Some instruments have been manufactured to overcome problems inherent in the designs described above. The various disturbances that can occur to the mass record can be considerably reduced by use of a symmetrical thermobalance, in which sample balance pan and counter balance pan are suspended from the balance arm into two identical furnaces. Both furnaces are programmed, so that buoyancy and convection effects are almost eliminated from the weight record. Another manufacturer produces a differential motion TG apparatus, which is based on a top-loading arrangement in which the sample and counter balance pans are supported on a system of beams and subbeams so that the distance between the pans is small enough to be incorporated into the same furnace. Hence, again, the pans are subjected to the same environment, which reduces errors in the weight record.

It is evident that measuring mass changes accurately as a function of temperature is not an entirely simple matter. Regular calibration, blank runs, and buoyancy checks under conditions identical to those used in a set of experiments need to be done and the instrument needs to be calibrated at the operating temperature in order to determine the magnitude of any errors. Determining the purity of a known compound by the mass change is another way of checking the accuracy of the mass measurements.

Errors in Temperature Measurement

Accurately measuring the temperature of a sample in a TG apparatus is still a difficult task, mainly because of the inherent design of the equipment. The most significant factor is that the thermocouple measuring the sample temperature is not actually in contact with the sample, or even with the sample pan, but is usually a few millimetres from the sample, as shown in Figure 7. The actual temperature of the sample will differ from the temperature reading when the sensor is not in contact with the sample holder. The difference in temperature between the sample and thermocouple is geometry dependent as well, particularly so if the thermocouple is above or below the sample, as the difference will vary both with temperature and with heating rate (Garn et al., 1981). In addition, the sample-sensor temperature difference can be affected by the atmosphere and its flow rate. This is because gases of different thermal conductivity will carry heat away from the sample with different efficiency. For accurate work, therefore, the temperature calibration of the TG apparatus should be carried out under experimental conditions identical to those used in the actual experiments. The use of null-deflection balances is an advantage, as the sample assembly stays a constant distance from the thermocouple. The worst situation is with a deflection balance. If the sample gains mass, then the distance between the thermocouple and sample will decrease, whereas if the sample loses mass, the distance between the thermocouple and sample will increase.

One of the better calibration methods involves the use of the Curie point transition in metal samples. In this procedure, a ferromagnetic material is placed in the sample crucible as the test specimen, and a magnet is located above or below the crucible, which creates a magnetic flux aligned to the gravitational field. When the material is heated, at a particular temperature the ferromagnetic material becomes paramagnetic. The point at which the magnetic properties completely disappear is defined as the Curie temperature (see TECHNIQUES TO MEASURE MAGNETIC DOMAIN STRUCTURES). At the Curie point, a significant apparent weight change in the specimen occurs (Norem et al., 1970).

Five metals have been certified as ICTAC Certified Reference Materials for Thermogravimetry, GM761 (see Table 6; Garn et al., 1981). The materials cover the temperature range 200 to 800°C. The experimental data in a round-robin investigation have been reported by Garn (1982) and showed that intralaboratory results were reasonably precise, with a mean standard deviation of 3.6 ± 1.1°C. However, there was a wide range of results reported from interlaboratory studies and/or depending on the type of instrument used. In addition, the temperature range and standard deviation increased as the ferromagnetic temperature increased.

A more recent study by Gallagher et al. (1993) reported that more reproducible and precise results for determining transition temperature can be achieved using simultaneous thermomagnetometry/differential thermomagnetometry/DTA (TM/DTM/DTA). The results from five different laboratories, based on DTM, showed that a very high

Table 6. Measured Values for T_e Using ICTAC Certified Reference Materials for Thermogravimetry, GM761

Material	Temperature Range of Transition (°C)	Mean (°C)	Standard Deviation
Permanorm 3	242–263	253.3	5.3
Nickel	343–360	351.4	4.8
Mumetal	363–392	377.4	6.3
Permanorm 5	435–463	451.1	6.7
Trafoperm	728–767	749.5	10.9

degree of reproducibility between the laboratories was obtained with a 2σ value of 0.2°C. Gundlach and Gallagher (1997) have investigated the potential of nickel-cobalt and nickel-copper alloys, which give magnetic transitions from 1100°C to below room temperature.

The obvious advantage of the Curie point method is that the ferromagnetic material calibrates temperature directly at the sample position, and the thermobalance can be calibrated under the same conditions as used with a sample. The magnetic transitions are reversible, so that the calibrant can be encapsulated to protect it against oxidation and used repeatedly for calibration purposes. A criticism is that the thermal conductivity of the alloy is much higher than for other materials such as minerals or polymers, and so there may be some minor discrepancy in temperature measurement because of differences in thermal lag between the alloy and the sample. Another problem could be the ability to satisfactorily place the magnet in a suitable position.

McGhie et al. (1983) have suggested an alternative method that allows the melting points of metals to be used for temperature calibration. In this procedure, a mass is suspended within the sample crucible of the thermobalance by a thin wire of the temperature calibration material. When the system is heated, at the melting point of the wire the weight drops either on the sample crucible, causing a short disturbance on the weight record, or through a hole in the base of the sample crucible giving a large and rapid weight change. This method has been used to provide new estimations for the transition temperature of the ICTAC standards (Blaine and Fair, 1983). A disadvantage of this method is that the thin wire is not at the same position as the sample. This criticism has been partially met by a study that demonstrated that the temperatures determined by the Curie point method and the thin-wire method were similar (Gallagher and Gyorgy, 1986).

If the sample is visible when placed in the TG sample pan, then the melting of a pure compound can be used for calibration purposes. The method is to heat the calibrant to just below its melting point and then increase the temperature in small increments of say 1°C until the calibrant just melts. Sets of melting calibration standards are available from organizations such as ICTAC and NIST covering the temperature range ambient to 1000°C. The obvious disadvantage of this method is that the calibrant needs to be visible, and the calibration is carried out under near-isothermal conditions instead of the rising-temperature program most commonly used for experimental purposes.

There is no universally accepted way of calibrating temperature in a thermobalance at present, and there is not likely to be because of the various instrument designs and different spatial relationships between the measuring thermocouple and the sample. The choice of the above methods will depend on the accuracy required and what can be achieved with a particular TG apparatus. Even then there is likely to be significant error, so that studies undertaken by TG that require high accuracy in the temperature measurement, such as kinetic studies involving the calculation of rate constants, are likely to be subject to significant error. For these studies it is much more appropriate to use simultaneous TG-DTA, where the thermocouple is in contact with the sample crucible and the instrument can be calibrated using ICTAC standards for DTA (see SIMULTANEOUS TECHNIQUES INCLUDING ANALYSIS OF GASEOUS PRODUCTS).

APPENDIX: REPORTING THERMAL ANALYSIS RESULTS

It has been stressed that TG results are very dependent on the sample properties and the experimental conditions used. To facilitate a comparison of results obtained by different workers, it follows that these various parameters, such as particle size and heating rate, should be reported.

The existing recommendations for reporting thermal methods of analysis were developed by the Standardisation Committee of the ICTAC in the late 1960s and early 1970s (McAdie, 1967, 1972, 1974) and are also in various standards, such as ASTM E472-86. The recommendations are presently in revision to take into account current practice (Dunn, 1993). The draft document is reproduced below, although at the time of writing it had not been officially ratified by the ICTAC Council. There has been some change of emphasis in the new draft, and more emphasis has been placed on accurate characterization of the sample, as well as on giving details on the way in which the computer acquires and processes data. The section relating to the experimental conditions is largely unchanged. This document does not address safety problems associated with the use of the related materials or equipment. It is the responsibility of the user to establish the appropriate safety standards and work within the validity of the given safety laws.

Information Required for All Thermal Analysis Techniques

Accompanying each thermal analysis record should be information about the:

1. Properties of substances.
   - 1.1 Identification of all substances (sample, reference, diluent) by a definitive name, an empirical formula, or equivalent compositional information.
   - 1.2 A statement of the source of all substances, details of their histories, pretreatments, physical properties, and chemical purities, as far as they are known.
     - 1.2.1 "Histories" includes method of acquisition or manufacture of the sample (how it was isolated or made, manufacturing conditions, e.g., grinding and sizing), previous thermal and mechanical treatments (e.g., repeated grinding, sintering, all

experimental conditions), surface modification, and any other physical or chemical treatment.

1.2.2 "Pretreatments" includes preparation of the sample prior to the thermal analysis experiment.

1.2.3 "Physical properties" includes particle size, surface area, porosity.

1.2.4 "Chemical purities" includes elemental analysis, phase composition, and chemical homogeneity of sample.

2. Experimental conditions.

2.1 A clear statement of the temperature environment of the sample during measurement or reaction, including initial temperature, final temperature, rate of temperature change if linear, or details if not linear.

2.2 Identification of the sample atmosphere by pressure, composition, and purity: whether the atmosphere is static, self generated or dynamic through or over the sample. Where applicable, the ambient atmospheric pressure and humidity should be specified. If the pressure is other than atmospheric, full details of the method of control should be given.

2.3 A statement of the dimensions, geometry and materials of the sample holder, and the method of loading the sample where applicable.

2.4 Identification of the abscissa scale in terms of time or temperature at a specified location. Time or temperature should be plotted to increase from right to left.

2.5 A statement of the methods used to identify intermediate or final products.

2.6 Faithful reproductions of all original records.

2.7 Wherever possible, each thermal event should be identified and supplementary supporting evidence stated.

2.8 Sample mass and dilution of sample.

2.9 Identification of the apparatus, by the provision of the manufacturer's name and model number. More detail should be provided if significant modifications to the standard commercial model have been made, or if the apparatus is new or novel, or if the apparatus is not commercially available.

3. Data acquisition and manipulation methods.

3.1 Identification of the instrument manufacturers software version, or details of any self-developed versions.

3.2 Equations used to process data, or reference to suitable literature.

3.3 The frequency of sampling, filtering and averaging of the signal.

3.4 An indication of the smoothing and signal conditioning used to convert analogue to digital signals, or reference to suitable literature. Similar information for subsequent processing of the digital data is also needed.

The following information is required specifically for Thermogravimetry (TG).

1. The ordinate scale should indicate the mass scale. Mass loss should be plotted as a downward trend and deviations from this practice should be clearly marked. Additional scales (for example, fractional decomposition, molecular composition) may be used for the ordinate where desired.
2. The method used for the calibration of the temperature and mass.
3. If derivative thermogravimetry is employed, the method of obtaining the derivative should be indicated and the units of the ordinate specified.

DIFFERENTIAL THERMAL ANALYSIS AND DIFFERENTIAL SCANNING CALORIMETRY

INTRODUCTION

Differential thermal analysis (DTA) and differential scanning calorimetry (DSC) are two closely related methods in which a material under investigation is typically subjected to a programmed temp3erature change and thermal effects in the material are observed. (Isothermal methods are also possible though they are less common.) The term "differential" indicates that the difference in behavior between the material under study and a supposedly inert reference material is examined. In this manner the temperature at which any event either absorbs or releases heat can be found. This allows the determination of, e.g., phase transition temperatures and the study of order-disorder transitions and chemical reactions. Similarly, heat capacity measurements can be performed, although DTA and DSC differ significantly in the ease and precision of such measurements. These two methods are ideally suited for quality control, stability, and safety studies.

Measurement of heat capacity can be performed by other methods. Adiabatic calorimetry and drop calorimetry typically can provide heat capacity values roughly an order of magnitude more precise than those obtainable by thermal analysis methods. However, those calorimetric techniques are far more difficult to conduct than are the thermal analysis methods being discussed here. Relatively large samples are needed compared with the requirements of thermal analysis methods. In addition, commercial instruments are generally not readily available for adiabatic or drop calorimetry. Only when the highest precision is an absolute necessity would a researcher shun thermal analysis. The terminology in this area has become somewhat confused, and we will follow the recommendations of the International Confederation for Thermal Analysis Nomenclature Committee given below (Mackenzie, 1985).

In DTA, the temperature difference between a substance and a reference material is measured as a function

of temperature while the substance and reference material are subjected to a controlled temperature program.

The record is the differential thermal, or DTA, curve; the temperature difference (ΔT) should be plotted on the ordinate with endothermic reactions downward and temperature or time on the abscissa increasing from left to right.

The term "quantitative differential thermal analysis" (quantitative DTA) covers those uses of DTA where the equipment is designed to produce quantitative results in terms of energy and/or any other physical parameter.

In DSC, the difference in energy inputs into a substance and a reference material is measured as a function of temperature while the substance and reference material are subjected to a controlled temperature program.

Two modes, power compensation differential scanning calorimetry (power compensation DSC) and heat-flux differential scanning calorimetry (heat-flux DSC), can be distinguished, depending on the method of measurement used. A system with multiple sensors (e.g., a Calvet-type arrangement) or with a controlled heat leak (Boersma-type arrangement) would be heat-flux DSC, whereas systems without these or equivalent arrangements would be quantitative DTA.

These thermal analysis methods can be conducted simultaneously with other measurement methods to provide a greatly enhanced ability to understand material behavior (see Specimen Modification).

We will not dwell here on the historical development of these techniques, which has been amply summarized elsewhere (Boerio-Goates and Callanan, 1992). However, there is widespread confusion in the literature and elsewhere regarding the terms DTA and DSC that stems, in part, from how these methods developed. Early DTA procedures (classical DTA) involved thermocouples embedded in the sample and reference materials under study (Fig. 1A). Because of uncertain heat transfer considerations, quantitative measurements of, e.g., enthalpies of transformation could not be made reliably. An innovation due to Boersma (1955) led to significantly improved quantitative measurements. He recommended removing the thermocouples from direct contact with the samples and introducing a controlled heat leak between the sample and the reference containers (Fig. 1B). In subsequent years this arrangement and its various incarnations have come to be referred to as "heat-flux DSC." In 1964, the Perkin-Elmer Corporation developed and patented a differential scanning calorimeter (DSC-1) that involved separate heaters for the sample and reference containers with the differential power needed to keep the sample and the reference at the same temperature measured directly (Watson et al., 1964; Fig. 1C). This technique is currently referred to as "power-compensated DSC." As a result, the brief designation DSC is often used without clarification for both methods.

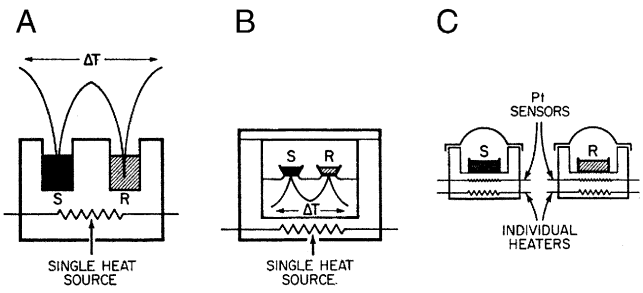

Figure 1. Schematic representation of the three principal thermal analysis systems: (**A**) classical DTA; (**B**) "Boersma" DTA; (**C**) DSC. (Courtesy of Perkin-Elmer.)

PRINCIPLES OF THE METHOD

In the extensive literature on thermal analysis methods, there are a great many explanations of the principles of the method (Boerio-Goates and Callanan, 1992). The treatment by Mraw (1988) is particularly instructive in that it enables the reader to understand the differences in principle among the three main variants of thermal analysis methods—classical DTA, heat-flux DSC, and power-compensated DSC—without dealing with endothermic or exothermic effects. Here, we develop the basic equations describing thermal analysis, following Mraw, with emphasis on the similarities and differences among the basic techniques.

Consider the schematic thermal analysis system shown in Figure 2. A sample (designated by subscript s) and an inert reference material (subscript r) are contained in pans and placed in the instrument. The notation used in the following analysis is shown in Figure 2. The total heat capacity is C_j (where j is either s or r), T_j is the actual temperature of the sample or reference, and $T_{j,\mathrm{m}}$ is the temperature indicated by the measuring thermocouple. Because of the thermal resistances R_j and R'_j, measured and actual temperatures may differ. The temperature of the heat source (T_h) may similarly be different. With these definitions we can proceed with an abbreviated derivation of the relevant relations.

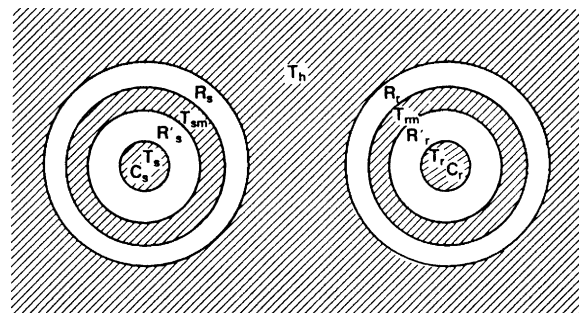

Figure 2. General considerations common to almost any type of thermal analysis instrument: C_s, total heat capacity of sample plus sample pan; T_h, temperature of the heat source; T_sm, temperature of the point where thermometer is located on the sample side; T_s, actual temperature of the sample and its pan; R_s, thermal resistance to heat flow between temperature T_h and T_sm; R'_S, thermal resistance to heat flow between temperature T_sm and T_s. The parameters C_r, T_rm, T_r, R_r, and R'_r have analogous meanings for the reference side. (From Mraw, 1988. Reproduced with permission.)

For simplicity, we consider all the heat capacities and thermal resistances to be constant. This will be approximately correct over a narrow temperature range in the determination of, for example, solidus or liquidus temperatures. Following Mraw, we take $R_s = R_r$ and $R'_s = R'_s$. Note that R and R' are not equal. Heat flow in the system is assumed to follow the simple one-dimensional law:

$$\frac{dq}{dt} = a\,\Delta T \tag{1}$$

where dq/dt is the rate of heat exchange between two bodies differing in temperature by ΔT. The heat transfer coefficient a is just $1/R$. We now examine heat exchange for the sample and reference assuming that heat flow from T_h to $T_{j,m}$ equals that from $T_{j,m}$ to T_j. This follows because we have assumed no other heat transfer processes in the system.

For the sample being subjected to a temperature scan at the rate dT_s/dt, we thus have

$$\frac{dq_s}{dt} = \frac{1}{R_s}(T_h - T_{sm}) = \frac{1}{R'_s}(T_{sm} - T_s) \tag{2}$$

and

$$\frac{dq_s}{dt} = C_s \frac{dT_s}{dt} \tag{3}$$

Similarly, for the reference,

$$\frac{dq_r}{dt} = \frac{1}{R_r}(T_h - T_{rm}) = \frac{1}{R'_r}(T_{rm} - T_r) \tag{4}$$

and

$$\frac{dq_r}{dt} = C_r \frac{dT_r}{dt} \tag{5}$$

The differences among the various thermal analysis techniques arise from differences in various parameters in the above equations. We next proceed to analyze these techniques within the framework of this simplified mathematical model.

In classical DTA (Fig. 1A), the thermocouples are imbedded within the sample. Therefore, $T_{j,m} = T_j$, i.e., there is no resistance R'. The measured signal is the difference in temperature between the reference and sample thermocouples ($T_r - T_s$). With the additional assumption that $R_s = R_r = R$, we subtract Equation 4 from Equation 2 and find an equation for the measured signal:

$$T_r - T_s = R\left(\frac{dq_s}{dt} - \frac{dq_r}{dt}\right) \tag{6}$$

By combining Equation 6 with Equations 3 and 5, we have

$$T_r - T_s = R\left(C_s \frac{dT_s}{dt} - C_r \frac{dT_r}{dt}\right) \tag{7}$$

During a programmed temperature scan at a rate dT/dt, a steady state is attained at which the sample and the reference temperatures are changing at the same rate. Equation 7 then becomes

$$T_r - T_s = R\frac{dT}{dt}(C_s - C_r) \tag{8}$$

The measured signal is thus seen to be proportional to the difference in heat capacities, but the value of R is needed to calculate the heat capacity of the sample. Because the thermocouples are embedded in the sample and reference, R will depend on, among other factors, the thermal conductivity of the sample. A calibration is, in principle, needed for every temperature range and sample configuration, making quantitative work difficult at best.

We turn next to power-compensated DSC (Fig. 1C). In this case, there are separate heaters for the sample and reference each with an associated thermometer. For this simple analysis we assume no thermal resistance, i.e., $R_j = 0$. The temperature-measuring system controls power to the two heaters to maintain the sample and reference at the same temperature; thus $T_{sm} = T_{rm}$. The measured signal in this method is the difference in power between the sample and reference sides. Thus, again assuming that steady-state heating rates have been attained, we have

$$\frac{dq_s}{dt} - \frac{dq_r}{dt} = \frac{dT}{dt}(C_s - C_r) \tag{9}$$

The measured signal for this case is again proportional to the difference in heat capacity, but the proportionality constant only includes the operator-selected heating rate and not a heat transfer coefficient. Quantitative work is therefore considerably more reliable.

Finally, using the same set of simplified equations, we turn to heat-flux DSC (Fig. 1B). Mraw's analysis is particularly valuable in dealing with this method in that he includes both R and R'. In this type of instrument the measuring thermocouples are mounted on a plate under the sample and reference pans. We can proceed as before with classical DTA but now recognize that $T_{j,m} \neq T_j$. The resulting equation, analogous to Equation 8, is

$$T_{rm} - T_{sm} = R\frac{dT}{dt}(C_s - C_r) \tag{10}$$

The difference between Equations 8 and 10 is that the R in Equation 10 is an instrument constant and can be found independent of the nature of the sample. Indeed, some manufacturers include the calibration in the electronics of the instrument so that the user obtains a differential power output.

In both power-compensated and heat-flux DSC there will be a temperature difference between T_s and T_{sm}. From Equations 2 and 3 we find

$$T_{sm} - T_s = R'_s C_s \frac{dT_s}{dt} \tag{11}$$

As an example of the temperature lag involved, the values given by Mraw for the Perkin-Elmer DSC-2 are $R'_s \approx 0.06$ K · s/mJ, $C_s \approx 50$ mJ/K, and $dT_s \approx /dt\ 0.167$ K/s and lead to a calculated temperature lag of ~0.5 K.

For the case in which an endothermic or exothermic process occurs, it is no longer acceptable to assume that $dT_s/dt = dT_r/dt$. The relevant equations are a straightforward extension of the derivation given above. These equations are given by Gray (1968), among others, and are simply reproduced here without detailed derivation. For a sample generating heat at a rate dH/dt, we have, for classical DTA or heat-flux DSC,

$$\frac{dH}{dt} = \frac{1}{R(T_s - T_r)} + (C_s - C_r)\frac{dT_r}{dt} + C_s\frac{d}{dt}(T_s - T_r) \quad (12)$$

For power-compensated DSC, assuming that the reference temperature changes at the same rate as the heat source, we have

$$\frac{dH}{dt} = -\left(\frac{dq_s}{dt} - \frac{dq_r}{dt}\right) + (C_s - C_r)\frac{dT_r}{dt} - RC_s\frac{d}{dt}\left(\frac{dq_s}{dt} - \frac{dq_r}{dt}\right) \quad (13)$$

Equations 12 and 13 are quite similar. Both contain three terms involving the signal: $T_s - T_r$ or $dq_s/dt - dq_r/dt$, a heat capacity difference $C_s - C_r$, and a derivative of the signal. Note that it is the negative of the signal that is the first term in Equation 13. Of primary importance is the presence of a thermal resistance factor in the first term of Equation 12, but the factor only appears in the third term of Equation 13.

Modulated DSC

Modulated DSC (MDSC) is a relatively new technique that improves upon the classical DSC performance in terms of increased ability to analyze complex transitions, higher sensitivity, and higher resolution. While classical DSC uses a linear heating or cooling program of the form

$$T = \alpha + \beta t \quad (14a)$$

$$\frac{dT}{dt} = \beta \quad (14b)$$

modulated DSC employs a linear heating or cooling program with a small sinusoidal component superimposed:

$$T = \alpha + \beta t + A_t \sin(\omega t) \quad (15a)$$

$$\frac{dT}{dt} = \beta + A_T\omega\cos(\omega t) \quad (15b)$$

so that the heating rate oscillates between $\beta + A_T\omega$ and $\beta - A_T\omega$ with an average underlying heating rate β. Here, A_T is the temperature modulation amplitude (in kelvin) and ω is the angular frequency of the temperature modulation (in radians per second) equal to $2\pi/P$, where P is the temperature modulation period (in seconds). To illustrate the modulated DSC capabilities, it is possible to recast Equation 13 as follows:

$$\left(\frac{dq_s}{dt} - \frac{dq_r}{dt}\right) = (C_s - C_s)\frac{dT_r}{dt} - \frac{dH}{dt} - RC_s\frac{d}{dt}\left(\frac{dq_s}{dt} - \frac{dq_r}{dt}\right) \quad (16)$$

which upon combining the last two terms on the right-hand side, denoting differences between sample and reference quantities with Δ, and replacing dT_r/dt with dT/dt transforms into

$$\frac{d\Delta q}{dt} = \Delta C\frac{dT}{dt} - F(T,t) \quad (17)$$

In modulated DSC terminology, the term on the left-hand side is the total heat flow, while the first term on the right-hand side is the reversing heat flow or heat capacity component and the second term on the right-hand side is the nonreversing heat flow or kinetic component. Classical DSC (both power compensated and heat flux) measures and puts out the total heat flow. Modulated DSC is different in that it measures and puts out the instantaneous heat flow (Fig. 3), which takes on the modulated character of the temperature. From the modulated heat flow, it is then possible to obtain both the total heat flow (roughly by averaging or, more precisely, using Fourier transform analysis; Fig. 3) and its heat capacity component (roughly by taking the ratio of the modulated heat flow amplitude A_q and A_T or, more precisely, using Fourier transform analysis; Fig. 4). An algebraic difference of these two

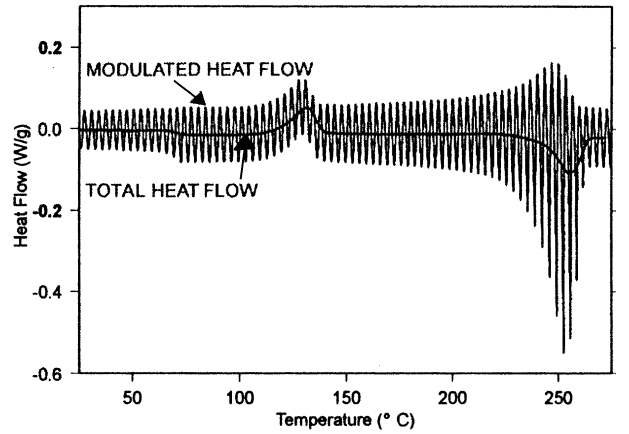

Figure 3. Modulated DSC of a quench-cooled polymer: obtaining total heat flow from modulated heat flow. (Courtesy of TA Instruments.)

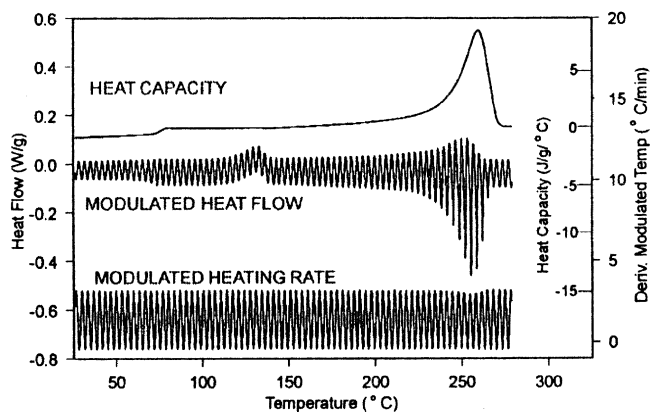

Figure 4. Modulated DSC of a quench-cooled polymer: obtaining the heat capacity (reversing) components from modulated heat flow and modulated heating rate. (Courtesy of TA Instruments.)

quantities, yields the kinetic component of the total heat flow (Fig. 5). This significantly improves the ability to separate overlapping thermal events with different behavior, e.g., crystallization (nonreversing) and glass transition (reversing) in polymer blends. Sensitivity and resolution are also improved. In addition, the presence of noninstrumental phase lag between the modulated temperature and the modulated heat flow leads to the formulation of complex heat capacity c_p^*, which can be split into its real (c_p') and imaginary (c_p'') components and analyzed separately.

PRACTICAL ASPECTS OF THE METHOD

The DSC/DTA signal is usually recorded as a function of time, $S(t)$, or temperature, $S(T)$. Conversion between $S(t)$ and $S(T)$ can easily be made since the dependence $T(t)$ is known (see Equation 14a or 15a). In the following paragraphs, we shall use S to denote both $S(t)$ and $S(T)$, unless indicated otherwise.

Zero-Line Optimization

Following Höhne et al. (1996), we shall make a distinction here between the zero line and the baseline (see below). The zero line, S_0, is the signal recorded with both the sample and the reference holders empty. It represents the thermal behavior of the instrument itself. As the name suggests, the zero line should ideally be constant and equal to zero over the whole temperature range. This, of course, is never the case, and every effort should be made to adjust the instrument controls according to manufacturers' specifications to produce a zero line as flat and as close to zero as possible. Zero-line optimization should be followed by the zero-line repeatability check. Five or more (n) zero lines, S_0^i, are recorded over the whole temperature range at a selected scan rate. The temperature-dependent deviation (standard deviation or maximum deviation, absolute or relative) from the mean zero line, $\bar{S}_0 = \sum S_0^i/n$, is the zero-line repeatability. This uncertainty projects directly into absolute heat flow determinations, which involve calculations of the type $S - S_0$, e.g., heat capacity measurements by the scanning method (see below).

Calibration

Quantitative DSC/DTA data can only be obtained if the instrument has been properly calibrated with respect to both temperature (DSC/DTA) and heat flow or enthalpy (DSC). Calibrants should ideally be certified reference materials (values of transition temperature and/or transition enthalpy have been determined for a particular lot of material) or at least high-purity materials for which literature values exist. The most commonly used calibrants with approximate values of their transition properties are given in Table 1. Temperature calibration is a process of determining the difference, δT, between the actual sample temperature, T_s, and the indicated temperature, T_{ind}, and then either incorporating it into the final data treatment or eliminating it by instrument control adjustment. The temperature difference is, in general, a function of the indicated temperature and the heating rate:

$$\delta T = T_s - T_{ind} = f(T_{ind}, \beta) \tag{18}$$

The T_{ind} dependence of δT should be determined with at least two calibrants bracketing the temperature range of interest (two-point calibration) as closely as possible. Using one or more calibrants within the temperature range of interest is always beneficial (multipoint calibration) for checking and, if applicable, correcting the linearity assumption of the two-point calibration. The dependence of δT on β is due to increasing the thermal lag of T_s behind T_{ind} at higher scanning rates. Isothermal calibration furnishes the value of δT for a zero heating rate, δT_0, while calibration at the scanning rate of the experiment furnishes the thermal lag, δT_β. Hence, δT can be calculated as

$$\delta T = \delta T_0 + \delta T_\beta \tag{19}$$

At a given temperature, δT_0 might be of either sign but δT_β is always negative in heating and positive in cooling. A simpler method of temperature calibration is sometimes suggested by instrument manufacturers that omits the

Table 1. DSC/DTA Calibrants, Their Transition Temperatures, and Their Transition Enthalpies

Material	T_{tr}(K)	$\Delta_{tr}H°$(J/g)

Zinc (Zn)	693	108
Potassium sulfate (K_2SO_4)	858	33
Potassium chromate K_2CrO_4	944	36

isothermal calibration and yields a universal temperature correction $\delta T'$. This method is strictly valid only for very small samples.

Heat flow or enthalpy calibration is a process of determining the signal-to-heat-flow conversion factor or the area-to-enthalpy conversion factor, respectively, under scanning conditions. Heat flow calibration is used for heat capacity measurements by the scanning method (see below). Enthalpy calibration is used for measurements of heat capacity by the enthalpy method (see below) and for general enthalpy measurements. Heat flow calibration is almost universally performed with two calibrants, namely α-alumina (sapphire) for superambient operation and benzoic acid for subambient operation. Heat capacities for both materials have been accurately measured by adiabatic calorimetry, and both are available as standard reference materials. Heat flow dH/dt is assumed to be proportional to the signal $S(t)$:

$$\frac{dH}{dt} = K(t)S(t) \tag{20}$$

where K is the signal-to-heat-flow conversion factor (K is ideally temperature independent but in practice varies slightly with temperature and this dependence needs to be determined). The relation between heat capacity $c_p(t)$ and $S(t)$ is then

$$c_p(t) = \frac{dH}{dT(t)} = K(t)S(t)\left(\frac{dT}{dt}\right)^{-1} \tag{21}$$

so that $K(t)$ can be determined from the known calibrant heat capacity $c_p^{\text{cal}}(t)$, scan rate dT/dt, and calibrant signal $S^{\text{cal}}(t)$ as

$$K(t) = \frac{c_p^{\text{cal}}(t)(dT/dt)}{S^{\text{cal}}(t)} \tag{22}$$

Enthalpy calibration is usually performed with one or ideally more of the calibrants listed in Table 1. Rearranging Equation 20 leads to a relationship between the enthalpy and the integrated peak area A at some temperature of interest,

$$H = K\int S(t)\,dt = KA \tag{23}$$

so that K can be determined from the known transition enthalpy H^{cal} and the integrated calibrant peak area A^{cal} as

$$K = \frac{H^{\text{cal}}}{A^{\text{cal}}} \tag{24}$$

Note that the signal-to-heat-flow conversion factor and the area-to-enthalpy conversion factor are identical. This is only the case if the signal is considered a function of time, $S(t)$. For the signal as a function of temperature, $S(T)$, the signal-to-heat-flow conversion factor K' and the area-to-enthalpy conversion factor K'' are not identical:

$$K'' = K'\left(\frac{dT}{dt}\right)^{-1} \tag{25}$$

Instrument Parameter Selection

It is important that appropriate values of instrument parameters be selected for each experiment. To facilitate correct baseline interpolation (see below), the temperature range should extend well below and above the characteristic temperature of the thermal event under investigation. Subambient studies require a cooling accessory such as an ice-water bath, mechanical refrigeration, or liquid nitrogen cooling. Ideally, it should be possible to obtain identical results in both heating and cooling modes. However, most studies are performed in the heating mode because it is difficult to sustain higher cooling rates over large temperature ranges (especially at lower temperatures) and because temperature calibrations in the cooling mode tend to be less accurate due to nonreproducible calibrant undercooling. The scan rate β (together with sample size, see below) has a profound influence on sensitivity and resolution. High scan rates improve sensitivity because the signal is proportional to the scan rate, e.g., Equation 21, but lead to a loss of resolution and vice versa. A compromise is always necessary. Scan rates from 5 to 20 K/min are most commonly used. For modulated DSC, values for the amplitude A_T and period P of temperature modulation need to be selected. They are typically 0.5−3 K for A_T and 40−100 s for P. The sample must be able to follow the modulated temperature profile. This can be checked by analyzing the modulated heating rate profile and the modulated heat flow profile, or a Lissajous plot of these, for nonsinusoidal distortions. Purge gas compatible with the sample, sample pan, and sample holder needs to be selected. Inert gases (e.g., Ar, N_2, or He) are commonly used for superambient operation while dry He is preferred for subambient operation. Purge gas flow rates on the order of 10 cm^3/min are generally used. Higher flow rates up to 100 cm^3/min can be used with samples generating corrosive and/or condensable gases.

Typical Applications

The principal use of DSC/DTA is, and all the other uses of DSC/DTA are derived from, the measurement of transition temperature, the measurement of transition enthalpy, and the measurement of heat capacity. Transition temperature is determined as extrapolated onset temperature, and transition enthalpy is determined by integration of the signal with special methods used for the glass transition (see Data Analysis and Initial Interpretation). Heat capacity measurements are dealt with in detail below.

The simplest use of DSC/DTA is in identification and characterization of materials. Identification is the determination of sample transition temperature and/or transition enthalpy (see below), e.g., solid to liquid, for an unknown sample, followed by a comparison with a list of possible candidates with their transition temperatures

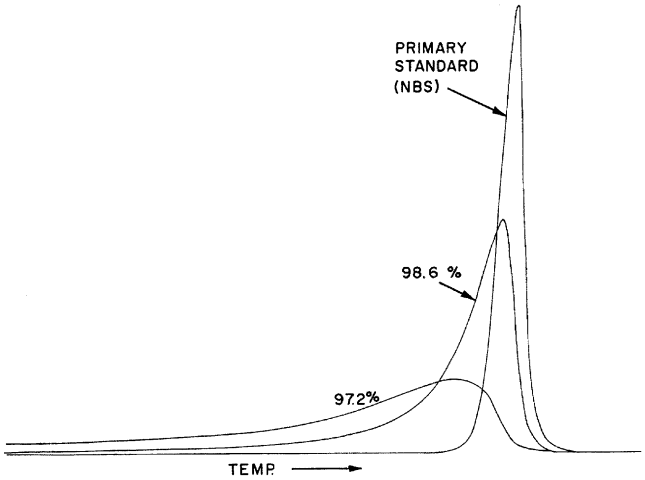

Figure 6. Effect of purity on DSC melting peak shapes. Lower purity leads to peak shift to lower temperature and peak broadening. (Courtesy of Perkin-Elmer.)

and/or enthalpies. Characterization is the determination of transition temperature and/or enthalpy for a known sample. The DSC/DTA technique has found widespread use in purity determination of materials, e.g., pharmaceuticals. This application rests upon the van't Hoff equation (Lewis and Randall, 1923) for melting point depression:

$$\Delta T = -\frac{RT_0^2 x_2}{\Delta_{\text{fus}}H} \tag{26}$$

where ΔT is the melting point depression, R is the universal gas constant, x_2 is the mole fraction of the impurity, and $\Delta_{\text{fus}}H$ is the enthalpy of fusion. Both ΔT and $\Delta_{\text{fus}}H$ are determined simultaneously and x_2 is calculated. The influence of sample purity on a DSC melting peak is shown in Figure 6.

As illustrated in Figure 7 for a simple binary eutectic system, DSC/DTA can be used in the determination of phase diagrams. In addition to scans of both pure components (A, B), several scans at different intermediate compositions are performed (C, D). These exhibit two endothermic peaks, one due to the eutectic melting ($\sim$77°C) and the other one due to the crossing of the liquidus curve. The enthalpy associated with the eutectic melting is a simple function of composition (E) and can be used to determine the eutectic composition. The final phase diagram is shown in F.

The glass transition in glasses and polymers can be successfully studied by DSC/DTA. While there is no enthalpy change associated with the glass transition, the heat capacity does change abruptly. A typical scan through a glass transition temperature T_g and its determination are shown in Figure 8.

The scanning method is the one more commonly used for heat capacity determination by DSC. Three runs, each starting and finishing with an isothermal section and each spanning the same temperature range at the same heating rate, are necessary: empty pan, calibrant, and sample, producing three raw signals $S_{\text{raw}}^{\text{emp}}(t)$, $S_{\text{raw}}^{\text{cal}}(t)$ and $S_{\text{raw}}^{\text{smp}}(t)$, respectively. Although ideally constant and equal to zero, the initial and final isothermal sections of

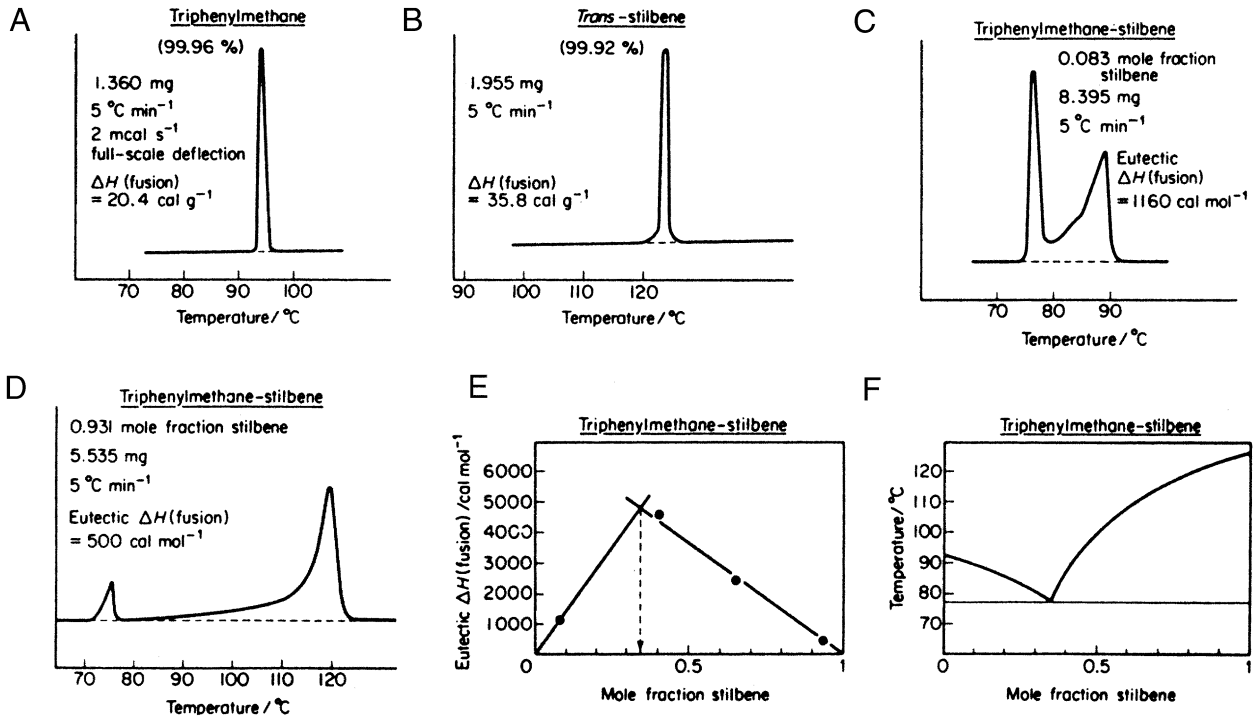

Figure 7. Binary phase information from DSC: (**A**, **B**) scans of the pure compounds; (**C**, **D**) scans of mixtures of the two compounds; (**E**) measured enthalpy change at the eutectic temperature; (**F**) binary phase diagram. (Courtesy of Perkin-Elmer.)

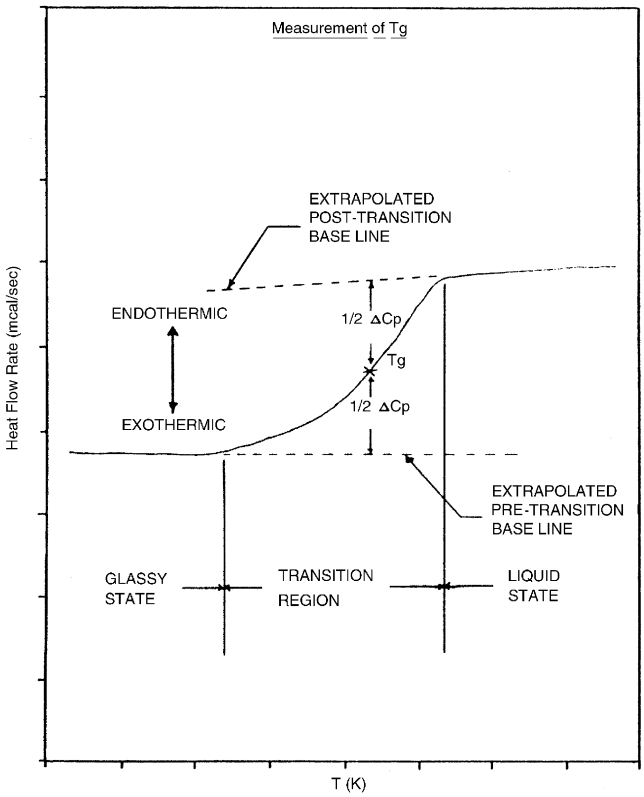

Figure 8. Measured T_g. The glass transition manifests itself as a shift, rather than a peak, in the signal. (Courtesy of Perkin-Elmer.)

the three runs differ. A baseline balancing procedure (Richardson, 1984, 1992) is needed to bring the initial and final isothermal sections into coincidence (Fig. 9), so that two net signals, $S^{\text{cal}}(t) = S^{\text{cal}}_{\text{raw}}(t) - S^{\text{emp}}_{\text{raw}}(t)$ and $S^{\text{smp}}(t) = S^{\text{smp}}_{\text{raw}}(t) - S^{\text{emp}}_{\text{raw}}(t)$, respectively, can be calculated. The signal-to-heat-flow conversion factor is determined

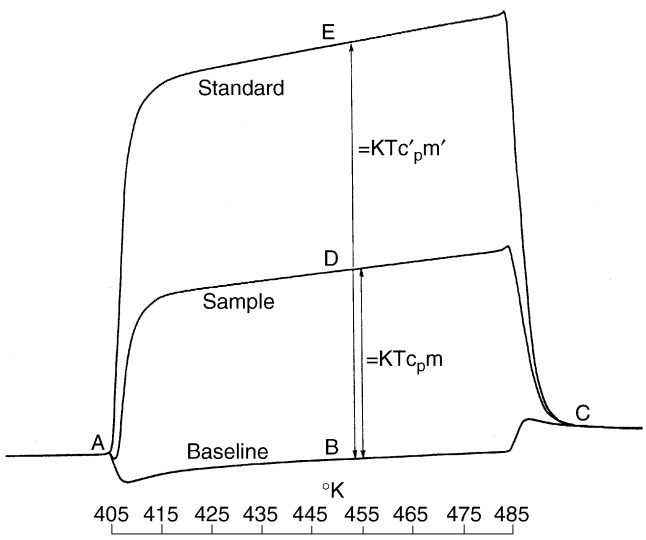

Figure 9. Typical specific heat determination. Initial and final isothermal signals have been brought into coincidence by applying a baseline-balancing procedure. (Richardson, 1984, 1992; courtesy of Perkin-Elmer.)

from Equation 22. The unknown heat capacity is then determined from Equation 21 with $S^{\text{smp}}(t)$ in place of $S(t)$. Even though it is possible to substitute Equation 22 back into Equation 21 to yield

$$c_p(t) = c_p^{\text{cal}}(t)\frac{S^{\text{smp}}(t)}{S^{\text{cal}}(t)} \tag{27}$$

valuable information about the behavior of $K(t)$, indicative of instrument performance, is lost and this method is, thus, not recommended. A continuous heat capacity curve, $c_p(t)$, can be determined over a 100 K or larger temperature range rather quickly. Heat capacity can, alternatively, be determined by the enthalpy method, which approximates the method of classical adiabatic calorimetry, although temperature scanning is still involved. The same three runs under identical conditions as in the scanning method are necessary; however, the scanning temperature interval T_{fin} to T_{ini} is narrower (e.g., 5 to 20 K). The area-to-enthalpy conversion factor is determined from Equation 24. The enthalpy involved in the scan is calculated from Equation 23. The heat capacity at the midpoint of the scanning temperature interval, T_{mid}, is then calculated as

$$C_p(T_{\text{mid}}) = \frac{H}{T_{\text{fin}} - T_{\text{ini}}} \tag{28}$$

so that, for a given temperature range, discrete values of $C_p(T)$ are obtained, their number depending on the width of the individual scanning temperature interval.

Reaction onset temperatures and enthalpies can be determined by DSC by the scanning method or by the isothermal method. In the isothermal method, the reaction mixture sample is heated rapidly from a temperature at which it is inert to some elevated temperature. The signal at that temperature is then recorded until it reaches a constant value S_{end}. The reaction enthalpy is calculated as

$$H = K\int [S(t) - S_{\text{end}}]\,dt \tag{29}$$

In the scanning method, where heat capacity changes will usually be significant due to the larger temperature range involved, it is advantageous to repeat the experiment with the already reacted sample to yield the product heat capacity signal, $S_{cp}(t)$. Assuming the validity of the Neumann-Kopp rule (Kubaschewski and Alcock, 1929) the reaction enthalpy can then be calculated as

$$H = K\int [S(t) - S_{cp}(t)]\,dt \tag{30}$$

Application of modulated DSC in determining reaction enthalpies is particularly valuable because of its ability to separate heat capacity and enthalpy changes.

The DSC/DTA technique can also be used to study the rates of thermal processes, e.g., phase transformations or chemical reactions. Measurements of the onset temperature and enthalpy of the process are analogous to the corresponding thermodynamic measurements and will not be discussed further here. However, determinations of the

rate of these processes involve somewhat different methods and are briefly discussed below. Two approaches to this problem exist: isothermal and scanning. In the isothermal method, a sample of interest is held in the instrument for a given time at a temperature at which the process will take place. The sample is then programmed through the reaction regime. This process is repeated for various times and temperatures. The observed change in the exothermal peak area can then be related to the extent of reaction undergone during the isothermal hold. From these measurements, information on the rate of the process can be obtained. In the scanning method, the reacting mixture is scanned through a temperature range in which the reaction takes place. It is assumed that the rate of reaction is proportional to the rate of heat evolution and that only one reaction is taking place. The use of this technique to determine reaction mechanisms, activation energies, and other kinetic parameters is difficult and subject to a variety of uncertainties. Some of the difficulties of using thermal analysis methods for the study of kinetics have been identified (Flynn et al., 1987). With respect to the scanning method of kinetic studies, Flynn et al. remark: "it is impossible to separate unequivocally the temperature-dependent and concentration-dependent parts of a rate expression by experiments in which temperature and concentration are changing simultaneously."

METHOD AUTOMATION

All modern DSC/DTA instruments employ computerized control, data acquisition, and data analysis. Instrumental parameters are set through and the experiment is initiated and controlled by a computer and data are acquired, saved, and analyzed (in real time or after the experiment) using sophisticated programs. Although this significantly reduces operator labor involved in producing data, it might also lead to misinterpretation of data. It is, therefore, important that the operator have access to the algorithms used in the data analysis.

The need for higher throughput in routine analyses has led to the development of autosamplers, which are now available for most commercial DSC/DTA instruments. These allow for unattended analysis of up to 60 samples.

DATA ANALYSIS AND INITIAL INTERPRETATION

An endothermic or exothermic event will give rise to a peak in the DSC/DTA curve. In power-compensated DSC, endotherms are plotted in the positive direction and exotherms are plotted in the negative direction. In heat-flux DSC and DTA, the opposite is true. The following discussion will use power-compensated DSC as an example but can readily be extended to heat-flux DSC and DTA.

A peak associated with fusion of an ultrapure metal is shown in Figure 10. The vertex of the peak is not strictly the melting temperature. Rather, the leading edge of the peak is extrapolated down to the baseline with their intersection defined as the extrapolated onset temperature (Fig. 10). It can be shown that the slope of the leading edge is equal to $(1/R_0)\,(dT/dt)$, where R_0 is the controlling thermal resistance between the sample pan and the sample holder. Since R_0 does not change from sample to sample (using the same or the same type pan), the true melting temperature of any other sample is determined as an extrapolated onset temperature using the slope determined with an ultrapure metal (Fig. 11).

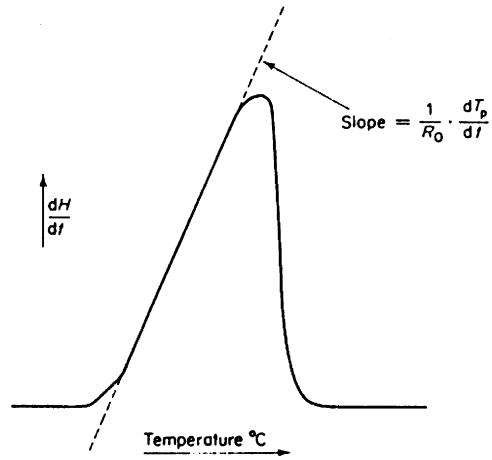

Figure 10. Thermogram for the fusion of 99.999% pure indium. (Courtesy of Perkin-Elmer.)

The enthalpy associated with a thermal event when there is little change in heat capacity before and after the transition (Fig. 11) can be calculated by drawing-in a linear baseline $S_b(t)$ and integrating:

$$H = K \int [S(t) - S_b(t)]\, dt \tag{31}$$

However, when the change in specific heat is large, a more rigorous method of establishing the baseline must be used. Several have been proposed. The principle behind the correction of Brennan et al. (1969) is outlined in Figure 12. Once the nonlinear baseline is established, Equation 29 is used to calculate the enthalpy.

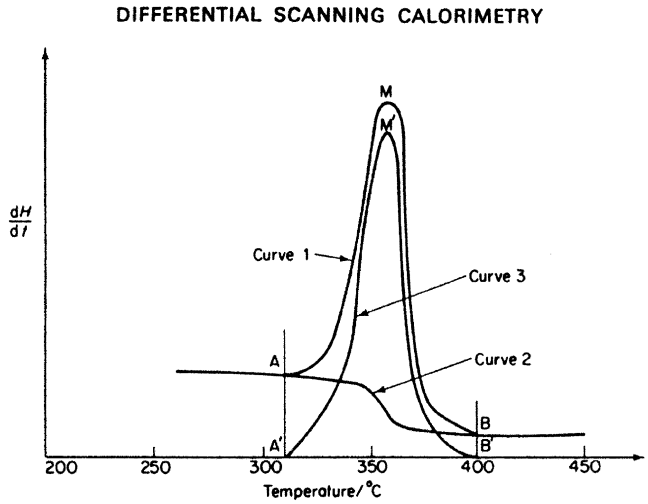

Figure 12. Correction of observed enthalpy data for the change in heat capacity: curve 1, uncorrected signal; curve 2, hypothetical signal for a reaction with zero enthalpy; curve 3, signal corrected for change in heat capacity by subtracting curve 2 from curve 1. The area under curve 3 represents the enthalpy of the reaction. (Brennan et al., 1969; courtesy of Perkin-Elmer.)

SAMPLE PREPARATION

One of the most appealing features of DSC/DTA is the small sample size and easy sample preparation. Typical sample mass is ~10 mg. While transition and reaction temperatures are independent of sample size, determination of transition and reaction enthalpies requires knowledge of accurate sample mass. For the typical sample, a $\pm$0.1-mg error in mass represents a 1% error in enthalpy. To ensure good thermal contact with the sample pan (~5 mm in diameter), disk-shaped samples lying flat on the bottom of the sample pan are preferred. Hence, a material with a density of 1 g/cm^3 would need to be formed into a disk ~0.5 mm thick. Filmlike materials, e.g., polymers, only need to be punched out to the right diameter (and stacked if the film is too thin). Solid materials, e.g., metals and alloys, need to be cut to the right size with a flat surface, if possible, toward the bottom of the pan. Powders need to be compacted into a pellet using a right diameter die. Liquids in the right amount can be measured out directly into the sample pan. Given the small DSC/DTA sample size, representative sampling of the material is crucial. Use of larger samples under otherwise identical conditions improves sensitivity but leads to deterioration of resolution (could be compensated for by lower scan rates). Using larger samples at lower scan rates is generally preferable to using smaller samples at higher scan rates.

The large variety of sample pans available from DSC/DTA instrument manufacturers (see Appendix) can be characterized by material of construction and sealability. The material of construction needs to be selected so that there are no reactions between the sample pan and the sample, and between the sample pan and the sample holder, within the temperature range of interest. At the same time, the material of construction should have the highest thermal conductivity. This makes aluminum the most frequently used sample pan material. Table 2 lists a number of commonly used sample pan materials. Most samples can be enclosed in nonhermetic sample pans. Metallic sample pans usually come with a lid that can be crimped onto the sample pan with a crimper tool; however, this makes the pans and lids single use. Graphite and ceramic sample pans also come with covers and can be reused. For special applications such as studies of volatile materials, materials generating corrosive or condensable gases, and air-sensitive materials, hermetically sealed metallic sample pans can be used. The sample pans are sealed in air, in a protective atmosphere, or under vacuum. Hermetic sample pans become pressurized at high temperatures and should be handled with caution.

SPECIMEN MODIFICATION

Specimen modification in DSC/DTA results from the exposure to high and/or low temperatures and is an integral part of the method, e.g., solid-to-liquid transformation in purity determination. In some cases, however, specimen modification can be detrimental, e.g., denaturation of biological samples, and needs to be taken into account. The nature and extent of specimen modification are frequently important for elucidation of DSC/DTA data. In such cases, auxiliary methods of analysis, e.g., x-ray diffraction analysis, are applied prior to and following a DSC/DTA experiment. If changes in the sample that occurred at higher temperature are reversible upon cooling to room temperature (for sample removal and analysis), the cooling rate has to be increased to the maximum (up to 500 K/min), effectively quenching the sample, or a simultaneous analysis technique can be applied. Simultaneous techniques are extremely valuable for elucidation of complex DSC/DTA data. The most common combinations are

Table 2. DSC/DTA Sample Pan Materials, Their Properties, and Purge Gas Compatibility

Sample Pan Material	Upper Temperature Limit[a]	Thermal Conductivity	Purge Gas
Aluminum (Al)	873 K	Excellent	Inert, reducing, oxidizing
Noble metals (Cu, Ag, Au, Pt, Ti, Ni, Ta, etc.)	>1173 K, 100 K below respective T_m	Excellent	Inert, reducing
Stainless steel	1273 K	Good	Inert, reducing
Graphite (C)	2273 K	Excellent	Inert, reducing
Oxides (SiO_2, Al_2O_3, Y_2O_3, BeO, etc.)	>1273 K, 100 K below respective T_m	Poor	Inert, oxidizing

[a]Caution! Reactions with sample and/or sample holder might occur at a lower temperature due to the existence of lower melting eutectics.

DSC/DTA + thermal gravimetric analysis (TGA; see THERMOGRAVIMETRIC ANALYSIS), DSC/DTA + mass spectrometry (MS; see SIMULTANEOUS TECHNIQUES INCLUDING ANALYSIS OF GASEOUS PRODUCTS), and DSC/DTA + Fourier transform infrared spectroscopy (FTIR; see SIMULTANEOUS TECHNIQUES INCLUDING ANALYSIS OF GASEOUS PRODUCTS). With the advent of synchrotron light sources, combinations such as DSC/DTA + x-ray absorption fine structure (XAFS; Tröger et al., 1997) and DSC/DTA + x-ray diffraction (XRD; Lexa, 1999) became possible.

PROBLEMS

Heat-flux DSC and DTA instruments use thermocouples to detect temperature. Because of interdiffusion at the junction, it is possible that thermocouple calibrations will change. This is particularly troublesome for cases of extended times of operation near the upper limit of the temperature range of the thermocouple. Periodic temperature calibration of the instrument is recommended.

Reactions with sample pans are a chronic problem that must be considered, particularly for high-temperature work. A variety of DTA/DSC sample pans are commercially available (see Table 2). It is usually possible to find suitable materials, but it is important to verify that no significant reaction has taken place. Serious errors and damage to equipment can result from ignoring this possibility.

Resolution of close peaks can present difficulties. Indeed, the experimenter may not even be aware of the existence of hidden peaks. It is important when working with unfamiliar systems to conduct scans at several heating/cooling rates. Lower rates allow resolution of closely lying peaks, at the expense, however, of signal strength. Examination of both heating and cooling traces can also be useful.

It should be obvious that caution should be observed to avoid the presence of an atmosphere in the DSC/DTA system that could react with either the sample or the crucible. Less obvious, perhaps, is the need to be aware of vapors that may be evolved from the sample that can damage components of the experimental system. Evolution of chloride vapors, e.g., can be detrimental to platinum components. Vaporization from the sample can also significantly alter the composition and the quantity of sample present. Sealable pans are commercially available that can minimize this problem.

Because DSC/DTA typically involves scanning during a programmed heating or cooling cycle, slow processes can be troublesome. In measuring melting points, e.g., severe undercooling is commonly observed during a cooling cycle. An instantaneous vertical line characterizes the trace when freezing begins. In studying phase diagrams, peritectic transformations are particularly sluggish and troublesome to define.

APPENDIX: ACQUIRING A DSC/DTA INSTRUMENT

Acquisition of a DSC/DTA instrument should be preceded by a definition of its intended use, e.g., routine quality control analyses vs. research and development. While in the former setting an easy-to-use model with an available autosampler might be called for, the latter setting will likely require a highly flexible model with a number of user-selectable controls. A technical specification checklist (Höhne et al., 1996, used with permission) should then be compiled for different instruments from values obtained from manufacturers:

Manufacturer	...
Type of measuring system	Heat-flux disk type Heat-flux cylinder type Power compensation
Special feature	...
Sample volume (standard crucible)	mm^3
Atmosphere (vacuum?, which gases?, pressure?)	...
Temperature range	From ... to ... K
Scanning rates	From ... to ... K/min
Zero-line repeatabilty	From ± ... μW (at ... K) to ± ... μW (at ... K)
Peak-area repeatability	± ... % (at ... K)
Total uncertainty for heat	± ... % (at ... K)
Extrapolated peak-onset temperature	
Repeatability	± ... K (at ... K)
Total uncertainty for temperature	± ... K (at ... K)
Scanning noise (pp) at ... K/min	From ± ... μW (at ... K) to ± ... μW (at ... K)
Isothermal noise (pp)	From ± ... μW (at ... K) to ± ... μW (at ... K)
Time constant with sample	... s
Additional facilities	...

The lists should then be compared with each other and with a list of minimum requirements for the intended use. (Fiscal considerations will, undoubtedly, also play a role.) Manufacturer data should be critically evaluated as to the conditions under which the same have been determined. For instance, the majority of manufacturers give the same value for isothermal noise of their instruments as 0.2 μW. This value has apparently been obtained under extremely well controlled conditions and will not be reproduced in everyday use, where isothermal noise levels of ~1 μW are more realistic.

COMBUSTION CALORIMETRY

INTRODUCTION

In the absence of direct experimental information, one often must rely on a knowledge of thermodynamic properties to predict the chemical behavior of a material under operating conditions. For such applications, the standard molar Gibbs energy of formation $\Delta_f G^\circ_m$ is particularly powerful; it is frequently derived by combining the standard molar entropy of formation $\Delta_f S^\circ_m$ and the standard molar enthalpy of formation ($\Delta_f G^\circ_m = \Delta_f H^\circ_m - T \cdot \Delta_f S^\circ_m$), often as functions of temperature and pressure. It follows, therefore, that the standard molar enthalpy of formation, $\Delta_f H^\circ_m$, is among the most valuable and fundamental thermodynamic properties of a material. This quantity is defined as the enthalpy change that occurs upon the formation of the compound in its standard state from the component elements in their standard states, at a designated reference temperature, usually (but not necessarily) 298.15 K, and at a standard pressure, currently taken to be 100 kPa or 101.325 kPa.

Many methods have been devised to obtain $\Delta_f H^\circ_m$ experimentally. Those include the so-called second- and third-law treatments of Knudsen effusion and mass-spectrometric results from high-temperature vaporization observations, as well as EMF results from high-temperature galvanic cell studies (Kubaschewski et al., 1993). Each of those techniques yields $\Delta_f G^\circ_m$ for the studied process at a given temperature. To derive values of $\Delta_f H^\circ_m$, the high-temperature results for $\Delta_f G^\circ_m$ must be combined with auxiliary thermodynamic information (heat capacities and enthalpy increments at elevated temperatures). Frequently, it turns out that the latter properties have not been measured, so they must be estimated (Kubaschewski et al., 1993), with a consequent degradation in the accuracy of the derived $\Delta_f H^\circ_m$. Furthermore, high-temperature thermodynamic studies of the kind outlined here often suffer from uncertainties concerning the identities of species in equilibrium. Another potential source of error arises from chemical interactions of the substances or their vapors with materials of construction of Knudsen or galvanic cells. All in all, these approaches do not, as a rule, yield precise values of $\Delta_f H^\circ_m$. Sometimes, however, they are the only practical methods available to the investigator.

Alternative procedures involve measurements of the enthalpies (or enthalpy changes) of chemical reactions, $\Delta_r H^\circ_m$, of a substance and the elements of which it is composed. Experimentally, the strategy adopted in such determinations is dictated largely by the chemical properties of the substance. The most obvious approach involves direct combination of the elements, an example of which is the combustion of gaseous H_2 in O_2 to form H_2O. In the laboratory, however, it is often impossible under experimental conditions to combine the elements to form a particular compound in significant yield. An alternative, albeit less direct route has been used extensively for the past century or more, and involves measurements of the enthalpy change associated with a suitable chemical reaction of the material of interest. Here, the compound is "destroyed" rather than formed. Such chemical reactions have

involved, *inter alia*, dissolution in a mineral acid or molten salt (Marsh and O'Hare, 1994), thermal decomposition to discrete products (Gunn, 1972), or combustion in a gas such as oxygen or a halogen. This last method is the the subject matter of this unit. As an example of the latter technique, we mention here the determination of $\Delta_f H^\circ_m$ of ZrO_2 (Kornilov et al., 1967) on the basis of the combustion of zirconium metal in high-pressure $O_2(g)$

$$Zr(cr) + O_2(g) = ZrO_2(cr) \quad (1)$$

where $\Delta_f H^\circ_m(ZrO_2) = \Delta_c H^\circ_m(Zr)$, the standard molar enthalpy of combustion of Zr in $O_2(g)$, i.e., the standard molar enthalpy change associated with the reaction described in Equation 1. It is essential when writing thermochemical reactions that the physical states of the participants be stated explicitly; thus, (cr) for crystal, (s) for solid, (g) for gas, and (l) for liquid. Enthalpies of formation of numerous oxides of metals (Holley and Huber, 1979) are based on similar measurements. These are special cases in that they involve oxidation of single rather than multiple elements, as in the combustion of aluminum carbide (King and Armstrong, 1964)

$$Al_4C_3(cr) + 6O_2(g) = 2Al_2O_3(cr) + 3CO_2(g) \quad (2)$$

Of all the materials studied thermodynamically by combustion, organic substances have been predominant, for the simple reason (apart from their numerousness) that most of them react cleanly in oxygen to give elementary and well defined products. Thus, the combustion in high-pressure oxygen of benzoic acid, a standard reference material in calorimetry, proceeds as follows

$$C_6H_5COOH(cr) + (15/2)O_2(g) = 7CO_2(g) + 3H_2O(l) \quad (3)$$

The enthalpy of formation of benzoic acid is the enthalpy change of the reaction

$$7C(cr) + 3H_2(g) + O_2(g) = C_7H_6O_2(cr) \quad (4)$$

where all substances on both sides of Equation 4 are in their standard states. It should be noted that the reference state of C is not merely the crystalline form but, more exactly, "Acheson" graphite (CODATA, 1989). Obviously, a direct determination of the enthalpy change of the reaction in Equation 4 is not possible, and it is in addressing such situations that combustion calorimetry has been particularly powerful. Similarly, with reference to Equation 3, separate equations may be written for the formation of $CO_2(g)$ and $H_2O(l)$

$$C(cr) + O_2(g) = CO_2(g) \quad (5)$$

$$H_2(g) + (1/2)O_2(g) = H_2O(l) \quad (6)$$

where $\Delta_r H^\circ_m$ for Equation 5 $= \Delta_f H^\circ_m(CO_2, g)$, and $\Delta_r H^\circ_m$ for Equation 6 $= \Delta_f H^\circ_m(H_2O, l)$. By appropriate combination of Equations 3, 5, and 6, one obtains Equation 4. In other words

$$\begin{aligned}\Delta_f H^\circ_m(C_7H_6O_2) &= -\Delta_r H^\circ_m\,(\text{Equation 3}) + 7 \cdot \Delta_r H^\circ_m\,(\text{Equation 5}) \\ &\quad + 3 \cdot \Delta_r H^\circ_m\,(\text{Equation 6}) \\ &= -\Delta_r H^\circ_m\,(\text{Equation 3}) + 7 \cdot \Delta_f H^\circ_m(CO_2, g) \\ &\quad + 3 \cdot \Delta_f H^\circ_m(H_2O, l) \end{aligned} \quad (7)$$

Thus, the standard molar enthalpy of formation of benzoic acid is obtained as the difference between its standard molar enthalpy of combustion in oxygen and the standard molar enthalpies of formation of the products, {$CO_2(g)$ and $H_2O(l)$}, the latter being multiplied by the appropriate stoichiometric numbers, 7 and 3, respectively. This is a general rule for calculations of $\Delta_f H^\circ_m$ from reaction calorimetric data.

Not surprisingly, oxygen bomb calorimetry has also been productive in thermochemical studies of organometallic materials. In that connection, the work of Carson and Wilmshurst (1971) on diphenyl mercury is taken as an example. These authors reported the massic energy of the combustion reaction

$$\begin{aligned}&Hg(C_6H_5)_2(cr) + (29/2)O_2(g) \\ &\quad = Hg(l) + 12CO_2(g) + 5H_2O(l)\end{aligned} \quad (8)$$

and derived $\Delta_f H^\circ_m$ {$Hg(C_6H_5)_2$}. Corrections were applied to the experimental results to allow for the formation of small amounts of byproduct HgO and $HgNO_3$, both of which were determined analytically.

Notice that values of $\Delta_f H^\circ_m$ are required for the products shown in Equation 3 and Equation 8. Because the value of $\Delta_f H^\circ_m$ varies as a function of temperature and pressure, it must always, for compounds interconnected by a set of reactions, refer to the same standard pressure and reference temperature.

PRINCIPLES OF THE METHOD

Thermodynamic Basis of Combustion Calorimetric Measurements

Investigations of combustion calorimetric processes are based on the first law of thermodynamics

$$U_f - U_i = \Delta U = Q - W \quad (9)$$

where U_i and U_f are the internal energies of a system in the initial and final states, respectively; Q is the quantity of heat absorbed between the initial and final states; and W is the work performed by the system. Frequently, the only work performed by a system is against the external pressure; thus

$$U_f - U_i = Q - \int_{V_i}^{V_f} p \cdot dV \quad (10)$$

where V_i and V_f are, respectively, the initial and final volumes of the system. In the case of a process at constant volume, $W = 0$, and $Q = Q_V$, from which

$$Q_V = U_f - U_i = \Delta U \quad (11)$$

Therefore, the quantity of heat absorbed by the system or released to the surroundings at constant volume is equal to the change in the internal energy of the system. Measurements of energies of combustion in a sealed calorimetric bomb are of the constant-volume type.

If a process occurs at constant pressure, Equation 10 can be rewritten as

$$U_f - U_i = Q_p - p \cdot (V_f - V_i) \tag{12}$$

whence

$$Q_p = (U_f + p \cdot V_f) - (U_i + p \cdot V_i) \tag{13}$$

where p denotes the external pressure. By substituting $H = U + p \cdot V$, one obtains

$$Q_p = H_f - H_i = \Delta H \tag{14}$$

where H denotes enthalpy. Reactions at constant pressure are most frequently studied in apparatus that is open to the atmosphere.

The relation between Q_p and Q_V is as follows

$$Q_p = Q_V + p \cdot (V_f - V_i) = Q_V + \Delta\nu^g \cdot R \cdot T \tag{15}$$

where $\Delta\nu^g$ is the change in stoichiometric numbers of gaseous substances involved in a reaction, R is the gas constant, and T is the thermodynamic temperature.

Equation 15 permits the experimental energy change determined in combustion calorimetric experiments (constant volume) for a given reaction to be adjusted to the enthalpy change (constant pressure). For example, $\Delta v^g = 1 - 2 - 1 = -2$ for the combustion of gaseous methane

$$CH_4(g) + 2O_2(g) = CO_2(g) + 2H_2O(l) \tag{16}$$

PRACTICAL ASPECTS OF THE METHOD

The Combustion Calorimeter

The combustion calorimeter is the instrument employed to measure the energy of combustion of substances in a gas (e.g., Sunner, 1979). A common theme running through the literature of combustion calorimetry is the use of apparatus designed and constructed by individual investigators for problem-specific applications. To the best of our knowledge, only two calorimetric systems are commercially available at this time, and we shall give details of those later.

In general, combustion calorimetry is carried out in a closed container (reaction vessel, usually called the bomb) charged with oxidizing gas to a pressure great enough ($\sim$3 MPa of O_2, for example) to propel a reaction to completion. The bomb rests in a vessel filled with stirred water which, in turn, is surrounded by a 1-cm air gap (to minimize convection) and a constant-temperature environment, usually a stirred-water thermostat. Occasionally, a massive copper block in thermostatically controlled air (aneroid calorimeter) is used for this purpose (Carson, 1979). Most thermostats used in combustion calorimetry are maintained at, or close to, a temperature of 298.15 K. The combination of bomb and water-filled vessel is usually referred to as the calorimetric system, but this really includes auxiliary equipment such as a thermometer, stirrer, and heater.

Apparatuses that have constant-temperature surroundings are most common, and are called isoperibol calorimeters. Rarer is the adiabatic combustion calorimeter (Kirklin and Domalski, 1983); its jacket temperature is designed to track closely that of the calorimeter so that the heat exchanged with the surroundings is negligible. For the purposes of the present discussion, we shall deal only with the isoperibol calorimeter, although what we say here, with the exception of the corrected temperature change, applies to both types.

A typical combustion bomb is illustrated in Figure 1. The bomb body (A) is usually constructed of stainless steel with a thickness sufficient to withstand not only the initial pressure of the combustion gas, but also the instantaneous surge in pressure that follows the ignition of a sample.

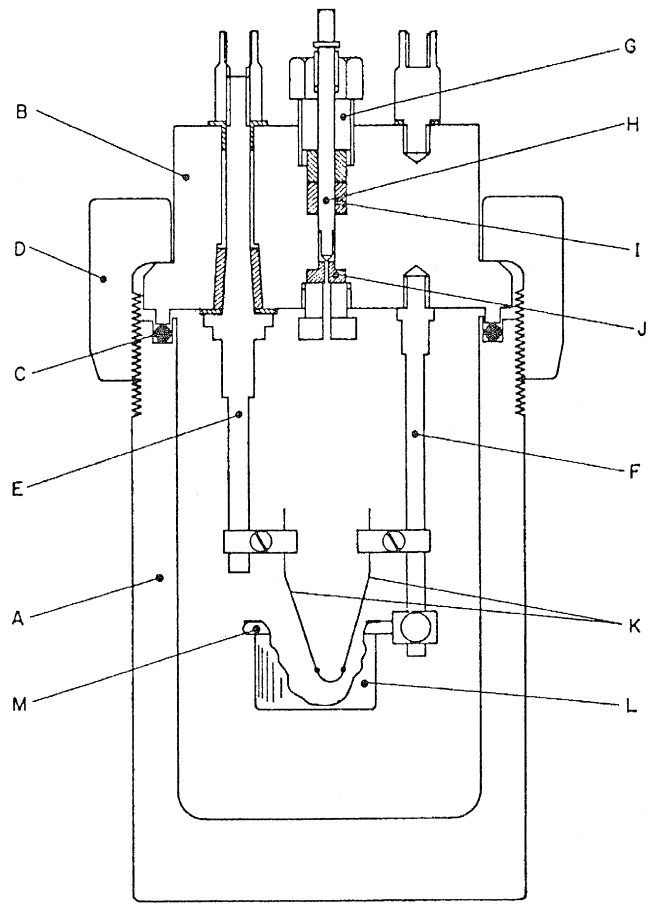

Figure 1. Cross-section of typical calorimetric bomb for combustions in oxygen. A, bomb body; B, bomb head; C, sealing O-ring; D, sealing cap; E, insulated electrode for ignition; F, grounded electrode; G, outlet valve; H, needle valve; I, packing gland; J, valve seat; K, ignition wire; L, crucible; M, support ring for crucible.

Copper has also been used as a bomb material; it has a thermal conductivity superior to that of stainless steel, but is mechanically weaker and chemically more vulnerable. In Figure 1, B is called the bomb head or lid. It is furnished with a valve (G) for admitting oxygen gas before an experiment and for discharging excess O_2 and gaseous products of combustion through the needle valve (H) after an experiment. This valve is surrounded with a packing gland (I) and is also fitted with a valve seat (J) against which it seals. The bomb head (B) also acts as a platform to support components of an electrical ignition circuit, namely, an electrically insulated electrode (E) and a grounded electrode (F). These electrodes are connected by means of a thin wire (K) that is usually made of platinum, although other wires may be used, depending on the specific application. A ring (M) attached to the grounded electrode supports a platinum crucible (L) in which the combustion sample rests (in one example mentioned above, this would be a compressed pellet of benzoic acid). The entire lid assembly is inserted in the bomb body and tightened in position by means of the sealing cap (D), which brings force to bear against the rubber O-ring (C). Thus, a properly functioning bomb can be charged with O_2 to the desired pressure while the contents are hermetically sealed.

Figure 2 gives a simplified view of the most common combustion calorimeter, that with a constant temperature environment (isoperibol). A combustion bomb (A) is supported in the water-filled calorimeter vessel (E) which, in turn, is surrounded by the air gap and thermostat (C), whose inner surface (D) can also be discerned. Note that the lid of the thermostat (F) is connected to the main thermostat; thus, water circulating at a uniform temperature surrounds the calorimetric system at all times. The thermometer used to measure the temperature of the calorimeter is inserted at G, and a stirrer is connected at J (to ensure that the energy released during the combustion is

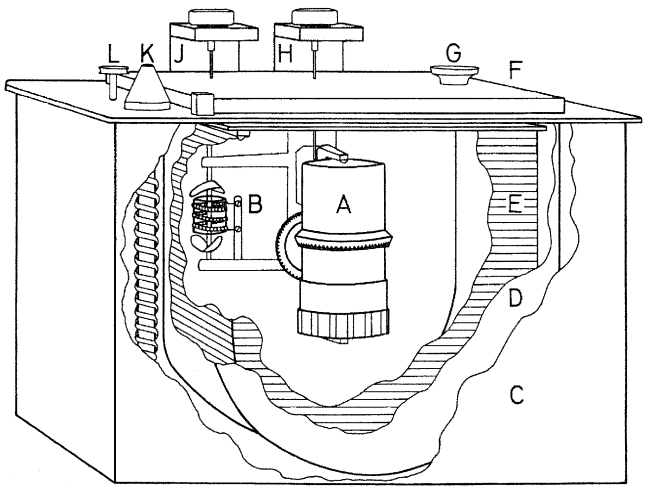

Figure 2. Cross-section of assembled isoperibol calorimeter. A, combustion bomb; B, calorimeter heater for adjusting starting temperature; C, outer surface of thermostat; D, inner surface of thermostat; E, calorimeter can; F, lid of thermostat; G, receptacle for thermometer; H, motor for rotation of bomb; J, calorimeter stirrer motor; K, thermostat heater control; L, thermostat stirrer.

expeditiously transferred to the calorimeter so that the combustion bomb, the water, and the vessel are quickly brought to the same temperature). A heater (B) is used to adjust the temperature of the calorimeter to the desired starting point of the experiment. A synchronous motor (H) can be used to rotate the bomb for special applications that are outside the scope of the present discussion. A pump (L) circulates water (thermostatted by unit K) through the jacket and lid. While the combustion experiment is in progress, the temperature of the calorimeter water is recorded as a function of time, and that of the thermostat is monitored.

The thermometer is an essential part of all calorimeters (see THERMOMETRY). In the early days of combustion calorimetry, mercury-in-glass thermometers of state-of-the-art accuracy were used. These were superceded by platinum resistance thermometers which, essentially, formed one arm of a Wheatstone (Mueller) bridge, and the change in resistance of the thermometer was determined with the help of the bridge and a galvanometer assembly. Electrical resistances of such thermometers were certified as an accurate function of temperature by national standards laboratories. Thus, a particular value of the resistance of the thermometer corresponded to a certified temperature. Thermistors have also been used as temperature sensors and, more recently, quartz-crystal thermometers. The latter instruments read individual temperatures with an accuracy of at least $\pm 1 \times 10^{-4}$ K, and give temperature differences (the quantities sought in combustion calorimetric studies) accurate to $2-3 \times 10^{-5}$ K. They display an instantaneous temperature reading that is based on the vibrational frequency of the quartz crystal. Nowadays, quartz-crystal thermometers are interfaced with computers that make it possible to record and process temperatures automatically and are, therefore, much less labor-intensive to use than their Wheatstone bridge and galvanometer predecessors.

Most ignition systems for combustion calorimetry are designed to release a pulse of electrical energy through a wire fuse from a capacitor of known capacitance charged to a preset voltage. Thus, the ignition energy introduced into the calorimeter, which usually amounts to $\sim$1 J, can be accurately calculated or preprogrammed. Overall energies of reaction must be corrected for the introduction of this "extra" energy.

As we have mentioned previously, a stirrer helps to disperse the energy released during the combustion throughout the calorimetric system. Its design is usually a compromise between efficiency and size: if the stirrer is too small, it does not dissipate the energy of reaction efficiently; if it is too bulky, an undesirable quantity of mechanical heat is introduced into the experiment. Usually, stirrer blades have a propeller design with a major axis of $\sim$1 to 2 cm in length. They are attached via a shaft to a synchronous motor to ensure that the stirring energy is constant, and also by means of a nylon (or other thermal insulator) connector to minimize the transfer of heat by this route from the calorimeter to the surroundings.

Most conventional combustion calorimeters are equipped with a heater, the purpose of which is to save time by quickly raising the temperature of the calorimeter to a value that is close to the planned starting point of the

experiment. Such heaters, typically, have resistances of $\sim 150\ \Omega$.

Outline of a Typical Combustion Calorimetric Experiment. In brief, a combustion is begun by discharging an accurately known quantity of electrical energy through a platinum wire bent in such a way (see Fig. 1) that it is close to the combustion crucible when the bomb is assembled. Usually, a short cotton thread is knotted to the wire and the free end is run beneath the material to be burned. This sparks ignition of the sample in the high-pressure O_2, and initiates a combustion reaction such as that depicted in Equation 3. Complete combustion of the sample often requires some preliminary experimentation and ingenuity. Although many organic compounds oxidize completely at $p(O_2) = 3$ MPa, some require higher, others occasionally lower, pressures, to do so. Cleaner combustions can sometimes be realized by changing, on a trial and error basis, the mass of the crucible. Some investigators have promoted complete combustion by adding an auxiliary substance to the crucible. For example, a pellet of benzoic acid placed beneath a pellet of the substance under study has often promoted complete combustion of a material that was otherwise difficult to burn. Paraffin oil has also been used for this purpose. Needless to say, allowance must be made for the contribution to the overall energy of reaction of the chosen auxiliary material.

Role of Analytical Chemistry in Combustion Calorimetry

There are, usually, two main underlying reasons for performing combustion calorimetry. One may wish to determine the energy of combustion of a not necessarily pure substance as an end in itself. An example is the measurement of the "calorific value" of a food or coal, where one simply requires a value (J/g) for the energy released when 1 g of a particular sample is burned in O_2 at a specified pressure. Here, the sample is not a pure compound and may not be homogeneous. It is usually necessary to dry a coal sample, but few, if any, analytical procedures are prerequisite.

On the other hand, the ultimate research objective may be the establishment of the enthalpy of formation of a compound, a fundamental property of the pure substance, as we have pointed out. In that case, a number of crucial operations must be an integral part of an accurate determination of the energy of combustion, and it is recommended that most of these procedures, for reasons that will become apparent, be performed even before calorimetric experiments are begun. The underlying philosophy here is governed by the first law of thermodynamics. The first law, in brief, demands exact characterization of the initial states of the reactants and final states of the products, in that they must be defined as precisely as possible in terms of identity and composition. An unavoidable consequence of these criteria is the need for extensive analytical characterization of reagents and products, which, in the experience of this writer, may require more time and effort than the calorimetric measurements themselves. Consequently, combustion processes must be as "clean" as possible, and incomplete reactions should be avoided to eliminate the time and expense required to define them. For example, in combustion calorimetric studies of a compound of iron, it is clearly preferable to produce Fe(III) only, rather than a mixture of Fe(III) and Fe(II). In dealing with organic compounds, the formation of CO_2 only, to the exclusion of CO, is a constant objective of combustion calorimetrists. Such desiderata may require preliminary research on suitable arrangements of the sample, experiments on the effects of varying the pressure of O_2, or the addition of an auxiliary kindler, as mentioned previously.

Although it may seem trivial, it is essential that the experimental substance be identified. For example, the x-ray diffraction pattern of an inorganic compound should be determined. For the same reason, melting temperatures and refractive indices of organic compounds, together with the C, H, and O contents, are used as identifiers.

Impurities above minor concentrations (mass fractions of the order of 10^{-5}) can exercise a consequential effect on the energy of combustion of a material. This is a particularly serious matter when the difference between the massic energies of combustion (J/g) of the main and impurity phases is large. In the case of organic compounds, water is a common impurity; it acts as an inert contaminant during combustions in O_2. Thus, if H_2O is present at a mass fraction level of 0.05, then, in the absence of other impurities, the experimental energy of combustion will be lower (less exothermic) than the correct value by 5 percent. For most applications, this would introduce a disastrous error in the derived enthalpy of formation.

Isomers can be another form of impurity in organic materials. Fortunately, the energy difference between the substance under investigation and its isomer may be small. In that case, a relatively large concentration of the latter may introduce little difference between the experimental and correct energies of combustion. When isomeric contamination is possible, it is essential that organic materials be examined, by methods such as gas chromatography or mass spectrometry, prior to the commencement of calorimetric measurements.

In summary then, it is vital that substances to be studied by combustion calorimetry in oxygen be analyzed as thoroughly as possible. Inorganics should be assayed for principal elements (especially when the phase diagram raises the possibility of nonstoichiometry), and traces of metals and of C, H, O, and N. In the case of organics, impurities such as H_2O and structural isomers should be sought, and elemental analyses (for C, H, O, N, etc.) should be performed as a matter of course. Fractional freezing measurements may also be used to determine contaminant levels. A further check on the purity, but not the presence, of isomers is obtained by carefully weighing the gaseous products of reaction, usually CO_2 and H_2O. This is not a trivial procedure, but has been described in detail (Rossini, 1956).

Because oxygen takes part in the combustion, its purity, too, is of importance. Gas with mole fraction $x(O_2)$=0.9999 is acceptable and can be purchased commercially. Exclusion of traces of organic gases and CO is crucial here; their participation in the combustion process introduces a source of extraneous energy that usually cannot be quantified. Efforts are also made routinely to eliminate or minimize N_2(g) because it forms HNO_3 and HNO_2 in

the combustion vessel. These acids can be assayed accurately, and are routinely sought and corrected for in carefully conducted combustion calorimetric experiments.

We have dwelt at some length on the efforts that must be made analytically to characterize calorimetric samples. From this facet of a study, one or more of the following conclusions may generally be drawn: (1) the sample can be regarded with impunity as pure; (2) trace impurities are present at such a level that they play a significant thermal role in the combustion and must be corrected for; and/or (3) major element analyses show the sample to be nonstoichiometric, or stoichiometric within the uncertainties of the analyses. By fractional freezing, recrystallization, distillation, or other methods of purification, organic substances can be freed of contaminants to the extent that none are detected by techniques such as infrared spectroscopy and gas chromatography. In such cases, the measured energy of combustion is attributed to the pure compound. It is uncommon, apart from the pure elements and specially synthesized substances such as semiconductors or glasses, to encounter inorganic materials devoid of significant levels of contamination. In applying thermochemical corrections here, a certain element of guesswork is often unavoidable. In titanium carbide (TiC), for instance, trace nitrogen is likely to be combined as TiN. But how would trace silicon be combined? As SiC or $TiSi_x$? As in this case, there are frequently no guidelines to help one make such a decision. Small amounts of an extraneous phase can be difficult to identify unequivocally. The predicament here is compounded if the massic energies of combustion of the putative phases differ significantly. In such cases, one may have no alternative but to calculate the correction for each assumed form of the contaminant, take a mean value, and adopt an uncertainty that blankets all the possibilities. Recall that an impurity correction is based not only on the amount of contaminant but on the difference between its massic energy of combustion and that of the major phase.

When major element analyses suggest that a substance is nonstoichiometric, one must be sure that this finding is consistent with phase diagram information from the literature. A stoichiometric excess of one element over the other in a binary substance could mean, for example, that a separate phase of one element is present in conjunction with the stoichiometric compound. At levels of ~0.1 mass percent, x-ray analyses (see X-RAY TECHNIQUES) may not reveal that separate phase. Microscopic analyses (OPTICAL MICROSCOPY and REFLECTED-LIGHT OPTICAL MICROSCOPY) can be helpful in such cases.

Products of combustion must be examined just as thoroughly as the substance to be oxidized. When they are gaseous, analyses by Fourier transform infrared (FTIR) spectroscopy may be adequate. If a unique solid is formed, it must be identified—by x-ray diffraction (X-RAY POWDER DIFFRACTION) and, preferably, by elemental analyses. A complete elemental analysis, preceded by x-ray diffraction examination, must be performed where two or more distinct solids are produced; thus, their identities and relative concentrations are determined.

It is wise to carry out and interpret the analytical characterization, as much as possible, before accurate determinations of the energy of combustion are begun. It would clearly be unfortunate to discover, after several weeks of calorimetric effort, that the substance being studied did not correspond to the label on the container, or that sufficient contamination was present in the sample to make the measurements worthless.

Details of Calorimetric Measurements

In practice, once the analytical characterization has been completed, a satisfactory sample arrangement devised, and the bomb assembled and charged with O_2, the remaining work essentially involves measurements, as a function of time, of the temperature change of the calorimetric system caused by the combustion. As we have already mentioned, the temperature-measuring devices of modern calorimeters are interfaced with computers, by means of which the temperature is recorded and stored automatically at preset time intervals. When a quartz-crystal thermometer is used, that time interval is, typically, ~10 sec or 100 sec.

The change in energy to be measured in an experiment, and thus the temperature change, depends on the mass and massic energy of combustion of the sample. Thus, the combustion in O_2 of 1 g of benzoic acid, whose massic energy of combustion is -26.434 kJ/g, will result in an energy release of -26.434 kJ. What will be the corresponding approximate temperature rise of the calorimeter? That depends on a quantity known as the energy equivalent of the calorimetric system, ε(calor), and we shall shortly describe its determination. Simply put, this is the quantity of energy required to increase the temperature of the calorimeter by 1 K. Thus, the combustion of 1 g of benzoic acid will increase the temperature of a conventional macro calorimeter with $\varepsilon(\text{calor}) = 13200$ J/K by ~2 K. It is worth noting that, because many of the most interesting organic materials are available in only milligram quantities, some investigators (Månsson, 1979; Mackle and O'Hare, 1963; Mueller and Schuller, 1971; Parker et al., 1975; Nagano, 2000) constructed miniature combustion calorimeters with $\varepsilon(\text{calor}) \leq 1$ kJ/K.

In principle, it is desirable to aim for an experimental temperature change of at least 1 K. However, that may be impossible in a macro system because of, e.g., the paucity of sample, and one may have to settle for a temperature change of 0.5 K or even 0.1 K. Needless to say, the smaller this quantity, the greater the scatter of the results. In short, then, the energy change of the experiment will be given by the product of the energy equivalent of the calorimetric system and the temperature change of the calorimeter. At this point, we shall discuss the determination of the latter quantity.

Figure 3 shows a typical plot of temperature against time for a combustion experiment, and three distinct regions of temperature are apparent. Those are usually called the fore period, the main period, and the after period. Observations begin at time t_i; here the calorimeter temperature (say, at $T = 297$ K) drifts slowly and uniformly upward because the temperature of the surroundings is higher ($T = 298.15$ K). When a steady drift rate has been established (fore period) and recorded, the sample is

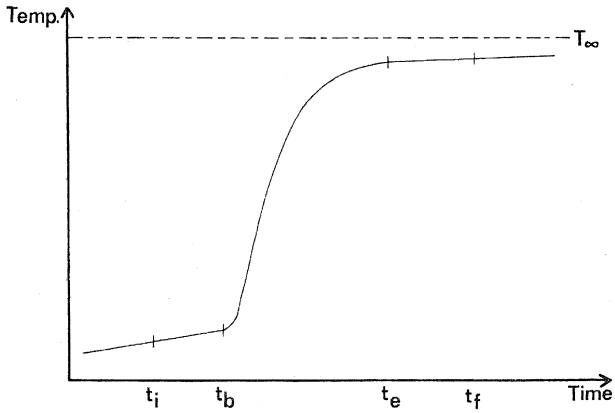

Figure 3. Typical temperature versus time curve for calorimetric experiment. t_i, initial temperature of fore-period; t_b, final temperature of fore-period; t_e, initial temperature of after period; t_f, final temperature of after period.

ignited at time t_b, whereupon the temperature rises rapidly (main period) until, at time t_e (for a representative macro combustion calorimeter, $t_e - t_b \sim 10$ min), the drift rate is once again uniform. The temperature of the calorimeter is then recorded over an after period of ~10 min, and, at t_f, the measurements are terminated. At the end of an experiment (typical duration ~0.5 hr), one has recorded the temperature at intervals of, say, 10 sec, from t_i to t_f, from which the temperature rise of the calorimeter is calculated. To be more exact, the objective is to calculate the correction that must be applied to the observed temperature rise to account for the extraneous energy supplied by stirring and the heat exchanged between the calorimeter and its environment (recall that a stirrer is used to bring the temperature of the calorimeter to a uniform state, and that there are connections between the calorimeter and the surroundings, by way of the stirrer, thermometer, ignition, and heater leads, all of which afford paths for heat leaks to the environment).

It is not within the scope of this unit to give particulars of the calculation of the correction to the temperature change. That procedure is described in detail by several authors including Hubbard et al. (1956) and Sunner (1979). Modern calorimeters, as we have mentioned, are programmed to carry out this calculation, once the time versus temperature data have been acquired.

Suffice it to say that the correction, which is based on Newton's law of cooling, can be as much as 1 percent of the observed temperature rise in isoperibol calorimeters, and therefore cannot be ignored. By contrast, adiabatic calorimeters are designed in such a way that the correction to the temperature rise is negligible (Kirklin and Domalski, 1983). Why, then, are not all combustion calorimeters of the adiabatic kind? The simple answer is that the isoperibol model is easier than the adiabatic to construct and operate.

Calibration of the Calorimetric System

Earlier in the discussion, we quickly passed over details of the determination of ε(calor), the energy equivalent of the calorimeter, defined as the amount of energy required to increase the temperature of the calorimeter by 1 K. It can also be thought of as the quantity by which the corrected temperature rise is multiplied to obtain the total energy measured during the combustion. In practice, to obtain ε(calor), one must supply a precisely known quantity of energy to the calorimeter, and, as part of the same experiment, determine the accompanying corrected temperature rise as outlined above.

The most precise determination of ε(calor) is based on the transfer to the calorimeter of an accurately measured quantity of electrical energy through a heater placed, preferably, at the same location as the combustion crucible. If the potential drop across the heater is denoted by E, the current by i, and the length of time during which the current flows by t, then the total electrical energy is given by Eit, and $\varepsilon(\text{calor}) = Eit/\Delta\theta_c$, where $\Delta\theta_c$ denotes the corrected temperature rise of the calorimeter caused by the electrical heating.

Because most laboratories that operate isoperibol calorimeters are not equipped for electrical calibration, a protocol has been adopted which, in essence, transfers this procedure from standardizing to user laboratories. Thus, standard reference material benzoic acid, whose certified energy of combustion in O_2 has been measured in an electrically calibrated calorimeter, can be purchased, e.g., from the National Institute of Standards and Technology (NIST) in the U.S.A. The certified value of the massic energy of combustion in pure O_2 of the current reference material benzoic acid (NIST Standard Reference Material SRM 39j) is -26434 J/g, when the combustion is performed within certain prescribed parameters (of pressure of O_2, for example). An accompanying certificate lists minor corrections that must be applied to the certified value when the experimental conditions deviate from those under which the energy of combustion was determined at the standardizing laboratory. It is desirable that the combustion gases be free from CO, and that soot and other byproducts not be formed. While it is possible to correct for the formation of soot and CO, for example, it is always preferable that combustions yield only those chemical entities, CO_2 and H_2O, obtained during the certification process. Thus, by simultaneous measurement of $\Delta\theta_c$, one determines ε(calor). Usually, a series of seven or eight calibration experiments is performed, and the mean value of the energy equivalent of the calorimetric system, $\langle\Delta\varepsilon(\text{calor})\rangle$, and its standard deviation, are calculated. In carefully performed calibrations with calorimeters of the highest accuracy, ε(calor) can be determined with a precision of ~0.006 percent.

