IMAGING), and Mössbauer spectroscopy (MOSSBAUER SPECTROMETRY) measurements. In particular, the cross-sections obtained from diffuse polarized neutron scattering can be written

$$\left.\frac{d\sigma}{d\omega}\right|_{\zeta} = \frac{d\sigma^{\mathrm{N}}}{d\omega} + \zeta\frac{d\sigma}{d\omega} + \frac{d\sigma^{\mathrm{M}}}{d\omega} \qquad (24)$$

where $\zeta = +1(-1)$ if the neutrons are polarized (anti-) parallel to the magnetization (see MAGNETIC NEUTRON SCATTERING). The nuclear component $d\sigma^{\mathrm{N}}/d\omega$ is proportional to the compositional correlation function, $\alpha(\mathbf{q})$ (closely related to the Warren-Cowley short-range order parameters). The magnetic component $d\sigma^{\mathrm{M}}/d\omega$ is proportional to $\chi(\mathbf{q})$. Finally $d\sigma^{\mathrm{NM}}/d\omega$ describes the magneto-compositional correlation function $\gamma(\mathbf{q})\alpha(\mathbf{q})$ (Marshall, 1968; Cable and Medina, 1976). By interpreting such experimental measurements by such calculations, electronic mechanisms which underlie the correlations can be extracted (Staunton et al., 1990; Cable et al., 1989).

Up to now, everything has been discussed with respect to spin-polarized but non-relativistic electronic structure. We now touch briefly on the relativistic extension to this approach to describe the important magnetic property of magnetocrystalline anisotropy.

MAGNETIC ANISOTROPY

At this stage, we recall that the fundamental "exchange" interactions causing magnetism in metals are intrinsically isotropic, i.e., they do not couple the direction of magnetization to any spatial direction. As a consequence they are unable to provide any sort of description of magnetic anisotropic effects which lie at the root of technologically important magnetic properties such as domain wall structure, linear magnetostriction, and permanent magnetic properties in general. A fully relativistic treatment of the electronic effects is needed to get a handle on these phenomena. We consider that aspect in this subsection. In a solid with

an underlying lattice, symmetry dictates that the equilibrium direction of the magnetization be along one of the cystallographic directions. The energy required to alter the magnetization direction is called the magnetocrystalline anisotropy energy (MAE). The origin of this anisotropy is the interaction of magnetization with the crystal field (Brooks, 1940) i.e., the spin-orbit coupling.

Competitive and Related Techniques for Calculating MAE

Most present-day theoretical investigations of magnetocrystalline anisotropy use standard band structure methods within the scalar-relativistic local spin-density functional theory, and then include, perturbatively, the effects from spin-orbit coupling, a relativistic effect. Then by using the force theorem (Mackintosh and Anderson, 1980; Weinert et al., 1985), the difference in total energy of two solids with the magnetization in different directions is given by the difference in the Kohn-Sham single-electron energy sums. In practice, this usually refers only to the valence electrons, the core electrons being ignored.

There are several investigations in the literature using this approach for transition metals (e.g. Gay and Richter, 1986; Daalderop et al., 1993), as well as for ordered transition metal alloys (Sakuma, 1994; Solovyev et al., 1995) and layered materials (Guo et al., 1991; Daalderop et al., 1993; Victora and MacLaren, 1993), with varying degrees of success. Some controversy surrounds such perturbative approaches regarding the method of summing over all the "occupied" single-electron energies for the perturbed state which is not calculated self-consistently (Daalderop et al., 1993; Wu and Freeman, 1996). Freeman and coworkers (Wu and Freeman, 1996) argued that this "blind Fermi filling" is incorrect and proposed the state-tracking approach in which the occupied set of perturbed states are determined according to their projections back to the occupied set of unperturbed states. More recently, Trygg et al. (1995) included spin-orbit coupling self-consistently in the electronic structure calculations, although still within a scalar-relativistic theory. They obtained good agreement with experimental magnetic anisotropy constants for bcc Fe, fcc Co, and hcp Co, but failed to obtain the correct magnetic easy axis for fcc Ni.

Practical Aspects of the Method

The MAE in many cases is of the order of μeV, which is several (as many as 10) orders of magnitude smaller than the total energy of the system. With this in mind, one has to be very careful in assessing the precision of the calculations. In many of the previous works, fully relativistic approaches have not been used, but it is possible that only a fully relativistic framework may be capable of the accuracy needed for reliable calculations of MAE. Moreover either the total energy or the single-electron contribution to it (if using the force theorem) has been calculated separately for each of the two magnetization directions and then the MAE obtained by a straight subtraction of one from the other. For this reason, in our work, some of which we outline below, we treat relativity and magnetization (spin polarization) on an equal footing. We also calculate the energy difference directly, removing many systematic errors.

Strange et al. (1989a, 1991) have developed a relativistic spin-polarized version of the Korringa-Kohn-Rostoker (SPR-KKR) formalism to calculate the electronic structure of solids, and Ebert and coworkers (Ebert and Akai, 1992) have extended this formalism to disordered alloys by incorporating coherent-potential approximation (SPR-KKR-CPA). This formalism has successfully described the electronic structure and other related properties of disordered alloys (see Ebert, 1996 for a recent review) such as magnetic circular x-ray dichroism (X-RAY MAGNETIC CIRCULAR DICHROISM), hyperfine fields, magneto-optic Kerr effect (SURFACE MAGNETO-OPTIC KERR EFFECT). Strange et al. (1989a, 1989b) and more recently Staunton et al. (1992) have formulated a theory to calculate the MAE of elemental solids within the SPR-KKR scheme, and this theory has been applied to Fe and Ni (Strange et al., 1989a, 1989b). They have also shown that, in the nonrelativistic limit, MAE will be identically equal to zero, indicating that the origin of magnetic anisotropy is indeed relativistic.

We have recently set up a robust scheme (Razee et al., 1997, 1998) for calculating the MAE of compositionally disordered alloys and have applied it to Ni_cPt_{1-c} and Co_cPt_{1-c} alloys and we will describe our results for the latter system in a later section. Full details of our calculational method are found elsewhere (Razee et al., 1997) and we give a bare outline here only. The basis of the magnetocrystalline anisotropy is the relativistic spin-polarized version of density functional theory (see e.g. MacDonald and Vosko, 1979; Rajagopal, 1978; Ramana and Rajagopal, 1983; Jansen, 1988). This, in turn, is based on the theory for a many electron system in the presence of a "spin-only" magnetic field (ignoring the diamagnetic effects), and leads to the relativistic Kohn-Sham-Dirac single-particle equations. These can be solved using spin-polarized, relativistic, multiple scattering theory (SPR-KKR-CPA).

From the key equations of the SPR-KKR-CPA formalism, an expression for the magnetocrystalline anisotropy energy of disordered alloys is derived starting from the total energy of a system within the local approximation of the relativistic spin-polarized density functional formalism. The change in the total energy of the system due to the change in the direction of the magnetization is defined as the magnetocrystalline anisotropy energy, i.e., $\Delta E = E[n(\mathbf{r}),\ \mathbf{m}(\mathbf{r},\hat{e}_1)] - E[n(\mathbf{r}),\ \mathbf{m}(\mathbf{r},\hat{e}_2)]$, with $\mathbf{m}(\mathbf{r},\hat{e}_1)$, $\mathbf{m}(\mathbf{r},\hat{e}_2)$ being the magnetization vectors pointing along two directions $\hat{e}_1$ and $\hat{e}_1$ respectively; the magnitudes are identical. Considering the stationarity of the energy functional and the local density approximation, the contribution to ΔE is predominantly from the single-particle term in the total energy. Thus, now we have

$$\Delta E = \int^{\varepsilon_{F1}} \varepsilon n(\varepsilon, \hat{e}_1)\, d\varepsilon - \int^{\varepsilon_{F2}} \varepsilon n(\varepsilon, \hat{e}_2)\, d\varepsilon \qquad (25)$$

where ε_{F1} and ε_{F2} are the respective Fermi levels for the two orientations. This expression can be manipulated into one involving the integrated density of states and where a cancellation of a large part has taken place, i.e.,

$$\Delta E = -\int^{\varepsilon_{F1}} d\varepsilon (N(\varepsilon, \hat{e}_1) - N(\varepsilon, \hat{e}_2)) - \frac{1}{2} N(\varepsilon_{F2}, \hat{e}_2)(\varepsilon_{F1} - \varepsilon_{F2})^2 + O(\varepsilon_{F1} - \varepsilon_{F2})^3 \qquad (26)$$

In most cases, the second term is very small compared to the first term. This first term must be evaluated accurately, and it is convenient to use the Lloyd formula for the integrated density of states (Staunton et al., 1992; Gubanov et al., 1992).

MAE of the Pure Elements Fe, Ni, and Co

Several groups including ours have estimated the MAE of the magnetic 3*d* transition metals. We found that the Fermi energy for the [001] direction of magnetization calculated within the SPR-KKR-CPA is ~1 to 2 mRy above the scalar relativistic value for all the three elements (Razee et al., 1997). We also estimated the order of magnitude of the second term in the equation above for these three elements, and found that it is of the order of 10^{-2} μeV, which is one order of magnitude smaller than the first term. We compared our results for bcc Fe, fcc Co, and fcc Ni with the experimental results, as well as the results of previous calculations (Razee et al., 1997). Among previous calculations, the results of Trygg et al. (1995) are closest to the experiment, and therefore we gauged our results against theirs. Their results for bcc Fe and fcc Co are in good agreement with the experiment if orbital polarization is included. However, in case of fcc Ni, their prediction of the magnitude of MAE, as well as the magnetic easy axis, is not in accord with experiment, and even the inclusion of orbital polarization fails to improve the result. Our results for bcc Fe and fcc Co are also in good agreement with the experiment, predicting the correct easy axis, although the magnitude of MAE is somewhat smaller than the experimental value. Considering that in our calculations orbital polarization is not included, our results are quite satisfactory. In case of fcc Ni, we obtain the correct easy axis of magnetization, but the magnitude of MAE is far too small compared to the experimental value, but in line with other calculations. As noted earlier, in the calculation of MAE, the convergence with regard to the Brillouin zone integration is very important. The Brillouin zone integrations had to be done with much care.

DATA ANALYSIS AND INITIAL INTERPRETATION

The Energetics and Electronic Origins for Atomic Long- and Short-Range Order in NiFe Alloys

The electronic states of iron and nickel are similar in that for both elements the Fermi energy is placed near or at the top of the majority-spin *d* bands. The larger moment in Fe as compared to Ni, however, manifests itself via a larger exchange-splitting. To obtain a rough idea of the electronic structures of Ni_cFe_{1-c} alloys, we imagine aligning the Fermi energies of the electronic structures of the pure elements. The atomic-like *d* levels of the two, marking the center of the bands, would be at the same energy for the majority spin electrons, whereas for the minority spin electrons, the levels would be at rather different energies, reflecting the differing exchange fields associated with each sort of atom (Fig. 2). In Figure 1, we show the density of states of $Ni_{75}Fe_{25}$ calculated by the SCF-KKR-CPA, and we interpreted along those lines. The majority spin density of states possesses very sharp structure, which indicates that in this compositionally disordered alloy majority spin electrons "see" very little difference between the two types of atom, with the DOS exhibiting "common-band" behavior. For the minority spin electrons the situation is reversed. The density of states becomes "split-band"-like owing to the large separation of levels (in energy) and due to the resulting compositional disorder. As pointed out earlier, the majority spin *d* states are fully occupied, and this feature persists for a wide range of concentrations of fcc Ni_cFe_{1-c} alloys: for *c* greater than 40%, the alloys' average magnetic moments fall nicely on the negative gradient slope of the Slater-Pauling curve. For concentrations less than 35%, and prior to the Martensitic transition into the bcc structure at around 25% (the famous "Invar" alloys), the Fermi energy is pushed into the peak of majority-spin *d* states, propelling these alloys away from the Slater-Pauling curve. Evidently the interplay of magnetism and chemistry (Staunton et al., 1987; Johnson et al., 1989) gives rise to most of the thermodynamic and concentration-dependent properties of Ni-Fe alloys.

The ferromagnetic DOS of fcc Ni-Fe, given in Figure 1A, indicates that the majority-spin *d* electrons cannot contribute to chemical ordering in Ni-rich Ni-Fe alloys, since the states in this spin channel are filled. In addition, because majority-spin *d* electrons "see" little difference between Ni and Fe, there can be no driving force for chemical order or for clustering (Staunton et al., 1987; Johnson et al., 1989). However, the difference in the exchange splitting of Ni and Fe leads to a very different picture for minority-spin *d* electrons (Fig. 2). The bonding-like states in the minority-spin DOS are mostly Ni, whereas the antibonding-like states are predominantly Fe. The Fermi level of the electrons lies between these bonding and anti-bonding states. This leads to the Cu-Au-type atomic short-range order and to the long-range order found in the region of $Ni_{75}Fe_{25}$ alloys. As the Ni concentration is reduced, the minority-spin bonding states are slowly depopulated, reducing the stability of the alloy, as seen in the heats of formation (Johnson and Shelton, 1997). Ultimately, when enough electrons are removed (by adding more iron), the Fermi level enters the majority-spin *d* band and the anomalous behavior of Ni-Fe alloys occurs: increases in resistivity and specific heat, collapse of moments (Johnson et al., 1987), and competing magnetic states (Johnson et al., 1989; Abrikosov et al., 1995).

Moment Alignment Versus Moment Formation in fcc Fe. Before considering the last aspect, that of competing magnetic states and their connection to volume effects, it is instructive to consider the magnetic properties of Fe on an fcc lattice, even though it exists only at high temperatures. Moruzzi and Marcus (1993) have reviewed the calculations of the energetics and moments of fcc Fe in both antiferromagnetic (AFM) and ferromagnetic (FM) states for a range of lattice spacings. Here we refer to a comparison with the DLM paramagnetic state (PM; Pinski et al., 1986; Johnson et al., 1989). For large volumes (lattice spacings), the FM state has large moments and is lowest in energy. At small volumes, the PM state is lowest in energy and is the global energy minimum. At intermediate

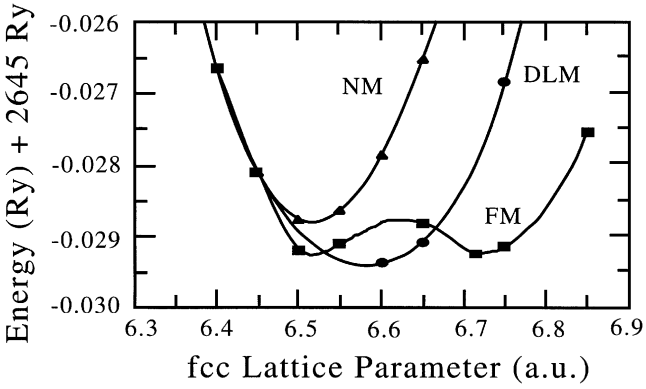

Figure 3. The volume dependence of the total energy of various magnetic states of $Ni_{25}Fe_{75}$. The total energy of the states of fcc $Ni_{25}Fe_{75}$ with the designations FM (moments aligned), the DLM (moments disordered), and NM (zero moments) are plotted as a function of the fcc lattice parameter. See Johnson et al. (1989), and Johnson and Shelton (1997).

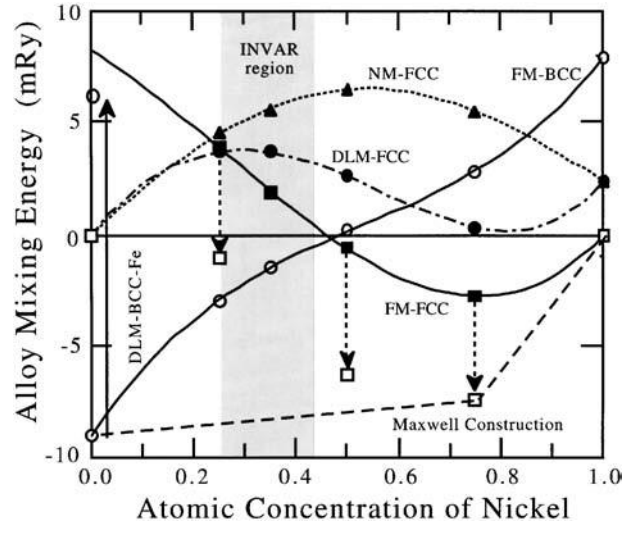

Figure 4. The concentration dependence of the total energy of various magnetic states of Ni-Fe Alloys. The total energy of the some magnetic states of Ni-Fe alloys are plotted as a function of concentration. Note that the Maxwell construction indicates that the ordered fcc phases, $Fe_{50}Ni_{50}$ and $Fe_{75}Ni_{25}$, are metastable. Adapted from Johnson and Shelton (1997).

volumes, however, the AFM and PM states have similar-size moments and energies, although at a value of the lattice constant of 6.6 a.u. or 3.49 Å, the local moments in the PM state collapse. These results suggest that the Fe-Fe magnetic correlations on an fcc lattice are extremely sensitive to volume and evolve from FM to AFM as the lattice is compressed. This suggestion was confirmed by explicit calculations of the magnetic correlations in the PM state (Pinski et al., 1986).

In Figure 9 of Johnson et al. (1989), the energetics of fcc $Ni_{35}Fe_{65}$ were a particular focal point. This alloy composition is well within the Invar region, near to the magnetic collapse, and exhibiting the famous negative thermal expansion. The energies of four magnetic states—i.e., non-magnetic (NM), ferromagnetic (FM), paramagnetic (PM), represented by the disordered local moment state (DLM), and anti-ferromagnetic (AFM)—were within 1.5 mRy, or 250 K of each other (Fig. 3). The $Ni_{35}Fe_{65}$ calculations were a subset of many calculations that were done for various Ni compositions and magnetic states. As questions still remained regarding the true equilibrium phase diagram of Ni-Fe, Johnson and Shelton (1997) calculated the heats of formation, ΔE_f, or mixing energies, for various Ni compositions and for several magnetic fcc and bcc Ni-Fe phases relative to the pure endpoints, NM-fcc Fe and FM-fcc Ni.

For the NM-fcc Ni-rich alloys, they found the function ΔE_f (as a function of composition) to be positive and convex everywhere, indicating that these alloys should cluster. While this argument is not always true, we have shown that the calculated ASRO for NM-fcc Ni-Fe does indeed show clustering (Staunton et al., 1987; Johnson et al., 1989). This was a consequence of the absence of exchange-splitting in a Stoner paramagnet and filling of unfavorable antibonding *d*-electron states. This, at best, would be a state seen only at extreme temperatures, possibly near melting. Thermochemical measurements at high temperatures in Ni-rich, Ni-Fe alloys appear to support this hypothesis (Chuang et al., 1986).

In the past, the NM (possessing zero local moments) state has been used as an approximate PM state, and the energy difference between the FM and NM state seems to reflect well the observed non-symmetric behavior of the Curie temperature when viewed as a function of Ni concentration. However, this is fortuitous agreement, and the lack of exchange-splitting in the NM state actually suppresses ordering.

As shown in figure 2 of Johnson and Shelton (1997) and in Figure 4 of this unit, the PM-DLM state, with its local exchange-splitting on the Fe sites, is lower in energy, and therefore a more relevant (but still approximate) PM state. Even in the Invar region, where the energy differences are very small, the exchange-splitting has important consequences for ording.

While the DLM state is much more representative of the PM state, it does not contain any of magnetic short-range order (MSRO) that exists above the Curie temperature. This shortcoming of the model is relevant because the ASRO calculated from this approximate PM state yields very weak ordering (spinodal-ordering temperature below 200 K) for $Ni_{75}Fe_{25}$, which is not, however, of $L1_2$ type. The ASRO calculated for fully-polarized FM $Ni_{75}Fe_{25}$ is $L1_2$-like, with a spinodal around 475 K, well below the actual chemical-ordering temperature of 792 K (Staunton et al., 1987; Johnson et al., 1989). Recent diffuse scattering measurements by Jiang et al. (1996) find weak $L1_2$-like ASRO in Ni_3Fe samples quenched from 1273 K, which is above the Curie temperature of 800 K. It appears that some degree of magnetic order (both short- or long-range) is required for the ASRO to have $\mathbf{k} = (1,0,0)$ wavevector instabilities (or $L1_2$ type chemical ordering tendencies). Nonetheless, the local exchange splitting in the DLM state, which exists only on the Fe sites (the Ni moments are quenched), does lead to weak ordering, as compared

to the tendency to phase-separate that is found when local exchange splitting is absent in the NM case.

Importantly, this indicates that sample preparation (whether above or below the Curie point) and the details of the measuring procedure (e.g., if data is taken *in situ* or after quench) affect what is measured. Two time scales are important: roughly speaking, the electron hopping time is 10^{-15} sec, whereas the chemical hopping time (or diffusion) is 10^{-3} to 10^{+6} sec. Now we consider diffuse-scattering experiments. For samples prepared in the Ni-rich alloys, but below the Curie temperature, it is most likely that a smaller difference would be found from data taken *in situ* or on quenched samples, because the (global) FM exchange-split state has helped establish the chemical correlations in both cases. On the other hand, in the Invar region, the Curie temperature is much lower than that for Ni-rich alloys and lies in the two-phase region. Samples annealed in the high-temperature, PM, fcc solid-solution phase and then quenched should have (at best) very weak ordering tendencies. The electronic and chemical degrees of freedom respond differently to the quench. Jiang et al. (1996) have recently measured ASRO versus composition in Ni-Fe system using anomalous x-ray scattering techniques. No evidence for ASRO is found in the Invar region, and the measured diffuse intensity can be completely interpreted in terms of static-displacement (size-effect) scattering. These results are in contrast to those found in the 50% and 75% Ni samples annealed closer to, but above, the Curie point and before being quenched.

The calculated ASRO intensities in 35%, 50%, and 75% Ni FM alloys are very similar in magnitude and show the Cu-Au ordering tendencies. Figure 2 of Johnson and Shelton (1997) shows that the Cu-Au-type $T = 0$ K ordering energies lie close to one another. While this appears to contradict the experimental findings (Jiang et al., 1996), recall that the calculated ASRO for PM-DLM Ni_3Fe shows ordering to be suppressed. The scattering data obtained from the Invar alloy was from a sample quenched well above the Curie temperature. Theory and experiment may then be in agreement: the ASRO is very weak, allowing size-effect scattering to dominate. Notably, volume fluctuations and size effects have been suggested as being responsible for, or at least contributing to, many of the anomalous Invar properties (Wassermann, 1991; Mohn et al., 1991; Entel et al., 1993, 1998). In all of our calculations, including the ASRO ones, we have ignored lattice distortions and kept an ideal lattice described by only a single-lattice parameter.

From anomalous x-ray scattering data, Jiang et al. (1996) find that for the differing alloy compositions in the fcc phase, the Ni-Ni nearest-neighbor (NN) distance follows a linear concentration dependence (i.e., Vegard's rule), the Fe-Fe NN distance is almost independent of concentration, and the Ni-Fe NN distance is actually smaller than that of Ni-Ni. This latter measurement is obviously contrary to hard-sphere packing arguments. Basically, Fe-Fe like to have larger "local volume" to increase local moments, and for Ni-Fe pairs the bonding is promoted (smaller distance) with a concomitant increase in the local Ni moment. Indeed, experiment and our calculations find about a 5% increase in the average moment upon chemical ordering in Ni_3Fe. These small local displacements in the Invar region actively contribute to the diffuse intensity (discussed above) when the ASRO is suppressed in the PM phase.

The Negative Thermal Expansion Effect. While many of the thermodynamic behaviors and anomalous properties of Ni-Fe Invar have been explained, questions remain regarding the origin of the negative thermal expansion. It is difficult to incorporate the displacement fluctuations (thermal phonons) on the same footing as magnetic and compositional fluctuations, especially within a first-principles approach. Progress on this front has been made by Mohn et al. (1991) and others (Entel et al., 1993, 1998; Uhl and Kubler, 1997). Recently, a possible cause of the negative thermal-expansion coefficient in Ni-Fe has been given within an effective Grüneisen theory (Abrikosov et al., 1995). Yet, this explanation is not definitive because the effect of phonons was not considered, i.e., only the electronic part of the Grüneisen constant was calculated.

For example, at 35% Ni, we find within the ASA calculations that the Ni and Fe moments respectively, are 0.62 μ_B and 2.39 μ_B for the $T = 0$ K FM state, and 0.00 μ_B and 1.56 μ_B in the DLM state, in contrast to a NM state (zero moments). From neutron-scattering data (Collins, 1966), the PM state contains moments of $\sim$1.42 μ_B on iron, similar to that found in the DLM calculations (Johnson et al., 1989).

Now we move on to consider a purely electronic explanation. In Figure 3, we show a plot of energy versus lattice parameter for a 25% Ni alloy in the NM, PM, and FM states. The FM curve has a double-well feature, i.e., two solutions, one with a large lattice parameter with high moments; the other, at a smaller volume has smaller moments. For the spin-restricted NM calculation (i.e. zero moments), a significant energy difference exists, even near low-spin FM minimum. The FM moments at smaller lattice constants are smaller than 0.001 Bohr magnetons, but finite. As Abrikosov et al. (1995) discuss, this double solution of the energy-versus-lattice parameter of the $T = 0$ K FM state produces an anomaly in the Grüneisen constant that leads to a negative thermal expansion effect. They argue that this is the only possible electronic origin of a negative thermal expansion coefficient. However, if temperature effects are considered—in particular, thermally induced phonons and local moment disorder—then it is not clear that this double-solution behavior is relevant near room temperature, where the lattice measurements are made.

Specifically, calculations of the heats of formation as in Figure 4 indicate that already at $T = 0$ K, neglecting the large entropy of such a state, the DLM state (or an AFM state) is slightly more energetically stable than the FM state at 25% Ni, and is intermediate to the NM and FM states at 35% Ni. Notice that the energy differences for 25% Ni are $\sim$0.5 mRy. Because of the high symmetry of the DLM state, in contrast to the FM case, a double-well feature is not seen in the energy-versus-volume curve (see Fig. 3). As Ni content is increased from 25%, the

low-spin solution rises in energy relative to high-spin solution before vanishing for alloys with more than 35% Ni (see figure 9 of Johnson et al., 1989). Thus, there appears to be less of a possibility of having a negative thermal expansion from this double-solution electronic effect as the temperature is raised, since thermal effects disorder the orientations of the moments (i.e. magnetization versus T should become Brillouin-like) and destroy, or lessen, this double-well feature. In support of this argument, consider that the Invar alloys do have signatures like spin-glasses—e.g., magnetic susceptibility—and the DLM state at $T = 0$ K could be supposed to be an approximate uncorrelated spin-glass (see discussion in Johnson et al., 1989). Thus, at elevated temperatures, both electronic and phonon effects contribute in some way, or, as one would think intuitively, phonons dominate.

The data from figure 3 and figure 9 of Johnson et al. (1989) show that a small energy is associated with orientation of disordering moments at 35% (an energy gain at 25% Ni) and that this yields a volume contraction of ~2%, from the high-spin FM state to (low-spin) DLM-PM state. On the other hand, raising the temperature gives rise to a lattice expansion due to phonon effects of ~1% to 2%. Therefore, the competition of these two effects lead to a small, perhaps negative, thermal expansion. This can only occur in the Invar region (for compositions greater than 25% and less than 40% Ni) because here states are sufficiently close in energy, with the DLM state being higher in energy. A Maxwell construction including these four states rules out the low-spin FM solution. A more quantitative explanation remains. Only by merging the effects of phonons with the magnetic disorder at elevated temperatures can one balance the expansion due to the former with the contraction due to the latter, and form a complete theory of the INVAR effect.

Magnetic Moments and Bonding in FeV Alloys

A simple schematic energy level diagram is shown in Figure 2B for Fe_cV_{1-c}. The d energy levels of Fe are exchange-split, showing that it is energetically favorable for pure bcc iron to have a net magnetization. Exchange-splitting is absent in pure vanadium. As in the case of the Ni_cFe_{1-c} alloys, we assume charge neutrality and align the two Fermi energies. The vanadium d levels lie much more closer in energy to the minority-spin d levels of iron than to its majority-spin ones. Upon alloying the two metals in a bcc structure, the bonding interactions have a larger effect on the minority-spin levels than those of the majority spin, owing to the smaller energy separation. In other words, Fe induces an exchange-splitting on the V sites to lower the kinetic energy which results in the formation of bonding and anti-bonding minority-spin alloy states. More minority-spin V-related d states are occupied than majority-spin d states, with the consequence of a moment on the vanadium sites anti-parallel to the larger moment on the Fe sites. The moments are not sustained for concentrations of iron less than 30%, since the Fe-induced exchange-splitting on the vanadium sites diminishes along with the average number of Fe atoms surrounding a vanadium site in the alloy. As for the majority-spin levels, well separated in energy, "split bands" form, i.e., states which reside mostly on one constituent or the other. In Figure 1B, we show the spin-polarized density of states of an iron-rich FeV alloy determined by the SCF-KKR-CPA method, where all these features can be identified.

Since the Fe and V majority-spin d states are well separated in energy, we expect a very smeared DOS in the majority-spin channel, due to the large disorder that the majority-spin electrons "see" as they travel through the lattice. On the other hand, the minority (spin-down) electron DOS should have peaks associated with the lower-energy, bonding states, as well as other peaks associated with the higher-energy, antibonding states. Note that the majority-spin DOS is very smeared due to chemical disorder, and the minority-spin DOS is much sharper, with the bonding states fully occupied and the antibonding states unoccupied. Note that the vertical line indicates the Fermi level, or chemical potential, of the electrons, below which the states are occupied. The Fermi level lies in this trough of the minority density of states for almost the entire concentration range. As discussed earlier, it is this positioning of the Fermi level holding the minority-spin electrons at a fixed number which gives rise to the mechanism for the straight 45° line on the left hand side of the Slater-Pauling curve. In general, the DOS depends on the underlying symmetry of the lattice and the subtle interplay between bonding and magnetism. Once again, we emphasize that the rigidly-split spin densities of states seen in the ferromagnetic elemental metals clearly do not describe the electronic structure in alloys. The variation of the moments on the Fe and V sites, as well as the average moments per site versus concentration as described by SCF-KKR-CPA calculations, are in good agreement with experimental measurement (Johnson et al., 1987).

ASRO and Magnetism in FeV

In this subsection we describe our investigation of the atomic short-range order in iron-vanadium alloys at (or rapidly quenched from) temperatures T_0 above any compositional ordering temperature. For these systems we find the ASRO to be rather insensitive to whether T_0 is above or below the alloy's magnetic Curie temperatures T_c, owing to the presence of "local exchange-splitting" in the electronic structure of the paramagnetic state. Iron-rich FeV alloys have several attributes that make them suitable systems in which to investigate both ASRO and magnetism. Firstly, their Curie temperatures (~1000 K) lie in a range where it is possible to compare and contrast the ASRO set up in both the ferromagnetic and paramagnetic states. The large difference in the coherent neutron scattering lengths, $b_{Fe} - b_V \approx 10$ fm, together with the small size difference, make them good candidates for neutron diffuse scattering experimental analyses.

In figure 1 of Cable et al. (1989), the neutron-scattering cross-sections as displayed along three symmetry directions measured in the presence of a saturating magnetic field for a $Fe_{87}V_{13}$ single crystal quenched a ferromagnetically ordered state. The structure of the curves is attributed to nuclear scattering connected with the ASRO,

$c(1-c)(b_{Fe}-b_V)^2\alpha(\mathbf{q})$. The most intense peaks occur at (1,0,0) and (1,1,1), indicative of a β-CuZn(B2) ordering tendency. Substantial intensity lies in a double peak structure around (1/2,1/2,1/2). We showed (Staunton et al., 1990, 1997) how our ASRO calculations for ferromagnetic $Fe_{87}V_{13}$ could reproduce all the details of the data. With the chemical potential being pinned in a trough of the minority-spin density of states (Fig. 1B), the states associated with the two different atomic species are substantially hybridized. Thus, the tendency to order is governed principally by the majority-spin electrons. These split-band states are roughly half-filled to produce the strong ordering tendency. The calculations also showed that part of the structure around (1/2,1/2,1/2) could be traced back to the majority-spin Fermi surface of the alloy.

By fitting the direct correlation function $S^{(2)}(\mathbf{q})$ in terms of real-space parameters

$$S^{(2)}(\mathbf{q}) = S_0^{(2)} + \sum_n \sum_{i\in n} S_n^{(2)} \exp(i\mathbf{q}\cdot\mathbf{R}_i) \qquad (27)$$

we found the fit is dominated by the first two parameters which determine the large peak at 1,0,0. However, the fit also showed a long-range component that was derived from the Fermi-surface effect. The real-space fit of data produced by Cable et al. (1989) showed large negative values for the first two shells, also followed by a weak long-ranged tail.

Cable et al. (1989) claimed that the effective temperature, for at least part of the sample, was indeed below its Curie temperature. To investigate this aspect, we carried out calculations for the ASRO of paramagnetic (DLM) $Fe_{87}V_{13}$ (Staunton et al., 1997). Once again, we found the largest peaks to be located at (1,0,0) and (1,1,1) but a careful scrutiny found less structure around (1/2,1/2,1/2) than in the ferromagnetic alloy. The ordering correlations are also weaker in this state. For the paramagnetic DLM state, the local exchange-splitting also pushes many antibonding states above the chemical potential ν (see Fig. 5). This happens although ν is no longer wedged in a valley in the density of states. The compositional ordering mechanism is similar to, although weaker than, that of the ferromagnetic alloy. The real space fit of $S^{(2)}(\mathbf{q})$ also showed a smaller long-ranged tail. Evidently the "local-moment" spin fluctuation disorder has broadened the alloy's Fermi surface and diminished its effect upon the ASRO.

Figure 3 of Pierron-Bohnes et al. (1995) shows measured neutron diffuse scattering intensities from $Fe_{80}V_{20}$ in its paramagnetic state at 1473 K and 1133 K (the Curie temperature is 1073 K) for scattering vectors in both the (1,0,0) and (1,−1,0) planes, following a standard correction for instrumental background and multiple scattering. Maximal intensity lies near (1,0,0) and (1,1,1) without subsidiary structure about (1/2, 1/2,1/2). Our calculations of the ASRO of paramagnetic $Fe_{80}V_{20}$, very similar to those of $Fe_{87}V_{13}$, are consistent with these features.

We also studied the type and extent of magnetic correlations in the paramagnetic state. Ferromagnetic correlations were shown which grow in intensity as T is reduced. These lead to an estimate of $T_c = 980$ K, which agrees well

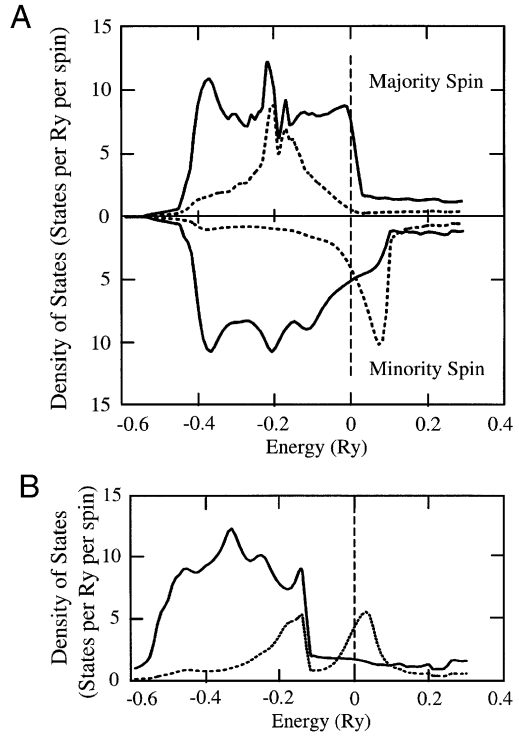

Figure 5. (**A**) The local electronic density of states for $Fe_{87}V_{13}$ with the moment directions being disordered. The upper half displays the density of states for the majority-spin electrons, the lower half, for the minority-spin electrons. Note that in the lower half the axis for the abscissa is inverted. These curves were calculated within the SCF-KKR-CPA (see Staunton et al., 1997). The solid line indicated contributions on the iron sites; the dashed line, the vanadiums sites. (**B**) The total electronic density of states for $Fe_{87}V_{13}$ with the moment directions being disordered. These curves were calculated within the SCF-KKR-CPA, see Johnson et al. (1989), and Johnson and Shelton (1997). The solid line indicates contributions on the iron sites; the dashed line, the vanadium sites.

with the measured value of 1073 K. (The calculated T_c for $Fe_{87}V_{13}$ of 1075 K also compares well with the measured value of 1180 K.) We also examined the importance of modeling the paramagnetic alloy in terms of local moments by repeating the calculations of ASRO, assuming a Stoner paramagnetic (NM) state in which there are no local moments and hence zero exchange splitting of the electronic structure, local or otherwise. The maximum intensity is now found at about (1/2,1/2,0) in striking contrast to both the DLM calculations and the experimental data.

In summary, we concluded that experimental data on FeV alloys are well interpreted by our calculations of ASRO and magnetic correlations. ASRO is evidently strongly affected by the local moments associated with the iron sites in the paramagnetic state, leading to only small differences between the topologies of the ASRO established in samples quenched from above and below T_c. The principal difference is the growth of structure around (1/2,1/2,1/2) for the ferromagnetic state. The ASRO strengthens quite sharply as the system orders magnetically, and it would be interesting if an *in situ*,

polarized-neutron, scattering experiment could be carried out to investigate this.

The ASRO of Gold-Rich AuFe Alloys: Dependence Upon Magnetic State

In sharp contrast to FeV, this study shows that magnetic order, i.e., alignment of the local moments, has a profound effect upon the ASRO of AuFe alloys. In Chapter 18 we discussed the electronic hybridization (size) effect which gives rise to the $\mathbf{q} = \{1,0,0\}$ ordering in NiPt. This is actually a more ubiquitous effect than one may at first imagine. In this subsection we show that the observed $\mathbf{q} = (1,1/2,0)$ short-range order in paramagnetic AuFe alloys that have been fast quenched from high temperature results partially from such an effect. Here we point out how magnetic effects also have an influence upon this unusual $\mathbf{q} = (1,1/2,0)$ short-range order (Ling et al., 1995b). We note that there has been a lengthy controversy over whether these alloys form a Ni_4Mo-type, or (1,1/2,0) special-point ASRO when fast-quenched from high temperatures, or whether the observed x-ray and neutron diffuse scattering intensities (or electron micrograph images) around (1,1/2,0) are merely the result of clusters of iron atoms arranged so as to produce this unusual type of ASRO. The issue was further complicated by the presence of intensity peaks around small $\mathbf{q} = (0,0,0)$ in diffuse x-ray scattering measurements and electron micrographs of some heat-treated AuFe alloys.

The uncertainty about the ASRO in these alloys arises from their strong dependence on thermal history. For example, when cooled from high temperatures, AuFe alloys in the concentration range of 10% to 30% Fe first form solid solutions on an underlying fcc lattice at around 1333 K. Upon further cooling below 973 K, α-Fe clusters begin to precipitate, coexisting with the solid solution and revealing their presence in the form of subsidiary peaks at $\mathbf{q} = (0,0,0)$ in the experimental scattering data. The number of α-Fe clusters formed within the fcc AuFe alloy, however, depends strongly on its thermal history and the time scale of annealing (Anderson and Chen, 1994; Fratzl et al., 1991). The miscibility gap appears to have a profound effect on the precipitation of α-Fe clusters, with the maximum precipitation occurring if the alloys had been annealed in the miscibility gap, i.e., between 573 and 773 K (Fratzl et al., 1991). Interestingly, all the AuFe crystals that reveal $\mathbf{q} = (0,0,0)$ correlations have been annealed at temperatures below both the experimental and our theoretical spinodal temperatures. On the other hand, if the alloys were homogenized at high temperatures outside the miscibility gap and then fast quenched, no αFe nucleation was found.

We have modeled the paramagnetic state of Au-Fe alloys in terms of disordered local moments in accord with the theoretical background described earlier. We calculated both $\alpha(\mathbf{q})$ and $\chi(\mathbf{q})$ in DLM-paramagnetic $Au_{75}Fe_{25}$ and for comparison have also investigated the ASRO in ferromagnetic $Au_{75}Fe_{25}$ (Ling et al., 1995b). Our calculations of $\alpha(\mathbf{q})$ for $Au_{75}Fe_{25}$ in the paramagnetic state show peaks at (1,1/2,0) with a spinodal ordering temperature of 780 K. This is in excellent agreement with experiment. Remarkably, as the temperature is lowered below 1600 K the peaks in $\alpha(\mathbf{q})$ shift to the (1,0.45,0) position with a gradual decrease towards (1,0,0) (Ling et al., 1995b). This streaking of the (1,1/2, 0) intensities along the (1,1,0) direction is also observed in electron micrograph measurements (van Tendeloo et al., 1985). The magnetic SRO in this alloy is found to be clearly ferromagnetic, with $\chi(\mathbf{q})$ peaking at (0,0,0). As such, we explored the ASRO in the "fictitious" FM alloy and find that $\alpha(\mathbf{q})$ shows peaks at (1,0,0).

Next, we show that the special point ordering in paramagnetic $Au_{75}Fe_{25}$ has its origins in the inherent "locally exchange-split" electronic structure of the disordered alloy. This is most easily understood from the calculated compositionally averaged densities of states (DOS), shown in Figure 5. Note that the double peak in the paramagnetic DLM Fe density of states in Figure 5A arises from the "local" exchange splitting, which sets up the "local moments" on the Fe sites. Similar features exist in the DOS of DLM $Fe_{87}V_{13}$. Within the DLM picture of the paramagnetic phase, it is important to note that this local DOS is obtained from the local axis of quantization on a given site due to the direction of the moment. All compositional and moment orientations contributing to the DOS must be averaged over, since moments point randomly in all directions. In comparison to a density of states in a ferromagnetic alloy, which has one global axis of quantization, the peaks in the DLM density of states are reminiscent of the more usual FM exchange splitting in Fe, as shown in Figure 5B.

What is evident from the DOS is that the chemical potential in the paramagnetic DLM state is located in an "antibonding"-like, exchange-split Fe peak. In addition, the "hybridized" bonding states that are created below the Fe d band are due to interaction with the wider-band Au (just as in NiPt). As a result of these two electronic effects, one arising from hybridization and the other from electronic exchange-splitting, a competition arises between (1,0,0)-type ordering from the t_{2g} hybridization states well below the Fermi level and (0,0,0)-type "ordering" (i.e., clustering) from the filling of unfavorable antibonding states. Recall again that the filling of bonding-type states favors chemical ordering, while the filling of antibonding-type states opposes chemical ordering, i.e., favors clustering. The competition between (1,0,0) and (0,0,0) type ordering from the two electronic effects yields a (1,1/2,0)-type ASRO. In this calculation, we can check this interpretation by artificially changing the chemical potential (or Fermi energy at $T = 0$ K) and then perform the calculation at a slightly different band-filling, or e/a. As the Fermi level is lowered below the higher-energy, exchange-split Fe peak, we find that the ASRO rapidly becomes (1,0,0)-type, simply because the unfavorable antibonding states are being depopulated and thus the clustering behavior suppressed.

As we have already stated, the ferromagnetic alloy exhibits (1,0,0)-type ASRO. In Figure 5B, at the Fermi level, the large antibonding, exchange-split, Fe peak is absent in the majority-spin manifold of the DOS, although it remains in the minority-spin manifold DOS. In other words, half of the states that were giving rise to the clustering behavior have been removed from consideration.

This happens because of the global exchange-splitting in the FM alloy; that is, a larger exchange-splitting forms and the majority-spin states become filled. Thus, rather than changing the ASRO by changing the electronic band-filling, one is able to alter the ASRO by changing the distribution of electronic states via the magnetic properties. Because the paramagnetic susceptibility $\chi(\mathbf{q})$ suggests that the local moments in the PM state are ferromagnetically correlated (Ling et al., 1995b), the alloy already is susceptible to FM ordering. This can be readily accomplished, for example, by magnetic-annealing the $Au_{75}Fe_{25}$ when preparing them at high temperatures, i.e. by placing the samples *in situ* into a strong magnetic field to align the moments. After the alloy is thermally annealed, the chemical response of the alloy is dictated by the electronic DOS in the FM disordered alloy, rather than that of the PM alloy, with the resulting ASRO being of (1,0,0)-type.

In summary, we have described two competing electronic mechanisms responsible for the unusual (1,1/2,0) ordering propensity observed in fast-quenched gold-rich AuFe alloys. This special point ordering we find to be determined by the inherent nature of the disordered alloy's electronic structure. Because the magnetic correlations in paramagnetic $Au_{75}Fe_{25}$ are found to be clearly ferromagnetic, we proposed that AuFe alloys grown in a magnetic field after homogenization at high temperature in the field, and then fast quenching, will produce a novel (1,0,0)-type ASRO in these crystals (Ling et al., 1995b).

We now move on and describe our studies of magnetocrystalline anisotropy in compositionally disordered alloys and hence show the importance of relativistic spin-orbit coupling upon the spin-polarized electronic structure.

Magnetocrystalline Anisotropy of Co_cPt_{1-c} Alloys

Co_cPt_{1-c} alloys are interesting for many reasons. Large magnetic anisotropy (MAE; Hadjipanayis and Gaunt, 1979; Lin and Gorman, 1992) and large magneto-optic Kerr effect (SURFACE MAGNETO-OPTIC KERR EFFECT) signals compared to the Co/Pt multilayers in the whole range of wavelengths (820 to 400 nm; Weller et al., 1992, 1993) make these alloys potential magneto-optical recording materials. The chemical stability of these alloys, a suitable Curie temperature, and the ease of manufacturing enhance their usefulness in commercial applications. Furthermore, study of these alloys may lead to an improved understanding of the fundamental physics of magnetic anisotropy; the spin-polarization in the alloys being induced by the presence of Co whereas a large spin-orbit coupling effect can be associated with the Pt atoms.

Most experimental work on Co-Pt alloys has been on the ordered tetragonal phase, which has a very large magnetic anisotropy ~400 μeV, and magnetic easy axis along the *c* axis (Hadjipanayis and Gaunt, 1979; Lin and Gorman, 1992). We are not aware of any experimental work on the bulk disordered fcc phase of these alloys. However, some results have been reported for disordered fcc phase in the form of thin films (Weller et al., 1992, 1993; Suzuki et al., 1994; Maret et al., 1996; Tyson et al., 1996). It is found that the magnitude of MAE is more than one order of magnitude smaller than that of the bulk ordered phase, and that the magnetic easy axis varies with film thickness. From these data we can infer that a theoretical study of the MAE of the bulk disordered alloys provides insight into the mechanism of magnetic anisotropy in the ordered phase as well as in thin films. We investigated the magnetic anisotropy of disordered fcc phase of Co_cPt_{1-c} alloys for $c = 0.25$, 0.50, and 0.75 (as well as the pure elements Fe, Ni, and Co, and also Ni_cPt_{1-c}). In our calculations, we used self-consistent potentials from spin-polarized scalar-relativistic KKR-CPA calculations and predicted that the easy axis of magnetization is along the ⟨111⟩ direction of the crystal for all the three compositions, and the anisotropy is largest for $c = 0.50$.

In this first calculation of the MAE of disordered alloys we started with atomic sphere potentials generated from the self-consistent spin-polarized scalar relativistic KKR-CPA for Co_cPt_{1-c} alloys and constructed spin-dependent potentials. We recalculated the Fermi energy within the SPR-KKR-CPA method for magnetization along the ⟨001⟩ direction. This was necessary since earlier studies on the MAE of the 3*d* transition metal magnets were found to be quite sensitive to the position of the Fermi level (Daalderop et al., 1993; Strange et al., 1991). For all the three compositions of the alloy, the difference in the Fermi energies of the scalar relativistic and fully relativistic cases were of the order of 5 mRy, which is quite large compared to the magnitude of MAE. The second term in the expression above for the MAE was indeed small in comparison with the first, which needed to be evaluated very accurately. Details of the calculation can be found elsewhere (Razee et al., 1997).

In Figure 6, we show the MAE of disordered fcc-Co_cPt_{1-c} alloys for $c = 0.25$, 0.5, and 0.75 as a function of temperature between 0 K and 1500 K. We note that for all the three compositions, the MAE is positive at all temperatures, implying that the magnetic easy axis is always along the ⟨111⟩ direction of the crystal, although the magnitude of MAE decreases with increasing temperature. The magnetic easy axis of fcc Co is also along the ⟨111⟩ direction but the magnitude of MAE is smaller. Thus, alloying

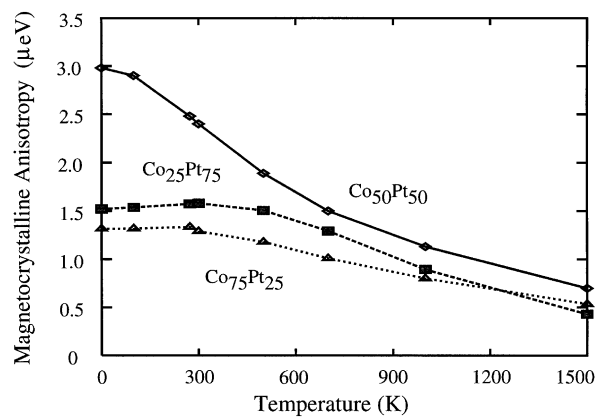

Figure 6. Magneto-anisotropy energy of disordered fcc-Co_cPt_{1-c} alloys for $c = 0.25$, 0.5, and 0.75 as a function of temperature. Adapted from Razee et al. (1997).

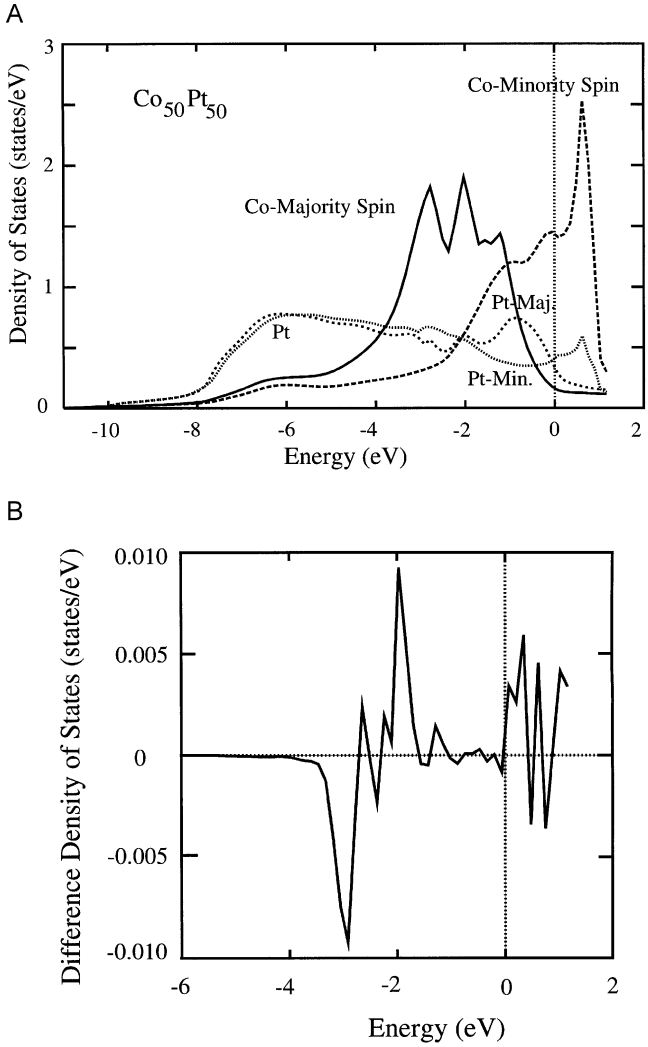

Figure 7. (**A**) The spin-resolved density of states on Co and Pt Atoms in the $Co_{0.50}Pt_{0.50}$ alloy magnetized along the ⟨001⟩ direction. (**B**) The density of states difference between the two magnetization directions for $Co_{0.50}Pt_{0.50}$. Adapted from Razee et al. (1997).

with Pt does not alter the magnetic easy axis. The equiatomic composition has the largest MAE, which is ~3.0 μeV at 0 K. In these alloys, one component (Co) has a large magnetic moment but weak spin-orbit coupling, while the other component (Pt) has strong spin-orbit coupling but small magnetic moment. Adding Pt to Co results in a monotonic decrease in the average magnetic moment of the system with the spin-orbit coupling becoming stronger. At $c = 0.50$, both the magnetic moment as well as the spin-orbit coupling are significant; for other compositions either the magnetic moment or the spin-orbit coupling is weaker. This trade-off between spin-polarization and spin-orbit coupling is the main reason for the MAE being largest around this equiatomic composition.

In finer detail, the magnetocrystalline anisotropy of a system can be understood in terms of its electronic structure. In Figure 7A, we show the spin-resolved density of states on Co and Pt atoms in the $Co_{0.50}Pt_{0.50}$ alloy magnetized along the ⟨001⟩ direction. The Pt density of states is rather structureless, except around the Fermi energy where there is spin-splitting due to hybridization with Co *d* bands. When the direction of magnetization is oriented along the ⟨111⟩ direction of the crystal, the electronic structure also changes due to redistribution of the electrons, but the difference is quite small in comparison with the overall density of states. So in Figure 7B, we have plotted the density of states difference for the two magnetization directions. In the lower part of the band, which is Pt-dominated, the difference between the two is small, whereas it is quite oscillatory in the upper part dominated by Co *d*-band complex. There are also spikes at energies where there are peaks in the Co-related part of the density of states. Due to the oscillatory nature of this curve, the magnitude of MAE is quite small; the two large peaks around 2 eV and 3 eV below the Fermi energy almost cancel each other, leaving only the smaller peaks to contribute to the MAE. Also, due to this oscillatory behavior, a shift in the Fermi level will alter the magnitude as well as the sign of the MAE. This curve also tells us that states far removed from the Fermi level (in this case, 4eV below the Fermi level) can also contribute to the MAE, and not just the electrons near the Fermi surface.

In contrast to what we have found for the disordered fcc phase of Co_cPt_{1-c} alloys, in the ordered tetragonal CoPt alloy the MAE is quite large (~400 μeV), two orders of magnitude greater than what we find for the disordered $Co_{0.50}Pt_{0.50}$ alloy. Moreover, the magnetic easy axis is along the *c* axis (Hadjipanayis and Gaunt, 1979). Theoretical calculations of MAE for ordered tetragonal CoPt alloy (Sakuma, 1994; Solovyev et al., 1995), based on scalar relativistic methods, do reproduce the correct easy axis but overestimate the MAE by a factor of 2. Currently, it is not clear whether it is the atomic ordering or the loss of cubic symmetry of the crystal in the tetragonal phase which is responsible for the altogether different magnetocrystalline anisotropies in disordered and ordered CoPt alloys. A combined effect of the two is more likely; we are studying the effect of atomic short-range order on the magnetocrystalline anisotropy of alloys.

PROBLEMS AND CONCLUSIONS

Magnetism in transition metal materials can be described in quantitative detail by spin-density functional theory (SDFT). At low temperatures, the magnetic properties of a material are characterized in terms of its spin-polarized electronic structure. It is on this aspect of magnetic alloys that we have concentrated. From this basis, the early Stoner-Wohlfarth picture of rigidly exchange-split, spin-polarized bands is shown to be peculiar to the elemental ferromagnets only. We have identified and shown the origins of two commonly occurring features of ferromagnetic alloy electronic structures, and the simple structure of the Slater-Pauling curve for these materials (average magnetic moment versus electron per atom ratio), can be traced back to the spin-polarized electronic structure.

The details of the electronic basis of the theory can, with care, be compared to results from modern spectroscopic

experiment. Much work is ongoing to make this comparison as rigorous as possible. Indeed, our understanding of metallic magnets and their scope for technological application are developing via the growing sophistication of some experiments, together with improvements in quantitative theory.

Although SDFT is "first-principled," most applications resort to the local approximation (LSDA) for the many electron exchange and correlation effects. This approximation is widely used and delivers good results in many calculations. It does have shortcomings, however, and there are many efforts aimed at trying to improve it. We have referred to some of this work, mentioning the "generalized gradient approximation" GGA and the "self-interaction correction" SIC in particular.

The LDA in magnetic materials fails when it is straightforwardly adapted to high temperatures. This failure can be redressed by a theory that includes the effects of thermally induced magnetic excitations, but which still maintains the spin-polarized electronic structure basis of standard SDFT. "Local moments," which are set up by the collective behavior of all the electrons, and are associated with atomic sites, change their orientations on a time scale which is long compared to the time that itinerant *d* electrons take to progress from site to site. Thus, we have a picture of electrons moving through a lattice of effective magnetic fields set up by particular orientations of these "local moments." At high temperatures, the orientations are thermally averaged, so that in the paramagnetic state there is zero magnetization overall. Although not spin-polarized "globally"—i.e., when averaged over all orientational configurations—the electronic structure is modified by the local-moment fluctuations, so that "local spin-polarization" is evident. We have described a mean field theory of this approach and have described its successes for the elemental ferromagnetic metals and for some iron alloys. The dynamical effects of these spin fluctuations in a first-principles theory remain to be included.

We have also emphasized how the state of magnetic order of an alloy can have a major effect on various other properties of the system, and we have dealt at length with its effect upon atomic short-range order by describing case studies of NiFe, FeV, and AuFe alloys. We have linked the results of our calculations with details of "globally" and "locally" spin-polarized electronic structure. The full consequences of lattice displacement effects have yet to be incorporated. We have also discussed the relativistic generalization of SDFT and covered its implication for the magnetocrystalline anisotropy of disordered alloys, with specific illustrations for CoPt alloys.

In summary, the magnetic properties of transition metal alloys are fundamentally tied up with the behavior of their electronic "glues." As factors like composition and temperature are varied, the underlying electronic structure can change and thus modify an alloy's magnetic properties. Likewise, as the magnetic order transforms, the electronic structure is affected and this, in turn, leads to changes in other properties. Here we have focused upon the effect on ASRO, but much could also have been written about the fascinating link between magnetism and elastic properties—"Invar" phenomena being a particularly dramatic example. The electronic mechanisms that thread all these properties together are very subtle, both to understand and to uncover. Consequently, it is often required that a study be attempted that is parameter-free as far as possible, so as to remove any pre-existing bias. This calculational approach can be very fruitful, provided it is followed alongside suitable experimental measurements as a check of its correctness.

KINEMATIC DIFFRACTION OF X RAYS

INTRODUCTION

Diffraction by x rays, electrons, or neutrons has enjoyed great success in crystal structure determination (e.g., the structures of DNA, high-T_c superconductors, and reconstructed silicon surfaces). For a perfectly ordered crystal, diffraction results in arrays of sharp Bragg reflection spots periodically arranged in reciprocal space. Analysis of the Bragg peak locations and their intensities leads to the identification of crystal lattice type, symmetry group, unit cell dimensions, and atomic configuration within a unit cell. On the other hand, for crystals containing lattice defects such as dislocations, precipitates, local ordered domains, surface, and interfaces, diffuse intensities are produced in addition to Bragg peaks. The distribution and magnitude of diffuse intensities are dependent on the type of imperfection present and the x-ray energy used in a diffraction experiment.

Diffuse scattering is usually weak, and thus more difficult to measure, but it is rich in structure information that often cannot be obtained by other experimental means. Since real crystals are generally far from perfect, many properties exhibited by them are therefore determined by the lattice imperfections present. Consequently, understanding of the atomic structures of these lattice imperfections (e.g., atomic short-range order, extended vacancy defect complexes, phonon properties, composition fluctuation, charge density waves, static displacements, and superlattices) and of the roles these imperfections play (e.g., precipitation hardening, residual stresses, phonon softening, and phase transformations) is of paramount importance if these materials properties are to be exploited for optimal use.

This unit addresses the fundamental principles of diffraction based upon the kinematic diffraction theory for x rays. (Nevertheless, the diffraction principles described in this unit may be extended to kinematic diffraction events involving thermal neutrons or electrons.) The accompanying DYNAMICAL DIFFRACTION is concerned with dynamic diffraction theory, which applies to diffraction from single crystals of high quality so that multiple scattering becomes significant and kinematic diffraction theory becomes invalid. In practice, most x-ray diffraction experiments are carried out on crystals containing a sufficiently large number of defects that kinematic theory is generally applicable.

This unit is divided into two major sections. In the first section, the fundamental principles of kinematic diffraction of x rays will be discussed and a systematic treatment of theory will be given. In the second section, the practical aspects of the method will be discussed; specific expressions for kinematically diffracted x-ray intensities will be described and used to interpret diffraction behavior from real crystals containing lattice defects. Neither specific diffraction techniques and analysis nor sample preparation methods will be described in this unit. Readers may refer to X-RAY TECHNIQUES for experimental details and specific applications.

PRINCIPLES OF THE METHOD

Overview of Scattering Processes

When a stream of radiation (e.g., photons or neutrons) strikes matter, various interactions can take place, one of which is the scattering process that may be best described using the wave properties of radiation. Depending on the energy, or wavelength, of the incident radiation, scattering may occur on different levels—at the atomic, molecular, or microscopic scale. While some scattering events are noticeable in our daily routines (e.g., scattering of visible light off the earth's atmosphere to give a blue sky and scattering from tiny air bubbles or particles in a glass of water to give it a hazy appearance), others are more difficult to observe directly with human eyes, especially for those scattering events that involve x rays or neutrons.

X rays are electromagnetic waves or photons that travel at the speed of light. They are no different from visible light, but have wavelengths ranging from a few hundredths of an angstrom (Å) to a few hundred angstroms. The conversion from wavelength to energy for all photons is given in the following equation with wavelength λ in angstroms and energy in kilo-electron volts (keV):

$$\lambda(\text{Å}) = \frac{c}{\nu} = \frac{12.40(\text{Å}\cdot\text{keV})}{E(\text{keV})} \qquad (1)$$

in which c is the speed of light (3×10^{18} Å/s) and ν is the frequency. It is customary to classify x rays with a wavelength longer than a few angstroms as "soft x rays" as opposed to "hard x rays" with shorter wavelengths ($\lesssim$1 Å) and higher energies ($\gtrsim$ keV).

In what follows, a general scattering theory will be presented. We shall concentrate on the kinematic scattering theory, which involves the following assumptions:

1. The traveling wave model is utilized so that the x-ray beam may be represented by a plane wave formula.
2. The source-to-specimen and the specimen-to-detector distances are considered to be far greater than the distances separating various scattering centers. Therefore, both the incident and the scattering beam can be represented by a set of parallel rays with no divergence.
3. Interference between x-ray beams scattered by elements at different positions is a result of superposition of those scattered traveling waves with different paths.
4. No multiple scattering is allowed: that is, the once-scattered beam inside a material will not rescatter. (This assumption is most important since it separates kinematic scattering theory from dynamic scattering theory.)
5. Only the elastically scattered beam is considered; conservation of x-ray energy applies.

The above assumptions form the basis of the kinematic scattering/diffraction theory; they are generally valid

assumptions in the most widely used methods for studying scattering and diffraction from materials. In some cases, such as diffraction from perfect or nearly perfect single crystals, dynamic scattering theory must be employed to explain the nature of the diffraction events (DYNAMICAL DIFFRACTION). In other cases, such as Compton scattering, where energy exchanges occur in addition to momentum transfers, inelastic scattering theories must be invoked.

While the word "scattering" refers to a deflection of beam from its original direction by the scattering centers that could be electrons, atoms, molecules, voids, precipitates, composition fluctuations, dislocations, and so on, the word "diffraction" is generally defined as the constructive interference of coherently scattered radiation from regularly arranged scattering centers such as gratings, crystals, superlattices, and so on. Diffraction generally results in strong intensity in specific, fixed directions in reciprocal (momentum) space, which depend on the translational symmetry of the diffracting system. Scattering, however, often generates weak and diffuse intensities that are widely distributed in reciprocal space. A simple picture may be drawn to clarify this point. For instance, interaction of radiation with an amorphous substance is a "scattering" process that reveals broad and diffuse intensity maxima, whereas with a crystal it is a "diffraction" event, as sharp and distinct peaks appear. Sometimes the two words are interchangeable, as the two events may occur concurrently or indistinguishably.

Elementary Kinematic Scattering Theory

In Figure 1, an incoming plane wave P_1, traveling in the direction specified by the unit vector $\mathbf{s}_0$, interacts with the specimen, and the scattered beam, another plane wave P_2, travels along the direction $\mathbf{s}$, again a unit vector. Taking into consideration increments of volume within the specimen, ΔV_1, waves scattered from different increments of volume will interfere with each other: that is, their instantaneous amplitudes will be additive (a list of symbols used is contained in the Appendix). Since the variation of amplitude with time will be sinusoidal, it is necessary to keep track of the phase of the wave scattered from individual volume elements. Therefore the scattered wave along $\mathbf{s}$ is made up of components scattered from the individual volume elements, the path differences traveled by each individual ray traveling from P_1 to P_2. In reference to an arbitrary point O in the specimen, the path difference between a ray scattered from the volume element ΔV_1 and that from O is

$$\Delta r_1 = \mathbf{r}_1 \cdot \mathbf{s} - \mathbf{r}_1 \cdot \mathbf{s}_0 = \mathbf{r}_1 \cdot (\mathbf{s} - \mathbf{s}_0) \tag{2}$$

Thus, the difference in phase between waves scattered from the two points will be proportional to the difference in distances that the two waves travel from P_1 to P_2—a path difference equal to the wavelength λ, corresponding to a phase difference ϕ of 2π radians:

$$\frac{\phi}{2\pi} = \frac{\Delta r_1}{\lambda} \tag{3}$$

In general, the phase of the wave scattered from the jth increment of volume ΔV_j, relative to the phase of the wave scattered from the origin O, will thus be

$$\phi_j = \frac{2\pi(\mathbf{s} - \mathbf{s}_0) \cdot \mathbf{r}_j}{\lambda} \tag{4}$$

Equation 4 may be expressed by $\phi_j = 2\pi \mathbf{K} \cdot \mathbf{r}_j$, where $\mathbf{K}$ is the scattering vector (Fig. 2),

$$\mathbf{K} = \frac{\mathbf{s} - \mathbf{s}_0}{\lambda} \tag{5}$$

The phase of the scattered radiation is then expressed by the plane wave $e_j^{i\phi}$, and the resultant amplitude is obtained by summing over the complex amplitudes scattered from each incremental scattering center:

$$A = \sum_j f_j e^{2\pi i \mathbf{K} \cdot \mathbf{r}_j} \tag{6}$$

where f_j is the scattering power, or scattering length, of the jth volume element (this scattering power will be further discussed a little later). For a continuous medium viewed on a larger scale, as is the case in small-angle scattering,

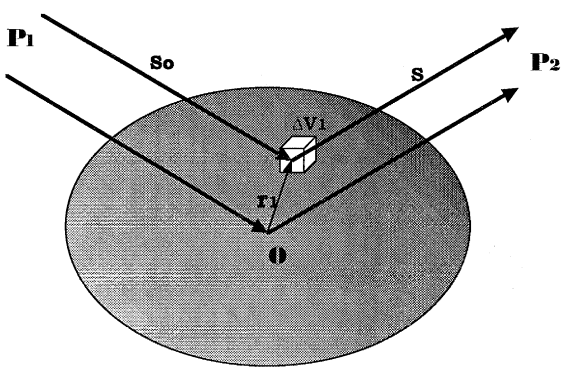

Figure 1. Schematics showing a diffracting element ΔV_1 at a distance $\mathbf{r}_1$ from an arbitrarily chosen origin O in the crystal. The incident and the diffraction beam directions are indicated by the unit vectors, $\mathbf{s}_0$ and $\mathbf{s}$, respectively.

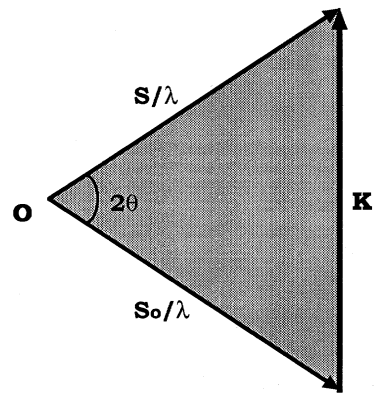

Figure 2. The diffraction condition is determined by the incident and the scattering beam direction unit vectors normalized against the specified wavelength (λ). The diffraction vector $\mathbf{K}$ is defined as the difference of the two vectors $\mathbf{s}/\lambda$ and $\mathbf{s}_0/\lambda$. The diffraction angle, 2θ, is defined by these two vectors as well.

the summation sign in Equation 6 may be replaced by an integral over the entire volume of the irradiated specimen.

The scattered intensity, $I(\mathbf{K})$, written in absolute units, which are commonly known as electron units, is proportional to the square of the amplitude in Equation 6:

$$I(\mathbf{K}) = AA^* = \left| \sum_j f_j e^{2\pi i \mathbf{K}\cdot\mathbf{r}_j} \right|^2 \tag{7}$$

Diffraction from a Crystal

For a crystalline material devoid of defects, the atomic arrangement may be represented by a primitive unit cell with lattice vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ that display a particular set of translational symmetries. Since every unit cell is identical, the above summation over the diffracting volume within a crystal can be replaced by the summation over a single unit cell followed by a summation over the unit cells contained in the diffraction volume:

$$I(\mathbf{K}) = \left| \sum_j^{\text{u.c.}} f_j e^{2\pi i \mathbf{K}\cdot\mathbf{r}_j} \right|^2 \left| \sum_n e^{2\pi i \mathbf{K}\cdot\mathbf{r}_n} \right|^2 = |F(\mathbf{K})|^2 |G(\mathbf{K})|^2 \tag{8}$$

The first term, known as the structure factor, $F(\mathbf{K})$, is a summation of all scattering centers within one unit cell (u.c.). The second term defines the interference function, $G(\mathbf{K})$, which is a Fourier transformation of the real-space point lattice. The vector $\mathbf{r}_n$ connects the origin to the nth lattice point and is written as:

$$\mathbf{r}_n = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3 \tag{9}$$

where n_1, n_2, and n_3 are integers. Consequently, the single summation for the interference function may be replaced by a triple summation over n_1, n_2, and n_3:

$$|G(\mathbf{K})|^2 = \left| \sum_{n_1}^{N_1} e^{2\pi i \mathbf{K}\cdot n_1\mathbf{a}_1} \right|^2 \left| \sum_{n_2}^{N_2} e^{2\pi i \mathbf{K}\cdot n_2\mathbf{a}_2} \right|^2 \left| \sum_{n_3}^{N_3} e^{2\pi i \mathbf{K}\cdot n_3\mathbf{a}_3} \right|^2 \tag{10}$$

where N_1, N_2, and N_3 are numbers of unit cells along the three lattice vector directions, respectively. For large N_i, Equation 10 reduces to

$$|G(\mathbf{K})|^2 = \frac{\sin^2(\pi\mathbf{K}\cdot N_1\mathbf{a}_1)}{\sin^2(\pi\mathbf{K}\cdot\mathbf{a}_1)} \frac{\sin^2(\pi\mathbf{K}\cdot N_2\mathbf{a}_2)}{\sin^2(\pi\mathbf{K}\cdot\mathbf{a}_2)} \frac{\sin^2(\pi\mathbf{K}\cdot N_3\mathbf{a}_3)}{\sin^2(\pi\mathbf{K}\cdot\mathbf{a}_3)} \tag{11}$$

A general display of the above interference function is shown in Figure 3. First, the function is a periodic one. Maxima occur at specific $\mathbf{K}$ locations followed by a series of secondary maxima with much reduced amplitudes. It is noted that the larger the N_i the sharper the peak, because the width of the peak is inversely proportional to N_i while the peak height equals N_i^2. When N_i approaches

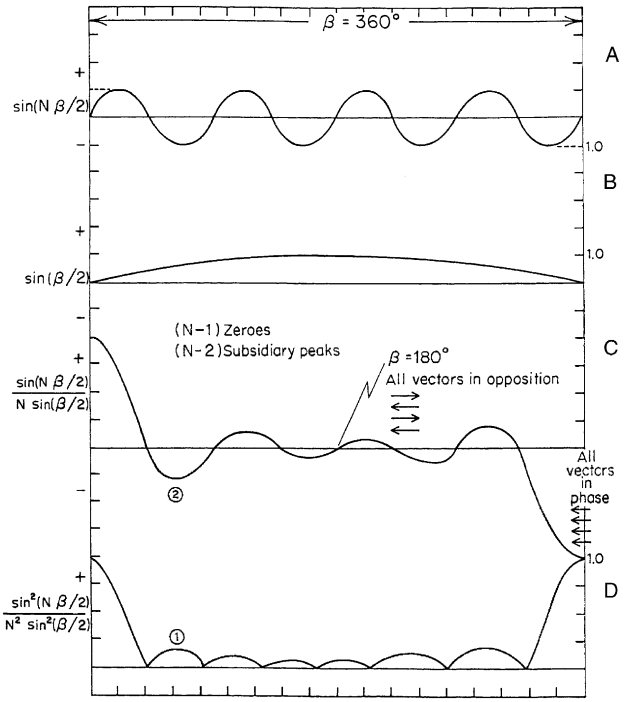

Figure 3. Schematic drawing of the interference function for $N = 8$ showing periodicity with angle β. The amplitude of the function equals N^2 while the width of the peak is proportional to $1/N$, where N represents the number of unit cells contributing to diffraction. There are $N - 1$ zeroes in (**D**) and $N - 2$ subsidary maxima besides the two large ones at $\beta = 0°$ and 360°. Curves (**C**) and (**D**) have been normalized to unity. After Buerger (1960).

infinity, the interference function is a delta function with a value N_i. Therefore, when $N_{i\to\infty}$, Equation 11, becomes

$$|G(\mathbf{K})|^2 = N_1N_2N_3 = N_v \tag{12}$$

where N_v is the total number of unit cells in the diffracting volume.

For diffraction to occur from such a three-dimensional (3D) crystal, the following three conditions must be satisfied simultaneously to give constructive interference, that is, to have significant values for $G(\mathbf{K})$

$$\mathbf{K}\cdot\mathbf{a}_1 = h, \quad \mathbf{K}\cdot\mathbf{a}_2 = k, \quad \mathbf{K}\cdot\mathbf{a}_3 = l \tag{13}$$

where h, k, and l are integers. These are three conditions known as Laue conditions. Obviously, for diffraction from a lower-dimensional crystal, one or two of the conditions are removed. The Laue conditions, Equation 13, indicate that scattering is described by sets of planes spaced h/a_1, k/a_2, and l/a_3 apart and perpendicular to $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$, respectively. Therefore, diffraction from a one-dimensional (1D) crystal with a periodicity a would result in sheets of intensities perpendicular to the crystal direction and separated by a distance $1/a$. For a two-dimensional (2D) crystal, the diffracted intensities would be distributed along rods normal to the crystal plane. In three dimensions

(3D), the Laue conditions define arrays of points that form the reciprocal lattice.

The reciprocal lattice may be defined by means of three reciprocal space lattice vectors that are, in turn, defined from the real-space primitive unit cell vectors as in Equation 14:

$$\mathbf{b}_i = \frac{\mathbf{a}_j \times \mathbf{a}_k}{V_a} \tag{14}$$

where i, j, and k are permutations of three integers, 1, 2, and 3, and V_a is the volume of the primitive unit cell constructed by $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$. There exists an orthonormal relationship between the real-space and the reciprocal space lattice vectors, as in Equation 15:

$$\mathbf{a}_i \cdot \mathbf{b}_j = \delta_{ij} \tag{15}$$

where δ_{ij} is the Kronecker delta function, which is defined as

$$\begin{aligned} \delta_{ij} &= 1 \qquad \text{for} \quad i = j \\ &= 0 \qquad \text{for} \quad i \neq j \end{aligned} \tag{16}$$

A reciprocal space vector $\mathbf{H}$ can thus be expressed as a summation of reciprocal space lattice vectors:

$$\mathbf{H} = h\,\mathbf{b}_1 + k\,\mathbf{b}_2 + l\,\mathbf{b}_3 \tag{17}$$

where h, k, and l are integers. The magnitude of this vector, $\mathbf{H}$, can be shown to be equal to the inverse of the interplanar spacing, d_{hkl}. It can also be shown that the vector $\mathbf{H}$ satisfies the three Laue conditions (Equation 13). Consequently, the interference function in Equation 11 would have significant values when the following condition is satisfied

$$\mathbf{K} = \mathbf{H} \tag{18}$$

This is the vector form of Bragg's law.

As shown in Equation 18 and Figure 2, when the scattering vector $\mathbf{K}$, as defined according to the incident and the diffracted beam directions and the associated wavelength, matches one of the reciprocal space lattice vectors $\mathbf{H}$, the interference function will have significant value, thereby showing constructive interference—Bragg diffraction. It can be shown by taking the magnitudes of the two vectors $\mathbf{H}$ and $\mathbf{K}$ that the familiar scalar form of the Bragg's law is recovered:

$$2d_{hkl} \sin\theta = n\lambda \qquad n = 1, 2, \ldots \tag{19}$$

By combining Equations 12 and 8, we now conclude that when Bragg's law is met (i.e., when $\mathbf{K} = \mathbf{H}$), the diffracted intensity becomes

$$I(\mathbf{K}) = N_v |F(\mathbf{K})|^2 \tag{20}$$

Structure Factor

The structure factor, designated by the symbol F, is obtained by adding together all the waves scattered from one unit cell; it therefore displays the interference effect among all scattering centers within one unit cell. Certain extinction conditions may appear for a combination of h, k, and l values as a result of the geometrical arrangement of atoms or molecules within the unit cell. If a unit cell contains N atoms, with fractional coordinates x_i, y_i, and z_i for the ith atom in the unit cell, then the structure factor for the hkl reflection is given by

$$F(hkl) = \sum_i^N f_i e^{2\pi i(hx_i + ky_i + lz_i)} \tag{21}$$

where the summation extends over all the N atoms of the unit cell. The parameter F is generally a complex number and expresses both the amplitude and phase of the resultant wave. Its absolute value gives the magnitude of diffracting power as given in Equation 20.

Some examples of structure-factor calculations are given as follows:

1. For all primitive cells with one atom per lattice point, the coordinates for this atom are 0 0 0. The structure factor is

$$F = f \tag{22}$$

2. For a body-centered cell with two atoms of the same kind, their coordinates are 0 0 0 and $\frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}$, and the structure factor is

$$F = f\left(1 + e^{\pi i(h+k+l)}\right) \tag{23}$$

This expression may be evaluated for any combination of h, k, and l integers. Therefore,

$$\begin{aligned} F &= 2f \qquad \text{when } (h+k+l) \text{ is even} \\ F &= 0 \qquad \text{when } (h+k+l) \text{ is odd} \end{aligned} \tag{24}$$

3. Consider a face-centered cubic (fcc) structure with identical atoms at $x, y, z = 0\ 0\ 0$, $\frac{1}{2}\ \frac{1}{2}\ 0$, $\frac{1}{2}\ 0\ \frac{1}{2}$, and $0\ \frac{1}{2}\ \frac{1}{2}$. The structure factor is

$$\begin{aligned} F &= f\left(1 + e^{\pi i(h+k)} + e^{\pi i(k+l)} + e^{\pi i(l+h)}\right) \\ &= 4f \qquad \text{for } h, k, l \text{ all even or all odd} \\ &= 0 \qquad \text{for mixed } h, k, \text{ and } l \end{aligned} \tag{25}$$

4. Zinc blend (ZnS) has a common structure that is found in many Group III-V compounds such as GaAs and InSb and there are four Zn and four S atoms per fcc unit cell with the coordinates shown below:

$$\begin{aligned} \text{Zn:} \quad & 0\ 0\ 0, \ \ \frac{1}{2}\,\frac{1}{2}\,0, \ \ \frac{1}{2}\ 0\,\frac{1}{2}, \ \ \text{and} \ \ 0\,\frac{1}{2}\,\frac{1}{2} \\ \text{S:} \quad & \frac{1}{4}\,\frac{1}{4}\,\frac{1}{4}, \ \ \frac{3}{4}\,\frac{3}{4}\,\frac{1}{4}, \ \ \frac{3}{4}\,\frac{1}{4}\,\frac{3}{4}, \ \ \text{and} \ \ \frac{1}{4}\,\frac{3}{4}\,\frac{3}{4} \end{aligned}$$

The structure factor may be reduced to

$$F = \left(f_{\text{Zn}} + f_{\text{S}} e^{\frac{\pi i}{2}(h+k+l)}\right)\left(1 + e^{\pi i(h+k)} + e^{\pi i(k+l)} + e^{\pi i(l+h)}\right) \tag{26}$$

The second term is equivalent to the fcc conditions as in Equation 25, so h, k, and l must be unmixed integers. The first term further modifies the structure factor to yield

$$\begin{aligned} F &= f_{Zn} + f_S \quad \text{when} \quad h+k+l = 4n \text{ and } n \text{ is integer} \\ &= f_{Zn} + if_S \quad \text{when} \quad h+k+l = 4n+1 \\ &= f_{Zn} - f_S \quad \text{when} \quad h+k+l = 4n+2 \\ &= f_{Zn} - if_S \quad \text{when} \quad h+k+l = 4n+3 \end{aligned} \tag{27}$$

Scattering Power and Scattering Length

X rays are electromagnetic waves; they interact readily with electrons in an atom. In contrast, neutrons scatter most strongly from nuclei. This difference in contrast origin results in different scattering powers between x rays and neutrons even from the same species (see Chapter 13).

For a stream of unpolarized, or randomly polarized, x rays scattered from one electron, the scattered intensity, I_e, is known as the Thomson scattering per electron:

$$I_e = \frac{I_0 e^4}{m^2 r^2 c^4}\left(\frac{1+\cos^2 2\theta}{2}\right) \tag{28}$$

where I_e is the incident beam flux, e is the electron charge, m is the electron mass, c is the speed of light, r is the distance from the scattering center to the detector position, and 2θ is the scattering angle (Fig. 2). The factor $(1 + \cos^2 2\theta)/2$ is often referred to as the polarization factor. If the beam is fully or partially polarized, the total polarization factor will naturally be different. For instance, for synchrotron storage rings, x rays are linearly polarized in the plane of the ring. Therefore, if the diffraction plane containing vectors $\mathbf{s}_0$ and $\mathbf{s}$ in Figure 2 is normal to the storage ring plane, the polarization is unchanged during scattering.

Scattering of x rays from atoms is predominantly from the electrons in the atom. Because electrons in an atom do not assume a fixed position but rather are described by a wave function that satisfies the Schrodinger equation in quantum mechanics, the scattering power for x rays from an atom may be expressed by an integration of all waves scattered from these electrons as represented by an electron density function, $\rho(\mathbf{r})$,

$$f(\mathbf{K}) = \int_{\text{atom}} \rho(\mathbf{r}) e^{2\pi i \mathbf{K}\cdot\mathbf{r}} dV_{\mathbf{r}} \tag{29}$$

where $dV_{\mathbf{r}}$ is the volume increment and the integration is taken over the entire volume of the atom. The quantity f in Equation 29 is the scattering amplitude of an atom relative to that for a single electron. It is commonly known as the atomic scattering factor for x rays. The magnitude of f for different atomic species can be found in many text and reference books.

There are dispersion corrections to be made to f. These include a real and an imaginary component: the real part is related to the bonding nature of the negatively charged electrons with the positively charged nucleus, whereas the imaginary part concerns the absorption effect. Thus the true atomic scattering factor should be written

$$f = f_0 + \Delta f' + i\Delta f'' \tag{30}$$

Tabulated values for these correction terms, often referred to as the Honl corrections, can be found in the International Table for X-ray Crystallography (1996) or other references.

In conclusion, the intensity expressions shown in Equations 7, 8, and 20 are written in electron units, an absolute unit independent of incident beam flux and polarization factor. These intensity expressions represent the fundamental forms of kinematic diffraction. Applications of these fundamental diffraction principles to several specific examples of scattering and diffraction will be discussed in the following section.

PRACTICAL ASPECTS OF THE METHOD

Lattice defects may be classified as follows: (1) intrinsic defects, such as phonons and magnetic spins; (2) point defects, such as vacancies, substitutional, and interstitial solutes; (3) linear defects, such as dislocations, 1D superlattices, and charge density waves; (4) planar defects, such as twins, grain boundaries, surfaces, and interfaces; and (5) volume defects, such as voids, inclusions, precipitate particles, and magnetic clusters. In this section, kinematically scattered x-ray diffuse intensity expressions will be presented to correlate to lattice defects. Specific examples include: (1) thermal diffuse scattering from phonons, (2) short-range ordering or clustering in binary alloys, (3) surface/interface diffraction for reconstruction and interface structure, and (4) small-angle x-ray scattering from nanometer-sized particles dispersed in an otherwise uniform matrix. Not included in the discussion is the most fundamental use of the Bragg peak intensities for the determination of crystal structure from single crystals and for the analysis of lattice parameter, particle size distribution, preferred orientation, residual stress, and so on, from powder specimens. Discussion of these topics may be found in X-RAY POWDER DIFFRACTION and in many excellent books [e.g., Azaroff and Buerger (1958), Buerger (1960), Cullity (1978), Guinier (1994), Klug and Alexander (1974), Krivoglaz (1969), Noyan and Cohen (1987), Schultz (1982), Schwartz and Cohen (1987), and Warren (1969)].

Thermal Diffuse Scattering (TDS)

At any finite temperature, atoms making up a crystal do not stay stationary but rather vibrate in an cooperative manner; this vibrational amplitude usually becomes bigger at higher temperatures. Because of the periodic nature of crystals and the interconnectivity of an atomic network coupled by force constants, the vibration of an atom at a given position is related to the vibrations of others via atomic displacement waves (known as phonons) traveling through a crystal. The displacement of each atom is the sum total of the effects of these waves. Atomic vibration is considered one “imperfection” or “defect” that is intrinsic

to the crystal and is present at all times. The scattering process for phonons is basically inelastic, and involves energy transfer as well as momentum transfer. However, for x rays the energy exchange in such an inelastic scattering process is only a few hundredths of an electron volt, much too small compared to the energy of the x-ray photon used (typically in the neighborhood of thousands of electron volt) to allow them to be conveniently separated from the elastically scattered x rays in a normal diffraction experiment. As a result, thermal diffuse x-ray scattering may be treated in either a quasielastic or elastic manner. Such is not the case with thermal neutron scattering since energy resolution in this case is sufficient to separate the inelastic scattering due to phonons from other elastic parts. In this section, we shall discuss thermal diffuse x-ray scattering only.

The development of the scattering theory of the effect of thermal vibration on the x-ray diffraction in crystals is associated primarily with the Debye (1913a,b,c, 1913–1914), Waller (1923), Faxen (1918, 1923), and James (1948). The whole subject was brought together for the first time in a book by James (1948). Warren (1969), who adopted the approach of James, has written a comprehensive chapter on this subject on which this section is based. What follows is a short summary of the formulations used in the thermal diffuse x-ray scattering analysis. Examples of TDS applications may be found in Warren (1969) and in papers by Dvorack and Chen (1983) and by Takesue et al. (1997).

The most familiar effect of temperature vibration is the reduction of the Bragg reflections by the well-known Debye-Waller factor. This effect may be seen from the structure factor calculation:

$$F(\mathbf{K}) = \sum_{m}^{\text{u.c.}} f_m e^{2\pi i \mathbf{K}\cdot\mathbf{r}_m} \tag{31}$$

where the upper limit, u.c., means summation over the unit cell.

Let $\mathbf{r}_m = \mathbf{r}_m^0 + \mathbf{u}_m(t)$, where $\mathbf{r}_m^0$ represents the average location of the mth atom and $\mathbf{u}_m$ is the dynamic displacement, a function of time t. Thus,

$$F(\mathbf{K}) = \sum_{m}^{\text{u.c.}} f_m e^{2\pi i \mathbf{K}\cdot\mathbf{r}_m^0} e^{2\pi i \mathbf{K}\cdot\mathbf{u}_m} \tag{32}$$

As a first approximation, the second exponential term in Equation 32 may be expanded into a Taylor series up to the second-order terms:

$$e^{2\pi i \mathbf{K}\cdot\mathbf{u}_m} \approx 1 + 2\pi i \mathbf{K}\cdot\mathbf{u}_m - 2\pi^2(\mathbf{K}\cdot\mathbf{u}_m)^2 + \cdots \tag{33}$$

A time average may be performed for Equation 33, as a typical TDS experiment measuring interval is much longer than the phonon vibrational period, so that

$$\langle e^{2\pi i \mathbf{K}\cdot\mathbf{u}_m}\rangle \approx 1 - 2\pi^2\langle(\mathbf{K}\cdot\mathbf{u}_m)^2\rangle + \cdots \tag{34}$$

In arriving at Equation 34, the linear average of the displacement field is set to zero, as is true for a random thermal vibration. Thus,

$$\langle e^{2\pi i \mathbf{K}\cdot\mathbf{u}_m}\rangle \approx e^{-2\pi^2\langle(\mathbf{K}\cdot\mathbf{u}_m)^2\rangle} = e^{-M_m} \tag{35}$$

where $M_m = 2\pi^2\langle(\mathbf{K}\cdot\mathbf{u}_m)^2\rangle$, known as the Debye-Waller temperature factor for mth atom.

Therefore, the total scattering intensity that is proportional to the square of the structure factor reduces to

$$I(\mathbf{K}) \propto \langle|F(\mathbf{K})|^2\rangle \approx \left|\sum_{m}^{\text{u.c.}} f_m e^{-M_m} e^{2\pi i \mathbf{K}\cdot\mathbf{r}_m^0}\right|^2 \tag{36}$$

It now becomes obvious that thermal vibrations of atoms reduce the x-ray scattering intensities by the effect of the Debye-Waller temperature factor, exp(–M), in which M is proportional to the mean-squared displacement of a vibrating atom and is 2θ dependent. The effect of the Debye-Waller factor is to decrease the amplitude of a given Bragg reflection but to keep the diffraction profile unaltered. The above approximation assumed that each individual atom vibrates independently from others; this is naturally incorrect, as correlated vibrations of atoms by way of lattice waves (phonons) are present in crystals. This cooperative motion of atoms must be included in the TDS treatment. A more rigorous approach, in accord with the TDS treatment of Warren (1969), is now described for a cubic crystal with one atom per unit cell.

Starting with a general intensity equation expressed in terms of electron units and defining the time-dependent dynamic displacement vector $\mathbf{u}_m$, one obtains

$$\begin{aligned} I(\mathbf{K}) &= \left\langle \left| \sum_{m}^{\text{u.c.}} f_m e^{2\pi i \mathbf{K}\cdot\mathbf{r}_m} \right|^2 \right\rangle \\ &= \left\langle \sum_{m}^{\text{u.c.}} f_m e^{2\pi i \mathbf{K}\cdot\mathbf{r}_m} \sum_{n}^{\text{u.c.}} f_n e^{-2\pi i \mathbf{K}\cdot\mathbf{r}_n} \right\rangle \\ &= \left\langle \left| \sum_{m}^{\text{u.c.}} \sum_{n}^{\text{u.c.}} f_m f_n^* e^{2\pi i \mathbf{K}\cdot\mathbf{r}_m n} \right|^2 \right\rangle \\ &= \sum_{m}^{\text{u.c.}} \sum_{n}^{\text{u.c.}} |f_m f_n^*| e^{2\pi i \mathbf{K}\cdot\mathbf{r}_{mn}^0} \langle e^{2\pi i \mathbf{K}\cdot\mathbf{u}_{mn}}\rangle \end{aligned} \tag{37}$$

in which $\mathbf{r}_{mn} = \mathbf{r}_m - \mathbf{r}_n$, $\mathbf{r}_{mn}^0 = \mathbf{r}_m^0 - \mathbf{r}_n^0$, and $\mathbf{u}_{mn} = \mathbf{u} - \mathbf{u}_n$. Therefore, coupling between atoms is kept in the term $\mathbf{u}_{mn}$. Again, the approximation is applied with the assumption that a small vibrational amplitude is considered, so that a Taylor expansion may be used and the linear average set to zero:

$$\begin{aligned} \langle e^{2\pi i \mathbf{K}\cdot\mathbf{u}_{mn}}\rangle &\approx 1 - 2\pi^2\langle(\mathbf{K}\cdot\mathbf{u}_{mn})^2\rangle \approx e^{-2\pi^2\langle(\mathbf{K}\cdot\mathbf{u}_{mn})^2\rangle} \\ &= e^{\langle P_{mn}^2\rangle/2} \end{aligned} \tag{38}$$

where

$$\langle P_{mn}^2\rangle \equiv 4\pi^2\langle(\mathbf{K}\cdot\mathbf{u}_{mn})^2\rangle \tag{39}$$

The coupling between atomic vibrations may be expressed by traveling sinusoidal lattice waves, the concept of "phonons." Each lattice wave may be represented by a wave vector $\mathbf{g}$ and a frequency ω_{gj}, in which the j subscript denotes the jth component ($j = 1, 2, 3$) of the $\mathbf{g}$ lattice wave. Therefore, the total dynamic displacement of the nth atom is the sum of all lattice waves as seen in Equation 40

$$\mathbf{u}_n = \sum_{g,j} \mathbf{u}_n(g,j) \tag{40}$$

where

$$\mathbf{u}_n(g,j) = a_{gj}\mathbf{e}_{gj}\cos(\omega_{gj}t - 2\pi\mathbf{g}\cdot\mathbf{r}_n^0 - \delta_{gj}) \tag{41}$$

and a_{gj} is the vibrational amplitude; $\mathbf{e}_{gj}$ is the unit vector of the vibrating direction, that is, the polarization vector, for the gj wave; $\mathbf{g}$ is the propagation wave vector; δ_{gj} is an arbitrary phase factor; ω_{gj} is the frequency; and t is the time.

Thus, Equation 39 may be rewritten

$$\langle P_{mn}^2\rangle = 4\pi^2\left\langle\left\{\left[\sum_{gj}\mathbf{K}\cdot a_{gj}\mathbf{e}_{gj}\cos(\omega_{gj}t - 2\pi\mathbf{g}\cdot\mathbf{r}_m^0 - \delta_{gj})\right] - \left[\sum_{g'j'}\mathbf{K}\cdot a_{g'j'}\mathbf{e}_{g'j'}\cos\left(\omega_{g'j'}t - 2\pi\mathbf{g}'\cdot\mathbf{r}_n^0 - \delta_{g'j'}\right)\right]\right\}^2\right\rangle \tag{42}$$

After some mathematical manipulation, Equation 42 reduces to

$$\langle P_{mn}^2\rangle = \sum_{gj}\left\{(2\pi\mathbf{K}\cdot\mathbf{e}_{gj})^2\langle a_{gj}^2\rangle[1 - \cos(2\pi\mathbf{g}\cdot\mathbf{r}_{mn}^0)]\right\} \tag{43}$$

Defining $G_{gj} = \frac{1}{2}(2\pi\mathbf{K}\cdot\mathbf{e}_{gj})^2\langle a_{gj}^2\rangle$ and $\sum_{gj} G_{gj} = 2M$ causes the scattering equation for a single element system to reduce to

$$I(\mathbf{K}) = \sum_m^{\text{u.c.}}\sum_n^{\text{u.c.}} |fe^{-M}|^2 e^{2\pi i\mathbf{K}\bullet\mathbf{r}_{mn}^0}\cdot e^{\sum_{gj}G_{gj}\cos(2\pi\mathbf{g}\cdot\mathbf{r}_{mn}^0)} \tag{44}$$

where the first term in the product is equivalent to Equation 36, which represents scattering from the average lattice—that is, Bragg reflections—modified by the Debye-Waller temperature factor. The phonon coupling effect is contained in the second term of the product. The Debye-Waller factor $2M$ is the sum of G_{gj}, which is given by

$$2M \equiv \sum_{gj} G_{gj} = \sum_{gj}\frac{1}{2}(2\pi\mathbf{K}\cdot\mathbf{e}_{gj})^2\langle a_{gj}^2\rangle = \left(\frac{4\pi\sin\theta}{\lambda}\right)^2\left[\sum_{gj}\frac{1}{2}\langle a_{gj}^2\rangle\cos^2(\mathbf{K},\mathbf{e}_{gj})\right] \tag{45}$$

where the term in brackets is the mean-square displacement projected along the diffraction vector $\mathbf{K}$ direction.

Again, assuming small vibrational amplitude, the second term in the product of Equation 44 may be expanded into a series:

$$e^x \approx 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \cdots \tag{46}$$

Therefore, Equation 44 becomes

$$I(\mathbf{K}) \approx \sum_m\sum_n |fe^{-M}|^2 e^{2\pi i\mathbf{K}\cdot\mathbf{r}_{mn}^0}\cdot\left[1 + \sum_{gj}G_{gj}\cos(2\pi\mathbf{g}\cdot\mathbf{r}_{mn}^0) + \frac{1}{2}\sum_{gj}\sum_{g'j'}G_{gj}G_{g'j'}\cos(2\pi\mathbf{g}\cdot\mathbf{r}_{mn}^0)\times\cos(2\pi\mathbf{g}'\cdot\mathbf{r}_{mn}^0) + \cdots\right] \tag{47}$$

The first term, the zeroth-order thermal effect, in Equation 47 is the Debye-Waller factor−modified Bragg scattering followed by the first-order TDS, the second-order TDS, and so on. The first-order TDS is a one-phonon scattering process by which one phonon will interact with the x ray resulting in an energy and momentum exchange. The second-order TDS involves the interaction of one photon with two phonons. The expression for first-order TDS may be further simplified and related to lattice dynamics; this is described in this section. Higher-order TDS (for which force constants are required) usually become rather difficult to handle. Fortunately, they become important only at high temperatures (e.g., near and above the Debye temperature).

The first-order TDS intensity may be rewritten as follows:

$$I_1^{\text{TDS}}(\mathbf{K}) = \frac{1}{2}f^2e^{-2M}\sum_{gj}G_{gj}\left[\sum_m\sum_n e^{2\pi i(\mathbf{K}+\mathbf{g})\cdot\mathbf{r}_{mn}^0} + \sum_m\sum_n e^{2\pi i(\mathbf{K}-\mathbf{g})\cdot\mathbf{r}_{mn}^0}\right] \tag{48}$$

To obtain Equation 48, the following equivalence was used

$$\cos(x) = \frac{e^{ix} + e^{-ix}}{2} \tag{49}$$

The two double summations in the square bracket are in the form of the 3D interference function, the same as $G(\mathbf{K})$ in Equation 11, with wave vectors $\mathbf{K} + \mathbf{g}$ and $\mathbf{K} - \mathbf{g}$, respectively. We understand that the interference function has a significant value when its vector argument, $\mathbf{K} + \mathbf{g}$ and $\mathbf{K} - \mathbf{g}$ in this case, equals to a reciprocal lattice vector, $\mathbf{H}(hkl)$. Consequently, the first-order TDS reduces to

$$I_1^{\text{TDS}}(\mathbf{K}) = \frac{1}{2}f^2e^{-2M}\sum_{gj}G_{gj}[G(\mathbf{K}+\mathbf{g}) + G(\mathbf{K}-\mathbf{g})] = \frac{1}{2}N_v^2f^2e^{-2M}\sum_j G_{gj} \tag{50}$$

when $\mathbf{K} \pm \mathbf{g} = \mathbf{H}$, and N_v is the total number of atoms in the irradiated volume of the crystal.

Approximations may be applied to G_{gj} to relate it to more meaningful and practical parameters. For example, the mean kinetic energy of lattice waves is

$$\frac{1}{2}\left\langle \sum_n m \frac{d\mathbf{u}_n}{dt} \right\rangle^2 \tag{50a}$$

in which the displacement term $\mathbf{u}_n$ has been given in Equations 40 and 41, and m is the mass of a vibrating atom. If we take a first derivative of Equation 40 with respect to time (t), the kinetic energy (K.E.) becomes

$$\text{K.E.} = \frac{1}{4} mN \sum_{gj} \omega_{gj}^2 \langle a_{gj}^2 \rangle \tag{51}$$

The total energy of lattice waves is the sum of the kinetic and potential energies. For a harmonic oscillator, which is assumed in the present case, the total energy is equal to two times the kinetic energy. That is,

$$E_{\text{total}} = 2[\text{K.E.}] = \frac{1}{2} mN \sum_{gj} \omega_{gj}^2 \langle a_{gj}^2 \rangle = \sum_{gj} \langle E_{gj} \rangle \tag{52}$$

At high temperatures, the phonon energy for each gj component may be approximated by

$$\langle E_{gj} \rangle \approx kT \tag{53}$$

where k is the Boltzman constant. Thus, from Equation 52 we have

$$\langle a_{gj}^2 \rangle = \frac{2\langle E_{gj} \rangle}{mN\omega_{gj}^2} \approx \frac{2kT}{mN\omega_{gj}^2} \tag{54}$$

Substituting Equation 54 for the term $\langle a_{gj}^2 \rangle$ in Equation 50, we obtain the following expression for the first-order TDS intensity

$$I_1^{\text{TDS}}(\mathbf{K}) = f^2 e^{-2M} \frac{NkT}{m} \left(\frac{4\pi \sin\theta}{\lambda} \right)^2 \sum_{j=1}^{3} \frac{\cos^2(\mathbf{K}, \mathbf{e}_{gj})}{\omega_{gj}^2} \tag{55}$$

in which the scattering vector satisfies $\mathbf{K} \pm \mathbf{g} = \mathbf{H}$ and the cosine function is determined based upon the angle spanned by the scattering vector $\mathbf{K}$ and the phonon eigenvector $\mathbf{e}_{gj}$. In a periodic lattice, there is no need to consider elastic waves with a wavelength less than a certain minimum value because there are equivalent waves with a longer wavelength. The concept of Brillouin zone is applied to restrict the range of $\mathbf{g}$.

The significance of a measurement of the first-order TDS at various positions in reciprocal space may be observed in Figure 4, which represents the $hk0$ section of the reciprocal space of a body-centered cubic (bcc) crystal. At point P, the first-order TDS intensity is due only to elastic waves with the wave vector equal to $\mathbf{g}$, and hence only to waves propagating in the direction of $\mathbf{g}$. There are generally three independent waves for a given $\mathbf{g}$, and even in the general case, one is approximately longitudinal and the other two are approximately transverse waves. The cosine term appearing in Equation 55 may be considered as a geometrical extinction factor, which can further modify the contribution from the various elastic waves with the wave vector $\mathbf{g}$. Through appropriate strategy, it is possible to separate the phonon wave contribution from different branches. One such example may be found in Dvorack and Chen (1983).

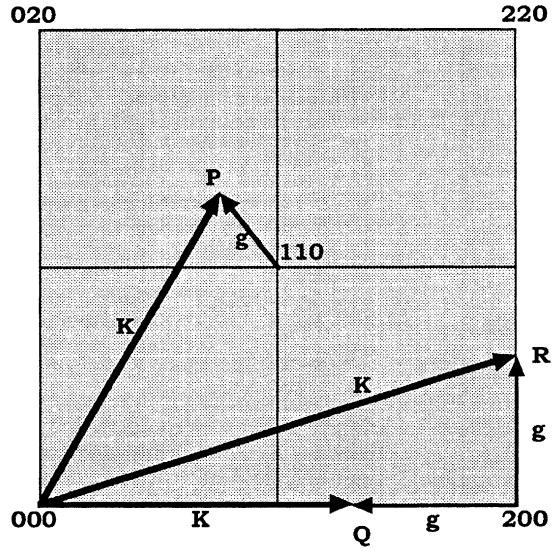

Figure 4. The ($hk0$) section of the reciprocal space corresponding to a bcc single crystal. At the general point P, there is a contribution from three phonon modes to the first-order TDS. At position Q, there is a contribution only from [100] longitudinal waves. At point R, there is a contribution from both longitudinal and transverse [100] waves.

From Equation 55, it is seen that the first-order TDS may be calculated for any given reciprocal lattice space location $\mathbf{K}$, so long as the eigenvalues, ω_{gj}, and the eigenvectors, $\mathbf{e}_{gj}$, of phonon branches are known for the system. In particular, the lower branch, or the lower-frequency phonon branches, contribute most to the TDS since the TDS intensity is inversely proportional to the square of the phonon frequencies. Quite often, the TDS pattern can be utilized to study soft-mode behavior or to identify the soft modes. The TDS intensity analysis is seldom carried out to determine the phonon dispersion curves, although such an analysis is possible (Dvorack and Chen, 1983); it requires making the measurements with absolute units and separating TDS intensities from different phonon branches. Neutron inelastic scattering techniques are much more common when it comes to determination of the phonon dispersion relationships. With the advent of high-brilliance synchrotron radiation facilities with milli-electron volt or better energy resolution, it is now possible to perform inelastic x-ray scattering experiments.

The second- and higher-order TDS might be appreciable for crystal systems showing soft modes, or close to or above the Debye temperature. The contribution of

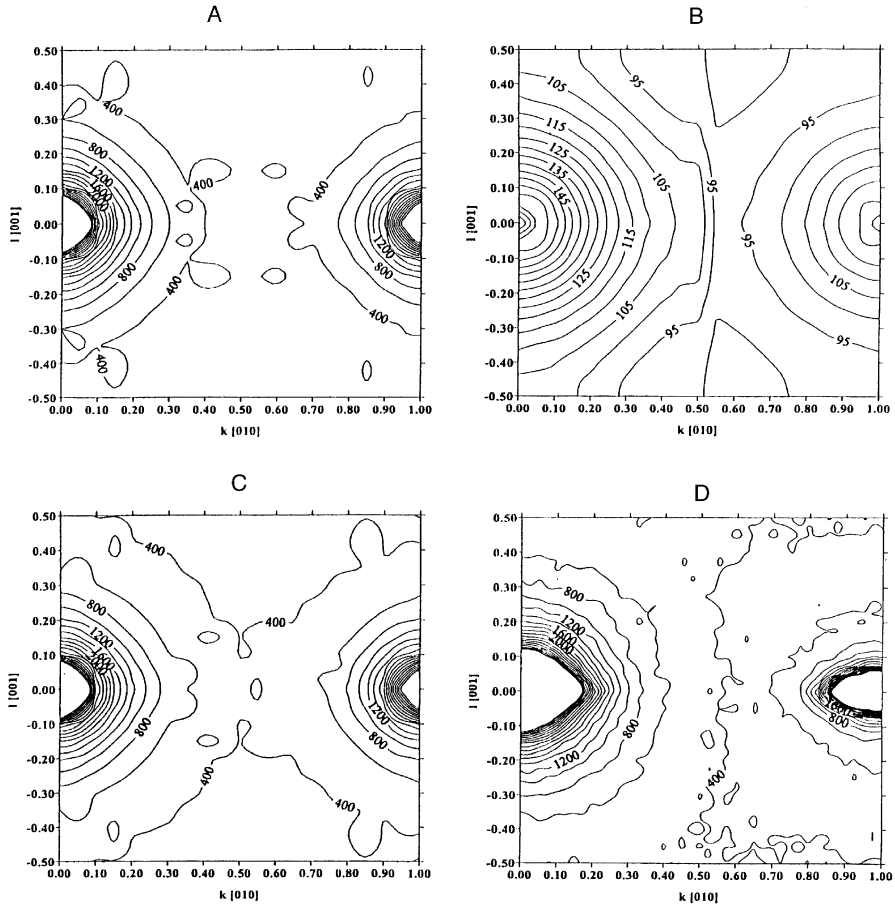

Figure 5. Equi-intensity contour maps, on the (100) plane of a cubic $BaTiO_3$ single crystal at 200°C. Calculated first-order TDS in (**A**), second-order TDS in (**B**), and the sum of (**A**) and (**B**) in (**C**), along with observed TDS intensities in (**D**).

second-order TDS represents the interaction between two phonon wave vectors with x rays and it can be calculated if the phonon dispersion relationship is known. The higher-order TDS can be significant and must be accounted for in diffuse scattering analysis in some cases. Figure 5 shows the calculated first- and second-order TDS along with the measured intensities for a $BaTiO_3$ single crystal in its paraelectric cubic phase (Takesue et al., 1997). The calculated TDS pattern shows the general features present in the observed data, but a discrepancy exists near the Brillouin zone center where measured TDS is higher than the calculation. This discrepancy is attributed to the overdamped phonon modes that are known to exist in $BaTiO_3$ due to anharmonicity.

Local Atomic Arrangement—Short-Range Ordering

A solid solution is thermodynamically defined as a single phase existing over a range of composition and temperature; it may exist over the full composition range of a binary system, be limited to a range near one of the pure constituents, or be based on some intermetallic compounds. It is, however, not required that the atoms be distributed randomly on the lattice sites; some degree of atomic ordering or segregation is the rule rather than the exception. The local atomic correlation in the absence of long-range order is the focus of interest in the present context.

The mere presence of a second species of atom, called solute atoms, requires that scattering from a solid solution produce a component of diffuse scattering throughout reciprocal space, in addition to the fundamental Bragg reflections. This component of diffuse scattering is modulated by the way the solute atoms are dispersed on and about the lattice sites, and hence contains a wealth of information. An elegant theory has evolved that allows one to treat this problem quantitatively within certain approximations, as have related techniques for visualizing and characterizing real-space, locally ordered atomic structure. More recently, it has been shown that pairwise interaction energies can be obtained from diffuse scattering studies on alloys at equilibrium. These energies offer great promise in allowing one to do realistic kinetic Ising modeling to understand how, for example, supersaturated solid solutions decompose.

An excellent, detailed review of the theory and practice of the diffuse scattering method for studying local atomic order, predating the quadratic approximation, has been given by Sparks and Borie (1966). More recent reviews on this topic were described by Chen et al. (1979) and by Epperson et al. (1994). In this section, the scattering principles for the extraction of pairwise interaction energies

are outlined for a binary solid solution showing local order. Readers may find more detailed experimental procedures and applications in XAFS SPECTROMETRY. This section is written in terms of x-ray experiments, since x rays have been used for most local order diffuse scattering investigations to date; however, neutron diffuse scattering is in reality a complementary method.

Within the kinematic approximation, the coherent scattering from a binary solid solution alloy with species A and B is given in electron units by

$$I_{\text{eu}}(\mathbf{K}) = \sum_p \sum_q f_p f_q e^{i\mathbf{K}\cdot(\mathbf{R}_p - \mathbf{R}_q)} \tag{56}$$

where f_p and f_q are the atomic scattering factors of the atoms located at sites p and q, respectively, and $(\mathbf{R}_p - \mathbf{R}_q)$ is the instantaneous interatomic vector. The interatomic vector can be $\boldsymbol{\beta}$ written as

$$(\mathbf{R}_p - \mathbf{R}_q) = \langle \mathbf{R}_p - \mathbf{R}_q \rangle + (\boldsymbol{\delta}_p - \boldsymbol{\delta}_q) \tag{57}$$

where $\boldsymbol{\delta}_p$ and $\boldsymbol{\delta}_q$ are vector displacements from the average lattice sites. The $\langle\rangle$ brackets indicate an average over time and space. Thus

$$I_{\text{eu}}(\mathbf{K}) = \sum_p \sum_q f_p f_q e^{i\mathbf{K}(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)} e^{\langle i\mathbf{K}\cdot(\mathbf{R}_p - \mathbf{R}_q)\rangle} \tag{58}$$

In essence, the problem in treating local order diffuse scattering is to evaluate the factor $f_p f_q e^{i\mathbf{K}(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)}$ taking into account all possible combinations of atom pairs: AA, AB, BA, and BB.

The modern theory and the study of local atomic order diffuse scattering had their origins in the classical work by Cowley (1950) in which he set the displacement to zero. Experimental observations by Warren et al. (1951), however, soon demonstrated the necessity of accounting for this atomic displacement effect, which tends to shift the local order diffuse maxima from positions of cosine symmetry in reciprocal space.

Borie (1961) showed that a linear approximation of the exponential containing the displacements allowed one to separate the local order and static atomic displacement contributions by making use of the fact that the various components of diffuse scattering have different symmetry in reciprocal space. This approach was extended to a quadratic approximation of the atomic displacement by Borie and Sparks (1971). All earlier diffuse scattering measurements were made using this separation method. Tibbals (1975) later argued that the theory could be cast so as to allow inclusion of the reciprocal space variation of the atomic scattering factors. This is included in the state-of-art formulation by Auvray et al. (1977), which is outlined here.

Generally, for a binary substitutional alloy one can write

$$\begin{aligned}\langle f_p f_q e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)}\rangle &= X_{\text{A}} P_{pq}^{\text{AA}} f_{\text{A}}^2 \langle e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{A}} - \boldsymbol{\delta}_q^{\text{A}})}\rangle \\ &+ X_{\text{A}} P_{pq}^{\text{BA}} f_{\text{A}} f_{\text{B}} \langle e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{A}})}\rangle \\ &+ X_{\text{B}} P_{pq}^{\text{AB}} f_{\text{A}} f_{\text{B}} \langle e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{A}} - \boldsymbol{\delta}_q^{\text{B}})}\rangle + X_{\text{B}} P_{pq}^{\text{BB}} f_{\text{B}}^2 \langle e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{B}})}\rangle\end{aligned} \tag{59}$$

where X_{A} and X_{B} are atom fractions of species A and B, respectively, and P_{pq}^{AB} is the conditional probability of finding an A atom at site p provided there is a B atom at site q, and so on. There are certain relationships among the conditional probabilities for a binary substitutional solid solution:

$$X_{\text{A}} P_{pq}^{\text{BA}} = X_{\text{B}} P_{pq}^{\text{AB}} \tag{60}$$

$$P_{pq}^{\text{AA}} + P_{pq}^{\text{BA}} = 1 \tag{61}$$

$$P_{pq}^{\text{BB}} + P_{pq}^{\text{AB}} = 1 \tag{62}$$

If one also introduces the Cowley-Warren (CW) order parameter (Cowley, 1950),

$$\alpha_{pq} = 1 - \frac{P_{pq}^{\text{BA}}}{X_{\text{B}}} \tag{63}$$

Equation 59 reduces to

$$\begin{aligned}\langle f_p f_q e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p - \boldsymbol{\delta}_q)}\rangle &= (X_{\text{A}}^2 - X_{\text{A}} X_{\text{B}} \alpha_{pq}) f_{\text{A}}^2 \langle e^{i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{A}} - \boldsymbol{\delta}_q^{\text{A}})}\rangle \\ &+ 2X_{\text{A}} X_{\text{B}} (1 - \alpha_{pq}) f_{\text{A}} f_{\text{B}} \langle e^{\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{A}})}\rangle \\ &+ (X_{\text{B}}^2 + X_{\text{A}} X_{\text{B}} \alpha_{pq}) f_{\text{B}}^2 \langle e^{\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{B}})}\rangle\end{aligned} \tag{64}$$

If one makes series expansions of the exponentials and retains only quadratic and lower-order terms, it follows that

$$\begin{aligned}I_{\text{eu}}(\mathbf{K}) = &\sum_p \sum_q (X_{\text{A}} f_{\text{A}} + X_{\text{B}} f_{\text{B}})^2 e^{i\mathbf{K}\cdot\mathbf{R}_p q} \\ &+ \sum_p \sum_q X_{\text{A}} X_{\text{B}} (f_{\text{A}} - f_{\text{B}}) 2\alpha_{pq} e^{i\mathbf{K}\cdot\mathbf{R}_{pq}} \\ &+ \sum_p \sum_q \Big[(X_{\text{A}}^2 + X_{\text{A}} X_{\text{B}} \alpha_{pq}) f_{\text{A}}^2 \langle i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{A}} - \boldsymbol{\delta}_q^{\text{A}})\rangle \\ &+ 2X_{\text{A}} X_{\text{B}} (1 - \alpha_{pq}) f_{\text{A}} f_{\text{B}} \langle i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{A}})\rangle \\ &+ (X_{\text{B}}^2 + X_{\text{A}} X_{\text{B}} \alpha^p q) f_{\text{B}}^2 \langle i\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{B}})\rangle \Big] e^{i\mathbf{k}\cdot\mathbf{R}_{pq}} \\ &- \frac{1}{2} \sum_p \sum_q \Big[(X_{\text{A}}^2 + X_{\text{A}} X_{\text{B}} \alpha_{pq}) f_{\text{A}}^2 \Big\langle \Big[\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{A}} - \boldsymbol{\delta}_q^{\text{A}})\Big]^2 \Big\rangle \\ &+ 2X_{\text{A}} X_{\text{B}} (1 - \alpha_{pq}) f_{\text{A}} f_{\text{B}} \Big\langle \Big[\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{A}})\Big]^2 \Big\rangle \\ &+ (X_{\text{B}}^2 + X_{\text{A}} X_{\text{B}} \alpha_{pq}) f_{\text{B}}^2 \Big\langle \Big[\mathbf{K}\cdot(\boldsymbol{\delta}_p^{\text{B}} - \boldsymbol{\delta}_q^{\text{B}})\Big]^2 \Big\rangle \Big] e^{i\mathbf{K}\cdot\mathbf{R}_{pq}}\end{aligned} \tag{65}$$

where $e^{i\mathbf{K}\cdot\mathbf{R}_{pq}}$ denotes $e^{\langle i\mathbf{K}\cdot(\mathbf{R}_p - \mathbf{R}_q)\rangle}$. The first double summation represents the fundamental Bragg reflections for the average lattice. The second summation is the atomic-order modulated Laue monotonic, the term of primary interest here. The third sum is the so-called first-order atomic displacements, and it is purely static in nature. The final double summation is the second-order atomic displacements and contains both static and dynamic contributions. A detailed derivation would show that the second-order displacement series does not converge to zero. Rather, it represents a loss of intensity by the Bragg reflections; this is how TDS and Huang scattering originate. Henceforth, we shall use the term second-order displacement

scattering to denote this component, which is redistributed away from the Bragg positions. Note in particular that the second-order displacement component represents additional intensity, whereas the first-order size effect scattering represents only a redistribution that averages to zero. However, the quadratic approximation may not be adequate to account for the thermal diffuse scattering in a given experiment, especially for elevated temperature measurements or for systems showing a soft phonon mode. The experimental temperature in comparison to Debye temperature of the alloy is a useful guide for judging the adequacy of the quadratic approximation.

For cubic alloys that exhibit only local ordering (i.e., short-range ordering or clustering), it is convenient to replace the double summations by N times single sums over lattice sites, now specified by triplets of integers (lmn), which denote occupied sites in the lattice; N is the number of atoms irradiated by the x-ray beam. One can express the average interatomic vector as

$$\langle \mathbf{R}_{lmn} \rangle = l\mathbf{a}_1 + m\mathbf{a}_2 + n\mathbf{a}_3 \tag{66}$$

where $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ are orthogonal vectors parallel to the cubic unit cell edges. The continuous variables in reciprocal space (h_1, h_2, h_3) are related to the scattering vector by

$$\mathbf{K} = 2\pi\left(\frac{\mathbf{S}-\mathbf{S}_0}{\lambda}\right) = 2\pi(h_1\mathbf{b}_1 + h_2\mathbf{b}_2 + h_3\mathbf{b}_3) \tag{67}$$

where $\mathbf{b}_1$, $\mathbf{b}_2$, and $\mathbf{b}_3$ are the reciprocal space lattice vectors as defined in Equation 14. The coordinate used here is that conventionally employed in diffuse scattering work and is chosen in order that the occupied sites can be specified by a triplet of integers. Note that the 200 Bragg position becomes 100, and so on, in this notation. It is also convenient to represent the vector displacements in terms of components along the respective real-space axes as

$$(\boldsymbol{\delta}_p^{\mathrm{A}} - \boldsymbol{\delta}_q^{\mathrm{A}}) \equiv \boldsymbol{\delta}_{pq}^{\mathrm{AA}} = X_{lmn}^{\mathrm{AA}}\mathbf{a}_1 + Y_{lmn}^{\mathrm{AA}}\mathbf{a}_2 + Z_{lmn}^{\mathrm{AA}}\mathbf{a}_3 \tag{68}$$

If one invokes the symmetry of the cubic lattice and simplifies the various expressions, the coherently scattered diffuse intensity that is observable becomes, in the quadratic approximation of the atomic displacements,

$$\begin{aligned}\frac{I_D(h_1,h_2,h_3)}{NX_{\mathrm{A}}X_{\mathrm{B}}(f_{\mathrm{A}}-f_{\mathrm{B}})^2} = {} & \sum_l\sum_m\sum_n \alpha_{lmn}\cos 2\pi(h_1 l + h_2 m + h_3 n) \\ & + h_1\eta Q_x^{\mathrm{AA}} + h_1\xi Q_x^{\mathrm{BB}} + h_2\eta Q_y^{\mathrm{AA}} \\ & + h_2\xi Q_y^{\mathrm{BB}} + h_3\eta Q_z^{\mathrm{AA}} + h_3\xi Q_z^{\mathrm{BB}} \\ & + h_1^2\eta^2 R_x^{\mathrm{AA}} + 2h_1^2\eta\xi R_x^{\mathrm{AB}} + h_1^2\xi^2 R_x^{\mathrm{BB}} \\ & + h_2^2\eta^2 R_y^{\mathrm{AA}} + 2h_2^2\eta\xi R_y^{\mathrm{AB}} + h_2^2\xi^2 R_y^{\mathrm{BB}} \\ & + h_3^2\eta^2 R_z^{\mathrm{AA}} + 2h_3^2\eta\xi R_z^{\mathrm{AB}} + h_3^2\xi^2 R_z^{\mathrm{BB}} \\ & + h_1h_2\eta^2 S_{xy}^{\mathrm{AA}} + 2h_1h_2\eta\xi S_{xy}^{\mathrm{AB}} + h_1h_2\xi^2 S_{xy}^{\mathrm{BB}} \\ & + h_1h_3\eta^2 S_{xz}^{\mathrm{AA}} + 2h_1h_3\eta\xi S_{xz}^{\mathrm{AB}} + h_1h_3\xi^2 S_{xz}^{\mathrm{BB}} \\ & + h_2h_3\eta^2 S_{yz}^{\mathrm{AA}} + 2h_2h_3\eta\xi S_{yz}^{\mathrm{AB}} + h_2h_3\xi^2 S_{yz}^{\mathrm{BB}}\end{aligned} \tag{69}$$

where

$$\eta = \frac{f_{\mathrm{A}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} \tag{70}$$

and

$$\xi = \frac{f_{\mathrm{B}}}{f_{\mathrm{A}} - f_{\mathrm{B}}} \tag{71}$$

The Q_i functions, which describe the first-order size effects scattering component, result from simplifying the third double summation in Equation 65 and are of the form

$$\begin{aligned}Q_x^{\mathrm{AA}} = {} & -2\pi\sum_l\sum_m\sum_n\left(\frac{X_{\mathrm{A}}}{X_{\mathrm{B}}} + \alpha_{lmn}\right)\langle X_{lmn}^{\mathrm{AA}}\rangle \\ & \times \sin 2\pi h_1 l \cos 2\pi h_2 m \cos 2\pi h_3 n\end{aligned} \tag{72}$$

where $\langle X_{lmn}^{\mathrm{AA}}\rangle$ is the mean component of displacement, relative to the average lattice, in the x direction of the A atom at site lmn when the site at the local origin is also occupied by an A-type atom.

The second-order atomic displacement terms obtained by simplification of the fourth double summation in Equation 65 are given by expressions of the type

$$\begin{aligned}R_x^{\mathrm{AA}} = {} & -4\pi^2\sum_l\sum_m\sum_n\left(\frac{X_{\mathrm{A}}}{X_{\mathrm{B}}} + \alpha_{lmn}\right)\langle X_o^{\mathrm{A}}X_{lmn}^{\mathrm{A}}\rangle \\ & \times \cos 2\pi h_1 l \cos 2\pi h_2 m \cos 2\pi h_3 n\end{aligned} \tag{73}$$

and

$$\begin{aligned}S_{xy}^{\mathrm{AB}} = {} & -8\pi^2\sum_l\sum_m\sum_n\left(\frac{X_{\mathrm{A}}}{X_{\mathrm{B}}} + \alpha_{lmn}\right)\langle X_o^{\mathrm{A}}Y_{lmn}^{\mathrm{A}}\rangle \\ & \times \sin 2\pi h_1 l \sin 2\pi h_2 m \cos 2\pi h_3 n\end{aligned} \tag{74}$$

In Equations 73 and 74, the terms in angle brackets represent correlations of atomic displacements. For example, $\langle X_o^{\mathrm{A}}Y_{lmn}^{\mathrm{A}}\rangle$ represents the mean component of displacement in the Y direction of an A-type atom a vector distance lmn from an A-type atom at the local origin.

The first summation in Equation 69 (I_{SRO}) contains the statistical information about the local atomic ordering of primary interest; it is a 3D Fourier cosine series whose coefficients are the CW order parameters. The first term in this series ($\alpha 000$) is a measure of the integrated local order diffuse intensity, and, provided the data are normalized by the Laue monotonic unit $[X_{\mathrm{A}}X_{\mathrm{B}}(f_{\mathrm{A}}-f_{\mathrm{B}})^2]$, should have the value of unity.

A schematic representation of the various contributions due to I_{SRO}, Q, and R/S components to the total diffuse intensity along an $[h00]$ direction is shown in Figure 6 for a system showing short-range clustering. As one can see, beside sharp Bragg peaks, there are I_{SRO} components concentrated near the fundamental Bragg peaks due to local clustering, the oscillating diffuse intensity due to static displacements (Q), and TDS-like intensity (R and S) near the tail of the fundamental reflections. Each of these diffuse-intensity components can be separated and

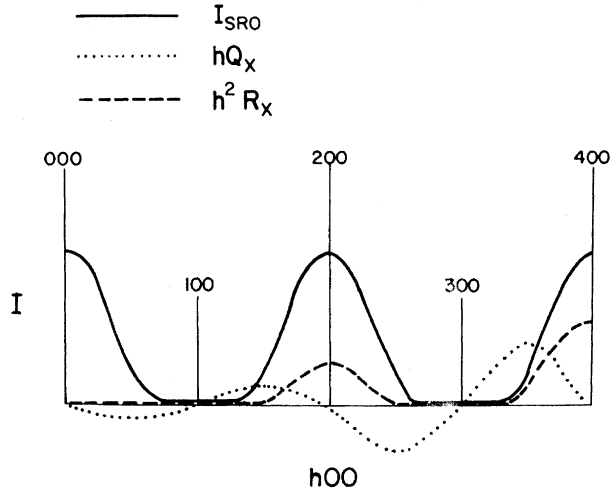

Figure 6. Schematic representation of the various contributions to diffuse x-ray scattering (l) along an [h00] direction in reciprocal space, from an alloy with short-range ordering and displacement. Fundamental Bragg reflections have all even integers; other sharp peak locations represent the superlattice peak when the system becomes ordered.

analyzed to reveal the local structure and associated static displacement fields.

The coherent diffuse scattering thus consists of 25 components for the cubic binary substitutional alloy, each of which possesses distinct functional dependence on the reciprocal space variables. This fact permits the components to be separated. To effect the separation, intensity measurements are made at a set of reciprocal lattice points referred to as the "associated set." These associated points follow from a suggestion of Tibbals (1975) and are selected according to crystallographic symmetry rules such that the corresponding 25 functions (I_{SRO}, Q, R, and S) in Equation 69 have the same absolute value. Note, however, that the intensities at the associated points need not be the same, because the functions are multiplied by various combinations of h_i, η, and ξ. Extended discussion of this topic has been given by Schwartz and Cohen (1987). An associated set is defined for each reciprocal lattice point in the required minimum volume for the local order component of diffuse scattering, and the corresponding intensities must be measured in order that the desired separation can be carried out.

The theory outlined above has heretofore been used largely for studying short-range-ordering alloys (preference for unlike nearest neighbors); however, the theory is equally valid for alloy systems that undergo clustering (preference for like nearest neighbors), or even a combination of the two. If clustering occurs, local order diffuse scattering will be distributed near the fundamental Bragg positions, including the zeroth-order diffraction; that is, small-angle scattering (SAS) will be observed. Because of the more localized nature of the order diffuse scattering, analysis is usually carried out with rather a different formalism; however, Hendricks and Borie (1965) considered some important aspects using the atomistic approach and the CW formalism.

In some cases, both short-range ordering and clustering may coexist, as in the example by Anderson and Chen (1994), who utilized synchrotron x rays to investigate the short-range-order structure of an Au–25 at.% Fe single crystal at room temperature. Two heat treatments were investigated: a 400°C aging treatment for 2 days and a 440°C treatment for 5 days, both preceded by solution treatment in the single-phase field and water quenched to room temperature. Evolution of SRO structure with aging was determined by fitting two sets of Cowley-Warren SRO parameters to a pair of 140,608-atom models. The microstructures, although quite disordered, showed a trend with aging for an increasing volume fraction of an Fe-enriched and an Fe-depleted environment—indicating that short-range ordering and clustering coexist in the system. The Fe-enriched environment displayed a preference for Fe segregation to the {110} and {100} fcc matrix planes. A major portion of the Fe-depleted environment was found to contain elements (and variations of these elements) of the $D1a$ ordered superstructure. The SRO contained in the Fe-depleted environment may best be described in terms of the standing wave packet model. This model was the first study to provide a quantitative real-space view of the atomic arrangement of the spin-glass system Au-Fe.

Surface/Interface Diffraction

Surface science is a subject that has grown enormously in the last few decades, partly because of the availability of new electron-based tools. X-ray diffraction has also contributed to many advances in the field, particularly when synchrotron radiation is used. Interface science, on the other hand, is still in its infancy as far as structural analysis is concerned. Relatively crude techniques, such as dissolution and erosion of one-half of an interface, exist but have limited application. Surfaces and interfaces may be considered as a form of defect because the uniform nature of a bulk crystal is abruptly terminated so that the properties of the surfaces and interfaces often differ significantly from the bulk.

In spite of the critical role that they play in such diverse sciences as catalysis, tribology, metallurgy, and electronic devices and the expected richness of the 2D physics of melting, magnetism, and related phase transitions, only a few surface structures are known, most of those are known only semiquantitatively (e.g., their symmetry; Somorjai, 1981). Our inability in many cases to understand atomic structure and to make the structure/properties connection in the 2D region of surfaces and interfaces has significantly inhibited progress in understanding this rich area of science.

X-ray diffraction has been an indispensable tool in 3D materials structure characterization despite the relatively low-scattering cross-section of x-ray photons compared with electrons. But the smaller number of atoms involved at surfaces and interfaces has made structural experiments at best difficult and in most cases impossible. The advent of high-intensity synchrotron radiation sources has definitely facilitated surface/interface x-ray diffraction. The nondestructive nature of the technique together

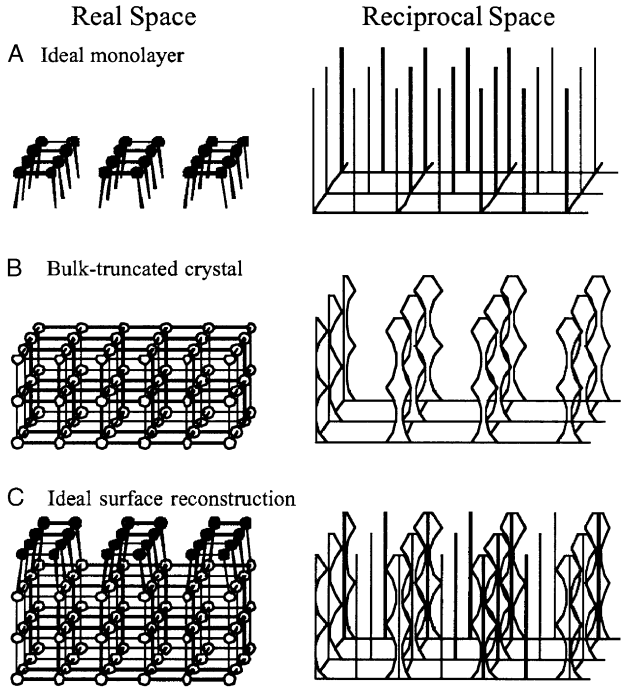

Figure 7. Real-space and reciprocal space views of an ideal crystal surface reconstruction. (**A**) A single monolayer with twice the periodicity in one direction producing featureless 2D Bragg rods whose periodicity in reciprocal space is one-half in one direction. The grid in reciprocal space corresponds to a bulk (1×1) cell. (**B**) A (1×1) bulk-truncated crystal and corresponding crystal truncation rods (CTRs). (**C**) An ideal reconstruction combining features from (**A**) and (**B**); note the overlap of one-half the monolayer or surface rods with the bulk CTRs. In general, 2D Bragg rods arising from a surface periodicity unrelated to the bulk (1×1) cell in size of orientation will not overlap with the CTRs.

with its high penetration power and negligible effect due to multiple scattering should make x-ray diffraction a premier method for quantitative surface and interface structural characterization (Chen, 1996). Up to this point we have considered diffraction from 3D crystals based upon the fundamental kinematic scattering theory laid out in the section on Diffraction from a Crystal. For diffraction from surfaces or interfaces, modifications need to be made to the intensity formulas that we shall discuss below.

Schematic pictures after Robinson and Tweet (1992) illustrating 2D layers existing at surfaces and interfaces are shown in Figure 7; there are three cases for consideration. Figure 7A is the case where an ideal 2D monolayer exists, free from interference of any other atoms. This case is hard to realize in nature. The second case is more realistic and is the one that most surface scientists are concerned with: the case of a truncated 3D crystal on top of which lies a 2D layer. This top layer could have a structure of its own, or it could be a simple continuation of the bulk structure with minor modifications. This top layer could also be of a different element or elements from the bulk. The surface structure may sometimes involve arrangement of atoms in more than one atomic layer, or may be less than one monolayer thick.

The term "interface" usually refers to the case when two bulk media of the same or different material are in contact, as Figure 7C shows. Either one or both may be crystalline, and therefore interfaces include grain boundaries as well. Rearrangement of atoms at interfaces may occur, giving rise to unique 2D diffraction patterns. By and large, the diffraction principles for scattering from surfaces or interfaces are considered identical. Consequently, the following discussion applies to both cases.

Rods from a 2D Diffraction. Diffraction from 2D structures in the above three cases can be described using Equations 8, 9, 10, 11, and 12 and Equation 20. If we take $\mathbf{a}_3$ to be along the surface/interface normal, the isolated monolayer is a 2D crystal with $N_3 = 1$. Consequently, one of the Laue conditions is relaxed, that is, there is no constraint on the magnitude of $\mathbf{K} \cdot \mathbf{a}_3$, which means the diffraction is independent of $\mathbf{K} \cdot \mathbf{a}_3$, the component of momentum transfer perpendicular to the surface. As a result, in 3D reciprocal space the diffraction pattern from this 2D structure consists of rods perpendicular to the surface, as depicted in Figure 7A. Each rod is a line of scattering extending out to infinity along the surface-normal direction, but is sharp in the other two directions parallel to the surface. For the surface of a 3D crystal, the diffuse rods resulting from the scattering of the 2D surface structure will connect the discrete Bragg peaks of the bulk. If surface/ interface reconstruction occurs, new diffuse rods will occur; these do not always run through the bulk Bragg peaks, as in the case shown in Figure 7C.

The determination of a 2D structure can, in principle, be made by following the same methods that have been developed for 3D crystals. The important point here is that one has to scan across the diffuse rods, that is, the scattering vector $\mathbf{K}$ must lie in the plane of the surface—the commonly known "in-plane" scan. Only through measurements such as these can the total integrated intensities, after resolution function correction and background subtraction, be utilized for structure analysis. The grazing-incidence x-ray diffraction technique is thus developed to accomplish this goal SURFACE X-RAY DIFFRACTION. Other techniques such as the specular reflection, standing-wave method can also be utilized to aid in the determination of surface structure, surface roughness, and composition variation.

Figure 7C represents schematically the diffraction pattern from the corresponding structure consisting of a 2D reconstructed layer on top of a 3D bulk crystal. We have simply superimposed the 3D bulk crystal diffraction pattern in the form of localized Bragg peaks (dots) with the Bragg diffraction rods deduced from the 2D structure. One should be reminded that extra reflections, that is, extra rods, could occur if the 2D surface structure differs from that of the bulk. For a 2D structure involving one layer of atoms and one unit cell in thickness, the Bragg diffraction rods, if normalized against the decaying nature of the atomic scattering factors, are flat in intensity and extend to infinity in reciprocal space. When the 2D surface structure has a thickness of more than one unit cell, a pseudo-2D structure or a very thin layer is of concern, and the Bragg diffraction rods will no longer be flat in their intensity profiles but instead fade away monotonically

from the zeroth-order plane normal to the sample surface in reciprocal space. The distance to which the diffraction rods extends is inversely dependent on the thickness of the thin layer.

Crystal Truncation Rods. In addition to the rods originating from the 2D structure, there is one other kind of diffuse rod that contributes to the observed diffraction pattern that has a totally different origin. This second type of diffuse rod has its origin in the abrupt termination of the underlying bulk single-crystal substrate, the so-called crystal truncation rods, CTRs. This contribution further complicates the diffraction pattern, but is rich in information concerning the surface termination sequence, relaxation, and roughness; therefore, it must be considered. The CTR intensity profiles are not flat but vary in many ways that are determined by the detailed atomic arrangement and static displacement fields near surfaces, as well as by the topology of the surfaces. The CTR intensity lines are always perpendicular to the surface of the substrate bulk single crystal and run through all Bragg peaks of the bulk and the surface. Therefore, for an inclined surface normal that is not parallel to any crystallographic direction, CTRs do not connect all Bragg peaks, as shown in Figure 7B.

Let us consider the interference function, Equation 11, along the surface normal, $\mathbf{a}_3$, direction. The numerator, $\sin^2(\pi \mathrm{K} \cdot N_3 \mathbf{a}_3)$, is an extremely rapid varying function of $\mathbf{K}$, at least for large N_3, and is in any case smeared out in a real experiment because of finite resolution. Since it is always positive, we can approximate it by its average value of $\frac{1}{2}$. This gives a simpler form for the limit of large N_3 that is actually independent of N_3:

$$|G_3(\mathbf{K})|^2 = \frac{1}{2\sin^2(\pi \mathbf{K} \cdot \mathbf{a}_3)} \tag{75}$$

Although the approximation is not useful at any of the Bragg peaks defined by the three Laue conditions, it does tell us that the intensity in between Bragg peaks is actually nonzero along the surface normal direction, giving rise to the CTRs. Another way of looking at CTRs comes from convolution theory. From the kinematic scattering theory presented earlier, we understand that the scattering cross-section is the product of two functions, the structure factor $F(\mathbf{K})$ and the interference function $G(\mathbf{K})$, expressed in terms of the reciprocal space vector $\mathbf{K}$. This implies, in real space, that the scattering cross-section is related to a convolution of two real-space structural functions: one defining the positions of all atoms within one unit cell and the other covering all lattice points. For an abruptly terminated crystal at a well-defined surface, the crystal is semi-infinite, which can be represented by a product of a step function with an infinite lattice. The diffraction pattern is then, by Fourier transformation, the convolution of a reciprocal lattice with the function $(2\pi \mathbf{K} \cdot \mathbf{a}_3)^{-1}$. It was originally shown by von Laue (1936) and more recently by Andrews and Cowley (1985), in a continuum approximation, that the external surface can thus give rise to streaks emanating from each Bragg peak of the bulk, perpendicular to the terminating crystal surface. This is what we now call the CTRs.

It is important to make the distinction between CTRs passing through bulk reciprocal lattice points and those due to an isolated monolayer 2D structure at the surface. Both can exist together in the same sample, especially when the surface layer does not maintain lattice correspondence with the bulk crystal substrate. To illustrate the difference and similarity of the two cases, the following equations may be used to represent the rod intensities of two different kinds:

$$I_{2\mathrm{D}} = I_0 N_1 N_2 |F(\mathbf{K})|^2 \tag{76}$$

$$I_{\mathrm{CTR}} = I_0 N_1 N_2 |F(\mathbf{K})|^2 \frac{1}{2\sin^2(\pi \mathbf{K} \cdot \mathbf{a}_3)} \tag{77}$$

The two kinds of rod have the same order-of-magnitude intensity in the "valley" far from the Bragg peaks at $\mathbf{K} \cdot \mathbf{a}_3 = l$. The actual intensity observed in a real experiment is several orders of magnitude weaker than the Bragg peaks. For the 2D rods, integrated intensities at various (hk) reflections can be measured and Fourier inverted to reveal the real-space structure of the 2D ordering. Patterson function analysis and difference Patterson function analysis are commonly utilized, along with least-squares fitting to obtain the structure information. For the CTRs, the stacking sequences and displacement of atomic layers near the surface, as well as the surface roughness factor, and so on, can be modeled through the calculation of the structure factor in Equation 77. Experimental techniques and applications of surface/interface diffraction techniques to various materials problems may be found in SURFACE X-RAY DIFFRACTION. Some of our own work may be found in the studies of buried semiconductor surfaces by Aburano et al. (1995) and by Hong et al. (1992a,b, 1993, 1996) and in the determination of the terminating stacking sequence of *c*-plane sapphire by Chung et al. (1997).

Small-Angle Scattering

The term "small-angle scattering" (SAS) is somewhat ambiguous as long as the sample, type of radiation, and incident wavelength are not specified. Clearly, Bragg reflections of all crystals when investigated with high-energy radiation (e.g., γ rays) occur at small scattering angles (small 2θ) simply because the wavelength of the probing radiation is short. Conversely, crystals with large lattice constants could lead to small Bragg angles for a reasonable wavelength value of the radiation used. These Bragg reflections, although they might appear at small angles, can be treated in essentially the same way as the large-angle Bragg reflections with their origins laid out in all previous sections. However, in the more specific sense of the term, SAS is a scattering phenomenon related to the scattering properties at small scattering vectors $\mathbf{K}$ (with magnitudes $K = 2 \sin \theta/\lambda$), or, in other words, diffuse scattering surrounding the direct beam. It is this form of diffuse SAS that is the center of discussion in this section.

SAS is produced by the variation of scattering length density over distances exceeding the normal interatomic distances in condensed systems. Aggregates of small

particles (e.g., carbon black and catalysts) in air or vacuum, particles or macromolecules in liquid or solid solution (e.g., polymers and precipitates in alloys), and systems with smoothly varying concentration (or scattering length density) profiles (e.g., macromolecules, glasses, and spinodally decomposed systems) can be investigated with SAS methods. SAS intensity appears at low **K** values, that is, **K** should be small compared with the smallest reciprocal lattice vector in crystalline substances. Because the scattering intensity is related to the Fourier transform properties, as shown in Equation 7, it follows that measurements at low K will not allow one to resolve structural details in real space over distances smaller than $d_{\min} \approx \pi/K_{\max}$, where $K_{\max}$ is the maximum value accessible in the SAS experiment. If, for example, $K_{\max} = 0.2$ Å^{-1}, then $d_{\min} = 16$ Å, and the discrete arrangement of scattering centers in condensed matter can in most cases be replaced by a continuous distribution of scattering length, averaged over volumes of about d_{min}^3. Consequently, summations over discrete scattering sites as represented in Equation 7 and the subsequent ones can be replaced by integrals.

If we replace the scattering length f_j by a locally averaged scattering length density $\rho(\mathbf{r})$, where $\mathbf{r}$ is a continuously variable position vector, Equation 7 can be rewritten

$$I(\mathbf{K}) = \left| \int_V \rho(\mathbf{r}) e^{2\pi i \mathbf{K}\cdot\mathbf{r}} d^3\mathbf{r} \right|^2 \tag{78}$$

where the integration extends over the sample volume V. The scattering length density may vary over distances of the order $d_{\min}$ as indicated earlier, and it is sometimes useful to express

$$\rho(\mathbf{r}) = \Delta\rho(\mathbf{r}) + \rho_0 \tag{79}$$

where ρ_0 is averaged over a volume larger than the resolution volume of the instrument (determined by the minimum observable value of K). Therefore, by discounting the Bragg peak, the diffuse intensity originating from inhomogeneities is

$$I(\mathbf{K}) = \left| \int_V \Delta\rho(\mathbf{r}) e^{2\pi i \mathbf{K}\cdot\mathbf{r}} d^3\mathbf{r} \right|^2 \tag{80}$$

Two-Phase Model. Let the sample contain N_p particles with a homogeneous scattering length density ρ_p, and let these particles be embedded in a matrix of homogeneous scattering length density ρ_m. From Equation 80, one obtains for the SAS scattering intensity per atom:

$$I_a(\mathbf{K}) = \frac{1}{N} |\rho_p - \rho_m|^2 \left| \int_V e^{2\pi i \mathbf{K}\cdot\mathbf{r}} d^3\mathbf{r} \right|^2 \tag{81}$$

where N is the total number of atoms in the scattering volume and the integral extends over the volume V occupied by all particles in the irradiation sample. In the most general case, the above integral contains spatial and orientational correlations among particles, as well as effects due to size distributions. For a monodispersed system free of particle correlation, the single-particle form factor is

$$F_p(\mathbf{K}) = \frac{1}{V_p} \int_{V_p} e^{2\pi i \mathbf{K}\cdot\mathbf{r}} d^3\mathbf{r} \tag{82}$$

where V_p is the particle volume so that $F(0) = 1$; we can write for N_p identical particles

$$I_a(\mathbf{K}) = \frac{N_p V_p^2}{N} |\rho_p - \rho_m|^2 |F_p(\mathbf{K})|^2 \tag{83}$$

The interference (correlation) term in Equation 81 that we have neglected to arrive at in Equation 83, is the Fourier transform $\Psi(\mathbf{K})$ of the static pair correlation function,

$$\Psi(\mathbf{K}) = \frac{1}{N_p} \sum_{i=j} e^{2\pi i \mathbf{K}\cdot(\mathbf{r}_i - \mathbf{r}_j)} \tag{84}$$

where $\mathbf{r}_i$ and $\mathbf{r}_j$ are the position vectors of the centers of particles labeled i and j. This function will only be zero for all nonzero **K** values if the interparticle distance distribution is completely random, as is approximately the case in very dilute systems. Equation 84 is also valid for oriented anisotropic particles if they are all identically oriented. In the more frequent cases of a random orientational distribution or discrete but multiple orientations of anisotropic particles, the appropriate averages of $F_p(\mathbf{K})^2$ have to be used.

Scattering Functions for Special Cases. Many different particle form factors have been calculated by Guinier and Fournet (1955), some of which are reproduced as follows for the isotropic and uncorrelated distribution, i.e., spherically random distribution of identical particles.

Spheres. For a system of noninteracting identical spheres of radius R_s, the form factor is

$$F_s(KR_S) = \frac{3[\sin(2\pi KR_S) - 2\pi KR_S \cos(2\pi KR_S)]}{(2\pi K)^3 R_S^3} \tag{85}$$

Ellipsoids. Ellipsoids of revolution of axes $2a$, $2a$, and $2av$ yield the following form factor:

$$|F_e(K)|^2 = \int_0^{2\pi} |F_s|^2 \left(\frac{2\pi Kav}{\sqrt{\sin^2\alpha + v^2\cos^2\alpha}} \right) \cos\beta \, d\beta \tag{86}$$

where F_s is the function in Equation 85 and $\alpha = \tan^{-1}(v \tan\beta)$.

Cylinders. For a cylinder of diameter $2a$ and height $2H$, the form factor becomes

$$|F_c(K)|^2 = \int_0^{\frac{\pi}{2}} \frac{\sin^2(2\pi KH\cos\beta)}{(2\pi K)^2 H^2 \cos^2\beta} \frac{4J_1^2(2\pi Ka\sin\beta)}{(2\pi K)^2 a^2 \sin^2\beta} \sin\beta \, d\beta \tag{87}$$

where J_1 is the first-order spherical Bessel function. Porod (see Guinier and Fournet, 1955) has given an

approximation form for Equation 87 valid for $KH \gg 1$ and $a \ll H$ which, in the intermediate range $Ka < 1$, reduces to

$$|F_c(K)|^2 \approx \frac{\pi}{4\pi KH} e^{-(2\pi K)^2 a^2/4} \tag{88}$$

For infinitesimally thin rods of length $2H$, one can write

$$|F_{\text{rod}}(K)|^2 \approx \frac{S_i(4\pi KH)}{2\pi KH} - \frac{\sin^2(2\pi KH)}{(2\pi K)^2 H^2} \tag{89}$$

where

$$S_i(x) = \int_0^x x \frac{\sin t}{t} dt \tag{90}$$

For the case $KH \gg 1$, Equation 87 reduces to

$$|F_{\text{rod}}(K)|^2 \approx \frac{1}{4KH} \tag{91}$$

For flat disks (i.e., when $H \ll a$), the scattering function for $KH \ll 1$ is

$$|F_{\text{disk}}(K)|^2 = \frac{2}{(2\pi K)^2 a^2} \left\{ 1 - \frac{1}{2\pi Ka} J_1(4\pi Ka) \right\} \tag{92}$$

where J_1 is the Bessel function. For $KH < 1 \ll Ka$, Equation 92 reduces to

$$|F_{\text{disk}}(K)|^2 \approx \frac{2}{(2\pi K)^2 a^2} e^{-4\pi^2 K^2 H^2/3} \tag{93}$$

The expressions given above are isotropic averages of particles of various shapes. When preferred alignment of particles occurs, modification to the above expressions must be made.

General Properties of the SAS Function. Some general behavior of the scattering functions shown above are described.

Extrapolation to K = 0. If the measured scattering curve can be extrapolated to the origin of reciprocal space (i.e., $K = 0$) one obtains, from Equation 83, a value for the factor $V_p^2 N_p (\rho_p - \rho_m)^2/N$, which, for the case of $N_p = 1$, $\rho_m = 0$, and $\rho_p = Nf/V_p$, reduces to

$$I_a(K) = Nf^2 \tag{94}$$

For a system of scattering particles with known contrast and size, Equation 94 will yield N, the total number of atoms in the scattering volume. In the general case of unknown V_p, N_p, and $(\rho_p - \rho_m)$, the results at K = 0 have to be combined with information obtained from other parts of the SAS curve.

Guinier Approximation. Guinier has shown that at small values of Ka, where a is a linear dimension of the particles, the scattering function is approximately related to a simple geometrical parameter called the radius of gyration, R_G. For small angles, $K \approx 2\theta/\lambda$, the scattering amplitude, as shown in Equation 80, may be expressed by a Taylor's expansion up to the quadratic term:

$$\begin{aligned} A &= \int_v \Delta\rho\, e^{2\pi i \mathbf{K}\cdot\mathbf{r}} d^3\mathbf{r} \\ &\approx \Delta\rho \left\{ \int_v d^3\mathbf{r} + \int_v 2\pi i \mathbf{K}\cdot\mathbf{r} d^3\mathbf{r} - \frac{4\pi^2}{2} \int_v (\mathbf{K}\cdot\mathbf{r})^2 d^3\mathbf{r} \right\} \end{aligned} \tag{95}$$

If one chooses the center of gravity of a diffracting object as its origin , the second term is zero. The first term is the volume V of the object times $\Delta\rho$. The third integral is the second moment of the diffracting object, related to R_G.

$$K^2 R_G^2 = \frac{1}{V} \int_v (\mathbf{K}\cdot\mathbf{r})^2 d^3\mathbf{r} \tag{96}$$

Thus the scattering amplitude in Equation 95 becomes

$$A \approx \Delta\rho \left\{ V - \frac{4\pi^2}{2} V R_G^2 K^2 \right\} \approx \Delta\rho V e^{-2\pi^2 R_G^2 K^2} \tag{97}$$

and for the SAS intensity for n independent, but identical, objects:

$$I(K) = A^* \cdot A \approx n(\Delta\rho)^2 V^2 e^{-4\pi^2 R_G^2 K^2} \tag{98}$$

Equation 98 implies that for the small-angle approximation, that is, for small K or small 2θ, the intensity can be approximated by a Gaussian function versus K^2. By plotting $\ln I(K)$ versus K^2 (known as the Guinier plot), a linear relationship is expected at small K with its slope proportional to R_G, which is also commonly referred as the Guinier radius.

The radius of gyration of a homogeneous particle has been defined in Equation 96. For a sphere of radius R_s, $R_G = (\frac{3}{5})^{1/2} R_s$, and the Gaussian form of the SAS intensity function, as shown in Equation 98, coincides with the correct expression, Equations 83 and 85, up to the term proportional to K^4. Subsequent terms in the two series expansions are in fair agreement and corresponding terms have the same sign. For this case, the Guinier approximation is acceptable over a wide range of KR_G. For the oblate rotational ellipsoid with $\upsilon = 0.24$ and the prolate one with $\upsilon = 1.88$, the Guinier approximation coincides with the expansion of the scattering functions even up to K^6. In general, the concept of the radius of gyration is applicable to particles of any shapes, but the K range, where this parameter can be identified, may vary with different shapes.

Porod Approximation. For homogeneous particles with sharp boundaries and a surface area A_p, Porod (see Guinier and Fournet, 1995) has shown that for large K

$$I(\mathbf{K}) \approx \frac{2\pi A_p}{V_p^2 (2\pi K)^4} \tag{99}$$

describes the average decrease of the scattering function. Damped oscillations about this average curve may occur in systems with very uniform particle size.

Integrated Intensity (The Small-Angle Invariant). Integration of SAS intensity over all K values yields an invariant, Q. For a two-phase model system, this quantity is

$$Q = V^2 C_p (1 - C_p)(\rho_p - \rho_m)^2 \qquad (100)$$

where C_p is the volume fraction of the dispersed particles. What is noteworthy here is that this quantity enables one to determine either C_p or $(\rho_p - \rho_m)$ if the other is known. Generally, the scattering contrast $(\rho_p - \rho_m)$ is known or can be estimated and thus measurement of the invariant permits a determination of the volume fraction of the dispersed particles.

Interparticle Interference Function. We have deliberately neglected interparticle interference terms (cf. Equation 84), to obtain Equation 83; its applicability is therefore restricted to very dilute systems, typically $N_p V_p < 0.01$. As long as the interparticle distance remains much larger than the particle size, it will be possible to identify single-particle scattering properties in a somewhat restricted range, as interference effects will affect the scattering at lower K values only. However, in dense systems one approaches the case of macromolecular liquids, and both single-particle as well as interparticle effects must be realized over the whole K range of interest.

For randomly oriented identical particles of arbitrary shape, interference effects can be included by writing (cf. Equations 83 and 84)

$$I(\mathbf{K}) \propto \{\overline{|F_p(\mathbf{K})|}^2 - \overline{|F_p(\mathbf{K})|}^2 + \overline{|F_p(\mathbf{K})|}^2 W_i(\mathbf{K})\} \qquad (101)$$

where the bar indicates an average of all directions of $\mathbf{K}$, and the interference function

$$W_i(\mathbf{K}) = \overline{\Psi(\mathbf{K})} + 1 \qquad (102)$$

with the function Ψ given in Equation 84. The parameter $W_i(\mathbf{K})$ is formally identical to the liquid structure factor, and there is no fundamental difference in the treatment between the two. It is possible to introduce thermodynamic relationships if one defines an interaction potential for the scattering particles. For applications in the solid state, hard-core interaction potentials with an adjustable interaction range exceeding the dimensions of the particle may be used to rationalize interparticle interference effects. It is also possible to model interference effects by assuming a specific model, or using a statistical approach.

As $W_i(\mathbf{K}) \to 0$ for large $\mathbf{K}$, interference between particles is most prominently observed at the lower $\mathbf{K}$ values of the SAS curve. For spherical particles, the first two terms in Equation 101 are equal and the scattering cross-section, or the intensity, becomes

$$I(\mathbf{K}) = C_1 \overline{|F_s(KR_s)|}^2 W_i(\mathbf{K}, C_s) \qquad (103)$$

where C_1 is a constant factor appearing in Equation 83, F_s is the single-particle scattering form factor of a sphere, and W_i is the interference function for rigid spheres of different concentration $C_s = N_p V_p / V$. The interference effects become progressively more important with increasing C_s. At large C_s values, the SAS curve shows a peak characteristic of the interference function used.

When particle interference modifies the SAS profile, the linear portion of the Guinier plot usually becomes inaccessible at small $\mathbf{K}$. Therefore, any straight line found in a Guinier plot at relatively large $\mathbf{K}$ is accidental and gives less reliable information about particle size.

Size Distribution. Quite frequently, the size distribution of particles also complicates the interpretation of SAS patterns, and the single-particle characteristics such as R_G, L_p, V_p, A_p, and so on, defined previously for identical particles, will have to be replaced by appropriate averages over the size distribution function. In many cases, both particle interference and size distribution may appear simultaneously so that the SAS profile will be modified by both effects.

Simple expressions for the scattering from a group of nonidentical particles can only be expected if interparticle interference is neglected. By generalizing Equation 83, one can write for the scattering of a random system of nonidentical particles without orientational correlation:

$$I(\mathbf{K}) = \frac{1}{N} \sum_v V_{pv}^2 N_{pv} \Delta\rho_v^2 \overline{|F_{pv}(\mathbf{K})|}^2 \qquad (104)$$

where v is a label for particles with a particular size parameter. The bar indicates orientational averaging. If the Guinier approximation is valid for even the largest particles in a size distribution, an experimental radius of gyration determined from the lower-$\mathbf{K}$ end of the scattering curve in Guinier representation will correspond to the largest sizes in the distribution. The Guinier plot will show positive curvature similar to the scattering function of nonspherical particles. There is obviously no unique way to deduce the size distribution of particles of unknown shape from the measured scattering profile, although it is much easier to calculate the cross-section for a given model. For spherical particles, several attempts have been made to obtain the size distribution function or certain characteristics of it experimentally, but even under these simplified conditions wide distributions are difficult to determine.

ACKNOWLEDGMENTS

This chapter is dedicated to Professor Jerome B. Cohen of Northwestern University, who passed away suddenly on November 7, 1999. The author received his education on crystallography and diffraction under the superb teaching of Professor Cohen. The author treasures his over 27 years of collegial interaction and friendship with Jerry.

The author also wishes to acknowledge J. B. Cohen, J. E. Epperson, J. P. Anderson, H. Hong, R. D. Aburano, N. Takesue, G. Wirtz, and T. C. Chiang for their direct or

indirect discussions, collaborations, and/or teaching over the past 25 years. The preparation of this unit is supported in part by the U.S. Department of Energy, Office of Basic Energy Science, under contract No. DEFH02-96ER45439, and in part by the state of Illinois Board of Higher Education, under a grant number NWU98 IBHE HECA through the Frederick Seitz Materials Research Laboratory at the University of Illinois at Urbana-Champaign.

KEY REFERENCES

Cullity, 1978. See above.

Purpose of this book is to acquaint the reader who has little or no previous knowledge of the subject with the theory of x-ray diffraction, the experimental methods involved, and the main applications.

Guinier, 1994. See above.

Begins with the general theory of diffraction, and then applies this theory to various atomic structures, amorphous bodies, crystals, and imperfect crystals. Author has assumed that the reader is familiar with the elements of crystallography and x-ray diffraction. Should be especially useful for solid-state physicists, metallorgraphers, chemists, and even biologists.

International Table for Crystallography 1996. See above.

Purpose of this series is to collect and critically evaluate modern, advanced tables and texts on well-established topics that are relevant to crystallographic research and for applications of crystallographic methods in all sciences concerned with the structure and properties of materials.

James, 1948. See above.

Intended to provide an outline of the general optical principles underlying the diffraction of x rays by matter, which may serve as a foundation on which to base subsequent discussions of actual methods and results. Therefore, all details of actual techniques, and of their application to specific problems have been considered as lying beyond the scope of the book.

Klug, and Alexander, 1974. See above.

Contains details of many x-ray diffraction experimental techniques and analysis for powder and polycrystalline materials. Serves as textbook, manual, and teacher to plant workers, graduate students, research scientists, and others who seek to work in or understand the field.

Schultz, 1982. See above.

The thrust of this book is to convince the reader of the universality and utility of the scattering method in solving structural problems in materials science. This textbook is aimed at teaching the fundamentals of scattering theory and the broad scope of applications in solving real problems. It is intended that this book be augmented by additional notes dealing with experimental practice.

Schwartz, and Cohen, 1987. See above.

Covers an extensive list of topics with many examples. It deals with crystallography and diffraction for both perfect and imperfect crystals and contains an excellent set of advanced problem solving home works. Not intended for beginners, but serves the purpose of being an excellent reference for materials scientists who wish to seek solutions by means of diffraction techniques.

Warren, 1969. See above.

The emphasis of this book is a rigorous development of the basic diffraction theory. The treatment is carried far enough to relate to experimentally observable quantities. The main part of this book is devoted to the application of x-ray diffraction methods to both crystalline and amorphous materials, and to both perfect and imperfect crystals. This book is not intended for beginners.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

$\mathbf{s}_0$	incident x-ray direction
$\mathbf{s}$	scattered x-ray direction
$\mathbf{r}_n$	vector from origin to nth lattice point
$\mathbf{u}_n(t)$	time-dependent dynamic displacement vector
$\mathbf{K}$	scattering vector, reciprocal lattice space location
f	scattering power, length, or amplitude (of an atom relative to that of a single electron)
$I(\mathbf{K})$	scattering intensity
$F(\mathbf{K})$	structure factor
$G(\mathbf{K})$	interference function
N_i	number of unit cell i
δ_{ij}	Kronecker delta function
δ_{gj}	arbitrary phase factor
δ_p, δ_q	vector displacements
$\mathbf{H}$	reciprocal space vector, reciprocal lattice vector
I_e	Thomson scattering per electron
$\rho(\mathbf{r})$	electron density function, locally averaged scattering length intensity
M	Debye-Waller temperature factor
$\mathbf{g}$	lattice wave, propogation wave vector
a_{gj}	vibrational amplitude for the gj wave
$\mathbf{e}_{gj}$	polarization vector for the gj wave
k	Boltzmann's constant
ω_{gj}	eigenvalue of the phonon branches
$\mathbf{e}_{gj}$	eigenvector of the phonon branches
α_{pq}	Cowley-Warren parameter
$\mathbf{R}_{lmn}$	interatomic vector
Q	first-order size effects scattering component
R, S	second-order atomic displacement terms
R_G	radius of gyration
C_p	volume fraction of the dispersed particles

DYNAMICAL DIFFRACTION

INTRODUCTION

Diffraction-related techniques using x rays, electrons, or neutrons are widely used in materials science to provide basic structural information on crystalline materials. To

describe a diffraction phenomenon, one has the choice of two theories: kinematic or dynamical.

Kinematic theory, described in KINEMATIC DIFFRACTION OF X RAYS, assumes that each x-ray photon, electron, or neutron scatters only once before it is detected. This assumption is valid in most cases for x rays and neutrons since their interactions with materials are relatively weak. This single-scattering mechanism is also called the first-order Born approximation or simply the Born approximation (Schiff, 1955; Jackson, 1975). The kinematic diffraction theory can be applied to a vast majority of materials studies and is the most commonly used theory to describe x-ray or neutron diffraction from crystals that are imperfect.

There are, however, practical situations where the higher-order scattering or multiple-scattering terms in the Born series become important and cannot be neglected. This is the case, for example, with electron diffraction from crystals, where an electron beam interacts strongly with electrons in a crystal. Multiple scattering can also be important in certain application areas of x-ray and neutron scattering, as described below. In all these cases, the simplified kinematic theory is not sufficient to evaluate the diffraction processes and the more rigorous dynamical theory is needed where multiple scattering is taken into account.

Application Areas

Dynamical diffraction is the predominant phenomenon in almost all electron diffraction applications, such as low-energy electron diffraction (LOW-ENERGY ELECTRON DIFFRACTION) and reflection high-energy electron diffraction. For x rays and neutrons, areas of materials research that involve dynamical diffraction may include the situations discussed in the next six sections.

Strong Bragg Reflections. For Bragg reflections with large structure factors, the kinematic theory often overestimates the integrated intensities. This occurs for many real crystals such as minerals and even biological crystals such as proteins, since they are not ideally imperfect. The effect is usually called the extinction (Warren, 1969), which refers to the extra attenuation of the incident beam in the crystal due to the loss of intensity to the diffracted beam. Its characteristic length scale, extinction length, depends on the structure factor of the Bragg reflection being measured. One can further categorize extinction effects into two types: primary extinction, which occurs within individual mosaic blocks in a mosaic crystal, and secondary extinction, which occurs for all mosaic blocks along the incident beam path. Primary extinction exists when the extinction length is shorter than the average size of mosaic blocks and secondary extinction occurs when the extinction length is less than the absorption length in the crystal.

Large Nearly Perfect Crystals and Multilayers. It is not uncommon in today's materials preparation and crystal growth laboratories that one has to deal with large nearly perfect crystals. Often, centimeter-sized perfect semiconductor crystals such as GaAs and Si are used as substrate materials, and multilayers and superlattices are deposited using molecular-beam or chemical vapor epitaxy. Bulk crystal growers are also producing larger high-quality crystals by advancing and perfecting various growth techniques. Characterization of these large nearly perfect crystals and multilayers by diffraction techniques often involves the use of dynamical theory simulations of the diffraction profiles and intensities. Crystal shape and its geometry with respect to the incident and the diffracted beams can also influence the diffraction pattern, which can only be accounted for by dynamical diffraction.

Topographic Studies of Defects. X-ray diffraction topography is a useful technique for studying crystalline defects such as dislocations in large-grain nearly perfect crystals (Chikawa and Kuriyama, 1991; Klapper, 1996; Tanner, 1996). With this technique, an extended highly collimated x-ray beam is incident on a specimen and an image of one or several strong Bragg reflections are recorded with high-resolution photographic films. Examination of the image can reveal micrometer (μm)-sized crystal defects such as dislocations, growth fronts, and fault lines. Because the strain field induced by a defect can extend far into the single-crystal grain, the diffraction process is rather complex and a quantitative interpretation of a topographic image frequently requires the use of dynamical theory and its variation on distorted crystals developed by Takagi (1962, 1969) and Taupin (1964).

Internal Field-Dependent Diffraction Phenomena. Several diffraction techniques make use of the secondary excitations induced by the wave field inside a crystal under diffraction conditions. These secondary signals may be x-ray fluorescence (X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ANALYSIS) or secondary electrons such as Auger (AUGER ELECTRON SPECTROSCOPY) or photoelectrons. The intensities of these signals are directly proportional to the electric field strength at the atom position where the secondary signal is generated. The wave field strength inside the crystal is a sensitive function of the crystal orientation near a specular or a Bragg reflection, and the dynamical theory is the only theory that provides the internal wave field amplitudes including the interference between the incident and the diffracted waves or the standing wave effect (Batterman, 1964). As a variation of the standing wave effect, the secondary signals can be diffracted by the crystal lattice and form standing wave-like diffraction profiles. These include Kossel lines for x-ray fluorescence (Kossel et al., 1935) and Kikuchi (1928) lines for secondary electrons. These effects can be interpreted as the optical reciprocity phenomena of the standing wave effect.

Multiple Bragg Diffraction Studies. If a single crystal is oriented in such a way that more than one reciprocal node falls on the Ewald sphere of diffraction, a simultaneous multiple-beam diffraction will occur. These

simultaneous reflections were first discovered by Renninger (1937) and are often called Renninger reflections or detour reflections (Umweganregung, "detour" in German). Although the angular positions of the simultaneous reflections can be predicted from simple geometric considerations in reciprocal space (Cole et al., 1962), a theoretical formalism that goes beyond the kinematic theory or the first-order Born approximation is needed to describe the intensities of a multiple-beam diffraction (Colella, 1974). Because of interference among the simultaneously excited Bragg beams, multiple-beam diffraction promises to be a practical solution to the phase problem in diffraction-based structural determination of crystalline materials, and there has been a great renewed interest in this research area (Shen, 1998; 1999a,b; Chang et al., 1999).

Grazing-Incidence Diffraction. In grazing-incidence diffraction geometry, either the incident beam, the diffracted beam, or both has an incident or exit angle, with respect to a well-defined surface, that is close to the critical angle of the diffracting crystal. Full treatment of the diffraction effects in a grazing-angle geometry involves Fresnel specular reflection and requires the concept of an evanescent wave that travels parallel to the surface and decays exponentially as a function of depth into the crystal. The dynamical theory is needed to describe the specular reflectivity and the evanescent wave-related phenomena. Because of its surface sensitivity and adjustable probing depth, grazing-incidence diffraction of x rays and neutrons has evolved into an important technique for materials research and characterization.

Brief Literature Survey

Dynamical diffraction theory of a plane wave by a perfect crystal was originated by Darwin (1914) and Ewald (1917), using two very different approaches. Since then the early development of the dynamical theory has primarily been focused on situations involving only an incident beam and one Bragg-diffracted beam, the so-called two-beam case. Prins (1930) extended Darwin's theory to take absorption into account, and von Laue (1931) reformulated Ewald's approach and formed the backbone of modern-day dynamical theory. Reviews and extensions of the theory have been given by Zachariasen (1945), James (1950), Kato (1952), Warren (1969), and Authier (1970). A comprehensive review of the Ewald–von Laue theory has been provided by Batterman and Cole (1964) in their seminal article in *Review of Modern Physics*. More recent reviews can be found in Kato (1974), Cowley (1975), and Pinsker (1978). Updated and concise summaries of the two-beam dynamical theory have been given recently by Authier (1992, 1996). A historical survey of the early development of the dynamical theory was given in Pinsker (1978).

Contemporary topics in dynamical theory are mainly focused in the following four areas: multiple-beam diffraction, grazing-incidence diffraction, internal fields and standing waves, and special x-ray optics. These modern developments are largely driven by recent interests in rapidly emerging fields such as synchrotron radiation, x-ray crystallography, surface science, and semiconductor research.

Dynamical theory of x rays for multiple-beam diffraction, with two or more Bragg reflections excited simultaneously, was considered by Ewald and Heno (1968). However, very little progress was made until Colella (1974) developed a computational algorithm that made multiple-beam x-ray diffraction simulations more tractable. Recent interests in its applications to measure the phases of structure factors (Colella, 1974; Post, 1977; Chapman et al., 1981; Chang, 1982) have made multiple-beam diffraction an active area of research in dynamical theory and experiments. Approximate theories of multiple-beam diffraction have been developed by Juretschke (1982, 1984, 1986), Hoier and Marthinsen (1983), Hümmer and Billy (1986), Shen (1986, 1999b,c), and Thorkildsen (1987). Reviews on multiple-beam diffraction have been given by Chang (1984, 1992, 1998), Colella (1995), and Weckert and Hümmer (1997).

Since the pioneer experiment by Marra et al. (1979), there has been an enormous increase in the development and use of grazing-incidence x-ray diffraction to study surfaces and interfaces of solids. Dynamical theory for the grazing-angle geometry was soon developed (Afanasev and Melkonyan, 1983; Aleksandrov et al., 1984) and its experimental verifications were given by Cowan et al. (1986), Durbin and Gog (1989), and Jach et al. (1989). Meanwhile, a semikinematic theory called the distorted-wave Born approximation was used by Vineyard (1982) and by Dietrich and Wagner (1983, 1984). This theory was further developed by Dosch et al. (1986) and Sinha et al. (1988), and has become widely utilized in grazing-incidence x-ray scattering studies of surfaces and near-surface structures. The theory has also been extended to explain standing-wave-enhanced and nonspecular scattering in multilayer structures (Kortright and Fischer-Colbrie, 1987), and to include phase-sensitive scattering in diffraction from bulk crystals (Shen, 1999b,c).

Direct experimental proof of the x-ray standing wave effect was first achieved by Batterman (1964) by observing x-ray fluorescence profiles while the diffracting crystal was rotated through a Bragg reflection. While earlier works were mainly on locating impurity atoms in bulk semiconductor materials (Batterman, 1969; Golovchenko et al., 1974; Anderson et al., 1976), more recent research activities focus on determinations of atom locations and distributions in overlayers above crystal surfaces (Golovchenko et al., 1982; Funke and Materlik, 1985; Durbin et al., 1986; Patel et al., 1987; Bedzyk et al., 1989), in synthetic multilayers (Barbee and Warburton, 1984; Kortright and Fischer-Colbrie, 1987), in long-period overlayers (Bedzyk et al., 1988; Wang et al., 1992), and in electrochemical solutions (Bedzyk et al., 1986). Recent reviews on x-ray standing waves are given by Patel (1996) and Lagomarsino (1996).

The rapid increase in synchrotron radiation-based materials research in recent years has spurred new developments in x-ray optics (Batterman and Bilderback, 1991; Hart, 1996). This is especially true in the areas of x-ray wave guides for producing submicron-sized beams (Bilderback et al., 1994; Feng et al., 1995), and x-ray phase plates and polarization analyzers used for studies on magnetic materials (Golovchenko et al., 1986; Mills, 1988; Belyakov

and Dmitrienko, 1989; Hirano et al., 1991; Batterman, 1992; Shen and Finkelstein, 1992; Giles et al., 1994; Yahnke et al., 1994; Shastri et al., 1995). Recent reviews on polarization x-ray optics have been given by Hirano et al. (1995), Shen (1996a), and Malgrange (1996).

An excellent collection of articles on these and other current topics in dynamical diffraction can be found in *X-ray and Neutron Dynamical Diffraction Theory and Applications* (Authier et al., 1996).

Scope of This Unit

Given the wide range of topics in dynamical diffraction, the main purpose of this unit is not to cover every detail but to provide readers with an overview of basic concepts, formalisms, and applications. Special attention is paid to the difference between the more familiar kinematic theory and the more complex dynamical approach. Although the basic dynamical theory is the same for x rays, electrons, and neutrons, we will focus mainly on x rays since much of the original terminology was founded in x-ray dynamical diffraction. The formalism for x rays is also more complex—and thus more complete—because of the vector-field nature of electromagnetic waves. For reviews on dynamical diffraction of electrons and neutrons, we refer the readers to an excellent textbook by Cowley (1975), Moodie et al. (1997), and a recent article by Schlenker and Guigay (1996).

We will start in the Basic Principles section with the fundamental equations and concepts in dynamical diffraction theory, which are derived from classical electrodynamics. Then, in the Two-Beam Diffraction section, we move onto the widely used two-beam approximation, essentially following the description of Batterman and Cole (1964). The two-beam theory deals only with the incident beam and one strongly diffracted Bragg beam, and the multiple scattering between them; multiple scattering due to other Bragg reflections are ignored. This theory provides many basic concepts in dynamical diffraction, and is very useful in visualizing the unique physical phenomena in dynamical scattering.

A full multiple-beam dynamical theory, developed by Colella (1974), takes into account all multiple-scattering effects and surface geometries as well as giving the most complete description of the diffraction processes of x rays, electrons, or neutrons in a perfect crystal. An outline of this theory is summarized in the Multiple-Beam Diffraction section. Also included in that section is an approximate formalism, given by Shen (1986), based on second-order Born approximations. This theory takes into account only double scattering in a multiple-scattering regime yet provides a useful picture of the physics of multiple-beam interactions. Finally, an approximate yet more accurate multiple-beam theory (Shen, 1999b) based on an expanded distorted-wave approximation is presented, which can provide accurate accounts of three-beam interference profiles in the so-called reference-beam diffraction geometry (Shen, 1998).

In the Grazing-Angle Diffraction section, the main results for grazing-incidence diffraction are described using the dynamical treatment. Of particular importance is the concept of evanescent waves and its applications. Also described in this section is a so-called distorted-wave Born approximation, which uses dynamical theory to evaluate specular reflections but treats surface diffraction and scattering within the kinematic regime. This approximate theory is useful in structural studies of surfaces and interfaces, thin films, and multilayered heterostructures.

Finally, because of limited space, a few topics are not covered in this unit. One of these is the theory by Takagi and Taupin for distorted perfect crystals. We refer the readers to the original articles (Takagi, 1962, 1969; Taupin, 1964) and to recent publications by Bartels et al. (1986) and by Authier (1996).

BASIC PRINCIPLES

There are two approaches to the dynamical theory. One, based on work by Darwin (1914) and Prins (1930), first finds the Fresnel reflectance and transmittance for a single atomic plane and then evaluates the total wave fields for a set of parallel atomic planes. The diffracted waves are obtained by solving a set of difference equations similar to the ones used in classical optics for a series of parallel slabs or optical filters. Although it had not been widely used for a long time due to its computational complexity, Darwin's approach has gained more attention in recent years as a means to evaluate reflectivities for multilayers and superlattices (Durbin and Follis, 1995), for crystal truncation effects (Caticha, 1994), and for quasicrystals (Chung and Durbin, 1995).

The other approach, developed by Ewald (1917) and von Laue (1931), treats wave propagation in a periodic medium as an eigenvalue problem and uses boundary conditions to obtain Bragg-reflected intensities. We will follow the Ewald–von Laue approach since many of the fundamental concepts in dynamical diffraction can be visualized more naturally by this approach and it can be easily extended to situations involving more than two beams.

In the early literature of dynamical theory (for two beams), the mathematical forms for the diffracted intensities from general absorbing crystals appear to be rather complicated. The main reason for these complicated forms is the necessity to separate out the real and imaginary parts in dealing with complex wave vectors and wave field amplitudes before the time of computers and powerful calculators. Today these complicated equations are not necessary and numerical calculations with complex variables can be easily performed on a modern computer. Therefore, in this unit, all final intensity equations are given in compact forms that involve complex numbers. In the author's view, these forms are best suited for today's computer calculations. These simpler forms also allow readers to gain physical insights rather than being overwhelmed by tedious mathematical notations.

Fundamental Equations

The starting point in the Ewald–von Laue approach to dynamical theory is that the dielectric function $\varepsilon(\mathbf{r})$ in a

crystalline material is a periodic function in space, and therefore can be expanded in a Fourier series:

$$\varepsilon(\mathbf{r}) = \varepsilon_0 + \delta\varepsilon(\mathbf{r}) \quad \text{with} \quad \delta\varepsilon(\mathbf{r}) = -\Gamma \sum_{\mathrm{H}} F_{\mathrm{H}}\, e^{-i\mathbf{H}\cdot\mathbf{r}} \qquad (1)$$

where $\Gamma = r_e\lambda^2/(\pi V_c)$ and $r_e = 2.818 \times 10^{-5}$ Å is the classical radius of an electron, λ is the x-ray wavelength, V_c is the unit cell volume, and $-\Gamma F_{\mathrm{H}}$ is the coefficient of the **H** Fourier component with F_{H} being the structure factor. All of the Fourier coefficients are on the order of 10^{-5} to 10^{-6} or smaller at x-ray wavelengths, $\delta\varepsilon(\mathbf{r}) \ll \varepsilon_0 = 1$, and the dielectric function is only slightly less than unity.

We further assume that a monochromatic plane wave is incident on a crystal, and the dielectric response is of the same wave frequency (elastic response). Applying Maxwell's equations and neglecting the magnetic interactions, we obtain the following equation for the electric field **E** and the displacement vector **D**:

$$(\nabla^2 + k_0^2)\mathbf{D} = -\nabla \times \nabla \times (\mathbf{D} - \varepsilon_0\mathbf{E}) \qquad (2)$$

where $\mathbf{k}_0$ is the wave vector of the monochromatic wave in vacuum, $k_0 = |\mathbf{k}_0| = 2\pi/\lambda$. For treatment involving magnetic interactions, we refer to Durbin (1987). If we assume an isotropic relation between $\mathbf{D}(\mathbf{r})$ and $\mathbf{E}(\mathbf{r})$, $\mathbf{D}(\mathbf{r}) = \varepsilon(\mathbf{r})\mathbf{E}(\mathbf{r})$, and $\delta\varepsilon(\mathbf{r}) \ll \varepsilon_0$, we have

$$(\nabla^2 + k_0^2)\mathbf{D} = -\nabla \times \nabla \times (\delta\varepsilon\mathbf{D}) \qquad (3)$$

We now use the periodic condition, Equation 1, and substitute for the wave field **D** in Equation 3 a series of Bloch waves with wave vectors $\mathbf{K}_{\mathrm{H}} = \mathbf{K}_0 + \mathbf{H}$,

$$\mathbf{D}(\mathbf{r}) = \sum_{\mathrm{H}} \mathbf{D}_{\mathrm{H}} e^{-i\mathbf{K}_{\mathrm{H}}\cdot\mathbf{r}} \qquad (4)$$

where **H** is a reciprocal space vector of the crystal. For every Fourier component (Bloch wave) **H**, we arrive at the following equation:

$$[(1 - \Gamma F_0)k_0^2 - K_{\mathrm{H}}^2]\mathbf{D}_{\mathrm{H}} = -\Gamma \sum_{\mathrm{G}\neq\mathrm{H}} F_{\mathrm{H-G}}\mathbf{K}_{\mathrm{H}} \times (\mathbf{K}_{\mathrm{H}} \times \mathbf{D}_{\mathrm{G}}) \quad (5)$$

where *H–G* is the difference reciprocal space vector between H and G, the terms involving Γ^2 have been neglected and $\mathbf{K}_{\mathrm{H}} \cdot \mathbf{D}_{\mathrm{H}}$ are set to zero because of the transverse wave nature of the electromagnetic radiation. Equation 5 forms a set of fundamental equations for the dynamical theory of x-ray diffraction. Similar equations for electrons and neutrons can be found in the literature (e.g., Cowley, 1975).

Dispersion Surface

A solution to the eigenvalue equation (Equation 5) gives rise to all the possible wave vectors $\mathbf{K}_{\mathrm{H}}$ and wave field amplitude ratios inside a diffracting crystal. The loci of the possible wave vectors form a multiple-sheet three-dimensional (3D) surface in reciprocal space. This surface is called the dispersion surface, as given by Ewald (1917).

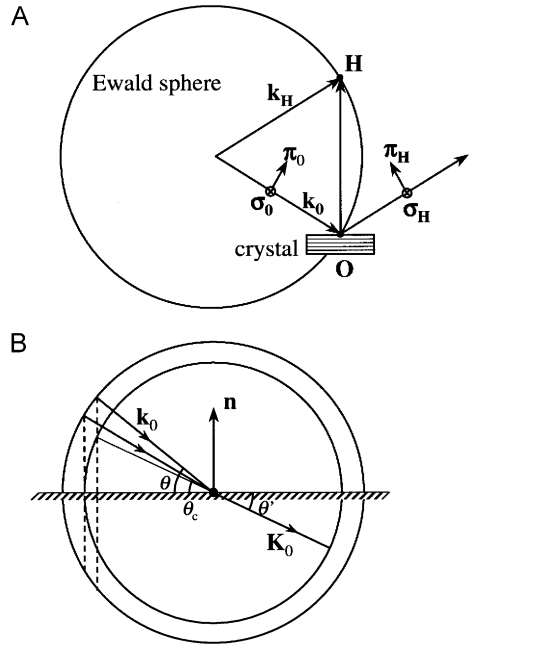

Figure 1. (**A**) Ewald sphere construction in kinematic theory and polarization vectors of the incident and the diffracted beams. (**B**) Dispersion surface in dynamical theory for a one-beam case and boundary conditions for total external reflection.

The introduction of the dispersion surface is the most significant difference between the kinematic and the dynamical theories. Here, instead of a single Ewald sphere (Fig. 1A), we have a continuous distribution of "Ewald spheres" with their centers located on the dispersion surface, giving rise to all possible traveling wave vectors inside the crystal.

As an example, we assume that the crystal orientation is far from any Bragg reflections, and thus only one beam, the incident beam $\mathbf{K}_0$, would exist in the crystal. For this "one-beam" case, Equation 5 becomes

$$[(1 - \Gamma F_0)k_0^2 - K_0^2]\mathbf{D}_0 = 0 \qquad (6)$$

Thus, we have

$$K_0 = k_0/(1 + \Gamma F_0)^{1/2} \cong k_0(1 - \Gamma F_0/2) \qquad (7)$$

which shows that the wave vector $\mathbf{K}_0$ inside the crystal is slightly shorter than that in vacuum as a result of the average index of refraction, $n = 1 - \Gamma F_0'/2$ where F_0' is the real part of F_0 and is related to the average density ρ_0 by

$$\rho_0 = \frac{\pi\Gamma F_0'}{r_e\lambda^2} \qquad (8)$$

In the case of absorbing crystals, $\mathbf{K}_0$ and F_0 are complex variables and the imaginary part, F_0'' of F_0, is related to the average linear absorption coefficient μ_0 by

$$\mu_0 = k_0\Gamma F_0'' = 2\pi\Gamma F_0''/\lambda \qquad (9)$$

Equation 7 shows that the dispersion surface in the one-beam case is a refraction-corrected sphere centered around the origin in reciprocal space, as shown in Figure 1B.

Boundary Conditions

Once Equation 5 is solved and all possible waves inside the crystal are obtained, the necessary connections between wave fields inside and outside the crystal are made through the boundary conditions. There are two types of boundary conditions in classical electrodynamics (Jackson, 1974). One states that the tangential components of the wave vectors have to be equal on both sides of an interface (Snell's law):

$$\mathbf{k}_t = \mathbf{K}_t \tag{10}$$

Throughout this unit, we use the convention that outside vacuum wave vectors are denoted by **k** and internal wave vectors are denoted by **K**, and the subscript t stands for the tangential component of the vector.

To illustrate this point, we again consider the simple one-beam case, as shown in Figure 1B. Suppose that an x-ray beam $\mathbf{k}_0$ with an angle θ is incident on a surface with **n** being its surface normal. To locate the proper internal wave vector $\mathbf{K}_0$, we follow along **n** to find its intersection with the dispersion surface, in this case, the sphere with its radius defined by Equation 7. However, we see immediately that this is possible only if θ is greater than a certain incident angle θ_c, which is the critical angle of the material. From Figure 1B, we can easily obtain that $\cos\theta_c = K_0/k_0$, or for small angles, $\theta_c = (\Gamma F_0)^{1/2}$. Below θ_c no traveling wave solutions are possible and thus total external reflection occurs.

The second set of boundary conditions states that the tangential components of the electric and magnetic field vectors, **E** and $\mathbf{H} = \hat{\mathbf{k}} \times \mathbf{E}$ ($\hat{\mathbf{k}}$ is a unit vector along the propagation direction), are continuous across the boundary. In dynamical theory literature, the eigenequations for dispersion surfaces are expressed in terms of either the electric field vector **E** or the electric displacement vector **D**. These two choices are equivalent, since in both cases a small longitudinal component on the order of ΓF_0 in the **E**-field vector is ignored, because its inclusion only contributes a term of Γ^2 in the dispersion equation. Thus **E** and **D** are interchangeable under this assumption and the boundary conditions can be expressed as the following:

$$\mathbf{D}_t^{in} = \mathbf{D}_t^{out} \tag{11a}$$

$$(\hat{\mathbf{k}} \times \mathbf{D}^{in})_t = (\hat{\mathbf{K}} \times \mathbf{D}^{out})_t \tag{11b}$$

In dynamical diffraction, the boundary condition, Equation 10, or Snell's law selects which points are excited on the dispersion surface or which waves actually exist inside the crystal for a given incident condition. The conditions, Equation 11a and Equation 11b, on the field vectors are then used to evaluate the actual internal field amplitudes and the diffracted wave intensities outside the crystal.

Dynamical theory covers a wide range of specific topics, which depend on the number of beams included in the dispersion equation, Equation 5, and the diffraction geometry of the crystal. In certain cases, the existence of some beams can be predetermined based on the physical law of energy conservation. In these cases, only Equation 11a is needed for the field boundary condition. Such is the case of conventional two-beam diffraction, as discussed in the Internal Fields section. However, both sets of conditions in Equation 11 are needed for general multiple-beam cases and for grazing-angle geometries.

Internal Fields

One of the important applications of dynamical theory is to evaluate the wave fields inside the diffracting crystal, in addition to the external diffracted intensities. Depending on the diffraction geometry, an internal field can be a periodic standing wave as in the case of a Bragg diffraction, an exponentially decayed evanescent wave as in the case of a specular reflection, or a combination of the two. Although no detectors per se can be put inside a crystal, the internal field effects can be observed in one of the following two ways.

The first is to detect secondary signals produced by an internal field, which include x-ray fluorescence (X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ANALYSIS), Auger electrons (AUGER ELECTRON SPECTROSCOPY), and photoelectrons. These inelastic secondary signals are directly proportional to the internal field intensity and are incoherent with respect to the internal field. Examples of this effect include the standard x-ray standing wave techniques and depth-sensitive x-ray fluorescence measurements under total external reflection.

The other way is to measure the elastic scattering of an internal field. In most cases, including the standing wave case, an internal field is a traveling wave along a certain direction, and therefore can be scattered by atoms inside the crystal. This is a coherent process, and the scattering contributions are added on the level of amplitudes instead of intensities. An example of this effect is the diffuse scattering of an evanescent wave in studies of surface or near-surface structures.

TWO-BEAM DIFFRACTION

In the two-beam approximation, we assume only one Bragg diffracted wave $\mathbf{K}_H$ is important in the crystal, in addition to the incident wave $\mathbf{K}_0$. Then, Equation 5 reduces to the following two coupled vector equations:

$$\begin{cases} [(1-\Gamma F_0)k_0^2 - K_0^2]\,\mathbf{D}_0 = -\Gamma F_{\bar{H}} \mathbf{K}_0 \times (\mathbf{K}_0 \times \mathbf{D}_H) \\ [(1-\Gamma F_0)k_0^2 - K_H^2]\,\mathbf{D}_H = -\Gamma F_{\bar{H}} \mathbf{K}_H \times (\mathbf{K}_H \times \mathbf{D}_0) \end{cases} \tag{12}$$

The wave vectors $\mathbf{K}_0$ and $\mathbf{K}_H$ define a plane that is usually called the scattering plane. If we use the coordinate system shown in Figure 1A, we can decompose the wave field amplitudes into σ and π polarization directions. Now the equations for the two polarization states decouple and can be solved separately

$$\begin{cases} [(1-\Gamma F_0)k_0^2 - K_0^2]\,D_{0\sigma,\pi} - k_0^2 \Gamma F_{\bar{H}} P D_{H\sigma,\pi} = 0 \\ -k_0^2 \Gamma F_H P D_{0\sigma,\pi} + [(1-\Gamma F_0)k_0^2 - K_H^2]\,D_{H\sigma,\pi} = 0 \end{cases} \tag{13}$$

where $P = \sigma_H \cdot \sigma_0 = 1$ for σ polarization and $P = \pi_H \cdot \pi_0 = \cos(2\theta_b)$ for π polarization, with θ_B being the Bragg angle. To seek nontrivial solutions, we set the determinant of Equation 13 to zero and solve for K_0:

$$\begin{vmatrix} (1-\Gamma F_0)k_0^2 - K_0^2 & -k_0^2\Gamma F_H^- P \\ -k_0^2\Gamma F_H P & (1-\Gamma F_0)k_0^2 - K_H^2 \end{vmatrix} = 0 \qquad (14)$$

where K_H^2 is related to $\mathbf{K}_0$ through Bragg's law, $K_H^2 = |\mathbf{K}_0 + \mathbf{H}|^2$. Solution of Equation 14 defines the possible wave vectors in the crystal and gives rise to the dispersion surface in the two-beam case.

Properties of Dispersion Surface

To visualize what the dispersion surface looks like in the two-beam case, we define two parameters ξ_0 and ξ_H, as described in James (1950) and Batterman and Cole (1964):

$$\begin{aligned} \xi_0 &\equiv [K_0^2 - (1-\Gamma F_0)k_0^2]/2k_0 = K_0 - k_0(1-\Gamma F_0/2) \\ \xi_H &\equiv [K_H^2 - (1-\Gamma F_0)k_0^2]/2k_0 = K_H - k_0(1-\Gamma F_0/2) \end{aligned} \qquad (15)$$

These parameters represent the deviations of the wave vectors inside the crystal from the average refraction-corrected values given by Equation 7. This also shows that in general the refraction corrections for the internal incident and diffracted waves are different. With these deviation parameters, the dispersion equation, Equation 14, becomes

$$\xi_0\xi_H = \frac{1}{4}k_0^2\Gamma^2P^2F_H^-F_H \qquad (16)$$

Hyperboloid Sheets. Since the right-hand side of Equation 16 is a constant for a given Bragg reflection, the dispersion surface given by this equation represents two sheets of hyperboloids in reciprocal space, for each polarization state P, as shown in Figure 2A. The hyperboloids have their diameter point, Q, located around what would be the center of the Ewald sphere (determined by Bragg's law) and asymptotically approach the two spheres centered at the origin **O** and at the reciprocal node **H**, with a refraction-corrected radius $k_0(1-\Gamma F_0/2)$. The two corresponding spheres in vacuum (outside crystal) are also shown and their intersection point is usually called the Laue point, L. The dispersion surface branches closer to the Laue point are called the α branches ($\alpha\sigma$, $\alpha\pi$), and those further from the Laue point are called the β branches ($\beta\sigma$, $\beta\pi$). Since the square-root value of the right-hand side constant in Equation 16 is much less than k_0, the gap at the diameter point is on the order of 10^{-5} compared to the radius of the spheres. Therefore, the spheres can be viewed essentially as planes in the vicinity of the diameter point, as illustrated in Figure 2B. However, the curvatures have to be considered when the Bragg reflection is in the grazing-angle geometry (see the section Grazing-Angle Diffraction).