It is recommended practice to examine, from time to time, the performance of combustion calorimeters. Check materials are used for that purpose; they are not standard reference materials but, rather, substances for which consistent values of the massic energies of combustion have been reported from a number of reputable laboratories. Examples include succinic acid, nicotinic acid, naphthalene, and anthracene.

Standard State Corrections in Combustion Calorimetry

So far, we have discussed the analytical characterization of the reactants and products of the combustion and the

determination of the corrected temperature rise. At this point, when, so to speak, the chemical and calorimetric parts of the experiment have been completed, we recall that we are in pursuit of the change of energy associated with the combustion of a substance in O_2, where all reactants and products are in their standard reference states at a particular temperature, usually 298.15 K. Therefore, it is essential to compute the energy difference between the state in the bomb of each species involved in the reaction and its standard reference state. If, for example, one studies the combustion of a hydrocarbon at a pressure of 3 MPa of O_2 at $T = 297.0$ K, a correction must be made that takes into account the energy change for the (hypothetical) compression of the solid or liquid from the initial $p = 3$ MPa to $p = 0.1$ MPa, the reference pressure, and to $T = 298.15$ K. Similarly, the energy change must be calculated for the expansion of product CO_2(g) from a final pressure of ~3 MPa and $T = 298.10$ K, to $p = 0$ and $T = 298.15$ K. Among other things, allowance must be made for the separation of CO_2 from the solution it forms by reaction with product H_2O and adjustment of its pressure to $p = 0.1$ MPa and temperature to $T = 298.15$ K. There are numerous such corrections. Their sum is called the standard state correction. It is beyond the scope of the present treatment to itemize them, and detail how they are calculated. This topic has been dealt with extensively by Hubbard et al. (1956) and by Månsson and Hubbard (1979).

Normally, six to eight measurements are performed. The mean value and standard deviation of the massic energy of combustion are calculated. In thermochemical work, uncertainties are conventionally expressed as twice the standard deviation of the mean (see MASS AND DENSITY MEASUREMENTS).

Combustion Calorimetry in Gases Other Than Oxygen

Several times in this unit we referred to the desirability of obtaining so-called "clean" combustions. The impression may have been given that it is always possible, by hook or by crook, to design combustion experiments in oxygen that leave no residue and form reaction products that are well defined. Unfortunately, that is not so. For example, combustions of inorganic sulfur–containing metal sulfides generally yield mixtures of oxides of the metal and of sulfur. A good example is the reaction of MoS_2 which forms a mixture of MoO_2(cr), MoO_3(cr), SO_2(g), SO_3(g) and, possibly, an ill-defined ternary (Mo, S, O). Recall that reliable calorimetric measurements require not only that the products of reaction be identified, but that they be quantified as well. Thus, a determination of the standard energy of combustion of MoS_2 in oxygen would require extensive, and expensive, analytical work. One could give additional similar examples of "refractory" behavior, such as the combustion of UN to a mixture of uranium oxides, nitrogen oxides, and N_2(g).

In such instances, O_2(g) is clearly not a powerful enough oxidant to drive the reaction to completion: MoS_2 to MoO_3 and $2SO_3$, and UN to $(1/3)U_3O_8$ and $(1/2)N_2$(g). Because of the expanding interest in the thermochemistry of inorganic materials, scientists, of necessity, began to explore more potent gaseous oxidants, among them the halogens: F_2, Cl_2, Br_2, and interhalogens such as BrF_3 and ClF_3.

Of the oxidants just listed, F_2 has been used most frequently, and it will be discussed briefly here. Its clear advantage over O_2 is illustrated by the reaction with MoS_2

$$MoS_2(cr) + 9F_2(g) \rightarrow MoF_6(g) + 2SF_6(g) \qquad (17)$$

Here, simple, well-characterized products are formed, unlike the complicated yield when O_2 is used. Comparatively little analytical characterization is required, apart from identification of the hexafluorides by infrared spectroscopy. Unfortunately, the very reactivity that makes F_2 so effective as a calorimetric reagent imposes special requirements (apart from those that arise from its toxicity), particularly with regard to materials of construction, when it is used in thermochemical studies. Combustion vessels must be constructed of nickel or Monel, and seals that are normally made of rubber or neoprene, suitable for work with oxygen, must be fashioned from Teflon, gold, lead, or other fluorine-resistant substances. Other precautions, too numerous to detail here, are listed in a recent book that deals with fluorine bomb calorimetry (Leonidov and O'Hare, 2000).

DATA ANALYSIS AND INITIAL INTERPRETATION

Computation of Enthalpies of Formation From Energies of Combustion

As we pointed out in the introduction to this article, massic energies of combustion are generally determined in order to deduce the standard molar enthalpy of formation. In this section, we will show how the calculations are performed that lead to $\Delta_f H^\circ_m$ for an organic and inorganic substance.

Ribeiro da Silva et al. (2000) reported the standard massic energy of combustion in oxygen $\Delta_c u^\circ$ of D-valine ($C_5H_{11}NO_2$) according to the following reaction

$$C_5H_{11}NO_2(cr) + (27/4)O_2(g) = 5CO_2(g) + (11/2)H_2O(l) + (1/2)N_2(g) \qquad (18)$$

$\Delta_c u^\circ = -(24956.9 \pm 10.2)\,J \cdot g^{-1}$. The molar mass of valine, based on the atomic weights from IUPAC (1996), is 117.15 $g \cdot mol^{-1}$; therefore, the standard molar energy of combustion $\Delta_c U^\circ_m$ is given by: $(0.11715) \cdot (-24956.9 \pm 10.2)\,kJ \cdot mol^{-1} = -(2923.7 \pm 1.2)\,kJ \cdot mol^{-1}$. For the combustion reaction of valine, $\Delta\nu^g \cdot R \cdot T = -3.1\ kJ \cdot mol^{-1}$ (on the basis of Equation 18), where $R = 8.31451\,J \cdot K^{-1} \cdot mol^{-1}$ and T = 298.15 K. Thus, $\Delta_c H^\circ_m = \{-(2923.7 \pm 1.2) - 3.1\}\,kJ \cdot mol^{-1} = -(2926.8 \pm 1.2)\,kJ \cdot mol^{-1}$ which, combined with the standard molar enthalpies of formation of $(11/2)H_2O$(l) and $5CO_2$(g) (CODATA, 1989), yields

$$\begin{aligned}\Delta_f H^\circ_m(C_5H_{11}NO_2, cr, 298.15\,K)/(kJ \cdot mol^{-1}) &= (11/2) \cdot (-285.83 \pm 0.04) + 5 \cdot (-393.51 \pm 0.13) \\ &\quad + (2926.8 \pm 1.2) \\ &= -(612.8 \pm 1.4)\,kJ \cdot mol^{-1}\end{aligned} \qquad (19)$$

Johnson et al. (1970) determined calorimetrically the massic energy of combustion in oxygen of a specimen of $PuC_{0.878}$, according to the following equation

$$PuC_{0.878}(cr) + 1.878O_2(g) = PuO_2(cr) + 0.878CO_2(g) \quad (20)$$

and reported $\Delta_c u^\circ = -(5412.0 \pm 10.5)\ J \cdot g^{-1}$. On the basis of the molar mass of the carbide, $M = 249.66\ g \cdot mol^{-1}$, the molar energy of combustion $\Delta_c U_m^\circ$ is calculated to be $-(1351.2 \pm 2.6)\ kJ \cdot mol^{-1}$. From Equation 20, $\Delta\nu^g \cdot R \cdot T = -2.5\ kJ \cdot mol^{-1}$ and, thence, $\Delta_c H_m^\circ = -(1353.7 \pm 2.6)\ kJ \cdot mol^{-1}$. We take $\Delta_f H_m^\circ\ (PuO_2) = -(1055.8 \pm 0.7)\ kJ \cdot mol^{-1}$ and $\Delta_f H_m^\circ(CO_2, g) = -(393.51 \pm 0.13)\ kJ \cdot mol^{-1}$ (CODATA, 1989), and calculate $\Delta_f H_m^\circ(PuC_{0.878}, Cr) = -(47.6 \pm 2.7)\ kJ \cdot mol^{-1}$.

In these examples, the original studies gave uncertainties of the $\Delta_c u^o$ results. These were, in turn, combined in quadrature by the authors with uncertainties associated with the values of $\Delta_f H_m^\circ$.

SAMPLE PREPARATION

The preparation of a sample for combustion calorimetry is governed by the desideratum that all the sample, or as much as possible of it, be reacted to completion in a well-defined combustion process.

The choice of physical form of the specimen is fairly limited: a massive piece of material (for example, a compressed pellet of an organic substance, or part of a button of an inorganic compound prepared by arc melting) should be used in initial experiments, and, if it fails to react completely, combustions of the powdered form at progressively finer consistencies should be explored. The experience of numerous combustion calorimetrists suggests, however, that organics almost always react more completely in pellet form. It is believed that most such reactions occur in the gas phase, after some material is initially vaporized from the hot zone. This behavior is also true of some inorganic substances, but others melt, however, and react in the liquid phase, in which case chemical interaction with the sample support is a distinct possibility. Even after prolonged exploration of the effect of subdivision of the material, acceptable combustions sometimes cannot be designed, at which point, as we have mentioned earlier, other variables such as sample support, auxiliary combustion aid, and gas pressure are investigated.

What the experimentalist is attempting here is to concentrate, as sharply as possible, the hot zone at the core of the combustion. That the local temperatures in a combustion zone can be substantial is demonstrated by the discovery of small spheres of tungsten, formed from the molten metal, that remained in calorimetric bombs after combustions of tungsten in fluorine to form tungsten hexafluoride (Leonidov and O'Hare, 2000).

In any case, it is important to avoid contamination during the comminution of pure materials to be used in calorimetry. Operations such as grinding should be performed with clean tools in an inert atmosphere. Needless to say, if exploratory experiments indicate the use of powder, it is that material, and not the bulk sample, that should be subjected to the exhaustive analytical characterization detailed elsewhere in this article.

PROBLEMS

The most common problems in combustion calorimetry have to do with: (1) characterization of the sample and reaction products; (2) attainment of complete combustion of the sample; (3) accurate measurement of the temperature change in an experiment; and (4) the proper functioning of the calorimeter.

It is clear from our earlier discussions that characterization of the sample and combustion products and, therefore, the problems related to it, lie entirely in the realm of analytical chemistry. Each calorimetric investigation has its own particular analytical demands, but those lie outside the scope of the present unit and will not be considered here.

The major practical problem with any combustion calorimetric study is the attainment of a complete, well-defined reaction. When burnt in oxygen, organic substances containing C, H, and O ideally form H_2O and CO_2 only. However, side-products such as carbon and CO may also be present, and their appearance indicates that the combustion did not reach an adequately high local temperature. One solution to this problem is to raise the combustion pressure, say from the typical 3 MPa to 3.5 MPa or even 4 MPa. Other solutions include lessening the mass of the combustion crucible, reducing the mass of sample, or adding an auxiliary combustion aid. The latter is usually a readily combustible material with large massic energy of combustion (numerous authors have used benzoic acid or plastic substances such as polyethylene capsules). Problems encountered with inorganic substances can also be addressed by raising or in some cases lowering the combustion gas pressure. A lower combustion pressure can moderate the reaction and prevent the melting and consequent splattering of the specimen. Complete combustions of refractory inorganic substances have been achieved by placing them on secondary supports which are themselves consumed in the reaction. In fluorine-combustion calorimetry, for example, tungsten metal serves this purpose very well, as it boosts the combustion of the sample while itself being converted to the gaseous WF_6.

It is clear that, even with well-characterized samples and products and "clean" combustions, a calorimetric experiment will not be reliable if the temperature-measuring device is not performing accurately. Thus, thermometers to be used for combustion calorimetry should be calibrated by standardizing laboratories, or, alternatively, against a thermometer that itself has been calibrated in this way, as are, for example, many quartz-crystal thermometers used in present-day studies (see THERMOMETRY). As we pointed out in the earlier part of this unit, temperature differences, not absolute temperature values, are the values obtained in calorimetric work.

Finally, we address problems related to the proper functioning of the calorimeter itself. Examples of such

problems might include the following: (1) the thermostatted bath that surrounds the calorimeter is not maintaining a constant temperature over the course of an experiment; (2) the stirrer of the calorimetric fluid is functioning erratically, so that the stirring energy is not constant (as is assumed in the calculations of the corrected temperature change of the calorimeter); or (3) the oxidizing gas is leaking through the reaction vessel gasket. All such problems can be pinpointed (as an example, by monitoring the temperature of the calorimetric jacket with a second thermometer). However, other systematic errors may not be so easily diagnosed.

Investigators traditionally check the proper functioning of a combustion calorimeter by using it to measure the energy of combustion of a "secondary reference" material. For combustions in oxygen, succinic acid is recommended. Its energy of combustion has been accurately determined with excellent agreement in numerous studies since the advent of modern calorimetry, and is thus well known. If, in check experiments, disagreement with this value (beyond the uncertainty) arises, it should be taken as an indication that a systematic error or errors are present.

THERMAL DIFFUSIVITY BY THE LASER FLASH TECHNIQUE

INTRODUCTION

Thermal diffusivity is a material transport property characterizing thermal phenomena significant in many engineering applications and fundamental materials studies. It is also directly related to thermal conductivity, another very important thermophysical property. The relationship between thermal diffusivity α and thermal conductivity λ is given by $\alpha = \lambda/C_p\rho$, where ρ and C_p are (respectively) density and specific heat at constant pressure of the same material. Contrary to the thermal conductivity, whose measurements involve measuring heat fluxes that are difficult to control and measure accurately, particularly at elevated temperatures, measuring thermal diffusivity basically involves the accurate recording of the temperature caused by a transient or periodic thermal disturbance at the sample boundary. It is thus frequently easier to measure thermal diffusivity than thermal conductivity. The two other properties involved in the relationship, density and specific heat, are thermodynamic properties and are either known or can be relatively easily measured.

Thermal diffusivity experiments are usually short and relatively simple. In most cases they require small samples, disks a few millimeters in diameter and less than 4 mm thick. Although the derivation of thermal diffusivity from recorded experimental data may involve complex mathematics, availability of large-capacity personal computers and the ease with which thermal diffusivity experiments can be interfaced and automated compensate for this limitation. Another important feature of thermal diffusivity methods is that the temperature variation in the sample during measurement can be quite small, so the measured property is related to an accurately known temperature. This advantage enables studies of phase transitions via thermal diffusivity throughout transition ranges, which is often not feasible with thermal conductivity measurements whose methods involve appreciable temperature gradients.

Thermal diffusivity techniques have been used in the temperature range from 4.2 to 3300 K. In general, diffusivity/specific heat techniques are not well suited for cryogenic temperatures. Diffusivity values decrease rapidly and specific heat values increase rapidly with decreasing temperature, and their product cannot be determined with great accuracy. Therefore, the most popular temperature range for thermal diffusivity measurements is from near room temperature to 2000 K. According to the shape of the temperature disturbance, diffusivity techniques may be categorized into two basic groups: the transient heat flow and the periodic heat flow techniques. Transient techniques are divided into two subgroups, depending upon whether the temperature disturbance is relatively short (pulse techniques) or long (monotonic heating). These methods are discussed in detail in several chapters of Maglic et al. (1984).

Periodic heat flow variants are based on the measurement of the attenuation or the phase shift of temperature waves propagating through the material. Periodic heat flow methods are divided into two groups. The first constitutes temperature wave techniques, which are predominantly devoted to lower and medium temperatures and are frequently called multiproperty, because they can provide data on a number of thermophysical properties within a single experiment. The second group constitutes the high-temperature variants, where the energy input is effected by modulated electron or photon beams bombarding the sample.

The laser flash technique is the most popular method. According to some statistics, 75% of thermal diffusivity data published in the 1980s were measured with this technique.

In summarizing advantages and disadvantages of the techniques, the laser flash and the wave techniques may be considered within same category. Both generally require small samples and vacuum conditions, and measurements are made within very narrow temperature intervals. The latter characteristic makes them convenient for studying structural phenomena in the materials to very high temperatures. Contrary to wave methods which need two types of apparatus for the whole temperature range, the laser flash method can cover the entire range with minor modifications in traversing from subzero to elevated temperatures. The laser flash measurements last less than 1 s and do not require very stable temperatures, while wave techniques require quasi-stationary conditions. Both methods are well studied and in both consequences of the main sources of error can be adequately compensated. There is a large volume of competent literature on this subject. Basic components of the laser flash equipment as well as complete units are commercially available from Anter Laboratories, Pittsburgh, PA, and Theta Industries, Port Washington, NY. In addition, there are well-established research and testing laboratories available for thermophysical property testing, such as TPRL, Inc., West Lafayette, IN. Temperature wave variants cover a very wide materials range and are suitable for operation under high pressures and for multiproperty measurement. Of particular advantage is the possibility of cross checking results by comparing data

derived from the amplitude decrement and the phase lag information. The wave techniques have proved particularly convenient for measuring thermal conductivity and thermal diffusivity of very thin films and deposits on the substrates. This feature is very important, as properties of very thin films typically differ from the properties of the bulk of the respective materials. The laser flash method is still establishing its place in this area.

A less attractive feature of wave techniques is that the measurements generally have to be carried out in vacuum. This limits these methods to materials in which ambient gas does not contribute to the energy transport. Mathematical procedures involved in corrections for both the laser flash and wave techniques utilize sophisticated data reduction procedures. The potential user of this equipment should be proficient in this area. Due to small samples, techniques are not well suited for coarse matrix materials where local inhomogeneities may compare with the sample thickness as well as for optically translucent or thermally transparent materials.

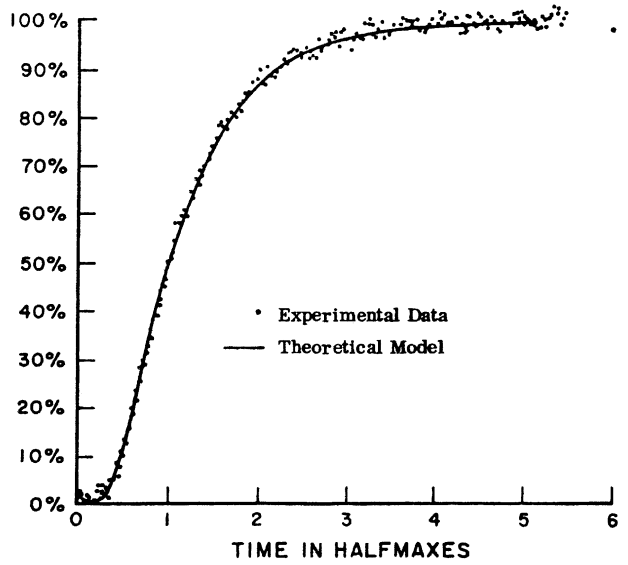

Figure 1. Comparison of normalized rear-face temperature rise with the theoretical model.

PRINCIPLES OF THE METHOD

The flash method of measuring thermal diffusivity was first described by Parker et al. (1961). Its concept is based on deriving thermal diffusivity from the thermal response of the rear side of an adiabatically insulated infinite plate whose front side was exposed to a short pulse of radiant energy. The resulting temperature rise of the rear surface of the sample is measured, and thermal diffusivity values are computed from the temperature-rise-versus-time data. The physical model assumes the following ideal boundary and initial conditions: (a) infinitely short pulse, (b) one-dimensional heat flow normal to the plate face, (c) adiabatic conditions on both plate faces, (d) uniform energy distribution over the pulse, (e) pulse absorption in a very thin layer of investigated material, (f) homogeneous material, and (g) relevant materials properties constant within the range of disturbance. As shown in the Appendix, the last two assumptions reduce the general heat diffusion equation to the form

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial x^2} \tag{1}$$

where the parameter α represents the thermal diffusivity of the plate material. The solution of this equation relates the thermal diffusivity of the sample to any percent temperature rise and the square of the sample thickness (L):

$$\alpha = K_x \frac{L^2}{t_x} \tag{2}$$

where K_x is a constant corresponding to an x percent rise and t_x is the elapsed time to an x percent rise. Table 2 in the Appendix relates values of K calculated for specific x percent rises.

Parker et al. (1961) selected the point corresponding to 50% of the temperature rise to its maximum value, $t_{0.5}$, relating thermal diffusivity of the material to the square of the plate thickness, and the time needed for the rear temperature to reach 50% of its maximum:

$$\alpha = 0.1388 \frac{L^2}{t_{0.5}} \tag{3}$$

Clark and Taylor (1975) showed that the rear-face temperature rise curve could be normalized and all experimental data could be immediately compared to the theoretical (Carslaw and Jaeger, 1959) solution on-line. Figure 1 shows this comparison and Table 1 gives the corresponding diffusivity (α) values for various percent rises along with the elapsed time to reach those percentages. The calculated values are all 0.837 $\pm$ 0.010 cm^2/s, even though the calculations involved times that varied by almost a factor of 3. Thermal diffusivity experiments using the energy flash technique were one of the first to utilize rapid data acquisition to yield thermal transport data on small, simple-shaped specimens. The original techniques used a flash lamp, but the invention of the laser greatly improved the method by increasing the distance between the heat source and sample, thus permitting measurements at high temperature and under vacuum conditions.

Table 1. Computer Output For Diffusivity Experiment[a]

α (cm^2/s)	Rise (%)	Value (V)	Time (s)

[a] Maximum, 5.40477 V; half maximum, 3.63739 V; baseline, 1.870 V.

The flash technique did not remain limited to conditions prescribed by the ideal model. The theoretical and experimental work of many researchers continuing from the 1960s supplemented the original concept with corrections, which accounted for heat exchange between sample and ambient, finite pulse shape and time, nonuniform heating, and in-depth absorption of the laser pulse. The result was extension of the method to, e.g., high temperatures, thin samples, layered structures, dispersed composites, and semitransparent or semiopaque materials. The review of these developments is presented elsewhere (Taylor and Maglic, 1984; Maglic and Taylor, 1992), supplemented here in further sections below with information on the literature published during the 1990s.

The capabilities of modern data acquisition and data reduction systems offer advantages over the direct approach, i.e., procedures limited to the analysis of the half-rise time or a discrete number of points. The inverse method relies on the complete transient response for thermal diffusivity measurement. This approach results in excellent agreement between theoretical and experimental curves. The parameter estimation procedure is convenient for the flash method, as it enables simultaneous determination of more than one parameter from the same temperature response. The capabilities and advantages of such determinations will be presented in Data Analysis and Initial Interpretation.

PRACTICAL ASPECTS OF THE METHOD

Implementation of the laser flash method for thermal diffusivity measurement requires the following (see Fig. 2): in a sample holder, a furnace or a cooler capable of maintaining and recording the sample reference temperature; a vacuum-tight enclosure equipped with two windows for the laser and the detector; a pulse laser with characteristics adequate for the range of materials to be studied, including available sample diameters and thicknesses; a system for measuring and recording the rear-face temperature transient; a power supply for the furnace or the cooling unit; an adequate vacuum system; and a computer for controlling the experiment, data acquisition, and subsequent data processing.

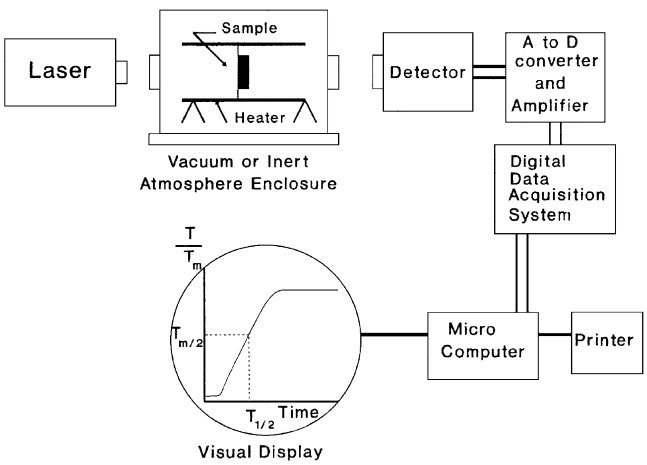

Figure 2. Schematic view of the laser flash apparatus.

Measurement times of less than 1 s are often involved. The ambient temperature is controlled with a small furnace tube. The flash method is shown schematically in Figure 2, which includes the temperature response of the rear face of the sample. This rear-face temperature rise is typically 1 to 2 K. The apparatus consists of a laser, a high-vacuum system including bell jar with windows for viewing the sample, a heater surrounding a sample holding assembly, an infrared (IR) detector, appropriate biasing circuits, amplifiers, analog-to-digital (A/D) converters, crystal clocks, and a computer-based digital data acquisition system capable of accurately taking data in the 100-μs time domain. The computer controls the experiments, collects the data, calculates the results, and compares the raw data with the theoretical model. The method is based on the Carslaw and Jaeger (1959) solution of the heat conduction equation for such a case.

The furnace should be of low thermal inertia and equipped with a programmable high-stability power supply to enable quick changes in reference temperature. Typical examples are electroresistive furnaces heated by direct passage of electrical current through a thin metallic foil or a graphite tube.

Vacuum- and/or gas-tight enclosures are mandatory for preventing heat exchange between sample and ambient by convection and gas conduction and protecting furnace and sample from chemical damage. They must have two windows along the optical axis of the sample, the front allowing entrance of the laser pulse and the rear for optical access to the sample rear side. The windows should be protected with rotating shields against evaporated deposits, as the vapor from both the heater and the sample material can condense on the cold window surfaces, reducing or completely blocking optical access. The transmittance of the rear window should be high within the infrared optical detector bandwidth.

The pulse laser [now most commonly neodymium/yttrium aluminum garnet (Nd:YAG)] should be capable of supplying pulses preferably lasting less than 1 ms and of 30 to 40 J in energy with a beam diameter of 16 mm and an energy distribution as homogeneous as possible. Usual sample diameters for homogeneous materials range from 6 to 12 mm, but some applications require diameters as large as 16 mm. Studies of thin films or samples where half times are of the order of 1 ms require much shorter pulses and *Q*-switched laser operation.

Systems for measuring reference temperature might be contact or contactless. For most metallic samples, miniature thermocouples spot welded to the specimen rear face are most convenient. For samples where this is not feasible, it is common to use a thermocouple accommodated in the sample holder or to provide a blackbody-like hole in the holder for measurement using an optical pyrometer. In both latter cases the sample temperature must be calibrated against the measured sample holder temperature.

The rear-face temperature transients should be detected with optical detectors adequate for the corresponding temperature ranges, meaning that they

should be much faster than the change they are recording and be sufficiently linear within small temperature excursions. Optical detectors should be interfaced to the computer via a suitable A/D converter.

The power supply should be matched with the furnace characteristics to easily and rapidly cover the whole temperature range of measurement. It should be capable of maintaining the prescribed temperature during the period of a few seconds of measurement for the baseline recording and up to ten half times after the laser discharge. The measurement should be effected at constant temperature or in the presence of a small and constant temperature gradient that can be compensated for in the data processing procedure. For realizing temperatures below ambient, a miniature chamber cooled by circulation of fluid from an outside cooling unit is adequate.

Thermal diffusivity values are calculated from the analysis of the temperature-time dependence of the rear face of a thin sample, whose front face has been exposed to a pulse of radiant energy. The duration of the pulse originally had to be approximately one-hundredth of the time needed for the temperature of the rear face to reach 50% of its maximum value. However, present methods for correcting deviations from the initial and boundary conditions, along with data processing possibilities, have reduced this requirement considerably. When the samples are small and homogeneous, lasers are the best means for providing energy pulses. When high accuracy is not the primary requirement and where samples have to be larger, flash lamps may sometimes be adequate, particularly at low temperatures. After establishing that the heat flow from the front to the rear sample face is sufficiently unidirectional, the accurate measurement of the rear-face temperature change is actual. Originally thermocouples were the most common device used for this purpose, but IR and other contactless detectors now provide far better service because of increased accuracy and reliability. Distortion of signals caused by contact temperature detectors may lead to significant errors in the measured thermal diffusivity. The laser flash technique has been used from 100 to 3300 K, but its most popular application has been from near room temperature to 2000 K. This technique has been successfully applied to metals in the solid and liquid states, ceramics, graphites, biological products, and many other materials with diffusivities in the range 10^{-7} to 10^{-3} m^2/s. The method is primarily applicable to homogeneous materials but has been applied successfully to certain heterogeneous materials. Even with manually driven hardware, the whole range from room temperature to the maximum temperature can be traversed within one day. With more sophisticated equipment, laser flash thermal diffusivity measurements can be quite fast.

Methods based on monotonic heating have been used from the lowest temperature limit of 4.2 K to as high as 3000 K. They proved convenient for a range of materials: ceramics, plastics, composites, and thermal insulators with thermal diffusivity values falling in the range from 10^{-8} to 10^{-5} m^2/s. They are irreplaceable for coarse-matrix and large-grain materials and porous materials in which part of thermal energy is transported via gas-filled interstices. They are also useful for property measurements over large temperature intervals carried out in relatively short times, e.g., on materials undergoing chemical or structural changes during heating. The cost is reduced accuracy, but it is usually adequate for industrial purposes. The monotonic heating techniques comprise two subgroups, for measurements in the narrow and in very wide temperature intervals, so-called regular regime and quasi-stationary regime methods.

The temperature wave variants may be applied from 60 to 1300 K, but they are generally used between 300 and 1300 K. They are convenient for metals and nonmetals and also fluids and liquid metals with thermal diffusivity in the range 10^{-7} to 10^{-4} m^2/s. This technique has a large variety of variants and their modifications, depending on the sample geometry and direction of propagation of the temperature waves. They include information on the mean temperature field and the amplitude and phase of the temperature waves. This opens the possibility of multiproperty measurements, i.e., simultaneous measurement of thermal conductivity, thermal diffusivity, and specific heat on the same sample. The high-temperature variants (modulated electron beam or modulated light beam) can be used from 330 to 3200 K, but their usual range is between 1100 and 2200 K. These high-temperature variants have been applied to refractory metals in the solid and in the molten state. They also have been used for high melting metal oxides, whose thermal diffusivity is in the range 10^{-7} to 5×10^{-5} m^2/s. Improvements in techniques, measurement equipment, and computing analysis are continuing to be made.

The measurement consists of heating or cooling the sample to the desired temperature, firing the laser, digitizing and recording the data, and possibly repeating the measurements for statistical purposes before changing to the next temperature level. The main difficulties that can be encountered include (1) deviations from assumed ideal conditions due to time of passage of the heat pulse through the sample being comparable with the pulse duration, heat exchange occurring between sample and environment, nonuniform heating of the sample surface, subsurface absorption of the laser pulse, and combined mechanisms of heat transmission through the sample; (2) interference in the transient response signal due to passage of the laser light between sample and sample holder directly to the IR detector and thermal radiation from the sample holder; (3) changes of sample chemical composition due to evaporation of alloying constituents at high temperatures and chemical interaction with the sample holder or optical barrier; and (4) errors in determining sample reference temperature.

Deviations from assumed ideal conditions manifest in the shape of the transient response, each of them deforming it in a specific manner. Procedures for correcting all deviations have been developed and are a part of standard data processing. They are included in Data Analysis and Initial Interpretation.

Transient response is also affected by the laser light passing between the sample and the sample holder or reflected laser light reaching the optical sensor. If either of these occur, the sensor may saturate, deforming the initial portion of the signal rise, thus making it difficult

to define the baseline. Precautions therefore should be taken to eliminate detector saturation.

If the thermal diffusivity of the sample holder is higher than that of the sample or the holder is partially translucent to the laser light and if stray laser pulse light hits the holder, then the optical detector could measure contributions from both the sample and its holder. This will deform the transient curve. To avoid this, the proper choice of the sample holder material and the careful design of its dimensions are necessary.

Operation at high temperatures may change the chemical composition of the sample due to the preferential evaporation of some alloying constituents. A convenient way to reduce this effect is to shorten the time that the sample is exposed to high temperatures. This is accomplished either by devoting one sample solely to high-temperature measurements and performing these as quickly as possible or by reducing the number of experiments at temperatures beyond the thermal degradation point. In addition, the sample holder material should be selected so that chemical interaction between it and the sample is minimized.

Errors in determining sample reference temperature can be significant depending upon many factors. These include the location of the temperature sensor with respect to the sample or its holder, the quality of thermal contact between the sample and the holder, and the measurement temperature and sample emissivity. It may be possible to avoid some of the errors by proper selection of the method and by establishing the relationship between the true sample temperature and that measured in the holder.

METHOD AUTOMATION

Powerful personal computers are presently available at reasonable cost. This offers ample opportunity for automation of all measurement procedures contributing to productivity and ease with which measurements are performed. Excessive automation, however, might relegate decisions to the computer that are too subtle to be automated. The following paragraph therefore reviews tasks that can be entrusted to modern computers and those that should be reserved for the operators who are knowledgeable about the limitations of the experimental technique and the physics of the properties being measured.

Desirable automation involves continuous checking of experimental conditions. This include achieving and maintaining the required level of vacuum and temperature as well as controlling the heating rates between specified temperature levels. Computers are capable of executing all these steps, as well as positioning samples when a multisample accessory is involved. Computers should also be involved in performing tasks such as firing the laser and collecting and processing the data. However, all significant phases of experiment and processing of the data should be performed by the operator. He or she should first ensure that prescribed temperature stability has been achieved. After the laser has fired and the initial data set is collected, the quality of the data should be inspected, making sure that the moment of laser discharge is recognizable, the shape of transient agrees with expectation, and possible noise on the signal will not affect the data processing. As the processing progresses, visual insight into transformation of initial experimental data is necessary before proceeding to each successive step of the procedure.

Full automation of the experiment, where the choice of accepting or rejecting the initial data set and selection of correcting procedures to be involved are left to computer, makes the experiment susceptible to various sources of systematic error. If nothing else, suspicion of their existence ought always be present. For reliable results in flash diffusivity measurements, the operator should be highly experienced.

DATA ANALYSIS AND INITIAL INTERPRETATION

After the sample has been brought to a desired temperature and its stability established, the experiment is started by initiating the program that records the baseline, fires the laser, and acquires and records data on the rear-face temperature transient. Insight into the shape of the resulting data curve indicates whether it is acceptable for extracting results or the experiment should be repeated. To increase the statistical weight of the data points, several measurements should be taken at the same temperature.

Experimental data necessary for the calculation of thermal diffusivity include baseline, which represents the equilibrium temperature of the specimen prior to laser discharge, the time mark of the laser discharge, and the transient temperature curve, extending over at least ten lengths of the characteristic half time, $t_{0.5}$. It is also useful to have a working knowledge of the shape of the laser pulse (especially its duration and intensity distribution across the beam) and the response characteristics of the temperature detector (response time, linearity). The sample thickness measurement should be done as precisely as possible prior to the diffusivity measurement.

It is important that the transient response curve be thoroughly analyzed to verify the presence or absence of laser pulse duration comparable with the time of passage of the temperature disturbance through the material (finite-pulse-time effect), heat exchange between sample and environment (heat losses or gains), nonuniform heating, subsurface heating by the laser beam, or other effects that can cause errors in thermal diffusivity calculations. This means comparing the normalized rise curve with the ideal curve for the theoretical model.

It should be noted that these four effects can be regarded merely as deviations from an ideal situation in which such effects are assumed to be negligible. It is entirely feasible to develop models that incorporate and account for these effects. This has been done for all four of these effects. Once the mathematical (analytical or numerical) expression for temperature rise is known, parameter estimation techniques can be used to calculate the thermal diffusivity of the sample. However, other unknown model parameters such as heat loss coefficients, duration and shape of the heat pulse, spatial distribution characteristics of the pulse, and effective penetration depth of the pulse must be estimated simultaneously. Even

today, when advanced parameter estimation techniques are available and high-speed, high-capacity computers can be used, estimating all parameters simultaneously is sometimes quite difficult. Careful and nontrivial mathematical analysis of so-called sensitivity coefficients [see Beck and Arnold (1977) for details] has to be conducted to find out, if it is possible to calculate all of these unknown parameters from the given model for the temperature response.

We will briefly describe how to analyze the response curve with regard to all of the above-mentioned effects.

To normalize the experimental curve and as an inherent part of determining the half time (or the time to reach any other percentage temperature rise), it is necessary to determine accurately the temperature baseline and maximum temperature rise. It is not a trivial task, especially when the signal is noisy and the temperature of the sample was not perfectly stable. Standard smoothing procedures, e.g., cubic-spline smoothing, can be used. The baseline temperature can be obtained conveniently by measuring the detector response for a known period prior to charging the laser flash tube capacitor bank and extrapolating the results to the time interval in which the rear-face temperature is rising.

The normalized experimental temperature rise (in which the baseline temperature is set to zero, the maximum temperature is equal to 1, and the time scale unit is set to the experimental half time) is then compared with the ideal dimensionless temperature rise, given by

$$V(t') = 1 + 2\sum_{n=1}^{\infty}(-1)^n \exp(-0.1388 n^2 \pi^2 t') \qquad (4)$$

where $t' = t/t_{0.5}$ is dimensionless time.

When there are no evident deviations of the experimental normalized temperature rise curve from the ideal one (analysis of residuals is a useful tool for this purpose), then any of the data reduction methods based on the simple ideal model can be used for the thermal diffusivity calculations. The result should be later checked by the other correction procedures, which should give the same answers.

The presence of the finite-pulse-time effect (without other effects being present) can be readily determined from a comparison of the normalized experimental curve to the theoretical model. The distinguishing features are that (1) the experimental curve lags the theoretical ideal curve by from an ~5% to a 50% rise, (2) the experimental curve leads the ideal theoretical curve by from an ~59% to an ~98% rise, and (3) a long, flat maximum is observed.

Of these major effects, the finite-pulse-time effect is the easiest to handle. Cape and Lehman (1963) developed general mathematical expressions for including pulse time effects. Taylor and Clark (1974) tested the Cape and Lehman expressions experimentally. Larson and Koyama (1968) presented experimental results for a particular experimental pulse characteristic of their flash tube. Heckman (1976) generated tabular values for triangular shaped pulses. Taylor and Clark (1974) showed how calculated diffusivity varied with percent rise for a triangular shaped heat pulse. They also showed how to correct diffusivities at percent rises other than the half-rise value so that the diffusivity values could be calculated over the entire experimental curve rather than at one point.

A procedure based on the Laplace transform was used to correct the finite-pulse-time effect in the data reduction method proposed by Gembarovic and Taylor (1994a). Experimental data are first transformed with the Laplace transformation and then fitted with the transform of the theoretical time-domain relation. More realistic heat pulse shapes can be calculated with this method.

Using data reduction method based on discrete Fourier transformation can eliminate errors from a noisy signal and unstable baseline conditions (Gembarovic and Taylor, 1994b).

Azumi and Takahashi (1981) proposed one of the simplest and universal methods for the correction of the finite-pulse-time effect. This correction consists of taking as the time origin the effective irradiation time (center of gravity of the pulse). Degiovanni (1987) used this technique to correct simultaneously both the finite-pulse-time and heat loss effects.

The presence of heat losses is shown by the following features: (1) the experimental curve slightly lags the theoretical curve from an ~5% to a 50% rise, (2) the experimental curve leads the theoretical curve from 50% to 100%, and (3) a relatively short maximum is observed followed by a pronounced smooth decline.

The calculated value of thermal diffusivity increases with increasing percent rise at an increasing rate.

Radiation heat losses may be corrected for by the method of Cowan (1963) or Heckman (1976). Cowan's method involves determining the values of the normalized temperature rise at $5t_{0.5}$ or $10t_{0.5}$. From these values one can estimate the radiation loss parameter and correct α.

Heat losses can also be corrected by the so-called ratio method (Clark and Taylor, 1975). In this method, the experimental data are compared at several particular points with the theoretical rear-face temperature rise with heat losses. The Clark and Taylor method has the advantage of using the data collected during the initial rise rather than the cooling data, which are subject to greater uncertainties caused by conduction to the sample holder. Clark and Taylor tested their procedure under severe conditions and showed that corrections of 50% could be made satisfactorily.

The data reduction method proposed by Degiovanni and Laurent (1986) uses the temporal moments of order zero and -1 of the defined temperature interval of the rising part of the experimental curve to correct the heat loss effect.

Koski (1982) proposed an integrated data reduction method in which both the finite-pulse-time effect and heat losses are corrected using the form

$$V(L,t) = 2\sum_{m=1}^{M} F(\tau_m) \sum_{n=1}^{\infty} \frac{\beta_n(\beta_n \cos\beta_n + L_g \sin\beta_n)}{\beta_n^2 + L_g^2 + 2L_g} \times \exp\left[\frac{-\beta_n^2 \alpha(t-\tau_m)}{L^2}\right] \Delta\tau_m \qquad (5)$$

where the pulse time τ is divided into M subintervals τ_1, τ_2, ..., τ_M, the function F represents the heat pulse shape at the time τ_m, $\Delta\tau_m = \tau_m - \tau_{m-1}$, L_g is the heat loss parameter, and β_n are roots of the transcendental equation

$$(\beta^2 - L_g)\tan\beta = 2L_g\beta \tag{6}$$

Other original methods (Balageas, 1982; Vozar et al., 1991a,b) are based on the assumption that the experimental temperature rise is less perturbed by heat losses at times closer to the origin (i.e., time of the flash). The thermal diffusivity is obtained by extrapolating the time evolution of calculated values of an apparent diffusivity to zero time.

Nonlinear least-squares fitting procedures have been developed (Takahashi et al., 1988; Gembarovic et al., 1990) in which all experimental points of the experimental temperature rise can be used for the determination of the thermal diffusivity. The methods are particularly useful in the case of noisy data, which are otherwise close to an ideal model.

A data reduction method for heat loss correction is described by Beck and Dinwiddie (1997). A parameter estimation technique was used to calculate thermal diffusivity in the case when heat loss parameters from the front and rear faces of the sample are different. Finite-pulse-time effects and radiative heat losses only occur in selective cases; i.e., finite-pulse-time effects occur with thin samples of high-diffusivity materials and radiative heat losses occur at high temperatures with thicker samples. In contrast, nonuniform heating can occur during any flash diffusivity experiment. However, very little has been published on the effects of nonuniform heating. Beedham and Dalrymple (1970), Mackay and Schriempf (1976), and Taylor (1975) have described the results for certain nonuniformities. These results show that when the heating is uniform over the central portion of the sample, reasonably good results can be obtained. However, a continuous nonuniformity over the central portion can lead to errors of at least ten times the usual error. Nonuniform heating can be corrected by properly designing the experiment. If the laser beam is nonhomogeneous in cross-section, then an optical system that homogenizes the beam can be used, the sample surface can be covered with an absorbative layer that will homogenize the beam, or a thicker sample that is less prone to this effect can be used.

If the sample is not completely opaque to the laser beam, then subsurface heating can distort experimental temperature rise. The presence of a spike and shift of baseline temperature to a new higher level after the laser flash indicates when the beam is completely penetrating the sample. It is more difficult to detect the case where the laser beam is absorbed in a surface layer of a finite thickness. It is not recommended to eliminate this effect using mathematical means. Covering the sample surface with one or more protective layers can eliminate this effect.

Data reduction procedures for layered structures are based on two- or three-layer models (see, e.g. Taylor et al., 1978). Thicknesses, densities, and specific heats of all layers have to be known, along with the thermal diffusivities of all but the measured layer. Parameter estimation techniques or other nonlinear fitting procedures are used to calculate the desired value of the thermal diffusivity of the measured layer. If the known layers are relatively thin and highly conductive and the contact thermal resistance is low, then the results of the two- or three-layer thermal diffusivity calculation are the same as for a homogeneous (one-layer) sample with the thickness given as a sum of all layers. Application of the laser flash method to very thin, highly conductive multilayer structures still remains an unsolved problem and a big challenge to experimenters.

SAMPLE PREPARATION

Preparing opaque specimens for flash diffusivity measurement is generally simple. The diameter of the sample has to conform to the size of the most homogeneous part of the laser energy pulse, and its thickness to the permissible ratio between the laser pulse duration and the characteristic time of heat passage through the specimen. Problems might arise from satisfying the requirement of plane-parallelism of the specimen flat sides. If the sample material is magnetic or if its length is sufficient to be held during machining and the material is readily machinable, no serious problem exists. However, if it has to be made thin or very thin or the material is hard and brittle or difficult to be fixed to a substrate, a lot of ingenuity on the part of the sample manufacturer will be necessary. Coping with its transparency to thermal radiation or the laser pulse may be difficult. Often it can be solved by coating the front or both sample faces with a thin metallic or graphite layer. This overlayer has to absorb the laser pulse energy within its finite thickness and convert it into a single thermal function. Layers of refractory metals are thinner and longer lasting, but their high reflectivity allows only a small portion of the pulse to be absorbed. Graphite is much better in this respect, but laser pulses, particularly those with higher energies, tend to evaporate the layer. Attaching the coating to the sample may be a real challenge, particularly if the sample material is smooth and slippery. The lifetime of a layer in terms of pulses is shorter as temperature increases.

As machining of metallic samples always involves mechanical deformation of the sample material, it is advisable to relieve strains (which may affect the measured diffusivity values) by methods well known to metallurgists.

SPECIMEN MODIFICATION

Experimenting with the flash diffusivity technique may affect the specimen in a few ways. The most obvious include modifications due to exposure to elevated temperature in vacuum, contamination from the coating layer material, and damage caused by the laser pulse action due to structural changes caused by fast heating or cooling.

Often repeated cycling of experiments will not affect the outcome of measurements, but this will depend on the material and the maximum temperature reached. If

the specimen structure is in a state that is susceptible to thermal treatment, temperature cycling will definitely involve specimen modification. If the specimen material is an alloy whose alloying components preferentially evaporate at temperatures much below its melting point, experiments above this temperature will lead to undesirable modifications of specimen composition. A vacuum environment will definitely stimulate this process. How big the damage will be and how much it will affect the outcome of the flash diffusivity results will depend on the specimen diameter-to-thickness ratio, the maximum operating temperature, and the length of time that the specimen is exposed to undesirable temperatures as well as the relative vapor pressures of the constituents.

For flash diffusivity measurements, specimens of materials that are partly or totally transparent or translucent must be coated. If the sample is porous, colloidal graphite from the coating may penetrate the specimen structure, evidenced by a change of its color, and will most likely influence its overall thermal properties. Such a change of the sample's thermal optical properties, however, does not necessarily preclude the measurement of thermal diffusivity by this technique. Within the small specimen temperature excursion caused by the laser pulse, a small amount of graphite within grain interstices will not affect the basic mechanisms governing energy transport through it.

Although the powerful laser energy pulse might cause damage to the specimen surface, in testing common materials like metals, graphites, and ceramics and with energy densities of $\sim$10 J/cm^2, adverse effects of specimen modification have not been observed. More danger lies in defining the depth of the energy pulse absorption in the case of rough surfaces typical of, e.g., composite materials, as this affects the basic geometry parameter L, which enters as a squared term in Equation 3.

PROBLEMS

Some of the most common problems are discussed below:

1. Optimum half-rise time is 40 to 100 ms. Half times are controlled by sample thickness and diffusivity value. Longer times have larger heat loss corrections. Shorter times have finite-pulse-time effects and greater uncertainty in baseline values.
2. Very thin samples have large uncertainty in sample thickness (which enters as a squared term), larger surface damage effects (sample preparation), and possibly too large a temperature rise (nonlinear IR detector response). Also, thin samples may not be sufficiently homogeneous.
3. Rear-face temperature rise may be too large (resulting in nonlinear IR response and laser damage) or too small (resulting in noisy signal). Sample emissivity and laser power should be controlled to change the energy absorbed and linearity of the IR detector response. Heat-resistive paints can be effectively used to increase sample resistivity in the case of a small signal.
4. A nonuniform laser beam can be a major problem. The uniformity should be checked using laser foot print paper with a partially absorbing solution to reduce laser power to the paper. Copper sulfate solution is very good for this purpose (for Nd:YAG primary frequency). If the beam is nonuniform, adjusting the dielectric mirrors or using optics may improve homogeneity.
5. Scattered radiation can cause spurious signals and even temporarily saturate the IR detector, making baseline determinations difficult.
6. Applying a coating to translucent samples may result in a thermal contact resistance. Thermal contact resistance may lower the value of the measured thermal diffusivity of the sample material. Coatings applied to high-diffusivity samples are especially prone to this problem.
7. Diffusivity values for porous materials can be strongly affected by the surrounding gas and its moisture content. The diffusivity values for gases are very large, even though their conductivity values are quite small.

The laser flash technique is an ASTM (1993) standard (E-1461) and the step-by-step procedures are given there. This standard is easily obtained and cannot be duplicated here. Also included in ASTM E1461-92 is a discussion of the measurement errors and the "nonmeasurement" errors. The latter arise from the nonobeyance of the initial and boundary conditions used in the data analysis. In general, the nonmeasurement errors cause greater uncertainty in the results than measurement errors, which simply involve length and time measurements. Both of these can generally be measured to a high degree of accuracy. Heat losses and finite-pulse-time effects have been studied intensively and procedures for correcting these are generally adequate. Nonuniform heating is more insidious since there is an infinite variety of nonuniformities possible and the nonuniformity can change with time as room temperature varies and the operating characteristics of the laser change. Testing with an acceptable standard such as a fine-grain, isotropic graphite AXM5Q (Hust, 1984; ASTM, 1993) is useful, but the errors in the actual tests may be significantly different due to, e.g., sample translucency, significantly different emissivity, and rise times.

APPENDIX

The heat balance equation for transient conditions may be written as

$$\nabla \cdot \lambda \, \nabla T + (\text{internal sources and sinks}) = C_p \rho \frac{\partial T}{\partial t} \quad (7)$$

where λ is the thermal conductivity, C_p is the specific heat at constant pressure, and ρ is the density. If there are no internal sources and sinks,

$$\nabla \cdot \lambda \, \nabla T = C_p \rho \frac{\partial T}{\partial t} \quad (8)$$

For homogeneous materials whose thermal conductivity is nearly independent of temperature, we may treat λ as a constant. Then $\nabla \cdot \lambda \nabla T$ becomes $\lambda \nabla^2 T$, and Equation 8 can be written as

$$\lambda \, \nabla^2 T = C_p \rho \frac{\partial T}{\partial t} \quad (9)$$

or

$$\nabla^2 T = \frac{C_p \rho}{\lambda}\frac{\partial T}{\partial t} = \frac{1}{\alpha}\frac{\partial T}{\partial t} \tag{10}$$

where $\alpha = \lambda/C_{p\rho}$ is the thermal diffusivity. For one-dimensional heat flow

$$\alpha \frac{\partial^2 T}{\partial x^2} = \frac{\partial T}{\partial t} \tag{11}$$

The assumed adiabatic conditions at the faces of a plate of thickness L result in boundary conditions

$$\frac{\partial T(0,t)}{\partial x} = \frac{\partial T(L,t)}{\partial x} = 0 \qquad t > 0 \tag{12}$$

The solution of Equation 11 defining temperature at a given time at position x within the plate is then given by

$$T(x,t) = \frac{1}{L}\int_0^L f(x')\,dx' + \frac{2}{L}\sum_{n=1}^{\infty} \exp\left(\frac{-n^2\pi^2\alpha t}{L^2}\right) \times \cos\frac{n\pi x}{L}\int_0^L f(x')\cos\frac{n\pi x'}{L}\,dx' \tag{13}$$

The function *f(x)* represents the temperature field in the plate resulting from a short pulse of energy Q instantaneously absorbed in a thin surface layer of thickness g.

The initial conditions defining temperature distribution in the plate at time $t = 0$ are

$$f(x) = \begin{cases} \frac{Q}{\rho C_p g} & 0 \le x \le g \\ 0 & g < x < L \end{cases} \tag{14}$$

For simplicity, plate reference temperature is assumed to be zero. For these initial conditions, Equation 13 transforms to

$$T(x,t) = \frac{Q}{\rho C_p L}\left[1 + 2\sum_{n=1}^{\infty} \exp\left(\frac{-n^2\pi^2\alpha t}{L^2}\right) \times \cos\frac{n\pi x}{L}\frac{\sin(n\pi g/L)}{n\pi g/L}\right] \tag{15}$$

For opaque solids the ratio g/L is sufficiently small that the approximation $\sin(n\pi g/L) \approx n\pi g/L$ can be valid, simplifying Equation 15 for the plate rear face to

$$T(L,t) = \frac{Q}{\rho C_p L}\left[1 + 2\sum_{n=1}^{\infty}(-1)^n \exp\left(\frac{-n^2\pi^2\alpha t}{L^2}\right)\right] \tag{16}$$

After infinite time the rear-face temperature will be reduced to the first member in the square brackets:

$$T_{L,\max} = \frac{Q}{\rho C_p L} \tag{17}$$

Table 2. Values of K_x in Equation 19

x (%)	K_x	x (%)	K_x
10	0.0661	60	0.1622
20	0.0843	66.7(2/3)	0.1811
25 (1/4)	0.0927	70	0.1919
30	0.1012	75 (3/4)	0.2105
33.3 (1/3)	0.1070	80	0.2332
40	0.1190	90	0.3035
50 (1/2)	0.1388		

For practical application it is useful to relate thermal diffusivity to the percent rise in the rear-face temperature *V(L,t)*:

$$V(L,t) = \frac{T(L,t)}{T_{L,\max}} = 1 + 2\sum_{n=1}^{\infty}(-1)^n \exp\left(\frac{-n^2\pi^2\alpha t}{L^2}\right) \tag{18}$$

From Equation 18 the thermal diffusivity of the material can be related to any percent rise and the square of the plate thickness L:

$$\alpha = K_x \frac{L^2}{t_x} \tag{19}$$

where K_x is a constant corresponding to an x percent rise and t_x is the elapsed time to an x percent rise. Table 2 relates values of K_x calculated for specific x percent rises.

The detailed theory of one-layer homogeneous samples is in Watt (1966).

SIMULTANEOUS TECHNIQUES INCLUDING ANALYSIS OF GASEOUS PRODUCTS

INTRODUCTION

The concept of concurrently using two or more techniques of thermal analysis on a single substance has been promoted by advances in microprocessor control. This has made it possible to program and collect the data and process the information in many ways. Strictly speaking, the nomenclature "simultaneous" applied in such circumstance is not always correct. The mass change in thermogravimetry (TG) is generally the first signal received. The signal from the differential thermal analysis (DTA) probe will be received a little later as the heat has to diffuse through the sample and the crucible before reaching

the sensing thermocouple. The sample is defined as the material (usually a solid) under investigation. Likewise, in evolved gas analysis (EGA), the gases are sampled but it then takes a finite time for the gas to be analyzed. In the mass spectrometer, there is an interface to allow the gas to be analyzed. In gas chromatography (GC), the signal of gas analysis takes considerable time to process, and consequently the gas analysis signal is intermittent and not received in "real time." In the literature, there are descriptions of both TG (see THERMOGRAVIMETRIC ANALYSIS) and DTA (see DIFFERENTIAL THERMAL ANALYSIS AND DIFFERENTIAL SCANNING CALORIMETRY) being coupled with techniques such as Fourier transform infrared (FTIR) spectrometry and x-ray diffraction.

In common with all other thermal analysis techniques, the following parameters must be considered: the sample characteristics, its mass, the sample holder, the temperature range for study, the rate of heating, and the atmosphere.

It must be remembered that a single thermal analysis method may not give the investigator sufficient information. Thus DTA will indicate if a transformation is exothermic or endothermic. It needs thermogravimetric analysis to indicate if there is mass change as well as gas analysis to identify any gaseous products involved.

Although "simultaneous techniques" is the approved term used by the International Union of Pure and Applied Chemistry (IUPAC), the recommended nomenclature for such simultaneous techniques is to use a hyphen to separate the two techniques, e.g., TG-DSC. This has led to such techniques being called "hyphenated" techniques.

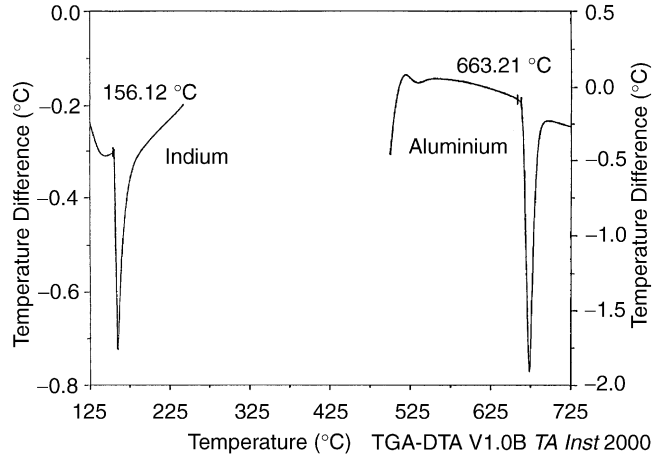

Figure 1. The melting DTA trace for indium and aluminum used to calibrate the equipment.

PRINCIPLES OF THE METHOD

New Studies Made Possible by Use of Simultaneous TG-DTA

Evaporation. The use of simultaneous TG-DTA can lead to interpretations not possible using conventional TG and DTA separately. An example is the study of evaporation. Because the DTA in the simultaneous unit cannot be operated in the usual manner with a covered crucible, evaporation may become a predominating feature (Lerdkanchanaporn and Dollimore, 1997).

Calibration. Calibration of TG is always a problem. With simultaneous TG-DTA, the calibration for temperature becomes much easier. The DTA trace can be used for temperature calibration in the simultaneous unit. The melting DTA trace for a metal can be used to calibrate the equipment. Figure 1 shows two runs in such a unit for indium and aluminum allowing the melting point to be established. Temperature for these materials and other standard calibration materials is the subject of extensive studies from the group in Germany reporting their findings to the International Confederation for Thermal Analysis and Calorimetry (ICTAC) and the IUPAC (Sarge et al., 1997).

Complex Thermal Degradations. Complex degradation patterns are observed in many salts. Magnesium nitrate hexahydrate, $Mg(NO_3)_2 \bullet 6H_2O$ melts at 90°C (see Fig. 2) and then water is lost from the system. The loss of water continues up to 350°C (42% loss), leaving an anhydrous salt that is a solid. This melts at 390°C and then decomposes to MgO at 600°C (residue 15.7%). All loss of water is endothermic and the dissociation to the oxide is also endothermic. Evolved gas analysis and hot-stage microscopy (HSM) would be additional simultaneous thermal analysis techniques that could provide details of this degradation.

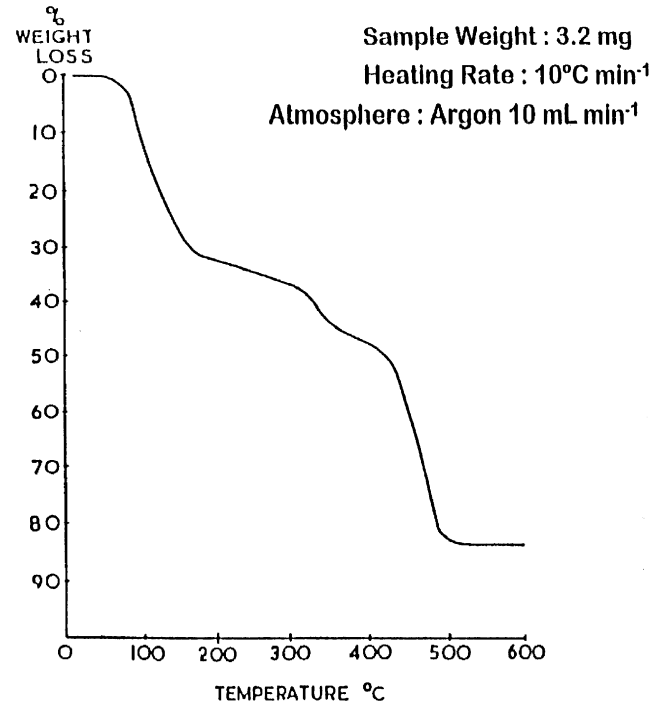

Figure 2. Complex degradation patterns of magnesium nitrate hexahydrate [$Mg(NO_3)_2 \bullet 6\ H_2O$].

PRACTICAL ASPECTS OF THE METHOD

General Comment on the Advantages and Disadvantages of Simultaneous Thermal Analysis Techniques

The obvious advantage of the simultaneous thermal analysis systems is that the same sample of the material under investigation is being studied. When two thermal analysis systems, e.g., DTA and TG, are investigated separately, the samples may vary in behavior. This is especially true for materials such as coal, geological samples, and building materials.

A further advantage of using the simultaneous techniques concerns the environment around the sample. The temperature and the gaseous environment in the simultaneous technique are the same for both the TG and the DTA signal. It is of course possible to combine more than two techniques in simultaneous thermal analysis. Such a system was devised to explore the nature of the soils on Mars (Bollin, 1969). Uden et al. (1976) have combined a variety of thermal analysis units into a complex simultaneous thermal analysis unit.

The economic advantages and disadvantages of using simultaneous thermal analysis techniques have to be considered carefully. It might be more advantageous to use a mass spectrometer in the laboratory rather than to dedicate the equipment to a simultaneous thermal analysis unit. On the other hand, if thermal analysis experiments are necessary on many samples so that a 100% usage is approached, then there is a definite economic advantage in using the simultaneous techniques.

Simultaneous TG-DTA/DSC

The most frequently used techniques of thermal analysis quoted in the literature are TG, DTA, and differential scanning calorimetry (DSC; see DIFFERENTIAL THERMAL ANALYSIS AND DIFFERENTIAL SCANNING CALORIMETRY). With the advent of the computer workstation, DTG (derivative thermogravimetry) can be produced from any TG curve, so it is not considered here as a separate technique. However, numerous commercial units involving TG-DTA or TG-DSC fulfill an obvious need in organic, pharmaceutical, and inorganic fields.

Advantages of Simultaneous TG-DTA

The Sample. The advantage of obtaining data in the same sample for both TG and DTA is obvious. There is a distinct possibility that different samples of the same material will show different signals, especially with DTA or DSC, where heat transitions may be affected by impurities present. In cases such as pharmaceutical stearic acid or magnesium stearate, the presence of other carboxylic acids can cause marked differences in both TG and DTA signals. For coal samples and other natural products (both geologically and biologically based), the use of different samples in obtaining the TG and DTA data could produce conflicting results due to the inhomogeneity of the samples.

The Mass of the Sample. Both TG and the DTA signals will be affected by the mass of material. In TG, the presence of large samples can cause kinetic features to change, usually from reaction interface kinetics for the small samples to diffusion-based kinetics for the large samples. The DTA is most sensitive when small samples are used. Thus many dehydration stages are often shown on the DTA unit when only one is seen on the TG unit. By having the same mass of material for both TG and DTA, the interpretation has to combine both TG and DTA data from the same sample.

The Sample Holder. Early work showed that in both TG and DTA the sample holder could affect the data. Thus long, narrow sample holders could cause diffusion to predominate whereas an open-tray sample would probably be best for studying kinetics based on reaction interface movement. Most obvious is the use of a crimped closed container in DTA to prevent mass loss (usually by evaporation). The TG data would be meaningless in such a situation. The use of an open crucible suitable for both TG and DTA would mean that the data from both techniques can be analyzed. It should be noted, however, that the DTA data may not correspond to the conventional DTA signal.

The Temperature Range of Study. The temperature range of study is exactly the same in the simultaneous experiment but may not be so when each technique is used separately.

The Heating Rate. It has been noted (Lerdkanchanaporn et al., 1997) that during a transition (phase change or chemical reaction) the imposed heating rate is perturbed. This phenomenon is unfortunately ignored by most investigators. It is, however, an important feature of simultaneous techniques, where one can be assured that any temperature perturbation is the same for both the TG and the DTA signal.

The Atmosphere. In the simultaneous technique the sample is subjected to the same gaseous environment while two thermal analysis signals are generated. This would not necessarily be the case if the TG and DTA signals were generated in two separate runs on two samples. It is important to note that there are two aspects to the environmental atmosphere: the nature of the gas and the rate of flow.

Description of Commercial TG-DTA Equipment

The Derivatograph manufactured in Hungary has been described by Paulik et al. (1958) and more recently by Paulik (1995) and ranks among the first commercial instruments to provide simultaneous TG, DTG, and DTA signals, as shown in Figure 3.

A TGA-DTA unit manufactured by TA Instruments that can operate up to 1650°C in controlled-temperature and gaseous environments is shown in Figure 4. It has a double-beam balance shown in the figure. Another unit described by TA Instruments as TGA-DSC operates up to 700°C and differs only in the temperature range, which allows it to be calibrated as a DSC unit. In both units

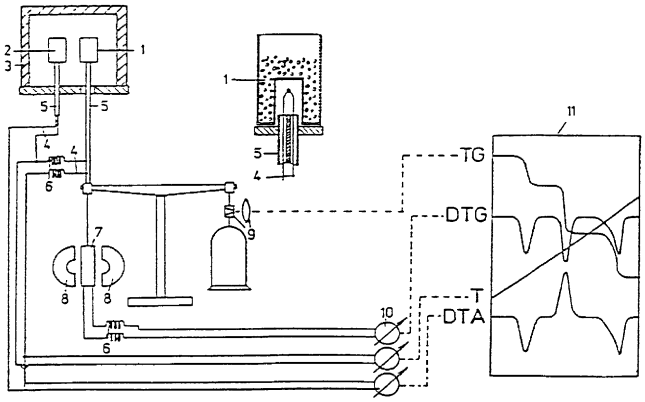

Figure 3. Derivatograph for simultaneous TG, DTG, and DTA.

special holders provide appropriate contact between the sample and the temperature sensor.

A similar TG-DSC manufactured by Netzsch contains the sample and the reference materials in a special crucible supported on a heat flux DSC plate. This system has a temperature range from −120 to 1500°C. The subambient temperature is achieved by use of a liquid nitrogen assembly. There is some difficulty in calibrating above 750°C so the equipment provided by Netzsch up to 2400°C is described as TG-DTA (Netzsch, 1997).

Setaram provides a TG-DSC system (described as SETARAM TG-DSC III) that uses symmetrical twin furnaces each with a Calvet microcalorimeter (Parlover, 1987).

The Use of Gas Analysis in Simultaneous Thermal Analysis Units

Even in the most obvious and simple process of material decomposition, there is a need to confirm the evolution of gaseous products in thermal decomposition as well as to identify the solid residue.

This applies in dehydrations,

$$CaC_2O_4 \bullet 2H_2O(s) \rightarrow CaC_2O_4(s) + 2H_2O(g) \qquad (1)$$

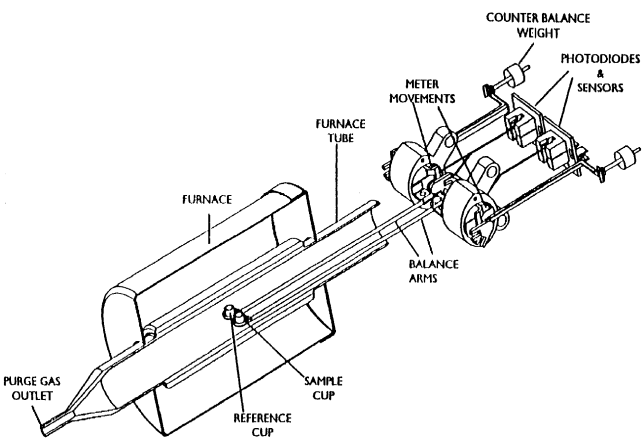

Figure 4. The SDT 2960 simultaneous TG-DTA (TA Instruments) showing a double-beam balance.

in decomposition of carbonates,

$$CaCO_3(s) \rightarrow CaO(s) + CO_2(g) \qquad (2)$$

in the dehydroxylation of hydroxides,

$$Mg(OH)_2(s) \rightarrow MgO(s) + H_2O(g) \qquad (3)$$

and in the gasification of carbon in air,

$$C(s) + O_2(g) \rightarrow CO_2(g) \qquad (4)$$

In fact, amorphous carbon gasified in air produces a mixture of CO and CO_2, the exact amounts depending on the sample and the experimental conditions. In many amorphous carbons, the surface complexes can produce water on gasification and small amounts of many volatile organic compounds.

The decomposition of calcium hydroxide often reveals small quantities of CO_2 being evolved, as a result of the $Ca(OH)_2$ partially carbonating on storage:

$$Ca(OH)_2(s) + CO_2(g) \rightarrow CaCO_3(s) + H_2O(g) \qquad (5)$$

In all combustion reactions of organic compounds, especially natural organic macromolecules such as starch or cellulose, the degradation process breaks down the sample into many simpler volatile organic compounds. Subsequent combustion then produces only CO, CO_2, and water.

The general themes outlined above serve to demonstrate the need to identify gaseous products in thermal analysis and explain why EGA is found so often in descriptions of simultaneous thermal analysis techniques.

A wide range of techniques are available to determine both the nature and the amount of gaseous products in thermal analysis, including GC, infrared (IR) spectroscopy or mass spectroscopy (MS), or using specific gas detectors. There is a real possibility that gases evolved as mixtures from the solid material degradation at high temperatures may themselves undergo gaseous reaction processes or gas condensation during transfer to the gas analysis device at room temperature. The gas analysis takes place some finite time after sampling, and in GC and certain other techniques the analysis takes place some time after the sampling process.

The following methods of analyzing gases in simultaneous thermal analysis can be noted: MS, GC, IR spectroscopy, condensation of volatile products, and chemical analysis.

The detectors used in GC may be used independently of chromatographic columns to detect gaseous product evolution. Furthermore, mass spectrometers and IR spectrometers may be used as detecting devices in gas analysis based on chromatography.

Mass Spectroscopy Used for Evolved Gas Analysis in Thermal Degradation Studies

The MS unit is generally used to identify and analyze gaseous samples from a TG, DTA, or DSC unit. The main difficulty is that the mass spectrometer works well under

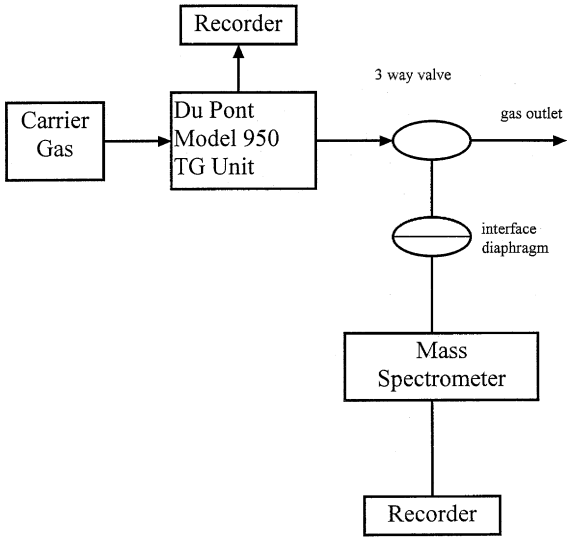

Figure 5. Schematic of a TG-MS unit.

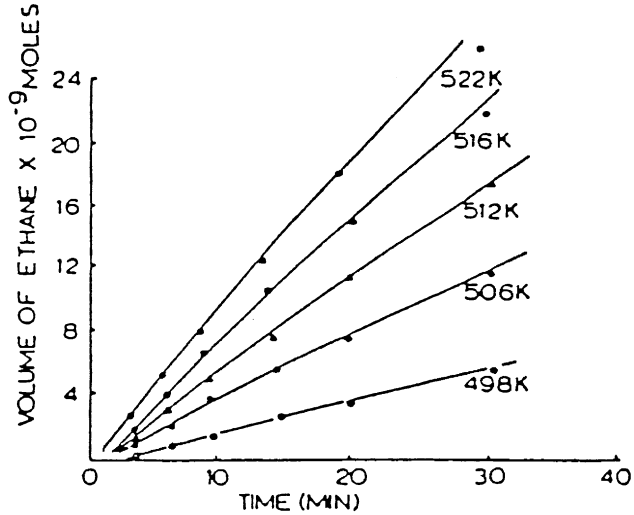

Figure 7. Volume of ethane evolved after various isothermal heating times at five temperatures of methanol chemisorbed on the nickel-silica catalyst.

vacuum but sampling is generally performed at 1 atm. There is a need for an efficient interface between the sampling of the gases at 1 atm and their analysis under high vacuum. A schematic of a typical TG-MS unit is shown in Figure 5. To eliminate side reactions, the interface should be located near the decomposing sample. Carbon monoxide presents problems because it has the same molar mass as N_2. It may be better in such cases to use IR methods (vide infra). Water also presents problems because it is difficult to degas from the equipment. A distinction must be drawn between (1) MS thermal analysis in which the samples are actually located in the mass spectrometer and (2) MS coupled to DTA, TG, or both. The latter is most often used by commercial instrument manufacturers. When the mass spectrometer is used in the laboratory for a variety of other uses, an economic solution to the problem is to collect the volatile products that have evolved and take the collected sample to the mass spectrometer. A scheme for such a set-up is shown in Figure 6. The equipment is simple, economical, and very suitable for kinetic evaluation (Galwey et al., 1975). Using this arrangement, the sample vessels (A, B, C, D, etc.) are closed, detached, and then presented to the mass spectrometer for analysis at different periods of time. Dollimore and Jones (1979) were able to study the desorption and decomposition of methanol on a supported nickel oxide oxidation catalyst. Figure 7 shows volumes of ethane evolved after various times of isothermal heating at five temperatures from methanol chemisorbed on a nickel-silica catalyst. Similar behavior was found for the production of methane and of ethene.

Equipment in which the sample is heated in the mass spectrometer has been described by Gallagher (1978) and by Price et al. (1978). This equipment had good temperature control, the sample decomposed under high vacuum, and the product gases had little time to react further, so side reactions could be eliminated. The disadvantage was that such results must not be expected to coincide with thermal decomposition studies carried out conventionally at 1 atm.

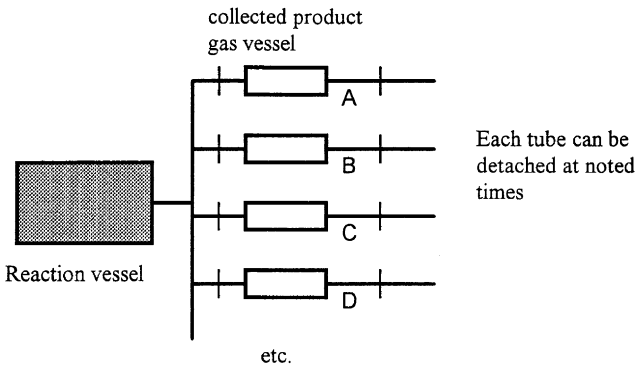

Figure 6. Schematic showing sample vessels that can be detached and presented to the mass spectrometer.

Evolved Gas Analysis and Chromatography

The choice of detector used in GC depends very much on the gases being analyzed. The four types of detectors usually used are the Katharometer (also called the thermal conductivity detector), the gas density detector, the ionization detector, and the infrared detector.

The Katharometer consists of two matched electronically heated filaments situated in the sample and reference streams and connected into a bridge circuit so that their resistances may be compared (see Fig. 8). The filaments are used as matched pairs on inlet and outlet gas systems. When the temperatures of the filaments are not equal, their resistances also differ and the unbalanced bridge gives a signal proportional to the temperature difference. The temperature of each filament depends on the operating conditions (e.g., the voltage across the filament, the temperature of the filament housing, and the

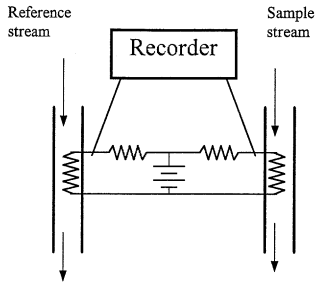

Figure 8. Katharometer.

rate of gas flow), the thermal conductivity of the gas stream, and the composition of the effluent gas.

If the operational factors are standardized, the bridge output is proportional to the difference in the thermal conductivity of the sample and reference streams; i.e., the evolved gas is detected by the change it imparts to the thermal conductivity of the carrier gas. The carrier gas is restricted because large differences are required between the thermal conductivity of the carrier gas and evolved product gases. In this context, it should be noted that hydrogen and helium have a high thermal conductivity while that for argon is low.

When using a gas density detector, the reference stream is usually split into two streams (see Fig. 9). If evolved gas is produced, the gas stream over the sample has a different density from that of the reference. The sensitivity of the measurement depends on the difference between the molecular weight of the evolved gas (M_e) and the molecular weight of the carrier gas (M_c). A peak area correction factor is given by

$$\text{Peak area} = \frac{M_c}{M_e - M_c} \tag{6}$$

Hence the molecular weight of the evolved gas must be known.

The advantage of the gas density method is that it can be used with corrosive gases. Any carrier gas can be used provided its molecular weight is different from that of the evolved gas.

Several types of ionization detectors are used in gas analysis, including argon triode and electron-capture detectors. In a flame ionization detector, the sample effluent is mixed with hydrogen and burned, and the resistance of the hydrogen flame is measured continuously with polarized (direct current) electrodes connected to an electrometer. Combustible materials introduced into the flame give enhanced ion concentrations. The resistance of the flame is reduced. These detectors are good for organic vapors but not for water vapor.

Gas detection devices utilizing IR spectroscopy have become so important that they are dealt with here as a separate subject (vide infra).

A problem with using gas-liquid chromatography (GLC) for EGA is that the gas cannot be passed continuously into the GLC column. A rapid intermittent injection procedure has to be utilized. Cold traps to trap out the volatile products or cold traps set at different temperatures to induce fractional condensation may be used. An alternative is to use an automatic feed device. However, the rate of sampling is conditioned by the retention time. Let t_r represent the retention time of the first component eluted from the column. Then the maximum number of samples that can be analyzed in GLC is given by

$$n = \frac{T_h - T_l}{\beta t_r} \tag{7}$$

where T_l and T_h are the low and high limits of the temperature range over which the gas analysis is attempted and β is the heating rate in degrees Celsius per minute. Therefore, it can be seen that the retention time determines the number of samplings.

Infrared Spectrometry

This section is labeled infrared spectrometry because equipment sold in the market allows these units to provide a wide range of gas analyses coupled with either TG or DTA. However, specialized and simple IR detectors can be used to analyze the concentration of evolved gases such as CO and CO_2. This involves nondispersive IR analyzers. Carbon monoxide and CO_2 are especially difficult gases to analyze accurately on a mass spectrometer. This type of IR spectroscopy is well suited to on-stream analysis (Morgan, 1977). It is not, however, restricted to the above gases but there is special merit in applying the method to them.

In an IR radiometer, the output from an IR source is split to pass through the sample and the reference effluent streams and the radiation intensities are then compared. Figure 10 shows this arrangement schematically.

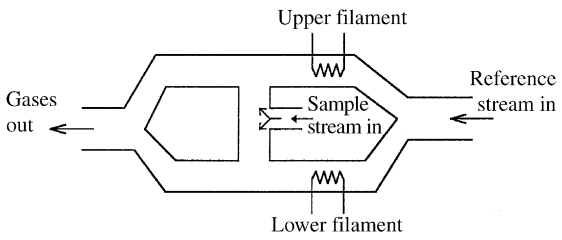

Figure 9. Gas density detector.

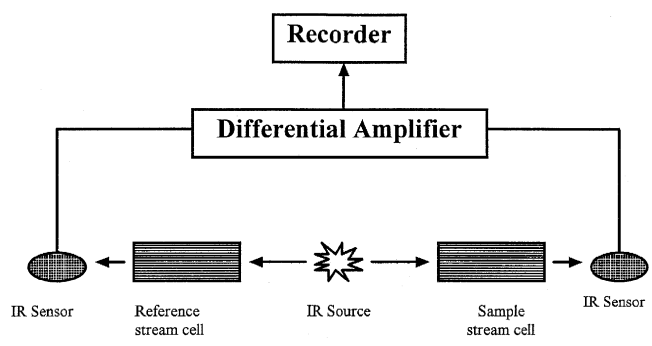

Figure 10. Schematic illustrating the IR radiometer.

Table 1. Wavelength, Path Length, and Amplification Required on a Miran 104 Portable Gas Analyzer Set to Detect CO_2, CO, and H_2O

	CO_2 Detection	CO Detection	H_2O Detection
Wavelength, μm	4.25	4.7	6.6
Path length, mm	1.5	14.5	5.5
Amplification	×2	×5	×5

An example of the use of IR detectors to analyze single gas may be quoted from Hoath (1983) where CO, CO_2, and H_2O were analyzed by such equipment using a Miran 104 portable gas analyzer. Details of the wavelength, path-length, and the signal amplification are given in the Table 1. Figure 11 shows the detection of H_2O, CO, and CO_2 in evolved gas stream passed over α-cellulose subjected to controlled heating program.

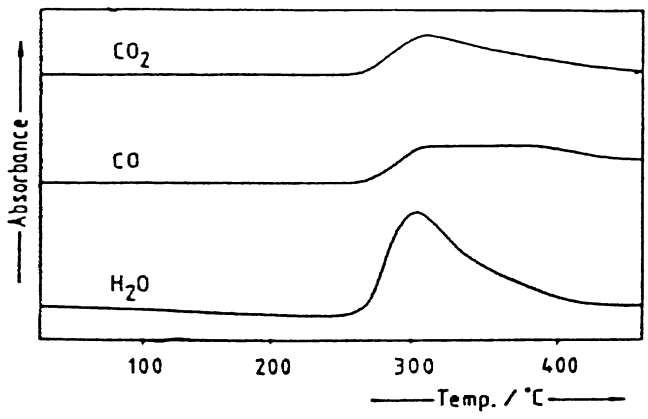
In dispersive IR spectrometers, the IR radiation from the IR source is focused by mirror optics onto the sample. To reduce IR absorption, the sample is placed in between windows of ionic materials. Dispersion of the radiation is achieved by a grating or prism and detection is usually achieved by thermocouple or pyroelectric detector units.

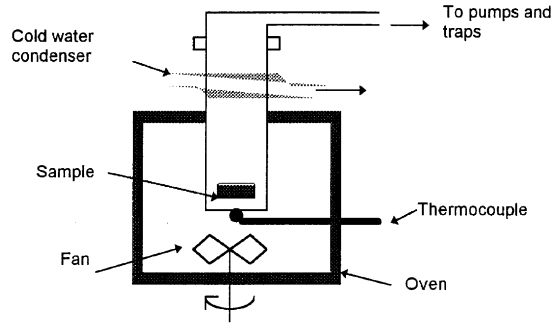
On the other hand, FTIR spectrometry uses similar sources, sampling units, and detectors but uses the interference of two IR beams controlled by a mirror system. The Fourier transform software then converts the interferogram to a spectrum of transmittance plotted against wave number. The software provided allows the production of a total evolution profile.

In attenuated total reflection (ATR) units the sample is in contact with a prism of high refractive index. Sample preparation is minimal, and thermal ATR instruments are available so that the sample spectrum can be monitored as a function of temperature.

Separate Collection of the Gases and Volatile Products

In many cases, the analysis of gaseous samples collected may not occur during the original thermal analysis experiment. The system can still be considered as simultaneous because the sampling was achieved at the same time as all the other measurements. The volatile products can be collected by passing the carrier gas through an absorber, a cold trap, or selective gas detectors or by fractional condensation. McNeill (1970, 1977) has described a technique called thermal volatilization analysis (TVA) in which the sample heated in vacuum (see Fig. 12) is progressively condensed by passage through traps at a series of low temperatures.





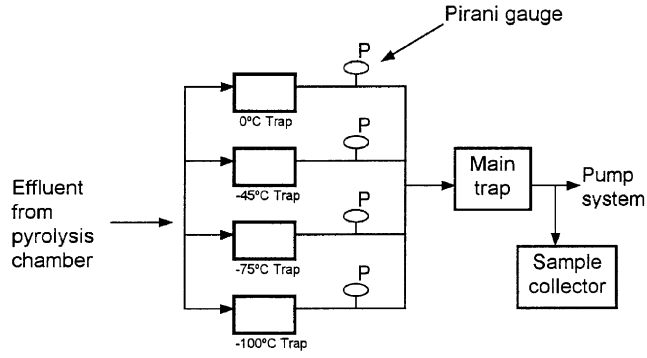


Figure 11. The EGA of α-cellulose decomposed in nitrogen.

the pyrolysis chamber

Trap system for differential condensation

Figure 12. Thermal volatilization equipment.

Chemical and Physical Methods of Evolved Gas Detection

In certain cases it has been found possible to identify and analyze product gases by chemical means. Evolved CO_2 is measured by noting the changes in conductivity of a barium hydroxide solution. Keattch (1964) used such a method to determine the CO_2 evolved on heating samples of hardened concrete through a predetermined temperature range.

Acids such as HCl from the degradation of polyvinylchloride can be detected and estimated by absorbing the gas in a solvent such as aqueous alkali and measuring the change in pH. McGhie et al. (1985) similarly dissolved evolved ammonia in water and used a continuous measurement of pH of a constantly renewed solution to monitor the evolution of the ammonia in the decomposition of $(NH_4 \bullet H_3O)_{1.67}\ MgO_{0.67}\ Al_{10.37}O_{17}$ (ammonium/hydronium beta alumina). This helped to identify multiple mass losses on the TG data as due to NH_3 below 400°C.

Gas-sensing membrane electrodes have been described for CO_2, NO_2, H_2S, SO_2, and NH_3 (Fifield and Kealey, 1990). Brinkworth et al. (1981) used a coulometric detector to measure SO_2 formed in coal combustion studies.

DuPont instruments (Hassel, 1976) made an electrochemical cell operated in a nitrogen atmosphere to analyze for water over a temperature range from 0 to 1000°C. This is a physical method. The moisture is transferred by nitrogen as a carrier gas into an electrolytic cell detector where it is absorbed by phosphorus pentoxide coated onto platinum electrodes. The water is electrolyzed and the product gases hydrogen and oxygen carried away by the gas stream. The electrolysis current is integrated and gives the amount of water directly. It forms the basis of method D4019 of the American Society for Testing and Materials (ASTM). A capacitance probe (Diefenderfer, 1979) and a dew point instrument (Gallagher et al., 1982) have been used to detect water.

METHOD AUTOMATION

The Role of the Digital Computer in Simultaneous Techniques

The computer plays many important roles in the present-day lifestyle and is a pivotal part of any research laboratory. Today laboratories are equipped with many computers, either standalone, or with network capability, or linked with one or more instruments.

The use of computers in the thermal analysis laboratory may be classified into four categories (Haines, 1995):

1. Controlling the operation of the instrument;
2. Making the collection, interpretation, storage, and retrieval of instrumental data easier for the operator;
3. Making calculation of the experimental results easy and accurate; and
4. Simulating the behavior of the instrument or the sample under special conditions.

The computer may be programmed to operate a variety of thermal analysis experiments. The tasks the computer can control may include programming the experimental conditions (received in input from the operator via a keyboard), loading the sample from a robotics autosampler into the analyzer, carrying out the run, acquiring the experimental signals, storing the data into a memory or onto disk, retrieving the stored data, analyzing the data according to a selected program, displaying the results, and then printing a report. The computer can also perform more than one task at the same time. For example, while the experiment is being carried out, the data stored in its memory can be retrieved and analyzed.

Data acquisition is far more frequent and precise than human capability and results in a huge array of signals. Again, calculations on this large amount of information are much quicker and more accurate with the aid of computer codes. The basic software may be sold as part of the instrument and the computer workstation, whereas the specific programs may be offered separately. To avoid paying for an expensive program, operators are well advised to analyze their data via a spreadsheet or other common mathematics programs or even to write their own program.

However, getting accurate results requires not only good computer programs and instruments but also proper experimental plans, sample preparation, and experimental conditions as well as critical thinking.

PROBLEMS

Disadvantages of Simultaneous TG-DTA

Equipment used for TG-DTA is generally operated at high temperatures, perhaps as high as 1650°C. This means that the normal calibration for enthalpy is inadequate as the limiting temperature for DSC is normally around 700°C. Equipment made available as TG-DSC can be used for accurate determination of heat input and output. Such measurement may not correspond with similar heat measurements on DSC or DTA alone. The reason is that DSC and DTA used alone are most often operated in a closed container to prevent loss of material during the study. Benzoic acid may be quoted as an example. This material is a standard reference material, and in a closed container the signal generated in a DSC unit can be used to indicate both the temperature and the constant required for enthalpy determinations using the known heat of fusion at the melting point. In TG-DTA or TG-DSC equipment, the DTA or DSC signal has to be generated from an open crucible, and it is easy to demonstrate that considerable sublimation occurs, which was suppressed in the conventional calibration of DTA or DSC alone when using a closed container.

A further disadvantage of this simultaneous signal is that in DTA or DSC alone, the best signal is generated with extremely small sample size. However, to accurately record the mass loss or gain in the sample, a minimum amount of sample has to be compatible with balance sensitivity and accuracy. This may mean that the mass of sample used to get a good TG signal is in excess of the smaller amount required by the DTA sensor to give the best DTA trace. This results in a compromise being needed between the optimal requirements for the two techniques.

Another disadvantage of TG-DTA is that a DTA unit requires specially shaped crucibles to fit over the thermocouple sensors. This precludes using TG in such a system to investigate shaped materials, i.e., films or granules, which will not fit into these specially shaped containers.

It should be noted that the highest sensitivity of a DTA experiment is achieved at a high heating rate whereas for TG a low heating rate will give the best result. Once again, a compromise has to be achieved in simultaneous TG-DTA units.

ELECTRICAL AND ELECTRONIC MEASUREMENTS

INTRODUCTION

Electrical and electronic measurements of materials are among the most powerful techniques available for materials characterization. These measurements can reveal information that completely characterizes the electrical transport properties of a material. Furthermore, modern instrumentation makes precision measurements and computer interfacing straightforward at reasonable cost.

Conductivity measurements yield information on the conductivity (resistivity) of materials and indirectly the mobility of current carriers. Resistivity is one of the most sensitive measures of the electrical transport in materials and can vary from 10^{12} ohm-cm for the best insulators to 10^{-6} ohm-cm in pure normal metals. Measurements include both DC and AC techniques. The Hall effect is a versatile technique, yielding such information as carrier concentrations and mobility, and indirectly, estimates of scattering mechanisms, all of which affect the conductivity as a function of temperature. Careful experimental technique can also yield information about the ionization energy of dopants contributing to the electrical transport. These measurements, used in conjunction with solid-state spectroscopies, can yield information about the band structure of semiconductors.

The capacitance-voltage (C-V) measurement is the standard method of "profiling" free carrier concentrations as a function of position below the surface. A C-V measurement is the most common of the carrier profiling techniques due to its simplicity and low cost. Deep level transient spectroscopy (DLTS) is a transient capacitance measurement, which permits identification of deep traps within the forbidden gap of a semiconductor. This highly effective and elegant measurement technique yields information regarding the energy levels of these defects, their capture and emission rates, and their concentration. Equipment for measuring both C-V and DLTS are often combined in a single apparatus. The use of C-V measurements, DLTS characterization, and the Hall effect yields a potent suite of characterization techniques that can completely describe the electronic transport properties of a material.

Semiconductor materials can be prepared with either electrons or holes as the majority current carriers. Most measurement techniques are useful in characterizing a single carrier type, or, at best, the net carrier type for mixed transport. It is often useful to gain insight into transport across a junction formed between materials at which the carrier type changes abruptly from holes (p-type material) to electrons (n-type material). Transport measurements at pn–junctions yield information on the transport of both holes and electrons and can determine transport mechanisms as a function of carrier (current) density.

The carrier lifetime is one of the most sensitive measurements available for detecting impurities in semiconductors. At its most sensitive, this materials-characterization technique is capable of detecting impurity concentrations as low as one impurity atom per 10^{12} host atoms. Techniques available for carrier lifetime measurements are varied and plentiful. Optical techniques rely upon excitation of the material from its equilibrium state, typically by using a short optical (laser) pulse, then carefully measuring the return to equilibrium. Because the optical excitation can be finely focused, these techniques have the added ability to spatially map a material.

Transport measurements, particularly those techniques that yield information on carrier concentration, mobility, and scattering mechanisms, are useful educational tools for undergraduate science and engineering students. Students can perform experiments that reinforce lectures in courses such as solid state physics, physical chemistry, materials science, and device physics. Furthermore, the use of such apparatus as high input-impedance electrometers, capacitance meters, phase-sensitive detectors, lasers for optical excitation, spectrometers, and photon counting equipment greatly enriches students' knowledge of the equipment and instrumentation used in the study of materials. Thus, experiments centered upon materials characterization prepares a student for graduate study or entrance into the work force. The student is equipped with both knowledge of electrical transport in materials and the sophisticated yet inexpensive equipment used in their measurement.

PETER A. BARNES

CONDUCTIVITY MEASUREMENT

INTRODUCTION

A material's conductivity, σ, (or the inverse property, resistivity, ρ, where $\rho = 1/\sigma$,) relates to its ability to conduct electricity. In metals, conduction of electricity is tantamount to conduction of electrons, which depends on charge density and on scattering of the electrons by the crystal lattice (phonons) or by lattice imperfections. In semiconductors, conductivity is determined by the number of available charge carriers (electrons or holes) and the carrier mobilities. Because of the different mechanisms for conductivity, its dependence on temperature also differs. Conductivity increases with increasing temperature for semiconductors (more carriers are generated) and it decreases with increasing temperature for metals (more scattering by the lattice). Conductivity also depends on

physical structure. In crystals, the crystal type and orientation affect conductivity because the electronic structure is intimately tied to the crystal structure. The size of the crystallites (grains) in polycrystalline materials is also important as it affects the scattering of carriers, and, at very small sizes may also affect electronic structure.

For a rectangular slab of homogeneous material with length L, width W, and thickness t (in m), the resistance, R (in ohms, Ω) along the length of the slab is related to the resistivity ρ in Ω-m by

$$R = \frac{\rho}{t}\frac{L}{W} \tag{1}$$

Units for conductivity are most often expressed in terms of siemens per meter (S/m), or by the equivalent terms 1/(Ω-m) and (less common) mhos/m. In the semiconductor field, the quantity ρ/t is termed sheet or surface resistance, R_s, and quoted in units of Ω per square. The number of "squares" of a thin-film conductor or resistor material is given by the ratio L/W.

The accurate determination of a material's conductivity can be critical for understanding material composition or device performance. The method used to determine conductivity depends on whether the material is a bulk sample or a thin film. This unit begins with a section on bulk measurements (see the discussion of Bulk Measurements). Two-point measurement using an inexpensive ohmmeter is perhaps the simplest approach, although its accuracy is limited and fairly large samples are required. A four-point bulk measurement is only slightly more complicated, but yields much better accuracy. Both of these methods are potentially destructive to the sample, depending upon how electrical contacts are made. These measurements are described along with advice on how to make the most accurate measurements in different situations.

In the second section (see discussion of Surface Methods), two thin-film approaches are presented which are most frequently used in semiconductor characterization: four-point probing and the Van der Pauw method. These methods require more expensive test equipment but are very accurate. Four-point probing requires little sample preparation, although it can cause damage to the surface. The Van der Pauw approach generally requires the creation of a test pattern on the surface but can take up less test space on a semiconductor than four-point probing.

In the third section (see discussion of Non-Contact Methods) measurement approaches are presented that offer the possibility of measurements without damaging the material. These approaches are not as well developed as the contact approaches described in the first two sections. Specialized equipment is required, and accuracy can be rather limited. Extracting conductivity values often depends upon qualitative comparison to standard data. The most widely used non-contact approach is the eddy current method, which can be used for metals and semiconductors, and which is implemented in a variety of ways. Also described in this section is the relaxation method.