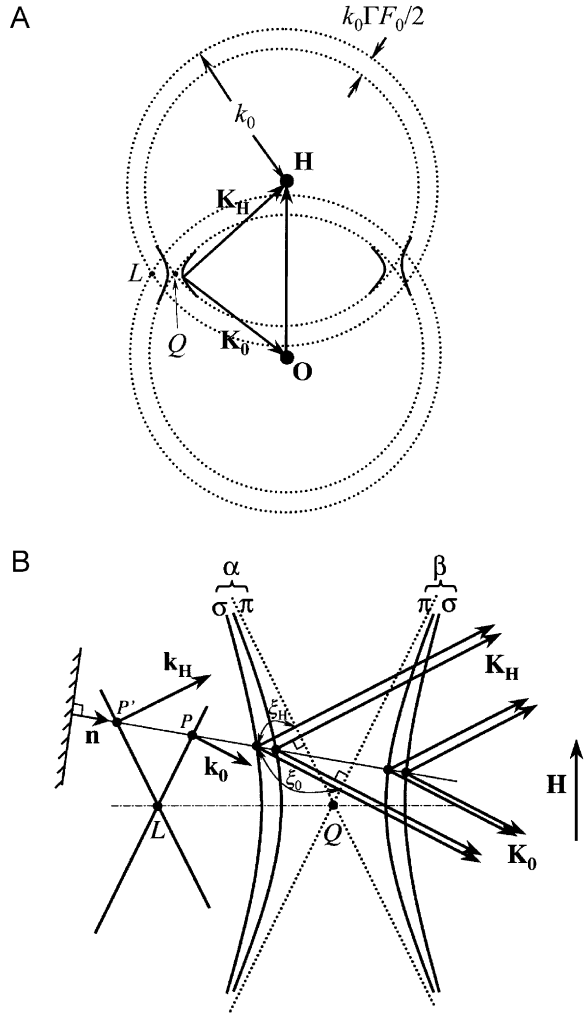

Figure 2. Dispersion surface in the two-beam case. (**A**) Overview. (**B**) Close-up view around the intersection region.

Wave Field Amplitude Ratios. In addition to wave vectors, the eigenvalue equation, Equation 13, also provides the ratio of the wave field amplitudes inside the crystal for each polarization. In terms of ξ_0 and ξ_H, the amplitude ratio is given by

$$D_H/D_0 = -2\xi_0/k_0\Gamma PF_H^- = -k_0\Gamma PF_H/2\xi_H \qquad (17)$$

Again, the actual ratio in the crystal depends entirely on the tie points selected by the boundary conditions. Around the diameter point, ξ_0 and ξ_H have similar lengths and thus the field amplitudes D_H and D_0 are comparable. Away from the exact Bragg condition, only one of ξ_0 and ξ_H has an appreciable size. Thus either D_0 or D_H dominates according to their asymptotic spheres.

Boundary Conditions and Snell's Law. To illustrate how tie points are selected by Snell's law in the two-beam case, we consider the situation in Figure 2B where a crystal surface is indicated by a shaded line. We start with an incident condition corresponding to an incident vacuum

wave vector $\mathbf{k}_0$ at point P. We then construct a surface normal passing through P and intersecting four tie points on the dispersion surface. Because of Snell's law, the wave fields associated with these four points are the only permitted waves inside the crystal. There are four waves for each reciprocal node, **O** or **H**; altogether a total of eight waves may exist inside the crystal in the two-beam case. To find the external diffracted beam, we follow the same surface normal to the intersection point P', and the corresponding wave vector connecting P' to the reciprocal node **H** would be the diffracted beam that we can measure with a detector outside the crystal.

Depending on whether or not a surface normal intercepts both α and β branches at the same incident condition, a diffraction geometry is called either the Laue transmission or the Bragg reflection case. In terms of the direction cosines γ_0 and γ_H of the external incident and diffracted wave vectors, $\mathbf{k}_0$ and $\mathbf{k}_H$, with respect to the surface normal **n**, it is useful to define a parameter b:

$$b \equiv \gamma_0/\gamma_H \equiv \mathbf{k}_0 \cdot \mathbf{n}/\mathbf{k}_H \cdot \mathbf{n} \tag{18}$$

where $b > 0$ corresponds to the Laue case and $b < 0$ the Bragg case. The cases with $b = \pm 1$ are called the symmetric Laue or Bragg cases, and for that reason b is often called the asymmetry factor.

Poynting Vector and Energy Flow. The question about the energy flow directions in dynamical diffraction is of fundamental interests to scientists who use x-ray topography to study defects in perfect crystals. Energy flow of an electromagnetic wave is determined by its time-averaged Poynting vector, defined as

$$\mathbf{S} = \frac{c}{8\pi}(\mathbf{E} \times \mathbf{H}^*) = \frac{c}{8\pi}|\mathbf{D}|^2\hat{\mathbf{K}} \tag{19}$$

where c is the speed of light, $\hat{\mathbf{K}}$ is a unit vector along the propagation direction, and terms on the order of Γ or higher are ignored. The total Poynting vector $\mathbf{S}_T$ at each tie point on each branch of the dispersion surfaces is the vector sum of those for the **O** and **H** beams

$$\mathbf{S}_T = \frac{c}{8\pi}(D_0^2\hat{\mathbf{K}}_0 + D_H^2\hat{\mathbf{K}}_H) \tag{20}$$

To find the direction of $\mathbf{S}_T$, we consider the surface normal **v** of the dispersion branch, which is along the direction of the gradient of the dispersion equation, Equation 16:

$$\begin{aligned}\mathbf{v} = \nabla(\xi_0\xi_H) = \xi_0\nabla\xi_H + \xi_H\nabla\xi_0 = \frac{\xi_0}{\xi_H}\hat{\mathbf{K}}_H + \frac{\xi_H}{\xi_0}\hat{\mathbf{K}}_0 \\ \propto D_0^2\hat{\mathbf{K}}_0 + D_H^2\hat{\mathbf{K}}_H \propto \mathbf{S}_T\end{aligned} \tag{21}$$

where we have used Equation 17 and assumed a negligible absorption ($|F_{\bar{H}} = |F_H|$). Thus we conclude that $\mathbf{S}_T$ is parallel to **v**, the normal to the dispersion surface. In other words, the total energy flow at a given tie point is always normal to the local dispersion surface. This important theorem is generally valid and was first proved by Kato (1960). It follows that the energy flow inside the crystal is parallel to the atomic planes at the full excitation condition, that is, the diameter points of the hyperboloids.

Special Dynamical Effects

There are significant differences in the physical diffraction processes between kinematic and dynamical theory. The most striking observable results from the dynamical theory are Pendellösung fringes, anomalous transmission, finite reflection width for semi-infinite crystals, x-ray standing waves, and x-ray birefringence. With the aid of the dispersion surface shown in Figure 2, these effects can be explained without formally solving the mathematical equations.

Pendellösung. In a Laue case, the α and β tie points across the diameter gap of the hyperbolic dispersion surfaces are excited simultaneously at a given incident condition. The two sets of traveling waves associated with the two branches can interfere with each other and cause oscillations in the diffracted intensity as the thickness of the crystal changes on the order of $2\pi/\Delta K$, where ΔK is simply the gap at the diameter point. These intensity oscillations are termed Pendellösung fringes and the quantity $2\pi/\Delta K$ is called the Pendellösung period. From the geometry shown in Figure 2B, it is straightforward to show that the diameter gap is given by

$$\Delta K = k_0\Gamma|P|\sqrt{F_H F_{\bar{H}}}/\cos\theta_B \tag{22}$$

where θ_B is the internal Bragg angle. As an example, at 10 keV, for Si(111) reflection, $\Delta K = 2.67 \times 10^{-5}$ Å^{-1}, and thus the Pendellösung period is equal to 23 μm.

Pendellösung interference is a unique diffraction phenomenon for the Laue geometry. Both the diffracted wave (**H** beam) and the forward-diffracted wave (**O** beam) are affected by this effect. The intensity oscillations for these two beams are 180° out of phase to each other, creating the effect of energy flow swapping back and forth between the two directions as a function of depth into the crystal surface. For more detailed discussions of Pendellösung fringes we refer to a review by Kato (1974).

We should point out that Pendellösung fringes are entirely different in origin from interference fringes due to crystal thickness. The thickness fringes are often observed in reflectivity measurements on thin film materials and can be mostly accounted for by a finite size effect in the Fraunhofer diffraction. The period of thickness fringes depends only on crystal thickness, not on the strength of the reflection, while the Pendellösung period depends only on the reflection strength, not on crystal thickness.

Anomalous Transmission. The four waves selected by tie points in the Laue case have different effective absorption coefficients. This can be understood qualitatively from the locations of the four dispersion surface branches relative to the vacuum Laue point L and to the average refraction-corrected point Q. The β branches are further from L and are on the more refractive side of Q. Therefore the waves associated with the β branches have larger than average refraction and absorption. The α branches, on the other

hand, are located closer to L and are on the less refractive side of Q. Therefore the waves on the α branches have less than average refraction and absorption. For a relatively thick crystal in the Laue diffraction geometry, the α waves would effectively be able to pass through the thickness of the crystal more easily than would an average wave. What this implies is that if the intensity is not observed in the transmitted beam at off-Bragg conditions, an anomalously "transmitted" intense beam can actually appear when the crystal is set to a strong Bragg condition. This phenomenon is called anomalous transmission; it was first observed by Borrmann (1950) and is also called the Borrmann effect.

If the Laue crystal is sufficiently thick, then even the $\alpha\pi$ wave may be absorbed and only the $\alpha\sigma$ wave will remain. In this case, the Laue-diffracting crystal can be used as a linear polarizer since only the σ-polarized x rays will be transmitted through the crystal.

Darwin Width. In Bragg reflection geometry, all the excited tie points lie on the same branch of the dispersion surface at a given incident angle. Furthermore, no tie points can be excited at the center of a Bragg reflection, where a gap exists at the diameter point of the dispersion surfaces. The gap indicates that no internal traveling waves exist at the exact Bragg condition and total external reflection is the only outlet of the incident energy if absorption is ignored. In fact, the size of the gap determines the range of incident angles at which the total reflection would occur. This angular width is usually called the Darwin width of a Bragg reflection in perfect crystals. In the case of symmetric Bragg geometry, it is easy to see from Figure 2 that the full Darwin width is

$$w = \frac{\Delta K}{k_0 \sin \theta_B} = \frac{2\Gamma|P|\sqrt{F_H F_{\overline{H}}}}{\sin 2\theta_B} \tag{23}$$

Typical values for w are on the order of a few arc-seconds.

The existance of a finite reflection width w, even for a semi-infinite crystal, may seem to contradict the mathematical theory of Fourier transforms that would give rise to a zero reflection width if the crystal size is infinite. In fact, this is not the case. A more careful examination of the situation shows that because of the extinction the incident beam would never be able to see the whole "infinite" crystal. Thus the finite Darwin width is a direct result of the extinction effect in dynamical theory and is needed to conserve the total energy in the physical system.

X-ray Standing Waves. Another important effect in dynamical diffraction is the x-ray standing waves (XSWs) (Batterman, 1964). Inside a diffracting crystal, the total wave field intensity is the coherent sum of the **O** and **H** beams and is given by (σ polarization)

$$|\mathbf{D}|^2 = |\mathbf{D}_0 e^{-i\mathbf{K}_0\cdot\mathbf{r}} + \mathbf{D}_H e^{-i\mathbf{K}_H\cdot\mathbf{r}}|^2 = |\mathbf{D}_0|^2 \times \left|1 + \frac{D_H}{D_0} e^{-i\mathbf{H}\cdot\mathbf{r}}\right|^2 \tag{24}$$

Equation 24 represents a standing wave field with a spatial period of $2\pi/|\mathbf{H}|$, which is simply the d spacing of the Bragg reflection. The field amplitude ratio D_H/D_0 has well-defined phases at α and β branches of the dispersion surface. According to Equation 17 and Figure 2, we see that the phase of D_H/D_0 is $\pi + \alpha_H$ at the α branch, since ξ_H is positive, and is α_H at the β branch, since ξ_H is negative, where α_H is the phase of the structure factor F_H and can be set to zero by a proper choice of real-space origin. Thus the α mode standing wave has its nodes on the atomic planes and the β mode standing wave has its antinodes on the atomic planes.

In Laue transmission geometry, both the α and the β modes are excited simultaneously in the crystal. However, the β mode standing wave is attenuated more strongly because its peak field coincides with the atomic planes. This is the physical origin of the Borrmann anomalous absorption effect.

The standing waves also exist in Bragg geometry. Because of its more recent applications in materials studies, we will devote a later segment (Standing Waves) to discuss this in more detail.

X-ray Birefringence. Being able to produce and to analyze a generally polarized electromagnetic wave has long benefited scientists and researchers in the field of visible-light optics and in studying optical properties of materials. In the x-ray regime, however, such abilities have been very limited because of the weak interaction of x rays with matter, especially for production and analysis of circularly polarized x-ray beams. The situation has changed significantly in recent years. The growing interest in studying magnetic and anisotropic electronic materials by x-ray scattering and spectroscopic techniques have initiated many new developments in both the production and the analyses of specially polarized x rays. The now routinely available high-brightness synchrotron radiation sources can provide naturally collimated x rays that can be easily manipulated by special x-ray optics to generate x-ray beams with polarization tunable from linear to circular. Such optics are usually called x-ray phase plates or phase retarders.

The principles of most x-ray phase plates are based on the linear birefringence effect near a Bragg reflection in perfect or nearly perfect crystals due to dynamical diffraction (Hart, 1978; Belyakov and Dmitrienko, 1989). As illustrated in Figure 2, close to a Bragg reflection **H**, the lengths of the wave vectors for the σ and the π polarizations are slightly different. The difference can cause a phase shift Δ between the σ and the π wave fields to accumulate through the crystal thickness t: $\Delta = (K_\sigma - K_\pi)t$. When the phase shift Δ reaches $\pm 90^\circ$, circularly polarized radiation is generated, and such a device is called a quarter-wave phase plate or retarder (Mills, 1988; Hirano et al., 1991; Giles et al., 1994). In addition to these transmission-type phase retarders, a reflection-type phase plate also has been proposed and studied (Brummer et al., 1984; Batterman, 1992; Shastri et al., 1995), which has the advantage of being thickness independent. However, it has been demonstrated that the Bragg transmission-type phase retarders are more robust to incident beam divergences and thus are very practical x-ray circular polarizers. They have been used for measurements of magnetic dichroism in hard permanent

magnets and other magnetic materials (Giles et al., 1994; Lang et al., 1995). Recent reviews on x-ray polarizers and phase plates can be found in articles by Hart (1991), Hirano et al. (1995), Shen (1996a), and Malgrange (1996).

Solution of the Dispersion Equation

So far we have confined our discussions to the physical effects that exist in dynamical diffraction from perfect crystals and have tried to avoid the mathematical details of the solutions to the dispersion equation, Equation 11 or 12. As we have shown, considerable physical insight concerning the diffraction processes can be gained without going into mathematical details. To obtain the diffracted intensities in dynamical theory, however, the mathematical solutions are unavoidable. In the summary of these results that follows, we will keep the formulas in a general complex form so that absorption effects are automatically taken into account.

The key to solving the dispersion equations (Equation 14 or 16) is to realize that the internal incident beam $\mathbf{K}_0$ can only differ from the vacuum incident beam $\mathbf{k}_0$ by a small component K_{0n} along the surface normal direction of the incident surface, which in turn is linearly related to ξ_0 or ξ_H. The final expression reduces to a quadratic equation for ξ_0 or ξ_H, and solving for ξ_0 or ξ_H alone results in the following (Batterman and Cole, 1964):

$$\xi_0 = \frac{1}{2}k_0|P|\Gamma\sqrt{|b|F_H F_{\bar{H}}}\left[\eta \pm (\eta^2 + b/|b|)^{1/2}\right] \qquad (25)$$

where η is the reduced deviation parameter normalized to the Darwin width

$$\eta \equiv \frac{2b}{w\sqrt{|b|}}(\Delta\theta - \Delta\theta_0) \qquad (26)$$

$\Delta\theta = \theta - \theta_B$ is the angular deviation from the vacuum Bragg angle θ_B, and $\Delta\theta_0$ is the refraction correction

$$\Delta\theta_0 \equiv \frac{\Gamma F_0(1 - 1/b)}{2\sin 2\theta_B} \qquad (27)$$

The dual signs in Equation 25 correspond to the α and β branches of the dispersion surface. In the Bragg case, $b < 0$ so the correction $\Delta\theta_0$ is always positive—that is, the θ value at the center of a reflection is always slightly larger than θ_B given by the kinematic theory. In the Laue case, the sign of $\Delta\theta_0$ depends on whether $b > 1$ or $b < 1$. In the case of absorbing crystals, both η and $\Delta\theta_0$ can be complex, and the directional properties are represented by the real parts of these complex variables while their imaginary parts are related to the absorption given by F_0'' and w.

Substituting Equation 25 into Equation 17 yields the wave field amplitude ratio inside the crystal as a function of η

$$\frac{D_H}{D_0} = -\frac{|P|}{P}\sqrt{|b|F_H/F_{\bar{H}}}[\eta \pm (\eta^2 + b/|b|)^{1/2}] \qquad (28)$$

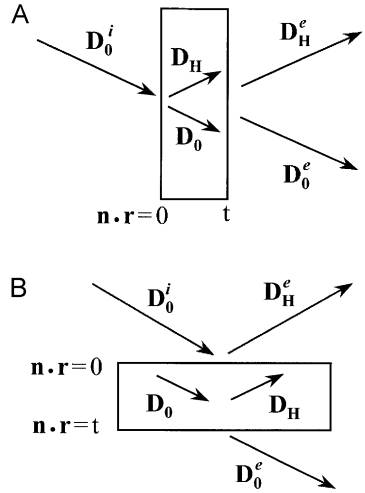

Figure 3. Boundary conditions for the wave fields outside the crystal in (**A**) Laue case and (**B**) Bragg case.

Diffracted Intensities

We now employ boundary conditions to evaluate the diffracted intensities.

Boundary Conditions. In the Laue transmission case (Fig. 3A), assuming a plane wave with an infinite cross-section, the field boundary conditions are given by the following equations:

$$\text{Entrance surface: } \begin{cases} \mathbf{D}_0^i = \mathbf{D}_{0\alpha} + \mathbf{D}_{0\beta} \\ 0 = \mathbf{D}_{H\alpha} + \mathbf{D}_{H\beta} \end{cases} \qquad (29)$$

$$\text{Exit surface: } \begin{cases} \mathbf{D}_0^e = \mathbf{D}_{0\alpha}e^{-i\mathbf{K}_{0\alpha}\cdot\mathbf{r}} + \mathbf{D}_{0\beta}e^{-i\mathbf{K}_{0\beta}\cdot\mathbf{r}} \\ \mathbf{D}_H^e = \mathbf{D}_{H\alpha}e^{-i\mathbf{K}_{H\alpha}\cdot\mathbf{r}} + \mathbf{D}_{H\beta}e^{-i\mathbf{K}_{H\beta}\cdot\mathbf{r}} \end{cases} \qquad (30)$$

In the Bragg reflection case (Fig. 3B), the field boundary conditions are given by

$$\text{Entrance surface: } \begin{cases} \mathbf{D}_0^i = \mathbf{D}_{0\alpha} + \mathbf{D}_{0\beta} \\ \mathbf{D}_H^e = \mathbf{D}_{H\alpha} + \mathbf{D}_{H\beta} \end{cases} \qquad (31)$$

$$\text{Back surface: } \begin{cases} \mathbf{D}_0^e = \mathbf{D}_{0\alpha}e^{-i\mathbf{K}_{0\alpha}\cdot\mathbf{r}} + \mathbf{D}_{0\beta}e^{-i\mathbf{K}_{0\beta}\cdot\mathbf{r}} \\ 0 = \mathbf{D}_{H\alpha}e^{-i\mathbf{K}_{H\alpha}\cdot\mathbf{r}} + \mathbf{D}_{H\beta}e^{-i\mathbf{K}_{H\beta}\cdot\mathbf{r}} \end{cases} \qquad (32)$$

In either case, there are six unknowns, $\mathbf{D}_{0\alpha}$, $\mathbf{D}_{0\beta}$, $\mathbf{D}_{H\alpha}$, $\mathbf{D}_{H\beta}$, $\mathbf{D}_0^e$, $\mathbf{D}_H^e$, and three pairs of equations, Equations 28, 29, 30, or Equations 28, 31, 32, for each polarization state. Our goal is to express the diffracted waves $\mathbf{D}_H^e$ outside the crystal as a function of the incident wave $\mathbf{D}_0^i$.

Intensities in the Laue Case. In the Laue transmission case, we obtain, apart from an insignificant phase factor,

$$\mathbf{D}_H^e = \mathbf{D}_0^i e^{-\mu_0 t/4(1/\gamma_0 + 1/\gamma_H)}\sqrt{\left|\frac{bF_H}{F_{\bar{H}}}\right|}\frac{\sin(A\sqrt{\eta^2+1})}{\sqrt{\eta^2+1}} \qquad (33)$$

where A is the effective thickness (complex) that relates to real thickness t by (Zachariasen, 1945)

$$A \equiv \frac{\pi\Gamma|P|t\sqrt{F_{\mathrm{H}}F_{\overline{\mathrm{H}}}}}{\lambda\sqrt{|\gamma_0\gamma_{\mathrm{H}}|}} \tag{34}$$

The real part of A is essentially the ratio of the crystal thickness to the Pendellösung period.

A quantity often measured in experiments is the total power P_{H} in the diffracted beam, which is equal to the diffracted intensity multiplied by the cross-section area of the beam. The power ratio P_{H}/P_0 of the diffracted beam to the incident beam is given by the intensity ratio, $|\mathbf{D}_{\mathrm{H}}^{\mathrm{e}}/\mathbf{D}_0^{\mathrm{i}}|^2$ multiplied by the area ratio, $1/|b|$, of the beam cross-sections

$$\frac{P_{\mathrm{H}}}{P_0} = \frac{1}{|b|}\left|\frac{\mathbf{D}_{\mathrm{H}}^{\mathrm{e}}}{\mathbf{D}_0^{\mathrm{i}}}\right|^2 = e^{-\mu_0 t/2[1/\gamma_0+1/\gamma_{\mathrm{H}}]}\left|\frac{F_{\mathrm{H}}}{F_{\overline{\mathrm{H}}}}\right| \times \frac{|\sin(A\sqrt{\eta^2+1})|^2}{|\eta^2+1|} \tag{35}$$

A plot of P_{H}/P_0 versus η is usually called the rocking curve. Keeping in mind that η can be a complex variable due essentially to F_0'', Equation 35 is a general expression that is valid for both nonabsorbing and absorbing crystals. A few examples of the rocking curves in the Laue case for nonabsorbing crystals are shown in Figure 4A.

For thick nonabsorbing crystals, A is large ($A \gg 1$) so the $\sin^2$ oscillations tend to average to a value equal to $\frac{1}{2}$. Thus, Equation 35 reduces to a simple Lorentzian shape

$$\frac{P_{\mathrm{H}}}{P_0} = \frac{1}{2(\eta^2+1)} \tag{36}$$

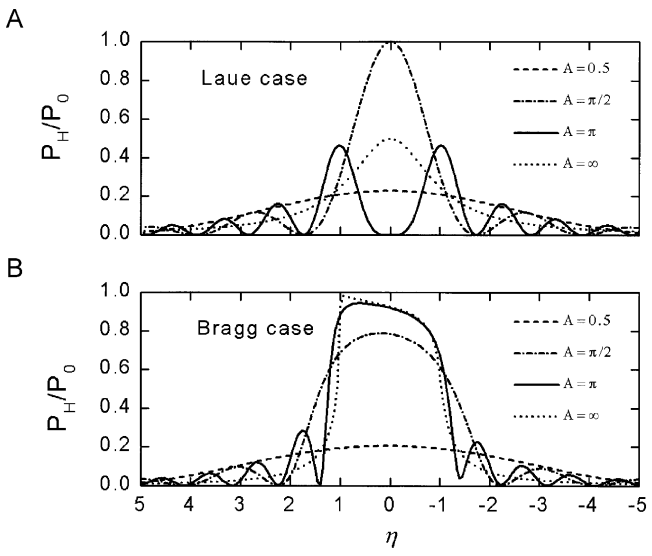

Figure 4. Diffracted intensity P_{H}/P_0 in (**A**) nonabsorbing Laue case, and (**B**) absorbing Bragg case, for several effective thicknesses. The Bragg reflection in (**B**) is for GaAs(220) at a wavelength 1.48 Å.

For thin nonabsorbing crystals ($A \ll 1$), we rewrite Equation 35 in the following form:

$$\frac{P_{\mathrm{H}}}{P_0} = \left[\frac{\sin(A\sqrt{\eta^2+1})}{\sqrt{\eta^2+1}}\right]^2 \approx \left[\frac{\sin(A\eta)}{\eta}\right]^2 \tag{37}$$

This approximation (Equation 37) can be realized by expanding the quantities in the square brackets on both sides to third power and neglecting the A^3 term since $A \ll 1$. We see that in this thin-crystal limit, dynamical theory gives the same result as kinematic theory. The condition $A \ll 1$ can be restated as the crystal thickness t is much less than the Pendellösung period.

Intensities in the Bragg Case. In the Bragg reflection case, the diffracted wave field is given by

$$\mathbf{D}_{\mathrm{H}}^{\mathrm{e}} = \mathbf{D}_0^{\mathrm{i}}\sqrt{\left|\frac{bF_{\mathrm{H}}}{F_{\overline{\mathrm{H}}}}\right|}\frac{1}{\eta + i\sqrt{\eta^2-1}\cot(A\sqrt{\eta^2-1})} \tag{38}$$

The power ratio P_{H}/P_0 of the diffracted beam to the incident, often called the Bragg reflectivity, is

$$\frac{P_{\mathrm{H}}}{P_0} = \left|\frac{F_{\mathrm{H}}}{F_{\overline{\mathrm{H}}}}\right|\frac{1}{|\eta + i\sqrt{\eta^2-1}\cot(A\sqrt{\eta^2-1})|^2} \tag{39}$$

In the case of thick crystals ($A \gg 1$), Equation 39 reduces to

$$\frac{P_{\mathrm{H}}}{P_0} = \left|\frac{F_{\mathrm{H}}}{F_{\overline{\mathrm{H}}}}\right|\frac{1}{|\eta \pm \sqrt{\eta^2-1}|^2} \tag{40}$$

The choice of the signs is such that a smaller value of P_{H}/P_0 is retained.

On the other hand, for semi-infinite crystals ($A \gg 1$), we can go back to the boundary conditions, Equations 31 and 32, and ignore the back surface altogether. If we then apply the argument that only one of the two tie points on each branch of the dispersion surface is physically feasible in the Bragg case because of the energy flow conservation, we arrive at the following simple boundary condition:

$$\mathbf{D}_0^{\mathrm{i}} = \mathbf{D}_0 \qquad \mathbf{D}_{\mathrm{H}}^{\mathrm{e}} = \mathbf{D}_{\mathrm{H}} \tag{41}$$

By using Equations 41 and 28, the diffracted power can be expressed by

$$\frac{P_{\mathrm{H}}}{P_0} = \left|\frac{F_{\mathrm{H}}}{F_{\overline{\mathrm{H}}}}\right|\left|\eta \pm \sqrt{\eta^2-1}\right|^2 \tag{42}$$

Again the sign in front of the square root is chosen so that P_{H}/P_0 is less than unity. The result is obviously identical to Equation 40.

Far away from the Bragg condition, $\eta \gg 1$, Equation 40 shows that the reflected power decreases as $1/\eta^2$. This asymptotic form represents the "tails" of a Bragg reflection (Andrews and Cowley, 1985), which are also called the crystal truncation rod in kinematic theory (Robinson,

1986). In reciprocal space, the direction of the tails is along the surface normal since the diffracted wave vector can only differ from the Bragg condition by a component normal to the surface or interface. More detailed discussions of the crystal truncation rods in dynamical theory can be found in Colella (1991), Caticha (1993, 1994), and Durbin (1995).

Examples of the reflectivity curves, Equation 39, for a GaAs crystal with different thicknesses in the symmetric Bragg case are shown in Figure 4B. The oscillations in the tails are entirely due to the thickness of the crystal. These modulations are routinely observed in x-ray diffraction profiles from semiconductor thin films on substrates and can be used to determine the thin-film thickness very accurately (Fewster, 1996).

Integrated Intensities. The integrated intensity R_H^η in the reduced η units is given by integrating the diffracted power ratio P_H/P_0 over the entire η range.

For nonabsorbing crystals in the Laue case, in the limiting cases of $A \ll 1$ and $A \gg 1$, R_H^η can be calculated analytically as (Zachariasen, 1945)

$$R_H^\eta = \int_{-\infty}^{\infty} \left(\frac{P_H}{P_0}\right) d\eta = \begin{cases} \pi A, & A \ll 1 \\ \pi/2, & A \gg 1 \end{cases} \tag{43}$$

For intermediate values of A or for absorbing crystals, the integral can only be calculated numerically. A general plot of R_H^η versus A in the nonabsorbing case is shown in Figure 5 as the dashed line.

For nonabsorbing crystals in the Bragg case, Equation 39 can be integrated analytically (Darwin, 1922) to yield

$$R_H^\eta = \int_{-\infty}^{\infty} \left(\frac{P_H}{P_0}\right) d\eta = \pi \tanh(A) = \begin{cases} \pi A, & A \ll 1 \\ \pi, & A \gg 1 \end{cases} \tag{44}$$

A plot of the integrated power in the symmetric Bragg case is shown in Figure 5 as the solid curve. Both curves in Figure 5 show a linear behavior for small A, which is consistent with kinematic theory.

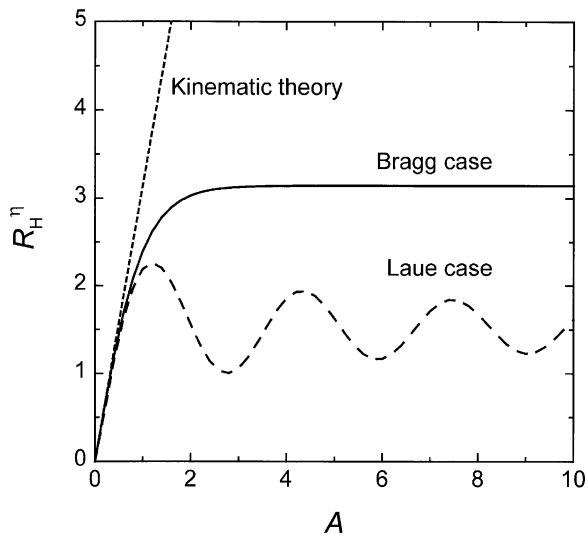

Figure 5. Comparison of integrated intensities in the Laue case and the Bragg case with the kinematic theory.

If we use the definitions of η and A, we obtain that the integrated power R_H^θ over the incident angle θ in the limit of $A \ll 1$ is given by

$$R_H^\theta = \int_{-\infty}^{\infty} \left(\frac{P_H}{P_0}\right) d\theta = \frac{w}{2} R_H^\eta = \frac{\pi}{2} wA = \frac{r_e^2 \lambda^3 P^2 |F_H|^2 t}{V_c \sin 2\theta_B} \tag{45}$$

which is identical to the integrated intensity in the kinematic theory for a small crystal (Warren, 1969). Thus in some sense kinematic theory is a limiting form of dynamical theory, and the departures of the integrated intensities at larger A values (Fig. 5) is simply the effect of primary extinction. In the thick-crystal limit $A \gg 1$, the θ-integrated intensity R_H^θ in both Laue and Bragg cases is linear in $|F_H|$. This linear rather than quadratic dependence on $|F_H|$ is a distinct and characteristic result of dynamical diffraction.

Standing Waves

As we discussed earlier, near or at a Bragg reflection, the wave field amplitudes, Equation 24, represent standing waves inside the diffracting crystal. In the Bragg reflection geometry, as the incident angle increases through the full Bragg reflection, the selected tie points shift from the α branch to the β branch. Therefore the nodes of the standing wave shift from on the atomic planes ($r = 0$) to in between the atomic planes ($r = d/2$) and the corresponding antinodes shift from in between to on the atomic planes.

For a semi-infinite crystal in the symmetric Bragg case and σ polarization, the standing wave intensity can be written, using Equations 24, 28, and 42, as

$$I = \left| 1 + \sqrt{\frac{P_H}{P_0}} e^{i(\nu + \alpha_H - \mathbf{H}\cdot\mathbf{r})} \right|^2 \tag{46}$$

where ν is the phase of $\eta \pm \sqrt{\eta^2 - 1}$ and α_H is the phase of the structure factor F_H, assuming absorption is negligible. If we define the diffraction plane by choosing an origin such that α_H is zero, then the standing wave intensity as a function of η is determined by the phase factor $\mathbf{H} \cdot \mathbf{r}$ with respect to the origin chosen and the d spacing of the Bragg reflection (Bedzyk and Materlik, 1985). Typical standing wave intensity profiles given by Equation 46 are shown in Figure 6. The phase variable ν and the corresponding reflectivity curve are also shown in Figure 6.

An XSW profile can be observed by measuring the x-ray fluorescence from atoms embedded in the crystal structure since the fluorescence signal is directly proportional to the internal wave field intensity at the atom position (Batterman, 1964). By analyzing the shape of a fluorescence profile, the position of the fluorescing atom with respect to the diffraction plane can be determined. A detailed discussion of nodal plane position shifts of the standing waves in general absorbing crystals has been given by Authier (1986).

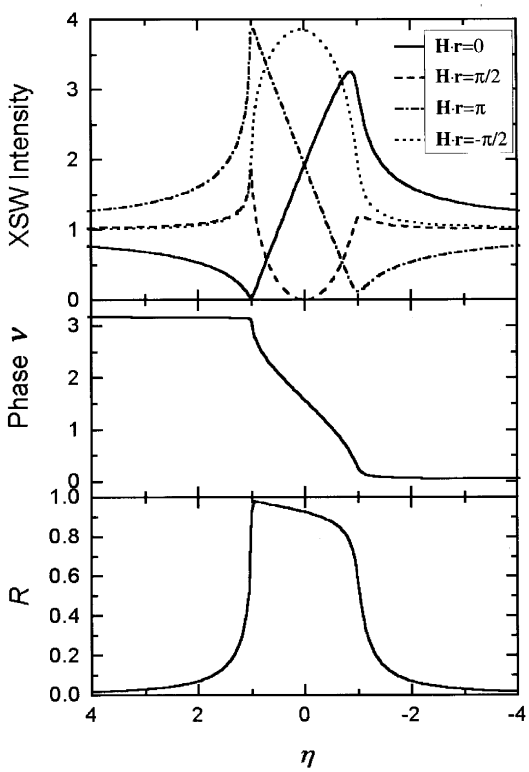

Figure 6. XSW intensity and phase as a function of reduced angular parameter η, along with reflectivity curve, calculated for a semi-infinite GaAs(220) reflection at 1.48 Å.

The standing wave technique has been used to determine foreign atom positions in bulk materials (Batterman, 1969; Golovchenko et al., 1974; Lagomarsino et al., 1984; Kovalchuk and Kohn, 1986). Most recent applications of the XSW technique have been the determination of foreign atom positions, surface relaxations, and disorder at crystal surfaces and interfaces (Durbin et al., 1986; Zegenhagen et al., 1988; Bedzyk et al., 1989; Martines et al., 1992; Fontes et al., 1993; Franklin et al., 1995; Lyman and Bedzyk, 1997). By measuring standing wave patterns for two or more reflections (either separately or simultaneously) along different crystallographic axes, atomic positions can be triangulated in space (Greiser and Materlik, 1986; Berman et al., 1988). More details of the XSW technique can be found in recent reviews by Patel (1996) and Lagomarsino (1996).

The formation of XSWs is not restricted to wide-angle Bragg reflections in perfect crystals. Bedzyk et al. (1988) extended the technique to the regime of specular reflections from mirror surfaces, in which case both the phase and the period of the standing waves vary with the incident angle. Standing waves have also been used to study the spatial distribution of atomic species in mosaic crystals (Durbin, 1998) and quasicrystals (Chung and Durbin, 1995; Jach et al., 1999). Due to a substantial (although imperfect) standing wave formation, anomalous transmission has been observed on the strongest diffraction peaks in nearly perfect quasicrystals (Kycia et al., 1993).

MULTIPLE-BEAM DIFFRACTION

So far, we have restricted our discussion to diffraction cases in which only the incident beam and one Bragg-diffracted beam are present. There are experimental situations, however, in which more than one diffracted beam may be significant and therefore the two-beam approximation is no longer valid. Such situations involving multiple-beam diffraction are dealt with in this section.

Basic Concepts

Multiple-beam diffraction occurs when several sets of atomic planes satisfy Bragg's laws simultaneously. A convenient way to realize this is to excite one Bragg reflection and then rotate the crystal around the diffraction vector. While the **H** reflection is always excited during such a rotation, it is possible to bring another set of atomic planes, **L**, into its diffraction condition and thus to have multiple-beam diffraction. The rotation around the scattering vector **H** is defined by an azimuthal angle, ψ. For x rays, multiple-beam diffraction peaks excited in this geometry were first observed by Renninger (1937); hence, these multiple diffraction peaks are often called the "Renninger peaks." For electrons, multiple-beam diffraction situations exist in almost all cases because of the much stronger interactions between electrons and atoms.

As shown in Figure 7, if atomic planes **H** and **L** are both excited at the same time, then there is always another set of planes, **H–L**, also in diffraction condition. The diffracted beam $\mathbf{k}_L$ by **L** reflection can be scattered again by the **H–L** reflection and this doubly diffracted beam is in the same direction as the **H**-reflected beam $\mathbf{k}_H$. In this sense, the photons (or particles) in the doubly diffracted beam have been through a "detour" route compared to the photons (particles) singly diffracted by the **H** reflection. We usually call **H** the main reflection, **L** the detour reflection, and **H–L** the coupling reflection.

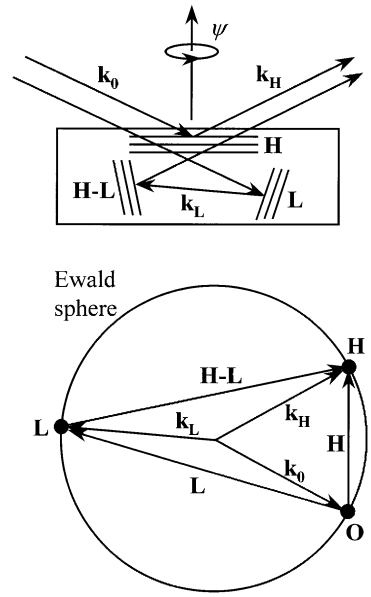

Figure 7. Illustration of a three-beam diffraction case involving **O**, **H**, and **L**, in real space (upper) and reciprocal space (lower).

Depending on the strengths of the structure factors involved, a multiple reflection can cause either an intensity enhancement (peak) or reduction (dip) in the two-beam intensity of **H**. A multiple reflection peak is commonly called the Umweganregung ("detour" in German) and a dip is called the Aufhellung. The former occurs when **H** is relatively weak and both **L** and **H–L** are strong, while the latter occurs when both **H** and **L** are strong and **H–L** is weak. A semiquantitative intensity calculation can be obtained by total energy balancing among the multiple beams, as worked out by Moon and Shull (1964) and Zachariasen (1965).

In most experiments, multiple reflections are simply a nuisance that one tries to avoid since they cause inaccurate intensity measurements. In the last two decades, however, there has been renewed and increasing interest in multiple-beam diffraction because of its promising potential as a physical solution to the well-known "phase problem" in diffraction and crystallography. The phase problem refers to the fact that the data collected in a conventional diffraction experiment are the intensities of the Bragg reflections from a crystal, which are related only to the magnitude of the structure factors, and the phase information is lost. This is a classic problem in diffraction physics and its solution remains the most difficult part of any structure determination of materials, especially for biological macromolecular crystals. Due to an interference effect among the simultaneously excited Bragg beams, multiple-beam diffraction contains the direct phase information on the structure factors involved, and therefore can be used as a way to solve the phase problem.

The basic idea of using multiple-beam diffraction to solve the phase problem was first proposed by Lipcomb (1949), and was first demonstrated by Colella (1974) in theory and by Post (1977) in an experiment on perfect crystals. The method was then further developed by several groups (Chapman et al., 1981; Chang, 1982; Schmidt and Colella, 1985; Shen and Colella, 1987, 1988; Hümmer et al., 1990) to show that it can be applied not only to perfect crystals but also to real, mosaic crystals. Recently, there have been considerable efforts to apply multibeam diffraction to large-unit-cell inorganic and macromolecular crystals (Lee and Colella, 1993; Chang et al., 1991; Hümmer et al., 1991; Weckert et al., 1993). Progress in this area has been amply reviewed by Chang (1984, 1992), Colella (1995, 1996), and Weckert and Hümmer (1997). A recent experimental innovation in reference-beam diffraction (Shen, 1998) allows parallel data collection of three-beam interference profiles using an area detector in a modified oscillation-camera setup, and makes it possible to measure the phases of a large number of Bragg reflections in a relatively short time.

Theoretical treatment of multiple-beam diffraction is considerably more complicated than for the two-beam theory, as evidenced by some of the early works (Ewald and Heno, 1968). This is particularly so in the case of x rays because of mixing of the σ and π polarization states in a multiple-beam diffraction process. Colella (1974), based upon his earlier work for electron diffraction (Colella, 1972), developed a full dynamical theory procedure for multiple-beam diffraction of x rays and a corresponding computer program called NBEAM. With Colella's theory, multiple-beam dynamical calculations have become more practical and more easily performed. On today's powerful computers and software and for not too many beams, running the NBEAM program can be almost trivial, even on personal computers. We will outline the principles of the NBEAM procedure in the NBEAM Theory section.

NBEAM Theory

The fundamental equations for multiple-beam x-ray diffraction are the same as those in the two-beam theory, before the two-beam approximation is made. We can go back to Equation 5, expand the double cross-product, and rewrite it in the following form:

$$\left[\frac{k_0^2}{K_i^2} - (1 + \Gamma F_0)\right]\mathbf{D}_i + \Gamma \sum_{j \neq i} F_{i-j}[\mathbf{u}_i(\mathbf{u}_i \cdot \mathbf{D}_j) - \mathbf{D}_j] = 0 \quad (47)$$

Eigenequation for *D*-field Components. In order to properly express the components of all wave field amplitudes, we define a polarization unit-vector coordinate system for each wave j:

$$\begin{aligned} \mathbf{u}_j &= \mathbf{K}_j/|\mathbf{K}_j| \\ \sigma_j &= \mathbf{u}_j \times \mathbf{n}/|\mathbf{u}_j \times \mathbf{n}| \\ \pi_j &= \mathbf{u}_j \times \sigma_j \end{aligned} \quad (48)$$

where **n** is the surface normal. Multiplying Equation 26 by σ_j and π_j yields

$$\begin{aligned} \left[\frac{k_0^2}{K_i^2} - (1 + \Gamma F_0)\right] D_{i\sigma} &= \Gamma \sum_{j \neq i} F_{i-j}[(\sigma_j \cdot \sigma_i) D_{j\sigma} + (\pi_j \cdot \sigma_i) D_{j\pi}] \\ \left[\frac{k_0^2}{K_i^2} - (1 + \Gamma F_0)\right] D_{i\pi} &= \Gamma \sum_{j \neq i} F_{i-j}[(\sigma_j \cdot \pi_i) D_{j\sigma} + (\pi_j \cdot \pi_i) D_{j\pi}] \end{aligned} \quad (49)$$

Matrix form of the Eigenequation. For an NBEAM diffraction case, Equation 49 can be written in a matrix form if we define a $2N \times 1$ vector $\underline{\mathbf{D}} = (D_{1\sigma}, \ldots, D_{N\sigma}, D_{1\pi}, \ldots, D_{N\pi})$, a $2N \times 2N$ diagonal matrix $\mathbf{T}_{ij}$ with $T_{ii} = k_0^2/K_i^2$ $(i = j)$ and $T_{ij} = 0$ $(i \neq j)$, and a $2N \times 2N$ general matrix $\mathbf{A}_{ij}$ that takes all the other coefficients in front of the wave field amplitudes. Matrix $\underline{\mathbf{A}}$ is Hermitian if absorption is ignored, or symmetric if the crystal is centrosymmetric. Equation 49 then becomes

$$(\underline{\mathbf{T}} + \underline{\mathbf{A}})\underline{\mathbf{D}} = 0 \quad (50)$$

Equation 50 is equivalent to

$$(\underline{\mathbf{T}}^{-1} + \underline{\mathbf{A}}^{-1})\underline{\mathbf{D}} = 0 \quad (51)$$

Strictly speaking the eigenvectors in Equation 51 are actually the **E** fields: $\underline{\mathbf{E}} = \underline{\mathbf{T}} \cdot \underline{\mathbf{D}}$. However, $\underline{\mathbf{D}}$ and $\underline{\mathbf{E}}$ are exchangeable, as discussed in the Basic Principles section.

To find nontrivial solutions of Equation 51, we need to solve the secular eigenvalue equation

$$|\underline{\mathbf{T}}^{-1} + \underline{\mathbf{A}}^{-1}| = 0 \tag{52}$$

with $T_{ii}^{-1} = K_i^2/K_0^2\,(i=j)$ and $T_{ij}^{-1} = 0\,(i \neq j)$. We can write k_j^2 in the form of its normal (n) and tangential (t) components to the entrance surface:

$$K_j^2 = (k_{0\mathrm{n}} + H_{j\mathrm{n}})^2 + k_{j\mathrm{t}}^2 \tag{53}$$

which is essentially Bragg's law together with the boundary condition that $K_{j\mathrm{t}} = k_{j\mathrm{t}}$.

Strategy for Numerical Solutions. If we treat $\mu = K_{0\mathrm{n}/k_0}$ as the only unknown, Equation 52 takes the following matrix form:

$$|\mu^2 - \mu\underline{\mathbf{B}} + \underline{\mathbf{C}}| = 0 \tag{54}$$

where $B_{ij} = -(2H_{j\mathrm{n}}/k_0)\delta_{ij}$ is a diagonal matrix and $C_{ij} = (A-1)_{ij} + \delta_{ij}(H_{j\mathrm{n}}^2 + k_{j\mathrm{t}}^2/k_0^2$. Equation 54 is a quadratic eigenequation that no computer routines are readily available for solving. Colella (1974) employed an ingenious method to show that Equation 51 is equivalent to solving the following linear eigenvalue problem:

$$\begin{pmatrix} \underline{\mathbf{B}} & -\underline{\mathbf{C}} \\ \underline{\mathbf{I}} & 0 \end{pmatrix} \begin{pmatrix} \underline{\mathbf{D}}' \\ \underline{\mathbf{D}} \end{pmatrix} = \mu \begin{pmatrix} \underline{\mathbf{D}}' \\ \underline{\mathbf{D}} \end{pmatrix} \tag{55}$$

where $\underline{\mathbf{I}}$ is a unit matrix, and $\underline{\mathbf{D}}' = \mu\underline{\mathbf{D}}$, which is a redundant $2N$ vector with no physical significance.

Equation 55 can now be solved with standard software routines that deal with linear eigenvalue equations. It is a $4N$th-order equation for $K_{0\mathrm{n}}$, and thus has $4N$ solutions, denoted as $K_{0\mathrm{n}}^l, l = 1, \ldots, 4N$. For each eigenvalue $K_{0\mathrm{n}}$, there is a corresponding $2N$ eigenvector that is stored in $\underline{\mathbf{D}}$, which now is a $2N \times 4N$ matrix and its element labeled $D_{j\sigma}^l$ in its top N rows and $D_{j\pi}^l$ in its bottom N rows. These wave field amplitudes are evaluated at this point only on a relative scale, similar to the amplitude ratio in the two-beam case. For convenience, each $2N$ eigenvector can be normalized to unity:

$$\sum_j^N (|D_{j\sigma}^l|^2 + |D_{j\pi}^l|^2) = 1 \tag{56}$$

In terms of the eigenvalues $K_{0\mathrm{n}}^l$ and the eigenvectors $\mathbf{D}_j^l = (D_{j\sigma}^l, D_{j\pi}^l)$, a general expression for the wave field inside the crystal is given by

$$\mathbf{D}(\mathbf{r}) = \sum_l q_l \sum_j \mathbf{D}_j^l e^{-i\mathbf{K}_j^l \cdot \mathbf{r}} \tag{57}$$

where $\mathbf{K}_j^l = \mathbf{K}_0^l + \mathbf{H}_j$ and q_l's $(l = 1, \ldots, 4N)$ are the coefficients to be determined by the boundary conditions.

Boundary Conditions. In general, it is not suitable to distinguish the Bragg and the Laue geometries in multiple-beam diffraction situations since it is possible to have an internal wave vector parallel to the surface and thus the distinction would be meaningless. The best way to treat the situation, as pointed out by Colella (1974), is to include both the back-diffracted and the forward-diffracted beams in vacuum, associated with each internal beam j. Thus for each beam j, we have two vacuum waves defined by $\mathbf{k}_{\pm j} = \mathbf{k}_{j\mathrm{t}} \pm \mathbf{n}(k_0^2 - k_{j\mathrm{t}}^2)^{1/2}$, where again the subscript t stands for the tangential component. Therefore for an N-beam diffraction from a parallel crystal slab, we have altogether $8N$ unknowns: $4N$ q_l values for the field inside the crystal, $2N$ wave field components of $\mathbf{D}_{-j}^e$ above the entrance surface, and $2N$ components of the wave field $\mathbf{D}_j^e$ below the back surface.

The $8N$ equations needed to solve the above problem are fully provided by the general boundary conditions, Equation 11. Inside the crystal we have

$$\mathbf{E}_j = \sum_l q_l \mathbf{D}_j^l e^{-i\mathbf{K}_j^l \cdot \mathbf{r}} \tag{58}$$

and $\mathbf{H}_j = \mathbf{u}_j \times \mathbf{E}_j$, where the sum is over all eigenvalues l for each jth beam. (We note that in Colella's original formalism converting $\mathbf{D}_j$ to $\mathbf{E}_j$ is not necessary since Equation 51 is already for $\mathbf{E}_j$. This is also consistent with the omissions of all longitudinal components of $\mathbf{E}$ fields, after the eigenvalue equation is obtained, in dynamical theory.) Outside the crystal, we have $\mathbf{D}_j^e$ at the back surface and $\mathbf{D}_{-j}^e$ plus incident beam $\mathbf{D}_0^i$ at the entrance surface. These boundary conditions provide eight scalar equations for each beam j, and thus the $8N$ unkowns can be solved for as a function of $\mathbf{D}_0^i$.

Intensity Computations. Both the reflected and the transmitted intensities, I_{-j} and I_j, for each beam j can be calculated by taking $I_j = |\mathbf{D}_j^e|^2/|\mathbf{D}_0^i|^2$. We should note that the whole computational procedure described above only evaluates the diffracted intensity at <u>one</u> crystal orientation setting with respect to the incident beam. To obtain meaningful information, the computation is usually repeated for a series of settings of the incident angle θ and the azimuthal angle ψ. An example of such two-dimensional (2D) calculations is shown in Figure 8A, which is for a three-beam case, GaAs(335)/(551). In many experimental situations, the intensities in the θ direction are integrated either purposely or because of the divergence in the incident beam. In that case, the integrated intensities versus the azimuthal angle ψ are plotted, as shown in Figure 8B.

Second-Order Born Approximation

From the last segment, we see that the integrated intensity as a function of azimuthal angle usually displays an asymmetric intensity profile, due to the multiple-beam interference. The asymmetry profile contains the phase information about the structure factors involved. Although the NBEAM program provides full account for these multiple-beam interferences, it is rather difficult to gain physical insight into the process and into the structural parameters it depends on.

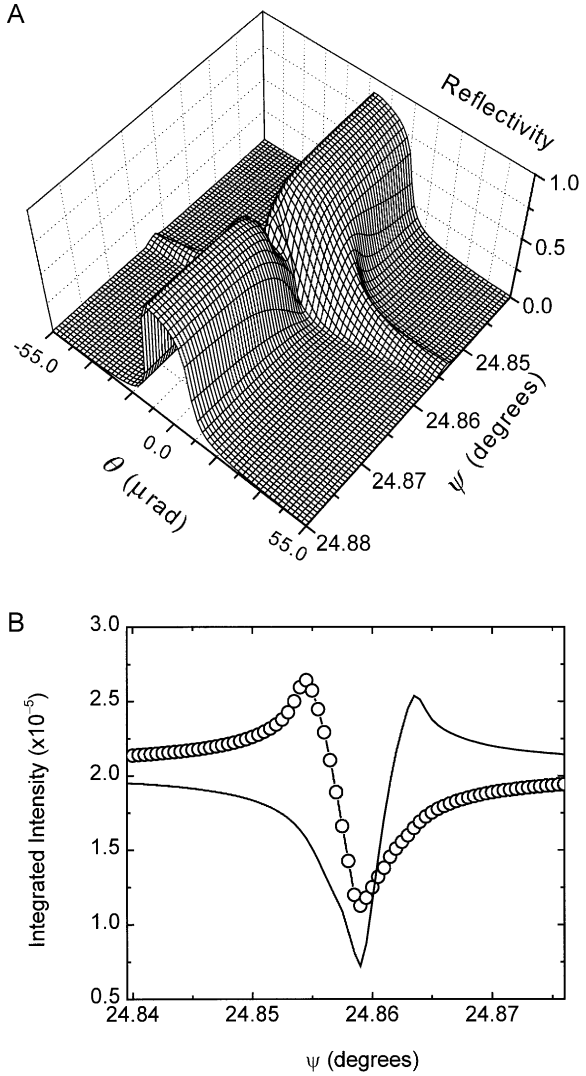

Figure 8. (**A**) Calculated reflectivity using NBEAM for the three-beam case of GaAs(335)/(551), as a function of Bragg angle θ and azimuthal angle ψ. (**B**) Corresponding integrated intensities versus ψ (open circles). The solid-line-only curve corresponds to the profile with an artificial phase of π added in the calculation.

In the past decade or so, there have been several approximate approaches for multiple-beam diffraction intensity calculations based on Bethe approximations (Bethe, 1928; Juretschke, 1982, 1984, 1986; Hoier and Marthinsen, 1983), second-order Born approximation (Shen, 1986), Takagi-Taupin differential equations (Thorkildsen, 1987), and an expanded distorted-wave approximation (Shen, 1999b). In most of these approaches, a modified two-beam structure factor can be defined so that integrated intensities can be obtained through the two-beam equations. In the following section, we will discuss only the second-order Born approximation (for x rays), since it provides the most direct connection to the two-beam kinematic results. The expanded distorted-wave theory is outlined at the end of this unit following the standard distorted-wave theory in surface scattering.

To obtain the Born approximation series, we transform the fundamental Equation 3 into an integral equation by using the Green's function and obtain the following:

$$\mathbf{D}(\mathbf{r}) = \mathbf{D}^{(0)}(\mathbf{r}) + \frac{1}{4\pi}\int d\mathbf{r}' \frac{e^{-ik_0|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|}\nabla' \times \nabla' \times [\delta\varepsilon(\mathbf{r}')\mathbf{D}(\mathbf{r}')] \tag{59}$$

where $\mathbf{D}^{(0)}(\mathbf{r}) = \mathbf{D}_0 e^{-i\mathbf{k}_0\cdot\mathbf{r}}$ is the incident beam. Since δε is small, we can calculate the scattered wave field $\mathbf{D}(\mathbf{r})$ iteratively using the perturbation theory of scattering (Jackson, 1975). For first-order approximation, we substitute $\mathbf{D}(\mathbf{r}')$ in the integrand by the incident beam $\mathbf{D}^{(0)}(\mathbf{r})$, and obtain a first-order solution $\mathbf{D}^{(1)}(\mathbf{r})$. This solution can then be substituted into the integrand again to provide a second-order approximation, $\mathbf{D}^{(2)}(\mathbf{r})$, and so on. The sum of all these approximate solutions gives rise to the true solution of Equation 59,

$$\mathbf{D}(\mathbf{r}) = \mathbf{D}^{(0)}(\mathbf{r}) + \mathbf{D}^{(1)}(\mathbf{r}) + \mathbf{D}^{(2)}(\mathbf{r}) + \cdots \tag{60}$$

This is essentially the Born series in quantum mechanics.

Assuming that the distance r from the observation point to the crystal is large compared to the size of the crystal (far field approximation), it can be shown (Shen, 1986) that the wave field of the first-order approximation is given by

$$\mathbf{D}^{(1)}(\mathbf{r}) = Nr_e F_{\mathrm{H}} \mathbf{u} \times (\mathbf{u} \times \mathbf{D}_0)(e^{-ik_0 r}/r) \tag{61}$$

where N is the number of unit cells in the crystal, and only one set of atomic planes **H** satisfies the Bragg's condition, $k_0\mathbf{u} = \mathbf{k}_0 + \mathbf{H}$, with **u** being a unit vector. Equation 61 is identical to the scattered wave field expression in kinematic theory, which is what we expect from the first-order Born approximation.

To evaluate the second-order expression, we cannot use Equation 61 as $\mathbf{D}^{(1)}$ since it is valid only in the far field. The original form of $\mathbf{D}^{(1)}$ with Green's function has to be used. For detailed derivations we refer to Shen's (1986). The final second-order wave field $\mathbf{D}^{(2)}$ is expressed by

$$\mathbf{D}^{(2)} = -Nr_e \frac{e^{-ik_0 r}}{r}\mathbf{u} \times \left[\mathbf{u} \times \Gamma \sum_{\mathbf{L}} F_{\mathrm{H-L}} F_{\mathrm{L}} \frac{\mathbf{k}_{\mathrm{L}} \times (\mathbf{k}_{\mathrm{L}} \times \mathbf{D}_0)}{k_0^2 - k_{\mathrm{L}}^2}\right] \tag{62}$$

It can be seen that $\mathbf{D}^{(2)}$ is the detoured wave field involving **L** and **H–L** reflections, and the summation over **L** represents a coherent superposition of all possible three-beam interactions. The relative strength of a given detoured wave is determined by its structure factors and is inversely proportional to the distance $k_0^2 - K_{\mathrm{L}}^2$ of the reciprocal lattice node **L** from the Ewald sphere.

The total diffracted intensity up to second order in Γ is given by a coherent sum of $\mathbf{D}^{(1)}$ and $\mathbf{D}^{(2)}$:

$$\begin{aligned} I &= |\mathbf{D}^{(1)} + \mathbf{D}^{(2)}|^2 \\ &= \left| Nr_e \frac{e^{-ik_0 r}}{r}\mathbf{u} \times \left[\mathbf{u} \times F_{\mathrm{H}}\left(\mathbf{D}_0 - \Gamma \sum_{\mathbf{L}} \frac{F_{\mathrm{H-L}} F_{\mathrm{L}}}{F_H} \frac{\mathbf{k}_{\mathrm{L}} \times (\mathbf{k}_{\mathrm{L}} \times \mathbf{D}_0)}{k_0^2 - k_{\mathrm{L}}^2}\right)\right]\right|^2 \end{aligned} \tag{63}$$

Equation 63 provides an approximate analytical expression for multiple-beam diffracted intensities and represents a modified two-beam intensity influenced by multiple-beam interactions. The integrated intensity can be computed by replacing F_H in the kinematic intensity formula by a "modified structure factor" defined by

$$F_H \mathbf{D}_0 \rightarrow F_H \left(\mathbf{D}_0 - \Gamma \sum_{\mathbf{L}} \frac{F_{H-L} F_L}{F_H} \frac{\mathbf{k}_L \times (\mathbf{k}_L \times \mathbf{D}_0)}{k_0^2 - k_L^2} \right) \quad (64)$$

Often, in practice, multiple-beam diffraction intensities are normalized to the corresponding two-beam values. In this case, Equation 63 can be used directly since the prefactors in front of the square brackets will be canceled out. It can be shown (Shen, 1986) that Equation 63 gives essentially the same result as the NBEAM as long as the full three-beam excitation points are excluded, indicating that the second-order Born approximation is indeed a valid approach to multiple-beam diffraction simulations. Equation 63 becomes divergent at the exact three-beam excitation point $k_0 = k_L$. However, the singularity can be avoided numerically if we take absorption into account by introducing an imaginary part in the wave vectors.

Special Multiple-Beam Effects

The second-order Born approximation not only provides an efficient computational technique, but also allows one to gain substantial insight to the physics involved in a multiple-beam diffraction process.

Three-Beam Interactions as the Leading Dynamical Effect. The successive terms in the Born series, Equation 60, represent different levels of multiple-beam interactions. For example, $\mathbf{D}^{(0)}$ is simply the incident beam (**O**), $\mathbf{D}^{(1)}$ consists of two-beam (**O**, **H**) diffraction, $\mathbf{D}^{(2)}$ involves three-beam (**O**, **H**, **L**) interactions, and so on. Equation 62 shows that even when more than three beams are involved, the individual three-beam interactions are the dominant effects compared to higher-order beam interactions. This conclusion is very important to computations of NBEAM effects when N is large. It can greatly simplify even the full dynamical calculations using NBEAM, as shown by Tischler and Batterman (1986). The new multiple-beam interpretation of the Born series also implies that the three-beam effect is the leading term beyond the kinematic first-order Born approximation and thus is the dominant dynamical effect in diffraction. In a sense, the three-beam interactions ($\mathbf{O} \rightarrow \mathbf{L} \rightarrow \mathbf{H}$) are even more important than the multiple scattering in the two-beam case since that involves $\mathbf{O} \rightarrow \mathbf{H} \rightarrow \mathbf{O} \rightarrow \mathbf{H}$ (or higher order) scattering, which is equivalent to a four-beam interaction.

Phase Information. Equation 63 shows explicitly the phase information involved in the multiple-beam diffraction. The interference between the detoured wave $\mathbf{D}^{(2)}$ and the directly scattered wave $\mathbf{D}^{(1)}$ depends on the relative phase difference between the two waves. This phase difference is equal to phase ν of the denominator, plus the phase triplet δ of the structure factor phases α_{H-L}, α_L, and α_H: $\delta = \alpha_{H-L} + \alpha_L - \alpha_H$. It can be shown that although the individual phases α_{H-L}, and α_H depend on the choice of origin in the unit cell, the phase triplet Δ does not; it is therefore called the invariant phase triplet in crystallography. The resonant phase ν depends on whether the reciprocal node **L** is outside ($k_0 < k_L$) or inside ($k_0 > k_L$) the Ewald sphere. As the diffracting crystal is rotated through a three-beam excitation, ν changes by π since **L** is swept through the Ewald sphere. This phase change of π in addition to the constant phase triplet Δ is the cause for the asymmetric three-beam diffraction profiles and allows one to measure the structural phase δ in a diffraction experiment.

Polarization Mixing. For noncoplanar multiple-beam diffraction cases (i.e., **L** not in the plane defined by **H** and $\mathbf{k}_0$), there is in general a mixing of the σ and π polarization states in the detoured wave (Shen, 1991, 1993). This means that if the incident beam is purely σ polarized, the diffracted beam may contain a π-polarized component in the case of multiple-beam diffraction, which does not happen in the case of two-beam diffraction. It can be shown that the polarization properties of the detour-diffracted beam in a three-beam case is governed by the following 2×2 matrix

$$\underline{\mathbf{A}} = \begin{pmatrix} k_L^2 - (\mathbf{L} \cdot \sigma_0)^2 & -(\mathbf{L} \cdot \sigma_0)(\mathbf{L} \cdot \pi_0) \\ -(\mathbf{k}_L \cdot \pi_H)(\mathbf{L} \cdot \sigma_0) & k_L^2 (\pi_H \cdot \pi_0) - (\mathbf{k}_L \cdot \pi_H)(\mathbf{L} \cdot \pi_0) \end{pmatrix} \quad (65)$$

The off-diagonal elements in $\underline{\mathbf{A}}$ indicate the mixing of the polarization states.

This polarization mixing, together with the phase-sensitive multiple-beam interference, provides an unusual coupling to the incident beam polarization state, especially when the incident polarization contains a circularly polarized component. The effect has been used to extract acentric phase information and to determine noncentrosymmetry in quasicrystals (Shen and Finkelstein, 1990; Zhang et al., 1999). If we use a known noncentrosymmetric crystal such as GaAs, the same effect provides a way to measure the degree of circular polarization and can be used to determine all Stokes polarization parameters for an x-ray beam (Shen and Finkelstein, 1992, 1993; Shen et al., 1995).

Multiple-Beam Standing Waves. The internal field in the case of multiple-beam diffraction is a 3D standing wave. This 3D standing wave can be detected, just like in the two-beam case, by observing x-ray fluorescence signals (Greiser and Matrlik, 1986), and can be used to determine the 3D location of the fluorescing atom—similar to the method of triangulation by using multiple separate two-beam cases. Multiple-beam standing waves are also responsible for the so-called super-Borrmann effect because of additional lowering of the wave field intensity around the atomic planes (Borrmann and Hartwig, 1965).

Polarization Density Matrix

If the incident beam is partially polarized—that is, it includes an unpolarized component—calculations in the case of multiple-beam diffraction can be rather complicated. One can simplify the algorithm a great deal by using a polarization density matrix as in the case of magnetic x-ray scattering (Blume and Gibbs, 1988). A polarization matrix is defined by

$$\underline{\rho} = \frac{1}{2}\begin{pmatrix} 1+P_1 & P_2 - iP_3 \\ P_2 + iP_3 & 1-P_1 \end{pmatrix} \tag{66}$$

where (P_1, P_2, P_3) are the normalized Stokes-Poincaré polarization parameters (Born and Wolf, 1983) that characterize the σ and π linear polarization, $\pm 45^\circ$ tilted linear polarization, and left- and right-handed circular polarization, respectively.

A polarization-dependent scattering process, where the incident beam ($D_{0\sigma}, D_{0\pi}$) is scattered into ($D_{\mathrm{H}\sigma}, D_{\mathrm{H}\pi}$), can be described by a 2×2 matrix $\underline{\mathbf{M}}$ whose elements $M_{\sigma\sigma}, M_{\sigma\pi}$, and $M_{\pi\pi}$ represent the respective $\sigma \rightarrow \sigma$, $\sigma \rightarrow \pi, \pi \rightarrow \sigma$, and $\pi \rightarrow \pi$ scattering amplitudes:

$$\begin{pmatrix} D_{\mathrm{H}\sigma} \\ D_{\mathrm{H}\pi} \end{pmatrix} = \begin{pmatrix} M_{\sigma\sigma} & M_{\pi\sigma} \\ M_{\sigma\pi} & M_{\pi\pi} \end{pmatrix} \begin{pmatrix} D_{0\sigma} \\ D_{0\pi} \end{pmatrix} \tag{67}$$

It can be shown that with the density matrix $\underline{\rho}$ and scattering matrix $\underline{\mathbf{M}}$, the scattered new density matrix $\underline{\rho}_{\mathrm{H}}$ is given by $\underline{\rho}_{\mathrm{H}} = \underline{\mathbf{M}}\underline{\rho}\underline{\mathbf{M}}^{\dagger}$, where $\underline{\mathbf{M}}^{\dagger}$ is the Hermitian conjugate of $\underline{\mathbf{M}}$. The scattered intensity I_{H} is obtained by calculating the trace of the new density matrix

$$I_{\mathrm{H}} = \mathrm{Tr}(\underline{\rho}_{\mathrm{H}}) \tag{68}$$

This equation is valid for any incident beam polarization, including when the beam is partially polarized. We should note that the method is not restricted to dynamical theory and is widely used in other physics fields such as quantum mechanics. In the case of multiple-beam diffraction, the matrix $\underline{\mathbf{M}}$ can be evaluated using either the NBEAM program or one of the perturbation approaches.

GRAZING-ANGLE DIFFRACTION

Grazing-incidence diffraction (GID) of x rays or neutrons refers to situations where either the incident or the diffracted beam forms a small angle less than or in the vicinity of the critical angle of a well-defined crystal surface. In these cases, both a Bragg-diffracted beam and a specular-reflected beam can occur simultaneously. Although there are only two beams, **O** and **H**, inside the crystal, the usual two-beam dynamical diffraction theory cannot be applied to this situation without some modifications (Afanasev and Melkonyan, 1983; Cowan et al., 1986; Hoche et al., 1986). These special considerations, however, can be automatically taken into account in the NBEAM theory discussed in the Multiple-Beam Diffraction section, as shown by Durbin and Gog (1989).

A GID geometry may include the following situations: (1) specular reflection, (2) coplanar GID involving highly asymmetric Bragg reflections, and (3) GID in an inclined geometry. Because of the substantial decrease in the penetration depths of the incident beam in these geometries, there have been widespread applications of GID using synchrotron radiation in recent years in materials studies of surface structures (Marra et al., 1979), depth-sensitive disorder and phase transitions (Dosch, 1992; Rhan et al., 1993; Krimmel et al., 1997; Rose et al., 1997), and long-period multilayers and superlattices (Barbee and Warburton, 1984; Salditt et al., 1994). We devote this section first to the basic concepts in GID geometries. A recent review on these topics has been given by Holy (1996); see also SURFACE X-RAY DIFFRACTION. In the Distorted-wave Born Approximation section, we present the principle of this approximation (Vineyard, 1982; Dietrich and Wagner, 1983, 1984; Sinha et al., 1988), which provides a bridge between the dynamical Fresnel formula and the kinematic theory of surface scattering of x rays and neutrons.

Specular Reflectivity

It is straightforward to show that the Fresnel's optical reflectivity, which is widely used in studies of mirrors (e.g., Bilderback, 1981), can be recovered in the dynamical theory for x-ray diffraction. We recall that in the case of one beam, the solution to the dispersion equation is given by Equation 7. Assuming a semi-infinite crystal and using the general boundary condition, Equation 11, we have the following equations across the interface (see Appendix for definition of terms):

$$\begin{aligned} D_0^{\mathrm{i}} + D_0^{e} &= D_0 \\ k_0 \sin\theta (D_0^{\mathrm{i}} - D_0^{\mathrm{e}}) &= k_0 \sin\theta' D_0 \end{aligned} \tag{69}$$

where θ and θ' are the incident angles of the external and the internal incident beams (Fig. 1B). By using Equation 7 and the fact that $\mathbf{K}_0$ and $\mathbf{k}_0$ can differ only by a component normal to the surface, we arrive at the following wave field ratios (for small angles):

$$r_0 \equiv \frac{D_0^{\mathrm{e}}}{D_0^{\mathrm{i}}} = \frac{\theta - \sqrt{\theta^2 - \theta_{\mathrm{c}}^2}}{\theta + \sqrt{\theta^2 - \theta_{\mathrm{c}}^2}} \tag{70a}$$

$$t_0 \equiv \frac{D_0}{D_0^{\mathrm{i}}} = \frac{2\theta}{\theta + \sqrt{\theta^2 - \theta_{\mathrm{c}}^2}} \tag{70b}$$

with the critical angle defined as $\theta_{\mathrm{c}} = (\Gamma F_0)^{1/2}$. For most materials, θ_{c} is on the order of a few milliradians. In general, θ_{c} can be complex in order to take into account absorption. Obviously, Equations 70 gives the same reflection and transmission coefficients as the Fresnel theory in visible optics (see, e.g., Jackson, 1974). The specular reflectivity R is given by the square of the magnitude of Equation 70a: $R = |r_0|^2$, while $|t_0|^2$ of Equation 70b is the internal wave field intensity at the surface. An example of $|r_0||^2$ and $|t_0|^2$ is shown in Figure 9A,B for a GaAs surface.

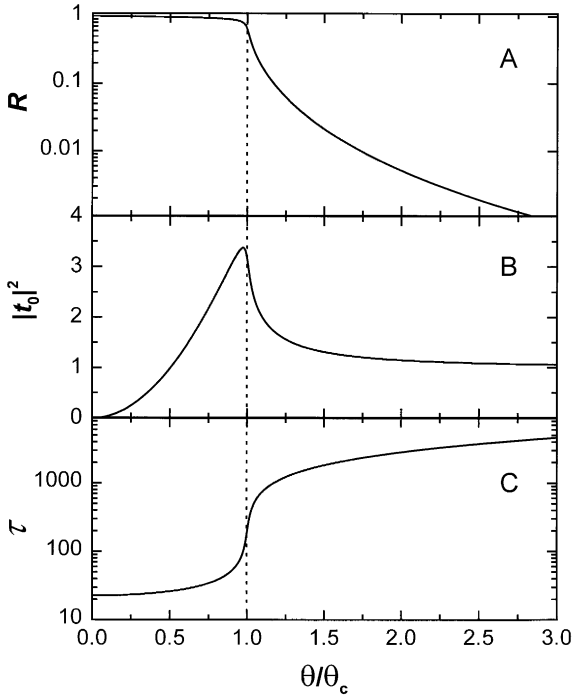

Figure 9. (**A**) Fresnel's reflectivity curve for a GaAs surface at 1.48 Å. (**B**) Intensity of the internal field at the surface. (**C**) Penetration depth.

At $\theta \gg \theta_c$, θ in Equations 70a,b should be replaced by the original sin θ and the Fresnel reflectivity $|r_0|^2$ varies as $1/(2\sin\theta)^4$, or as $1/q^4$ with q being the momentum transfer normal to the surface. This inverse fourth power law is the same as that derived in kinematic theory (Sinha et al., 1988) and in the theory of small-angle scattering (Porod, 1952, 1982). At first glance, the $1/q^4$ asymptotic law is drastically different from the crystal truncation rod $1/q^2$ behavior for the Bragg reflection tails. A more careful inspection shows that the difference is due to the integral nature of the reflectivity over a more fundamental physical quantity called differential cross-section, $d\sigma/d\Omega$, which is defined as the incident flux scattered into a detector area that forms a solid angle $d\Omega$ with respect to the scattering source. In both Fresnel reflectivity and Bragg reflection cases, $d\sigma/d\Omega \sim 1/q^2$ in reciprocal space units. Reflectivity calculations in both cases involve integrating over the solid angle and converting the incident flux into an incident intensity; each would give rise to a factor of 1/sin θ (Sinha et al., 1988). The only difference now is that in the case of Bragg reflections, this factor is simply 1/sin θ_B, which is a constant for a given Bragg reflection, whereas for Fresnel reflectivity cases, sin $\theta \sim q$ results in an additional factor of $1/q^2$.

Evanescent Wave

When $\theta < \theta_c$, the normal component K_{0n} of the internal wave vector $\mathbf{K}_0$ is imaginary so that the x-ray wave field inside the material diminishes exponentially as a function of depth, as given by

$$\mathbf{D}_0(\mathbf{r}) = t_0 e^{-\mathrm{Im}(K_{0n})r_n} e^{-i\mathbf{k}_t\cdot\mathbf{r}_t} \qquad (71)$$

where t_0 is given by Equation 70b and r_n and $\mathbf{r}_t$ are the respective coordinates normal and parallel to the surface.

The characteristic penetration depth $\tau(1/e)$ value of the intensity) is given by $\tau = 1/[2\,\mathrm{Im}(K_{0n})]$, where $\mathrm{Im}\,(K_{0n})$ is the imaginary part of K_{0n}. A plot of τ as a function of the incident angle θ is shown in Figure 9C. In general, a penetration depth (known as skin depth) as short as 10 to 30 Å can be achieved with Fresnel's specular reflection when $\theta < \theta_c$. The limit at $\theta = 0$ is simply given by $\tau = \lambda/(4\pi\theta_c)$ with λ being the x-ray wavelength. This makes the x-ray reflectivity–related measurement a very useful tool for studying surfaces of various materials.

At $\theta > \theta_c$, τ becomes quickly dominated by true photoelectric absorption and the variation is simply geometrical. The large variation of τ around $\theta \sim \theta_c$ forms the basis for such depth-controlled techniques as x-ray fluorescence under total external reflection (de Boer, 1991; Hoogenhof and de Boer, 1994), grazing-incidence scattering and diffraction (Dosch, 1992; Lied et al., 1994; Dietrich and Hasse, 1995; Gunther et al., 1997), and grazing-incidence x-ray standing waves (Hashizume and Sakata, 1989; Jach et al., 1989; Jach and Bedzyk, 1993).

Multilayers and Superlattices

Synthetic multilayers and superlattices usually have long periods of 20 to 50 Å. Since the Bragg angles corresponding to these periods are necessarily small in an ordinary x-ray diffraction experiment, the superlattice diffraction peaks are usually observed in the vicinity of specular reflections. Thus dynamical theory is often needed to describe the diffraction patterns from multilayers of amorphous materials and superlattices of nearly perfect crystals.

A computational method to calculate the reflectivity from a multilayer system was first developed by Parratt (1954). In this method, a series of recursive equations on the wave field amplitudes is set up, based on the boundary conditions at each interface. Assuming that the last layer is a substrate that is sufficiently thick, one can find the solution of each layer backward and finally obtain the reflectivity from the top layer. For details of this method, we refer the readers to Parratt's original paper (1954) and to a more recent matrix formalism reviewed by Holy (1996).

It should be pointed out that near the specular region, the internal crystalline structures of the superlattice layers can be neglected, and only the average density of each layer would contribute. Thus the reflectivity calculations for multilayers and for superlattices are identical near the specular reflections. The crystalline nature of a superlattice needs to be taken into account near or at Bragg reflections. With the help of Takagi-Taupin equations, lattice mismatch and variations along the growth direction can also be taken into account, as shown by Bartels et al. (1986). By treating a semi-infinite single crystal as an extreme case of a superlattice or multilayer, one can calculate the reflectivity for the entire range from specular to all of the Bragg reflections along a given crystallographic axis (Caticha, 1994).

X-ray diffraction studies of laterally structured superlattices with periods of ~0.1 to 1 μm, such as surface

gratings and quantum wire and dot arrays, have been of much interest in materials science in recent years (Bauer et al., 1996; Shen, 1996b). Most of these studies can be dealt with using kinematic diffraction theory (Aristov et al., 1988), and a rich amount of information can be obtained such as feature profiles (Shen et al., 1993; Darhuber et al., 1994), roughness on side wall surfaces (Darhuber et al., 1994), imperfections in grating arrays (Shen et al., 1996b), size-dependent strain fields (Shen et al., 1996a), and strain gradients near interfaces (Shen and Kycia, 1997). Only in the regimes of total external reflection and GID are dynamical treatments necessary as demonstrated by Tolan et al. (1992, 1995) and by Darowski et al. (1997).

Grazing-Incidence Diffraction

Since most GID experiments are performed in the inclined geometry, we will focus only on this geometry and refer the highly asymmetric cases to the literature (Hoche et al., 1988; Kimura and Harada, 1994; Holy, 1996).

In an inclined GID arrangement, both the incident beam and the diffracted beam form a small angle with respect to the surface, as shown in Figure 10A, with the scattering vector parallel to the surface. This geometry involves two internal waves, **O** and **H**, and three external waves, incident **O**, specular reflected $\overline{\mathbf{O}}$ and diffracted **H** beams. With proper boundary conditions, the diffraction problem can be solved analytically as shown by several authors (Afanasev and Melkonyan, 1983; Cowan et al., 1986; Hoche et al., 1986; Hung and Chang, 1989; Jach et al., 1989). Durbin and Gog (1989) applied the NBEAM program to GID geometry.

A characteristic dynamical effect in GID geometry is a double-critical-angle phenomenon due to the diameter gap of the dispersion surface for **H** reflection. This can be seen intuitively from simple geometric considerations. Inside the crystal, only two beams, **O** and **H**, are excited and thus the usual two-beam theory described in the Two-Beam Diffraction section applies. The dispersion surface inside the crystal is exactly the same as shown in Figure 2A. The only difference is the boundary condition. In the GID case, the surface normal is perpendicular to the page in Figure 2, and therefore the circular curvature out of the page needs to be taken into account. For simplicity, we consider only the diameter points on the dispersion surface for one polarization state. A cut through the diameter points L and Q in Figure 2 is shown schematically in Figure 10B; this consists of three concentric circles representing the hyperboloids of revolution α and β branches, and the vacuum sphere at point L. At very small incident angles, we see that no tie points can be excited and only total specular reflection can exist. As the incident angle increases so that $\phi > \phi_c^{\alpha}$, α tie points are excited but the β branch remains extinguished. Thus specular reflectivity would maintain a lower plateau, until $\phi > \phi_c^{\beta}$ when both α and β modes can exist inside the crystal. Meanwhile, the Bragg reflected beam should have been fully excited when $\phi_c^{\alpha} < \phi < \phi_c^{\beta}$, but because of the partial specular reflection its diffracted intensity is much reduced. These effects can be clearly seen in the example shown in Figure 11, which is for a Ge(220) reflection with a (1-11) surface orientation.

If the Bragg's condition is not satisfied exactly, then the circle labeled L in Figure 10B will be split into two concentric ones representing the two spheres centered at **O** and **H**, respectively. We then see that the exit take-off angles can be different for the reflected **O** beam and the diffracted **H** beam. With a position-sensitive linear detector and a range of incident angles, angular profiles (or rod profiles) of diffracted beams can be observed directly, which can provide depth-sensitive structural information near a crystal surface (Dosch et al., 1986; Bernhard et al., 1987).

Distorted-Wave Born Approximation

GID, which was discussed in the last section, can be viewed as the dynamical diffraction of the internal evanescant wave, Equation 71, generated by specular reflection under grazing-angle conditions. If the rescattering mechanism is relatively weak, as in the case of a surface layer, then dynamical diffraction theory may not be necessary and the Born approximation can be substituted to evaluate the scattering of the evanescant wave. This approach is called the distorted-wave Born approximation (DWBA) in quantum mechanics (see, e.g., Schiff, 1955), and was first applied to x-ray scattering from surfaces by Vineyard (1982) and by Dietrich and Wagner (1983, 1984). It was noted by Dosch et al. (1986) that Vineyard's original treatment did not handle the exit-angle dependence properly because of a missing factor in its reciprocity arrangement.

The DWBA has been applied to several different scattering situations, including specular diffuse scattering from a rough surface, crystal truncation rod scattering near a surface, diffuse scattering in multilayers, and near-surface diffuse scattering in binary alloys (X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS). The underlying principle is the same for all these cases and we will only discuss specular diffuse scattering to illustrate these principles.

From a dynamical theory point of view, the DWBA is schematically shown in Figure 12A. An incident beam $\mathbf{k}_0$ creates an internal incident beam $\mathbf{K}_0$ and a specular reflected beam $\mathbf{k}_{\bar{0}}$. We then assume that the internal beam $\mathbf{K}_0$ is scattered by a weak "Bragg reflection" at a lateral momentum transfer $\mathbf{q}_t$. Similar to the two-beam case in dynamical theory, we draw two spheres centered at $\mathbf{q}_t$ shown as the dashed circles in Figure 12A. However, the internal diffracted wave vector is determined by kinematic scattering as $\mathbf{K}_{\bar{q}} = \mathbf{K}_0 + \mathbf{k}$, where $\mathbf{q}$ includes both the lateral component $\mathbf{q}_t$ and a component $\mathbf{q}_n$ normal to the surface, defined by the usual 2θ angle. Therefore only one of the tie points on the internal sphere is excited, giving rise to $\mathbf{K}_{\bar{q}}$. Outside the surface, we have two tie points that yield $\mathbf{k}_q$ and $\mathbf{k}_{\bar{q}}$, respectively, as defined in dynamical theory. Altogether we have six beams, three associated with $\mathbf{O}$ and three associated with $\mathbf{q}$. The connection between the $\mathbf{O}$ and the $\mathbf{q}$ beams is through the internal kinematic scattering

$$\mathbf{D}_{\bar{q}} = S(\mathbf{q}_t)\mathbf{D}_0 \tag{72}$$

where $S(\mathbf{q}_t)$ is the surface scattering form factor. As will be seen later, $|S(\mathbf{q}_t)|^2$ represents the scattering cross-section per unit surface area defined by Sinha et al. (1988) and equals the Fourier transform of the height-height correlation function $C(\mathbf{r}_t)$ in the case of not-too-rough surfaces.

To find the diffuse-scattered exit wave field $\mathbf{D}^e_{\bar{q}}$, we use the optical reciprocity theorem of Helmhotz (Born and Wolf, 1983) and reverse the directions of all three wave vectors of the $\mathbf{q}$ beams. We see immediately that the situation is identical to that discussed at the beginning of this section for Fresnel reflections. Thus, we should have

$$\mathbf{D}^e_{\bar{q}} = t_q \mathbf{D}_{\bar{q}} \qquad t_q \equiv \frac{2\theta_q}{\theta_q + \sqrt{\theta_q^2 - \theta_c^2}} \tag{73}$$

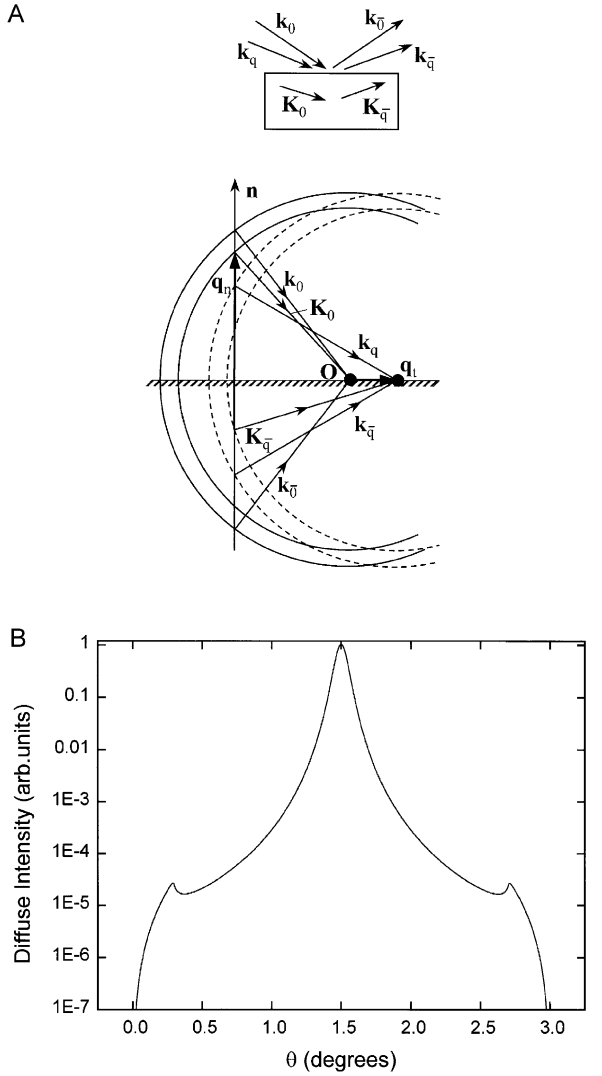

Figure 12. (**A**) Dynamical theory illustration of the distorted-wave Born approximation. (**B**) Typical diffuse scattering profile in specular reflectivity with Yoneda wings.

Using Equations 70b and 72, we obtain that

$$\mathbf{D}^e_{\bar{q}} = t_0 t_q S(\mathbf{q}_t)\mathbf{D}^i_0 \tag{74}$$

and the diffuse scattering intensity is simply given by

$$I_{\text{diff}} = |\mathbf{D}^e_{\bar{q}}/\mathbf{D}^i_0|^2 = |t_0|^2|t_q|^2|S(\mathbf{q}_t)|^2 \tag{75}$$

Apart from a proper normalization factor, Equation 75 is the same as that given by Sinha et al. (1988). Of course, here the scattering strength $|S(\mathbf{q}_t)|^2$ is only a symbolic quantity. For the physical meaning of various surface roughness correlation functions and its scattering forms, we refer to the article by Sinha et al. (1988) for more a detailed discussion.

In a specular reflectivity measurement, one usually uses so-called rocking scans to record a diffuse scattering profile. The amount of diffuse scattering is determined by

the overall surface roughness and the shape of the profile is determined by the lateral roughness correlations. An example of computer-simulated rocking scan is shown in Figure 12B for a GaAs surface at 1.48 Å with the detector $2\theta = 3^\circ$. The parameter $|S(\mathbf{q}_t)|^2$ is assumed to be a Lorentzian with a correlation length of 4000 Å. The two peaks at $\theta \sim 0.3^\circ$ and 2.7° correspond to the situation where the incident or the exit beam makes the critical angle with respect to the surface. These peaks are essentially due to the enhancement of the evanescent wave (standing wave) at the critical angle (Fig. 9B) and are often called the Yoneda wings, as they were first observed by Yoneda (1963).

Diffuse scattering of x rays, neutrons, and electrons is widely used in materials science to characterize surface morphology and roughness. The measurements can be performed not only near specular reflection but also around nonspecular crystal truncation rods in grazing-incidence inclined geometry (Shen et al., 1989; Stepanov et al., 1996). Spatially correlated roughness and morphologies in multilayer systems have also been studied using diffuse x-ray scattering (Headrick and Baribeau, 1993; Baumbach et al., 1994; Kaganer et al., 1996; Paniago et al., 1996; Darhuber et al., 1997). Some of these topics are discussed in detail in KINEMATIC DIFFRACTION OF X RAYS and in the units on x-ray surface scattering (see X-RAY TECHNIQUES).

Expanded Distorted-Wave Approximation

The scheme of the distorted-wave approximation can be extended to calculate nonspecular scattering that includes multilayer diffraction peaks from a multilayer system where a recursive Fresnel's theory is usually used to evaluate the distorted-wave (Kortright and Fischer-Colbrie, 1987; Holy and Baumbach, 1994). Recently, Shen (1999b,c) has further developed an expanded distorted-wave approximation (EDWA) to include multiple-beam diffraction from bulk crystals where a two-beam dynamical theory is applied to obtain the distorted internal waves. In Shen's EDWA theory, a sinusoidal Fourier component **G** is added to the distorting susceptibility component, which represents a charge-density modulation of the **G** reflection. Instead of the Fresnel theory, a two-beam dynamical theory is employed to evaluate the distorted-wave, while the subsequent scattering of the distorted-wave is again handled by the first-order Born approximation. We now briefly outline this EDWA approach.

Following the formal distorted-wave description given in Vineyard (1982), $\delta\varepsilon(\mathbf{r})$ in the fundamental equation 3 is separated into a distorting component $\delta\varepsilon_1(\mathbf{r})$ and the remaining part $\delta\varepsilon_2(\mathbf{r}) : \delta\varepsilon(\mathbf{r}) = \delta\varepsilon_1(\mathbf{r}) + \delta\varepsilon_2(\mathbf{r})$, where $\delta\varepsilon_1(\mathbf{r})$ contains the homogeneous average susceptibility, plus a single predominant Fourier component **G**:

$$\delta\varepsilon_1(\mathbf{r}) = -\Gamma(F_0 + F_G e^{-i\mathbf{G}\cdot\mathbf{r}} + F_{\mathrm{G}}^{-} e^{i\mathbf{G}\cdot\mathbf{r}}) \tag{76}$$

and the remaining $\delta\varepsilon_2(\mathbf{r})$ is

$$\delta\varepsilon_2(\mathbf{r}) = -\Gamma \sum_{L \neq 0, \pm \mathrm{G}} F_{\mathrm{L}} e^{-i\mathbf{L}\cdot\mathbf{r}} \tag{77}$$

Since $F_{\mathrm{G}} = |F_G| \exp(i\alpha_{\mathrm{C}})$ and $F_{\mathrm{G}}^{-} = F_{\mathrm{G}}^{*} = |F_{\mathrm{G}}| \exp(-i\alpha_{\mathrm{G}})$ if absorption is negligible, it can be seen that the additional component in Equation 76 represents a sinusoidal distortion, $-2\Gamma|F_{\mathrm{G}}| \cos(\alpha_{\mathrm{G}} - \mathbf{G}\cdot\mathbf{r})$

The distorted wave $\mathbf{D}_1(\mathbf{r})$, due only to $\delta\varepsilon_1(\mathbf{r})$, satisfies the following equation:

$$(\nabla^2 + k_0^2)\mathbf{D}_1 = -\nabla \times \nabla \times (\delta\varepsilon_1 \mathbf{D}_1) \tag{78}$$

which is a standard two-beam case since only **O** and **G** Fourier components exist in $\delta\varepsilon_1(\mathbf{r})$, and can therefore be solved by the two-beam dynamical theory (Batterman and Cole, 1964; Pinsker, 1978). It can be shown that the total distorted wave $\mathbf{D}_1(\mathbf{r})$ can be expressed as follows:

$$\mathbf{D}_1(\mathbf{r}) = \mathbf{D}_0(r_0 e^{-i\mathbf{K}_0\cdot\mathbf{r}} + r_{\mathrm{G}} e^{i\alpha_{\mathrm{G}}} e^{-i\mathbf{K}_{\mathrm{G}}\cdot\mathbf{r}}) \tag{79}$$

where

$$\begin{cases} r_0 = 1 \\ r_{\mathrm{G}} = -\sqrt{|b|}(\eta_{\mathrm{G}} \pm \sqrt{\eta_{\mathrm{G}}^2 - 1}) \end{cases} \tag{80}$$

in the semi-infinite Bragg case and

$$\begin{cases} r_0 = \cos(A\eta_{\mathrm{G}}) + i \sin(A\eta) \\ r_{\mathrm{G}} = i\sqrt{|b|} \sin(A\eta_{\mathrm{G}})/\eta_{\mathrm{G}} \end{cases} \tag{81}$$

in the thin transparent Laue case. Here standard notations in the Two-Beam Dynamical Theory section are used. It should be noted that the amplitudes of these distorted waves, given by Equations 80 and 81, are slow varying functions of depth z through parameter A, since A is much smaller than $K_0 \cdot \mathbf{r}$ or $\mathbf{K}_{\mathrm{G}} \cdot \mathbf{r}$ by a factor of $\sim \Gamma|F_{\mathrm{G}}|$, which ranges from 10^{-5} to 10^{-6} for inorganic to 10^{-7} to 10^{-8} for protein crystals.

We now consider the rescattering of the distorted-wave $\mathbf{D}_1(\mathbf{r})$, Equation 79, by the remaining part of the susceptibility $\delta\varepsilon_2(\mathbf{r})$ defined in Equation 77. Using the first-order Born approximation, the scattered wave field $\mathbf{D}(\mathbf{r})$ is given by

$$\mathbf{D}(\mathbf{r}) = \frac{e^{-ik_0 r}}{4\pi r} \int d\mathbf{r}'\, e^{ik_0 \mathbf{u}\cdot\mathbf{r}'} \nabla' \times \nabla' \times [\delta\varepsilon_2(\mathbf{r}')\mathbf{D}_1(\mathbf{r}')] \tag{82}$$

where **u** is a unit vector and r is the distance from the sample to the observation point, and the integral is evaluated over the sample volume. The amplitudes r_0 and r_{G} can be factored out of the integral because of their much weaker spatial dependence than $\mathbf{K}_0 \cdot \mathbf{r}$ $\mathbf{K}_{\mathrm{G}} \cdot \mathrm{r}$ as mentioned above. The primary extinction effects in Bragg cases and the Pendellösung effects in Laue cases are taken into account by first evaluating intensity $I_{\mathrm{H}}(z)$ scattered by a volume element at a certain depth z, and then taking an average over z to obtain the final diffracted intensity.

It is worth noting that the distorted wave, Equation 79, can be viewed as the new incident wave for the Born approximation, Equation 59, and it consists of two beams, $\mathbf{K}_0$ and $\mathbf{K}_{\mathrm{G}}$. These two incident beams can each produce its own diffraction pattern. If reflection **H** satisfies Bragg's

law, $k_0\mathbf{u} = \mathbf{K}_0 + \mathbf{H} \equiv \mathbf{K}_H$, and is excited by $\mathbf{K}_0$, then there always exists a reflection **H–G**, excited by $\mathbf{K}_G$, such that the doubly scattered wave travels along the same direction as $\mathbf{K}_H$, since $\mathbf{K}_G + \mathbf{H} - G = \mathbf{K}_H$. With this in mind and using the algebra given in the Second Order Born Approximation section, it is easy to show that Equation 82 gives rise to the following scattered wave:

$$\mathbf{D}_H = Nr_e\mathbf{u} \times (\mathbf{u} \times \mathbf{D}_0)\frac{e^{-ik_0r}}{r}(F_H r_0 + F_{H-G} r_G e^{i\alpha_G}) \qquad (83)$$

Normalizing to the conventional first-order Born wave field $\mathbf{D}_H^{(1)}$ defined by Equation 61, Equation 83 can be rewritten as

$$\mathbf{D}_H = \mathbf{D}_H^{(1)}(r_0 + |F_{H-G}/F_H| r_G e^{i\delta}) \qquad (84)$$

where $\delta = \alpha_{H-G} + \alpha_G - \alpha_H$ is the invariant triplet phase widely used in crystallography. Finally, the scattered intensity into the $\mathbf{k}_H = \mathbf{K}_H = k_0\mathbf{u}$ direction is given by $I_H = (1/t)\int_0^t |\mathbf{D}_H|^2 dz$, which is averaged over thickness t of the crystal as discussed in the last paragraph. Numerical results show that the EDWA theory outlined here provides excellent agreement with the full NBEAM dynamical calculations even at the center of a multiple reflection peak. For further information, refer to Shen (1999b,c).

SUMMARY

In this unit, we have reviewed the basic elements of dynamical diffraction theory for perfect or nearly perfect crystals. Although the eventual goal of obtaining structural information is the same, the dynamical approach is considerably different from that in kinematic theory. A key distinction is the inclusion of multiple scattering processes in the dynamical theory whereas the kinematic theory is based on a single scattering event.

We have mainly focused on the Ewald–von Laue approach of the dynamical theory. There are four essential ingredients in this approach: (1) dispersion surfaces that determine the possible wave fields inside the material; (2) boundary conditions that relate the internal fields to outside incident and diffracted beams; (3) intensities of diffracted, reflected, and transmitted beams that can be directly measured; and (4) internal wave field intensities that can be measured indirectly from signals of secondary excitations.

Because of the interconnections of different beams due to multiple scattering, experimental techniques based on dynamical diffraction can often offer unique structural information. Such techniques include determination of impurity locations with x-ray standing waves, depth profiling with grazing-incidence diffraction and fluorescence, and direct measurements of phases of structure factors with multiple-beam diffraction. These new and developing techniques have benefited substantially from the rapid growth of synchrotron radiation facilities around the world. With more and newer-generation facilities becoming available, we believe that dynamical diffraction study of various materials will continue to expand in application and become more common and routine to materials scientists and engineers.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

A	Effective crystal thickness parameter
b	Ratio of direction cosines of incident and diffracted waves
$\mathbf{D}$	Electric displacement vector
$\mathbf{D}_0$	Incident electric displacement vector
$\mathbf{D}_{\bar{0}}$	Specular reflected wave field
$\mathbf{D}_\mathrm{H}$	Fourier component $\mathbf{H}$ of electric displacement vector
$\mathbf{D}_0^\mathrm{i}, \mathbf{D}_\mathrm{H}^\mathrm{i}$	Internal wave fields
$\mathbf{D}_0^\mathrm{e}, \mathbf{D}_\mathrm{H}^\mathrm{i}$	External wave fields
$\mathbf{E}$	Electric field vector
F_0'	Real part of F_0
F_0''	Imaginary part of F_0
F_H	Structure factor of reflection $\mathbf{H}$
$\mathbf{G}$	Reciprocal lattice vector for reference reflection
$\mathbf{H}$	Reciprocal lattice vector
$\overline{\mathbf{H}}$	Negative of $\mathbf{H}$
$\mathbf{H}$–$\mathbf{G}$	Difference between two reciprocal lattice vectors
I_H	Intensity of reflection $\mathbf{H}$
$K_{0\mathrm{n}}$	Component of internal incident wave vector normal to surface
$\mathbf{K}_0$	Incident wave vector inside crystal
$\mathbf{k}_0$	Incident wave vector outside crystal
$\mathbf{K}_\mathrm{H}$	Wave vector inside crystal
$\mathbf{k}_\mathrm{H}$	Wave vector outside crystal
$\mathbf{L}$	reciprocal lattice vector for a detour reflection
$\underline{\mathbf{M}}, \underline{\mathbf{A}}$	Matrices used with polarization density matrix
n	Index of refraction
N	Number of unit cells participating in diffraction
$\mathbf{n}$	Unit vector along surface normal
$\mathbf{O}$	Reciprocal lattice origin
P	Polarization factor
P_1, P_2, P_3	Stokes-Poincare polarization parameters
P_H/P_0	Total diffracted power normalized to the incident power
$\mathbf{r}$	Real-space position vector
R	Reflectivity
r_0, r_G	Distorted-wave amplitudes in expanded distorted-wave theory
r_0, t_0	Fresnel reflection and transmission coefficient at an interface
r_e	Classical radius of an electron, 2.818×10^{-5} angstroms
$S, \mathbf{S}_\mathrm{T}$	Poynting vector
$\underline{\mathbf{T}}, \underline{\mathbf{A}}, \underline{\mathbf{B}}, \underline{\mathbf{C}}$	Matrices used in NBEAM theory
$\mathbf{u}$	Unit vector along wave propagation direction
w	Intrinsic diffraction width, Darwin width
Γ	$= r_e\lambda^2(\pi V_\mathrm{c})$
α_H	Phase of FH, structure factor of reflection $\mathbf{H}$
α, β	Branches of dispersion surface
$\delta\varepsilon(\mathbf{r})$	Susceptibility function of a crystal
$\varepsilon(\mathbf{r})$	Dielectric function of a crystal
ε_0	Dielectric constant in vacuum
γ_0	Direction cosine of incident wave vector
γ_H	Direction cosine of diffracted wave vector
η, η_G	Angular deviation from θ_B normalized to Darwin width
λ	Wavelength
μ_0	Linear absorption coefficient
ν	Intrinsic dynamical phase shift
π	Polarization unit vector within scattering plane
θ	Incident angle
θ_B	Bragg angle
θ_c	Critical angle
$\underline{\rho}$	Polarization density matrix
ρ_0	Average charge density
$\rho(\mathbf{r})$	Charge density
σ	Polarization unit vector perpendicular to scattering plane
τ	Penetration depth of an evanescent wave
ξ_0	Correction to dispersion surface $\mathbf{O}$ due to two-beam diffraction
ξ_H	Correction to dispersion surface $\mathbf{H}$ due to two-beam diffraction
ψ	Azimuthal angle around the scattering vector

COMPUTATION OF DIFFUSE INTENSITIES IN ALLOYS

INTRODUCTION

Diffuse intensities in alloys are measured by a variety of techniques, such as x ray, electron, and neutron scattering. Above a structural phase-transformation boundary, typically in the solid-solution phase where most materials processing takes place, the diffuse intensities yield valuable information regarding an alloy's tendency to order. This has been a mainstay characterization technique for binary alloys for over half a century. Although multicomponent metallic alloys are the most technologically important, they also pose a great experimental and theoretical challenge. For this reason, a vast majority of experimental and theoretical effort has been made on binary systems, and most investigated "ternary" systems are either limited to a small percentage of ternary solute (say, to investigate electron-per-atom effects) or they are pseudo-binary systems. Thus, for multicomponent alloys the questions are: how can you interpret diffuse scattering experiments on such systems and how does one theoretically predict the ordering behavior?

This unit discusses an electronic-based theoretical method for calculating the structural ordering in multicomponent alloys and understanding the electronic origin for this chemical-ordering behavior. This theory is based on the ideas of concentration waves using a modern electronic-structure method. Thus, we give examples (see Data Analysis and Initial Interpretation) that show how we determined the electronic origin behind the unusual ordering behavior in a few binary and ternary alloy systems that were not understood prior to our work. From the start, the theoretical approach is compared and contrasted to other complimentary techniques for completeness. In addition, some details are given about the theory and its underpinnings. Please do not let this deter you from jumping ahead and reading Data Analysis and Initial Interpretation and Principles of the Method. For those not familiar with electronic properties and how they manifest themselves in the ordering properties, the discussion following Equation 27 may prove useful for understanding Data Analysis and Initial Interpretation.

Importantly, for the more general multicomponent case, we describe in the context of concentration waves how to extract more information from diffuse-scattering experimental data (see Concentration Waves in Multicomponent Alloys). Although developed to understand the calculated diffuse-scattering intensities, this analysis technique allows one to determine completely the type of ordering described in the numerous chemical pair correlations that must be measured. In fact, what is required (in addition to the ordering wavevector) is an ordering "polarization" of the concentration wave that is contained in the diffuse intensities. The example case of face-centered cubic (fcc) Cu_2NiZn is given.

For definitions of the symbols used throughout the unit, see Table 1.

For binary or multicomponent alloys, the atomic short-range order (ASRO) in the disordered solid-solution phase is related to the thermally induced concentration fluctuations in the alloy. Such fluctuations in the chemical site occupations are the (infinitesimal) deviations from a homogeneously random state, and are directly related to the chemical pair correlations in the alloy (Krivoglaz, 1969). Thus, the ASRO provides valuable information on the atomic structure to which the disordered alloy is tending—i.e., it reveals the chemical ordering tendencies in the high-temperature phase (as shown by Krivoglaz, 1969; Clapp and Moss, 1966; de Fontaine, 1979; Khachaturyan, 1983; Ducastelle, 1991). Importantly, the ASRO can be determined experimentally from the diffuse scattering intensities measured in reciprocal space either by x rays (X-RAY AND NEUTRON DIFFUSE SCATTERING MEASUREMENTS), neutrons (NEUTRON TECHNIQUES), or electrons (LOW-ENERGY ELECTRON DIFFRACTION; Sato and Toth, 1962; Moss, 1969; Reinhard et al., 1990). However, the underlying microscopic or electronic origin for the ASRO cannot be determined from such experiments, only their observed indirect effect on the order. Therefore, the calculation of diffuse intensities in high-temperature, disordered alloys based on electronic density-functional theory (DFT; SUMMARY OF ELECTRONIC STRUCTURE METHODS) and the subsequent connection of those intensities to its microscopic origin(s) provides a fundamental understanding of the experimental data and phase instabilities. These are the principal themes that we will emphasize in this unit.

The chemical pair correlations determined from the diffuse intensities are written usually as normalized probabilities, which are then the familiar Warren-Cowley parameters (defined later). In reciprocal space, where scattering data is collected, the Warren-Cowley parameters are denoted by $\alpha_{\mu\nu}(\mathbf{k})$, where μ and ν label the species (1 to N in an N-component alloy) and where $\mathbf{k}$ is the scattering wave vector. In the solid-solution phase, the sharp Bragg diffraction peaks (in contrast to the diffuse peaks) identify the underlying Bravais lattice symmetry, such as, fcc and body-centered cubic (bcc), and determine the possible set of available wave vectors. (We will assume heretofore that there is no change in the Bravais lattice.) The diffuse maximal peaks in $\alpha_{\mu\nu}(\mathbf{k})$ at wave vector $\mathbf{k}_0$ indicate that the disordered phase has low-energy ordering fluctuations with that periodicity, and $\mathbf{k}_0$ is not where the Bragg reflection sits. These fluctuations are not stable but may be long-lived, and they indicate the nascent ordering tendencies of the disordered alloy. At the so-called spinodal temperature, T_{sp}, elements of the $\alpha_{\mu\nu}(\mathbf{k}=\mathbf{k}_0)$ diverge, indicating the absolute instability of the alloy to the formation of a long-range ordered state with wavevector $\mathbf{k}_0$. Hence, it is clear that the fluctuations are related to the disordered alloy's stability matrix. Of course, there may be more than one (symmetry unrelated) wavevector prominent, giving a more complex ordering tendency.

Because the concentrations of the alloy's constituents are then modulated with a wave-like periodicity, such orderings are often referred to as "concentration waves" (Khachaturyan, 1972, 1983; de Fontaine, 1979). Thus, *any* ordered state can be thought of as a modulation of the disordered state by a thermodynamically stable concentration wave. Keep in mind that any arrangement of atoms on a Bravais lattice (sites labeled by i) may be

Table 1. Table of Symbols

Symbol	Meaning
AuFe	Standard alloy nomenclature such that underlined element is majority species, here Au-rich
$L1_0$, $L1_2$, $L1_1$, etc.	Throughout we use the Strukturbericht notation (http://dave.nrl,navy.mil) lattice where A are monotonic (e.g., A_1 = fcc; A_2 = bcc), B_2 [e.g., CsCl with (111) wavevector ordering], and $L1_0$ (e.g., CuAu with ⟨100⟩ wavevector ordering), and so on
⟨...⟩	Thermal/configurational average
Bold symbols	Vectors
k and **q**	Wavevectors in reciprocal space
$\mathbf{k}_0$	Specific set of symmetry-related, ordering wavevector
Star of **k**	The star of a wavevector is the set of symmetry equivalent **k** values, e.g., in fcc, the star of **k** = (100) is {(100), (010), (001)}
N	Number of elements in a multicomponent alloy, giving $N-1$ independent degrees of freedom because composition is conserved
(h, k, l)	General k-space (reciprocal lattice) point in the first Brillouin zone
i, j, k, etc.	Refer to enumeration of real-space lattice site
μ, ν, etc.	Greek symbols refer to elements in alloy, i.e., species labels
$\mathbf{R}_i$	Real-space lattice position for ith site
$\xi_{\mu,i}$	Site occupation variable (1, if μ-type atoms at ith site, 0 otherwise)
σ	Branch index for possible multicomponent ordering polarizations, i.e., sublattice occupations relative to "host" element (see text).
$c_{\mu,i}$	Concentration of μ type atoms at ith site, which is the thermal average of $\xi_{\mu,i}$. As this is between 0 and 1, this can also be thought of as a site-occupancy probability.
$\delta_{\mu,\nu}$	Kronecker delta (1 if subscripts are same, 0 otherwise). Einstein summation is not used in this text.
$q_{\mu\nu,ij}$	Real-space atomic pair-correlation function (not normalized). Generally, it has two species labels, and two site indices.
$\alpha_{\mu\nu,ij}$	Normalized real-space atomic pair-correlation function, traditionally referred to as the Warren-Cowley short-range-order parameter. Generally, it has two species labels, and two site indices. $\alpha_{ii} = 1$ by definition (see text).
$q_{\mu\nu}(\mathbf{k})$	Fourier transform of atomic pair-correlation function
$\alpha_{\mu\nu}(\mathbf{k})$	Experimentally measured Fourier transform of normalized pair-correlation function, traditionally referred to as the Warren-Cowley short-range-order parameter. Generally, it has two species labels. For binary alloy, no labels are required, which is more familiar to most people.
$\mathbf{e}^{\sigma}_{\mu}(\mathbf{k})$	For N-component alloys, element of eigenvector (or eigenmode) for concentration-wave composed of $N-1$ branches σ and $N-1$ independent species μ. This is 1 for binary alloy, but between 0 and 1 for an N-component alloy. As we report, this can be measured experimentally to determine the sublattice ordering in a multicomponent alloy, as done recently by ALCHEMI measurements.
$\eta^{\sigma}_{S}(T)$	Temperature-dependent long-range-order parameter for branch index σ, which is between 0 (disordered phase) and 1 (fully ordered phase)
T	Temperature (units are given in text)
F	Free energy
Ω	Grand potential of alloy. With subscript "*e*," it is the electronic grand potential of the alloy, where the electronic degrees of freedom have not been integrated out
$N(E)$	The electronic integrated density of states at an energy E
$n(E)$	The electronic density of states at an energy E
$t_{\alpha,i}$	Single-site scattering matrix, which determines how an electron will scatter off a single atom
$\tau_{\alpha,ii}$	Electronic scattering-path operator, which completely details how an electron scatters through an array of atoms

Fourier-wave decomposed, i.e., considered a "concentration wave." For a binary ($A_{1-c}B_c$), the concentration wave (or site occupancy) is simply $c_i = c + \Sigma_k[Q(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{R}_i} + \text{c.c.}]$, with the wavevectors limited to the Brillouin zone−associated $Q(\mathbf{k})$ with the underlying Bravais lattice of the disordered alloy, and where the amplitudes dictate strength of ordering (c.c. stands for complex conjugate). For example, a peak in $\alpha_{\mu\nu}(\mathbf{k}_0 = \{001\})$ within a 50-50 binary fcc solid solution indicates an instability toward alternating layers along the z direction in real space, such as in the Cu-Au structure [designated as $L1_0$ in Strukturbericht notation (see Table 1) and having alternating Cu/Au layers along (001)]. Of course, at high temperatures, all wavevectors related by the symmetry operations of the disordered lattice (referred to as a *star*) are degenerate, such as the ⟨100⟩ star comprised of (100), (010), and (001). In contrast, a $\mathbf{k}_0 = (000)$ peak indicates clustering because the associated wavelength of the concentration modulation is very long range. Interpretation of the results of our first-principles calculations is greatly facilitated by the concentration wave concept, especially for multicomponent alloys, and we will explain results in that context.

In the high-temperature disordered phase, where most materials processing takes place, this local atomic ordering governs many materials properties. In addition, these incipient ordering tendencies are *often* indicative of the long-range order (LRO) found at lower temperatures, even if the transition is first order; that is, the ASRO is a precusor of the LRO phase. For these two additional reasons, it is important to predict and to understand fundamentally this ubiquitous alloying behavior. To be precise for the experts and nonexperts alike, strictly speaking,

the fluctuations in the disordered state reveal the low-temperature, long-range ordering behavior for a second-order transition, with critical temperature $T_c = T_{sp}$. On the other hand, for first-order transitions (with $T_c > T_{sp}$), symmetry arguments indicate that this can be, but does not have to be, the case (Landau, 1937a,b; Lifshitz, 1941, 1942; Landau and Lifshitz, 1980; Khachaturyan, 1972, 1983). It is then possible that the system undergoes a first-order transition to an ordering that preempts those indicated by the ASRO and leads to LRO of a different periodicity unrelated to $\mathbf{k}_0$. Keep in mind, while not every alloy has an experimentally realizable solid-solution phase, the ASRO of the hypothetical solid-solution phase is still interesting because it is indicative of the ordering interactions in the alloy, and, is typically indicative of the long-ranged ordered phases.

Most metals of technological importance are alloys of more than two constituents. For example, the easy-forming, metallic glasses are composed of four and five elements (Inoue et al., 1990; Peker and Johnson, 1993), and traditional steels have more than five active elements (Lankford et al., 1985). The enormous number of possible combinations of elements makes the search for improved or novel metallic properties a daunting proposition for both theory and experiment. Except for understanding the "electron-per-atom" (e/a) effects due to small ternary additions, measurement of ASRO and interpretation of diffuse scattering experiments in multicomponent alloys is, in fact, a largely uncharted area. In a binary alloy, the theory of concentration waves permits one to determine the structure indicated by the ASRO given *only* the ordering wavevector (Khachaturyan, 1972, 1983; de Fontaine, 1975, 1979). In multicomponent alloys, however, the concentration waves have additional degrees of freedom corresponding to polarizations in "composition space," similar to "branches" in the case of phonons in alloys (Badalayan et al., 1969; de Fontaine, 1973; Althoff et al., 1996); thus, more information is required. These polarizations are determined by the electronic interactions and they determine the sublattice occupations in partially ordered states (Althoff et al., 1996).

From the point of view of alloy design, and at the root of alloy theory, identifying and understanding the electronic origins of the ordering tendencies at high temperatures and the reason why an alloy adopts a specific low-temperature state gives valuable guidance in the search for new and improved alloys via "tuning" an alloy's properties at the most fundamental level. In metallic alloys, for example, the electrons cannot be allocated to specific atomic sites, nor can their effects be interpreted in terms of pairwise interactions. For addressing ASRO in specific alloys, it is generally necessary to solve the many-electron problem as realistically and as accurately as possible, and then to connect this solution to the appropriate compositional, magnetic, or displacive correlation functions measured experimentally.

To date, most studies from first-principle approaches have focused on binary alloy phase diagrams, because even for these systems the thermodynamic problem is extremely nontrivial, and there is a wealth of experimental data for comparison. This unit will concentrate on the techniques employed for calculating the ASRO in binary and multicomponent alloys using DFT methods. We will not include, for example, simple parametric phase stability methods, such as CALPHAD (Butler et al., 1997; Saunders, 1996; Oates et al., 1996), because they fail to give any fundamental insight and cannot be used to predict ASRO. In what follows, we give details of the chemical pair correlations, including connecting what is measured experimentally to that developed mathematically. Because we use an electronic DFT based, mean-field approach, some care will be taken throughout the text to indicate innate problems, their solutions, quantitative and qualitative errors, and resolution accomplished within mean-field means (but would agree in great detail with more accurate, if not intractable, means). We will also discuss at some length the interesting means of interpreting the type of ASRO in multicomponent alloys from the diffuse intensities, important for both experiment and theory. Little of this has been detailed elsewhere, and, with our applications occurring only recently, this important information is not widely known.

Before presenting the electronic basis of the method, it is helpful to develop a fairly unique approach based on classical density-functional theory that not only can result in the well-known, mean field equations for chemical potential and pair correlation but may equally allow a DFT-based method to be developed for such quantities. Because the electronic DFT underpinnings for the ASRO calculations are based on a rather mathematical derivation, we try to discuss the important physical content of the DFT-based equations through truncated versions of them, which give the essence of the approach. In the Data Analysis and Initial Interpretation section, we discuss the role of several electronic mechanisms that produce strong CuAu [$L1_0$ with (001) wavevector] order in NiPt, Ni_4Mo [or $(1\frac{1}{2}0)$ wavevector] ordering in AuFe alloys, both commensurate and incommensurate order in fcc Cu-Ni-Zn alloys, and the novel CuPt [or $L1_1$, with $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$ wave vector] order in fcc CuPt. Prior to these results, and very relevant for NiPt, we discuss how charge within a homogeneously random alloy is actually correlated through the local chemical environment, even though there are no chemical correlations.

At minimum, a DFT-based theory of ASRO, whose specific advantage is the ability to connect features in the ASRO in multicomponent alloys with features of the electronic structure of the disordered alloy, would be very advantageous for establishing trends, much the way Hume-Rothery established empirical relationships to trends in alloy phase formation. Some care will be given to list briefly where such calculations are relevent, in evolution or in defect, as well as those that complement other techniques. It is clear then that this is not an exhaustive review of the field, but an introduction to a specific approach.

Competitive and Related Techniques

Traditionally, DFT-based band structure calculations focus on the possible ground-state structures. While it is clearly valuable (and by no means trivial) to predict the

ground-state crystal structure from first principles, it is equally important to expand this to partially ordered and disordered phases at high temperatures. One reason for this is that ASRO measurements and materials processing take place at relatively high temperatures, typically in a disordered phase. Basically, today, this calculation can be done in two distinct (and usually complementary) ways.

First, methods based on effective chemical interactions obtained from DFT methods have had successes in determining phase diagrams and ASRO (Asta and Johnson, 1997; Wolverton and Zunger, 1995a; Rubin and Finel, 1995). This is, e.g., the idea behind the cluster-expansion method proposed by Connolly and Williams (1983), also referred to as the structural inversion method (SIM). Briefly, in the cluster-expansion method a fit is made to the formation energies of a few (up to several tens of) ordered lattice configurations using a generalized Ising model (which includes 2-body, 3-body, up to N-body clusters, whatever is required [in principle] to produce effective-chemical interactions (ECIs). These ECIs approximate the formation energetics of all other phases, including homogeneously random, and are used as input to some classical statistical mechanics approach, like Monte Carlo or the cluster-variation method (CVM), to produce ASRO or phase-boundary information.

While this is an extremely important first-principles method, and is highlighted elsewhere in this chapter (PREDICTION OF PHASE DIAGRAMS), it is difficult from this approach to discern any electronic origin because all the underlying electronic information has been integrated out, obscuring the quantum mechanical origins of the ordering tendencies. Furthermore, careful (reiterative) checks have to be made to validate the convergence of the fit with a number of structures, of stoichiometries, and the range and multiplet structure of interactions. The inclusion of magnetic effects or multicomponent additions begins to add such complexity that the cluster expansion becomes more and more difficult (and delicate), and the size of the electronic-structure unit cells begins to grow very large (depending on the DFT method, growing as N to N^3, where N is the number of atoms in the unit cell). The use of the CVM, e.g., quickly becomes uninviting for multicomponent alloys, and it then becomes necessary to rely on Monte Carlo methods for thermodynamics, where interpretation sometimes can be problematic. Nevertheless, this approach can provide ASRO and LRO information, including phase-boundary (global stability) information. If, however, you are interested in calculating the ASRO for just one multicomponent alloy composition, it is more reliable and efficient to perform a *fixed-composition* SIM using DFT methods to get the effective ECIs, because fewer structures are required and the subtleties of composition do not have to be reproduced (McCormack et al., 1997). In this mode, the fitted interactions are more stable and multiplets are suppressed; however, global stability information is lost.

A second approach (the concentration-wave approach), which we shall present below, involves use of the (possible) high-temperature disordered phase (at fixed composition) as a reference and looks for the types of local concentration fluctuations and ordering instabilities that are energetically allowed as the temperature is lowered. Such an approach can be viewed as a linear-response method for thermodynamic degrees of freedom, in much the same way that a phonon dynamical matrix may be calculated within DFT by expanding the vibrational (infinitesimal) displacements about the ideal Bravais lattice (i.e., the high-symmetry reference state; Gonze, 1997; Quong and Lui, 1997; Pavone et al., 1996; Yu and Kraukauer, 1994). Such methods have been used for three decades in classical DFT descriptions of liquids (Evans, 1979), and, in fact, there is a 1:1 mapping from the classical to electronic DFT (Györffy and Stocks, 1983). These methods may therefore be somewhat familiar in mathematical foundation. Generally speaking, a theory that is based on the high-temperature, disordered state is not biased by any *a priori* choice of chemical structures, which may be a problem with more traditional total-energy or cluster-expansion methods. The major disadvantage of this approach is that no global stability information is obtained, because only the local stability at one concentration is addressed. Therefore, the fact that the ASRO for a specific concentration can be directly addressed is both a strength and shortcoming, depending upon one's needs. For example, if the composition dependence of the ASRO at five specific compositions is required, only five calculations are necessary, whereas in the first method described above, depending on the complexity, a great many alloy compositions and structural arrangements at those compositions are still required for the fitting (until the essential physics is somehow, maybe not transparently, included). Again, as emphasized in the introduction, a great strength of the first-principles concentration-wave method is that the electronic mechanisms responsible for the ordering instabilities may be obtained.

Thus, in a great many senses, the two methods above are very complementary, rather than competing. Recently, the two methods have been used simultaneously on binary (Asta and Johnson, 1997) and ternary alloys (Wolverton and de Fontaine, 1994; McCormack et al., 1997). Certain results from both methods agree very well, but each method provides additional (complementary) information and viewpoints, which is very helpful from a computer alloy design perspective.

Effective Interactions from High-Temperature Experiments

While not really a first-principles method, it is worth mentioning a third method with a long-standing history in the study of alloys and diffuse-scattering data—using inverse Monte Carlo techniques based upon a generalized Ising model to extract ECIs from experimental diffuse-scattering data (Masanskii et al., 1991; Finel et al., 1994; Barrachin et al., 1994; Pierron-Bohnes et al., 1995; Le Bolloc'h et al., 1997). Importantly, such techniques have been used typically to extract the Warren-Cowley parameters in real space from the **k**-space data because it is traditional to interpret the experiment in this fashion. Such ECIs have been used to perform Monte Carlo calculations of phase boundaries, and so on. While it may be useful to extract the Warren-Cowley parameters via this route, it is important to understand some fundamental points

that have not been appreciated until recently: the ECIs so obtained (1) are **not** related to any fundamental alloy Hamiltonian; (2) are **parameters** that achieve a best fit to the measured ASRO; and (3) should not be trusted, in general, for calculating phase boundaries.

The origin and consequences of these three remarks are as follows. It should be fairly obvious that, given enough ECIs (i.e., fitting degrees of freedom), a fit of the ASRO is possible. For example, one may use many pairs of ECIs, or fewer pairs if some multiplet interactions are included, and so on (Finel et al., 1994; Barrachin et al., 1994). Therefore, it is clear that the fit is not unique and does not represent anything fundamental; hence, points 1 and 2 above. The only important matter for the fitting of the ASRO is the **k**-space location of the maximal intensities and their heights, which reveal both the type and strength of the ASRO, at least for binaries where such a method has been used countless times. Recently, a very thorough study was performed on a simple model alloy Hamiltonian to exemplify some of these points (Wolverton et al., 1997). In fact, while different sets of ECIs may satisfy the fitting procedure and lead to a good reproduction of the experimental ASRO, there is no *a priori* guarantee that all sets of ECIs will lead to equivalent predictions of other physical properties, such as grain-boundary energies (Finel et al., 1994; Barrachin et al., 1994).

Point 3 is a little less obvious. If both the type and strength of the ASRO are reproduced, then the ECIs are accurately reproducing the energetics associated with the infinitesimal-amplitude concentration fluctuations in the high-temperature disordered state. They may not, however, reflect the strength of the finite-amplitude concentration variations that are associated with a (possibly strong) first-order transition from the disordered to a long-range ordered state. In general, the energy gained by a first-order transformation is larger than suggested by the ASRO, which is why $T_c > T_{sp}$. In the extreme case, it is quite possible that the ASRO produces a set of ECIs that produce ordering type phase boundaries (with a negative formation energy), whereas the low-temperature state is phase separating (with a positive formation energy). An example of this can be found in the Ni-Au system (Wolverton and Zunger, 1997).

Keep in mind, however, that this is a generic comment and much understanding can certainly be obtained from such studies. Nevertheless, this should emphasize the need (1) to determine the underlying origins for the fundamental thermodynamic behavior, (2) to connect high and low temperature properties and calculations, and (3) to have complementary techniques for a more thorough understanding.

PRINCIPLES OF THE METHOD

After establishing general definitions and the connection of the ASRO to the alloy's free energy, we show, a simple standard Ising model, the well-known Krivoglaz-Clapp-Moss form (Krivoglaz, 1969; Clapp and Moss, 1966), connecting the so-called "effective chemical interactions" and the ASRO. We then generalize these concepts to the more accurate formulation involving the electronic grand potential of the disordered alloy, which we base on a DFT Hamiltonian.

Since we wish to derive the pair correlations from the electronic interactions inherent in the high-temperature state, it is most straightforward to employ a simple two-state, Ising-like variable for each alloy component and to enforce a single-occupancy constraint on each site in the alloy. This approach generates a model which straightforwardly deals with an arbitrary number of species, in contrast to an approach based on an N-state spin model (Ceder et al., 1994), which produces a mapping between the spin and concentration variables that is nonlinear.

With this Ising-like representation, any atomic configuration of an alloy (whether ordered, partially ordered, or disordered) is described by a set of occupation variables, $\{\xi_{\mu,i}\}$, where μ is the species label and i labels the lattice site. The variable $\xi_{\mu,i}$ is equal to 1 if an atom of species μ occupies the site i; otherwise it is 0. Because there can be only one atom per lattice site (i.e., a single-occupancy constraint: $\Sigma_\mu \xi_{\mu,i} = 1$) there are $(N - 1)$ independent occupation variables at each site for an N-component alloy. This single-occupancy constraint is implemented by designating one species as the "host" species (say, the Nth one) and treating the host variables as dependent. The site probability (or sublattice concentration) is just the thermodynamic average (denoted by $\langle \ldots \rangle$) of the site occupations, i.e., $c_{\mu,i} = \langle \xi_{\mu,i} \rangle$ which is between 0 and 1. For the disordered state, with no long-range order, $c_{\mu,i} = \bar{c}_\mu$ for all sites i. (Obviously, the presence of LRO is reflected by a nonzero value of $c_{\mu,i} = \bar{c}_\mu$, which is one possible definition of a LRO parameter.) In all that follows, because the meaning without a site index is obvious, we will forego the overbar on the *average* concentration.

General Background on Pair Correlations

The atomic pair-correlation functions, that is, the correlated fluctuations about the average probabilities, are then properly defined as:

$$\begin{aligned} q_{\mu\nu,ij} &= \langle (\xi_{\mu,i} - c_{\mu,i})(\xi_{\nu,j} - c_{\nu,j}) \rangle \\ &= \langle \xi_{\mu,i} \xi_{\nu,j} \rangle - \langle \xi_{\mu,i} \rangle \langle \xi_{\nu j} \rangle \end{aligned} \tag{1}$$

which reflects the presence of ASRO. Note that pair correlation is of rank $(N - 1)$ for an N-component alloy because of our choice of independent variables (the "host" is dependent). Once the portion of rank $(N - 1)$ has been determined, the "dependent" part of the full N-dimensional correlation function may be found by the single-occupancy constraint. Because of the dependencies introduced by this constraint, the N-dimensional pair-correlation function is a singular matrix, whereas, the "independent" portion of rank $(N - 1)$ is nonsingular (it has an inverse) everywhere above the spinodal temperature.

It is important to notice that, by definition, the site-diagonal part of the pair correlations, i.e., $\langle \xi_{\mu,i}\, \xi_{\mu,j} \rangle$, obeys a sum rule because $(\xi_{\mu,i})^2 = \xi_{\mu,i}$,

$$q_{\mu\nu,ii} = c_\mu (\delta_{\mu\nu} - c_\nu) \tag{2}$$

where $\delta_{\mu\nu}$ is a Kronecker delta (and there is no summation over repeated indices). For a binary alloy, with $c_A + c_B = 1$, there is only one independent composition, say, c_A and c_B is the "host" so that there is only one pair correlation and $q_{AA,ii} = c_A(1 - c_A)$. It is best to define the pair correlations in terms of the so-called Warren-Cowley parameters as:

$$\alpha_{\mu\nu,ij} = \frac{q_{\mu\nu,ij}}{c_\mu(\delta_{\mu\nu} - c_\nu)} \tag{3}$$

Note that for a binary alloy, the single pair correlation is $\alpha_{AA,ij} = q_{AA,ij}/[c_A(1 - c_A)]$ and the AA subscripts are not needed. Clearly, the Warren-Cowley parameters are normalized to range between ± 1, and, hence, they are the joint probabilities of finding two particular types of atoms at two particular sites.

The pair correlations defined in Equation 3 are, of course, the same pair correlations that are measured in diffuse-scattering experiments. This is seen by calculating the scattering intensity by averaging thermodynamically the square of the scattering amplitude, $A(\mathbf{k})$. For example, the $A(\mathbf{k})$ for a binary alloy with N_s atoms is given by $(1/N_s)\Sigma_i[f_A\xi_{A,i} + f_B(1 - \xi_{A,i}))]e^{i\mathbf{k}\cdot\mathbf{R}_i}$, for on site i you are either scattering off an "A" atom or "not an A" atom. Here f_μ is the scattering factor for x rays; use b_μ for neutrons. The scattering intensity, $I(\mathbf{k})$, is then

$$\begin{aligned} I(\mathbf{k}) &= \langle |A(\mathbf{k})|^2 \rangle \\ &= \delta_{\mathbf{k},0}[c_A f_A + (1 - c_A)f_B]^2 \qquad \text{(Bragg term)} \\ &\quad + (f_A - f_B)^2 \frac{1}{N_s} \Sigma_{ij} q_{\mu\nu,ij} e^{i\mathbf{k}\cdot(\mathbf{R}_i - \mathbf{R}_j)} \qquad \text{(diffuse term)} \end{aligned} \tag{4}$$

The first term in the scattering intensity is the Bragg scattering found from the average lattice, with an intensity given by the compositionally averaged scattering factor. The second term is the so-called diffuse-scattering term, and it is the Fourier transform of Equation 1. Generally, the diffuse scattering intensity for an N-component alloy (relevant to experiment) is then

$$I_{\text{diff}}(\mathbf{k}) = \sum_{\mu \neq \nu = 1}^{N} (f_\mu - f_\nu)^2 q_{\mu\nu}(\mathbf{k}) \tag{5}$$

or the sum may also go from 1 to $(N - 1)$ if $(f_\mu - f_\nu)^2$ is replaced by $f_\mu f_\nu$. The various ways to write this arise due to the single-occupancy constraint. For direct comparison to scattering experiments, theory needs to calculate $q_{\mu\nu}(\mathbf{k})$. Similarly, the experiment can only measure the $\mu \neq \nu$ portion of the pair correlations because it is the only part that has scattering contrast (i.e., $f_\mu - f_\nu \neq 0$) between the various species. The remaining portion is obtained by the constraints. In terms of experimental Laue units [i.e., $I_{\text{laue}} = (f_\mu - f_\nu)^2 c_\mu(\delta_{\mu\nu} - c_\nu)$], $I_{\text{diff}}(\mathbf{k})$ may also be easily given in terms of Warren-Cowley parameters.

When the free-energy curvature, i.e., $q^{-1}(\mathbf{k})$, goes through zero, the alloy is unstable to chemical ordering, and $q(\mathbf{k})$ and $\alpha(\mathbf{k})$ diverge at T_{sp}. So measurements or calculations of $q(\mathbf{k})$ and $(\mathbf{k})$ are a direct means to probe the free energy associated with concentration fluctuations. Thus, it is clear that the chemical fluctuations leading to the observed ASRO arise from the curvature of the alloy free energy, just as phonons or positional fluctuations arise from the curvature of a free energy (the dynamical matrix).

It should be realized that the above comments could just as well have been made for magnetization, e.g., using the mapping $(2\xi - 1) \rightarrow \sigma$ for the spin variables. Instead of chemical fields, there are magnetic fields, so that $q(\mathbf{k})$ becomes the magnetic susceptibility, $\chi(\mathbf{k})$. For a disordered alloy with magnetic fluctuations present, one will also have a cross-term that represents the magnetochemical correlations, which determine how the magnetization on an atomic site varies with local chemical fluctuations, or vice versa (Staunton et al., 1990; Ling et al., 1995a). This is relevant to magnetism in alloys covered elsewhere in this unit (see Coupling of Magnetic Effects and Chemical Order).

Sum Rules and Mean-Field Errors

By Equations 2 and 3, $\alpha_{\mu\nu,ii}$ should always be 1; that is, due to the (discrete) translational invariance of the disordered state, the Fourier transform is well defined and

$$\alpha_{\mu\nu,ii} = \alpha_{\mu\nu}(\mathbf{R} = 0) = \int d\mathbf{k}\alpha_{\mu\nu}(\mathbf{k}) = 1 \tag{6}$$

This intensity sum rule is used to check the experimental errors associated with the measured intensities (see SYMMETRY IN CRYSTALLOGRAPHY, KINEMATIC DIFFRACTION OF X RAYS and DYNAMICAL DIFFRACTION). Within most mean-field theories using model Hamiltonians, unless care is taken, Equations 2 and 6 are violated. It is in fact this violation that accounts for the major errors found in mean-field estimates of transition temperatures, because the diagonal (or intrasite) elements of the pair correlations are the largest. Lars Onsager first recognized this in the 1930s for interacting electric dipoles (Onsager, 1936), where he found that a mean-field solution produced the wrong physical sign for the electrostatic energy. Onsager found that by enforcing the equivalents of Equations 4 or 6 (by subtracting an approximate field arising from self-correlations), a more correct physical behavior is found. Hence, we shall refer to the mathematical entities that enforce these sum rules as Onsager corrections (Staunton et al., 1994). In the 1960s, mean-field, magnetic-susceptibility models that implemented this correction were referred to as mean-spherical models (Berlin and Kac, 1952), and the connection to Onsager corrections themselves were referred to as reaction or cavity fields (Brout and Thomas, 1967). Even today this correction is periodically rediscovered and implemented in a variety of problems. As this has profound effects on results, we shall return to how to implement the sum rules within mean-field approaches later, in particular, within our first-principles technique, which incorporates the corrections self-consistently.

Concentration Waves in Multicomponent Alloys

While the concept of concentration waves in binary alloys has a long history, only recently have efforts returned to

the multicomponent alloy case. We briefly introduce the simple ideas of ordering waves, but take this as an opportunity to explain how to interpret ASRO in a multicomponent alloy system where the wavevector alone is not enough to specify the ordering tendency (de Fontaine, 1973; Althoff et al., 1996).

As indicated in the introduction, any arrangement of atoms on a Bravais lattice may be thought of as a modulation of the disordered state by a thermodynamically stable concentration wave. That is, one may Fourier decompose the ordering wave for each site and species on the lattice:

$$c_{\alpha i} = c_{\alpha}^{0} + \sum_{j} [Q_{\alpha}(\mathbf{k}_j) e^{i\mathbf{k}_j \cdot \mathbf{R}_i} + c.c] \tag{7}$$

A binary $A_c B_{(1-c)}$ alloy has a special symmetry: on each site, if the atom is not an A type atom, then it is definitely a B type atom. One consequence of this A-B symmetry is that there is only *one* independent local composition, $\{c_i\}$ (for all sites i), and this greatly simplifies the calculation and the interpretation of the theoretical and experimental results. Because of this, the structure (or concentration wave) indicated by the ASRO is determined *only* by the ordering wavevector (Khachaturyan, 1972, 1983; de Fontaine, 1975, 1979); in this sense, the binary alloys are a special case. For example, for CuAu, the low-temperature state is a layered $L1_0$ state with alternating layers of Cu and Au. Clearly, with $c_{\mathrm{Cu}} = 1/2$, and $c_{\mathrm{Au}} = 1 - c_{\mathrm{Cu}}$, the "concentration wave" is fully described by

$$c_{\mathrm{Cu},i}(\mathbf{R}_i) = \frac{1}{2} + \frac{1}{2}\eta(T) e^{i(2\pi/a)(001)\cdot\mathbf{R}_i} \tag{8}$$

where a single wavevector, $\mathbf{k}$=(001), in units of $2\pi/a$, where a is the lattice parameter, indicates the type of modulation. Here, $\eta(T)$ is the long-range order parameter. So, knowing the composition of the alloy and the energetically favorable ordering wavevector, you fully define the type of ordering. Both bits of information are known from the experiment: the ASRO of CuAu indicates (Moss, 1969) the star of $\mathbf{k} = (001)$ is the most energetically favorable fluctuation. The amplitude of the concentration wave is related to the energy gain due to ordering, as can be seen from a simple chemical, pairwise-interaction model with interactions $V(R_i - R_j)$. The energy difference between the disordered and short-range ordered state is $\frac{1}{2}\sum_{\mathbf{k}} |Q(\mathbf{k})|^2 V(\mathbf{k})$ for infinitesimal ordering fluctuations.

Multicomponent alloys (like an A-B-C alloy) do not possess the binary A-B symmetry and the ordering analysis is therefore more complicated. Because the concentration waves have additional degrees of freedom, more information is needed from experiment or theory. For a bcc ABC_2 alloy, for example, the particular ordering also requires the relative polarizations in the Gibbs "composition space," which are the concentrations of "A relative to C" and "B relative to C" on each sublattice being formed. The polarizations are similar to "branches" for the case of phonons in alloys (Badalayan et al., 1969; de Fontaine, 1973; Althoff et al., 1996). The polarizations of the ordering wave thus determine the sublattice occupations in partially ordered states (Althoff et al., 1996).

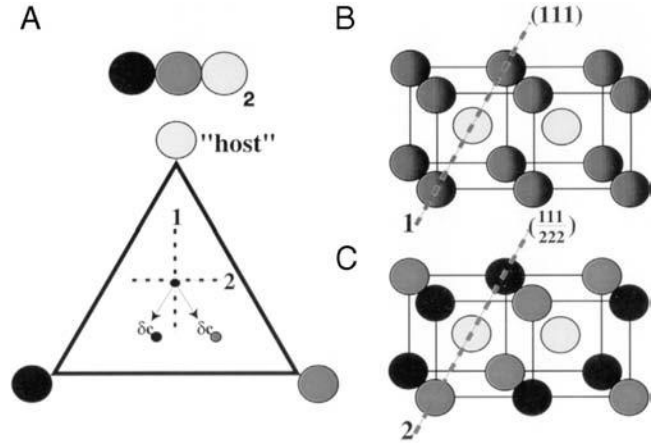

Figure 1. (**A**) the Gibbs triangle with an example of two possible polarization paths that ultimately lead to a Heusler or $L2_1$ type ordering at fixed composition in a bcc ABC_2 alloy. Note that unit vectors that describe the change in the A (black) and B (dark gray) atomic concentrations are marked. First, a $B2$-type order is formed from a $\mathbf{k}_0 = (111)$ ordering wave; see (**B**); given polarization 1 (upper dashed line), A and B atoms randomly populate the cube corners, with C (light gray) atoms solely on the body centers. Next, the polarization 2 (lower dashed line) must occur, which separates the A and B onto separate cube corners, creating the Huesler structure (via a $\mathbf{k}_1 = \mathbf{k}_0/2$ symmetry allowed periodicity); see (**C**). Of course, other polarizations for $B2$ state are possible as determined from the ASRO.

An example of two possible polarizations is given in Figure 1, part A, for the case of $B2$-type ordering in a ABC_2 bcc alloy. At high temperatures, $\mathbf{k} = (111)$ is the unstable wave vector and produces a $B2$ partially ordered state. However, the amount of A and B on the two sublattices is dictated by the polarization: with polarization 1, for example, Figure 1, part B, is appropriate. At a lower temperature, $\mathbf{k} = (\frac{1}{2}\frac{1}{2}\frac{1}{2})$ ordering is symmetry allowed, and then the alloy forms, in this example, a Heusler-type $L2_1$ alloy because only polarization 2 is possible (see Figure 1, part C; in a binary alloy, the Heusler would be the DO_3 or Fe_3Al prototype because there are two distinct "Fe" sites). However, for $B2$ ordering, keep in mind that there are an infinite number of polarizations (types of partial order) that can occur, which must be determined from the electronic interactions on a system-by-system basis.

In general, then, the concentration wave relevant for specifying the type of ordering tendencies in a ternary alloy, as given by the wavevectors in the ASRO, can be written as (Althoff et al., 1996)

$$\begin{bmatrix} c_A(\mathbf{R}_i) \\ c_B(\mathbf{R}_i) \end{bmatrix} = \begin{bmatrix} c_A \\ c_B \end{bmatrix} + \sum_{s,\sigma} \eta_s^{\sigma}(T) \begin{bmatrix} e_A^{\sigma}(\mathbf{k}_s) \\ e_B^{\sigma}(\mathbf{k}_s) \end{bmatrix} \left\{ \sum_{j_s} \gamma^{\sigma}(\mathbf{k}_{j_s};\, \{e_{\alpha}^{\sigma}\}) e^{i\mathbf{k}j_s \cdot \mathbf{R}_i} \right\} \tag{9}$$

The generalization to N-component alloys follows easily in this vector notation. The same results can be obtained by mapping the problem of "molecules on a lattice" investigated by Badalayan et al. (1969). Here, the amplitude of the ordering wave has been broken up into a product of a temperature-dependent factor and two others:

$Q_\alpha(\mathbf{k}_{j_s}) = \eta_s(T)e_\alpha(\mathbf{k}_s)\gamma(\mathbf{k}_{j_s})$, in a spirit similar to that done for the binary alloys (Khachaturyan, 1972, 1983). Here, the η are the temperature-dependent, long-range-order parameters that are normalized to 1 at zero temperature in the fully ordered state (if it exists); the e_α are the eigenvectors specifying the relative polarizations of the species in the proper thermodynamic Gibbs space (see below; also see de Fontaine, 1973; Althoff et al., 1996); the values of γ are geometric coefficients that are linear combinations of the eigenvectors at finite temperature, hence the k dependence, but must be simple ratios of numbers at zero temperatures in a fully ordered state (like the $\frac{1}{2}$ in the former case of CuAu). In regard to the summation labels: s refers to the contributing stars [e.g., (100) or $(1\frac{1}{2}0)$; σ refers to branches, or, the number of chemical degrees of freedom (2 for a ternary); j_s refers the number of wavevectors contained in the star [for fcc, (100) has 3 in the star] (Khachaturyan, 1972, 1983; Althoff et al., 1996).

Notice that only $\eta_s^\sigma(T)$ are quantities not determined by the ASRO, for they depend on thermodynamic averages in a partially or fully ordered phase with those specific probability distributions. For $B2$-type (two sublattices, I and II) ordering in an ABC_2 bcc alloy, there are two order parameters, which in the partially ordered state can be, e.g., $\eta_1 = c_A(\mathrm{I}) - c_A(\mathrm{II})$ and $\eta_2 = c_B(\mathrm{I}) - c_B(\mathrm{II})$. Scattering measurements in the partially ordered state can determine these by relative weights under the superlattice spots that form, or they can be obtained by performing thermodynamic calculations with Monte Carlo or CVM. On a stoichiometric composition, the values of γ are simple geometric numbers, although, from the notation, it is clear they can be different for each member of a star, hence, the different ordering of Cu-Au at $L1_2$ and $L1_0$ stoichiometries (Khachaturyan, 1983). Thus, the eigenvectors $e_\alpha(\mathbf{k}_s)$ at the unstable wavevector(s) give the ordering of A (or B) relative to C. These eigenvectors are completely determined by the *electronic interactions*. What are these eigenvectors and how does one get them from any calculation or measurement? This is a bit tricky.

First, let us note what the $e_\alpha(\mathbf{k}_s)$ are not, so as to avoid confusion between high-T and low-T approaches which use concentration-wave ideas. In the high-temperature state, each component of the eigenvector is degenerate among a given star. By the symmetry of the disordered state, this must be the case and it may be removed from the "j_s" sum (as done in Equation 9). However, below a first-order transition, it is possible that the $e_\alpha(\mathbf{k}_s)$ is temperature and star dependent, for instance, but this cannot be ascertained from the ASRO. Thus, from the point of view of determining the ordering tendency from the ASRO, the $e_\alpha(\mathbf{k}_s)$ do not vary among the members of the star, and their temperature dependence is held fixed after it is determined just above the transition. This does not mean, as assumed in pair-potential models, that the interactions (and, therefore, polarizations) are given *a priori* and do not change as a function of temperature; it only means that averages in the disordered state cannot necessarily give you averages in the partially ordered state. Thus, in general, the $e_\alpha(\mathbf{k})$ may also have a dependence on members of the star, because $e_\alpha(\mathbf{k}_{j_s})\gamma(\mathbf{k}_{j_s})$ has to reflect the symmetry operations of the ordered distribution when writing a concentration wave. We do not address this possibility here.

Now, what is $e_\alpha(\mathbf{k})$ and how do you get it? In Figure 1, part A; the unit vectors for the fluctuations of A and B compositions are shown within the ternary Gibbs triangle: only within this triangle are the values of c_A, c_B, and c_C allowed (because $c_A + c_B + c_C = 1$). Notice that the unit vectors for δc_A and δc_B fluctuations are at an oblique angle, because the Gibbs triangle is an oblique coordinate system. The free energy associated with concentration fluctuations is $\Delta F = \delta\mathbf{c}^T\mathbf{q}^{-1}\delta\mathbf{c}$, using matrix notation with species labels suppressed (note that superscript T is a transpose operation). The matrix $\mathbf{q}^{-1}(\mathbf{k})$ is symmetric and square in $(N-1)$ species (let us take species C as the "host"). As such, it seems "obvious" that the eigenvectors of $\mathbf{q}^{-1}$ are required because they reflect the "principal directions" in free energy space which reveal the true order. However, its eigenvectors, $\mathbf{e}_C$, produce a host-dependent, unphysical ordering! That is, Equation 9 would produce negative concentrations in some cases.

Immediately, you see the problem. The Gibbs triangle is an oblique coordinate system and, therefore, the eigenvectors must be obtained in a properly orthogonal Cartesian coordinate system (de Fontaine, 1973). By an oblique coordinate transform, defined by $\delta\mathbf{c} = \mathbf{T}\mathbf{x}$, $\Delta F_x = \mathbf{x}^{\mathrm{T}}(\mathbf{T}^{\mathrm{T}}\mathbf{q}^{-1}\mathbf{T})\mathbf{x}$, but still $\Delta F_x = \Delta F$. From $\mathbf{T}^{\mathrm{T}}\mathbf{q}^{-1}\mathbf{T}$, we find a set of host-independent eigenvectors, $\mathbf{e}_X$; in other words, regardless of which species you take as the host, you always get the same eigenvectors! Finally, the physical eigenvectors we seek in the Gibbs space are then $\mathbf{e}_G = \mathbf{T}\mathbf{e}_X$ (since $\delta\mathbf{c} = \mathbf{T}\mathbf{x}$). It is important to note that $\mathbf{e}_C$ is not the same as $\mathbf{e}_G$ because $\mathbf{T}^{\mathrm{T}} \neq \mathbf{T}^{-1}$ in an oblique coordinate system like the Gibbs triangle, and, therefore, $\mathrm{T}\mathbf{T}^{\mathrm{T}}$ is not 1.

It is the $\mathbf{e}_G$ that reveal the true principal directions in free-energy space, and these parameters are related to linear combinations of elements of $\mathbf{q}^{-1}(\mathbf{k} = \mathbf{k}_0)$ at the pertinent unstable wavevector(s). If nothing else, the reader should take away that these quantities can be determined theoretically or experimentally via the diffuse intensities. Of course, any error in the theory or experiment, such as not maintaining the sum rules on $\mathbf{q}$ or α, will create a subsequent error in the eigenvectors and hence the polarization. Nevertheless, it is possible to obtain from the ASRO both wavevector and "wave polarization" information which determines the ordering tendencies (also see the appendix in Althoff et al., 1996).

To make this a little more concrete, let us reexamine the previous bcc ABC_2 alloy. In the bcc alloys, the first transformation from disordered $A2$ to the partially order $B2$ phase is second order, with $\mathbf{k} = (111)$ and no other wavevectors in the star. The modulation (111) indicates that the bcc lattice is being separated into two distinct sublattices. If the polarization 1 in Figure 1, part A, was found, it indicates that species C is going to be separated on its own sublattice; whereas, if polarization 2 was found initially, species C would be equally placed on the two sublattices. Thus, the polarization already gives a great deal of information about the ordering in the $B2$ partially ordered phase and, in fact, is just the slope of the line in the Gibbs triangle. This is the basis for the recent graphical representation of ALCHEMI (atom location by channeling

electron microscopy) results in $B2$-ordering ternary intermetallic compounds (Hou et al., 1997). There are, in principle, two order parameters because of the two branches in a ternary alloy case. The order-parameter η_2, say, can be set to zero to obtain the $B2$-type ordering, and, because the eigenvalue, λ_2, of eigenmode e_2 is higher in energy than that of e_1, i.e., $\lambda_1 < \lambda_2$, only e_1 is the initially unstable mode. See Johnson et al. (1999) for calculations in Ti-Al-Nb bcc-based alloys, which are directly compared to experiment (Hou, 1997).

We close this description of interpreting ASRO in ternary alloys by mentioning that the above analysis generalizes completely for quaternaries and more complex alloys. The important chemical space progresses: binary is a line (no angles needed), ternary is a triangle (one angle), quaternaries are pyramids (two angles, as with Euler rotations), and so on. So the oblique transforms become increasingly complex for multidimensional spaces, but the additional information, along with the unstable wavevector, is contained within the ASRO.

Concentration Waves from a Density-Functional Approach

The present first-principles theory leads naturally to a description of ordering instabilities in the homogeneously random state in terms of static concentration waves. As discussed by Khachaturyan (1983), the concentration-wave approach has several advantages, which are even more relevant when used in conjunction with an electronic-structure approach (Staunton et al., 1994; Althoff et al., 1995, 1996). Namely, the method (1) allows for interatomic interaction at arbitrary distances, (2) accounts for correlation effects in a long-range interaction model, (3) establishes a connection with the Landau-Lifshitz thermodynamic theory of second-order phase transformations, and (4) does not require *a priori* assumptions about the atomic superstructure of the ordered phases involved in the order-disorder transformations, allowing the possible ordered-phase structures to be predicted from the underlying correlations.

As a consequence of the electronic-structure basis to be discussed later, realistic contributions to the effective chemical interactions in metals arise, e.g., from electrostatic interactions, Fermi-surface effects, and strain fields, all of which are inherently long range. Analysis within the method is performed entirely in reciprocal space, allowing for a description of atomic clustering and ordering, or of strain-induced ordering, none of which can be included within many conventional ordering theories. In the present work, we neglect all elastic effects, which are the subject of ongoing work. As with the experiment, the electronic theory leads naturally to a description of the ASRO in terms of the temperature-dependent, two-body compositional-correlation function in reciprocal space. As the temperature is lowered, (usually) one wavevector becomes prominent in the ASRO, and the correlation function ultimately diverges there.

It is probably best to derive some standard relations that are applicable to both simple models and DFT-based approaches. The idea is simply to show that certain simplifications lead to well-known and venerable results, such as the Krivoglaz-Clapp-Moss formula (Krivoglaz, 1969; Clapp and Moss, 1966), where, by making fewer simplifications, an electronic DFT-based theory can be formulated, which nevertheless, is a mean-field theory of configurational degrees of freedom. While it is certainly much easier to derive approximations for pair correlations using very standard mean-field treatments based on effective interactions, as has been done traditionally, an electronic-DFT-based approach would require much more development along those lines. Consequently, we shall proceed in a much less common way, which can deal with all possibilities. In particular, we shall give a derivation for binary alloys and state the result for the N-component generalization, with some clarifying remarks added.

As shown for an A-B binary system (Györffy and Stocks, 1983), it is straightforward to adapt the density-functional ideas of classical liquids (Evans, 1979) to a "lattice-gas" model of alloy configurations (de Fontaine, 1979). The fundamental DFT theorem states that, in the presence of an external field, $H_{\text{ext}} = \Sigma_n \varpi_n \xi_n$ with external chemical potential, ϖ_n, there is a grand potential (not yet the thermodynamic one),

$$\mathbf{\Omega}[T, V, N, \nu, \{c_n\}] = F[T, V, N, \{c_n\}] - \Sigma_n(\varpi_n - \nu)c_n \quad (10)$$

such that the internal Helmholtz free energy $F[\{c_n\}]$ is a unique functional of the local concentrations c_n, that is, $\langle \xi_n \rangle$, meaning F is independent of ϖ_n. Here, T, V, N, and ν are, respectively, the temperature, volume, number of unit cells, and chemical potential difference $(\nu_A - \nu_B)$. The equilibrium configuration is specified by the stationarity condition;

$$\left.\frac{\partial \Omega}{\partial c_n}\right|_{\{c_n^0\}} = 0 \quad (11)$$

which determines the Euler-Lagrange equations for the alloy problem. Most importantly, from arguments given by Evans (Evans, 1979), it can be proven that Ω is a minimum at $\{c_n^0\}$ and equal to the proper thermodynamic grand potential $\Omega[T, V, N, \nu]$ (Györffy et al., 1989). In terms of $\nu_i = (\varpi_i - \nu)$, an effective chemical potential difference, Ω is a generating function for a hierarchy of correlation functions (Evans, 1979). The first two are

$$-\frac{\partial \Omega}{\partial \nu_i} = c_i \qquad \text{and} \qquad -\frac{\partial^2 \Omega}{\partial \nu_i \partial \nu_j} = \beta q_{ij} \quad (12)$$

This second generator is the correlation function that we require for stability analysis.

Some standard DFT tricks are useful at this point and these also happen to be the equivalent tricks originally used to derive the electronic-DFT Kohn-Sham equations (also known as the single-particle Schrödinger equations; Kohn and Sham, 1965). Although F is not yet known, we can break this complex functional up into a known non-interacting part (given by point entropy for the alloy problem):

$$F_0 = \beta^{-1} \sum_n [c_n \ln c_n + (1 - c_n) \ln(1 - c_n)] \quad (13)$$

and an interacting part Φ, defined by $F = F_0 - \Phi$. Here, β^{-1} is the temperature, $k_B T$ where k_B is the Boltzmann constant. In the DFT for electrons, the noninteracting part was taken as the single-particle kinetic energy (Kohn and Sham, 1965), which is again known exactly. It then follows from Equation 11 that the Euler-Lagrange equations that the $\{c_n^0\}$ satisfy are:

$$\beta^{-1}\ln\left[\frac{c_n^0}{(1-c_n^0)}\right] - S_n^{(1)} - \nu_n = 0 \tag{14}$$

which determines the contribution to the local chemical potential differences in the alloy due to all the interactions, if $S^{(1)}$ can be calculated (in the physics literature, $S^{(1)}$ would be considered a self-energy functional). Here it has been helpful to define a new set of correlation functions generated from the functional derivatives of Φ with respect to concentration variable; the first two correlation functions being:

$$S_i^{(1)} \equiv -\frac{\partial\Phi}{\partial c_i} \qquad \text{and} \qquad S_{ij}^{2} \equiv -\frac{\partial^2\Phi}{\partial c_i \partial c_j} \tag{15}$$

In the classical theory of liquids, the $S^{(2)}$ is an Ornstein-Zernike (Ornstein, 1912; Ornstein and Zernike, 1914 and 1918; Zernike, 1940) direct-correlation function (with density instead of concentration fluctuations; Stell, 1969).

Note that there are as many coupled equations in Equation 14 as there are atomic sites. If we are interested in, for example, the concentration profile around an antiphase boundary, Equation 14 would in principle provide that information, depending upon the complexity of Φ and whether we can calculate its functional derivatives, which we shall address momentarily. Also, recognize that $S^{(2)}$ is, by its very nature, the stability matrix (with respect to concentration fluctuations) of the interacting part of the free energy. Keep in mind that Φ, in principle, must contain all many-body-type interactions, including all entropy contributions beyond the point entropy that was used as the noninteracting portion. If it was based on a fully electronic description, it must also contain "particle-hole" entropy associated with the electronic density of states at finite temperature (Staunton et al., 1994).

The significance of $S^{(2)}$ can immediately be found by performing a stability analysis of the Euler-Lagrange equations; that is, take the derivatives of Equation 14 w.r.t. c_i, or, equivalently, expand the equation to find the fluctuations about c_i^0 (i.e., $c_i = c_i^0 + \delta c_i$), to find out how fluctuations affect the local chemical potential difference. The result is the stability equations for a general inhomogeneous alloy system:

$$\frac{\delta_{ij}}{\beta c_i(1-c_i)} - S_{ij}^{(2)} - \frac{\partial\nu_i}{\partial c_j} = 0 \tag{16}$$

Through the DFT theorem and generating functionals, the response function $\partial\nu_i/\partial c_j$, which tells how the concentrations vary with changes in the applied field, has a simple relationship to the true pair-correlation function:

$$\frac{\partial\nu_i}{\partial c_j} = \left(\frac{\partial c_j}{\partial\nu_i}\right)^{-1} \equiv \left(\frac{\delta^2\Omega}{\delta\nu_i\delta\nu_j}\right)^{-1} \equiv \beta^{-1}(q^{-1})_{ij} \equiv [\beta c(1-c)]^{-1}(\alpha^{-1})_{ij} \tag{17}$$

where the last equality arises through the definition of Warren-Cowley parameters. If Equation 16 is now evaluated in the random state where (discrete) translational invariance holds, and the connection between the two types of correlation functions is used (i.e., Equation 17), we find:

$$\alpha(\mathbf{k}) = \frac{1}{1 - \beta c(1-c)S^{(2)}(\mathbf{k})} \tag{18}$$

Note that here we have evaluated the exact functional in the homogeneously random state with $c_i^0 = c\,\forall\, i$, which is an approximation because in reality there are some changes to function induced by the developed ASRO. In principle, we should incorporate this ASRO in the evaluation to more properly describe the situation. For peaks at finite wavevector $\mathbf{k}_0$, it is easy to see that absolute instability of the binary alloy to ordering occurs when $\beta c(1-c)S^{(2)}(\mathbf{k}=\mathbf{k}_0) = 1$ and the correlations diverge. The alloy would be unstable to ordering with that particular wavevector. The temperature, T_{sp}, where this may occur, is the so-called "spinodal temperature." For peaks at $\mathbf{k}_0 = 0$, i.e., long-wavelength fluctuations, the alloy would be unstable to clustering.

For the N-component case, a similar derivation is applicable (Althoff et al., 1996; Johnson, 2001) with multiple chemical fields, $\varpi_{\alpha n}$, chemical potential differences, ν_α (relative to the ν_N), and effective chemical potential differences $\nu_{\alpha n} = (\varpi_{\alpha n} - \nu_\alpha)$. One cannot use the simple c and $(1-c)$ relationship in general and must keep all the labels relative to the Nth component. Most importantly, when taking compositional derivatives, the single-occupancy constraint must be handled properly, i.e., $\partial c_{\alpha i}/\partial c_{\beta j} = \delta_{ij}[(\delta_{\alpha\beta} - \delta_{\alpha N})(1-\delta_{\beta N})]$. The generalized equations for the pair correlations are, when evaluated in the homogeneously random state:

$$\left[q^{-1}(\mathbf{k})\right]_{\alpha\beta} = \left[\frac{\delta_{\alpha\beta}}{c_\alpha} + \frac{1}{c_N}\right] - \beta S_{\alpha\beta}^{(2)}(\mathbf{k}) \tag{19}$$

where neither α nor β can be the Nth component. This may again be normalized to produce the Warren-Cowley pairs. With the constraint implemented by designating the Nth species as the "host," the (nonsingular) portion of the correlation function matrices are rank $(N-1)$. For an A-B binary, $c_\alpha = c_A = c$ and $c_N = c_B = 1 - c$ because only the $\alpha = \beta = A$ term is valid ($N = 2$ and matrices are rank 1), and we recover the familiar result, Equation 18.

Equation 19 is, in fact, a most remarkable result. It is completely general and exact! However, it is based on some still unknown functional $S^{(2)}(\mathbf{k})$, which is not a pairwise interaction but a pair-correlation function arising

from the interacting part of the free energy. Also, Equations 18 and 19 properly conserve spectral intensity, $\alpha_{\alpha\beta}(\mathbf{R}=0)=1$, as required in Equation 6. Notice that $S^{(2)}(\mathbf{k})$ has been defined without referring to pair potentials or any larger sets of ECIs. In fact, we shall discuss how to take advantage of this to make a connection to first-principles electronic-DFT calculations of $S^{(2)}(\mathbf{k})$. First, however, let us discuss some familiar mean-field results in the theory of pair correlations in binary alloys by picking approximate $S^{(2)}(\mathbf{k})$ functionals. In such a context, Equation 18 may be cautiously thought of as a generalization of the Krivoglaz-Clapp-Moss formula, where $S^{(2)}$ plays the role of a concentration- and (weakly) temperature-dependent effective pairwise interaction.

Connection to Well-Known Mean-Field Results

In the concentration-functional approach, one mean-field theory is to take the interaction part of the free energy as the configurational average of the alloy Hamiltonian, i.e., $\Phi_{\mathrm{MF}}=-\langle H[\{\xi_n\}]\rangle$, where the averaging is performed with an inhomogeneous product probability distribution function, $P[\{\xi_n\}]=\prod_n P_n(\xi_n)$, with $P_n(1)=c_n$ and $P_n(0)=1-c_n$. Such a product distribution yields the mean-field results $\langle\xi_i\xi_j\rangle=c_ic_j$, e.g., usually called the random-phase approximation in the physics community. For an effective chemical interaction model based on pair potentials and using $\langle\xi_i\xi_j\rangle=c_ic_j$, then

$$\Phi\rightarrow\Phi_{\mathrm{MF}}=\frac{1}{2}\sum_{ij}c_iV_{ij}c_j \tag{20}$$

and therefore, $S^{(2)}(\mathbf{k})=-V(\mathbf{k})$, which no longer has a direct electronic connection for the pairwise correlations. As a result, we recover the Krivoglaz-Clapp-Moss result (Krivoglaz, 1969; Clapp and Moss, 1966), namely:

$$\alpha(\mathbf{k})=\frac{1}{[1+\beta c(1-c)V(\mathbf{k})]} \tag{21}$$

and the Gorsky-Bragg-Williams equation of state would be reproduced by Equation 14. To go beyond such a mean-field result, fluctuation corrections would have to be added to Φ_{MF}. That is, the probability distribution would have to be more than a separable product. One consequence of the uncorrelated configurational averaging (i.e., $\langle\xi_i\xi_j\rangle=c_ic_j$) is a substantial violation of the spectral intensity sum rule $\alpha(\mathbf{R}=0)=1$. This was recognized early on and various scenarios for normalizing the spectral intensity have been used (Clapp and Moss, 1966; Vaks et al., 1966; Reinhard and Moss, 1993).

A related effect of such a mean-field averaging is that the system is "overcorrelated" through the mean fields. This occurs because the effective chemical fields are produced by averaging over all sites. As such, the local composition on the ith site interacts with all the remaining sites through that average field, which already contains effects from the ith site; so the ith site has a large self correlation. The "mean" field produces a correlation because it contains field information from all sites, which is the reason that although assuming $\langle\xi_i\xi_j\rangle=c_ic_j$, which says that no pairs are correlated, we managed to obtain atomic short-range order, or a pair correlation. So, the mean-field result properly has a correlation, although it is too large a self-correlation, and there is a slight lack of consistency due to the use of "mean" fields. In previous comparisons of Ising models (e.g., to various mean-field results), this excessive self-correlation gave rise to the often quoted 20% error in transition temperatures (Brout and Thomas, 1965).

Improvements to Mean-Field Theories

While this could be a chapter unto itself, we will just mention a few key points. First, just because one uses a mean-field theory does not necessarily make the results bad. That is, there are many different breeds of mean-field approximations. For example, the CVM is a mean-field approximation for cluster entropy, being much better than the Gorsky-Bragg-Williams approximation, which uses only point entropy. In fact, the CVM is remarkably robust, giving in many cases results similar to "exact" Monte Carlo simulations (Sanchez and de Fontaine, 1978, 1980; Ducastelle, 1991). However, it too does have limitations, such as a practical restriction to small interaction ranges or multiplet sizes.

Second, when addressing an alloy problem, the complexity of Φ (the underlying Hamiltonian) matters, not only how it is averaged. The overcorrelation in the mean-field approximation, e.g., while often giving a large error in transition temperatures in simple alloy models, is not a general principle. If the correct physics giving rise to the ordering phenomena in a particular alloy is well described by the Hamiltonian, very good temperatures can result. If entropy was the entire driving force for the ordering, and Φ did not have any entropy included, we would get quite poor results. On the other hand, if electronic band filling was the overwhelming contribution to the structural transformation, then a Φ that included that information in a reasonable way, but that threw out higher-order entropy, would give very good results; much better, in fact, than the often quoted "20% too high in transition temperature." We shall indeed encounter this in the results below.

Third, even simple improvements to mean-field methods can be very useful, as we have already intimated when discussing the Onsager cavity-field corrections. Let us see what the effect is of just ensuring the sum rule required in Equation 6. The Onsager corrections (Brout and Thomas, 1967) for the above mean-field average amounts to the following coupled equations in the alloy problem (Staunton et al., 1994; Tokar, 1997; Boriçi-Kuqo et al., 1997), depending on the mean-field Φ used

$$\alpha(\mathbf{k},T)=\frac{1}{1-\beta c(1-c)[S^{(2)}_{\mathrm{MF}}(\mathbf{k},T)-\Lambda(T)]} \tag{22}$$

and, using Equation 6,

$$\nabla(T)=\frac{1}{\Omega_{\mathrm{BZ}}}\int d\mathbf{k}S^{(2)}_{\mathrm{MF}}(\mathbf{k})\alpha(\mathbf{k},T;\Lambda) \tag{23}$$

where Λ is the temperature-dependent Onsager correction and Ω_{BZ} is the Brillouin zone volume of the random alloy Bravais lattice. This coupled set of equations may be solved by standard Newton-Raphson techniques. For the N-component alloy case, these become a coupled set of matrix equations where all the matrices (including Λ) have two subscripts identifying the pairs, as given in Equation 19 and appropriate internal sums over species are made (Althoff et al., 1995, 1996). An even more improved and general approach has been proposed by Chepulskii and Bugaev (1998a,b).

The effect of the Onsager correction is to renormalize the mean-field $S^{(2)}(\mathbf{k})$ producing an effective $S^{(2)}_{\text{eff}}(\mathbf{k})$ which properly conserves the intensity. For an exact $S^{(2)}(\mathbf{k})$, Λ is zero, by definition. So, the closer an approximate $S^{(2)}(\mathbf{k})$ satisfies the sum rule, the less important are the Onsager corrections. At high temperatures, where $\alpha(\mathbf{k})$ is 1, it is clear from Equation 23 that $\Lambda(T)$ becomes the average of $S^{(2)}(\mathbf{k})$ over the Brillouin zone, which turns out to be a good "seed" value for a Newton-Raphson solution. It is important to emphasize that Equations 22 and 23 may be derived in numerous ways. However, for the current discussion, we note that Staunton et al. (1994) derived these relations from Equation 14 by adding the Onsager cavity-field corrections while doing a linear-response analysis that can add additional complexity, (i.e., more q dependence than evidenced by Equation 22 and Equation 23). Such an approach can also yield the equivalent to a high-T expansion to second order in β—as used to explain the temperature-dependent shifts in ASRO (Le Bulloc'h et al., 1998). Now, for an Onsager-corrected mean-field theory, as one gets closer to the spinodal temperature, $\Lambda(T \cong T_{\text{sp}})$ becomes larger and larger because $\alpha(\mathbf{k})$ is diverging and more error has to be corrected. Improved entropy mean-field approaches, such as the CVM, still suffer from errors associated with the intensity sum rule, which are mostly manifest around the transition temperatures (Mohri et al., 1985).

For a pairwise Hamiltonian, it is assumed that $V_{ii} = 0$, otherwise it would just be an arbitrary shift of the energy zero, which does not matter. However, an interesting effect in the high-T limit for the (mean-field) pair-potential model is that $\Lambda = \frac{1}{\Omega_{BZ}} \int d\mathbf{k} V(\mathbf{k}) = V_{ii}$, which is not generally zero, because V_{ii} is not an interaction but a self-energy correction, (i.e., Φ_{ii}, which must be finite in mean-field theory just to have a properly normalized correlation function). As evidenced from Equation 16, the correlation function can be written as $\underline{\underline{\alpha}}^{-1} = \underline{\underline{\Sigma}} - \underline{\underline{V}}$ in terms of a self-energy Σ, as can be shown more properly from field-theory (Tokar, 1985, 1997). However, Σ in this case is the exact self-energy, rather than just $[\beta c(1-c)]^{-1}$ for the Krivoglaz-Clapp-Moss mean-field case. Moreover, the zeroth-order result for the self-energy yields the Onsager correction (Masanskii et al., 1991; Tokar, 1985, 1997), i.e., $\Sigma = [\beta c(1-c)]^{-1} + \Lambda(T)$. Therefore, V_{ii}, or more properly $\Lambda(T)$, is manifestly not arbitrary. These techniques have little to say regarding complicated many-body Hamiltonians, however.

It would be remiss not to note that for short-range order in strongly correlated situations the mean-field results, even using Onsager corrections, can be topologically incorrect. An example is the interesting toy model of a disordered (electrostatically screened) binary Madelung lattice (Wolverton and Zunger, 1995b; Boriçi-Kuqo et al., 1997), in which there are two types of point charges screened by rules depending on the nearest-neighbor occupations. In such a pairwise case, including intrasite self-correlations, the intensity sums are properly maintained. However, self-correlations beyond the intrasite (at least out to second neighbors) are needed in order to correct $\underline{\underline{\alpha}}^{-1} = \underline{\underline{\Sigma}} - \underline{\underline{V}}$ and its topology (Wolverton and Zunger, 1995a,b; Boriçi-Kuqo et al., 1997).

In less problematic cases, such as backing out ECIs from experimental data on real alloys, it is found that the zeroth-order (Onsager) correction plus additional first-order corrections agrees very well with those ECIs obtained using inverse Monte Carlo methods (Reinhard and Moss, 1993; Masanskii et al., 1991). When a second-order correction was included, no difference was found between the ECIs from mean-field theory and inverse Monte Carlo, suggesting that lengthy simulations involved with the inverse Monte Carlo techniques may be avoided (Le Bolloc'h et al., 1997). However, as warned before, the inverse mapping is not unique, so care must be taken when using such information.

Notice that even in problem cases, improvements made to mean-field theories properly reflect most of the important physics, and can usually be handled more easily than more exacting approaches. What is important is that a mean-field treatment is not in itself patently inappropriate or wrong. It is, however, important to have included the correct physics for a given system. Including the correct physics for a given alloy is a system-specific requirement, which usually cannot be known *a priori*. Hence, our choice is to try and handle chemical and electronic effects, all on an equal footing, and represented from a highly accurate, density-functional basis.

Concentration Waves from First-Principles, Electronic-Structure Calculations

What remains to be done is to connect the formal derivation given above to the system-dependent, electronic structure of the random substitutional alloy. In other words, we must choose a Φ, which we shall do in a mean-field approach based on local density approximation (LDA) to electronic DFT (Kohn and Sham, 1965). In the adiabatic approximation, $\Phi_{\text{MF}} = -\langle \Omega_e \rangle$, where Ω_e is the electronic grand potential of the electrons for a specific configuration (where we have also lumped in the ion-ion contribution). To complete the formulation, a mean-field configurational averaging of Ω_e is required in analytic form, and must be dependent on all sites in order to evaluate the functional derivatives analytically. Note that using a local density approximation to electronic DFT is also, in effect, a mean-field theory of the electronic degrees of freedom. So, even though they will be integrated out, the electronic degrees of freedom are all handled on a par with the configurational degrees of freedom contained in the noninteracting contribution to the chemical free energy.

For binaries, Györffy and Stocks (1983) originally discussed the full adaptation of the above ideas and its

implementation including only electronic band-energy contributions based on the Korringa-Kohn-Rostocker (KKR) coherent potential approximation (CPA) electronic-structure calculations. The KKR electronic-structure method (Korringa, 1947; Kohn and Rostoker, 1954) in conjunction with the CPA (Soven, 1967; Taylor, 1968) is now a well-proven, mean-field theory for calculating electronic states and energetics in random alloys (e.g., Johnson et al., 1986, 1990). In particular, the ideas of Ducastelle and Gautier (1976) in the context of tight-binding theory were used to obtain $\langle \Omega_e \rangle$ within an inhomogeneous version of the KKR-CPA, where all sites are distinct so that variational derivatives could be made.

As shown by Johnson et al. (1986, 1990), the electronic grand potential for any alloy configuration may be written as:

$$\Omega_e = -\int_{-\infty}^{\infty} d\varepsilon N(\varepsilon;\mu) f(\varepsilon-\mu) + \int_{-\infty}^{\mu} d\mu' \int_{-\infty}^{\infty} d\varepsilon \frac{dN(\varepsilon;\mu')}{d\mu'} f(\varepsilon-\mu') \qquad (24)$$

where the first term is the single-particle, or band-energy, contribution, which produces the local (per site) electronic density of states, $n_i(\varepsilon;\mu)$, and the second term properly gives the "double-counting" corrections. Here $f(\varepsilon - \mu)$ is the Fermi occupation factor from finite-temperature effects on the electronic chemical potential, μ (or Fermi energy at $T = 0$ K). Hence, the band-energy term contains all electron-hole effects due to electronic entropy, which may be very important in some high-T alloys. The $N(\varepsilon;\mu) = \Sigma_i \int_{-\infty}^{\varepsilon} d\varepsilon' n_i(\varepsilon;\mu)$, and is the integrated density of states as typically discussed in band-structure methods. We may obtain an analytic expression for Ω_e as long as an analytic expression for $N(\varepsilon;\mu)$ exists (Johnson et al., 1986, 1990). Within the CPA, an analytic expression for $N(\varepsilon;\mu)$ in either a homogeneously or inhomogeneously disordered state is given by the generalized Lloyd formula (Faulkner and Stocks, 1980). Hence, we can determine Ω^{CPA} for a inhomogeneously random state. As with any DFT, besides the extrinsic variables T, V, and μ (temperature, volume, and chemical potential, respectively), Ω_e^{CPA} is only a functional of the CPA charge density, $\{\rho_{\alpha,i}\}$ for all species and sites.

In terms of KKR multiple-scattering theory, the inhomogeneous CPA is pictorially understood by "replacing" the individual atomic scatterers at the ith site (i.e., $t_{\alpha,i}$) by a CPA effective scatterer per site (i.e., $t_{c,i}$) (Györffy and Stocks, 1983; Staunton et al., 1994). It is more appropriate to average scattering properties rather than potentials to determine a random system's properties (Soven, 1967; Taylor, 1968). For an array of CPA scatterers, $\tau_{c,ii}$ is a (site-diagonal) KKR scattering-path operator that describes the scattering of an electron from all sites given that it starts and ends at the ith site. The t_c values are determined from the requirement that replacing the effective scatterer by any of the constituent atomic scatterers (i.e., $t_{\alpha,i}$) does not on average change the scattering properties of the entire system as given by $\tau_{c,ii}$ (Fig. 2). This

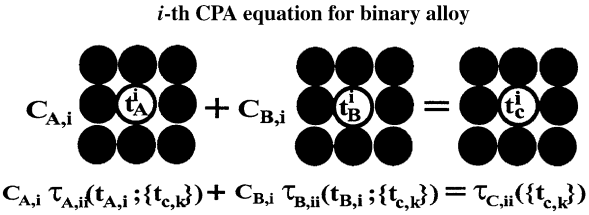

Figure 2. Schematic of the required average scattering condition, which determines the inhomogeneous CPA self-consistent equations. t_c and t_α are the site-dependent, single-site CPA and atomic scattering matrices, respectively, and τ_c is the KKR scattering path operator describing the entire electronic scattering in the system.

requirement is expressed by a set of CPA conditions, $\Sigma_\alpha c_{\alpha,i}\tau_{\alpha,ii} = \tau_{c,ii}$, one for each lattice site. Here, $\tau_{\alpha,ii}$ is the site-diagonal, scattering-path operator for an array of CPA scatterers with a single impurity of type α at the ith site (see Fig. 2) and yields the required set of $\{\rho_{\alpha,i}\}$. Notice that each of the CPA single-site scatterers can in principle be different (Györffy et al., 1989). Hence, the random state is inhomogeneous and scattering properties vary from site to site. As a consequence, we may relate any type of ordering (relative to the homogeneously disordered state) directly to electronic interactions or properties that lower the energy of a particular ordering wave.

While these inhomogeneous equations are generally intractable for solution, the inhomogeneous CPA must be considered to calculate analytically the response to variations of the local concentrations that determine $S_{ij}^{(2)}$. This allows all possible configurations (or different possible site occupations) to be described. By using the homogeneous CPA as the reference, all possible orderings (wave vectors) may be compared simultaneously, just as in with phonons in elemental systems (Pavone et al., 1996; Quong and Lui, 1997). The conventional single-site homogeneous CPA (used for total-energy calculations in random alloys; Johnson et al., 1990) provides a soluble highest symmetry reference state to perform a linear-response description of the inhomogeneous CPA theory.

Those ideas have been recently extended and implemented to address multicomponent alloys (Althoff et al., 1995, 1996), although the initial calculations still just include terms involving the band-energy only (BEO). For binaries, Staunton et al. (1994) have worked out the details and implemented calculations of atomic-short-range order that include all electronic contributions, e.g., electrostatic and exchange correlation. The coupling of magnetic and chemical degrees of freedom have been addressed within this framework by Ling et al. (1995a, b), and references cited therein. The full DFT theory has thus far been applied mostly to binary alloys, with several successes (Staunton et al., 1990; Pinski et al., 1991, 1998; Johnson et al., 1994; Ling et al., 1995; Clark et al., 1995). The extension of the theory to incorporate atomic displacements from the average lattice is also ongoing, as is the inclusion of all terms beyond the band energy for multicomponent systems.

Due to unique properties of the CPA, the variational nature of DFT within the KKR-CPA is preserved, i.e., $\delta\Omega_e^{\mathrm{CPA}}/\delta\rho_{\alpha,i} = 0$ (Johnson et al., 1986, 1990). As a result, only the explicit concentration variations are required to obtain equations for $S^{(1)}$, the change in (local) chemical potentials, i.e.:

$$\frac{\delta\Omega^{\mathrm{CPA}}}{\partial c_{\alpha,i}} = -(1-\delta_{\alpha N})Im\int_{-\infty}^{\infty} d\varepsilon f(\varepsilon-\mu_e) \times [N_{\alpha,i}(\varepsilon) - N_{N,i}(\varepsilon)] + \cdots \quad (25)$$

Here, $f(\varepsilon-\mu)$ is the Fermi filling factor and μ_e is the electronic chemical potential (Fermi energy at $T = 0$ K); $N_\alpha(\varepsilon)$ is the CPA site integrated density of states for the α species, and the Nth species has been designated the "host." The ellipses refer to the remaining direct concentration variations of the Coulomb and exchange-correlation contributions to Ω^{CPA}, and the term shown is the band-energy-only contribution (Staunton et al., 1994). This band-energy term is completely determined for each site by the change in band-energy found by replacing the "host" species by an α species. Clearly, $S^{(1)}$ is zero if the α species is the "host" because this cannot change the chemical potential.

For the second variation for $S^{(2)}$, it is not so nice, because there are implicit changes to the charge densities (related to $\tau_{c,ii}$ and $\tau_{\alpha,ii}$) and the electronic chemical potentials, μ. Furthermore, these variations must be limited by global charge neutrality requirements. These restricted variations, as well as other considerations, lead to dielectric screening effects and charge "rearrangement"–type terms, as well as standard Madelung-type energy changes (Staunton et al., 1994).

At this point, we have (in principle) kept all terms contributing to the electronic grand potential, except for static displacements. However, in many instances, only the terms directly involving the underlying electronic structure predominantly determine the ordering tendencies (Ducastelle, 1991), as it is argued that screening and near-local charge neutrality make the double-counting terms negligible. This is in general not so, however, as discussed recently (Staunton et al., 1994; Johnson et al., 1994). For simplicity's sake, we consider here only the important details within the band-energy-only (BEO) approach, and only state important differences for the more general case when necessary. Nonetheless, it is remarkable that the BEO contributions actually address a great many alloying effects that determine phase stability in many alloy systems, such as, band filling (or electron-per-atom, e/a; Hume-Rothery, 1963), hybridization (arising from diagonal and off-diagonal disorder), and so-called electronic topological transitions (Lifshitz, 1960), which encompass Fermi-surface nesting (Moss, 1969) and van Hove singularity (van Hove, 1953) effects. We shall give some real examples of such effects (how they physically come about) and how these effects determine the ASRO, including in disordered fcc Cu-Ni-Zn (see Data Analysis and Initial Interpretation).

Within a BEO approach, the expression for the band-energy part of $S^{(2)}_{\alpha\beta}(\mathbf{q};\varepsilon)$ is

$$S^{(2)}_{\alpha\beta}(\mathbf{q};\varepsilon) = -\frac{1}{\pi}(1-\delta_{\alpha N})(1-\delta_{\beta N})\,Im\int_{-\infty}^{\infty} d\varepsilon f(\varepsilon-\mu) \times \left\{\sum_{L_1L_2L_3L_4} M_{\alpha,L_1L_2}(\varepsilon) X_{L_2L_1;L_3L_4}(\mathbf{q};\varepsilon) M_{\beta,L_3L_4}(\varepsilon)\right\} \quad (26)$$

where L refers to angular momentum indices of the spherical harmonic basis set (i.e., contributions from s, p, d, etc. type electrons in the alloy), and the matrix elements may be found in the referenced papers (multicomponent: Johnson, 2001; binaries: Györffy and Stocks, 1983; Staunton et al., 1994). This chemical "ordering energy," arising only from changes in the electronic structure from the homogeneously random, is associated with perturbing the concentrations on two sites. There are $N(N-1)/2$ independent terms, as we expected. There is some additional q dependence resulting from the response of the CPA medium, which has been ignored for simplicity's sake to present this expression. Ignoring such q dependence is the same as what is done for the generalized perturbation methods (Duscastelle and Gautier, 1976; Duscastelle, 1991).

As the key result, the main q dependence of the ordering typically arises mainly from the convolution of the electronic structure given by

$$X_{L_2L_1;L_3L_4}(\mathbf{q};\varepsilon) = \frac{1}{\Omega_{\mathrm{BZ}}}\int d\mathbf{k}\left[\tau_{c;L_2L_3}(\mathbf{k}+\mathbf{q};\varepsilon)\tau_{c;L_4L_1}(\mathbf{k};\varepsilon)\right] - \tau_{c;ii;L_2L_3}(\varepsilon)\tau_{c;ii;L_4L_1}(\varepsilon) \quad (27)$$

which involves only changes to the CPA medium due to off-diagonal scattering terms. This is the difficult term to calculate. It is determined by the underlying electronic structure of the random alloy and must be calculated using electronic density functional theory. How various types of chemical ordering are revealed from $S^{(2)}_{\alpha\beta}(\mathbf{q};\varepsilon)$ is discussed later (see Data Analysis and Initial Interpretation). However, it is sometimes helpful to relate the ordering directly to the electronic dispersion through the Bloch spectral functions $A_{\mathrm{B}}(\mathbf{k};\varepsilon) \propto \mathrm{Im}\ \tau_c(\mathbf{k};\varepsilon)$ (Györffy and Stocks, 1983), where τ_c and the configurationally averaged Green's functions and charge densities are also related (Faulkner and Stocks, 1980). The Bloch spectral function defines the average dispersion in the alloy system. For ordered alloys, $A_{\mathrm{B}}(\mathbf{k};\varepsilon)$ consists of delta functions in $\mathbf{k}$-space whenever the dispersion relationship is satisfied, i.e., $\delta(\varepsilon-\varepsilon_k)$, which are the electronic "bands." In a disordered alloy, these "bands" broaden and shift (in energy) due to disorder and alloying effects. The loci of peak positions at ε_{F}, if the widths of the peaks are small on the scale of the Brillouin zone dimension, defines a "Fermi surface" in a disordered alloy. The widths reflect, for example, the inverse lifetimes of electrons, determining such quantities as resistivity (Nicholson and Brown, 1993). Thus, if only electronic states near the Fermi surface play the dominant role in determining the ordering tendency from the convolution integral, the reader can already imagine how

Fermi-surface nesting gives a large convolution from flat and parallel portions of electronic states, as detailed later.

Notably, the species- and energy-dependent matrix elements in Equation 26 can be very important, as discussed later for the case of NiPt. To appreciate how band-filling effects (as opposed to Fermi-surface-related effects) are typically expected to affect the ordering in an alloy, it is useful to summarize as follows. In general, the band-energy-only part of $S^{(2)}_{\alpha\beta}(\mathbf{q};\varepsilon)$ is derived from the filling of the electronic states and harbors the Hume-Rothery electron-per-atom rules (Hume-Rothery, 1963), for example. From an analysis using tight-binding theory, Ducastelle and others (e.g., Ducastelle, 1992) have shown what ordering is to be expected in various limiting cases where the transition metal alloys can be characterized by diagonal disorder (i.e., difference between on site energies is large) and off-diagonal disorder (i.e., the constituent metals have different d band widths). The standard lore in alloy theory is then as follows: if the d band is either nearly full or empty, then $S^{(2)}_{\text{Band}}(\mathbf{q})$ peaks at $|\mathbf{q}| = 0$ and the system clusters. On the other hand, if the bands are roughly half-filled, then $S^{(2)}_{\text{Band}}(\mathbf{q})$ peaks at finite $|\mathbf{q}|$ values and the system orders. For systems with the d band nearly filled, the system is filling antibonding type states unfavorable to order, whereas, the half-filled band would have the bonding-type states filled and the antibonding-type states empty favoring order (this is very similar to the ideas learned from molecular bonding applied to a continuum of states). Many alloys can have their ordering explained on this basis. However, this simple lore is inapplicable for alloys with substantial off-diagonal disorder, as recently discussed by Pinski et al. (1991, 1998), and as explained below (see Data Analysis and Initial Interpretation) sections.

While the "charge effects" are important to include as well (Mott, 1937), let us mention the overall gist of what is found (Staunton et al., 1994). There is a "charge-rearrangement" term that follows from implicit variations of the charge on site i and the concentration on site j, which represents a dielectric response of the CPA medium. In addition, charge density-charge density variations lead to Madelung-type energies. Thus, $S^{(2)}_{\text{total}}(\mathbf{q}) = S^{(2)}_{c,c}(\mathbf{q}) + S^{(2)}_{c,\rho}(\mathbf{q}) + S^{(2)}_{\rho,\rho}(\mathbf{q})$. The additional terms also affect the Onsager corrections discussed above (Staunton et al., 1994). Importantly, the density of states at the Fermi energy reflects the number of electrons available in the metal to screen excess charges coming from the solute atoms, as well as local fluctuations in the atomic densities due to the local environments (see Data Analysis and Initial Interpretation). In a binary alloy case, e.g., where there is a large density of states at the Fermi energy (ε_F), $S^{(2)}$ reduces mainly to a screened Coulomb term (Staunton et al., 1994), which determine the Madelung-like effects. In addition, the major q dependence arises from the excess charge at the ion positions via the Fourier transform (FT) of the Coulomb potential, $C(\mathbf{q}) = \text{FT}|R_i - R_j|^{-1}$,

$$S^{(2)}(\mathbf{q}) \approx S^{(2)}_{c,c}(\mathbf{q}) - \frac{e^2 \Delta Q^2 [C(\mathbf{q}) - R_{nn}^{-1}]}{1 + l_{\text{scr}}^2 [C(\mathbf{q}) - R_{nn}^{-1}]} \qquad (28)$$

where $\Delta Q = q_A - q_B$ is the difference in average excess charge (in units of e, electron charge) on a site in the homogeneous alloy, as determined by the self-consistent KKR-CPA. The average excess charge $q_{\alpha,i} = Z_{\alpha i} - \int_{\text{cell}} d\mathbf{r}\, \rho_{\alpha i}(\mathbf{r})$ (with Z_i the atomic number on a site). Here, l_{scr} is the system-dependent, metallic screening length. The nearest-neighbor distance, R_{nn}, arises due to charge correlations from the local environment (Pinski et al., 1998), a possibly important intersite electrostatic energy within metallic systems previously absent in CPA-based calculations—essentially reflecting that the disordered alloy already contains a large amount of electrostatic (Madelung) energy (Cole, 1997).

The proper (or approximate) physical description and importance of "charge correlations" for the formation energetics of random alloys have been investigated by numerous approaches, including simple models (Magri et al., 1990; Wolverton and Zunger, 1995b), in CPA-based, electronic-structure calculations (Abrikosov et al., 1992; Johnson and Pinski, 1993; Korzhavyi et al., 1995), and large supercell calculations (Faulkner et al., 1997), to name but a few. The sum of the above investigations reveal that for disordered and partially ordered metallic alloys, these atomic (local) charge correlations may be reasonably represented by a single-site theory, such as the coherent potential approximation. Including only the average effect of the charges on the nearest-neighbors shell (as found in Equation 28) has been shown to be sufficient to determine the energy of formation in metallic systems (Johnson and Pinski, 1993; Korzhavyi et al., 1995; Ruban et al., 1995), with only minor difference between various approaches that are not of concern here. Below (see Data Analysis and Initial Interpretation) we discuss the effect of incorporating such charge correlations into the concentration-wave approach for calculating the ASRO in random substitutional alloys (specifically fcc NiPt; Pinski et al., 1998).

DATA ANALYSIS AND INITIAL INTERPRETATION

Hybridization and Charge Correlation Effects in NiPt

The alloy NiPt, with its d band almost filled, is an interesting case because it stands as a glaring exception to traditional band-filling arguments from tight-binding theory (Treglia and Ducastelle, 1987): a transition-metal alloy will cluster, i.e., phase separate, if the Fermi energy lies near either d band edge. In fact, NiPt strongly orders in the CuAu (or ⟨100⟩-based) structure, with its phase diagram more like an fcc prototype (Massalski et al., 1990). Because Ni and Pt are in the same column of the periodic table, it is reasonable to assume that upon alloying there should be little effect from electrostatics and only the change in the band energy should really be governing the ordering. Under such an assumption, a tight-binding calculation based on average off-diagonal matrix elements reveals that no ordering is possible (Treglia and Ducastelle, 1987).

Such a band-energy-only calculation of the ASRO in NiPt was, in fact, one of the first applications of our thermodynamic linear-response approach based on the CPA (Pinski et al., 1991, 1992), and it gave almost quantitative

Table 2. The Calculated $\mathbf{k_0}$ (in Units of $2\pi/a$, Where a is the Lattice Constant) and T_{sp} (in K) for fcc Disordered NiPt (Including Scalar-relativistic Effects) at Various Levels of Approximation Using the Standard KKR-CPA (Johnson et al., 1986) and a Mean-field, Charge-correlated KKR-CPA (Johnson and Pinski, 1993), Labeled scr-KKR-CPA (Pinski et al., 1998)

Method	BEO[a]		BEO + Onsager[b]		BEO + Coulomb[c]		BEO + Coulomb + Onsager[d]	
KKR-CPA	100	1080	100	780	100	6780	$\frac{1}{2}\frac{1}{2}\frac{1}{2}$	1045
scr-KKR-CPA	100	1110	100	810	100	3980	100	905

[d]Results of the full theory. Experimentally, NiPt has a T_c of 918 K (Massalski, et al., 1990).

agreement with experiment. However, our more complete theory of ASRO (Staunton et al., 1994), which includes Madelung-type electrostatic effects, dielectric effects due to rearrangement of charge, and Onsager corrections, yielded results for the transition temperature and unstable wavevector in NiPt that were simply wrong, whereas for many other systems we obtained very good results (Johnson et al., 1994). By incorporating the previously described screening contributions to the calculation of ASRO in NiPt (Pinski et al., 1998), the wave vector and transition temperature were found to be in exceptional agreement with experiment, as evidenced in Table 2.