The fourth section (see discussion of Microwave Techniques) briefly describes the most common microwave techniques that can be employed to determine conductivity information at high frequencies. Expensive test equipment is required for these approaches, along with specialized test apparatus to probe or hold the samples. The conductivity is not directly measured, but is typically extracted from loss tangent determination.

Some general characteristics for the methods described in these four sections are listed in Table 1.

Electrical conductivity (resistivity) is a fundamental materials property and as such finds its value incorporated in many complex and sophisticated treatments of materials

Table 1. General Characteristics for Conductivity Measurement Methods

Method	Favoredmaterial Type	Favored Material Form	Estimated Measurement Range	Estimated Frequency Range
Two-point measurement	High-resistance metals	Solid bar	10^2–10^9Ω	DC AC (<300 Hz)
Four-point measurement	Metals	Solid bar	10^{-7}–10^4 Ω	DC AC (<300 Hz)
Four-point probe	Semiconductor surface, thin metallic films	Planar solid	10^{-3}–10^5 Ω-cm	DC
Van der Pauw	Semiconductor surface, thin metallic films	Planar solid	10^{-3}–10^5 Ω-cm	DC
Eddy current	Metals, semiconductors, Insulators	Solid wafer, cylinder, containerized liquid	10^{-10}–10^{10} Ω-cm	10–10^6 Hz
Relaxation	Metals, semiconductors	Solid wafer, containerized liquid	10^{-8}–1 Ω-cm	10^{-1}–10^7 Hz
Coaxial probe	Semiconductors, insulators	Flat surfaced solid, liquid	10^{-3}–10^5 Ω-cm	2×10^8 to 2×10^{10} Hz
Transmission line	Semiconductors, insulators	Precision-machined sample, containerized liquid	10–10^6 Ω-cm	10^8–10^{10} Hz
Free-space radiation	Metals, moderate to high loss materials	Large area, flat solid sample	10–10^5 Ω-cm	10^9–10^{11} Hz
Cavity resonator	Metals, moderate to high loss materials	Machined solid sample	10–10^8 Ω-cm	5×10^8 to 10^{11} Hz

behavior. Whereas this value is often "plugged-in" from a table of known properties, it may also be deduced from the governing relations if other pertinent factors are known. This unit does not attempt to describe the universe of indirect measurement possibilities in regard to conductivity and resistivity.

BULK MEASUREMENTS

Principles of the Method

The conductivity or resistivity of a bulk sample is based on accurate measurement of both resistance and the sample dimensions. The resistance is the ratio of the voltage measured across the sample to the current driven through the sample or of the voltage applied across the sample to the measured current.

For a homogeneous bar of length, L, and uniform cross-section, A, the resistance, R, is related to the resistivity, ρ, by

$$R = \rho L/A \tag{2}$$

In Figure 1A, the bar is connected in a "two-point" arrangement, so-called since the measurement apparatus is connected to the bar at the two end-points. The measurement apparatus is represented by an ideal current source in parallel with a high-impedance voltmeter. The apparatus can also be realized using an ideal voltage source in series with a low-impedance ammeter, as shown in Figure 1B. A more realistic view of a two-point measurement using an ohmmeter is shown in Figure 2. A voltage source and a variable range resistor (R_r) supply the current, where R_r is adjusted to provide a convenient voltage across the voltmeter. Typical values of R_r range from 100 to 10,000 Ω. R_c represents series resistance in the cable and the wire-to-sample contact resistance. The resistance in the bar is calculated as

$$R = \frac{(R_r V_m/V_s)}{[1 - (V_m/V_s)]} - 2R_c \tag{3}$$

A long bar of resistive material is desirable to minimize the effect of extra resistance in the measurement system or inaccurate length measurement.

A more accurate method, especially for low-resistance materials, is provided by the "four-point" arrangement, a simple schematic of which is shown in Figure 3. The resistance now is a function of the length between the voltage probes, L', or

$$R = \rho L'/A \tag{4}$$

The current through the high-impedance voltmeter is very small and minimizes the effect of cable and contact resistance. The four-point approach, when used with a micro-ohmmeter, is capable of measuring down to 10^{-7} Ω.

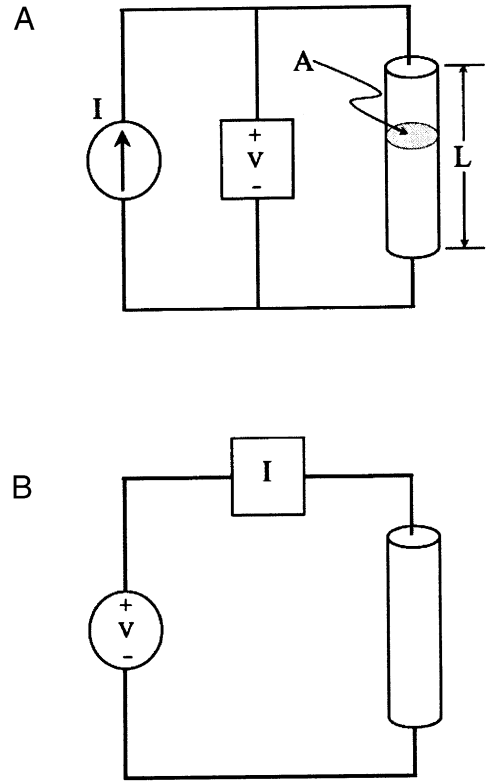

Figure 1. Two-point measurement of a resistive bar of length, L, and cross-sectional area, A, using (**A**) an ideal voltmeter in parallel with an ideal current source, and (**B**) an ideal ammeter in series with an ideal voltage source.

Practical Aspects of the Method

The two-point approach is most accurate for high-resistance measurements where the usually small R_c term (generally less than 2 Ω) can be ignored. These measurements are often made using ohmmeters contained within multimeters capable of measuring voltage, current, and resistance. The ohmmeter within the multimeter performs like the measurement circuits shown in Figure 1, and is realized using a variety of circuit implementations [see, e.g., Witte (1993) or Coombs (1995)]. Inexpensive multimeters (<$50) can measure resistance between 0.1 Ω and

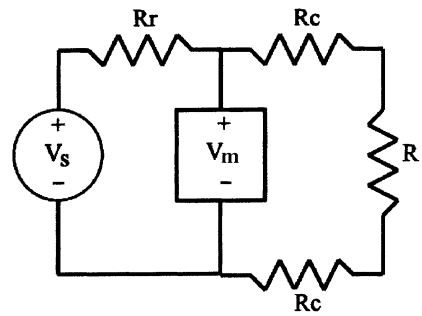

Figure 2. Two-point ohmmeter measurement circuit, which includes contact and cable resistance, R_c.

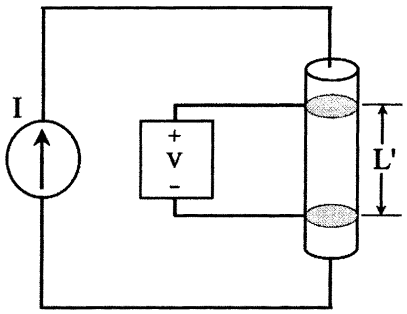

Figure 3. Four-point measurement circuit drives a known current through the sample, and a high-impedance voltmeter measures voltage drop along a designated length, L'.

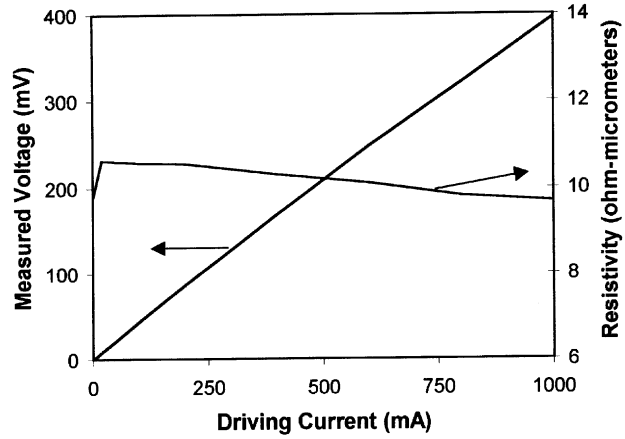

Figure 4. Measured voltage across a 2.5-cm length section of graphite rod (0.0889 cm diameter) versus the driving current, along with the extracted resistivity.

10 kΩ. More expensive meters (~$1000) can measure 100 μΩ to 100 MΩ and are provided with an extra pair of terminals for performing four-point measurements, described below. Dedicated ohmmeters can also be purchased for special measurements. For instance, high-resistance meters are capable of measurements up to 10^9 Ω. These meters require large, precision voltage sources (in the vicinity of 1000 V) along with very low−current measurement capability, perhaps as low as 10^{-15} A. Also, since ohmmeters have internal capacitance, C, the large time constant, $\tau = RC$, for a high-resistance measurement can be excessive and it may be extremely difficult to make a steady-state measurement.

At low resistance, the cable and contact resistance can seriously degrade measurement accuracy. Some ohmmeters have a "zero-adjust" feature, where the test leads are shorted together and the meter is adjusted to zero. Such an adjustment compensates for cable resistance and for measurement drift internal to the ohmmeter. In a related approach, the user can measure a short circuit, perhaps employing the same electrical contact strategy as for the actual test device, in order to determine R_c. Another approach to account for R_c is to make measurements on a pair of devices having the same cross-section but different lengths. The difference in resistance between the two measurements should result in the resistance due only to the difference in length of the bar.

In the four-point approach, it is im portant to keep the voltage contacts very thin so an accurate measurement of L' can be made. Voltage probes should be well away from the current probes to avoid "spreading resistance" interference. This spreading resistance is a consequence of the current spreading radially from the probe tip into the sample, with a considerable amount of resistance encountered near the tip. As a rule of thumb, current and voltage probes should be separated by a distance of at least 1.5× the thickness of the measured sample (ASTM B193, 1987).

As an illustration of bulk measurement, a 6-cm-long graphite rod of diameter 0.0889 cm was measured at room temperature using a two-point ohmmeter. Measurement of 1.9 Ω on a 5.8-cm length (distance between the two mechanical clips) yielded a resistivity of 20 Ω-μm. No attempt was made to remove cable and contact resistance from this measurement. Next, a four-point measurement was made using a driving current ranging from 1 mA up to 1 A that was connected to each end of the rod, and a voltmeter connected at points 2.5 cm apart near the center of the rod. The measured voltage as a function of driving current is shown in Figure 4. The resistivity from this four-point approach is ~10 Ω-μm. This value is about half of that measured using the two-point approach, indicating the presence of considerable contact and/or cable resistance that is avoided by the four-point approach. There is slight curvature on the voltage plot, resulting in a measured drop in resistivity at higher currents. This can be explained by graphite's decrease in resistance as a function of temperature, since the rod heats up as more current is driven through it.

Method Automation

A number of companies make digital multimeters, current sources, and voltage meters with GPIB (general purpose interface bus) connections suitable for test control and automatic data recording. The software package LabView (National Instruments Corp.) is routinely employed to handle such measurements.

Sample Preparation

Making an accurate resistance measurement requires good electrical contacts to the sample. A minimum spacing between voltage and current contacts of 1.5× the cross-sectional perimeter of the sample is recommended (ASTM B193, 1987), and care should be taken to prevent any alternative conductive path (for instance, a solder bridge between a current and a voltage probe). Making good electrical contacts often consists of mechanical contact (i.e., alligator clips or probing with a sharp probe tip) or soldering a wire to a clean surface on the sample. For troublesome surfaces, silver paint or indium (a soft metal) can provide a contacting layer.

Problems

Even with good contacts and a good four-point measurement setup, other factors should be considered. For instance, appreciable power dissipation in the resistive material can result in heating that will affect the conductivity value. Also, some resistive materials are non-ohmic, meaning the current is not a linear function of the voltage. This nonlinearity is most often noticed at high voltage levels. For semiconductors, carriers may be generated by light or by high-frequency radiation. This excess carrier generation can be avoided by testing semiconductors in an adequately shielded dark chamber.

SURFACE MEASUREMENTS

Principles of the Method

The two most common approaches for measuring sheet or surface conductivity are the four-point probe method and the Van der Pauw method. Both approaches are similar to four-point measurements in that current is driven between a pair of probes or connections and the voltage is measured across the other two. The four-point probe method is most often realized by contacting a flat film surface with four equally spaced in-line probes (Valdes, 1954; Hall, 1967). The Van der Pauw method can measure resistivity of small, arbitrarily shaped layers where the four contacts are typically placed around the periphery of the sample.

The four-point probe method, as indicated in Figure 5, has four equally spaced in-line probes with probe tip diameters small compared to the probe spacing, s. An ohmic contact is assumed between the probe tip and the sample. Current is most commonly passed between the outer two probes, and the voltage difference is measured between the two inner probes. Resistivity in a four-point probe measurement is given by

$$\rho = 2\pi s F V/I \tag{5}$$

where F is a correction factor. For placement of probes near the center of a medium of area large relative to the probe spacing, and of a semi-infinite thickness, the correction factor, F, is unity. However, few practical measurements are made on semi-infinitely thick media. The factor F accounts for more realistic thickness and other nonidealities (Combs and Albert, 1963; Albert and Combs, 1964; Albers and Berkowitz, 1985). This factor is itself the product of a factor to correct for sample thickness, F_1, and a factor to account for lateral dimensions of the wafer, F_2. For a sample of conductive layer thickness, t, with a conducting bottom side

$$F_1 = \frac{t/s}{2\ln(\cosh(t/s)/\cosh(t/2s))} \tag{6}$$

If the bottom side is nonconducting,

$$F_1 = \frac{t/s}{2\ln(\sinh(t/s)/\sinh(t/2s))} \tag{7}$$

For a circular wafer of diameter, d, the correction factor F_2 is

$$F_2 = \frac{\ln 2}{\ln 2 + \ln\left[\dfrac{(d/s)^2+3}{(d/s)^2-3}\right]} \tag{8}$$

Note that F_2 approaches unity for $d > 40s$.

Locating the probes closer than four probe spacings from the wafer edge can also result in measurement error. Correction factors to account for edge proximity can be found in Schroder (1990).

The Van der Pauw method can determine the resistivity of small, arbitrarily shaped layers and generally requires less surface area than the four-point probe method (Van der Pauw, 1958). It is often used in integrated circuit processing. The method considers four small contacts placed around the periphery of a homogeneous, uniform thickness (t) sample, as indicated in Figure 6. In this figure, a resistance $R_{ab,cd}$ is determined by driving a current from point a to b and measuring the voltage from point c to d, or

$$R_{ab,cd} = \frac{|V_c - V_d|}{|I_{ab}|} \tag{9}$$

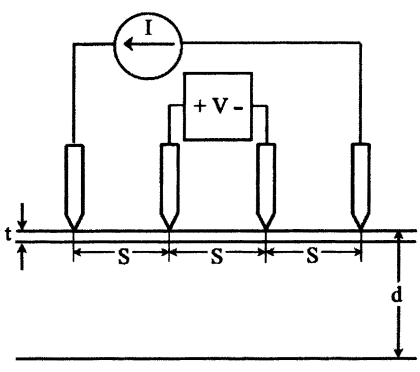

Figure 5. In-line four-point probe measurement of a conductive film of thickness, t, uses a known current source, high-impedance voltmeter, and spring-loaded sharp probes.

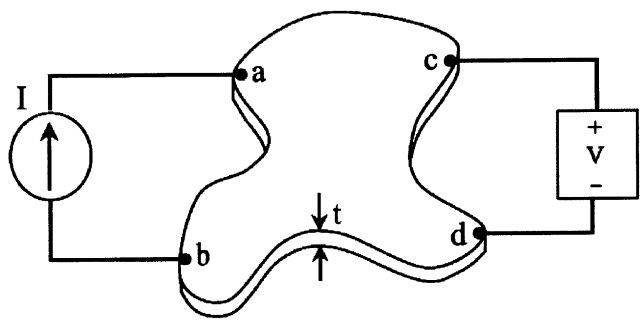

Figure 6. Van der Pauw measurement of an arbitrarily shaped sample uses a known current and a high-impedance voltmeter.

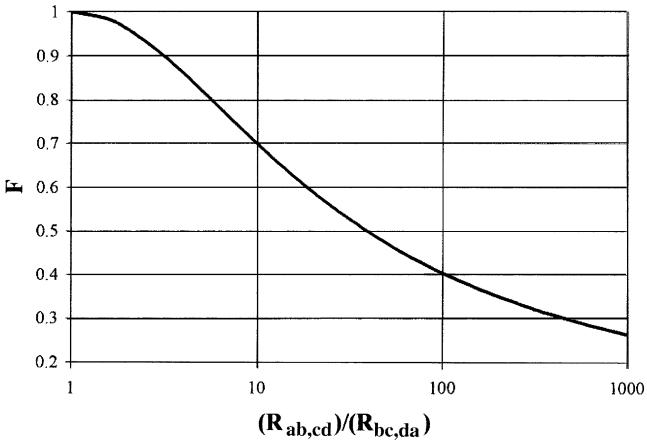

Figure 7. Van der Pauw function, F, plotted versus resistance ratio.

Using a conformal mapping approach Van der Pauw shows that

$$\exp\left[\frac{-\pi R_{\mathrm{ab,cd}} t}{\rho}\right] + \exp\left[\frac{-\pi R_{\mathrm{bc,da}} t}{\rho}\right] = 1 \qquad (10)$$

Solving for resistivity gives

$$\rho = \frac{\pi t}{\ln 2} \frac{R_{\mathrm{ab,cd}} + R_{\mathrm{bc,da}}}{2} F \qquad (11)$$

where the value of F is given by

$$\frac{R_{\mathrm{ab,cd}} - R_{\mathrm{bc,da}}}{R_{\mathrm{ab,cd}} + R_{\mathrm{bc,da}}} = \frac{F}{\ln 2} \operatorname{arccosh}\left[\frac{\exp(\ln 2/F)}{2}\right] \qquad (12)$$

This equation is used to plot F as a function of the resistance ratio $R_{\mathrm{ab,cd}}/R_{\mathrm{bc,da}}$ in Figure 7.

Equation 11 is simplified for 4-fold symmetrical shapes. For instance, the rotation of the structures in Figure 8 by 90° should result in the same measured resistance for a uniform-thickness, homogeneous film with identical contacts. In such a case, $F = 1$ and

$$\rho = \frac{\pi t}{\ln 2} R_{\mathrm{ab,cd}} = 4.532 t R_{\mathrm{ab,cd}} \qquad (13)$$

Practical Aspects of the Method

Like the four-point method used for bulk resistivity measurements, separating the current source from the high-impedance voltage meter avoids errors associated with contact resistance. Also, when considering semiconductor measurements, sufficient separation between the current and voltage probes is required so that minority carriers injected near the current probes recombine before their presence can be felt at the voltage probes. The probes

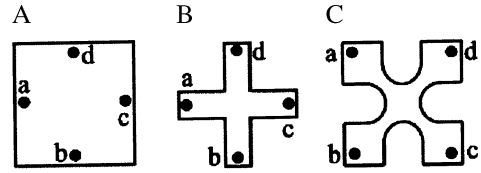

Figure 8. Common Van der Pauw structures: (**A**) square (contacts placed on edges, or placed on each corner), (**B**) "Greek Cross," and (**C**) clover leaf.

themselves have a tightly controlled spacing, typically 1 mm ± 0.01 mm, and the probe tips are individually spring-loaded with a force typically between 1 and 2 N to minimize damage to the film surface during probing. Hard tungsten probe tips are common, but osmium tips are also available, which can make good contact when heated on a semiconductor. A typical measurement range for such a system is 0.001 Ω-cm to 1000 Ω-cm.

In Van der Pauw measurements, it is common to calculate resistivity from two sets of measurements ($R_{\mathrm{ab,cd}}$ and $R_{\mathrm{bc,da}}$). For uniform samples with good contacts, the same results should be measured. The square pattern shown in Figure 8A, or a circular pattern with four points equidistant about the periphery, can be made very small for integrated-circuit film measurements and are often used in practice. However, because of probe alignment difficulties and problems making ideal probe to sample contacts, the "Greek Cross" of Figure 8B or the clover leaf structure of Figure 8C is often used. These shapes isolate the contacts and reduce the error encountered for finite-sized probe tips that are not located all the way out to the periphery of the sample.

Method Automation

As with bulk measurements, four-point probes are routinely connected to current sources and voltage meters for automated measurements. Four-point probing systems typically contain an adjustable constant current source used in conjunction with a high-impedance voltmeter. These systems automatically test and average both forward and reverse signals to reduce errors from thermal effects and rectifying contacts. More elaborate Van der Pauw measurement apparatus will make multiple measurements ($R_{\mathrm{ab,cd}}$ and $R_{\mathrm{bc,da}}$) and average the results.

Problems

The measured surface resistance depends on the doping profile, which affects both carrier concentration and carrier mobility. The conductivity of such a doped semiconductor is therefore a function of depth into the semiconductor. Measuring the surface resistance of a doped semiconductor assumes that the substrate below the junction depth is much more resistive than the layer to be measured. If the substrate is appreciably conductive, then a surface resistance measurement can still be made by forming a reverse-biased diode with the substrate.

NON-CONTACT METHODS

Principles of the Method

Contact-free test methods are useful when electrical contacts are difficult to make or when the sample must not be damaged. Also, a contactless measurement can be much quicker, since the time it takes to make contacts is eliminated. Eddy current approaches and relaxation techniques are often used for non-contact measurement. While such methods are not as accurate as the contact approaches discussed above, errors below 5% are achievable.

The most widely used approach for contactless measurement of conductivity is the eddy current method (ASTM E1004, 1991). In its most straightforward realization, an alternating current-carrying coil is placed close to a conductive sample. The magnetic fields generated by the coil induce circulatory currents, called eddy currents, in the sample which act to oppose the applied magnetic field. Small impedance changes are then measured in the coil as it is loaded by the conductive sample. The measured impedance is a function of sample conductivity, and also of the sample's mechanical structure near the surface. In fact, eddy current testing is routinely used to inspect the mechanical condition of conductive surfaces (Cartz, 1995).

Figure 9 illustrates the general measurement approach. The coil is driven by a sinusoidal current source, and measurement with a high-impedance voltmeter determines the coil impedance, $Z = V/I$. The current through the coil induces eddy currents in the conductive sample which act to oppose the change in magnetic flux. The induced eddy currents are in a plane parallel to a plane containing the coil loops and are a function of sample conductivity, magnetic permeability, and thickness, along with driving coil properties such as number of turns and distance from the sample. The coil itself may also be wrapped around or contained within a ferrite block to enhance the magnetic field.

An equivalent circuit for the simple test setup is shown in Figure 10, where the mutual inductance term M accounts for field coupling into the sample, which appears as a series RL circuit.

It can be shown (Cartz, 1995) that the impedance looking into the circuit is

$$Z = R_T + jX_T = \left[R + \frac{\omega^2 M^2 R'}{R'^2 + \omega^2 L'^2}\right] + j\left[\omega L - \frac{\omega^3 M^2 L'}{R'^2 + \omega^2 L'^2}\right] \quad (14)$$

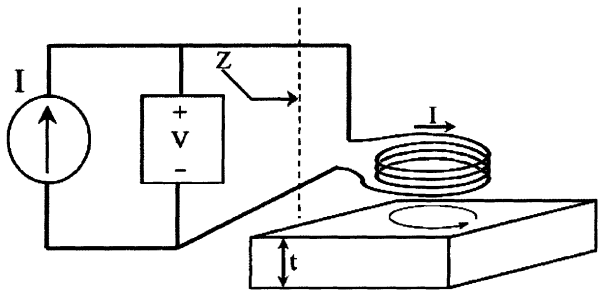

Figure 9. Single coil eddy-current measurement circuit. The impedance, Z, looking into the coil is changed by eddy currents induced in the sample.

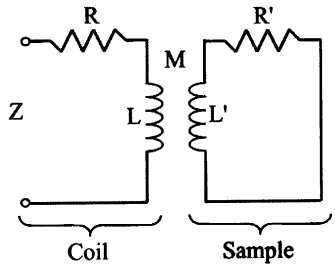

Figure 10. Equivalent circuit for the single coil eddy-current measurement approach.

where R_T and X_T represent the total real and imaginary parts of the impedance, respectively, and j is the imaginary square root of (-1). A plot of X_T versus R_T for a series of samples traces a conductivity curve as shown in Figure 11. This is a comparison method where samples of known conductivity are plotted, and the test sample behavior is then inferred from its location on the chart.

Another non-contact method is the relaxation approach, where a voltage step function applied to a resistive-reactive circuit will result in an exponential response. For instance, when the switch in Figure 12 is opened, the capacitor discharges through the resistor such that

$$V_r(\tau) = V_s \exp(-\tau/RC) \quad (15)$$

When time τ equals one "RC time constant," the voltage has dropped to e^{-1} of its initial value. Most often, this approach is used with a known value of resistance in order to measure the reactive component, but knowing the reactive component allows computation of the resistance. This is illustrated in Figure 13, where the voltage V_R from Figure 12 is initially charged to 1 V, and at time $\tau = 0$ the switch is thrown which allows this voltage to discharge through a 1-μF capacitor. The relaxation for three different resistance values is shown.

This relaxation approach has been used in conjunction with eddy currents where the sample is excited and the fields are measured as they decay (Kos and Fickett, 1994).

Practical Aspects of the Method

The eddy current approach requires two or more calibration standards covering the range of expected sample

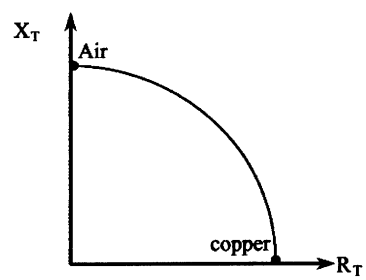

Figure 11. Impedance plane chart showing a typical conductivity curve.

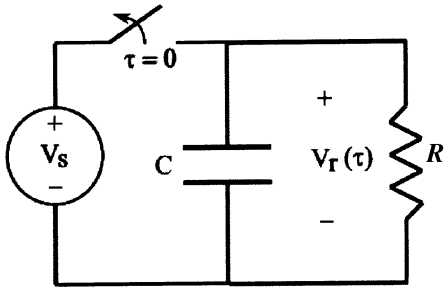

Figure 12. RC network used in relaxation method.

conductivity. Test conditions, such as driving current and frequency, must be the same for both calibration and test samples. The sample thickness and the distance between the coil and the sample surface (termed the "lift-off") must be carefully controlled. Finally, the coil should not be placed within two coil diameters of a sample discontinuity (such as a hole or edge).

In the simple method presented, the driving coil is also used for measurement. Improved eddy-current probes separate the driving and measuring coils, using them to sandwich the test sample. Since very little current is in the measurement coil, eddy currents induced in the sample are essentially all from the driving coil. The measurement coil sees fields from both the driving coil and from the eddy currents in the sample. For best sensitivity, the driving coil fields can be removed from the measurement using a lock-in amplifier circuit (Crowley and Rabson, 1976). Further improvement in the measurement circuit uses an additional set of coils for compensation. Such an approach has been used with miniature radio frequency (RF) coils to provide resistivity mapping with a 4 mm spatial resolution (Chen, 1989). An interesting variation on this method uses a driving coil and a pair of resonant coils to monitor in situ aluminum thin films deposited by chemical vapor deposition (Ermakov and Hinch, 1997).

The magnitude of the eddy currents attenuate by $e^{-y/\delta}$ as they penetrate a depth y into the sample, reaching a value of e^{-1} of the surface value at one skin depth, δ, given by

$$\delta = 1/\sqrt{\pi f \mu \sigma} \tag{16}$$

where f is frequency and μ is sample magnetic permeability. For a single-coil system, the effect of thickness is negligible for samples that are at least 2.6 skin depths thick. Note that for measuring surface defects, or the resistivity near the surface, higher frequencies may be employed. For a system where the measuring coil is on the other side of the sample from the driving coil, samples thinner than a skin depth are required.

The eddy current method is also used to measure conductivity of cylindrical samples. This is done by comparing the impedance of the coil with and without a cylindrical sample inserted (Zimmerman, 1961). Other approaches have relied on mutual inductance measured between a driving coil and measurement coil wrapped around the cylindrical sample (Rosenthal and Maxfield, 1975).

In the relaxation approach, the step function excites all possible resonances, with the one showing the longest decay time being proportional to the sample resistivity. It may be necessary to determine this time constant with a curve-fitting routine after sufficient time has passed for the other resonances to subside. Also, the time constant for the measurement coils must be much shorter than the sample time constant. This approach is most often used for low-resistivity samples (metals with $\rho < 10^{-4}$ ohm-micrometer), since otherwise the time constant is excessive.

A relaxation approach can also find semiconductor resistivity, provided the electrical permittivity is known. Here, a semiconductor wafer is inserted between conductive plates to form a parallel resistive-capacitive circuit. A step voltage is applied to the capacitors, and the current is measured versus time to arrive at an RC time constant equal to the product of the sample resistivity ρ and electrical permittivity, ε, called the "space charge relaxation time." Details of such a procedure used to map the resistivity profile across a gallium arsenide wafer are provided in Stibal et al. (1991).

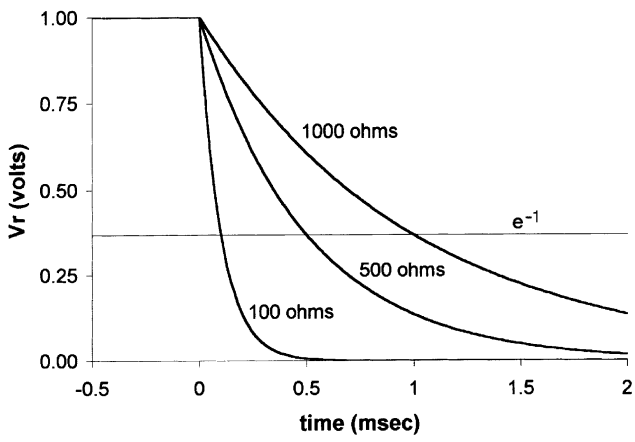

Figure 13. Response of the RC network with a 1-μF capacitor that has been initially charged to 1 V. The relaxation is shown for three values of resistance. The line at 0.368 indicates when the voltage has decayed to e^{-1} of its initial value.

MICROWAVE TECHNIQUES

Principles of the Method

A number of approaches exist to determine dielectric sample conductivity at high frequencies. The primary approaches use open-ended coaxial probes, coaxial or waveguide transmission lines, free-space radiation, and cavity resonators. Scattering parameter measurements are made using vector network analyzers, which are available at considerable expense, to perform measurements up to 10^{11} Hz. These scattering parameters can be related to the sample's electrical permittivity and loss tangent, from which the conductivity can be extracted.

From Maxwell's equations for time harmonic fields

$$\nabla \times \mathbf{H} = (\sigma + j\omega\varepsilon)\mathbf{E} \tag{17}$$

where E and H are the electric and magnetic fields, respectively, and ω is the angular frequency. Here we consider the conductivity σ and the permittivity ε within the dielectric. It is convenient to express Equation 17 as

$$\nabla \times \mathbf{H} = j\omega\varepsilon_c \mathbf{E} \tag{18}$$

where ε_c is a complex permittivity

$$\varepsilon_c = \varepsilon - j\frac{\sigma}{\omega} \tag{19}$$

Plotting the imaginary part of Equation 19 versus the real part reveals where the term loss tangent, tan δ, arises

$$\tan\delta = \frac{\sigma}{\omega\epsilon} \tag{20}$$

Here δ is the angle made with the real axis. Note that this δ has nothing to do with skin depth, which inconveniently shares the same symbol. The term loss tangent is typically applied when discussing dielectric materials, for which a small value is desirable.

Extracting the complex permittivity from scattering parameter data is far from trivial and is almost always performed using software within the network analyzer or in post-processing. In the cavity resonator, waveguide transmission line, and free space approaches, it is also possible to extract the material's complex permeability from the measured scattering parameters (Application Note 1217; see Literature Cited). This can be useful for the study of magnetic materials.

Practical Aspects of the Method

The four general approaches are briefly described below, along with suitable references. Of particular interest are the publications of Bussey (1967) and Baker-Jarvis et al. (1992).

Coaxial probes. In this approach, the open end of a coaxial probe is placed against the flat face of a solid sample as shown in Figure 14A. The probe may also be immersed in a liquid sample. The fringing fields between the center and the outer conductors are affected by the sample material. Complex permittivity is extracted from measurements of the reflection scattering parameter S_{11}. This approach is typically used to measure complex permittivity over a frequency range from 2×10^8 Hz up to 2×10^{10} Hz, and has the advantage that no special sample preparation is required. In addition, stainless steel coaxial probes have performed at temperatures up to 1000°C (Gershon et al., 1999).

Transmission lines. In the various transmission line methods, a material sample is snugly inserted into a section of coaxial transmission line, rectangular waveguide, or circular waveguide (Srivastava and Jain, 1971; Ligthart, 1983; Wolfson and Wentworth, 2000). More than one measurement is required for extraction of complex permittivity data from one port measurements. This can be accomplished by using more than one length of sample or by terminating the guide containing the sample in more than one load. The measured complex reflection coefficients can be manipulated to extract complex permittivity. Two-port measurements can be performed on a single sample where in addition to reflection, the transmission properties are measured. Precise machining of the samples to fit inside the transmission line is critical, which can be somewhat of a disadvantage for the coaxial approach (shown in Figure 14B) where an annular sample is required. An advantage of the coaxial approach is that measurements can be made over a much broader frequency range than is possible with the waveguide procedure. Common problems for the transmission line techniques include air gaps, resonances at sample lengths corresponding to half wavelengths, and excitation of higher-order propagating modes.

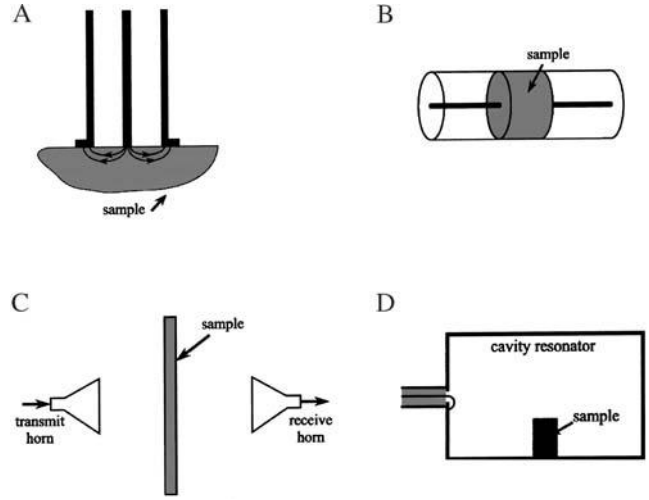

Figure 14. Microwave measurement approaches: (**A**) open-ended coaxial probe in contact with sample, (**B**) sample inserted into coaxial transmission line, (**C**) free-space approach where sample is placed between horn antennas, and (**D**) sample placed within a cavity resonator.

Free-space radiation. Microwaves are passed through material samples using transmitting and receiving antennas as shown in Figure 14C. In addition to measurements through the sample, the transmitting and receiving antennas may be placed at angles on the same side of the sample and a reflection measurement taken. The samples used in free-space techniques must be fairly large, with flat surfaces. Measurement approaches and data processing proceeds as with the transmission line approaches. The free-space approach is a noncontacting method that can be especially useful for making measurements at high temperature or under harsh environmental conditions. It has been employed in measurements ranging from 2×10^9 Hz up to 1.1×10^{11} Hz (Otsuka et al., 1999).

Cavity resonators. Here, a sample of precisely known geometry is placed within a microwave cavity and changes in the resonant frequency and the resonator Q are measured and processed to yield the complex permittivity (Kraszewski and Nelson, 1992). As shown in Figure 14D,

a coaxial probe inserted into the center of one wall of the cavity is used to supply energy for resonance. If the sample dimensions are precisely known, and if calibration standards of the same dimensions are available, then this approach can yield very accurate results for both complex permittivity and complex permeability, although it tends to have limited accuracy for low-loss materials. It has been employed in measurements ranging from 5×10^8 Hz up to 1.1×10^{11} Hz.

ACKNOWLEDGMENT

The author would like to thank Professor Peter A. Barnes for his helpful suggestions on this work.

HALL EFFECT IN SEMICONDUCTORS

INTRODUCTION

The Hall effect, which was discovered in 1879 (Hall, 1879), determines the concentration and type (negative or positive) of charge carriers in metals, semiconductors, or insulators. In general, the method is used in conjunction with a conductivity measurement to also determine the mobility (ease of movement) of the charge carriers. At low temperatures and high magnetic fields, quantum effects are sometimes evident in lower dimensional structures; however, such effects will not be considered here. Also, this unit will concentrate on semiconductors, rather than metals or insulators, although the same theory generally applies (Gantmakker and Levinson, 1987).

Three, strong advantages of Hall effect measurements are ease of instrumentation, ease of interpretation, and wide dynamic range. With respect to implementation, the only elements necessary, at the lowest level, are a current source, a voltmeter, and a modest-sized magnet. The carrier concentration can then be calculated within a typical accuracy of 20% without any other information about the material. In our laboratory, we have measured concentrations ranging from 10^4 to 10^{20} cm^{-3}. Also, the type (n or p) can be unambiguously determined from the sign of the Hall voltage.

Competing techniques include capacitance-voltage (C-V) measurements to determine carrier concentration (see CAPACITANCE–VOLTAGE (C-V) CHARACTERIZATION OF SEMICONDUCTORS); thermoelectric probe (TEP) measurements to determine carrier type; and magnetoresistance (MR) measurements to determine mobility (Look, 1989). The C-V measurements have an advantage of depth profile information but a disadvantage of requiring a Schottky barrier. The TEP measurements require a temperature gradient to be imposed and are often ambiguous in the final conclusions. The MR measurements require a high mobility μ or high magnetic field strength B to implement, because the signal varies as μ^2B^2 rather than μB, as in the Hall effect. Further comparisons of these techniques, as well as others, can be found in monographs by Runyan (1975), Look (1989), and Schroder (1990).

PRINCIPLES OF THE METHOD

A phenomenological equation of motion for electrons of charge $-e$ moving with velocity $\mathbf{v}$ in the presence of electric field $\mathbf{E}$ and magnetic field $\mathbf{B}$ is

$$m^*\dot{\mathbf{v}} = -e(\mathbf{E} + \mathbf{v} \times \mathbf{B}) - m^*\frac{\mathbf{v} - \mathbf{v}_{eq}}{\tau} \tag{1}$$

where m^* is the effective mass, $\mathbf{v}_{eq}$ is the velocity at equilibrium (steady state), and τ is the velocity or (momentum) relaxation time, i.e., the time in which oscillatory phase information is lost through collisions. Consider a rectangular sample, as shown in Figure 1, with an external electric field $\mathbf{E}_{ex} = E_x\mathbf{x}$ and magnetic field $\mathbf{B} = B_z\mathbf{z}$. Then, if no current is allowed to flow in the y direction (i.e., $v_y = 0$), the steady-state condition $\dot{\mathbf{v}} = 0$ requires that $E_y = -v_xB_z$, and E_y is known as the Hall field. For electron concentration n, the current density $j_x = nev_x$, and thus, $E_y = -j_xB_z/en \equiv -j_xB_zR_H$, where $R_H = -1/en$ is the Hall coefficient. Thus, simple measurements of the quantities E_y, j_x, and B_z yield a very important quantity, n, although a more detailed analysis given below slightly modifies this relationship.

The above analysis assumes that all electrons are moving with the same velocity $\mathbf{v}$ (constant τ), which is not true in a semiconductor. To relieve this constraint, we note that Equation 1 consists of three, coupled differential equations (in v_x, v_y, v_z) that can be solved by standard techniques. After averaging over energy, the steady-state currents can then be shown to be

$$j_x = \sigma_{xx}E + \sigma_{xy}E_y \tag{2}$$

$$j_y = \sigma_{yx}E_x + \sigma_{yy}E_y \tag{3}$$

where the σ_{ij} are elements of the conductivity tensor, defined by

$$\sigma_{xx} = \sigma_{yy} = \left\langle \frac{\tau}{1 + \omega_c^2\tau^2} \right\rangle \tag{4}$$

$$\sigma_{xy} = -\sigma_{yx} = -\left\langle \frac{\omega_c\tau^2}{1 + \omega_c^2\tau^2} \right\rangle \tag{5}$$

Here $\omega_c = eB/m^*$ is the cyclotronic frequency, where B is the magnitude of $\mathbf{B}$, and the brackets denote an average over energy ε taken as follows:

$$\langle F(\varepsilon)\rangle = \frac{\int_0^\infty F(\varepsilon)\varepsilon^{3/2}\frac{\partial f_0}{\partial \varepsilon}d\varepsilon}{\int_0^\infty \varepsilon^{3/2}\frac{\partial f_0}{\partial \varepsilon}d\varepsilon} \rightarrow \frac{\int_0^\infty F(\varepsilon)\varepsilon^{3/2}e^{-\varepsilon/kT}d\varepsilon}{\int_0^\infty \varepsilon^{3/2}e^{-\varepsilon/kT}d\varepsilon} \tag{6}$$

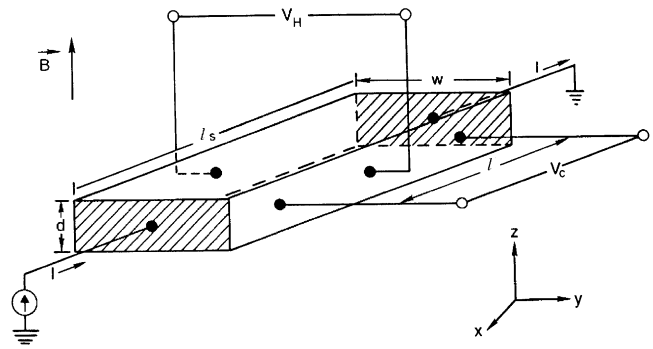

Figure 1. Hall bar configuration for resistivity and Hall effect measurements.

where $F(\varepsilon)$ is any function of ε and f_0 is the Fermi-Dirac distribution function. The second equality in Equation 6 holds for nondegenerate electrons, i.e., those describable by a Boltzmann distribution function. For small magnetic fields, i.e., $\omega_c\tau \ll 1$, and under the usual constraint $j_y=0$, it is easy to show that

$$j_x = \frac{ne^2\langle\tau\rangle}{m^*}E_x \equiv -ne\mu_c E_x \tag{7}$$

$$R_H = \frac{E_y}{j_x B} = -\frac{1}{ne}\frac{\langle\tau^2\rangle}{\langle\tau\rangle^2} = -\frac{r}{en} \tag{8}$$

where r is the "Hall factor" and $\mu_c = e\langle\tau\rangle/m^*$ is known as the "conductivity" mobility, since the quantity $ne\mu_c$ is just the conductivity σ. We define the "Hall" mobility as $\mu_H = R_H\sigma = r\mu_c$ and the "Hall" concentration as $n_H = n/r = -1/eR_H$. Thus, a combined Hall effect and conductivity measurement gives n_H and μ_H, not n and μ_c; fortunately, however, r is usually within 20% of unity and almost never as large as 2. In any case, r can often be calculated or measured $[r = R_H(\mu_B \ll 1)/R_H(\mu_B \gg 1)]$ so that an accurate value of n can usually be determined.

The relaxation time $\tau(\varepsilon)$ depends on how the electrons interact with the lattice vibrations as well as with extrinsic elements, such as charged impurities and defects. For example, acoustical-mode lattice vibrations scatter electrons through the deformation potential (leading to a relaxation time τ_{ac}) and piezoelectric potential (τ_{pe}); optical-mode vibrations through the polar potential (τ_{po}); ionized impurities and defects through the screened coulomb potential (τ_{ii}); and charged dislocations, also through the coulomb potential (τ_{dis}). The strengths of these various scattering mechanisms depend upon certain lattice parameters, such as dielectric constants and deformation potentials, and extrinsic factors, such as donor, acceptor, and dislocation concentrations N_D, N_A, and N_{dis}, respectively (Rode, 1975; Wiley, 1975; Nag, 1980; Look, 1989). The total momentum scattering rate, or inverse relaxation time, is

$$\tau^{-1}(\varepsilon) = \tau_{ac}^{-1}(\varepsilon) + \tau_{pe}^{-1}(\varepsilon) + \tau_{po}^{-1}(\varepsilon) + \tau_{ii}^{-1}(\varepsilon) + \tau_{dis}^{-1}(\varepsilon) \tag{9}$$

This expression is then used to determine $\langle\tau(\varepsilon)\rangle$ and $\langle\tau^2(\varepsilon)\rangle$ via Equation 6, and thence, $\mu_H = e\langle\tau^2\rangle/m^*\langle\tau\rangle$. Since μ_H is a function of temperature T, a fit of μ_H vs. T can often be used to determine N_D, N_A, and N_{dis}. The μ_H-vs.-T curve should be solved simultaneously with the n-vs.-T curve, given by the charge-balance equation (CBE)

$$n + N_A = \frac{N_D}{1 + n/\phi_D} \tag{10a}$$

where $\phi_D = (g_0/g_1)N_C' \exp(\alpha_D/k)T^{3/2}\exp(-E_{D0}/kT)$. Here, g_0/g_1 is a degeneracy factor ($= 1/2$ for an s-state), $N_C' = 2(2\pi m_n^* k)^{3/2}/h^3$, where h is Planck's constant, E_D is the donor energy, k is Boltzmann's constant, and E_{D0} and α_D are defined by $E_D = E_{D0} - \alpha_D T$. If more than one donor exists within a few kT of the Fermi energy, then equivalent terms are added on the right-hand side of Equation 10a.

For a p-type sample, we use the nearly equivalent equation

$$p + N_D = \frac{N_A}{1 + p/\phi_A} \tag{10b}$$

where p is the hole concentration and $\phi_A = (g_1/g_0)N_V' \exp(\alpha_A/k)T^{3/2}\exp(-E_{A0}/kT)$, and where $N_V' = 2(2\pi m_p^* k)^{3/2}/h^3$ and $E_A = E_{A0} - \alpha_A T$.

The mobility analysis described above, known as the relaxation time approximation (RTA), is limited to elastic (energy-conserving) scattering processes, because for these, a relaxation time $\tau(\varepsilon)$ can be well defined. Unfortunately, this is usually not the case for polar optical-mode (po) scattering, since the energy exchanged in the po scattering event is typically $\gg kT$. However, we can often approximate τ_{po} by an analytic formula, and, in any case, at low temperatures, po scattering is not very important. Nevertheless, for the most accurate calculations, the Boltzmann transport equation (BTE) should be solved directly, as discussed in several references (Rode, 1975; Nag, 1980; Look, 1989).

Hall samples do not have to be rectangular, such as that shown in Figure 1; in fact, we will discuss arbitrarily shaped specimens below (see Practical Aspects of the Method). However, the above analysis does assume that n and μ are homogeneous throughout the sample. If n and μ vary with depth z only, then the measured quantities are

$$\sigma_{sq} = \int_0^d \sigma(z)\,dz = e\int_0^d n(z)\mu(z)\,dz \tag{11}$$

$$R_{Hsq}\sigma_{sq}^2 = \int_0^d n(z)\mu^2(z)\,dz \tag{12}$$

where d is the sample thickness and the subscript "sq" denotes a sheet (areal) quantity (in reciprocal centimeters squared) rather than a volume quantity (in reciprocal cubic centimeters). If some of the carriers are holes rather than electrons, then the sign of e for those carriers must be reversed. The general convention is that R_H is negative for electrons and positive for holes. In some cases, the hole and electron contributions to $R_{Hsq}^2\sigma_{sq}$ exactly balance at a given temperature, and this quantity vanishes.

PRACTICAL ASPECTS OF THE METHOD

Useful Equations

The Hall bar structure of Figure 1 is analyzed as follows: $E_x = V_c/l$, $E_y = V_H/w$, and $j_x = I/wd$, so that

$$\sigma = \rho^{-1} = \frac{j_x}{E_x} = \frac{Il}{V_c wd} \tag{13}$$

$$R_H = \frac{E_y}{j_x B} = \frac{V_H d}{IB} \tag{14}$$

$$\mu_H = R\sigma = \frac{V_H l}{V_c wB} \tag{15}$$

$$n_H = (eR)^{-1} \tag{16}$$

In the meter-kilogram-second (mks) system, current I is in amperes, voltage V in volts, magnetic field strength B in tesla, and length l, width w, and thickness d in meters. By realizing that $1\ \mathrm{T} = 1\ \mathrm{V \cdot s/m^2}$, $1\ \mathrm{A} = 1\ \mathrm{C/s}$, and $1\ \Omega = 1\ \mathrm{V/A}$, we find that σ is in units of $\Omega^{-1}\mathrm{m}^{-1}$, R_H in $\mathrm{m^3/C}$, μ_H in $\mathrm{m^2/V \cdot s}$, and n_H in $\mathrm{m^{-3}}$. However, it is more common to denote σ in $\Omega^{-1}\ \mathrm{cm^{-1}}$, R_H in $\mathrm{cm^3/C}$, μ_H in $\mathrm{cm^2/V \cdot s}$, and n_H in $\mathrm{cm^{-3}}$, with obvious conversion factors ($1\ \mathrm{m} = 10^2\ \mathrm{cm}$). Since B is often quoted in gauss, it is useful to note that $1\ \mathrm{T} = 10^4\ \mathrm{G}$.

Although the Hall bar configuration discussed above is the simplest and most straightforward geometry to analyze, it is not the most popular shape in use today. The reason stems from a very convenient formulation by van der Pauw (1958) in which he solved the potential problem for a thin layer of arbitrary shape. A convenient feature of the van der Pauw technique is that no dimension need be measured for the calculation of sheet resistance or sheet carrier concentration, although a thickness must of course be known for volume resistivity and concentration. Basically, the validity of the van der Pauw method requires that the sample be flat, homogeneous, isotropic, and a singly connected domain (no holes) and have line electrodes on the periphery, projecting to point contacts on the surface, or have true point contacts on the surface. The last requirement is the most difficult to satisfy, so that much work has gone into determining the effects of finite contact size.

Consider the sample shown in Figure 2A. Here, a current I flows between contacts 1 and 2, and a voltage V_c is measured between contacts 3 and 4. Let resistance $R_{ij,kl} \equiv V_\mathrm{kl}/I_\mathrm{ij}$, where the current enters contact i and leaves contact j and $V_{kl} = V_k - V_l$. [These definitions, as well as the contact numbering, correspond to ASTM (1988) Standard F76.] The resistivity ρ, with $B = 0$, is then calculated as

$$\rho = \frac{\pi d}{\ln(2)}\left(\frac{R_{21,34} + R_{32,41}}{2}\right) f \tag{17}$$

where f is determined from a transcendental equation:

$$\frac{Q-1}{Q+1} = \frac{f}{\ln(2)}\operatorname{arccosh}\left[\frac{1}{2}\exp\left(\frac{\ln(2)}{f}\right)\right] \tag{18}$$

Here, $Q = R_{21,34}/R_{32,41}$ if this ratio is greater than unity; otherwise, $Q = R_{32,41}/R_{21,34}$. A curve of f vs. Q accurate to $\approx 2\%$ is presented in Figure 3 (van der Pauw, 1958). Also useful is a somewhat simpler analytical procedure

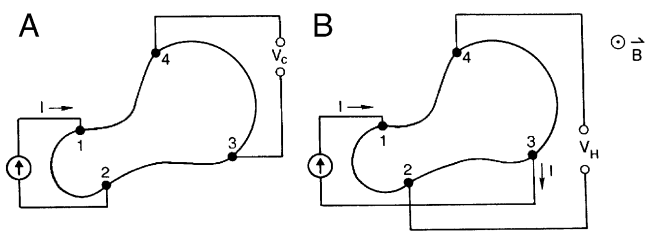

Figure 2. Arbitrary shape for van der Pauw measurements: (**A**) resistivity; (**B**) Hall effect.

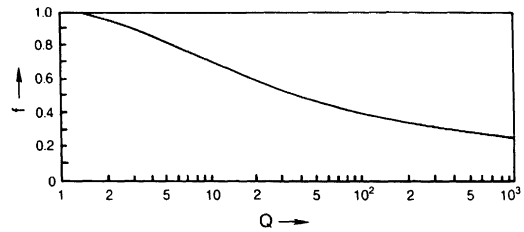

Figure 3. Resistivity ratio function used to correct the van der Pauw results for asymmetric sample shape.

for determining f due to Wasscher and reprinted in Weider (1979). First calculate α from

$$Q = \frac{\ln(1/2 - \alpha)}{\ln(1/2 + \alpha)} \tag{19}$$

and then calculate f from

$$f = \frac{\ln(1/4)}{\ln(1/2 + \alpha) + \ln(1/2 - \alpha)} \tag{20}$$

Here, it is of course required that $-1/2 < \alpha < 1/2$, but this range of α covers $Q = 0$ to $Q = \infty$. For example, a ratio $Q = 4.8$ gives a value $\alpha \approx 0.25$, and then $f \approx 0.83$. Thus, the ratio must be fairly large before ρ is appreciably reduced.

It is useful to further average ρ by including the remaining two contact permutations, and also reversing current for all four permutations. Then

$$\rho = \frac{\pi d}{\ln(2)}\left[\frac{(R_{21,34} - R_{12,34} + R_{32,41} - R_{23,41})f_\mathrm{A}}{8} + \frac{(R_{43,12} - R_{34,12} + R_{14,23} - R_{41,23})f_\mathrm{B}}{8}\right] \tag{21}$$

where f_A and f_B are determined from Q_A and Q_B, respectively, by applying either Equation 18 or 19. Here,

$$Q_\mathrm{A} = \frac{R_{21,34} - R_{12,34}}{R_{32,41} - R_{23,41}} \tag{22}$$

$$Q_\mathrm{B} = \frac{R_{43,12} - R_{34,12}}{R_{14,23} - R_{41,23}} \tag{23}$$

The Hall mobility is determined by using the configuration of Figure 2B, in which the current and voltage contacts are crossed. The Hall coefficient becomes

$$R_\mathrm{H} = \frac{d}{B}\left(\frac{R_{31,42} + R_{42,13}}{2}\right) \tag{24}$$

In general, to minimize magnetoresistive and other effects, it is useful to average over current and magnetic field polarities. Then

$$R_\mathrm{H} = (d/B)[R_{31,42}(+B) - R_{13,42}(+B) + R_{42,13}(+B) - R_{24,13}(+B) + R_{13,42}(-B) - R_{31,42}(-B) + R_{24,13}(-B) - R_{42,13}(-B)]/8 \tag{25}$$

Sensitivity

The most common magnetic field strength used by researchers for Hall effect measurements in 5 kG = 0.5 T. Also, typical semiconductor materials (e.g., GaAs) vary in resistivity ρ from 10^{-4} to 10^{9} $\Omega \cdot$ cm, depending on intrinsic factors as well as impurity and defect concentrations. Finally, typical sample thicknesses d may range from 10^{-5} to 10^{-1} cm. Consider the worst case on the high-resistivity end of the spectrum. Let $\rho = 10^{9}$ $\Omega \cdot$ cm, $d = 10^{-5}$ cm, and $l/w \approx 1$. Then, if a voltage of 100 V can be applied, the current will be 1 pA, which can be measured with an electrometer. If the mobility $\mu_H \approx 10^{3}$ cm^2/V $\cdot$ s, then the Hall coefficient R will be 10^{12} cm^3/C, and the Hall voltage V_H will be 5 V. Conversely, let $\rho = 10^{-4}$ $\Omega \cdot$ cm and $d = 10^{-1}$ cm. Then, the resistance is about 10^{-3} Ω, and we will not be able to apply more than about 10^{-3} V in order to avoid sample heating. Such a voltage will produce 1 A of current and a resulting Hall voltage of 50 μV, again easily measurable. Of course, if $\mu H \approx 1$ cm^2/V $\cdot$ s, then $V_H \approx 50$ nV, which can still probably be measured if noise levels are low. We may note that the lowest mobility that we have measured in our laboratory, by using our standard dc techniques, is 0.1 cm^2/V s.

METHOD AUTOMATION

A basic design for a high-impedance, automated van der Pauw–Hall apparatus, which can accommodate samples of up to 10^{12} Ω is given in Figure 4. All components are commercially available, and the electrometers can, of course, be replaced by high-impedance, unity-gain buffer amplifiers, although possibly at some sacrifice in input impedance. The inputs and outputs of the high-impedance scanner and the inputs to the ammeter and electrometers are of triaxial design, which has the advantage that the inner shields can be driven by the unity-gain output of the electrometers, which effectively reduces cable-charging effects. The outer shields are all grounded at a common point, although in practice the grounding may not be critical. The current source should have an effective output impedance of about 10^{12} Ω and be able to regulate currents of 10^{-10} A. At higher resistance levels, the current regulation will cross over to voltage regulation, and the currents will diminish; however, the data will still be accurate as long as the actual current and voltage are both measured. The low-impedance scanner should be mainly designed for low thermal offsets (say, a few microvolts) since current leakage is not a problem on this side of the electrometers. Note that although the ammeter needs to be of electrometer design, to be able to measure the very low currents, the voltmeter does not, since the electrometer output impedances are only a few kilohms.

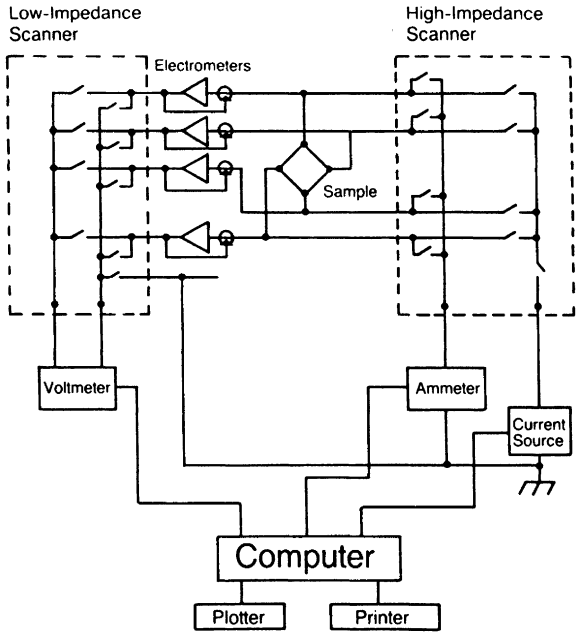

Figure 4. Schematic of an automated, high-impedance Hall effect apparatus.

The wiring to the high-impedance scanner in this design allows the current source and current sink to be individually applied to any desired sample contact. Also, the high input and low input on the voltmeter can be connected to any electrometer unity-gain output through the low-impedance scanner. Figure 4 does not represent the most efficient design in terms of the minimum number of scanner switches, but it does illustrate the main ideas quite well. Although not shown here, for very low resistance samples it is desirable, and sometimes necessary, to be able to bypass the electrometers, since their typical noise levels of 10-μV peak to peak may be unacceptably high.

We will not discuss the computer and peripherals in any detail here, because so many variations available today will work well. However, we would recommend that the system be designed around the standard IEEE-488 interface bus, which allows new instruments to be added at will and effectively eliminates serious hardware problems.

Complete Hall systems, including temperature and magnetic field control, are available from several companies, including Bio-Rad Semiconductor, Keithley Instruments, Lake Shore Cryotronics, and MMR Technologies.

DATA ANALYSIS AND INITIAL INTERPRETATION

The primary quantities determined from Hall effect and conductivity measurements are the Hall carrier concentration n_H or p_H and mobility μH. As already discussed, $n_H = -1/eR_H$, where R_H is given by Equation 24 (for a van der Pauw configuration) and $\mu_H = R_H\sigma = R_H/\rho$, where ρ is given by Equation 21. Although simple 300-K values of ρ, n_H, and μ_H are quite important and widely used, it is in temperature-dependent Hall (TDH) measurements that the real power of the Hall technique is demonstrated, because then the donor and acceptor concentrations and energies can be determined. We will illustrate the methodology with a two-layer GaN problem.

The GaN sample discussed here was a square (6 $\times$ 6-mm) layer grown on sapphire to a thickness $d = 20$ μm.

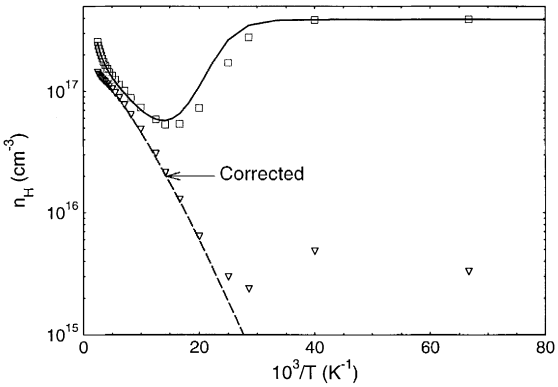

Figure 5. Uncorrected Hall concentration data (squares) and fit (solid line) and corrected data (triangles) and fit (dashed line) vs. inverse temperature.

Small indium dots were soldered on the corners to provide ohmic contacts, and the Hall measurements were carried out in an apparatus similar to that illustrated in Figure 4. Temperature control was achieved by using a He exchange-gas dewar. The temperature dependences of n_H and μ_H are shown by the squares in Figures 5 and 6, respectively. At temperatures below 30 K (i.e., $10^3/T > 33$), the carriers (electrons) in the main part of the layer "freeze out" on their parent donors and thus are no longer available for conduction. However, this sample had a very thin, strongly n-type layer between the sapphire and GaN, and the carriers in such a layer do not freeze out and, in fact, have a temperature-independent concentration and mobility, as seen at low T (high $10^3/T$) in Figures 5 and 6, respectively. Thus, we need to use the depth-profile analysis given by Equations 11 and 12.

For two layers, Equations 11 and 12 give

$$\mu_H = R_{sq}\sigma_{sq} = \frac{R_{sq}\sigma_{sq}^2/d}{\sigma_{sq}/d} = \frac{\mu_{H1}^2 n_{H1} + \mu_{H2}^2 n_{Hsq2}/d}{\mu_{H1} n_{H1} + \mu_{H2} n_{Hsq2}/d} \tag{26}$$

$$n_H = \frac{n_{Hsq}}{d} = \frac{1}{eR_{sq}d} = \frac{\sigma_{sq}^2/d^2}{eR_{sq}\sigma_{sq}^2/d} = \frac{(\mu_{H1} n_{H1} + \mu_{H2} n_{Hsq2}/d)^2}{\mu_{H1}^2 n_{H1} + \mu_{H2}^2 n_{Hsq2}/d} \tag{27}$$

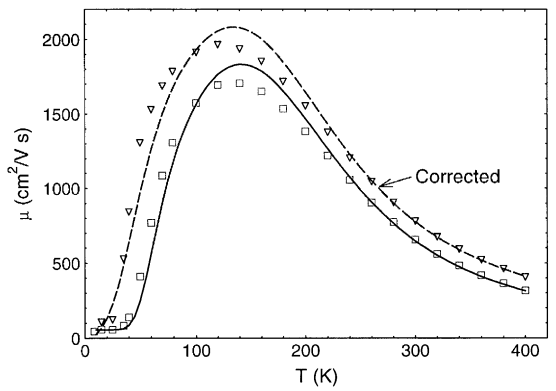

Figure 6. Uncorrected Hall mobility data (squares) and fit (solid line) and corrected data (triangles) and fit (dashed line) vs. temperature.

where layer 1 is the main, 20-μm-thick GaN growth and layer 2 is the very thin interface region. Since we do not know the thickness of layer 2, we simply normalize to thickness $d = 20$ μm for plotting purposes. From the figures, we get $\mu_{H2} = 55$ cm^2/V · s and $n_{Hsq2}/d = 3.9 \times 10^{17}$ cm^{-3}. Because these values are constant, we can invert Equations 26 and 27 and solve for μ_{H1} and n_{H1} at each temperature. (The resulting equations are given later.) To fit the uncorrected data (squares), we parametrize n vs. T by Equation 10a and μ_H vs. T by $\mu_H = e\langle\tau^2\rangle/m^*\langle\tau\rangle$, where τ is given by Equation 9. Because $n = n_H r = n_H\langle\tau^2\rangle/\langle\tau\rangle^2$ the fits of n_H vs. T and μ_H vs. T must be carried out simultaneously. In this case r varies only from about 1.2 to 1.4 as a function of T.

Formulas for $\tau_{ac}, \tau_{pe}, \tau_{po}$, and τ_{ii} are given below. For ionized impurity (or defect) scattering in a nondegenerate, n-type material,

$$\tau_{ii}(\varepsilon) = \frac{2^{9/2}\pi\varepsilon_0^2 (m^*)^{1/2}\varepsilon^{3/2}}{e^4(2N_A + n)[\ln(1+y) - y/(1+y)]} \tag{28}$$

where $y = 8\varepsilon_0 m^* kT\varepsilon/\hbar^2 e^2 n$. Here ε_0 is the low-frequency (static) dielectric constant. [If the sample is p type, let $(2N_A + n) \rightarrow (2N_D + p)$]. For acoustic-mode deformation-potential scattering,

$$\tau_{ac}(\varepsilon) = \frac{\pi\hbar^4\rho_d s^2\varepsilon^{-1/2}}{2^{1/2}E_1^2 (m^*)^{3/2} kT} \tag{29}$$

where ρ_d is the density, s is the speed of sound, and E_1 is the deformation potential. For acoustic-mode piezoelectric-potential scattering,

$$\tau_{pe}(\varepsilon) = \frac{2^{2/3}\pi\hbar^2\varepsilon_0\varepsilon^{1/2}}{e^2P^2(m^*)^{1/2}kT} \tag{30}$$

where P is the piezoelectric coupling coefficient [$P = (h_{pz}^2/\rho s^2\varepsilon_0)^{1/2}$]. Finally, for polar optical-mode scattering, a rough approximation can be given

$$\tau_{po}(\varepsilon) = (C_{po}2^{3/2}\pi\hbar^2(e^{T_{po}/T} - 1)[0.762\varepsilon^{1/2} + 0.824(kT_{po})^{1/2} - 0.235(kT_{po})^{-1/2}\varepsilon])/[e^2 kT_{po}(m^*)^{1/2}(\varepsilon_\infty^{-1} - \varepsilon_0^{-1})] \tag{31}$$

where T_{po} is the Debye temperature, ε_∞ is the high-frequency dielectric constant, and C_{po} is a fitting parameter, of order unity, to correct for the inexact nature of $\tau_{po}(\varepsilon)$. That is, if we had *only* po scattering, then the exact (i.e., BTE) calculation of μH vs. T would be almost identical with the RTA calculation (i.e., $\mu_H = e\langle\tau^2\rangle/m*\langle\tau\rangle$), with $C_{po} = 1$. However, if other scattering mechanisms are also important, then the correction factor C_{po} will be dependent on the relative strengths of these other mechanisms. As an example, to get a good fit to high-temperature (>300 K) μ_H-vs.-T data in GaN (Fig. 6), we use $C_{po} \approx 0.6$. Fortunately, below 150 K, the po mechanism

is no longer important in GaN, and the RTA approach is quite accurate.

The RTA analysis discussed above and the CBE analysis discussed earlier (Equation 10a or 10b) constitute a powerful method for the determination of N_D, N_A, and E_D in semiconductor material. It can be easily set up on a personal computer, using, e.g., MATHCAD software. In many cases, it is sufficient to simply assume $n = n_H$ (i.e., $r = 1$) in Equations 10a and 28, but a more accurate answer can be obtained by using the following steps: (1) let $n = n_H = 1/eR_H$ at each T; (2) fit μ_H vs. T using $\mu_H = \langle\tau^2\rangle/m^*\langle\tau\rangle$, and get a value for N_A; (3) calculate $r = \langle\tau^2\rangle/\langle\tau\rangle^2$ at each T; (4) calculate a new $n = rn_H$ at each T; and (5) fit n vs. T to Equation 10a and get values of N_D and E_D. Further iterations can be carried out, if desired, but usually add little accuracy.

For the benefit of the reader who wishes to set up such an analysis, we give the scattering strength parameters and fitting parameters used for the GaN data fits in Figures 5 and 6. Further discussion can be found in the work of Look and Molnar (1997). From the GaN literature we find: $E_1 = 9.2$ eV $= 1.47 \times 10^{-18}$ J; $P = 0.104$, $\varepsilon_0 = 10.4(8.8542 \times 10^{-12})$ F/m; $\varepsilon_\infty = 5.47(8.8542 \times 10^{-12})$ F/m; $T_{po} = 1044$ K; $m^* = 0.22(9.1095 \times 10^{-31})$ kg; $\rho_d = 6.10 \times 10^3$ kg/m^3; $s = 6.59 \times 10^3$ m/s; $g_0 = 1$; $g_1 = 2$; $\alpha_D = 0$; and $N'_C = 4.98 \times 10^{20}$ m^{-3}. With all the parameters in mks units, μH is in units of m^2/V$\cdot$ s; a useful conversion is μ_H (cm^2/V$\cdot$ s) $= 10^4$ μ_H (m^2/V $\cdot$ s). To fit the high-T μ_H data, we also have to set $C_{po} = 0.56$, as mentioned earlier. However, before carrying out the RTA and CBE analyses, it was necessary in this case to correct for a degenerate interface layer, having $\mu_{H2} = 55$ cm^2/V$\cdot$ s and $n_{Hsq2}/d = 3.9 \times 10^{17}$ cm^{-3}. The corrected data, also shown in Figures 5 and 6, are calculated by inverting Equations 26 and 27:

$$\mu_{H1} = \frac{\mu_H^2 n_H - \mu_{H2}^2 n_{Hsq2}/d}{\mu_H n_H - \mu_{H2} n_{Hsq2}/d} \tag{32}$$

$$n_{H1} = \frac{(\mu_H n_H - \mu_{H2} n_{Hsq2}/d)^2}{\mu_H^2 n_H - \mu_{H2}^2 n_{Hsq2}/d} \tag{33}$$

The fitted parameters are $N_D = 2.1 \times 10^{17}$ cm^{-3}, $N_A = 5 \times 10^{16}$ cm^{-3}, and $E_D = 16$ meV.

SAMPLE PREPARATION

In deciding what kind of geometrical structure to use for a particular application, several factors should be considered, including (1) available size, (2) available fabrication techniques, (3) limitations of measurement time, (4) necessary accuracy, and (5) need for magnetoresistance data.

In considering these factors, we will refer to Figure 7, which depicts six of the most popular structures.

The available size can be a severe constraint. In our laboratory, we have often measured bulk samples of dimension 2 mm or less, which virtually rules out any complicated shapes, such as (B), (D), or (F) in the figure; in fact, it is sometimes not possible to modify an existing sample shape at all. Thus, the best procedure for small samples

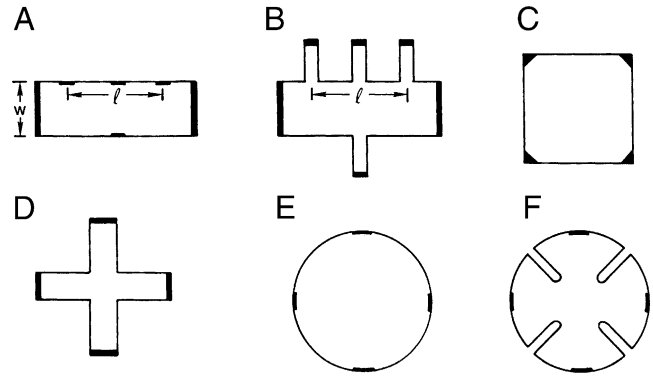

Figure 7. Various specimen/contact patterns commonly used for resistivity and Hall effect measurements: (**A**) Hall bar; (**B**) Hall bar with contact arms; (**C**) square; (**D**) Greek cross; (**E**) circle; (**F**) cloverleaf.

is simply to put four very small contacts around the periphery and apply the standard van der Pauw analysis. We have found that indium, applied with a soldering iron, works well for almost any semiconductor material. Contact size errors can be estimated if the shape is somewhat symmetrical. The simple Hall bar structure (A) is not recommended for a very small bulk sample unless the sample is already in that form, because it is then necessary to measure l and w, which can introduce large errors.

For larger bulk samples, there is a greater choice among the various structures. The availability of an ultrasonic cutting tool opens up the possibility of using structures (B), (D), (E), or (F), if desired. Here, it might be noted that (B) is rather fragile compared to the others. If the samples must be cleaved from a wafer, then the shapes are basically limited to (A) and (C). In our laboratory, for example, it is common to use a square (C) of about 6 × 6 mm and then put contacts of dimension 1 mm or less on the corners.

If photolithographic capabilities are available, then one of the more complex test structures (B), (D), or (F) should be used, because of the advantages they offer. Most manufacturers of discrete semiconductor devices or circuits include Hall bar or van der Pauw structures at several points on the wafer, sometimes one in every reticle (repeated unit).

Another possible constraint is measurement time. By comparing Equation 13 with Equation 17 and Equation 14 with Equation 24, it appears that a typical van der Pauw experiment should take about twice as long as a Hall bar experiment, and indeed, this is experimentally the case. Thus, in an experiment that involves many measurements on the same sample, such as a temperature dependence study, it may well be a distinct advantage to use a Hall bar instead of a van der Pauw pattern. Also, if a contact-switching network (Fig. 4) is not part of the available apparatus, then a van der Pauw structure cannot be conveniently used.

If high accuracy is necessary for the Hall effect measurements, then structures (B), (D), and (F) are the best, because contact size effects are much stronger for Hall effect data than for resistivity data. The same structures,

along with (A), should be used if μB must be made large, since structures (C) and (E) do not have as good a V_H-vs.-B linearity. From a heat dissipation point of view, structures (A) and (B) are the worst, since they are required to be long and narrow, and thus the Hall voltage is relatively small for a given current, since $V_H \propto w$. A high heat dissipation can lead to large temperature gradients, and thus stronger thermomagnetic effects, or may simply raise the sample temperature an unacceptable amount.

Finally, it is important to ask whether or not the same sample is going to be used for magnetoresistance measurements, because, if so, structures (A) and (B) are undoubtedly the best. The reason is that the analysis of magnetoresistance is more complicated in van der Pauw structures than in Hall bar structures, and, in general, a simple formula cannot be found. It may be noted that in Shubnikov–de Haas and quantum Hall measurements, in which magnetic field dependence is critical, the Hall bar is nearly always used.

PROBLEMS

Contact Size and Placement Effects

Much has been written about this subject over the past few decades. Indeed, it is possible to calculate errors due to contact size and placement for any of the structures shown in Figure 7. For (A), (C), and (E), great care is necessary, while for (B), (D), and (F), large or misplaced contacts are not nearly as much of a problem. In general, a good rule of thumb is to keep contact size and distance from the periphery each below 10% of the smallest sample edge dimension. For Hall bar structures (A) and (B), in which the contacts cover the ends, the ratio $l/w > 3$ should be maintained.

Thermomagnetic Errors

Temperature gradients can set up spurious electromotive forces that can modify the measured Hall voltage. Most of these effects, as well as misalignment of the Hall contacts in structure (B), can be averaged out by taking measurements at positive and negative values of both current and magnetic field and then applying Equations 21 and 25.

Conductive Substrates

If a thin film is grown on a conductive substrate, the substrate conductance may overwhelm the film conductance. If so, and if μ_{sub} and n_{sub} are known, then Equations 32 and 33 can be applied, where layer 2 is the substrate. If the substrate and film are of different types (say, a p-type film on an n-type substrate), then a current barrier (p-n junction) will be set up, and the measurement can possibly be made with no correction. However, in this case, the contacts must not overlap both layers.

Depletion Effects in Thin Films

Surface states as well as film-substrate interface states can deplete a thin film of a significant fraction of its charge carriers. Suppose these states lead to surface and interface potentials ϕ_s and ϕ_i, respectively. Then regions of width w_s and w_i will be depleted of their free carriers, where

$$w_{s(i)} = \left[\frac{2\varepsilon_0 \phi_{s(i)}}{e(N_D - N_A)}\right]^{1/2} \tag{34}$$

Here it is assumed that $\phi_{(s)i} \gg kT/e$ and $e\phi_{(s)i} \gg \varepsilon_C - \varepsilon_F$. The electrical thickness of the film will then be given by $d_{elec} = d - w_s - w_i$. Typical values of ϕ_s and ϕ_i are 1 V, so that if $N_D - N_A = 10^{17}$ cm^{-3}, then $w_s + w_i \approx 2000$ Å $= 0.2$ μm in GaN. Thus, if $d \approx 0.5$ μm, 40% of the electrons will be lost to surface and interface states, and $d_{elec} \approx 0.3$ μm.

Inhomogeneity

A sample that is inhomogeneous in depth must be analyzed according to Equations 11 and 12. In simple cases (e.g., for two layers) such an analysis is sometimes possible, as was illustrated in Figures 5 and 6. However, if a sample is laterally inhomogeneous, it is nearly always impossible to carry out an accurate analysis. One indication of such inhomogeneity is a resistivity ratio $Q \gg 1$ (Fig. 3) in a symmetric sample, which would be expected to have $Q = 1$. The reader should be warned to never attempt an f correction (Fig. 3) in such a case, because the f correction is valid only for sample shape asymmetry, not inhomogeneity.

Nonohmic Contacts

In general, high contact resistances are not a severe problem as long as enough current can be passed to get measurable values of V_c and V_H. The reason is that the voltage measurement contacts carry very little current. However, in some cases, the contacts may set up a p-n junction and significantly distort the current flow. This situation falls under the "inhomogeneity" category, discussed above. Usually, contacts this bad show variations with current magnitude and polarity; thus, for the most reliable Hall measurements, it is a good idea to make sure the values are invariant with respect to the magnitudes and polarities of both current and magnetic field.

ACKNOWLEDGMENTS

The author would like to thank his many colleagues at Wright State University and Wright-Patterson Air Force Base who have contributed to his understanding of the Hall effect and semiconductor physics over the years. He would also like to thank Nalda Blair for help with the manuscript preparation. Finally, he gratefully acknowledges the support received from the U.S. Air Force under Contract F33615-95-C-1619.

DEEP-LEVEL TRANSIENT SPECTROSCOPY

INTRODUCTION

Defects are responsible for many different characteristic properties of a semiconductor. They play a critical role in determining the viability of a given material for device applications. The identification and control of defects have always been among the most important and crucial tasks in materials and electronic device development. The performance and reliability of devices can be significantly affected by only minute concentrations of undesirable defects. Since the determination of the type and quality of defects in a material depends on the sensitivity of a characterization technique, the challenge in materials characterization has been to develop detection methods with improved sensitivity.

Whereas electrical characterization methods are more sensitive than physical characterization techniques, they may arguably be less sensitive than some optical techiques. However, since device operation depends largely on the electrical properties of its components, it is conceivable that a characterization from an electrical point of view is more relevant. Also, the activation of defects due to electrical processes requires scrutiny, as it has a direct impact on the performance and reliability of a device.

Deep-level transient spectroscopy (DLTS) probes the temperature dependence of the charge carriers escaping from trapping centers formed by point defects in the material. This technique is able to characterize each type of trapping center by providing the activation energy of the defect level relative to one of the energy band edges and the capture cross-section of the traps. It can also be used to compute the concentration and depth profile of the trapping centers.

Although several electrical characterization techniques exist, such as Hall effect (see HALL EFFECT IN SEMICONDUCTORS), current-voltage, capacitance-voltage (see CAPACITANCE-VOLTAGE (C-V) CHARACTERIZATION OF SEMICONDUCTROS), and carrier lifetime measurements (see CARRIER LIFETIME: FREE CARRIER ABSORPTION, PHOTOCONDUCTIVITY, AND PHOTOLUMINESCENCE), very few of them exploit spectroscopy. The spectroscopic nature of DLTS is a key feature that provides both convenience and sensitivity.

Deep-level transient spectroscopy has been widely used for many different semiconductors. This technique has distinguished itself in contributing to the resolution of many defect-related problems in several technologically important semiconductors such as silicon, the Group III to V and II to VI compounds, and alloys. Many variations of basic DLTS have also been developed for improved sensitivity and for more specialized applications in device structures different from the normal *p-n* or Schottky barrier diodes.

Deep-level transient spectroscopy is not able to determine the chemistry or the origin of a defect. Deep-level transient spectroscopy data should therefore be used in conjunction with other techniques. A successful study of defects requires the concerted efforts of many researchers using various characterization techniques in order to derive a more accurate and consistent picture of the defect structure of a given material.

Defects in Semiconductors

In a real crystal, the periodic symmetry of the lattice can be broken by defects. Lattice defects produce localized energy states that may have energy levels occurring within the

band gap. A charge carrier (electron or hole) bound to such a defect in a lattice has a localized wave function as opposed to a carrier in the allowed energy bands (conduction or valence bands) that is free to move.

Crystal imperfections known as point defects can be vacancies or impurities introduced either deliberately or unintentionally during the growth process. Processing of materials during device fabrication can also introduce point defects. Some defects are unavoidable, and they play a key role in determining the properties of a semiconductor. Chemical impurities that form point defects may exist interstitially or substitutionally in the lattice. An interstitial atom may be of the same species as the atoms in the lattice (intrinsic defects) or of a different species (extrinsic defects). Defects can also consist of vacant lattice sites. There are also defect complexes that are conglomerations of different point defects.

In addition to point defects, there are also one-dimensional defects such as dislocations, two-dimensional defects such as surfaces and grain boundaries, and three-dimensional defects such as micropipes and cavities (voids).

Defects obey the laws of thermodynamics and the law of mass action. Hence, the removal or suppression of one type of defect will enhance the effects of another type. For instance, the removal of defects such as grain boundaries and dislocations increases the significance of point defects.

The presence of defects in semiconductors can be either beneficial or detrimental, depending on the nature of the defects and the actual application of the material in devices.

Gold impurities in silicon junctions are used to provide fast electron-hole recombination, resulting in faster switching time. Impurities such as gold, zinc, and mercury in silicon and germanium produce high-quantum-efficiency photodetectors. The emission wavelength of light-emitting diodes (LEDs) is determined by the presence of deep defect levels. In undoped semi-insulating GaAs, a family of deep donor levels, commonly known as EL2, compensates the acceptor levels due to carbon impurities to impart the high resistivity or semi-insulating properties to these materials. Chromium is also used to dope GaAs to produce semi-insulating GaAs-Cr, although this is no longer in widespread use.

Device performance and reliability are greatly affected by the presence of defects. The success of fiber-optics-based telecommunication systems employing laser diodes depends critically on the lifetime of the laser diodes and LEDs. Degradation of laser diodes and LEDs has been widely attributed to formation of local regions where nonradiative recombination occurs. There is general agreement that these regions result from the motion of dislocations that interact with defect centers to promote nonradiative recombination. A dislocation array can also propagate from a substrate into active layers resulting in device failure. This is a reason why it is crucial that electronic materials have a low dislocation density.

Device fabrication processes can involve ion implantation, annealing, contact formation, mechanical scribing, and cleaving, all of which introduce dislocations and point defects. Dislocations in devices may be of little significance by themselves. The problems only arise when these dislocations are "decorated" by point defects. Impurities tend to gather around dislocations, and the diffusion of impurities is also enhanced at dislocations. It is difficult to differentiate between the effects of point defects and dislocations because the production of dislocations also generates point defects such as interstitial atoms and vacancies.

The topic of reliability and degradation of devices is wide ranging, and the above examples serve only to show the importance of the study of defects in devices.

The location of localized states within the band gap can range from a few milli-electron-volts to a few tenths of an electron volt from either the bottom of the conduction band or the uppermost valence band. The determination of whether a level can be considered deep or shallow is rather arbitrary. A depth of $\geq$0.1 eV is usually termed "deep level." It must also be noted that the accuracy in the determination of any level $<$0.1 eV is questionable in any experiment that involves the electrical or photoelectronic measurement of the thermal emission of carriers from the trapping levels.

A defect center can either be a recombination or a trapping center depending on the probabilities with which each of the two processes will occur. If a carrier bound to a defect center recombines with another carrier of opposite polarity before it can be thermally released to the nearest allowed energy band, then that center is a recombination center. However, if the carrier can escape to the nearest energy band through thermal excitation before recombination can occur, then that center is a trapping center. The probability of escape of a carrier from a defect center is therefore higher if the energy level of the center is nearer to either the valence or conduction band. This means that a donor or acceptor level near either the valence or conduction band is more likely to be a trapping center.

The defect structure in a semiconductor consists of a group of well-defined carrier trapping levels. Deep-level transient spectroscopy is an effective method to characterize the defect structure of a semiconductor. Since different semiconductors would have different combinations of defect levels with different activation energies and capture cross-sections, a DLTS curve taken at a known rate window can be used as a defect signature that is characteristic of the material. A knowledge of the various defect levels in a semiconductor is important to the understanding of the electronic properties of the material. Deep-level transient spectroscopy curves do not describe the exact nature or the chemical origin of the defects. Deep-level transient spectroscopy data require a proper and informed interpretation. They are best used in conjunction with other appropriate methods described in this book.

PRINCIPLES OF THE METHOD

Deep-level transient spectroscopy was first introduced by Lang (1974, 1979) based on the theoretical groundwork of Sah et al. (1970) and Milnes (1973). The basis of this method is the dependence of the capacitance of a space-charge region on the occupancy of the traps within the space-charge region in a semiconductor. Under

a nonequilibrium condition such as that existing in a space-charge region, a trapped carrier can escape from a trapping center by thermal excitation to the nearest energy band.

To characterize a semiconductor, it is necessary to fabricate a junction diode such as a *p-n* or Schottky barrier diode on the material of interest. A space-charge region is formed by reverse biasing the *p-n* or Schottky barrier diode. The diode is initially reverse biased to empty the traps. When the bias across the junction is reduced (or even forward biased), the width of the space-charge region is reduced. An equilibrium condition is established in the neutralized region with the majority carriers populating the traps. When the reverse bias is restored, the space-charge region is again created as before, with the only difference being that there are trapped carriers now residing in the defect centers within the space-charge region. The nonequilibrium condition thus created causes the trapped carriers to be thermally reemitted to the relevant energy band. The rate of thermal emission, or "detrapping," of a carrier is temperature dependent. The change of the occupancy of these trapping centers is reflected in the capacitance of the junction producing a capacitance transient. Minority-carrier injection can also occur when the junction is forward biased during the bias pulse. In essence, both majority and minority carriers are involved, which makes this method all the more effective because the emission of each type of carrier can be detected by monitoring the capacitance transients. The activation energy of the trap, or the depth of the trapping level from the nearest energy band edge, and the capture cross-section can be determined from the temperature dependence of the emission rate. The trap concentration can be determined from the in ensity of the capacitance peak, and the polarity of the carriers can be found from the sign of the capacitance change. The DLTS technique can be applied to the study of trapping centers along a critical current conduction path in any device structure in which a depletion region can be formed when appropriately biased. This technique is suitable not only for the study of bulk semiconductor materials but also for the characterization of actual device structures such as *p-n* diodes, Schottky barrier diodes, metal-insulator-semiconductor (MIS) device, or any devices that contain such basic structures. Examples would be bipolar junction transistors, field-effect transistors, or derivatives thereof.

Emission Rate

Consider an *n*-type semiconductor with only a single deep electron trapping level within the band gap in addition to the donor level, as shown in Figure 1. Assume also that the trapping level is located at an energy level E_T from the conduction band edge, E_C. The donor level is indicated by a shallow energy level E_D that is closer to the conduction band edge.

The probability that an electron is captured by the deep electron trap is given by

$$c_n = n v_{th} \sigma_n \tag{1}$$

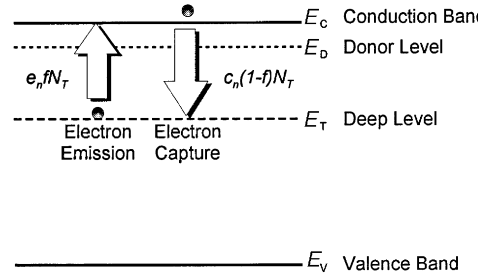

Figure 1. Electron transitions between the trapping level and the conduction band.

where n is the electron concentration, v_{th} is the thermal velocity, and σ_n is the electron capture cross-section. The rate of capture of an electron not only depends on the capture probability c_n but also on the availability of a vacant trap as measured by the concentration of unoccupied traps N_T^0. The electron capture rate can therefore be expressed as

$$\frac{dc_n}{dt} = c_n N_T^0 = n v_{th} \sigma_n N_T^0 \tag{2}$$

The concentration of unoccupied traps N_T^0 can be written in terms of the probability that a given trap out of the total concentration of traps N_T is empty, i.e.,

$$N_T^0 = (1 - f) N_T \tag{3}$$

where $1 - f$ is the probability that a trap is vacant and f is the Fermi-Dirac probability factor (defined below).

Therefore, the rate of electron capture can now be written as

$$\frac{dc_n}{dt} = n v_{th} \sigma_n (1 - f) N_T \tag{4}$$

The rate of electrons escaping from the traps is dependent on both the emission rate e_n and the concentration of occupied traps N_T^-. Therefore, the electron detrapping rate can be written as

$$\frac{de_n}{dt} = e_n N_T^- \tag{5}$$

The concentration of occupied traps N_T^- can also be expressed in terms of the probability that a fraction of the total concentration of traps N_T is filled. This probability is represented by the Fermi-Dirac probability factor f. Therefore,

$$\frac{de_n}{dt} = e_n f N_T \tag{6}$$

According to the principle of detailed balance, the rate of electron capture should balance the rate of electron emission. This means that the concentration of free electrons should remain constant, or

$$\frac{dn}{dt} = 0 = e_n f N_T - n v_{th} \sigma_n (1 - f) N_T \tag{7}$$

Therefore,

$$e_n f N_T = n \nu_{th} \sigma_n (1-f) N_T \tag{8}$$

or

$$e_n = n \nu_{th} \sigma_n \frac{1-f}{f} \tag{9}$$

The Fermi-Dirac probability factor f is given by

$$f = \frac{1}{1 + (1/g) e^{(E_T - E_F)/kT}} \tag{10}$$

where g is the degeneracy factor, E_F is the Fermi level, k is the Boltzmann constant, and T is the temperature. The degeneracy factor takes into consideration that a given energy level can be occupied by an electron of either spin or by no electron at all. The Fermi level can be defined as the energy level where the probability of being occupied at temperature T is 1/2.

The free-electron concentration n is given by

$$n = N_C e^{(E_F - E_C)/kT} \tag{11}$$

where N_C is the density of states in the conduction band and $E_C - E_F \geq 2kT$.

Substituting for f and n, the electron emission rate e_n can be written as

$$e_n = \frac{N_c \nu_{th} \sigma_n}{g} e^{-(E_C - E_T)/kT} \tag{12}$$

By using the relationships

$$N_C = \left(\frac{2\pi m_e^* kT}{h^2} \right)^{3/2} \tag{13}$$

where m_e^* is the electron effective mass and h is Planck's constant, and

$$\nu_{th} = \sqrt{\frac{8kT}{\pi m_e^*}} \tag{14}$$

the equation for the electron emission rate e_n can be expressed as

$$e_n = \frac{16\pi m_e^* k^2 \sigma_n T^2}{g h^3} e^{-(E_C - E_T)/kT} \tag{15}$$

By taking the natural logarithm, we arrive at the equation

$$\ln \frac{e_n}{T^2} = \ln \left(\frac{16\pi m_e^* k^2 \sigma_n}{g h^3} \right) - \frac{E_C - E_T}{kT} \tag{16}$$

It can been seen from this equation that the slope of the Arrhenius plot of $\ln(e_n/T^2)$ against $1/T$ gives the activation energy of the electron trap relative to the conduction band edge, $E_C - E_T$. The y intercept of this plot gives the capture cross-section σ_n of the electron trap.

The next task is to determine the emission rate e_n at a range of temperatures so that an Arrhenius plot can be made.

Junction Capacitance Transient

We consider, for simplicity, a Schottky barrier diode formed on an n-type semiconductor. The energy band diagram of a Schottky barrier diode under different bias condition is shown in Figure 2. Figure 2A shows the diode in the reverse-bias condition. In the space-charge or depletion region, denoted by the shaded area in the figure, all the electron traps above the Fermi level are ionized or empty. In Figure 2B, the reverse bias is reduced by introducing a short pulse (one can also apply a short forward-bias pulse), thus reducing the width of the depletion region. By doing so, the electrons are now allowed to be captured at the traps, thus filling up the traps. Figure 2C shows that when the bias is returned to the original reverse-bias condition, the electrons begin to be thermally excited or emitted to the conduction band by absorbing thermal energy. The capacitance of the junction will vary in response to changes in the width w_d of the space-charge region according to

$$C = \frac{\varepsilon A}{w_d} \tag{17}$$

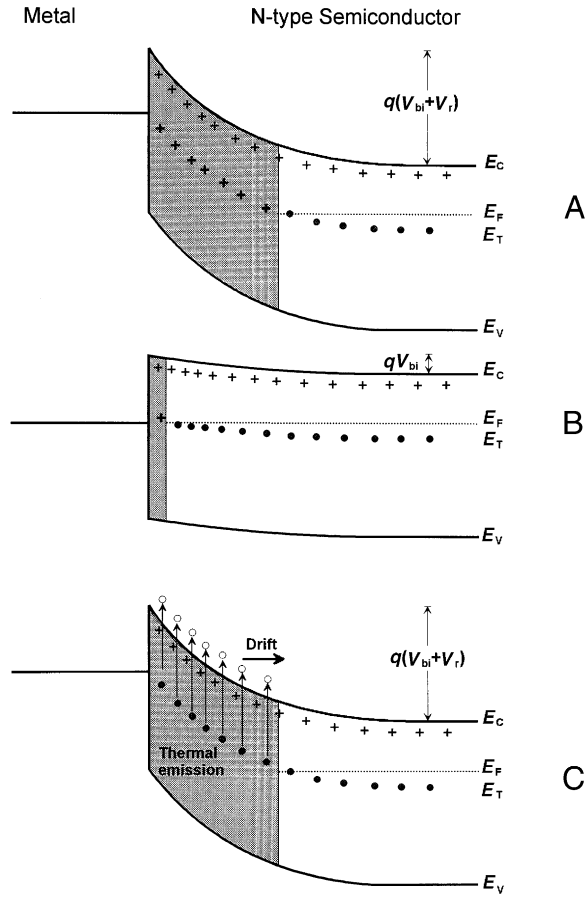

Figure 2. Energy band diagrams for a diode under (**A**) reverse bias; (**B**) reduced bias pulse; and (**C**) restored reverse bias.

where ε is the permittivity of the semiconductor and A is the surface area of the gate contact.

The width w_d is in turn dependent on the concentration of charged states or electron-trapping centers in the material as well as the applied bias across the junction, as shown by the equation

$$w_d = \sqrt{\frac{2\varepsilon[V_{bi} + V_r - (kT/q)]}{q(N_D^+ + N_T)}} \tag{18}$$

where V_{bi} is the built-in potential of the barrier, V_r is the applied reverse bias, q is the magnitude of the electronic charge, and N_D^+ is the concentration of ionized donor centers.

If we assume that the falling edge of the pulse coincides with time $t = 0$, we can denote the capacitance at time $t = 0$ as $C(0)$ and the capacitance at a sufficiently long delay ($t = \infty$) after the end of the pulse as $C(\infty)$. The capacitance $C(\infty)$ is actually the capacitance of the junction under the quiescent reverse-bias condition. It is commonly accepted, within certain restrictions (Look, 1989), that the difference in the capacitance at $t = 0$, $\Delta C(0)$, is related to the concentration of the electron traps by

$$\frac{\Delta C(0)}{C(\infty)} \cong \frac{N_T}{2N_D} \tag{19}$$

where N_D is the net dopant concentration.

The time variation of the capacitance following the applied bias pulse is shown in Figure 3. As the trapped electrons are emitted into the conduction band following the termination of the bias pulse, the capacitance of the junction will decay exponentially with a time constant τ_n according to the equation

$$C(t) = C(0)e^{-t/\tau_n} \tag{20}$$

The decaying time constant τ_n of the capacitance transient is related to the emission rate of the trapped electrons according to

$$e_n = \frac{1}{\tau_n} \tag{21}$$

Equation 20 can therefore be written as

$$C(t) = C(0)e^{-e_n t} \tag{22}$$

If the decaying capacitance transient is measured at two different time delays t_1 and t_2 from the termination of the bias pulse, then the difference in the capacitances will be given by

$$S = \Delta C = C(t_1) - C(t_2) = C(0)(e^{-e_n t_1} - e^{-e_n t_2}) \tag{23}$$

The capacitance difference S is the DLTS signal. It can be seen from Figure 4 that as the temperature changes, the time constant of the decaying transient also changes. The strong temperature dependence of trap emission rate and capacitance can be seen in Equations 15 and 20. The time constant at low temperature is longer, reflecting the low emission rate of the trapped electrons due to inadequate thermal energy for the electrons to escape. As the temperature of the sample increases, the time constant becomes shorter, corresponding to a faster rate of emission of the trapped electrons since there is an increasing availability of the thermal energy required for excitation into the conduction band. By monitoring the DLTS signal S, which is the difference in the capacitances at two different delay times, as a function of temperature, it can be seen that at low temperatures ($T \ll T_m$) and at high temperatures ($T \gg T_m$), the signal is very small. However, at an intermediate temperature T_m, the signal will go through a maximum value. At this temperature, T_m, the variation of the DLTS signal S with temperature can be described by

$$\frac{dS}{dT} = \frac{dS}{de_n} \times \frac{de_n}{dT} = 0 \tag{24}$$

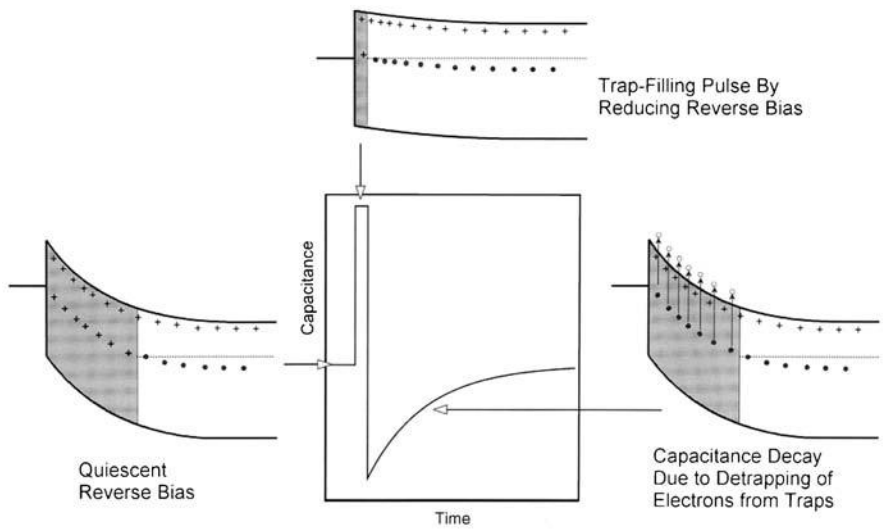

Figure 3. Time variation of junction capacitance during different biasing conditions for a majority-carrier trap.

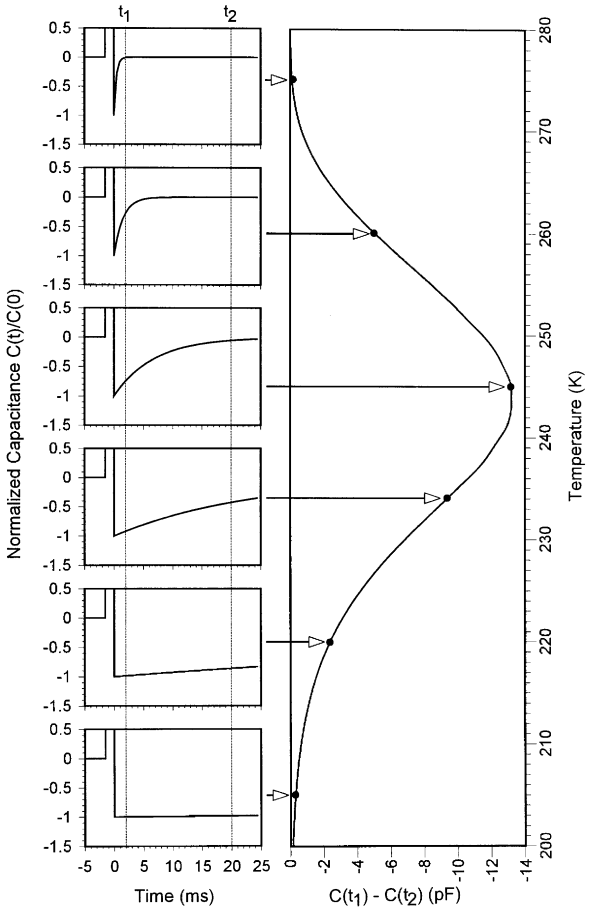

Figure 4. Temperature dependence of the time constant of a capacitance transient.

Therefore,

$$\frac{dS}{de_n} = -t_1 e^{-e_n t_1} + t_2 e^{-e_n t_2} = 0 \tag{25}$$

which gives

$$e_n = \frac{\ln(t_2/t_1)}{t_2 - t_1} \tag{26}$$

This equation shows that if the time delays t_2 and t_1 are known, then at the temperature T_m at which the signal S is a maximum, the emission rate of the trapped electron, valid only for that particular temperature T_m, can be calculated. By varying t_2 and t_1 but keeping the ratio t_2/t_1 constant (thus changing to a different value of e_n) and repeating the temperature scan, a different curve will be obtained, with the signal S peaking at a different temperature T_m. By repeating the procedure for several values of e_n and obtaining the corresponding set of temperatures T_m, an Arrhenius plot of $\ln(e_n/T^2)$ against $1/T$ can give the activation energy and the capture cross-section of the electron traps.

The efficiency of DLTS lies in the way in which the trapping parameters (activation energy and capture cross-section) are obtained experimentally. In the experiment, the capacitance transients are sampled at two different instants of time t_1 and t_2 from the end of the bias pulse. The expression $(t_2 - t_1)/\ln(t_2/t_1)$ can be considered as a time window. The reciprocal of this time window is the rate window. In essence, as the temperature changes, the emission rate of the carriers also varies until a temperature is reached at which the emission rate matches the rate window set by t_2 ant t_1.

Figure 5 shows an example of how an Arrhenius plot is made from the DLTS signals.

PRACTICAL ASPECTS OF THE METHOD AND METHOD AUTOMATION

The first DLTS experimental setup was reported by Lang (1974) and is popularly known as the boxcar technique. A block diagram of a basic DLTS spectrometer using the boxcar technique is shown in Figure 6. The high-frequency capacitance meter measures the capacitance across the junction device and typically has a 1 MHz test frequency. A pulse generator with variable pulse width and pulse height as well as a variable dc offset bias is required to provide a steady-state or quiescent reverse bias as well as the trap-filling pulse. A standard dc power supply can also be used instead of the dc offset bias of the pulse generator. In fact, a standard dc power supply may be able to give a wider range of reverse bias. An analog-to-digital converter is needed to digitize the analog output of the capacitance

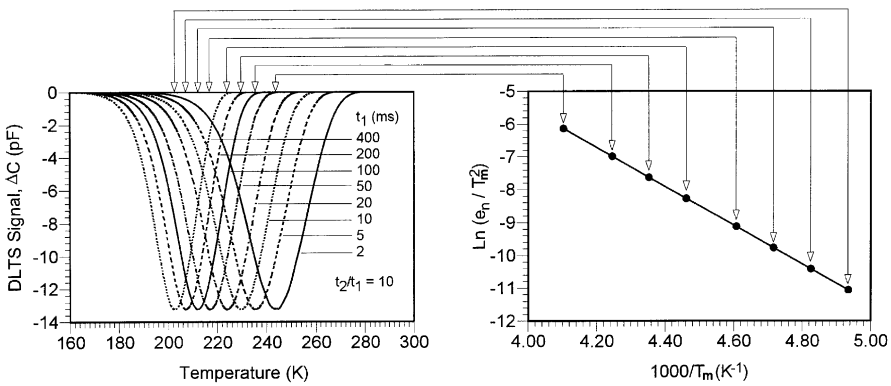

Figure 5. Deriving Arrhenius plots from DLTS signals.

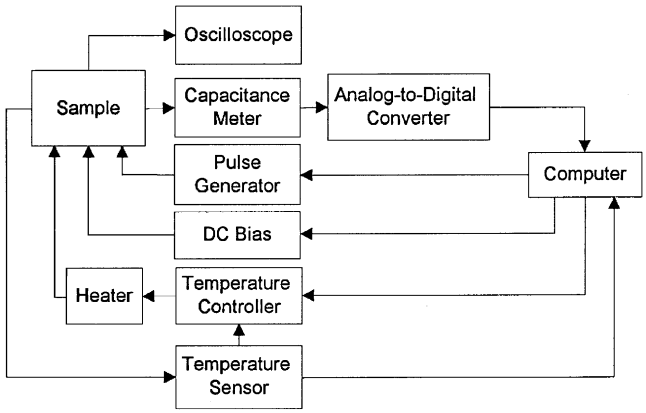

Figure 6. A DLTS spectrometer using the boxcar technique.

meter. A fast digital voltmeter with digital output to a computer can also be used for this purpose. It is also helpful to have an oscilloscope to visually monitor the capacitance transient. Poor or degraded contacts on the sample can give a noisy or spurious signal, and an oscilloscope is a good diagnostic tool for detecting any problem. A computer is necessary for data collection, analysis, and archiving. In the past, an analog *x-y* pen recorder was commonly used, but such recording devices do not allow for data manipulation, analysis, or storage. The temperature of the sample must be variable. A wide temperature range is required to detect the trapping levels from near the energy band edges to the middle of the band gap. A temperature range of about 77 to 380 K would be sufficient to detect trapping levels from about 0.1 eV to ~0.85 eV for most semiconductors. A higher temperature is needed for wide-band-gap semiconductors. Since the sample temperature needs to be as low as 77 K, a mechanical pump and a vacuum sample chamber or cryostat are needed to prevent ambient moisture from condensing on the sample. Although a temperature controller would be helpful for precise temperature control, it is not a necessity if the sample temperature can be slowly varied at a rate small enough to avoid any temperature lag between the temperature sensor and the sample.

The DLTS system shown in Figure 6 is more flexible in the way the data can be processed. The system would allow for the complete decay transient to be digitized, and the rate window technique can then be applied by writing a simple program to analyze the stored data files after the experiment. However, in addition to saving the complete data for later analysis, it is advisable that the DLTS signal be plotted in real time on the computer by simply plotting the difference between two capacitance values taken from the data file at two fixed delay times against the sample temperature at which the data were measured. In this manner, it is possible to see immediately whether there is any peak in the DLTS curve. In the event that there is no peak observed as the temperature is scanned, the operator can choose to terminate the experiment early without wasting much time. The operator should consider different choices of delay times and biasing conditions in order to obtain an optimum DLTS curve. A typical experiment would consist of gradually heating the sample from the low end of the temperature range to the high end and recording the capacitance transient at an appropriate temperature interval. If the complete transient is recorded, then only a single temperature scan is needed. Previously, DLTS temperature scans had to be repeated several times because only a single fixed-rate window can be applied at each scan. This is tedious and sometimes detrimental to the sample because repeated temperature cycling may degrade the sample. The automated approach described here is akin to a multichannel approach in which all the rate windows can be applied simultaneously. Obviously, if the complete transient can be digitized using the system in Figure 6, then it is also possible, especially with the power of modern desktop personal computers, to extract the time constants numerically by nonlinear curve fitting of each transient.

An alternative method to extract the DLTS curves that employs an instrumental approach as opposed to the digital technique described above is shown in Figure 7. In this method, an electronic circuit is used to perform the subtraction of the capacitance values to give the DLTS signal. The circuit essentially has two sample-and-hold amplifiers, each of which is separately triggered to hold the analog voltage corresponding to a capacitance value at a preset time delay from the end of the bias pulse. Since there are two sample-and-hold amplifiers, two analog voltages corresponding to the capacitances at two different parts of the capacitance transient are stored. The outputs from the sample-and-hold amplifiers are then fed into a differential amplifier to give an analog signal that is proportional to the difference between the two capacitances. This analog signal is the DLTS signal and can be further amplified and recorded by a digital voltmeter or analog-to-digital converter and then transferred to a computer. Each circuit can only provide one rate window or a single DLTS curve. The circuit can be built as a module, and by using several modules together, several DLTS curves corresponding to different rate windows can be obtained at the same time in a single temperature scan.

The elegance of the original DLTS lies in the instrumental extraction of the time constant from the capacitance decay without the use of numerical analysis. Other instrumental methods (Auret, 1986; Day et al., 1979; Kimerling, 1976; Miller et al., 1975, 1977) are available to measure the rate window. Various automated DLTS

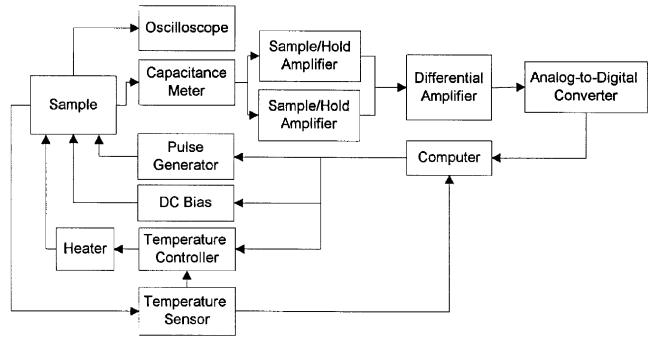

Figure 7. A DLTS spectrometer using the sample-and-hold amplifiers technique.

systems have also been reported (Chang et al., 1984; Holzlein et al., 1986; Kirchner et al., 1981; Okuyama et al., 1983; Wagner et al., 1980). A standard test method for using the DLTS technique has also been published (ASTM, 1993). Due to the spectroscopic character of DLTS and the significance of electrically active defects in devices, this technique can be adapted for industrial semiconductor process control (Jack et al., 1980).

Since the introduction of DLTS, many variations of the technique have been introduced. Examples of such variations are electron beam scanning DLTS (Petroff and Lang, 1977), photo-excited DLTS (Brunwin et al., 1979; Mitonneau et al., 1977; Takikawa and Ikoma, 1980), current or conductance DLTS (Borsuk and Swanson, 1980; Wessels, 1976), constant-capacitance DLTS (Johnson et al., 1979) and double-correlation DLTS (Lafevre and Schultz, 1977).

DATA ANALYSIS AND INITIAL INTERPRETATION

For each value of the emission rate e_n corresponding to a set of t_1 and t_2, a graph of the DLTS signal as a function of temperature is plotted. The emission rate e_n is related to t_1 and t_2 according to Equation 26. The temperature T_m at which the peak occurs is recorded. This graphing procedure is repeated for several emission rates, which are obtained experimentally by changing t_1 and t_2. For each value of e_n, there is a corresponding value of T_m. An Arrhenius plot of e_n/T_m^2 against $1/T_m$ is then produced. From Equation 16, it can be seen that the slope of the linear graph will give the activation energy and the y intercept will give the capture cross-section. The concentration of the defects can be calculated according to Equation 19. The concentration can also be derived from the DLTS peak only if t_1 is chosen to be very near to $t = 0$ and $t_2 \neq t_1$ (or $t_2 \div \infty$). See Principles of the Method for further details.

SAMPLE PREPARATION

A sample for DLTS measurement must contain a voltage-controlled depletion region. Schottky barrier diodes and p-n diodes are suitable samples. A Schottky barrier diode is the most convenient type of sample. This diode is simply a metal placed in contact with a semiconductor to form an energy barrier or Schottky barrier at the interface. The selected metal must have a sufficiently high Schottky energy barrier to produce a rectifying contact with a low leakage current. The surface of the semiconductor must be clean, because surface impurities can reduce the effective barrier height and increase current leakage. The metal film, or gate contact, can be deposited on the semiconductor by vacuum evaporation, sputtering, or chemical vapor deposition. For standard capacitance-voltage measurement, a mercury probe in contact with the semiconductor is adequate to form a Schottky barrier diode. However, this contacting technique is not advisable in DLTS because the temperature of the sample has to be varied over a wide range. Schottky barrier diodes are easily formed on semiconductors of low dopant concentration. They tend to exhibit large leakage current with increasing dopant concentration. Deep-level transient spectroscopy measurement does not work well with leaky diodes.

A p-n diode is made by forming a junction between an n- and a p-type material. Because the interface between the n- and p-type materials must be clean, this type of diode is usually formed by controlled introduction of dopants either by alloying, diffusion, or ion implantation or during epitaxial growth.

Both Schottky and p-n diodes also need low-resistivity ohmic contacts to allow for electrical connections between the semiconductors and the electronic equipment. It is easier to form an ohmic contact on a semiconductor of high dopant concentration ($\sim 10^{18}$ cm^{-3}) than one with a low dopant concentration, because the narrow width of the Schottky barrier formed by a metal on a highly doped semiconductor encourages current conduction by carrier tunneling through the thin barrier. Ohmic contact formation on highly doped material may or may not require alloy formation by thermal annealing. In some semiconductors, it is possible to get some metals to form good ohmic contacts even when the semiconductors have a low carrier concentration of about 10^{14} to 10^{15} cm^{-3}. The formation of ohmic contacts in such cases would invariably include alloy formation through rapid thermal annealing of the metal-semiconductor interface. A common sample configuration is one in which the semiconductor material of interest is grown on a highly doped or low-resistivity substrate of the same material. Schottky or p-n diodes are formed on the top surface while ohmic contact is made at the back of the low-resistivity substrate.

In DLTS experiments using Schottky diodes, it is possible to avoid ohmic contact problems by making the back contact on the substrate larger than the cross-sectional area of the depletion region of the sample. In practice, the size of the gate contact is made smaller than the back contact. In this configuration, the larger back contact will have a larger capacitance than that of the depletion region. The resultant capacitance will be largely that of the depletion region, which is the region of interest.

It is often necessary for the diode cross-sectional area to be known so that it can be used in data analysis. In Schottky diodes, diode structures of the required size can be made by vacuum evaporation or by sputtering of metal through a shadow mask containing holes of the required dimensions. Alternatively, the metal film can be patterned through photolithography and etching to produce Schottky diode structures of different sizes. The p-n junction diodes can only be patterned through photolithography and etching.

Since any sample containing a bias-controlled depletion region can be used for DLTS measurement, this technique can be applied not only to individual discrete diodes but also to junction diodes found in devices such as bipolar and field-effect transistors. It can also be used for measurement of interface state density at an insulator–semiconductor interface in an MIS device. Deep-level transient spectroscopy can therefore be used for analysis of actual transistors. The potential applications of DLTS

as a diagnostic tool for actual devices make it a powerful technique for understanding the role of electrically active defects in device performance and reliability.

PROBLEMS

The shortcoming of DLTS, or any method that requires a depletion region, is that it is not effective for high-resistivity materials due to the problems involved in obtaining suitable junctions on such materials. Furthermore, due to the low concentration of free carriers in such materials, an application of a reverse bias may cause the whole sample to be depleted. This shortcoming led to the introduction of photo-induced current transient spectroscopy (PICTS or PITS; Fairman et al., 1979; Hurtes et al., 1978; Look, 1983; Tin et al., 1987; Yoshie and Kamihara, 1983a,b, 1985), which employs the same gating technique but uses a light pulse instead of a voltage pulse and does not require a depletion region to be formed.

The interpretation of DLTS curves is susceptible to errors. For example, a high circuit impedance (which could be due to high sample resistivity or poor contacts) will cause a disproportionately large time constant that is due to the increase in the reactance-capacitance time constant of the measurement setup and not to a very deep trapping center. In such cases, the DLTS curves lack sharp or well-defined peaks. Such samples are commonly encountered in studies of irradiation effects in semiconductors (Lang, 1977; Tin et al., 1991a,b). A broad peak can also be indicative of a range of closely spaced energy levels producing capacitance transients with multiexponential characteristics. In certain cases, it is possible to separate the closely spaced peaks by using large t_2/t_1 ratios or large values of $t_2 - t_1$. When using DLTS for depth profiling of defects, the effect of fringing capacitance around the gate contact also needs to be considered.

A featureless or flat DLTS curve does not mean an absence of trapping centers. Experiments with different quiescent bias and pulse height settings should be tried to determine the optimum parameters for subsequent high-resolution scans.

Traps with very large or very small capture cross-sections are not easily detected (Miller et al., 1977). Different experimental conditions and samples should be used to provide as much detail of the defect structure as possible.

The steady-state capacitance of the sample changes with temperature. This causes the DC level to shift with temperature. A baseline restoring circuit will resolve this problem (Miller et al., 1975). Another solution to this problem is to reduce the rate of temperature increase to ensure that the sample temperature does not change appreciably while the capacitance is relaxing to its steady-state value after each bias pulse.

During the peak of each bias pulse, the capacitance meter will show an overload. The capacitance meter should have a fast pulse overload recovery in order to measure fast transients.

Data acquisition should only be initiated after the meter has recovered from overload.

CARRIER LIFETIME: FREE CARRIER ABSORPTION, PHOTOCONDUCTIVITY, AND PHOTOLUMINESCENCE

INTRODUCTION

The charge carrier lifetime is one of the most important parameters characterizing a semiconductor. This is mainly for two reasons: (1) the carrier lifetime determines the performance of devices while, at the same time, (2) it is a sensitive measure of material quality and cleanliness. Carrier lifetime may impact device operation directly, such as by affecting the turn-off speed of a diode or a thyristor operating at high injections or the leakage current of a *pn*-junction. Carrier lifetime may also affect operation indirectly, e.g., by affecting the current gain of a bipolar transistor. Thus, a high carrier lifetime is desirable in many cases, whereas a low lifetime favors specific applications (e.g., high-speed operation). Furthermore, for optically active devices, one is interested in radiative recombination, and other recombination mechanisms must be suppressed to enhance quantum efficiency.

To monitor material quality and cleanliness, the carrier lifetime is one of the most sensitive parameters available, able to detect impurities down to a level of $\sim 10^{10}$ cm^{-1} (Schroder, 1997), i.e., one impurity atom per $\sim 10^{12}$ host atoms! In fact, for silicon, the highest lifetimes ever reported (Yablonovitch et al., 1986; Pang and Rohatgi, 1991) are still believed to be limited by impurity/defect recombination and not by intrinsic recombination mechanisms such as radiative recombination. This makes lifetime characterization an important tool for verifying material quality and also for monitoring contamination during subsequent processing. Thus, lifetime measurements are also performed during CMOS processing even though field-effect transistors are unipolar devices, and thus not directly affected by the carrier lifetime (except for leakage current).

Carrier lifetimes and lifetime-characterization techniques have been studied extensively since the start of semiconductor research. This has resulted in the development of a large number of techniques based on different physical principles (Orton and Blood, 1990; Schroder, 1990). Yet, very few standard techniques exist and no single

technique is dominant. This is in part due to the different requirements for various semiconductor materials, reflecting vastly different lifetime values, but also due to different geometry and probing depths. Finally, different recombination mechanisms or injection ranges are addressed by the different methods as they focus on various applications of the material or the device. As a consequence, different lifetime measurement techniques often yield vastly different results, even for the same sample!

This unit reviews the theory and common concepts in carrier-lifetime measurement methodology and focuses on a few important and general techniques used to characterize lifetime in semiconductor materials. Thus, device lifetime characterization methods have been left out. We do not intend to provide detailed descriptions of the reviewed methods; this information can be gathered from the cited references. Our aim is instead to present basic principles of the methods, methodology, and associated difficulties, such that the reader will be able to critically analyze data provided by the methods and to perform simple measurements using the techniques. Also, a selection guide is provided to direct users to the most appropriate method for their specific needs.

The three methods described in this unit are free carrier absorption (FCA), photoconductivity (PC), and photoluminescence (PL). We have selected these methods based on the following criteria.

Free Carrier Absorption is not of widespread use but is a very general tool applicable to most semiconductor materials and also to devices. It provides an exceptional advantage, as different geometries and very different injection regimes can be realized, and therefore many different materials and recombination mechanisms may be characterized. We use it here to illustrate many common concepts in lifetime measurement methods, and, as a consequence, it is presented first.

Photoconductivity is one of the few standard methods used both for wafer fabrication quality monitoring and for clean-room process monitoring. However, at wafer fabrication the transient conductivity following a laser excitation pulse is detected by electrical contacts on a crystal boule while process monitoring is performed using contactless probing of the conductivity.

Photoluminescence is a particularly useful method for characterizing direct-band-gap semiconductors, but has also been applied to indirect band-gap materials. This relies on the extreme sensitivity of many photodetectors, whereby even single-photon counting is available in most optical laboratories. The PL method has also become the workhorse when small volumes must be analyzed, such as in thin-film studies, for quantum-well characterization, or for the rapidly expanding field of semiconductor nanostructures.

The unit commences with a review (see discussion of Theory, below) of the carrier-lifetime concept and various recombination mechanisms, also illustrating some major difficulties affecting lifetime characterization, such as trapping and surface recombination. The next section (Theory) briefly outlines the different techniques and their fundamental principles of operation. Next, the three different techniques are described in detail. Finally, a selection guide is provided for the different lifetime applications.

THEORY

Carrier-Lifetime Concept

In a semiconductor at equilibrium at a certain temperature, a balance exists between thermal generation of carriers, i.e., electron-hole pairs, and recombination of carriers, such that the electron and hole concentrations, designated by n and p, respectively, remain constant (for a general textbook see Sze, 1981). In this way, the law of mass action, $np = n_i^2$, is fulfilled, where n_i is the intrinsic carrier concentration at this temperature. For any departures of the carrier concentrations from this balance such that the mass action law is no longer valid, the system will try to revert to equilibrium. In a general case this is governed by the continuity equation

$$\frac{dn}{dt} = \frac{1}{q}\frac{\partial J_n}{\partial x} + (G_n - R_n) \tag{1}$$

where q is the elementary charge, J_n the electron current density, and G_n and R_n the generation and recombination rates for electrons in the semiconductor. A similar equation holds for holes. Assuming that no electric field is present, the current density is given only by a diffusion current

$$\frac{dn}{dt} = D_n\frac{\partial^2 n}{\partial x^2} + (G_n - R_n) \tag{2}$$

which is known as the diffusion equation, where D_n is the electron diffusion coefficient, which has been assumed independent of concentration and position. In a **homogeneous** case, the derivative with respect to x vanishes and a very simple equation remains. However, to treat the generation and recombination terms more easily, one may expand carrier densities in terms of excess concentrations Δn and Δp

$$n = n_0 + \Delta n; \qquad p = p_0 + \Delta p \tag{3}$$

Also, one may note that band-to-band recombination must be proportional to the product of n and p: i.e., $R_n = Bnp$, where B is the radiative recombination coefficient. In thermal equilibrium, this recombination must be balanced by the band-to-band generation rate; thus, $G_n = Bn_0p_0$. Inserting into Equation 2, and for the homogeneous case one arrives at

$$\frac{d\Delta n}{dt} = -B(n_0\Delta p + p_0\Delta n + \Delta n\Delta p) \tag{4}$$

From this expression, it is clear that the system will revert to equilibrium both from a case where **excess carriers** have been introduced (i.e., when Δn and Δp are positive) as well as for a case where a **carrier deficit** is present (when Δn and Δp are negative). Examples of these situations are the return to equilibrium, (a) following an optical

generation pulse and, (b) following a reverse biasing pulse forming a depletion layer as in a deep level transient spectroscopy (DLTS) experiment (DEEP-LEVEL TRANSIENT SPECTROSCOPY).

Examination of Equation 4 further reveals that two cases may be distinguished: (1) When Δn and Δp are small with respect to their equilibrium values (n_0,p_0) and (2) when they are much larger than they are at equilibrium. The former case is called low-level injection (ll) case, which is sometimes called **minority carrier injection**, while the latter case is referred to as the **high level injection** (hl) case. We see that recombination is linear in Δn for the ll case and quadratic in Δn for the hl case for band-to-band recombination. As a final simplification, we will consider the case when Δn equals Δp, as in optical generation of carriers or during forward injection in a *pn*-junction diode (in a case of negligible trapping; see discussion of Trapping, below). For minority carrier injection, Equation 4 reduces to

$$\frac{d\Delta n}{dt} = -B(n_0 + p_0)\Delta n \tag{5}$$

The solution to this equation is a simple exponential decay

$$\Delta n(t) = \Delta n(0) \cdot \exp(-t/\tau) \tag{6}$$

with lifetime $\tau = 1/[B(n_0 + p_0)]$ as given by Equation 5. The exponential decay and the lifetime defined in this manner are analogous to the decay of radioactive isotopes. More generally, the lifetime may be defined using a general recombination term R according to

$$\tau = \frac{\Delta n}{\Delta R} = -\frac{\Delta n}{(d\Delta n/dt)} \tag{7}$$

where R is the recombination rate of excess electron-hole pairs. The lifetime may not be a constant as in Equation 5, but may be a complicated function of injected carrier density, i.e., of Δn and Δp, and of other parameters.

Recombination Mechanisms

In the derivation of the rate equation governing recombination leading to Equation 5, radiative band-to-band recombination was assumed to be the single recombination mechanism, dominant in direct-band-gap semiconductors. However, several physically different recombination mechanisms exist, each of them adding a recombination term to Equation 2. Indeed, all of these mechanisms also have their corresponding generation mechanism, as stated in the **principle of detailed balance** (Van Roosbroeck and Schockley, 1954). Thus, a generation term must be added for each of them. This ensures that dn/dt equals zero at equilibrium, such that the carrier concentrations are maintained at the n_0 and p_0 values. Note that all equations are valid both for intrinsic material as well as for doped semiconductors.

In Figure 1, common recombination mechanisms are depicted. The first one, the **Shockley-Reed-Hall** (SRH) or **multiphonon** mechanism (Hall, 1952; Shockley and Reed, 1952) dominates recombination in most indirect bandgap semiconductors, such as Si, and involves the trapping of an electron at a defect level within the bandgap followed by the capture of a hole to the same state (and at the same physical location). The reaction may start with the hole capture, depending on the relative capture strengths for holes and electrons and their relative concentrations, but effectively results in the loss of one pair of carriers upon completion. Since recombination is directly proportional to the trap concentration, the corresponding lifetime is a measure of the defect concentration in the sample. The lifetime may be calculated (Sze, 1981) from the effective SRH recombination rate (actually $G-R$ in Equation 2)

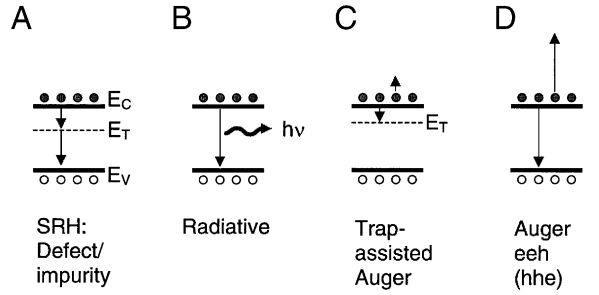

Figure 1. Fundamental recombination mechanisms in semiconductors. From left to right: (**A**) recombination through deep traps (SRH); (**B**) radiative recombination; (**C**) trap-assisted Auger recombination; (**D**) Auger recombination.

$$R_{SRH} = \frac{pn - n_i^2}{\tau_p\{n + n_i\exp[(E_T - E_i)/kT]\} + \tau_n\{p + n_i\exp[(E_i - E_T)/kT)]\}} \tag{8}$$

where E_T and E_i are the trap energy level and the Fermi energy level for intrinsic material, respectively, T is the absolute temperature, and k is the Boltzmann constant. τ_p and τ_n are defined as

$$\tau_p = \frac{1}{\sigma_p v_{th} N_T}; \qquad \tau_n = \frac{1}{\sigma_n v_{th} N_T} \tag{9}$$

where v_{th}, N_T, σ_p, and σ_n denote thermal velocity, trap density, and cross-sections for hole and electron capture by the trap, respectively. The SRH lifetime may be derived using Equations 3 and 7, and is given by the expression

$$\tau_{SRH} = \frac{\tau_p(\Delta n + n_0 + n_i e^{(E_T - E_i)/kT}) + \tau_n(\Delta n + p_0 + n_i e^{(E_i - E_T)/kT})}{p_0 + n_0 + \Delta n} \tag{10}$$

assuming $\Delta n = \Delta p$. Figure 2 displays the functional form of τ_{SRH} versus carrier injection level, and with trap energy level, relative to the edge of the conduction band ($E_C - E_T$). In this example, *n*-type Si with a doping concentration of 1×10^{15} cm^{-3} was selected, and lifetime values were fixed to $\tau_p = 10$ μs and $\tau_n = 44$ μs, respectively. From the figure, it is

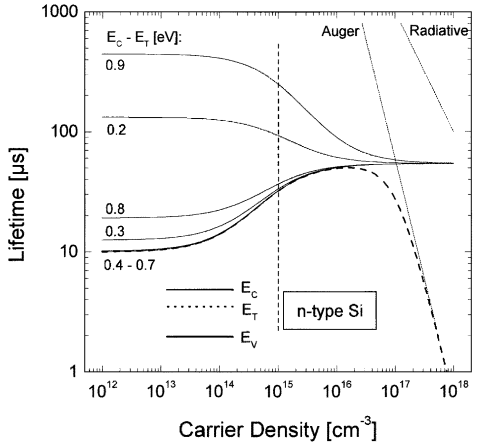

Figure 2. The lifetime injection dependence in n-type Si, doped to 10^{15} cm^{-3}, for recombination through traps according to the SRH formalism (solid curves) with trap energy level as parameter ($\tau_p =$ 10 μs, $\tau_n = 44$ μs). The radiative and Auger recombination rates are shown as dashed lines using generally accepted values for their respective cross-sections. The long-dash line includes SRH ($E_C - E_T = 0.5$ eV) and Auger recombination.

clear that trap energy levels close to the middle of the band gap are most efficient under minority carrier injection, while at high injections all levels are equally effective. The high-injection lifetime, from Equation 10 for infinite Δn, is given by

$$\tau_{hl} = \tau_n + \tau_p \tag{11}$$

The second recombination mechanism depicted in Figure 1 is the **radiative** process, or band-to-band recombination, where an electron and a hole recombine, resulting in the emission of a photon with the characteristic energy of the band gap. From Equation 4, the radiative lifetime is given by

$$\tau_{RAD} = \frac{1}{B(p_0 + n_0 + \Delta n)} \tag{12}$$

which is valid also at high carrier injection. While the intrinsic radiative lifetime dominates recombination in direct-bandgap semiconductors, B is about four orders of magnitude smaller in indirect semiconductors such as Si and Ge (see discussion of Photoluminescence, below, and Table 1).

The third recombination process depicted in Figure 1 is **trap-assisted Auger** recombination (Landsberg, 1987). Here, the capture of an electron (or a hole) at a trap is

Table 1. Measured Carrier Lifetimes and Typical Recombination Coefficients in Some Selected Semiconductors at 300 K[a]

Material	Measured Lifetimes	Radiative Coefficient (cm^3s^{-1})	Auger Coefficients (C_n) (cm^6s^{-1})	Auger Coefficients C_p (cm^6s^{-1})	C_n+C_p (hl)
Indirect					
Si	Typical: 10 to 200 μs Highest: 40 ms[e] Lowest: ~1 ps[f]	1×10^{-14} [b]	2.8×10^{-31} [c]	1×10^{-31} [c]	1.35×10^{-30} [d]
Ge	Typical: 1 to 200 μs	5.2×10^{-14} [g]	8×10^{-32} [g]	2.8×10^{-31} [g]	1.1×10^{-31} [h]
4H-SiC	Typical: 10 to 500 ns Highest: 2 μs[i]	1.5×10^{-12} [j]	$<5 \times 10^{-31}$ [j]		7×10^{-31} [j]
Direct					
GaAs	Typical: 1 ns to 2 μs[k]	2×10^{-10} [g]	1.8×10^{-31} [g]	4×10^{-30} [g]	7×10^{-30} [l]

[a] The resulting effective lifetime can be obtained using Equations 12–16, noting the appropriate injection level, Δn, in a particular measurement. The "measured lifetime" is determined by impurity/defect recombination (SRH) except for clean material of direct-band-gap type semiconductors where the lifetime is set by the radiative lifetime. The last column refers to measurements at high level injection.

not accompanied by phonon emission as in the usual SRH case, but its energy is instead transferred to a second electron (or hole). The rate equation in this case predicts a quadratic dependence in carrier concentrations (i.e., proportional to *np*, *nn,* or *pp*) just as in the case of radiative recombination; however, the rate constant is also proportional to the trap density. Therefore, radiative and trap-assisted Auger may be combined into a common radiative coefficient according to

$$B = B_{\mathrm{RAD}} + \beta_{\mathrm{TRAP}} \cdot N_{\mathrm{T}} \tag{13}$$

where B_{RAD} signifies the purely radiative coefficient and β_{TRAP} is a coefficient for the trap-assisted process.

Finally, **Auger recombination**, depicted as the fourth mechanism in Figure 1, is the recombination of an electron and a hole while the energy is transferred to a third carrier. As three carriers are involved, Auger recombination only dominates at very high injections. However, in highly doped semiconductors, as in emitter regions of devices, Auger recombination becomes large and often sets the lifetime in these regions. At high injections, the Auger lifetime is given by

$$\tau_{\mathrm{AUG}} = \frac{1}{(C_{\mathrm{p}} + C_{\mathrm{n}}) \cdot \Delta n^2} = \frac{1}{\gamma \cdot \Delta n^2}; \gamma \equiv C_{\mathrm{p}} + C_{\mathrm{n}} \tag{14}$$

where C_{p} and C_{n} are the Auger coefficients for the *hhe* and the *eeh* processes, respectively. In the minority carrier regime, the Auger lifetime is defined as

$$\tau_{\mathrm{Auger}} = \frac{1}{C_{\mathrm{p}} p_0^2}; \quad \tau_{\mathrm{Auger}} = \frac{1}{C_{\mathrm{n}} n_0^2} \tag{15}$$

representing the Auger lifetime in highly doped p-type and n-type material, respectively. Note that both C and γ are used to denote Auger coefficients and B and β are used for the radiative coefficient.

For calculating the resulting total lifetime, one may note that according to Equation 2, recombination is additive, and when using Equation 7, lifetimes should be summed as inverse numbers

$$\frac{1}{\tau} = \frac{1}{\tau_{\mathrm{SRH}}} + \frac{1}{\tau_{\mathrm{RAD}}} + \frac{1}{\tau_{\mathrm{Auger}}} \tag{16}$$

In Figure 2 the resulting total lifetime injection dependence is shown as a dashed line where Auger and radiative recombination in Si have been included with traditional values for B, C_{p}, and C_{n} (Schlangenotto et al., 1974; Dziewior and Schmid, 1977). The individual contributions of these recombination rates are shown as dotted lines. For the minority carrier **doping dependence** in Si, see, e.g., Häcker and Hangleiter (1994) and Rohatgi et al. (1993).

Finally, Table 1 reports typically measured carrier lifetimes for a few indirect-band-gap semiconductors and for GaAs. Radiative and Auger coefficients have also been included in the table. Coefficients for radiative and Auger recombination for other semiconductors may be found in Schroder (1990).

Generation Lifetime

When a carrier deficit exists, i.e., when both Δn and Δp are negative, recombination according to Equation 8 is negative, meaning that carriers are generated. This carrier generation is mediated through the trap level acting as a stepping stone to cross the band gap and is much more efficient than ordinary band-to-band generation. Such a situation exists, e.g., in the depletion layer in a device, and carrier generation results in additional leakage currents. As a consequence, recombinative defects are also important for majority carrier (unipolar) devices such as MOS transistors.

The generation lifetime may be derived from the SRH expression, Equation 8, in the limit when pn reduces to zero (also $n = p = 0$) and is given by

$$\tau_{\mathrm{g}} = \tau_{\mathrm{p}} \exp[(E_{\mathrm{T}} - E_{\mathrm{i}})/kT] + \tau_{\mathrm{n}} \exp[(E_{\mathrm{i}} - E_{\mathrm{T}})/kT] \tag{17}$$

Analyzing Equation 17, one finds that for $E_{\mathrm{T}} \cong E_{\mathrm{i}}$, the generation lifetime is of the same magnitude as τ_{n} and τ_{p}. However, for trap levels far from the intrinsic Fermi level, E_{i}, the generation lifetime may be orders of magnitude larger than the corresponding recombination lifetime. Thus, we conclude that lifetime measurement techniques probing the generation lifetime, e.g., the **pulsed MOS capacitance** technique, should not be used to measure the recombination lifetime, which is important for bipolar devices as in the base of a transistor, for example. This is extensively discussed in Schroder (1990) and Baliga (1987).

Trapping

In the treatment of recombination so far, it has been assumed that $\Delta n = \Delta p$ and that a single defect center is active with a single trap energy level. If, however, the defect concentration, N_{T}, is high relative to the doping density and injected carrier densities, Δn and Δp, recombination rates may be different for electrons and holes [due to their different capture cross-sections, $\sigma_{n(p)}$]. This leads to unbalanced carrier densities, resulting in nonexponential carrier decays.

A similar situation also occurs when a high concentration of a shallow defect level is present in addition to the main recombination level. The shallow level then acts as a trap which temporarily holds the carrier before releasing it to the band again (the difference with a deep center being that emission to the band of an electron is far more probable than completion of the recombination by the capture of a hole). This results in a variable time delay before recombination through the main recombination level takes place, yielding a nonexponential excess carrier decay transient. According to the most general definition (in Ryvkin, 1964, and in other textbooks) any level in the forbidden gap acts as a recombination level if its position is between the quasi-Fermi levels for electrons and holes. On the contrary, levels that are outside this region (i.e., outside quasi-Fermi levels at the particular injection) act as temporary traps. Examples are porous Si and amorphous Si containing a large density of trap centers of different energy levels, E_T, which in most experiments

exceeds the injected carrier density by several orders. For porous Si the decay transient follows a **stretched exponential** shape according to $I = I_0 \exp(-(t/\tau)^p)$ where τ is a characteristic lifetime and p is a power index describing the curvature in a semilogarithmic plot. We conclude that because the recombination lifetime for high trap densities may not be derived in a simple way, the observed lifetime is multiplied by a factor dependent on the delay time of each trap energy level.

Aspects of Surface Recombination and Diffusion

Inspection of Equation 2 reveals that the local excess carrier decay is not only affected by recombination, which is of primary interest here, but is also affected by carrier gradients. Carrier gradients may result not only from an inhomogeneous excess carrier excitation, but also from differences in the local recombination rate. The effect may be dramatic, such that the diffusion term (all three coordinate directions need to be considered) totally dominates dn/dt and no useful information can be extracted for the recombination term. In fact, diffusion is a limiting factor for most lifetime measurement techniques, and, for an initially homogeneous excess carrier profile, local lifetime information is only obtained within a radius of a **diffusion length**, L_D, given by

$$L_D = \sqrt{D \cdot \tau} \tag{18}$$

For low carrier lifetimes, as occurs in direct-band-gap semiconductors, the diffusion length is relatively short and the spatial resolution is usually set by the specific lifetime measurement technique. In contrast, in indirect-gap semiconductors of good quality material, characterized by high carrier lifetimes, the diffusion length may be several hundred microns. In this case carriers easily reach sample or wafer surfaces and the state of these surfaces becomes critical. Thus, high surface recombination results in a flow of carriers towards the surfaces, leading to a drainage of carriers in the interior bulk and an incorrectly determined value for the carrier lifetime. This is illustrated in the leftmost schematic of Figure 3 and confirmed by the experimental data of Figure 4. In this figure, instant carrier density profiles are shown in a 1-mm-thick Si sample as

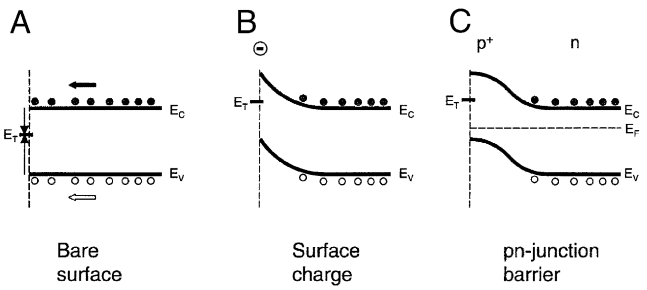

Figure 3. Influence of surface on carrier dynamics. From left to right, schematics illustrate (**A**) high surface recombination at a bare, nonpassivated surface; (**B**) shielding of surface states due to charge-induced band-bending; and, finally, (**C**) barriers introduced by a *pn*-junction (also shielding the surface).

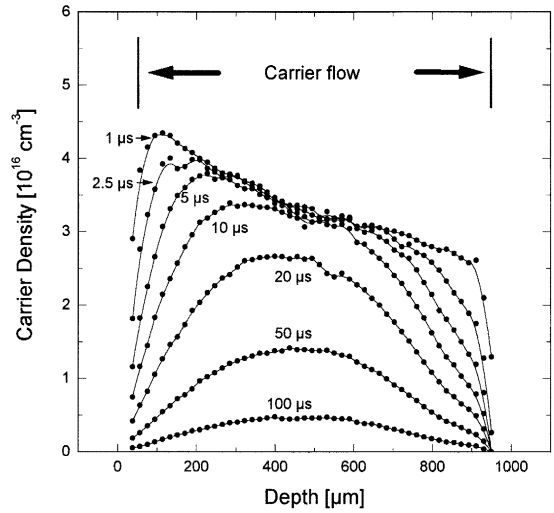

Figure 4. Depth resolved free-carrier-absorption measurements in a 1-mm-thick Si sample illustrating diffusive flow of carriers to surfaces of high surface recombination rate. Data have been recorded at full excitation (top curve) and at successive time moments after the excitation pulse (as given in µs at each respective curve). The optical excitation pulse of wavelength $\lambda = 1.06$ µm impinged onto the sample from the left, yielding the slightly inhomogeneous initial excitation.

measured following a short optical generation pulse. The data clearly illustrate the effect of surface recombination, which, in this case, totally dominates the observed lifetime. Notably, surface recombination is not a different recombination mechanism, but simply SRH recombination occurring at the surface, e.g., at dangling bonds. By the same token, defects **close** to the surface may not be distinguished from defects **at** the surface.

Recombination at or near the surface can be described by the surface recombination velocity, s, in units of cm/s. Its defining equation is

$$D\frac{\partial n}{dx} = -s \cdot n \tag{19}$$

The solutions of the diffusion equation, Equation 2, in a one-dimensional transient case, with boundary values for the surface recombination velocity according to Equation 19, are nonanalytic (Waldmeyer, 1988). For long times after the initial excitation, however, a "steady-state" carrier profile develops, resulting in an exponential excess carrier decay. The corresponding effective lifetime, τ, is modified by the "surface lifetime," τ_s, according to

$$\frac{1}{\tau} = \frac{1}{\tau_b} + \frac{1}{\tau_s} \approx \frac{1}{\tau_b} + \frac{1}{d\left(\frac{1}{2s} + \frac{d}{D\pi^2}\right)} \tag{20}$$

where τ_b is the bulk lifetime, D the diffusivity at the appropriate injection, and d the smallest dimension of the sample (usually the wafer thickness). The last approximate equality was proposed by Grivickas et al. (1989), the uncertainty being less than 4% over the entire range of s values.

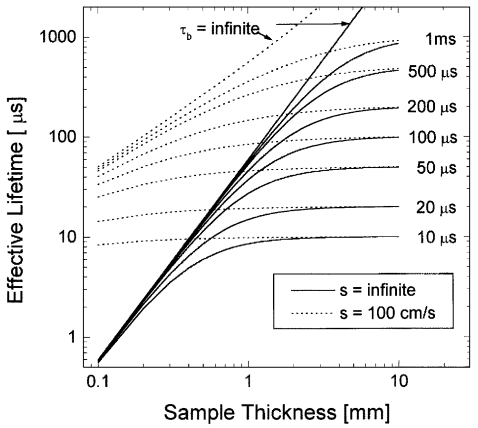

Figure 5. Calculated effective lifetime in silicon, with bulk lifetime as a parameter, versus sample thickness, assuming infinite surface recombination (solid lines) and an ambipolar diffusion coefficient of 17 cm^2/s. The dotted curves were calculated using Equation 20 with a surface recombination velocity of 100 cm^2/s.

Note that, for a single surface, the factor of two in the denominator of Equation 20 should be removed.

Figure 5 shows the results of a calculation according to Equation 20 of the effective lifetime in a Si wafer as a function of thickness. Data for two values of the surface recombination velocity are displayed, and in the calculation an ambipolar diffusivity of $D_a = 17$ cm^2/s was used (Linnros and Grivickas, 1994). The data illustrate well the limitation in measured lifetime imposed by surface recombination, which may only be solved using well-passivated sample surfaces or extremely thick samples ($d^2 \gg D\ \pi\tau_b$).

Methods to reduce high surface-recombination rates are nontrivial, and, in general, such methods may alter the lifetime distribution or may involve etching of the surface. For silicon, a thermal oxide of good quality may reduce surface recombination substantially, although the high formation temperature would probably alter the defect distribution of the sample. Other methods involve different surface passivation schemes, or even measurements with the Si wafer immersed in a passivating HF bath (Yablonovitch et al., 1986). A different approach involves the creation of charges at the surface, resulting in a surface band bending, as illustrated in the middle panel of Figure 3 (Katayama et al., 1991). Finally, the right part of Figure 3 shows the situation when a *pn*-junction is present, as in a highly doped emitter in a device. In this case, the bending of the bands results in barriers, which reflect either electrons or holes (being minority carriers in the highly doped region) such that recombination is inhibited (Linnros, 1998a). Thus, a measurement in the *n* region would reflect the "true" bulk lifetime.

Related Physical Quantities

Although the primary concern of this unit is lifetime measurement techniques, several of these methods may be used to extract other related physical quantities. In fact, some methods do not even measure the lifetime directly, but extract the lifetime from the measurement of other quantities such as the diffusion length. A summary of related physical quantities and a brief comment on how they can be measured is displayed in Table 2.

OVERVIEW OF CARRIER LIFETIME CHARACTERIZATION TECHNIQUES

In this section, a brief overview of the most common methods for carrier lifetime characterization will be given. We do not intend to provide a full list of all methods; examples can be found in the textbook of Schroder (1990) and that of Orton and Blood (1990). Instead, we will focus on fundamental principles of operation, applicability, and strengths and weaknesses. Finally, a comparison of a few techniques from the viewpoint of certain criteria will be provided together with a selection guide.

Table 2. Carrier Lifetime and Related Physical Quantities[a]

Physical Quantity	Symbol	Injection Case	Dominant Regime	Measurement Principle (Examples)
SRH lifetime	τ_{SRH}(ll)	ll	Indirect semiconductor	See techniques of this unit
	τ_{SRH}(hl)	hl		
Radiative lifetime	τ_{RAD}(ll)	ll	Direct semiconductor	PL-transient
	τ_{RAD}(hl)	hl		PL-transient
Auger lifetime	τ_{Auger}(ll); $\gamma_n\gamma_p$	ll	High doping	Measure ll-lifetime
	τ_{Auger}(hl); γ	hl	High injection	Nonexponential transient
Diffusion length	L_D	ll	—	e.g., EBIC/OBIC
Diffusivity	D_nD_p	ll	—	Time-of-flight, transient grating
	D_a (ambipolar)	hl		Transient grating
Mobility	$\mu_n\mu_p$ (majority)	ll		Conductivity/Hall
	$\mu_n\mu_p$ (minority)	ll		Haynes-Shockley
Surface recomb. velocity	s_ns_p	ll, hl	—	See several techniques of this unit

[a] Some of these quantities may be determined in lifetime-type experiments. The fourth column indicates for which type of material a recombination mechanism is dominating while the fifth column indicates suitable measurement methods.

For an overview, the different methods may be sorted in several different ways: either according to physical principles, according to methods used for carrier injection, according to methods used for probing of excess carriers, or according to whether techniques are contactless, nondestructive etc. Unfortunately, there are no unambiguous ways to perform such sorting, partly because variants of the same method would fall into different categories. The approach taken here is to divide the methods into **optical techniques**, **diffusion-length-based methods**, and **device-related techniques**. We note that this distinction is not clear, as optical techniques may contain current probing (as in photoconductivity) and diffusion-length-based methods normally use optical excitation for carrier injection. In addition, several variants exist of techniques where electrical injection is replaced by optical injection, or vice versa. Finally, all techniques may be classified into steady-state methods, modulated methods, or transient/pulsed methods. Several of the methods presented here, indeed, exist in two or all three of these variants.

Optical Techniques

Figure 6 shows the principles of three different techniques based on optical injection of excess carriers. The carriers, i.e., electron-hole pairs, are normally generated by a laser or other light source with photon energy larger than the fundamental energy gap of the semiconductor. The impinging light beam may be continuous, modulated, or pulsed. The resulting excess carrier concentration is either maintained at a higher nonequilibrium value depending on lifetime (if the impinging light is continuous), mimics the imposed modulation with some possible delay (if the light is modulated), or exhibits a transient decay following the initial excitation pulse (if the light is pulsed).

In the PC method, excess carriers represent a modulation of sample conductivity, which is sensed as a current

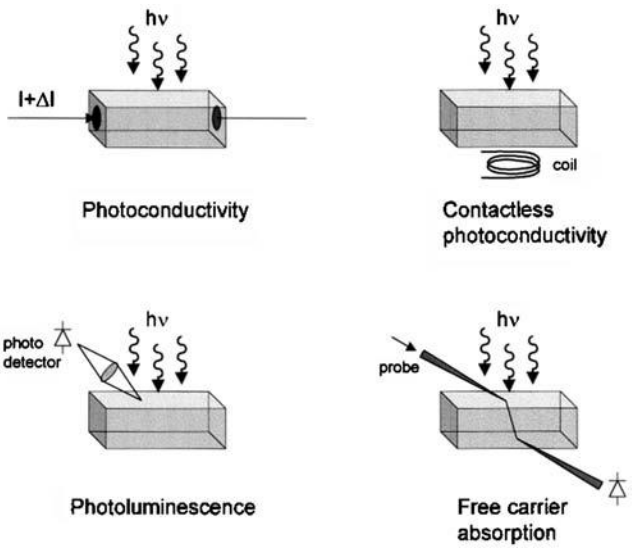

Figure 6. Principles of common optical techniques to measure carrier lifetime.

increase in the external circuit. Contactless variants of this method are the **microwave PC-decay** method and the **radiofrequency PC-decay** method. In the former method, excess carriers are probed by microwaves reflected due to a change in the dielectric constant of the sample resulting from the excess carriers. In the latter technique, excess carriers are detected by a coil reacting on the difference in sample conductivity (see Fig. 6).

The PL method is only applicable for semiconductors exhibiting radiative recombination. This is not a severe limitation, as PL techniques are extremely sensitive and may also be used for semiconductors of indirect bandgap. The excess carrier density is probed by the resulting increase in PL yield. Filtering to a specific wavelength range is a main advantage, reducing background noise and allowing recombination studies of a particular material (e.g., in multiple layer structures). Note that the PL yield tracks the excess carrier density through the radiative process, even in the presence of other possibly dominant recombination mechanisms.

Finally, in the FCA method, excess carriers are sensed by an infrared (IR) beam (or a visible beam, provided that the photon energy is lower than the bandgap energy) transmitted through the sample. The absorption is more or less proportional to the excess carrier density, allowing a calibration of the injected carrier density. The two-beam method can support several different geometries, facilitating depth-resolved studies.

Diffusion-Length-Based Methods

According to Equation 18, the carrier lifetime is proportional to the carrier diffusion length squared. The diffusion coefficient is taken to be constant. This is a good approximation in the low-injection case and for homogeneously doped material where the value of D can be found from mobility-doping data using Einstein's relation, $D = kT\mu/e$. At higher injection levels, however, this is no longer true, as the diffusion coefficient may change substantially when the ambipolar injection regime is approached, and for even higher injection levels, a decrease has been observed due to carrier-carrier scattering (for Si see Linnros and Grivickas, 1994). Thus, we conclude that the carrier lifetime may only be obtained safely from a measurement of the diffusion length in the minority carrier regime. Furthermore, we note that, due to the short radiative lifetimes of direct-bandgap semiconductors, diffusion lengths are extremely short, making diffusion-length-based methods less attractive for these materials.

Figure 7 presents principal schemes of four popular methods to measure diffusion lengths. In the **optical beam induced current** (OBIC) method or in the **electron beam induced current** (EBIC) method, excess carriers are generated locally by a focused laser beam or electron beam, respectively. The carriers diffuse in all directions and the fraction collected by an adjacent *pn*-junction will be detected as a current increase, ΔI, in the outer circuit. By varying the distance of impingement of the generation beam from the *pn*-junction depletion edge, the diffusion length can be measured and the local lifetime extracted.

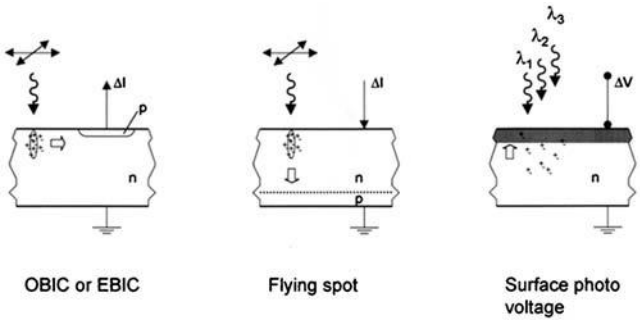

Figure 7. Principles of techniques to measure carrier diffusion lengths for lifetime derivation. Block arrows indicate direction of carrier flow toward *pn*-junction, or, for the surface photovoltage technique, toward the surface (shaded area indicating depletion zone due to band bending).

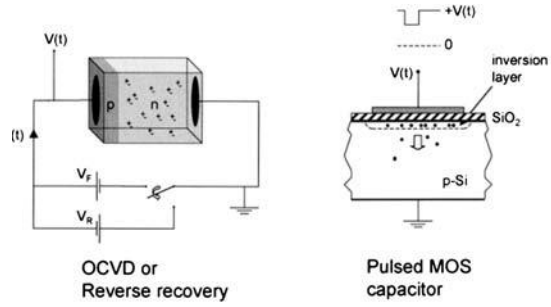

Figure 8. Principles of some device-related techniques.

Using a different geometry, where the *pn*-junction is present at the backside of a sample, lifetime mapping may be performed. Here, the fraction of carriers that reach the *pn*-junction will be collected as illustrated by the block arrow in the center panel of Figure 7. This geometry may be used both in EBIC and OBIC experiments where, for the latter, it is sometimes called the **flying spot** technique (Bleichner et al., 1986). A main disadvantage of the technique is the sensitivity to surface recombination and charging effects on the surface (because in this case only a small fraction of the generated carriers are collected by the *pn*-junction).

Another technique which is suitable for lifetime mapping of bare wafers (without *pn*-junctions) is the **surface photo voltage** technique (SPV), see the right-hand panel of Figure 7. The surface of the probed sample is treated chemically to provide surface charges, inducing surface band bending. Excess carriers, generated optically, reach the surface to induce a voltage shift, ΔV, at the surface, which is measured by a local contact probe. The diffusion length can be extracted by measurements at different wavelengths to provide different penetration depths in the semiconductor (see Schroder, 1990).

Device Related Techniques

Lifetime techniques based on device measurements fall into a separate class of methods, not because of different physical principles, but because they provide **local measurements** of the lifetime in operating devices. This is also a restriction, as for large component areas only an effective lifetime is obtained, averaged over device area and depth. The main advantage is the relatively simple setup, as measurements may be performed directly on the processed wafer, e.g., at a probe station, facilitating automated measurements on a number of devices and with the help of only electrical instruments. In a few cases, measurements may also be performed without the detrimental effects of surface recombination, e.g., for devices covered with a passivating oxide.

The left panel of Figure 8 shows a schematic of lifetime measurements performed on diode structures. In a first period of the measurement, electron-hole pairs are generated continuously during forward conduction by injection from emitters. Then, the circuit is broken by a fast electrical switch, resulting in an open circuit for the rest of the measurement interval, as in the **open circuit voltage decay** (OCVD) technique. If the lifetime of the excess carriers is significantly longer than the switching time, the carriers will remain within the device, their concentration decreasing as a result of recombination. For this time period, the diode will work as a solar cell, providing an open circuit voltage that decays logarithmically with carrier concentration. Thus, from the measured *V(t)* transient, the carrier lifetime can be deduced.

In the alternative technique of **reverse recovery** (RR), the switch is not left open but is switched immediately to a reverse voltage. Under such conditions, the remaining excess carriers will support a large current in the reverse direction until carriers have been depleted at the *pn*-junction such that a depletion layer may form.

Finally, in the **pulsed MOS capacitor** technique, minority carriers are provided by an inversion layer, as in an MOS transistor channel. By subjecting the top electrode of the MOS diode to a voltage pulse, the minority carrier concentration in the inversion layer must change accordingly. However, this cannot happen instantaneously since, for a positive pulse (*p*-type Si), minority carriers must be generated thermally or, for a negative pulse, minority electrons must recombine. In the latter case electrons are pushed into the substrate to recombine with majority holes. Thus, for positive pulses, a transient measurement of the capacitance provides the generation lifetime, whereas a negative pulse yields the recombination lifetime. As described above (see Theory), these lifetimes generally have very different values. The main advantage of the method remains practical, as MOS diodes may be easily provided as test structures to obtain lifetime information on fully processed CMOS wafers.

STEADY-STATE, MODULATED, AND TRANSIENT METHODS

As stated in the beginning of this unit, lifetime determination methods divide naturally into three basic groups: steady-state methods, modulated methods, and pulsed or transient methods (Ryvkin, 1964; Orton and Blood, 1990). Steady-state methods depend on measuring the dc magnitude of physical quantities such as PC,

photoelectromagnetic (PEM) effect, or PL. A number of modulated methods for monitoring carrier lifetime depend on simultaneously monitoring the amplitude and the phase lag between a measured signal and a sine- or square-wave modulated excitation. Pulse methods depend on measuring the decay of the carrier density following an excitation pulse. These three concepts themselves cover many of the somewhat more specialized device-related techniques (e.g., carrier collection in depletion regions of *pn* junction devices) and most of lifetime measurements based on diffusion length determination (Orton and Blood, 1990; Schroder, 1990). Here, a question naturally comes into mind as to whether there is any advantage or disadvantage to the measurement of lifetime by each of these methods.

The answer can follow two distinct paths. A simple answer is that in describing carrier lifetime we have to choose a preferable technique suited for a particular material, an expected range of lifetimes, and an expected accuracy of the measurement. For instance, one might prefer to use the modulated PL technique for characterizing light-emitting, highly doped, direct-band-gap semiconductors where the radiation yield is high and a lifetime is expected in 10^{-7} to 10^{-9} s range. It can be imagined that any dc method, from a sensitivity point of view, or a pulsed method based on PC, will have difficulties providing the necessary short pulses and would pose much greater demands on the detection system. Another answer is related to a more fundamental aspect of the carrier lifetime and its relation to other material parameters affecting recombination, as will be clarified below for modulated and quasi-steady-state-type methods. Transient methods are, therefore, explicitly described in forthcoming sections of the unit.

Principles of the Modulation-Type Method

The principle can be demonstrated by an oversimplified model. Suppose the sample is irradiated uniformly by a harmonic modulated optical source at frequency ω with a generation intensity $I = I_0 + I_1\exp(i\omega t)$, $i^2 = -1$. The concentration of minority carriers throughout the sample can easily be given from the continuity equation (Equation 1) under steady-state conditions, neglecting surface effects and nonlinear recombination terms. A solution can be presented of the form

$$\Delta n = \Delta n_0 + \Delta n_1 \exp(i\omega t) \tag{21}$$

where Δn_1 is complex (an expression of the fact that Δn and I have different phases). The expressions for amplitude and phase are

$$|\Delta n_1| = \frac{\tau I_1}{\sqrt{1+\omega^2\tau^2}} \quad \text{and} \quad \tan\varphi = -\omega\tau \tag{22}$$

The behavior of $|\Delta n_1|$ and φ are illustrated in Figure 9. It is clear that either parameter may be used to obtain τ when the signal is measured as a function of modulation frequency. The sensitivity of the phase lag is high enough in the interval $0.1 < \omega\tau < 10$ since the phase lag is 45° at

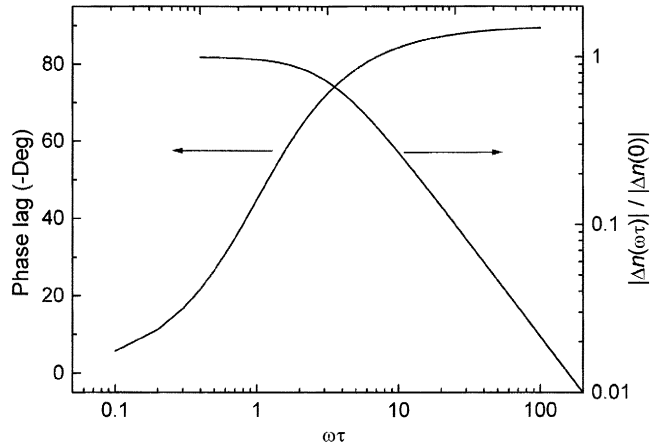

Figure 9. The frequency dependence of $|\Delta n_1|$ and φ as given by Equation 22, showing that both parameters may be used to measure carrier lifetime under harmonic modulation conditions.

$\omega\tau = 1$. To obtain τ from the amplitude versus frequency curve demands measurements up to frequencies of at least a factor of ten higher, i.e., when $\omega\tau \sim 10$. Note that the effective lifetime τ' in a modulated measurement is given by

$$\tau' = \frac{\tau}{\sqrt{1+i\omega\tau}} \tag{23}$$

and the effective carrier diffusion length from the relation $L_D = (D\tau)^{1/2}$ follows as

$$L_D' = \frac{L_D}{\sqrt{1+i\omega\tau}} \tag{24}$$

This clarifies the principle of the modulation methods. The phase shift can be determined very precisely at a single selected frequency, using a narrow-band receiver and lock-in detection, thus separating noise problems, which are usually associated with a direct measurement of a transient response in any pulsed lifetime method. In practice, it is important to study both amplitude and phase shift over a wide frequency range in order to establish an appropriate regime, after which routine characterization may rely on a single measurement of phase shift at a moderately low frequency.

Principles of the Quasi-Steady-State-Type Method

From Figure 9, it also follows that if the modulation frequency varies very slowly compared to the effective lifetime, $\omega\tau \ll 1$, the phase lag approaches zero. In this case a quasi-steady-state condition is reached and the amplitude of the slowly modulated signal offers an expedient method for steady-state lifetime measurement. Under steady-state illumination, a balance exists between the generation and the recombination of electron-hole pairs. Expressing the photogeneration and recombination rates as photoinduced current and recombination current densities (J_{ph} and J_{rec}, respectively) it may be stated as

$$J_{\text{ph}} = J_{\text{rec}} \tag{25}$$

As a consequence of this balance, an excess concentration of electrons and holes is established in the material. The total recombination in a sample of thickness d can conveniently be expressed in terms of an average excess-carrier density Δn_{av} and an average lifetime τ_{av}, leading to:

$$J_{ph} = \Delta n_{av} q d / \tau_{av} \tag{26}$$

which, in essence, is a version of the classic relationship, $\Delta n = \Delta G \tau_{av}$ (Ryvkin, 1964). For clarity, we state the classical analysis of the photoconductance, which, therefore, is a nearly direct way of probing the excess carrier density. Equations 25 and 26 can be iterated to find the average carrier lifetime as

$$\tau_{av} = \Delta\sigma / [J_{ph}(\mu_n + \mu_p)] \tag{27}$$

where μ_n and μ_p are corresponding mobility of electrons and holes. The conductance $\Delta\sigma$ and the incident light intensity can be measured using a calibrated instrument and a reference solar cell or photodiode, respectively. For a given illumination, J_{ph} can be estimated through available computer programs or lookup tables. In a typical 380-μm-thick silicon wafer with low reflection losses, the standard global AM1.5 solar spectrum produces a total photogeneration J_{ph} of ~38 mA/cm^2 (AM1.5 standard reference spectrum defined in ASTME 892). The value of J_{ph} relative to the reference solar cell can be adjusted for a particular sample to take into account different surface reflectivities, sample thicknesses or illumination spectra.

Compared to a transient decay approach, the quasi-steady-state method allows a lifetime measurement without fast electronics or short light pulses. The range of measurable lifetimes is only limited by signal strength. Thus, the measurement is preferred for samples of low dark conductance. To measure very short lifetimes, the light intensity can be increased. Note, however, that the average lifetime determined does not depend on the details of the carrier distribution within the sample. The local excess carrier density is essentially equal to the average Δn_{av} obtained from Equation 26 when the surfaces of the sample are well passivated and the carrier diffusion length is greater than the sample thickness. It is possible to find general steady-state solutions of the one-dimensional continuity equation subjected to boundary conditions for surface recombination in a semiconductor wafer (or in n^+p junctions) as, for example, expressed by Schroder (1990). The short-circuit current versus open-circuit voltage ($I_{sc} - V_{oc}$) characteristics can be equivalent to steady-state photoconductance measurements in solar-cell-type devices (Sinton and Cuevas, 1996).

Data Interpretation Problems

In practice, however, there are many cases where nonuniform carrier generation, surface recombination, nonuniform bulk recombination or nonlinear dependencies of recombination parameters introduce complications for both modulation and steady-state methods. The problem can be further complicated by various sensitivity factors for detecting Δn_1. All these effects imply that carrier diffusion currents at characteristic frequencies of the higher recombination terms (for modulated frequency $\omega\tau_i$) have to be considered. As a consequence, solutions for Δn_1 will be modified substantially. To calculate these expressions for the phase shift between the induced signal and the generation term, some kind of expression can be adopted. However, the resulting general expressions are too complicated to be useful.

A better procedure is to derive approximate expressions for the measured quantity by introducing various simplifying conditions in the steady state. Then, to make the appropriate substitution of τ' for τ (Equation 23) or L' for L (Equation 24), a number of expressions for modulated methods, where the algebra is reasonably tractable, is provided by Orton and Blood (1990). Specific microwave lifetime expressions by a harmonic optical generation method, which allows separation of the bulk lifetime and the surface recombination velocity on two wafer sides, is presented by Otaredian (1993).

An even more complicated situation can appear if carrier bulk lifetime is determined by the distributed recombination levels in the energy band, as is the typical case in amorphous semiconductors. Some guiding expressions for frequency-resolved modulated luminescence methods in amorphous semiconductors are provided by Stachowitz et al. (1995). Therefore, decay measurements can hardly be converted to modulation measurement data and vice versa, since mathematical procedures depend on the interpretation of the particular lifetime distribution function.

Summary of Strengths and Weakness

From the fundamental nature of the carrier lifetime and its relation to other material parameters, the strengths and weakness of different types of lifetime methods can be summarized as follows.

Steady-State and Modulation-Type Methods. The major strength of these methods is that they provide a rapid and less complicated measurement. The lifetime may be obtained either from the amplitude or the phase lag of Δn_1. The equipment is typically inexpensive.

The major weakness of these methods is the complicated interpretation of the recorded data. In particular, this becomes important if a weak feature of the lifetime has to be extracted correctly. Interpretation in terms of injection-dependent recombination parameters is typically not allowed. In steady-state type methods, the probe samples a relatively large volume, determined by the carrier diffusion length, preventing high-resolution measurements.

Pulsed-Type Methods. As explicitly shown by examples in the following sections, the major strength of these methods is an adequate interpretation of the measurement results. Injection dependency of the lifetime and other related material parameters (carrier diffusivity, surface recombination) can be interpreted with the same algorithm. There is a large background of knowledge related to pulsed methods that has been developed over the past

40 years. Some of the equipment operating in narrow bandwidth range can be relatively inexpensive, while other methods can provide very sophisticated measurements with high lateral or depth resolution for the extracted lifetime.

The weakness of pulse-type methods is that measurements typically require specialized equipment for working on different materials and in different bandwidth ranges. Pulsed techniques are sensitive to background noise problems and reference standards must be used for quantitative measurements.

The impact of recombination centers (usually generalized as carrier trapping) on the lifetime measurement type under steady state or transient conditions is, therefore, not clear. This is particularly the case if recombination of carriers in semiconductors takes place via several parallel recombination channels. The analysis of the experimental data, which is intended to unravel the individual contributions of the participating recombination channels is, however, often done on an intuitive basis rather than by a physically motivated formalism. The typical presumption that $\Delta n = \Delta p$ is only valid for the case of perfectly symmetric capture rates of electrons and holes at recombination centers, and holds for high excitation conditions. Some authors claim that while this presumption is a reasonable approximation for steady-state conditions, it may lead to grossly erroneous results for transient conditions even in the limit of a small concentration of recombination centers (Brandt et al., 1996). On the other hand, the shape of the transient measurement, in certain cases, makes possible the visualization of the evolution of carrier trapping quite evidently.

FREE CARRIER ABSORPTION

The FCA method is a noncontact, fully optical pump-probe technique suitable for bulk lifetime measurements. It is based on optical injection of excess carriers, most often by a short laser pulse, and probing of the excess carrier decay by a continuous wave, long-wavelength laser beam transmitted through the sample (Ling et al., 1987; Waldmeyer, 1988). It is less common as compared to other techniques described in this unit and no commercial apparatus has been developed. Yet, it is a quite universal technique, able to accommodate very different sample structures and semiconductor materials. The technique can also be easily set up in a research laboratory that has access to a pulsed laser of appropriate wavelength. So far, the technique has been applied to indirect type semiconductors (Si, Ge, SiC, porous Si, etc.).

Another advantageous feature is a possibility for control of the injection level. This results from a homogeneous excitation volume, enabling a calibration of the carrier density. Thus, lifetime extraction may be performed at different injections probing different recombination mechanisms. This feature has inspired the selection of the FCA method as a demonstration unit to illustrate various concepts, as stated in the previous Theory section. For general reviews of the technique, see Linnros (1998a,b), Grivickas et al. (1992), and Waldmeyer (1988).

Principles of the Method

The absorption of long-wavelength light induced by free carriers in a semiconductor, i.e., for photon energies less than E_g, can be used to derive the carrier density in a sample. The absorption mechanism is related to acceleration of electrons and holes by the electric field of the incident radiation and generally increases with wavelength (Pidgeon, 1980). Elementary theory predicts a dependence of the absorption according to (for free electrons of density n)

$$\alpha_{\mathrm{FCA}} = \frac{\lambda^2 q^3}{4\pi^2 c^3 n^* \varepsilon_0} \cdot \frac{n}{m_{\mathrm{n}}^2 \mu_{\mathrm{n}}} \tag{28}$$

where λ is the wavelength, q the electron charge, c the velocity of light, n^* the real part of the refractive index, ε_0 the permittivity in vacuum, and m_{n} and μ_{n} the electron mass and mobility, respectively. In reality, different absorption mechanisms may dominate and the quadratic dependence on wavelength may be replaced by a more general power law: $\alpha \sim \lambda_{\nu}$ where ν is a power index to be experimentally determined. The most important consequence of Equation 28 is the linear dependence of the absorption on carrier concentration, n.

For lifetime measurements, free carrier absorption may consequently be used to monitor the instant excess carrier density following optical injection of electron-hole pairs. As carriers are generated and recombine in pairs (assuming negligible trapping) it follows that the measured absorption is the sum of the contributions from electrons and holes, even though their individual absorption cross-sections may be different.

The transmitted probe beam intensity through a sample is described by

$$I(t) = I_0 \exp[-\alpha_{\mathrm{probe}}(t) \cdot d]; \quad \alpha_{\mathrm{probe}}(t) = \alpha_0 + \Delta\alpha(t) \tag{29}$$

where I_0 is the incident beam intensity, d the sample thickness, and α_0 a constant absorption coefficient related to, for example, dopant-induced free carriers. $\Delta\alpha(t)$ is the absorption coefficient, which is related to the density of **free excess carriers** within the sample. Usually, a linear dependence as in Equation 28 is assumed

$$\Delta\alpha(t) = \sigma_{\mathrm{FCA}} \cdot \Delta n(t) \tag{30}$$

where $\Delta n(t)$ is the excess carrier density ($\Delta n = \Delta p$). Figure 10 shows measurements of $\Delta\alpha$ versus Δn in silicon for two different probe wavelengths. The data indicate a linear behavior up to $\Delta n = \sim 10^{17}$ cm^{-3}, followed by a slightly increased absorption cross-section at higher carrier concentrations.

In a general case, the carrier density may not be homogenous throughout the probed volume of the sample, and Equation 30 may be replaced by

$$\Delta\alpha(t) = \sigma_{\mathrm{FCA}} \int_0^d \Delta n(z,t) dz \tag{31}$$

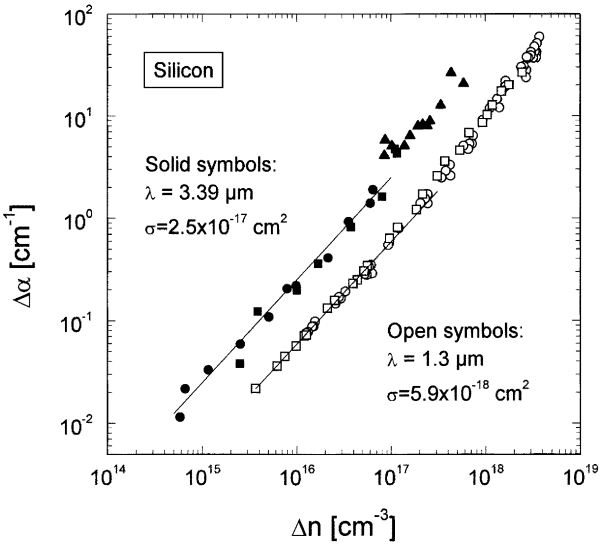

Figure 10. Absorption induced by excess carriers in silicon for two probe wavelengths. The excess carrier concentration was calculated using measured absorbed optical power within a sample and assuming a unity quantum efficiency for the conversion of photons to electron-hole pairs.

where $\Delta n(z,t)$ is the local excess carrier density along the probe beam trajectory z within the sample, and a linear cross-section has been assumed as in Equation 30.

The pump beam photons generate free carriers in the form of electron-hole pairs, provided that the wavelength matches the fundamental absorption edge of the semiconductor sample. In the transient FCA method, the pump beam is represented by a short laser pulse. The carrier density depth profile can be calculated from the generation function described by

$$g(z,t) = g_0(t) \cdot \frac{\alpha_{\text{exc}}(1-R)^2 \exp(-\alpha_{\text{exc}} \cdot z)}{1 - R^2 \cdot \exp(-2\alpha_{\text{exc}} \cdot z)} \qquad (32)$$

where $g_0(t)$ is the incident flux density of photons, R the sample reflection coefficient (assuming equal reflectivity on front and back surfaces), and α_{exc} the absorption coefficient for the pump beam. An inspection of Equation 32 suggests that for an in-depth, homogeneously excited sample, $\alpha_{\text{exc}} \cdot d$ should be less than unity, and therefore, the penetration depth should be large compared to the sample thickness (refer to the experimental data of Figure 4 where this condition is barely fulfilled, $\alpha_{\text{exc}} \sim 10$ cm^{-1} yielding $\alpha_{\text{exc}} \cdot d \sim 1$).

Figure 11 is a schematic of a **transient** FCA measurement setup using a **parallel** geometry, i.e., both excitation and probe beams enter the sample from the same side. The pump beam is pulsed and the excited area should be large compared to typical diffusion lengths in the sample. The probe beam is from a continuous wave laser with a wavelength tuned toward the IR compared to the band-gap absorption. By focusing, the probed sample area is smaller than the excitation area and may, therefore, be regarded as laterally homogenous. The transmitted probe beam is

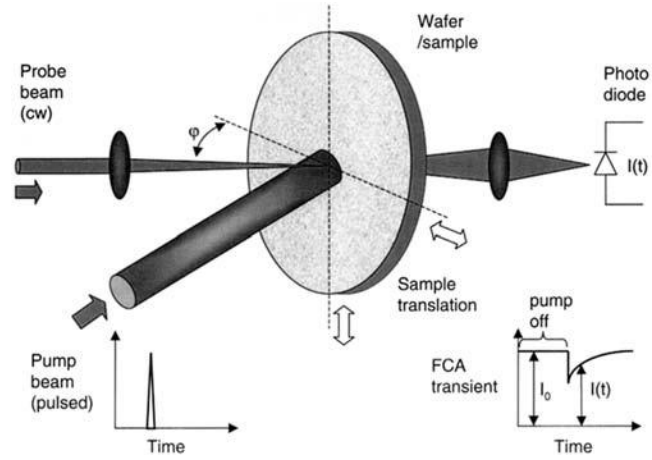

Figure 11. Schematic of a pump-probe experiment to measure carrier lifetime in a parallel geometry. Note that $90^\circ - \varphi$ should be close to the Brewster angle to minimize multiple reflection of the probe beam.

collected by a lens and focused onto a photodetector, usually a *pin*-photodiode. To allow measurements on different areas of the sample, such as for lifetime mapping, the sample may be scanned in the plane of intersection of the two beams (e.g., by motorized translators). The two inserted time diagrams depict the laser-pulse shape and the detected absorption transient. The characteristic time for the FCA signal to revert to equilibrium is a measure of the carrier lifetime. Indeed, the temporal pulse width of the excitation laser must be short compared to the carrier lifetime of the sample in order not to affect the lifetime extraction.

An alternative geometry is the perpendicular setup (Grivickas et al., 1992; Linnros et al., 1993), shown in Figure 12, where the probe beam impinges on a cross-sectioned surface of a sample, i.e., at right angles with

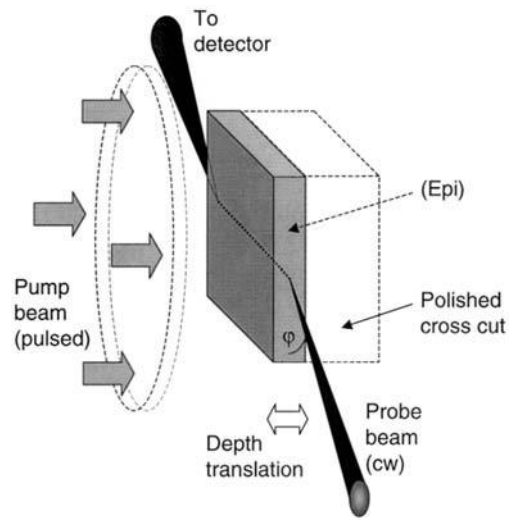

Figure 12. Schematic of a pump-probe experiment to measure carrier lifetime in a perpendicular geometry. Dashed lines show geometry when a surface epilayer is investigated.

respect to the pump beam. This geometry enables depth-resolved measurements by moving the probe beam impingement spot on the cross-sectioned surface, or rather by moving the sample in the depth direction. As indicated by dashed lines, this geometry also allows lifetime characterization of an epilayer on top of a substrate, provided the epilayer is sufficiently thick that the probe beam may be focused and confined in this layer (Galeckas et al., 1997a).

In the selection between the parallel and the perpendicular geometry, one notes that the parallel scheme results in a measurement of the average lifetime throughout a wafer (provided the penetration depth of the pump beam is large with respect to sample thickness). This is advantageous in many cases, such as during lifetime mapping. On the other hand, the perpendicular scheme provides a few other important advantages in addition to depth resolution. First, a uniform excitation is ensured along the beam path, even though excitation may be fairly inhomogeneous in depth. Second, samples may be cut in such a way that the probe beam path is quite extended, yielding a high sensitivity in terms of detected carrier concentration (refer to Equations 29 and 30, using a large d). This is often a prerequisite to reach low-level injection conditions.

Finally, a related method is the modulated free carrier absorption technique (Sanii et al., 1992; Glunz and Warta, 1995) where, instead of a pulsed excitation beam, a modulated (usually sinusoidal) excitation beam generates carriers. The probe beam then monitors the resulting carrier modulation amplitude (or phase lag), which drops to zero (phase lag increases to 180°) at frequencies approaching the inverse lifetime ($f \sim 1/\tau$) as carriers are unable to follow the imposed modulation (see Principle of the Modulation-Type Method).

Practical Aspects of the Method

Pump Laser Selection. For measurement of bulk lifetimes, a homogeneous excess carrier excitation in the sample is preferable to ensure the extraction of an in-depth average value of the bulk lifetime. As stated previously, this demands a relatively low absorption coefficient of the pump light, in turn requiring a photon energy close to the energy band gap. As an example, a yttrium-aluminum-garnet (YAG) laser operating at $\lambda = 1.06$ μm is ideally suited for Si wafers, as the absorption is ~ 10 cm^{-1}, yielding a depth inhomogeneity of the initial carrier concentration less than ~30% for normal 350-μm thick wafers (also see Fig. 4, where absorption at this wavelength is illustrated by the initial carrier concentration, i.e., the top depth profile).

In contrast, when thin layers close to a semiconductor surface must be analyzed (in a parallel geometry as in Fig. 11), a higher absorption coefficient is desirable. An example is the extraction of the carrier lifetime in a thin epitaxial layer on top of a substrate (Galeckas et al., 1997b). In such a geometry, the part of the generated excess carrier profile penetrating into the substrate needs to be suppressed, requiring an excitation wavelength considerably shorter than for the previous case. One should keep in mind, however, that the result of such a measurement must be critically analyzed, since diffusion of carriers towards the surface and into the bulk becomes a more serious limitation as the thickness of the probed layer is reduced, and could seriously affect the measured carrier lifetime. In other words, the useful time domain of the expected lifetimes is pushed toward very short lifetimes, often into the ns or ps regime.

Finally, pulse duration and beam size must be considered. Whereas pulse duration must be kept below the shortest expected lifetime in the sample, minimum beam size should be at least a few carrier diffusion lengths in diameter. From practical aspects and ease of alignment, a diameter of a few millimeters is desirable, often necessitating the use of a beam expander.

Probe Laser Selection. The selection of probe laser wavelength is determined by sensitivity and focusing requirements. Generally, a high sensitivity is the primary requirement in speeding up lifetime measurements, in particular for lifetime mapping. As free carrier absorption increases with wavelength (refer to Equation 28; notice the predicted quadratic dependence), long wavelengths toward the IR range are preferable and the choice is often set by laser availability. For increased lateral or depth resolution, short wavelengths are advantageous. But, optimizing resolution is not a simple task, as the optical resolution is not set simply by the Airy-focusing spot size. Instead, the **effectively probed volume** in the sample determines the resolution as set by sample thickness, focusing lens, and wavelength. For a more detailed treatment, the reader is referred to Linnros (1998a). Finally, carrier diffusion most often sets the practical resolution, at least for indirect-band-gap materials with lifetimes in the μs range.

As probe lasers, HeNe lasers of ~1-mW power were traditionally used at operating wavelengths of 3.39, 1.3, or 0.632 μm, depending on band gap and the above selection criteria. For increased sensitivity, a CO_2 laser with 10.6-μm wavelength would be preferable (Polla, 1983). Recently, semiconductor lasers have become abundant, offering several wavelengths in the visible and near-IR at affordable prices. Also, relatively intense lasers have become available (100 mW) offering increased measurement speed, although care must be taken not to affect the carrier dynamics by heating. A polarized laser is to be preferred (see Geometrical Considerations).

Detection Electronics. The signal from the photodetector is normally amplified and subsequently fed into an oscilloscope. To reduce noise, it is important to limit the bandwidth to a minimum with respect to characteristic times as set by the detected recombination transients. This may most easily be achieved by reducing the oscilloscope bandwidth, an ability provided by most modern equipment. Even though transients might be observed by the eye on the oscilloscope screen, digital oscilloscopes are far superior, providing digital averaging on a large number of transients. In the selection of a digital oscilloscope, two features (besides analog bandwidth and sampling rate, which need to be compatible with expected lifetimes)

are particularly important for FCA measurements: (1) The ability to average detected transients, usually from an 8-bit A/D converter, into a 16-bit memory, providing greatly enhanced sensitivity to small FCA transients; and (2) an arbitrary offset bias on the input channel, offering the possibility to offset the steady-state I_0 value and increase the gain on the transient part of the signal.

Geometrical Considerations. To design the geometry of the setup, one needs to pay particular attention to interference effects of the probe beam within the sample. This results from the high index of refraction of semiconductors, yielding typical reflection coefficients of ~30%. For very rough surfaces, interference effects may be reduced, but in some cases (for normal Si wafers with nonpolished backside) the problem may still persist. The remedy is to lower the reflected part of the beam using a polarized probe beam and a Brewster angle geometry, as defined by $\tan(\theta_i) = 1/n_s$, where n_s is the semiconductor refractive index and θ_i the incidence angle. For Si the Brewster angle is ~74°. Therefore, the sample needs to be inclined with respect to the probe beam as indicated in Figures 11 and 12 [where φ corresponds to $(90^\circ - \Theta)$]. For depth profiling using the perpendicular geometry, the same holds for the probe beam entering the cross-sectioned surface of the sample.

As for the pump beam, interference is not a critical issue, but, the use of a Brewster-angle geometry definitely reduces the pulse-to-pulse noise of absorbed power and the resulting injected carrier density.

Method Automation

Computer Interfacing. The automation of lifetime measurements using the FCA technique is more or less mandatory, as the absorption transient may only be observed directly on an oscilloscope screen under strong carrier injection. The first automation step is the interfacing of a digital oscilloscope with a computer. The interface should have high data transmission capability, usually in the range of ~1 Mb/s, as found in modern instrument bus interfaces. A computer code to handle the reading of decay data may be written in any programming language and should be able to handle storage and presentation of data, preferably also including conversion of raw data to carrier concentration.

Lifetime Depth Profiling. For depth-resolved measurements (Linnros et al., 1993), computer control of a motorized micropositioner is needed. The micropositioner should be able to handle movements of 1 μm with good precision. The actual depth scan is performed by stepwise motion to the next position after the accumulation and readout of an averaged FCA transient. As focusing of the probe beam is crucial, the measurement is preceded by scanning the probe intensity across the depth. The fall-off of the intensity at sample edges is an indication of probe beam focusing. Thus, several such scans using different lens-to-sample distances allows the determination of correct focusing by optimizing for steep edges.

Lifetime Mapping. Lifetime mapping demands a high degree of automation and precision-motorized positioners in the two orthogonal scanning directions (Glunz and Warta, 1995; Linnros et al., 1995; Linnros, 1998b). As in the case of depth profiling, data accumulation and readout is followed by stepwise motion to the next position. The computer code controlling the mapping now becomes relatively sophisticated in order to optimize speed (becoming a primary issue), data handling, selection of positions within the periphery of a wafer, and finally ease of handling for the user. Data storage also becomes critical, and normally only the extracted lifetime is stored for each sample position. Here, the procedure for correct lifetime extraction is essential, as signal-to-noise ratio must be traded against measurement speed.

Data Analysis and Initial Interpretation

Extraction of Carrier Decay Transient. The measured absorption transient, as recorded by a digital oscilloscope and transferred to a computer, may be transformed to a carrier decay transient using Equations 29 and 30 and solving for $\Delta n(t)$

$$\Delta n(t) = \frac{1}{\sigma_{FCA}} \cdot \frac{1}{d} \ln \frac{I_0}{I(t)} \tag{33}$$

where α_0 now has been lumped together with I_0 as it represents a constant absorption during the measurement. To correctly define I_0, a few data points before the actual beginning of the pump pulse are needed, as shown in the inset of Figure 11. Thus, triggering of the oscilloscope starts slightly before the pump pulse. Finally, sample thickness must be measured and an appropriate absorption cross-section must be inserted. However, to extract the lifetime, neither thickness nor cross-section is needed, as is evident from Equation 7.

Lifetime Analysis. The lifetime may be derived straightforwardly by applying Equation 7 with some numerical averaging profile over a few data points. An alternative route is by plotting $\log\Delta[n(t)]$ versus t followed by fitting of a straight line to some limited range of data points. This yields a better control of the lifetime extraction procedure, as different recombination mechanisms may be distinguished in the carrier decay transient. This is illustrated in Figure 13, where a recorded absorption decay transient has been converted to excess carrier density. The measurement was made on a p-type Si wafer doped to 3×10^{16} cm^{-3} with boron, and a $\lambda = 3.39$-μm probe beam was used (excitation by a pulsed $\lambda = 1.06$-μm beam). To increase the signal-to-noise ratio, averaging of several thousand decays was performed at a repetition frequency of 100 Hz. This yielded a detection sensitivity of $<10^{14}$ carriers/cm^3 (signal-to-noise level), as seen in the figure.

Analyzing the decay shape, one may distinguish three distinct regions. (1) At high injections nonexponential recombination is present due to Auger recombination (2), while at slightly lower injection, but still above the doping density, a linear region is observed where a high-injection lifetime may be extracted. Finally, (3) at low injections, the

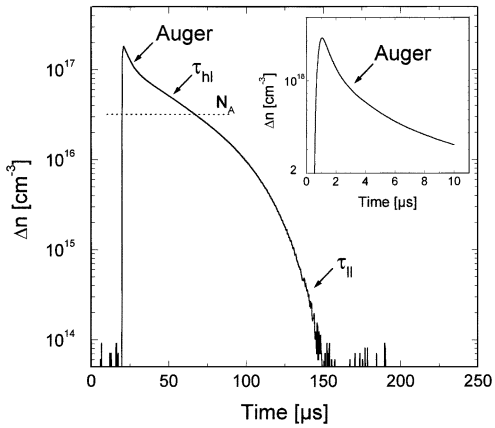

Figure 13. Excess carrier decay transients following an optical generation pulse in Si (p-type, $N_A = 3 \times 10^{16}$ cm^{-3}, thickness: $d = 430$ μm). The excess carrier density has been calculated using a linear cross-section (see Fig. 10), from absorption transients of a 3.39-μm probe beam. Inset demonstrates Auger recombination at high injections.

minority carrier lifetime may be derived. The inset shows a transient recorded at very high injection, where Auger recombination prevails.

In Figure 14, extracted lifetimes from the data of Figure 13 and a few additional recorded transients are displayed. Lifetimes were derived by a stepwise linearizing procedure of the data points in the transients. Solid lines represent a fit to the SRH formula (assuming a mid-gap trap energy level; see Equation 10 and Fig. 2), accomplished by varying the high- and low-injection lifetimes.

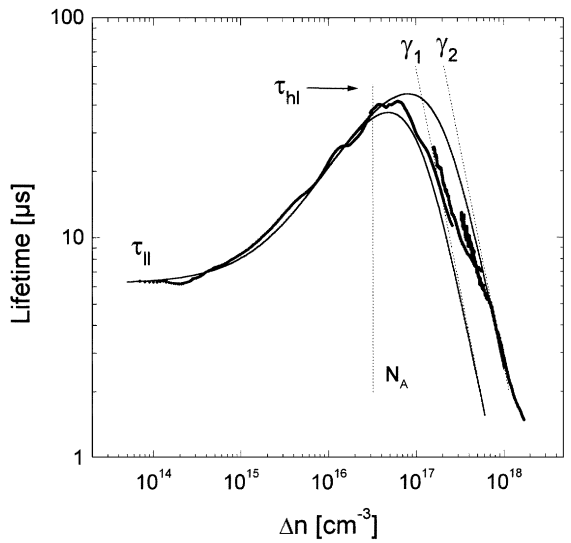

Figure 14. Calculated lifetime-injection dependence (solid circles) from experimental excess carrier decays as displayed in Figure 13. The two solid curves have been calculated according to the SRH theory (using Equations 10, 14, and 16) assuming a minority carrier (electron) lifetime of 6 μs and a high injection lifetime of 60 μs, and for two Auger coefficients. $\gamma_1 = 1.7 \times 10^{-30}$ cm^{-6}/s and $\gamma_2 = 3.8 \times 10^{-31}$ cm^{-6}/s (from Dziewior and Schmid, 1977, and Grivickas and Willander, 1999, respectively).