In the experimental diffuse scattering on NiPt, a (100) ordering wave vector was found, which is indicative of CuAu ($L1_0$)-type short-range order (Dahmani et al., 1985), with a first-order transition temperature of 918 K. From Table 2, we see that using the improved screened (scr)-KKR-CPA yields a (100) ordering wave vector with a spinodal temperature of 905 K. If only the band-energy contributions are considered, for either the KKR-CPA or its screened version, the wave vector is the same and the spinodal temperature is about 1100 K (without the Onsager corrections). Essentially, the BEO approximation is reflecting most of the physics, as was anticipated based on their being in the same column of the periodic table. What is also clear is that the KKR-CPA, which contains a much larger Coulomb contribution, has necessarily much larger spinodal temperature (T_{sp}) before the Onsager correction is included. While the Onsager correction therefore must be very large to conserve spectral intensity, it is, in fact, the dielectric effects incorporated into the Onsager corrections that are trying to reduce such a large electrostatic contribution and change the wave vector into disagreement, i.e., $\mathbf{q} = (\frac{1}{2}\frac{1}{2}\frac{1}{2})$, even though the T_{sp} remains fairly good at 1045 K. The effect of the screening contributions to the electrostatic energy (as found in Equation 28) is to reduce significantly the effect of the Madelung energy (T_{sp} is reduced 40% before Onsager corrections); therefore, the dielectric effects are not as significant and do not change the wave vector dependence.

Ultimately, the origin for the ASRO reduces back to what is happening in the band-energy-only situation, for it is predominantly describing the ordering and temperature dependence and most of the electrostatic effects are canceling one another. The large electronic density of states at the Fermi level (Fig. 3) is also important for it is those electrons that contribute to screening and the dielectric response.

What remains to tell is why fcc NiPt wants to order with $\mathbf{q} = (100)$ periodicity. Lu et al. (1993) stated that relativistic effects induce the chemical ordering in NiPt. Their work showed that relativistic effects (specifically, the Darwin and mass-velocity terms) lead to a contraction of the s states, which stabilized both the disordered and ordered phases relative to phase separation, but their work did not explain the origin of the chemical ordering. As marked in electronic density of states (DOS) for disordered NiPt in Figure 3 (heavy, hatched lines), there is a large number of low-energy states below the Ni-based d band that arise due to hybridization with the Pt sites. These d states are of t_{2g} symmetry whose lobes point to the nearest-neighbor sites in an fcc lattice. Therefore, the system can lower its energy by modulating itself with a (100) periodicity to create lots of such favorable (low-energy, d-type) bonds between nearest-neighbor Ni and Pt sites. This basic explanation was originally given by Pinski et al. (1991, 1992).

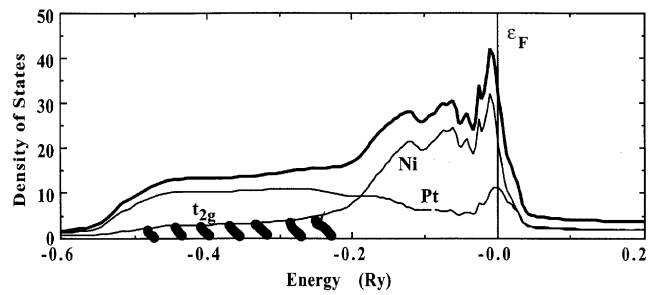

Figure 3. The calculated scr-KKR-CPA electronic density of states (states/Ry-atom) versus energy (Ry) for scalar-relativistic, disordered $Ni_{50}Pt_{50}$. The hybridized d states of t_{2g}-symmetry created due to an electronic size effect related to the difference in electronic bandwidths between Ni and Pt are marked by thick, hatched lines. The apparent pinning of the density of states at the Fermi level for Ni and Pt reflect the fact that the two elements fall in the same column of the periodic table, and there is effectively no "charge transfer" from electronegativity effects.

Pinski et al. (1991, 1992) pointed out that this hybridization effect arises due to what amounts to an electronic "size effect" related to the difference in bandwidths between Ni (little atom, small width) and Pt (big atom, large width), which is related to off-diagonal disorder in tight-binding theory. The lattice constant of the alloy plays a role in that it is smaller (or larger) than that of Pt (or Ni) which further increases (decreases) the bandwidths, thereby further improving the hybridization. Because Ni and Pt are in the same column of the periodic table, the Fermi level of the Ni and Pt d bands is effectively pinned, which greatly affects this hybridization phenomenon. See Pinski et al. (1991, 1992) for a more complete treatment.

It is noteworthy that in metallic NiPt ordering originates from effects that are well below the Fermi level. Therefore, usual ideas regarding reasons for ordering used in substitutional metallic alloys about e/a effects, Fermi-surface nesting, or filling of (anti-) bonding states, that is, all effects are due to the electrons around the Fermi level, should not be considered "cast in stone." The real world is much more interesting! This in hindsight turns out also to explain the failure of tight binding for NiPt: because off-diagonal disorder is important for Ni-Pt, it must be well described, that is, not to approximate those matrix elements by usual procedures. In effect, some system-dependent information of the alloying and hydridization must be included when establishing the tight-binding parameters.

Coupling of Magnetic Effects and Chemical Order

This hybridization (electronic "size") effect that gives rise to (100) ordering in NiPt is actually a more ubiquitous effect than one may at first imagine. For example, the observed $\mathbf{q} = (1\frac{1}{2}0)$, or Ni_4Mo-type, short-range order in paramagnetic, disordered AuFe alloys that have been fast quenched from high-temperature, results partially from such an effect (Ling, 1995b). In paramagnetic, disordered AuFe, two types of disorder (chemical and magnetic) must be described simultaneously [this interplay is predicted to allow changes to the ASRO through magnetic annealing (Ling et al., 1995b)].

For paramagnetic disordered AuFe alloys, the important point in the present context is that a competion arises between an electronic band-filling (or e/a) effect, which gives a clustering, or $\mathbf{q} = (000)$ type ASRO, and the stronger hybridization effect, which gives a $\mathbf{q} = (100)$ ASRO. The competition between clustering and ordering arises due to the effects from the magnetism (Ling et al., 1995b). Essentially, the large exchange splitting between the Fe majority and minority d band density of states results in the majority states being fully populated (i.e., they lie below the Fermi level), whereas the Fermi level ends up in a peak in the minority d band DOS (Fig. 4). Recall from usual band-filling-type arguments that filling bonding-type states favor chemical ordering, while filling antibonding-type states oppose chemical ordering (i.e., favor clustering). Hence, the hybridization "bonding states" that are created below the Fe d band due to interaction with the wider band Au (just as in NiPt) promotes ordering (Fig. 4), whereas the band filling of the minority

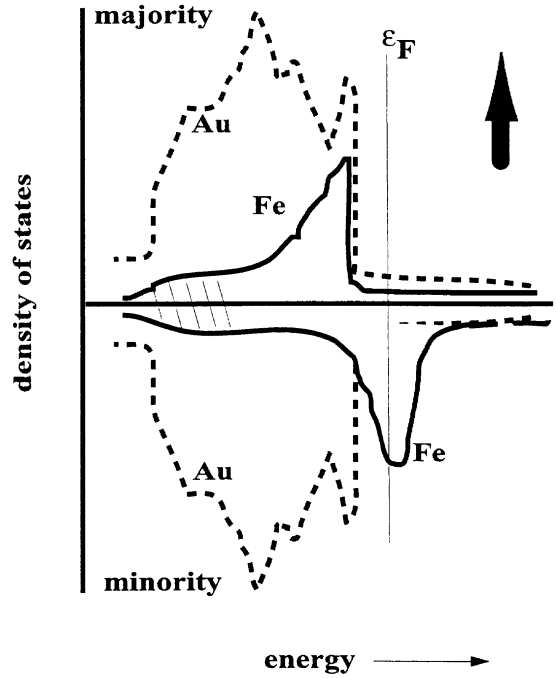

Figure 4. A schematic drawing of the electronic density of states (states/Ry-atom) versus energy (Ry) for scalar-relativistic, chemically disordered, and magnetically disordered (i.e., paramagnetic) $Au_{75}Fe_{25}$ using the CPA to configurationally average over both chemical and magnetic degrees of freedom. This represents the "local" density of states (DOS) for a site with its magnetization along the local z axis (indicated by the heavy vertical arrow). Due to magnetic disorder, there are equivalent DOS contributions from $-z$ direction, obtained by reflecting the DOS about the horizontal axis, as well as in the remaining 4π orientations. As with NiPt, the hybridized d states of t_{2g} symmetry are marked by hatched lines for both majority ($\uparrow$) and minority ($\downarrow$) electron states.

d band (which behave as "antibonding" states because of the exchange splitting) promotes clustering, with a compromise to $(1\frac{1}{2}0)$ ordering.

In the calculation, this interpretation is easily verified by altering the band filling, or e/a, in a rigid-band sense. As the Fermi level is lowered below the exchange-split minority Fe peak in Figure 4, the calculated ASRO rapidly becomes (100)-type, simply because the unfavorable antibonding states are being depopulated. Charge-correlation effects that were important for Ni-Pt are irrelevant for Au-Fe. By "magnetic annealing" the high-T AuFe in a magnetic field, we can utilize this electronic interplay to alter the ASRO to $\langle 100 \rangle$.

Multicomponent Alloys: Fermi-Surface Nesting, van Hove Singularities, and e/a in fcc Cu-Ni-Zn

Broadly speaking, the ordering in the related fcc binaries of Cu-Ni-Zn might be classified according to their phase diagrams (Massalski et al., 1990) as strongly ordering in NiZn, weakly ordering in CuZn, and clustering in CuNi. Perhaps then, it is no surprise that the phase diagram of Cu-Ni-Zn alloys (Thomas, 1972) reflects this, with clustering in Zn-poor regions, K-state effects (e.g., reduced

resistance with cold working), ⟨100⟩ short- (Hashimoto et al., 1985) and long-range order (van der Wegen et al., 1981), as well as $(1\frac{1}{4}0)$ (or DO_{23}-type) ASRO (Reinhard et al., 1990), and incommensurate-type ordering in the Ni-poor region.

Hashimoto et al. (1985) has shown that the three Warren-Cowley pair parameters for Cu_2NiZn reflect the above ordering tendencies of the binaries with strong ⟨100⟩-type ASRO in the Ni-Zn channel, and no fourfold diffuse scattering patterns, as is common in noble-metal-based alloys. Along with the transmission electron microscopy results of van der Wegen et al. (1981), which also suggest ⟨100⟩-type long-range order, it was assumed that Fermi-surface nesting, which is directly related to the geometry of the Fermi surface and has long been known to produce fourfold diffuse patterns in the ASRO, is not operative in this system. However, the absence of fourfold diffuse patterns in the ASRO, while necessary, is not sufficient to establish the nonexistence of Fermi-surface nesting (Althoff et al., 1995, 1996).

Briefly stated, and most remarkably, Fermi-surface effects (due to nesting and van Hove states) are found to be responsible for all the commensurate and incommensurate ASRO found in the Cu-rich, fcc ternary phase field. However, a simple interpretation based solely in terms of e/a ratio (Hume-Rothery, 1963) is not possible because of the added complexity of disorder broadening of the electronic states and because both composition and e/a may be independently varied in a ternary system, unlike in binary systems. Even though Fermi-surface nesting is operative, which is traditionally said to produce a four-fold incommensurate peak in the ASRO, a [100]-type of ASRO is found over an extensive composition range for the ternary, which indicates an important dependence of the nesting wavevector on e/a and disorder. In the random state, the broadening of the alloy's Fermi surface from the disorder results in certain types of ASRO being stronger or persisting over wider ranges of e/a than one determines from sharp Fermi surfaces.

For the fcc Cu-Ni-Zn, the electron states near the Fermi energy, ε_F, play the dominant role in determining the ordering tendency found from $S^{(2)}(\mathbf{q})$ (Althoff et al., 1995, 1996). In such a case, it is instructive to interpret (not calculate) $S^{(2)}(\mathbf{q})$ in terms of the convolution of Bloch spectral functions $A_B(\mathbf{k}; \varepsilon)$ (Györffy and Stocks, 1983). The Bloch spectral function defines the average dispersion in the system and $A_B(\mathbf{k}; \varepsilon) \propto \mathrm{Im}\,\tau_c(\mathbf{k}; \varepsilon)$. As mentioned earlier, for ordered alloys $A_B(\mathbf{k}; \varepsilon)$ consists of delta functions in $\mathbf{k}$ space whenever the dispersion relationship is satisfied, i.e., $\delta(\varepsilon - \varepsilon_k)$, which are the electronic "bands." In a disordered alloy, these "bands" broaden and shift (in energy) due to disorder and alloying effects. The loci of peak positions at ε_F, if the widths of the peaks are small on the scale of the Brillouin zone dimension, defines a "Fermi surface" in a disordered alloy.

Provided that k-, energy-, and species-dependent matrix elements can be roughly neglected in $S^{(2)}(\mathbf{q})$, and that only the energies near ε_F are pertinent because of the Fermi factor (NiPt was a counterexample to all this), then the q-dependent portion of $S^{(2)}(\mathbf{q})$ is proportional to a convolution of the spectral density of states at

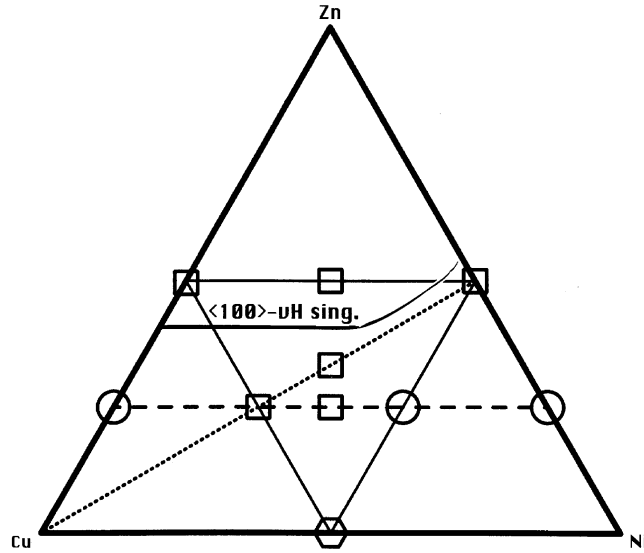

Figure 5. The Cu-Ni-Zn Gibbs triangle in atomic percent. The dotted line is the Cu isoelectronic line. The ASRO is designated as: squares, ⟨100⟩ ASRO; circles, incommensurate ASRO; hexagon, clustering, or (000) ASRO. The additional line marked ⟨100⟩-vH establishes roughly where the fcc Fermi surface of the alloys has spectral weight (due to van Hove singularities) at the ⟨100⟩ zone boundaries, suggesting bcc is nearing in energy to fcc. For fcc CuZn, this occurs at 40% Zn, close to the maximum solubility limit of 38% Zn before transformation to bcc CuZn. Beyond this line a more careful determination of the electronic free energy is required to determined fcc or bcc stability.

ε_F (the Fermi surface; Györffy and Stocks, 1983; Györffy et al., 1989), i.e.:

$$S^{(2)}_{\alpha\beta}(\mathbf{q}) \propto \int d\mathbf{k} A_B(\mathbf{k}; \varepsilon_F) A_B(\mathbf{k} + \mathbf{q}; \varepsilon_F) \qquad (29)$$

With the Fermi-surface topology playing the dominate role, ordering peaks in $S^{(2)}(\mathbf{q})$ can arise from states around ε_F in two ways: (1) due to a spanning vector that connects parallel, flat sheets of the Fermi surface to give a large convolution (so-called **Fermi-surface nesting**; Györffy and Stocks, 1983), or, (2) due to a spanning vector that promotes a large joint density of states via convolving points where van Hove singularities (van Hove, 1953) occur in the band structure at or near ε_F (Clark et al., 1995). For fcc Cu-Ni-Zn, both of these Fermi-surface-related phenomena are operative, and are an ordering analog of a Peierls transition.

A synopsis of the calculated ASRO is given in Figure 5 for the Gibbs triangle of fcc Cu-Ni-Zn in atomic percent. All the trends observed experimentally are completely reproduced: Zn-poor Cu-Ni-Zn alloys and Cu-Ni binary alloys show clustering-type ASRO; along the line $Cu_{0.50+x}Ni_{0.25-n}Zn_{0.25}$ (the dashed line in the figure), $Cu_{75}Zn$ shows $(1\frac{1}{4}0)$-type ASRO, which changes to commensurate (100)-type at Cu_2NiZn, and then to fully incommensurate around $CuNi_2Zn$, where the K-state effects are observed. K-state effects have been tied to the short-range order (Nicholson and Brown, 1993). Most interestingly, a large

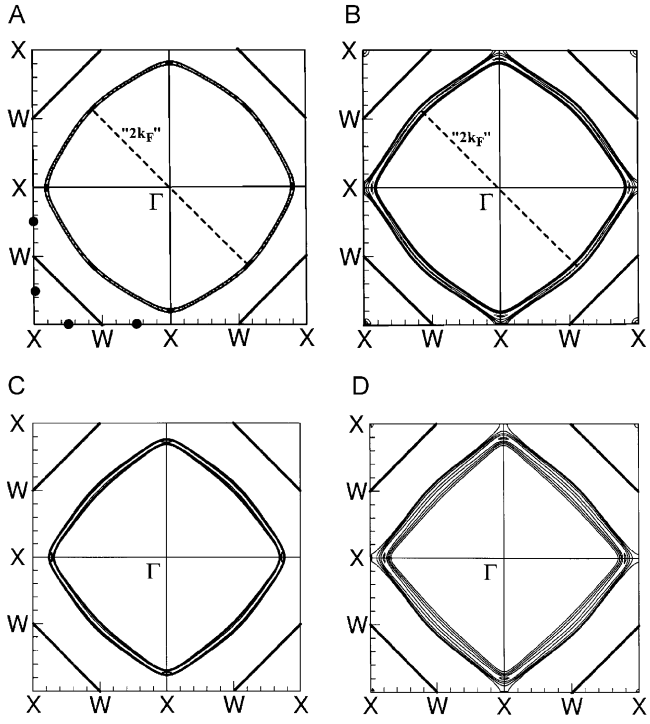

Figure 6. The Fermi surface, or $A_B(\mathbf{k};\varepsilon_F)$, in the {100} plane of the first Brillouin zone for fcc alloys with a lattice constant of 6.80 a.u.: (**A**) $Cu_{75}Zn_{25}$, (**B**) $Cu_{25}Ni_{25}Zn_{50}$, (**C**) $Cu_{50}Ni_{25}Zn_{25}$, and (**D**) $Ni_{50}Zn_{50}$. Note that (**A**) and (**B**) have $e/a = 1.25$ and (**C**) and (**D**) have $e/a = 1.00$. As such, the caliper dimensions of the Fermi surface, as measured from peak to peak (and typically referred to as "$2k_F$"), are identical for the two pairs. The widths change due to increased disorder: NiZn has the greatest difference between scattering properties and therefore the largest widths. In the lower left quadrant of (**A**) are the fourfold diffuse spots that occur due to nesting. The fourfold diffuse spots may be obtained graphically by drawing circles (actually spheres) of radius "$2k_F$" from all Γ points and finding the common intersection of such circles along the *X-W-X* high symmetry lines.

region of (100)-type ordering is calculated around the Cu isoelectronic line (the dotted line in the figure), as is observed (Thomas, 1972).

The Fermi surface in the ⟨100⟩ plane of $Cu_{75}Zn$ is shown in Figure 6, part A, and is reminiscient of the Cu-like "belly" in this plane. The caliper dimensions, or so-called "$2k_F$," of the Fermi surface in the [110] direction is marked; it is measured peak to peak and determines the nesting wavevector. It should be noted that perpendicular to this plane ([001] direction) this rather flat portion of Fermi surface continues to be rather planar, which additionally contributes to the convolution in Equation 29 (Althoff et al., 1996). In the lower left quadrant of Figure 6, part A, are the fourfold diffuse spots that occur due to the nesting. As shown in Figure 6, parts C and D, the caliper dimensions of the Fermi surface in the ⟨100⟩ plane are the same along the Cu isoelectronic line (i.e., constant e/a = 1.00). For NiZn and Cu_2NiZn, this "$2k_F$" gives a (100)-type ASRO because its magnitude matches the $\Delta k = |(000) - (110)|$, or $\Gamma - X$, distance perfectly. The spectral widths change due to increased disorder. NiZn has the greatest difference between scattering properties and therefore the largest widths (see Fig. 6). The increasing disorder with decreasing Cu actually helps improve the convolution of the spectral density of states, Equation 29, and strengthens the ordering, as is evidenced experimentally through the phase-transformation temperatures (Massalski et al., 1990).

As one moves off this isoelectronic line, the caliper dimensions change and an incommensurate ASRO is found, as with $Cu_{75}Zn$ and $CuNi_2Zn$ (see Fig. 6, parts A and B). As Zn is added, eventually van Hove states (van Hove, 1953) appear at (100) points or X-points (see Fig. 6, part D) due to symmetry requirements of the electronic states at the Brillouin zone boundaries. These van Hove states create a larger convolution integral favoring (100) order over incommensurate order. For $Cu_{50}Zn_{50}$, one of the weaker ordering cases, a competition with temperature is found between spanning vectors arising from Fermi-surface-nesting and van Hove states (Althoff et al., 1996). For compositions such as $CuNiZn_2$, the larger disorder broadening and increase in van Hove states make the (100) ASRO dominant.

It is interesting to note that the appearance of van Hove states at (100) points, such as for $Cu_{60}Zn_{40}$, where Zn has a maximum solubility of 38.5% experimentally (Thomas, 1972; Massalski et al., 1990) occurs like precursors to the observed fcc-to-bcc transformations (see rough sketch in the Gibbs triangle; Fig. 5). A detailed discussion that clarifies this correlation has been given recently about the effect of Brillouin zone boundaries in the energy difference between fcc and bcc Cu-Zn (Paxton et al., 1997).

Thus, all the incommensurate and commensurate ordering can be explained in terms of Fermi-surface mechanisms that were dismissed experimentally as a possibility due to the absence of fourfold diffuse scattering spots. Also, disorder broadening in the random alloy plays a role, in that it actual helps the ordering tendency by improving the (100) nesting features. The calculated T_{sp} and other details may be found in Althoff et al. (1996). This highlights one of the important roles for theory: to determine the underlying electronic mechanism(s) responsible for order and make predictions that can be verified from experiment.

Polarization of the Ordering Wave in Cu_2NiZn

As we have already discussed, a ternary alloy like fcc $ZnNiCu_2$ does not possess the A-B symmetry of a binary; the analysis is therefore more complicated due to the concentration waves having "polarization" degrees of freedom, requiring more information from experiment or theory. In this case, the extra degree of freedom introduced by the third component leads also to additional ordering transitions at lower temperatures. These polarizations (as well as the unstable wavevector) are determined by the electronic interactions; also they determine the sublattice occupations that are (potentially) made inequivalent in the partially ordered state (Althoff et al., 1996).

The relevent star of $\mathbf{k}_0 = \langle 100 \rangle$ ASRO—comprised of (100), (010), (001) vectors—found for $ZnNiCu_2$ is a precursor to the partially ordered state that may be determined

approximately from the eigenvectors of $q^{-1}(\mathbf{k}_0)$, as discussed previously (see Principles of the Method). We have written the alloy in this way because Cu has been arbitrarily taken as the "host." If the eigenvectors are normalized, then there is but one parameter that describes the eigenvectors of Δ_F in the Cartesian or Gibbsian coordinates, which can be written:

$$\begin{bmatrix} e_1^{\mathrm{zn}}(\mathbf{k}_0) \\ e_1^{\mathrm{Ni}}(\mathbf{k}_0) \end{bmatrix} = \begin{bmatrix} \sin\theta_{\mathbf{k}_0} \\ -\cos\theta_{\mathbf{k}_0} \end{bmatrix} ; \begin{bmatrix} e_2^{\mathrm{zn}}(\mathbf{k}_0) \\ e_2^{\mathrm{Ni}}(\mathbf{k}_0) \end{bmatrix} = \begin{bmatrix} \cos\theta_{\mathbf{k}_0} \\ \sin\theta_{\mathbf{k}_0} \end{bmatrix} \qquad (30)$$

If $\theta_{\mathbf{k}}$ is taken as the parameter in the Cartesian space, then in the Gibb's space the eigenvectors are appropriate linear combinations of $\theta_{\mathbf{k}}$. The "angle" $\theta_{\mathbf{k}}$ is fully determined by the electronic interactions and plays the role of "polarization angle" for the concentration wave with the $\mathbf{k}_0$ wavevector. Details are fully presented in the appendix of Althoff et al. (1996). However, the lowest energy concentration mode in Gibbs space at $T = 1000\,\mathrm{K}$ for the $\mathbf{k}_0 = \langle 100 \rangle$ is given by $e^{\mathrm{Zn}} = 1.0517$ and $e^{\mathrm{Ni}} = -0.9387$, where one calculates $T_{\mathrm{sp}} = 985\,\mathrm{K}$, including Onsager corrections (experimental $T_{\mathrm{c}} = 774$ K; Massalski et al., 1990).

For a ternary alloy, the matrices are of rank 2 due to the independent degrees of freedom. Therefore, there are two possible order parameters, and hence, two possible transitions as the temperature is lowered (based on our knowledge from high-T information). For the partially ordered state, the long-range order parameter associated with the higher energy mode can be set to zero. Using this information in Equation 9, as discussed by Althoff et al. (1996), produces an atomic distribution in real space for the partially ordered state as in Table 3. Clearly, there is already a trend to a tetragonal, $L1_0$-like state with Zn-enhanced on cube corners, as observed (van der Wegen et al., 1981) in the low-temperature, fully ordered state (where Zn is on the fcc cube corners, Cu occupies the faces in the central plane, and Ni occupies the faces in the Zn planes). However, there is still disorder on all the sublattices. The $\langle 100 \rangle$ wave has broken the disordered fcc cube into a four-sublattice structure, with two sublattices degenerate by symmetry.

Unfortunately, the partially ordered state assessed from TEM measurements (van der Wegen et al, 1981) suggests that it is $L1_2$-like, with Cu/Ni disordered on all the cube faces and predominately Zn on the fcc corners. Interestingly, if domains of the calculated $L1_0$ state occur with an equal distribution of tetragonal axes, then a state with $L1_2$ symmetry is produced, similar to that supposed by TEM. Also, because the discussion is based on the stability of the high-temperature disordered state, the temperature for the second transition cannot be gleaned from the eigenvalues directly. However, a simple estimate can be made. Before any sublattice has a negative occupation value, which occurs for $\eta = 0.49$ (see Ni in Table 3), the second long-range order parameter must become finite and the second mode becomes accessible. As the transition temperature is roughly proportional to $\Delta \mathrm{E}_{\mathrm{order}}$, or η^2, then $T^{\mathrm{II}} = (1 - \eta^2) T^{\mathrm{I}}$ (assuming that the Landau coefficients are the same). Therefore, $T^{\mathrm{II}}/T^{\mathrm{I}} = 0.76$, which is close to the experimental value of 0.80 (i.e., 623 K/774 K) (Massalski et al., 1990). Further discussion and comparison with experiment may be found elsewhere (Althoff et al., 1996), along with allowed ordering due to symmetry restrictions.

Table 3. Atomic Distributions in Real Space of the Partially Ordered State to which the Disordered State with Stochiometry Cu_2NiZn is Calculated to be Unstable at T_c

Sublattice	Alloy Component	Site-Occupation Probability[a]
	Zn	$0.25 + 0.570\eta(T)$
1: Zn rich	Ni	$0.25 - 0.510\eta(T)$
	Cu	$0.50 - 0.060\eta(T)$
	Zn	$0.25 - 0.480\eta(T)$
2: Ni rich	**Ni**	$0.25 + 0.430\eta(T)$
	Cu	$0.50 + 0.050\eta(T)$
	Zn	$0.25 - 0.045\eta(T)$
3 and ≤ 4: Random	Ni	$0.25 + 0.040\eta(T)$
	Cu	$0.50 + 0.005\eta(T)$

[a] η is the long-range-order parameter, where $0 \leq \eta \leq 1$. Values were obtained from Althoff et al. (1996).

Electronic Topological Transitions: van Hove Singularities in CuPt

The calculated ASRO for $Cu_{50}Pt_{50}$ (Clark et al., 1995) indicates an instability to concentration fluctuations with a $\mathbf{q} = (\frac{1}{2}\frac{1}{2}\frac{1}{2})$, consistent with the observed $L1_1$ or CuPt ordering (Massalski et al., 1990). The $L1_1$ structure consists of alternating fcc (111) layers of Cu and Pt, in contrast with the more common $L1_0$ structure, which has alternating (100) planes of atoms. Because CuPt is the only substitutional metallic alloy that forms in the $L1_1$ structure (Massalski et al., 1990), it is appropriate to ask: what is so novel about the CuPt system and what is the electronic origin for the structural ordering?

The answers follow directly from the electronic properties of disordered CuPt near its Fermi surface, and arise due to what Lifshitz (1960) termed an "electronic topological transition." That is, due to the topology of the electronic structure, electronic states, which are possibly unfavorable, may be filled (or unfilled) due to small changes in lattice or chemical structure, as arising from Peierls instabilities. Such electronic topological transitions may affect a plethora of observables, causing discontinuities in, e.g., lattice constants and specific heats (Bruno et al., 1995). States due to van Hove singularities, as discussed in fcc Cu-Ni-Zn, are one manifestation of such topological effects, and such states are found in CuPt. In Figure 7, the Fermi surface of disordered CuPt around the L point has a distinctive "neck" feature similar to elemental Cu. Furthermore, because ε_F cuts the density of states near the top of a feature that is mainly Pt-d in character (see Fig. 8, part A) pockets of d holes exist at the X points (Fig. 7). As a result, the ASRO has peaks at $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$ due to the spanning vector $X - L = (0, 0, 1) - (\frac{1}{2}\frac{1}{2}\frac{1}{2})$ (giving a large joint electron density of states in Equation 29), which is a member of the star of L. Thus, the $L1_1$ structure is stabilized by a Peierls-like mechanism arising from the

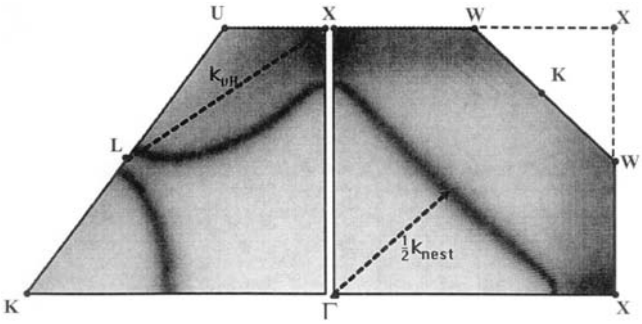

Figure 7. $A_B(\mathbf{k}; \varepsilon_F)$ for disordered fcc CuPt, i.e., the Fermi surface, for portions of the ⟨110⟩ (Γ-*X*-*U*-*L*-*K*), and ⟨100⟩ (Γ-*X*-*W*-*K*-*W*-*X*-*L*) planes. Spectral weight is given by relative gray scale, with black as largest and white as background. Note the neck at *L*, and the smeared pockets at *X*. The widths of the peaks are due to the chemical disorder experienced by the electrons as they scatter through the random alloy. The spanning vector, k_{vH}, associated with states near van Hove singularities, as well as typical "$2k_F$" Fermi-surface nesting are clearly labeled. The more Cu in the alloy the fewer *d* holes, which makes the "$2k_F$" mechanism more energetically favorable (if the dielectric effects are accounted for fully; Clark et al., 1995).

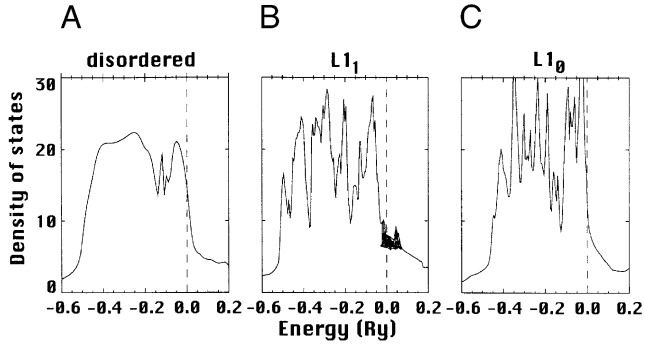

Figure 8. Scalar-relativistic total densities of states for (**A**) disordered CuPt, using the KKR-CPA method; ordered CuPt in the (**B**) $L1_1$ and (**C**) $L1_0$ structures, using the LMTO method. The dashed line indicates the Fermi energy. Note the change of scale in partial Pt state densities. The bonding (antibonding) states created by the $L1_1$ concentration wave just below (above) the Fermi energy are shaded in black.

hybridization between van Hove singularities at the high-symmetry points. This hybridization is the only means the system has to fill up the few remaining (antibonding) Pt *d* states, which is why this $L1_1$ ordering is rather unique to CuPt. That is, by ordering along the (111) direction, all the states at the *X* points—(100), (010), and (001)—may be equally populated, whereas only the states around (100) and (010) are fully populated with an (001) ordering wave consistent with $L1_0$ type order. See Clark et al. (1995) for more details.

This can be easily confirmed as follows. By increasing the number of *d* holes at the *X* points, $L1_1$ ordering should not be favored because it becomes increasingly more difficult for a $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$ concentration wave to occupy all the *d* holes at *X*. Indeed, calculations repeated with the Fermi level lowered by 30 mRy (in a rigid-band way) into the Pt *d*-electron peak near ε_F results in a large clustering tendency (Clark et al., 1995). By filling the Pt *d* holes of the disordered alloy (raise ε_F by 30 mRy, see Fig. 8), thereby removing the van Hove singularities at ε_F, there is no great advantage to ordering into $L1_1$ and $S^{(2)}(\mathbf{q})$ now peaks at all *X* points, indicating $L1_0$-type ordering (Clark et al., 1995).

This can be confirmed from ordered band-structure calculations using the linear muffin tin orbital method (LMTO) within the atomic sphere approximation (ASA). In Figure 8, we show the calculated LMTO electronic densities of states for the $L1_0$ and $L1_1$ configurations for comparison to the density of states for the CPA disordered state, as given by Clark et al. (1995). In the disordered case, Figure 8, part A, ε_F cuts the top of the Pt *d* band, which is consistent with the *X* pockets in the Fermi surface. In the $L1_1$ structure, the density of states at ε_F is reduced, since the modulation in concentration introduces couplings between states at ε_F. The $L1_0$ density of states in Figure 8, part C demonstrates that not all ordered structures will produce this effect. Notice the small Peierls-type set of bonding and antibonding peaks that exist in the $L1_1$ Pt *d*-state density in Figure 8, part B (darkened area). Furthermore, the $L1_0 - L1_1$ energy difference is 2.3 mRy per atom with LMTO (2.1 mRy with full-potential method; Lu et al., 1991) in favor of the $L1_1$ structure, which confirms the associated lowering of energy with $L1_1$-type ordering. We also note that without the complete description of bonding (particularly *s* contributions) in the alloy, the system would not be globally stable, as discussed by (Lu et al., 1991).

The ordering mechanism described here is similar to the conventional Fermi surface nesting mechanism. However, conventional Fermi surface nesting takes place over extended regions of *k* space with spanning vectors between almost parallel sheets. The resulting structures tend to be long-period superstructures (LPS), which are observed in Cu-, Ag-, and Au-rich alloys (Massalski et al., 1990). In contrast, in the mechanism proposed for CuPt, the spanning vector couples only the regions around the *X* and *L* points in the fcc Brillouin zone, and the large joint density of states results from van Hove singularities that exist near ε_F. The van Hove mechanism will naturally lead to high-symmetry structures with short periodicities, since the spanning vectors tend to connect high-symmetry points (Clark et al., 1995).

What is particularly interesting in $Cu_{1-c}Pt_c$ is that the $L1_1$ ordering (at $c \approx 0.5$) and the one-dimensional LPS associated with Fermi-surface nesting (at $c \approx 0.73$) are both found experimentally (Massalski et al., 1990). Indeed, there are nested regions of Fermi surface in the (100) plane (see Fig. 7) associated with the *s*-*p* electrons, as found in Cu-rich Cu-Pd alloys (Györffy and Stocks, 1983). The Fermi-surface nesting dimension is concentration dependent, and, $\alpha(\mathbf{q})$ peaks at $\mathbf{q} = (1,0.2,0)$ at 73% Cu, provided both band-energy and double-counting terms are included

(Clark et al., 1995). Thus, a cross-over is found from a conventional Fermi-surface ordering mechanism around 75% Cu to ordering dominated by the novel van Hove-singularity mechanism at 50%. At higher Pt concentrations, $c \approx 0.25$, the ASRO peaks at L with subsidiary peaks at X, which is consistent with the ordered tetragonal fcc-based superstructure of $CuPt_3$ (Khachaturyan, 1983). Thus, just as in Cu-Ni-Zn alloys, nesting from s-p states and van Hove singularities (in this case arising from d states) both play a role, only here the effects from van Hove singularities cause a novel, and observed, ordering in CuPt.

On the Origin of Temperature-Dependent Shifts of ASRO Peaks

The ASRO peaks in Cu_3Au and Pt_8V at particular (h, k, l) positions in reciprocal-space have been observed to shift with temperature. In Cu_3Au, the four-fold split diffuse peaks at $(1k0)$ positions about the (100) points in reciprocal-space coalesce to one peak at T_c, i.e., $k \rightarrow 0$; whereas, the splitting in k increases with increasing temperature (Reichert et al., 1996). In Pt_8V, however, there are twofold split diffuse peaks at $(1 \pm \Delta h,0,0)$ and the splitting, Δh, decreases with increasing temperature, distinctly opposite to Cu_3Au (Le Bulloc'h et al., 1998).

Following the Cu_3Au observations, several explanations have been offered for the increased splitting in Cu_3Au, all of which cite entropy as being responsible for increasing the fourfold splitting (Reichert et al., 1996, 1997; Wolverton and Zunger, 1997). It was emphasized that the behavior of the diffuse scattering peaks shows that its features are not easily related to the energetics of the alloy, i.e., the usual Fermi-surface nesting explanation of fourfold diffuse spots (Reichert et al., 1997). However, entropy is not an entirely satisfactory explanation for two reasons. First, it does not explain the opposite behavior found for Pt_8V. Second, entropy by its very nature is dimensionless, having no q dependence that can vary peak positions.

A relatively simple explanation has been recently offered by Le Bulloc'h et al. (1998), although it is not quantitative. They detail how the temperature dependence of peak splitting of the ASRO is affected differently depending on whether the splitting occurs along $(1k0)$, as in Cu_3Au and Cu_3Pd, or whether it occurs along $(h00)$ as in Pt_8V. However, the origin of the splitting is always just related to the underlying chemical interactions and energetics of the alloy. While the electronic origin for the splitting would be obtained directly from our DFT approach, this subtle temperature and entropy effect would not be properly described by the method under its current implementation.

CONCLUSION

For multicomponent alloys, we have described how the "polarization of the ordering waves" may be obtained from the ASRO. Besides the unstable wavevector(s), the polarizations are the additional information required to define the ordering tendency of the alloy. This can also be obtained from the measured diffuse scattering intensities, which, heretofore, have not been appreciated. Furthermore, it has been the main purpose of this unit to give an overview of an electronic-structure-based method for calculating atomic short-range order in alloys from first principles. The method uses a linear-response approach to obtain the thermodynamically induced ordering fluctuations about the random solid solution as described via the coherent-potential approximation. Importantly, this density functional-based concentration-wave theory is generalized in a straightforward manner to multicomponent alloys, which is extremely difficult for most other techniques.

While the approach is clearly mean-field (as thoroughly outlined), it incorporates on an equal footing many of the electronic and entropic mechanisms that may compete on a system-by-system basis. This is especially notable when in metals the important energy differences are the order of a few mRy, where 1 mRy is 158 K; thus, even a 10% error in calculated temperature scales at this point is amazingly good, although for some systems we have done much better. When the ASRO indicates the low-temperature, ordered state (as is usually the case), then it is possible to determine the underlying electronic mechanism responsible for the phase transformation. In any case, it does determine the origin of the atomic short-range order. Nevertheless, the first-principles concentration wave theory does not include possibly important effects, such as statistical fluctuations beyond mean field or cluster entropy, which may give rise to first-order transformations entirely distinct from the premonitory fluctuations or temperature effects in the ASRO. In such cases, more accurate statistical methods, such as Monte Carlo, may be employed if the energetics that are relevant (as determined by some means) can also be obtained with sufficient relative accuracy.

A few electronic mechanisms were showcased which gave rise to ordering in various binary and ternary alloys. Fermi-surface effects explain all the commensurate and incommensurate ordering tendencies in fcc Cu-Ni-Zn alloys, in contrast to interpretations made from experimental data. A hybridization effect that occurs well below the Fermi level produces the strong $L1_0$-type order in NiPt. The hybridization and well-known band-filling (or, e/a) effects explain the ASRO in AuFe alloys, if magnetic exchange splitting is incorporated. A novel van Hove singularity mechanism, which arises due to the topology of the electronic structure of the disordered alloy, explains the unique $L1_1$-type order found in CuPt. Without the ability to connect the ASRO to electronic effects, many of these effects would have been impossible to identify via traditional band-structure applications, even for the cases of long-range order, which speaks to the usefulness of the technique. The first-principles, concentration-wave technique may be even more useful in multicomponent alloys. Currently, several ternary alloy systems are under investigation to determine the site-occupancy preferences for partially ordered $B2$ Nb-Al-Ti alloys, as recently measured by Hou et al. (1997) and Johnson et al. (1999). Nevertheless, contributions from size and electrostatic effects

must still be included in the multicomponent case. At this point, only more applications and comparisons with experiment on a system-by-system basis will reveal important new insights into origins of alloy phase stability.

ACKNOWLEDGMENTS

This work was supported by the Division of Materials Science, Office of Basic Energy Sciences, U.S. Department of Energy when Dr. Johnson was at Sandia National Laboratories (contract DE-AC04-94AL85000) and recently at the Frederick Seitz Materials Research Laboratory (contract DEFG02-96ER45439). Dr. Johnson would like to thank Alphonse Finel for informative discussions regarding his recent work, and, the NATO AGARD program for making the discussion possible with a visit to O.N.E.R.A., France. It would be remiss not to acknowledge also the many collaborators throughout developments and applications: Jeff Althoff, Mark Asta, John Clark, Beniamino Ginatempo, Balazs Györffy, Jeff Hoyt, Michael Ling, Bill Shelton, Phil Sterne, and G. MECHANICAL TESTING

INTRODUCTION

The mechanical behavior of materials is concerned primarily with the response of materials to forces or loads. This behavior ultimately governs the usefulness of materials in a variety of applications from automotive and jet engines to skyscrapers, as well as to more common products such as scissors, electric shavers, coffee mugs, and cooking utensils. The forces or loads that these materials experience in their respective applications make it necessary to identify the limiting values that can be withstood without failure or permanent deformation. Indeed, in many cases it is necessary to know not only the response of the materials to an applied load, but also to be able to predict their behavior under repeated loading and unloading. In other applications, it is also necessary to determine the time-dependent behavior and routine wear of materials under the applied loads and under operating conditions.

Knowledge of the mechanical behavior of materials is also necessary during manufacturing processes. For example, it is often necessary to know the values of temperature and loading rates that minimize the forces necessary during mechanical forming and shaping of components. Determination of the resulting microstructures during shaping and forming is an integral part of these operations. This is an area that clearly combines the determination of mechanical properties with that of the microstructure. Of course, the atomistic concept of flow and materials failure is an integral part of the determination of mechanical properties.

Basic mechanical property and materials strength measurements are obtained by standardized mechanical tests, many of which are described in this chapter. Each unit in this chapter not only covers details, principles, and practical aspects of the various tests, but also provides comprehensive reference to the standard procedures and sample geometries dictated by the ASTM or other standards agencies. This chapter also covers additional mechanical testing techniques such as high-strain-rate testing, measurements under pressure, and tribological and wear testing. As such, the chapter covers a broad spectrum of techniques used to assess materials behavior in a variety of engineering applications.

Whereas mechanical testing has a long history and is largely a mature field, methods continue to take advantage of advances in instrumentation and in fundamental understanding of mechanical behavior, particularly in more complex systems. Indeed, the first category of materials one thinks of that benefits from knowledge and control of mechanical properties is that of structural materials, i.e., substantial components of structures and machines. However, these properties are also crucial to the most technologically sophisticated applications in, for example, the highest-density integrated electronics and atom-by-atom deposited multilayers. In this respect, mechanical testing remains an active field at the forefront of modern technology.

REZA ABBASCHIAN

TENSION TESTING

INTRODUCTION

Of all mechanical properties, perhaps the most fundamental are related to what happens when a material is subjected to simple uniaxial tension. In its essence, a tensile test is carried out by attaching a specimen to a load-measuring device, applying a load (or imposing a given deformation), and measuring the load and corresponding deformation. A schematic of a specimen and test machine is provided in Figure 1 (Schaffer et al., 1999).

The result obtained from a tensile test is a so-called stress/strain curve, a plot of stress (force/unit area) versus strain (change in length/original length), illustrated schematically in Figures 1 and 2 (Dieter, 1985). The results of such a test (along with the results of other tests, to be sure) are basic to determination of the suitability of a given material for a particular load-bearing application. In this regard the results obtained from such a test are of great engineering significance. Tensile-test results also provide a great deal of information relative to the fundamental mechanisms of deformation that occur in the specimen. Coupled with microscopic examination, tensile test results are used to develop theories of hardening and to develop new alloys with improved properties. Tensile tests can be used to obtain information on the following types of property:

Elastic Properties. These are essentially those constants that relate stresses to strains in the (usually) small strain regime where deformation is reversible. This is the linear region in Figures 1B and 2. Deformation is said to be reversible when a specimen or component that has been subjected to tension returns to its original dimensions after the load is removed. Young's modulus (the slope of the linear, reversible portion of Fig. 1B) and Poisson's ratio (the ratio of strain in the loading direction to strain in the transverse direction) are typical examples of elastic properties.

Plastic Properties. Plastic properties are those that describe the relationships between stresses and strains when the deformation is large enough to be irreversible. Typical plastic properties are the yield stress (the stress at which deformation become permanent, denoted by the symbol σ_{ys}), the extent of hardening with deformation (referred to as strain hardening), the maximum in the

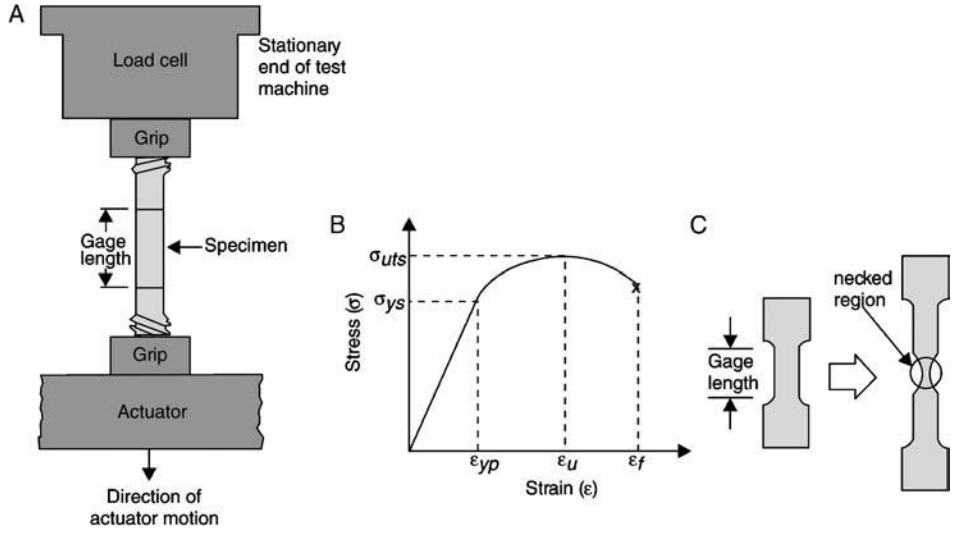

Figure 1. Schematic of specimen attached to testing machine (Schaffer et al., 1999).

stress/strain plot (the ultimate tensile strength, denoted σ_{uts}), the total elongation, and the percent reduction in area. These various quantities are illustrated in Figure 2 and discussed in more detail below.

Indication of the Material's Toughness. In a simplified view, toughness is the ability of a material to absorb energy in being brought to fracture. Intuitively, toughness is manifested by the absorption of mechanical work and is related to the area under the curve of stress versus strain, as shown in Figure 3 (Schaffer et al., 1999).

Tensile testing is carried out at different temperatures, loading rates, and environments; the results of these tests are widely used in both engineering applications and scientific studies.

In the following sections, basic principles are developed, fundamentals of tensile testing are pointed out, and references are provided to the detailed techniques employed in tensile testing.

Competitive and Related Techniques

In addition to the mechanical tests described in the following sections, information can be obtained about elastic properties through vibrational analysis, and information about plastic properties (e.g., tensile strength) may be obtained from microhardness testing (HARDNESS TESTING). While such information is limited, it can be obtained quickly and inexpensively.

PRINCIPLES OF THE METHOD

Analysis of Stress/Strain Curves

The stress/strain curve will typically contain the following distinct regions.

1. An initial linear portion in which the deformation is uniform and reversible, meaning that the specimen

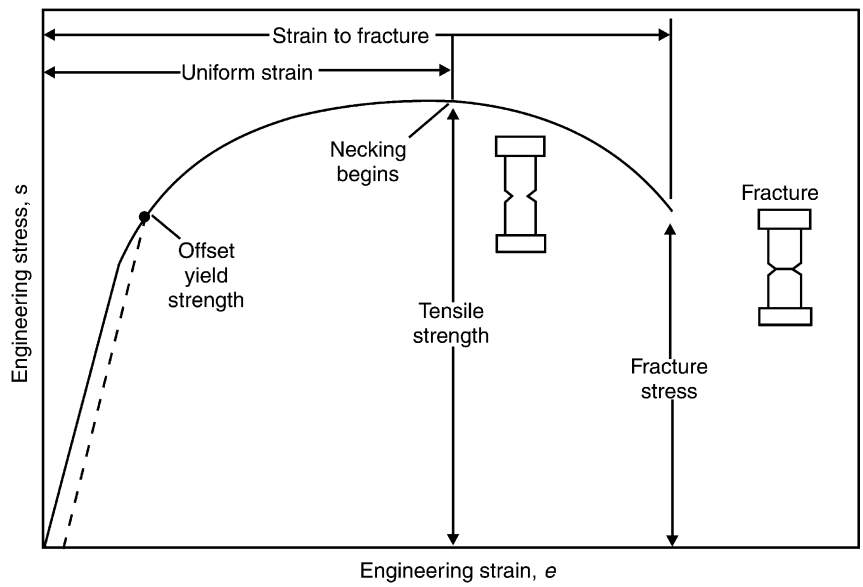

Figure 2. Schematic stress/strain curve for metallic material (Dieter, 1985).

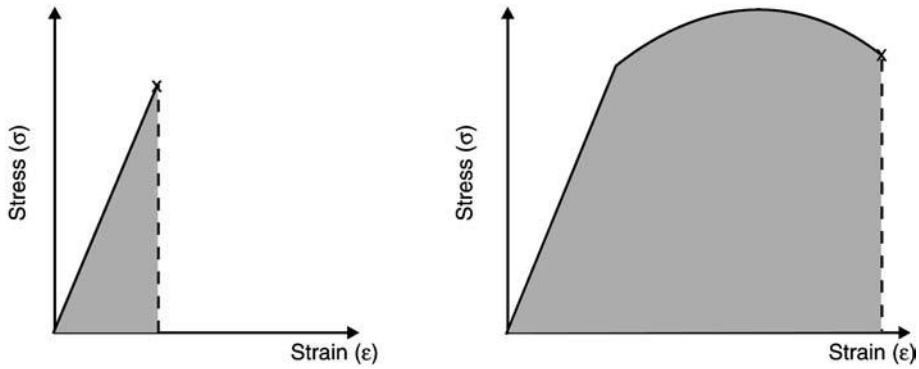

Figure 3. Area under stress/strain curve for (left) brittle and (right) ductile materials (Schaffer et al., 1999).

comes back to its original shape when the load is released. Such behavior is referred to as elastic and is seen in the initial straight-line regions of Figures 1 and 2.

2. A region of rising load in which the deformation is uniform and permanent (except, of course, for the elastic component), as illustrated in Figure 1.
3. A region in which the deformation is permanent and concentrated in a small localized region or "neck." The region of nonuniform deformation is indicated in Figure 1, and necking is illustrated schematically in Figure 4 (Dieter, 1985).

These regions are discussed in the sections that follow.

Elastic Deformation

Under the application of a specified external load, atoms (or molecules) are displaced by a small amount from their equilibrium positions. This displacement results in an increase in the internal energy and a corresponding force, which usually varies linearly for small displacements from equilibrium. This initial linear variation (which is reversible upon release of the load) obeys what is known as Hooke's law when expressed in terms of force and displacement:

$$\mathbf{F} = k\mathbf{x} \tag{1}$$

where k is the Hooke's law constant, $\mathbf{x}$ = displacement, and $\mathbf{F}$ is the applied force.

In materials testing, Hooke's law is more frequently expressed as a relationship between stress and strain:

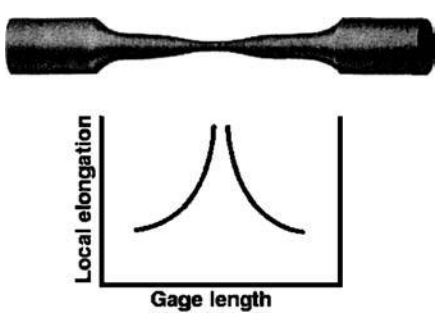

Figure 4. Illustration of necking in a metallic specimen and the local variation in the strain (Dieter, 1985).

$$\sigma = E \cdot \varepsilon \tag{2}$$

where σ is stress (in units of force/area normal to force), ε = strain (displacement/initial length), and E = Young's modulus.

Definitions of Stress and Strain

While stress always has units of force/area, there are two ways in which stress may be calculated. The true stress, usually represented by the symbol σ, is the force divided by the *instantaneous* area. The engineering stress is usually represented by the symbol S and is the force divided by the *original* area. Since the cross-sectional area decreases as the specimen elongates, the true stress is always larger than the engineering stress. The relationship between the true stress and the engineering stress is easily shown to be:

$$\sigma = S(1 + e) \tag{3}$$

where e is the *engineering* strain.

The engineering strain is defined as displacement (Δl) divided by the original length (l_0) and is denoted by e. That is:

$$e = \frac{\Delta l}{l_0} \tag{4}$$

The true strain is given by

$$\varepsilon = \int_{l_0}^{l} \frac{dl}{l} = \ln\left(\frac{i}{l_0}\right) \tag{5}$$

where l is the instantaneous length. This term is simply the sum of all of the instantaneous strains. The true strain and engineering strain are related by the equation:

$$\varepsilon = \ln(1 + e) \tag{6}$$

There is not a significant difference in the true strain and engineering strain until the engineering strain reaches ~10%. The difference between the conventional engineering stress/strain curve and the true stress/strain curve is illustrated in Figure 5 (from Schaffer et al., 1999).

Young's modulus is an indicator of the strength of the interatomic (or intermolecular) bonding and is related to the curvature and depth of the energy-versus-position

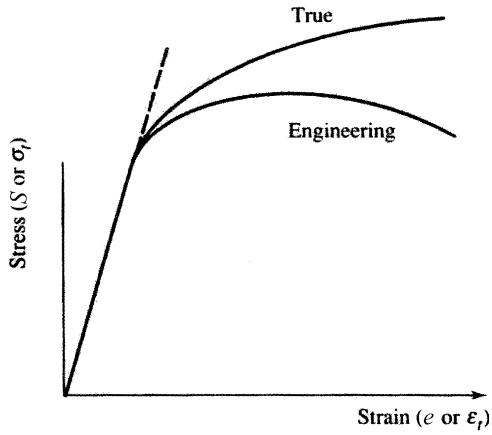

Figure 5. Illustration of the difference between the engineering and true stress/strain curves (Schaffer et al., 1999).

curve. Young's modulus may be obtained from the initial portion of the stress/strain curves shown in Figures 1 and 2.

Uniform Plastic Deformation

After the initial linear portion of the stress-strain curve (obtained from the load deflection curve), metallic and polymeric materials will begin to exhibit permanent deformation (i.e., when the load is released the object being loaded does not return to its initial no-load position). For most metals, the load required to continue deformation will rise continually up to some strain level. Throughout this regime, all deformation is uniform, as illustrated in Figures 1 and 2.

In some materials, such as low-carbon steels that have been annealed, there is an initial post-yield increment of nonuniform deformation, which is termed Luder's strain. Luder's strain is caused by bands of plastic activity passing along the gage length of the specimen, and is associated with dynamic interactions between dislocations (the defect responsible for plastic deformation) and carbon atoms. This is shown in Figure 6 (Dieter, 1985). In Figure 6, the stress at which there is a dropoff is referred to as the upper yield point and the plateau stress immediately following this drop is called the lower yield point. Such behavior is

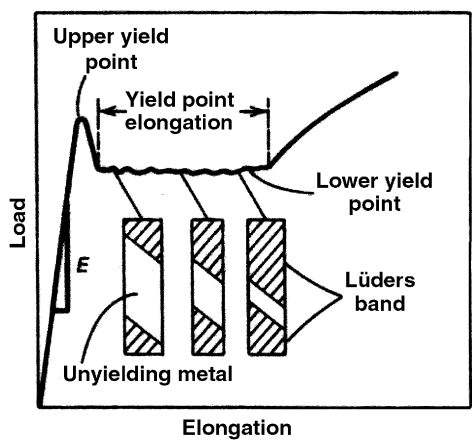

Figure 6. Illustration of the upper and lower yield points and Lüders strain in a mild steel tensile curve (Dieter, 1985).

predominantly limited to annealed steels with low carbon content.

Stress-strain curves for many metals in the region of uniform strain are well described by the following equation:

$$\sigma = K\varepsilon^n \tag{7}$$

where K is strength coefficient and n is strain-hardening exponent.

The strength coefficient and strain-hardening coefficients can be obtained by representing the stress/strain curve on a log/log basis:

$$\log\sigma = n\log\varepsilon + \log K \tag{8}$$

The slope of Equation 8 is the strain-hardening exponent. The value of K is simply obtained by noting that it is the value of the stress at a strain of 1.

Nonuniform Plastic Deformation

At some point, the increased strength of the material due to strain hardening is no longer able to balance the decreased cross-sectional area due to deformation. Thus a maximum in the load/displacement or stress/strain curve is reached. At this point $dP = 0$ (i.e., zero slope, which implies that elongation occurs with no increment in the load P) and if Equation 7 is obeyed, the strain value is given by:

$$\varepsilon_n = n \tag{9}$$

In Equation 9 the subscript n refers to "necking," by which it is meant that at this point all subsequent deformation is concentrated in a local region called a "neck" (Fig. 4) and is nonuniform. This nonuniformity is usually referred to as "plastic instability." Independent of the form of the stress/strain curve, the onset of plastic instability (assuming that deformation takes place at constant volume) occurs when the following condition is achieved:

$$\frac{d\sigma}{e} = \frac{\sigma}{1+e} \tag{10}$$

Equation 10 is the basis of the so-called Considere construction, which may be used to find the onset of plastic instability. This is done by projecting a tangent to the stress/strain curve from the point $(-1,0)$. If this is done, Equation 10 is obviously satisfied and the point of tangency represents the necking strain. It is important to realize that in this case the term σ is the true stress and e is the engineering strain. The Considere construction is illustrated in Figure 7 (Dieter, 1985).

Factors Affecting the Form of the Stress/Strain Curve

The stress/strain curve that is obtained depends upon the following variables:

The material and its microstructure;

The test temperature;

The testing rate;

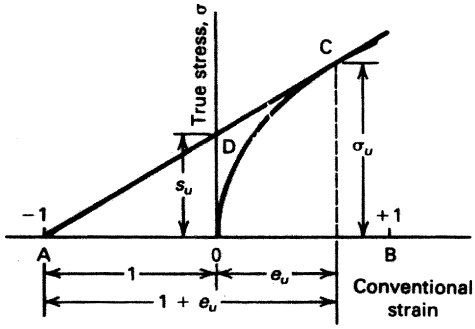

Figure 7. Considere's construction for determining the onset of necking (Dieter, 1985). Here, "u" refers to the point of necking.

The geometry of the test specimen;

The characteristics of the testing machine (as discussed above);

The mode in which the test is carried out.

By the "mode" is meant whether the test is carried out by controlling the rate of load application (load control), the rate of machine displacement (displacement control), or the rate of specimen strain (strain control).

Of these six factors, the first three may be considered intrinsic factors. The effects of the last three (discussed in Practical Aspects and Method Automation) tend to be less appreciated, but they are no less important. Indeed, some results that are considered to be fundamental to the material are largely influenced by the latter three variables, which may be considered to be extrinsic to the actual material. The first three factors are discussed below.

Material and Microstructure

The material and microstructure plays a critical role on the form of the stress/strain curve. This is illustrated in Figure 8 (Schaffer, 1999) for three different materials. The curve labeled Material I would be typical of a very brittle material such as a ceramic, a white cast iron, or a high-carbon martensitic steel. The curve labeled Material II is representative of structural steels, low-strength aluminum alloys, and copper alloys, for example. The curve labeled Material III is representative of polymeric materials.

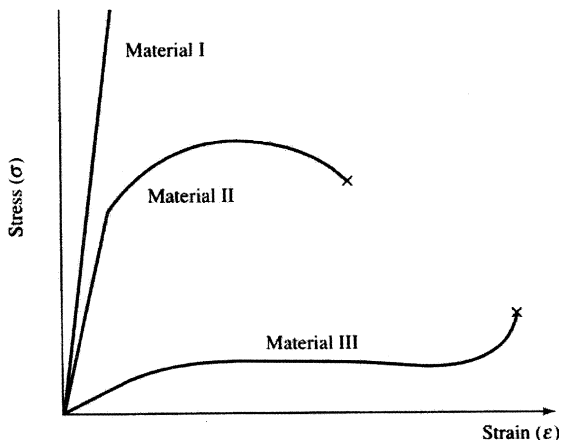

Figure 8. Schematic illustration of stress/strain curves for a brittle material (I), a ductile metal (II), and a polymer (III) (Schaffer et al., 1999).

The details of the microstructure are also very important. For example, if a given type of metal contains precipitates it is likely to be harder and to show less extension than if it does not contain precipitates. Precipitates are typically formed as a result of a specific heat treatment, which in effect is the imposition of a time/temperature cycle on a metal. In the heat treatment of steel, the formation of martensite is frequently a necessary intermediate phase. Martensite is very strong but is intrinsically brittle, meaning it has little or no ductility. It will have a stress-strain curve similar to that of Material I. If the martensitic material is heated to a temperature in the range of 200°C, precipitates will form and the crystal structure will change to one that is intrinsically more ductile; a stress/strain curve similar to Material II will then be obtained. Grain size also has a significant effect. Fine-grained materials both are stronger and exhibit more ductility than coarse-grained materials of the same chemistry. The degree of prior cold working is also important. Materials that are cold worked will show higher yield strengths and less ductility, since cold working produces defects in the crystalline structure that impede the basic mechanisms of plastic deformation.

Effects of Temperature and Strain Rate

Since deformation is usually assisted by thermal energy, the stress/strain curve at high temperature will usually lie below that at low temperature. Related to the effects of thermal energy, stress/strain curves at high rate will usually lie above those obtained at low rates, since at high rate more of the energy must be supplied athermally. The stress as a junction of strain rate for a given strain and temperature is usually expressed through the simplified equation:

$$\sigma_{\varepsilon,T} = C\dot{\varepsilon}^m \tag{11}$$

where C and m are material constants and $\dot{\varepsilon}$ is the strain rate.

Yield-Point Phenomena

In some materials, such as mild steels, a load drop is observed at the onset of plastic deformation, as shown in Figures 6 and 9B. This is easily understood in terms of some elementary concepts in the physics of deformation.

There is a fundamental relationship between the strain rate, the dislocation density, and the velocity of dislocation movement. (Dislocations are defects in the material that are responsible for the observed deformation behavior.) The strain rate is given by:

$$\dot{\varepsilon} = b\rho v \tag{12}$$

where b = Burger's vector (presumed to be constant), v = velocity of dislocation movement, and ρ is density of dislocations.

At the yield point, there is a rapid increase in the density of mobile dislocations. Since b is constant, this means

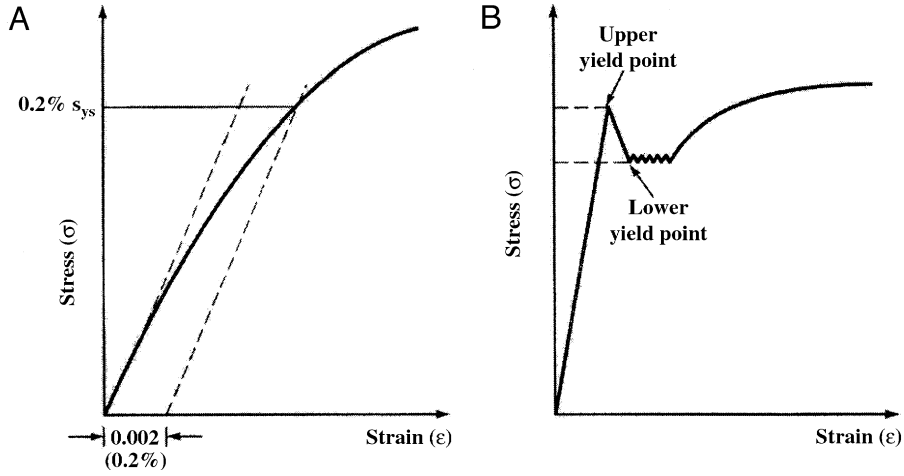

Figure 9. Illustration of stress/strain curves (**A**) for typical metals and (**B**) for mild steel in which there is an upper and lower yield point. Determination of the 0.2% offset yield is also shown in (**A**).

that v must decrease if a constant strain rate is being maintained. However, there is a relationship between dislocation velocity and stress that is expressed as:

$$\frac{v}{v_0} = \left(\frac{\sigma}{\sigma_0}\right)^n \tag{13}$$

where $\mathbf{V}_0$ and σ_0 are constants and n is an exponent on the order of 30 or 40 depending on the material. Now if **v** decreases, then Equation 13 shows that the stress σ will decrease, resulting in a load drop. However, if the control mode is a given rate of load application (i.e., load control), then no load drop will be observed since when the density of mobile dislocations increases, the machine will simply move faster in order to maintain the constant rate of loading.

PRACTICAL ASPECTS OF THE METHOD

The Basic Tensile Test

The basic tensile test consists of placing a specimen in a test frame, loading the specimen under specified conditions, and measuring the loads and corresponding displacements. The fundamental result of the tensile test is a curve relating the simultaneous loads and displacements. This curve is called the load displacement record. The load displacement record is converted to a stress/strain curve by dividing the load by the cross-sectional area and the elongation by the gage-length of the specimen as discussed in the following sections. To carry out a tensile test, four essential components are required. They are:

- A specimen of appropriate geometry;
- A machine to apply and measure the load;
- A device to measure the extension of the specimen;
- An instrument to record the simultaneous values of load and displacement.

Testing may be done at high or low temperatures and in a variety of environments other than air. Accessories are required to carry out such tests, which would include a high-temperature furnace, an extensometer adapted for use with such a furnace, and possibly a chamber for testing in inert or aggressive environments or under vacuum.

Typically, the following information can be obtained from the load displacement record of a tensile test or from the specimen:

- Young's modulus, E;
- The yield strength, σ_{ys}—or, more conventionally, the 0.2% offset yield as defined in Figure 9A (Schaffer et al., 1999);
- The strength coefficient and strain hardening exponent (Eq. 7);
- The ultimate tensile strength ($\sigma_{uts} = P_{max}/A_0$) as defined in Figures 1B and 2(P_{max} is maximum load);
- The total strain to failure, $\varepsilon_f = (l_f - l_0)/l_0$;

The percent reduction in area from the specimen, $\%RA=(A_0 - A_f)/A_0$ (where A_0 and A_f are the initial and final areas, respectively).

The ASTM has developed a standard test procedure for tensile testing (ASTM, 1987, E 8 & E 8M) that provides details on all aspects of this test procedure. The reader is strongly encouraged to consult the following documents related to tensile testing, calibration, and analysis of test results (all of which can be found in ASTM, 1987):

- Designation E 8: Standard Methods of Tension Testing of Metallic Materials (pp. 176–198).
- Designation E 8M: Standard Methods of Tension Testing of Metallic Materials [Metric] (pp. 199–222).
- Designation E 4: Standard Practices for Load Verification of Testing Machines (pp. 119–126).
- Designation E 83: Standard Practice for Verification and Classification of Extensometers (pp. 368–375).
- Designation E 1012: Standard Practice for Verification of Specimen Alignment Under Tensile Loading (pp. 1070–1078).

Designation E 21: Standard Recommended Practice for Elevated Temperature Tests of Metallic Materials (pp. 272–281).

Designation E 74: Standard Practices of Calibration of Force-Measuring Instruments for Verifying the Load Indication of Testing Machines (pp. 332–340).

Designation E 1 1 1: Standard Test Method for Young's Modulus, Tangent Modulus, and Chord Modulus (pp. 344–402).

The specimens and apparatus used in testing are considered in the sections that follow.

Specimen Geometry

The effect of geometry is also significant. As discussed above, the total elongation is made up of a uniform and a nonuniform component. Since the nonuniform component is localized, its effect on the overall elongation will be less for specimens having a long gage section. This means that the total strain to failure for a given material will be less for a long specimen of given diameter than it will be for a short specimen of the same diameter. Thus care must be exercised when comparing test results to ensure that geometrically similar specimens were used. It is standard in the US to use specimens in which the ratio of the length to diameter is 4:1. Since the total strain depends upon this ratio, comparisons can be made between different specimen sizes provided that this ratio is maintained. A more fundamental measure of the ductility is the percent reduction in area (%RA), which is independent of the specimen diameter. Typical specimen geometries are illustrated in ASTM (1987), E 83.

Test Machines, Extensometers, and Test Machine Characteristics

Test Machine. Testing is carried out using machines of varying degrees of sophistication. In its most basic form, a machine consists of:

a. A load cell attached to an upper support and a linkage to connect the load cell to the specimen;
b. A lower crosshead (or piston) that connects to the specimen via another linkage; and
c. A means to put the lower crosshead or piston into motion and thereby apply a force to the specimen.

The applied forces are transmitted through a load frame, which may consist of two or more columns, and the lower crosshead or piston may be actuated either mechanically or hydraulically. The load cell consists of a heavy metal block onto which strain gages are attached, usually in the configuration of a Wheatstone bridge. As force is applied, the load cell suffers displacement,and this displacement is calibrated to the applied load (ASTM, 1987, E 4). Most modern test machines have sophisticated electronic controls to aid in applying precise load-time or displacement-time profiles to the specimen.

Extensometers. The extension of the specimen must be measured with an extensometer in order to obtain the displacement corresponding to a given load. There are various ways to measure small displacements with great accuracy. One technique that has become very popular is the so-called clip-on gage. This gage consists of two spring arms attached to a small block. Strain gages are attached to both spring arms and are connected to form a Wheatstone bridge similar to the load cell. However, the calibration is done in terms of displacement (ASTM, 1987, E 83), and it is possible to measure very small displacements with great accuracy using this instrument.

While some indication of the specimen deformation can be obtained by monitoring the displacement of the crosshead (or hydraulic ram, depending on the nature of the test machine), it is, of course, preferable to attach an extensometer directly to the specimen. In this way the extension of the specimen is measured unambiguously. Two problems arise if the extension of the specimen is equated to the displacement of the lower crosshead or piston: (1) the gage length is assumed to be the region between the shoulders of the specimen and, more importantly, (2) deflection in the load train occurs to a rather significant degree. Thus, unless the machine stiffness is known and factored into account, the extension of the specimen will be overestimated.

In addition, even if the machine stiffness is accounted for, the rate of straining of the specimen will be variable throughout the plastic region since the proportion of actual machine and specimen deflection changes in a nonlinear way. Given these sources of error it is highly desirable to measure the machine deflection directly using an extensometer. Of course this is not always possible, especially when testing in severe environments and/or at high temperatures. In such cases other techniques must be used to obtain reasonable estimates of the strain in the specimen. Typical extensometers are shown in Martin (1985).

Testing Machine Characteristics and Testing Mode. The characteristics of the testing machine are also very important. If a machine is "soft" (i.e., there is considerable deflection in the load train during testing), then events that would tend to give rise to load drops (such as initial yielding in low-carbon steels, as discussed previously) can be masked by soft machines. In essence, the machine will spring back during the event that would otherwise cause a load drop and tend to maintain, at least to some degree, a constant load. Similarly, testing under conditions of load control would fully mask load drops, while testing under strain control would, by the same token, maximize the observability of load-drop phenomena.

The preceding brief discussion illustrates that due care must be exercised when carrying out a test in order to obtain the maximum amount of information.

Testing at Extreme Temperatures and in Controlled Environments

While it is clearly not possible to consider all possible combinations of test temperature and environment, a few general comments on the subject of testing at low and high

temperatures and in environments other than ambient are in order. These are important in various advanced technology applications. For example, jet and rocket engines operate at temperatures that approach 1500 K, power generation systems operate at temperatures only slightly lower, and cryogenic applications such as refrigeration systems operate well below room temperature. Furthermore, a wide range of temperatures is encountered in the operation of ships and planes.

High-Temperature Testing. Care must be exercised to assure a uniform temperature over the gage length of the specimen. For practical purposes, the temperature should not vary by more than a few degrees over the entire gage length. If the specimen is heated using a resistance furnace, a so-called "chimney effect" can occur if the top of the furnace is open. This occurs because hot air rises, and as it rises in the tube of the furnace, cold air is drawn in, which tends to cool the bottom of the specimen and create an excessive temperature gradient. This effect can be reduced by simply providing shutters at the top of the furnace that just allow the force rods to enter into the heating chamber but that block the remaining open area.

Testing in a resistance furnace is also complicated by the way in which the extensometer is attached to the specimen and by the need to avoid temperature gradients. A small access hole is provided in the furnace and probes of alumina or quartz are attached to the specimen to define the gage length. These arms are then attached to the clip-on gage mentioned previously to measure specimen displacement. In some cases, "divots" are put in the specimen to assure positive positioning of the probe arms. However, this practice is not recommended since the divots themselves may affect the test results, especially the measured ductility. It is possible to adjust the radius of curvature of the probe arms and the tension holding the extensometer to the specimen so that slippage is avoided. A very popular way of heating the specimen is to use an induction generator and coil. By careful design of the coil, a very constant temperature profile can be established and the extensometer can be easily secured to the specimen by putting the probe arms through the coil.

Low-Temperature Testing. Problems similar to those discussed above apply to low-temperature testing. Refrigeration units with circulating gases or fluids can be used, but constant mixing is required to avoid large temperature gradients. Uniform temperatures can be achieved with various mixtures of liquids and dry ice. For example, dry ice and acetone will produce a constant-temperature bath, but the temperature is limited. Extensometry becomes even more difficult than at high temperatures if a fluid bath is used. In such instances, an arrangement in which a cylindrical linearly variable differential transformer (i.e., LVDT-based extensometer) is attached to the specimen may be useful. The body of the LVDT is attached to the bottom of the gage section and the core is attached to the top. As the specimen elongates, a signal is generated that is proportional to the relative displacement of the core and LVDT body.

Environmental Testing. Tensile testing is also carried out in various environments or in vacuum. Since environmental attack is accelerated at high temperatures, such testing is often done at high temperatures. In such instances, an environmental chamber is used that can be evacuated and then, if appropriate, back-filled with the desired environment (e.g., oxygen in a neutral carrier gas at a prescribed partial pressure). All of the comments that were made relative to extensometry and temperature control apply here as well, with the added complication of the apparatus used to provide environmental control. In addition to being able to measure the temperature, it is highly desirable to measure the gaseous species present. These may arise from so-called "internal" leaks (e.g., welds that entrap gasses but that have a very small hole allowing such gasses to escape) or from impure carrier gasses. Gaseous species can be measured by incorporating a mass spectrometer into the environmental chamber.

METHOD AUTOMATION

As discussed above, the basic needs are a machine to apply a force, an instrument to measure the extension of the specimen, and a readout device to record the experimental results. However, it is frequently desirable to apply the load to the specimen in a well-defined manner. For example, it is well known that materials are sensitive to the rate at which a strain is applied and it is thus important to be able to load the specimen in such a way as to maintain a constant strain rate. In essence, this requirement imposes two conditions on the test:

a. The control mode must be of the displacement type; and
b. The displacement that is measured and controlled must be specimen displacement, as opposed to displacement of the crosshead or hydraulic ram.

In this situation the following are required:

a. An extensometer attached directly to the specimen, and
b. A machine with the ability to compare the desired strain/time profile to the actual strain/time profile and make instantaneous adjustments in the strain rate so as to minimize, as far as possible, the differences between the command signal (i.e., the desired strain rate) and the resultant signal (i.e., the actual strain rate).

Clearly these conditions cannot be met if the test machine can only move the lower crosshead at a predetermined rate, since this will not take deflection in the load train into account as discussed above. The control mode just described is referred to as "closed-loop control," and is the way in which most modern testing is carried out. Modern machines are instrumented in such as way as to be able to operate in strain control, load control, and displacement control modes. In addition, manufacturers now supply controllers in which a combined signal may

be used as the control mode. This is called combinatorial control. An example of combinatorial control would be to load a specimen such that the rate of stress × strain (i.e., power) was constant. A schematic of the closed-loop control concept is provided in Martin (1985).

It is important to realize that the results that are obtained can depend quite sensitively on the control mode. Essentially, the results of a tensile test reflect not only the material's intrinsic properties but also, more fundamentally, the interaction between the material being tested and the test machine. This is perhaps best illustrated for mild steel. If tested under strain control (or under displacement control, if the test machine is very stiff relative to the specimen), this material will exhibit an upper and lower yield point. On the other hand, the upper and lower yield points are completely eliminated if the specimen is tested under load control and the machine is very compliant relative to the specimen. The yield-point phenomenon is illustrated in Figure 5. Reasons for this behavior are discussed above (see Principles of the Method).

SAMPLE PREPARATION

What sort of test specimen should be used will depend upon the form of the material that is being tested and its ductility. The ASTM (1987, E 8 & E 8M) has defined a variety of specimens that can be used for various product forms; typical specimens are shown in ASTM (1987) E 8. It is important to ensure that the tolerances shown in these figures are respected, since excessive nonparallelism and variations in thickness will adversely affect the interpretation and reliability of results.

Generally speaking, specimen preparation for metallic materials requires tools found in most machine shops, such as lathes and surface grinding machines. Within reasonable limits, the tensile and yield strengths are not affected by surface finish except in the case of materials of very limited ductility, for which low-stress grinding is used to obtain honed surfaces with no residual stresses or disturbed surface layers. The parameters for steels and high-temperature Ni-base alloys can be found in ASM (1985). Safety considerations for metallic materials specimen preparation involves only those considerations which are normal in good machining practice. For composites with a polymer matrix, specimens are generally made by infiltration of the polymer (usually an epoxy) around the fibers. In this case, vacuum equipment may be used and care must be taken to ensure proper venting of hazardous fumes.

An additional requirement for obtaining reliable results is that the alignment of the load cell of the test machine and the specimen be coaxial. This will eliminate bending moments and produce a result in which only tensile forces are measured. Techniques for alignment are discussed in detail in ASTM (1987), E 1012.

DATA ANALYSIS AND INITIAL INTERPRETATION

As previously mentioned, the fundamental result of a tensile test is a load-displacement curve. Since the load required to bring a specimen to a given state (e.g., to fracture) depends upon the cross-sectional area, load is not a fundamental measure of material behavior. Therefore, the load must be converted to stress by dividing by the cross-sectional area. Similarly, the extension depends upon the actual length of the specimen and is also not a fundamental quantity. Elongation is put on a more fundamental basis by dividing by the length of the specimen, and the resulting quantity is called strain. The result of a tensile test is then a stress/strain curve, as shown in Figures 1B and 2. There are typically three distinct regions to a stress/strain curve, which have been discussed above (see Principles of the Method).

When comparing test results, it is generally found that the yield and tensile strength are independent of specimen geometry. However, this is not the case for the percent elongation which is often used as a measure of ductility. If specimens of circular cross-section are considered, then the percent elongation will be higher the smaller the ratio of the gage length to diameter. This can be understood in part by noting that the elongation associated with necking will be constant for a given diameter. Thus, the contribution of the nonuniform deformation to the total percent elongation will increase as the gage length decreases. Since different length/diameter specimens are used in different countries, care must be exercised in making comparisons. However, the percent reduction in area (%RA) is independent of diameter. Since this quantity is a good measure of ductility and is independent of diameter, it is recommended for making ductility comparisons.

The scatter associated with such tests is very small (<1%) for well-machined and well-aligned specimens.

Table 1. Typical Tensile Properties of Engineering Materials

Material	Modulus (MPa)	Tensile Strength (MPa)	Yield Strength (MPa)	Elongation (%)	Reduction in Area (%)
1020 steel (As-rolled)	206,850	448.2	330.9	36	59
4340 steel (normalized)	206,850	1279	861.8	12	36
4341 steel (quenched and tempered at 205°C)	206,850	1875	1675	10	38
2024-T3 Al	70,329	393	290	12	—
7075-T6 Al	70,329	538	483	7	—
Ti-6Al-4V (titanium alloy, solution-treated and aged)	119,973	1180	1085	6	11

Differences in yield and ultimate strengths are then indications of differences in material properties. It is customary to use three to five tests to characterize tensile properties. To have a statistically valid test, it is usually considered that the specimen diameter should be at least 25 times the average grain size. For larger grains, specimen-to-specimen variation becomes more pronounced.

Some typical tensile properties are listed in Table 1.

SUMMARY

Very important engineering and scientific information can be obtained from a tensile test. While the test is relatively straightforward to perform, care must be exercised in all aspects of the test, including:

a. selection of the appropriate specimen geometry;
b. proper specimen fabrication;
c. careful alignment of the specimen within the testing machine;
d. appropriate control of the testing conditions including temperature, loading rate, and control mode;
e. analysis and presentation of the test results.

Well-established standards are available that, if followed, will ensure the validity of the results that are obtained.

HIGH-STRAIN-RATE TESTING OF MATERIALS

INTRODUCTION

Experimental methods of probing material behavior at high rates of strain are concerned with measuring the variation of mechanical properties, such as strength and ductility, that can vary with strain rate. Strain rate, $\dot{\varepsilon}$, is the rate of change of strain (defined as the relative change in the length of a test sample) with respect to time (t). Little scientific or engineering attention was historically paid to the effects of high strain rates until increased manufacturing production techniques (Lindholm, 1971, 1974; Follansbee, 1985; Field et al., 1994)—i.e., high-speed wire drawing and cold rolling—as well as studies supporting military technologies concerned with ballistics (Hopkinson, 1914; Carrington and Gayler, 1948), armor, and detonation physics necessitated further knowledge. Interest in the high-rate mechanical behavior of materials has continued to expand during the last four decades, driven by demands for increased understanding of material response in impact events. High-rate tests also provide the data critically needed to create predictive constitutive model descriptions of materials. These descriptions strive to capture the fundamental relationships between the ways that each of the independent variables—stress, strain rate, strain, and temperature—independently affect the constitutive behavior of materials (Follansbee and Kocks, 1988; Klepaczko, 1988; Chen and Gray, 1996). Robust material models capturing the physics of high-rate material response are required for large-scale finite-element simulations of (1) automotive crashworthiness; (2) aerospace impacts, including foreign-object damage such as that during bird ingestion in jet engines and meteorite impact on satellites; (3) dynamic structural loadings such as that occurring during earthquakes; (4) high-rate manufacturing processes, including high-rate forging and machining; and (5) projectile/armor interactions.

Measurements of the mechanical properties of materials are normally conducted via loading test samples in compression, tension, or torsion. Mechanical testing frames can be used to achieve nominally constant loading rates for limited plastic strains and thereby a constant engineering strain rate. Typical screw-driven or servohydraulic testing machines are routinely used to measure

the stress-strain response of materials up to strain rates as high as $1\,s^{-1}$. Specially designed testing machines, typically equipped with high-capacity servohydraulic valves and high-speed control and data acquisition instrumentation, can be used during compression testing to achieve strain rates as high as $200\,s^{-1}$. Above this strain rate regime, $\dot{\varepsilon} > 200\,s^{-1}$, alternate techniques using projectile-driven impacts to induce stress-wave propagation have been developed.

Chief among these techniques is the split-Hopkinson pressure bar, which is capable of achieving the highest uniform uniaxial stress loading of a specimen in compression at nominally constant strain rates of the order of $10^3\,s^{-1}$. Stress is measured by using an elastic element in series with the specimen of interest. Stress waves are generated via an impact event and the elastic elements utilized are long bars such that the duration of the loading pulse is less than the wave transit time in the bar. Utilizing this technique, the dynamic stress-strain response of materials at strain rates up to $2\times10^4\,s^{-1}$ and true strains of 0.3 can be readily achieved in a single test.

Historical Background

The Hopkinson bar technique is named after Bertram Hopkinson (Hopkinson, 1914) who, in 1914, used the induced wave propagation in a long elastic bar to measure the pressures produced during dynamic events. Through the use of momentum traps of different lengths, Hopkinson studied the shape and evolution of stress pulses as they propagated down long rods as a function of time. Based on this pioneering work, the experimental apparatus utilizing elastic stress-wave propagation in long rods to study dynamic processes was named the Hopkinson pressure bar. Later work by Davies (1948a,b) and Kolsky (1949) utilized two Hopkinson pressure bars in series, with the sample sandwiched in between, to measure the dynamic stress-strain response of materials. (A note on nomenclature: The terms input/incident bar and output/transmitted bar will be used interchangeably.) This technique thereafter has been referred to as either the split-Hopkinson pressure bar (Lindholm and Yeakly, 1968; Follansbee, 1985), Davies bar (Kolsky, 1964), or Kolsky bar (Kolsky, 1949; Follansbee, 1985).

This unit describes the techniques involved in measuring the high-strain-rate stress-strain response of materials in compression utilizing a split-Hopkinson pressure bar, hereafter abbreviated as SHPB. Emphasis will be given to the method for collecting and analyzing compressive high-rate mechanical property data and to discussion of the critical experimental variables that must be controlled to yield valid and reproducible high-strain-rate stress-strain data.

Competitive and Related Techniques

In addition to the original split-Hopkinson pressure bar developed to measure the compressive response of a material, the Hopkinson technique has been modified for loading samples in uniaxial tension (Harding et al., 1960; Lindolm and Yeakley, 1968), torsion (Duffy et al., 1971), and simultaneous torsion-compression (Lewis and Goldsmith, 1973). The basic theory of bar data reduction based upon one-dimensional stress wave analysis, as presented below (see Principles of the Method), is common to all three loading states. Of the different Hopkinson bar techniques—compression, tension, and torsion—the compression bar remains the most readily analyzed and least complex method to achieve a uniform high-rate stress state.

The additional complications encountered in the tensile and torsional Hopkinson techniques are related to (1) the modification of the pressure bar ends to accommodate gripping of complex samples, which can alter wave propagation in the sample and bars; (2) the potential need for additional diagnostics to calculate true stress; (3) an increased need to accurately incorporate inertial effects into data reduction to extract quantitative material constitutive behavior; and (4) the more complicated stress-pulse generation systems required for tensile and torsion bars. Alteration of the bar ends to accommodate threaded or clamped samples leads to complex boundary conditions at the bar/specimen interface and therefore introduces uncertainties in the wave mechanics description of the test (Lindholm and Yeakley, 1968). When complex sample geometries are used, signals measured in the pressure bars record the structural response of the entire sample, not just the gauge section, where plastic deformation is assumed to be occurring. When plastic strain occurs in the sections adjacent to the sample's uniform gauge area, accurate determination of the stress-strain response of the material is more complicated. In these cases, additional diagnostics, such as high-speed photography, are mandatory to quantify the loaded section of the deforming sample. In the tensile bar case, an additional requirement is that exact quantification of the sample cross-sectional area as a function of strain is necessary to achieve true-stress data.

An additional complexity inherent to both the tension and torsion Hopkinson loading configurations has to do with the increased sample dimensions required. Valid dynamic characterization of many material product forms, such as thin sheet materials and small-section bar stock, may be significantly complicated or completely impractical using either tensile or torsion Hopkinson bars due to an inability to fabricate test samples.

High-rate tensile loading of a material may also be conducted utilizing an expanding ring test (Hoggatt and Recht, 1969; Gourdin et al., 1989). This technique, which requires very specialized equipment, employs the sudden radial acceleration of a ring due to detonation of an explosive charge or electromagnetic loading. Once loaded via the initial impulse, the ring expands radially and thereafter decelerates due to its own internal circumferential stresses. While this technique has been utilized to determine the high-rate stress-strain behavior of a material, it is complicated by the fact that the strain rate changes throughout the test. This variable rate is determined first by the initial loading history, related to the initial shock and/or magnetic pulse, and then by the rapid-strain-rate decelerating gradient during the test following the initial

impulse. The varied difficulties of the expanding ring technique, along with the expense, sample size, and shape, have limited its use as a standard technique for quantitative measurement of dynamic tensile constitutive behavior.

The remaining alternate method of probing the mechanical behavior of materials at high strain rates, of the order of $10^3\,s^{-1}$, is the Taylor rod impact test. This technique, named after its developer G.I. Taylor (1948), entails firing a solid cylinder of the material of interest against a massive and rigid target as shown schematically in Figure 1.

The deformation induced in the rod by the impact shortens the rod as radial flow occurs at the impact surface. The fractional change in the rod length can then, by assuming one-dimensional rigid-plastic analysis, be related to the dynamic yield strength. By measuring the overall length of the impacted cylinder and the length of the undeformed (rear) section of the projectile, the dynamic yield stress of the material can be calculated according to the formula (Taylor, 1948):

$$\sigma = \frac{\rho V^2 (L - X)}{2(L - L_1)\ln(L/X)} \tag{1}$$

where σ is the dynamic yield stress of the material, ρ is the material's density, V is the impact velocity, and L, X, and L_1 are the dimensional quantities of the bar length and deformed length as defined in Figure 1. The Taylor test technique offers an apparently simplistic method to ascertain some information concerning the dynamic strength properties of a material. However, this test represents an integrated test, rather than a unique experiment with a uniform stress state or strain rate like the split-Hopkinson pressure bar test. Accordingly, the Taylor test has been most widely used as a validation experiment in concert with two-dimensional finite-element calculations. In this approach, the final length and cylinder profile of the Taylor sample is compared with code simulations to validate the material constitutive model implemented in the finite-element code (Johnson and Holmquist, 1988; Maudlin et al., 1995, 1997). Comparisons with the recovered Taylor sample provide a check on how accurately the code can calculate the gradient in deformation stresses and strain rates leading to the final strains imparted to the cylinder during the impact event.

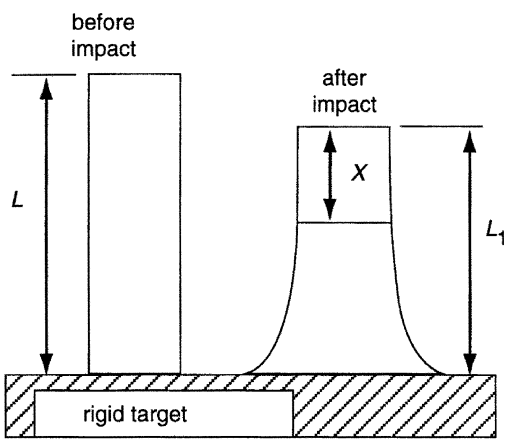

Figure 1. Schematic of Taylor impact test showing the initial and final states of the cylindrical sample (Taylor, 1948).

New Developments

The split-Hopkinson pressure bar technique, as a tool for quantitative measurement of the high-rate stress-strain behavior of materials, is far from static, with many new improvements still evolving. One- and two-dimensional finite-element models of the split-Hopkinson pressure bar have proven their ability to simulate test parameters and allow pretest setup validation checks as an aid to planning. Novel methods of characterizing sample diametrical strains are being developed using optical diagnostic techniques (Valle et al., 1994; Ramesh and Narasimhan, 1996). Careful attention to controlling wave reflections in the SHPB has also opened new opportunities to study defect/damage evolution in brittle materials during high-rate loading histories (Nemat-Nasser et al., 1991). Finally, researchers are exploring exciting new methods for in situ dispersion measurements (Wu and Gorham, 1997) on pressure bars, which offer opportunities for increased signal resolution in the future.

PRINCIPLES OF THE METHOD

The determination of the stress-strain behavior of a material being tested in a Hopkinson bar, whether it is loaded in compression as in the present instance or in a tensile bar configuration, is based on the same principles of one-dimensional elastic-wave propagation within the pressure loading bars (Lindholm, 1971; Follansbee, 1985).

As identified originally by Hopkinson (1914) and later refined by Kolsky (1949), the use of a long, elastic bar to study high-rate phenomena in materials is feasible using remote elastic bar measures of sample response because the wave propagation behavior in such a geometry is well understood and mathematically predictable. Accordingly, the displacements or stresses generated at any point can be deduced by measuring the elastic wave at any point, x, as it propagates along the bar.

In what follows, the subscripts 1 and 2 will be used to denote the incident and transmitted side of the specimen, respectively. The strains in the bars will be designated $\varepsilon_i, \varepsilon_r, \varepsilon_t$ and the displacements of the ends of the specimen u_1, u_2 at the input bar/specimen and specimen/output bar interfaces as given schematically in the magnified view of the specimen in Figure 2.

From elementary wave theory, it is known that the solution to the wave equation

$$\frac{\partial^2 u}{\partial x^2} = \frac{1}{c_b^2}\frac{\partial^2 u}{\partial t^2} \tag{2}$$

can be written

$$u = f(x - c_b t) + g(x + c_b t) = u_i + u_r \tag{3}$$

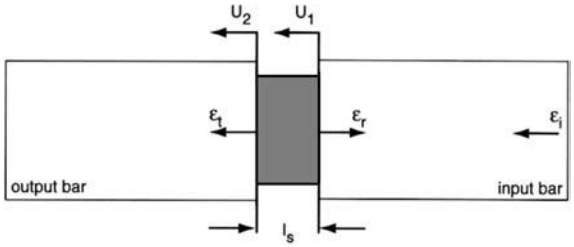

Figure 2. Expanded view of input bar/specimen/output bar region.

for the input bar, where f and g are functions describing the incident and reflected wave shapes and c_b is the wave speed in the rod.

By definition, the one-dimensional strain is given by

$$\varepsilon = \frac{\partial u}{\partial x} \tag{4}$$

So differentiating Equation 3 with respect to X, the strain in the incident rod is given by

$$\varepsilon = f' + g' = \varepsilon_i + \varepsilon_r \tag{5}$$

Differentiating Equation 3 with respect to time and using Equation 5 gives

$$\dot{u} = c_b(-f' + g') = c_b(-\varepsilon_i + \varepsilon_r) \tag{6}$$

for the input bar.

Since the output bar has only the transmitted wave, $u = h(x - c_b t)$, propagating in it,

$$\dot{u} = -c_b \varepsilon_t \tag{7}$$

in the output bar.

Equations 6 and 7 are true everywhere, including at the ends of the pressure bars.

The strain rate in the specimen is, by definition, given by

$$\dot{\varepsilon} = \frac{(\dot{u}_1 - \dot{u}_2)}{l_s} \tag{8}$$

where l_s is the instantaneous length of the specimen and $\dot{u}_1$ and $\dot{u}_2$ are the velocities at the incident bar–specimen and specimen–output bar interfaces, respectively.