Auger recombination is also included (see Theory) where γ_1 and γ_2 represent two different Auger coefficients (Grivickas and Willander, 1999). One may note the good correspondence with theory and the broad transition range between the pure high-level (hl), low-level (ll), and Auger-injection case, complicating the interpretation of extracted lifetimes.

From the discussion above, one may conclude that the FCA technique allows a detailed study of carrier recombination at different injection levels, whereas an accurate determination of the minority carrier lifetime and/or the high injection lifetime may only be derived from plots similar to Figure 14 (by extrapolating to the pure ll or hl limit). In most cases, however, the lifetime may be estimated at one particular injection level, allowing comparison of different samples or lifetime mapping. Thus, the extracted lifetime value may not be the "true" minority carrier lifetime but represents a characteristic lifetime describing sample purity. The appropriate injection level for lifetime extraction depends on practical considerations (detection sensitivity) as well as on device applications for the analyzed sample/material (a tentative device may operate under high level injection and, therefore, the hl-lifetime is of primary interest).

Analysis of Lifetime Mapping Data. Figure 15A and B show examples of lifetime maps for two Si wafers. Carrier lifetimes were extracted from decay data at each position after the conversion to carrier concentration. The lifetime fit was performed using a fixed injection interval (as an example, the high injection lifetime could be derived from Figure 13 by a fit to the data in the interval 4×10^{16} to 7×10^{16} cm^{-3}). The mapping data have been displayed in the form of contour plots using the software Surfer for Windows (Golden Software).

Sample Preparation

Sample preparation ranges over the entire spectrum, depending on semiconductor material, surface properties, and measurement geometry. The listing below is structured according to different types of applications.

Virgin Wafers: Surface Passivation. To extract the bulk lifetime in virgin wafers, at least for Si wafers of good quality, is probably the most difficult task for any lifetime measurement technique. The reason is surface recombination in combination with large diffusion lengths of carriers (see Fig. 5). Indeed, the manufacturer specification for lifetimes is usually based on measurements on boules before cutting into wafers.

There are a couple of approaches to circumvent this problem. One technique is based on a passivation of the "dangling bonds" at the surface by hydrogen. This may be performed by a low-temperature chemical process (Linnros, 1998b), in a bath of HF (Yablonovitch et al., 1986), or by other chemical passivation methods (Horanyi et al., 1993). An alternative is to charge the native oxide of a Si wafer with ultraviolet (UV) light (Katayama et al., 1991) in order to provide band bending that will prevent carrier diffusion to surfaces (see center panel of Fig. 3).

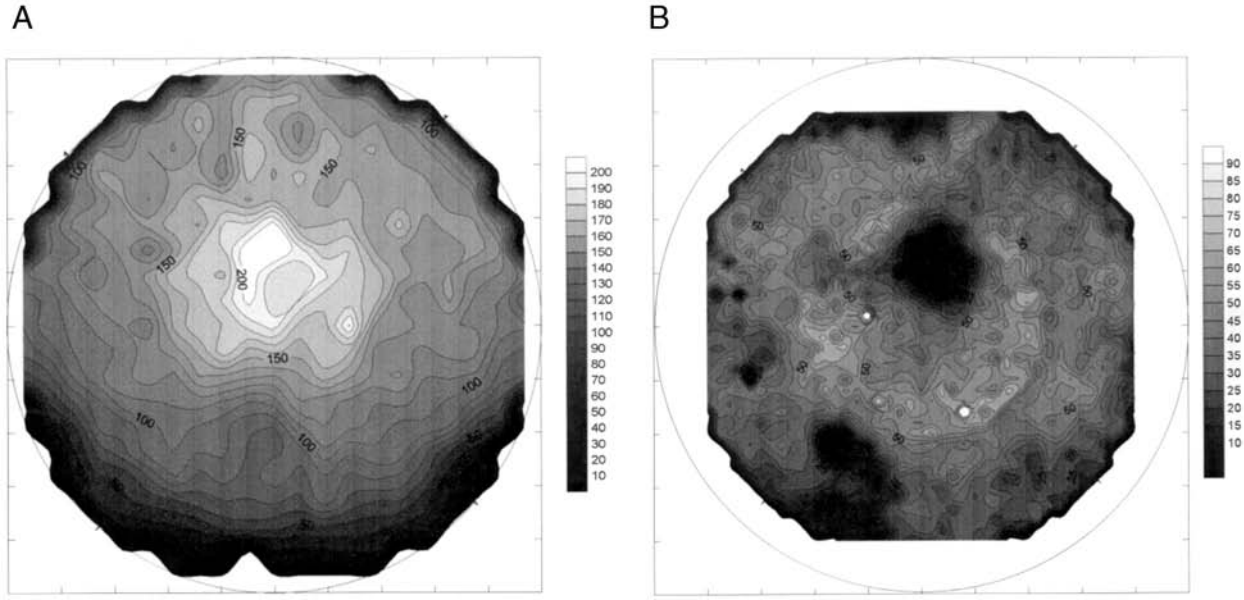

Figure 15. Examples of lifetime maps from processed Si wafers of FZ-NTD material. The data have been gray-scale coded with highest lifetimes in white. Circles at the periphery of the mapped areas indicate 4-in. wafer area. (**A**) Furnace-annealed wafer at 1050°C, 4 h, where low-lifetime area at lower part indicates contamination from the boat. (**B**) Wafer having passed a full thyristor process sequence. Note central high lifetime area corresponding to a ~45-mm diameter device as well as black, low-lifetime areas indicating contaminated regions (Linnros et al., 1995).

Common to all these methods are, however, problems with stability and repeatability.

Naturally, for Si wafers or other semiconductors with short carrier lifetimes, the problem of surface recombination is reduced, but, it still needs to be carefully addressed. Finally, an optical problem may arise for wafers/samples with nonpolished backsides as this may spread the probe beam such that the detector signal vanishes. In such cases it is necessary to polish the backside.

Processed Wafers and Devices: Removal of Metal and Highly doped Layers. In many cases, processed wafers are excellent for measurements of the bulk lifetime using the FCA technique, often without any preparation (Fig. 15). The reason for this is that furnace processing often results in a surface oxide, which may provide a very low surface recombination velocity. Another advantageous case is when dopants are diffused from the surfaces. This results in *pn*-junctions, nn^+- or pp^+-junctions that serve as barriers for carrier diffusion towards surfaces (see right panel of Fig. 3). For highly doped emitters, however, the probe beam may be completely attenuated by the high permanent concentration of carriers in these layers. A solution would then be to either remove this layer partly (by etching or polishing) or by decreasing the absorption using a shorter probe beam wavelength (Fig. 10 and Equation 28). For devices, metal layers must be removed to ensure transparency to pump and probe beams (Linnros et al., 1995).

Depth Profiling: Cross-Sectioning of Samples. For depth-resolved measurements using the perpendicular geometry, a cross-section must be cut from the wafer/sample. Special attention has to be paid to the parallelism of the surfaces and to the thickness of the cross-section. The latter determines the obtainable depth resolution and a graph for simple estimations for Si samples may be found in Linnros (1998a). The parallel surfaces of the cross-section normally have to be polished for the probe beam to enter and exit the sample and still remain collimated. Using a good cutting machine with a diamond blade, however, a mirror-like surface may be obtained. Polishing should be performed using conventional procedures, employing either diamond paste or abrasive paper of decreasing grain size.

Problems

As for most carrier lifetime measurement techniques, surface recombination is one of the main problems. This results from carrier diffusion, and the critical parameter is the diffusion length of carriers in comparison to sample dimensions. Thus, for short carrier lifetimes (e.g., in direct-band-gap materials) the effects of surface recombination may be negligible. On the other hand, one may be interested in carrier lifetimes of thin films or epilayers, and surface or interface recombination may again be a limiting factor. Different passivation methods to overcome surface recombination are briefly addressed above and in Linnros (1998a).

The diffusion length also excludes using the technique for local lifetime determination, as, e.g., in the top surface region of active devices. In such cases, one needs to resort to lifetime techniques based on generation lifetime as in a depleted *pn*-junction.

A specific problem with the FCA technique is the determination of minority carrier lifetime under very low injection conditions, as needed for wafers with low levels of doping. This is due to the limited sensitivity of optical absorption techniques at low carrier concentrations. The sensitivity may be optimized using large samples (in the probe beam direction), long wavelength probing, and extended averaging. In silicon, sensitivities reaching $\sim 10^{11}$ carriers/cm^3 have been reached (Grivickas et al., 1992) although the injection level during lifetime mapping is, for practical reasons, limited to $\Delta n > 10^{15}$ cm^{-3}.

Another problem, although very rarely encountered, is the measurement of extremely long carrier lifetimes (roughly for $\tau > 1$ ms in Si). In such cases the diffusion length may approach several millimeters, and a large excitation spot is needed to reduce effects of radial outdiffusion of carriers from the excited area (Linnros, 1998a).

PHOTOCONDUCTIVITY

The measurement of PC decay in various experimental modifications is widely used as a convenient method for measuring carrier lifetimes in semiconductors. As an example, the archetypal method of PC-decay under a constant current applied by means of ohmic contacts has been set as a standard technique for measurement of the minority-carrier lifetime in bulk germanium and silicon for >30 years (Standard Method for Measuring the Minority-Carrier Lifetime in Bulk Germanium and Silicon, F28 in ASTM, 1987). Numerous noncontact PC methods, such as microwave reflectance and rf bridges, have recently become quite popular because their nondestructive quality and also their suitability for use in a clean-room environment. Most of the considered techniques do not require particularly expensive and bulky instruments. This motivates the wide diffusion of noncontact PC decay techniques into diverse areas of carrier lifetime measurements including on-line processing of silicon wafers.

Principle of PC Decay Methods

The principle of the experiment involves shining a pulse of light into the semiconductor sample to generate excess carriers and monitoring the time decay of the corresponding excess conductivity. Since electrons and holes have opposite charge, the total conductivity is the sum of the partial conductivities, which is always positive. Consequently, conductivity can be written in the form

$$\Delta\sigma(t) = q[\Delta n(t)\mu_n + \Delta_p(t)\mu_p] \cong q\Delta n(t)[(\mu_n + \mu_p)] \quad (34)$$

where q is the electron charge and μ_n, μ_p are the corresponding drift mobilities of electrons and holes that characterize PC for different injection levels.

Before proceeding to details, it is worthwhile to reiterate two general points. First, the approximate equality for the last term of Equation 34 is valid in the absence of asymmetric capture within an impurity recombination model (Blakemore, 1962) or the absence of carrier trapping (Ryvkin, 1964). In general, these conditions are valid at high injections for carrier generation by the electromagnetic radiation in the fundamental band with a photon energy $h\nu \geq E_g$, where E_g is the forbidden gap energy. Then both Δn and Δp are proportional to the optical energy absorbed in that time and in the unit volume. Numerous experiments have shown that recombination misbalance effects can be neglected at any injection for measured lifetimes in the range 1 to 500 μs of crystalline Si and Ge (Graff and Fisher, 1979). However, we note that the approximate equality in Equation 34 does not hold for low injection conditions in some highly irradiated, highly damaged crystalline semiconductors and in polycrystalline or amorphous films (an example is provided by Brüggemann, 1997). The same indeterminate equation may appear in compensated compound semiconductor materials, since some of them may contain a substantial concentration of nonstoichiometric deep centers acting as carrier traps. These cases might require quite specific methods for carrier lifetime extraction from PC measurements. In the following, we shall assume that the approximate equality in Equation 34 is an inherent property of the semiconductor material. This assumption leaves complicated interpretation of PC transients out of the scope of this unit.

Second, it has usually been assumed that the PC decay process senses the carrier concentration decay where mobilities are constant parameters. Such an assumption may be made in the great majority of actual cases. However, this cannot be true at high injection where electron-hole scattering reduces mobility substantially, for example, in high-resistivity Si (Grivickas et al., 1984). A few papers have also reported that carrier mobility was changed during PC transients in high-resistivity polycrystalline and compound semiconductors because of the effective recharging of scattering clusters. We do not attempt to provide an exhaustive accounting for these effects. As explained earlier (see Theory), in an extrinsic semiconductor, under low injection conditions, we shall assume that the decay of excess carrier concentration is always controlled by minority carriers through SRH recombination and either by a direct band-to-band or an Auger-type recombination mechanism.

Practical Aspects of the Standard PC Decay Method

By the standard technique, PC decay is monitored through the change of sample conductance in a constant electric field. Current is passed through a monocrystalline semiconductor specimen by means of ohmic contacts. The experimental arrangement in its simplest form is shown in Figure 16. The sample is bar-shaped with dimensions of typically $l \gg d$, w and has ohmic contacts on its end faces. The light beam is oriented normal to the applied electric field (a case of transverse PC). The intensity decreases with depth in the sample according to Beer's law. Neglecting multiple reflection, the photoconductance of the whole sample can be obtained (Ryvkin, 1964) as

$$\begin{aligned}\Delta G &= (w/l)q(\mu_n + \mu_p)I_0[1 - \exp(-kd)] \\ &= (w/l)q(\mu_n + \mu_p)\int_0^d \Delta n_x dx, \end{aligned} \quad (35)$$

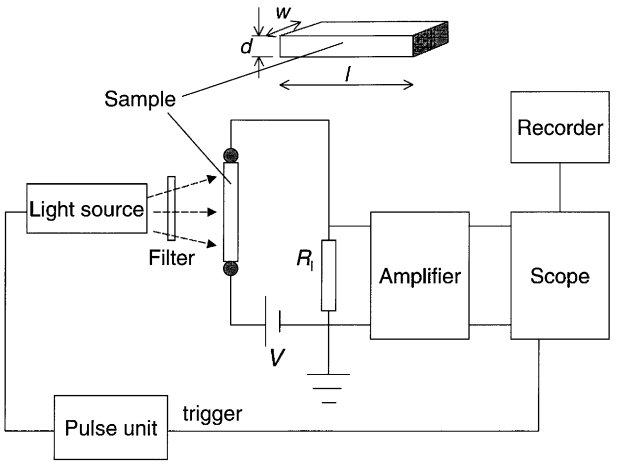

Figure 16. Basic experimental setup for photoconductive decay measurements in a constant electric field. Excess carriers are monitored as an increase in sample conductance.

where I_0 is intensity penetrated from the front surface of the sample and k is the absorption coefficient. For sufficiently thick samples ($kd \gg 1$) all light energy is absorbed in the sample and the photoconductance is independent of the absorption coefficient. Therefore, in this case the carrier distribution in the x direction is highly inhomogeneous.

In addition to the transverse PC (Fig. 16), the longitudinal PC is sometimes investigated. In this type of experiment, a semitransparent electrode is illuminated with the light beam parallel to the field. In general, the longitudinal case has a more complex relationship with fundamental semiconductor parameters. We confine our discussion in this unit to transverse photoconductivity.

As shown in Figure 16, the sample is connected in series with a battery supplying a voltage V and a load resistance R_L. Consequently, interrupting the light, the current in the circuit has a constant component and an alternating one. The voltage drop may be monitored with an oscilloscope or by a signal averager between the ohmic contacts (or between a second pair of potential contacts in a four-terminal measurement). If, in general, voltage drop is monitored on the load resistance R_L, a rather complex relationship between the alternating voltage received at the amplifier input and the variation of ΔG can be expected under the action of light. In some special cases, this relationship is simpler (Ryvkin, 1964). For example, if a small load resistance is used, $R_L \ll (G_0 + \Delta G)^{-1}$, where G_0 is the equilibrium conductance, then the relationship is linear because the illumination does not greatly alter the electric field distribution in the sample and the load resistance. This case sometimes is called the **constant field** regime. The resistor must be nonreactive, with a resistance at least 20 times less that of the sample in the excited state, to provide a condition of essentially constant field. As described by Ryvkin (1964), two other regimes, such as the **constant current** regime, $R_L \gg (G_0 + \Delta G)^{-1}$, or the **maximum-sensitivity** regime, $R_L = (G_0)^{-1}\,[1 + \Delta G/G_0]^{-1/2}$, can be frequently used. While the last two regimes, in general, do not imply proportionality between the signal and ΔG, a linearity is obtained when the relative change of the photoconductance is small ($\Delta G/G_0 \ll 1$). Thus, a constant current regime is recommended for minority carrier lifetime measurements in bulk Si and Ge by the ASTM standard F28 (ASTM, 1987).

The threshold of ΔG measurement sensitivity depends on various types of noise superimposed on the measured signal and the type of recording instrument. The minimum detectable photoconductance is also governed by the value of the equilibrium conductance, G_0, other conditions being equal (Ryvkin, 1964).

PC Method Automation for High-Frequency Range

Ordinary PC transient measurements are quite restricted on a nanosecond time scale because capacitance and/or induction of conventional electrical circuit elements produce failure effects. Recently, PC lifetime measurements in the 1- to 15-GHz frequency range have been developed through strip-line techniques by driving so-called Auston switches (Lee, 1984). Coplanar metal waveguides have been monolithically integrated on the semiconductor sample to provide characteristic impedance $\sim$50 Ω, with a corresponding spacing (photoconductive gap) of a few micrometers wide. Free carriers can be generated in the photoconductive gap by sharp femtosecond laser pulses and accelerated in an applied dc bias field, producing an electrical transient. The output of the circuit can be measured via high-frequency connectors attached to the striplines by a fast sampling oscilloscope. In this case, lifetime resolution down to $\sim$30 ps can be achieved.

Sampling experiments can also be performed without the need for an expensive fast oscilloscope. In this case, two photoconductive switches, one serving as a gate and having a very fast response function, can be connected in parallel and excited with delayed optical pulses. The temporal profile of an incident signal voltage pulse, $v_{\text{sign}}(t)$, can be measured by scanning the time delay, Δt, between the signal pulse and the gate pulse. The sampling yields a dc current given by the signal correlation

$$I(\Delta t) = \int \nu_{\text{sign}}(t) f_{\text{samp}}(t - \Delta t)\, dt \qquad (36)$$

where f_{samp} is the known sampling function corresponding to the optical gate pulse. Relatively inexpensive lock-in amplifiers can measure dc currents, provided that colliding optical pulses are chopped at low frequency. The lifetime can be estimated from mathematical simulations of the correlation function $I(\Delta t)$. The time resolution is limited by the duration of the sampling function of the gate switch. The ideal sampling function is a delta pulse, and, in fact, this has motivated the fabrication of a gate switch made from semiconductor materials with reduced carrier lifetime in a subpicosecond range (Smith et al., 1981). Therefore, the gate sample in this case should be regarded as a distributed circuit element, and the propagation of the wave through the photoconductive gap should be properly treated (Lee, 1984). Four factors have been shown to be of special importance. These are the free carrier lifetime, local dynamic screening, velocity overshoot, and the

carrier transient time from the photoconductive gap (Jacobsen et al., 1996).

High-frequency measurements usually involve high excitation levels and high electric fields. In these cases, carrier recombination is affected by fundamental processes of carrier momentum randomization, carrier thermalization, and energy relaxation in the bands (Othonos, 1998). At very high injections, PC in semiconductors usually obeys a nonlinear dependence as a function of light intensity. The most probable cause of any nonlinearity in a photoconductor is related to carrier lifetime. Pasiskevicius et al. (1993) have proposed to use PC correlation effects for measuring nonlinearities in ultrafast photoconductors. In this way, correlation signals are recorded on a single switch using a double pulse excitation scanned relative to one another. A peak will be observed on the autocorrelation traces when the photocurrent is a superlinear function of optical power and a dip when this function is sublinear. The widths of these extrema will be determined by the duration for which the switch remains in the nonlinear state.

The typical experimental setup used by Jacobsen et al. (1996) is sketched in Figure 17. Colliding pulses (100 fs) of a mode-locked Ti:sapphire laser are divided into two beams, with one beam passing through a delay line. Both beams are mechanically chopped and focused onto a biased photoconductive switch, and the relative arrival time is varied by mechanically moving the delay line. The current flowing in the photoconductive gap is measured by using a current-sensitive preamplifier, and the signal is sent to a lock-in amplifier. The preamplifier operation is slow compared to the time scale of the carrier dynamics, so a time average of the current is measured. In order to suppress noise when performing a photocurrent correlation measurement, the two beams are chopped at different frequencies f_1 and f_2, and the lock-in amplifier is referenced to the difference frequency $|f_1 - f_2|$. In this way, the correlation measurement integrates only the product of the carrier

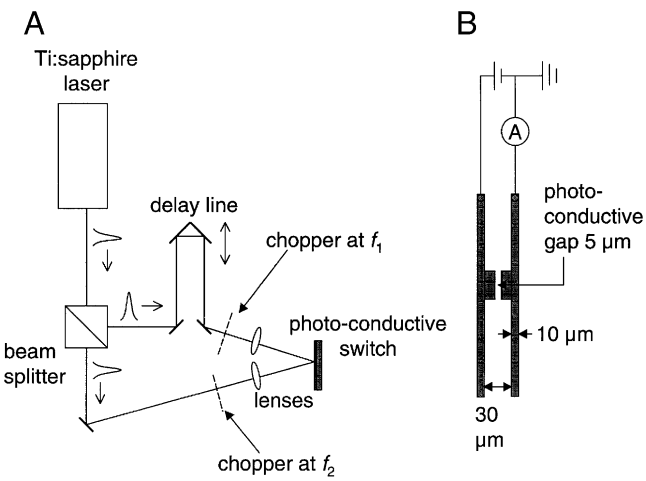

Figure 17. (**A**) The experimental setup for the photocurrent autocorrelation measurements in subpicosecond range. (**B**) Antenna design used as a photoconductive switch. The laser spot is focused in the 5-μm gap in the middle of the transmission line. Bias is applied across the gap and the current is measured.

density and the local electric field that corresponds to both pulses. Therefore, a rapid recharging of the photoconductive switch is required by a short recombination lifetime. Lifetimes as short as 200 fs have been measured using this correlation scheme.

Additional information on PC processes can be obtained from a set of compatible electrooptic techniques based on Pockels, Kerr, Franz-Keldysh effects, as reviewed by Cutolo (1998).

Detailed protocols of minority-carrier lifetime determination in bulk Si and Ge by a classical PC technique are provided in F28 in the Annual Book of ASTM Standards (ASTM, 1987). Other applicable documents of ASTM Standards are E177 (Recommended Practice for Use of the Terms Precision and Accuracy as Applied to Measurement of a Property of a Material (ASTM, 1987, Vol. 14.02) and F43 Test Methods for Resistivity of Semiconductor Materials (ASTM, 1987, Vol. 10.05).

The specimen resistivity should be uniform. The lowest resistivity value should not be <90% of the highest value (see Test Methods F 43; ASTM, 1987). The precision expected when the F28 method is used by competent operators in a number of laboratories is estimated to be better than ±50% for minority-carrier lifetime measurements on Ge or ±135% for measurements on Si, as defined in Recommendation Practice E177.

A similar, but not equivalent method is under the responsibility of Germany DIN Committee NMP 221. This is DIN 50440/1, Measurement of Carrier Lifetime in Silicon Single Crystals by Means of Photoconductive Decay: Measurement on Bar-Shaped Test Samples. This document is available from Beuth Verlag GmbH, Burggrafenstrasse 4-10, D-1000 Berlin 30, Germany.

Data Analysis and Related Effects

For reliable interpretation of the experimental data by the standard PC method it is important that the measuring electric field E be uniform throughout the sample. This implies the use of good ohmic contacts, and it is also necessary for contacts to cover the whole area of the end faces. Also, the sample cross-section and resistivity must remain constant over the sample length. Another requirement is that the magnitude of the electric field be low, such that the injected carrier density is not disturbed by excess carrier sweepout. The appropriate criterion can be obtained applying a drift term to the continuity equation (Orton and Blood, 1990). This leads to the condition

$$(\mu E)^2/4D \ll \tau_{\text{eff}}^{-1} \tag{37}$$

where D is carrier diffusion coefficient. If $\mu = 10^3$ $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$ and $\tau_{\text{eff}} = 1$ μs, and applying the Einstein relation, $D = k_{BT} \cdot \mu/q$, for the diffusivity, this results (at 300 K) in the requirement that E should be much less than 10 V/cm. It is advisable to check experimentally that a change in E has no effect on the measured decay time.

Another possible source of error lies in the generation of photovoltages at the contacts if these are not ohmic. The signal should be observed without applied voltage in order to determine the magnitude of such a photovoltage. The

amplitude of any photovoltaic signal should be less than 1% of the desired photoconductive signal. Also, the same PC amplitude with applied voltage must be observed for both polarities of the constant-voltage source. If the specimen voltages for the two polarities agree to within 5%, the contacts may be considered as nonrectifying. All connections to the contacts should be made with shielded cables, which must be as short as possible. The requirements for the performance of the preamplifier should be considered together at the same time. For working in the small-signal regime, it is advisable to mask contacts and illuminate only the central part of the semiconductor bar (F28, ASTM, 1987).

For the measurement of minority carrier lifetime, a finite injection level is required under low-level injection conditions. This level can be obtained by the standard PC measurement technique from the ratio of the voltage change, ΔV, across the illuminated specimen, to the voltage, V, across the specimen when the specimen is not illuminated. When the ratio $\Delta V/V$ is restricted to <0.01, the corrections to the lifetime value may be ignored. When the modulation of the measured voltage across the specimen exceeds 0.01, a correction is required to find the minority carrier lifetime, τ_{ll}. From the voltage decay time, τ_V, which is the quantity actually measured, a correction to the minority carrier lifetime is recommended as determined by the following equation (F28, ASTM, 1987)

$$\tau_{ll} = \tau_v[-(\Delta V/V)] \tag{38}$$

Sample Preparation

The largest possible specimen should be used, to minimize the contribution of surface recombination to the observed lifetime value. By the method description in ASTM Standard F28 (ASTM, 1987), it is also recommended that surface effects be attenuated by reducing surface recombination. Alternatively, the specimen surface can be sandblasted or ground to produce a reference surface for which a limiting high surface recombination rate may be calculated (see Equation 20 and Fig. 5). It is recommended that the corrections applied to an observed filamentary specimen lifetime never exceed the observed value. That is, the condition for low level-injection lifetime, $\tau_{ll} > \tau_b/2$, should never be violated. Tables 3 and 4 show the maximum values of the bulk lifetime, τ_b, which may, therefore, be determined on three standard small-sized specimens according to the F28 method.

Although many methods may be used for making contact connections (e.g., diffusion or implanted n^{++} or p^{++} layers), it is suggested by F28 that pressure contacts of metal braid or metal wool can be used for measurements at low injection. Thick sheets of Pb or In have also been found to be acceptable for this purpose. The ends of Ge specimens should be plated with either Ni, Rh, or Au. Nickel plating is satisfactory on the ends of n-type Si specimens and rhodium plating on the ends of p-type Si specimens. Copper should be avoided in the plating operation. Electrical contacts formed by alloying with an Au-Sb-Si eutectic can be recommended for PC measurements on n-Si at high-injection levels (Grivickas et al., 1984).

Different technological procedures for minority-carrier lifetime retention in Si wafers—before and after thermal heat treatment in various atmospheres, as well as after chemical treatments, after final deionized water rinsing, etc.—have been presented with respect to minority-carrier lifetime analysis by Blais and Seiler (1980), Graff and Pieper (1980), and Graff and Fisher (1979).

Table 3. Dimensions of the Three Small-Sized Filamentary Specimens for which Limiting Bulk Lifetime Data are Presented in Table 4

Size Designation	Length (cm)	Cross-Section (cm)
A	1.5	0.25 × 0.25
B	2.5	0.5 × 0.5
C	2.5	1.0 × 1.0

Table 4. Maximum Values of Bulk Lifetime, τb, in μs, for the Three Size Designations in Table 3, as Recommended by the F28 Photoconductivity Method for Minority-Carrier Lifetime Measurements at 300 K

Material	Size A (μs)	Size B (μs)	Size C (μs)
p-type Ge	32	125	460
n-type Ge	64	250	950
p-type Si	90	350	1340
n-type Si	240	950	3600

Microwave PC Decay Method

A wide range of alternative PC decay methods, which have the advantage of not requiring electrical contacts to the sample, depend on the measurement of **microwave reflectance** power. Due to the plasma effect, the dielectric constant of the semiconductor is a function of excess conductivity. A variety of experimental arrangements is possible depending on available microwave frequencies: e.g., through strip line systems (1–4 GHz), or through X-band (8–12.4 GHz), or through the Ka-band waveguide apparatus (28.5–40 GHz). The choice can be made between transmission or reflection systems, the use of a resonant cavity, or geometrical configurations within a partially closed system or outside it. Some methods are described by Orton and Blood (1990). Several commercial apparatus for microwave reflectance lifetime measurements are also available. Therefore, we briefly describe the most common experimental system, which illustrates the general features of microwave methods.

A simplified example of such a setup is shown in Figure 18A. Radiation from a frequency-stabilized microwave source is divided at the circulator. Power reflected from the sample arm is again split and is transmitted to a crystal detector in the other arm. Also mounted in the sample arm is a sliding short circuit that allows the sample to be placed in the position of a uniform microwave field. In other representative setups, the sample is simply backed by a metallic plate, which serves to increase the reflected power. The power reflection coefficient R' describes

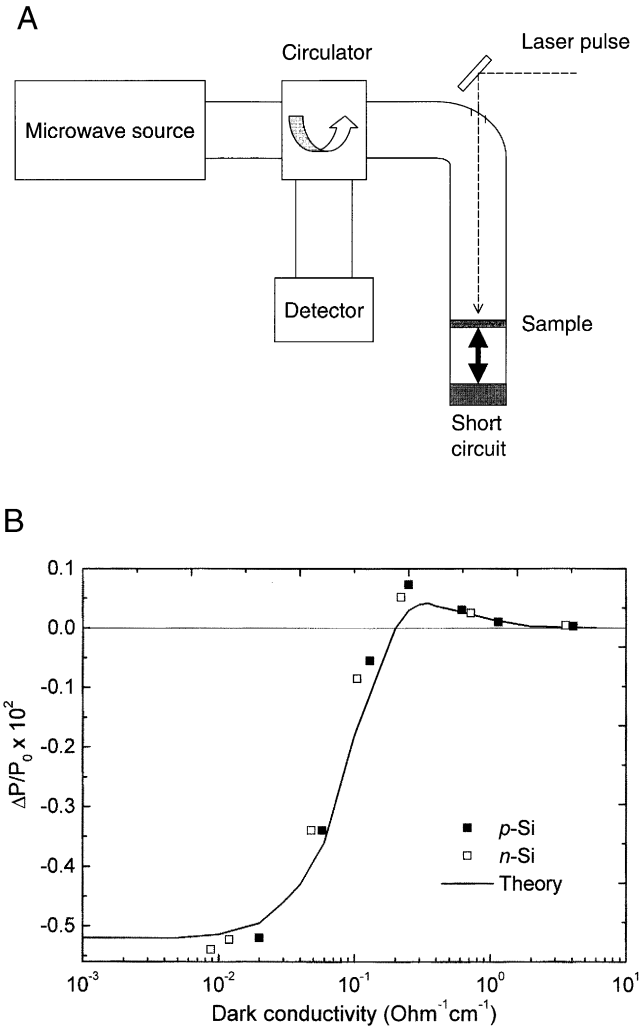

Figure 18. (**A**) Schematic representation of the microwave setup to perform quantitative lifetime measurements by microwave reflectivity. (**B**) Microwave conductivity signal amplitude at 35.5 GHz induced by exciting p-Si and n-Si wafers of 1 mm thickness with 1064-nm YAG light plotted versus the dark conductivity of the samples, as measured by Kunst and Beck (1988).

macroscopically the interaction between the sample and the microwaves. The change of the reflected microwave power from the sample is measured as a function of time when the sample is subjected to pulsed illumination. The time resolution is determined by the sharpness of the pulse, which could easily be in the nanosecond range. An oscilloscope (not shown in Fig. 18A) monitors the detector signal.

A usual approximation to the time-resolved microwave signal change $\Delta P(t)/P_0$ is given by

$$\Delta P(t)/P_0 = A \cdot \Delta\sigma(t) \tag{39}$$

A is called the **sensitivity factor** and is given by

$$A = \left(\frac{1}{R'(\sigma_0)}\right)\left(\frac{\partial R'(\sigma_0)}{\partial \sigma_0}\right) \tag{40}$$

Hence, A can be determined by measuring R' for different values of dark conductivity, σ_0, in a fixed cell geometry. It can also be calculated from electromagnetic theory (Kunst and Beck, 1988; Otaredian, 1993; Swiatkowski et al., 1995). For a first-order perturbation, two effects of an increase in the conductivity can be distinguished. First, an increase in the conductivity leads to an increase of the microwave absorption within the sample (if the microwave field in the sample remains constant) and, second, an increase in the conductivity leads to a decrease in the absorption due to the dark conductivity σ_0. The first effect yields a decrease in R' and the second leads to an increase in R' with the conductivity. However, it is obvious that the second effect is only important if the dark conductivity is large. In a general case, A can be positive or negative depending on the dark conductivity. In the low dark conductivity range, where $R'(\sigma_0)$ decreases linearly with increasing conductivity, higher-order terms can be neglected, and the relation

$$R' = 1 - A\sigma_0 \tag{41}$$

has been derived (Kunst and Beck, 1988).

Figure 18B demonstrates the amplitude of the microwave signal $\Delta P/P_0$ as a function of dark conductivity range for 1-mm-thick Si wafers measured by Kunst and Beck (1988), as determined at a microwave frequency of 35.5 GHz. All data are normalized to a constant excitation density below 10^{14} cm^{-3}. The solid curve represents a theoretical calculation. At higher dark conductivity, the absolute value of the sensitivity factor decreases until it becomes zero at $\sim 10^{-1}$ $(\Omega\text{cm})^{-1}$. Thereafter the sensitivity factor is positive, and, after a short increase, diminishes with increasing conductivity. So, for some combinations of conductivity and sample thickness, a frequency exists at which the sensitivity equals zero. A comprehensive calculation of reflection coefficient and conductivity sensitivity functions [10^{-5} to 10^{1} $(\Omega\ \text{cm})^{-1}$ range] for frequencies $f =$ 0.1 to 100 GHz has been provided by Otaredian (1993).

The sensitivity factor is proportional to the square of the microwave electric-field strength, $A \approx E^2(z)$, where z is a direction along the waveguide. The dependence of $A(z)$ on z is determined exclusively by the nonuniformity of the probing microwave field in the z direction. As $E(z)$ has a sinusoidal behavior, the sample should be placed at a maximum of the standing microwave. Thus, it is recommended that the thickness of the sample should be much less than a quarter-wavelength ($d < 10$ mm for X-band and $d < 2$ mm for Ka-band) even for low dark conductance samples.

Reference to sensitivity resolution leads one to consider the question of the skin depth, which determines the depth of material actually monitored by the microwave probe. At 10 GHz, skin depth is $\sim$500 μm for a conductivity of $1\,(\Omega\text{cm})^{-1}$ and varies approximately as ($\sigma_0 \times$ frequency)$^{-1/2}$. As quantitatively shown by Swiatkowski et al. (1995), the decay process has to be interpreted with care for the intermediate dark conductance range and in cases of higher injection because of the inhomogeneous excess photoconductivity in the z direction. Also, diffusion processes during the transient must be considered. In

general, for higher-conductance samples, data acquisition at lower microwave frequency is preferred.

In order to overcome this problem, the use of a constant-bias light in combination with a small excitation laser pulse has been successfully applied by some researchers for microwave reflectivity decay measurements (Stephens et al., 1994). Consequently, the modulation of the excess carrier concentration due to the laser pulse is small compared to the background injection level from the bias light, also eliminating differences in skin depths (see also Otaredian, 1993). The measured effective lifetime is shown to be a differential quantity, which may differ significantly from the actual effective lifetime (Schuurmans et al., 1997).

A number of researchers extended the microwave method to obtain minority carrier lifetime maps over whole semiconductor slices by mounting the sample on a positioning table. Spatial resolution may be obtained by focusing the light beam to a small spot or by monitoring the local resistivity with a small microwave probe. A lateral resolution of <100 μm is possible. It was shown that the signal could be maximized in terms of $\Delta P/P_0$ if the sample is excited in the center of a microwave cavity resonator, which typically has a higher-quality factor than a simple waveguide system. However, the rather cumbersome handling (instability) and the large time constants of microwave cavity resonators with high-quality factors have to be taken into account.

Radio Frequency PC Decay Method

In the radio frequency (rf) method, rf bridges, operating in the 1 to 900 MHz range, have been implemented for monitoring transient PC of semiconductors. The basic idea of the technique is that a semiconductor sample can be coupled to a rf bridge without the need for actual physical wire contact. Either inductive coupling by a 2 to 5 turn radio coil (Yablonovitch and Gmitter, 1992) or capacitive coupling by two flat electrodes (Tiedje et al., 1983) can be utilized (Fig. 19A and B). In effect, the coil or the capacitor is the primary of the transformer circuit and the semiconductor wafer is a secondary. The rf apparatus monitors the absolute sheet conductivity of the semiconductor, both in static and pulsed modes. The effective resistance in the secondary circuit is boosted by the coil turn ratio squared, when monitored in the primary circuit. Tuning capacitors are included in the circuit. One starts the measurement by adjusting the bridge with the sample mounted but without the light source. This procedure effectively nulls out the sample's dark conductance. The circuits are designed to digitize the reflected rf signal due to the impedance imbalance caused by the sheet conductivity changes in a semiconductor when the light is on. Small conductivity changes in the semiconductor will only perturb the tuning, and the reflected rf wave from the primary circuit will be linearly proportional to sheet conductivity. The output bridge signal is then mixed with an adjustable phase-shifter signal of the same frequency to give sum and difference output components. The difference component is a signal that is detected and recorded using an oscilloscope. Because there is no direct contact with the sample,

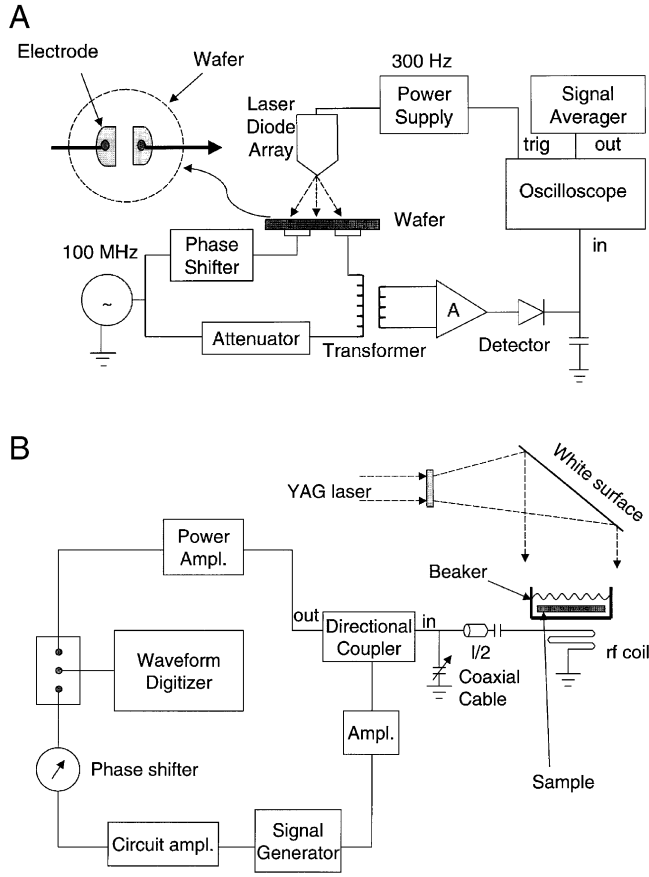

Figure 19. Schematic of the rf bridges for carrier lifetime measurements. (**A**) Setup with capacitator coupling at 100 MHz as used by Tiedje et al. (1983). (**B**) Setup with inductive coupling at 500 MHz as utilized by Yablonovitch and Gmitter (1992).

electronic measurements can be performed both in aqueous media (Fig. 19B) as well as in a vacuum.

The measured quantity is proportional to $\Delta\sigma$ where the constant of proportionality can be found by calibrating the detection circuit with semiconductor wafers of known conductivity (Tiedje et al., 1983). In general, a higher frequency increases the sample signal and also gives the circuit a better time response to monitor changes of the sample's conductance. The setup of Figure 19B, operating at 500 MHz frequency, extends measurements in the nanosecond time range to detect lifetimes on III-V semiconductors. While the skin depth is lower at lower frequencies, at 100 MHz it allows the electromagnetic radiation to penetrate even highly doped samples of 10 $(\Omega\text{cm})^{-1}$ to a thickness of a few hundred microns. Lateral resolution of the lifetime by the rf method is, however, quite limited due to the large area of coupling, and is of the order of several mm^2.

Problems

All PC decay measurements suffer from the following limitations.

1. It is very difficult to obtain separate quantitative information on the electron and the hole PC alone,

since both are equally present in the total PC. Partial conductivities may be obtained only in some specific cases. Such cases appear in damaged (amorphous) semiconductors at low injection levels (see Trapping).

2. Carrier mobilities are always weighting factors for the PC decay. In addition, the sensitivity factor A in all microwave reflectivity techniques, or the proportionality factor in rf techniques, must be properly calibrated for each particular thickness and dark conductance of the sample. Linearity of these constants should be checked and maintained for PC transients.

Except for the microwave technique, where local resolution is possible, only integrated lifetime over a relatively large area of the excited material can be represented by the PC decay.

While PC can be utilized in either a near-surface or bulk excitation mode, the main problems (as in any volume-integrated measurement) are the precise knowledge of the injection level and separation between surface and bulk contributions.

PHOTOLUMINESCENCE

Measurement of minority carrier lifetime in direct band gap semiconductors is usually performed by the PL technique, since emission yield is rather high. This is a nondestructive and noninvasive measurement that is very time-efficient. For process control and evaluation, one can measure lifetime in a simple structure and evaluate its performance. The individual components of multiple epitaxial layers can often be separately probed where only small quantities of material are needed. The lifetime, the diffusion length, and the quantum efficiency could be inferred. The main advantage is based on the fact that PL is an optical spectroscopic technique, i.e., it gives energetically resolved information. In particular, it is sensitive to the chemical species of impurities, which can be detected even at very low densities (see PHOTOLUMINESCENCE SPECTROSCOPY). This motivates the wide diffusion of this technique in the field of materials science and solid-state physics.

Principles of the PL Method

The PL decay method measures the radiation emitted by a material after optical excitation; in other words, it monitors various radiative recombination paths of photoexcited electron-hole pairs. The transient decay of the PL signal is called the PL lifetime. When combined with a model of the transient response, which is derived from the continuity equation, the minority-carrier lifetime and other recombination lifetimes are calculated. The principle of the experiment is very simple: excess carriers are injected by an appropriate light source in their fundamental absorption band, and the corresponding emission range is selected by a suitable monochromator and detected by a photoreceiver. The photoluminescence spectrum can usually be divided into three main energy regions whose width depends on the particular material. The numbers quoted in the following are characteristic of direct gap semiconductor crystals, e.g., GaAs of $E_g = 1.43$ eV.

Near-Band-Gap Emission ($E_g - 2E_{ex} < \hbar\omega < E_g + 2kT$, Where E_{ex} Is The Exciton Binding Energy). In this region, interband transitions, free and bound exciton recombination, and bound electron-free hole transitions are observed. At room temperature and above, exciton and shallow donor-related luminescence is thermally quenched. Band-to-band recombination dominates the spectra, and the PL edge position can even be used to determine the alloy composition of compound semiconductors such as $Al_xGa_{1-x}As$ (Pavesi and Guzzi, 1994).

Shallow Impurity Emission ($E - 200$ meV $< \hbar\omega < E_g - 2E_{ex}$). In this region, acceptor-related recombination is present. The information that one obtains from luminescence in this region also reflects the chemical species of the impurities involved in the transition, their relative densities, compensation ratios, etc.

Deep Level Luminescence ($\hbar\omega < E_g - 200$ meV). In this region, the recombination of deep impurities and defects is observed. The study of low-energy luminescence also gives information on important properties of the crystal such as stoichiometry, nonradiative recombination channels, defect densities, etc.

The radiative band-to-band recombination rate R of free electrons and holes (Fig. 1) is given by

$$R = B \times pn(\mathrm{cm^{-3}s^{-1}}) \tag{42}$$

Here p and n denote total concentrations of holes and electrons. The B-coefficient is specific to a particular semiconductor and is proportional to the dipole matrix elements between the conduction and valence band wave functions. This coefficient can be established by calculation from the integrated absorption spectrum using the detailed balance relationship (Van Roosbroeck and Shockley, 1954). Therefore, experimentally determined B coefficients are much larger for direct than for indirect band gap materials and have quite different temperature dependencies. For example, B is 2×10^{-10} cm^3/s for GaAs and $\sim 10^{-14}$ cm^3/s for Si at 300 K (see Table 1).

The PL decay is bimolecular into high injection conditions. The simplest recombination process, however, consists of direct band-to-band radiative recombination under low injection conditions. From Equation 12, the low-injection radiative lifetime is

$$\tau_{RAD} = 1/(BN) \tag{43}$$

where N is the majority-carrier density. In this case, the total PL output is simply given by summing the excess minority carriers over the active volume and multiplying by the radiative probability. When self-absorption and reflection of the internally generated photon are taken into account, the PL intensity is modified by

$$I_{PL}(t) = \frac{1}{\tau_{RAD}} \int_V A'(\mathbf{r}) \Delta n(\mathbf{r}, t)\, dV \tag{44}$$

Here Δn is excess minority carrier concentration in a p-type semiconductor (Δp in n-type) and $A'(\mathbf{r})$ is an optical interaction function accounting for self-absorption and interfacial reflection of internally generated photons, the extraction factor which accounts for the light-collection geometry, etc. For now, we will take $A'(\mathbf{r}) = 1$. We see from Equation 44 that $I_{PL}(t)$ tracks $\Delta n(t)$ in time. However, the photoluminescence decays with the minority-carrier lifetime only when there is no charge flow out of the active volume. A more accurate measurement of minority-carrier lifetime is therefore obtained from confinement structures which prevents minority-carrier diffusion loss, such as from $n^+/n/n^+$ AlGaAs type heterostructures (Ahrenkiel, 1992).

Practical Aspects of the Method

It is important to recognize that the external PL decay $I_{PL}(t)$ measures the overall minority carrier lifetime, not the radiative lifetime, because, in general, the recombination rates add as given by Equation 16. All nonradiative recombination paths (e.g., via deep recombination centers) compete with the radiative process in the bulk of the semiconductor and also with surface (or interface) recombination (see Theory) in the context of the decay concept. It is convenient to note that the internal efficiency η_i, defined as the ratio of radiative to total recombination rate, can be expressed in terms of Equation 43

$$\eta_i = \frac{\tau_{\text{eff}}}{\tau_{\text{RAD}}} = \tau_{\text{eff}} BN \tag{45}$$

For a steep absorption edge and high emission efficiency, the reabsorption of the photons generated by radiative recombination, termed **photon recycling**, leads to an increase in both the lifetime and the diffusion length of minority carriers. According to the calculations of Asbeck (Asbeck, 1977), this behavior produces an apparent increase in radiative lifetime which, for an active layer thickness d, can be written in terms of a photon recycling factor $\phi(d)$ as

$$\tau_{\text{eff}}^{-1} = \tau_{\text{nonRAD}}^{-1} + [\phi(d)\tau_{\text{RAD}}]^{-1} \tag{46}$$

where τ_{nonRAD} is the bulk minority carrier nonradiative lifetime. The parameter $\phi(d)$ is a complicated function of the internal radiative efficiency, the critical angle for total internal reflection, and the absorption coefficient, and can only be calculated numerically. The Asbeck calculations of $\phi(d)$ for GaAs heterostructures with different double $Al_xGa_{1-x}As$ window layer compositions are shown in Figure 20. One sees that the curves are not linear below 10 μm thickness where the transition to near-linear response appears. The recycling factor is ~10 for 1.2×10^{18} cm^{-3} doped GaAs active layer with a 10 μm thickness.

Method Automation

The experimental setup complexity is proportional to the needs; for characterization, a very simple and cheap apparatus is sufficient. The earlier references describe a number of techniques (Orton and Blood, 1990; Schroder, 1990).

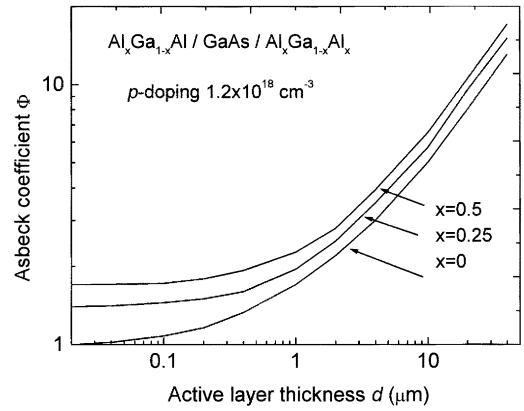

Figure 20. Calculations of the Asbeck coefficient for photon recycling in a double heterostructure $Al_xGa_{1-x}As/GaAs/Al_xGa_{1-x}As$.

Most workers have used short pulses from a laser or light-emitting diode (LED) to generate excess carriers. Alternative methods of excitation are also possible, the most popular being the injection from a metal contact or a pn-junction. The so-called cathodoluminescence decay method differs only in the use of a pulsed electron beam or x ray as the excitation source.

A more advanced technique for measuring photoluminescence decay with a high sensitivity and a fast time resolution is called time-correlated single-photon counting (Ahrenkiel, 1992). In order to use this technique, the photodetector must be able to detect single photons produced by the emitted light. The typical commercial photodetectors with sufficient sensitivity for photon counting are cooled photomultiplier tubes or microchannel plates (MCP). The transient time is greatly reduced in an MCP down into the picosecond range. The photodetector is followed by a high-speed amplifier, which is connected to the photon-counting apparatus. A schematic of the experimental setup is shown in Figure 21A. The photons emitted by the sample are focused on the input slit of a scanning monochromator tuned to the appropriate wavelength. The time-correlated photon counting electronics are identical in the remainder of the detection system. Using a beam splitter and a photodiode, a small fraction of the excitation pulse is deflected to a fast photodiode. The electric output of the photodiode triggers the time-to-amplitude converter (TAC). The pulse-height discriminator is necessary to block electrical pulses produced by thermal and other nonphotonic sources. The first collected PL photon initiates an electrical pulse in the photodetector, which is passed by the amplitude discriminator. The electrical pulse produces a stop message at the TAC. The TAC output is a ramp generator with amplitude proportional to the time delay between the laser pulse and the arrival of the first photon. The TAC signal is fed to a multichannel pulse-height analyzer (MCA), which collects one count per detected photon. A count is stored in a channel appropriate to the time delay and a maximum of one count is recorded for every laser pulse. In this way, a histogram of the PL decay is built in terms of counts versus time.

Many different techniques have been used for obtaining time resolution in luminescence spectroscopy (Fleming,

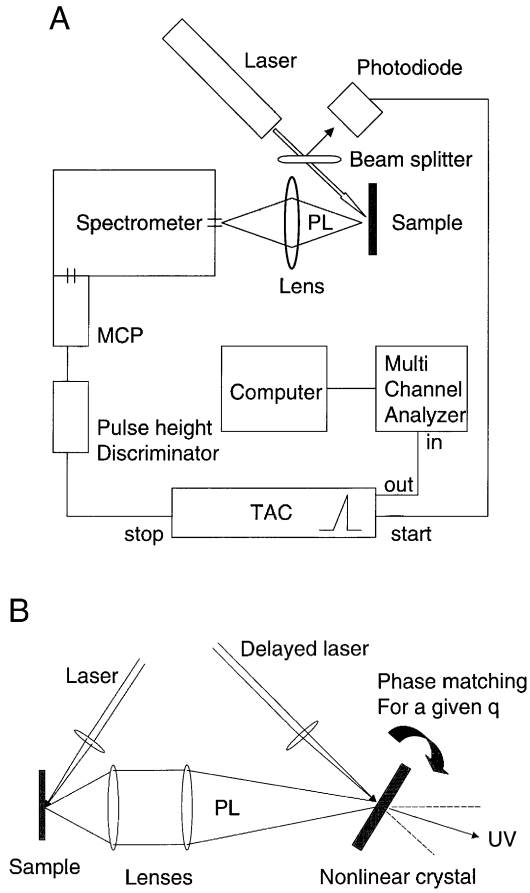

Figure 21. (**A**) Schematic of the PL decay measurement apparatus with time-correlated single-photon counting. (**B**) Schematic arrangement for the collection of luminescence for up-conversion. Sum frequency radiation is generated in a nonlinear crystal.

1986). While some photodetectors can be made with much faster response times than a typical photomultiplier of ~50 ps, their low sensitivity restricts their use in detecting weak signals. Another technique, preferred for obtaining time resolution in the 1 to 100-ps range, has been to use a streak camera. Some single-shot streak cameras offer a time resolution of better than 1 ps in certain cases. However, a drawback is the spectral response of the photocathode, which typically does not extend beyond ~900 nm.

The best hope for achieving luminescence time resolution comparable to today's available lasers of fs pulse width appears to be techniques that use nonlinearity induced by the laser pulse as a gate for recording the luminescence. In this technique, the luminescence excited by an ultrafast laser is mixed with the laser in a nonlinear crystal ($LiIO_3$, β-BaB_2O_4, CS_2) to generate sum or difference frequency radiation (see Fig. 21B). Since the mixing process takes place only during the presence of a delayed laser pulse, this provides time resolution comparable to the laser pulse width, as given by the experimental implementation of Shah (1988). Sum frequency generation, also known as wavelength up-conversion, is widely used because the availability of excellent photomultipliers in the visible and UV spectral regions makes this technique extremely attractive for time-resolved luminescence spectroscopy of infrared luminescence.

Data Analysis and Interpretation

The net effect of PL lifetime has to be analyzed in terms of SRH and surface recombination in the same way as for other methods. A model case of an n-type semiconductor with excess injected carriers ($\Delta n = \Delta p$) exceeding the doping density, N_D, will be analyzed here as an example. In contrast to previous analyses (see description in the Theory section) we assume here that SRH recombination and radiative recombination are the only two main recombination channels that have to be considered in direct-bandgap semiconductors. From Equations 7 and 10, it follows that the instantaneous lifetime becomes (Ahrenkiel, 1992)

$$\frac{\partial I}{\partial t} = \frac{I + I^2}{\tau_p[1 + I] + \tau_n I} \tag{47}$$

where the instantaneous injection level is $I = \Delta p(t)/N_D$ and the SRH electron and hole lifetimes τ_n, τ_p are described by Equation 9. The decay rate is nonexponential over an appreciable range of excess hole densities. The solutions of Equation 47 are

$$\begin{aligned} I(t) &= \exp(-t/\tau_p) \quad (I \ll 1) \\ I(t) &= \exp[-t/(\tau_p + \tau_n)] \quad (I \gg 1) \end{aligned} \tag{48}$$

One can fit the decay with these asymptotic rates and then define the initial injection ratio used in the experiment. The characteristic downturn of the decay curve has been seen in numerous devices and is an indicator of SRH recombination. When surface or interface recombination is the dominant mechanism (in thin devices), the photoluminescence decay may be fit with a function of Equations 47 and 48, replacing electron and hole lifetimes with the corresponding effective lifetimes: $\tau_{sp} = d/(2s_p)$ and $\tau_{sn} = d/(2s_n)$. The quantities s_p and s_n are interface recombination velocities for holes and electrons, respectively (refer to Equations 19 and 20). By varying the active layer thickness d, one can determine if the dominant recombination mechanism is bulk or surface related.

If a substantial concentration of excitons is present in a semiconductor at low temperatures, the PL decay becomes quite complex. The exciton level population should be included in the analysis as governed by the rates of formation and dissociation of excitons. Some description can be found in Orton and Blood (1990) and in Itoh et al. (1996). Usually, a strong coupling condition between the free exciton level and the conduction band can be used as a starting point. In a general case, the PL decay of free carriers can be approximated by two exponentials, and it becomes different from the carrier lifetime associated with PC (Ridley, 1990).

In disordered materials (such as amorphous, polycrystalline, or porous semiconductors) the PL decay and lifetime is usually represented either by a stretched-exponential or a power-law line shape. Physical interpretation of effective lifetimes or a characteristic distribution

Table 5. Application of Selected Transient Lifetime Techniques for Characterization of Different Semiconductor Materials

Lifetime Technique	Need for Contacts	Measured Quantity	Application for semiconductors		
			Indirect Band Gap	Direct Band Gap	Amorphous
PC direct	Yes	Photoconductance	++	+	+++
PC-microwave	No	Reflected microwave power	+++	+	+
PC-rf bridge	No	Eddy current (electromotive force)	++	++	+
FCA	No	Photoinduced absorption	+++	+	+
PL	No	Photoemission yield	+	+++	++

[a] All the considered techniques share the common feature of using a pulsed laser beam for excitation of excess electron hole pairs. Symbols: +, Applicable, but scarcely used; ++, relevant, commonly used; +++, beneficial, frequently used.

of lifetime parameters, however, very much depends on the particular assumptions for the recombination and transport models (Stachowitz et al., 1995; Roman and Pavesi, 1996).

Problems

From the discussion above, PL also has some disadvantages that can be summarized as follows:

1. It is very difficult to obtain quantitative information on the lifetime-doping-density relation or the lifetime-trap-concentration relation by PL alone. Some efforts, however, have been made in this direction, but the proposed methods require very accurate calibrations, checking very carefully the line shape of the spectrum (Schlangenotto et al., 1974; Pavesi and Guzzi, 1994).
2. Photoluminescence provides information on radiative transitions. Only indirectly can one study the nonradiative recombination processes, essentially by analyzing the quantum efficiency.
3. Photoluminescence is not a bulk characterization technique, as briefly explained above. Only a thin, near-surface region can be investigated, defined roughly by the larger of the light penetration depth and minority carrier diffusion length.

SUMMARY AND SELECTION GUIDE

The three lifetime characterization methods described in more detail in this chapter—free carrier absorption (FCA), photoconductivity (PC), and photoluminescence (PL)—have in common optical generation of excess carriers by a pulsed light source. Their common advantages may be summarized as:

1. They offer the possibility of controlling the injection level, Δn, by varying the laser pulse energy (enabling the minority or the high-injection lifetime to be studied).
2. They offer the possibility of localized measurements by focusing the excitation beam.
3. They are versatile techniques that may be used for several different semiconductors.
4. They are contactless techniques (except for the direct PC technique) allowing simple (or no) sample preparation.

Table 6. Comparison between Selected Lifetime Techniques for Limiting Parameters of Measurement Conditions

Lifetime Technique	Sensitivity Range (Δn) (cm^{-3})[a]		Dark Conductivity Range (σ_0)[b] $(\Omega_0 cm)^{-1}$	Measurement Bandwidth[c]	Commercial Apparatus
	Minimal	Maximal			
PC direct	10^{11}	5×10^{19}	<100	<40 THz	Yes
PC-microwave	10^{9}	5×10^{16}	<5	<10 GHz	Yes
PC-RF bridge	10^{13}	3×10^{17}	<10	<1 GHz	No information
FCA	10^{11}	10^{19}	≤200	<100 GHz	No information
PL	10^{9}[d]	10^{19}	≤1000	<500 GHz	Yes

[a] Specified for material of low dark conductivity, $\sigma_0 = 0.01\ (\Omega cm)^{-1}$.
[b] Specified for sample thickness of 500 μm.
[c] The exact value of the bandwidth is also a function of the time duration of the utilized laser pulses. Also, detection electronics may reduce these values considerably.
[d] For Group III-V semiconductors, which are characterized by high radiation yield.

Table 7. Comparison between Selected Lifetime Techniques for Sensitivity, Speed, hl/ll Lifetime, Depth Resolution, and Lateral Resolution

Lifetime Technique	Typical Decay Interval (Decades)[a]	hl/ll Lifetime[b]	Depth Resolution (μm)	Mapping Resolution (μm)	Mapping Speed
PC direct	2	++	—[c]	—	—
PC-microwave	2–3	+	—[c]	<100	Medium
PC-RF bridge	2–3	+	—[c]	—	—
FCA (∥)	3	+ +	—[c]	<10	Low
FCA (⊥)	3–5	+ + +	5	—	—
PL	3–5	+	—[c]	<1	High

[a]The exact sensitivity can be a function of the characteristics of the semiconductor material under test.
[b]Symbols: +, possible, however, causes methodical problems; ++, medium, some methodical problems; + + +, easy, small methodical problems.
[c]Indirectly through the measurements with variable absorption depth.

Their disadvantages may be summarized as:

1. They may yield erroneous lifetime values when carrier trapping is dominant (in this case a modulated or quasi-steady-state variant of the technique may successfully be applied).
2. Carrier diffusion and surface recombination may dominate recombination and, thus, the sought-after material parameter such as minority carrier lifetime or high injection lifetime may not be evaluated (as true for almost any lifetime measurement technique).
3. They require relatively complex experimental setup.

Tables 5–7 compare the different methods reviewed in this unit, and may be used as a selection guide for different semiconductor applications. Thus, Table 5 evaluates the advantages of each method for different types of semiconductors, while Table 6 summarizes the sensitivity and ultimate frequency range of the different methods. Notably, the frequency range indicated represents the ultimate limit of the measurement principle, while standard laboratory equipment such as photodetectors or oscilloscopes often yield a frequency limit much below 1 GHz. An exception is the PL up-conversion technique (see Fig. 21B) where pico- or femtosecond lasers may be used for characterizing ultrashort lifetimes. Finally, Table 7 summarizes some aspects of the techniques which are important for detailed recombination studies (e.g., several decades of the decay must be measured to safely extract the hl/ll-lifetime and the the radiative and Auger recombination rates). Also indicated is the applicability of the techniques for lifetime mapping and for depth-resolved studies.

As a final comment, one may note that even though the principle of each method is relatively simple, some experience must be gained to evaluate aspects of, e.g., surface recombination or carrier diffusion, before the derived lifetimes can be trusted as true characteristics of the semiconductor material bulk properties or as measures of the material's purity. It is, indeed, recommended that alternative methods be used to analyze the same sample. If other methods are not at one's disposal, one may gain further insight by varying the experimental conditions widely, e.g., by using different injection levels, different excitation and probe areas, etc. This may hopefully unravel different recombination mechanisms and separate carrier diffusion effects from true recombination phenomena.

CAPACITANCE-VOLTAGE (C-V) CHARACTERIZATION OF SEMICONDUCTORS

INTRODUCTION

Hillibrand and Gold (1960) first described the use of capacitance-voltage (C-V) methods to determine the majority carrier concentration in semiconductors. C-V measurements are capable of yielding quantitative information about the diffusion potential and doping concentration in semiconductor materials. The technique employs *pn* junctions, metal-semiconductor (MS) junctions (Schottky barriers), electrolyte-semiconductor junctions, metal-insulator-semiconductor (MIS) capacitors, and MIS field effect transistors (MISFETSs). The discussions to follow will emphasize *pn* junctions and Schottky barrier techniques.

C-V measurements yield accurate information about doping concentrations of majority carriers as a function of distance (depth) from the junction. The major competing technique to C-V measurements is the Hall effect (HALL EFFECT IN SEMICONDUCTORS), which, while yielding added information about the carrier mobility, requires difficult, time-consuming procedures to determine carrier-depth profiles. In fact, C-V profiling and Hall measurements can be considered complementary techniques.

In concert with deep-level transient spectroscopy (DLTS; DEEP-LEVEL TRANSIENT SPECTROSCOPY), C-V measurements can quantitatively describe the free carrier concentrations together with information about traps. Defects

appearing as traps at energies deep within the forbidden gap of a semiconductor can add or remove free carriers. The same Schottky diode can be used for both C-V measurements and DLTS measurements. The C-V apparatus and the DLTS apparatus are often a "bundled" setup.

C-V profiling to determine the doping profile of the mobile majority carriers in a semiconductor is a powerful quantitative technique. Some precautions must be taken, especially in dealing with multiple layered structures such as high-to-low doping levels, quantum wells, and the presence of traps. However, most of the problems encountered have been addressed in the literature. Major considerations and precautions to be taken in dealing with C-V profiling data acquisition and reduction are also covered in the ASTM standard (ASTM, 1985). The cost of assembling a C-V profiling apparatus will range between six thousand dollars for a simple, single temperature, manual apparatus to sixty thousand dollars for a fully automated apparatus. C-V profiling used in concert with deep-level transient spectroscopy (DEEP-LEVEL TRANSIENT SPECTROSCOPY) to identify traps, as well as with Hall effect (HALL EFFECT IN SEMICONDUCTORS), to address transport mechanisms, provides a powerful set of tools at reasonable cost.

PRINCIPLES OF THE METHOD

The capacitance at a *pn* or MS junction depends upon the properties of the charge-depletion layer formed at the junction. The depletion region is in the vicinity of the *pn* junction and is "depleted" of free carriers (Fig. 1A) due to the drift field (Fig. 1B) required to maintain charge neutrality. These properties are well known and are discussed in detail in standard texts such as Grove (1967), Sze (1981), McKelvey (1966), and Pierret (1996). This latter reference includes examples of computer simulations and programs for duplication by the reader.

Following Sze (1981) we show an abrupt *pn* junction in Figure 1. In this figure, the band gap of the semiconductor $E_G = (E_C - E_V)$ is defined by the difference between the conduction band energy, E_C, and the valance band energy, E_V. The Fermi energy E_F defines the equilibrium condition for charge neutrality. The difference in energy between the conduction bands as one crosses the *pn*-junction is called the diffusion potential, V_{bi} (or built-in potential). In Figure 2, we show the equivalent case for an MS junction. Here, the barrier potential at the MS junction is ϕ_{bn} in *n*-type material and ϕ_{bp} in *p*-type material. Although MS contacts for both *p*- and *n*-type materials are shown, the discussion will be restricted to *n*-type material only. Consider first the *pn* junction. The regions denoted by $\oplus$ and $\ominus$ indicate the junction region depleted of free carriers, leaving behind ionized donors and acceptors. In this region, we solve Poisson's equation

$$-\frac{\partial^2 V}{\partial x^2} = \frac{\partial E}{\partial x} = \frac{\rho(x)}{\varepsilon} = \frac{q}{\varepsilon}[p(x) - n(x) + N_D^+(x) - N_A^-(x)] \quad (1)$$

or for regions predominately doped *p*-type

$$-\frac{\partial^2 V}{\partial x^2} \approx \frac{q}{\varepsilon} N_D^+ \qquad \text{for} \quad 0 < x \le x_n \quad (2)$$

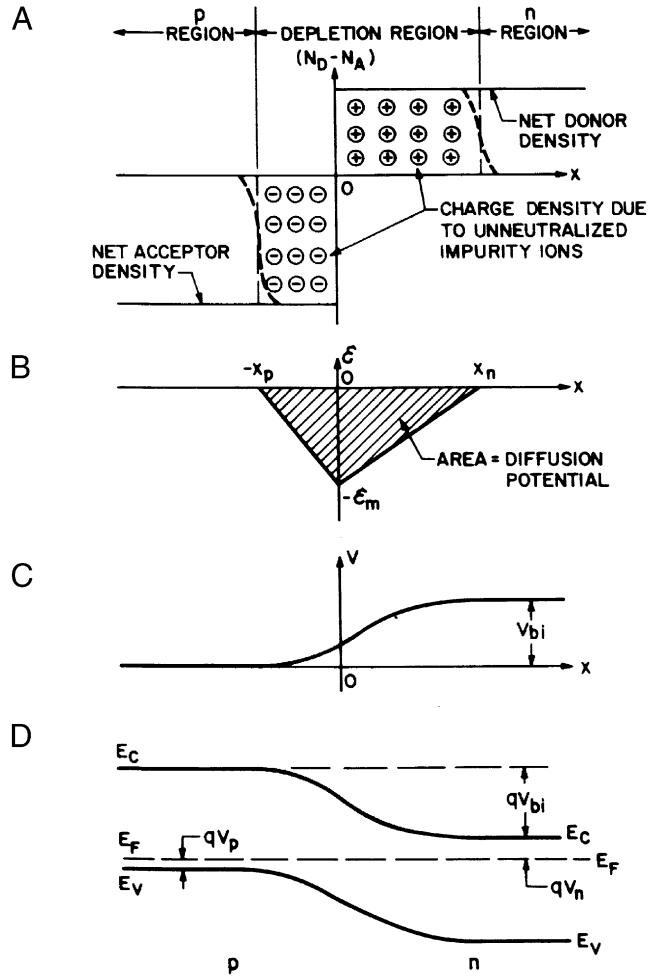

Figure 1. Abrupt *pn* junction in thermal equilibrium (no bias). After Sze (1981). (**A**) Space charge distribution in the depletion approximation. The dashed lines indicate the majority carrier distribution tails. (**B**) Electric field across the depletion region. (**C**) Potential distribution due to the electric field where V_{bi} is the (built-in) diffusion potential. (**D**) Energy band diagram.

or for *n*-type

$$-\frac{\partial^2 V}{\partial x^2} \approx \frac{q}{\varepsilon} N_A^- \qquad \text{for} \quad -x_p \le x < 0 \quad (3)$$

In these equations, V is the voltage, E the electric field, q the electronic charge, $p(x)$ and $n(x)$ the hole and electron concentrations (electric potential) comprising the mobile carriers, $N_D(x)$ and $N_A(x)$ the donor and acceptor doping concentrations, and $\varepsilon = K_S \varepsilon_0$, the permittivity with dielectric coefficient K_S. The spatial dependence, x, is measured relative to the physical location of the *pn*-junction. The solution of these equations in a form useful for C-V measurements is

$$V(x) = V_{bi}\left[2\left(\frac{x}{W}\right) - \left(\frac{x}{W}\right)^2\right] \quad (4)$$

where

$$V_{bi} = \frac{kT}{q} \cdot \ln\left(\frac{N_A N_D}{n_i^2}\right) \quad (5)$$

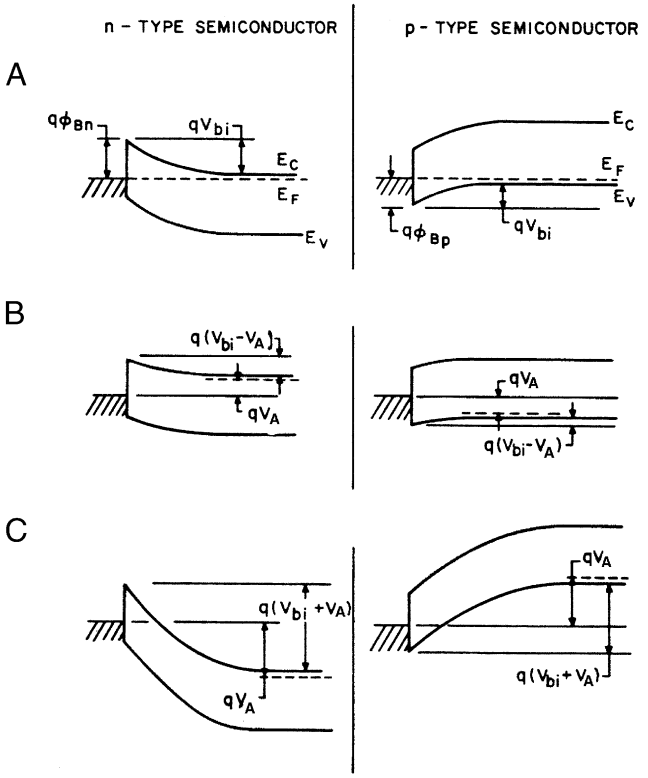

Figure 2. Energy band diagram of metal semiconductor (MS) contacts: ϕ_{Bn} (n-type) and ϕ_{Bp} (p-type) are the barrier heights at the MS interface required to establish equilibrium between the two materials. E_C, E_V, and E_F denote the conduction band energy, the valance band energy, and the equilibrium Fermi energy, respectively. Note that the diffusion potential is defined as $qV_{bi} = \phi B - (E_C - E_F)$. Diagrams after Sze (1981). (**A**) Thermal equilibrium for n- and p-type material. (**B**) Forward bias, $V = +V_A$. (**C**) Reverse bias $V = -V_A$.

is the diffusion potential, previously defined, and

$$n_i^2 = N_C N_V e^{E_G/kT} = 2.332 \times 10^{31} \left(\frac{m_{dc} M_{dv}}{m_0^2}\right)^{3/2} T^3 e^{E_G/kT} \tag{6}$$

in units of cm^{-6}. The intrinsic carrier concentration, n_i, contains the density of available states in the conduction (valence) band, $N_C(N_V)$, and m_{dc} and m_{dv} are the density of states effective masses in the conduction band and valence band respectively, while m_0 is the free electron mass. The band gap is $E_G = (E_C - E_V)$ and T is the absolute temperature. All these physical properties are tabulated in the literature. The depletion width $W = x_n + x_p$ is given by

$$x_n = \left[\frac{2K_S\varepsilon_0}{q} \cdot \frac{N_A}{N_D(N_A + N_D)} \cdot V_{bi}\right]^{1/2} \tag{7}$$

and

$$x_n = \left[\frac{2K_S\varepsilon_0}{q} \cdot \frac{N_D}{N_A(N_A + N_D)} \cdot V_{bi}\right]^{1/2} \tag{8}$$

Thus,

$$W = x_n + x_p = \left[\frac{2K_S\varepsilon_0}{q} \cdot \frac{(N_A + N_D)}{N_A N_D} \cdot V_{bi}\right]^{1/2} \tag{9}$$

See Figure 1A regarding the locations of W, $x_{n,}$ *and* x_p. The depletion width will widen under applied reverse bias, $-V_A$, and V_{bi} must be replaced by $(V_{bi} - V_A) > V_{bi}$. We are now able to calculate the capacitance of the depletion region, assumed to be a parallel-plate capacitor of plate separation W and area A,

$$C = \frac{K_S\varepsilon_0 A}{W} = \frac{K_S\varepsilon_0 A}{\left[\frac{2K_S\varepsilon_0}{q} \cdot \frac{(N_A+N_D)}{N_A N_D} \cdot (V_{bi} - V_A)\right]^{1/2}} \tag{10}$$

for a pn junction. Since C-V measurements cannot separately determine N_A and N_D in pn junctions, the usefulness of C-V profiling is quantitative for p^+n and n^+p junctions only. p^+ and n^+ designate very heavily doped regions reducing x_p and $x_{n,}$ respectively, to negligible thickness in the depletion layer. In this case, Equation 10 reduces to

$$C = \frac{K_S\varepsilon_0 A}{W} = \frac{K_S\varepsilon_0 A}{\left[\frac{2K_S\varepsilon_0}{qN_B} \cdot (V_{bi} - V_A)\right]^{1/2}} = \left[\frac{2K_S\varepsilon_0}{2(V_{bi} - V_A)}\right]^{1/2} A \tag{11}$$

where $N_B = N_D$ for the lightly doped side of p^+n junctions and $N_B = N_A$ for the lightly doped side of n^+p junctions. This same equation obtains for an MS junction, because the depletion layer in the metal is infinitesimally small.

For MS junctions on n-type semiconductors the diffusion potential is given by

$$V_{bi} = \phi_B - (E_C - E_F) = \phi_B - \frac{kT}{q}\ln\left(\frac{N_C}{N_D}\right) \tag{12}$$

where ϕ_B is the barrier height blocking the flow of carriers at the MS interface, E_C is the conduction band energy, and E_F the Fermi energy as previously defined and shown in Figure 2. The density of available states in the conduction band is given by

$$N_C = 2\left(\frac{2\pi m_{dc} kT}{h^2}\right)^{3/2} \tag{13}$$

where h is Planck's constant. For n-GaAs, $m_{dc}/m_o = 0.067$, so that for $T = 300$ K, $N_C = 4.35 \times 10^{17}/cm^3$.

PRACTICAL ASPECTS OF THE METHOD

In Table 1 are listed calculated depletion widths and capacitance for p^+n junctions in GaAs. The p^+ side is heavily doped to 2×10^{18} holes/cm^3, while three representative device-level donor doping levels are given for the n-side. The diodes are assumed to have typical areas of 1 mm^2.

Table 1. Depletion Widths and Capacitance for a GaAs p^+n Junctions[a]

		W (μm)			C (pF)		
N_D (cm^{-3})	V_{bi}(V)	$V_A = 0$	$V_A = -2$	$V_A = -10$	$V_A = 0$	$V_A = -2$	$V_A = -10$
1×10^{15}	1.228	1.30	2.11	3.94	84.9	52.4	28.1

[a] p^+ doping; $N_A = 2 \times 10^{18}$ cm^{-3}; $T = 300$ K; dielectric constant, $K_S = 13.2$; junction area, $A = 1$ mm^2.

Table 2 lists calculated values for a metal-GaAs Schottky barrier. Note that the significant difference is the diffusion potential V_{bi}.

The equations thus far assume that the doping concentration is uniform and that all of the dopants are ionized (i.e., $n = N_D$ in n-type material). In fact, a test of uniformity is to plot $1/C^2$ versus V_A which according to Equation 11 should be a straight line with slope proportional to the inverse of the doping concentration and the intercept on the positive abscissa equal to V_{bi}. This is illustrated in Figure 3 for capacitance normalized to its value at zero bias plotted versus V_A/V_{bi}.

C-V measurements are most useful if the differential form of the equations given above can be used. Rearranging and differentiating Equation 11 with respect to V we find

$$\frac{1}{C^2} = \frac{2(V_{bi} - V_A)}{qK_S\varepsilon_0 N_B A^2} \tag{14}$$

which leads to

$$N_B(W) = \frac{2}{qK_S\varepsilon_0 A^2}\left[-\frac{1}{d(1/C^2)/dV}\right] \tag{15}$$

The depth dependence of N_B can be determined from the measured capacitance, C

$$W = \frac{K_S\varepsilon_0 A}{C} \tag{16}$$

Equations 15 and 16 imply that it is possible to probe the semiconductor locally as a function of depth from the junction by merely increasing the reverse bias. We now wish to determine if our equations remain valid for the more general case of nonuniform doping. In the discussion below we follow the excellent description by Palmer (1990). In Figure 4 we depict a nonuniform doping profile, where for an n-type semiconductor $N_D(x)$ varies with position x. From Equations 1 and 2, we see that the electric field will vary according to the charge density $qN_D(x)$. Thus the areas under the $E(x)$ versus x curves are the voltages $V_1 = (V_{bi} + V_{A1})$ and $V_2 = (V_{bi} + V_{A2})$. If $V_{A2} = V_{A1} + \Delta V_A \ll V_{A1}$ then a small change in the depletion width will result, i.e., $\Delta W = W(V_{A2}) - W(V_{A1}) \ll W(V_{A1})$. Now, from Figure 4 we see that

$$V_2 - V_1 = V_{A2} - V_{A1} = E(W)W \tag{17}$$

And because we assumed ΔV_A to be small, we may write

$$E(W) = [dE(x)/dx] \cdot \Delta W = qN_D(x)\Delta W/(K_S\varepsilon_0) \tag{18}$$

But $qN_D(x)\Delta W$ is the charge per unit junction area, i.e., $qN_D(x)\ \Delta W = \Delta Q/A$. Thus, combining this result with Equations 17 and 18 we find

$$\Delta V_A = \Delta QW/(AK_S\varepsilon_0) \tag{19}$$

Since $C \equiv \Delta Q(W)/\Delta V_A$, we recover the relationship derived in Equations 10 and 11.

All of the equations developed above included the doping concentrations N_D (or N_A for p-type semiconductors). However, it is the mobile majority carriers, electrons of concentration n, or holes of concentration p, which respond to the varying applied bias. The donors N_D (or acceptors, N_A) are tightly bound in the lattice. Thus, the condition under which $N_D(W) = n(W)$ requires that the donor ionization energy be small compared to kT (at room temperature, $kT = 0.026$ eV, while the ionization energy for most shallow dopants is 0.010 eV or less). This condition is called

Table 2. Depletion Widths and Capacitance for a Metal n-GaAs Schottky Barrier[a]

		W (μm)			C (pF)		
N_D (cm^{-3})	V_{bi}(V)	$V_A = 0$	$V_A = -2$	$V_A = -10$	$V_A = 0$	$V_A = -2$	$V_A = -10$
1×10^{15}	0.744	1.01	1.95	3.85	109	56.8	28.7
1×10^{16}	0.803	0.33	0.62	1.22	331	177	90.4
1×10^{17}	0.863	0.11	0.20	0.40	989	543	279

[a] Barrier height, $\varphi_{Bn} = 0.9$ eV; $T = 300$ K, dielectric constant, $K_S = 13.2$, junction area, $A = 1$ mm^2.

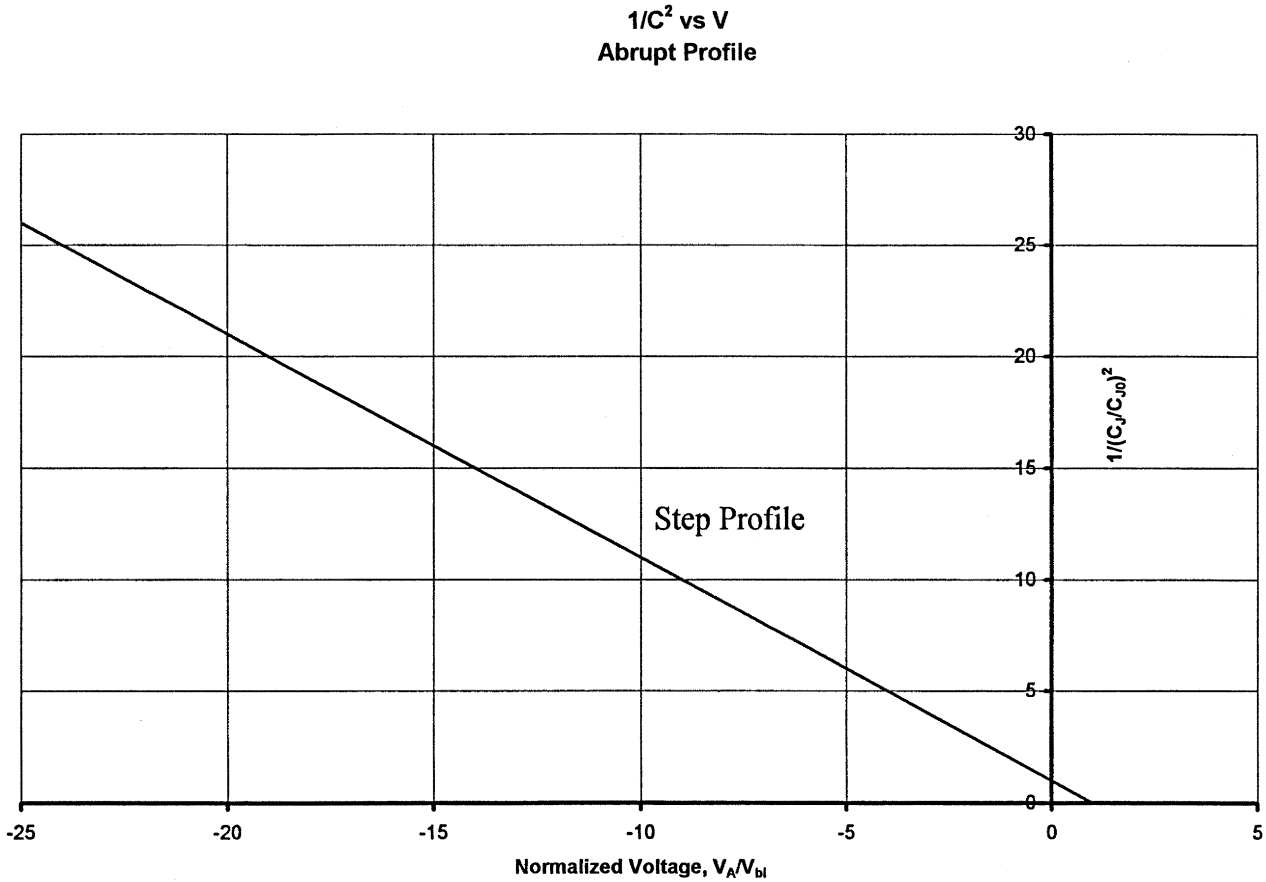

Figure 3. Normalized plot of C^{-2} versus V_A/V_{bi} for a uniform doping distribution indicating the expected straight line plot.

the extrinsic range of operation. Note that if the temperature is too high, however, the semiconductor becomes intrinsic and the free carrier concentration is determined by Equation 6, independently of the dopant concentration. We will show later that if traps are present deep within the forbidden energy gap, Equations 14 and 15 are not strictly true and do not represent either n or N_D. Since the depletion depth is determined by the number of immobile positive charges exposed (in an n-type semiconductor), then a more correct way to write Equation 15 is

$$N^+(W) = \frac{2}{qK_S\varepsilon_0 A^2}\left[-\frac{1}{d(1/C^2)/dV}\right] \tag{20}$$

and depth below the junction is written as

$$x = W(V_A) = \frac{K_S\varepsilon_0 A}{C} = \left[\frac{2K_s\varepsilon_0}{qN_B}(V_{bi} - V_A)\right]^{1/2} \tag{21}$$

Note that for shallow donors (i.e., with donor ionization energy $<kT$ as discussed above) and no traps, $N^+ = N_D{}^+ = n$. However, in general, Equation 20 and Equation 21 are the "working" equations to be used in C-V profiling.

C-V PROFILING EQUIPMENT

In order to apply Equations 20 and 21, the apparatus shown schematically in Figure 5 is employed. The C-V meter superimposes a small ac signal (typically 10 to 15 mV) onto the dc bias so that the voltage drop across the junction is $V_A + v_{ac}$. During the positive half of the ac signal, the reverse bias is reduced slightly, causing a small reduction in the depletion width ($W = W_A - |w_{ac}|$). The depletion width increases slightly during the negative portion of the cycle. Typical of capacitance meters used is the Boonton 72B meter. It operates at a fixed frequency of 1 MHz and has an amplitude of 15 mV. Its capacitance range covers 1 pf to 3000 pf, sufficient to cover the range of capacitance found in Schottky barriers and *pn* junctions (see Tables 1 and 2). Other meters used for C-V measurements include the variable frequency Hewlett-Packard models HP-4271B and HP-44297A LCR meters and the Keithley −590 capacitance meter. The Keithley meter permits measurements at 100 kHz as well as 1 mHz. Most of the apparatuses in use are also interfaced to a computer for automation of the measurement plus real-time data reduction and plotting. Several manufacturers offer bundled C-V profiling packages with turn-key operation.

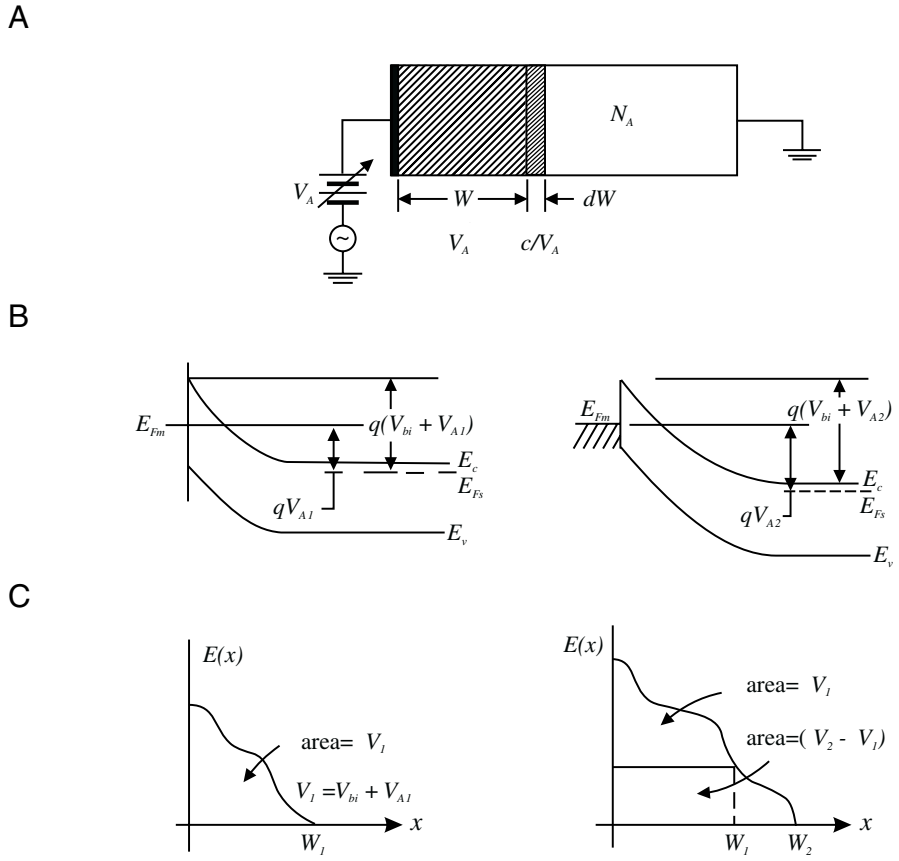

Figure 4. A plot of the electric field versus distance for a nonuniform doping profile. Compare the electrical field here with the electrical field in Figure 1 where the doping on either side of the junction was uniform. $V_{A2} > V_{A1}$. (**A**) Biasing circuit. (**B**) MS junction for applied potentials V_{A1} and V_{A2} with $|V_{A2}| > |V_{A1}|$. (**C**) Electric field versus position for a nonuniform carrier distribution corresponding to V_{A1} and V_{A2} in (**B**).

OTHER C-V PROBING PROCEDURES

Mercury Probe Contacts

The disadvantage of all carrier concentration measurement techniques is the need to establish contacts to the material under investigation. For Schottky barriers, a metal of precise area is deposited onto the wafer using photolithographic techniques. A low-resistance ohmic contact must also be formed in order to complete the circuit. These procedures are destructive, and the material is lost to further use. In an attempt to eliminate these Schottky barrier fabrication procedures, mercury probes have been developed to make temporary contact to the semiconductor surface. A schematic representation of an Hg probe is shown in Figure 6 (Schroder, 1990). The Hg is forced against the semiconductor by pulling it down against a precisely defined area using a vacuum. Simultaneously the Hg is siphoned up against the semiconductor making intimate contact (Jones and Corbett, 1989). The larger-area contact in the figure is the second contact to complete

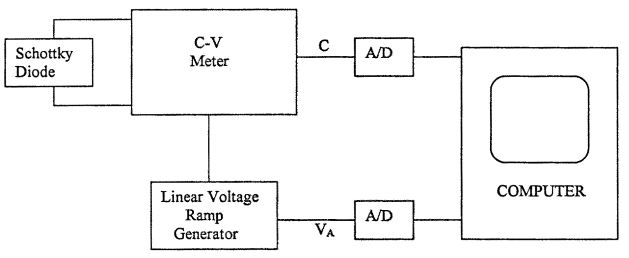

Figure 5. Schematic diagram of a typical automated C-V apparatus. Linear ramp generator provides the reverse bias to the Schottky diode. A/D, analog/digital converters.

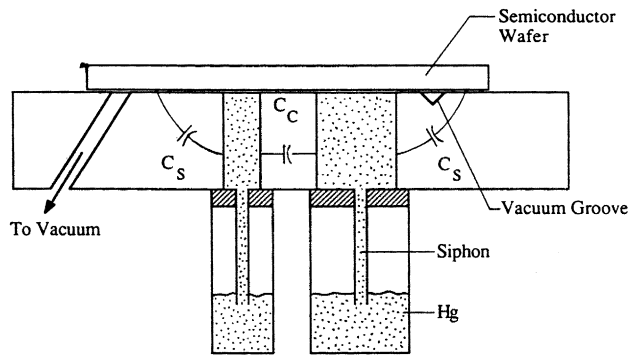

Figure 6. Typical mercury probe. The smaller contacting area is the reverse-biased Schottky barrier. (After Schroder, 1990.)

the circuit. Its area is many times that of the profiling contact, so that the two capacitances in series essentially look like the small reverse biased probing capacitance acting alone. Unfortunately, reproducible results are difficult to obtain, requiring careful surface preparation, very clean Hg, and careful cleaning of the semiconductor surface after use. Furthermore, Hg is toxic and safe procedures must be observed. Good discussions of the use of Hg probes may be found in Jones and Corbett (1989) and Schaffer and Lally (1983).

Electrochemical Profiling

This is another attempt to simplify C-V profiling, in which the Schottky barrier is formed at an electrolyte-semiconductor interface [see SEMICONDUCTOR PHOTOELECTROCHEMISTRY]. Ambridge and Faktor (1975) have described the description of the electrochemical profiler in detail. The measurements can be performed at a constant dc voltage (no modulating signal) and the depth is changed by electrolytically etching the semiconductor between capacitance measurements. The cell cross-section shown in Figure 7 is taken from the review article by Blood (1986). The Schottky barrier is formed by the electrolyte, and the back contact by springs or a plunger, which press the semiconductor against a sealing ring that also serves to define the area of the Schottky contact. The light source is used to generate holes in n-type semiconductors so that etching can take place under reverse bias. When the sample is illuminated, the etch rate is proportional to the photo-induced current flowing through the cell. For p-type material, illumination is not needed because etching takes place under forward bias. Thus, for p-type material the procedure involves forward biasing to etch away material, followed by reverse biasing to make the C-V measurements. Because in principle it is possible to etch to any depth, electrolytic profiling places no limit on the depth that can be probed. Complete details for electrolytic C-V depth profiling can be found in the excellent review by Blood (1986).

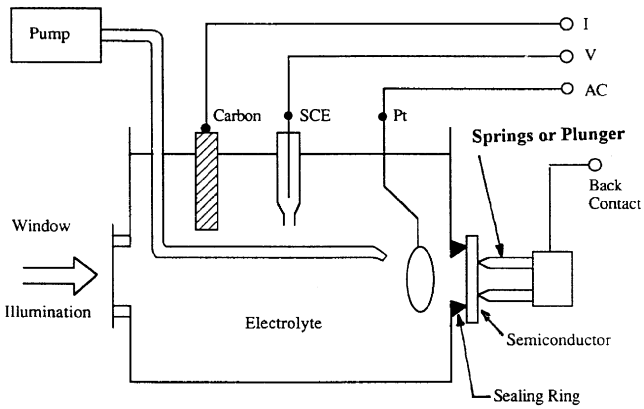

Figure 7. Schematic diagram of an electrochemical cell. The pump is used to agitate the electrolyte to maintain a uniform concentration at the semiconductor surface and to disperse bubbles from the surface. SCE is a saturated calomel electrode, used to maintain the correct overpotential in the cell. Diagram after Blood (1986).

DATA ANALYSIS: TYPICAL C-V RESULTS

An example of a uniformly doped n-GaAs layer grown in the authors' laboratory, using a halide vapor phase epitaxy (VPE) reactor, is shown in Figure 8A. The Schottky diode was fabricated by evaporating a 1.13-mm diameter gold guard ring structure ($A = 1$ mm^2) using photolithographic lift-off. Precise definition of the diode diameter is essential because it enters Equation 20 as the fourth power of d. The measurement of the area in Equation 20 is the largest source of error in determining N^+. This example is chosen to illustrate several points. The doping concentration is $\sim 3.6 \times 10^{15}$ cm^{-3}. The following observations may be made.