Substituting Equations 6 and 7 into Equation 8 gives

$$\dot{\varepsilon} = \frac{c_b}{l_s}(-\varepsilon_i + \varepsilon_r + \varepsilon_t) \tag{9}$$

By definition, the forces in the two bars are

$$F_1 = AE(\varepsilon_i + \varepsilon_r) \tag{10}$$

$$F_2 = AE\varepsilon_t \tag{11}$$

where A is the cross-sectional area of the pressure bar and E is the Young's modulus of the bars (normally equal, given identical material is used for the input and output bars).

Assuming that after an initial ringing up period (the period during which the forces on the ends of the specimen become equal), where the exact time depends on the sample sound speed and sample geometry, the specimen is in force equilibrium; and assuming that the specimen is deforming uniformly, a simplification can be made equating the forces on each side of the specimen, i.e., $F_1 = F_2$. Comparing Equations 10 and 11 therefore means that

$$\varepsilon_t = \varepsilon_i + \varepsilon_r \tag{12}$$

Substituting this criterion into Equation 9 yields

$$\dot{\varepsilon} = \frac{2c_b\varepsilon_r}{l_s} \tag{13}$$

The stress is calculated from the strain gauge signal measure of the transmitted force divided by the instantaneous cross-sectional area of the specimen, A_s:

$$\sigma(t) = \frac{AE\varepsilon_t}{A_s} \tag{14}$$

Utilizing Equations 13 and 14 to determine the dynamic stress-strain curve of a material is termed a "one-wave" analysis because it uses only the reflected wave for strain in the sample and only the transmitted wave for stress in the sample. Hence, it assumes that stress equilibrium is assured in the sample. Conversely, the stress in the sample at the incident bar–sample interface can be calculated using a momentum balance of the incident and reflected wave pulses, termed a "two-wave" stress analysis since it is a summation of the two waves at this interface. However, it is known that such a condition cannot be correct at the early stages of the test because of the transient effect that occurs when loading starts at the input bar–specimen interface while the other face remains at rest. Time is required for stress-state equilibrium to be achieved.

Numerous researchers have adopted a "three-wave" stress analysis that averages the forces on both ends of the specimen to track the ring-up of the specimen to a state of stable stress. The term "three-wave" indicates that all three waves are used to calculate an average stress in the sample; the transmitted wave to calculate the stress at the specimen–transmitted interface (back stress) and the combined incident and reflected pulses to calculate the stress at the incident bar–specimen interface (front stress). In the three-wave case, the specimen stress is then simply the average of the two forces divided by the combined interface areas:

$$\sigma(t) = \frac{F_1(t) + F_2(t)}{2A_s} \tag{15}$$

Substituting Equations 10 and 11 into Equation 15 then gives

$$\sigma(t) = \frac{AE}{2A_s}(\varepsilon_i + \varepsilon_r + \varepsilon_t) \tag{16}$$

From these equations, the stress-strain curve of the specimen can be computed from the measured reflected and transmitted strain pulses as long as the volume of the specimen remains constant, i.e., $A_0 l_0 = A_s l_s$ (where l_0 is the original length of the specimen and A_0 its original cross-sectional area) and the sample is free of barreling (i.e., friction effects are minimized). (*Note*: The stipulation of constant volume precludes, by definition, the testing of foams or porous materials.)

PRACTICAL ASPECTS OF THE METHOD

While there is no worldwide standard design for a split-Hopkinson pressure bar test apparatus, the various designs share common features. A compression bar test apparatus consists of (1) two long, symmetric, high-strength bars, (2) bearing and alignment fixtures to allow the bars and striking projectile to move freely but in precise axial alignment, (3) a gas gun or alternate device for accelerating a projectile to produce a controlled compressive wave in the input bar, (4) strain gauges mounted on both bars to measure the stress wave propagation, and (5) the associated instrumentation and data acquisition system to control, record, and analyze the wave data.

A short sample is sandwiched between the input and output bar as shown schematically in Figure 3. The use of a bar on each side of the material sample to be tested allows measurement of the displacement, velocity, and/or stress conditions, and therefore provides an indication of the conditions on each end of the sample.

The bars used in a Hopkinson bar setup are most commonly constructed from a high-strength material: AISI-SAE 4340 steel or maraging steel or a nickel alloy such as Inconel. This is because the yield strength of the pressure-bar material determines the maximum stress attainable within the deforming specimen. Bars made of Inconel, whose elastic properties are essentially invariant up to 600°C, are often utilized for elevated-temperature Hopkinson bar testing. Because a lower-modulus material increases the signal-to-noise level, the selection of a material with lower strength and lower elastic modulus for the bars is sometimes desirable to facilitate high-resolution dynamic testing of low-strength materials such as polymers or foams. Researchers have utilized bar materials ranging from maraging steel (210 GPa) to titanium (110 GPa) to aluminum (90 GPa) to magnesium (45 GPa) and finally to polymer bars (< 20 GPa) (Gary et al., 1995, 1996; Gray et al., 1997).

The length, l, and diameter, d, of the pressure bars are chosen to meet a number of criteria for test validity as well as the maximum strain rate and strain level desired. First, the length of the pressure bars must assure one-dimensional wave propagation for a given pulse length; for experimental measurements on most engineering materials this requires ~10-bar diameters. To allow wave reflection, each bar should exceed a l/d ratio of ~20. Second, the maximum strain rate desired must be considered in selecting the bar diameter, where the highest-strain-rate tests require the smallest diameter bar. The third consideration affecting the selection of the bar length is the amount of total strain desired to be imparted into the specimen; the absolute magnitude of this strain is related to the length of the incident wave. The pressure bar must be at least twice as long as the incident wave if the incident and reflected waves are to be recorded without interference. In addition, since the bars remain elastic during the test, the displacement and velocity of the bar interface between the sample and the bar can be accurately determined. Depending on the sample size, for strains >30% it may be necessary for the split-Hopkinson bars to have a l/d ratio of 100 or more.

For proper operation, split-Hopkinson bars must be physically straight, free to move without binding, and carefully mounted to assure optimum axial alignment. Precision bar alignment is required for both uniform and one-dimensional wave propagation within the pressure bars as well as for uniaxial compression within the specimen during loading. Bar alignment cannot be forced by overconstraining or forceful clamping of curved pressure bars in an attempt to "straighten" them, as this clamping violates the boundary conditions for one-dimensional wave propagation in an infinite cylindrical solid. Bar motion must not be impeded by the mounting bushings utilized; the bar must remain free to move readily along its axis. Accordingly, it is essential to apply precise dimensional specifications during construction and assembly. In typical bar installations, as illustrated schematically in Figure 3, the pressure bars are mounted to a common rigid base to provide a rigid, straight mounting platform. Individual mounting brackets with slip bearings through which the bars pass are typically spaced every 100 to 200 mm,

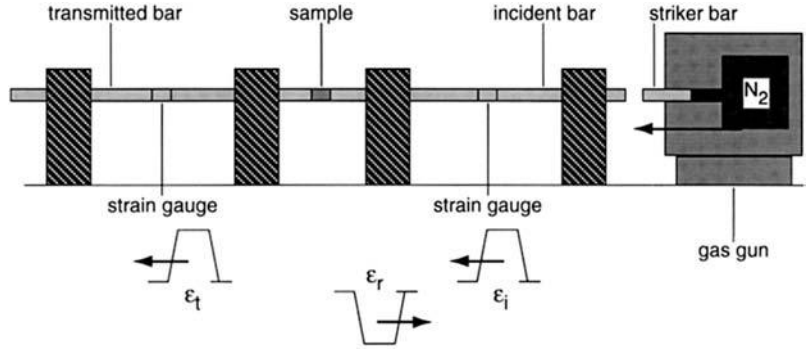

Figure 3. Schematic of a split-Hopkinson bar.

depending on the bar diameter and stiffness. Mounting brackets are generally designed so that they can be individually translated to facilitate bar alignment.

The most common method of generating an incident wave in the input bar is to propel a striker bar to impact the incident bar. The striker bar is normally fabricated from the same material and is of the same diameter as the pressure bars. The length and velocity of the striker bar are chosen to produce the desired total strain and strain rate within the specimen. While elastic waves can also be generated in an incident bar through the adjacent detonation of explosives at the free end of the incident bar, as Hopkinson did, it is more difficult to ensure a one-dimensional excitation within the incident bar by this means.

The impact of a striker bar with the free end of the incident bar develops a longitudinal compressive incident wave in this bar, designated ε_i, as denoted in Figure 3. Once this wave reaches the bar–specimen interface, a part of the pulse, designated ε_r, is reflected while the remainder of the stress pulse passes through the specimen and, upon entering the output bar, is termed the transmitted wave, ε_t. The time of passage and the magnitude of these three elastic pulses through the incident and transmitted bars are recorded by strain gauges normally cemented at the midpoint positions along the length of the two bars. Figure 4 is an illustration of the data measured as a function of time for the three wave signals. The incident and transmitted wave signals represent compressive loading pulses, while the reflected wave is a tensile wave.

If we use the wave signals from the gauges on the incident and transmitted bars as a function of time, the forces and velocities at the two interfaces of the specimen can be determined. When the specimen is deforming uniformly, the strain rate within the specimen is directly proportional to the amplitude of the reflected wave. Similarly, the stress within the sample is directly proportional to the amplitude of the transmitted wave. The reflected wave is also integrated to obtain strain and is plotted against stress to give the dynamic stress-strain curve for the specimen.

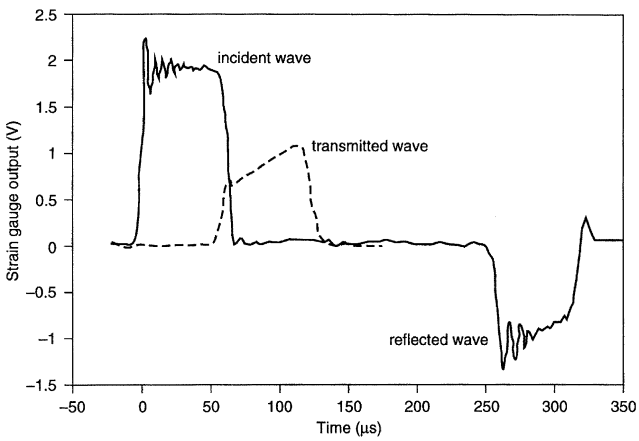

Figure 4. Strain gauge data, after signal conditioning and amplification, from a Hopkinson bar test of a nickel alloy sample showing the three waves measured as a function of time. (Note that the transmitted wave position in time is arbitrarily superimposed on the other waveforms.)

To analyze the data from a Hopkinson bar test, the system must be calibrated prior to testing. Calibration of the entire Hopkinson bar setup is obtained in situ by comparing the constant amplitude of a wave pulse with the impact velocity of the striker bar for each bar separately. Operationally, this is accomplished by applying a known-velocity pulse to the input bar, and then to the transmitted bar, with no sample present. Thereafter, the impact of the striker with the input bar in direct contact with the transmitted bar, with no specimen, gives the coefficient of transmission. Accurate measurement of the velocity, V, of the striker bar impact into a pressure bar can be obtained using the linear relationship

$$\varepsilon_j = \frac{V}{2c_b} \tag{17}$$

where ε_j is the strain in the incident or transmitted bar, depending on which is being calibrated, and c_b is the longitudinal wave speed in the bar. Equation 17 applies if the impacting striker bar and the pressure bar are the same material and have the same cross-sectional area. Careful measurement of the striker velocity—using a laser interruption scheme, for example, in comparison to the elastic strain signal in a pressure bar—can then be used to calculate a calibration factor for the pressure bar being calibrated.

Optimum data resolution requires careful design of the sample size for a given material followed by selection of an appropriate striker bar length and velocity to achieve test goals. Determination of the optimal sample length first requires consideration of the sample rise time, t, required for a uniform uniaxial stress state to equilibrate within the sample. It has been estimated (Davies and Hunter, 1963) that this requires three (actually π) reverberations of the stress pulse within the specimen to achieve equilibrium. For a plastically deforming solid obeying the Taylor–von Karman theory, time follows the relationship

$$t^2 > \frac{\pi^2 \rho_s l_s^2}{\partial\sigma/\partial\varepsilon} \tag{18}$$

where ρ_s is the density of the specimen, l_s is the specimen length, and $\partial\sigma/\partial\varepsilon$ is the stage II work hardening rate of the true-stress/true-strain curve for the material to be tested. For rise times less than that given by Equation 18, the sample should not be assumed to be deforming uniformly and stress-strain data will accordingly be in error.

One approach for achieving a uniform stress state during split-Hopkinson pressure-bar testing is to decrease the sample length, such that the rise time, t, from Equation 18 is as small as possible. Because other considerations of scale (see Sample Preparation) limit the range of l/d ratios appropriate for a specimen dependent on material, the specimen length may not be decreased without a concomitant decrease in the specimen and bar diameters. The use of small-diameter bars (<6 mm) to achieve higher strain

rates is a common practice in split-Hopkinson pressure-bar testing.

Because the value of t from Equation 18 has a practical minimum, an alternate method to achieve stress-state equilibrium at low strains is to increase the rise time of the incident wave. Utilizing self-similar impedance materials for the striker and incident bar (i.e., a symmetric impact) yields a short-rise-time pulse that approximates a square wave. The rise time of such a square-wave pulse is likely to be less than t in Equation 18 in most instances. Contrarily, if the rise time of the incident wave pulse is increased to a value more comparable with the time required to ring up the specimen, then the data will be valid at a lower strain. Furthermore, because the highly dispersive short-wavelength components arise from the leading and trailing edges of the waves, a longer-rise-time pulse will contain fewer of these components than will a sharply rising pulse (Frantz et al., 1984; Follansbee, 1985). The tradeoff to this solution is a lowering of the applied strain rate.

Experimentally, the rise time of the incident wave can be increased by placing a soft, deformable metal shim between the striker and the incident bar during impact. The choice of material and thickness for this shim, or "tip material" (Frantz et al., 1984), depends on the desired strain rate and the strength of the specimen. Typically, the tip material is selected to have the same strength as the specimen and is 0.1 to 2 mm in thickness. An additional benefit of this layer is that it can result in a more uniform strain rate throughout the experiment. However, for thick shims the strain rate will not be constant and will ramp up during the test. The exact selection of the optimal tip material and thickness for a given test sample is not readily calculated and remains a matter of experience via trial and error.

Test Setup

Once the system has been calibrated and the optimal specimen length, l_s, has been selected, preparations for testing can be considered. At a constant strain rate, the maximum strain that can be achieved in a specimen is directly proportional to the length of the striker bar utilized, L:

$$\varepsilon = 2\,\dot{\varepsilon}\frac{L}{C_b} \tag{19}$$

The nominal strain rate in the specimen may be very roughly approximated, erring on the low side, by considering momentum conservation between the striker bar and incident bar. It can similarly be shown (Follansbee, 1985) that

$$\dot{\varepsilon} = \frac{V}{l_s} \tag{20}$$

where V is the striker bar velocity; this will overestimate the strain rate. This relationship has been found to be a good first approximation for soft metals, such as annealed copper, at high striker bar velocities. Equations 19 and 20 can be used to approximate the striker bar length and striker bar velocity required to achieve a desired strain and strain rate for a given sample size. These formulas provide a good starting point for selecting test parameters to achieve a valid SHPB test. However, for samples possessing high initial yield strengths, the yield drops (this is often seen in low-carbon steels or other refractory metals) and/or very high strain-hardening responses will necessitate increased striker bar lengths and impact velocities to achieve the desired strain value.

Stress-State Equilibrium

The classic split-Hopkinson pressure bar equations relating strain gauge measurement to stress-strain behavior in the deforming specimen require that the specimen must deform uniformly; this is opposed by both radial and longitudinal inertia and by frictional constraint at the specimen/pressure bar interfaces. To understand the procedure for validating attainment of a uniform stress state in the sample in a SHPB test, it is instructive to examine the different analyses used to calculate sample stress from the pressure bar strains. In the one-wave analysis, the sample stress is directly proportional to the bar strain measured in the output bar as calculated using Equation 14. This waveform characteristically exhibits low oscillation amplitude because the deforming sample effectively damps much of the high-frequency oscillations inherent in the incident pulse as it propagates through the sample. More importantly, the one-wave stress analysis reflects the conditions at the sample-transmitted bar interface and is often referred to as the sample "back stress."

Alternatively, in a two-wave analysis, the sum of the synchronized incident and reflected bar waveforms (which are opposite in sign) is proportional to the sample front stress and represents the conditions at the interface between the incident/reflected bar and the sample. Unfortunately, both the incident and reflected waveforms contain substantial inherent oscillations that, compared to the transmitted waveform, cause uncertainty in the interpretation of stress, especially near the yield point. In addition, these harmonic oscillations are subject to dispersion due to the wave speed dependence of different frequencies that causes asynchronization of the raw overlapped waveforms and, therefore, inaccuracy in the calculation of the front stress.

A dispersion correction analysis has been developed (Follansbee and Frantz, 1983; Frantz et al., 1984; Follansbee, 1985) to account for these changes in phase angle of the primary mode harmonic oscillation of all three strain signals. This analysis results in more accurate and smoother stress-strain curves, especially near the yield point. Finally, a third stress-calculation variation that considers the complete set of three measured bar waveforms, the three-wave analysis, is simply the average of the front and back stress. The three-wave average is calculated as described by Equation 16.

Sample equilibrium can be checked by comparing the one-wave and three-wave (or two-wave) stress-strain response (Follansbee and Frantz, 1983; Gray et al., 1997; Wu and Gorham, 1997). Recent studies have shown that both inertia and wave propagation effects can significantly affect the stress differences across the length of a specimen deformed in a compression SHPB (Gray et al., 1997; Wu and Gorham, 1997).

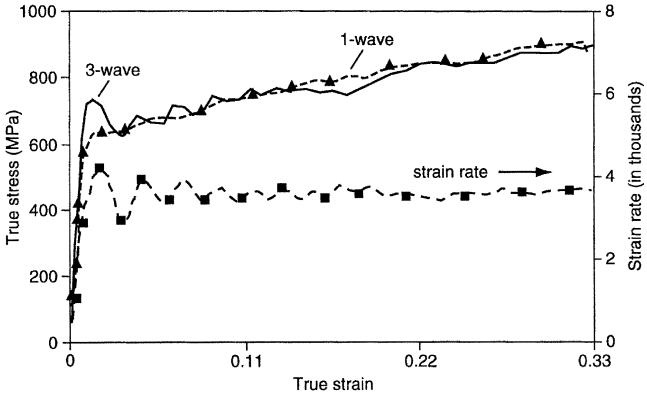

Figure 5. Comparison of stress-strain response of a drawing-sheet steel (DQSK) showing the one- and three-wave stress curves and the strain rate.

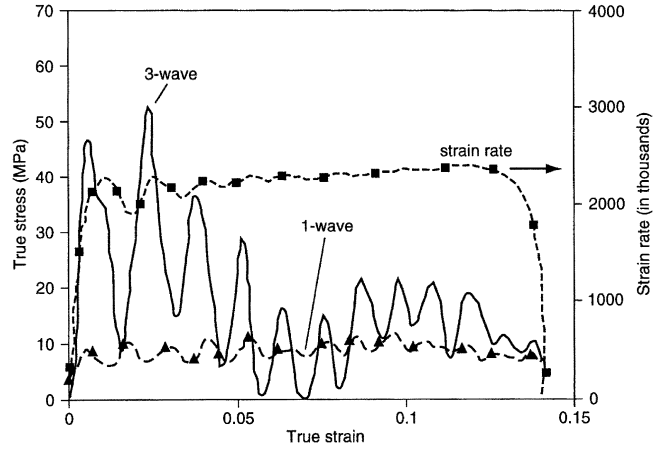

Figure 6. Comparison of room temperature stress-strain response of the polymer Adiprene-L100 (Gray et al., 1997) for a 6.35-mm long sample showing the one- and three-wave stress curves in addition to strain rate.

When the stress state is uniform throughout the sample, the three-wave stress oscillates equally above and below the one-wave stress. Figure 5 shows the one-wave, three-wave, and strain rate data as a function of strain for a SHPB test conducted on a drawing-quality sheet steel. In this illustration, the front and back stress data reductions exhibit very similar response beyond $\sim$0.02 strain, verifying that the sample attained a uniform stress state. This check on the stress equilibrium, when taken with the verification of attaining an essentially constant strain rate throughout the test through a careful balance of striker-bar length, striker-bar velocity, and tip material, demonstrates a high-precision, valid material characterization measurement.

Contrarily, when the stress state is *not* uniform throughout the SHPB sample, the three-wave stress diverges and exceeds the one-wave stress values. Previous Hopkinson bar studies of ceramic materials using this one-wave versus three-wave comparison have shown quite dramatically that a sample is not in stress equilibrium when divergence is observed (Blumenthal and Gray, 1989). In ceramic and cermet materials, this divergence correlates very well with the onset of nonuniform plastic flow and/or premature fracture events.

Similar results have revealed that the slow longitudinal sound speeds typical for some polymeric materials make stress equilibrium during SHPB testing difficult to achieve (Walley et al., 1991; Walley and Field, 1994; Gary et al., 1996). The pronounced difference in the initial one- and three-wave signals for an Adiprene L-100 sample, as shown in Figure 6, can accordingly be viewed as an indication of a sluggish sample ring-up to stress-state equilibrium, compared to the incident wave risetime, and a marginally valid Hopkinson bar test at strains $>5\%$, even though a stable strain rate is indicated throughout the entire test. The data in Figure 6 therefore substantiate the need to examine the technique of using thinner sample aspect ratios when studying the high strain rate constitutive response of low-sound-speed, dispersive materials (Gray et al., 1997; Wu and Gorham, 1997).

Because of the transient effects that are dominant during the ring-up until stress equilibrium is achieved (well over 1% plastic strain in the sample), it is impossible to accurately measure the compressive Young's modulus of materials at high strain rates using the SHPB. The compressive Young's modulus of a material is best measured using ultrasonic techniques.

Increased resolution of the ring-up during SHPB testing of materials with high sound speeds and/or low fracture toughness values can be achieved by directly measuring the strain in the sample via strain gauges bonded directly on the sample (Blumenthal, 1992). Testing of ceramics, cermets, thermoset epoxies, and geological materials requires accurate measurement of the local strains. The difficulty with this technique is that (1) reproducible gauge application on small samples is challenging and labor intensive, and (2) the specimens often deform to strains greater than the gauges can survive (nominally 5% strain) and so can only be used once.

Testing as a Function of Temperature

The derivation of a robust model description of mechanical behavior often requires quantitative knowledge of the coincident influence of temperature variations. Accurate measurement of the high-rate response utilizing a SHPB at temperatures other than ambient, however, presents several technical and scientific challenges. Because the stress and strain as a function of time within the deforming specimen are determined by strain gauge measurements made on the elastic pressure bars, the longitudinal sound speed and elastic modulus of the pressure bars, both of which vary with temperature, are important parameters. The pronounced effect of temperature on the elastic properties of viscoelastic materials, which have been proposed as alternate bar materials to achieve increased stress resolution, has been a chief barrier to their adoption as a means to measure the high-rate response of polymers over a range of temperatures (Gray et al., 1997). In this case, both a rate and temperature-dependent constitutive model for the elastomer pressure bar material itself would be required to reduce SHPB data for the sample of interest.

The combined length of both pressure bars (which can easily exceed 2 m) makes it operationally impossible to heat or cool the entire bar assembly with any uniformity of temperature. Even if this were feasible, it would require a bar material capable of withstanding the high or low temperatures desired as well as the development of new temperature-calibrated strain gauges and robust epoxies to attach them to the bars. Operationally, therefore, the most common techniques for elevated-temperature testing include heating only the sample and perhaps a short section of the pressure bars and then correcting for the temperature-gradient effects on the properties of the pressure bars if they are significant. Researchers have shown that based on an assessment of the temperature gradient, either estimated or measured with a thermocouple, the strain gauge signals can be corrected for the temperature-dependent sound velocity and elastic modulus in the bars (Lindholm and Yeakley, 1968). This procedure has been utilized at temperatures up to 613°C (Lindholm and Yeakley, 1968). The selection of a bar material, such as Inconel, that exhibits only a small variability in its elastic properties up to ~600°C is an alternative that avoids the need for corrections.

An alternate method of performing elevated-temperature SHPB tests that eliminates the need for corrections to the strain gauge data is to heat only the specimen and no part of the bars. This is accomplished by starting with the bars separated from the sample. The sample is heated independently in a specially designed furnace. Just prior to firing the striker bar the pressure bars are automatically brought into contact with the heated sample (Frantz et al., 1984). If the contact time between the sample and the bars is minimized to <200 ms, the specimen temperature and the temperature at the ends of the bars remain approximately constant. This approach, while requiring careful attention to the timing between the movement of the pressure bars and the firing of the striker bar, has been used successfully at temperatures up to 1200°C (Sizek and Gray, 1993).

METHOD AUTOMATION

Acquisition of split-Hopkinson-bar data requires a high degree of automation due to the high-speed nature of the stress loading technique and the need for signal measurement and storage equipment capable of corresponding acquisition speeds. The measurement instrumentation required for a split-Hopkinson pressure bar test includes two strain gauge signal conditioners and a means of recording these signals. The straingauge signal conditioners must have a frequency response of ≥1 MHz to achieve adequate data resolution; units with sampling frequencies as high as 1 GHz are now available. Until recently, oscilloscopes were used almost exclusively to capture and record the strain gauge signal pulses. When using one oscilloscope to capture the strain gauge data, the transmitted wave and integrated reflected wave can be fed to an oscilloscope with *x-y* capability to directly yield the dynamic stress-strain curve for the specimen; the reflected wave may be fed through an operational amplifier to yield a signal directly proportional to the strain in the specimen, but without dispersion correction.

The three wave signals are now often saved using high-speed analog-to-digital recorders or high-speed analog-to-digital data acquisition computer modules that are directly interfaced with a personal computer. Using either platform, it is now possible to digitize the raw data directly and perform the integration numerically. With the improved availability of the digitized data, more robust Hopkinson bar data reduction software is now regularly used by research labs conducting split-Hopkinson-bar testing. This software can be used to adjust the timing between the transmitted and reflected waves to account for the transit time through the specimen as well as calculate the elastic wave dispersion in the measured data.

Strain-gauge signal conditioners range in signal responses and gain factors; all manufacturers offer units of various resolutions and gains. The same is true for the digitizing oscilloscopes used to store strain-gauge data. At this writing, experimenters must write their own software for data handling. The authors use an Ectron Model 778 strain-gauge signals conditioner, which has a variable gain from 1 to 1000 times, and Tektronix TDS 754A four-channel digitizing oscilloscope operating at 500 MHz and 2 GS/s (the four channels allow all three waves to be recorded on a single oscilloscope).

DATA ANALYSIS AND INITIAL INTERPRETATION

If we apply the basic theoretical equations given above (see Principles of the Method), the stress-strain behavior of the specimen can be computed from the measured incident, reflected, and transmitted strain pulses made on the elastic bars. By knowing the timing required for the elastic wave signals to traverse from the specimen to the gauges on the input and output bars, it is possible to synchronize the reflected and transmitted pulses to coincide at the specimen interface. If we integrate Equation 14—remembering that $\varepsilon = \ln(l_0/l_s)$ in compression—where l_0 is the initial length of the specimen, it is possible to calculate $\varepsilon(t)$ and $l_s(t)$ in the specimen. Assuming that the volume of the specimen does not change during the course of deforming the specimen, it is then possible to calculate $A_s(t)$ and therefore $\sigma(t)$ from Equation 14. The average true stress-true strain curve is then produced by removing time as a variable between the stress and strain data.

The one- and three-wave analyses used to calculate average stress (see Principles of the Method) implicitly assume that the strain-time pulses measured at the strain gauges are identical with those at the ends of the bars in contact with the specimen. This assumption is, however, not correct, because the specimen is normally smaller in diameter than the bar such that the bar ends are not uniformly loaded across their diameter and therefore will indent elastically. In addition, as the bars are compressed longitudinally, albeit elastically, they expand radially in response to the applied force, i.e., the Poisson effect. While the exact mathematical descriptions of these effects on the propagation of an elastic pulse through a large elastic rod are very complex, the result is that different frequencies of

pulses induced in the bars disperse with distance traveled in the bar. The result of this dispersion is that the pulse induced in the input bar through the impact of the striker bar does not immediately rise into a steady square-wave impulse of fixed amplitude, but rather rings up. These end effects quickly dampen after the wave has propagated ~10-bar diameters (Follansbee and Frantz, 1983).

The wave propagation behavior thereafter becomes fully described by the equation of motion in an infinite cylindrical solid. The solution of the equation of motion for these boundary conditions was derived independently during the late 19th century by Pochhammer (1876) and Chree (1889). These relations were later specifically applied to address dispersion in the SHPB (Davies, 1948a; Kolsky, 1964; Gorham, 1980; Follansbee and Frantz, 1983). The pressure bars have been determined to vibrate predominantly in a fundamental mode: i.e., while there are an infinite number of potential solutions to the equation of motion according to the vibrational mode, only one frequency appears to dominate in long elastic bars.

This vibration of the bar leads to wave dispersion that can mask resolution of fine details in the stress-strain data of interest, particularly at higher strain rates where the period of the oscillations can be a large fraction of the total strain measured. While this elastic dispersion cannot be eliminated, techniques have been adopted based on the Pochhammer-Chree equation of motion to correct for any additional dispersion that occurs during the wave propagation from the specimen–bar interfaces to the gauge locations (Gorham, 1980; Follansbee and Frantz, 1983).

At any position, z, along the pressure bar, the wave, $f(t)$, may be represented by an infinite cosine Fourier series:

$$f(t) = \frac{A_0}{2} + \sum_{n=1}^{\infty} D_n \cos(n\omega_0 t - \delta_n) \qquad (21)$$

where ω_0 is the frequency of the longest wavelength component ($n = 1$) and δ_n is the phase angle of component $n\omega_0$. The wave dispersion in the pressure bars occurs because higher-frequency components travel more slowly than lower-frequency components and thus lag behind the leading edge of the wave. This dispersion alters the phase angle, δ, such that at a position $z + \Delta z$, the new phase angle can be calculated:

$$\delta(z + \Delta z) = \delta(z) + \frac{n\omega_0 \Delta z}{C_0}\left(\frac{C_0}{C_n} - 1\right) \qquad (22)$$

where C_0 is the longitudinal wave speed in the bar and C_n is the velocity of component $n\omega_0$. The value of C_n depends on the wavelength and on the mode of vibration; in the SHPB case, this is dominated by the fundamental mode (Davies, 1948a). The phase angle at any position along the bar can be calculated using Equation 22 and the wave reconstructed at that new position using Equation 21. Accordingly, the raw stress-versus-strain data calculated using either the one- or three-wave analysis can be dispersion corrected by mathematically moving the wave to a common point on the bar (e.g., the bar–sample interface). This correction removes a large amount of the inherent wave dispersion, yielding smoother final stress-strain curves (Gorham, 1980; Follansbee and Frantz, 1983; Frantz et al., 1984; Gary et al., 1991).

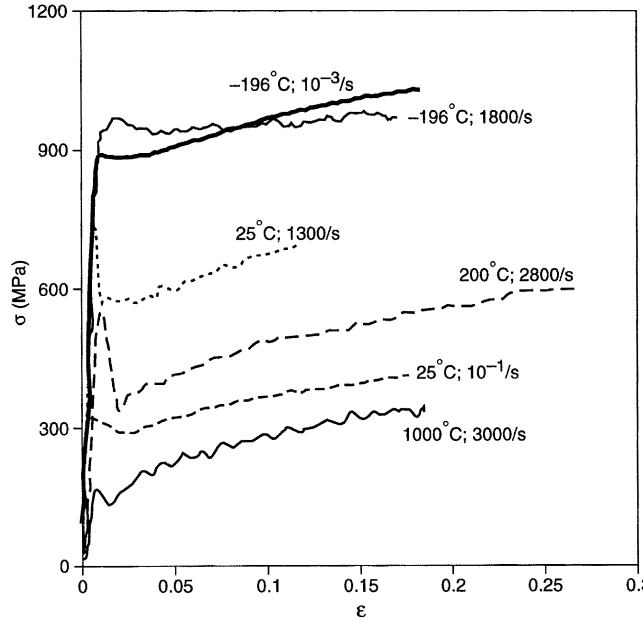

Figure 7. Stress-strain response of high-purity tantalum as a function of strain rate and temperature.

High-rate testing is currently performed on a large number of materials of scientific and engineering interest (Harding, 1983; Follansbee, 1986; Nicholas and Rajendran, 1990; El-Magd et al., 1995; Chen and Gray, 1996). Figures 7 and 8 show the stress-strain responses of high-purity tantalum and copper measured in compression at various strain rates and temperatures. The

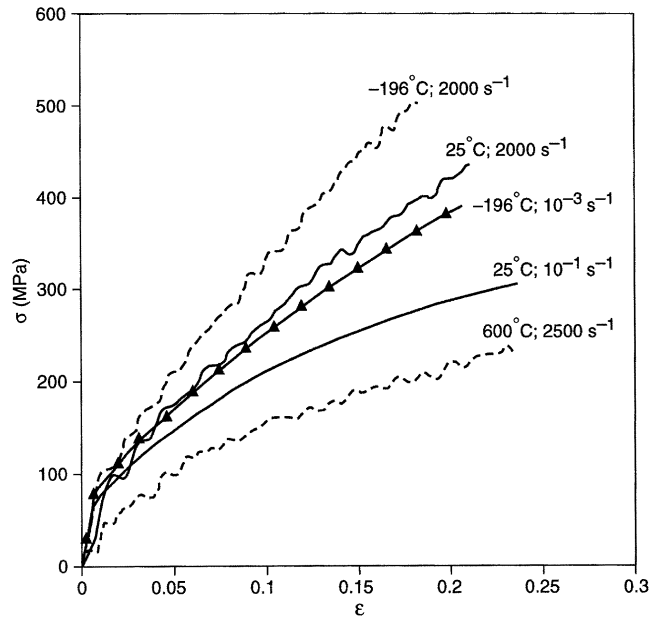

Figure 8. Stress-strain response of oxygen-free high-conductivity (OFHC) copper as a function of strain rate and temperature.

lower-strain-rate tests were performed on a standard screw-driven Instron testing machine using the same specimen geometry as the dynamic tests. All the stress-strain comparisons, as a function of temperature and strain rate, are true values. While the SHPB data at strains below ~1% to 2% are not in stress-state equilibrium, the curves are plotted in their entirety from load inception. Increasing strain rate at ambient temperature, 298 K, is seen to increase the flow stress of tantalum equivalent to a decrease in temperature at a constant strain rate.

The response of Ta is similar to that of other body-centered cubic (bcc) [Fe, W, Mo, Nb] metals and alloys and hexagonal close-packed metals and alloys [Zr, Be, Zn, Ti] (Kocks et al., 1975; Gray, 1991). Contrarily, in this class of metals strain-hardening responses after yielding are nearly invariant as a function of strain rate; i.e., the stress-strain curves are all nearly parallel in slope although offset in their initial yields.

Other materials, including high-purity face-centered cubic (fcc) metals in an annealed condition, such as Cu, Ni, Al, and Ag, exhibit nearly strain-rate-independent yielding behavior while their post-yield strain hardening is strongly rate dependent. The stress-strain behavior of oxygen-free-high-conductivity (OFHC) copper given in Figure 8 is typical of this class of materials. In-depth knowledge of the simultaneous influence of temperature and strain rate is utilized as the basis for advanced materials model development to describe high-strain-rate material response.

In addition to the direct influence of strain rate on stress-strain behavior caused by modification of defect generation and storage processes, high-rate deformation additionally alters the measured mechanical response due to the adiabatic heating accompanying high-rate plastic deformation. While adiabatic heating can be neglected during quasistatic deformation, the effect of adiabatic heating on the measured stress-strain behavior of materials must be considered. To extract an isothermal curve of the material response at high rate, a relationship between temperature and stress must be assumed and the data corrected accordingly. The temperature increase, ΔT, for mechanical tests at strain rates above $500\,s^{-1}$ can be calculated assuming a certain percentage (ψ) of the work of plastic deformation is converted into heat (Taylor and Farren, 1925; Quinney and Tayor, 1937):

$$\Delta T = \frac{\psi}{\rho C_p} \int \sigma(\varepsilon)\delta\varepsilon \qquad (23)$$

where σ and ε are the true stress and strain, ρ is the density, and C_p is the temperature-dependent heat capacity. Adiabatic heating makes a large difference to stress-strain curves measured at high strain rates, particularly at higher strains. Careful consideration of adiabatic effects on overall constitutive response is crucial to accurate material model development.

SAMPLE PREPARATION

Errors due to radial and longitudinal inertia as well as friction effects can be reduced by choosing a sample size that (1) minimizes the areal mismatch between the sample and the bar diameter, and (2) maintains a l/d ratio of 0.5 to 1.0.

For a given bar diameter, the sample diameter is typically chosen to be ~80% of the bar diameter; such a ratio allows ~30% true strain to be imparted into the sample before the sample exceeds the bar diameter. Samples for split-Hopkinson-bar testing, similar to conventional low-rate compression testing, need to be machined such that the two loading faces are flat, parallel to 0.01 mm (0.001 in.) or better, and the sides of the sample are orthogonal to the loading faces. For brittle materials this tolerance must be an order of magnitude greater. Orthogonality, as well as precision machining of parallel flat loading faces, is crucial to attaining uniform elastic loading and thereafter achieving a uniform stress state in the sample.

While most investigators utilizing the split-Hopkinson bar routinely use right-regular cylindrical samples, cubes, as well as other square-sided shapes, can be utilized. Ease of machining on a lathe to achieve accurate and reproducible sample specifications also favors cylindrical samples. The selection of the optimal sample diameter and l/d ratio is dependent on the maximum strain rate desired as well as on the sample size requirement necessary to have specimens sufficiently large to assure measurement of "bulk" properties of the material of interest. Coarse-scaled microstructures or composite materials require larger sample sizes than fine-scaled ones. An approximate rule of thumb is that the specimen diameter needs to be at least 10 times the "representative" microstructural unit size for polycrystalline metals and alloys. Coarse-scaled materials, in particular engineering composites such as concrete (Albertini et al., 1997) or polymeric lay-ups, require careful sample size selection as well as specifically designed split-Hopkinson bars to achieve valid high-strain-rate stress-strain data.

Sample design for split-Hopkinson pressure-bar testing of materials exhibiting low resistance to brittle axial cracking, such as ceramics and cermets and/or composite matrix/reinforcement debonding, require specialized sample designs. The use of "dog-bone" samples, originally designed by Tracey (see Blumenthal, 1992), makes it possible to achieve stable uniaxial stress in ceramics during Hopkinson-bar testing. By suppressing axial cracking, and/or brittle fracture processes in ceramic or cermet samples, due to the larger diameter ends of the samples, valid Hopkinson-bar tests can be achieved.

SPECIMEN MODIFICATION

Following testing in the split-Hopkinson pressure bar, samples can be examined and subsequently analyzed to evaluate the influence of high-strain-rate prestraining on microstructure evolution, stored energy, and damage evolution. This is particularly informative when repeated reloadings are done as a means of increasing the total strain, as discussed below (see Problems, section on friction). For substructure analysis, samples can be cross-sectioned, polished, and etched for examination using

optical metallography or scanning electron microscopy, and/or thinned to electron transparency for high-magnification substructure studies using transmission electron microscopy. Detailed structural studies of this type, as a function of SHPB testing over a range of strain rats and temperatures, are used to provide physical insight into the deformation mechanisms (such as dislocation slip, deformation twinning, and stress-induced phase product) to allow the construction of physically based constitutive materials models. Samples that undergo damage evolution processes, such as intergranular or transgranular cracking and/or ductile void formation (if loaded in tension), during SHPB testing can also be analyzed to quantify damage initiation and evolution processes in materials subjected to high-rate deformation loading paths.

PROBLEMS

In addition to the care needed to assure the achievement of stress equilibrium during SHPB testing, several additional problems can be encountered during experimental investigations studying the mechanical behavior of materials at high rates of loading. These are associated with inertia effects in the test machine, sample constraint due to friction at the points of contact, and issues related to assuring accurate strain gauge measurements on the pressure bars.

Inertia

Even when the specimen has been evaluated to be deforming uniformly, longitudinal and radial inertia due to the rapid particle accelerations imposed during high strain rate testing can influence the measured stress-strain behavior (Follansbee, 1985; Gorham, 1991). The errors due to both longitudinal and radial inertia have been analyzed and corrections have been derived (Davies and Hunter, 1963). This analysis predicts that errors are minimized if the strain rate is held constant or if the term inside the brackets is set to zero by choosing specimen dimensions are selected such that

$$\frac{l_s}{d} = \sqrt{\frac{3\nu_s}{4}} \tag{24}$$

where l_s is the specimen length, d is the diameter, and ν_s is the Poisson ratio.

For a Poisson ratio of 0.33, Equation 24 suggests that the optimum sample l_s/d ratio to minimize errors due to inertia is 0.5. This l_s/d ratio is less than that determined to be the most favorable for the minimization of errors due to friction in ASTM Standard E9, which specifies that $1.5 < l_s/d < 2.0$ (Follansbee, 1985). However, because the total strain in a split-Hopkinson pressure bar test is typically limited to ~25% to reduce the area mismatch between the specimen and the pressure bar, samples with an l_s/d of 0.5 are not expected to introduce any serious errors.

Radial inertia considerations limit the strain rate for which the SHPB technique is valid to $\sim 10^5\,s^{-1}$ for a high-sound-speed material. This is because as the strain rate is increased the specimen size must be decreased accordingly. Eventually the specimen required becomes so small that it no longer reflects bulk material response. Only very fine-grained materials, such as nanocrystalline structured materials with high sound speeds, can be tested with valid results at the very highest strain rates using this technique.

Friction

Friction is an important consideration in determining the validity of all compression testing (Klepaczko and Malinowski, 1978). The optimum l_s/d ratio to minimize friction for a split-Hopkinson pressure-bar compression test specimen is approximately one-half that determined to be most favorable for minimizing errors due to friction for low-rate tests. Lubrication is therefore required at the specimen–pressure bar interfaces.

Early workers studying the SHPB were concerned about longitudinal inertial effects (i.e., how long it takes the forces on the ends of the specimen to become equal), or the ringing-up time. Accordingly, they tested thin wafers of material with a thickness/diameter ratio of 0.1. Such extreme sample-aspect ratios are known to maximize the effect of friction, as the measured yield pressure is related to the material flow stress (Gorham et al., 1984).

Care must therefore be exercised in lubricating samples prior to testing as well as in limiting the strain in a single test to strains less than ~20% to 25%. Repeated reloading of a sample, with intermediate remachining to assure flat and parallel sample loading surfaces, can be used to achieve higher total strains. Repetitive reloading offers the added benefit of minimizing adiabatic heating effects on the measured stress-strain behavior.

The use of an oil-based molybdenum disulfide lubricant has been shown to be effective for room temperature SHPB testing (Follansbee, 1985). For elevated-temperature tests, a thin layer of fine boron nitride powder can be used to lubricate the specimen/pressure bar interfaces. So far, no lubricant has been found that completely eliminates friction for metallic specimens in this geometry, though the frictional stresses can be reduced to ~4% of the metal's shear strength. Friction can, in principle, be measured using annular specimens, the idea being that the higher the friction, the smaller the ratio of the internal to external diameter for a given strain (Gorham et al., 1984; Walley et al., 1997). However, the presence of a layer of lubricant at these interfaces can influence the timing between the waves recorded on the incident and output pressure bars. Consequently, it is important to keep the layer of lubricant on the bar ends as thin as possible. Routine examination of the surface finish and flatness of the pressure-bar loading faces, in addition to checking for any possible cracking or erosion of the bar ends, are also critical to valid SHPB data acquisition.

Strain-Gauge Measurements

Since the stress-strain behavior of the material of interest is deduced from the elastic strain signals in the pressure bars, the details of the conditions controlling the accuracy and reproducibility of the strain gauges are crucial. A number of considerations related to strain-gauge installation and use can affect the elastic strain measurements obtained. Two gauges generally are mounted at diametrically opposite positions on each bar and connected so as to average out most bending strains in the bars, and increase the magnitude of the strain signal measured by a factor of 2. The use of four gauges arranged equidistantly around the bar diameter, comprising a complete Wheatstone strain-gauge bridge, will totally eliminate any bending effects on the strain data. The four-gauge arrangement additionally corrects for any magnetostriction effects (induced voltage in the strain gauges due to stress wave propagation in a ferromagnetic bar material). Utilization of nonmagnetic pressure-bar materials, such as Ti-6Al-4V or Mg, eliminates any potential magnetostriction errors in the strain gauge outputs. In addition to the elimination of bending forces through the use of multiple gauge locations, shielding of the wire leads from the strain gauges to the signal conditioners is important to minimize external noise given the small magnitude of the absolute strain signals and the level of amplification required to boost the signals to the levels required by the data acquisition system.

Finally, bonded strain gauges have a finite time response capability that is linked to the stiffness of the epoxy utilized to bond the gauges to the bars. Using an epoxy that is too compliant can dampen the signals transferred from the bar surface to the strain gauges. Conversely an epoxy that is too stiff and brittle will require frequent replacement. Careful selection, application, and maintenance of the gauges bonded to the SHPB is required to assure accurate bar operation.

FRACTURE TOUGHNESS TESTING METHODS

INTRODUCTION

With increasing use of steel structures such as railroads, bridges and tanks in the nineteenth century, the number of casualties due to the catastrophic failure of such structures also increased, and hence, attention was drawn to the brittle fracture of steels (Parker, 1957; Anderson, 1969). The problem of brittle failure was fully recognized when over 20% of all-welded ships built during World War II developed serious cracks (Rolfe and Barsom, 1977). The weld defects produced a tri-axial stress state that promoted the initiation and propagation of fracture by the cleavage mechanism. The implementation of notch-toughness testing methods (e.g., Charpy V-notch and Izod impact testing; ASTM, 1997a) for identifying the ductile-to-brittle transition temperature was helpful in selection of the low-strength steels used at that time. However, after World War II, new ultra-high-strength steels and aluminum alloys were developed for automobile and aircraft applications, for which the determination of the ductile-to-brittle transition was neither adequate nor relevant. Simultaneously, the fail-safe design, which is a damage-tolerant philosophy, was applied more to load-bearing structures. While the basic ideas leading to fracture mechanics can be traced to A. A. Griffith (Griffith, 1920), the concept of fracture toughness testing based on linear elastic fracture mechanics (LEFM) was developed by Irwin in the 1950s (Irwin, 1948, 1957). In the early 1960s, the American Society for Testing and Materials (ASTM) developed the first draft for plane strain fracture toughness testing. The oil crisis in the 1970s encouraged extensive off-shore drilling and resulted in the development of fracture testing techniques based on elastic-plastic fracture mechanics (Off-Shore Welded Structures, 1982). Presently, fracture toughness testing methods are applied to various types of materials including composites, intermetallics, plastics, and ceramics, as well as metals.

Fracture toughness is a measure of resistance to cracking in notched bodies. In general, during fracture toughness testing, the load-versus-displacement behavior of a pre-cracked specimen is recorded. The load-displacement curve depends on the size and geometry of the specimen as well as the loading mode. In practice, the goal of fracture toughness testing is to measure a single parameter (e.g., similar to yield strength) that is a material property and can be directly used in design. Fracture mechanics is a tool to translate the results of laboratory fracture toughness testing into engineering design. Depending on the material and the size and geometry of the specimen, different parameters can be evaluated. Stress intensity factor, K, is a parameter that describes the stress level as well as the stress distribution ahead of a crack (Westergaard, 1939; Irwin, 1957). Crack driving force, G, is a measure of the elastic energy released per unit thickness of the specimen and per unit length of the crack (Irwin, 1948). When extensive plastic deformation precedes crack initiation, the flow of energy to the crack tip can be evaluated using the J-integral approach (Rice, 1968). The amount of strain at the crack tip, known as crack tip opening displacement (CTOD), δ, is another parameter that can be calculated from the fracture toughness testing results (British Standard Institution, 1979).

To correlate the results of fracture toughness testing with a parameter that represents a material property, a fracture criterion needs to be established. Ideally, fracture toughness should be correlated with the onset of unstable fracture (fast fracture). However, depending on the type of material and the size of the specimen, catastrophic failure may not occur during testing. In these cases, the point of crack initiation can be chosen as a point value or the increase in resistance to cracking as a function of crack length can be evaluated (R-curve analysis).

Fracture toughness testing is a relatively expensive method in comparison to notched impact testing (ASTM, 1997a). However, the latter method provides only a qualitative measure of the toughness of materials, which cannot be used directly in engineering design or modeling of the fracture processes. Presently, many industries, including aerospace, automobile, and shipbuilding, follow codes and specifications that have material fracture toughness requirements. In research, the information obtained by fracture toughness testing in conjunction with fractographic and microstructural characterization techniques has been used for modeling the fracture behavior and developing new fracture-resistant materials.

There are many standard procedures established by ASTM (ASTM Standards, 1997b) where the reader can find the details of fracture toughness testing procedures. The purpose of this unit is to briefly summarize various fracture toughness testing techniques and to provide the basic principles of fracture behavior and fracture mechanics necessary for understanding and selecting the proper testing technique. Emphasis will be placed on macroscopic standard testing techniques for metallic materials. Special techniques for mixed-mode fracture, indentation fracture, crack arrest, creep fracture, and stress corrosion cracking as well as the atomistic concepts will not be discussed here. Furthermore, the discussion is limited to elastically isotropic materials.

There are mechanical testing methods that yield data related to the toughness of a material, but they do not provide an actual toughness value. For example Charpy V-Notch impact testing (ASTM, 1997a) and notched tensile testing (ASTM, 1997l) measure the energy absorbed during fracture and the stress required for fracture, respectively. Such tests may be used for screening materials based on toughness.

To conduct fracture toughness testing, a mechanical testing system, apparatus for measuring and recording load and displacement, as well as fixtures for holding the specimens, are required. The following are the two major companies in the United States that provide all the necessary equipment: Instron Corporation and MTS System Corporation.

PRINCIPLES OF THE METHOD

Fracture toughness is a measure of the resistance of a material to crack extension and is evaluated by loading a

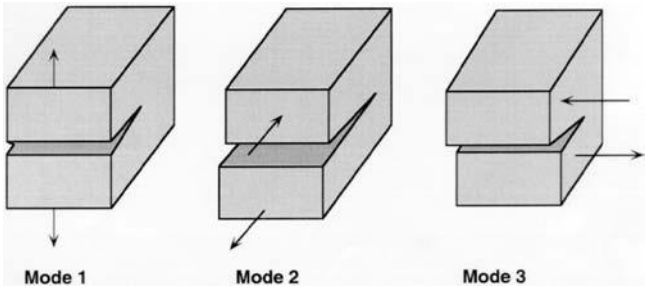

Figure 1. A schematic showing the three modes of loading.

pre-cracked specimen and recording the load-versus-displacement curve. The loading is usually performed under a displacement-controlled condition and, in most cases, is pursued until complete fracture of the specimen. A cracked solid may be loaded in three modes, as shown in Figure 1. While all three loading modes may be experienced during the fracture of a structural component, conventionally only mode 1 is used for fracture toughness testing. The rationale behind this is that almost pure mode 1 can be achieved easily while testing laboratory-size specimens, and furthermore, it represents the most severe condition for promoting brittle fracture without extensive permanent deformation near the crack tip.

When cracked bodies are loaded, very high elastic stresses are developed near the crack tip, as illustrated two-dimensionally in Figure 2A. The high density of line forces near the crack tip represents the development of high stresses. No load lines go through the crack because the atomic bonds are severed and cannot carry the load. Hence, the shaded triangles are not loaded. When the crack propagates, the density of the force lines in the vicinity of the crack increases and the "not-loaded" areas increase as shown in Figure 2B. These two phenomena—the increase in stresses at the crack tip and the release of the elastic energy due to unloading—provide the impetus or drive for crack extension. The level of the stress is evaluated by the stress intensity factor, K, and the rate of elastic energy released per thickness and unit crack extension

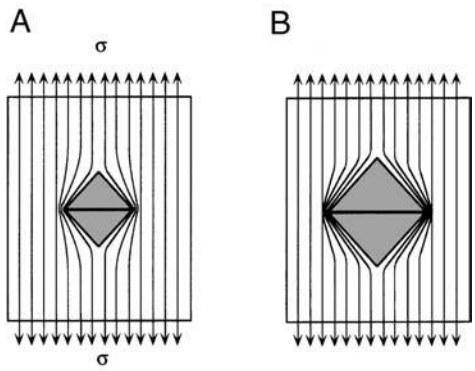

Figure 2. A representation of stress intensification near cracks, demonstrating how the volume of the material that does not carry load increases with an increase in the crack length (**A**) to (**B**). Note that σ is the applied remote stress.

is known as crack driving force, G. These two parameters are used for measuring the fracture toughness of materials.

In most materials, the very high stresses near the crack tip are relaxed by permanent (plastic) deformation. As long as the size of this plastic zone is small relative to the dimensions of the stressed body, the elastic stresses outside the plastic zone control the level and distribution of the stresses inside the plastic zone, and similarly the relationship between elastic energy that would be released upon crack propagation and the applied remote load is modified insignificantly. This condition is known as small-scale yielding and the theoretical treatment of the stresses is referred to as linear elastic fracture mechanics (LEFM). In this regime, K and G are related by (Irwin, 1948, 1957).

$$G = \frac{K^2}{E'} \tag{1}$$

In this equation, $E' = E$ (for plane-stress condition) or $E' = E/(1-\nu^2)$ (for plane-strain condition), where E is Young's modulus and ν is the Poisson's ratio of the material. If the crack extension occurs when the load is beyond the LEFM regime, the single parameter K does not represent the stress level and distribution near the crack tip, and the relationship between G and K fails. This regime is known as elastic-plastic fracture mechanics and the two parameters that have been used to evaluate fracture toughness in this regime are the J-integral, J, and the crack tip opening displacement, δ. Under the small-scale yielding condition, J and δ are related to G by (Rice, 1968; Wells, 1961):

$$G = \frac{K^2}{E'} = J = m\delta\sigma_{\text{flow}} \tag{2}$$

where m varies between 1 to 2 and depends on the plastic constraint at the crack tip (for plane stress, $m = 1$; for plane strain, $m = 2$). σ_{flow} is the flow stress of the material and is usually defined as $\sigma_{\text{flow}} = 1/2(\sigma_{\text{ys}} + \sigma_{\text{UTS}})$, where σ_{ys} and σ_{UTS} are the yield strength and the ultimate tensile strength of the material, respectively.

In the following sections, the load-displacement behaviors of notched specimens are discussed and a brief description of G, K, J, and δ are presented.

Load-Displacement Behaviors

In the absence of plasticity and slow (or stable) crack growth, the load-displacement curve of linear elastic materials is a straight line as depicted in Figure 3. The inverse of the slope of the curve, i.e., Δ/P, is known as the compliance of the specimen. As shown in Figure 3, for a given material and specimen geometry, compliance increases with an increase in the crack length. The nonlinearity in load-displacement curves can arise from two sources: one is the extension of the plasticity across the specimen ligament, and the other is the growth of a stable (or slow) crack. In the latter case, as illustrated in Figure 4, ideally, the displacement returns to zero upon unloading of the sample and the amount of crack extension is related to the decrease in the load-displacement slope (or the

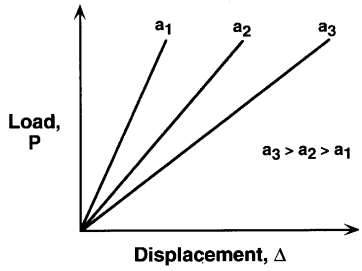

Figure 3. Linear load-displacement curves showing that crack growth results in an increase in the compliance (inverse of the slope of load-displacement curve).

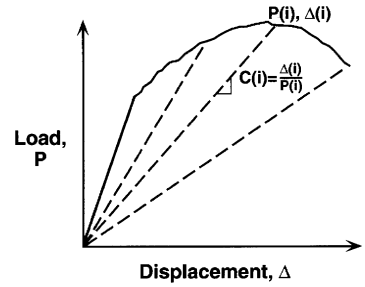

Figure 4. Nonlinearity in load-displacement curve due to slow crack growth. Note that in the absence of plasticity, displacement returns to zero upon unloading.

increase in the compliance). Figure 5 depicts the development of plasticity that leads to the nonlinear load-displacement behavior. As the extent of plastic deformation at the crack tip increases, the deviation from linear behavior becomes more prominent. At net-section yielding, the whole ligament of the specimen is plastically deformed. This load is known as the limit load, P_L, which depends on the yield strength of the material as well as its strain hardening behavior. Further increases in load would cause plastic instability, which is associated with a decrease in load and necking of the ligament.

Crack instability is associated with a drastic increase in the crack velocity, and hence is detected as a sudden decrease in the load. Fast fracture may occur anywhere on the load-displacement curve and can be preceded by plasticity and/or stable crack growth as illustrated in Figure 6. If the unstable crack propagation results in the complete fracture of the specimen, then the load drops to zero. Another phenomenon is crack arrest, which occurs after fast fracture and is characterized as a partial load drop (Figs. 6B and 6C). If the fast fracture develops only a short distance and then arrests, the phenomenon is known as "pop-in" (Fig. 6B).

The competition between fast fracture and plasticity for a given material and specimen geometry depends on many factors including loading rate, sharpness of the notch, and thickness of the specimen. The last parameter controls the stress state at the crack tip. A plane-strain condition is achieved in thick specimens and is associated with the development of high normal stresses (high tri-axial stress state) near the crack tip in the plastic zone (large plastic constraint). Consequently, the probability of brittle fracture, which is a stress-controlled fracture, is enhanced. In thin specimens, the stress state at the crack tip is a plane stress condition which results in a lower crack driving force at a given applied stress level (see discussion of Crack Driving Force, below) and lower levels of stress within the plastic zone. This stress state encourages plasticity and slow crack growth at the crack tip. In addition to the modification of the stress state at the crack tip, an increase in the specimen thickness increases the probability of finding defects that can potentially initiate brittle fracture, and hence the measured toughness will be lowered.

Crack Driving Force, *G*

Fracture mechanics, and hence fracture toughness testing, is based on the idea presented by Griffith on fracture of glass (Griffith, 1920). Griffith states that "if a body

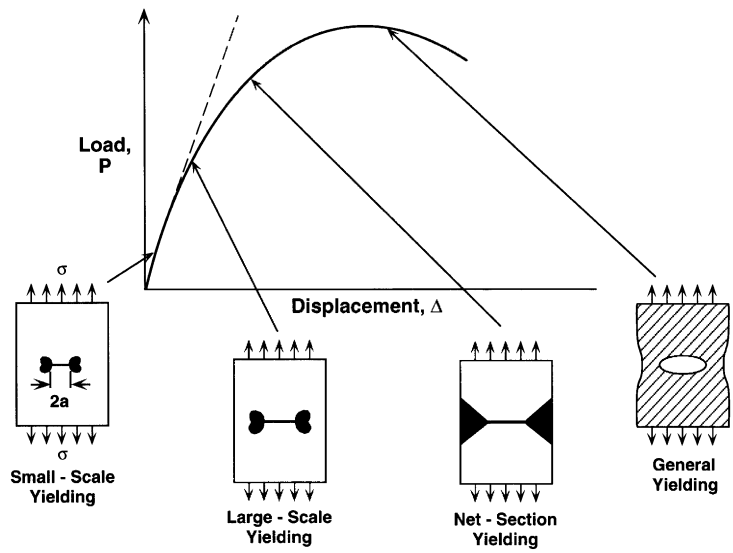

Figure 5. A schematic presenting the development of plasticity in a center-cracked panel. The black and cross-hatched areas represent plastic deformation.

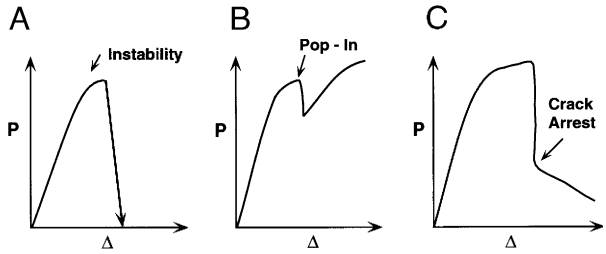

Figure 6. Manifestations of unstable crack growth as a sudden load drop. (**A**) Complete fracture of the specimen. (**B**) Development of a small unstable crack (pop-in phenomenon). (**C**) Arrest of an unstable crack.

having linear stress-strain relationships be deformed from the unstrained state to equilibrium by given (constant) surface forces, the potential energy of the latter is diminished by an amount equal to twice the surface energy. It follows that the net reduction in the potential energy is equal to the strain energy, and hence the total decrease in potential energy due to the formation of crack is equal to the increase in strain energy less the decrease in surface energy." Consider an infinite plate of unit thickness made of an homogeneous isotropic material loaded uniformly in tension by stress σ (refer to Fig. 2). The development of a through-thickness sharp central crack of length $2a$ is accompanied by an increase in energy equivalent to twice of $2a\gamma$ (note that two surfaces are produced), where γ is the surface energy, and by a decrease in energy due to a reduction in strain energy (unloading of the triangles in Fig. 2), which is given by $\sigma^2\pi a^2/E'$. The total change in the potential energy (ΔU) of the system due to the presence of the crack is given by

$$\Delta U = \frac{\sigma^2\pi a^2}{E'} - 4a\gamma \tag{3}$$

Note that the work done on the system is considered negative and the energy released by the system is taken as positive. The crack will extend in an unstable manner when:

$$\frac{\partial(\Delta U)}{\partial a} = 0 \quad \text{or} \quad \frac{\sigma^2\pi a}{E'} = 2\gamma \tag{4}$$

Equation 4 shows that whenever the elastic energy released per unit length of the crack, $G = \sigma^2\pi a/E'$ becomes equal or larger than the resistance to fracture, $R = 2\gamma$, the crack will propagate catastrophically. Since γ is a material property, the critical elastic energy release rate, $G_C = 2\gamma$ will also be a material property, and hence it can be used to represent the toughness of the material. G has units of energy/(length)^2 and can be interpreted as force per unit length of the crack. Except for a few intrinsically brittle materials (e.g., glasses, silicon, and alumina) plastic deformation always precedes propagation of fracture from existing cracks. Irwin and Orowan (Irwin, 1948; Orowan, 1955) modified the Griffith criterion for the case of elastic-plastic materials by adding a plastic term, γ_P, to the surface energy γ. The γ_P term is representative of the amount of plastic deformation that occurs at the crack tip before the crack can be extended. In this case the critical elastic energy release rate is given as:

$$G_c = 2(\gamma_P + \gamma) \tag{5}$$

It should be noted that although γ_P is much larger than γ, the former value is a function of the latter value (McMahon and Vietek, 1979). However, the plastic energy term is a material property only under the small-scale-yielding condition. Therefore, as will be discussed later, there are restrictions on the size of the fracture toughness testing specimens to ensure the validity of a test.

Other mechanisms besides plastic deformation can dissipate energy within the volume near the crack tip (usually referred to as the process zone; Ritchie, 1988) including microcracking, phase transformation, and bridging by second-phase particles, whiskers, or fibers. The dissipative processes shield the crack tip from the remote applied loads. The shielding results in an increasing crack resistance force with crack extension, known as R-curve behavior. In this case the instability criterion is defined as the point where $G = R$ and $\partial G/\partial a = \partial R/\partial a$, as depicted in Figure 7.

For finite-size specimens the value of G depends on the specimen geometry, and it can be shown to be related to the change in the compliance of the sample as (Broek, 1982).

$$G = \left(\frac{P^2}{2B}\right)\left(\frac{dC}{da}\right)_a, \qquad \sigma = \frac{P}{WB} \tag{6}$$

In this relationship, P is the applied load, B and W are the thickness and the width of the specimen, respectively, and C is the compliance of the specimen. Compliance increases with the crack length nonlinearly, and hence dC/da is also dependent on the crack length.

Stress Intensity Factor, *K*

The stress field in the vicinity of the crack tip for isotropic homogeneous materials is given as (Paris and Sih, 1965).

$$\sigma_{ij} = \left\{\frac{K}{(2\pi r)^{1/2}}\right\} f_{ij}(\theta) \tag{7}$$

where r is the radial distance from the crack tip and the function $f_{ij}(\theta)$ represents the variation of the stress

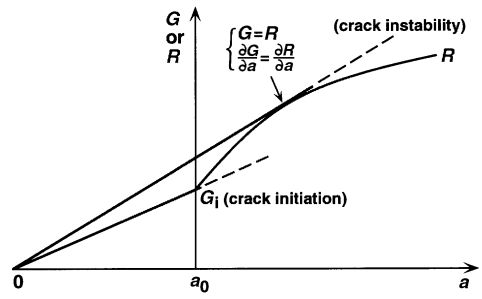

Figure 7. The R-curve behavior.

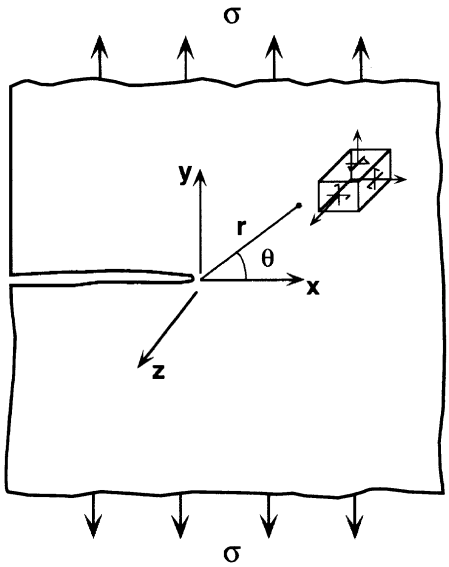

Figure 8. General mode 1 problem.

components with angle θ as illustrated in Figure 8. Each stress component is proportional to a single parameter, K, known as stress intensity factor. Values of σ_{ij} for the three loading modes, as well as the displacements, are given in Appendix A. Equation 7 is valid only for sharp cracks, and therefore ASTM standards for fracture toughness testing require that the fracture specimens have a sharp crack tip.

The K-value depends on the remote uniform applied stress, σ, and the crack length, a, as well as the specimen or component geometry. Several methods, including stress functions and numerical analysis, have been used to calculate K-values for different geometries. Many solutions can be found in Sih (1973). For an infinite plate containing a central through thickness crack of length $2a$, the stress intensity factor in mode 1 is given as:

$$K_1 = \sigma(\pi a)^{1/2} \tag{8}$$

In general, K_1 can be written as:

$$K_1 = Y\sigma a^{1/2} \tag{9}$$

where the function Y depends on the a/W ratio and is known for specific specimen geometries. K has units of force/(length)$^{3/2}$ or stress. $\sqrt{\text{length}}$, and is usually expressed in Ksi$\sqrt{\text{in}}$ or MPa$\sqrt{\text{m}}$.

The size of the plastic zone developed at a crack tip has been related to the applied crack using different approaches (Knott, 1973). In general, the plastic zone size, r_P, is given by

$$r_P = \alpha\left(\frac{K}{\sigma_{ys}}\right)^2 f(\theta) \tag{10}$$

where $f(\theta)$ is the function in Equation 7 and α depends on the stress state at the crack tip, the sharpness of the crack tip, and the strain-hardening rate of the material. The plane stress condition and a blunted crack tip promote larger plastic zone sizes. Within the small-scale yielding regime, $\alpha = 1/6\pi = 0.053$ for the plane strain condition and $\alpha = 1/\pi = 0.318$ for plane stress condition at $\theta = 0[f(\theta) = 1]$ in mode 1.

Since K and G are related in the LEFM regime, when G reaches the critical value at the point of crack instability, so does the $K(K_C = [G_C E']^{1/2})$. The K-value is also used for evaluation of slow crack initiation and propagation in thin sheets under the small-scale-yielding condition. The ASTM standards based on the stress intensity factor concept are E-399 (ASTM, 1997c), E-561 (ASTM, 1997d), E-812 (ASTM, 1997e,f), E-992 (ASTM, 1997g), E-1304 (ASTM, 1997h), and D-5045 (ASTM, 1997i).

J-Integral

Based on Eshelby's ideas (Eshelby, 1974), Rice (1968) introduced an integral, known as the J-integral, which bypasses the boundary-value problems associated with evaluating the stress (or strain) concentrations. This method is particularly useful in evaluating materials that show nonlinear load-displacement behavior. The integral J is defined as:

$$J = \int_\Gamma \{W\,dy - \mathbf{T}(\partial\mathbf{u}/\partial x)\,ds\} \tag{11}$$

where Γ is a curve surrounding the notch, W is the loading work per unit volume or strain energy density ($W = \int \sigma_{ij}\,d\varepsilon_{ij}$, for elastic bodies), $\mathbf{T}$ is the surface traction vector, $\mathbf{u}$ is the displacement vector, ds is an arc element along the curve, and x and y are the coordinates. This integral is independent of the path for elastic materials (linear or nonlinear) and therefore, its value away from the crack, which can be evaluated easily, also represents the value of the integral close to the crack tip. For linear elastic materials it can be shown that $J = G$. As long as unloading (slow crack growth) does not occur, plasticity can be dealt with as a nonlinear elastic behavior. When the crack extends upon loading, parts of the plastic zone also unload. This creates a closure effect which adds to the J-value needed to continue crack growth. Consequently, dJ/da has a positive value, but it decreases with crack extension. Begley and Landes (1972) demonstrated that J can be computed from the area under the load displacement curve. For a deeply notched specimen in which plasticity is limited to the ligament ahead of the crack, the J-integral can be calculated from (Turner, 1979).

$$\begin{aligned} J &= J_e + J_P = (\eta_e U_e/Bb) + (\eta_P U_P/Bb) \\ &= K^2/E' + (\eta_P U_P/Bb) \end{aligned} \tag{12}$$

where J_e and J_P are the elastic and plastic components of J, respectively, U_e and U_P are the areas under the elastic and plastic components of the load-displacement curve, respectively (see Fig. 9), $b = W - a$ is the ligament size, and η_e and η_P depend on the specimen geometry and size. J-integral is used for evaluating crack instability as well as crack initiation and crack propagation in materials.

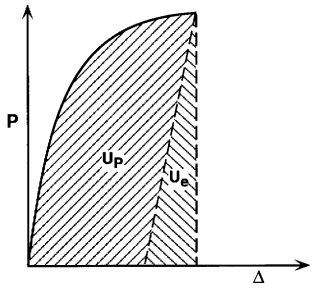

Figure 9. The division of the area under load-displacement curve to elastic, U_e, and plastic, U_p, components.

Following the ASTM nomenclature, J_{IC} refers to the toughness of materials near the onset of stable crack growth, J_C is the fracture toughness of materials at the point of crack instability with no prior slow crack extension, and J_u is defined as fracture toughness of materials at the point of crack instability with extensive prior slow crack growth. The E813 (ASTM, 1997e,f) and E1737 (ASTM, 1997j) are two ASTM standards for measuring the fracture behavior of materials under plane strain condition using J-integral.

Crack Tip Opening Displacement (CTOD), δ

The occurrence of plasticity at the tip of a sharp crack results in the blunting of the crack tip as shown in Figure 10. Within the LEFM regime, the CTOD is related to K and G according to Equation 2. In the case of large-scale deformation at the crack tip, the CTOD can be calculated from its simple geometrical relationship with the plastic component of the mouth opening displacement V_P, as illustrated in Figure 11. During CTOD testing usually the mouth opening displacement is recorded instead of the load line displacement. The CTOD is given by (British Standard Institution, 1979):

$$\delta = \delta_e + \delta_P = K^2/m\sigma_{flow}E + [r_p(W-a)V_P]/[r_p(W-a)+a+Z] \quad (13)$$

where δ_e and δ_P are the elastic and plastic components of the CTOD, respectively, r_p is the rotation factor, and Z is

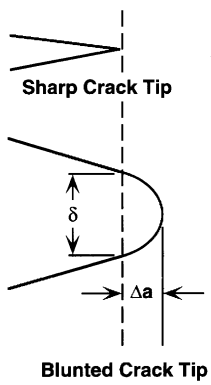

Figure 10. A schematic showing the blunting process and the development of the crack tip opening displacement, δ. (Top) Sharp crack tip. (Bottom) Blunted crack tip.

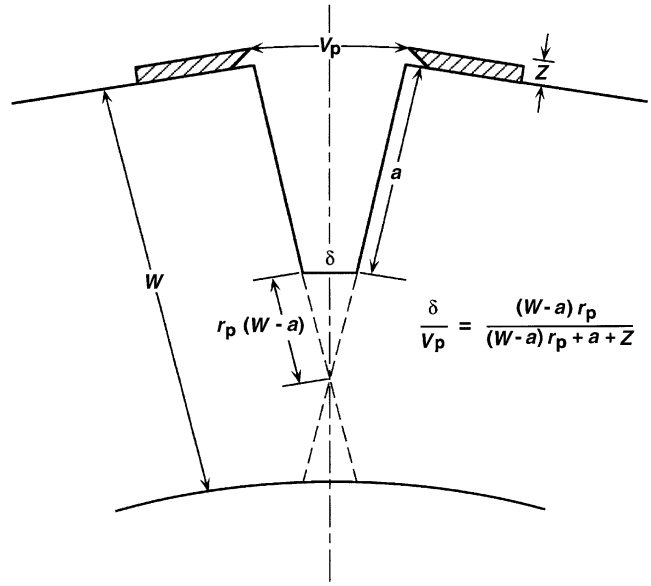

Figure 11. A geometrical representation of the relationship between the crack tip opening displacement, δ, and the plastic component of the mouth opening displacement, V_p.

the knife-edge thickness for cases where knife edges are used for mounting the clip gauge. The rotational factor changes slightly with CTOD and specimen geometry and has a value between 0.4 to 0.5. The CTOD can be evaluated at (1) the onset of stable crack growth, δ_i, (2) the onset of unstable fracture with no prior slow crack growth, δ_C, (3) the onset of unstable fracture with extensive prior slow crack extension, δ_u, and (4) the maximum load, δ_m. The E-1290 ASTM standard (ASTM, 1997k) is the standard used in the U.S. for evaluating the toughness of metallic materials by the CTOD method.

PRACTICAL ASPECTS OF THE METHOD

The most important practical aspects of fracture toughness testing are the preparation of the specimen and the instrumentation for measuring and recording the load displacement curve. Techniques for monitoring crack length extension during loading become important in cases where it is desirable to establish the J-R curve behavior. For specimen preparation, see Sample Preparation.

Apparatus for Measuring and Recording Load-Displacement Curves

To conduct fracture toughness testing, a stiff mechanical testing system capable of applying constant displacement rates, an apparatus for measuring and recording load and displacement, and fixtures for holding the specimens are required.

The mechanical testing system can be screw- or hydraulic-driven. The unloading of the test machine upon specimen fracture releases elastic energy, which adds to the crack-driving force. Therefore, it is very important for the compliance of the system to be very small compared

to the specimen's compliance. Similarly, the fixture used for holding the specimens should be bulky enough and made of a stiff material such as steel, so that the elastic deformation of the fixture does not contribute to the onset of the unstable fracture. For fatigue precracking of the metallic specimens, the testing system should be capable of operating under load control, and it should be capable of applying cyclic load-time functions (e.g., sinusoidal or square).

The load-measuring apparatus consists of a load cell, an amplifier, and a signal conditioner to amplify, balance, and calibrate the load signal. The load cell capacity and the full-scale range should be selected based on a guessed fracture load. The displacement is usually measured by attaching a clip gauge to the crack mouth opening of the specimen using a pair of knife edges (see Fig. 11), which can be machined with the specimen or can be attached to it with screw. In the case of compact tension (CT) specimens, the crack mouth opening is usually measured along the load line, and therefore represents the load-line displacement. For bend specimens, the load-line displacement can either be calculated from the mouth-opening displacement (Lin et al., 1982) or can be measured directly by placing an extensometer on the mid-span point. The load-displacement curve can be recorded using an analog *x-y* plotter or digitally using a computer via an A/D (analog/digital) convertor. In more recent models of mechanical testing systems the signal outputs are digital, and data acquisition as well as system control is performed using a computer. In the case of *J-R* curve analysis a very high resolution of data acquisition (16-bit or higher) is required.

Crack Extension Measurement

In the cases where one wants to establish the *J-R* curve (or δ-R curve), e.g., for ductile materials and composites, it is necessary to separate the contributions of plasticity and slow crack growth to the nonlinearity of the load-displacement curve. Therefore, the extent of the crack growth at several points on the load-displacement curve should be determined. This task can be achieved either by using multiple specimens or by detecting the crack length periodically during the loading of a single specimen.

The multiple-specimen technique involves loading similar specimens to various displacement levels and unloading them. In order to measure the crack length, the tip of the crack needs to be marked such that after complete fracture of the specimen, the tip can be recognized. Various methods can be used for marking the crack tip, including: (1) tinting the crack by heating metallic samples to elevated temperatures and fracturing the sample at room temperature, (2) fracturing samples at a low temperature where fracture proceeds by the cleavage mechanism and hence will be distinguishable from the slow crack (applicable to materials that can be cleaved), or (3) extending the crack further by cyclic loading of the specimen. After the complete fracture of a specimen, the extent of the slow crack growth can be measured using an optical or a scanning electron microscope (SEM). Because of the plane stress condition on the sides of the specimen, the front of slow cracks is usually not straight and has a thumb-nail shape. Therefore, crack length should be measured at many points on the crack front and an average should be used in calculating the toughness. The ASTM standards impose limitations on the crack length variation along the thickness of the specimen. These limitations guarantee the repeatability of the measurement, and hence the validity of the equations used for calculating the toughness of the material. In order to achieve a straight crack front, side grooving of the specimens is usually recommended.

The crack growth can be monitored in a single specimen using the unloading compliance technique or the electric potential drop technique (ASTM, 1997j). The unloading compliance technique involves periodic unloading of the specimen at various points on the load displacement curve. As was mentioned previously, the compliance of a specimen is dependent on its crack length. The a/W ratio can be expressed as a function of the product $E'BC$ for a given geometry (see Appendix B for functions for SENB and CT specimens). Since the change in crack length is usually very small, the load and displacement during unloading has to be measured with a very high resolution in order to accurately evaluate the change in the compliance. Presently, there are software packages available in conjunction with computer-controlled testing systems that allow unloading and measuring of the crack length via the evaluation of the slope of the load-displacement curve upon unloading. The electrical potential drop is applicable only to electrically conductive materials; however, it can provide many more data points than the elastic unloading compliance method. This technique involves applying a DC current to the specimen and measuring the potential drop across the crack plane. This difference in voltage depends on the geometry as well as the crack length of the specimen. The basic components needed are a constant current power supply, an amplifier, a precise voltmeter, and a recording device. Closed form solutions that relate the potential drop to the crack length are available for SENB and CT specimens. Details of this technique can be found in ASTM (1997j).

DATA ANALYSIS AND INITIAL INTERPRETATION

Load displacement curves obtained in mode 1 depend on the material as well as the specimen geometry and size. In order to analyze them, the elastic modulus (Young's modulus) and tensile (or compression) properties (yield strength and strain hardening behavior) of the material, for the temperature and loading rate of the test, should be known. The fracture behavior and the associated load-displacement response of the material may fall into three general categories.

Type A

Unstable fracture occurs with no, or an insignificant amount of, slow crack growth preceding it. Within this category the unstable fracture may occur on any point on the load displacement curve shown in Figure 5. If nonlinearity is observed in the load-displacement curve, its onset should correlate with the limit load of the specimen.

For many materials, the morphology and fracture markings of the slow crack growth are distinctly different from the unstable fracture. Therefore, microscopic observations using optical microscopy (see OPTICAL MICROSCOPY and REFLECTED-LIGHT OPTICAL MICROSCOPY) or scanning electron microscopy (see SCANNING ELECTRON MICROSCOPY) can assist in detecting the extent of the slow crack growth. Fracture load, P_f, is selected as the point of crack instability as shown in Figure 6. The K-value at this point can be calculated from a knowledge of load, crack length, and specimen geometry (see Appendix B for calculation of K for SENB and CT specimens). If fracture occurs within the linear region of the load-displacement curve and the specimen dimensions and the precracking procedure follow the ASTM E-399 standard (ASTM, 1997c), then the K-value can be qualified as the plane-strain fracture toughness, K_{IC}. As mentioned previously, these qualifications ensure that fracture occurs under contained small-scale yielding and plane strain conditions, and hence the toughness value is independent of the specimen geometry and size. Figure 12 presents an actual load-displacement curve for a SENB specimen of a structural steel (A36 steel) tested at -105°C. Note that the curve is almost linear; however, the specimen thickness and width do not satisfy the ASTM requirements for small scale yielding and plane-strain conditions (Equation 15).

If the load displacement curve shows nonlinearity, the J_C- and δ_C-values can be calculated from Equations 12 and 13, respectively. An equivalent K_C-value can be calculated from the J_C-value using the relationship given in Equation 2. These toughness values are usually referred to as the apparent fracture toughness, and it is understood that they depend on the specimen dimensions.

Type B

In this category the stable crack is initiated within the small-scale yielding regime, and hence the onset of nonlinearity in the load-displacement curve occurs at a load much smaller than the limit load of the specimen. In some materials the slow crack growth may lead to crack instability; otherwise the sample is usually unloaded after the attainment of a maximum in the load. The latter behavior is usually observed in relatively thin sheet materials. If fast fracture happens immediately after a short crack extension, plane strain fracture toughness may be calculated from the results. Figure 13 demonstrates the three possible scenarios. The ASTM E-399 standard (ASTM, 1997c) suggests that a line with a slope equal to 95% of the linear portion of the curve be drawn. The intersection of this point with the load displacement curve is designated as P_5, and represents the point at which the crack has grown such that the compliance is increased by 5%. If this load is less than the maximum load (load at the point of unstable fracture), then P_5 should be selected for the calculation of K (type I). If the instability appears as a pop-in (type II) then the load at this point is used for calculating K. If P_5 is past the point of instability (type III), then the maximum load is obviously the fracture load. The ASTM E-399 standard requires the P_{max}/P_5 to be equal or less than 1.1 in order for the K-value to qualify as the

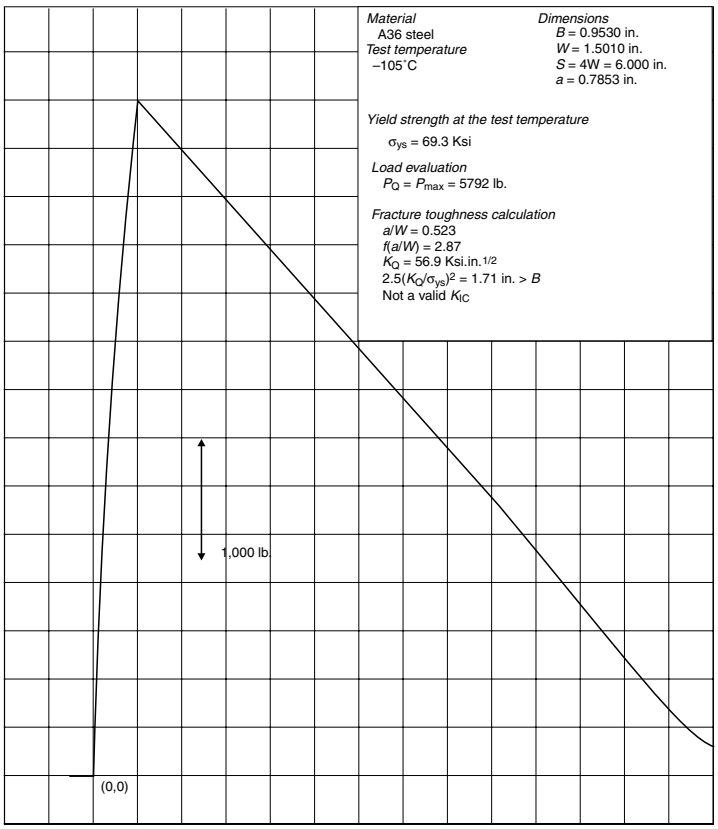

Figure 12. Actual load versus mouth-opening displacement curve obtained from testing a SENB specimen of an A36 steel at -105°C.

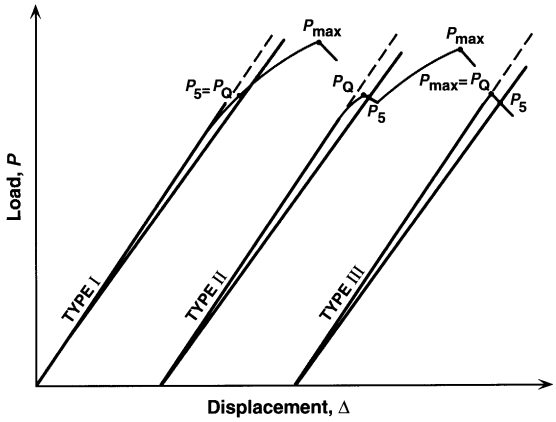

Figure 13. The three types of load-displacement behavior considered in the ASTM E-399 standard for calculating the plane-strain fracture toughness, K_{IC}.

plane strain fracture toughness. This requirement ensures that the extent of the slow crack growth prior to crack instability is insignificant. If this requirement is not fulfilled, the fracture toughness, K_C, is considered to be an apparent fracture toughness. Similar to type A behavior, J_C and δ_C can be calculated from the K_C-value. Note that while for type A behavior the K_C-value is calculated from the measured J_C-value, in type B behavior the J_C-value should be calculated from the measured K_C-value. Figure 14 presents an actual load-displacement curve for a SENB specimen of an ultrahigh strength steel (quenched and tempered 4150 steel) tested at room temperature. In contrast to the A36 steel (see Fig. 12), this material has a very high yield strength and slow crack growth occurs easily in it. Therefore, the load-displacement curve becomes nonlinear within the small-scale yielding regime. As demonstrated by the calculations shown on Figure 14, a valid K_{IC}-value could be calculated based on the ASTM requirements.

If fast fracture is not observed upon loading of the specimen, the fracture behavior can be analyzed using the *K-R* curve method. With reference to Figure 4, at each point, $P_{(i)}$ and $\Delta_{(i)}$, the compliance $C_{(i)}$ and the stress intensity factor $K_{(i)}$ can be calculated. The average crack length at each point, $a_{(i)}$, is estimated from the relationship between crack length and compliance for a given material and geometry (see Appendix B). The accuracy of the calculation can be evaluated by comparing the initial (a_0) and the unloading point (a_u) (or the point of the onset of the fast fracture) crack lengths, with the lengths measured directly on the fracture surface. The crack length used for the calculation of $K_{(i)}$ can be corrected for crack advancement due to plasticity by adding the plastic zone size (see Equation 10) to the crack length (ASTM, 1997d). This crack length is known as the effective crack length. The

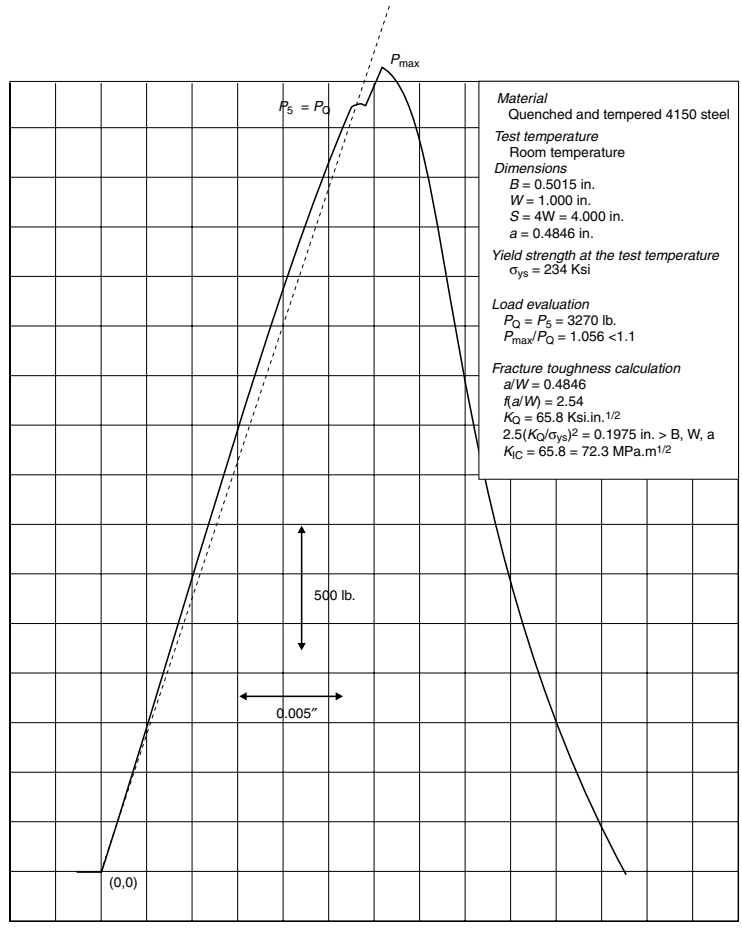

Figure 14. Actual load versus mouth-opening displacement curve obtained from testing a SENB specimen of a quenched and tempered 4150 steel at room temperature.

calculated $K_{(i)}$-values are plotted as a function of crack growth, $\Delta a = a_{(i)} - a_0$. As long as the crack propagates under small-scale yielding, J- or G-values can also be calculated from the K values using Equation 2, and hence, the J-R curve (or G-R curve), can be constructed. In the absence of fast fracture, the toughness at the instability point, K_C, may be found as demonstrated schematically in Figure 7. It should be noted that the applied G usually does not vary linearly with the crack length. Another parameter that can be calculated from the K-R curve (or J-R curve) is the toughness at the point of slow crack initiation. Since the exact point of crack initiation may be difficult to identify, an offset method, similar to the determination of the yield strength during tensile testing, is usually used. For example, an offset line at 0.2-mm crack growth can be chosen as the point of crack initiation. If the specimen geometry is such that the crack grows under the plane strain condition and the requirements set forth by the ASTM E-813 standard (ASTM, 1997e,f,) are met, then the fracture toughness value is reported as J_{IC}. This value, similar to K_{IC}, is believed to be a material property and independent of the specimen geometry and dimensions.

Type C

In many cases both plasticity and slow crack growth contribute to the non-linearity of the load-displacement curve. Consequently, it cannot be assumed that the unloading path would extend to the origin. Therefore, it is necessary to physically measure the crack length on various points on the load-displacement curve as was described in the section on crack extension measurement techniques. The best method for evaluation of the toughness for this type of behavior is the J-integral approach. At a point $[P_{(i)},\Delta_{(i)}]$, the crack length, $a_{(i)}$, is measured. From $a_{(i)}$ and $P_{(i)}$ the $K_{(i)}$ value is calculated. The $J_{p(i)}$ is calculated from the relationships given in Appendix B for single-edge notched bend (SENB) and compact tension (CT) specimens, and the total J is obtained using Equation 13. The J-R curve is established by plotting J as a function of crack extension. Similar to type B, the crack initiation point is established by an offset method. The fulfillment of ASTM E-1737 standard requirements (ASTM, 1997j) leads to the calculation of J_{IC}, which is a measure of fracture toughness at the point of crack initiation. The slope of the J-R curve, dJ/da, is representative of the resistance of the material to crack extension, and has been used to define a parameter called the tearing modulus, which is related to the tearing instability in materials exhibiting type C behavior (Paris et al., 1979).

Fracture, like all instability phenomena, is probabilistic in nature. Another characteristic of fracture is that it propagates discontinuously, i.e., fracture occurs as isolated microcracks that eventually join each other. Material processing defects, microstructure, and measurement inaccuracies contribute to the scatter in toughness data. Processing flaws—e.g., voids in sintered ceramics or solidification defects in cast or welded metallic components, can promote unstable fracture. Within the microstructure of a material, there are features that act as microcrack initiation sites. These features are usually the weakest component of the microstructure, for example, grain boundaries in ceramics, second phases in metallic alloys, or fibers in composites. In semibrittle materials plasticity precedes fracture. The inhomogenity in plastic deformation may result in formation of deformation bands, which locally raise the stresses high enough for initiation of brittle fracture (Ebrahimi and Shrivastava, 1998). In materials where unstable fracture occurs after some slow crack growth, the distribution of the stable microcracks at the crack tip influences the probability of unstable fracture (Ebrahimi and Seo, 1996). As mentioned previously, specimen dimensions affect the stress distribution at the crack tip, and consequently the toughness. Following the stringent requirements of the ASTM standards reduces the toughness variation but does not completely eliminate the scatter (Wallin, 1984; Ebrahimi and Ali, 1988). The scatter is particularly large near the ductile-to-brittle transition temperature of materials (Ebrahimi, 1988).

The number of specimens needed for toughness evaluation depends on the type of the material. Brittle materials, such as ceramics, intermetallics, and glasses show a wide scatter in data and require a large number of specimens ($\sim$10) per condition. Usually the Weibull distribution function (Weiss, 1971) is used to evaluate the variation in toughness of brittle materials. Three specimens per condition suffice for evaluation of fracture toughness of less brittle materials such as steels.

SAMPLE PREPARATION

The choice of geometry and size of the specimen depends on the availability of the material form (e.g., plate, tube, disc, or rod), toughness level (the tougher the material the larger the specimen size required to guarantee plane-strain and/or small-scale-yielding conditions), and the desired information to be extracted from the test (e.g., plane strain fracture toughness or R-curve behavior). Theoretically, one can use any notched specimen geometry as long as the compliance of the sample (or the Y function in Equation 9) as a function of crack length is known. Establishing this relationship requires loading of many specimens of the same size with different crack lengths from a material of known elastic modulus. However, these functions have been accurately established for many geometries (Sih, 1973). Figure 15 presents the two most widely used specimen geometries, single edge-notched bend (SENB) and CT specimens. The SENB specimen can be loaded in three points or in four points. The latter loading mode creates less constraint at the crack tip and is suggested for relatively brittle materials. The SENB specimens are easier to machine than the CT specimens. However, the latter specimens are more suitable for determination of the R-curve behavior. Other common specimen geometries include wedge-loaded compact tension, disc-shaped compact tension, arc-shaped tension, double-notched tensile, double-cantilever beam (tapered and straight) specimens, and center-cracked panels.

The specimen thickness and crack length size limitations are based on achieving contained small-scale yielding and plane-strain conditions at the crack tip. In many

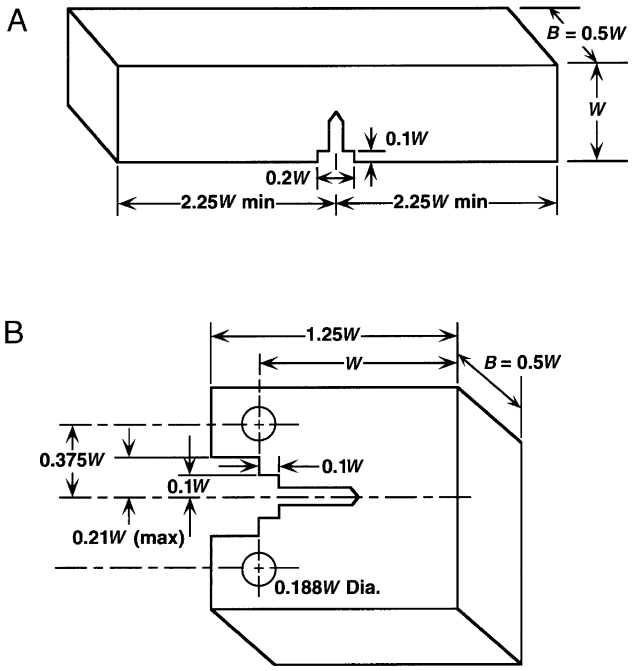

Figure 15. Standard (**A**) single-edge notch bend, SENB, and (**B**) compact tension, CT, specimens.

cases the size of the available material dictates the type of fracture toughness evaluation that can be performed. In order for the results obtained by plane strain fracture toughness testing to be valid according to the ASTM E-399 standard (ASTM, 1997c), the following requirement should be satisfied:

$$a \text{ and } B \geq 2.5(K_{IC}/\sigma_{ys})^2 \qquad (14)$$

For low-strength and tough materials, very large samples are needed to satisfy the above requirement. Usually, if the thickness is smaller than the above requirement, the load-displacement curve shows nonlinearity. In this case the toughness can be evaluated using J-integral or CTOD concepts.

The notch length, mouth opening, and shape should be carefully chosen, particularly for materials that may show extensive permanent deformation at the crack tip prior to crack extension. For example, short and wide notches may lead to the extension of plastic deformation to the surface of the specimen. According to the ASTM standards the a/W ratio is usually required to be within 0.45 to 0.55 (up to 0.7 for J-integral testing). The notch front can be straight through or have a chevron form. The latter is suitable for metallic materials in which it is difficult to initiate fatigue precracks. The loading direction as well as the position of the notch becomes important in anisotropic materials. Many processing methods, such as casting and forming, create directionality in the microstructure; therefore, the toughness of the material depends on the position of the crack front. In fiber-reinforced or laminated composites, the toughness varies considerably with the orientation of the notch. Similarly, the properties of single crystals depends on the crystallographic orientation.

Specimens are usually machined using conventional techniques. EDM (electric discharge machine) is an easy and accurate method to machine small metallic specimens. Since EDM cuts by locally melting the material, the damaged surface layer should be removed by mechanical polishing. Samples should have a fine finish, particularly on the sides. The specimens can be machined with built-in knife-edges for clipping the displacement gauge in between them, or knife-edges can be screwed on the face of the specimen (ASTM, 1997c).

As mentioned previously, the stress levels and the degree of plastic relaxation depend on the sharpness of the crack tip. For metallic materials, a sharp crack is produced by cyclic loading (fatigue) of notched specimens in tension-tension, with the maximum load much lower than the fracture load. In the case of plastics, a sharp crack tip can be produced by tapping or sliding a fresh razor blade in the notch. Sharp cracks are difficult to produce in brittle materials such as ceramics. Conventionally, unnotched bend specimens are precracked by using Vickers or Knoop indenters (Chantikul et al., 1981). Compression-compression fatigue loading has also been used to create sharp cracks in ceramics (Ewart and Suresh, 1987). Sharp straight crack fronts are also difficult to obtain in anisotropic and/or inhomogeneous materials such as single crystals and composites. Techniques using chevron-notched double torsion, and tapered double-cantilever beam specimens, are suggested as appropriate methods for measuring the toughness of brittle and composite materials (Freeman, 1984).

PROBLEMS

Most of the problems that may lead to misleading results have been mentioned throughout this article and explained in detail in the relevant ASTM standards. In general, the load and displacement measuring devices should be calibrated frequently. Load measurement and control of the applied displacement becomes crucial when dealing with small brittle specimens. If testing is conducted at a temperature other than room temperature, the thermocouple should be placed as close as possible to the notch tip without interfering with the stresses at the crack tip.

An important source of error is the alignment of the specimens, particularly bend specimens. Articulated bend fixtures with aligning guides are essential for obtaining accurate toughness values for brittle materials. Usually, if the alignment is not good, the crack may start preferentially on one corner of the specimen and/or deviate from the notch plane. A misaligned specimen experiences loading modes other than mode 1, and consequently the fracture toughness measured will be higher than the true mode 1 toughness.

A soft (compliant or not very stiff) fixture can cause premature fracture during fracture toughness testing by releasing elastic energy upon cracking (Paris et al., 1979). This problem usually arises in testing large specimens of relatively tough materials, whose fracture occurs at large

loads. To avoid this complication, short bulky fixtures should be used. For example, the rod that connects the load cell to the grip should be made of a high-elastic-modulus material, with maximum diameter and minimum length.

A frequent problem with fracture toughness testing is to obtain a straight, sharp crack tip. Fatigue precracks tend to be much shorter at the sides than at the mid-thickness (thumbnail shape). This is due to a change in the stress state from plane stress on the surfaces to plane strain in the midsection. Side grooving of the specimen usually helps with this problem. Uneven fatigue cracks may develop due to misalignment of the fixture or owing to the presence of a surface layer due to special surface treatments. If a sharp crack cannot be made, then it is understood that the toughness measured depends on the notch root radius and how it is made. At very small notch root radii (approximately less than the distance between microstructural features that cause crack initiation), the fracture toughness is not very sensitive to notch root radius; however at larger values the toughness measured can be much higher than the true value measured with a sharp crack.

APPENDIX A: STRESS FIELD OF A SHARP CRACK

This appendix presents the stress field of a sharp crack at the distance r and the angle θ (see Figure 8) for the three modes of loading (see Fig. 1).

Mode 1

$$\sigma_x = \frac{K_1}{(2\pi r)^{1/2}}\cos\frac{\theta}{2}\left[1 - \sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right] \tag{15}$$

$$\sigma_y = \frac{K_1}{(2\pi r)^{1/2}}\cos\frac{\theta}{2}\left[1 + \sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right] \tag{16}$$

$$\tau_{xy} = \frac{K_1}{(2\pi r)^{1/2}}\sin\frac{\theta}{2}\cos\frac{\theta}{2}\cos\frac{3\theta}{2} \tag{17}$$

$$\sigma_z = \nu(\sigma_x + \sigma_y) \tag{18}$$

$$\tau_{xz} = \tau_{yz} = 0 \tag{19}$$

$$u = \frac{K_1}{G}\left[\frac{r}{2\pi}\right]^{1/2}\cos\frac{\theta}{2}\left[1 - 2\nu + \sin^2\frac{\theta}{2}\right] \tag{20}$$

$$v = \frac{K_1}{G}\left[\frac{r}{2\pi}\right]^{1/2}\sin\frac{\theta}{2}\left[2 - 2\nu + \cos^2\frac{\theta}{2}\right], \quad w = 0 \tag{21}$$

Mode 2

$$\sigma_x = -\frac{K_2}{(2\pi r)^{1/2}}\sin\frac{\theta}{2}\left[2 + \cos\frac{\theta}{2}\cos\frac{3\theta}{2}\right] \tag{22}$$

$$\sigma_y = -\frac{K_2}{(2\pi r)^{1/2}}\sin\frac{\theta}{2}\cos\frac{\theta}{2}\cos\frac{3\theta}{2} \tag{23}$$

$$\tau_{xy} = -\frac{K_2}{(2\pi r)^{1/2}}\cos\frac{\theta}{2}\left[1 - \sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right] \tag{24}$$

$$\sigma_z = \nu(\sigma_x + \sigma_y) \tag{25}$$

$$\tau_{xz} = \tau_{yz} = 0 \tag{26}$$

$$u = \frac{K_2}{G}\left[\frac{r}{2\pi}\right]^{1/2}\sin\frac{\theta}{2}\left[2 - 2\nu + \cos^2\frac{\theta}{2}\right] \tag{27}$$

$$v = \frac{K_2}{G}\left[\frac{r}{2\pi}\right]^{1/2}\cos\frac{\theta}{2}\left[-1 + 2\nu + \sin^2\frac{\theta}{2}\right], \quad w = 0 \tag{28}$$

Mode 3

$$\tau_{xz} = -\frac{K_3}{(2\pi r)^{1/2}}\sin\frac{\theta}{2} \tag{29}$$

$$\tau_{yz} = -\frac{K_3}{(2\pi r)^{1/2}}\cos\frac{\theta}{2} \tag{30}$$

$$\sigma_x = \sigma_y = \sigma_z = \tau_{xy} = 0 \tag{31}$$

$$w = \frac{K_3}{G}\left[\frac{2r}{\pi}\right]^{1/2}\sin\frac{\theta}{2}, \quad u = v = 0 \tag{32}$$

APPENDIX B: RELATIONSHIPS FOR CALCULATING *K* AND *J* FOR SENB AND CT SPECIMENS

This appendix provides the relationships needed for calculation of K and J at a given point ($P_{(i)}$, $\Delta_{(i)}$) and the associated crack length, a, for SENB (loaded in three points) and CT specimens (ASTM, 1997c,j).

SENB Specimen (Three-Point Bending)

Calculation of K(i)

$$K_{(i)} = (P_{(i)}S/BW^{3/2}) \cdot f(a/W) \tag{33}$$

where:

$$f(a/W) = \frac{3(a/W)^{1/2}[1.99 - (a/W)(1 - a/W)(2.15 - 3.93a/W) + 2.7a^2/W^2]}{2(1 + 2a/W)(1 - a/W)^{3/2}} \quad (34)$$

Calculation of Compliance

$$C_{(i)} = \frac{\Delta_{(i)}}{P_{(i)}} = (S/E'BW) \cdot q(a/W) \quad (35)$$

where:

$$q(a/W) = 6(a/W)[0.76 - 2.28(a/W) + 3.87(a/W)^2 - 2.04(a/W)^3 + 0.66/(1 - a/W)^2] \quad (36)$$

Calculation of Crack Length

$$a_{(i)}/W = 0.997 - 3.95D + 2.982D^2 - 3.214D^3 + 51.52D^4 - 113.0D^5 \quad (37)$$

where:

$$D = \{1 + [(E'B\Delta_{(i)}/P_{(i)})(4W/S)]^{1/2}\}^{-1} \quad (38)$$

Calculation of $J_{(i)}$

$$J_{(i)} = \frac{(K_{(i)})^2}{E'} + J_{p_{(i)}} \quad (39)$$

$$J_{p_{(i)}} = \left[J_{p_{(i-1)}} + \left(\frac{2}{b_{(i-1)}}\right)\left(\frac{U_{p_{(i)}} - U_{p_{(i-1)}}}{B}\right)\right]\left[1 - \frac{a_{(i)} - a_{(i-1)}}{b_{(i-1)}}\right] \quad (40)$$

where:

$$b_{(i-1)} = W - a_{(i-1)} \quad (41)$$

Compact Tension (CT) Specimen

Calculation of $K_{(i)}$

$$K_{(i)} = (P_{(i)}/BW^{1/2}) \cdot f(a/W) \quad (42)$$

where:

$$f(a/W) = \frac{(2+a/W)[0.866 + 4.64a/W - 13.32(a/W)^2 + 14.72(a/W)^3 - 5.6(a/W)^4]}{(1 - a/W)^{3/2}} \quad (43)$$

Calculation of Compliance

$$C_{(i)} = \frac{\Delta_{(i)}}{P_{(i)}} = (1/E'B) \cdot q(a/W) \quad (44)$$

where:

$$q(a/W) = [19.75/(1 - a/W)^2][0.5 + 0.192(a/W) + 1.385(a/W)^2 - 2.919(a/W)^3 + 1.842(a/W)^4] \quad (45)$$

Calculation of Crack Length

$$a_{(i)}/W = 1.000 - 4.500D + 13.157D^2 - 172.551D^3 + 879.944D^4 - 1514.671D^5 \quad (46)$$

where:

$$D = 1/[1 + (E'B\Delta_{(i)}/P_{(i)})^{1/2}] \quad (47)$$

Calculation of $J_{(i)}$

$$J_{(i)} = \frac{(K_{(i)})^2}{E'} + J_{p_{(i)}} \quad (48)$$

$$J_{p_{(i)}} = \left[J_{p_{(i-1)}} + \left(\frac{\eta_{(i-1)}}{b_{(i-1)}}\right)\left(\frac{U_{p_{(i)}} - U_{p_{(i-1)}}}{B}\right)\right] \times \left[1 - \gamma_{(i-1)}\left(\frac{a_{(i)} - a_{(i-1)}}{b_{(i-1)}}\right)\right] \quad (49)$$

where:

$$\eta_{(i-1)} = 2.0 + 0.522b_{(i-1)}/W \quad (50)$$

and

$$\gamma_{(i-1)} = 1.0 + 0.76b_{(i-1)}/W \quad (51)$$

and

$$b_{(i-1)} = W - a_{(i-1)} \quad (52)$$

APPENDIX C: GLOSSARY OF TERMS AND SYMBOLS

P	load
B	thickness
W	width
a	crack length
$K_{(i)}$	stress intensity factors (see Appendix A)
S	load span (for SENB specimens)
Δ	mouth opening displacement (measured on the surface. If a attachable knife edges are used, as shown in Fig. 11, the mouth opening should be corrected for the height, Z.)
E'	effective Young's modulus (= E plane-stress condition, = $E/(1 - \nu^2)$ plane-strain condition
ν	Poisson's ratio
$Up_{(i)}$	the plastic component of the area under the load displacement curve (see Fig. 9)

Note that the $Up_{(i)}$ should be calculated from the load-line displacement rather than the mouth opening displacement. Therefore, the SENB specimen may require two displacement gauges. A load-line displacement measurement is required for J computation. The crack mouth opening displacement can be used to estimate the crack length using the elastic compliance technique.

HARDNESS TESTING

INTRODUCTION

Static indentation hardness tests such as Brinell, Rockwell, Vickers, and Knoop are frequently used methods for determining hardness. The basic concept utilized in all of these tests is that a set force is applied to an indenter in order to determine the resistance of the material to penetration. If the material is hard, a relatively small or shallow indentation will result, whereas if the material is soft, a fairly large or deep indentation will result.

These tests are often classified in one of two ways: either by the extent of the test force applied or the measurement method used. A "macro" test refers to a test where a load >1 kg is applied; similarly "micro" refers to a test where a load of ≤ 1 kg of force is applied. Additionally, some instruments are capable of conducting tests with loads as light as 0.01 g and are commonly referred to as ultralight or nanoindentation testers. Rockwell and Brinell testers fall into the macro category, whereas Knoop testers are used for microindentation tests. Vickers testers are employed for both macro and microindentation tests. The measurement methods available include a visual observation of the indentation or a depth measurement of the indentation. Rockwell and some nanoindentation testers are capable of determining the depth of the indentation, whereas Brinell, Knoop, and Vickers testers require an indentation diameter measurement. These visual measurements can be automated, as will be discussed later in this unit.

Hardness is not a fundamental property of a material, yet hardness testing is considered a useful quality-control tool. Many properties are predicted from hardness values when combined with additional information such as alloy composition. The following is a list of such properties: resistance to abrasives or wear, resistance to plastic deformation, modulus of elasticity, yield strength, ductility, and fracture toughness. Some of these properties, such as yield strength, have numerical relationships with hardness values, whereas others such as fracture toughness are based on observations of cracks surrounding the indentations. Data analysis and conversions will be discussed in greater detail later in this unit.

Other relationships have developed over time by empirical observations such as the link between machinability and hardness values. In general, 300 to 350 HB (Brinell scale) is considered to be the maximum tolerable hardness for production machining of steels. For the majority of machining operations, the optimum hardness is 180 to 200 HB. If the material is too soft—$<$160 HB—poor chip formation and a poor surface finish will result. The relationship between hardness and machinability, however, is not linear. Equations were developed by Janitzky (1938) and Henkin and Datsko (1963) for determining machinability if the Brinell hardness and tensile reduction of area are known.

Competitive and Related Techniques

Many techniques have been used historically to determine hardness. The tests focused on here—static indentation hardness test methods—are widely used because of the ease of use and repeatability of the technique. Rebound and ultrasonic tests are the next most common, due to portability. Several hardness techniques are listed below with an emphasis placed on either the specific applications for which these were developed or the limitations of these techniques in comparison to static indentation tests.

Rebound tests, routinely done with Scleroscope testers, consist of dropping a diamond-tipped hammer, which falls inside a glass tube under the force of its own weight from a fixed height, onto the test specimen and reading the rebound travel on a graduated scale. The advantage of such a method is that many tests can be conducted in a very short time. However, there are several limitations to consider. The column must be in an upright position, so that even if the tester is portable it must be positioned correctly. While newer testers have a digital readout, on the older models the height of the rebound had to be closely observed by the operator (Boyer et al., 1985).

In ultrasonic microhardness testing, a Vickers diamond is attached to one end of a magnetostrictive metal rod. The diamond-tipped rod is excited to its natural frequency. The resonant frequency of the rod changes as the free end of the rod is brought into contact with the surface of the test specimen. The area of contact between the indenter and the test material can be determined by the measured frequency. However, the Young's modulus of the material must be known in order to accomplish this calculation. Only a small indent is left on the surface, so the test is classified as nondestructive. The disadvantage of this is that it is difficult to confirm the exact location of the test (Meyer et al., 1985).

One of the earliest forms of hardness testing, scratch testing, goes back to Reaumur in 1722. His scale of testing consisted of a scratching bar, which increased in hardness from one end to the other. The degree of hardness was determined by the position on the bar that the metal being tested would scratch (Boyer, 1987). The next development was the Mohs scale, which has a series of ten materials used for comparison ranging from diamond with a hardness of 10, to talc with a hardness of 1 (Petty, 1971). Further developments include a file test where a series of hardened files of various Rockwell C values (HRC values; see Table 1) are used to determine the relative

Table 1. Standard Static Indentation Hardness Tests

	ASTM	ISO
Brinell	E10	6506, 156, 726, 410
Rockwell	E18	6508, 1024, 716, 1079, 674, 1355
Vickers	E92, E384	6507, 640, 146, 409
Knoop	E384	4545, 4546, 4547

surface hardness. With this particular test, it is up to the operator to determine how much pressure to apply, at what speed to drag the file, and the angle at which to hold the file. A more controlled method was developed which uses a diamond tip and a set force on a mechanical arm to drag across the material. The width of the resulting groove is examined to determine the hardness (Bierbaum, 1930). The advantage is that a single trace can be made through a microstructure and the relative hardness of the different phases and constituents can be assessed. For example, variation at grain boundaries or case-hardened surfaces would be observed. However, it is more difficult to relate this information to other properties or hardness scales.

Abrasion and wear tests are used to evaluate the life of a component under service conditions. Typically, abrasive is applied to the surface by various means such as a rotating disc, an abrasive and lubricant mixture, or steel shot impinged at a known velocity (see TRIBOLOGICAL AND WEAR TESTING). The material-removal rate is monitored to determine the hardness (Khruschov, 1957; Richardson, 1967). This method is explained in detail in TRIBOLOGICAL AND WEAR TESTING.

Instrumented indentation is one of the newer developments in hardness testing. This method takes dynamic hardness testing one step further. Not only is a loading and unloading curve developed, but also a continuous stiffness measurement is conducted throughout the time of contact between the indenter and the material. The record of the stiffness data along with the load displacement data allows the hardness and Young's modulus to be calculated as a function of depth (Oliver et al., 1992). This method is under development as are standards for the methodology.

PRINCIPLES OF THE METHOD

The basis of static indentation tests is that an indenter is forced into the surface of the material being tested for a set duration. When the force is applied to the test piece through contact with the indenter, the test piece will yield. After the force is removed, some plastic recovery in the direction opposite to the initial flow is expected, but over a smaller volume. Because the plastic recovery is not complete, biaxial residual stresses remain in planes parallel to the free surface after the force is removed. The hardness value is calculated by the amount of permanent deformation or plastic flow of the material observed relative to the test force applied. The deformation is quantified by the area or the depth of the indentation. The numerical relationship is inversely proportional, such that as the indent size or depth increases, the hardness value decreases.

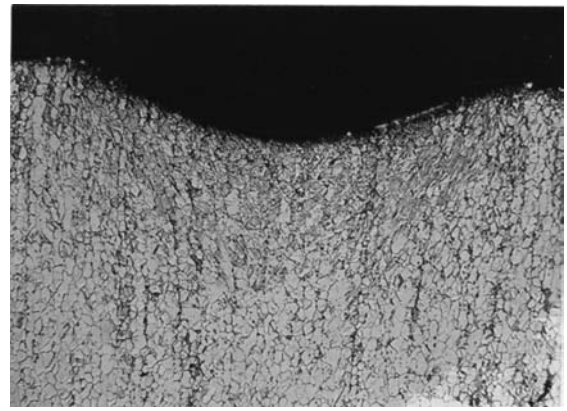

Figure 1. The cross-section of an indentation in a brass specimen demonstrates the deformation and material flow that occurs as the result of the applied force. Aqueous ferric chloride etch, 100× magnification.

The hardness is derived from two primary components: (1) a constraint factor for the test and (2) the uniaxial flow stress of the material being tested. The value of the constraint factor depends mainly on the shape of the indenter used in the hardness test. For relatively blunt indenters such as Brinell, Vickers, and Knoop, the constraint factor is approximately three. Prandtl first explained the origin of the constraint factor (Prandtl, 1920). He compared the blunt hardness indenters to the mean stress on a two-dimensional punch required for the onset of plastic flow beneath the punch. The material beneath the punch was assumed to flow plastically in plane strain, and the material surrounding the flow pattern was considered to be rigid. Hill generalized Prandtl's approach into what is now known as the slip line field theory. Hill calculated a constraint factor very similar to Prandtl. According to these theories, the material displaced by the punch is accounted for by upward flow (Hill et al., 1947). Both calculated values closely match the empirical data. The photomicrograph in Figure 1 demonstrates the stress and flow observed in the region around an indentation.

Hardness values can be directly compared only if the same test is used, since the geometry of the indenter and force applied influence the outcome of the test. For each type of hardness test conducted, a different equation is used to convert the measured dimension, depth or diameter, to a hardness value. The Brinell hardness value is calculated by dividing the test force by the surface area of the indentation. The test parameters taken into account are the test force and ball diameter while the indentation diameter is measured. For Rockwell tests, the hardness value is determined by the depth of indentation made by a constant force impressed upon the indenter. The test parameters taken into account are the test force (major and minor load) and the indenter geometry (ball or diamond cone), while the depth of penetration between the application of the minor load and major load is measured. Vickers hardness values are calculated in the same manner as Brinell tests. The projected area, instead of the surface area, is used when computing Knoop values. The

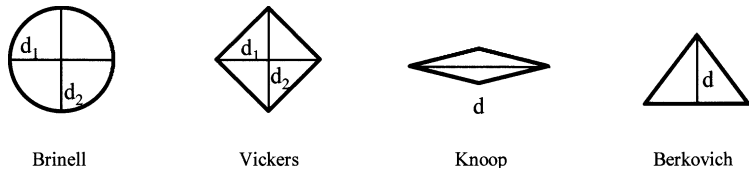

Figure 2. For the tests described in this unit, the hardness values are calculated based on the diameter of the indentation, *d*, which is measured differently for the different tests. Note that for the Brinell and Vickers tests, that diameter is an average of two measurements. See the Appendix for the equations in which these numbers are used.

test parameters taken into account for Vickers and Knoop tests are identical and include the test force and diamond indenter geometry while the indentation diameter is measured. In addition some ultralight tests are conducted with a Berkovich indenter, which has its own unique geometry. The illustrations in Figure 2 demonstrate the indentations that are measured by visual means and the dimensions of interest. The equations used to calculate the hardness values can be found in the Appendix.

The majority of hardness tests are conducted to verify that a particular processing step was done correctly. Typical processes that are evaluated include annealing, hardenability, cold working, recrystallization, surface treatments, and tempering. While an etchant could be used for visual examination of the microstructure variation, there might be other factors such as chemical composition or porosity level that would also influence the hardness value. For a known composition, the hardness associated with a particular structure will vary. For example, an alloy with a carbon content of 0.69 (wt. %) and a martensitic structure would have a hardness value of 65 HRC while an alloy with a carbon content of 0.25 and a martensitic structure would have an Rockwell C value of only 47 HRC (ASTM Standard A255, 1986).

A very common application for microindentation hardness tests is in verifying or derterminging case depth as a result of a heat-treatment process—i.e., case hardening. Case hardening may be defined as a process by which a ferrous material is hardened so that a surface layer, known as the case, becomes substantially harder than the remaining material, known as the core. The graph in Figure 3 is representative of an evaluation to determine an "effective" case depth. "Effective" case depth is the depth at which 50 Rockwell C is obtained. The "total" case depth is where hardness becomes constant. Often the visual transition is observed at a depth near the total case depth.

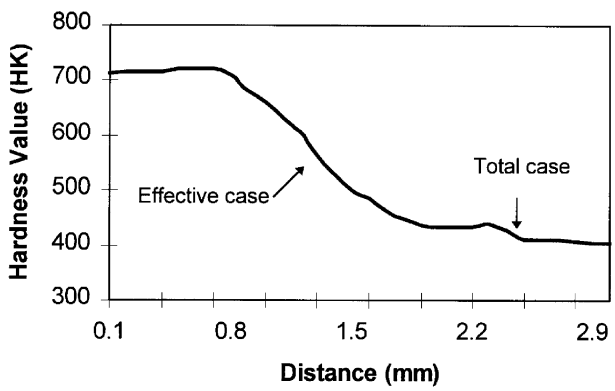

Figure 3. The effective and total case depth are noted in this typical case-depth determination graph. Even though the effective case is evaluated at 50 HRC, a Knoop (HK) test is required for this application.

PRACTICAL ASPECTS OF THE METHOD

General test methods for Brinell, Rockwell, Vickers, and Knoop tests can be found in ASTM and ISO standards. ASTM, ISO, DIN, SAE, APMI, and various other organizations also have written standards specific to certain materials, products, or processes. The standards listed in Table 1 contain information relative to the type of tester, general method, and calibration requirements.

The method described in the following paragraph has been generalized for any static indentation test. Prior to conducting the test, a specimen will typically undergo a certain level of preparation. The extent of preparation required is a function of the test force applied and is described in greater detail later in this unit (see Sample Preparation). Next, the specimen is secured through the use of a vise or an anvil. In the case of a portable tester, the tester must be secured. The main objective is to insure that the only movement observed during the course of the test is the impression of the indenter. The test force is then applied for a set duration. The measured dimension, depth, or diameter can then be used to calculate the hardness using the appropriate equation in the Appendix at the end of this unit. However, in most cases the instrument will provide a direct readout of the hardness value; otherwise a reference table containing solutions for set measurements/input values can be used.

In order to compare hardness values from one material to another, it is important for the same test conditions to be in place. Therefore, certain information needs to be provided with the hardness number. For example, 600 HBW 1/30/20 represents a Brinell hardness of 600 determined with a tungsten carbide ball 1 mm in diameter and a test force of 30 kgf (kilogram-force; 1 kgf ≡ 9.80665 N) applied for 20 s. In general, the key pieces of information to provide, in addition to the hardness value, are the test method used and test force applied (if not dictated by the method). Values such as 60 HRC or 850 HV 10, where 10 represents the test force applied in kg, are typical of the notations that would be observed on blueprints.

Of the static indentation test methods discussed, each has its advantages, intended applications, and limitations. The selection criteria to consider are as follows: hardness

Table 2. Common Applications and Nomenclature for Hardness Tests

Test	Abbreviation	Indenter	Test Load (kg)[a]	Application
Brinell	HBW	10-mm ball: tungsten carbide	3000	cast iron and steel
Brinell	HBS	10-mm ball: steel	500	copper, aluminum
Rockwell A	HRA	brale	60	very hard materials, cemented carbides
Rockwell B	HRB	$\frac{1}{16}$-in. ball	100	low-strength steel, copper alloys, aluminum alloys, malleable iron
Rockwell C	HRC	brale	150	high-strength steel, titanium, pearlitic malleable iron
Rockwell D	HRD	brale	100	high-strength steel, thin steel
Rockwell E	HRE	$\frac{1}{8}$-in. ball	100	cast iron, aluminum, and magnesium alloys
Rockwell F	HRF	$\frac{1}{16}$-in. ball	60	annealed copper alloys, thin soft metals
Superficial Rockwell T	30 T	$\frac{1}{16}$-in. ball	30	materials similar to Rockwell B, F, and G, but of thinner gauge
Superficial Rockwell N	30 N	brale	30	materials similar to Rockwell A, C, and D, but of thinner gauge
Vickers	HV	diamond	10	hard materials, ceramics, cemented carbides
Vickers	HV	diamond	0.5	all materials
Knoop	HK	diamond	0.5	all materials, case-depth determination

[a]The test load listed is specific to the application and not the only force available for the tester.

range of material to be tested, work environment, shape and size of workpiece, surface condition and whether or not the workpiece can be modified prior to testing, heterogeneity/homogeneity of the material, number of tests to be performed, and level of automation available. A majority of the factors listed above can be correlated with the test force applied and the corresponding size of the indentation.

Brinell testers can be used on a wide range of materials. When test forces in the range of 500 to 3000 kgf are applied with a 10-mm-diameter ball, a diameter will be created with an indentation between 2 and 7 mm. The large impression has its advantages with heterogeneous microstructures or segregation in that it averages out the variation. The disadvantage is that it is not sensitive enough to define a gradient in hardness and not suitable for testing small parts or thin sections. The thickness of the test piece must be ten times the depth of the indent.

Rockwell testers accommodate different materials through the use of various test forces and indenters. Each combination of indenter and force is given a specific scale designation, A to Z. For example, HRC tests are conducted with a brale indenter and 150 kgf while HRB tests are conducted with a 1/16-in. ball and 100 kgf. Superficial tests are conducted at three different forces and are designated accordingly. A 15T test is accomplished with a 1/16-in. ball and 15 kgf; likewise 30T and 45T tests use the same ball indenter with 30 and 45 kgf, respectively. Rockwell tests are used to determine bulk hardness, with the exception of superficial tests. These tests are used to evaluate coatings or surface treatments such as nitriding.

The advantage of microindentation hardness tests is the ability to monitor hardness as a function of position—e.g., placing an indent in a specific microconstituent in a multiphase material, determining case depth, or determining particle hardness. The Vickers test is considered to be relatively independent of test force; this is due to the geometrically similar impressions, as made by pyramidal indenters (Vander Voort, 1984). Testers are available that accommodate a range of test forces from 50 to 0.01 kgf. This enables direct comparison of bulk and phase-specific hardness values. Knoop indenters, on the other hand, are used most often when determining case depth, due to the elongated shape of the indenter. Table 2 lists common applications for the tests discussed (Lysaght et al., 1969; Boyer, 1987).

METHOD AUTOMATION

Automation is available on different levels for the hardness test equipment. Two types of automation are typical: (1) placement of the indentations and (2) image-analysis measurement methods. The placement of indentations can be automated with the use of a motorized stage. The most common application is with microindentation hardness tests, where as many as forty indentations may be required in a series to monitor a surface treatment. Also, the smaller specimen size lends itself more readily to being placed on a stage. Automated reading of the indentations is applied in situations where the operator would typically read the indent, for example, Knoop, Vickers, and Brinell tests. The systems are based on a specialized sequence of image analysis processes. Most systems utilize a grayscale camera system with a computer system. The indentations are detected based on either the level of contrast with the matrix material or the assumption that the indent will be made up of the darker gray pixels on the screen. The accuracy of the dimensional measurements will be based on the resolution of the system as a whole, which will be determined by a combination of the optics in the measuring device/microscope and the camera.

DATA ANALYSIS AND INITIAL INTERPRETATION

The majority of modern equipment displays the hardness value directly after the measurement has been made. For

Rockwell testers this means the value will be immediately displayed either on a digital readout or a dial. For a test where a visual measurement is conducted, the tester will either display the hardness value or simply the diameter value. In either case, most new testers are equipped with an RS232 interface either to automate the tester or to output the data for further analysis by the operator. For microindentation tests, one of the considerations is which data points to include and which are questionable. Due to the small size of the indentations, the values can be significantly altered by the presence of cracks, pores, and inclusions. One of the criteria to examine is if the shape of the indent is similar to that of the indenter. If a corner of the indent is missing or distorted or forms an asymmetrical indent, the value is highly questionable.

In some cases, creating cracks is actually the intent of the test (Palmquist, 1957). One case involves simply observing the force at which cracking begins. Typically, this method is employed when the material lacks enough ductility for other mechanical tests such as compression or tensile testing, or when there is a lack of material, since the hardness test requires only a small surface area. Crack-length observations are also used to calculate fracture toughness. A plot is constructed of the applied force versus the crack length, and a linear relationship is produced. The inverse of the slope in kg/mm is a measure of the fracture toughness.

Conversions from one scale to another are commonplace; however, a single conversion relationship does not hold true for all materials. Charts and equations are available for the following materials; nonaustenitic steels, nickel and high-nickel alloys, cartridge brass, austenitic stainless steel, copper, alloyed white iron, and wrought aluminum products in ASTM E140. Converted values should be used only when it is impossible to test the material under the condition specified.

Other properties of interest are tensile strength, yield strength, and hardenability (Siebert et al., 1977). Tensile-strength conversions have typically been developed around a particular material or class of materials. For example, with equations developed by Tabor (1951), a different constant is inserted for steel in comparison to copper. These findings have been duplicated in some cases and refuted in others (Taylor, 1942; Cahoon et al., 1971). Several other equations have been developed for specific hardness methods such as Brinell (Greaves et al., 1926; MacKenzie, 1946) or Vickers (Robinson et al., 1973). Likewise, yield strength conversions have been shown to vary with the material of interest (Cahoon et al., 1971; George et al., 1976). This observation was linked with the strain hardening coefficient. With aluminum alloys, the strain hardening coefficient is dependent on the strengthening mechanism, whereas for carbon steels the strain hardening coefficient varies directly with hardness.

SAMPLE PREPARATION

The degree of sample preparation required is inversely related to the depth of the indentation. For a relatively deep indentation, as is the case with Brinell tests, surface condition is less of a factor. The primary concern is that the indentation not be obscured when measuring the diameter. However, for a shallow indentation, a rough surface finish will cause a high level of variation in the readings. When conducting a superficial Rockwell test, for example, if the indenter were to slip into the valley of a groove, the depth measurement would be a combination of the impression and the slip, and the hardness value would be underestimated. Typically, for Rockwell tests, surface grinding to at least a 400-grit abrasive paper is recommended. For microindentation tests, such as Vickers and Knoop, rough polishing to a finish of 3 μm or better is recommended. With any test where the indentation diameter must be measured, the amount of deformation or scratches on the surface must not interfere with the operator's ability to determine the diameter. The surface finish requirements tend to be more stringent when automation is employed for the visual measurements.

SPECIMEN MODIFICATION

As a result of the material being forced aside by the indenter to make an impression in the specimen, the material surrounding the impression is disturbed and possibly work-hardened. For this reason, a minimum spacing requirement between indentations can be found for each type of hardness test in a corresponding standard. The spacing is specified in terms of indentation diameters, rather than units such as micrometers, to account for the greater amount of cold working that often occurs in soft materials that produce larger indentations. If indentations are too closely spaced, the hardness values can become erratic. For example, when a porous specimen is examined, the area around the indent is compressed as shown in Figure 4. Another test conducted in the compressed region would result in a higher hardness value. However, it is also possible for values to decrease, since, on contact with an existing indentation, the indenter may actually have less material to force aside and the result may be larger or deeper indentation.

Typically, loads are recommended that will result in an indent of sufficient size to be accurately measured, while

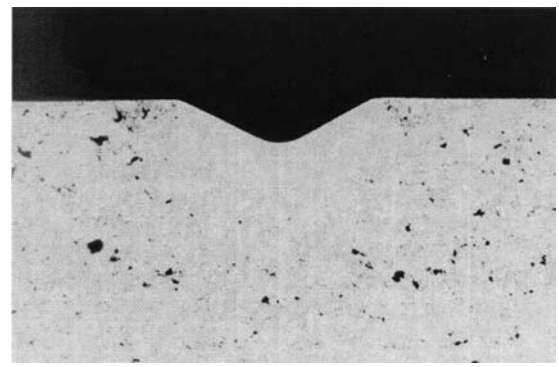

Figure 4. The cross-section of an indentation in a porous specimen demonstrating the compression of the porosity by the applied force (35× magnification).

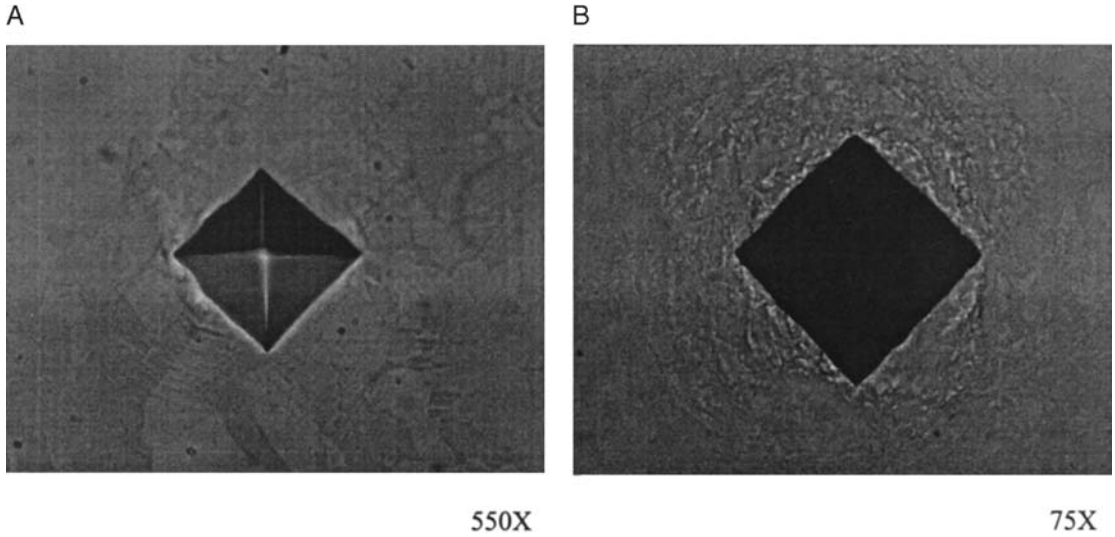

Figure 5. A comparison of the deformation around an indentation as a function of the force applied. For (**A**), a 100-g load was applied, resulting in a 41-μm-diameter indent, while for (**B**), a 10-kg load was applied, resulting in a 410-μm-diameter indent.

limiting the extent of the deformation. For example, Figure 5 displays a brass specimen with a hardness value of ~100 HV where loads of both 100 g and 10 kg have been applied. The 100-g load would be recommended. In the case of more brittle materials, such as ceramics, using too heavy a load can result in cracking of the specimen, evident at the corners of the indents, as well as chipping of the material around the indentation perimeter. Examples of materials, recommended loads, test methods, and typical hardness values are shown in Table 3.

Other concerns relate to the velocity of the indenter as it approaches the specimen, and the dwell time of the applied load. If the indenter impacts the specimen instead of applying the force, the repeatability of the test is compromised. This is also the case if the machine is set for short dwell times, since material creep rate is fastest at the beginning of the cycle. In general, creep is most readily observed during testing of low-melting-point metals at room temperature and in many metals at elevated temperatures. Hardness standards recommend a temperature range and dwell times to provide repeatable results. However, when working with low-melting point alloys and other materials more prone to creep, such as plastics, longer dwell times are suggested. In general, when creep occurs during indentation, the operator should permit the indenter to reach equilibrium before removing the load.

PROBLEMS

Problems are best detected by routine verification procedures. Calibrated test blocks are available to determine if the tester is in working condition; these can also serve as a training aid for new operators. The acceptable error observed from machine to machine using a known standard is dictated by the test standards. Some of the common problems observed are outlined in the following sections.

Instrument Errors

Concerns with the instrument are as follows: indenter-shape deviations, test-force deviations, velocity of force application, vibrations, angle of indentation, and indentation time. If the tester has passed calibration, the indenter shape, test force, and force velocity should be known. Vibrations arise from a combination of the work environment and robustness of the tester; often a vibration table will eliminate this concern. The indenter should be perpendicular to the specimen at the point of contact. The angle of indentation is determined by a combination of the machine and how well the specimen is secured and prepared. For some testers, this will be evident by an asymmetric indentation. Time should be held constant from test to test, but in most cases is a variable controlled by the operator.

Measurement Errors

The most common error is simply operator bias. It is common for each individual to measure an indent slightly undersized or oversized in comparison to another operator. Operators who do this work routinely, however, are self-consistent. Other measurement errors tend to be due to limitations of the equipment. In order to accurately measure the diameter or depth, the measuring device should be calibrated. For the visual measurement of small indentations, additional concerns are the resolving power of the objective (Buckle, 1954 and Buckle, 1959) or camera, and adequate lighting or image quality.

Material Errors

The quality of polish, poor surface finish, and low reflectivity can limit the feasibility of conducting a test, particularly if the indent diameter needs to be measured. Hardness values of highly porous specimens are referred to as apparent hardness values, since the measurement includes the compression of the pores along with the materials. When thickness is a concern, one should examine the backside of the test piece after conducting the test. If there is any sign of the indent's position, such as a bulge, the test piece was too thin. In some cases, after the removal of the indenter, elastic recovery can change the size and shape of the indentation. Changes tend to be more substantial in hard materials than in soft ones, as far as elastic recovery is concerned (O'Niell, 1967). However, distortion of the indent can also occur in the form of ridging or sinking around the indentation, making accurate visual measurements more difficult (Brown et al., 1951).

APPENDIX: CALCULATIONS OF THE HARDNESS VALUES

This appendix provides the equations with which the measured dimension, depth or diameter, is used to calculate the hardness value for each test.

Brinell

$$\text{HBS or HBW} = 0.102 \times \frac{2F}{\pi D(D - \sqrt{D^2 - d^2})} \qquad (1)$$

where D = diameter of the ball in mm, F = test force in N, and d = mean diameter of the indentation in mm. The Brinell hardness is denoted by the following symbols: HBS in cases where a steel ball is used or HBW in cases where a tungsten carbide ball is used.

Rockwell

Rockwell tests scales, A to Z, correlate with the choice of indenter and test force applied. The equations however are based on three cases as shown below.

1. Rockwell Test with Brale Indenter

$$\text{hardness} = 100 - e \qquad (2)$$

where e = permanent increase in depth of penetration under preliminary test force after removal of the additional force, the increase being expressed in units of 0.002 mm.

2. Rockwell Test with Ball Indenter

$$\text{hardness} = 130 - e \qquad (3)$$

where e = permanent increase in depth of penetration under preliminary test force after removal of the additional force, the increase being expressed in units of 0.002 mm.

3. Superficial Rockwell Test

$$\text{hardness} = 100 - e \qquad (4)$$

where e = permanent increase in depth of penetration under preliminary test force after removal of the additional force, the increase being expressed in units of 0.001 mm.

Vickers, Knoop, and Berkovitch

The same tester can be used for all three tests below. The equation is determined specifically by the indenter employed.

Vickers

$$\text{HV} = \frac{1854.4P}{d^2} \qquad (5)$$

where P = test force in gf, d = mean diagonal of the indentation in μm, and a square-based, pyramidal indenter with a 136° angle is used.

Knoop

$$\text{HV} = \frac{14{,}229.4P}{d^2} \qquad (6)$$

where P = test force in gf, d = long diagonal of the indentation in μm, and a rhombic-based, pyramidal indenter with included longitudinal edge angles of 172°, 30 min, and 130°, 0 min, is used.

Berkovich

$$\text{HV} = \frac{1569.7P}{d^2} \qquad (7)$$

where P = test force in gf, d = diagonal of indentation in μm, and a triangular pyramid indenter with an angle of 115° is used.

TRIBOLOGICAL AND WEAR TESTING

INTRODUCTION

Tribology is the science of friction, wear, and lubrication. More fundamentally, tribology is concerned with the interaction of contacting surfaces in relative motion. Friction is the resisting tangential force that occurs between two surfaces in contact when they move or tend to move relative to one another. For solid surfaces the magnitude of this force is characterized by the coefficient of friction, defined as the dimensionless ratio of the magnitude of the friction force to the magnitude of the normal force. In the absence of an externally applied normal force, this tangential force is sometimes referred to as sticktion. Wear is damage to a solid surface due to the relative motion between that surface and a contacting substance or substances. It involves the progressive loss of material. Lubrication is the ability of an interposing material to reduce either the friction between or the wear of surfaces.

The tribological behavior that a material exhibits is dependent on both the properties of the material and the contact conditions. As a result, parameters used to characterize the friction, wear, and lubrication of a material are system properties of the material, not intrinsic properties such as an elastic modulus or coefficient of thermal expansion. The collection of all those elements that can influence tribological behavior is referred to as the tribosystem. The primary elements of a tribosystem are (1) materials, (2) shapes and contours, (3) surface roughness, (4) motions, (5) loading, (6) lubrication, and (7) environment. More information on tribological behavior and phenomena can be found in Czichos (1978), Peterson and Winer (1980), Blau (1992), and Bayer (1994).

PRINCIPLES OF THE METHOD

The system nature of tribological properties result from the wide range of mechanisms that contribute to friction, wear, and lubrication. Not only the properties of the materials but also the nature and properties of the various elements of the tribosystem can influence these mechanisms, the mixture of these mechanisms that will operate in a given situation, and their interactions. In the case of wear, many mechanisms tend to have different relationships to and dependencies on material properties and contact conditions. These mechanisms can be divided into four classifications: adhesive mechanisms, single-cycle deformation mechanisms, repeated-cycle deformation mechanisms, and oxidative, or more general, chemical, mechanisms. While one mechanism often tends to predominate, these mechanisms can coexist and interact to form complex patterns of wear behavior. Adhesive mechanisms are those associated with the bonding between surfaces and the pulling out of material from the surface. Examples of single-cycle deformation mechanisms are cutting or chip formation and ploughing. These are often referred to as abrasive wear mechanisms. Fatigue or ratcheting mechanisms are examples of wear mechanisms requiring repeated cycling to produce damage. Oxide wear mechanisms are ones in which wear results from the formation and removal of oxide layers as a result of relative motion.

The situation is similar for friction. Friction mechanisms can be classified into three types, which are related to the first three types of wear mechanisms: adhesive mechanisms; abrasive mechanisms, such as ploughing and cutting; and hysteresis, associated with stress cycling during motion. In addition to these fundamental mechanisms, the friction and wear behavior of a material or system can also be influenced by the formation of tribofilms on or between the surfaces in contact. These films are composed of wear debris from either or both of the surfaces involved. Once formed, these films can act as lubricants, significantly modifying friction and wear behavior associated with a material. In general, the formation of these films depends not only on the properties of the materials involved but also on contact conditions, such as the presence or absence of lubricants, geometry, loading, and speed.

Materials can provide lubrication in a variety of ways. As with friction and wear, these mechanisms involve different types of dependencies on material parameters and contact conditions. Materials can function as lubricants by separating the surfaces, supporting some of the load, physically or chemically altering the surfaces, and providing cooling. Frequently, a combination of these mechanisms is involved. The degree of lubrication that a material can provide and the manner by which it does this depend not only on the properties of the material but also on the other elements of the tribosystem. There are four broad categories of lubrication: dry, boundary, fluid lubrication, and mixed lubrication. Dry lubrication is provided by solids, such as poly(tetrafluoroethylene) (PTFE or Teflon), MoS_2, and graphite particles and composite coatings. Solids frequently provide good lubrication when they are easily sheared and form tribofilms on the counterface. Boundary and fluid lubrications are provided by fluids, such as oils and greases. Fluid lubrication refers to situations where the surfaces are completely separated by the formation of hydrodynamic films. Boundary lubrication refers to situations where separation by hydrodynamic films is negligible and the lubrication is related to the existence of boundary layers formed by the lubricant. Mixed lubrication refers to situations where the two surfaces are not completely separated by hydrodynamic films and boundary-layer phenomena are still significant. With boundary and mixed lubrications, the ability of the fluid to form and maintain boundary layers and react with the surface is a major factor in its ability to lubricate. In the fluid range, fluid flow parameters such as viscosity and Reynolds number become the major factors, as do the shape of the counterfaces and the relative speed.

Tribological situations are classified in terms of the nature of the contact, the type of motion involved, the presence or absence of abrasives, and the type of lubrication. The nature of the contact may be categorized as one- versus two-body contact. In the former the surface is being worn by a fluid or a stream of particles. The term “erosion” is used to describe such situations. There are many subcategories of erosion, such as particle erosion, drop erosion,

cavitation erosion, and slurry erosion, that apply to specific types of erosive situations. When the friction and wear in a two-body situation are primarily associated with hard particles entrained between the two surfaces or hard protuberances on a surface, the situation is referred to as "abrasion." Abrasion is further subdivided into two-body abrasion, in which the abrasive is attached to a surface, and three-body abrasion, in which it is not. A further subdivision is based on the nature of the abrasion. Scratching abrasion, gouging abrasion, and slurry abrasion are examples of this classification.

For two-body contact the primary classification is done on the basis of the motion involved. Sliding, rolling, and impact are the major categories. However, these can be further divided in terms of mixtures of these primary motions, for example, sliding with impact or rolling with slip. For vibratory sliding, when the sliding amplitude is small, less than a few thousand micrometers, the situation is called fretting. Two-body wear situations can be further classified in terms of the nature of the contact, such as point, line, or conforming; the nominal stress level, e.g., above or below the elastic limit; and the relative amount of motion or contact each body experiences. Examples of this last aspect are the classification in terms of the ratio of the contact area to area of the wear track used by Czichos (1978) and the loaded/unloaded designation for each body proposed by Bayer et al. (1962). Wear situations can also be categorized in terms of lubrication, such as whether they are lubricated or not and the type of lubrication, e.g., dry or fluid.

Table 1 provides a classification for wear systems based on operational elements.

Friction, wear, and lubrication are interrelated but distinct phenomena. Thus, different parameters are needed to characterize their behavior. Since tribological parameters are system parameters and not fundamental material properties, a large number of different tribological and wear tests must be performed in order to quantify them, and new tests and modifications of existing tests are continually being developed. Tribological tests for friction, wear, and lubrication vary with the type of material involved, the application, and the interests of the tester. However, these tests share many features, differing only in the parameters used or how the data are analyzed. The discussion that follows will focus on these similarities and present the general features of these tests, rather than provide specific information on any one test (Bayer, 1994, pp. 147–156).

Table 1. Operational Classification of Wear Situations

One-body contact	
Impingement	Low or high angle
	With or without abrasives
Flow	Streamlined or turbulent
	With or without abrasives
Two-body contact	
Rolling	With or without slip
	With or without abrasives
	Type of lubrication[a]
Impact	With stationary or moving body
	With or without abrasives
	Type of lubrication[a]
Sliding	Unidirectional or cyclic
	Large or small amplitude
	Equal or unequal rubbing
	With or without abrasives
	Type of lubrication[a]

[a]None, dry, boundary, mixed, or fluid.

Simulation

The primary element of the common methodology for tribological testing is the need to simulate the tribological system for which the data are to be applied. This means that sliding tests should be used to determine values of tribological parameters for sliding situations, rolling tests for rolling situations, and abrasion tests for abrasive situations. In order to have good correlation between the test and the actual application, other elements of the tribosystem need to be simulated as well, and all elements of the tribosystem need to be considered for simulation. The extent to which each element needs to be simulated depends on the nature of materials, the nature of the wear or friction situation, and the purpose for which the test is intended. For example, with polymers, whose properties are significantly different above and below their glass transition temperatures, it is necessary to simulate those conditions that affect temperature to obtain good correlation with an application (ASTM D3702). Similarly, for lubricated systems, it is necessary to ensure that the same type of lubrication occurs in the test as in the application. For example, with an oil, it is necessary to select appropriate test geometries, loads, and speeds to ensure boundary lubrication if the application involves boundary lubrication. The simulation required for abrasive situations provides another example. Abrasives used in tribological tests should be similar to the abrasives encountered in the application, and the loading should be similar to that in the application. Size, shape, and hardness should be considered, as well as whether or not the loads are sufficient to fracture the abrasives. Because of the need for high correlation between tests and applications in engineering, tribological testing for engineering purposes often requires closer simulation than that used for fundamental research purposes.

A common technique for ensuring adequate simulation in wear tests is to compare the morphology of the wear scar produced in the test to that produced in the application. Another approach that can be used for both friction and wear tests is to compare rankings obtained with the tests and those found in the application.

Measures of Tribological Properties

The basic parameter used to characterize the friction behavior of a material or a material couple in two-body tribosystems is the coefficient of friction, that is, the ratio of the friction force to the normal force pressing the two bodies

together. Two coefficients are used: the coefficient of friction for sliding and the coefficient for rolling. In addition, a distinction is made between the friction force associated with initiation of motion and the force associated with sustained, uniform motion. For the former the coefficient of friction is referred to as the static coefficient of friction; for the latter, as the kinetic coefficient of friction. Since friction also results in the dissipation of energy, the energy lost in a tribosystem is sometimes used as an indirect measure of friction, such as in test methods by the American Society for Testing and Materials used to characterize the friction between rubbers and pavement (ASTM E303 and E707). Both use a pendulum-type device.

The situation for wear is not as simple. There is no equivalent parameter for wear that is as universally used and accepted as the coefficient of friction. However, the ability of materials to resist wear or to cause wear is often characterized by normalized parameters. In the case of sliding and abrasive wear, for example, this is often done by dividing the volume of material removed or displaced by the product of the load and sliding distance. The severity of the wear is sometimes characterized by multiplying this value by the hardness of the wearing surface to obtain a dimensionless wear coefficient. In erosion, wear volume is often divided by the amount of erodent used to cause the wear to provide a dimensionless measure. Other methods and parameters are also frequently used. Examples are the amount of motion or exposure required to produce a certain state of wear or the stress or load required to produce a given amount of wear for a fixed amount of motion, which is used to characterize the rolling wear resistance of metals (Morrison, 1968). In addition, parameters of specific models for wear are also used to characterize wear behavior; examples are those for characterizing wear behavior between silicon chips and various anodized surfaces (Bayer, 1981). Another example of this approach is the method used to evaluate the abrasivity of slurries (Miller and Miller, 1993).

The lubricating characteristics of a material are determined by comparing wear or friction with and without the material present. For example, the coefficients of friction with and without a particular lubricant present can be used as a measure of the material's ability to lubricate a surface. Relative lubricating characteristics are often obtained from friction or wear tests with different lubricants by comparing the friction or wear measured in tests with different lubricants. For example, in an ASTM test for evaluating the antiwear properties of lubricating greases, the size of the wear scar is used to rank lubricants (ASTM D2266). An additional important property of a material's ability to lubricate is the range of conditions under which it is able to provide lubrication. This might be the oxidative life of the lubricant, in the case of an oil, or the wear life of a bonded-solid lubricant. It can also be the maximum pressure or speed the lubricant can withstand before breakdown occurs. Parameters such as these are also used to characterize lubricant behavior and are determined in friction and wear tests designed to determine the limits of their ability. Such approaches are used in several ASTM tests for solid film and fluid lubricants (ASTM D2625; ASTM D3233).

PRACTICAL ASPECTS OF THE METHOD

General Tribological Testing

While somewhat lower in friction tests than in wear tests, the potential for scatter in tribological tests is very high. This results from the complex nature of tribological behavior and the range of friction and wear coefficients that are associated with such behavior. Examples of these ranges are shown in Tables 2 and 3. The characteristic range of the scatter depends on the nature of the test, the parameter measured, and the controls incorporated into the test. Scatter obtained with multiple test apparatuses tends to be higher than that obtained with a single apparatus. Coefficients of variation of $<30\%$ are considered good for the coefficient of friction and representative of well-designed and controlled tests. With many standard wear tests, variations by a factor of ≈ 2 are not uncommon and are often considered good. When there is inadequate control in wear tests, variations by an order of magnitude, and sometimes larger, are common. With proper controls the characteristic coefficient of variation for a wear test can often be reduced to 10% or 20% and generally $<50\%$. Because of this scatter, it is necessary to perform duplicate tests to obtain statistically significant data. Even in situations where this is not a major issue, a minimum of three replicates should be used. This is recommended because of the probability of obtaining results that are not typical (outliers). In tribological tests the probability of encountering outliers is generally considered to be high.

Another practical aspect of tribological testing is the need to clean specimens and counterfaces used in the tests. While cleaning tends to be less of a factor in erosion and lubricated tests than in unlubricated two-body wear tests, some cleaning is required to reduce scatter in all tribological tests. This element is discussed in more detail below.

Test Equipment and Measurement Techniques

The test equipment used for tribological testing consists of those elements needed to simulate the friction or wear situation and to perform the necessary measurements. For two-body situations, the essential elements consist of a mechanism for pressing the two bodies together with a known force, a mechanism for moving the two bodies relative to each other, and means of measuring friction, wear, or both. Typical methods for applying the normal force are dead-weight methods, often involving a system of levers,

Table 2. Friction Coefficients

Condition	Coefficient
Unlubricated sliding	
Metal/metal	0.3–1.4
Metal/ceramic	0.1–0.8
Metal/plastic	0.1–0.7
Plastic/plastic	0.05–0.8
Boundary-lubricated sliding	0.1–0.3
Fluid-lubricated sliding	<0.01
Rolling	
Steel/steel	≈ 0.001

Table 3. Wear Coefficients

Condition	Coefficient	
Sliding wear	(*wear volume* × *hardness*/*load* × *distance*)	
Self-mated metals, unlubricated	$2 \times 10^{-4} - 2 \times 10^{-1}$	
Self-mated metals, lubricated	$9 \times 10^{-7} - 9 \times 10^{-4}$	
Non-self-mated metals, unlubricated	$6 \times 10^{-4} - 2 \times 10^{-3}$	
Non-self-mated metals, lubricated	$9 \times 10^{-8} - 3 \times 10^{-4}$	
Plastics or metals, unlubricated	$8 \times 10^{-5} - 3 \times 10^{-7}$	
Plastics or metals, lubricated	$1 \times 10^{-6} - 5 \times 10^{-6}$	
Abrasion	(*wear volume* × *hardness*/*load* × *distance*)	
	Dry	Wet
Two-body abrasion		
File	5×10^{-2}	10^{-1}
New abrasive paper	10^{-2}	2×10^{-2}
Used abrasive paper	10^{-3}	2×10^{-3}
Coarse polishing	10^{-4}	2×10^{-4}
<100-μm particles	10^{-2}	—
>100-μm particles	10^{-1}	—
Three-body abrasion		
Coarse particles	10^{-3}	5×10^{-3}
Fine particles	10^{-4}	5×10^{-4}
Particle erosion	(*wear volume* × *hardness*/*particle volume* × *particle density* × *particle velocity*^{2})	
Soft steel	$8 \times 10^{-3} - 4 \times 10^{-2}$	
Steel	$1 \times 10^{-2} - 8 \times 10^{-2}$	
Hard steel	$1 \times 10^{-2} - 1 \times 10^{-1}$	
Aliminum	$5 \times 10^{-3} - 1.5 \times 10^{-2}$	
Copper	$5 \times 10^{-3} - 1.3 \times 10^{-2}$	

load cells, or deflection beams with strain gauges attached. For one-body situations or erosion, the essential elements consist of some means of providing the proper erosive action, holding the wear specimen, and measuring the wear. Typical ways of providing the erosive action are to use jets to create a stream of erodent or to move the wear surface through an erodent field. In addition to these essential elements, tribological tests often involve some means of controlling the environmental conditions of the test and maintaining an adequate supply of lubricant. The former is done to improve repeatability or to simulate the environmental conditions of applications, particularly for applications in hostile environments.

Friction is generally measured by the use of strain gauges, load cells, or some other force-measuring device. Perhaps the most common method is to directly measure the friction force and to obtain the coefficient of friction by dividing by the normal load. However, other options also exist. For example, in a test used to characterize the friction between a web material and a capstan or roller, the ratio of the tensions in the web on either side of the capstan is used to determine the coefficient of friction (ASTM G143). For this configuration the coefficient is obtained by dividing the natural logarithm of the ratio of the tensions by the angle of wrap. In an inclined-plane method for determining the coefficient of friction, such as is used for papers, the angle of inclination is used to determine the coefficient of friction (ASTM D4521). In this case, the static coefficient of friction is given by the tangent of the angle at which slip occurs. In friction tests that use dissipated energy as a measure of friction, other appropriate techniques are used. Power consumption in an electric motor is one; another is the height that the pendulum reaches after frictional contact is made in a pendulum test.

Volume of material lost or displaced is generally considered the more fundamental measurement of wear. However, it is not the only measure that may be used in wear tests. Different features of wear scars have been used, as well as functional characteristics of devices, such as bearing concentricity or roller-bearing noise and vibration. There are several reasons for this, including the ease of performing the measurement and the accuracy obtainable with the materials and geometries used in the test. Another is the significance of a particular mode, feature, or degree of damage to an application. For example, with optically transparent material or decorative finishes, the formation of fine scratches or haze on the surface is more significant than the volume of material removed. The analytical expressions used to analyze the data and relate the data to an application may also be a factor.

The wear measures that tend to be used most frequently can be grouped into four types based on the following properties: appearance, wear scar dimensions, volume lost or displaced, and mass loss. For some geometries volume can be determined from dimensional measurements or by scanning or three-dimensional profilometer techniques. If the density of the material is known, mass loss can also be used to determine volume. In tests that utilize appearance, wear scars are commonly evaluated by eye, by optical microscopy, or by scanning electron microscopy. For example, the unaided eye is used to examine the wear scar for characteristic damage in a standard test to evaluate galling resistance (ASTM G98). Galling is a sliding wear mode characterized by roughening and the creation of protrusions above the original surface.

Tribological Test Categories

The term "friction test" is applied to tribological tests designed solely to measure friction. The amount of wear typically generated in these tests are negligible. The term "wear test" is applied to tests designed to cause wear. However, two-body wear tests can also be used to measure friction, provided the apparatus provides some means of measuring the friction force. With this type of instrumentation, both initial friction and changes in friction that occur with use can be measured. Since wear is associated with progressive loss or damage, wear tests involve repeated cycles or exposure. Friction tests, on the other hand, often involve only a single cycle. However, neither are restricted to these situations. Some wear tests, such as those used to characterize galling resistance and scratch tests used to characterize abrasion resistance, measure wear after one cycle. Friction tests used to measure

the kinetic or dynamic coefficient of friction often involve repeated cycles or sustained motion but with negligible wear.

Since the ability of a material to lubricate is determined by comparison of friction and wear behavior with and without the material present, friction and wear tests are both used to evaluate lubrication. Friction tests provide a measure of a material's ability to reduce friction, generally with negligible wear. However, wear tests can provide a measure of a material's ability to reduce both friction and wear. When wear tests are used in this fashion, friction is monitored during the progression of the test. Lubrication tests to determine the limits of a material's lubricating ability often involve the progressive increase of some stressing element, such as load, speed, or temperature, coupled with either a single cycle or continuous motion. In these tests the failure point is identified by either a dramatic increase in friction, onset of catastrophic wear, or both, e.g., the occurrence of seizure. Direct and indirect methods are used for detecting such a point. For example, the fracture of a shear pin is used in a test to determine the failure point of oils as a function of load (ASTM D3233).

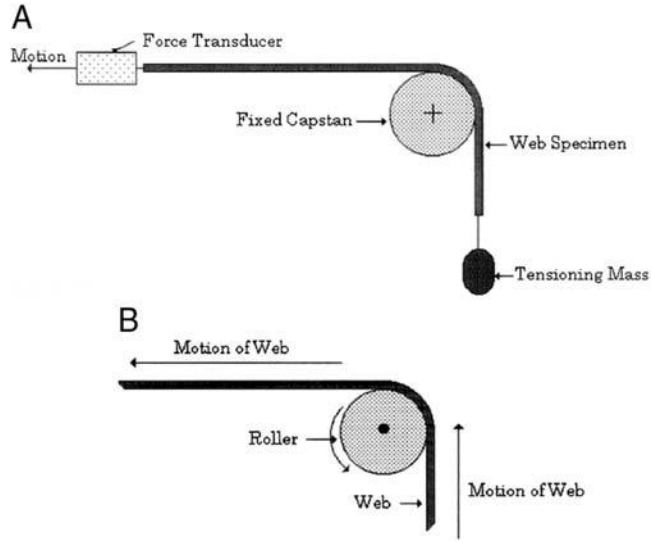

Figure 1. Similarity between test configuration used to characterize friction of web materials and contact configuration in applications involving transportation of web materials. (**A**) Test configuration used in ASTM G143. (**B**) Typical application.

Friction Tests

The basic element of a friction test is the measurement of the force required to initiate motion, maintain motion, or both. When the force is measured directly, these data are typically converted to a coefficient of friction. The static and kinetic coefficients of friction and fluctuations in friction can be measured with appropriate instrumentation and analysis techniques. This is possible only when friction is measured directly. Indirect approaches can provide information on either maximum friction or average friction, but not both. For example, the inclined plane test measures the static coefficient of friction (the force required to initiate motion), but not the kinetic coefficient of friction (the retarding force on a moving body). When dissipated energy is used as a measure of friction, as in a pendulum test, it is related to the average force needed to maintain motion. With such methods, it is not possible to observe fluctuation in friction behavior during the motion.

Simulation consists of replicating the nominal type of motion, shapes of bodies, nominal loading conditions, counterface conditions, and environmental conditions of the application. In the case of friction only minimal simulation of loading and contact geometry is needed to obtain significant correlation with applications. Provided the motion is appropriate and test specimens of the materials can be obtained, most friction tests provide information about trends, such as effects of speed and environmental conditions and coarse rankings. For example, most sliding tests for friction show that unlubricated metal pairs have coefficients of friction from 0.5 to 1, which are reduced to 0.1 to 0.3 when lubricated by oils; metal-polymer couples have coefficients between 0.1 and 0.3; and, depending on fillers and types, coefficients for elastomers can range from 0.5 to >1. This trend is consistent with what is generally found in applications.

However, coefficients of friction obtained from different tests with the same materials are not always identical, since friction is not completely independent of loading and geometry. As a result, some tests provide better correlation than others. For improved correlation, which allows more specific characterizations and finer rankings, it is necessary to replicate the nature of the shapes and the loading involved in the application. For example, consider the tests shown in Figures 1 and 2. Both are sliding friction tests that can be used to evaluate the coefficient of friction between a web material and materials used for capstans and rollers in web-handling systems. Figure 1 also shows the nominal contact situation between a roller and a capstan in these applications. It is evident that the capstan test provides a better simulation of this application.

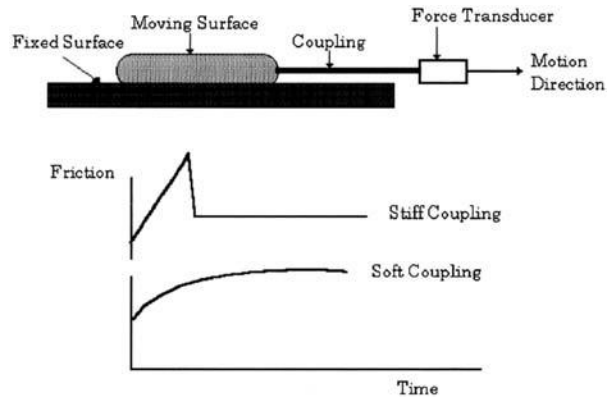

Figure 2. Effect of drive stiffness on measurement of friction. With a stiff coupling, such as a steel wire, there can be a pronounced difference between static and kinetic friction. With a flexible coupling, such as a piece of string, the difference can disappear.

Engineering experience with these two tests has shown that better correlation is obtained with the capstan test than with the sled test (Budinski, 1989).

Some applications require a high degree of simulation to obtain adequate correlation. Examples of this are some of the tests used for characterizing the friction of brake materials (Jacko et al., 1984; Tsang et al., 1985). In these not only are the geometries, loads, speeds, and environment replicated, but other characteristics of brake applications, such as pumping and prolonged braking, are incorporated into the test protocols.

Observed friction behavior is influenced by the instrumentation used to measure friction and by the design of the drive system. The detection and appearance of fluctuations in friction may be modified by sampling rate, instrument sensitivity, and frequency response of the measurement system. Short-term fluctuations can be missed and the appearance of sharp transitions modified as a result of the instrumentation used. The stiffness of the drive can also be a factor, as illustrated in Figure 2 in the case of a sled test. As the stiffness is reduced, differences between static and kinetic friction tend to be reduced and stick-slip behavior can be modified.

In many friction tests the normal load tends to fluctuate as a result of dynamic effects or variations in surface contours. In these situations it is desirable to measure the normal force in the same manner as the friction force, so that instantaneous values of the coefficient of friction can be obtained.

Wear Tests

Wear testing often requires more simulation than friction testing to obtain good correlation with applications. A useful technique for investigating the adequacy of the simulation provided by a wear test is by comparison of wear scar features obtained in the test with those observed in the application. The more similar they are, the better the simulation, and the more likely there will be good correlation. In these comparisons, the magnitude of the wear is not the important element. Appearance and morphological features, which are related to or indicative of mechanisms, are the more important aspects to be compared.

The overall design of a test apparatus tends to have characteristic influences on wear behavior that need to be considered for adequate control and simulation. For example, wear behavior can be influenced by the stiffness of the test apparatus as a result of dynamic effects and superimposed vibrations. Wear results can also be influenced by differences in the precision obtainable with different specimen mounting techniques, such as the difference between the use of a four- or three-jawed chuck to hold the cylindrical specimens in a crossed-cylinder test configuration (ASTM G83). In addition, such considerations as different specimen shapes or methods for applying loads, generating erosive streams, or providing motion tend to have unique characteristics that can affect wear behavior in different ways. Included in these characteristics is the effect that specimen wear has on test parameters. These issues also need to be considered for simulation and control. For example, when load cells or strain-gauged beams are used to generate the load in two-body wear tests, the load tends to decrease with wear. Consequently, in such situations it is necessary either to select load cells and beams so that the change in load is negligible over the wear range of interest or to use some monitoring and feedback system to maintain a constant load. Dead-weight methods do not have this problem. If not carefully designed, however, such systems, which often involve the use of levers, are prone to errors and variations in either the magnitude of the actual force applied or the line of action. For example, friction effects at bearing points can influence the magnitude, or tolerances may allow the line of action to vary.

Another example is the characteristics of test configurations commonly used in two-body wear tests. One such configuration involves a flat-ended specimen of uniform cross-section pressed against a flat or cylindrical surface. Initial alignment is a problem, as during the initial period of wear contact stresses tend to be high and inconsistent. However, once the surfaces are worn, the contact stress becomes much smaller, more constant, and more consistent. Another common configuration is a spherical surface against a flat or cylindrical surface. With this configuration there is no alignment problem and initial stress levels are more consistent. However, the contact stress continually decreases throughout the test at a decreasing rate. When cylindrical surfaces are used to obtain nominal line contact, both effects are present. There is an initial alignment problem and the contact stress decreases throughout the test. Since some wear mechanisms can be influenced by stress, wear behavior in tests with these different geometries may not be equivalent. The different characteristics of these contact geometries can also influence the duration and nature of any break-in or run-in period.

There are similar concerns with techniques used in erosion and abrasion testing. For example, in particle erosion tests, different designs of the nozzle used to produce particle streams can result in different dispersion characteristics, which influence erosion behavior. There can also be interaction between the shape of the wear scar and the erosion action of the stream as a result of particle rebound (Fig. 3). When this can occur, it is necessary to place a limit on the amount of wear that can be used for evaluating erosion behavior and comparing materials (ASTM G76).

While the basic element of a wear test is the measurement of wear after specified amounts of motion or duration, there are a number of different approaches used. One approach, which is frequently used to rank materials, is to measure wear after a specific duration, e.g., number of cycles, or exposure, e.g., amount of abrasive used. This approach is used in a four-ball test to evaluate the antiwear properties of greases, in a block-on-ring test for sliding wear resistance, and in a gouging abrasion test (ASTM D2266; ASTM G77; ASTM G81). The concept is to select a duration that is sufficiently long to be beyond any break-in or run-in behavior and to obtain stable wear behavior, as characterized by a constant or slowly changing wear rate. In many wear tests the amount of time required to achieve stable behavior depends on the materials being evaluated as well as the conditions of the tests. The duration or

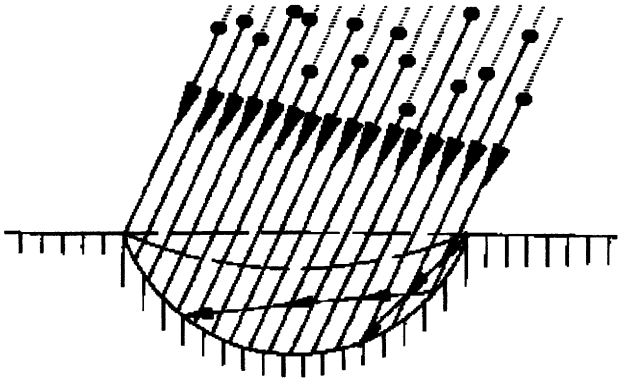

Figure 3. In particle erosion there is the possibility of deep wear scars of secondary impact from rebounding particles. As the depth of wear increases, the significance of these rebounding particles and secondary impacts tends to increase. This effect leads to a limit on the maximum amount of wear that can be used to compare materials in these types of tests.

exposure to be used in this type of testing approach must be determined empirically.

Another approach is to measure wear at different times or intervals so as to develop a wear curve, which plots wear as a function of accumulated motion or exposure. This method is used in a block-on-ring test for sliding wear resistance of plastics, in a cavitation erosion test using a jet, and in evaluating the impact wear resistance of elastomers, among others (ASTM G137; ASTM G134; Bayer, 1986). Wear curves may be developed in two ways: (1) removing and replacing the same sample and (2) using different samples for the different duration. There are concerns with both approaches. Removing and replacing the same sample can cause disruption in surface films and debris features, contamination, and a change in the position of the sample. As a consequence, wear behavior may be altered. With the second approach more samples are required and sample-to-sample variations may mask intrinsic wear behavior. The possible effects on apparent wear for both approaches are illustrated in Figure 4.

The shapes of wear curves vary with the wear test and the nature of the materials involved. However, they tend to be nonlinear, and initial wear rates are often significantly different than longer-term wear rates. The wear curves shown in Figure 4 are typical of those obtained in many sliding wear tests. Typical curves for particle and cavitation erosion are shown in Figure 5.

Wear curves are used in a variety of ways to evaluate and compare wear behavior. For semiquantitative or qualitative rankings and comparisons of materials often used for engineering, direct graphical comparisons are generally used. With this approach the wear curve is used to identify a test duration that is sufficiently long to obtain a constant or slowly changing wear rate. With this approach accumulated wear is the primary criterion for ranking. However, there is frequently some ambiguity in such comparisons, and only coarse rankings may be appropriate. This situation is illustrated in Figure 6, which shows a hypothetical but typical situation often encountered with wear data. Wear curves for six different materials are plotted. Based on accumulated wear, the materials

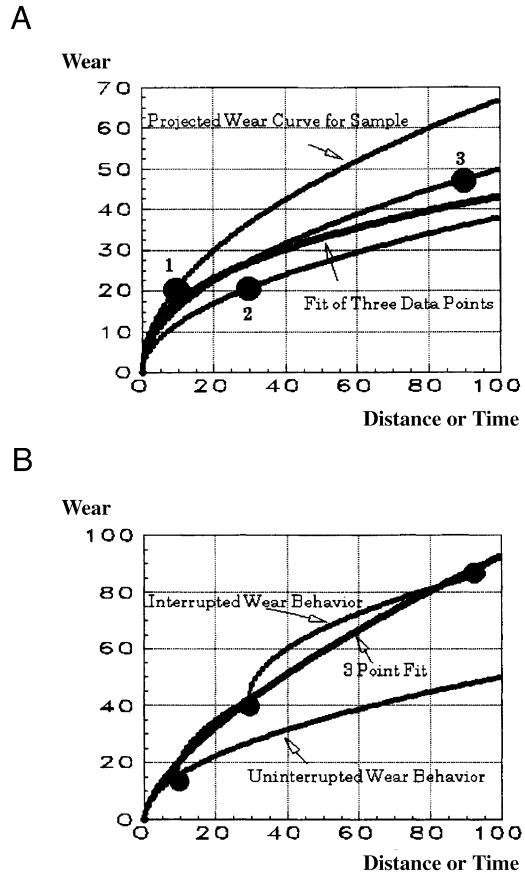

Figure 4. Errors associated with two methods of generating wear curves. Curves are typical of sliding wear data. (**A**) Possible effect of using different samples for different durations. Points 1, 2, and 3 refer to different samples. (**B**) Possible effect of using a single sample (arbitrary units).

are ranked in the order F, E, B, C, A, and D. However, the terminal slopes suggest that the order should be F, E, B, A, D, and C. It can also be seen that if a duration less than 70 units of distance is used, a different ranking would be obtained, namely, F, E, C, B, A, and D. For many practical engineering purposes the relative rankings of C, A, and D are considered immaterial and those of E and F are considered equivalent.

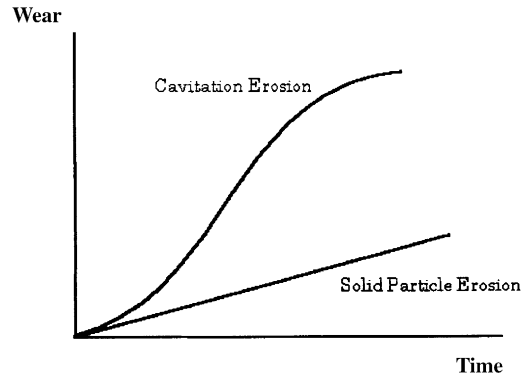

Figure 5. Typical wear curves for cavitation erosion and solid-particle erosion.

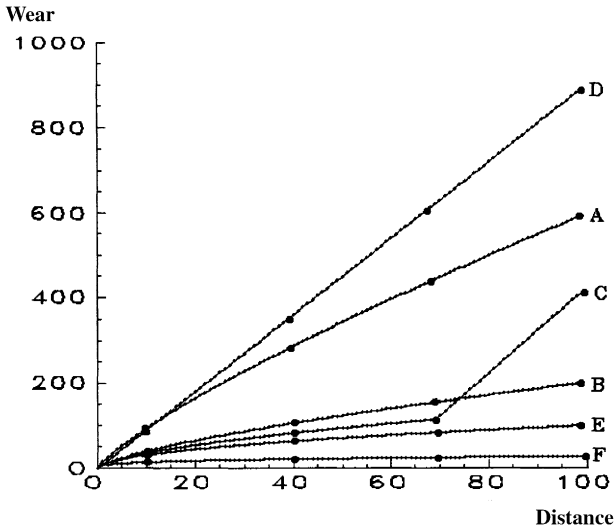

Figure 6. Possible results from sliding wear test used to compare six different materials. Units are arbitrary. Wear measurements were made at 10, 40, 70, and 100 distance units.

Another approach is to differentiate the curve to obtain a wear-rate-versus-usage curve such as shown in Figure 7. With this method wear behavior is characterized by wear rate, using either an absolute rate, such as wear volume per sliding distance or wear volume per unit volume of erodent, or a normalized rate, such as wear volume per load times sliding distance, wear volume times hardness per load times sliding distance, or wear volume times hardness per volume of erodent (see Table 3). This method is used in a block-on-ring test to evaluate the sliding wear resistance of plastics (ASTM G137). It is also used in tests for liquid impingement erosion (ASTM G73). In many wear tests the wear rates tend to stabilize with duration, becoming either constant or slowly varying. As a consequence longer term wear rates are used for comparing and evaluating materials.

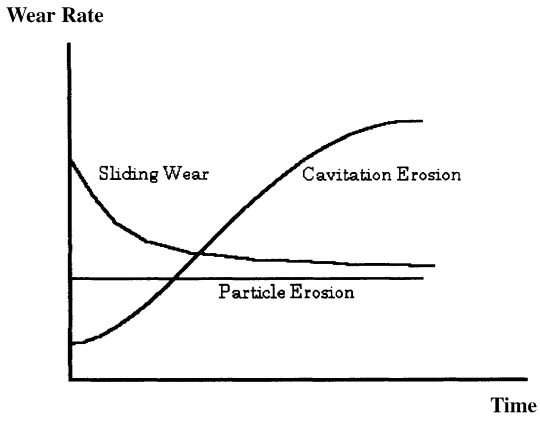

Figure 7. Wear rate curves typically obtained for sliding wear, cavitation erosion, and particle erosion. Time could be replaced by distance or volume of particles in the case of sliding wear and particle erosion, respectively.

A third approach is to analyze the wear curve by fitting the data to some empirical or theoretical model in order to obtain coefficients, which are used to compare or evaluate wear behavior. Examples of this approach are the methods associated with the implementations of engineering models for sliding and impact wear (Bayer, 1994, pp. 332–350; Engel, 1976, pp. 180–243). Another example is the method used for determining slurry abrasivity (Miller number) and the slurry abrasion response of a material (SAR number) for slurry abrasion (ASTM G75).

With either the single-point method or the wear-curve method, wear tests are run until stable behavior, as indicated by a constant or slowly changing wear rate, is achieved.

Another approach used for wear tests is to determine the value of some parameter required to produce a certain level of wear for a standard set of conditions. Duration or exposure and loading are often used for this purpose. For example, rolling wear resistance of materials is often evaluated and compared by using a wear test to determine either the number of revolutions for a fixed load or the load for a fixed number of revolutions required to produce cracking (Bayer, 1994, pp. 221–225). With this approach appearance is used as the measure of wear. Other more quantitative measures can be used, but implementation of the tests then becomes more complex.

In two-body wear tests, as in any two-body wear situation, either or both surfaces may wear. The relative potential for these surfaces to wear depends on the relative amount of motion that each surface experiences. For example, in the case of a small slider pressed against the surface of a large rotating disk, the small slider has the higher potential for wear because its surface experiences a larger amount of motion per unit area. For the thrust washer test configuration both surfaces experience the same amount of motion per unit area, and the potential for wear is the same for both.

While the potential for either body to wear in a two-body wear situation is an element that needs to be considered in simulation, it also is significant in other aspects of wear testing. One aspect is that counterfaces in two-body wear tests should be examined and measured for wear, just as the wear specimen is. A second aspect is the effect that the wear of the counterface has on the analysis method used, data interpretation, and the comparison of materials. In general, significant counterface wear makes these more complex. At the very least, the amount of wear on both members of the system needs to be considered in making any comparisons. One approach to doing this is shown in Figure 8 for a test that uses the single-point method, i.e., comparing the accumulated amount of wear. With this approach, material couples may also be compared by using the total wear of the system, i.e., the sum of the wear on both surfaces. Models that take into account simultaneous wear on both surfaces can also be used to analyze the data to obtain wear coefficients for the materials involved. Such an approach has been used to evaluate material pairs for electrical contacts (Bayer and Sirico, 1971).

Complexities associated with the wear of both surfaces can be avoided by selecting wear-test configurations that bias the wear to occur only on one member. This is done

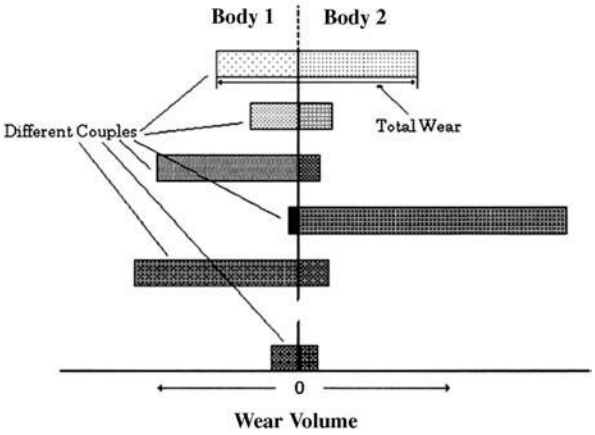

Figure 8. Example of wear data in two-body wear situations when both surfaces wear. The effect of counterface wear cannot be ignored in such cases. Total wear, the sum of wear on both surfaces, can be used to characterize the wear of the couple.

by selecting a configuration in which the wear specimen experiences much more motion than the counterface and by using hard materials for the counterface. This tends to reduce the degree of simulation between the test and application, but is often used in standard tests to evaluate different materials for generic wear situations.

The three most common ways of measuring wear volume are directly measuring the wear scar using scanning profilometer techniques; using a dimensional measurement, such as width or depth, in conjunction with some geometrical relationships; and measuring mass loss and dividing by density. While there are problems and limitations associated with all these techniques, mass loss measurement is the least preferred for several reasons. First, wear is primarily associated with volume loss, not mass loss. Therefore, for valid comparison of materials, the densities must be known, which is not always the case, particularly with coatings. Second, some wear situations result in the build-up or transfer of material, in which case mass loss does not correspond to volume loss. When this technique is used for dry sliding situations, a net mass gain, or negative wear, is frequently observed. With the other techniques it is generally possible to avoid this problem by the use of datum lines, based on unworn profiles, to determine the worn volume. These lines provide a reference for determining wear depth or area. This method is illustrated in Figure 9. A final problem with mass loss measurements is that small amounts of wear may not be detectable on large specimens.

Control in Tribological Testing

In addition to simulation, which is the most fundamental element of tribological testing, there are three other important elements associated with this type of testing: the control required, the acceleration, and the documentation of test results. Control refers to those aspects that relate to the repeatability of the test. Table 4 lists the components of a tribological test that need to be controlled to reduce scatter. The degree of control required for any of these

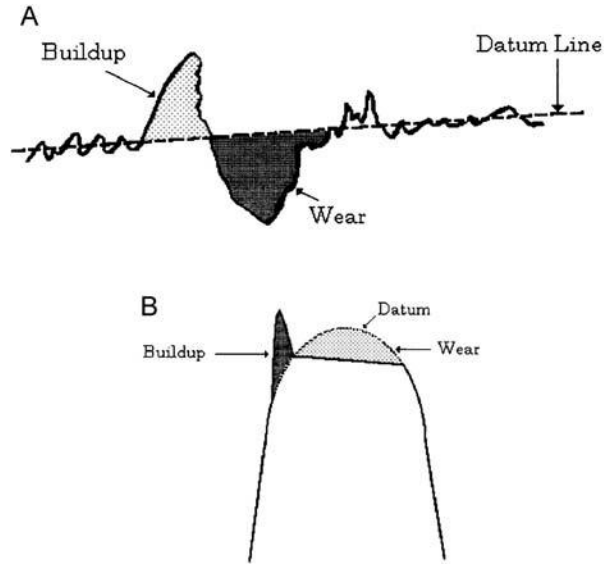

Figure 9. Examples of using datum lines to determine wear volume by profilometer techniques. (**A**) Use of a datum for a flat surface, where the average of the unworn surface is used to establish the datum. (**B**) Uses of a datum for a spherical specimen, where the datum is the unworn profile of the specimen.

components can vary, depending primarily on the nature of the materials involved and the amount of scatter that can be tolerated. However, insufficient control of any one of these can result in unacceptable scatter or erroneous data.

Three areas of control need to be stressed. (1) Since tribological behavior can be strongly influenced by surface films and the state of material near the surface, it is important to control specimen preparation and cleanliness. (2) Maintaining mechanical tolerances of specimens and equipment ensures that acceptable scatter is obtained. Loose tolerances can lead to variation in test specimen alignment and loading and to poor motion control, among other things. (3) Detailed test protocols should be developed and followed. Often, to ensure acceptable

repeatability, it is necessary to include in the protocols not only the major elements, such as loads, speeds, and measurement techniques, but elements such specimen handling and storage.

Tests with reference materials are frequently used to ensure adequate control. Initially, repeated tests with well-controlled materials are used to develop equipment and techniques to obtain acceptable repeatability. With established tests, similar tests are performed periodically to monitor equipment and implementation. If the results fall outside an acceptable range, the various test elements are then investigated to determine the cause and appropriate corrective action identified.

Another approach used with reference materials is to establish or obtain scaling factors. This is often done with abrasion and erosion tests, where it is generally difficult to adequately control lot-to-lot variations of the abrasive and erosive material used. Sometimes the test procedure is to include the simultaneous exposure of both the reference material and the test material, such as is done in a gouging abrasion test (ASTM G81). Still another approach is to perform tests with the reference material with each batch of abrasive or erosive to develop a scaling factor. An example is the method used to investigate the effect of hardness on the wear resistance of materials sliding against paper (Bayer, 1983).

Acceleration

Except for friction tests, most tribological tests involve an element of acceleration with respect to a real-world specific application. Basically this is because long wear lives and low wear rates are typical, or at least desired, characteristics of applications, whereas short test times are desirable in testing. This element of acceleration in a test runs contrary to the need to simulate the application as closely as possible. Nonetheless, some form and amount of acceleration can usually be reconciled with maintaining adequate simulation. The maximum amount of acceleration that can be used depends on the element selected to provide the acceleration, the materials involved, and the nature of the wear situation. The basic requirement for acceptable acceleration is not to change the significance of relevant friction, wear, and lubrication mechanisms. Conditions that are likely to cause significant changes in material behavior should be avoided, as well as those that can significantly affect tribofilm formation. For example, obtaining acceleration by increasing the load so that stresses are in the plastic range is generally not a valid way of providing acceleration for an application in which the stresses are in the elastic range. Similarly, testing polymeric materials under conditions where their temperature is above the glass transition temperature should not be used in applications where the temperature will be below their glass transition temperature. Typical ways of achieving acceleration in wear tests are to use higher loads or stresses, more severe environmental conditions, e.g., higher temperatures or relative humidity and higher speeds. Other options include higher concentrations of abrasives, higher impact velocities, continuous rather than interrupted motion, and more intense streams of erodents.

Reporting Test Results

An important element in tribological testing is documentation. In addition to the test results and the identification of the materials tested, test reports should include information on all the elements of the test tribosystem, as well as the test method. Figure 10 shows a form for reporting the results of tribological tests. In the figure "technical function of the tribosystem" refers to the nature of the wear situation, such as a sphere sliding on a flat or cavitation erosion by a vibrating horn. "Load profile," "velocity profile," and "temperature profile" include not only the magnitudes of these parameters but the variation over the test or test cycle. Other operating variables include other operating elements of the tribosystem, such as the method of introducing abrasives into the system or the nature of a run-in cycle. "Geometry" includes both size and shape; "chemical" refers to composition; "physical" refers to such things as hardness, modulus, and heat treatment; "topographical" refers to surface roughness characterization; and "surface layer properties" includes both chemical and physical properties. "Tribological interactions" refers to the possible ways the various elements of the tribosystem can interact and the sequence of those interactions. Other characteristics of interest can include contact resistance, features of wear debris, and the state of the lubricant.

There are ASTM guidelines for reporting friction and wear data that can be of use in determining what elements should be recorded and in what fashion (ASTM G115; ASTM G118). In addition, many standard tribological tests include a section on data reporting. For two-body wear tests it is essential to include information regarding the state of wear on the counterface, as well as on the primary surface or wear specimen.

METHOD AUTOMATION

Computer controls and automation are used in tribological testing to control loads and motions. These techniques

improve precision and consistency and also facilitate the implementation of complex test protocols such as progressively increasing the load in the test, using a raster pattern in sliding tests, or using a break-in procedure. Automated systems tend to have different characteristics than nonautomated systems, however. As a result, there is the possibility of bias between data obtained from nonautomated versus automated tests.

These techniques are also useful in measuring friction and the coefficient of friction. Automation is required to study short-term fluctuations in friction. If the normal force is simultaneously measured, instantaneous values of the coefficient of friction can be obtained. Automation can also be used to obtain average values of the coefficient of friction; this approach is used in many commercially available friction test apparatuses. When using such apparatuses, it is necessary to understand the algorithm that is used to determine the average value, as different algorithms can result in different values for complex friction profiles.

Automated *in situ* wear measurements are another application. However, at present these systems do not have the precision of off-line measuring techniques. As a result, they typically are only used to monitor coarse wear behavior during a test, and off-line techniques are used to measure wear for analysis and comparison purposes.

Automated three-dimensional scanning contact and noncontact surface profilometer methods are also used to measure and characterize wear scars. These approaches can be used to automatically determine wear scar volume and maximum depth as well as other properties of the scar, such as roughness.

DATA ANALYSIS AND INITIAL INTERPRETATION

Friction

In friction tests, where force is measured, the common method of analysis involves reducing the data to coefficients of friction, which are obtained by dividing the friction by the normal force. Typically, the data are analyzed to determine a static coefficient of friction, which is associated with the initiation of motion, and a dynamic coefficient of friction, which is associated with sustained motion. When there are fluctuations in friction, the coefficient should be determined on a point-by-point basis, rather than using average values for friction and load.

In wear tests in which friction is measured, changes in friction can frequently be correlated to changes in wear behavior. These correlations provide useful information for understanding and interpreting the friction and wear behavior of the system. However, high friction or low friction, by themselves, do not necessarily indicate high or low wear, respectively.

Wear

Analysis and interpretation methods for wear data depend on the nature of the test, the purpose of the test, and the model applied to the wear situation. Sometimes the wear data are directly compared without analysis; see Practical Aspects of the Method, Wear Tests. In other cases, the wear data are analyzed in terms of a particular model. In this case, the nature of the model dictates the method of analysis and guides the interpretation.

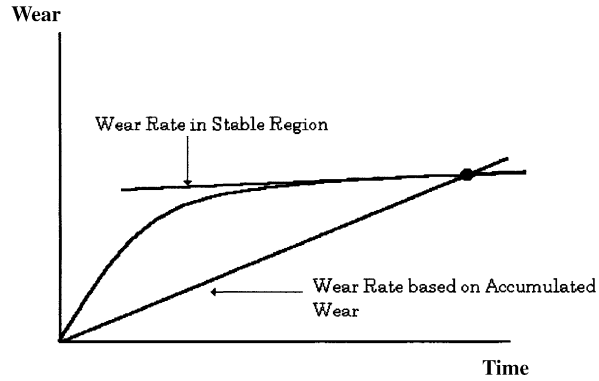

Figure 11. Possible error associated with using accumulated wear to determine wear rate.

A common way of reporting wear data, but not the only way, is to use a wear rate. For erosion this is in the form of volume lost per volume of erodent. For sliding and abrasive wear three different forms tend to be used: volume of wear per unit distance of sliding, volume of wear per unit distance of sliding per unit of load, and the former multiplied by the hardness of the wear specimen. The single-measurement method of wear testing is a poor choice if wear data are reported in this manner, as it is prone to considerable error because of the nonlinear nature of wear curves (see Fig. 11).

The last two wear rates used for sliding and abrasive wear involve normalization with respect to load and hardness, which is based on two simple models or equations for wear. These equations are the Archard equation for sliding wear and the Kruschov equation for abrasive wear (Bayer, 1994). Both have the same form:

$$V = KPS/H \tag{1}$$

where V is the volume of wear, P is the load, S is the distance of sliding, H is the hardness of the material, and K is a dimensionless wear coefficient. For sliding wear K is related to the probability of a wear fragment being formed; for abrasive wear K is related to the sharpness of the abrasives. While these equations provide a convenient way of analyzing wear data, there is considerable debate over their applicability, or that of any single equation, to all wear situations. Other models of wear often indicate different dependencies on load, distance, and hardness (Bayer, 1994, pp. 324–350; Ludema and Bayer, 1991).

As discussed earlier (see Practical Aspects of the Method, Wear Tests), the analysis and interpretation of wear data from two-body wear tests become more complex when there is significant wear on both surfaces. A common practice is to use the accumulated wear on both surfaces, rather than wear rates, for comparing and evaluating wear behavior. However, wear rates can also be obtained in these situations and used to characterize wear behavior.

SAMPLE PREPARATION

Sample preparation and sample control are key elements in reducing scatter and obtaining meaningful results. This is also true of the other materials used in tribological testing, such as counterfaces, abrasives, fluids, and lubricants. In general, it is important to control the composition, purity, dimensions, and surface topography, as appropriate, of these components. When machining is required, the method used should be the same as or equivalent to those used in the applications and be well controlled.

Surface films can have significant effects on tribological behavior. Consequently, it is necessary to clean the surfaces of wear specimens and counterfaces prior to a test and to use procedures that will maintain this state of cleanliness. Cleaning techniques vary with the type of material being cleaned as well as the type of surface film or contamination that is present. In most cases the goal of cleaning is to remove oil and grease films that result from handling, storing, and machining. This is done using detergents or solvents that will not harm the surface. Sometimes scrubbing with a mild abrasive is effective; in such cases care must be taken to avoid altering the surface topography and to clean the surface afterward to remove residual abrasives. In some cases more elaborate cleaning procedures may be required. Gloves are frequently used to avoid recontamination from handling.

PROBLEMS

The major systemic problem in tribological testing is inconsistency or variability of test results. This results from a lack of adequate control, which is a necessary and basic element of any tribological testing methodology. Inconsistency and variability can be caused by a number of factors. There are several ways of minimizing this problem. The fundamental one is to improve the precision of the various elements of the test apparatus and the consistency in the procedures used in conducting the test. One method for determining what is acceptable is by performing repeated tests with well-controlled or reference materials and systematically evaluating each of the elements that can contribute to the variability or scatter. Once the apparatus and test method are developed to a satisfactory level, it is advisable to periodically perform standard tests with these same well-controlled materials to monitor the condition of the equipment. These tests can also be used to train personnel in the techniques of tribological testing, which is a significant factor in obtaining consistent results.

Another recommendation is that the calibration of load cells, profilometers, speed controls, and other equipment be checked on a regular basis or before the start of a test. The apparatus should also be examined for signs of wear or deterioration. Protocols for handling and storage of materials should be followed, and records of the sources and batches of these materials should be kept. Such records are often a help in sorting out material problems from equipment problems. Recording the temperature and humidity of the laboratory is also good practice, since these may affect tribological behavior. It is not uncommon to find seasonal variations in data, and thus it is advisable to conduct tribological tests in environmentally controlled rooms or enclosures.