1. The profile depth starts at about $W = 0.55$ μm, corresponding to the zero bias depletion depth. C-V profiling is limited in how close to the MS junction data can be obtained by this zero bias distance. This minimum depth is calculated using Equation 21 with $V_A = 0$ and Equation 12 to calculate V_{bi}.
2. The profile is uniform, with no indication of carrier freeze-out at 80 K, indicating the ionization energy of the Te-donor atoms (~ 0.003 eV) is $< kT = 0.007$ eV.

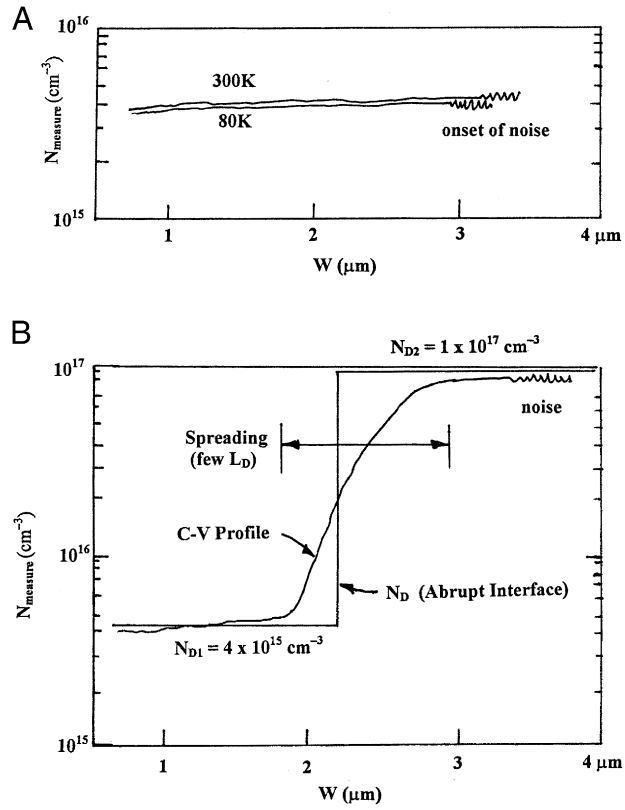

Figure 8. Carrier profiles determined in the authors' laboratory on VPE grown n-GaAs. (**A**) A single layer uniformly doped to $\sim 4 \times 10^{15}$ cm^{-3}. Note the onset of noise limiting the depth of the profile. (**B**) A double layer growth with a heavily doped layer grown first ($N_D = 1 \times 10^{17}$ cm^{-3}) followed by a less heavily doped cap layer ($N_D = 4 \times 10^{15}$ cm^{-3}). The solid straight vertical line indicates the actual abrupt growth interface. Note the gradual transition in the C-V profile due to spreading over several Debye lengths, L_D.

3. The maximum depth depends upon the thickness of the epitaxial layer on the underlying semi-insulating substrate or upon the breakdown voltage of the reverse-biased junction. The breakdown of reverse-biased metal-compound semiconductor Schottky barriers tends to be much lower than predicted from the maximum possible field strength. In this case, the onset of noisy signals at $V_A = -40$ V terminated the measurement. The predicted breakdown voltage for this doping concentration is $V_R = -190$ V. For more heavily doped material, voltage breakdown of the junction limits the maximum depth probed.

The second example in Figure 8B indicates the profile measured for a GaAs structure in which the two layers were grown with the first layer doped to a higher donor concentration of $N_D = 1 \times 10^{17}$ cm^{-3}, followed by a layer doped to $N_D = 4 \times 10^{15}$ cm^{-3}, the top surface layer onto which the Schottky barrier is fabricated. This allows us to observe another limitation of C-V profiling. Although the transition from the lightly doped to the heavily doped layer was abrupt, the C-V data indicate a gradual transition from the first to second layer. This deviation of the majority carriers, $n(x)$, from the dopant profile, N_D, is explained by considering the local distance required to establish equilibrium (see Problems, below).

The data reported in Figure 8 can be recorded and plotted as shown at a rate of ~10 min per figure with automated equipment. The time required to add data acquired at several temperatures is determined by (a) the time to electrically and thermally mount the test structure, and (b) the time required to reset each temperature in the cryostat.

SAMPLE PREPARATION

There is no standard sample preparation procedure for fabricating Schottky barrier devices to measure C-V profiles. In fact, Schottky barrier fabrication is material-specific for each semiconductor. An ideal Schottky barrier structure is one in which the semiconductor material of interest is grown on a heavily doped, low-resistivity substrate of the same material. This reduces the series resistance, R_S, and makes formation of the ohmic back-contact straightforward. After performing the cleaning procedure to be discussed below, the ohmic contact is formed first. This can be as simple as depositing a metal or metal combination followed by a low temperature sinter to "form" the ohmic contact. In a worst case scenario, the metal must be "alloyed" at a higher temperature to react it with the heavily doped substrate. After formation of the ohmic contact, the wafer must be recleaned to prepare the opposite surface for the Schottky barrier contact. Although cleaning procedures are also material-specific, there are certain generic steps common to all semiconductors. It is essential that the surface of the semiconductor be spotlessly clean. To accomplish this, the surface must be stripped of all organic residue and native oxides. Organic materials are removed by agitating the wafer in acetone followed by methanol and rinsing with deionized (18 MΩ) water. Native oxides formed in the water rinse and/or by exposure to laboratory air are usually removed using buffered hydrofluoric acid (buffered HF), a commercially available acid. However, not all semiconductors are etched this way. For example, the standard oxide etch for GaAs is one part hydrochloric acid in one part water (1:1 HCl:H_2O). By comparison, this same HCl:H_2O etch will destroy an InP sample in seconds. The study of newly evolving semiconductors will require developing procedures compatible with the material under study, often by trial and error. If the cleaning and etching procedure is successful, the sample surface will be completely dry as it is withdrawn from the acid etch (i.e., will be hydrophobic). If the surface has wet areas or spots, this means that the cleaning procedure has failed and must be repeated. The importance of the cleaning step prior to metallization cannot be overemphasized.

The sample should be loaded directly into the metallization station immediately after the etching step to minimize the formation of native oxide. A typical metallization for Si and the group III-V compound semiconductors is the deposition, usually by thermal evaporation in vacuum, of a thin (~40 nm) "adhesion" layer of a reactive metal such as chromium followed by a thicker (~400 nm) layer of a noble metal (gold) or a soft metal such as aluminum. This thickness of metal is adequate for wire bonding for cryostat mounting of the sample, or for probing using a standard probing station for single temperature measurements. The only requirement is that the metal in contact with the semiconductor form a low-leakage Schottky barrier. Often the equipment available governs the metal chosen and the procedures adopted in a given laboratory.

If the semiconductor of interest is grown on a high-resistivity substrate, ohmic contact formation may not be possible. In this case, a second large-area MS contact is fabricated simultaneously with the precisely defined Schottky barrier of known area. In a typical 5 × 5-mm test sample, this second contact will be at least 15 times larger than the Schottky gate, and since the capacitances are in series, will introduce an error of no more than 6%. To improve accuracy in this case, the diameter of the Schottky barrier contact is reduced (by a factor of two) to reduce the error to ~1%.

PROBLEMS

Instrument Limitations

The capacitance meter is the ultimate resolution-defining instrument in determining the $n(x)$ versus W profile. The meter should be of sufficient accuracy so that the Debye length, L_D, is the limiting factor for the spatial resolution. Amron (1967) has discussed in detail the limits to accuracy in C-V profiling. It would appear that large signals are desirable and that ΔC should be made as large as possible. But large ΔC deteriorates the spatial localization of the measurement. This can be seen from Equation 10 and Equation 11, where the differential changes in C and W are related through

$$\beta = \frac{\Delta C}{C} = -\frac{\Delta W}{W} \tag{22}$$

where β is a precision parameter introduced by Amron (1967) which sets the error limits in terms of an acceptable standard deviation in $n(x)$ and W. Amron shows that it is desirable to keep $\beta < 0.1$. For a uniform profile, and constant modulation voltage ΔV, ΔC decreases because W increases with reverse bias and C decreases (see Tables 1 and 2). Thus, as ΔC decreases, the profiles become noisier, limiting the depth to which the profiles can be measured. See the increased noise for increasing W in the profiles for GaAs in Figure 8.

We now address the problem of measuring real devices versus ideal structures discussed to this point. The capacitance meter sees the diode as an admittance of the form

$$Y = G + j\omega C \tag{23}$$

and measures the quadrature component, $j\omega C$. However, it is assumed in the measurement that any series resistance, R_S, is small. Series resistance, R_S, includes the bulk resistance of the device under test and any lead resistance. The circuit model is shown in Figure 9. Wiley and Miller (1975) have considered the effects of R_S on the measurement. Calculation of the admittance with R_S in the circuit yields the following equations for C and G

$$C_M = \frac{C}{(1 + R_S G)^2 + (\omega R_S C)^2} \tag{24}$$

and

$$G_M = \frac{G(1 + R_S G) + R_S \omega^2 C^2}{(1 + R_S G)^2 + (\omega R_S C)^2} \tag{25}$$

Only the measured capacitance, C_M, is of interest. For C_M to closely approximate the true capacitance, C, we require $R_S G \ll 1$ and $(\omega R_s C)^2 \ll 1$. Provided that careful fabrication procedures are followed, the $R_S G \ll 1$ specification is easily met, because in good diodes $G \to 0$. This condition requires that leakage currents be minimized, a condition easily met with careful fabrication procedures. The condition requiring $(\omega R_s C)^2 \ll 1$ is more difficult and must be addressed for individual diodes. For example, using a typical capacitance meter operating at $f = \omega/2\pi =$ 1 MHz, the condition on R_S to guarantee 1% accuracy is

$$R_S < 1.6 \times 10^4 / C(pf) \tag{26}$$

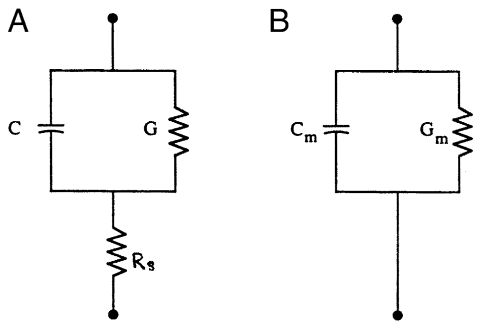

Figure 9. (**A**) Realistic circuit and (**B**) the ideal circuit describing a *pn* junction or Schottky barrier. Resistance, R_S, accounts for the bulk resistance of the semiconductor being measured, and the lead resistance. R_S must be minimized.

with the results being obtained in Ω. For the range of capacitance in Tables 1 and 2 this sets limits of $R_S < 16$ Ω for the largest capacitance (heaviest doping) and $R_S < 571$ Ω for the smallest capacitance (lightest doping). A rule of thumb is that the series resistance must always be <100 Ω. Thus, careful sample preparation is of great importance (see Sample Preparation).

In the discussion above of the data presented in Figure 8B for two layers of significant doping difference, we noted a gradual change in the profile as measured by the C-V apparatus. The reason for this apparent gradual transition in a region where the doping profile changes abruptly is as follows. This distance is the region over which the combination of the diffusion of electrons away from the concentration gradient at the junction is balanced by the drift due to the electric field, and is described by the Debye shielding length given by

$$L_D = \left[\frac{kTK_S\varepsilon_0}{q^2 N_D}\right]^{1/2} \tag{27}$$

L_D is a measure of the distance over which the mobile majority carriers eliminate any charge imbalance through diffusion and drift. Thus, at the abrupt interface, the spatial resolution of the $n(x)$ measurement is limited to a few Debye lengths. Johnson and Panous (1971) have presented detailed calculations of this effect. For further details of profiling errors and instrumental limitations see the excellent paper by Blood (1986).

TRAPS AND THEIR EFFECT ON C-V PROFILING

Finally, we present a short discussion of carrier trapping centers and their effect on carrier profiling using the C-V method. The effects of traps on C-V measurements can be profound, and only an outline of their effects will be presented here. Traps (defects) in semiconductors are a complementary area of study, and are discussed in DEEP-LEVEL TRANSIENT SPECTROSCOPY. Although traps can change the interpretation of C-V profiling, most workers ignore them. Detailed consideration of the effects of traps on C-V profiling can be found in the paper by Kimerling (1974).

We first define a trap as an energy level in the forbidden gap several kT below the shallow donor level (or above the acceptor level). Following the definitions in DEEP-LEVEL TRANSIENT SPECTROSCOPY they are designated acceptor traps if they have negative charge after trapping an electron, and as neutral when empty (i.e., the electron has vacated the trap). Similarly, donor traps are neutral when they possess a trapped electron and are positive after the electron has been emitted.

For discussion purposes we will consider only donors in n-type semiconductors and acceptor-like traps. Further, we assume the concentration of traps, N_{tr}, is $<N_D$. In Figure 10 we show two different trap levels. One is far from the conduction band and is not influenced by the band bending at the MS interface or the effects of reverse bias and the AC modulation of the capacitance measurement. The other trap is closer to the donor level and is

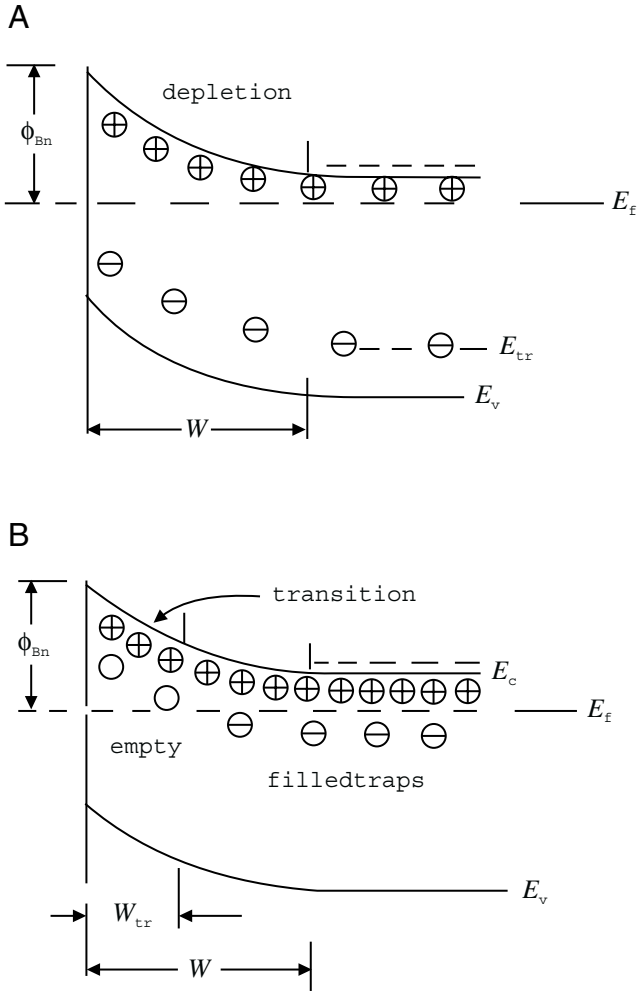

Figure 10. Schematic diagram of traps. (**A**) "Deep" traps, which do not contribute directly to the profile except to compensate some of the donors. (**B**) "Shallow" traps, which may contribute to the C-V profile due to rising above the Fermi level in the transition region. Note: "deep" and "shallow" refer to energy level within the forbidden gap, and not position.

influenced by both the band bending at the MS interface and the modulated signal used to measure the capacitance.

The deep trap, Figure 10A, behaves much like compensating acceptors in a Hall measurement (see HALL EFFECT IN SEMICONDUCTORS). In this case, no acceptor-like trap is ever above the Fermi level, so that in both the depletion region and the bulk semiconductor the measured carrier concentration for all values of reverse bias is

$$n(x) = N^+(x) = N_D(x) - N_{tr}(x) \tag{28}$$

where

$$(E_C - E_{tr}) \gg kT \tag{29}$$

If the trap energy rises above the Fermi level in the depletion region, it may influence the measured donor concentration if the traps can be "uncovered" by the modulation voltage of the capacitance meter. This is the case depicted in Figure 10B. There are now two distances into the depletion region of interest. The depletion region is still designated as W, but the region where the traps are above the Fermi level, and hence empty, is designated $W_{tr} < W$. The region between W and W_{tr} is called the transition region. In this region, if the emission rate, e_n from the trap is small compared to the modulation frequency of the capacitance meter, i.e., $e_n \ll \omega/2\pi$, then only those traps in the region $x < W_{tr}$ contribute to the measured carrier density. However, if $e_n \geq \omega/2\pi$, then the experimenter must account for the electrons emitted from the traps at W_{tr}. These "shallow" traps can confuse the interpretation of the carrier profile determined from a C-V measurement. The interested reader should consult the paper by Kimerling (1974). Fortunately, for most materials trap densities are much less than the doping densities (often N_{tr} is <1% of N_D) and can in many cases be neglected.

CHARACTERIZATION OF *pn* JUNCTIONS

INTRODUCTION

The *pn* junction of a semiconductor material forms part of many commercially important devices such as bipolar junction transistors (BJTs), heterojunction bipolar transistors (HBTs), junction field-effect transistors (JFETs), and various kinds of diodes (e.g., Zener, rectifying, laser, light emitting). Semiconductor engineers routinely use the current-voltage (*I-V*) measurement technique both for the design of semiconductor devices and for yield or process checks during manufacture. The *I-V* measurement technique is also considered to be a method in materials research because it is used to characterize semiconductor materials and processes used to create these materials. The *pn* junction *I-V* technique is useful in materials research because complementary techniques often do not definitively answer whether the material quality is sufficiently good to operate as required in a semiconductor device. The technique can definitely be used on *pn* junctions present in state-of-the-art semiconductor devices, but in most materials research laboratories, diodes with large feature sizes and considerably simplified sample preparation are preferred for rapid turnaround and lower equipment cost. The technique is most often used when the purpose of characterizing the material is for fabrication of *pn* junction devices such as BJTs, HBTs, JFETs, and diode structures for a number of applications, including semiconductor lasers and light-emitting diodes. In that case, the method can be used primarily as a measure of material quality in a device application or as routine intermediate process characterization during device fabrication.

Measurements of *pn* junctions do not measure material properties per se but rather are used to extract parameters from the ideal current equations presented below (see Principles of the Method). These parameters can be related to physical properties of the *pn* junction material (through theoretical analysis; see, e.g., Sze, 1981), but in practice, this is rarely done because the extracted parameters are more relevant as a qualitative evaluation of the semiconductor material. Some parameters commonly measured for *pn* junctions are the built-in voltage V_{bi} of the *pn* junction, the ideality factor n of current for a forward-biased *pn* junction, and the reverse-biased breakdown voltage V_{br}. Different semiconductors will deviate from the ideal equation in predictable ways. Practical examples of different materials characterized with the *pn* junction *I-V* technique will be presented later (see Practical Aspects of the Method).

Competitive and Complementary Techniques

A number of techniques can be used to study defects directly in semiconductors. They are often used when more insight is needed as to the specific nature of the recombination centers or breakdown characteristics of a *pn* junction structure. As such, they are more complementary than competitive and are used more often for fundamental studies, whereas the *pn* junction *I-V* method is an appropriate method for establishing the actual characteristics of the device of interest. Alhough many more techniques than those presented below can be used to characterize semiconductor material with *pn* junctions, the techniques summarized below are the main complements to *I-V*.

Cathodoluminescence (CL) is a technique in which an electron beam is used to excite electron-hole pairs in the sample and detect luminescence of radiative recombination pathways. By scanning the electron beam using methods similar to scanning electron microscopy (SEM; see TRANSMISSION ELECTRON MICROSCOPY), a map of the luminescence is obtained and is correlated with the spatial variation of defects in the material. The luminescence is analyzed for wavelength of the emission and can be related to different types of defects. Analysis and identification of the defects are empirical in nature, and correlation to theoretical modeling of the defects is often used. Cathodoluminescence is a powerful technique, but it is costly, time consuming, and not able to image defects with nonradiative transitions.

The electron-beam-induced current (EBIC) technique is another way of mapping the defects in a *pn* junction sample. An electron beam is scanned across a sample, and the current through the *pn* junction is measured at an electrode on the other side of the junction (commonly the backside of a doped semiconductor substrate). When the electron beam is scanned across a region with defects, the current through the sample will be reduced as the defects capture electrons and thereby reduce the current to the bottom electrode. As with CL, a defect map can be obtained by this method with equipment, ease of use,

and cost similar to CL. The EBIC method can be used to map defects that recombine by both radiative and nonradiative transitions and is a useful complement to CL. Both CL and the EBIC technique provide information not available by the *pn* junction *I-V* method, such as minority-carrier diffusion lengths (e.g., from a spatial measurement of the dark regions in the EBIC method). The EBIC technique can also yield information regarding the carrier diffusion lengths.

A newer defect mapping technique with less widespread use is near-field scanning optical microscopy (NSOM). It is similar to CL but with optical excitation in the place of electron excitation. Either the excitation or the detected signal (or both if one can accept the small signals) will be through an optical fiber that can be scanned to provide a defect map.

Deep-level transient spectroscopy (DLTS; see DEEP-LEVEL TRANSIENT SPECTROSCOPY) is another technique for studying defects in semiconductors. Its main advantage is that it yields information about defects deep within the forbidden gap. The method can be used for *pn* junctions as well as for Schottky barriers as long as a one-sided abrupt junction is used (abrupt separation of carrier dopants with one side of the junction heavily doped and the other side lightly doped). A number of different measurements are possible with many nuances. One type uses a constant capacitance as the temperature of the sample is scanned. The capacitance C changes abruptly as defect centers are populated or depopulated. These data are analyzed and compared to models to gain fundamental understanding of defects in *pn* junctions. Deep-level transient spectroscopy uses a very similar experimental setup as *pn* junction *I-V* or capacitance-voltage *C-V* methods (with the exception of temperature scanning of the sample) and gives complementary information. Its main drawback is that the data analysis and interpretation can be rather complicated.

Transmission electron microscopy (TEM; see SCANNING ELECTRON MICROSCOPY) is a powerful technique that images the structure of semiconductor materials at the atomic level. Defects are imaged directly. Alhough the power of TEM is undisputed, the technique is costly, sample preparation is difficult and time consuming, and perhaps most importantly, the fraction of the sample analyzed is very small and one cannot be sure if the defects imaged are representative of the entire sample. Its use is as a complementary technique for some of the most difficult problems.

Secondary ion mass spectroscopy (SIMS) can give unrelated but useful information. A beam of ions is used to sputter a sample, and the sputtered ions are mass analyzed to reveal the elemental analysis as a function of depth in the sample. Secondary ion mass spectroscopy can detect many elements with a sensitivity of better than one part in 10^6 and is useful for detecting many impurities and the diffusion broadening of the *pn* junction. This information is useful for distinguishing effects due to impurities from those due to crystalline defects. The SIMS equipment is large and costly to operate, but the commercial availability of reasonable cost analyses makes it an attractive option and a widely used complementary method.

Finally, the *pn* junction *C-V* technique (see CAPACITANCE-VOLTAGE (C-V) CHARACTERIZATION OF SEMICONDUCTORS) provides complementary information to the *I-V* technique. The spatial dependence of doping density extracted from the *C-V* technique is a useful complement to the breakdown voltage in determining material quality.

The *pn* junction *I-V* method is one of the simplest methods available to characterize the quality of semiconductor material. From the discussion above, it is apparent that many complementary techniques are available when the *I-V* data show indications of lesser material quality requiring a deeper understanding of the defects or impurities involved. These complementary techniques are also more generally applicable to any doped (as well as undoped for some techniques) semiconductor material, not just those involving *pn* junctions.

PRINCIPLES OF THE METHOD

The ideal diode equation has been derived by Shockley (1949, 1950) with the following assumptions: (1) there is an abrupt junction where the depletion approximation is valid, i.e., the built-in potential and applied voltages are modeled by a dipole layer with abrupt boundaries and the semiconductor is neutral outside of the boundaries; (2) no generation or recombination takes place in the depletion region; (3) injection currents are low such that injected minority-carrier densities are small compared with the majority-carrier densities; and (4) the Boltzmann approximation applies (used for deriving equations to calculate free carriers in each of the regions; generally assumes the semiconductor to be nondegenerate, i.e., doping levels are such that the Fermi level is not within $3kT$ of the conduction or valence band edges). The reader should consult introductory texts for derivation of the ideal diode equation and for a better understanding of the assumptions and their implications. In that case, the equations of state are solved for the current density,

$$J = q\left(\frac{D_{\mathrm{N}}}{L_{\mathrm{N}}}n_{\mathrm{P0}} + \frac{D_{\mathrm{P}}}{L_{\mathrm{P}}}p_{\mathrm{n0}}\right)\left[\exp\left(\frac{qV_j}{nkT}\right) - 1\right] \qquad (1)$$

where D_{N} and D_{P} are the electron and hole diffusion constants, n_{p0} and p_{n0} are the equilibrium electron and hole concentrations in the n and p regions, L_{N} and L_{P} are the Debye lengths for electrons and holes, V_{j} is the junction voltage, q is the magnitude of the electron charge, k is the Boltzmann constant, and T is the temperature. More generically,

$$J = J_0\left[\exp\left(\frac{qV_j}{nkT}\right) - 1\right] \qquad (2)$$

$$J = J_0\left[\exp\left(\frac{q(V_{\mathrm{a}} - IR)}{nkT}\right) - 1\right] \qquad (3)$$

The applied voltage $V_{\mathrm{a}} = V_{\mathrm{j}} + IR \approx V_{\mathrm{j}}$ for low currents, where R is the extrinsic diode resistance. The first term dominates for positive applied voltages (forward-biased junction) several times greater that kT, and the current

increases exponentially. The second term dominates for negative applied voltages (reverse-biased junction) several times greater than kT, and the reverse current approaches a constant value $-J_0$. In practice, this equation applies fairly well to Ge but less so to Si and GaAs semiconductors. The departures from ideality are mainly due to (1) surface-related currents, (2) the generation and recombination of carriers between states in the band gap, (3) the tunneling of carriers between states in the band gap, (4) the high injection condition, and (5) the series resistance in the diode.

Surface effects are complicated to model and are often neglected in diode measurements (although they are manifested more plainly in bipolar transistors). When recombination in the depletion region is taken into account, the current density can be given by the following expression for a p^+n junction, where p^+ refers to degenerately doped p-type material:

$$J = J_0\left[\exp\left(\frac{qV_j}{nkT}\right) - 1\right] + \frac{qn_iW}{2\tau_0}\left[\exp\left(\frac{qV_j}{nkT}\right) - 1\right] \quad (4)$$

where W is the depletion width, τ_0 is the effective lifetime, n_i is the intrinsic carrier concentration, and the other parameters are as defined previously. In forward-bias conditions, the exponential terms dominate. At very low positive V_j, the second term can dominate for semiconductors with small n_i (band gap $E_g \geq 1$ eV at room temperature as for Si and GaAs). This comes about because J_0 is proportional to $(n_i)^2$. This is illustrated in Figure 1, where the logarithm of current is plotted vs. voltage and region (a) shows an inverse logarithmic slope of $2kT/q$. At higher V_j, the inverse slope approaches the ideal kT/q value in region (b) but again deviates at higher applied bias in region (c). The current in region (c) has been attributed to effects of high injection (conditions where the injected minority carriers approach the same concentration as the majority carriers). The net result is an increase in recombination with an exponential slope of $2kT/q$. Region (b) has been described as ideal, but in practice, recombination can be significant over the entire range of bias and the exponential slope can have a value between kT/q and $2kT/q$. This is accounted for by writing the equation for a practical diode,

$$J = J_0\left[\exp\left(\frac{qV_a}{nKT}\right) - 1\right] \quad (5)$$

where the exponential slope is defined by the ideality factor n, which typically varies as $1 \leq n \leq 2$. A perfect semiconductor crystal will have some amount of recombination, illustrated by the different regions of Figure 1, but will usually have a region that is near ideal. Imperfect semiconductor materials will have defects (traps) or impurities that will cause excess recombination. Measurement of the minimum ideality factor is an important indicator for material characterization that comes out of the pn junction I-V method.

In region (d) of Figure 1, the exponential increase in current stops as the diode current becomes limited by the resistances of the undepleted regions of the diode. This increase follows the equation $V_a = V_j + IR$, with the IR component becoming the dominant term. For the ideal diode of Equations 1 to 3, the reverse current approaches a constant value for applied voltages more negative than $3kT$, but as in the forward-bias case, some assumptions of the ideal diode are not valid. In the depletion region, very little recombination takes place because there are so few carriers there (very few carriers are injected into this region in reverse bias) and generation of carriers is the dominant deviation from ideality. The generation current is given by the expression

$$J_{gen} = \frac{qn_iW}{\tau_e} \quad (6)$$

where τ_e is the electron recombination time. The reverse current is then given by

$$J_R = \frac{qn_i^2\sqrt{D_P}}{N_D\sqrt{\tau_p}} + \frac{qniW}{\tau_e} \quad (7)$$

where N_D is the donor impurity concentration, τ_p is the hole recombination time, and the other terms are as defined previously.

The first term is the diffusion current and the second term is the generation current. Since the depletion layer width is weakly dependent on the reverse bias according to

$$W \propto (V_{bi} + V_j)^{\gamma} \quad (8)$$

where γ is an empirical constant with a range $\frac{1}{3} \leq \gamma \leq \frac{2}{3}$. It is seen that J_R is given by a constant term and a second term weakly dependent on reverse bias.

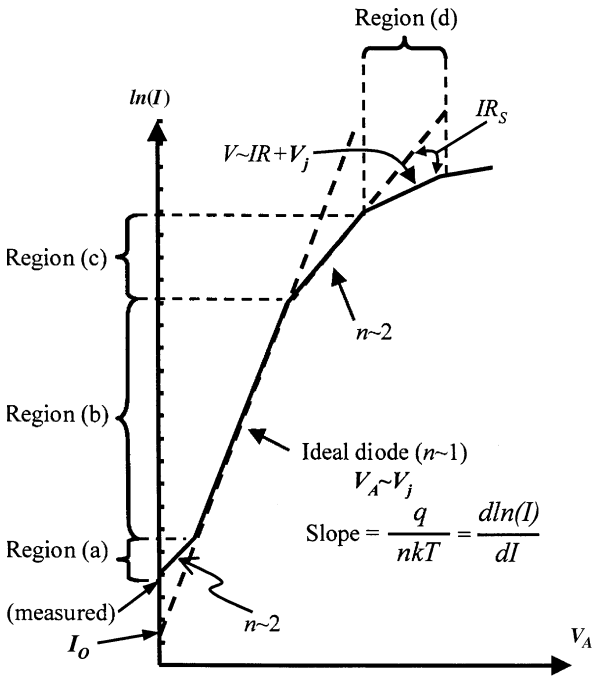

Figure 1. Deviations from the ideal forward-biased pn junction I-V characteristic.

The last subject of interest for this unit is the breakdown behavior of the diodes. There are two types of breakdown: tunneling and avalanche. Tunneling can occur with a narrow barrier (depletion region), which arises from high doping levels for most semiconductors. Applying the appropriate reverse bias matches filled valence band states with unfilled conduction band states, which satisfies the conditions required for tunneling. Tunneling is important for voltage regulator applications (Zener diodes) but is not of any real use for most materials characterization. Avalanche breakdown occurs from the creation of extra free carriers due to the electric field in the depletion region. As the depletion region is reversed biased with larger voltage, the electric field increases to the point at which some of the carriers accelerate so as to gain enough energy to create additional free carriers (termed impact ionization) when they collide with the lattice (or a defect in the lattice). With additional reverse bias, enough additional carriers can be created and gain enough energy accelerating in the field to participate in impact ionization. The term "avalanche" is used to describe this increase in current. The equation describing the breakdown voltage due to the avalanche process is given by

$$V_{\mathrm{br}} = 60\left(\frac{E_{\mathrm{g}}}{1.1}\right)^{3/2}\left(\frac{N_{\mathrm{B}}}{10^{16}}\right)^{-3/4} V \qquad (9)$$

where N_{B} is the background doping concentration and E_{g} is the band gap (Sze, 1981). For a one-sided abrupt junction, V_{br} is proportional to the inverse of the dopant concentration of the lightly doped side of the junction. Reverse breakdown voltages are a commonly measured parameter for *pn* junction semiconductor materials because breakdown voltages can be much smaller than expected if the material contains an excess of defects or if surface breakdown effects are possible.

PRACTICAL ASPECTS OF THE METHOD

The experimental aspects of *pn* junction *I-V* measurements are straightforward to implement and use routinely. The equipment required consists of a semiconductor parameter analyzer (or equivalent; refer to the Appendix), optional data collection and storage capability (typically a computer or workstation), and a probe station. The probe contacting the *n*-type electrode of the diode is grounded, and the other probe contacts the *p*-type electrode. The parameter analyzer is set up to scan the desired bias voltage range, and the data collection software is properly initialized. Unless the interest is in response to light (e.g., a photodetector), measures should be taken to exclude light or ascertain insensitivity to light. High-quality semiconductors with a small enough diode area often will have reverse currents that approach the electrical noise level of the instrumentation; therefore, some care is required in eliminating extraneous levels of electrical noise through proper grounding and proper cables.

As a first example of these measurements, an *I-V* plot for a commercial Si-rectifying diode based on a diffusion process is shown in Figure 2. Silicon *pn* junction *I-V* data

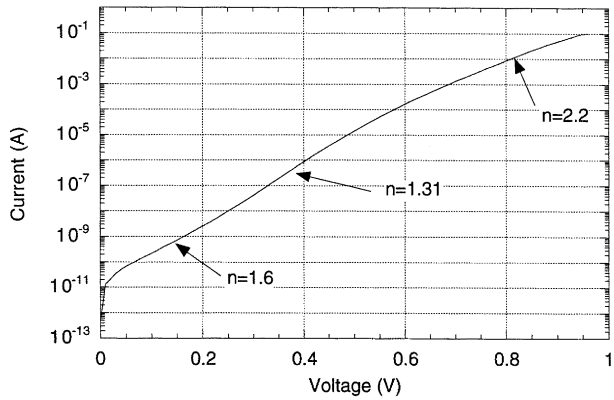

Figure 2. Current-voltage characteristics for a silicon *pn* junction diode.

are well represented in all of the reference texts, and not surprisingly, the data of the rectifying diode resembles that of Figure 1. Three different ideality factors are extracted for the regions of different logarithmic slope. For the "ideal" region, the ideality factor of 1.31 could be modeled for the particular diffusion process, if desired. This is a significant departure from 1.0 and is probably due to significant recombination from a relatively high doping level.

An example of another material system, *pn* diodes for GaAs devices, is shown in Figure 3 for both an HBT and a JFET. The JFET is ion implanted with a p^+ doping of $>10^{19}$ cm^{-3} and an *n*-channel doping of $\sim 3 \times 10^{17}$ cm^{-3}. The ideality factor $n = 1.37$. The JFET is contrasted with a base-collector diode of an HBT whose p^+n junction is grown by metal organic chemical vapor deposition (MOCVD) with a p^+ doping of 2×10^{19} cm^{-3} and an *n* doping of 8×10^{15} cm^{-3}. The ideality factor *n* is measured to be 1.01. The absolute current depends mainly on the area of the sample, which is larger for the HBT. This example illustrates the effect of different materials preparation and doping levels (higher for the JFET) in GaAs *pn* junctions. A large difference in the *n* doping level will introduce recombination, especially with the nonabrupt junctions that can be expected from ion implantation. Other differences are due to intrinsic defect levels from the two methods. The ion implantation process introduces considerable lattice damage that is incompletely removed by the implant activation process (e.g., annealing). The epitaxial growth of the HBT can produce higher quality GaAs, and the ideality factor can be used as a feedback mechanism to reduce the incorporation of point defects during the growth. Figure 3B presents data for the reverse-biased diodes. According to Equation 9, the differences in the breakdown voltages, 30 V for the HBT vs. 8 V for the JFET, can be expected due to the different doping levels in the *n* region. What is less expected is the large difference in the magnitude of the reverse current prior to breakdown. Because the current is weakly dependent on bias, as in Equations 7 and 8, the reverse current is probably due to generation in the depletion region, according to Equation 7.

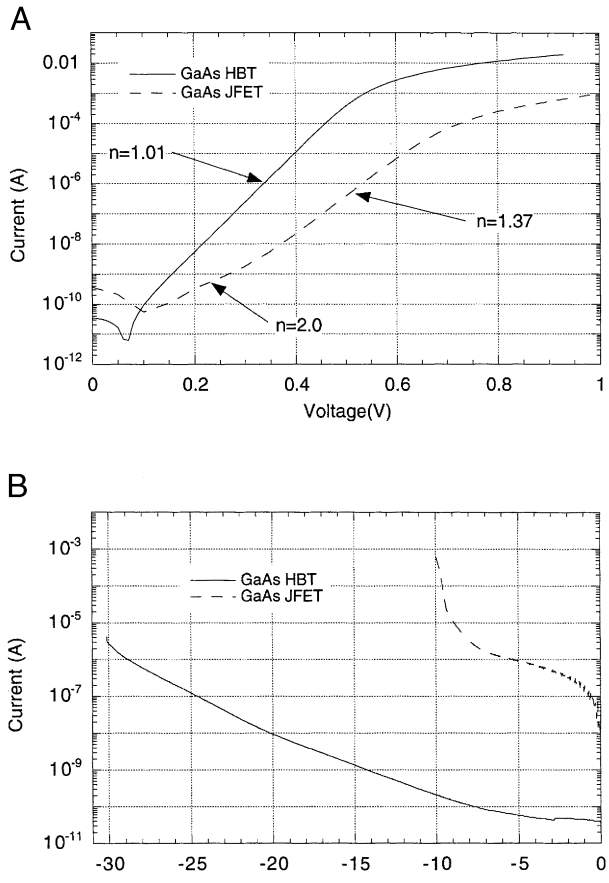

Figure 3. Current-voltage characteristics for GaAs *pn* junction in JFETs and HBTs in (**A**) forward bias and (**B**) reverse bias.

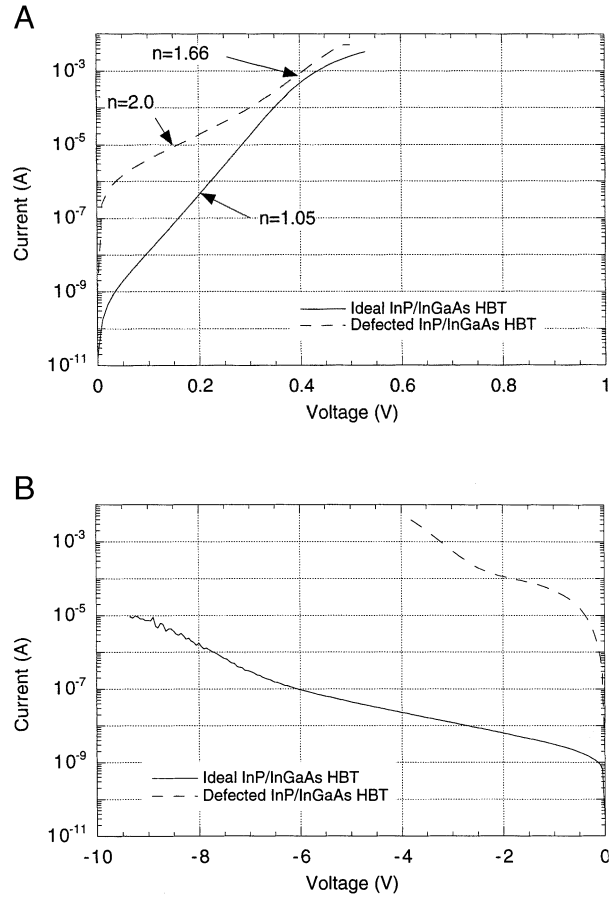

Figure 4. Current-voltage characteristics for the base-collector *pn* junction in near-ideal and InP/InGaAs HBTs in (**A**) forward bias and (**B**) reverse bias.

A third example illustrates the InGaAs material system lattice matched to an InP substrate ($E_g = 0.7$ V). Base-collector diodes are compared for near-ideal and defected HBT material. The base is Zn doped to 3×10^{18} cm^{-3}, whereas the collector is Si doped to 3×10^{16} cm^{-3}. The near-ideal sample shown in Figure 4A has a minimum ideality factor of 1.05, whereas the defected sample shows a minimum ideality factor of 1.66. The defected sample also shows very large recombination currents (second term of Equation 4) at low forward biases with an ideality factor of 2.0. Both samples were grown by MOCVD, but the defected sample contains a large concentration of point defects that are generated during the earlier growth of a degeneratively doped subcollector ($n > 1 \times 10^{19}$ cm^{-3}). Only a slight process change (to anneal out the point defects prior to the growth of the p^+ InGaAs to prevent rapid Zn diffusion) to the MOCVD growth can produce such drastic differences (Kobayashi et al., 1992). As in the GaAs case, a large increase in the reverse current of Figure 4B also accompanies the defected sample. Also, it should be noted that the lower band gap E_g of InGaAs plays a role in the lower breakdown voltages compared to GaAs.

From the examples it is seen how the ideality factor and the reverse currents can give qualitative information about the presence of defects in a *pn* junction. One can get a sense of how the equations presented above (see Principles of the Method) agree qualitatively with some aspects of a given sample. The presentation given here represents the needs of a majority of users of this method, including those without a need for detailed understanding of defects in semiconductors. Another approach, that of detailed theoretical modeling of *I-V* data, also has a role for certain well-characterized material systems but does not lend itself to a convenient summary in this unit.

SAMPLE PREPARATION

For ease of sample preparation, the *pn* junction should be made on a doped (conducting) substrate. A top contact can be made by shadow mask evaporation with a contact metal appropriate to the material (generally one that will make a good ohmic contact), and a back contact can be made with a second evaporation (no shadow mask).

The metal deposition takes place in a conventional metal evaporator. Briefly, this consists of a high-vacuum chamber (base pressure $<10^{-6}$ Torr) with the metal evaporated from a crucible with either an electron beam as the energy source or by thermal heating of the metal by

controllers appropriate for that purpose. The sample in close proximity to a shadow mask is placed in the vacuum chamber and pumped down. A shadow mask is typically a thin sheet of metal that contains openings (usually circular) through which evaporated metal can deposit onto the sample. Away from the openings, the evaporated metal deposits on the mask. After the evaporation, the sample is removed and separated from the shadow mask. A second evaporation to the backside does not need a pattern since it will serve as the sample ground during the electrical test. Temescal and CVC are two companies that market laboratory electron beam evaporators.

Both front and backside contacts should be ohmic, i.e., follow Ohm's law, $V = IR$, where R is the resistance of the contact. The contact resistance should also be sufficiently low so that the junction voltage V_j closely approximates the applied voltage. Aluminum is a common ohmic contact to heavily doped Si, and a GeAu eutectic capped with Ni forms a common ohmic contact material to GaAs after alloying to 400°C (Braslau et al., 1967).

In some cases, small-area diodes are desired or both junction contacts are required on the frontside of the sample. In such cases, photolithography will be required to form the topside contacts. Ohmic contact formation for certain material systems may then require an ohmic contact anneal. If a doped substrate is not feasible or if photolithography is desired, then a *pn* junction can be fabricated by conventional microelectronic processes for diode or transistor fabrication (Ghandi, 1983).

PROBLEMS

In general, the problems associated with this method are minor and manageable, and the method can be mastered with little trouble. Nevertheless, care must be taken to assure repeatable measurements. Poor probe contact can be one reason for poor repeatability. Probe contact problems can arise from, e.g., poor probes, improper force on the probe pad, and vibrations in the probe station. These problems must be carefully addressed and avoided if automated probe stations are to be used. Test algorithms with special open and shorted probe pads can be implemented. The effect of low light levels must be ascertained if sample measurement in room light is desired. Electrical noise can overwhelm low current levels, especially for high-quality reverse-biased samples. Setting the proper integration time of a parameter analyzer can minimize noise. For extremely low current levels (<1 pA), a shielded environment for the samples is desirable. This can be as simple as constructing a metal box around the probes with electrical feedthroughs for the cables.

It is possible for the measurement to degrade the sample due to high voltage or high current levels, and these problems are especially severe in low-band-gap materials because electrons can be sufficiently energetic to create lattice defects. Prior to setting test parameters, data should be verified by repeating measurements for candidate test parameters. In general, one can scan forward bias first. If a sample is sensitive to reverse-bias breakdown measurements, one can scan the reverse bias in the negative direction with a conservative compliance (current limit) level.

The modular series on solid-state devices is a set of self-contained topics suitable for the advanced undergraduate student. The pn junction diode, one of the six topics in this series, is covered thoroughly, with emphasis on clear presentation of assumptions and derivations. Where derivations are simplified, an outline of the more rigorous approach is also presented.

Shur, M. 1990. Physics of Semiconductor Devices. Prentice-Hall, Englewood Cliffs N.J.

Covers a wide range of topics similar in scope to Sze (1981) but with a more general representation suitable for the undergraduate level.

Sze, 1981. See above.

A widely used text in graduate and advanced undergraduate courses in semiconductor devices. The derivation of pn junction diodes are faily rigorous, which makes the text of most use to serious students of semiconductors.

APPENDIX: SOURCES AND CONSIDERATIONS FOR MEASUREMENT EQUIPMENT

Agilent Technologies (Palo Alto, CA) is a source for semiconductor parameter analyzers. One can also use a separate voltage source and an ammeter, such as those supplied by Keithley Instruments (Cleveland, OH). One should consider the sensitivity of the current measurement, ease of use, and interface to data collection computers and software in making a choice. A supplier of probe stations is The Micromanipulator Co. (Carson City, NV). Features to consider include the ease and accuracy of translation, automation capability, stability, and repeatability for auto probing, and interface to data collection software.

ELECTRICAL MEASUREMENTS ON SUPERCONDUCTORS BY TRANSPORT

INTRODUCTION

In this unit, we will focus on techniques for measuring the electrical behavior of technologically important superconducting wires, tapes, and other conductors. Depending on the conditions of measurement, electrical behavior can be interpreted to obtain many technologically important quantities. This unit will also discuss the interpretation for some of the most common of these quantities.

When characterizing the electrical behavior of superconductors, it is primarily the voltage-current relationships that are measured. All other quantities are derived from these. Background conditions for the measurements, including temperature, magnetic field, and stress-strain state, vary with the specific measurement and type of information being sought.

The most common parameter to be obtained from a transport current-voltage measurement is the transport critical current (I_c), which is the maximum current that can be carried by the superconductor in the superconducting state. Often this is determined as a function of temperature and magnetic field. Critical current and the corresponding critical current density (J_c) are the most important parameters in determining the utility of a superconducting material for applications. The value of J_c equals I_c normalized by the cross-sectional area perpendicular to the direction of the current flow. This area can be defined by a variety of methods that are discussed below. Closely related to I_c is the "n value" of the superconducting-to-normal (S/N) transition. The n value is an empirical quantity without physical meaning. It is very important, however, in the design of a superconducting magnet. The n value quantifies the sharpness of the superconducting transition and thus determines the critical current margin required for operating a superconducting magnet (i.e., it determines the required ratio of operating current to critical current). Measurements of I_c, J_c, and the n value can be performed on samples that are subjected to tensile, compressive, or bending loads to ascertain the effects of stress and strain on the electrical properties, which is important for magnet and other applications.

Electrical measurements of transport current are used to determine the critical temperature (T_c) of the superconductor. This is the temperature below which the material enters the superconducting state and above which it is in the normal state. Typically, T_c is determined by monitoring the voltage at constant current while decreasing and/or increasing the temperature. By measuring T_c as a function of magnetic field using such an electrical measurement, one can also learn about the magnetic behavior of a high-temperature superconductor.

In metallic low-temperature superconductors (LTSs), electrical measurements can be used to determine the upper critical field H_{c2}, and in high-temperature superconductors (HTSs), they are used to determine the irreversibility field H_{irr}. In both cases, the magnetic field at which $I_c(T,H)$ goes to zero is the desired quantity.

Electrical measurements are used to determine the properties of superconductors beyond the superconducting state. Measurements of the resistivity versus temperature (i.e., the current-voltage relationship as a function of temperature in the normal state) are important for the design of superconducting current leads and magnets. For cables and coils, electrical measurements provide insight into the stability and quench propagation (sudden reversion to the normal state from the superconducting state) behavior. Again, this information is key for the design of a superconducting magnet.

Lastly, electrical measurements can be used to estimate the AC losses (i.e., energy dissipation resulting from an alternating current) in a superconducting wire or cable. In this case, the hysteretic behavior is used to estimate the energy dissipation.

This unit concentrates on techniques for measuring the current-voltage (I-V) relationship in superconducting wires, tapes, and cables. Important differences between LTSs and HTSs are discussed. Emphasis is placed on the I-V measurement and on the interpretation of the results in the context of the technical information sought from the particular experiment.

Competitive and Related Techniques

From the perspective of developing superconducting applications, there are no techniques that compete with electrical measurements for providing key design information. There are, however, magnetic techniques for measuring the same or similar quantities as those measured electrically. Magnetic measurements on superconductors take advantage of the diamagnetism of the superconducting state. By measuring the diamagnetic signal from a superconductor, the current flow in the superconductor is deduced. Magnetization measurements are most commonly performed in a superconducting quantum interference device (SQUID) magnetometer (see MAGNETOMETRY and THERMOMAGNETIC ANALYSIS) but are also made using more novel techniques such as a cantilever beam magnetometer (Brooks et al., 1987: Naughton et al., 1997; Rossel et al., 1998) or Hall probes (Bentzon and Vase, 1999).

Magnetization measurements of J_c are fundamentally different from electrical measurements in that magnetization is the result of a combination of intragranular and intergranular current flow, while an electrical measurement is strictly an intergranular measurement (although it is influenced by intragranular effects). Unlike transport measurements, magnetization measurements are based upon the diamagnetic behavior of type II superconductors (see definition of type I and type II superconductors in Appendix C).

While electrical measurements directly measure I_c and derive J_c from I_c divided by area, magnetization is used to determine J_c by measuring the magnetization hysteresis with applied magnetic field. The difference between the magnetization when increasing the background field and the magnetization when decreasing the magnetic field (the width of the magnetization hysteresis, ΔM) is then proportional to the intragranular J_c and the characteristic scale length of the current loops. This can be the grain size,

the sample width, or a value in between. The specific relationship between ΔM, J_c, and the characteristic scale length also depends upon the sample shape and is determined by the Bean critical state model (Bean, 1962). Details of these calculations are beyond the scope of this unit. As a result of the uncertainty in actual current flow path and the characteristic scale length, it is difficult to obtain an accurate value for J_c from a magnetization hysteresis measurement. Magnetization hysteresis does not provide the key information for evaluating a conductor for superconducting applications, but rather provides a measure of the magnetic flux pinning within the superconducting grains.

In HTS materials, magnetization hysteresis is a common method for obtaining the irreversibility line $H_{irr}(T)$. In this case, the irreversibility field at the measurement temperature is the magnetic field for which $\Delta M(H)$ approaches zero or falls below a predetermined limiting value. Due to subtleties of the technique, this tends to give a low estimate of $H_{irr}(T)$. Similarly, the upper critical field can be obtained by magnetization. In this case, when the superconductor is no long diamagnetic, the upper critical field H_{c2} has been exceeded (see definition of type II superconductor in Appendix C for a discussion of the H_{c2}). Similar to electrical transport measurements, the range of background magnetic fields available for the experiment limits the effectiveness of magnetization for measuring $H_{irr}(T)$ and $H_{c2}(T)$. In general, higher magnetic fields are available for electrical transport because a smaller measurement space is required.

Magnetization is an effective method for measuring T_c of superconductors. Because the measurement is detecting the onset of diamagnetism, magnetization must be performed in the presence of a small magnetic field. Critical temperature T_c can be measured by monitoring the magnetization during either cooling or warming. Differences due to magnetic effects can be seen when the sample is first cooled without versus with an applied H field (zero-field cooling and field cooling) in magnetization measurements during warming. In general, however, magnetization is an effective method for measuring T_c independent of grain-to-grain coupling within the material. Thus, a material can have a sharp superconducting transition by magnetization but not carry any electrical supercurrent by transport.

The alternative to electrical transport measurements for determining the AC losses in a superconductor is calorimetry. In this case, direct thermal measurements (of the deposited energy) are made and the superconducting properties are not determined.

Included below are recent advances in the measurement of the electrical properties of metallic and oxide superconducting materials. The fundamental theory underlying the measurements to be discussed has not changed dramatically over the past 25 years; the technology used to implement the measurements, however, has changed, resulting in more rapid measurement and data analysis with increased accuracy. The application of electrical measurements to the determination of stress and strain effects on superconductors is not covered in this unit. Such a measurement requires the marriage of the techniques discussed here with the application of stress and strain and is thus beyond the scope of this unit. Note, however, that for such an experiment, the principles discussed in this unit remain applicable (also see MECHANICAL TESTING). We do not discuss the measurement and control of the temperature of the sample during measurement. Historically, most measurements have been made on samples that are bath cooled in liquid He or N_2. Recently, interest in variable-temperature measurements using conduction cooling and He gas cooling has increased dramatically. Issues for measurements on samples that are not bath cooled are discussed under Problems. We also do not discuss the measurement of transport *I-V* relationships in superconducting single crystals, superconducting thin films for electronics applications, or multistrand cables. While the general principles of the measurement do not change, the practical aspects of sample preparation and contacts are significantly different.

Techniques for applying transport current ranging from 1 mA to 1 kA for the purpose of measuring a resulting voltage ranging from <1 μV to tens of millivolts are presented in this unit. The application of *I-V* measurements to the determination of the superconducting properties of wires and tape conductors are also discussed, as are some aspects of measurements in the presence of a background magnetic field from the point of view of sample mounting and support, but not from the point of view of generating the background field (see GENERATION AND MEASUREMENT OF MAGNETIC FIELDS). Lastly, some of the primary problems and pitfalls associated with electrical measurements in superconductors are discussed at some length.

The authors refer readers to document IEC 60050-815, International Electrotechnical Vocabulary, Part 815: Superconductivity produced by VAMAS (*www.iec.ch*) for the definitions of important terminology (see Internet Resources). Some key definitions from this document are repeated in Appendix C.

PRINCIPLES OF THE METHOD

The method is based on passing a known current through the sample, typically increasing stepwise or with a smooth ramp, while measuring the voltage across a section of that sample, until the voltage reaches a predetermined level—the critical voltage. The corresponding current level is considered the critical current. Alternatively, a critical resistance level can be chosen to determine the critical current. In the past, voltage-current characteristics were often recorded using *x-y* plotters, resulting in a continuous curve. Currently, mostly digital voltmeters are used, resulting in discrete pairs of voltage and current values that describe the *I-V* characteristics.

Essential Theory

Four-Point Measurement. In a four-point measurement, the voltage drop is measured using two contact points on an object, while the current through the object is introduced using two separate connections that are placed on either side of the voltage contacts. The minimum separation between the current and voltage terminals is

determined by the extent of the voltages associated with the current introduction. Four-point measurements are used to determine the voltage across a section of superconductor, as well as to determine the voltage drop across a precision resistor, commonly referred to as a shunt, that is in series with the superconductor. With the known resistance of the shunt, the current through the superconductor is calculated using Ohm's law. Despite the discretization, the data are referred to as an *I-V* curve.

Ohm's Law. A sample that obeys Ohm's law (Equation 1) is characterized by a voltage drop that is proportional to the current it carries. The ratio of voltage and current is the resistance R:

$$V = IR \tag{1}$$

Superconductors obey Ohm's law when in the normal, non-superconducting state. In the superconducting state, the voltage is a non-linear function of current. Accordingly, resistance is defined as the ratio of voltage and current at a specific current level. Resistivity (ρ) is the intrinsic material property that is related to the resistance through the geometric parameters of length (l) and cross-sectional area (A), as in Equation 2:

$$R = (\rho l)/A \tag{2}$$

Current Sharing between Superconductor and Other Material. In most practical superconductors, the superconducting material is deposited on a substrate or surrounded by a sheath of conductive, non-superconducting material, thereby creating a composite structure. In the case of a LTS multifilamentary composite, the material surrounding the superconducting filaments is referred to as the matrix. For HTS, it is referred to as either the matrix or the sheath. When the transport current approaches the critical current, the superconductor is no longer a perfect conductor, and an electric field (E) and voltage develop. That causes a small redistribution of the transport current from the superconductor to the other element(s) of the composite, and the superconducting composite is said to be in the current-sharing regime. This regime extends to transport currents above the critical current until the point where the superconductor no longer carries a significant fraction of the transport current.

Power Law Transitions. The relationship between transport current and voltage for currents in the current-sharing regime is often approximated by an empirical power law. There are several embodiments of this law, describing electric field or voltage, as in Equation 3, or resistivity as proportional to the transport current, or current density (J), to the power n:

$$E/E_0 = (J/J_0)^n \qquad V/V_0 = (I/I_0)^n \tag{3}$$

where E_0 and V_0 are arbitrary reference electric field and voltage values and J_0 and I_0 are the corresponding current density and current. When E_0 is set to the critical current criterion (E_c), J_0 corresponds to the critical current density. Similarly, if V_0 is set to the criterion voltage (V_c), I_0 corresponds to the critical current.

Properties of Materials Used

Contact Materials. Solders are used to ensure a low-resistance connection to the current leads as well as to hold the sample in place. Rosin-core (60% Sn, 40% Pb) noneutetic solder, commonly used in electronics, is easy to use and provides good bonding to Cu or Ag surfaces, as encountered on LTSs and HTSs. It is generally used to solder to superconductors.

As some HTSs can be damaged by thermal shock and prolonged heating, solders with a melting point lower than rosin-core solder (which melts around 185°C) may be preferred. Several materials such as pure indium, indium alloys, and bismuth alloys are available. However, these materials often bond only moderately and risk poor mechanical and electrical contact.

Tin-silver solders (2% to 6% Ag) have higher melting point than rosin-core solder (e.g., 240°C for $SnAg_3$). They require the use of a separate flux, but their lower resistivity at cryogenic temperatures often justifies their use with high-current cabled conductors.

For low-current measurements (e.g., T_c measurements), solid indium can also be used. In this case, small indium "pads" are pressed onto the sample and the voltage and current wires are pressed into the pads. This is not a mechanically robust contact, but it is the least invasive to the sample and can be effective for small samples or samples of random geometry. This approach is not effective for large currents.

Empirical, Phenomenological, and Heuristic Aspects

Definition of Zero Voltage. From magnetization and trapped flux measurements, it is known that superconductors have a zero-resistance state, a state in which there is a DC current, but no dissipation and therefore no electric field or voltage. When measuring the voltage across a section of superconductor, however, a suitable voltmeter will rarely, if ever, indicate "0 V" when used at its maximum precision. Both random noise and unwanted temperature-dependent DC voltages keep the meter from indicating zero, even if the superconductor is in a zero-resistance state. Direct-current offsets on the order of 1 μV are common. The random noise level determines the lowest voltage rise that can be measured. Therefore, the current value corresponding to the onset of a voltage rise and the upper limit of the zero-voltage regime are dependent on the sensitivity of the instrumentation (see Practical Aspects of the Method).

Critical Current Criteria Options. The critical current of a composite superconductor is an essential parameter to describe the current-carrying capacity. It does not correspond to a single physical quantity, however, nor is it the maximum current that can flow through the conductor. Since conductors can be operated isothermally at current levels significantly above the onset of a voltage rise, a

criterion is required to determine I_c. The minimum detectable voltage is not a suitable criterion to characterize the current-carrying capability because it is instrumentation dependent. More suitable and commonly used are electric field criteria of 10^{-4} V/m (1 μV/cm) and 10^{-5} V/m (0.1 μV/cm). In these cases, the electric field is defined as the voltage divided by the distance between the voltage taps. The dimensions of a sample are better taken into account by a resistivity criterion, which enables the comparison of wires with different cross-sections. Critical current criteria are usually at resistivity levels between 10^{-11} and 10^{-14} Ω-m. Critical current can also be quoted at a specific power density value, i.e., the product of electric field and current density. Although not widely used, this is useful for applications that are sensitive to the heat balance. Other criteria exist, such as the current at which a quench to the normal state occurs or criteria based on the shape of the *I-V* curve. These are used infrequently as they are either difficult to determine with sufficient precision or dependent on circumstances during measurement. Regardless of which criterion is used, it must be clearly described when I_c is reported.

H_{c2} by Extrapolation and H_{irr}. The upper critical field, especially for temperatures that are a small fraction of T_c, is often higher than the maximum magnetic field available to the experimentalist. Thus, H_{c2} often cannot be measured directly. In LTSs, however, J_c, H, and H_{c2} are related through the magnetic flux pinning force density $F_p = J_c \times H$. According to Kramer's scaling law, this is proportional to $h^p(1-h)^q$, where $h = (H_{applied}/H_{c2})$ and p and q are constants (Kramer, 1973). When the $J_c(H)$ data are plotted as $J_c^{1/2}(\mu_0 H)^{1/4}$ versus $\mu_0 H$, known as the Kramer plot, a linear extrapolation toward higher fields intercepts the horizontal axis at H_{c2} (μ_0 is the vacuum permeability). In HTSs, the upper critical field can similarly be determined by electrical measurement of I_c to find the boundary between zero and finite I_c at a given temperature. This quantity is associated with the irreversibility field H_{irr}, which is more commonly obtained. Note that H_{c2} and H_{irr} are fundamentally different parameters, representing different physics: H_{c2} is the boundary between the superconducting and normal states; H_{irr} is the boundary between lossless and lossy current flow due to vortex motion. Crossing the H_{irr} boundary does not take the material out of the superconducting state. The field H_{irr} is also defined as the onset of a finite I_c but is derived from either DC magnetization, AC magnetization, or resistivity measurements. The latter is an electrical measurement. The quantity H_{irr} is determined from a set of *I-V* curves obtained at constant temperature for a range of magnetic fields and is defined as the point where the curvature changes from positive to negative. However, magnetic measurements are preferred for H_{irr}, as it is an intragranular property and thus more suitably measured with an intragranular technique. The electrical measurement (resistivity curvature) is suitable primarily when grain boundary effects are not a concern, i.e., in measurements on single crystals. An example of this is shown in Figure 1, where resistivity measurements as a function of magnetic field and temperature result in a phase

diagram of the magnetic behavior (Kwok et al., 1992). Similarly, these three methods are used to determine the irreversibility temperature T_{irr}. The line of irreversibility (zero current in a transport measurement or "zero" width of the magnetization hysteresis loop in a magnetization curve) points in an *H-T* plot is known as the irreversibility line. Note also that for HTS materials it is usually not possible to measure H_{c2} at low temperature because the values are higher than the highest magnetic fields that can presently be generated. Thus it is only estimated by extrapolation.

Subtle Assumptions and Approximations

Current Transfer and Transfer Length. When the current is introduced into a superconducting composite, it is typically introduced into the non-superconducting material,

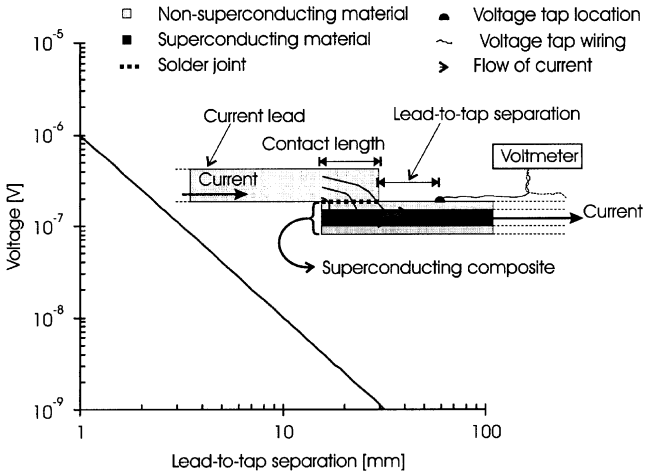

Figure 2. Cross-section of the connection between a current lead and a composite superconductor; all current transfers from the lead to the composite superconductor, and most of the current to the superconducting material within the composite, within the contact angle. A small fraction of the current will transfer from the non-superconducting part of the composite to the superconducting material outside the contact area. The graph represents an example of the unwanted transfer voltage measured versus the lead-to-tap separation for an arbitrary but realistic case.

since that material usually forms the outer surface of the conductor and is easier to make contacts (e.g., solder joints) to. The transfer of current to the superconductor extends beyond the contact area with the current leads (see Fig. 2). The non-superconductor current and its associated resistive voltage decrease quickly with distance from the contact area. It is assumed that the transfer is completed within the distance between the current contact and the voltage contact to the extent that the contact and current transfer area have no measurable effect on the current-voltage characteristic that is measured. See Practical Aspects of the Method for further discussion and references.

Current-carrying Area for Converting I_c to J_c, J_{ct}, J_e, and J_{cm}. The conversion from critical current to critical current density (J_c) is often a source of confusion and inaccuracy. One important source of confusion arises because the area used to calculate the current density can be merely the superconductor (which is still commonplace in HTSs), the nonstabilizer part of the conductor (most common in LTSs), or the entire cross-section. These conventions are all found in the literature. The latter is often, but not exclusively, referred to as the engineering current density J_e. For more detailed discussion regarding the sample cross-sectional area, see Data Analysis and Initial Interpretation.

The transport critical current density J_{ct} is sometimes used to denote J_c obtained by a resistivity or voltage measurement, as opposed to the magnetization J_c (J_{cm}) when magnetization measurements in combination with theoretical models are used. This distinction is particularly important when both electrical and magnetic measurements are used. A lack of distinction in the literature can be a source of confusion, as J_{ct} is the significant parameter for most applications, while J_{cm} is almost always the greater value. Measurement techniques for determining J_{cm} are discussed at length in MAGNETOMETRY.

PRACTICAL ASPECTS OF THE METHOD

Properties of Instruments to Generate Data/Signals

Current Supply. A generic schematic of equipment for electrical measurements is shown in Figure 3. A single-quadrant DC supply is required with a maximum current of at least the critical current. Concerning current stability, it is desirable to have a maximum periodic and random deviation of less than 2% within the bandwidth of 10 Hz to 10 MHz. Control of the current can be implemented in a number of ways, depending on the power supply design. Often supplies offer several options for control of the current. These options include software control, through an instrumentation bus or serial connection with a computer, and manual control using potentiometers or numeric keypads usually on the front panel of the supply. A third category entails external programming with a separately controlled resistance, voltage, or current source, usually to be wired to the back of the supply. This is also known as remote programming.

The current is changed as a function of time using either the step-and-hold approach or a constant ramp rate. A maximum rate corresponding to a 30-s rise time from 0 A to I_c has been suggested as a standard (VAMAS). A higher rate may be required if heat dissipation in the sample or sample support is an overriding issue, which may be the case for HTS-coated technologies. In the worst

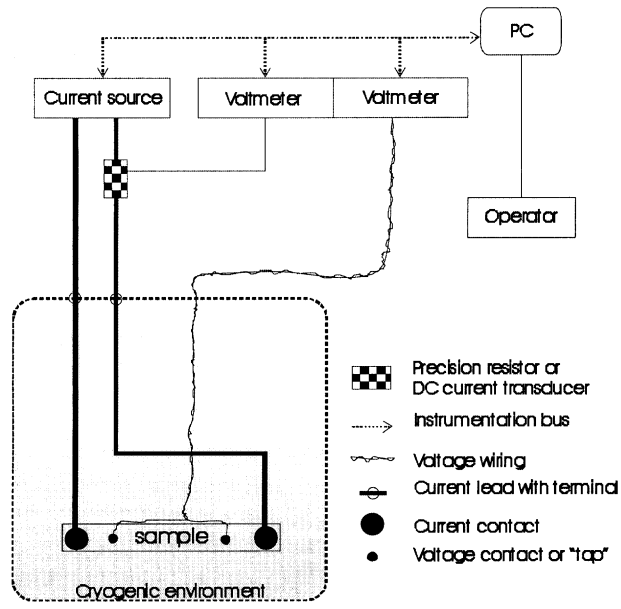

Figure 3. Equipment for electrical characterization of superconductors. No sample support structure (sample holder) is shown, which will generally support the sample, current leads, and voltage wiring in the cryogenic environment. Many variations on this schematic are possible.

cases, measurement times on the order of milliseconds may be required.

Voltmeter. The required accuracy of the voltage measurement depends on the sample length between the voltage connections ("taps") and the I_c criterion used. Typically, tap lengths are on the order of 0.01 to 0.05 m, and a common criterion is 10^{-4} V/m, often expressed as 1 μV/cm. Other criteria tend to lead to a lower critical voltage and lower I_c. Since a minimum precision of ~10% of the critical voltage is desirable, a high-precision voltmeter is required. A 6 1/2-digit voltmeter might have 10^{-7} V resolution but is likely to require extensive averaging to obtain a similar accuracy, resulting in a slow measurement. More accurate single-unit voltmeters or a combination of filters, preamplifiers, and voltmeters is recommended. Either system will be referred to, in the remainder of this unit, as a voltmeter.

An analog-to-digital-converter (ADC) forms the core of every voltage measurement system. The larger the number of bits specified for the ADC, the larger the number of discrete voltage levels that can be detected. This, together with the range of preamplifications available, determines the range and resolution of the voltmeter. The last step in the data acquisition process is to transfer the voltage value as an ASCII string to the software recording or controlling the measurement.

These elements can be implemented as a single-unit voltmeter connected to the computer and controlled through a driver (see Method Automation). Single-unit meters tend to offer convenience, a large range, and high sensitivity. Another approach is to separate the amplifier from the ADC. The latter can be a stand-alone unit or mounted on a card inside a computer. Either approach can be used to measure multiple voltages through the use of a multiplexer, which can be a separate unit or incorporated in the ADC unit or single-unit voltmeter. When each signal is amplified before the multiplexer, the option tends to offer the highest data acquisition speed, since the time required for analog-to-digital conversion with a given relative accuracy decreases significantly as the value of the voltage increases. Voltages below 1 μV may take on the order of one to multiple power-line cycles (16.7 or 20 ms per cycle) to convert, whereas one or a few milliseconds may suffice for signals in the millivolt range. A computer-mounted ADC is likely to offer the fastest transfer of measured voltage values to the software and further improve the data acquisition speed. Data acquisition speed is not the limiting factor in most measurements, however, and considerations of accuracy and cost determine the choice of voltmeter.

Sample Shape

The ideal shapes for electrical transport current measurements are a uniform, homogeneous, cylindrical wire or a rectangle. However, the geometry is beyond the control of the measurement technology and dictated by the processing factors that produce the sample. In electronics applications, patterning of the thin film is typical. This is not standard, however, on wire and tape-based conductors for large-scale applications.

Contacts

Current contact length. The measurement current is passed in and out of the conductor using two solder connections to current leads that are a permanent part of the measurement setup (see Figs. 2 and 3). As a guideline, the length of the contact area for tapes should be at least as long as the conductor width. A longer length will reduce the resistance, and therefore heating, in the contact. Clamping the conductor to the current leads is possible too, but this results in less reliable contacts with higher contact resistance and possible sample damage. For twisted conductors (either conductors with twisted filaments or cables with twisted or braided strands), a contact length of one twist pitch is recommended if the current is not introduced homogeneously around the circumference. Integer multiples of the pitch length are necessary if longer joints are used. This minimizes unevenness in the current distribution within the conductor due to unequal resistances to the leads.

Current Transfer Length. When the current is introduced to the outer surface of the conductor, it will flow through the sheath and/or matrix to the superconductor. The resulting distribution of current extends beyond the contact area itself, resulting in a measurable voltage drop near the contact area. These resistive voltages decrease quickly with the distance to the contact area and are dependent on the current density, matrix resistivity, and conductor geometry. Models have been developed and verified to calculate these voltages (Ekin, 1978; Ekin et al., 1978; Wilson, 1983b; Jones et al., 1989). As a general guideline for tape conductors, a minimum separation should be used between current lead and voltage tap equivalent to the tape width. The minimum separation for round wire is a multiple of the diameter. The required separation strongly depends on the measurement sensitivity and the resistivity of the non-superconducting material(s). It can be as high as two orders of magnitude larger than the sample diameter. A dedicated experiment may be required to determine the minimum separation to avoid measuring the current transfer voltage. Current transfer within a conductor (between filaments) can occur when the temperature, field strength, or field orientation changes abruptly over a short length of sample. When the voltage taps are too close to such a transition, extra noise or spurious, unstable voltages can result.

Voltage Tap Placement. The optimum length between voltage taps is a balance between the increased sensitivity that accompanies a long tap length and the need to have sufficient separation between the voltage taps and the current leads to avoid measuring the voltages associated with the current transfer.The assumption that iso-voltage planes are perpendicular to the long axis of the conductor is valid. Therefore, for tape conductors, the voltage taps can be placed either somewhere on the flat side or on the edge. The voltage tap length is measured along the axis of the conductor between the centers of the wires where they exit the solder.

Sample Handling and Soldering/Making Contacts. Many superconductors are sensitive to strain and, for some conductors, even small deformations can irreversibly affect the superconducting properties. All samples should be handled carefully, and measurement procedures should minimize handling. For ceramic superconductors, thermal shock and the length of time taken to solder leads and voltage taps must be minimized. The use of solders with a low melting point (and an appropriate soldering iron) or preheating the sample and the current leads can help prevent degradation when normal soldering procedures affect the superconducting properties. Often, especially for strain-sensitive conductors, it is not possible to unsolder a sample without damaging it.

Silver paste is also used to make electrical connections and avoids the heating issues associated with soldering. Drawbacks include a limited mechanical strength and creating a risk of unreliable connections. Electrical and mechanical properties vary strongly, depending on the manufacturer and type of paste.

Sample Holder. Typically, the sample is mounted on a sample holder that incorporates the current leads. Sample holders are usually custom designed and show broad variations driven by sample characteristics and experimental conditions. The connections to the leads keep the sample in place. As a result of the difference in thermal expansion between the superconductor and the holder, the sample is subjected to strain upon cooling from the temperature at which the connections are made to the cryogenic temperature at which the superconducting properties are measured. Thus, the holder material should be chosen based in part on the tolerable strain state of the superconductor at the measurement temperature. When a conductive sample holder is used, the current running in the holder should be subtracted from the transport current to determine the critical current. This calculation requires knowledge of the voltage-current characteristics of the section of the sample holder between the voltage tap positions, typically obtained from a dedicated measurement without a sample mounted.

Cooling Options and Procedures

Bath Cooling. The most thermally stable measurement environment is provided by a bath of a cryogenic liquid, such as helium, hydrogen, neon, oxygen, or nitrogen. Heat developed in submerged parts of the experiments will cause evaporation but no significant temperature variations as long as the heat flux is below that which would result in boiling ($\sim$0.35 W/cm^2 for liquid helium at atmospheric pressure). There are significant safety aspects associated with cryogenic liquids with which each user should be thoroughly familiarized. Care should be taken to avoid contamination of the cryogen, which will affect its boiling point. Both the liquid levels above the sample and the ambient pressure may have a significant effect on temperature, and thereby on the properties of the superconductor. To the extent that the properties of the cryogen and the experimental conditions allow, deliberate variations in pressure can be used to vary the bath temperature.

Liquid cryogens, especially liquid helium, are usually contained in a cryostat. These are typically double-walled stainless steel vessels where a vacuum and often radiation shields provide insulation between the inner and outer walls. Cryostats are usually equipped with safety and access valves and pressure and level gauges. Simpler double-walled containers made of glass are often referred to as dewars. Containers that rely on foam as insulator are used for short-term storage of liquid nitrogen. The generation or purchase of cryogenic liquids is beyond the scope of this unit.

Gas Flow. A larger range of temperatures is available when using a gas flow.There is a heat balance between the cooling effect of the gas flow and the heat conduction through the sample support plus thermal radiation from surrounding surfaces. Heaters in the gas flow or on the sample support and/or control of the flow rate is used to maintain a constant temperature and minimize the thermal gradients across the sample. As the heat transfer to the cooling medium is more limited than in the case of bath cooling, the tolerance for heat dissipation is reduced. The gas can be obtained from a liquid bath through a combination of transfer lines or valves and heaters or directly from a liquifier.

Conduction. Conduction cooling has gained in popularity with improvements in cryocooler technology and increased demand for "cryogen-free" systems. The sample, leads, and sample holder are placed in a vacuum, where thermal radiation and heat dissipation are balanced by conduction cooling through a connection to the cryocooler. Care is required to limit thermal gradients inherent in conduction-cooled systems, but electrical isolation should be maintained. Cryocoolers, for example of the Gifford-McMahon type or pulse tubes, can provide the cooling power. Both rely on compression and expansion of a gas. Both are commercially available.

Cooling Procedures. The sample can be cooled by mounting it on the holder, placing it in a cryostat, followed by a cooldown of the entire setup. Alternatively, it can be introduced to a cold cryostat. In either case, thermal shock and contamination of the cryostat are to be avoided. Depending on their porosity, ceramic superconductors tend to be more sensitive to thermal shock than metallic superconductors. For the former, unless specific cooling rate specifications are available, a cooling rate of no more than 1 K/s is a useful guideline. When a cryostat will be cooled down after positioning of the sample, pumping and purging with gas or flushing with gas will remove the air and the water vapor. If the cryostat is already cold and the sample support structure is cylindrical, sliding through an O-ring seal will allow slow introduction of the sample to cryogenic temperatures. The use of a load-lock, a chamber between two vacuum-tight valves and connected to a pump, allows complete separation between the cryogenic and ambient atmosphere. Contamination of the cryogenic liquid may affect its boiling point as mentioned

above, and frozen gases or water may block passages and mechanisms. The tolerance for contamination strongly depends on the properties of the equipment used and may or may not be a significant factor.

Current Ramp Rate and Shape

This section describes three common ways to vary the current as a function of time. Other approaches are often a combination or variation of the methods described here. Upon reaching the desired maximum current, the current is usually reduced to 0 A with an abrupt change, a linear ramp, or the same current-time profile used to increase it. The three approaches are illustrated in Figure 4.

Staircase Step. The most accurate measurements can be performed when the current is changed stepwise, allowing the current through and voltage across the sample to stabilize before each measurement of voltage and current. The time for each measurement is determined by the desired accuracy combined with the properties of the equipment used. This approach can be time consuming, resulting in a relatively high ohmic dissipation and possibly complicating temperature stability. In those cases, a compromise between accuracy and measurement time is required. The staircase step approach can alternately be optimized by tailoring the size of the current step such that it is small during the transition and larger where the derivative of the *I-V* curve changes little. The ramp rate between levels should be limited to minimize transient effects such as current overshoot and AC loss effects in the superconductor. Often, especially with relatively small steps, the maximum rate practically possible is low enough.

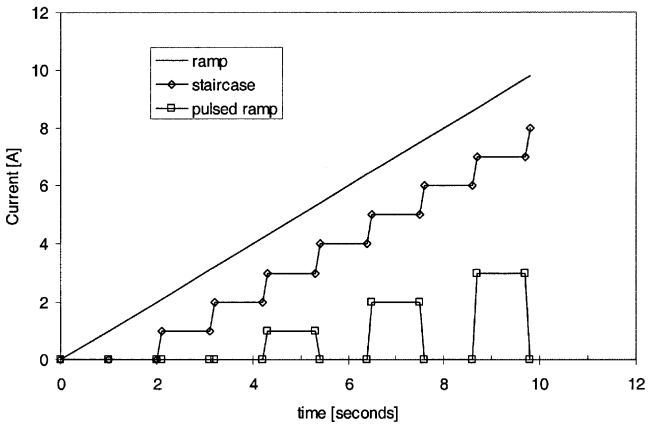

Figure 4. Three common current ramp options in a current-vs.time graph for increasing current and with a limited number of steps: (1) a 1-A/s continuous ramp; (2) a staircase pattern with 1-A steps, 1-s dwell per step, and 10-A/s ramp rate between steps; and (3) a pulsed ramp with 1-s dwell and 10-A/s ramp rate between steps. It is noted that there usually is a delay between a command to the current source and a change in output. This delay can range from less than 0.1 s to on the order of 1 s, depending on current source model and configuration. In reality, changes in ramp rate are not as sharp as depicted but either are more gradual or result in overshoot.

Pulsed Step. To reduce the average power dissipation but maintain the advantages of a staircase step approach, the pulsed-step method is used. In this case, the current is reduced to zero between each step in the pulsed-step approach. Since larger steps are taken, the issue of ramp rate between levels requires more careful consideration.

Continuous-current Ramp Measurements. Another approach is the continuous-current ramp measurement, where the current is changed using a linear ramp and the voltage and current measurements are synchronized. This approach should be taken if control of the sample temperature is poor or if the contact resistance is high, requiring quick measurements to minimize heating, or if the stabilization time is excessive. The ramp rate can vary from 0.1 to 100 A/s. A discussion of problems that result from this approach is given under Problems.

Electrical and Magnetic Phenomena

Superconducting properties vary with applied magnetic fields and may depend on the history of the applied field and, to a lesser extent, the rate of field change. This does not affect the individual *I-V* characterization, but the sequence of measurements and field changes should be carefully considered. The same argument holds for the temperature dependence of the superconducting properties. For HTSs, in particular, the magnetization state and electrical properties strongly depend on whether the superconducting state was reached through in-field cooling or zero-field cooling.

A stabilization period after a field change may be required to allow induced eddy currents to dissipate. As a general guideline, the spatial variation of the applied magnetic field should be below 1% over the length of the sample.

Determining Maximum Measurement Current

Factors that determine the maximum current in a measurement, other than the current supply limit, include the voltage range required for curve fitting in the data analysis, maximum tolerable power dissipation in the sample to maintain thermal control and/or avoid sample damage, and maximum tolerable Lorentz force from either the self-field or an applied magnetic field. It should also be noted that the value of the maximum current affects the magnetization state of the superconductor and may have a small effect on the critical current in subsequent repetitions of the *I-V* measurement.

Instrumentation and Data Acquisition

Usually a personal computer (PC) is the central hub in the measurement system, interfacing with the user, the current source, and the voltmeter. As a minimum, the sample and shunt voltages are read through software on the PC, the latter converted to current, and stored in a file. Additional elements can involve instruments that control or monitor the sample temperature, applied magnetic fields, mechanical loads, and other relevant parameters.

Multiplexers, also known as scanners, can be used to measure different signals with a single meter. Computer and instruments are connected to a bus system. Currently, the General Purpose Instrument(ation) Bus (GPIB) operating under the IEEE 488.2 standard is most commonly used, although serial connections under the RS 232 or RS 442 standard are not uncommon, particularly for power supplies. Converters between the two standards are commercially available.

Instrumentation and data acquisition are areas that are likely to see significant changes as new PC-based communications standards, equipment, and network protocols develop.

Troubleshooting

A quick means to short the current leads is convenient when troubleshooting or testing the operation of the current supply, as it avoids the risk of damaging the sample by overcurrent. When the voltmeter is connected to the sample at zero current, it should read a constant voltage of no more than $\sim 1\ \mu V$. A drifting voltage on the order of ~ 1 mV or more indicates an open circuit; drifting voltages well below 1 mV indicate the presence of parasitic thermocouples in the circuit. A more elaborate discussion of thermocouples and other potential problems follows under Problems. As it can be difficult to distinguish between the zero-voltage state of a superconductor carrying current and no signal at all, one must be concerned with the risk of damaging the sample by overcurrent. A low-current *I-V* measurement at a temperature above T_c is recommended (e.g., at room temperature) such that results can be used to verify proper operation.

Generic Protocol

A generic protocol for performing an electrical characterization of a superconductor follows:

1. Verify cryogenic liquid level and condition of cryogenic equipment.
2. Cut sample to size; prepare current lead and voltage tap connection areas. Measure dimensions. If the sample is easily damaged, the determination of dimensions can be postponed until after the measurement.
3. Verify wiring and leads of sample support by checking for top-to-bottom continuity and absence of shorts.
4. Mount the sample by placing on the support structure and connecting to current leads and voltage tap wires. Verify connections to the sample by resistance measurements from the warm end of the support structure or performing a room temperature *I-V* characterization.
5. Complete all connections.
6. Cool the sample at a controlled rate and bring the sample in the desired condition (e.g., magnetic field magnitude and orientation, stress-strain state).
7. Perform the *I-V* characterization, display, and save the data. At least a preliminary analysis is performed to verify that the data are valid and noise levels are acceptable.
8. Warm the sample at a controlled rate.
9. Dismount the sample.

When performing multiple measurements at varying magnetic fields, temperatures, and other conditions, history effects are important and usually determine the order of temperature changes, field changes (or any other condition), and measurements.

METHOD AUTOMATION

At the most basic level, only the data acquisition and storage are automated. The current is controlled through separate means, and the data are first analyzed after the measurement. In a more fully automated system, the control of the current source and the logic for how and when to change the current is incorporated in the software. This applies specifically to the determination of the maximum current, i.e., when to start reducing the current to zero. Real-time analysis is therefore a key element to automation. Data analysis during or immediately after a measurement will help assess if the obtained data are adequate. It is often pertinent to make that assessment immediately, as there may not be another opportunity to repeat the measurement.

Software to Control the Current Source, Read the Voltmeters, and File and Display the Raw Data

Drivers (software that handles the interaction with specific instruments) are often supplied with the instrument or are available through the National Instruments (NI; *http://www.ni.com*) website, thereby reducing the need for extensive programming. Additional software, usually developed in-house, can provide a graphic interface with the user for control of the instruments as well as for data storage, presentation, manipulation, and interpretation. A wide range of programming languages can be used.

Quench Detection

Quench detection is ideally performed by a circuit independent of the measurement system. When this circuitry determines that the voltage across the sample exceeds a threshold value, it assumes control of the current supply and reduces the transport current to a safe level (typically 0 A) before excessive heating occurs. Options for quench protection are reducing the output of the current supply, circuit breakers to interrupt the current, or a passive circuit using diodes and dump resistors. A shunt of appropriate dimensions and resistance can also be mounted in parallel with and close to the sample and connected to the same current leads. The latter solution may require a correction for the current through the shunt and limit the range of voltages for which the sample current can be accurately determined.

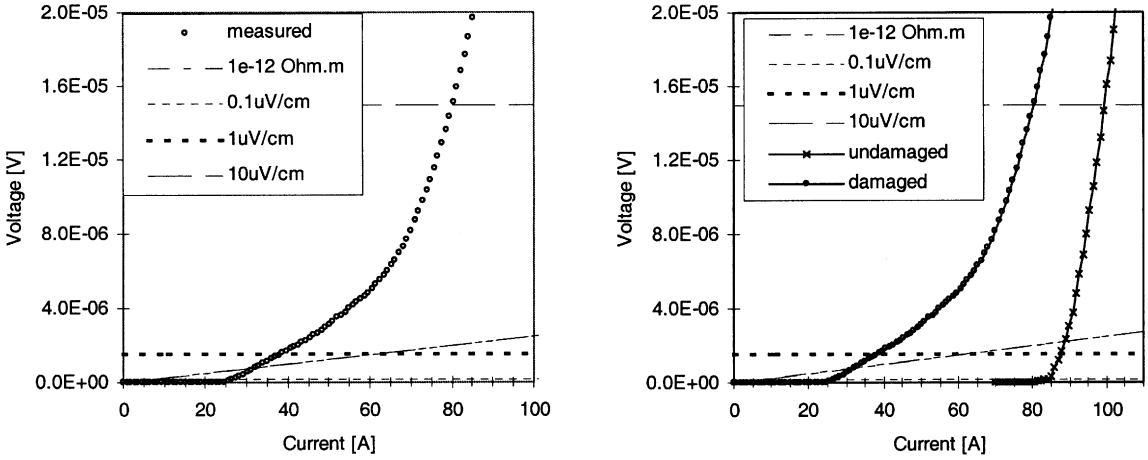

Figure 5. *I-V* characteristic of a damaged sample and a similar undamaged sample. Various critical current criteria are shown.

DATA ANALYSIS AND INITIAL INTERPRETATION

Determining T_c

The value of T_c can be determined electrically either indirectly by extrapolating $I_c(T)$ or directly from measuring the voltage (typically reported as resistance) versus temperature, although the latter is more typical, easier, and more accurate. Measurement of T_c and interpretation of the voltage-temperature data are discussed at length in the VAMAS document on Superconductivity, Part X. In particular, it specifies that T_c is the temperature at which the specified resistivity is 1×10^{-8} Ω-m in the self-field.

In the literature one often reads of the onset temperature and the zero-resistance temperature. In this case, the former refers to a sharp change in the slope of the voltage-temperature curve (observed while the temperature is decreasing), and the latter refers to a resistance or voltage criterion such as the 1×10^{-8} Ω-m established by VAMAS.

Determining I_c and J_c

Selecting the Appropriate Criterion. The appropriate criterion depends on the intended application of the conductor or the intended use of the data (see Principles of the Method). All criteria are somewhat arbitrary since none corresponds to an intrinsic physical quantity or parameter. All provide values between zero voltage and the completely resistive state. Thus, one can identify clear lower and upper bounds (see Figs. 5 and 6). The choice of criterion will affect the value of I_c significantly, especially for conductors with low n values. Comparing measurements on different conductors requires adoption of a single criterion. For example, VAMAS used 10^{-4} V/m. Multiple criteria can be applied to the same data, and the spread in the values, or the absence thereof, is indicative of the sharpness of the transition and implicitly of the quality of the conductor.

The Bseline. The starting point of *I-V* data analysis is the determination of the offset voltage. This offset is a measurement artifact and is subtracted from the *I-V* data before applying the I_c criteria or other data analysis. The simplest approach is to use the voltage corresponding to the lowest current value, usually near 0 A. A more accurate value is the intercept of a line fitting the *I-V* data up to the onset of a voltage rise. This segment of the *I-V* curve is the baseline. In case of a true zero-voltage regime in

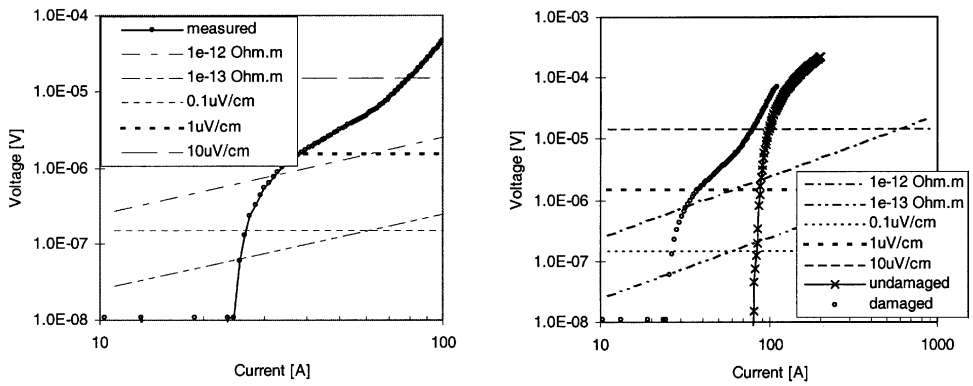

Figure 6. *I-V* characteristic of a damaged sample and a similar undamaged sample in a log-log representation. Various critical current criteria are shown.

the *I-V* characteristic, this value corresponds to the average of the voltage value over this range. There are several reasons why the baseline may have a slope beyond the result of random noise in the data. These reasons include resistive behavior from minor damage or other imperfections in the conductor and resistive behavior from current transfer voltages near the current lead connections. The latter may be subtracted from the data, since it does not represent the properties of the superconductor within the voltage taps, but this is somewhat controversial as it may be difficult to prove the source of the resistive behavior. A suggested guideline is to only subtract baseline slopes that correspond to less than half the critical voltage at I_c and otherwise reject the measurement.

If the *I-V* data were obtained using the current ramp method, the inductive voltage component will automatically be corrected for when using a baseline fit. The first current values might be measured before the ramp rate, and therefore the inductive voltage reaches a stable value and should in that case not be included in the baseline. (Note that the inductive voltage is the result of the self-inductance of the sample.)

Defining the Cross-sectional Area. When reporting J_c, the area used and how the area was measured need to be described in detail. For HTSs, the areas involved are often hard to determine with high accuracy and may vary along the length of the conductor. Tape conductors, for example, tend to have features similar to rounded, but not circular, edges, and in HTS tapes, often the "flat" side is not truly flat after the final heat treatment. Maximum width and maximum thickness are relatively easy to measure, but their product is an overestimation of the cross-sectional area. In addition, the internal geometry of stabilizer and nonstabilizer materials tends to be complex. Digital analysis of cross-sectional pictures in combination with repeated measurements using calipers and micrometers minimizes the errors and uncertainties in areas and therefore J_c and J_e.

Software (Algorithms) to Analyze the Data

A typical electrical measurement on a superconductor results in a number of pairs of corresponding voltage and current values. The main superconducting parameter, I_c, is defined by the intersection of curves describing electrical properties and criteria. Therefore, the pairs of *I-V* data have to be converted, preferably by software, to a curve by either a curve-fit or linear interpolation. Linear interpolation may be sufficiently accurate if the interval between current values is small, the noise level low, or the transition gradual. Linear interpolation in a log-log graph provides a straight *I-V* curve and accurate intersections if the *I-V* data follow the power law over the range of interest. The slope of the graph is the n value. When the data do not follow the power law (described by Equation 3) or if the noise level requires some smoothing, a polynomial fit can be used. Ninth- or tenth-order polynomials often provide a fit that follows the details of the characteristics while filtering out random noise, assuming that more than ~15 data points are available.

Determining *n* Value

Selecting an Algorithm to Determine n. Perhaps the most common method to obtain an n value of Equation 3 is through determination of the slope of the log(V)-log(I) graph in the region of interest. Alternatively, the n value can be determined from a direct fit to the *I-V* data. In the latter case, minimizing the sum of the absolute errors between measurement and fit may yield better results than optimizing for the sum of relative errors. Methods using numerical differentiation exist as well. The power law can be differentiated and rewritten to yield $n = (I/V)(dV/dI)$. The n value is thus interpreted as the ratio of resistance and differential resistance at a given current level. Discrete differentials based on measured data are used to calculate the derivative. Other formulations for the n value exist using first and second derivatives of the *I-V* characteristic (Warnes and Larbalestier, 1986). All calculations require an accurate determination of the voltage offset.

Selecting the Appropriate Data Range. Typically one or two orders of magnitude in voltage around I_c, and corresponding current values, are used to determine the n value when fits are used. If derivatives are involved, an n value is determined for each current value using neighboring data points. The range is then determined by the span of the derivative and the amount of filtering or smoothing required.

Estimating $H_{c2}(T)$ and $H_{irr}(T)$

Magnetic fields $H_{c2}(T)$ and $H_{irr}(T)$ can be estimated by measuring the values for which I_c approaches zero. This was discussed at length under Principles of the Method.

SAMPLE PREPARATION

Sample Geometry Options and Issues

Possible sample geometries include straight, circular, spiral and U-shaped samples. Experimental conditions, especially the volume in which the desired conditions exist, and the desired sample length often determine the sample shape. Some conductors (e.g., NbTi or very thin tapes) can be shaped and tolerate a significant range of bending diameters, but more often a heat treatment of the sample in the desired shape is necessary. If the sample is already heat treated, it tends to be straight or stored on a large-diameter spool. Measuring a straight section may be the only option.

Sample Support Issues

Sample support is mostly a sample holder issue and is discussed in Appendix A and Appendix B. Two aspects also affect sample preparation.