THERMAL ANALYSIS

INTRODUCTION

Thermal analysis is the name given to the measurement of a sample as the sample is programmed through a predetermined temperature regime in a specified atmosphere. The word sample is used to cover the substance placed in the apparatus and its solid reaction products. The temperature regime may take several forms, e.g., controlled rate at a specified heating rate, temperature jump where the temperature is held constant, or simply an isothermal run where the temperature is quickly brought to a predetermined temperature and then held constant for the remainder of the experiment. With the advent of computer control and processing, a variety of other temperature programs are available. The substance is usually studied in the condensed phase, i.e., solid or liquid, but a change from solid to gas or liquid to gas may be monitored. The gas thus produced generally escapes from the system under study. Temperature control is usually exercised over the gaseous environment containing the sample. The pressure of this environment may be controlled as well, from a vacuum through pressures in excess of an atmosphere, depending on the material under study and the intent of the measurement. At one atmosphere the gaseous environment may be stable or dynamic, i.e., the gas may either not be changed during the experiment, or one may control the flow of gas over the sample. The atmosphere in such circumstances may be oxidative (i.e., air or oxygen) or inert (e.g., helium, argon, or nitrogen). The material under study is typically placed in a crucible, and the nature of the crucible over an extended temperature range (be it of ceramic or metal), such as its expansion properties and any shape or volume changes should be carefully noted.

Over the years a network of national societies has arisen and of necessity an international confederation has been formed—the International Confederation of Thermal Analysis and Calorimetry (ICTAC). This is affiliated with IUPAC, the International Union of Pure and Applied Chemistry—which by many is regarded as the authority in such matters as formal definitions and nomenclature. Equipment for thermal analysis has been developed, and most of the apparatus is commercially available.

This chapter presents a collection of thermal analysis techniques available for the characterization of the thermal properties of materials. The general nature of the available equipment along with the formal definitions, codes of practice, and nomenclature for each of the principal methods are described early in the chapter. The most obvious property that can be measured against an imposed temperature regime is the sample mass; this is termed thermogravimetric analysis. Predating this is differential thermal analysis in which the enthalpy change or temperature change is noted. If the temperature perturbation is simply noted, then the method is known as differential thermal analysis, but if this is converted by suitable calibration to energy input or output, then the method is termed differential scanning calorimetry. With advancements in computer control and data acquisition technology comes the development of elaborate simultaneous techniques of thermal analysis, in which the sample is subjected to two or more analyses during a potentially highly sophisticated temperature program. A material's nature and composition may also be elucidated by the analysis and quantification of evolved gases released during a heating regime.

In addition to providing the materials scientist with information on the thermal stability and degradation products of a material under study, thermal analysis methods can reveal the phase properties, mechanical stabilities, thermal expansion coefficients, and electrical or magnetic properties as a function of temperature. Other properties of materials that are accessible using thermal analysis techniques include the temperatures and heats of phase transition, heat capacity, glass transition points, thermal stability, and purity. While the temperature dependence of the various methods contained throughout this volume will be presented whenever applicable, this chapter will compile the methods whose primary concern is the thermal properties and behavior of the material.

DAVID DOLLIMORE

THERMAL ANALYSIS—DEFINITIONS, CODES OF PRACTICE, AND NOMENCLATURE

INTRODUCTION

Those who practice the techniques of thermal analysis are well advised to notice and use the definitions, conventions, codes of practice, and methods of reporting data advocated by the International Confederation of Thermal Analysis and Calorimetry (ICTAC). These recommendations have been widely circulated and are to be found in the booklet *For Better Thermal Analysis* (Hill, 1991).

The recommended names and abbreviations of the various techniques in thermal analysis are listed in Table 1. The classification of thermal analysis techniques is given in Table 2. The definitions follow from these tables.

NOMENCLATURE

Distinction must be made between the terms *derivative* and *differential*. Differential methods involve the measurement of a difference in the property between the sample and a reference (e.g., differential thermal analysis). Derivative techniques involve the measurement or calculation of the first derivative, usually with respect to time (e.g., derivative thermogravimetry; DTG). With this point in mind, we can then proceed to the formal definitions.

Table 1. Recommended Terminology

Name
A. General
Thermal analysis
B. Methods associated with mass change
1. Static
Isobaric mass change determination
Isothermal mass change determination
2. Dynamic
Thermogravimetry (TG)
Derivative thermogravimetry (DTG)
3. Methods associated with evolved volatiles
Evolved gas detection (EGO)
Evolved gas analysis[a] (EGA)
C. Methods associated with temperature change
Heating curve determination[b]
Heating-rate curves
Inverse heating-rate curves[b]
Differential thermal analysis (DTA)
Derivative differential thermal analysis
D. Methods associated with enthalpy change
Differential scanning calorimetry (DSC)
E. Methods associated with dimensional change
Thermodilatometry
Derivative thermodilatometry
Differential thermodilatometry
F. Multiple techniques
Simultaneous TG and DTA, etc.

[a]The method of analysis should be clearly stated, and abbreviations such as MTA (mass spectrometric thermal analysis) and MDTA (mass spectrometry and differential thermal analysis) avoided.
[b]When determinations are performed during the cooling cycle, these become cooling curves, cooling-rate curves, and inverse cooling-rate curves, respectively.

Table 2. Classification of Thermoanalytical Techniques

Physical Property	Derived Technique(s)
Mass	Thermogravimetry
	Isobaric mass change determination
	Evolved gas detection
	Evolved gas analysis
	Emanation thermal analysis
	Thermoparticulate analysis
Temperature	Heating-curve determination[a]
	Differential thermal analysis
Enthalpy	Differential scanning calorimetry[b]
Dimensions	Thermodilatometry
Mechanical characteristics	Thermomechanical analysis (TMA)
	Dynamic thermomechanometry
Acoustic characteristics	Thermosonimetry
	Thermoacoustimetry
Optical characteristics	Thermoptometry
Electrical characteristics	Thermoelectrometry
Magnetic characteristics	Thermomagnetometry

[a]When the temperature program is in the cooling mode, this becomes cooling-curve determination.
[b]The confusion that has arisen about this term seems best resolved by separating the two modes (power-compensation DSC and heat-flux DSC), as described in the text.

Thermogravimetry (TG) is a technique by which the mass of a substrate is measured as a function of temperature while the substance is subjected to a controlled temperature program. The record is the TG curve; the mass is normally plotted on the ordinate, decreasing down toward the origin, and temperature (T) or time (t) is on the abscissa, increasing from left to right according to the basic rules for plotting any kind of graph. In decomposition reactions, the mass of reactants disappears and is often replaced by the increasing mass of solid products formed. Accordingly, in this and subsequent definitions, *substance* is to be understood to include the total mass of the system being weighed or investigated.

Derivative thermogravimetry (DTG) is a technique that yields the first derivative of the TG curve with respect to either time or temperature. The DTG curve is plotted with the rate of mass loss on the ordinate, and T or t is on the abscissa.

Isobaric mass change determination refers to the equilibrium mass of a substance at a constant partial pressure of the volatile product(s) measured as a function of temperature while the substance is subjected to a controlled temperature program.

Evolved gas detection (EGD) is a technique by which the evolution of gas from a substance is detected as a function of temperature while the substance is subjected to a controlled temperature program.

Evolved gas analysis (EGA) is a technique by which the nature and/or amount of volatile product(s) released by a substance is measured as a function of temperature while the substance is subjected to a controlled temperature program. The method of analysis should always be clearly stated.

Emanation thermal analysis is a technique by which the release of radioactive emanation (e.g., a radioactive gas such as radon) is measured as a function of temperature while the substance is subjected to a controlled temperature program.

Thermoparticulate analysis is a technique by which the release of particulate matter from a substance is measured as a function of temperature while the substance is subjected to a controlled temperature program.

Heating curve determination is a technique in which the temperature of a substance is measured as a function of the program temperature while the substance is subjected to a controlled temperature program.

Heating-rate curves plot the first derivative of the heating curve with respect to time (i.e., dT/dt) against temperature or time. The function dT/dt is plotted on the ordinate and T or t on the abscissa.

Inverse heating-rate curves plot the first derivative of the heating curve with respect to measured temperature (i.e., dt/dT) against either temperature or time. The function dt/dT is plotted on the ordinate and T or t on the abscissa.

Differential thermal analysis (DTA) is a technique in which the temperature difference between a substance and a reference material is measured as a function of temperature while the substance and reference material are subjected to a controlled temperature program. The

record is the DTA curve; the temperature difference (ΔT) is plotted on the ordinate, and T or t is on the abscissa. The temperature difference is considered to be negative in endothermic and positive in exothermic reactions.

When the equipment is calibrated, the DTA unit can be made quantitative with respect to the heat changes involved. The present tendency is to call this approach *differential scanning calorimetry* (DSC). DSC measures the difference in energy inputs into a substance and a reference material as a function of temperature while the substance and reference are subjected to a controlled temperature program.

Two modes—power-compensation DSC and heat-flux DSC—can be distinguished, depending on the method of measurement used. Two types of heat-flux calorimeters for DSC are produced commercially. The system may be provided with multiple temperature sensors (e.g., a Calvet-type arrangement) or with a controlled leak (e.g., a Boersma-type arrangement). For a general discussion on this topic see DIFFERENTIAL THERMAL ANALYSIS AND DIFFERENTIAL SCANNING CALORIMETRY or Haines and Wilburn (1995).

Thermodilatometry is a technique in which a dimension of a substance under negligible load is measured as a function of temperature while the substance is subjected to a controlled temperature program. The record is the thermodilatometric curve; the dimension is plotted on the ordinate, decreasing toward the origin, and T or t is on the abscissa. Linear thermodilatometry and volume thermodilatometry are distinguished on the basis of the dimensions measured.

Thermomechanical analysis (TMA) is a technique in which the deformation of a substance under a nonoscillatory load is measured as a function of temperature while the substance is subjected to a controlled temperature program. The mode, as determined by the type of stress applied (compression, tension, flexure, or torsion), should always be stated.

Dynamic thermomechanometry is a technique in which the dynamic modulus and/or damping of a substance under an oscillatory load is measured as a function of temperature while the substance is subjected to a controlled temperature program. Torsional braid analysis is a particular case of dynamic thermomechanometry in which the material is supported on a braid.

Thermosonimetry is a technique in which the sound emitted by a substance is measured as a function of temperature while the substance is subjected to a controlled temperature program.

Thermoacoustimetry is a technique in which the characteristics of imposed acoustic waves are measured as a function of temperature while the substance is subjected to a controlled temperature program.

Thermoptometry is a technique in which an optical characteristic of a substance is measured as a function of temperature while the substance is subjected to a controlled temperature program (for a general discussion on this topic, see Reading and Haines, 1995).

Measurement of total light, light of specific wavelength(s), refractive index, and luminescence leads to thermophotometry, thermospectrometry, thermorefractometry, and thermoluminescence, respectively; observation under the microscope leads to thermomicroscopy.

Thermoelectrometry is a technique in which an electrical characteristic of a substance is measured as a function of temperature while the substance is subjected to a controlled temperature program. The most common measurements are of resistance, conductance, and capacitance (see ELECTRICAL AND ELECTRONIC MEASUREMENT).

Thermomagnetometry is a technique in which the magnetic susceptibility of a substance is measured as a function of temperature while the substance is subjected to a controlled temperature program (see MAGNETISM AND MAGNETIC MEASUREMENT).

Sometimes in an investigation, a sample is characterized by more than one technique. The term for this is *simultaneous techniques*, and an example is simultaneous TG and DTA. The individual techniques are separated with a hyphen; thus the appropriate abbreviation is *simultaneous TG-DTA*. Unless contrary to established practice (some journals still do not accept the International Union of Pure and Applied Chemistry's (IUPAC) recommendations), all abbreviations should be written in capital letters without periods.

Gas analysis is rarely practiced as a separate thermal analysis technique. The two instruments involved are usually connected through an interface, e.g., DTA and mass spectrometry (MS). The term *interface* refers to a specific piece of equipment that enables the two instruments to be joined together. In this case, the DTA and the gas sampling occur at 1 atmosphere but the mass spectrometer must operate under a vacuum, and an interface is necessary for this to occur. Such a process is often described as a *coupled* simultaneous technique. Although the word simultaneous is used, in fact the two measurements are rarely absolutely simultaneous. Thus in gas analysis with thermogravimetry, the mass change is detected first, followed by gas sampling and gas analysis (MS) a finite time later. In such cases, the technique used first appears first in the abbreviation, e.g., TG-MS, not MS-TG. Sometimes the second technique does not involve continuous sampling. The proper term to use in such cases is *discontinuous* simultaneous techniques. An example is DTA and gas chromatography, in which discrete portions of evolved volatiles are collected from the sample situated in the instrument used for the first technique and then are analyzed by the second instrument.

SYMBOLS

The abbreviations for each technique have already been introduced. The confusion that can arise, however, between the use of, e.g., TG and T_g (glass-transition temperature), has led a number of investigators and instrument manufacturers to use TGA for TG. There are other aspects to the use of symbols, and a report of a subcommittee chaired by J. H. Sharp (1986) and presented to the Nomenclature Committee of the ICTA is summarized here.

1. The international system of units (SI) should be used wherever possible.

2. The use of symbols with superscripts should be avoided if possible.
3. The use of double subscripts should be avoided if possible.
4. The symbol T should be used for temperature, whether expressed in degrees Celsius (°C) or in kelvin (K). For temperature intervals, the symbol °C or K can be used.
5. The symbol t should be used for time, whether expressed in seconds (s), minutes (min), or hours (h).
6. The heating rate can be expressed either as dT/dt, when a true derivative is intended, or as β in K min^{-1} or °C min^{-1}. The heating rate so expressed need not be constant and can be positive or negative. If an isothermal experiment is carried out, it is best to state this fact in full.
7. The symbols m for mass and W for weight are recommended.
8. The symbol α is recommended for the fraction reacted or changed.
9. The following rules are recommended for subscripts.
   a. When the subscript relates to an object, it should be a capital letter, e.g., m_S is the mass of the sample and T_R is the temperature of the reference material.
   b. When the subscript relates to an action, it should be a lower case letter, e.g., T_g is the glass-transition temperature, T_c is the temperature of crystallization, T_m is the melting temperature, and T_σ is the solid-state-transition temperature.
   c. When the subscript relates to a specific point in time or point on a curve, it should be a lower case letter or a figure, e.g., T_i is the initial temperature, $m_{0.5}$ is the mass at which 50% of the material reacted, $t_{0.5}$ is the time at which 50% of the material reacted, $T_{0.3}$ is the temperature at which 30% of the material reacted, T_p is the peak temperature, and T_e is the extrapolated onset temperature (see description of TG technique).

STANDARDIZATION

It must be recognized that thermal methods of analysis can be applied to all states and conditions of matter. This flexibility is demonstrated by the design of equipment and choice of experimental conditions; therefore, it is imperative to select standards. Furthermore, no single thermal analysis instrument design or set of experimental conditions is optimum for all studies. The resultant data depend heavily on procedure. The major requirements in selecting standards are

1. To provide a common basis for selecting independently acquired data.
2. To enable equipment to be calibrated independently of the design of the particular instruments.
3. To provide the means for relating thermoanalytical data to physical and chemical properties determined by conventional isothermal procedures.

Such standards must be applicable to whatever experimental design is required for a particular purpose; otherwise, the value of the results is isolated, and the full potential of thermal analysis will not be realized. If curves of standard materials obtained under the conditions of a particular study are reported, readers will be able to relate the study results to the performance of their own instrumentation, to evaluate the quality of the published data, and to derive their own conclusions.

With this as its goal, the ICTA committee on standardization produced several sets of reference materials. Each instrument manufacturer will provide detailed advice on the calibration of its equipment using the proposed standards (Hill, 1991; Charsley et al., 1993). The reference materials and methods of calibration are currently under review by the German Thermal Analysis Society (GEFTA), and have not yet been approved by ICTAC or IUPAC.

The sets of ICTA reference materials include eight inorganic materials that exhibit solid-phase transitions, two high-purity metals, and four organic compounds (mainly of interest for their melting points). All standards are for temperature calibration in the heating mode and under normal operating conditions; consequently, the temperatures quoted are generally higher than the equilibrium values given in the literature. The temperature ranges of NIST-ICTAC (formerly known as NBS-ICTAC when NIST was named the National Bureau of Standards) certified reference materials are detailed in Table 3. Table 4 lists the transition temperatures that can serve as calibration points.

REPORTING THERMAL ANALYSIS DATA

ICTAC committees have defined *good practice* for both experimentation and reporting, so the information obtained

Table 3. Sets of Reference Materials Available[a]

GM-757 180–330 K	GM-758 125–435°C	GM-759 295–575°C	GM-760 570–940°C
1,2-Dichloroethane (melting)	Potassium nitrate	Potassium perchlorate	Quartz
Cyclohexane (transition, melting)	Indium	Silver sulfate	Potassium sulfate
Phenyl ether (melting)	Tin	Quartz	Potassium chromate
o-Terphenyl (melting)	Potassium perchlorate	Potassium sulfate	Barium carbonate
	Silver sulfate	Potassium chromate	Strontium carbonate

[a]Set GM-761 (a standard polystyrene sample with $T_g = 100$°C) is also available.

Table 4. Transition Temperatures (°C) of Reference Materials[a]

Material	Transition Type	Equilibrium Transition Temperature, °C	Extrapolated Onset Temperature, °C
	Inorganic		
KNO_3	Solid-solid	127.7	128 ± 5
In	Solid-liquid	156.6	154 ± 6
Sn	Solid-liquid	231.9	230 ± 5
$KClO_4$	Solid-solid	299.5	199 ± 6
Ag_2SO_4	Solid-solid	424	242 ± 7
SiO_2	Solid-solid	573	571 ± 5
K_2SO_4	Solid-solid	583	582 ± 7
K_2CrO_4	Solid-solid	665	665 ± 7
$BaCO_3$	Solid-solid	810	808 ± 8
$SrCO_3$	Solid-solid	925	928 ± 7
	Organic		
p-Nitrotoluene	Solid-liquid	51.5	51.5
Hexachloroethane	Solid-solid	71.4	—
Naphthalene	Solid-liquid	80.3	80.4
Hexamethyl benzene	Solid-solid	110.4	—
Benzoic acid	Solid-liquid	122.4	122.1
Adipic acid	Solid-liquid	151.4	151.0
Anisic acid	Solid-liquid	183.0	183.1
2-Chloroanthraquinone	Solid-liquid	209.1	209.4
Carbazole	Solid-liquid	245.3	245.2
Anthraquinone	Solid-liquid	284.6	283.9

[a]There are many references to these standards (Hill, 1991; Charsley et al., 1993).

and published is of maximum value. The recommendations of the committee were developed for authors, editors, and referees and are summarized below.

To accompany each DTA, TG, EGA, EGD, and/or thermochemical record, the following information should be reported.

1. Identification of all substances (sample, reference, diluent) by a definitive name and empirical formula or equivalent compositional data.
2. A statement of the source of all substances and details of their histories, pretreatments, and chemical purities, so far as these are known.
3. Measurement of the average rate of linear temperature change over the temperature range involving the phenomena of interest. Nonlinear temperature programming should be described in detail.
4. Identification of the sample atmosphere by pressure, composition, and purity and whether the atmosphere is static, self-generated, or dynamic throughout the sample. When applicable, the ambient atmospheric pressure and humidity should be specified. If the pressure is other than atmospheric, full details of the method of control should be given.
5. A statement of dimensions, geometry, and materials of the sample holder.
6. A statement of the method of loading (quasi-static, dynamic) when applicable.
7. Identification of the abscissa scale in terms of time or of temperature at a specified location. Time or temperature should be plotted to increase from left to right.
8. A statement of the method used to identify intermediates or final products.
9. Faithful reproduction of all original data.
10. Identification of the apparatus used by type and/or commercial name, together with details of the location of the temperature-measuring thermocouple.

THERMODYNAMIC BASIS FOR THERMAL ANALYSIS

Thermal analysis poses a problem in that some samples will achieve equilibrium at all temperatures, whereas others will be affected by the kinetics of chemical change. In many (but not all) DSC experiments, the interpretation can be solely in terms of thermodynamics. In many thermogravimetric experiments, a kinetic approach is possible. The reason for this lies in the conditions of the experiment imposed on the sample—it is partly owing to the experimental technique and partly owing to the nature of the sample under investigation.

This unit will not discuss thermodynamic relationships in detail; such information can be found in any textbook on physical chemistry (e.g., Atkins, 1994). In brief, however, the three laws of thermodynamics may be cited (also see THERMOMETRY). The first law of thermodynamics concerns the principle of the conservation of energy. At constant

pressure, the heat q_p absorbed by the system under consideration is given by the change in enthalpy ΔH:

$$\Delta H = q_p \tag{1}$$

Standard conditions in the past have been quoted: for gases, liquids, and solids (pure material) at the standard pressure of 1 atmosphere. The standard enthalpy of formation ΔH_f^0 is the change in standard enthalpy when 1 mol of substance is formed from its elements in their standard states; however, the definition of standard conditions is in a state of change, because recent textbooks are following the recommendations of IUPAC to quote the standard state as 1 bar (1 bar = 0.09869 atm).

For example,

$$\text{Zn (solid)} + \frac{1}{2}\text{O}_2(\text{gas}, 1\,\text{bar}) = \text{ZnO(solid)} \tag{2}$$

$$\Delta H^0_{\text{fZn0(solid)}} = -348.28\ \text{kJ mol}^{-1} \tag{3}$$

The heat absorbed by a system undergoing no chemical change is defined for a change in temperature of 1 K at constant pressure as the heat capacity at constant pressure C_p, which can be written:

$$C_p = \left(\frac{\partial H}{\partial T}\right)_p \tag{4}$$

This is itself a term that varies with temperature and is often given in the form:

$$C_p = a + bT + cT^2 \tag{5}$$

Thus for a system undergoing a reaction under standard conditions, the difference in enthalpy between products and reactants is given as ΔH^0, the heat released by the system. In the decomposition of a solid, such as calcite, however, the solid might be in a nonstandard condition. Nevertheless, the enthalpy of the solid-phase materials under standard conditions can be calculated for the dissociation:

$$\text{CaCO}_3\,\text{(solid)} = \text{CaO (solid)} + \text{CO}_2\,\text{(gas)} \tag{6}$$

$$\Delta H^0 = 178\ \text{kJ mol}^{-1} \tag{7}$$

The positive value of ΔH^0 implies that heat must be supplied to the system, i.e., it is an endothermic process.

An example of an exothermic reaction is

$$\text{CH}_4(\text{gas}) + 2\,\text{O}_2(\text{gas}) \rightarrow \text{CO}_2(\text{gas}) + 2\text{H}_2\text{O(liquid)} \tag{8}$$

$$\Delta H^0 = -890\ \text{kJ mol}^{-1} \tag{9}$$

The negative sign implies the process is exothermic.

To adjust the standard-state values to other conditions of pressure and temperature requires a knowledge of C_p for all chemical species involved and of how C_p varies with temperature.

Reactions in an isolated system reach an equilibrium state. Thus for

$$\text{CaCO}_3\,\text{(solid)} \rightarrow \text{CaO (solid)} + \text{CO}_2\,\text{(gas)} \tag{10}$$

it is possible to write

$$K_p = \frac{a_{\text{CaO}} a_{\text{CO}_2}}{a_{\text{CaCO}_3}} \tag{11}$$

where K_p is the equilibrium constant (which assumes a characteristic value at each temperature) and a_{CaO}, a_{CO_2} and a_{CaCO_3} are the activities of the indicated chemical species. Usually, the activities of the solid phase are assigned a value of unity, and a_{CO_2} can be approximated to the pressure P_{CO_2}, so that:

$$K_p = P_{\text{CO}_2} \tag{12}$$

It should be noted, however, that if the carbon dioxide is kept below this value and removed as it is formed, the reaction will proceed to completion.

The tendency for reactions to proceed is covered by the second law of thermodynamics. This driving force depends both on the change in enthalpy ΔH and on the change in entropy ΔS. The third law of thermodynamics states that entropy can be assigned a zero value at the temperature of absolute zero for perfectly crystalline solids. A simple way in which enthalpy and entropy changes can be combined to demonstrate this tendency for a transition to proceed is via the Gibbs free energy (G). The relationship is

$$G = H - TS \tag{13}$$

and for a transition at constant temperature:

$$\Delta G = \Delta H - T\Delta S \tag{14}$$

For a spontaneous reaction, ΔG is negative. The standard change in Gibbs free energy is related to the equilibrium constant K as follows:

$$\Delta G^0 = -RT \ln K \tag{15}$$

where R is the gas constant. The variation with temperature is given by

$$\ln K = -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} \tag{16}$$

which is called the van't Hoff equation.

All these relationships find application in the interpretation of thermal analysis data. One further point is that at equilibrium,

$$\Delta G = 0 \tag{17}$$

when

$$T_{\text{transition}} = \frac{\Delta H}{\Delta S} \tag{18}$$

This sets out a thermodynamic decomposition temperature under standard conditions. Thus for the dissociation of calcium carbonate:

$$T_{\text{dissociation}} \approx 950^{\circ}\text{C} \tag{19}$$

This equation must be regarded as giving an approximate temperature for the decomposition, because both ΔH and ΔS vary with temperature. Reference data for ΔH and ΔS are usually reported at room temperature. Furthermore, the experimental data of thermal analysis probably do not conform to standard conditions. For vaporization, T_{vap} at 1 atmosphere (the normal boiling point) is given by:

$$T_{\text{vap}} = \frac{\Delta H_{\text{vap}}}{\Delta S_{\text{vap}}} \tag{20}$$

If ΔS_{vap} is assumed to be constant for most liquids, then:

$$\Delta S \; T_{\text{vap}} = \Delta H_{\text{vap}} \tag{21}$$

or

$$T_b \cdot 85\,\text{J}\,\text{K}^{-1}\text{mol}^{-1} = \Delta H_{\text{vap}} \tag{22}$$

where T_b is the normal boiling point. Expressed this way, the above equation is a mathematical statement of Trouton's rule. Most of the relationships outlined above can be used for interpreting thermal analysis data.

KINETIC BASIS FOR THERMAL ANALYSIS

In many systems investigated using a rising temperature method, it is obvious that an equilibrium condition is not found. The classical way in which kinetic data are evaluated is by way of a specific reaction rate, defined by

$$\frac{d\alpha}{dt} = kf(\alpha) \tag{23}$$

where α is the fractional extent of the reaction and t is the time in an isothermal mode. The term $f(\alpha)$ often takes an "order" form:

$$\left.\begin{array}{r} \alpha \to 1 \\ f(\alpha) \to 1 \\ \dfrac{d\alpha}{dt} = k \end{array}\right\} \tag{24}$$

where k is taken to be the specific reaction rate and α is used here instead of the conventional concentration or pressure term, because there is no concentration term in solid-state reactions. If the temperature is varied at a heating rate of β in degrees Celsius per minute, then:

$$\beta = \frac{dT}{dt} \tag{25}$$

where t is the time and T is the temperature. From plots of α against T in such circumstances, the following relationship is obtained:

$$\frac{d\alpha}{dt} = \left(\frac{d\alpha}{dT}\right)\left(\frac{dT}{dt}\right) = \left(\frac{d\alpha}{dT}\right)\beta \tag{26}$$

Thus at any point on the thermal analysis plot (i.e., at any given temperature):

$$\left(\frac{d\alpha}{dT}\right)\beta = kf(\alpha) \tag{27}$$

$$k = \frac{(d\alpha/dT)\beta}{f(\alpha)} \tag{28}$$

If an Arrhenius relation is assumed, then:

$$k = Ae^{-E_{\text{act}}/RT} \tag{29}$$

and

$$\ln k = \ln A - \frac{E_{\text{act}}}{RT} \tag{30}$$

when

$$\ln\left[\frac{(d\alpha/dT)\beta}{f(\alpha)}\right] = \ln A - \frac{E_{\text{act}}}{RT} \tag{31}$$

When E_{act} is the activation energy and A is the Arrhenius preexponential constant, Equation 31 provides a route to the calculation of A and E_{act} from thermal analysis data, if $f(\alpha)$ can be determined. There are numerous publications dealing with this topic in detail (e.g., Dollimore and Reading, 1993).

PUBLICATIONS ON THERMAL ANALYSIS

Because of the diverse applications of thermoanalytical methods, the literature is widely scattered. Two international journals for publication of papers on thermal analysis—*Journal of Thermal Analysis* and *Thermochimica Acta*—are available, but both tend to publish data outside the precise definition of thermal analysis, particularly with reference to calorimetry. Ephemeral publications such as the newsletters issued by various societies to members (e.g., *ICTA Newsletter, Bulletin de 1'Association Française de Calorimetrie et d'Analyse Thermique, NATAS Notes*, and *Aicat Notizie*), serve a useful purpose by carrying information on recent developments, meetings, books, etc., that may be of interest.

Chemical Abstracts scans all entries for articles that deal with thermal analysis and produces *Chemical Abstracts Thermal Analysis Selects* every 2 weeks. These issues are used as the basis for a biannual review, which appears in *Analytical Chemistry*. The abstracts are available in computer-compatible form. Many articles on thermal analysis are included in materials science and pharmacological journals.

Every 4 years, the International Confederation for Thermal Analysis and Calorimetry holds its international conference. In the years between international conferences, the European societies hold a thermal analysis conference. The North American Thermal Analysis Society holds a conference every year, except when it hosts the international conference. The individual societies hold regular meetings, and some hold an annual conference. The papers presented at such conferences are usually published as edited books. *Thermochimica Acta* and *Journal of Thermal Analysis* both publish special issues of conference papers, on specific topics, or in honor of well-known scientists. There are an increasing number of books and monographs on thermal analysis, some of which serve as good textbooks. Hill (1991) includes a good bibliography.

Each year *The International Thermal Analysis, Calorimetry and Rheology Buyer's Guide* is published by B&K Publishing Company. The guide contains consumables, consultants, contract analytical service providers, providers of certified reference materials, instruments (new, used and refurbished), and reference literature/resources along with advertisements from vendors of thermal analysis equipment. The guide may be requested by sending an e-mail to guiderequest@bkpublishing.com. A weekly newsletter is also published and may be received via email by sending the message SUBSCRIBE to subscribe@bkpublishing.com.

THERMOGRAVIMETRIC ANALYSIS

INTRODUCTION

The formal definition of thermogravimetry (TG is the preferred abbreviation, although TGA is also used) has been given by the Nomenclature Committee of the International Confederation for Thermal Analysis and Calorimetry (ICTAC) as "a technique in which the mass of a substance is measured as a function of temperature whilst the substance is subjected to a controlled temperature programme" (Mackenzie, 1979, 1983).

In the above definition, a controlled temperature program means heating or cooling the sample at some predetermined and defined rate. Although it is common to have just one constant heating or cooling rate, it is also advantageous in some cases to have different rates over different temperature ranges and in some cases even a varying rate over a specific temperature range. Thus the heating rate could be started at 20°C/min up to 200°C, followed by an isothermal hold at 200°C for 10 min and then by further heating at 10°C/min.

An apparatus called a thermobalance is used to obtain a thermogravimetric curve. By means of a thermobalance the temperature range over which a reaction involving mass change occurs may be determined.

The sample is usually a solid, or more rarely a liquid. The heating/cooling rates typically cover the range 1° to $100°C/min^{-1}$, and the atmosphere can be varied from an inert one such as nitrogen to a reactive one such as oxygen or sulfur dioxide. Vacuum can be applied, with specialized instruments being able to achieve a hard vacuum up to 10^{-6} Torr. Experiments can usually be conducted in a relatively short time, so that at a typical heating rate of 20°C/min a sample can be heated to 1000°C in 50 min. Once the experiment is set up, it requires no further attention. If the furnace is fitted with a cooling device, then turnaround time is rapid and a new experiment can be started within 15 min.

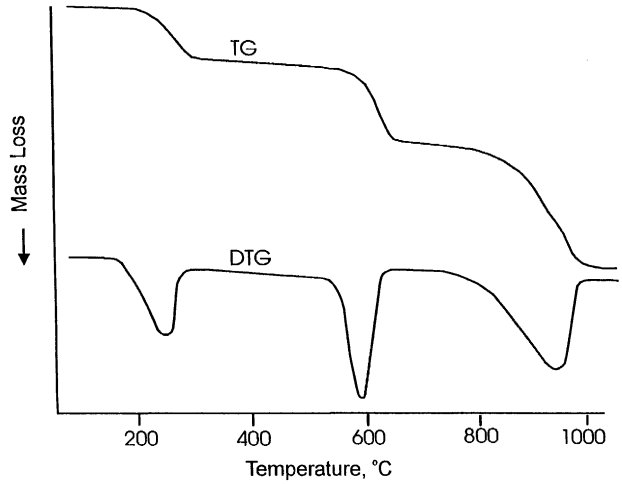

Figure 1. Schematic of TG and DTG curves.

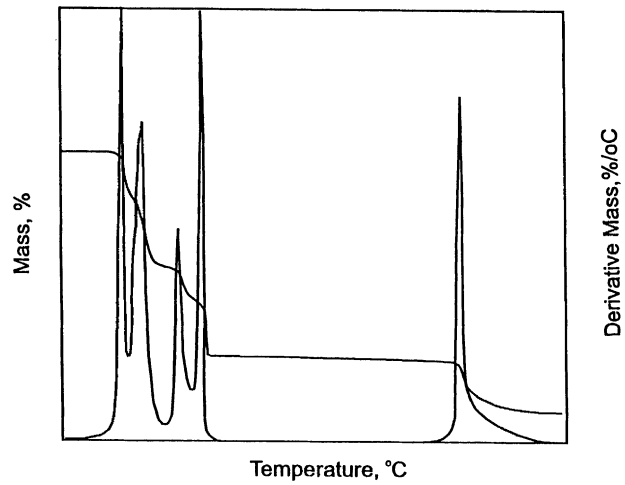

Figure 2. TG curve obtained from a controlled-rate experiment, in which the rate of mass loss is kept nearly constant,and the variable is the heating rate.

Thermogravimetric data can be presented in two ways. The TG curve is a plot of the mass against time or temperature, with the mass loss on the ordinate plotted downward and mass gains plotted upward relative to a baseline. Alternatively, data can be presented as a derivative thermogravimetric (DTG) curve, which is a plot of the rate of change of mass m with respect to time t or temperature T against time or temperature. The DTG mass losses should also be plotted downward and the gains upward. Schematic TG and DTG curves are shown in Figure 1. In practice, the mass losses may not nearly be so well resolved since the reactions are temperature-dependent rate processes that require time to reach completion. Hence the first reaction may not be complete before the second reaction commences, and the baseline between the reactions may be a slope rather than a plateau region. When a horizontal plateau is obtained in a TG curve, a minimum at which $dm/dt = 0$ is observed in the DTG curve (Fig. 1). A maximum in the DTG curve corresponds to a point of inflection in the TG curve at which mass is lost (or gained) most rapidly. Minima can also occur in a DTG curve at which $dm/dt > 0$, corresponding to a point of inflection in the TG curve rather than to a horizontal plateau.

Conventionally, thermal analysis experiments are carried out at a constant heating rate, and a property change is measured as a function of time. An alternative approach is to keep the change in property constant by varying the heating rate (Paulik and Paulik, 1971; Reading, 1992; Rouquerol, 1989). For TG, the rate of mass loss is kept constant by variation in heating rate. [This technique is given various names, although controlled-rate thermal analysis (CRTA) appears to have become the accepted terminology.] To achieve this, the mass change is monitored and the heating rate decreased as the mass loss increases, and vice versa. At the maximum rate of mass loss, the heating rate is a minimum. This gives mass losses over very narrow temperature ranges and sometimes enables two close reactions to be resolved (see Fig. 2). This method has the advantage of using fast heating rates when no thermal event is taking place and then slowing down the heating rate when a mass change is in progress.

Thermogravimetry does not give information about reactions that do not involve mass change, such as polymorphic transformations and double-decomposition reactions. Also, it is not useful for identification of a substance or mixture of substances unless the temperature range of the reaction has already been established and there are no interfering reactions. However, when a positive identification has been made, TG by its very nature is a quantitative technique and can frequently be used to estimate the amount of a particular substance present in a mixture or the purity of a single substance. The types of processes that can be investigated by TG are given in Table 1.

There is significant literature on TG, and for more extensive information the reader is referred to Keattch and Dollimore (1975), Earnest (1988), Wendlandt (1986), Dollimore (1992), Dunn and Sharp (1993), Haines (1995), and Turi (1997).

Other methods are available for the measurement of mass change as a function of temperature, although they are often limited to changes at set temperatures. Two modes of measurement can be distinguished:

Table 1. Processes That Can be Studied by TG

Process	Mass Gain	Mass Loss
Adsorption and absorption	•	
Desorption		•
Dehydration or desolvation		•
Vaporization		•
Sublimation		•
Decomposition		•
Oxidation	•	•
Reduction		•
Solid-gas reactions	•	•
Solid-solid reactions		•

1. The sample is heated to a specific temperature and the mass change followed at that temperature. After a time lapse, the sample may be heated to a higher constant temperature (or cooled to a lower constant temperature) and again the mass change observed. Quartz spring balances are often used in this application, which are cheap to construct but cumbersome to use. These systems are used to study, e.g., the adsorption/desorption of a gas on a solid at different temperatures.
2. The sample is weighed at room temperature, heated to a constant temperature for a certain time, then removed, cooled back to room temperature, and reweighed. This is the process used in gravimetric analysis and loss on ignition measurements. This method is inexpensive. However, unless the hot sample is put into an inert environment, the sample can readsorb gases from the atmosphere during cooling and hence give anomalous results.

The major disadvantage of both of the above methods is that the mass change is not followed continuously as a function of temperature.

The complementary techniques of differential thermal analysis (DTA) and differential scanning calorimetry (DSC) are dealt with in DIFFERENTIAL THERMAL ANALYSIS AND DIFFERENTIAL SCANNING CALORIMETRY. Thermogravimetry can be combined with either DTA or DSC in a single system to give simultaneous TG-DTA or TG-DSC; these techniques will be discussed in SIMULTANEOUS TECHNIQUES INCLUDING ANALYSIS OF GASEOUS PRODUCTS. To characterize the sample as well as identify reaction products at various temperatures, a range of other techniques are used, including wet chemical analysis, x-ray diffraction (XRD) (X-RAY TECHNIQUES), spectroscopic techniques such as Fourier transform infrared (FTIR) spectroscopy, optical techniques such optical microscopy (OM) (OPTICAL MICROSCOPY, REFLECTED-LIGHT OPTICAL MICROSCOPY), and scanning electron microscopy (SEM) (SCANNING ELECTRON MICROSCOPY). The information obtained from these techniques enables the reaction intermediates to be identified so that the reaction scheme can be written with some confidence.

Other techniques placed by the ICTAC Nomenclature Committee (Mackenzie, 1979, 1983) within the family of thermal analysis methods based on changes of mass are evolved gas detection, evolved gas analysis, and emanation thermal analysis. Emanation thermal analysis [developed by Balek (1991)] involves the release of radioactive emanation from a substance, which gives a change in mass if, for example, α-particles are emitted.

PRINCIPLES OF THE METHOD

The form of the TG/DTG curve obtained experimentally is dependent on the interplay of two major factors: the properties of the sample and the actual experimental conditions used, also called procedural variables. Both factors can affect the kinetics of any reaction that takes place, so that a change in either will have a subsequent effect on the form of the TG curve. It is also important to note that unless the sample is held at constant temperature, applying a heating or cooling rate produces nonequilibrium conditions.

It is possible to calculate a theoretical TG curve if the kinetic mechanism and parameters are known, on the assumption that heat transfer is instantaneous and no temperature gradient exists within the sample. Thus the kinetics of most reactions under isothermal conditions can be summarized by the general equation

$$\frac{d\alpha}{dt} = kf(\alpha) \tag{1}$$

Here α is the fraction reacted in time t and is equal to $w_i - w_t/w_i - w_f$, where w_i is the initial weight of the sample, w_t is the weight at time t, and w_f is the final weight of the sample; k is the rate of reaction; and (α) is some function of α. The various forms adopted by the function (α) and the integrated forms $g(\alpha)$ have been discussed elsewhere (Keattch and Dollimore, 1975; Satava and Skvara, 1969; Sharp, 1972; Sestak, 1972) and are given in the next section.

The temperature dependence of the rate constant follows the Arrhenius equation:

$$k = Ae^{-E/RT} \tag{2}$$

where T is the absolute temperature, A is the preexponential factor, E is the activation energy, and R is the gas constant.

For a linear heating rate,

$$T = T_0 + \beta t \tag{3}$$

where T_0 is the initial temperature and β is the heating rate.

Combination of Equations 1 and 2 give

$$\frac{d\alpha}{dt} = Af(\alpha)e^{-E/RT} \tag{4}$$

Substitution for dt using Equation 3 gives

$$\frac{d\alpha}{dT} = \frac{A}{\beta} f(\alpha)e^{-E/RT} \tag{5}$$

which, if rearranged, provides

$$\frac{d\alpha}{f(\alpha)} = \frac{A}{\beta} e^{-E/RT} dT \tag{6}$$

Equation 6 is the basic equation of the DTG curve, which when integrated is the equation of the TG curve. If the form of the function $f(\alpha)$ is known, integration of the left-hand side of the equation is straightforward and gives the associated function $g(\alpha)$. The integration limits are between the initial and final temperatures of the reaction, or between $\alpha = 0$ and $\alpha = 1$. The values of E and A have a marked influence on the temperature range over which the TG curve is observed, but they do not influence

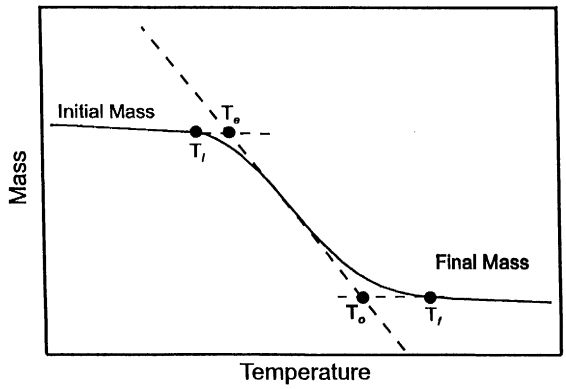

Figure 3. Various temperatures used to define the TG curve.

the shape of the curve too greatly (Satava and Skvara, 1969). The kinetic mechanism, i.e., the form of $f(\alpha)$ or $g(\alpha)$, however, determines the shape of the curve.

The TG curve can be defined in several ways. The temperature at which a change in mass is first detected—called the initial temperature T_i (see Fig. 3), or onset temperature, or procedural decomposition temperature—is not sufficiently well defined to use as a satisfactory reference point, since its detection is dependent on factors such as the sensitivity of the TG apparatus and the rate at which the initial reaction occurs. If the initial rate of mass loss is very slow, then the determination of T_i can be uncertain.

A more satisfactory approach is to use the extrapolated onset temperature, T_e, which provides consistent values (see Fig. 3). If, however, the decomposition extends over a wide temperature range and only becomes rapid in its final stages, the extrapolated onset temperature will differ considerably from the onset temperature. For this kind of reaction, it is more satisfactory to measure the temperature at which a fractional weight loss, α, has occurred (T_α) (see Fig. 4). Clearly the temperature $T_{0.05}$ is close to that at the start of the reaction and $T_{0.90}$ is close to that at the end of the reaction. To define the complete range of reaction, two further temperatures, T_0 and T_f may be identified, as shown in Figure 3. Similar comments apply to these as to the corresponding temperatures already discussed.

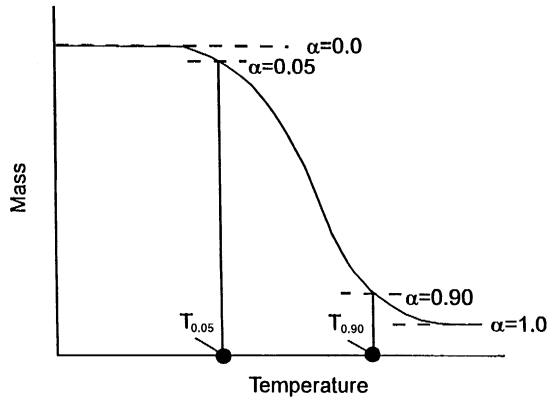

Figure 4. Measurement of the fraction reacted, α.

PRACTICAL ASPECTS OF THE METHOD

Apparatus

Thermobalance apparatus consist of the essential components of a balance and balance controller, a glass vessel to enclose the sample and balance to allow experiments to be carried out in a controlled atmosphere, a furnace and furnace controller, and a recorder system. Today it is common to purchase a thermobalance from a commercial source. Only in cases where the requirements are not met by the commercial sources should the construction of a self-designed system be contemplated, although most manufacturers will discuss possible modifications to existing systems.

Balances that monitor mass changes are of two types: deflection and null deflection. The deflection balance monitors the movement of the weight sensor, and the null-deflection balance the position of the beam. In the latter a servo system maintains the beam it in a quasi-equilibrium position, the power supply to the servo system being the measure of the mass change. An advantage of the null-deflection balance is that the sample stays in a constant position in the furnace, which assists in various ways that will be explained later. Most modern thermobalances are based on null-type electronic microbalances, which means that sample masses of typically 10 to 20 mg are sufficient to be able to detect mass changes accurately and reliably. Thermobalances capable of taking larger samples, in the gram range, are also available, although they tend to be used for specialized applications.

The automatic recording beam microbalance and ultra microbalances for use in vacuum and controlled environments have been reviewed by Gast (1974) and Czanderna and Wolsky (1980). The load-to-precision ratio (LPR) is often used as a means of comparing the performance of microbalances. A 1-g capacity beam balance with a precision of 2 μg will have an LPR of 5×10^5. This compares with LPR values for high-performance microbalances of 10^8 or better (Czanderna and Wolsky, 1980, p. 7). In the balance sensitivity category, for example, the highest quoted sensitivity for all the reviewed thermobalances is l pg, and the lowest is 50 pg. However, the lower sensitivity balances may also be capable of taking larger sample masses and so the LPR value may not vary significantly across the range. This needs to be checked for each specific balance. Details of the sensitivity or detection limit, precision, and accuracy of the balance are not always evident in the literature, and the terminology used is not always descriptive or accurate. Some degree of standardization would be helpful to the prospective buyer.

Thermobalances are enclosed in a glass envelope, or chamber, which can be sealed, partly to protect the balance against corrosion or damage but also to enable experiments to be carried out in a controlled atmosphere. Various ways are available for introducing the chosen gas. The most common way to introduce an inert gas is to

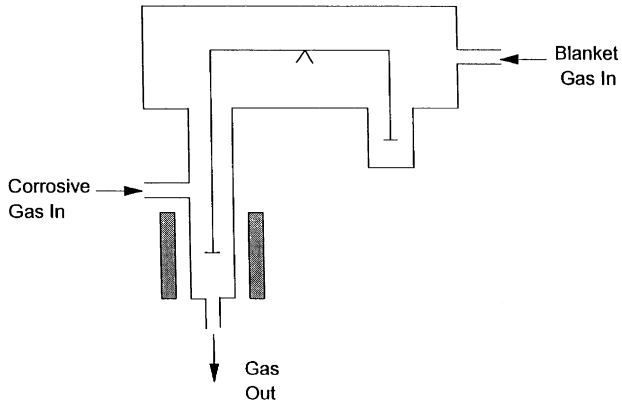

Figure 5. Protection of balance mechanism from corrosive gases by a secondary gas flow.

flow it first over the balance and then over the sample before exiting the system. This has the advantage of protecting the balance against any corrosive products generated by the decomposing sample as well as sweeping away any products that may condense on the hangdown arm of the balance and cause weighing errors.

When a corrosive reaction gas is employed, the balance needs to be protected. This can be achieved by flowing an inert gas over the balance and introducing the corrosive gas at some other point so it is swept away from the balance mechanism. One way of realizing this is shown in Figure 5. A flow of the blanket gas is established followed by the reactive (corrosive) gas. Some commercial thermobalances are equipped with flowmeters for gas control, but if they are not, then external rotameters need to be fitted. When corrosive gases are used, the flow of corrosive gas and inert gas needs to be carefully balanced in order to provide the proper protection. Examples of thermobalances that have been modified to work in different atmospheres are many, e.g., in a sulfur atmosphere (Rilling and Balesdent, 1975) or in sodium vapor (Metrot, 1975).

The problem of containing corrosive gases is considerably simplified by the magnetic balance designed by Gast (1975), where the balance and sample chambers are completely separated. This is a single-arm beam balance in which the pan is attached to a permanent magnet that is kept in suspension below an electromagnet attached to the hangdown wire. The distance between the two magnets is controlled electromagnetically. The sample chamber and the atmosphere containing the sample are thus isolated from the balance, and no attack on the mechanism can occur. This concept has been extended to microbalances (Pahlke and Gast, 1994).

The ability to have controlled flowing atmospheres is usually available, with gas flows of up to 150 mL min^{-1} being typical. Some instruments offer threaded gas valve connections, as well as a means of monitoring the gas flow. Work under vacuum down to 1×10^{-3} bar is common, and many thermobalances can operate down to 10^{-6} bar, although it is not usual to find instruments fitted with a means of monitoring the vacuum level. A commercial balance is reported to be able to operate up to 190 bars (Escoubes et al., 1984). Many examples of balances that work in high vacuum are reported at the vacuum microbalance conferences. For high-pressure work, there is a TG apparatus capable of working up to 300 bars and 350°C (Brown et al., 1972) and a versatile TG apparatus for operation between 10^{-8} and 300 bars in the temperature range −200 to 500°C (Gachet and Trambouze, 1975).

Table 2 . Common Furnace Windings and Their Approximate Maximum Working Temperature

Furnace Winding	Approximate Maximum Working Temperature (°C)
Nichrome	1000
Kanthal	1350
Platinum	1400
Platinum/10% rhodium	1500
Kanthal super ($MoSi_2$)	1600
Molybdenum	1800
Tungsten	2800

Furnaces can be mounted horizontally or vertically around the detector system. The most widely used furnaces are those wound with nichrome (nickel-chromium alloy) or platinum/rhodium heating wires. The most commonly used windings and their maximum temperatures of operation are given in Table 2. Molybdenum and tungsten windings need to be kept under a mildly reducing atmosphere to prevent oxidation.

Furnaces are frequently wound in a noninductive manner, i.e., in one direction and then the other, so that magnetic fields generated when a current is passed through the furnace windings are canceled, thus eliminating any interaction with a magnetic sample.

A requirement of a furnace is that there should be a region within which the temperature is constant over a finite distance. This distance is referred to as the hot zone. The hot zone diminishes as the temperature increases, as indicated in Figure 6. The sample should always be in the hot zone, so that all of the sample is at the same temperature. A thermocouple can be used to ensure that proper placement of the sample in relation to the hot zone is established. This is one reason to use a null-deflection balance, as the sample is always in the same position

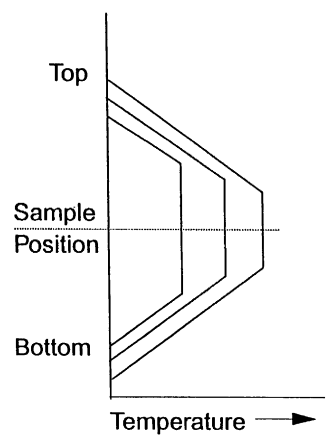

Figure 6. Schematic of the hot zone in a furnace.

in the furnace. Furnaces capable of very high heating rates have been used for TG experiments of textiles at heating rates approaching 3000°C/min (Bingham and Hill, 1975). These fast response furnaces can achieve isothermal temperatures rapidly. Alternative methods of heating include infrared and induction heating, which heat the sample directly without heating the sample chamber. Very fast heating rates on the order of 3000 to 6000°C min^{-1} can be achieved. Induction heating requires that the sample must be conducting, or placed in a conducting sample holder.

The temperature ranges for commercially available instruments given in the manufacturer's literature tend to be for the basic model, which operates typically in the temperature range ambient to 1000°C, but other models may operate from −196° to 500°C or ambient to 2400°C with steps in between.

There are three main arrangements of the furnace relative to the weighing arm of the balance. Lateral loading is a horizontal arrangement in which the balance arm extends horizontally into a furnace aligned horizontally. Two vertical arrangements are possible: one with the balance above the furnace with the sample suspended from the balance arm (bottom loading) and the other with the balance below the furnace and the sample resting on a flat platform supported by a solid ceramic rod rising from the balance arm (top loading). The following advantages are claimed for the horizontal mode:

1. Balance sensitivity is increased by virtue of the long balance arm.
2. It permits rapid gas purge rates, up to 1 L/min, since horizontal balance arms are perturbed less by a rapid gas flow than a vertical arrangement.
3. The influence of the Knudsen effect and convection errors can be ignored, i.e., chimney effects from the furnace are eliminated.
4. Evolved gas analysis is simplified.

The main advantage claimed for the vertical mode is that much higher temperatures can be achieved, since no change occurs in the length of the balance arm.

Escoubes et al. (1984) reported that the bottom-loading principle was adopted by about twice as many systems as the top-loading principle, with a small number of lateral-loading models apparent.

Temperature measurements are most commonly made with thermocouple systems, the most common being chromel-alumel, with an operating temperature range of ambient to 800°C; Pt–Pt/10% Rh at ambient to 1500°C; and Pt/6% Rh–Pt/30% Rh at ambient to 1750°C. The ideal location of the sample-measuring thermocouple is directly in contact with the sample platform. This requires that very fine wires made of the same material as the thermocouple are attached to the bottom of the platform. Such arrangements are found in simultaneous TG-DTA systems. The other alternative is to place the thermocouple at some constant distance from the sample and let the calibration technique compensate for the gap between the thermocouple and the sample. This method can only be adopted for a null-deflection balance, as this is the only system in which the distance between the sample platform and the thermocouple is constant. Two typical configurations are shown in Figure 7: one with the wires welded onto the bottom of the flat-plate thermocouple, which is kept at a constant distance from the sample pan, and the other a sideways configuration found in the horizontal balance arm arrangements.

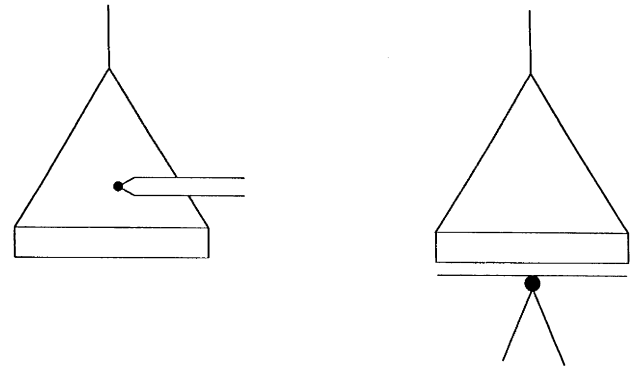

Figure 7. Typical configurations of the sample temperature-measuring thermocouple for a null-deflection balance. Left: lateral balance arm arrangement; right: bottom-loading balance.

The response of the thermocouple varies with age, and so calibration with an external calibrant is required from time to time. Thermocouples, like other devices, do not respond well to abuse. Hence, operation of the furnace above the recommended temperature or in a corrosive environment will result in relatively rapid changes to signal output and eventually render it inactive.

The chief functions of a temperature programmer are to provide a linear and reproducible set of heating rates and to hold a fixed temperature to within 1°C. The programmer is usually controlled by a thermocouple located close to the furnace windings but occasionally situated close to the sample. Modern programmers can be set to carry out several different heating/cooling cycles, although this function is being increasingly taken over by microprocessors.

The thermocouple output is usually fed to a microprocessor containing tabulated data on thermocouple readings, so that the conversion to temperature is made by direct comparison. Although heating rates often increase in steps, say, 1, 2, 5, 10, 30, 50, 100°C/min^{-1}, microprocessor-controlled systems allow increments of 0.1°C/min, which can be useful in kinetic studies based on multiple-heating-rate methods.

The recording device for most modern equipment is the computer. Thermobalances provide a millivolt output that is directly proportional to mass, and so it is possible to take this signal and feed it directly into a microprocessor via a suitable interface. This is by far the most common and best method for data acquisition and manipulation. Reading the direct millivolt output is the most accurate way of obtaining the measurement. Once stored, the data can be manipulated in various ways, and, e.g., the production of the derivative TG curve becomes a trivial task.

Data collection relies on a completely linear temperature rise uninterrupted by deviations induced by

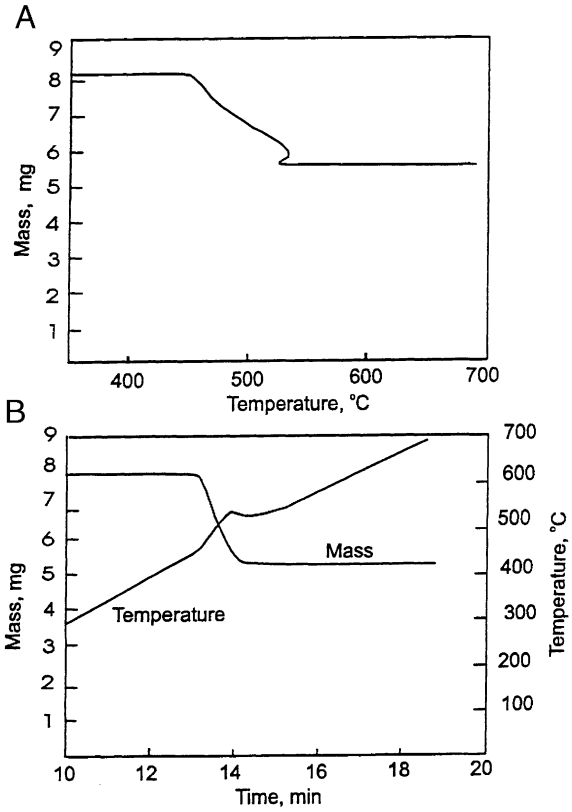

Figure 8 Distorted TG signal resulting from deviation of the linear programmed heating rate.

instrumental or experimental factors. For example, the oxidation of sulfide minerals is so exothermic that for a short time the temperature-recording thermocouple may be heated above the temperature expected for the linear heating program. If the TG plot is being recorded as a temperature-mass plot, then the TG trace will be distorted (see Fig. 8A). This can be overcome by converting the temperature axis to a time-based plot (Fig. 8B).

Experimental Variables

The shapes of TG and DTG curves are markedly dependent on the properties of the sample and the experimental variables that can be set on the thermobalance. These procedural variables include sample preparation (dealt with later), sample mass, sample containers, heating rate, and the atmosphere surrounding the sample.

The mass of the sample affects the mass and heat transfer, i.e., the diffusion of reaction products away from the sample or the interaction of an introduced reactive gas with the sample, and temperature gradients that exist within the sample. For a reaction in which a gas is produced, e.g., dehydration, dehydroxylation, or decomposition, the shape of the curve will depend on the thickness of the sample. For thick samples, gaseous products that evolved from the bottom layers of sample will take considerable time to diffuse away from the sample, and hence delay the completion of reaction. Therefore thick layers of sample will give mass losses over greater ranges of temperature than thin layers of sample.

Temperature gradients are inevitable in TG (or any thermal analysis method) because experiments are usually carried out at some constant heating or cooling rate. There is a temperature gradient between the furnace and the sample, as it takes a finite time for heat transfer to take place across the air gap between the furnace and the sample. Only under isothermal conditions will the sample and furnace temperatures be the same. At a constant heating rate this temperature gradient, commonly called the thermal lag, is approximately constant. The thermal lag increases as the heating or cooling rate increases or as the mass of the sample increases. A second and more important temperature gradient is that within the sample. Heat diffusion will be dependent on the thermal conductivity of the sample, so that heat gradients in metals will tend to be lower than those in minerals or polymers. If a large sample of a poorly conducting material is heated, then large temperature gradients can be expected, and the rate of reaction will be faster at the exterior of the sample because it is at a higher temperature than the interior. This will cause the reaction to occur over a greater temperature range relative to a smaller sample mass or one with a better thermal conductivity. These effects can be illustrated with reference to calcium carbonate (see Table 3), which decomposes above 600°C with the evolution of carbon dioxide (Wilburn et al., 1991). Both mass and heat transfer effects are operative, as the carbon dioxide has to diffuse out of the sample, which takes longer as the mass increases; also, significant thermal gradients between the furnace and sample and within the sample increase as the mass increases. The increase in $T_{0.1}$ with an increase in mass of 59°C is only related to the thermal lag of the sample with respect to the furnace, but the increase in $T_{0.9}$ with an increase in mass is the sum of the thermal lag, temperature gradients in the sample, and the mass transfer of the carbon dioxide. The increase in $T_{0.9}$ is somewhat larger at 97°C relative to the increase in $T_{0.1}$. In general, therefore, the interval between $T_{0.1}$ and $T_{0.9}$ increases as the sample mass increases.

For large samples, the heat generated during an exothermic reaction may be sufficient to ignite the sample. In this case, the mass loss will occur over a very narrow temperature range that will be different from that obtained under nonignition conditions.

In general, these problems were more significant with early thermobalances that required large sample masses to accurately record mass changes. Modern thermobalances,

Table 3. Effect of Sample Mass on Decomposition of Calcium Carbonate Heated in Nitrogen at 7°C/min

Sample Mass (mg)	$T_{0.1}$ (°C)	$T_{0.9}$ (°C)	$T_{0.9-0.1}$ (°C)
50	716	818	102
100	742	855	113
200	768	890	122
300	775	902	127
400	775	915	140

based on null-deflection microbalances, are much less troubled by these problems as the sample masses tend to be in the milligram rather than the hundreds of milligram mass ranges. Even so, it is sometimes necessary to use large samples, and so these constraints need to be considered.

Generally small samples spread as a fine layer are preferred. This ensures that (1) gaseous components can disperse quickly, (2) thermal gradients are small, and (3) reaction between solid and introduced reactive gas is rapid.

Both the geometry of the sample container and the material from which it is made can influence the shape of a TG curve. Deep, narrow-necked crucibles can inhibit gaseous diffusion processes and hence alter the shape and temperature of curves relative to a flat, open pan (Hagvoort, 1994). Sometimes these effects are quite marked, and it has been demonstrated that the rate of oxidation of pyrite decreases by about one-half as the wall height of the sample pan changes from 2 to 4 mm (Jorgensen and Moyle, 1986). Most crucibles can have a lid fitted with either a partial or complete seal, and this is useful for the prevention of sample loss as well as for holding the sample firmly in place. It is also of value to encapsulate the sample if it is being used as a calibrant, so that if the reaction is completely reversible, it can be used several times. Paulik et al. (1982) have designed what they call "labyrinth" crucibles, which have special lids that inhibit gaseous diffusion out of the cell. The partial pressure of the gaseous product reaches atmospheric pressure and remains constant until the end of the process, so leading to the technique being named quasi-isobaric.

Crucibles are usually fabricated from metal (often platinum) or ceramic (porcelain, alumina, or quartz), and their thermal conductivity varies accordingly. Care must be taken to avoid the possibility of reaction between the sample and its container. This can occur when nitrates or sulfates are heated or in the case of polymers, which contain halogens such as fluorine, phosphorus, or sulfur. Platinum pans are readily attacked by such materials. Only a very small number of experiments are required with sulfides heated to 700° to 800°C in an inert atmosphere to produce holes in a platinum crucible. Less obviously, platinum crucibles have been observed to act as a catalyst, causing change in the composition of the atmosphere; e.g., Pt crucibles promote conversion of SO_2 to SO_3. Hence, if sulfides are heated in air or oxygen, the weight gain due to sulfate formation is always greater if Pt crucibles are used, especially relative to ceramic crucibles. The reaction sequence is

$$\begin{aligned} \mathrm{MS(s)} + 1.5\mathrm{O_2(g)} &\rightarrow \mathrm{MO(s)} + \mathrm{SO_2(g)} \\ \mathrm{MO(s)} + \mathrm{SO_3(g)} &\rightarrow \mathrm{MSO_4(s)} \end{aligned} \tag{7}$$

The temperature range over which a TG curve is observed depends on the heating rate. As the heating rate increases, there is an increase in the procedural decomposition temperature, the DTG peak temperature, the final temperature, and the temperature range over which the mass loss occurs. The magnitude of the effect is indicated by the data in Table 4 for the decomposition of 50 mg of calcium carbonate heated in nitrogen at two different heating rates (Wilburn et al., 1991). The faster heating rate causes a shift to higher temperatures of $T_{0.1}$, as well as $T_{0.9}$, although the latter effect is greater than the former. Hence the mass loss occurs over a greater temperature range as the heating rate increases. Faster heating rates may also cause a loss of resolution when two reactions occur in similar temperature ranges, and the two mass losses merge.

Table 4. Effect of Heating Rate on Temperature of Decomposition of Calcium Carbonate

Heating Rate (°C/min)	$T_{0.1}$ (°C)	$T_{0.9}$ (°C)	$T_{0.9-0.1}$ (°C)
1	634	712	78
7	716	818	102

Fast heating rates combined with a large sample sometimes leads to a change in mechanism, which produces a significantly different TG curve.

The atmosphere above the sample is a major experimental variable in thermal analytical work. Two effects are important. First, the presence in the atmosphere of an appreciable partial pressure of a volatile product will suppress a reversible reaction and shift the decomposition temperature to a higher value. This effect can be achieved by having a large sample with a lid or introducing the volatile component into the inlet of the gas stream. When the atmosphere within the crucible is the result of the decomposition of the reactant, the atmosphere is described as "self-generated" (Newkirk, 1971).

An example of the decomposition of a solid material that is affected by the partial pressure of product gas is calcium carbonate, which decomposes according to the reaction

$$\mathrm{CaCO_3(s)} \rightarrow \mathrm{CaO(s)} + \mathrm{CO_2(g)} \tag{8}$$

In a pure CO_2 atmosphere, the decomposition temperature is greatly increased. This effect can be predicted from thermodynamics. If the values of the Gibbs free-energy change (ΔG°), the enthalpy change (ΔH°), and the entropy change (ΔS°), are fitted into the following equation, then the thermodynamic decomposition temperature T can be calculated for any partial pressure P of CO_2:

$$\begin{aligned} \Delta G^\circ = \Delta H^\circ - T\Delta S^\circ &= RT\ln P \\ 40{,}250 - 34.4T &= -4.6T\log P_{\mathrm{CO_2}} \\ \text{At 1 atm } \mathrm{CO_2}: \quad T &= 1170\,\mathrm{K}\,(897^\circ\mathrm{C}) \\ \text{At 0.1 atm } \mathrm{CO_2}: \quad T &= 1132\,\mathrm{K}\,(759^\circ\mathrm{C}) \end{aligned} \tag{9}$$

Hence, under equilibrium conditions, the decomposition temperature is lowered by 138°C. The temperatures found by thermal methods are always higher because these are dynamic techniques, although for small sample sizes and slow heating rates the correspondence is close. For calcium carbonate the difference between the onset temperature of decomposition and the calculated thermodynamic value was in the range 10° to 20°C (Wilburn et al., 1991).

The second major effect is the interaction of a reactive gas with the sample, which will change the course of the reaction. Under an inert atmosphere, organic compounds will degrade by pyrolytic decomposition, whereas in an oxidizing atmosphere oxidative decomposition obviously takes place. Hydrogen can be used to study reductive processes, although great care has to be taken to remove all oxygen from the system before carrying out the reaction. Other gases frequently studied are SO_2 and halogens.

It should be evident from the foregoing comments and examples that the conditions required to minimize the effects of heat and mass transfer, as well as decreasing the possibility of change in the reaction sequence, are to have (1) a small sample (10 to 20 mg), (2) finely ground material (<100 μm), (3) a slow heating rate (10° to 20°C/min); and (4) a thin film spread evenly in a flat open pan made of an inert material.

Such conditions will allow maximum resolution of close reactions and give well-defined mass losses over relatively narrow temperature ranges. However, it should be emphasized that when dealing with a sample of unknown properties, it is advisable to use a range of different conditions to ensure that the sample behaves in a similar manner. If the only effect noticed on increasing the heating rate is a modest shift to higher temperatures of the mass losses, it can be assumed that the reaction sequence is the same, and the increased temperature is just the result of an increase in the thermal lag of the sample. Any marked difference in the temperature or number of mass losses may indicate a change in reaction sequence.

In some circumstances it is not possible to use the above conditions. For example, measuring small mass changes may require large samples to give accurate mass values or in combined TG-evolved gas analysis (TG-EGA) experiments the evolved gas concentration needs to be high enough to be detected.

Applications

Thermogravimetry can be used in a wide variety of research and development and industrial applications. Rather than attempt to cover the entire range here, this section gives more general examples of the kinds of reactions that can be investigated by TG.

Kinetic Studies. The use of TG to obtain kinetic information is one of its oldest applications. Furthermore, the ability to carry out this type of work has been made even easier by the availability of software packages to take data from the TG curves and to calculate various kinetic parameters from the Arrhenius equation, such as the activation energy E and the preexponential factor A. Despite the large number of papers that have been published on this topic, there is still considerable difficulty in obtaining reliable absolute information from the technique. This is evident from the wide variety of published values for E and A for the same chemical reaction. Scientists wishing to engage in kinetic studies using TG should not only have read the relevant literature indicating the difficulties of interpreting the results (see, for example, Brown, 1997) but also preferably have spent some time in the company of people experienced in this type of application. It is, however, of relevance to point out that if absolute values of kinetic parameters are not required, then the TG method offers a very simple system for comparative studies. Thus the relative rates of oxidation of a variety of alloys with a particular gas mix or the relative oxidative stability of a range of polymers can be easily determined.

The reactions that can be studied by TG are decomposition reactions (mass loss), oxidation of metals or alloys (mass gain), reactions between a solid and a gas that produce a solid and another gas (could be mass loss or gain), and solid-solid reactions that produce a gas (mass loss). It is also obvious that there should only be one reaction taking place at one time, and overlapping reactions are difficult to treat unless the experimental variables can be manipulated to separate them. As an example of a reaction that cannot yield sensible results, the oxidation of pyrite has simultaneous oxidation and sulfation reactions taking place, and one of these gives a mass loss and the other a mass gain.

It has been demonstrated earlier that the kinetics of most reactions under isothermal conditions can be summarized by the general equation $d\alpha/dt = f(\alpha)$, where α is the fraction reacted in time t, k is the rate of reaction, and $f(\alpha)$ is some function of α (see Principles of the Method). The various mathematical equations that relate $f(\alpha)$ with the rate of some solid-state reaction are given in Table 5. The two forms of the equations, $g(\alpha)$ and $f(\alpha)$, are associated with the use of the TG data in their integral or differentiated forms, respectively. The former uses data directly from the TG curve, and the differentiated form uses data from the DTG curve. Each equation is associated with a particular model for the progress of the reaction, which may, for example, be gas diffusion into a solid particle or the appearance of product nuclei with subsequent growth of those nuclei. The shape of the TG curve will vary with the particular mechanism involved, as will the temperature at which $d\alpha/dt$ is a maximum.

The traditional method of conducting kinetic studies is the isothermal method. The method involves loading the sample into the TG apparatus, rapidly heating it to some specific temperature, and monitoring the mass change. The experiment is repeated with a new sample at another temperature, and a family of curves is generated such as those shown in Figure 9. The total mass loss for the reaction is found by heating the sample in a rising-temperature experiment until the mass loss is complete. A series of α and $d\alpha/dt$ values can then be calculated for a given temperature. These data are fitted to the expressions in Table 5, and the best fit suggests the model that is likely to apply to the reaction under test. From this expression, the average rate constant k can be calculated at each temperature. A plot of $\log k$ vs. $1/T$ should provide a straight-line graph of slope E/R from which E can be calculated, and the intercept gives the preexponential factor A.

The isothermal method is considered by some to give the most reliable data for kinetic studies but has been criticized for the following reasons.

Table 5. Broad Classification of Solid-State Rate Expressions

Classification	$g(\alpha) = kt$	$f(\alpha) = 1/k(d\alpha/dt)$
Acceleratory α-time curves		
P1 Power law	$\alpha^{1/n}$	$n(\alpha)^{(n-1)/n}$
E1 Exponential law	$\ln \alpha$	α
Sigmoidal α-time curves		
A2 Avrami-Erofeev	$[-\ln(1-\alpha)]^{1/2}$	$2(1-\alpha)[-\ln(1-\alpha)]^{1/2}$
A3 Avrami-Erofeev	$[-\ln(1-\alpha)]^{1/3}$	$3(1-\alpha)[-\ln(1-\alpha)]^{2/3}$
A4 Avrami-Erofeev	$[-\ln(1-\alpha)]^{1/4}$	$4(1-\alpha)[-\ln(1-\alpha)]^{3/4}$
B1 Prout-Tompkins	$\ln[\alpha/(1-\alpha)] + c$	$\alpha(1-\alpha)$
Deceleratory α-time curves		
1. Based on geometric models		
R2 Contracting area	$1-(1-\alpha)^{1/2}$	$2-(1-\alpha)^{1/2}$
R3 Contracting volume	$1-(1-\alpha)^{1/3}$	$3-(1-\alpha)^{2/3}$
2. Based on diffusion mechanisms		
D1 One dimensional	α^2	$1/2\alpha$
D2 Two dimensional	$(1-\alpha)\ln(1-\alpha) + \alpha$	$[-\ln(1-\alpha)]^{-1}$
D3 Three dimensional	$[1-(1-\alpha)^{1/3}]^2$	$3/2(1-\alpha)^{2/3}[1-(1-\alpha)^{1/3}]^{-1}$
D4 Ginstling-Brounshtein	$(1-2\alpha/3)-(1-\alpha)^{2/3}$	$3/2[(1-\alpha)^{-1/3}-1]^{-1}$
3. Based on order of reaction		
F1 First order	$-\ln(1-\alpha)$	$1-\alpha$
F2 Second order	$1/(1-\alpha)$	$(1-\alpha)^2$
F3 Third order	$[1/(1-\alpha)]^2$	$0.5(1-\alpha)^3$

1. It is difficult to determine exactly the time and temperature of the beginning of the reaction.
2. It requires several experiments and so is time consuming.
3. Each experiment requires a new sample, which must react in exactly the same way as all the other samples. This requires careful attention to standardization of the experimental procedures, which includes, e.g., the use of the same sample pan with the same sample packing and gas exchange. Duplicate experiments should be done to check the level of reproducibility.

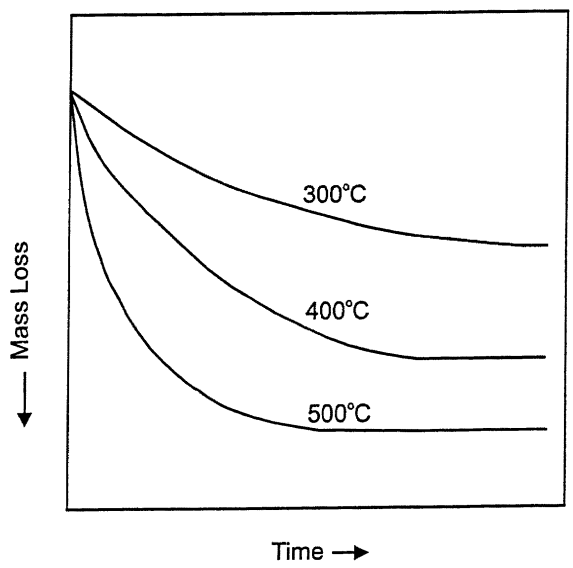

Figure 9. A family of TG curves generated at different isothermal temperatures.

The alternative to isothermal experiments is the rising-temperature method (Flynn, 1969; Sestak, 1972), which requires that the sample is heated at a constant rate over the reaction temperature range. The value of α is calculated at various temperatures, and $d\alpha/dt$ calculated for a small temperature interval. The same process of evaluation of the appropriate form of the rate-controlling equation is applied, and hence E and A are calculated. If the expression is differentiated, then $d\alpha/dt = -(dm/dt)/\Delta m$, where Δm is the total mass change and dm/dt can be obtained directly from the DTG curve.

This method has the advantage of being rapid, and duplicate experiments to check reproducibility may be all that is required. The choice of integral over differential methods is difficult. Earlier models of thermobalances had significant errors in the determination of $d\alpha/dt$, mainly because of signal noise, but sophisticated computerized data acquisition and manipulation have reduced this problem and produced renewed interest in differential methods. Integral methods have their own difficulties, because for rising-temperature experiments there is no definite integral for the right-hand side of the equation, and so approximations have to be made. Whatever the choice, some of the same criticisms apply to rising-temperature methods as apply to the isothermal method, especially the need for the development of a standardized procedure. Even small changes in sample packing, for example, will affect the results. It is also evident that multiple experiments at different heating rates are required in some cases to improve the reliability of the data.

Despite all the improvements in apparatus, technique, and data acquisition and computational methods, problems still arise. The best least-squares fit may not be given by the correct mechanism, because calculations for one model give results that are so close to another model that it is difficult to distinguish between them. It is possible to fit more than one mathematical expression to a given model. Different models can give the same mathematical expression. When any of these situations occur, analysis of the TG curve gives the mathematical relationship, but considerable judgment may be required to select the appropriate model. Efforts should be made to support the suggested reaction mechanism by other means. For example, viewing partially reacted materials by techniques such as microscopy or SEM will identify a mechanism controlled by gaseous diffusion inward or outward.

A final set of experimental methods is the controlled-rate group (CRTA), which controls one of the experimental variables, such as the temperature, evolved gas, or mass change, to keep the rate of reaction constant. The CRTA methods are claimed to have certain advantages for kinetic studies over other methods (Reading, 1988; Rouquerol, 1989).

Compositional Analysis. If the reactions that are recorded on the TG curve are for single reactions that are not interfered with by other reactions, then the mass change can be directly related to the quantity of reacting material present. Hence, TG is a technique that can be used to determine the purity of a compound or the components in a mixture. Some methods have been developed that are routinely used for quality control purposes, because TG methods can be faster and more accurate and give more information than other methods. The book edited by Earnest (1988) contains applications to areas such as drugs, polymers, inorganic compounds, minerals, fuels, and waste products.

Even when the reactions in the first experimental investigations are not separated, it may be possible to manipulate the experimental variables in such a way that separation can be achieved. Thus TG offers some flexibility to effect compositional analysis.

The simplest situation is when a single compound decomposes with an associated mass loss, and the purity of the sample is calculated. In some cases, the compound may be hydrated, and so two mass losses are observed, one associated with the loss of water and the other with the decomposition reaction. Many clays and inorganic compounds undergo this kind of reaction. Mixtures can be readily analyzed; e.g., a mixture of gypsum ($CaSO_4 \cdot 2H_2O$) and lime [$Ca(OH)_2$], which is commonly found in the plaster industry. The gypsum decomposes in an open pan in the temperature range of 100° to 150°C and the lime decomposes between 400° and 500°C, according to the equations

$$\begin{aligned} CaSO_4 \cdot 2H_2O(s) &\rightarrow CaSO_4(s) + 2H_2O(g) \\ Ca(OH)_2(s) &\rightarrow CaO(s) + H_2O(g) \end{aligned} \tag{10}$$

The first reaction is a simple dehydration process and the second a dehydroxylation reaction.

In an open pan, the dehydration of gypsum appears as a single mass loss, although the decomposition is a two-step process:

$$\begin{aligned} CaSO_4 \cdot 2H_2O(s) &\rightarrow CaSO_4 \cdot 0.5H_2O(s) + 1.5H_2O(g) \\ &\rightarrow CaSO_4(s) + 0.5H_2O(g) \end{aligned} \tag{11}$$

This reaction can be resolved into two steps by manipulation of the partial pressure of the water vapor above the sample. One way to achieve this is to seal the gypsum in a sample pan with a small leak. The water vapor trapped in the pan from the first reaction delays the commencement of the second step of the reaction by some 40° to 50°C. This method is used in the cement industry to check the composition of clinker-gypsum mixtures. When the two components are ground together, heat is generated, which may cause undesirable decomposition of gypsum to the hemihydrate. Hence phase analysis of the clinker-gypsum mixture for gypsum and hemihydrate content can be routinely carried out (Dunn et al., 1987).

Another way of separating reactions by manipulation of the atmosphere is to vary the concentration of the evolved gas in the flowing gas atmosphere. An example of this has already been given with respect to the decomposition of calcium carbonate, where a ten-fold change in the partial pressure of carbon dioxide changes the decomposition temperature by some 138°C. If some other noncarbonate decomposition reaction is interfering with the mass loss of calcium carbonate, then changing the atmospheric composition may resolve the problem.

Advantage can also be taken of changing the atmosphere from an inert one to a reactive one. In an inert atmosphere, pyrolytic decomposition of organic compounds such as polymers can occur. The analysis of rubber compounds has been carried out by TG methods for some time (Brazier and Nickel, 1980; Sirkar, 1977). Rubbers typically contain polymers, extending oils and other organic compounds, carbon black, and inorganic compounds. Heating the rubber in nitrogen volatilizes or decomposes the organic compounds and decomposes the polymer, so that the first mass loss can be related to the total content of these compounds. Changing the atmosphere to air oxidizes the carbon black to give a second mass loss, and the residue is the inorganic components converted to their oxides. This analysis can be done in less than 20 min and provides a rapid routine quality control method in the elastomer industry. The method can be automated using the computer system controlling the gas changes and heating rates. The decomposition of the pure polymer should be checked to ensure that it decomposes completely and does not form a char.

The inert/reactive atmosphere system can be used to measure the amount of an element in an inorganic material if the element has variable oxidation states. If the element is oxidized to a higher oxidation state, then a mass gain will be observed; if it is reduced to a lower oxidation state with a gas such as hydrogen or carbon monoxide, then a mass loss will take place.

Variation in the heating rate may be sufficient to separate overlapping reactions. Slowing the heating rate gives

additional time for the reaction to take place, and if necessary, an isothermal period may be required to establish a plateau in the TG curve before increasing the heating rate (Dunn and Sharp, 1993, p. 163).

In some circumstances total phase analysis can be achieved by TG methods in conjunction with other analytical methods. Thus an iron ore containing a clay, goethite (FeOOH), and hematite (Fe_2O_3) was analyzed for the first two components by TG, and the total iron was determined by dissolution and titrimetric analysis (Weissenborn et al., 1994).

Thermal Stability/Reactivity. The assessment of thermal stability has been mainly applied to polymeric materials, although the technique can be applied to a number of other materials ranging from inorganic compounds to oils (Dunn and Sharp, 1993). There are three different approaches:

1. The material is heated at some programmed rate and the temperature (either the extrapolated onset temperature or the temperature for a given fraction reacted) at which decomposition takes place is measured. This value is then used to rank the materials in relative order of thermal stability. A comparison of the stability in nitrogen and air or oxygen gives an indication of the role of oxygen in the breakdown mechanism. Some plastics are remarkably unaffected by the change in atmosphere, e.g., nylon, while others begin to decompose at much lower temperatures in an oxidizing atmosphere. The decomposition temperature provides the maximum operational temperature at which the polymer can exist but gives no indication of the long-term behavior at lower temperatures.
2. The material is heated at several different isothermal temperatures and a family of curves of mass loss against time are generated. This procedure does give information about the longer term stability at lower temperatures and sometimes reveals a critical temperature range above which decomposition is rapid.
3. The material is heated to a single isothermal temperature in an inert atmosphere, the atmosphere is changed to a reactive gas, and the time for the first major reaction to take place is measured. The oxidative stability of a material can be measured quantitatively by heating the material in an inert atmosphere to a given temperature below the decomposition temperature, establishing a stable baseline and then switching the atmosphere to oxygen. The time taken to produce the first weight loss after the admission of oxygen, called the induction period, is a measure of the oxidative stability at that temperature. By using this method, the effects of various additives on the thermal stability of materials can be compared (Hale and Bair, 1997).

Attempts have been made to use kinetic data derived from the decomposition of materials to predict their life expectancy, particularly for polymeric materials. Standard methods are time consuming and often ambiguous in interpretation. The TG methods have been developed as alternative accelerated test procedures and have achieved various degrees of success (Flynn, 1995). Flynn (1995) has argued that there are two main reasons why quantitative predictions cannot be made for polymers. First, the kinetics of decomposition below glass transition temperatures or other phase transitions will not be the same as those above the temperature of such transitions. Second, there is a temperature above which the system becomes thermodynamically unstable. If accelerated testing measurements are made above the phase transition temperature and/or the thermodynamic stability temperature when in practice the polymer use is below these temperatures, then a false picture will emerge of the lifetime capabilities.

Very reactive materials, such as organic compounds, sulfide minerals, and coal, can be ignited. Ignition can be defined as corresponding to the establishment of a self-sustaining combustion reaction after the termination of heat supply from an external source (Vilyunov and Zarko, 1989, p. 320). This definition assumes that there is a continuous supply of reactants once the ignition reaction has been initiated. A modified TG technique has been used to measure the relative ignition temperature of minerals such as sulfides and coal (Dunn et al., 1985; Dunn and Chamberlain, 1991; Dunn and Mackey, 1992). The technique involves heating the furnace to some preset temperature, establishing an air or oxygen flow, placing the sample in the pan and then raising the furnace around the sample. If the set furnace temperature is below the ignition temperature of the sample, then a slow oxidation process occurs. If the experiment is repeated with fresh samples and with increments in furnace temperature, then the sample will eventually reach a temperature at which it ignites. This gives a very rapid mass loss. The ignition temperatures of a range of minerals can be established and thus give some indication of their relative reactivity to processes such as flash smelting.

Thermogravimetry has been more recently applied to studies in cuprate family superconductors (Sale and Taylor, 1992). One of the prerequisites for a superconductor is the preparation of precursors that are homogeneous and of controlled particle size. This is achieved by making a gel followed by a drying stage and then a decomposition-oxidation stage. Thermogravimetry can be used to determine the thermal stability of the precursor as well as the reaction sequence for the decomposition-oxidation process. Furthermore, once the superconductor has been formed, TG can be used to determine the variable oxygen content as a function of temperature and partial pressure of oxygen.

Gas-Solid Reactions. The TG apparatus can be used as a minireactor to examine reactions between a solid and a gas. A number of reactions, such as oxidation and pyrolysis, have already been mentioned. The range of possibilities is obviously more extensive, and two examples are given by way of illustration.

In corrosion studies, the reaction between metals and different atmospheres can be investigated. Oxidation reactions are common (Das and Fraser, 1994; Joshi, 1992), but

gaseous mixtures containing oxygen and water (Webber, 1976), oxygen and bromine (Antill and Peakall, 1976), and various sulfur-containing atmospheres are also evident (Young et al., 1975; Dutrizac, 1977; Hunt and Strafford, 1981). Besides investigating the effect of various atmospheres on a single metal or alloy, the atmosphere can be kept constant and the composition of the alloy changed. The usual procedure is to heat the sample to a specific temperature and follow the mass change as a function of time. The data are then fitted to one of the four general equations describing the growth of corrosion products, i.e., parabolic, linear, logarithmic, or cubic.

Thermogravimetry has been extensively used to study most aspects of the life cycle of catalysts, from catalyst preparation to regeneration, and also to compare the effects of variables such as catalyst composition, operational temperatures, and gas flow rates on performance (Habersberger, 1977; Dollimore, 1981). Since most TG work is small scale and experiments can be carried out rapidly, much useful information can be gathered cheaply and quickly prior to large-scale tests. This work is further facilitated by use of TG-EGA systems to measure quantitatively the product yield. X-ray diffraction, infrared spectroscopy, and chemical analysis are frequently used to characterize the catalyst material at various stages in the cycle.

In the preparation stage, the aim is to prepare a material that has a high surface area of active sites. Many metal catalysts are prepared by adsorbing a solution of a salt onto the support material and then drying, calcining, and reducing the mixture. Each of these mass loss steps can be followed by TG, and the effect of variation in experimental conditions of heating rate, gas flow rate, and temperature range on the surface area of the metal can be determined by standard methods. Experimental studies have shown that, in general, the optimum reactivity of the catalyst is achieved at slow rates of reduction (Bartholomew and Farrauto, 1976). The lower the decomposition temperature of the parent compound, the higher the surface area of the final product (Pope et al., 1977).

Gaseous adsorption and desorption processes can be followed as mass changes, as can be catalyst efficiency and temperature stability.

Solid-Solid Reactions. The reaction between two solids to evolve a gas can be investigated by TG. An example is the reaction between a sulfide and a sulfate (Dunn and Kelly, 1977):

$$3NiS(s) + 2NiSO_4(s) \rightarrow Ni_3S_2(s) + 2NiO(s) + 3SO_2(g) \quad (12)$$

METHOD AUTOMATION

Computers that act as recorders can also be used as a control system, which enables a particular protocol to be established to carry out a repetitive test procedure. This control function can be extended to switching valves so that different atmospheres can be admitted to the TG equipment. Automatic sample loaders, which allow multiple samples to be sequentially introduced into the TG apparatus, are available.

DATA ANALYSIS AND INITIAL INTERPRETATION

In keeping with modern instrumentation, the data output from the TG apparatus is acquired through a suitable interface and the results processed and stored via appropriate software. In nearly all cases the full facility is available from the manufacturer of the thermobalance. The only drawback with this arrangement is that the algorithms are unknown and the operator has to accept what is provided. The ease of accepting the manufacturer's solutions has to be offset against the considerable time involved in writing specific in-house software. The manufacturer is in somewhat of a cleft stick, as the TG apparatus is increasingly taking on the twin roles of research and routine quality control. In the former situation the research scientist wants to be in control and make decisions on, e.g., the degree of smoothing that might be applied to a TG curve. This requires that the raw data are displayed and then various levels of smoothing applied. On the other hand, the operator in a quality control situation only wants a reliable and set system that produces comparable results from experiments, without the need for personal decision. Some companies will write user-specific software, and with some instruments it is possible for the operator to extract files and manipulate them.

There are many ways in which data can be manipulated with commercial software; some examples are as follows:

1. Rescaling either the ordinate or the abscissa, which means that it is rare for the operator to have to rerun the experiment because of an unfortunate choice of conditions.
2. Calculating the first derivative of the mass change to give the DTG curve.
3. Presenting a fully labeled TG/DTG curve on screen, with the various onset and completion temperatures identified and mass losses expressed in various units, including percentages. Labels identifying the sample, operator, and experimental conditions used can be added, and the final product can be printed out for inclusion in a report.
4. Carrying out various calculations, including a kinetic analysis of the data.

SAMPLE PREPARATION

Sample preparation in this context means both the treatments that may be applied to the sample prior to the TG experiment and the way in which the sample is introduced to the TG apparatus.

It is usual practice for a sample to be received in the laboratory and then treated in some way before any experimentation is carried out. In the simplest example, mineral samples can be received in lump form, which may be centimeters in diameter, and clearly unsuitable for experiment.

Such materials are ground and divided progressively to eventually produce a representative laboratory sample of 10 to 20 g with a particle size of typically <100 μm. Similarly, rubber samples may be presented as a sheet and then shaved down to give a number of flakes or as a circle punched out of the sheet and the experiment carried out on a flat disc.

One of the most significant characteristics of a solid sample is its particle size, as the smaller the particle size, the greater the surface area and the rate of reaction. Hence at any given temperature the value of α, the fraction reacted, will be greater for fine particles relative to large particles. Smaller particles will also heat more rapidly than larger particles. Usually the more finely divided the sample, the lower the temperature at the start and completion of the reaction. In most cases, a change in particle size will give similar TG curves that are displaced along the temperature axis. Less commonly, the actual mechanism of the reaction may change and a totally different TG curve be obtained. Overgrinding is to be avoided, as the mechanical energy may heat the sample as well as cause changes to its degree of crystallinity. In the former situation, decomposition of the sample may result, with loss of bound water and even the dehydroxylation of minerals; in the latter situation the surface of the solid may become quite active and adsorb moisture from the atmosphere to a greater extent than for an unground sample (Dunn and Sharp, 1993, p. 158).

Some materials, when heated, can be ejected from the sample pan and give a mass loss that may be incorrectly attributed to a chemical reaction rather than a physical loss. Samples in this category are those that decrepitate, i.e., dehydrate with subsequent dissolution of the solid in the water, which then boils with frothing. Advantage has been taken of this effect to assess the decrepitation of dolomites and limestones used in the glass-making industry. If the material is prone to decrepitation, then a mass loss is observed between 400° and 500°C, well before the main decomposition of the dolomite above 600°C. A nondecrepitating dolomite shows no mass loss below 600°C (Fig. 10). Organic samples, if heated under vigorous oxidizing conditions, may ignite and the solid material be carried away as a fine ash. Such problems can be solved by use of a cover on the sample pan.

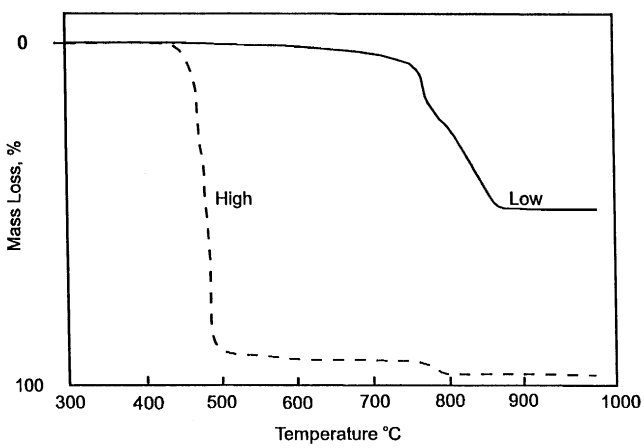

Figure 10. TG curve for a dolomite sample showing effects of decrepitation, contained in a sample crucible with and without a lid.

The use of pellets or deep beds of powder may lead to a change in mechanism from a rate-determining step based on the chemical reaction to one based on heat or mass transfer. There have been suggestions (Hills, 1967, 1968) that heat and mass transfer may be rate determining even when thin layers are used under isothermal conditions, involving reactions previously supposed to be controlled by reaction at the interface between the reactant and the product.

PROBLEMS

The major sources of errors in the TG technique are in the measurement of mass and sample temperature.

Errors in Mass Measurement

Several factors can contribute to incorrect measurement of mass. These include incorrect calibration, temperature fluctuation, electrostatic or magnetic forces, vibration, and atmospheric environment or buoyancy effects (Dunn and Sharp, 1993, p. 168).

The direct calibration of the microbalance through the use of standard weights is the simplest and the most straightforward calibration method (Schwoebel, 1980, p. 89). In this method, standardized masses are added to one arm of the balance and any necessary adjustment made. Regular checks are required. Standardized masses are often provided as part of the accessories when a commercial thermobalance is purchased, or sets of such mass calibrants can be obtained from organizations such as ICTAC, the National Physics Laboratory (United Kingdom), and the National Institutes of Standards and Technology (NIST, United States) (see MASS AND DENSITY MEASUREMENTS).

The mechanism of the balance is affected by changes in temperature. Any temperature fluctuation will result in drift in the zero point of the balance and hence will decrease the accuracy of the measurement. This problem becomes important if experiments over time periods of hours are undertaken in laboratories that are not temperature controlled. For high-accuracy work the thermobalance should be housed in a thermostatted enclosure (Sharp and Mortimer, 1968).

Spurious results can be obtained if electrostatic or magnetic forces are generated in the thermobalance and interact with the system. Electrical interference can be eliminated by grounding the system, while the magnetic effects can be overcome by shielding the furnace in a noninductive manner or winding the furnace coil in a noninductive manner.

Errors that derive from the resultant forces of the atmospheric environment include buoyancy effects, convection in the furnace atmosphere, and various molecular gas movements that act on the balance. The magnitude of the buoyancy effect, one of the major sources of error, arises from the volume of the atmosphere displaced by

the sample and its attendant sample pan and hangdown assembly. This results in an apparent increase in the mass of the sample, which increases as the temperature increases. The effect can be determined experimentally by heating sample crucibles containing an inert material such as calcined alumina as a substitute sample and using this value to adjust the results from subsequent experiments. Most software can store the buoyancy data and subtract the correction value from the experimental data. The experimental conditions must be similar to those used for the sample to be investigated. In older TG apparatus, where the volume of displaced gas was quite large because of the large sample mass and pan, the increase in mass would be of the order of several milligrams. In the systems based on the microbalance, the effect is much smaller, and for routine quality control purposes where only moderate accuracy is required, it is often ignored. It is also important to consider that during actual experiments the buoyancy of the sample itself will change, especially if there is a significant increase or decrease in sample mass by chemical reactions. This effect has been observed during the decomposition of $CaCO_3$ (Oswald and Wiedemann, 1977).