The interface between sample and holder should be uniform when the sample support is required to support the sample against Lorentz forces. However smooth the sample holder surface, additional measures are required when

the sample surface is not perfectly flat. One option is to glue the sample to the holder using an epoxy. This bond is strong and can be thermally conductive, depending on the type of epoxy. Removing the sample without major damage is usually not possible, and this method requires mechanical cleaning of the sample holder or replacement of part of the holder. Different types of grease have also shown good results for ensuring an even contact between the sample and holder. Thermal conductivity is low and excess grease should be removed. The elegance lies in the freezing of the grease at cryogenic temperatures while it is soft at room temperature. Thus, it is easily applied and removed.

A second preparation issue involving the sample holder is associated with thermal prestrain. The strain state of the sample is determined by the integrated thermal expansion of the sample relative to the holder from the temperature at which the solder in the joints solidifies to the temperature after cooling down. The sample and sample holder may not be at the same temperature when the solder solidifies, and a gradient may exist within one or both. Additional measures to ensure that sample and holder are at the correct temperature, such as preheating before soldering, may be required if the margin on thermal precompression is narrow.

Sample Contact Issues

The metallic surface of a sample should be clean before soldering to prevent unreliable contacts. For NbTi, this often means thorough removal of varnish-type insulation. Using an oxygen-free atmosphere as well as zirconium as an oxygen getter will prevent contamination of the surface of Nb_3Sn conductors during heat treatment. Pickling with a 10% to 30% nitric acid solution can remove surface oxidization and should be followed by a rinsing step. Sanding or scraping can clean metallic surfaces on all conductors mechanically, but this involves a significant risk of sample damage. Often solvents are of little use, but flux will improve a solder connection.

It is often difficult to make good connections to ceramic surfaces. Some HTS conductor production techniques result in ceramic outer surfaces, such as dip coating for BSCCO 2212 and most YBCO coated-conductor processing approaches. Application of silver paste followed by a heat treatment can result in contact areas that can carry a modest current density after soldering to a current lead. The heat treatment depends on the brand of Ag paste and properties of the superconductor, so each user should develop his or her own approach. On some conductors, the paste can be applied before the heat treatment that forms the superconductor. Note that large contact areas may be required to prevent high-current density contacts and thus excessive heating. Soldering with indium can give similar results but has the disadvantage that it is very hard to see if the solder wets the surface reasonably and is therefore less reliable. When in doubt about the contact resistance, it is advisable to place an additional set of voltage taps on the current leads just outside the contacts to monitor the heat dissipation during a measurement and compare the contact resistance between samples. The electrical characterization may have to be performed relatively quickly to limit heating, and active quench protection may be necessary to prevent sample burn-out when thermal runaway occurs.

The above also holds for coated ceramic YBCO conductors. The ceramic is typically deposited on a metallic tape substrate leaving one of the flat sides free, but insulating buffer layers between the metal substrate and superconductor make contacts on the metallic side ineffective.

SPECIMEN MODIFICATION

Thermal cycling can affect a sample in several ways. The most dramatic effect occurs in HTSs with pinholes, allowing liquid cryogen to creep into the porous ceramic core slowly. When the conductor is warmed after the measurement or during a quench, the cryogen warms, vaporizes, and expands more quickly than it can escape via the pinholes. The conductor develops localized blisters, and tape conductors may even balloon to near-circular cross-section.

A second sample modification has occurred when an initially straight sample is in the shape of an arc after measurement and warming up. This can occur with samples that are not completely fixed to the holder. Usually this implies that the sample was cooled much quicker than the holder, i.e., a large temperature difference between sample and holder occurred. The sample will contract faster than the support upon cooling and yield plastically when its contraction significantly exceeds that of the support. Thus, the sample has been stretched relative to the holder, stands as an arc upon reaching a stable cryogenic temperature, and remains in that shape. A second possible reason for arced samples is a Lorentz force that is outwardly normal to the sample holder surface, i.e., in the wrong direction.

A third, more subtle effect is elastic-plastic interaction between the superconductor and the matrix due to differences in thermal contraction upon first-time cooling. This is known to occur in ceramic superconductors with ductile pure silver in the matrix, where the stress-strain properties (measured at room temperature) are changed by a thermal cycle to cryogenic temperatures. The plastic yielding mostly occurs during cooling such that most of the change in mechanical properties takes place before electrical characterization. Many HTSs show a small decrease in critical current, on the order of 1%, when cooled down and measured a second time, implying that some degradation occurred. Continued cycling usually has no further effect.

PROBLEMS

Parameters Affecting the Signal-to-Noise Ratio

Pick-up Loops. Pick-up loops, the area between the voltage wires and the sample or the area between sections of the voltage wiring that are not in close contact, work as antennas and pick up electromagnetic noise (see Fig. 7). To minimize this effect, the voltage wiring should be

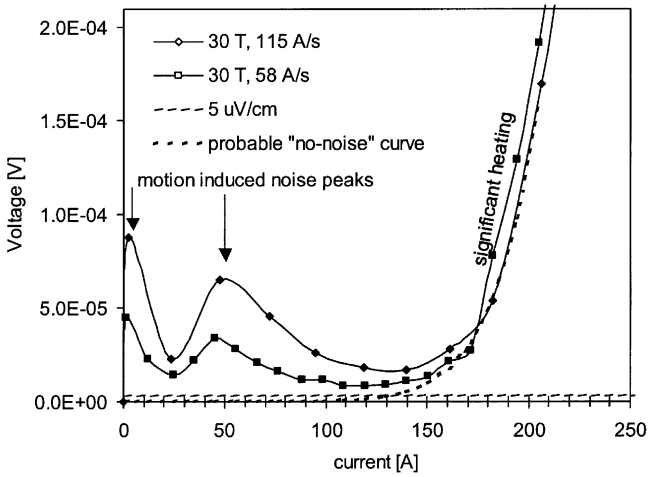

Figure 7. Measured *I-V* data at different current ramp rates of a sample in a magnetic field. The proportionality of the parasitic signal to the ramp rate (shown) and magnetic field (not shown) points to Lorentz force–induced motion and corresponding induced voltages as the source of one problem in this measurement. A second problem is sample heating.

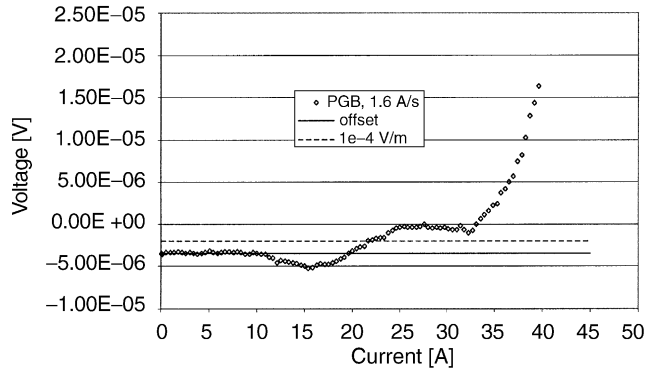

Figure 8. Measurement in which thermal emfs are suspected, given the unusual *I-V* characteristic. See Figure 7 for the standard *I-V* curve.

twisted until very close to the conductor and then follow the surface of the conductor closely until the voltage tap location. Possible sources of noise are the measurement current in the current leads, ambient electromagnetic fields, and applied background magnetic fields. The results can be an unusually high random noise level, voltage spikes when nearby equipment is switched on/off, and, when a background magnetic field is present, repeatable "bumps" that are most easily recognized in the superconducting part of the *I-V* curve. A possible worst-case scenario occurs when measuring electrical properties in a background magnetic field on a sample holder that is not sufficiently rigid. Not only will a loop pick up the ripple in the magnetic field, but also the slightest motion of the sample and holder under the Lorentz force will cause significant induced voltages.

Thermal Electromotive Forces. Thermal electromotive force (emf), or thermocouple voltage, is caused by temperature variations of junctions between dissimilar materials in the voltage circuit, such as solder connections and connectors. Ideally, the voltage wiring should consist of a pair of twisted pure copper wires (insulated), using only copper-to-copper clamped terminals, from the sample to the printboard of the meter. Parasitic DC voltages can originate from junctions that are not in a cryogen bath or submerged junctions exposed to gas bubbles. A draft on a connector at room temperature can easily cause drift of a few microvolts in 30 s. If the junction causing the thermal emf is on the sample itself, then the sample itself may not be at a constant temperature as well. Thermal emfs are not dependent on the polarity of the current, a feature that helps diagnose them when they are caused by the magnitude of the current and associated heating, as is shown in the following example.

Figure 8 shows a measurement in which thermal emfs are suspected to affect the *I-V* response of the superconductor. After switching polarity of both the current and voltage, a second *I-V* curve is measured. Both curves are displayed in Figure 9. Since the voltmeter polarity is changed, the thermal emfs now have the opposite effect on the measurement. The average between those curves approximates the superconductor properties, but caution is required when interpreting such manipulated data, as will be shown below. The above measurements are performed at a constant current ramp rate. When the ramp is interrupted by keeping the current constant for a few seconds at a time, the characteristic of Figure 10 is obtained. The measured voltage drifts at constant current, indicating that the temperature at the junctions causing the thermal emfs varies even at constant currents. Since no unusual temperature variations outside the cryostat are present in this case, it is suspected that the junctions formed by the solder connection between the sample and voltage wiring are exposed to varying temperatures. This implies severe boiling at the sample, since this sample is below the liquid helium surface. To assess the possibility that the sample is heated to temperatures significantly above 4.2 K, measurements at different ramp rates are performed. The temperature variations will decrease with current ramp rate as the total amount of dissipated

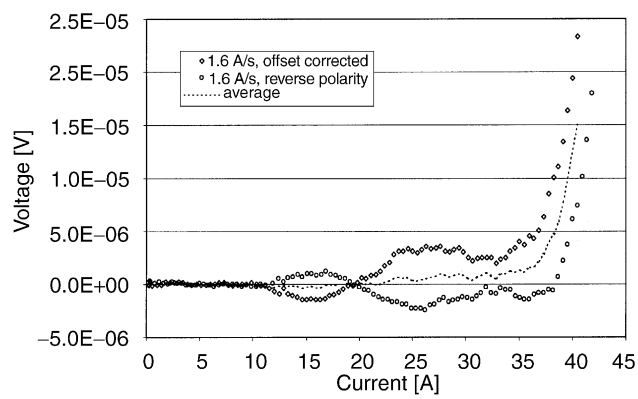

Figure 9. Two *I-V* measurements on the same conductor as in Figure 8, one with reversed polarities. Note the symmetry in the deviation from a standard *I-V* curve.

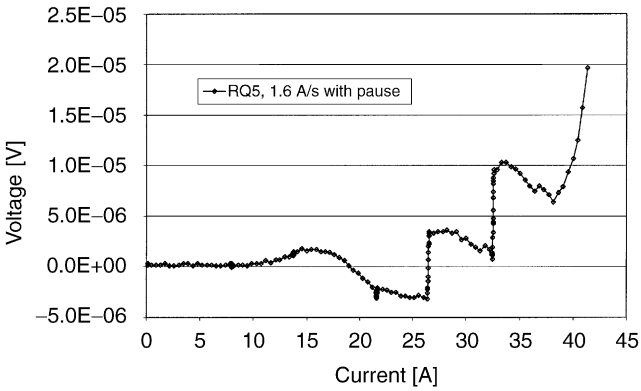

Figure 10. Measurement on the same conductor as in Figure 8, with interruptions of the otherwise constant current ramp. The voltage shows significant drift due to thermal emfs.

heat will decrease. As Figure 11 shows, the measured data strongly depend on ramp rate. It is now apparent that the temperature of the sample itself rises significantly during the measurement, even during the 23-A/s run, and that none of the curves in Figures 8 to 11 represent the properties of the superconductor at 4.2 K. The culprit in this case is a poor solder joint between the sample and the current leads.

Grounding. Only a single point in the circuits of the current and voltage wiring should be grounded. Ground loops should be avoided in this wiring and also in all other connections of the equipment involved. It is usually worthwhile to verify the grounding, or absence thereof, of all circuits, equipment, and wiring. It should be noted that, unlike oscilloscopes, many current sources and digital voltmeters have floating outputs and differential inputs and thus do not provide a ground by default. Voltmeters tend to perform optimally if a point close to the sample, or even on the sample between the voltage taps, is grounded with a dedicated wire to the case of the meter.

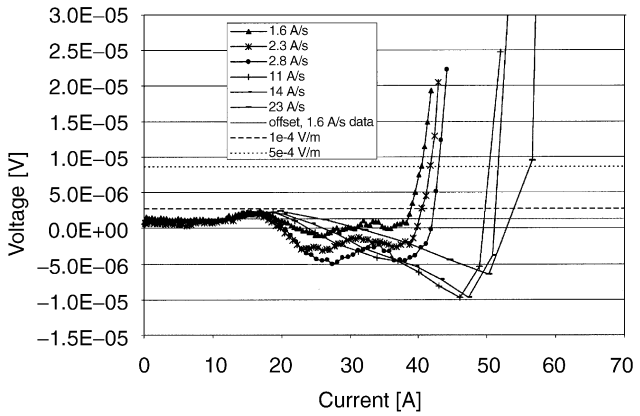

Figure 11. Measurements on the same conductor as in Figure 8 at different current ramp rates. Thermal emfs affect all measurements. The increase in transition current with ramp rate indicates that the temperature of the sample itself is not stable.

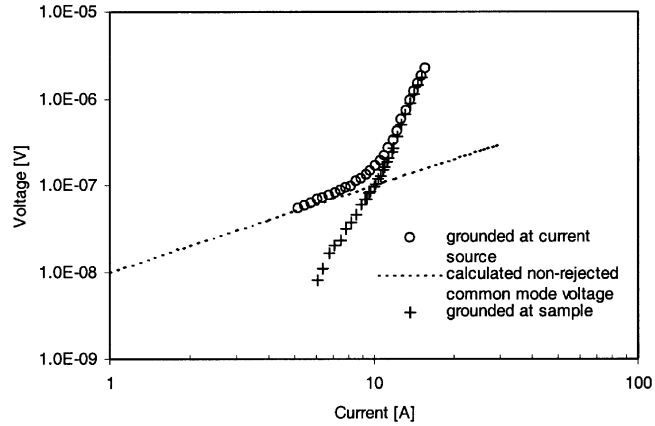

Figure 12. Measured data on one sample with either the current source output terminal or the sample grounded. The calculated nonrejected common-mode voltage with 140 dB common-mode rejection ratio and 0.1 Ω lead resistance explains the error when grounding at the current source.

This is related to the common-mode rejection ratio of the voltmeter (see Appendix A for more detailed discussion) and the resistance of the current leads. Here we compare two measurements on the same conductor in identical sample conditions, one measurement where the output terminal of the power supply is grounded closest to ground and one where the sample is grounded to the case of the voltmeter. The voltmeter has a common-mode rejection ratio of 140 dB (see Appendix A) and the current lead resistance between supply and sample is taken as 0.1 Ω. The increasing voltage drop across the leads with increasing current will cause the sample (common-mode) voltage to increase, unless the circuit is grounded on the sample. Not all of the common-mode voltage is rejected with power supply grounding, and the resulting voltage and its effect on the measured *I-V* curve are presented in Figure 12. If improper grounding is suspected, a multimeter can be used to verify what is grounded to what and where. The ground loops should be removed and the grounding varied, while maintaining safety, and its effect on the measurement assessed. When possible, sensitive equipment should be plugged into a different power outlet group than power equipment or known sources of electrical noise. This process can be time consuming but is a worthwhile investment.

Random Noise and Voltage Spikes. High-power or high-current equipment in the vicinity, especially when switched on or off, can cause voltage spikes and other random noise. Possible sources include overhead cranes, variable-speed motors controlled by pulse-width modulation, and pumps. Check for proper grounding and pick-up loops. Spikes in an *I-V* curve can cause software routines that calculate I_c to yield improper results or can trip quench detection circuits.

In measurements of metallic superconductors (NbTi and Nb_3Sn), reproducible voltage spikes in the low- or intermediate-current part of the superconductive baseline may not be a measurement problem per se but the result of

low-current instabilities in the internal distribution of the self-field, i.e., flux jumps. For more information on flux jumps, see Wilson (1983a). However, this is not a measurement problem that requires a solution, unless it is improperly interpreted by the controlling software.

Current Supply Noise and Related Effects. Noise originating in the current supply can affect the voltage measurement through several routes. First, AC components in the output current cause AC voltages across the sample, which are never perfectly rejected by the voltmeter. Those components may vary as a function of the output current. Switched power supplies also tend to have more high-frequency components in their output current and voltage compared to heavyweight current sources with electronics that are more traditional. Second, a path for noise is provided if the current leads are inductively coupled with the voltage wiring. The following third scenario also occurs, albeit rarely. Voltmeters operate best if the line voltage is stable, although a range of voltages is usually acceptable. If the meter is connected to a heavily loaded or overloaded group of voltage outlets, its input voltage and thereby performance may be affected. The varying load that a current source during a measurement places on the outlet group may then cause systematic errors in the measurement. Connecting sensitive equipment such as voltmeters to voltage outlet groups separate from high-current equipment may help avoid this.

Integration Period. Much of the AC noise has the frequency of the line voltage or a multiple thereof. Its effects are minimized by choosing the integration period of the voltage measurement as a power line cycle. Multiple readings can be averaged to reduce the effect of random variations.

Shorting of Leads

When current leads are shorted, part or most of the measurement current will bypass the sample but often not the shunt, leading to incorrect characterization of the conductor that may not be immediately obvious. In case of a short that allows a significant current through the sample, the transition will be less sharp, the measured I_c value will be too high, and repeatability of the measurement will likely be poor. Repeated or prolonged measurements may warm up parts of the current leads, increasing their resistance and leading to a change in the fraction of the current passing through the sample. If the ramped-current approach is used, a decrease of the inductive voltage without change in ramp rate may signal a short. Shorts may be detected early when the resistance between the leads is measured with the current source disconnected, before the sample is mounted.

Thermal Contraction of the Probe

Thermal contraction in itself is not a problem, but differences in thermal contraction can have very frustrating results. When a rigid current lead is immovably connected at two locations to a structure with a smaller thermal expansion, a thermal gradient will place the current lead in tension. Upon cooldown, the lead may fracture, interrupting the current path. Warming to room temperature for inspection will close the gap, and the circuit will seem intact again. Visual inspection rather than resistance measurements will facilitate finding the defect in the lead. Potential problems are avoided by mounting only one end of the current lead immovably or using flexible elements.

Sample Handling/Damage

Many superconducting materials are brittle and can be damaged by improper handling techniques. In particular, damage can occur during the process of mounting the sample to the probe and soldering/unsoldering the current leads and voltage taps. In addition, some HTSs that are processed with the superconducting oxide layer exposed to the atmosphere can suffer chemical attack from exposure to the air. Thus, these samples must be kept in proper storage before and after measurement, and exposure time to the atmosphere during mounting/dismounting must be kept to a minimum. For an example of the electrical properties of a damaged sample, see Figures 5 and 6.

Sample Heating and Continuous-Current Measurements

Continuous current-ramp measurements are often required when sample heating problems arise. Sample heating can be a significant problem, leading to inaccurate temperature determination and possibly sample burnout. It is most likely to occur when the samples are not bath cooled or when the sample/current lead contacts are problematic. Current ramp rate is one variable that can be used to avoid these problems. With samples that are gas flow or conduction cooled, typically a large ramp rate is used. When current stability after a step is an issue, a slow ramp may prove more effective. Several additional factors complicate continuous, rapid measurements compared to the pulsed or staircase step approach. The measured sample voltage includes an inductive component proportional to the ramp rate and sample inductance that has to be subtracted. The measured properties are no longer steady-state properties. The critical current, even after correction for inductive voltages, will decrease with increasing ramp rates. This effect will be negligible for a significant range of rates. At least initially, however, a number of rates should be tried to determine the effect the chosen ramp rates have. Finally, it should be noted that each pair of voltage and current values represents a range of current values and an effective average voltage over that range. This will tend to "smear out" features of the *I-V* characteristic where it is nonlinear.

Bath Temperature Fluctuations

The bath temperature of a liquid cryogen can fluctuate in time and result in reduced repeatability of *I-V* measurements. Although the effects on I_c are relatively small, they are significant in an accurate measurement. The boiling point of a cryogenic bath and therefore the sample temperature if submerged are affected by contamination of the cryogen bath and pressure variations. Pressure variations

can be caused by either variations of the ambient pressure or changes in the level of cryogen above the sample. The former is most relevant in liquid helium, the latter in liquid nitrogen, as it has a much higher density. The use of overpressure valves and recovery systems for helium gas will also affect the boiling point of the cryogenic liquid. The bath temperature of saturated liquid helium at atmospheric pressure varies 0.011 K/mbar (0.072 K/psi); the equivalent number for liquid nitrogen at 77.4 K is 0.084 K/mbar (0.58 K/psi). With knowledge of the relation between the critical current and temperature, one can calculate the relation between I_c and pressure in the bath at the sample. That slope, and therefore the relative error, will be highest for materials with a low T_c and/or when the bath temperature is close to T_c.

Self-Field Effects

The measurement of I_c of a superconducting sample in a zero background field is often viewed as a zero-field measurement. In fact, the sample self-field can be significant and may need to be factored into the interpretation of the measurement results. Otherwise, two samples that may have identical electrical behavior will appear quite different at "zero field." This can be particularly important for HTS materials, where dI_c/dB can be quite large at very low magnetic fields. As a result, it is often best to compare conductors in the presence of a background field that is sufficiently large that self-field effects become negligible.

Thermal Cycling

Thermal cycling of the sample can affect the sample, particularly if the heating and/or cooling are performed too quickly. This is the result of a combination of thermal expansion mismatch between the sample and the sample holder and fatigue. Even if temperature changes are effected properly (slowly), some property changes can occur in HTS samples during the first thermal cycle (see Specimen Modification).

Sample Quality Issues (Particularly for Powder-in-Tube HTSs)

One problem that can occur in powder-in-tube HTS samples is the penetration and subsequent expansion of the cryogen within the conductor, resulting in the destruction of the sample. This is discussed at length in Specimen Modification.

APPENDIX A: INSTRUMENTS

Current Supply

A single-quadrant DC power supply or current source is required with a maximum current of at least the critical current. A power supply offers the option of user control of either the output current or the output voltage, whereas only the current is user controlled in current sources. Both types can be used.

Ripple. It is desirable to have a maximum periodic and random current deviation of less than 2% of the output current within the bandwidth of 10 Hz to 10 MHz.

Resolution. A minimum current supply output resolution of 1% of the maximum current is suggested. A better resolution is required if the expected I_c is a small fraction of the maximum current, with the desired absolute precision in I_c as the lower limit.

Maximum Output Voltage. A 5-V output rating is generally sufficient with properly sized current leads from the current supply to the sample support and as part of the sample support.

Direct or Inductive with Feedback Loop. This issue is applicable only for currents greater than the kiloampere range and is thus outside the scope of this unit.

Voltmeter

A dedicated high-resolution DC voltmeter, a multimeter with adequate DC voltage specifications, or a multicomponent DC voltage measurement system is required. The latter consists of precision amplifiers, filters, and ADCs. Pen-and-paper X-Y recorders are considered outdated.

Common-mode Rejection. Common-mode rejection is rejection of undesirable AC or DC signal between the low (or minus) input and ground (earth). A suggested minimum ratio [Common-mode rejection ratio (CMMR)] is 120 dB when using a single power line cycle integration period. Every 20 dB represents a factor of 10 in reduction of effective noise.

AC Suppression. The suggested minimum AC normal-mode rejection ratio, i.e., rejection of undesirable AC signals across the DC voltage input terminals, of 60 dB is suggested when using a single power line cycle integration period without filtering.

Precision. A minimum accuracy of 10% of the critical voltage is desirable, where the critical voltage is determined by the I_c criterion and the voltage tap length. The reading resolution or precision of a single reading is always smaller than the accuracy, often by an order of magnitude or more. With typical tap lengths of 0.01 to 0.05 m and a 10^{-4}-V/m criterion, this corresponds to a minimum accuracy of 10^{-7} V and suggests a 10^{-8}-V minimum resolution, i.e., a 7 1/2 digit voltmeter, for this example.

Integration Period. It is desirable to have the option of an integration period of one power line cycle (PLC), since this allows relatively easy suppression of AC noise, compared to shorter integration periods. Increasing the measurement accuracy beyond that obtainable with one PLC is often best achieved by averaging multiple readings of one PLC, rather than increasing the integration period.

Sample Probe/Support

The sample support, also referred to as probe or insert, forms the connection between the sample during a measurement, the room temperature environment of the instrumentation, and the current source. It facilitates introduction of current to a sample on the cryogenic end without excessive heating and is equipped with terminals for current leads to the current source on the room temperature end. Similarly, it contains instrumentation wiring, including voltage tap wiring. In addition, the support provides mechanical support for the sample as needed to prevent motion and mechanical damage. This is particularly important for measurements in large background magnetic field. More details on the sample holder are discussed in Appendix B.

Software Selection and I/O Compatibility

Many software packages are suited for control, graphic representation, and analysis of an electrical characterization. Examples include Labview, C-based languages, and Visual Basic. Computer and instruments require input-output (I/O) capabilities for automation of a measurement and parallel or serial connections. Currently, the GPIB operating under the IEEE 488.2 standard is most commonly used, although serial connections under the RS

232 or RS 442 standard are not uncommon, particularly for power supplies. Converters between the two standards are commercially available. Instrumentation and data acquisition are areas that are likely to see significant changes as new communications standards, equipment, and network protocols develop. Instrument drivers for the software environments listed above are available for most instruments.

APPENDIX B: SAMPLE HOLDER

Sample holders can be made in a large variety of shapes, with different functions, and constructed of different materials. Most sample holders share the following functions:

1. Position the sample at the proper location.
2. Support the forces on the sample, Lorentz force, or otherwise.
3. Maintain a constant temperature or allow effective bath/gas cooling.
4. Separate cryogenic and ambient atmosphere.
5. Connect the sample to the current source and voltmeter and supply wiring for other instrumentation (e.g., temperature-, field-, strain-, and liquid-level sensors).
6. Protect the sample from impact when the sample holder is put in or removed from the cryostat.

Although no standard sample holder exists, commonly used materials include the following:

1. Stainless steel, for structural elements. Note that 304 or A2 grade stainless can be slightly magnetic or become magnetic due to welding or thermal cycling.
2. Copper, and to a lesser extend brass, for current leads. Current leads can be hollow and vapor cooled by cryogenic boil-off to offset or reduce heat input by thermal conduction and ohmic heating. The inlet of the vapor is just above the maximum helium level. Superconductors in parallel to the leads can be used to reduce heating below the vapor-cooled leads.
3. G-10 (glass cloth–epoxy composite) as a non conductive structural element. The thermal expansion of G-10 is anisotropic, with properties in the warp and fill directions comparable to those of many commercial HTS composites.
4. Ti6V4Al alloy to mount Nb_3Sn samples, usually spiral samples on a grooved alloy cylinder with copper end pieces as current connections.
5. Epoxies, in particular filled epoxies like Stycast 2850 FT and similar products.

APPENDIX C: DEFINITIONS

The following definitions are taken directly from VAMAS document IEC 60050-815.

Composite Superconductor. Conductor in the form of a composite of normal and superconducting materials.

Critical Current (I_c). The maximum electrical current that can be regarded as flowing without resistance through a superconductor.

Critical Current Density (J_c). A critical current per unit cross-sectional area of either the whole conductor (overall) or the nonstabilizer part of the conductor.

Critical Temperature (T_c). The temperature below which a superconductor exhibits superconductivity at zero magnetic field and current.

Flux Jump. The cooperative and transitional movements of pinned flux bundles or large number of flux lines as a result of a magnetic instability initiated by a mechanical, thermal, magnetic, or electrical disturbance within a type II superconductive material.

Matrix (of a Composite Superconductor). Continuous longitudinal component of metal, alloy, or other material that is in the normal state at the operating conditions in the composite superconductor.

Meissner State. Superconducting state in a superconductor characterized by perfect diamagnetism.

Mixed State. Superconducting state in which magnetic flux penetrates the type II superconductor in the form of fluxons.

Quench. Uncontrollable transition of a superconducting conductor or device (usually magnet) from the superconducting to the normal conducting state.

Superconducting Transition. The change between the normal and superconducting states.

Superconductivity. A property of many elements, alloys, and compounds in which the electrical resistivity to DC currents vanishes and they become strongly diamagnetic under appropriate conditions.

Type I Superconductor. Superconductor in which superconductivity appears with perfect diamagnetism below the critical magnetic field strength H_c but disappears above H_c when the demagnetization factor is zero.

Type II Superconductor. Superconductor that exists in the Meissner state when the magnetic field strength is below the lower critical magnetic field strength H_{c1}, exists in the mixed state for the field between H_{c1} and the upper critical field strength H_{c2}, and exists in the normal state above H_{c2} when the demagnetization factor is zero.

In addition, the following definition is presented here by the authors:

Current Introduction Length. When a current is introduced into a (composite) superconductor, there is a zone that extends beyond the joint where the current transfers from the matrix to the superconducting core/filaments. The length of this current transfer zone up to the point where the ohmic voltage associated with the remaining current in the matrix is below the sensitivity of the voltmeter determines the current introduction length.

MAGNETISM AND MAGNETIC MEASUREMENTS

INTRODUCTION

Magnetism and magnetic materials have a long and illustrious history. Lodestone (a variety of magnetite) was the first magnetic material of technological importance—which often means military importance as well—due to its seemingly mystical power of seeking direction, a feat which never fails to fascinate a first-time observer. Lodestones were known to the ancient Egyptian, Greek, and Chinese civilizations, and possibly others. About 2600 B.C., lodestone was instrumental in winning a decisive battle for the first emperor of China, fought in a dense fog against the invading barbarians.

The subject that we generally call magnetism began with the observation that some minerals, such as magnetite, could attract each other and certain other minerals. The name magnetism probably derives from Magnesia, a location in ancient Thessaly in Asia Minor, presumably where such minerals were found. Despite the early, albeit accidental, discovery of magnetic materials, interest in magnetism during the subsequent centuries was largely limited to the construction of better compasses, more in the realm of witchcraft than science. William Gilbert made the first serious scientific study of magnetism during the 16th century with the publication of *De Magnete*, only to be ignored for more than a century. It was not until the 18th century that scientific interest in electricity and magnetism was renewed with great intensity, culminating with the realization of the Maxwell equations in the 19th century. However, a fundamental understanding of magnetism had to await the advent of quantum mechanics and special relativity in the 20th century.

Today, magnetism enters many aspects of our lives, far beyond just compasses and refrigerator magnets. Magnetic materials and magnetic phenomena inconspicuously appear in many complex devices, for example, theft-prevention systems in department stores, magnetic recording disks and read heads in the ubiquitous computers and cellular phones, and in magnetic resonance imaging apparatus. Some of the more exciting new developments are the spintronic devices, which are on the verge of becoming realities. These new devices are based on the spin properties of electrons, as opposed to charge alone, as in conventional electronics.

The subject of magnetism is inseparable from electrical charges, their translational motion and their angular momenta. Magnetic fields can be generated by current-carrying wires, through which the electrical charges (most commonly the electrons) are transported. Magnetic fields can also be realized in the vicinity of magnetic materials with large magnetization, such as permanent magnets. There are various methods by which one generates magnetic fields, ranging from generation of magnetic fields by electrical circuits and permanent magnets to the use of hybrid superconducting magnets, Bitter magnets, and pulsed magnets, necessary for achieving very large magnetic fields. Roughly speaking, magnetic fields up to about 2 tesla (20 kOe) and 10 tesla (100 kOe) can be generated by laboratory electromagnets and superconducting magnets, respectively. There are also national facilities, such as the National High Magnetic Field Laboratory at Florida State University, which accommodate measurements at much higher magnetic fields.

All constituent atoms in a material respond to an external magnetic field, at least weakly due to diamagnetism. The direction of the small diamagnetically induced magnetization is opposite to that of the external magnetic field. However, virtually all magnetic materials of scientific or technological importance are those with sizable atomic moments, which respond strongly to external magnetic fields. The atomic magnetic moments are the results of orbital and spin angular momenta of the electrons in the partially filled atomic electronic shells. These atomic magnetic moments, with magnitude of the order of Bohr magneton (μ_B), are much larger than those induced by diamagnetism. Most of the elements in the periodic table do not have atomic magnetic moments, except some of the 3*d* transition-metals (e.g., Ni, Fe, Co, and Mn) and 4*f* rare-earth metals (e.g., Gd, Nd, etc.), which are the major constituents of all the important magnetic materials.

The atomic magnetic moments can interact with each other via the quantum mechanical exchange interactions. At high temperatures, the atomic moments are not ordered and are in the paramagnetic state. However, at sufficiently low temperatures, the atomic moments can spontaneously order. Those materials in which the atomic moments align parallel to each other are the ferromagnets, of which lodestones, refrigerator magnets, and other more powerful permanent magnets are examples. Those materials that exhibit nonaligned spin structures (e.g., antiferromagnetic and various other types of spin structures) are technologically not useful but scientifically fascinating. Each type of magnetic ordering has a unique order parameter, which, for example, is the magnetization for ferromagnets and sublattice magnetization for antiferromagnets. Various methods of magnetometry can be used to measure the magnetization of materials and the atomic magnetic moments. Neutron diffraction is particularly valuable for measuring the spin structure of magnetic ordering, particularly antiferromagnets and other more complex magnetic orderings, as described in NEUTRON TECHNIQUES.

Most people recognize that a piece of iron can easily be attracted by a permanent magnet, but iron itself cannot attract another piece of iron. This is because in iron there are magnetic domains, a general phenomenon in ferromagnets. Under a sufficiently large magnetic field, a

ferromagnetic material can always be swept into a single-domain state, where all the moments are aligned in one direction. In a small or zero magnetic field, many magnetic domains, separated by domain walls, may form in order to reduce the magnetostatic energy. Within each domain, all the moments remain aligned with a unique magnetization, but the magnetization axes among different domains are not aligned. The size and shape of the domains depend on many factors, most importantly the magnetic anisotropy. In a soft magnet, such as pure iron, domains can be readily formed and swept by a small field because of the small magnetic anisotropy. In a hard magnet, such as the refrigerator magnets and other more powerful permanent magnets, the magnetic anisotropy is so strong that it preserves the magnetization within the material. The magnetic domains, as small as a few tens of nanometers in size, have fascinating shapes and patterns. A variety of techniques have been developed to image magnetic domains and study the domain wall motion.

Electrons have both spin and charge. Many of the magnetic materials are electrical conductors. When electrons traverse magnetic materials, the external field and the magnetization **M** of the magnetic medium affect the conductivity. These are magneto-transport properties, which include a variety of interesting topics, such as magnetoresistance and the Hall effect, and the latter is described in ELECTRICAL AND ELECTRONIC MEASUREMENT. New magneto-transport properties due to spin-dependent scattering as well as spin-polarized conduction have recently been discovered in suitable magnetic heterostructures. These new effects form the basis for some of the new spintronic devices.

Most of the magnetic materials of technological importance are ferromagnets. These include permanent magnets (e.g., ferrite, $SmCo_5$, $Nd_2Fe_{14}B$) that can generate strong magnetic fields, soft magnetic materials (e.g., permalloy, amorphous ferromagnets) that can respond to small magnetic fields, materials that have large magneto-transport properties, and materials that can store magnetization, as in magnetic recording media (e.g., γ-Fe_2O_3, CoTa alloys).

The smallest magnetic entities are magnetic dipoles. Under a uniform magnetic field, a magnetic dipole of dipole moment $\boldsymbol{\mu}$ can only rotate. Under a nonuniform magnetic field **H**, the magnetic dipole can also have translational motion due to the force arising from the field gradient, $\mathbf{F}_\mu = (\mu \cdot \nabla)\mathbf{H}$. For a material of magnetization **M**, the total force per unit volume is $\mathbf{F}_v = (\mathbf{M} \cdot \nabla)\mathbf{H}$. The force on a ferromagnet is attractive and substantial, as evidenced by the refrigerator magnet. For nonmagnetic materials, the force is repulsive due to diamagnetism, and therefore usually weak. However, in an intense magnetic field gradient, the repulsive force can be quite substantial, so much so that it can actually lift or levitate an object against gravity.

Thus far, we have mentioned the magnetic properties due to the electrons in the atoms and the materials. We have ignored the nuclei and other particles because their magnetic moments are three orders of magnitude smaller. However, in certain phenomena, such as nuclear magnetic resonance, Mössbauer effect, muon spin resonance, and neutron scattering, these small magnetic moments are the only ones of importance as described in RESONANCE METHODS.

Units

The descriptions of magnetic properties must include the discussion of units. We are all supposed to be, and indeed have been, using the SI units (Systéme Internationale d'Unités). However, one notable exception is in magnetism, where the systems of units have been confusing and challenging even for seasoned practitioners. Although all the more recent physics textbooks have used exclusively the SI units to describe magnetic quantities as they should, most scientific literature in magnetism, both old and new, continues to use the cgs units, or a mixture of both cgs and SI units. The cgs units also persist on the instrument side. Most commercial magnetometers display magnetic moment in emu (electromagnetic unit) and most gaussmeters measure magnetic field in Oe (Oersted). A practitioner in magnetism therefore must know both the SI and the cgs units.

In the cgs units, the relation among magnetic induction or magnetic flux density (**B**), magnetic field intensity (**H**), and magnetization (**M**) is uniquely defined as

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M} \tag{1}$$

This expression is universally used without ambiguity. Since the units for B (gauss = G), H (oersted = Oe), and M (emu/cm^3) have the same dimension, sloppiness in describing the physical quantities is therefore tolerated (lightface symbols represent the scalar magnitude of the corresponding vector quantity). For example, one can describe the earth's magnetic field as about 0.5 G or 0.5 Oe, and the magnetization of a piece of iron can be specified as $M = 1700$ emu/cm^3 or $4\pi M = 21.7$ kG.

In the SI units, the corresponding relation is

$$\mathbf{B} = \mu_o(\mathbf{H} + \mathbf{M}) \tag{2}$$

where μ_o is a fundamental constant of $4\pi \times 10^{-7}$ N/A^2. The units for H and M are in A/m, whereas B is in tesla, or Wb/m^2. Most unfortunately, other forms, such as $\mathbf{B} = \mu_o\mathbf{H} + \mathbf{M}$, have also been used, creating endless confusion.

In Table 1, various common quantities used in magnetism are shown both in the cgs units and the SI units, as well as the conversion factors.

MAGNETIC SUSCEPTIBILITY AND PERMEABILITY

As described earlier, the applied external magnetic field, **H**, the magnetization, **M**, and the magnetic flux density, **B**, inside a medium are related by Equation 1 in cgs units and Equation 2 in SI units. An external field, **H**, induces certain magnetization, **M**, in a sample, and as a result, generates an internal flux density, **B**. We will use the cgs units in the discussion below for brevity. One can easily convert values into SI units by referring to Table 1.

The magnetic response of a medium to an external field is often characterized by two related parameters of

Table 1. Conversion Between cgs Units and SI Units for Selected Magnetic Quantities

Quantity	Symbol	cgs Units ($\mathbf{B} = \mathrm{H} + 4\pi\mathbf{M}$)	Conversion Factor (C) [(SI) = C(cgs)]	SI Units [$\mathbf{B} = \mu 0(\mathbf{H} + \mathbf{M})$] [$\mu 0/4\pi = 10-7\mathrm{N/A2}$]
Magnetic induction	B	Gauss (G)	10^{-4}	tesla(T) $\mathrm{Wb/m^2}$
Magnetic flux	Φ	G-$\mathrm{cm^2}$ Maxwell(Mx)	10^{-8}	weber(Wb)
Magnetic field intensity	H	Oersted(Oe)	$10^3/4\pi$	A/m
Magnetic moment	m	emu, erg/Oe	10^{-3}	A-$\mathrm{m^2}$, J/T
Magnetization	M	emu/$\mathrm{cm^3}$	10^3	A/m
	4πM	G	$10^3/4\pi$	A/m
Mass magnetization	M_g	emu/g	1	A-$\mathrm{m^2}$/kg
			$4\pi \times 10^{-7}$	Wb-m/kg
Volume susceptibility	χ	Dimensionless	4π	dimensionless
Mass susceptibility	χ_g	$\mathrm{cm^3/g}$	$4\pi \times 10^{-3}$	$\mathrm{m^3/kg}$
Permeability	μ	Dimensionless	$4\pi \times 10^{-7}$	Wb/A-m

magnetic susceptibility (χ) and permeability (μ), which are defined as

$$\chi = \mathrm{M}/\mathrm{H} \tag{3}$$

$$\mu = \mathrm{B}/\mathrm{H} \tag{4}$$

and $\mu = 1 + 4\pi\chi$. If the magnetization of a medium is proportional to H, χ is then a constant and becomes the most appropriate parameter to characterize the magnetic response. On the other hand, if M is not linear in H, χ and μ become functions of H, i.e., $\chi = \chi(\mathrm{H})$, $\mu = \mu(\mathrm{H})$. In some situations, such as the case of a ferromagnet, the behavior of M is hysteretic and, therefore, not uniquely determined by a given H. The concepts of χ and μ are no longer very useful, although still adopted, particularly in soft magnetic materials.

PARAMAGNETISM

A paramagnet consists of an assembly of magnetic dipole moments—μ—the atomic magnetic moments. Thermal disturbance randomizes the orientations of these moments. An external field, on the other hand, creates a tendency for a slight alignment of the moments along the field direction. Under the condition of $\mu\mathrm{H} \ll kT$, the induced **M** is proportional to **H**. If the interaction between the moments is negligible, the susceptibility is given by the Curie Law

$$\chi = C/T = N\mu_\mathrm{B}^2 p_\mathrm{eff}^2/3kT \tag{5}$$

where C is the Curie constant, N is the number of magnetic moments per unit volume, $\mu_\mathrm{B} = e\hbar/2mc$ is the Bohr magneton, and p_eff is the effective moment number in μ_B. Curie's Law offers an effective means to determine the magnitude of atomic or molecular magnetic moment in a system. Or, if the moment of interest is known, one can also determine the concentration of the magnetic component. In experiments, one often plots $1/\chi$ versus T. The slope of the straight line provides the information needed.

In many cases, there may exist some sort of interaction between the individual moments. The temperature dependence of χ is then described by the Curie-Weiss Law

$$\chi = C/(T - \theta) \tag{6}$$

where the constant θ is positive (negative) for interaction of ferromagnetic (antiferromagnetic) origin. Equation 6 can be used to determine θ, which is close to the ferromagnetic ordering temperature T_c.

The Curie or the Curie-Weiss Law becomes invalid when the condition of $\mu\mathrm{H} \ll kT$ is not met. This could happen when H is appreciable, or the magnetic moment (μ) of interest is large. The latter is particular relevant for a superparamagnetic system, which consists of a collection of ferromagnetic or ferrimagnetic particles with moments much larger than constituent atomic moments. Under these situations, M becomes the Brillouin function of H, and χ is field dependent.

A nonmagnetic metal or alloy can exhibit a positive and essentially temperature-independent susceptibility when subjected to a field. This phenomenon, called Pauli paramagnetism, is caused by the Zeeman splitting of the spin-up and spin-down conduction bands induced by the field. A thermal equilibrium process leads to the redistribution of the two types of electrons, leaving the system with a net magnetization. Pauli paramagnetic susceptibility is given by

$$\chi = \mu_\mathrm{B}^2 D(E_\mathrm{F}) = 3N\mu_\mathrm{B}^2/2E_\mathrm{F} \tag{7}$$

where $D(E_\mathrm{F})$ is the density of states at the Fermi level (E_F). It should be pointed out that Pauli susceptibility is at least one order of magnitude smaller than the paramagnetic susceptibility of magnetic ions. Discrepancy is often found between experiments and the predicted values according to Equation 7, which is derived from the free electron gas model. In reality, electron-electron or other types of interaction may not be omitted.

Another weak and temperature-independent susceptibility can be obtained from the second-order Zeeman effect, as was first proposed by van Vleck. This susceptibility depends on the energies of the low-lying exited states

$$\chi = 2N \sum |\langle \alpha_i | \mu_z | 0 \rangle|^2 / (E_{\alpha i} - E_0) \qquad (8)$$

where $\langle \alpha_i |$ and $|0\rangle$ represent the excited and the ground states.

The total susceptibility of a material is the sum of Equation 6, Equation 7, and Equation 8, plus the contribution from a negative susceptibility due to diamagnetism.

DIAMAGNETISM

According to Lenz's law of electromagnetism, application of an external field on an electron system induces an electrical current that will generate a field opposing the change of the external field. The microscopic current within an atom or molecule is dissipationless, and will create a magnetic moment vector opposite and proportional to the external field. This so-called diamagnetic susceptibility is a negative constant, given by

$$\chi = -(Ne^2/6mc^2) \sum \langle 0 | r_i^2 | 0 \rangle \qquad (9)$$

where r_i is the electron radius. Diamagnetism exists in all materials. Its susceptibility is small in comparison with Curie paramagnetism. It does not depend on temperature, and is proportional to the total number of electrons in an ion or a molecule. The temperature dependence of various paramagnetic and diamagnetic susceptibilities is shown schematically in Figure 1.

A superconductor displays a unique diamagnetism. The induced supercurrent on the surface of a type I superconductor suppresses completely the magnetic flux density (i.e., $\mathbf{B} = 0$) within the body of the superconductor. This perfect diamagnetism is called the Meissner effect. The susceptibility is, according to Equation 1, $\chi = -(1/4\pi)$ emu/cm^3, which is many orders of magnitude larger than that of ordinary diamagnets. In a type II superconductor, a magnetic field can partially penetrate into the superconductor. Therefore, the susceptibility is smaller than $1/4\pi$ emu/cm^3 in magnitude, and is dependent on the field strength.

Because of the negative susceptibility, there is a repulsive force between any diamagnetic material and the source of the external nonuniform field. A levitating superconductor on a magnet is a famous example for such repulsion. Researchers have also used a magnetic field to levitate liquid helium droplets (Weilert et al., 1997) and biological materials (Valles et al., 1997).

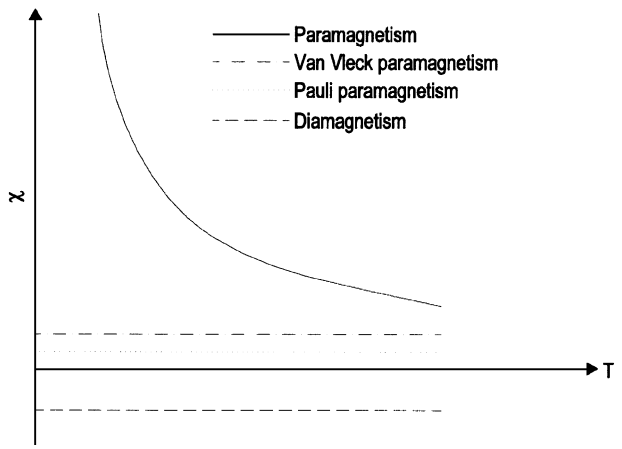

Figure 1. Temperature dependence of susceptibility for paramagnetic and diamagnetic systems.

ANTIFERROMAGNETISM

In an antiferromagnet, magnetic moments at adjacent atomic sites or planes develop a spontaneous antiparallel alignment below a critical phase transition temperature, T_N. The physical mechanism of antiferromagnetism is due to the exchange interaction, which originates from the many-body Coulomb interactions among electrons. Above T_N, the long-range order is destroyed, and the susceptibility is given by the Curie-Weiss Law (Equation 6) with a negative θ. Below T_N, the net magnetization is zero in the absence of an external field, because of the antiparallel configurations of the moments. An external field will induce spin canting and generate a net magnetization, which is proportional to H. In general, there are two susceptibilities, $\chi_\perp$ and $\chi_{||}$, corresponding to the external field perpendicular and parallel to the axis of the spins (easy-axis) respectively.

Figure 2 shows schematically the temperature dependence of susceptibility of an antiferromagnetic crystal. Below T_N, $\chi(T)$ changes abruptly from the Curie-Weiss behavior and branches into $\chi_\perp(T)$ and $\chi_{||}(T)$. As T approaches 0 K, $\chi_{||}$ tends to vanish rapidly. The quantity $\chi_\perp$, on the other hand, remains constant or weakly dependent on T. For polycrystalline or powder materials, $\chi(T)$ falls between $\chi_\perp(T)$ and $\chi_{||}(T)$ as a result of averaging.

FERROMAGNETISM

Ferromagnetic solids are an important class of materials used in a wide range of applications. Many magnetometry

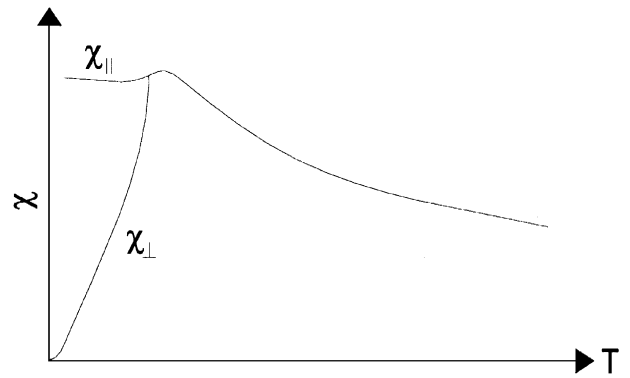

Figure 2. Temperature dependence of susceptibility for an antiferromagnetic system.

techniques have been developed to study the properties of these solids. With exchange interaction as its physical origin, ferromagnetism exhibits a long-range ordering of parallel magnetic moments below a second-order phase transition temperature T_c. Above T_c, the magnetic behavior can be described by the Curie-Weiss Law (Equation 6). From the slope [i.e., the constant C in Equation 5 and Equation 6 of the straight line $1/\chi(T)$ versus T], one can deduce the size of the atomic magnetic moment.

Below T_c, the magnetization is not uniquely dependent on external field H, but rather is determined by the magnetic history of the sample. Experimentally, one either plots M or B versus a cycling H. These plots are called the magnetic hysteresis loops. Since in a ferromagnet M tends to be much larger than H, the two loops (M versus H and B versus H) look similar. Figure 3 shows a schematic hysteresis loop of M versus H and the initial magnetization curve. In the unmagnetized state, the net M is zero because of the magnetic domain structure. As H is increased, M follows the initial magnetization curve until magnetic saturation is reached. Afterwards, the cycling of magnetic field between a positive and negative value causes the M to form a closed loop.

There are a few parameters to characterize the hysteresis loop. The saturation magnetization M_s corresponds to a complete parallel alignment of magnetic moments. The remnant magnetization M_r is the nonvanishing value when H is reduced to zero. The coercivity H_c is the reversing field needed to bring M to zero. The area enclosed by the hysteresis loop is related to the so-called energy product, which is a measure of the prowess of a permanent magnet.

For a permanent magnet, the larger the M_s, M_r, and H_c, the better. In other words, a loop with a large area and a large energy product is preferred. Because of the hysteretic nature of the magnetization process, the definitions of χ and μ according to Equation 3 and Equation 4 are not useful.

For a soft magnet, the H_c is in general very small ($\sim 10^{-2}$ Oe), and so is the loop area. Because of their low energy loss, soft magnetic materials are extensively used in applications involving alternating fields, such as transformers and RF inductors. One often uses modified definitions of susceptibility and permeability to characterize a soft magnetic material. Efforts have been made to enhance permeability for superior performance.

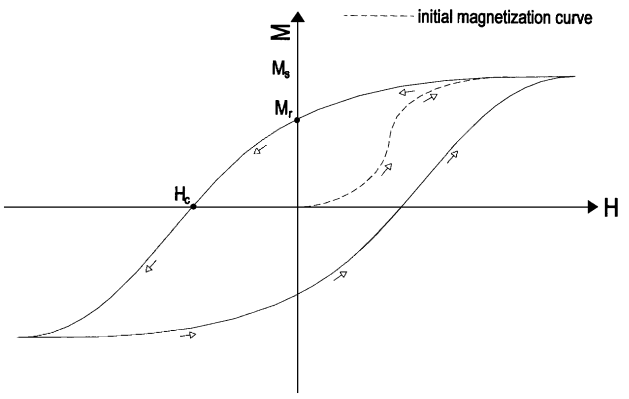

Figure 3. Hysteresis loop for a ferromagnetic system.

In some applications, such as in RF systems, the magnetic field scale is small. The relevant parameter is the initial permeability, defined as

$$\mu = (dB/dH)_{H=0} \tag{10}$$

As **H** increases, $\mu = B/H$ will increase and reach a certain maximum value, which is called maximum permeability μ_M. In some pure and well annealed soft magnetic materials, μ_M can be as large as 10^6. Often permeability data given in the literature refers to μ_M. At each given field, one can also specify a differential permeability $\mu = (dB/dH)_H$.

If a magnet is operated under a bias field ($\mathbf{H}_0$) plus a small alternating field ($\Delta\mathbf{H}$) around $\mathbf{H}_0$, **M**, and **B** will form a minor loop. In this case, one can also define an incremental permeability $\mu_D = (\Delta B/\Delta H)_H$.

When μ is large, as in a typical soft magnetic solid, χ is approximately proportional to $\mu(= 1 + 4\pi\chi \approx 4\pi\chi)$. The aforementioned definitions of various permeabilities can be extended to the corresponding susceptibilities.

GENERATION AND MEASUREMENT OF MAGNETIC FIELDS

INTRODUCTION

In basic science areas, such as semiconductor physics, superconductivity, structural biology, and chemistry, magnetic fields are used as a powerful tool for analysis of matter because they can change the physical state of a

system. In the presence of a magnetic field, the angular momenta (spins), the orbital motion of charged particles, and therefore the energy of the investigated physical system, are altered. We must realize, however, that the size of the induced effects are very modest compared to other physical quantities. One Bohr magneton (typical range of atomic magnetic moments) in a magnetic field of 10 tesla (T) (a 10 T field is ~200,000 times the strength of the earth's magnetic field) has an energy of 0.58 meV, corresponding to a temperature of 6.7 K, a small value in comparison to room temperature. On the other hand, the generation of a magnetic field of 10 T already requires a noticeable engineering effort, with continuous fields of 50 T being the upper limit of what can be achieved today. Pulsed magnetic fields can be generated up to 100 T for durations in the millisecond range, and up to 1000 T on the microsecond time scale. Therefore, experiments must be chosen judiciously. Very often, a low-noise sample environment, such as low mechanical vibrations, small field fluctuations (in the case of dc fields), and low temperatures are decisive to the success of scientific measurements in magnetic fields.

EFFECTS AND APPLICATIONS OF MAGNETIC FIELDS

The use of magnetic fields and their effects on matter are based on a few micro- and macroscopic principles. These principles are utilized not only in basic science areas but also for significant industrial applications (Schneider-Muntau, 1997), and most of them are also employed to measure magnetic fields. These include the following.

1. Magnetization of nuclei and its decay. This effect is the basis for nuclear magnetic resonance (NMR) and magnetic resonance imaging (MRI; NUCLEAR MAGNETIC RESONANCE IMAGING). A considerable industry has developed with numerous applications: NMR spectroscopy, imaging ("scanner") with relevance in medical science, structural biology, and pharmaceutical development, but also for the determination of material properties and nondestructive process and quality control. NMR allows the most accurate measurement of magnetic fields.
2. Induced currents. The electromagnetic induction, i.e., the interaction between conductors and magnetic fields, gives rise to many effects, the most significant applications of which are the generator and electromotor. Magnetic levitation of trains, magnetic propulsion, and magnetic damping of conductive liquids for crystal growth are based on this same effect. Rotating coil gauss meters and extraction flux integrators represent easy ways to measure magnetic fields. Pick-up coils are a standard method for the measurement of pulsed fields.
3. Force on moving charged particles ("Lorentz force"). Accelerators and detectors for particle physics, plasma confinement in fusion devices, isotope separation, ion cyclotron resonance mass spectrometers, and electron beam deflections in TV sets and computer monitors are the most significant applications of this effect. The Lorentz force is, as well, the primary limiting factor in the generation of high magnetic fields, since this force can easily exceed the mechanical strength of the conductors of an electromagnet. The Hall effect (see DEEP-LEVEL TRANSIENT SPECTROSCOPY) is widely implemented for sensors in industry, and it is also the most common device for the measurement of magnetic fields.
4. Magnetization. In a magnetic field, matter is polarized and its magnetic anisotropy results in a force. This effect is employed for separation, alignment of crystals, and levitation. Today's high-field magnets are so powerful that most diamagnetic matter, for instance water and therefore small animals and plants, can be suspended.
5. Energy content. The energy stored in a magnetic field can be effectively utilized in industrial applications. Small systems are available for improvement of the quality of electrical power. Several demonstration projects in the 10-kJ/10-kW range have proven the feasibility of magnets as energy storage systems.

GENERATION OF MAGNETIC FIELDS

Magnetic fields can be generated by magnets created from hard magnetic materials and by electromagnets. Permanent magnets offer a simple, fast, and cost-effective way to provide small-volume fields. *Permanent magnets* are being employed for MRI applications, accelerator storage rings, and wiggler magnets. Fields up to 4 T have been achieved. Devices exist that can produce variable fields or fields with changing orientation. The basic principles of permanent magnets and some applications are described below.

Permanent magnets can also be made from bulk high-temperature superconductors, such as $YBa_2Cu_3O_7$ single crystals. In recent developments it has been shown that a magnetic field of 10 T can be maintained in a mini-magnet of 2-cm diameter, cooled to 42 K (Weinstein et al., 1997).

High and very high fields can only be generated with *electromagnets*. First, some basic principles common to all electromagnets are described, followed by a more detailed treatment of *superconducting magnets*, *resistive magnets*, and *pulse magnets*.

Generation of the highest fields possible is limited by the strength of materials and, for resistive magnets, by the available energy or power source. Because of the resulting magnet size and therefore cost, as well as the required human resources and technical infrastructure, on one hand, and the need for high magnetic fields for research and technology developments, on the other hand, governments have established national facilities as central institutions to serve the scientific community. We provide a short overview of the most important *magnet laboratories* around the world. Each of these laboratories entertains an intensive user program, and access is usually free of charge.

Permanent Magnets

Modern permanent magnets are ideally suited to generate magnetic fields of magnitudes comparable to their spontaneous polarization J_s. Polarization (J), in tesla, is related to magnetization (M) in A/m by the equation $J = \mu_0 M$, where $\mu_0 = 4\pi \cdot 10^{-7}$ Tm/A. In the centimeter-gram-second (cgs) system, M is measured in emu/cm^3 (1 emu/cm^3 = 1 kA/m), $\mu_0 = 1$, and the polarization $4\pi M$ is measured in gauss (1 G = 10^{-4} T); the cgs energy product is measured in megagauss-oersteds (1 MGOe $\approx$ 8 kJ/m^3). The fields can be static or variable, uniform or nonuniform. They are generated by compact permanent magnet structures requiring no continuing expenditure of energy for their operation. The main classes of hard magnets are based on hexagonal ferrites, such as $BaFe_{12}O_{19}$, for which the intrinsic polarization of the pure phase is $J_s = 0.5$ T, and rare earth intermetallic compounds such as $Nd_2Fe_{14}B$, for which $J_s = 1.6$ T. Permanent magnets are now fully competitive with electromagnets for generating fields of up to $\sim$2 T; indeed when a field with a rapid spatial variation is required, they may offer the only practical solution.

Ferromagnetic materials normally have a multidomain structure below their Curie point. The atomic moments within each domain are aligned along some easy direction; the electric currents associated with the quantized spin and orbital moments of the electrons add to produce a net circulating current density of order 1 MA/m, which corresponds to the spontaneous magnetization M_s (1 MA/m $\equiv$ 1.26 T). In the unpolarized state, the moments of the different domains are aligned in different directions and the net magnetization is zero. The domain structure is eliminated by applying an external field, H, which is sufficiently large to align the magnetization of each domain and saturate polarization (Fig. 1). What happens when the field is removed depends on the nature of the material. In a soft magnetic material, the domain structure reforms as soon as the applied field is less than the local demagnetizing field, and hysteresis is negligible; in a hard magnetic material, the polarization remains close to its saturation value well into the second quadrant of the hysteresis loop, and falls to zero at a negative value known as the coercive field, H_c. The hysteresis loop is broad, and for a true permanent magnet the coercive field should be $>M_s/2$.

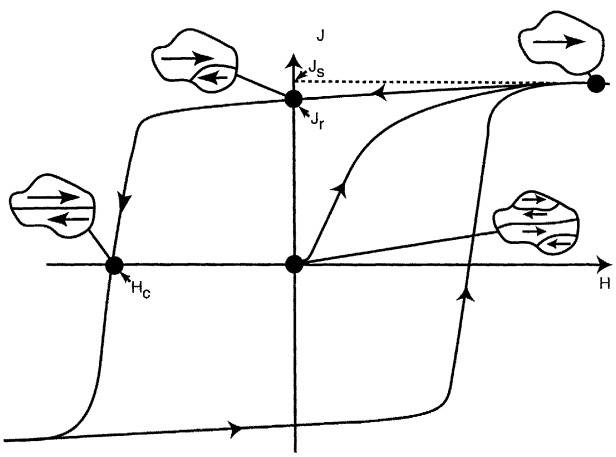

Figure 1. The hysteresis loop of a permanent magnet.

The fully magnetized state is inherently metastable and tends to revert to the equilibrium, multidomain configuration—a process that must be indefinitely delayed in practical magnets. There are two main strategies for achieving this. Permanent magnets are generally constituted of a main phase which has a uniaxial crystal structure (rhombohedral, tetragonal, hexagonal) and strong easy-axis anisotropy so that the magnetization can lie only along the c axis. The anisotropy energy is often represented by an equivalent anisotropy field, B_a. There is, therefore, an anisotropy energy barrier to magnetization reversal. Where the barrier is lowest, a reverse domain may nucleate, and eventually the domain wall may sweep across a particle, completely reversing its magnetization. One approach is to inhibit nucleation of reverse domains by producing a microstructure of tiny ($\sim$1 to 5 μm) crystallites with smooth surfaces, possibly separated by a nonmagnetic secondary phase. The hexagonal ferrites, $SmCo_5$ and $Nd_2Fe_{14}B$ are nucleation-type magnets. The other is to pin any domain walls by local defects associated with nanoscale inhomogeneity in the magnetic material. Sm_2Co_{17} is a pinning-type magnet. The decay of the permanent moment with the logarithm of time is an effect known as magnetic viscosity. It may be of the order of 1% in the first year after magnetizing the material, and cannot be avoided. The medium-term irreversible losses can, however, be exhausted by thermal aging.

The *energy product* $(BH)_{max}$ is the usual figure of merit for a permanent magnet; it corresponds to twice the maximum energy that can be stored in the magnetic field produced around an optimally shaped magnet. In order to maximize the polarization and energy product, the individual crystallites should be aligned with their c axes in a common direction. Details of the intrinsic magnetic properties (Curie temperature, T_C, spontaneous polarization, J_s, and anisotropy field, B_a) of a range of modern permanent magnet materials are listed in Table 1, together with the properties of typical magnets made from them—coercive field, H_c, remanent polarization, J_r, and energy product, $(BH)_{max}$. The polarization of the magnet is normally less than that of the hard phase because of imperfect crystallite alignment, or the presence of nonmagnetic secondary phases needed to achieve coercivity.

All of these magnets can be regarded as transparent, to a first approximation. This means that the polarization of any block of magnetic material is unaffected by the presence of other magnet blocks in its vicinity. Transparency greatly simplifies the design of magnetic circuits. The flux produced by an arrangement of permanent magnets at a point $\mathbf{r}$ is then the product of a geometric factor $f(\mathbf{r})$ and the polarization of the magnets.

The flux density, B, produced by a small magnet of moment $m = MV$ Am^2 is nonuniform and anisotropic. Here $M = J/\mu_0$ is the magnetization, μ_0 is the free space permeability, and V is the magnet volume. The two perpendicular components of the field produced in the plane of a small dipole are

$$B_r = (\mu_o m/4\pi r^3)2\cos\theta \quad \text{and} \quad B_\theta = (\mu_o m/4\pi r^3)\sin\theta \quad (1)$$

Table 1. Properties of Permanent Magnet Materials

Compound	Structure	T_C (K)	J_s (T)	B_a (T)	H_c (MA/m)	J_r (T)	$(BH)_{max}$ (kJ/m^3)
$BaFe_{12}O_{19}$	Hexagonal	723	0.48	1.65	0.28	0.39	28
$SmCo_5$	Hexagonal	993	1.05	40	1.40	0.88	150
Sm_2Co_{17}	Rhombohedral	1100	1.30	6.5	0.90	1.08	220
$Nd_2Fe_{14}B$	Tetragonal	585	1.61	7.6	1.00	1.25	300

In order to generate a uniform field over some region of space, segments magnetized in different directions need to be assembled. An effective way of doing this is to build the structure from long segments with a moment l Am. In this case, the field is given by

$$B_r = (\mu_o l/4\pi r^2)2\cos\theta \quad \text{and} \quad B_\theta = (\mu_o l/4\pi r^2)2\sin\theta \quad (2)$$

so that the magnitude

$$|B| = \sqrt{B_r^2 + B_\theta^2} \quad (3)$$

is now independent of θ, the angle between the radius vector and the magnetization. The dipole ring shown in Figure 2A is an ideal structure where the direction of magnetization in the magnet is given by $\alpha = 2\phi$, with $\phi = \pi - \theta$. The field generated is uniform within the ring and zero outside, provided the ring is very long. The value B_i of the field in the bore for a material with an ideal square hysteresis loop (J_S is the spontaneous magnetization) is

$$B_i = J_s \ln(r_2/r_1) \quad (4)$$

The device illustrates nicely the principle of flux concentration. For example the field generated at the end of a long bar magnet is just J_r, but larger values may be achieved in a magnetic circuit containing segments magnetized perpendicular to the field direction in the airgap. To obtain a field equal to the polarization, we need $r_2/r_1 = 2.7$, but a field of twice J_s needs a radius ratio of 7.4 and 20 times as much magnetic material. Even if materials existed with sufficient coercivity to withstand the large reverse fields acting on some regions of the structure, permanent magnets required to produce multi-tesla fields soon become impractically large.

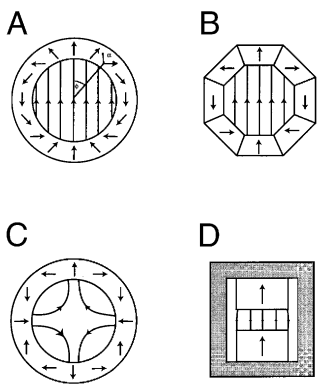

Figure 2. Permanent magnet structures used to generate (**A**) a uniform field, and (**C**) a quadrupole field. The structure shown in (**B**) is a simplified version of (**A**), and (**D**) is a different design, using a soft iron yoke (shaded).

The ring structures can be used to generate higher multiple fields with a different ratio of α and ϕ; for a quadrupole field, for example (Fig. 2C), $\alpha = 3\phi$.

The rings of Figure 2A and C are difficult to realize in practice, and simplified versions with their length comparable to their diameter can be constructed from trapezoidal segments (Fig. 2B). Other designs composed of prismatic segments generate uniform fields in rectangular or triangular bores. It may be advantageous to include soft material in the design to provide a return path for stray flux, as shown in the yoked design of Figure 2D.

These permanent magnet structures are also useful when a rotating magnetic field is needed, or when it is necessary to toggle a field between two directions differing by a fixed angle (such as 180°), in order to reverse the field.

The task of generating a uniform variable field may be undertaken with permanent magnets, provided some movement is permitted. A useful design (Leupold, 1996) consists of two nested dipole rings. The one illustrated in Figure 3A uses cylinders of the type shown in Figure 2B. Dimensions are chosen so that each cylinder produces

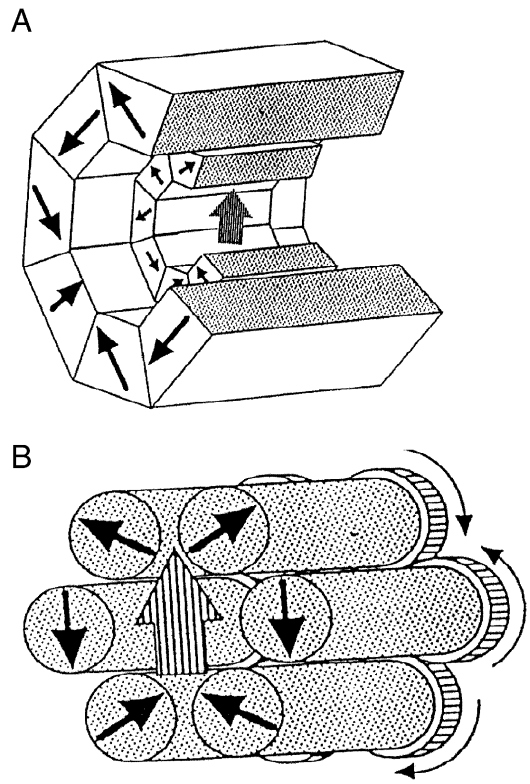

Figure 3. Practical permanent-magnet structures for generating variable fields. (**A**) A double cylinder ("magic cylinder"), and (**B**) a 4-rod design ("magic mangle").

the same field in its bore, and they can be independently rotated about their common axis. In this way, a field in the range $-2B_i < B < 2B_i$ can be produced in any direction in the plane perpendicular to the common axis of the cylinders. The same device can also generate a rotating field of any magnitude from zero up to $2B_i$. When access parallel to the field is desired, a different design, based on rotating cylindrical rods, is preferred. One with six rods is shown in Figure 3B. With four rods, the maximum field available is just J_s (Coey and Cugat, 1994).

There are innumerable applications of permanent magnets as flux sources. They are extensively used in small dc motors and actuators. One example, which accounts for a significant fraction of the global production of $Nd_2Fe_{14}B$, is the voice coil actuator that moves the read head across the surface of a hard disc. Static fields produced by permanent magnets are also used for magnetic separation, magnetic annealing, charged-particle beam control (e.g., wiggler magnets for synchrotron light sources), MRI, NMR spectroscopy, and oil and water treatment, among other applications. In the laboratory, permanent magnet flux sources of this type are the most versatile and convenient way of generating variable fields in the range 1 mT to 2 T. They are compact, and need no cooling water or high-current power supply. However, the limitation on the polarization of existing (Table 1) and foreseeable hard magnetic materials to less than ~2 T will mean that permanent magnet flux sources will only be economically justified for fields <3 T. For fields >3 T, superconducting solenoids with cryogenic or cryogen-free refrigeration will be needed. Fields >20 T call for Bitter or hybrid magnets. For most purposes, however, permanent magnet flux sources are destined to displace the iron-yoked electromagnet from the dominant position it has occupied over the past 150 years.

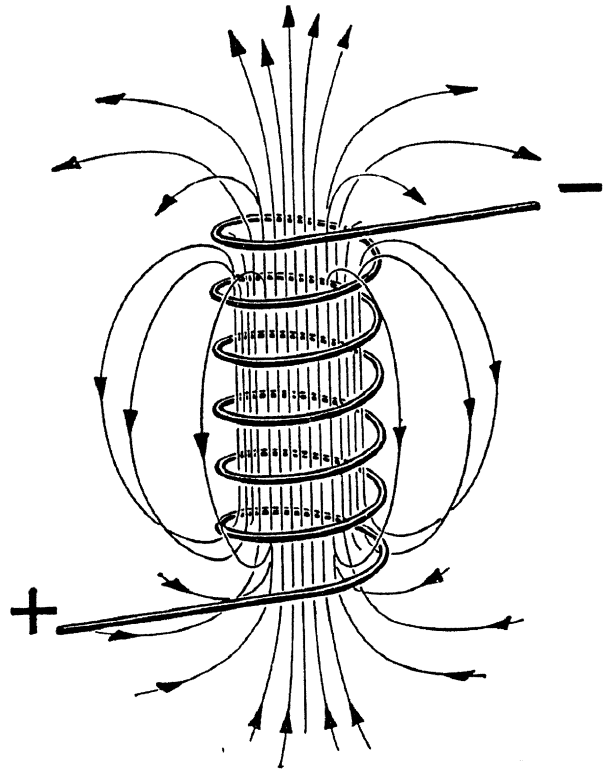

Figure 4. The magnetic field of a coil. (Courtesy of Gerthsen, 1966.)

Electromagnets

In this section, we consider a few basic relationships between current density and magnetic field for a solenoid coil geometry. In the second part, we briefly deal with electromagnetic forces ("Lorentz force") and a simplified description of the resulting stresses.

Figure 4 shows a single-layer coil, wound from a piece of conductor, and the resulting magnetic field as described by the magnetic field lines. Solenoids are coils with many turns and layers, and the current can be described as a current density in a volume element. The law of Biot and Savart gives the field contribution at the center of the coil, i.e., at $r = 0$ and $z = 0$, of a small volume element dV carrying the current density j [as in the literature, j is used here for current density (in units of A/m^2), to be distinguished from polarization J (in units of T) in permanent magnets] in circumferential direction (Fig. 5).

$$\mathbf{H} = \frac{1}{4\pi}\int \frac{\mathbf{r}' \times \mathbf{j}}{r'^3}\, dV \qquad (5)$$

From symmetry consideration it follows that on axis we only have an axial field component, B_z, which we can calculate by integrating over a magnet with inner radius a_1, outer radius a_2, total length $2b$, as shown in Figure 5. From here on, we use the magnetic induction $B = \mu_0 H$ for the magnetic field

$$\mathbf{B} = \frac{\mu_0}{4\pi}\int_0^{2\pi}\int_{a_1}^{a_2} 2\int_0^b \frac{\mathbf{r}' \times \mathbf{j}}{r_3'} r\, dr\, d\varphi\, dz \qquad (6)$$

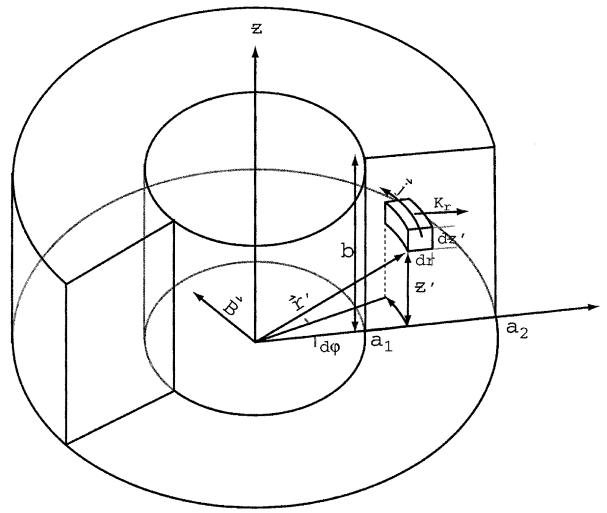

Figure 5. Field contribution of a conductor element.

We obtain for constant current density j over the coil volume the following expression for the magnetic field at the center of the solenoid with $\alpha = a_2/a_1$, and $\beta = b/a_1$.

$$B_z = \mu_0 j \ln \frac{\alpha + \sqrt{\alpha^2 + \beta^2}}{1 + \sqrt{1 + \beta^2}} \quad \text{or} \quad B_z = \mu_0 j a_1 F(\alpha, \beta) \qquad (7)$$

where $F(\alpha,\beta)$ is the so-called field factor that is entirely geometry dependent, i.e., the solenoidal magnet shape can be optimized (Montgomery, 1969). The cross-section of the coil with the overall current density j can be replaced by n turns of wire carrying a current of I occupying only a fraction λ of the total volume. This "space factor," λ, i.e., the ratio between the active section of the winding and its total section, is of great significance, since insulation, reinforcement, and wire shape tend to dilute the wire current density $j_{\text{wire}} = j/\lambda$, and, therefore, the achievable fields. Optimized designs, with the goal of either achieving minimum volume and, therefore minimizing wire cost, or of achieving the highest possible field, will deviate from the above assumption of an overall constant current density and subdivide the winding into regions of different constant current densities to match conductor characteristics with respect to critical current or stress/strain limitations.

Electromagnetic Forces. The design of magnets, especially of high-field magnets, is limited by the Lorentz force, i.e., the stress and strain levels induced by this force, via the coil geometry, on the conductor and the support structure. The precise description of the forces and resulting mechanical loading is extremely complicated and requires a detailed knowledge of the electromagnetic field distribution and the mechanical structure in all three dimensions. Extensive computer programs have been written to solve this issue satisfactorily (e.g., Markiewicz et al., 1999). We present here a simple approach to calculate, in an approximate way, stress levels in a magnet.

The Lorentz force K is a force per volume V (Fig. 5)

$$\frac{d\mathbf{K}}{dV} = \mathbf{j} \times \mathbf{B} \qquad (8)$$

Considering only the z component of the field B_z, a current density in circumferential direction j_t, and no mechanical coupling to other parts of the coil, one obtains a radial force component K_r of

$$dK_r = j_t B_z r \, dr \, dz \, d\varphi \qquad (9)$$

and the hoop stress σ_t of an unsupported current sheet results in

$$\sigma_t = j_t B_z r \qquad (10)$$

For instance, a 10-T solenoid with a current density of 4×10^8 A/m^2 has to support a hoop stress of 200 MPa in its innermost wire layer of 100-mm diameter. Since the magnetic field is proportional to the current density, the Lorentz force increases with the square of the magnetic field. The performance of most magnets and the achievable fields are limited by the materials available to support the induced stress or strain.

Superconducting Magnets

While all metal conductors show a gradual decrease in resistivity with lower temperature, superconductors show zero resistivity very abruptly below a certain temperature, the critical temperature T_c. Another typical property of superconductors is that they have a critical field, B_c, and a critical current density j_c, beyond which superconductivity is destroyed. Superconducting magnets have to be operated within the described B-j-T volume (A-C-E in Fig. 6) since the superconductor transitions into normal resistivity outside this volume. The prevailing conductors are alloys of niobium-titanium and niobium-tin with T_cs of ~12 K and 27 K, respectively (C in Fig. 6). Therefore, the magnets are operated at the temperature of liquid helium (4.2 K) or superfluid helium (1.9 K) (point F). At that temperature the conductor has a lower maximum current density (point D) at zero field, which is again considerably lower in a magnetic field (point G). A magnet is therefore operated along the load line F-G. The new development of high-temperature superconductors (HTS) will extend the useful region toward 100 K; however, at present they are competitive only at low temperatures. Figure 7 compares promising HTS conductors with commercially available low-temperature superconductors.

The generation of magnetic fields through the application of superconductivity can now be considered as a well established technology. Many difficult technical problems have been resolved in the last few years. Thousands of small research magnets are now in routine operation worldwide, producing fields in the range from 5 to 20 T. Both NMR and MRI are the key industrial applications (Killoran, 1997). These applications require extraordinarily high homogeneity of the magnetic field in space and time—typically 10^{-9}—which is achievable solely with superconducting technology. When the magnet is charged to full current, a superconducting switch is closed across the terminals, x, and the power supply is disconnected.

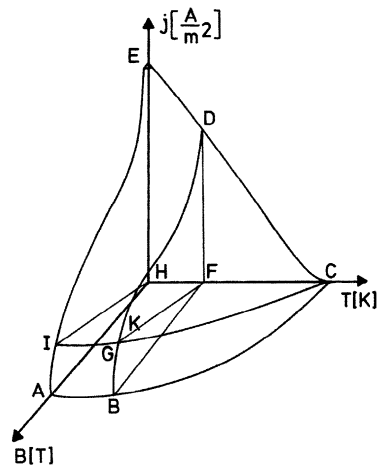

Figure 6. Critical B-j-T volume of a superconductor.

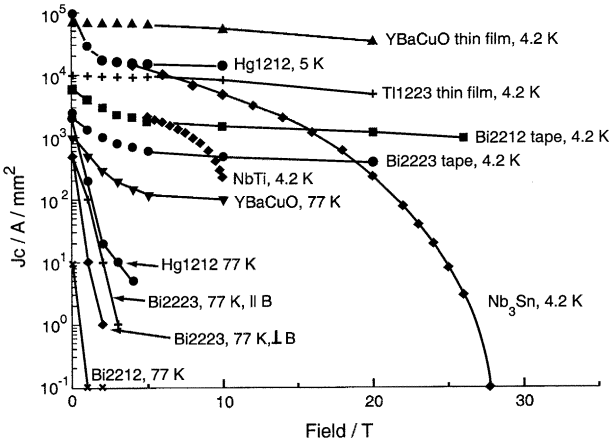

Figure 7. Critical current density within the superconductor of high-temperature superconductors as a function of field for 4.2 K and 77 K. NbTi and Nb_3Sn are plotted for comparison.

The current continues to flow in a closed loop ("persistent mode"), and because of its extremely low resistance—with a decay time of the order of 100,000 years—the magnet is almost a *perpetuum mobile*.

Quench and Training. Superconducting magnets quite often show a performance that is lower than the expectation, which is the field value computed from the short conductor sample characteristics; i.e., the magnets quench prematurely. This is indicated by point K on Figure 6 compared to G. The word "quench" has been coined to describe a process wherein the conductor, starting from a point in a magnet and expanding over the entire volume, passes from the superconducting into the normal state. The stored magnetic energy is dissipated as thermal energy within the coil volume. The heating is not uniform and "hot spots" are generated. The temperature peaks at the origin of the quench and can even result in the melting of the conductor. Modern designs, especially for magnets with high energy content, provide a quench-protection system and even heaters to assure uniform energy dissipation and temperature. Many magnets show a progressive improvement up to a certain level with repeated quenching. This effect is called "training." There is common agreement today that the problem is created by some sudden energy release as the current, and with it the mechanical loading through the Lorentz force, is ramped up. This may originate from some weak spots in the winding structure, cracking of the impregnation under the impact of the induced strain, and small rearranging of the conductor with friction. Because of the extremely small heat capacity of the materials at low temperatures, small energy releases create substantial temperature increases that bring the conductor temperature beyond the critical temperature, T_c. Heat conduction within the winding pack is poor and slow; therefore, the assumption of adiabatic heating is justified. The results necessitate that disturbances must be limited to extremely low values of the order of microjoules per cubic millimeter, corresponding to a maximum sudden wire movement of only a few micrometers. A sound mechanical structure, a precise winding pattern, crack-free epoxy impregnation, a design without slip planes and shear force releases, and a mindful attention to the many mechanical details, have proven to prevent training.

Protection. During a quench, a magnet may be exposed to excessive voltages or temperatures, and the magnet has to be protected against any damage. There are active and passive techniques for doing this. The active technique involves the discharge of the magnet energy into an external dump resistor. In the interest of maximum energy extraction, a small time constant $\tau = L/R_e$ (L is the inductance of the magnet, R_e the external resistor) is preferable. The discharge voltage across the terminals, $V_e = I_m R_e$ (I_m is the magnet current), however, increases and may damage components by arcing. The magnet designer's job is to find a compromise between maximum quench temperature and discharge voltage. This involves the appropriate selection of the operating current (defined by the energy content; $E = 0.5LI_m^2$), the conductor cross-section, and the inductance. A significant feature is a completely reliable quench detection and switch operation system.

Passive techniques are, per definition, reliable. The disadvantage, however, is that all of the energy is dissipated into the magnet volume and the coolant, i.e., liquid helium. The preferred solution is subdivision of the winding into a sufficiently large number of sections that are shunted by a resistor. The resistors can also be used to heat the windings to initiate a distributed quench for a more uniform temperature distribution. Another possibility exists in integrating shorted coupled resistive windings that take up a fraction of the energy. An optimized design will divide the magnet into many subcoils, grade the conductor to suit the local field, construct the coil reinforcement as a wire wound and short circuited overbending for quenchback and heating, and combine it with a quench detection system that dissipates the coil energy in quench heaters. Computer codes have been written that predict quench propagation and coil currents quite reliably by including ac losses (Eyssa et al., 1997). The passive protection has the disadvantage that there is also an energy loss, and therefore increased helium losses, when the magnet is energized or the current setting is altered.

Stability and Losses Due to Changing Fields. The critical-state model describes the penetration of a magnetic field into a superconductor. Because of the superconductor's zero resistivity, screening currents are induced. If the critical current density is surpassed, the screening currents decay resistively to the critical current, allowing the magnetic field to penetrate. All regions of a superconductor are, therefore, carrying either currents at the level of the critical current or no current at all. At full penetration, the current reaches the critical value, I_c. This state may become unstable because the critical current density falls with increasing temperature, and flux motion in the superconductor generates heat. The so-called "adiabatic stability criterion" can be derived from this, with the result that sufficiently thin conductors are stable against flux jumps. In a composite conductor, and above its critical current, the excess current is carried by the stabilizer. A voltage drop is set up which is determined by the stabilizer

resistivity. Copper is usually selected as matrix material as it provides good electrical and thermal conductivity and is essential to protect the conductor against burnout in case of a quench. However, a copper matrix retains the handicap that the filaments are coupled in a changing field via the resistance of the matrix. The solution to this problem consists of twisting the conductors, so that the induced currents cancel over one twist pitch. Twisting is effective against external fields; however, it is not effective against the self-field, induced by the transport current within the conductor. This then leads to the "transport current stability criterion," predicting that wires up to diameters of ~0.5 mm will be stable against flux jumps for the adiabatic case. Further improvements in the theory of stability have been achieved by including the time dependence of heat, current, and magnetic flux, resulting in the so-called "dynamic stability conditions." Obviously, heat conduction and surface cooling are most important for dynamic stability. Experience has shown, nevertheless, that filamentary conductors perform better than theory predicts. As a consequence, modern superconductors are the result of an ongoing development effort, and are tailored to their applications. Figure 8 shows, as an example of the highly advanced wire technology, a bronze route conductor developed especially for high-field NMR magnets.

A detailed knowledge of the induced losses in a changing magnetic field is important for determining operating conditions and the load for the cryogenic system. In superconductors, as in all conductors, changing magnetic fields induce voltages that generate a current flow through the resistance of the current loop. The difference to resistive conductors arises from the fact that the changing magnetic field generates a varying magnetic flux in the filaments. This variable flux results in induced voltages that act on the shielding currents. Heat is dissipated as described above, i.e., the loss mechanism is of a resistive nature. The resistance is highly nonlinear and the loss per cycle is independent of the cycle time. These losses are called hysteresis losses. Clearly, the induced currents, and with it the losses, depend to a high degree on the design of the conductor, the resistivity of the matrix, the resistance between filaments and the matrix ("coupling losses"), the direction of the pulsed magnetic field, and the twist pitch. In addition, we must deal with self-field losses if the transport current changes. Collectively, these losses are known as "ac losses," and their calculation is highly complicated. Many industrial applications (e.g., particle accelerator magnets, superconducting motors and generators, levitated trains, or energy-storage systems) involve changing magnetic fields. In general, hysteresis losses can be reduced by making the filaments as fine as is feasible. Coupling losses can be minimized by shortening the twist pitch, but only if the changing field is perpendicular to the conductor. Self-field losses can be controlled only by reducing the wire diameter.

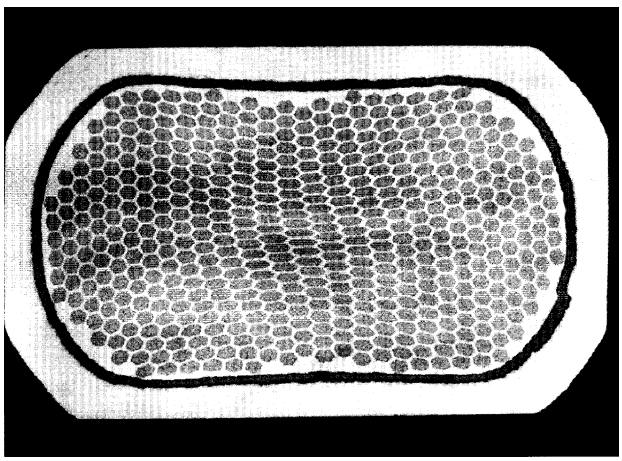

Figure 8. Modern large cross-section (3.17 × 1.97 mm^2) Nb_3Sn conductor with outer stabilizer (25% Cu) and Ta barrier. The conductor contains 123,000 filaments of 4-μm diameter. The critical current density at 20 T and 4.2 K is ~100 A/mm^2, and 200 A/mm^2 at 1.8 K. (Courtesy of Vacuumschmelze, Hanau, Germany.)

Resistive Magnets

Resistive magnets, unlike superconducting magnets, have no constraints, such as critical current density or temperature, imposed on their achievable performance. Resistive magnets require electrical power and, therefore, efficient cooling, but are not limited by any physical effect as superconductors—i.e., in principle it is possible to generate an infinitely high magnetic field. We will see later that power requirements become excessive very quickly, therefore, the generation of very high magnetic fields is only a question of economics.

Resistive magnets are optimized to generate the highest magnetic field possible with the available power. We will present the basic relationships between field, power, and different current density distributions to define the criteria for an optimum design.

Power-Field Relations. A small conductor element dV as shown in Figure 5 with resistivity ρ and current density j will dissipate the following amount of power

$$dW = j^2 \rho \lambda \, dV \tag{11}$$

If we assume a radial dependence of the current density, $j(r)$, but constant resistivity, ρ, and space factor λ, we obtain for a rectangular coil cross-section

$$W = 4\pi b \rho \lambda \int_{a_1}^{a_2} j(r)^2 r \, dr \tag{12}$$

From Equation 6, the same assumptions yield the following:

$$B_z = \mu_0 \int_{a_1}^{a_2} \frac{b}{\sqrt{b^2 + r^2}} j(r) dr \tag{13}$$

Equations 12 and 13 can be combined to the following general form:

$$B_z = \mu_0 G(\alpha, \beta) \sqrt{\frac{\lambda W}{\rho a_1}} \tag{14}$$

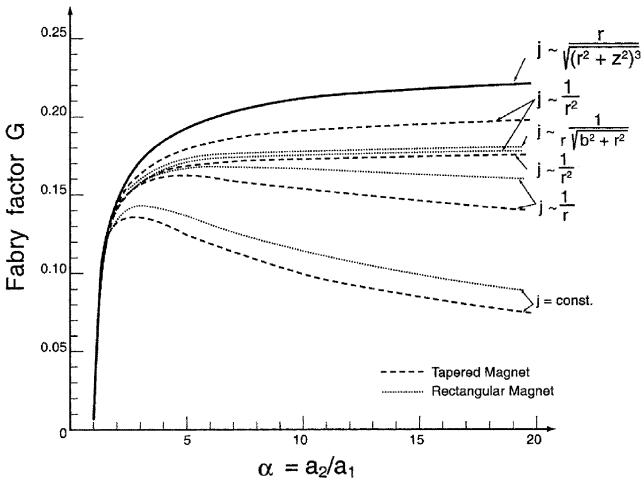

Figure 9. The Fabry factor for different radial current densities. β is optimized for each α value.

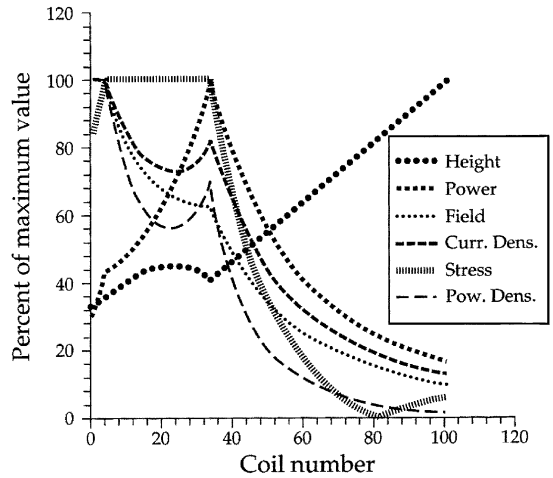

Figure 10. Optimization of a resistive magnet with the constraints of maximum power density and hoop stress.

where $G(\alpha,\beta)$ is the so-called Fabry factor, which is a geometry factor, and B_z is the magnetic field generated at the origin, i.e., in the midplane of the solenoid at $r = z = 0$. Since Equation 14 relates the generated field to the consumed power, it describes the efficiency of the chosen radial current density distribution and solenoid geometry. We can now compare the G-factor of different current density distributions and geometry. Figure 9 shows that, for constant current density and for $j \sim 1/r$, G has a maximum, but that for the other current density distributions, the efficiency can be increased by making the magnet bigger and bigger. Of special interest is the so-called Kelvin distribution (top line in Fig. 9), as it shows the highest efficiency. It is plotted here for a solution that allows the current density to change radially and axially. It is based on the concept that each volume element of the magnet should produce the same amount of field per watt of power input. Practical solutions approximate the optimum value quite closely by subdividing the magnet into several coils and properly selecting the power distribution.

The relationships shown here hold true for magnets with low power levels. High-field magnets have many additional constraints. The power levels are so extremely high that evacuation of the dissipated power through cooling, i.e., the heat flux, is limited by the available cooling surface. Additional cooling requires increased space, no longer available for current conduction, i.e., the space factor λ becomes a function of the power density. The stress levels are so intense that the use of copper alloys is necessitated, i.e., the resistivity ρ also becomes a function of the power level. Additionally, the required reinforcement further increases the space factor. The equations become so complicated that numerical methods are required to solve them. Figure 10 displays the result of a calculation made to illustrate the various constraints. The current density was illustrated only to vary radially. The magnet was split into 100 coils to obtain a quasi-continuous picture. Three regions can be distinguished: (1) the outer region where the optimization has no constraints and finds $j \sim 1/r^2$ and $b = r$, which is the most efficient geometry and power distribution (see Fig. 9); (2) the center region, where the current density is reduced because of the imposed hoop stress limitation; and (3) the inner region where the current density is reduced because the power density is limited for reasons of insufficient cooling surface. An optimum design will attempt to meet both limitations simultaneously. Due to these constraints, resistive magnets become rather inefficient with higher fields, i.e., their power requirements increase exponentially with field.

As result of a newly developed technology, ("Florida Bitter Magnet"), resistive magnets now generate up to 33 T in a 32-mm room temperature bore (Eyssa et al., 1998). These high-field magnets have a power dissipation of up to 20 MW; therefore, efficient and reliable cooling is a prerequisite. Due to the high power densities, the coolant has to be in direct contact with the conductor. Therefore, deionized water of high electrical resistivity is used. Efficient cooling requires high water velocities and a highly turbulent flow to reduce the laminar boundary layer and the temperature drop across this layer as much as possible. Typical values are 20 m/s for the water velocity as upper limit to avoid cavitation. A laminar layer of about only 5-μm results, which accounts for a temperature gradient of up to 40 K. The roughness and its structure determine heat transfer and friction factor, and its optimization is the aim of extended numerical efforts.

Hybrid Magnets. Hybrid magnets combine the advantages of superconducting and resistive magnets. They consist of an outer superconducting coil that provides the background or booster field for the resistive insert magnet. The outsert requires only negligible power compared to a resistive magnet, and power savings of 10 to 20 MW can be realized, depending on bore diameter and field level. Because of the necessary large bore, however, it represents a major capital investment. For the insert, normal, resistive conductors are utilized, as their current-carrying capability is unlimited in comparison to a superconductor. The design of hybrid magnets is a challenging task. The outer magnet has to generate a high field in a large bore

with the consequence of high hoop stresses (as follows from Equation 10). The insert has to withstand not only its own Lorentz forces but also those from the field contribution of the outsert. For economic reasons, the bore size of the outsert is kept as small as possible; therefore, the insert must dissipate its power in a rather small volume. In the case of a misalignment of the magnetic centers of the two systems, forces are generated that are transmitted through the cryostat of the superconducting magnet. In case of a partial burn-out or short-circuit of one of the magnets, these forces can reach the alarming magnitude of several MN. Because of the magnetic coupling, the outsert must also support induced currents arising from sudden field changes from the insert, for instance, in case of an emergency switch-off. Stability requirements and the Lorentz forces lead to a special conductor design for the outsert, the so-called cable-in-conduit conductor, where the conductor is in direct contact with superfluid helium. The stainless steel shell handles the mechanical forces.

There are several hybrid magnets in service worldwide. As of 1999, the highest field (44 T) was generated in the U.S. at the National High Magnetic Field Laboratory (NHMFL), followed by the magnet laboratory in Tsukuba, Japan (37 T). The NHMFL is working on a new insert design that will push the limit even higher, with a goal of generating 50 T in a 32-mm bore.

Pulse Magnets

The generation of pulsed magnetic fields represents an economic avenue to high fields at a small fraction of the cost of continuous magnets. Pulsed magnets are the only way to produce fields above the level of continuous magnets. Disadvantages are the induced voltages and eddy currents in the sample through the changing field. Pulse lengths are typically in the micro- to millisecond range. The use of pulsed fields for research purposes is, therefore, limited to systems where the above effects can be avoided, for instance, in samples of low conductivity. Modern electronics offer fast acquisition time and high resolution.

Devices to generate pulsed fields consist of an energy-storage system that is charged slowly and then discharged rapidly on the magnet. This may be a capacitor bank (typically in the range from 1 to 10 MJ) or a generator in which the energy is stored in the rotating mass of the winding, sometimes complimented by a flywheel. Generators can provide stored energies in the 100-MJ to 3-GJ range. There also exists the option of procuring energy pulses out of the power mains, if the locally available power grid is sufficiently stable.

Discharges from capacitor banks are uncontrolled in the sense that the resulting pulse form is determined by the circuit, i.e., a damped sine wave. Its pulse width is set by the inductance L of the magnet and the capacitance C of the bank, and the damping by the coil and circuit resistance. In first approximation, i.e., for negligible damping, we can write the following equation for the peak current (where V_0 is the voltage of the capacitor bank)

$$I_{\max} = V_0\sqrt{\frac{C}{L}} \tag{15}$$

Similarly, the following equations can be written for the peak power

$$N = V_0^2\sqrt{\frac{C}{L}} \tag{16}$$

and for the pulse-rise time

$$t_0 = \frac{\pi}{2}\sqrt{LC} \tag{17}$$

For the generation of high fields, a high peak current, and equally importantly a high power transfer, from the bank to the coil is needed. This requires a high-voltage capacitor bank and a low-inductance coil. For example, a 10-kV, 1-MJ bank would deliver in excess of 50 kA and 500 MW into an 80-T magnet (Li et al., 1998). Assuming an inner coil diameter of 10 mm, the stress on the conductor will be 2 GPa (Equation 10), i.e., in the range of the strongest materials available today. Often a "crowbar" is added to the discharge circuit to increase the pulse length. At peak current, the capacitor bank is disconnected and replaced by a resistor R, so that the current decays in the LR circuit with a time constant τ of

$$\tau = \frac{L}{R+r} \tag{18}$$

where r is the (time dependent) resistance of the magnet. The total pulse time is then $t \approx t_0 + 3\tau$.

Generators and power supplies fed from the power mains require a unit that controls the energy flow to the magnet and also rectifies the current. The control unit can be used to achieve various pulse forms. Figure 11 gives examples of the pulse shapes that can be generated with the unique 60-T magnet at the user facility of the NHMFL at Los Alamos National Laboratory (LANL).

The upper limit for the above-described technique is considered to be 100 T. There are no known materials that can withstand the Lorentz forces beyond this field level, and magnets inevitably become destructive. To

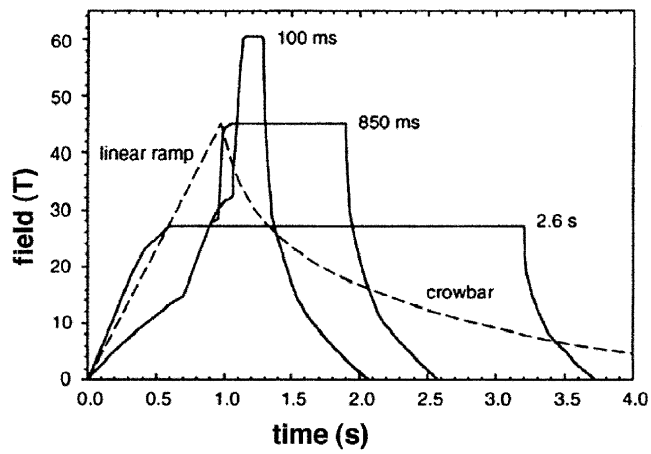

Figure 11. Some of the pulse forms obtainable with a controlled discharge at NHMFL user facility at LANL.

generate even higher fields, two concepts are applied. The first concept is delivering power into a coil faster than the time the coil takes to explode. Fields up to 300 T during microseconds can be created this way by the discharge of a low-inductance capacitor bank into a single turn coil of a few millimeters diameter. Although the coil explodes, because of the symmetry of the explosion, cryostat and sample remain intact. The second concept is to compress a large volume magnetic field into a small volume. Fields up to 500 T can be achieved through electromagnetic flux compression, and well above 1000 T through flux compression with explosives. In both cases, the peak field is achieved in a few microseconds, and the sample is destroyed at this moment.

MAGNET LABORATORIES FOR USERS

It may have become clear from the above that design, construction and operation of high-field magnets is a very challenging and also very costly task, requiring considerable efforts in manpower and installations. It is therefore obvious that a few specialized laboratories of significant size have developed with the goal of serving a broad user community. In the following we give a short overview of the most important laboratories. A detailed review can be found in Herlach and Perenboom (1995).

Continuous Magnetic Fields

It is interesting to realize that the number of laboratories where magnetic fields are used as a research tool has grown considerably over the last several years, accompanied by a more than proportional growth of publications in this area. The strong trend toward higher fields, made possible by new investments (Tallahassee, Tsukuba, Grenoble, and Nijmegen), and the development and evolution of new technologies and materials, will continue. A large and growing user community takes advantage of these central facilities, which are well-equipped with magnets in the 20- to 45-T range, along with the necessary scientific instrumentation (Crow et al., 1996). At present, the development goal is 50 T as the highest continuous field.

Superconducting magnets are now available up to 20 T, and many laboratories employ such a system. We list here only laboratories which can offer continuous fields above 25 T with resistive and hybrid magnets. These are: High Magnetic Field Laboratory, Grenoble, France; Nijmegen High Field Magnet Laboratory, Nijmegen, The Netherlands; High Field Laboratory for Superconducting Materials, Sendai, Japan; National High Magnetic Field Laboratory, Tallahassee, Florida, U.S.A.; and Tsukuba Magnet Laboratories, Tsukuba, Japan.

Pulsed Magnetic Fields

Pulsed magnetic fields represent an economical access to high fields in the 50- to 80-T range. Worldwide, many laboratories provide assistance and support a user program. Experimentation has become easier through the development of new techniques, such as digital data recording and miniaturization. Ultralow temperatures and extreme high pressures have been combined successfully with pulsed fields (Herlach, 1985). The most remarkable development is a 100-T system that will generate pulses in the 10- to 20-ms range, a factor of over 1000 above existing systems (Baca et al., 1999).

There are ~30 laboratories worldwide that do experimental work in pulsed magnetic fields, and which provide assistance to users. We list here only a subgroup, selected from Herlach and Perenboom (1995), which provide fields above 60 T. These are: Fachbereich Physik, Humboldt Universität, Berlin, Germany; H.H. Wills Physics Laboratory, University of Bristol, Bristol, U.K.; Katholieke Universiteit Leuven, Leuven, Belgium; National High Magnetic Field Laboratory, Los Alamos, New Mexico, U.S.A.; Research Center for Extreme Materials, Osaka University, Osaka, Japan; Princeton Plasma Physics Laboratory, Princeton University, Princeton, New Jersey, U.S.A.; National Pulsed Magnet Laboratory, University of New South Wales, Sydney, Australia; Megagauss Laboratory, Institute for Solid State Physics, Tokyo, Japan; Service National des Champs Magnétiques Pulsés, CNRS, Toulouse, France; and Tsukuba Magnet Laboratories, NRIM, Tsukuba, Japan.

A few laboratories provide fields above 100 T. These are: Fachbereich Physik, Humboldt Universität, Berlin, Germany; National High Magnetic Field Laboratory, Los Alamos, New Mexico, U.S.A.; Scientific Research Institute of Experimental Physics, VNIIEF, Sarov, Russia; Pulsed Magnetic Field Installation, Russian Academy of Science, St. Petersburg, Russia; and Megagauss Laboratory, Institute for Solid State Physics, Tokyo, Japan.

MEASUREMENTS OF MAGNETIC FIELDS

The knowledge about the strength and direction of a magnetic field is essential for the following three main purposes.

1. Calibration of a magnet as function of another parameter, typically the magnet current, so that it can be used for its application. The result also tells the magnet engineer how much the constructed magnet corresponds to its design values.
2. Determination of the magnetic environment of a sample to be investigated. Magnetic fields are used as a tool to measure the dependence of some parameters as a function of the applied magnetic field. Therefore, the investigator has to verify, through measurements, the properties of the desired field, e.g., strength, direction, homogeneity, and stability. Equally important for reference measurements is the knowledge of the zero field environment when the magnet is switched off. Magnetization of ferromagnetic parts, for instance, as housing or support structure, can produce noticeable low-field contributions.
3. Fringe fields of magnets have an impact on electronic devices and machinery. The knowledge of their existence is required to initiate and determine the necessary amount of countermeasures, such as

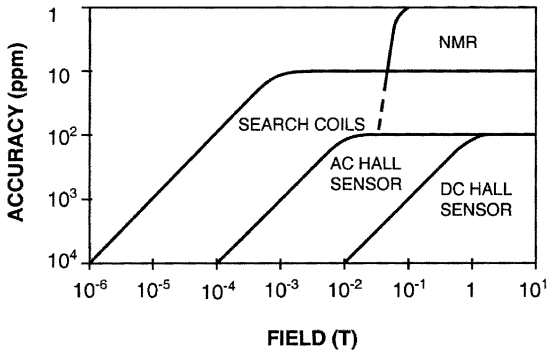

Figure 12. The main measurement methods for magnetic fields and their accuracy and field range. (After Henrichsen, 1992.)

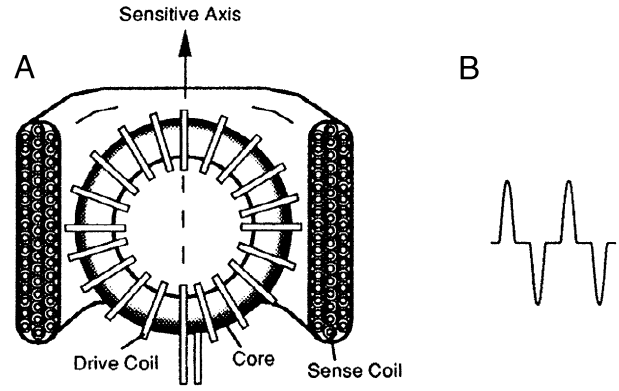

Figure 13. (**A**) Magnetometer with a toroidal core and (**B**) output pulses. (After Fraden, 1993.)

shielding or orientation with respect to the field lines. Fringe fields of high-field magnets can be important, especially with magnets with large bore diameters. Safety measures must be considered for health reasons (pacemakers, for instance), and the force on ferromagnetic parts, like chairs, racks, tools, or gas bottles. The space around a magnet, therefore, has to be cleared carefully of any apparatus and must be cordoned off as a restricted area for the protection of personnel.

The following describes a selection of important measuring devices of magnetic fields. We start the discussion with low-field devices: the compass and the flux-gate magnetometer. We then concentrate on medium-to-high-field measuring techniques: search coils, Hall sensors, and NMR devices. The Hall sensor is the singularly most important, and the most commonly used, device in the measurement of magnetic fields; as such we provide a more detailed description of a new development, the silicon Hall sensor. Figure 12 is a comparison of the most important measurement methods in view of their accuracy and effective useful field range (Henrichsen, 1992).

A large variety of instruments are commercially available for the measurement of magnetic fields.

Low-Field Sensors

Fringe Field Sensors. The existence of low magnetic fields, such as fringe fields of magnets or the fields of magnetized parts, can easily be demonstrated by a simple device: the magnetic compass. The magnetic compass was invented in China about 2500 B.C. and played a role in navigation as early as the 10th century A.D. For a simple demonstration of fringe fields, a screwdriver suspended on a thin thread works well. This can also serve as an indicator of the direction of the field lines and be used for a visual field mapping.

Another simple method to detect low magnetic fields is the monitor of a computer. Black and white cathode ray tube (CRT) monitors change their pattern at ~1 mT; color CRT monitors change their colors at about half that value and therefore, are also a very simple way to check for fringe fields.

Flux-Gate Magnetometer. The flux-gate magnetometer can be utilized for accurate measurements of weak magnetic fields. It is based on a ferromagnetic core with a rectangular hysteresis curve on which detection and excitation coils are wound. Whenever magnetic flux lines are drawn inside the ferromagnetic core, a pulse is induced in the detection coil. A pulse of opposite sign occurs when flux lines are pulled out. The amplitudes of these pulses are directly proportional to the flux intensity; their polarity indicates the direction of the flux lines. The alternate excitation current drives the core into and out of saturation. Figure 13 shows a magnetometer with a toroidal core. It has the advantage that the excitation flux cannot induce current in the sense coil. Flux-gate magnetometers offer linear measurement of the field and its direction, and are especially well suited for the detection of weak stray fields around magnets. Sensitivity can be as low as 20 pT. Commercial devices offer ranges of ~1 mT with a resolution of 1 nT.

High-Field Sensors

Hall Effect Sensors. The Hall effect is a galvanomagnetic effect that occurs by the interrelationship between the electrical currents flowing in a material that is being subjected to a magnetic field (see DEEP-LEVEL TRANSIENT SPECTROSCOPY). It can best be exploited in semiconductor materials in which a high carrier mobility and a low free carrier concentration is achievable. The force F on a free charge carrier with charge e in a semiconductor is driven by the electric field F_E and deflected by the Lorentz force F_L, which acts perpendicular to the direction of the motion and the magnetic flux density

$$\mathbf{F} = \mathbf{F}_E + \mathbf{F}_L = e\mathbf{E} + e[\mathbf{v} \times \mathbf{B}] \tag{19}$$

If a plate-shape piece of semiconductor material in the xy plane carries a current I in the x direction, then an applied flux density B in the z direction produces a transverse electric field in the y direction, the Hall field (Fig. 14).

The integral of this Hall field over the plate can be measured at its outer edges as the Hall voltage, V_H, and

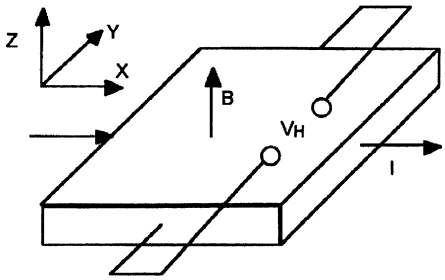

Figure 14. The Lorentz force acting on moving charge carriers in a semiconductor plate causes them to build up an electric field which can be measured by the Hall voltage.

is approximately proportional to the product of the flux density B and the current I

$$V_H = S_H IB \tag{20}$$

Magnetometers/Compound Semiconductor Sensors. A typical Hall effect magnetometer, often called a gaussmeter, incorporates several circuits and controls: a current supply for the sensor, an amplifier with sufficient gain to raise the level of the sensor output to drive an analog/digital converter, zero and calibration adjustments, and analog and/or digital display and voltage output, and either analog or digital signal processing hardware, as well as software to compensate for probe-temperature effects, nonlinearities, and voltage offsets. To date, the most commonly used Hall probes have been based on Hall generators made of compound semiconductors such as InSb and especially InAs. Such generators have a sensitivity S_H (as defined by Equation 20) ranging from 50 mV/AT to 3 V/AT, and enable the gaussmeter to offer full-scale ranges from 30 μT to 30 T, with an accuracy in the 0.1% to 1% range and a precision as high as 10 ppm full scale. Several versions of these Hall elements have been used to measure magnetic fields as high as ~34 T and at temperatures as low as 1.5 K (Rubin et al., 1975, 1986).

Theoretically, a high carrier mobility is crucial for achieving high sensitivity, low offset, and low noise. However, the application of the compound semiconductor Hall elements also implies some drawbacks, such as long-term instability and high-temperature cross-sensitivity. To overcome these difficulties, nowadays high-precision magnetometers are increasingly based on silicon Hall generators.

Silicon Hall Sensors. Although silicon is not a high-carrier-mobility material, it offers many other advantages that make up for this drawback. The doping is usually n-type, with a density around $10^{15}/cm^3$, so that at room temperature the device can be considered as strongly extrinsic. Large-series fabrication of these devices and the application of highly sophisticated and mature silicon technology result in narrow tolerances for the parameters. Moreover, the parasitic effects in these devices are well understood and can be described by simple equations. These characteristics allow efficient means to develop structural and analog electronic compensation of all parasitic effects. A typical value for the proportionality factor (equivalent to sensitivity) S_H, in a modern silicon device is 400 V/AT.

The Integrated Vertical Hall Sensor. Whereas early devices were made as bulk or thin-film discrete components, modern Hall sensors are made using highly advanced semiconductor integration technology, making large numbers of high-quality devices available at low cost. In addition, the sensors can be manufactured as buried devices featuring low noise and very good long-term stability. Their extremely small dimensions make them especially suitable for measurements with high spatial resolution, even in highly inhomogeneous fields.

Besides integrated Hall plates with conventional geometry, the above-described technology also made it possible to implement a sensor measuring the magnetic flux density parallel to the chip surface. In the vertical Hall device (Popovic, 1995), the general plate shape is chosen in such a way that all electrical contacts become available at the surface of the chip. Its geometry evolves from the conventional shape, applying a conformal mapping method where all angles are conserved along with the galvanomagnetic effects mentioned before (Fig. 15). Such devices are adapted to fabrication by integrated technology in an almost perfect way, since the main sources for noise and offset can be reduced to a minimum, yielding highly accurate magnetic sensors. These structures have also been realized to measure two or three components of the magnetic field synchronously in the same spot (Schott and Popovic, 1999), making them suitable for highly demanding tasks like scanning or controlling fields in rather complex magnetic systems.

Even in a modern vertical Hall magnetic sensor, the proportionality between the electrical output signal and the field applied on the device is not ideal. This is due to physical effects within the material of the active zone (charge carrier transport phenomena) as well as the structural composition of the device (depletion zones, surface effects) and the tolerances of the fabrication process itself (mask misalignment, gradients in doping profile). When working at high accuracy, all of these effects have to be taken into account. This can be achieved by applying two different compensation strategies: internal and external. Internal compensation eliminates the influences of offset and of voltage-dependent modulation of the active zone. It is based on mutual cancellation of parasitic effects by adding them with opposite sign.

External compensation eliminates the remaining quadratic temperature cross-sensitivity and the problem of nonlinear behavior in stronger fields. The Hall device follows simple equations with these parameters, so that the analog electronic compensation function can easily be synthesized. Operating the Hall devices in constant

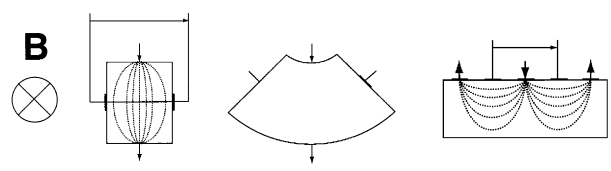

Figure 15. Derivation of the vertical Hall device by conformal mapping of Figure 14.

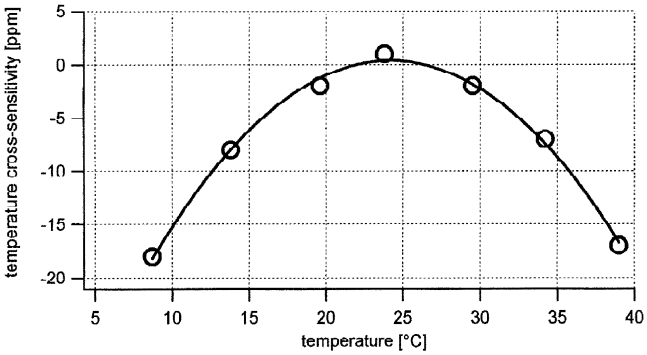

Figure 16. Dependence of sensitivity on temperature. A typical vertical Hall device varies $<5 \times 10^{-5}$ within ± 10 K around room temperature.

current mode allows for implementing all external compensation through bias-current modulation.

Temperature Cross-sensitivity. The Hall factor for electrons in n-type silicon around room temperature increases $\sim 0.1\%$/K. The device's input resistance also rises linearly with temperature. Profiting from this fact, the Hall device itself can be used as a temperature sensor. A simple resistor, put in parallel with the device's input resistance, compensates perfectly for first-order temperature dependence. The less critical remaining parabolic drop of sensitivity with temperature is eliminated by adding a corresponding supplementary current to the biasing current. As a result, sensitivity stays constant over a wide temperature range (Fig. 16).

Offset. Offset in integrated sensors is mainly due to doping nonuniformity and mask misalignment during the fabrication process. According to the Hall device circuit model (Popovic, 1995), offset can be put down to an asymmetry of the resistances between the current contacts and the Hall contacts. Therefore, it is directly correlated to the material resistivity, causing it to rise with temperature and, due to the magnetoresistance effect, also with magnetic field. Since it cannot be distinguished from the output signal resulting from a dc or slowly varying magnetic field, it has to be compensated internally. A first, coarse compensation is provided by the probe's structure (Fig. 17). Two

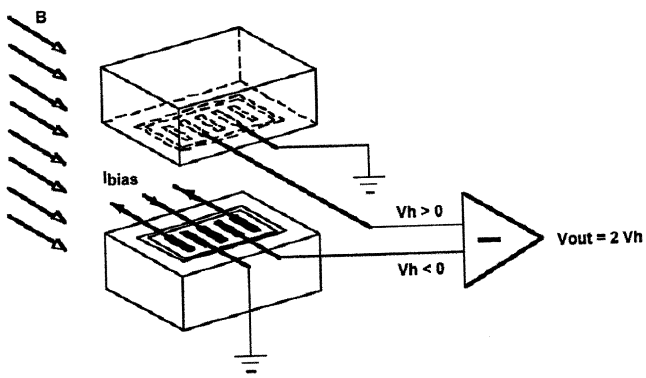

Figure 17. Two Hall devices, oriented in the field so that the Hall voltages are opposed, allow for direct compensation of offset and active zone modulation.

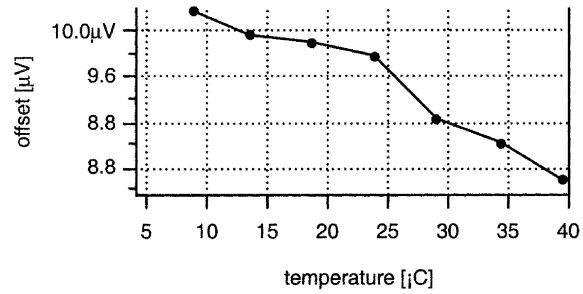

Figure 18. Dependence of the offset on temperature. The equivalent offset field in the specified temperature range from 15 to 35°C is <10 µT.

Hall devices, preferably neighboring elements from the wafer, are subjected to the same parameters during the fabrication process, and therefore, have similar offset. When mounted in such a way that they see an applied field in opposite directions, the value of the measured field can be extracted by subtracting their Hall voltages. This value contains only a very small residual offset, which is the difference in offset between both devices. Compensation of this residual offset makes use of the good correlation between offset drift and input voltage drift with temperature. It consists of subtracting a fraction of the input voltage from the output Hall voltage by electronic means. After the application of these methods, the remaining offset and its drift with temperature are limited to a minimum (Fig. 18).

Nonlinearity. Nonlinearity of Hall devices is described by the variation of sensitivity with the magnetic field H

$$\mathrm{NL} = (S_\mathrm{H} - S_{\mathrm{H}_0})/S_{\mathrm{H}_0}, \qquad \text{where} \quad S_\mathrm{H} = \Delta V_\mathrm{H}/\Delta B \quad (21)$$

Three different sources of nonlinearity can be distinguished. Two of them are technology-independent and described as material nonlinearity and geometry-related nonlinearity. These two depend on the same physical parameters in a similar way, so that they can be used for mutual cancellation in an adapted design. Residual nonlinearity is compensated by modulating the bias current through the Hall elements in a polynomial manner with the applied field, so that field transducers with linearity as good as 0.01% in fields up to 2 T can be produced. The third effect is of specific interest in buried devices like the vertical Hall device. In order to decrease leakage current and border effects, the active zone of the vertical Hall device is surrounded by a depletion layer, formed by a reverse-polarized pn-diode. Its thickness depends on the potential difference between the diode's p and n contacts. This causes the active volume to change in shape and the device to change in sensitivity with a rising Hall or input voltage, just as in a junction-field-effect transistor. However, these effects are significantly reduced when appropriate means for biasing are applied (Schott and Popovic, 1997) or by using two devices seeing the magnetic field in opposite direction.

Magnetoresistive Sensors. There are several materials that change their resistivity in a magnetic field. At low

temperatures, some materials like bismuth change their resistance by a factor of 10^6. The effect is caused by the Lorentz force, which forces the electrons to move on curved paths between collisions and thereby increases the resistivity. In contrast to the Hall effect sensor, the magnetoresistor, when made as a III-V semiconductor (InSb) can be divided into small, long connected strips. This results in a high initial resistance of 50 to 1000 Ω. Only small currents are needed, with the additional advantage that it is only a two-terminal device. Magnetoresistors are inexpensive and have wide industrial applications. They have proven to be useful for scientific measurements; with temperature stabilization an accuracy of 0.1% can be achieved (Weld and Mace, 1970; Brouwer et al., 1992).

Search Coils. Search coils are flux meters that consist of a pick-up coil and an integrator. The pick-up or search coil is exposed to a changing magnetic field. The induced voltage V is proportional to the change of the flux Φ threading the coil, i.e., its number of turns, N, and the coil area, A.

$$V = -NA\frac{dB}{dt} \tag{22}$$

With an NA of 1 m^2, a field change of 1 T will generate 1 V. The coil can be inserted in a field, i.e., moved from a place with $B = 0$ to the place where the field is to be measured, or vice versa. The difference between the two measurements will give a good indication of the accuracy of the chosen setup. In the case of a solenoid, a search coil is moved from a shielded space ($B = 0$) outside the magnet to the center, and the voltage is measured via an integrator. The coil is then moved back into the shielded space, and the voltage is measured again. In a perfect setup, both measurements should give the same result. Obvious requirements are that the induced voltages in the leads be negligible, and that the mechanical positioning of the coil and its angle with the field at the magnet center be precise. There are alternate solutions to the described method, which are to place the coil in the magnet center and ramp the magnet, or to flip the coil around its axis perpendicular to the magnetic field vector.

The accuracy of the search coil method depends on the knowledge of NA and the characteristics of the integrator. Commercially available fluxmeters incorporate state-of-the-art electronic integrators with drifts as low as ±1 μV/min. In addition to dc field measurement, they can measure ac fields at frequencies up to 100 kHz; the accuracy is several percent. For high-accuracy measurements, special attention must be paid to temperature control of the integrator, shielding, low-frequency noise, thermal voltages, and geometry changes of the search coil due to insertion into cryogenic fluids. Very high accuracies may be obtained with differential measurement techniques wherein a pair of search coils is connected in opposition with one coil moving and the other one fixed. Magnet current fluctuations can be eliminated this way. A large variety of search coil geometries and complex harmonic coil systems have been developed. For instance, the flux ball (Brown and Sweer, 1995) makes it possible to perform point measurements in inhomogeneous fields.

A search coil may also be rotated at some frequency, ω, and an ac voltage will develop. The value of B can then be determined by measuring either the peak-to-peak voltage, rms or with a phase-sensitive detector. The complete system is called a rotating-coil gaussmeter and is commercially available.

Search coils or pick-up coils are the ideal way to measure pulsed fields. Because of the high fields and the short times, relatively high voltages are generated and attention has to be given to insulation. For integration, simple passive RC integrators matching the cable impedance can be used.

Nuclear Magnetic Resonance. Nuclear magnetic resonance is a technique that can measure the magnitude of magnetic fields to high precision, down to parts per billion (NUCLEAR MAGNETIC RESONANCE IMAGING). In commercial NMR systems an important subsystem is the field frequency NMR lock. This device uses NMR signals to detect and control the drift of the magnetic field, measure and eliminate variations in the magnetic field intensity across the sample, and measure the average field intensity at the sample position.

NMR measures the motion of nuclear magnetization in a magnetic field. The nuclear magnetization comes from the nuclei (i.e., hydrogen, phosphorus, sodium, and silicon, to name a few) that possess a magnetic moment μ ($\mu = \gamma I$ with γ gyromagnetic ratio, I nuclear angular momentum.) When nuclei having a magnetic moment are placed in a magnetic field, H, the nuclei align parallel to the field. The collection of aligned nuclear moments gives rise to a magnetic moment.

For a magnetic moment M in a uniform and static magnetic field H the equation of motion (Slichter, 1992) is

$$\frac{d\mathbf{M}}{dt} = \gamma[\mathbf{M} \times H] \tag{23}$$

The solutions to this equation are:

$$\begin{aligned} M_y(t) &= M_y(0)\cos(2\pi ft) + M_x(0)\sin(2\pi ft) \\ M_x(t) &= M_x(0)\cos(2\pi ft) - M_y(0)\sin(2\pi ft) \\ M_z(t) &= M_z(0) \end{aligned} \tag{24}$$

where x, y, and z refer to directions in the laboratory frame and the magnetic field is in the z direction. The frequency f is given by $\gamma|H|$. For typical magnetic fields of 1 to 30 T, the frequency is in the radiofrequency (rf) range, 1 MHz to 1 GHz.

The motion of the nuclear magnetization is precession about the magnetic field at the frequency γH. If the precessing magnetization occurs in a coil, a voltage is induced in the coil with the frequency f. The technically simple task of measuring the frequency of the induced voltage and a knowledge of the gyromagnetic ratio, γ, gives a measurement of $|H|$. The gyromagnetic ratio (γ) of a proton is 42.5759 [MHz/T]; it is known to an accuracy of better than 10^{-7}.

In the case of a slightly inhomogeneous field, the equations given above become

$$\begin{aligned} M_y(t) &= [M_y(0)\cos(2\pi ft) + M_x(0)\sin(2\pi ft)]G(t) \\ M_x(t) &= [M_x(0)\cos(2\pi ft) - M_y(0)\sin(2\pi ft)G(t)] \\ M_z(t) &= M_z(0) \end{aligned} \qquad (25)$$

where $G(t)$ is a function expressing the fanning out of the xy magnetization due to the distribution of magnetic fields in this inhomogeneous field. $G(t)$ is a direct measurement of the magnetic field homogeneity in the sample volume.

In the case of a time-varying magnetic field, the frequency given by $\gamma|H|$ will be time dependent. Slowly varying magnetic fields will be seen as a time dependence in the frequency f.

There are two commonly employed interferometric techniques to detect NMR signals: pulse and continuous wave (CW; Fukushima and Roeder, 1981). Both techniques make use of high-stability rf sources, with a stability of 10^{-8}/day.

In pulse NMR, the sample is irradiated with a short, intense rf pulse at the rf source frequency to nutate the magnetization away from the z axis and establish the precessing magnetization. Following the rf pulse, the voltage induced in the coil is detected, amplified, and mixed with the signal from the frequency source to yield a signal at the difference frequency, $f_{rf} - \gamma|H|$ (see NUCLEAR MAGNETIC RESONANCE IMAGING). This signal is digitized and analyzed, providing information about the magnitude, homogeneity, and time stability of the magnetic field.

In CW NMR, the sample is continuously irradiated with a low-level rf signal to maintain a precessing component of the magnetization and an audiofrequency magnetic field to modulate the magnetic field. Two coils aligned in quadrature, or balanced coils, are used to remove or reduce the irradiating rf signal. The resulting signal from the precessing magnetization is amplified and mixed with the rf source signal to yield a signal that is then further demodulated in a lock-in amplifier. The lock-in amplifier output signal can be analyzed for information about the magnitude, homogeneity, and time stability of the magnetic field.

The biggest limitation to using NMR in measuring magnetic fields is that the field must be reasonably homogeneous and stable. The spatial variations, field gradients, temporal variations, and field fluctuations must be less than 0.01%. NMR is not usually done in fields less than 1 T because the signal intensity is proportional to the square of the field. There is no limit to the largest fields that can be measured by NMR. The technical problems of the high frequencies due to large fields are circumvented by choosing nuclei with a lower γ.

MAGNETIC MOMENT AND MAGNETIZATION

INTRODUCTION

The intrinsic magnetic properties of materials refer to

1. the origin, magnitude, and directions of atomic magnetic dipole moments;
2. the nature of the interaction between atomic magnetic dipole moments on neighboring atoms in the solid;
3. whether these result in collective magnetic phenomena; and
4. the resulting temperature dependence of the magnetization.

Materials exhibiting collective magnetic response possess additional intrinsic magnetic properties, including the strength of the coupling of magnetic moments to one another and to crystallographic directions, magnetoelastic coupling coefficients, and the temperature(s) at which magnetic phase transformations occur. The intrinsic magnetic properties of species at surfaces and interfaces are known to be distinctly different from those of the bulk in many cases. In the following discussion, we briefly review the theory of intrinsic magnetic properties, specifically of dipole moment and magnetization, as well as theory and examples of collective magnetic response.

MAGNETIC FIELD QUANTITIES

A discussion of the magnetic properties of materials begins with the definition of macroscopic field quantities. The **magnetic induction** (flux density), **B**, is related to the magnetic field, **H**, through the relationship

$$\mathbf{B} = \mu_0\mathbf{H}(\text{in SI units}) \quad \text{or} \quad \mathbf{B} = \mathbf{H}(\text{in cgs units}) \qquad (1)$$

where μ_0 is the **permeability of the vacuum**, which is taken as 1 in cgs units. (Henceforth, we will drop the SI and cgs annotations, which should be understood where two alternative equivalent forms of the same relation are given). In a magnetic material, the magnetic induction can be enhanced or reduced by the material's **magnetization** (defined as dipole moment per unit volume) so that

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) \quad \text{or} \quad \mathbf{B} = \mathbf{H} + 4\pi\mathbf{M} \qquad (2)$$

where the magnetization, **M**, is expressed in linear response theory as

$$\mathbf{M} = \chi_m\mathbf{H} \qquad (3)$$

where χ_m is called the "magnetic susceptibility." We can further express the induction $\mathbf{B} = \mu_r\mathbf{H}$ as

$$\mathbf{B} = \mu_0(1 + \chi_m)\mathbf{H} \quad \text{or} \quad \mathbf{B} = (1 + 4\pi\chi_m)\mathbf{H} \qquad (4)$$

and we see that the relative permeability μ_r can be expressed as

$$\mu_r = \mu_0(1 + \chi_m) \quad \text{or} \quad \mu_r = 1 + 4\pi\chi_m \qquad (5)$$

Where μ_r represents an enhancement factor of the flux density in a magnetic material. If we have $\chi_m < 0$ we speak of **diamagnetism** and $\chi_m > 0$ (and no collective magnetism) **paramagnetism**.

The definition of magnetization as magnetic dipole moment per unit volume suggests that discussion of a material's magnetization involves identification of the microscopic origin of the dipole moments as well as the

number of dipole moments per unit volume. In the following, we discuss five common origins of magnetic dipole moments. These include

1. dipole moments due to diamagnetic (orbital) currents in closed shells;
2. local magnetic dipole moments due to the Hund's rule ground state of atoms or ions with unfilled outer electronic shells;
3. itinerant electron magnetic dipole moments due to the splitting of spin-up and spin-down energy bands;
4. dipole moments due to atomic clusters (in spin glasses and superparamagnets); and
5. dipole moments due to macroscopic shielding currents in superconductors.

ATOMIC ORIGIN OF MAGNETIC DIPOLE MOMENTS

Closed and Core Shell Diamagnetism: Langevin Theory of Diamagnetism

Diamagnetism is an atomic magnetic response due to closed outer-shell orbits and core electrons. In our discussion of diamagnetism, we consider atomic moments. If we have a collection of like atoms, all of which have the same atomic moments, then the magnetization can be described as:

$$\mathbf{M} = N_a \mu_{atom} \tag{6}$$

where $\mathbf{M}$ is the magnetization vector, N_a is the number of dipole moments per unit volume, and μ_{atom} is the atomic dipole moment vector.

The classical picture of core and closed outer-shell diamagnetism begins with the physical interpretation of a dipole moment. The dipole moment of an orbiting electron has a magnitude IA where I is the "current" in the closed loop electronic orbit and $A = \pi r_2$ is the area swept out by the orbiting electron with orbital radius r. The magnetic dipole moment μ is directed normal to this area. Recognizing that $\mathbf{J}dV = Idr$, and $\mathbf{J}$ is the current density, the dipole moment is equivalently expressed as

$$\mu_{orbit} = \int \mathbf{r} \times \mathbf{J}\, dV \tag{7}$$

Now, if we wish to construct an atomic magnetic dipole moment we must consider the moment due to Z electrons that orbit the nucleus. Assuming that all Z electrons orbit the nucleus with the same angular frequency, ω_0, then we express the current, I, associated with charge $q = Ze$ as

$$I = \frac{dq}{dt} = \frac{Ze\omega_0}{2\pi} \tag{8}$$

The orbital atomic magnetic dipole moment is

$$\mu_{orbit} = \frac{Ze\omega_0}{2} \langle r^2 \rangle \tag{9}$$

where $\langle r^2 \rangle$ is the expectation value of r^2 for the orbit. Finally,recognizing that the angular momentum vector is expressed as $\mathbf{L} = \mathbf{r} \times m\mathbf{v}$, (where m is the electron mass and $\mathbf{v}$ its velocity vector) and has magnitude $mvr = m\omega_0 r^2$ again directed orthogonal to the current loop, then we express a fundamental relationship between magnetic dipole moment and the angular momentum vector

$$\boldsymbol{\mu}_{orbit} = \frac{e}{2m}\mathbf{L} \quad \text{or} \quad \boldsymbol{\mu}_{orbit} = \frac{e}{2mc}\mathbf{L} \tag{10}$$

We can also express a spin dipole moment associated with spin angular momentum.

The previous arguments will give us the ammunition we need to discuss permanent atomic dipole moments that are central to the phenomenon of paramagnetism. In general, however, for closed shells, although electrons do orbit the nuclei, the net current associated with their motion is 0 because of cancellation of their summed orbital angular momentum (i.e., $\mathbf{L} = 0$). On the other hand, even for a closed shell, in the presence of an applied field we do induce a net current. By **Lenz's law** this current results in a moment that opposes the applied field. The characteristic frequency of this circulating induced current is called the "Larmor frequency" and has the value

$$\omega_L = \frac{eB}{m} \text{ or } \frac{eB}{mc} \tag{11}$$

We can calculate the induced moment as the current multiplied by the area, recognizing that different electrons can be in different orbits, and therefore we calculate the expectation value of the square of the orbital radius as

$$\langle R^2 \rangle = \langle x^2 \rangle + \langle y^2 \rangle + \langle z^2 \rangle \tag{12}$$

Now for an isotropic environment

$$\langle x^2 \rangle = \langle y^2 \rangle = \langle z^2 \rangle = \frac{\langle R^2 \rangle}{3} \tag{13}$$

where the induced moment is thus given by

$$\mu_{induced} = -\frac{Ze}{2}\left(\frac{eB}{m}\right)\frac{\langle R^2 \rangle}{3} = \frac{Ze^2B}{6m}\langle R^2 \rangle \tag{14}$$

$\langle R^2 \rangle$ is the expectation value of r^2 averaged over all orbits; the negative sign reflects Lenz's law. This may be associated with the negative diamagnetic susceptibility (for N atoms/volume)

$$\chi + \frac{N\mu_{induced}}{B} + \frac{-NZe^2}{6m}\langle R^2 \rangle \tag{15}$$

which well describes the diamagnetism of core electrons and of closed-shell systems. Typically, molar diamagnetic susceptibilities are on the order of $\chi_m = 10^{-6}$ to 10^{-5} cm^3/mol.

Atomic and Ionic Magnetism: The Origin of Local Atomic Moments

In discussion to this point, we have described angular momentum due to orbital motion and spin. Both of these angular momentum terms give rise to magnetic dipole moments and in both cases the magnetic dipole moments are quantized. These magnetic dipole moments will be crucial to the future discussion of magnetism. The physical description of a magnetic dipole moment is in terms of an electron current (circulating) multiplied by the area of the current loop that, in turn, can be related to the quantity $(e/2m)$ multiplied by the angular momentum vector

$$\mu = \frac{e}{2m}\Pi \quad \text{or} \quad \mu = \frac{e}{2mc}\Pi \tag{16}$$

where Π is a generic angular momentum vector. In the classes both of orbital and spin angular momentum the angular momentum is quantized, i.e., its projections along the field axis, z, have an eigenvalue that takes on integral or half-integral values. For orbital angular momentum

$$L_z = m_l\hbar \quad \text{and} \quad \mu = l\left(\frac{e\hbar}{2m}\right)$$
$$l = 0, 1, 2, 3 \ldots \tag{17}$$

The quantity $(e\hbar/2m)$ takes on special significance as the fundamental unit of magnetic moment that is called the "Bohr magneton"

$$\mu_B = \left(\frac{e\hbar}{2m}\right) = 9.27 \times 10^{-24} \text{ amp-m}^2 \tag{18}$$

In addition to the orbital moment of an electron, it is also possible to have an additional contribution to the magnetic moment of an electron, i.e., that due to spin. Spin is a quantum mechanical property, although we can view it semiclassically if we consider the electron as a particle with a rotating surface current. If we considered this problem classically, we would arrive at a spin moment identical to that which is derived in the quantum mechanical description, exactly 1 μ_B. The spin angular momentum is quantized as $S = 1/2$ and its possible projections on the z-axis of the chosen coordinate system (i.e., the field axis) are $m_s = \pm 1/2$. The two spin eigenvalues are denoted spin up and spin down, respectively.

Insight into the filling of atomic orbitals, and especially spectral assignments, can be gained by exploring Hund's rules. This allows us to fully describe the ground state multiplet including the m_l and m_s eigenstates, and allows us to calculate the total orbital, **L**, total spin, **S**, and overall total angular momentum, **J**. The magnitudes of the total orbital and spin angular momenta are constructed as quantum mechanical sums of the angular momentums over a multielectron shell containing n electrons

$$L = \sum_{i=1}^{n} (m_l)_i S = \sum_{i=1}^{n} (m_S)_i \tag{19}$$

The magnitude of the total angular momentum vector $(\mathbf{J} = \mathbf{L} + \mathbf{S})$, J, is given by: $J = |L - S|$ for less than half-filled shells and $J = |L + S|$ for greater than half-filled shells.

To determine the occupation of eigenstates of **S**, **L**, and **J**, we use Hund's rules. For a closed electronic shell $\mathbf{J} = \mathbf{L} = \mathbf{S} = 0$. For an open-shell atom: (1) Fill m_s states $(2l + 1 - \text{fold degenerate})$ in such a way as to maximize total spin, and (2) fill m_l states so as to maximize $|\mathbf{L}|$. To illustrate these rules, consider the ions of the transition metal series, TM^{2+}, i.e., ions that have given up $2s$ electrons to yield the $3d^n$ outer-shell configuration shown in Figure 1. The ground state J, L, and S quantum numbers for rare earth, RE^{3+}, ions are shown in Figure 1.

In conventional paramagnetic response we consider atomic dipole moments that are permanent and arise from unfilled electronic shells. Another type of paramagnetic response, *Pauli paramagnetism*, is associated with

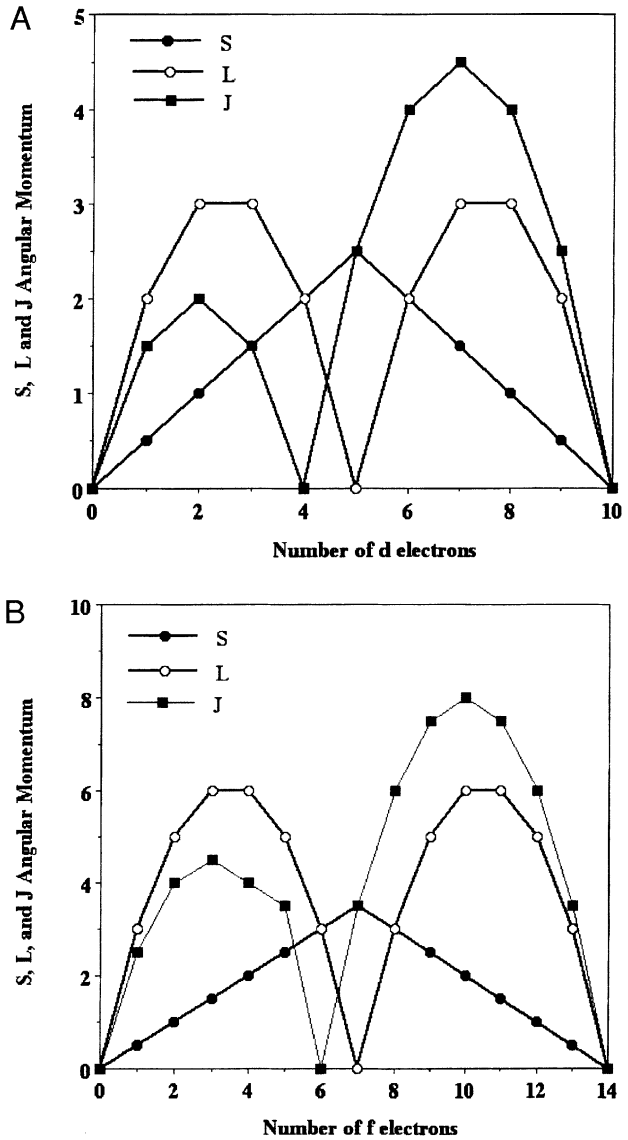

Figure 1. Ground state J, L, and S quantum numbers for the (**A**) transition metal ions, TM^{2+}, and (**B**) rare earth ions, RE^{3+}.

itinerant electrons in energy bands. Paramagnetic response is distinguished from ferromagnetic response in that there is no internal field present to align the permanent local atomic moments in the absence of an applied field. We can understand the origin of the atomic magnetic dipole moment present for paramagnetic atoms by considering again Hund's rules for unfilled shells. The (orbital) angular momentum operator can be expressed as

$$\mathbf{L} = \frac{\hbar}{i}(\mathbf{r} \times \nabla) \tag{20}$$

For a single electron, the magnitude of $\mathbf{L}$ is quantized as in Equation 17, $\mathbf{L} = l[*\hbar(l = 0, 1, 2\ldots)$ and the orbital magnetic dipole moment is also quantized in integer multiples of μ_B. To determine the occupation of states, and therefore $\mathbf{S}$, $\mathbf{L}$, and $\mathbf{J}$, for a given open-shell multielectron atom, we use Hund's rules. Examples of Hund's rules ground states for transition metals (TM) and rare earth (RE) ions are shown in Table 1, including $L = |\mathbf{L}|, S = |\mathbf{S}|$, and $J = |\mathbf{J}|$ angular momenta for each element.

Describing L, S, and J for a given element is termed determination of the ground-state multiplet. This multiplet is written more compactly using the spectroscopic term symbol

$$^{2S+1}L_J \tag{21}$$

where L is the alphabetic symbol for orbital angular momentum ($L = 0 \equiv S$, $L = 1 \equiv P$, $L = 2 \equiv D$, $L = 3 \equiv F$, etc.) and $2S + 1$ and J are the numerical values of the same. For example, Cr^{3+} with $L = 3, S = 3/2$ and $J = 3/2$ would be assigned the term symbol: $^4F_{3/2}$. We can further relate the permanent local atomic moment with the total angular momentum, $\mathbf{J}$, quantum number

$$\mu = \gamma\hbar\,\mathbf{J} = -g\mu_B\mathbf{J} \tag{22}$$

where γ is called the "gyromagnetic factor" and $g = g(J, L, S)$ is called the "Lande g-factor" and is given by

$$g = g(J, L, S) = \frac{3}{2} + \frac{1}{2}\left[\frac{S(S+1) - L(L+1)}{J(J+1)}\right] \tag{23}$$

The Lande g factor accounts for the precession of the angular momentum components (Fig. 2). For identical ions with angular momentum J we can define an effective magnetic moment in units of μ_B

$$p_{\text{eff}} = g(J, L, S)[J(J+1)]^{1/2} \tag{24}$$

For certain solids (e.g., transition metal solids) the orbital angular momentum can be quenched as a result of crystal

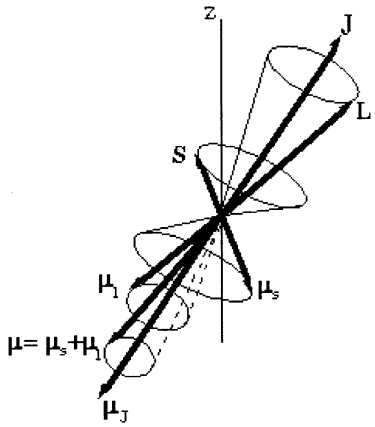

Figure 2. Vector (analogous to planetary orbit) model for the addition of angular momentum with spin angular momentum precessing around the orbital moment that precesses about the total angular momentum vector. The parameter z is the field axis (axis of quantization).

field effects. This implies $L = 0$ and that only spin angular momentum needs to be considered, i.e., $J = S$. In this case $g = 2$ and $p_{\text{eff}} = 2[S(S+1)]^{1/2}$. The addition of angular momentum is conveniently explained by the vector addition diagram of Figure 2.

Collective Magnetism

In magnetic materials, the field and temperature dependence of the magnetization is determined by the nature of the coupling of the atomic magnetic dipole moments. In the case of paramagnetism, the local dipole moments are uncoupled, resulting in a Curie law dependence of the magnetic susceptibility (see Introduction). Ferromagnetic response is an example of correlated or collective magnetism. To describe ferromagnetism we can start with the premise (as was the case for paramagnetism) of **permanent local atomic dipole moments** or consider an **energy band picture of the magnetic state**. Unlike the case for paramagnetic response, however, ferromagnetic response is distinct in that oriented magnetic dipole moments remain coupled even in the absence of an applied field. As a result, a ferromagnetic material possesses a nonzero or **spontaneous magnetization**, $\mathbf{M}_s$, over a macroscopic volume, called a "domain," containing many atomic sites, even for $\mathbf{H} = 0$. Ferromagnetism is said to be a collective phenomenon, since individual atomic moments interact so as to promote alignment with one another. The interaction between individual atomic moments, which gives rise to the collective phenomenon of ferromagnetism, has been explained alternately by two models as follows.

1. **Mean-Field Theory** considers the existence of a nonlocal internal magnetic field, called the Weiss field, which acts to align magnetic dipole moments even in the absence of an applied field, $\mathbf{H}_a$.
2. **Heisenberg Exchange Theory** considers (usually) a local (often nearest neighbor) interaction between atomic moments (spins), which acts to align adjacent moments even in the absence of a field.

Both of these theories will be considered below, since both capture the essence of the phenomenon of ferromagnetism. The two theories do lead to somewhat different pictures of certain aspects of the collective phenomena and the ferromagnetic phase transformation. Both theories lend themselves to quite convenient representations of other collective magnetic phenomena such as antiferromagnetism, ferrimagnetism, helimagnetism, etc. An understanding of the nature of the coupling of magnetic dipole moments allows for the description of the field and temperature dependence of the magnetization as discussed below.

The Band Theory of Magnetism

The **band theory of solids** considers the broadening of localized atomic states with discrete eigenvalues into a continuum of states for more itinerant electrons over a range of energies. The theory allows for calculation of energy dispersion (i.e., energy as a function of wave vector) and orbital-angular-momentum-specific and spin-resolved densities of states. The calculation of spin-resolved energy bands and densities of states allows for the description of atom-resolved magnetic dipole moments and therefore spontaneous magnetization of elemental and alloy magnetic solids. Among the successes of the band theory description of magnetic properties are the following:

1. The prediction of nonintegral or half-integral atomic dipole moments and resulting ground state magnetizations in metals and alloys.
2. The prediction that band widths and **exchange splittings** (energy differences between spin-up and spin-down bands) are intimately dependent on magnetic coordination number and atomic volume.

Table 2 summarizes 0 K and room temperature (where applicable) magnetizations and atomic dipole moments for some important transition metal and rare earth elemental magnets. Also shown are **Curie temperatures** (ferromagnetic ordering temperatures, discussed below) which are not ground-state properties directly calculable from band theory.

A simple schematic view of the band theory of solids and especially the existence of spin-polarized bands exists in the **Stoner theory** of magnetism. The Stoner model of ferromagnetism is equivalent to the free-electron model, with the added feature of spin polarized densities of states.

Table 2. Spontaneous and Room Temperature Magnetizations, Magnetic Dipole Moments, and Curie Temperatures for Elemental Ferromagnets

Element	M_s (Room Tem.)	M_s (0 K)	μ (0 K)/μ_B	T_c (K)
Fe	1707G	1740G	2.22	1043

Dy	—	2920G	10.2	88

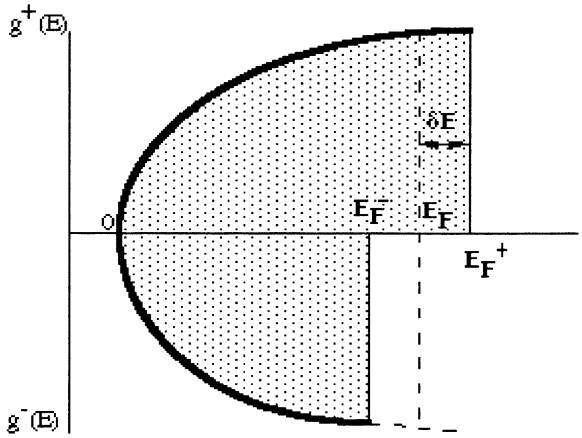

Figure 3. Spin-up and spin-down densities of states in the Stoner theory of ferromagnetism, taken to have a common zero of energy and different Fermi energies in the two spin bands.

With reference to their respective zeroes of energy, the spin-up and spin-down bands, respectively, are depicted in Figure 3, where E_F^+ and E_F^- are the spin-up and spin-down Fermi levels, respectively, E_F is the Fermi level in the non-spin-polarized state and $\delta E = E_F^+ - E_F = E_F - E_F^-$. Letting an exchange interaction energy between spin-up and spin-down electrons be

$$H_{ex} = Un_+n_- \tag{25}$$

where n_+ and n_- are as defined as spin-up and spin-down electron densities as in Equation 31, and U is the exchange energy. The magnetization is $M = (n_+ - n_-)\mu_B$. We define a reduced magnetization, $m = M/n\mu_B = (n_+ - n_-)/n$, and $n = n_+ + n_-$.

ΔE_M, the difference in exchange energy between the magnetic and the nonmagnetic states, can be expressed as

$$\Delta E_M = Un_+n_- - \frac{1}{4}Un^2m^2 \tag{26}$$

and is opposed by an increased kinetic energy:

$$\Delta E_K = \frac{1}{2}(n_+ - n_-)\delta E = \frac{1}{2}nm\delta E \tag{27}$$

where δE reflect the splitting (exhange) between the two spin bands. The total change in energy is given by

$$\Delta E_T = \frac{n^2m^2}{4g(E_F)}[1 - g(E_F)U] \tag{28}$$

so that the criterion for the stability of the magnetic state (determined by minimizing ΔE_T with respect to m) can be expressed as

$$g(E_F)U \geq 1 \tag{29}$$

Finally, the Pauli paramagnetic susceptibility in the Stoner theory is given by

$$\chi = R\chi_0 \tag{30}$$

where $\chi_0 = 2N\mu_0\mu B^2 g\ (E_F)$ is the 0 K susceptibility, N is the number of magnetic atoms per unit volume and $R = [1 - Ug(E_F)]^{-1}$ is the so-called **Stoner Enhancement factor**.

More sophsiticated band structure techniques use the so-called one-electron and local density approximations—e.g., the Layer Korring Kohn Rostoker (LKKR) technique (MacLaren et al., 1989), whose results we consider below. These treat the electronic potential more accurately, but still not at the level of consideration of all individual electron-electron interactions. These result, for example, in densities of states with more structure than in the simple free-electron model and in a more accurate description of the magnetic states in solids. A detailed discussion of band-structure techniques is beyond the scope of this unit. However, Figure 4 illustrates some examples of the results of band theory in describing magnetic dipole moments in solids.

Figure 4A shows the famous **Slater-Pauling curve** that illustrates the variation of the mean atomic magnetic dipole moment as a function of composition in transition metal alloy systems. Figure 4C and D show spin-resolved densities of states $g_+(E)$ and $g_-(E)$ for Co and Fe atoms, in an equiatomic FeCo alloy, as a function of energy (where the Fermi energy, E_F, is taken as the zero of energy). The number of spin-up, n_+, and spin-down, n_-, electrons in each band can again be calculated by integrating these densities of state

$$n_+ = \int_0^{E_F^+} g_+(E)dE \quad \text{and} \quad n_- = \int_0^{E_F^-} g_-(E)dE \tag{31}$$

The Fermi energies, E_F, are the same and the zeroes of energy different for the two spin bands. The atom-resolved (i.e., Fe or Co) magnetic dipole moments can be calculated as (where a unit volume density of states is implied)

$$\mu = (n_+ - n_-)\mu_B \tag{32}$$

Knowledge of atomic volumes or alloy density, then, allows for the direct calculation of the alloy magnetization. Figure 4B shows the band theory prediction of average dipole moment in $Fe_{1-x}Co_x$ alloys as a function of x to be in good quantitative agreement with the experimentally derived Slater-Pauling curve. It should be noted that the moments determined are spin-only moments. Thus, for good quantitative agreement, the orbital moments must also be included. These are expected to be small, however, since the orbital angular momentum is nearly quenched in $3d$ transition metal alloys. Thus, we would expect that the inclusion of the orbital moments could increase the total moment by approximately $0.1 - 0.2\,\mu_B$.

Spin Glass and Cluster Magnetism

Another distinct and interesting magnetic response occurs in **spin glass materials**. Spin glasses can show interesting manifestations of cluster magnetism as well as distinct collective magnetic response. If we consider dilute magnetic impurities in a non-magnetic host, the previously

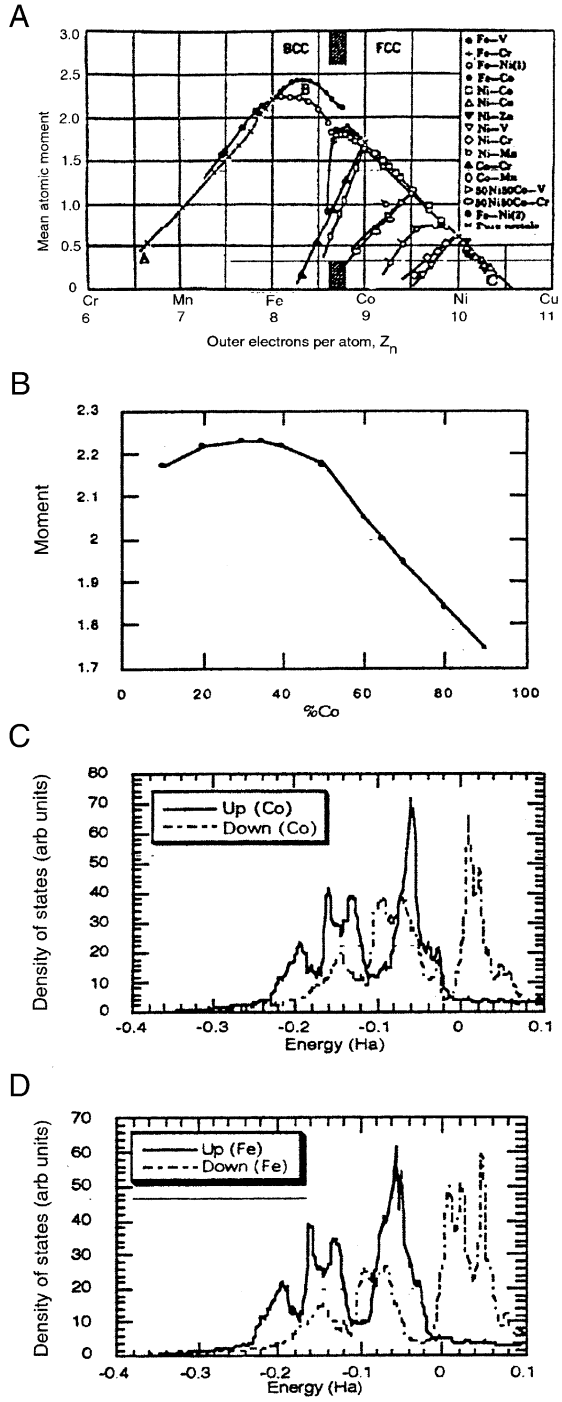

Figure 4. (**A**) Slater-Pauling curve for TM alloys. (After Bozorth.) (**B**) Spin-only Slater-Pauling curve for the ordered Fe-Co alloy as determined from LKKR band structure calculations. Density of states for Co (**C**) and Fe (**D**) in the ordered equi-atomic alloy (MacLaren et al., 1999). The Fermi level is taken as the zero of energy.

discussed theory of paramagnetism can be used to describe local moments and the temperature dependence of the magnetization for noninteracting moments. If, however, the local dipole moments couple though exchange or dipolar interactions, then a distinct "frozen" magnetic state can arise with cooperative or collective magnetism, which has features similar to ferromagnetic or antiferromagnetic states, but with other manifestations that are decidedly distinct. The current view in the evolving description of spin glasses is that the glassy or frozen state constitutes a new state of magnetism.

A spin glass is a magnetic system in which the geometric arrangement of magnetic ions, frozen in structural disorder, and/or random exchange interactions result in "frustration". Frustration refers to the inability of the magnetic moment configuration on a given magnetic site to simultaneously satisfy the constraints of exchange interactions with neighboring atoms. As a result, traditional long-range ferromagnetic or antiferromagnetic long range order is not possible in spin glasses. Below a freezing (spin glass) transition temperature, T_g, an ordered state is said to exist. The precise description of this state is still controversial, although a variety of universal experimental observations identify the spin glass state. These include the following.

1. A large difference between the field cooled and zero-field cooled magnetizations (in low fields) for temperatures below the spin glass freezing temperature, T_g.
2. Strong magnetic hysteresis below the spin glass transition temperature.
3. A peak (cusp) in the alternating current (ac) magnetic susceptibility.
4. A change in the magnetic heat capacity at T_g.

Spin glass behavior can also involve interactions between clusters of magnetic atoms with a distinct "cluster moment" as opposed to an atomic dipole moment. In such a case the previous arguments made based on atomic dipole moments need only be modified to consider cluster dipole moments. Figure 5 illustrates several experimental manifestations of spin glass response in an Al-Mn-Ge quasicrystalline alloy. These include different field cooled (FC) and zero-field cooled (ZFC) susceptibilities, magnetic relaxation, a cusp in the ac susceptibility, and magnetic contributions to the specific heat below the spin glass freezing temperature.

Magnetization of Superconductors

Superconductivity is the unique and complicated phenomenon in which the "free" electrons in a conductor pair up and move cooperatively below a critical temperature, T_c, called the "superconducting transition temperature." This pairing constitutes a magnetic phase transition involving only the electrons in the superconducting material (i.e., atom positions do not change below T_c). Paired electrons are able to correlate their motion with the vibrating crystalline lattice (phonons) so as to avoid electronic scattering by the lattice. This is accompanied by remarkable changes in both the electrical transport and the magnetic properties of the superconducting material. Notable among these changes are the loss of electrical resistivity below T_c, and exclusion of magnetic flux (the **Meissner effect**).

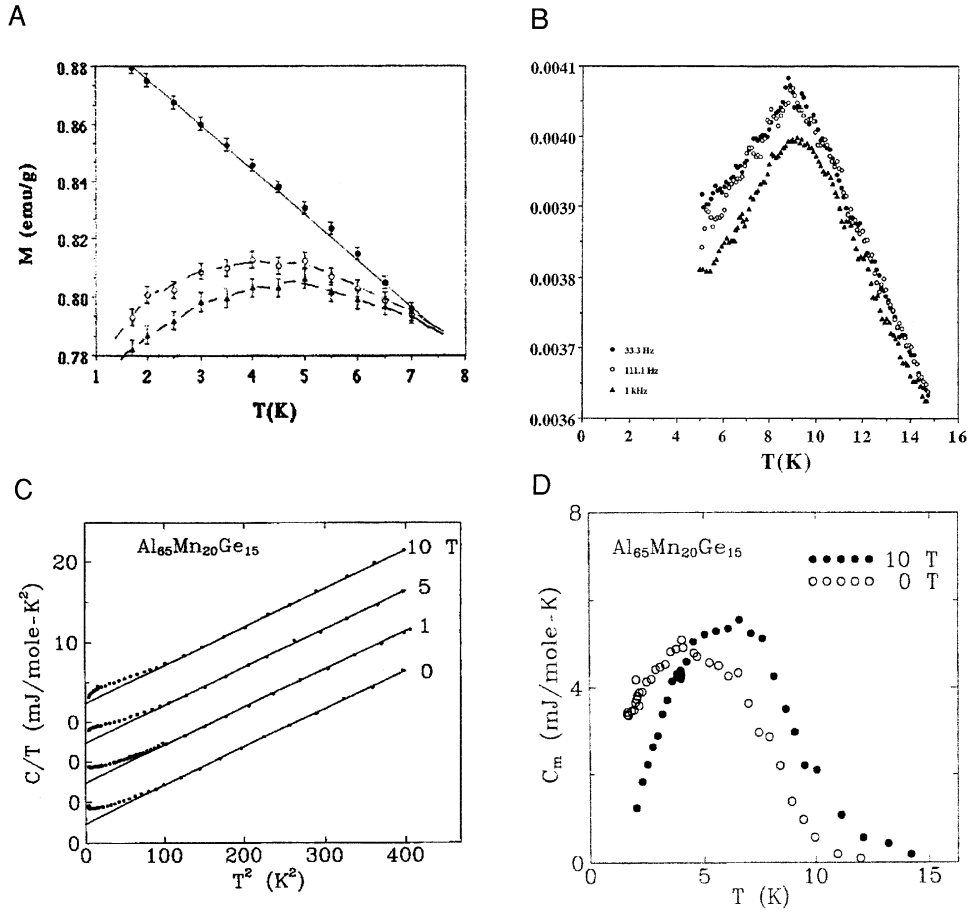

Figure 5. (**A**) Low T field cooled (filled circles) and zero field cooled [after 1 s (filled triangles) and 180 s (open circles)] susceptibilities for $Al_{65}Mn_{20}Ge_{15}$ showing spin glass freezing at a temperature $T_g \approx 8$ K. (**B**) The real component of the ac susceptibility, χ', (arbitrary units) as a function of T, $H = 10$ Oe rms and $\omega = 33.3$, 111.1 and 1000 Hz, respectively, showing a cusp (or maximum) in $\chi'(T)$. (**C**) Specific heat versus T plotted as C/T versus T^2 at 0, 1, 5, and 10 T. The data have been vertically offset for clarity. Solid lines indicate the nonmagnetic background specific heat; (**D**) The magnetic specific heat C_M plotted versus T at $H = 0$ (open circles) and 10 T (solid circles). Data from Hundley et al. (1992).

A fundamental experimental manifestation of superconductivity is the Meissner effect (exclusion of flux from a superconducting material). This observation preceded and motivated the development of London electrodynamics (London and London, 1935; London, 1950). The Meissner effect identifies the superconducting state as a true thermodynamic state and distinguishes it from perfect conductivity. This is illustrated in Figure 6, which compares the magnetic flux distribution near a perfect conductor and a superconductor, respectively, for conditions where the materials are cooled in a field (FC) or for cooling in zero-field (ZFC) with subsequent application of a field. Note the difference between flux density distributions for a perfect conductor and superconductor when field cooled. After zero-field cooling, however, the superconductor and perfect conductor have the same response. Both the perfect conductor and superconductor exclude magnetic flux lines in the ZFC case. This can be understood as resulting from diamagnetic screening currents which oppose dB/dt in accordance with Lenz's law. It is the first case, that of field cooling, that distinguishes a superconductor from a perfect conductor. As illustrated, the flux profile in a perfect conductor does not change on cooling below a hypothetical temperature where perfect conductivity occurs (since there is no dB/dt). On the other hand, a superconductor expels magnetic flux lines upon

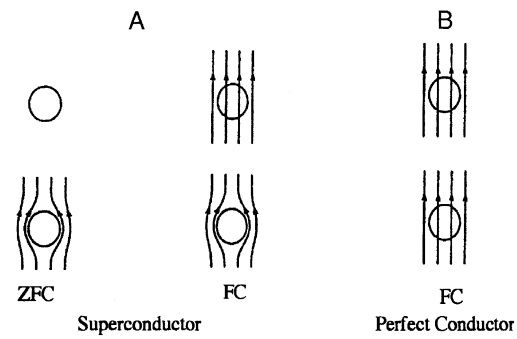

Figure 6. Flux densities for a superconductor, (**A**), zero-field cooled (ZFC) or field-cooled (FC) to $T < T_c$ and for a perfect conductor, (**B**), which is field cooled (FC).

field cooling, distinguishing the superconducting state from perfect conductivity. The extent to which field is excluded in a real type II superconductor (see below) is determined by magnetic flux pinning. In a clean superconductor (i.e., without pinning), flux is excluded to maintain $B = 0$ in the superconductor. This Meissner effect implies that:

$$\mathbf{B} = 0 = \mathbf{H} + 4\pi M \tag{33}$$

or that the magnetic susceptibility, $\chi = M/H = -1/4\pi$ for a superconductor.

Equilibrium superconductors are also distinguished by their critical magnetic field, H_c. At any temperature below the critical temperature, there is a critical magnetic field above which the superconductor becomes a normal conductor with finite resistance. Thus, if a magnetic field is applied to the superconducting sample, the shielding currents increase to maintain perfect diamagnetism and, at a critical value of the magnetic field, the sample becomes a normal conductor. The critical magnetic field of a superconductor varies with temperature, reaching a maximum at 0 K.

It should be noted that two distinct types of superconductors have been found. Until this point we have focused on type I superconductors, which lose superconductivity at $H_c(T)$. In a type I superconductor, perfect diamagnetism is observed until $H = H_c(T)$ where superconductivity (and diamagnetism) is abruptly lost. There is a second type of superconductor that goes through a mixed state with the application of a field, where some areas are superconducting while regions at the core of magnetic vortices (flux lines) are normal. These are called type II superconductors and the higher-temperature superconductors belong to this group. Type II superconductors were not recognized as being another class of superconductors until the work of Abrikosov (1957). A type II superconductor has perfect diamagnetism until a critical field called the lower critical field, H_{c1}. However, unlike a type I material, superconductivity does not disappear at H_{c1}. Instead, the superconducting and normal states coexist (by virtue of entrance of quantized magnetic vortices—flux lines—into the material) in equilibrium until another critical field, the upper critical field, H_{c2}, is reached where superconductivity is lost entirely.

The coexistence of the superconducting and normal states in the so-called mixed state is accomplished by letting single (quantized) magnetic flux lines into the sample for $H > H_{c1}$. Figure 7 shows the magnetic phase diagram for a type I and type II superconductor. In practical superconductors, it is important to pin these magnetic flux lines so that they do not dissipate energy by motion resulting from a Lorentz force interaction with the supercurrent density. In the newly discovered high-temperature superconductors, anisotropic crystal structures and short superconducting coherence lengths make a **vortex melting transition**, $H^*(T)$, possible that adds further complexity to the H-T phase diagram.

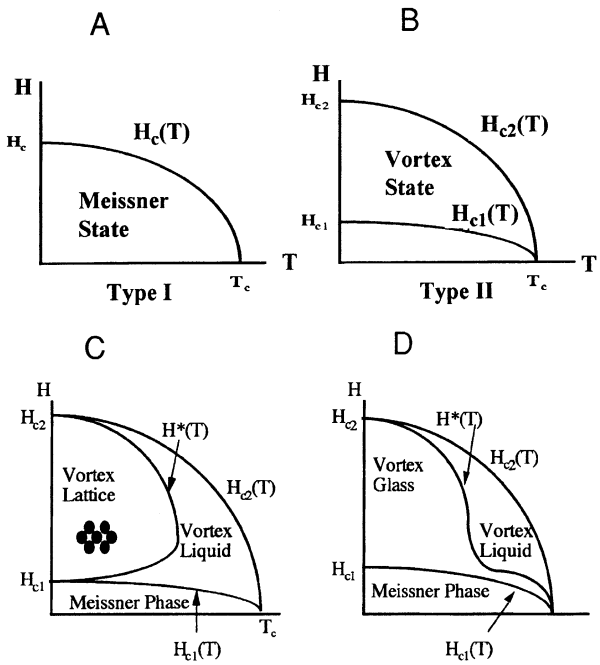

Figure 7. (**A**) Magnetic phase diagram for a type I superconductor; (**B**) magnetic phase diagram for a type II superconductor; (**C**) magnetic phase diagram for a type II superconductor with vortex melting to a vortex liquid state; and (**D**) magnetic phase diagram for a type II superconductor with a vortex glass state (McHenry and Sutton, 1994).

COUPLING OF MAGNETIC DIPOLE MOMENTS

Classical and Quantum Theories of Paramagnetism

Paramagnetism results from the existence of permanent magnetic moments on atoms as discussed above. In the absence of a field, a permanent atomic dipole moment arises from the incomplete cancellation of the electron's angular momentum vector. In a paramagnetic material in the absence of a field, the local atomic moments are uncoupled. For a collection of atoms in the absence of a field, these atomic moments will be aligned in random directions so that $\langle \mu \rangle = 0$ and therefore $\mathbf{M} = 0$. We now wish to consider the influence of an applied magnetic field on these moments. Consider the induction $\mathbf{B}$ in our paramagnetic material arising from an applied field $\mathbf{H}$. Each individual atomic dipole moment has a potential energy in the field $\mathbf{B}$ given by

$$U_p = -\mu \cdot \mathbf{B} = -\mu B \cos\theta \tag{34}$$

The distinction between the classical and quantum theories of paramagnetism lies in the fact that continuous values of θ, and therefore continuous projections of $\mathbf{M}$, on the field axis are allowed in the classical theory. In the quantum theory only discrete values of θ and projected moments, μ, are allowed, consistent with the quantization of angular momentum. The quantum theory of paramagnetism is discussed in the next section. Notice that in either case the potential energy predicted by Equation 34 is minimized when local atomic moments and induction, $\mathbf{B}$, are parallel.

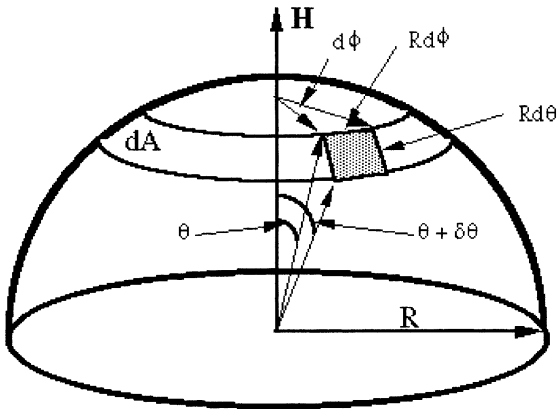

Figure 8. Distribution of magnetic dipole moment vector angles with respect to the field axis.

We are now interested in determining the temperature-dependent magnetic susceptibility for a collection of local atomic moments in a paramagnetic material. In the presence of an applied field, at 0 K, all atomic moments in a paramagnetic material will align themselves with the induction vector, **B**, so as to lower their potential energy, U_{p}. At finite temperatures, however, thermal fluctuations will cause misalignment, i.e., thermal activation over the potential energy barrier leading to a temperature dependence of the susceptibility, $\chi(T)$. To determine $\chi(T)$ for a classical paramagnet, we express the total energy of a collection of atomic magnetic dipole moments as

$$U_{\mathrm{p}}^{\mathrm{total}} = \sum_{atoms,i} -\mu_{\mathrm{m}}^{\mathrm{atom}}(\mu_0 \mathrm{H})\cos\theta_{\mathrm{i}} \tag{35}$$

where θ_{i} is the angle between the ith atomic dipole moment and B. If we consider (1) a field along the z axis, and (2) the set of vectors $\mathrm{n}_i = \mu/|\mu_i|$, which are unit vectors in the direction of the ith atomic moment, then to determine $\chi(T)$ we wish to discover the temperature distribution function of the angle θ_i. The probability of a potential energy state being occupied is given by Boltzman statistics

$$p = C\exp\left[\frac{-E_p}{kT}\right] = C\exp\left[\frac{-\mu_{\mathrm{m}}^{\mathrm{atom}}(\mu_0 \mathrm{H})\cos\theta}{k\mathrm{T}}\right] \tag{36}$$

where $p = p(E_{\mathrm{p}}) = p(\theta)$. As shown in Figure 8, the number of spins for a given θ at $T = 0\,\mathbf{K}, H = 0$ is given by $dn = 2\pi sin\theta\, d\theta$, since all angles are equally probable. At finite T, H

$$dn = C\exp\left[\frac{-\mu_{\mathrm{m}}^{\mathrm{atom}}(\mu_0 \mathrm{H})\cos\theta}{kT}\right]2\pi\sin\theta\, d\theta \tag{37}$$

and

$$N = \int_0^{\pi} dn \tag{38}$$

gives the number of spins. We calculate the average projected moment (along the axis of **B**) as

$$\langle\mu_{\mathrm{m}}^{\mathrm{atom}}\rangle = \frac{\int_0^{2\pi}\mu\cos\theta\, dn}{\int_0^{2\pi} dn} = \frac{\int_0^{2\pi} C\exp\left[\frac{-\mu_{\mathrm{m}}^{\mathrm{atom}}(\mu_0 \mathrm{H})\cos\theta}{kT}\right]\mu_{\mathrm{m}}^{\mathrm{atom}}\cos\theta\cdot 2\pi\sin\theta d\theta}{\int_0^{2\pi} C\exp\left[\frac{-\mu_{\mathrm{m}}^{\mathrm{atom}}(\mu_0 \mathrm{H})\cos\theta}{kT}\right]2\pi\sin\theta d\theta} \tag{39}$$

and using the substitution $a = -\mu_{\mathrm{m}}^{\mathrm{atom}}\,\mu_0 \mathrm{H}/kT$, then

$$\frac{\langle\mu_{\mathrm{m}}^{\mathrm{atom}}\rangle}{\mu_{\mathrm{m}}^{\mathrm{atom}}} = \frac{\int_0^{2\pi}\exp[a\cos\theta]\cos\theta\sin\theta\, d\theta}{\int_0^{2\pi}\exp[a\cos\theta]\sin\theta\, d\theta} \tag{40}$$

and evaluation of the integrals reveals

$$\frac{\langle\mu_{\mathrm{m}}^{\mathrm{atom}}\rangle}{\mu_{\mathrm{m}}^{\mathrm{atom}}} = \coth(a) - \frac{1}{a} = L(a) \tag{41}$$

where $L(a)$ is called the Langevin function. The Langevin function has two interesting attributes as illustrated in Figure 9

$$(1)a \overset{\lim}{\to} \infty L(a) = 1 (2) a \overset{\lim}{\to} 0 \frac{dL(a)}{da} = \frac{1}{3} \tag{42}$$

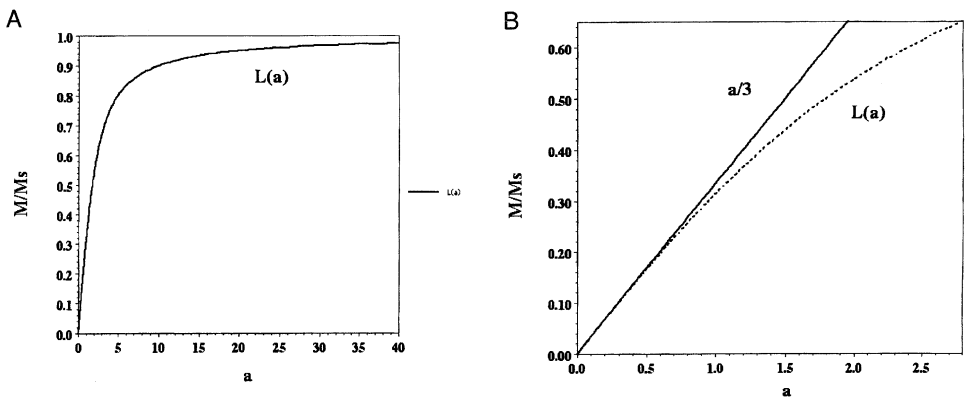

Figure 9. (**A**) Langevin function and (**B**) its low-temperature limiting form.

To calculate the magnetization we remember that M is defined as the total dipole moment per unit volume (we are interested in the component of **M** parallel to **B**), thus

$$\mathbf{M} = N_{\mathrm{m}}\langle\mu_{\mathrm{m}}^{\mathrm{atom}}\rangle = N_{\mathrm{m}}\mu_{\mathrm{m}}^{\mathrm{atom}}L(a) \tag{43}$$

where N_{m} is the number of magnetic dipoles per unit volume. In the large a limit $L(a) = 1$, and we infer that the saturation magnetization, M_{s}, is given by

$$M_{\mathrm{s}} = N_{\mathrm{m}}\mu_{\mathrm{m}}^{\mathrm{atom}} \tag{44}$$

and

$$M = M_{\mathrm{s}}L(\mathrm{a}) \tag{45}$$

in the low a limit (low field, high temperature), $L(a) \sim a/3$ and

$$M = M_{\mathrm{s}}\left(\frac{1}{3}\frac{\mu_0\mu_{\mathrm{m}}^{\mathrm{atom}}}{k}\right)\cdot\frac{H}{T} \tag{46}$$

and

$$\chi = \frac{M}{H} = \frac{N_{\mathrm{m}}\mu_0(\mu_{\mathrm{m}}^{\mathrm{atom}})^2}{3kT} = \frac{C}{T} \tag{47}$$

which is the Curie law of paramagnetism. Notice that if we know N_{m} (the concentration of magnetic atoms) from an independent experimental measurement, then an experimental determination of $\chi(T)$ allows us to solve for C as the slope of χ versus $1/T$ and therefore $\mu_{\mathrm{m}}^{\mathrm{atom}}\cdot\mu_{\mathrm{m}}^{\mathrm{atom}}$ is associated with the local effective moment as given by Hund's rules.

To further describe the response of the **quantum paramagnet**, we again consider an atom left with a permanent magnetic dipole moment, μ, due to its unfilled shells. We can now consider its magnetic behavior in an applied field. The magnetic induction, **B**, will serve to align the atomic dipole moments. The potential energy of a dipole oriented at an angle θ with respect to the magnetic induction is given by Equation 34 to yield

$$U_{\mathrm{p}} = -\boldsymbol{\mu}\cdot\mathbf{B} = -\mu\mathrm{B}\cos\theta = g\mu_{\mathrm{B}}\mathbf{J}\cdot\mathbf{B} \tag{48}$$

Now, our quantum mechanical description of angular momentum tells us that $|J_z|$, the projection of the total angular momentum on the field axis must be quantized, i.e.:

$$U_{\mathrm{p}} = (g\mu_{\mathrm{B}})m_{\mathrm{J}}\mathrm{B} \tag{49}$$

where $m_{\mathrm{J}} = J, J-1\ldots -J$ and $J = |\mathbf{J}| = |\mathbf{L}+\mathbf{S}|$ may take on integral or half-integral values. In the case of spin only, $m_{\mathrm{J}} = m_{\mathrm{s}} = \pm 1/2$. The quantization of J_z requires that only certain angles θ are possible for the orientation of μ with respect to **B**. The ground state corresponds to $\boldsymbol{\mu}\|\,\mathbf{B}$. However, with increasing thermal energy it is possible to misalign μ so as to occupy excited angular momentum states. If we consider the simple system with spin only we can consider the Zeeman splitting for spin only. Where eigenstates are split by $\mu_{\mathrm{B}}B$, the lower-lying state corresponds to $m_{\mathrm{J}} = m_{\mathrm{s}} = -1/2$ with the spin moment parallel to the field. The higher energy state corresponds to $m_{\mathrm{J}} = m_{\mathrm{s}} = 1/2$ and an antiparallel spin moment. For this simple two level system we can use Boltzmann statistics to describe the population of these two states. Now, if we have N such isolated atoms per unit volume in a field then we can define

$$N_1 = N_{\uparrow} = D\exp\left[\frac{\mu_{\mathrm{B}}B}{kT}\right] N_2 = N_{\downarrow} = D\exp\left[\frac{-\mu_{\mathrm{B}}B}{kT}\right] \tag{50}$$

where D is an unspecified constant. Recognizing that $N = N_1 + N_2$. Finally the net magnetization (dipole moment/volume) is then $M = (N_1 - N_2)\,\mu$ or

$$M = \frac{N}{D(e^x + e^{-x})}\cdot D(e^x - e^{-x})\mu = N\mu\frac{e^x - e^{-x}}{e^x + e^{-x}} = N\mu\ \tanh(x) \tag{51}$$

where $\mathrm{x} = \mu_{\mathrm{B}}B/kt$ notice that for small values of x, tanh(x) $\sim x$ can approximate μ

$$M = N\frac{\mu^2 B}{kT} \quad \text{and} \quad \chi = \frac{M}{B} = \frac{N\mu^2}{kT} \tag{52}$$

This expression relating χ to $1/T$ is called the "paramagnetic Curie law."

For the case where we have both spin and orbital angular momentum, we are interested in the J quantum number and the $2J+1$ possible values of M_J, each giving a different projected value (J_z) of **J** along the field (z) axis. In this case we no longer have a two level system but instead a $(2J+1)$-level system. The $2J+1$ projections are equally spaced in energy. Considering a Boltzmann distribution to describe thermal occupation of the excited states, we find that $\mu\cdot\mathbf{B} = (J_z/J)\mu_{\mathrm{B}}B$, and

$$\mu = \sum_j \frac{J_z}{J}\mu_{\mathrm{B}}\exp\left[\frac{J_{\mathrm{Z}}}{J}\frac{\mu_{\mathrm{B}}B}{kT}\right]$$

and

$$N = \sum_J \exp\left[\frac{J_{\mathrm{Z}}}{J}\frac{\mu_{\mathrm{B}}B}{kT}\right] \tag{53}$$

so that finally

$$M = N\mu = \frac{\sum_j \frac{J_{\mathrm{Z}}}{J}\exp\left[\frac{J_{\mathrm{Z}}}{J}\frac{\mu_{\mathrm{B}}B}{kT}\right]}{\sum_j \exp\left[\frac{J_{\mathrm{Z}}}{\mathrm{J}}\frac{\mu_{\mathrm{B}}B}{kT}\right]} = N_g J\mu_{\mathrm{B}}B_{\mathrm{j}}(x)\left(x = \frac{gJ\mu_{\mathrm{B}}B}{kT}\right) \tag{54}$$

where $B_J(x)$ is called the Brillouin function and is expressed

$$B_{\mathrm{J}}(x) = \frac{2J+1}{J}\coth\left[\frac{(2j+1)x}{2J}\right] - \frac{1}{2J}\coth\left[\frac{x}{2J}\right] \tag{55}$$

Note that for $J = 1/2, B_J(x) = tanh(x)$ as before. Now for $x \ll 1$

$$B_J(x) \sim \frac{(2J+1)^2 - 1}{3(2J^2)} - \frac{J(J+1)}{3J^2}x \tag{56}$$

For small x, we then see that

$$\chi = \frac{M}{B} = \frac{Ng^2\mu_B^2 J(J+1)}{3kT} = \frac{np_{\text{eff}}^2}{3kT} \tag{57}$$

where $p_{\text{eff}} = g[J(J+1)]^{1/2}\,\mu_B$ is called the "effective local moment." Now this expression is again called a "Curie law" with

$$\chi = \frac{C}{T} \quad \text{and} \quad C = \frac{Np_{\text{eff}}^2}{3k} \tag{58}$$

Experimentally derived magnetic susceptibility versus T data can be plotted as $1/\chi$ versus T to determine C (from the slope) and therefore p_{eff} (if the concentration of paramagnetic ions is known). Figure 10 shows the behavior of M versus H/T for a paramagnetic material (GdC_x nanoparticles). At low temperature $M(x) \sim x/3$. $M(H)$ is well described by a Brillouin function with a characteristic H/T scaling bringing curves from different temperatures into coincidence.

Superparamagnetism is a form of cluster or fine particle magnetism in which the magnetic entities consist of large clusters or fine particles of magnetic atoms. Conventional internal magnetic order exists within the clusters (i.e., ferromagnetism, antiferromagnetism, etc.), but the clusters themselves need not be coupled for ferromagnetic techniques to measure magnetic ordering transitions. From the standpoint of magnetic dipoles and magnetization, superparamagnetic response differs in that the dipole moments are associated with the atoms in aggregate in the entire fine particle, and coupling with a field is determined using the conventional theory of paramagnetism, but with particle moments. Superparamagnetism is distinguished from cluster spin glass behavior in that no interaction between the fine particles is assumed in the former.

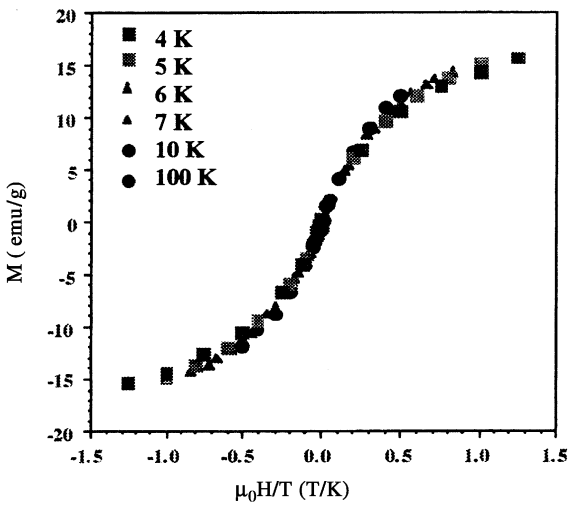

Figure 10. Magnetic response of Gd^{3+}ions in Gd_2C_3 nanocrystals exhibiting H/T scaling (Diggs et al., 1994).

Superparamagnetic response also concerns the probability of thermally activated switching of magnetic fine particle moments. This thermally activated switching can be described by an Arrhenius law for which the zero field activation energy barrier is $K_u\langle V\rangle$, where $\langle V\rangle$ is the particle volume and K_u is a (uniaxial) magnetic anisotropy energy density which ties the magnetization vector to a particular direction (crystallographic or otherwise). The switching frequency becomes larger for smaller particle size, smaller anisotropy energy density, and at higher T. Above a blocking temperature, T_B, the switching time is less than the experimental observation time, and net magnetization is lost, i.e. the coercive force becomes zero. Above T_B the magnetization scales with field and temperature in the same way as does a classical paramagnetic material, with the exception that the inferred dipole moment is a particle moment and not an atomic moment. $M(H,T)$ can be fit to a Langevin function, L, using the relation: $M/M_0 = L(x) = \coth(x) - 1/x$ where M_0 is the 0 K saturation magnetization and $x = \mu H/kT$. The particle moment, μ, is given by the product $M_s\langle V\rangle$ where M_s is the saturation magnetization and $\langle V\rangle$ is the average particle volume.

Below the blocking temperature, hysteretic response is observed for which the coercivity (field width of the magnetization curve) has a temperature dependence: $H_c = H_{c0}[1 - (T/T_B)^{1/2}]$. In the theory of superparamagnetism, the blocking temperature represents the temperature at which the metastable hysteretic response is lost for a particular experimental time frame. In other words, below the blocking temperature, hysteretic response is observed since thermal activation is not sufficient to allow the immediate alignment of particle moments with the applied field. For spherical particles with a uniaxial anisotropy axis, the rotational energy barrier to alignment is $K_u\langle V\rangle$. For hysteresis loops taken over ~ 1 h, the blocking temperature should roughly satisfy the relationship: $T_B = K_u\langle V\rangle/30k$. The factor of 30 represents $\ln(\omega_0/\omega)$, where ω is the inverse of the experimental time constant ($\sim 10^{-4}$ Hz) and ω_0 a switching attempt frequency (~ 1 GHz).

Ferromagnetism

Mean-Field Theory for Ferromagnets. We begin our discussion of ferromagnetism by introducing mean-field theory as introduced by Pierre Weiss in 1907. Weiss postulated the existence of an **internal magnetic field** (the Weiss field), $\mathbf{H}_{\text{INT}}$, which acts to align the atomic moments even in the absence of an external applied field, $\mathbf{H}_a$. The basic assumption of the mean field theory is that this internal field is nonlocal and is directly proportional to the magnetization of the sample

$$\mathbf{H}_{\text{INT}} = \lambda\mathbf{M} \tag{59}$$

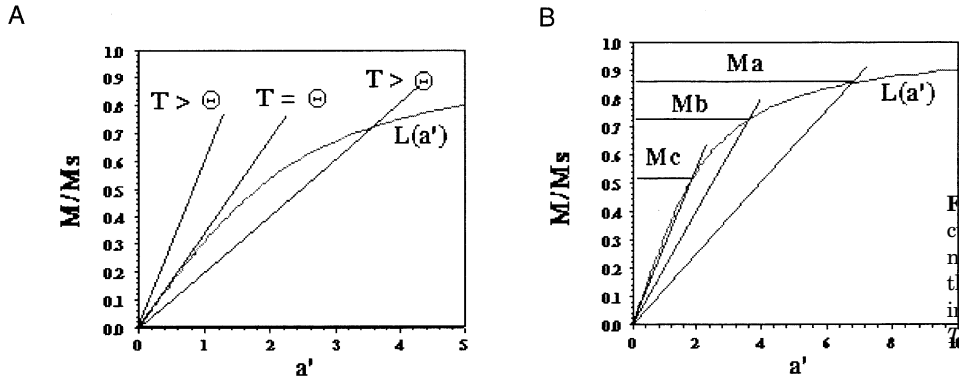

Figure 11. (**A**) Intersection between the curves 7.49a and 7.49b for $T < T_c$ gives a nonzero stable ferromagnetic state (**B**) the locus of $M(T)$ can be determined by intersections at various temperatures $T < T_c$.

where the constant of proportionality, λ, is called the "Weiss molecular field constant" (we can think of it as a crystal field constant). We now wish to consider the effects on ferromagnetic response of application of an applied field, $\mathbf{H}_a$, and the randomizing effects of temperature. We can treat this problem identically to that of a paramagnet, except that in this case we must now consider the superposition of the applied and internal magnetic fields. By analogy we conclude that

$$\langle \mu_m \rangle = \mu_m^{atom} L(\alpha') \tag{60}$$

where $\alpha' = \mu_0 \mu_m^{atom}[H + \lambda M]$, for a collection of classical dipoles. Also, $M_s = N_m \langle \mu_m^{atom} \rangle$ and

$$\frac{M}{N_m \mu_m^{atom}} = \frac{M}{M_S} = L\left\{\frac{\mu m \mu_0}{kT}[H + \lambda M]\right\} \tag{61}$$

where this rather simple expression represents a formidable transcendental equation to solve. Under appropriate conditions, this leads to solutions for which there is a nonzero magnetization (**spontaneous magnetization**) even in the absence of an applied field. We can show this graphically considering $M(H = 0)$ and defining the variables

$$\alpha' = \frac{\mu_m^{atom} \mu_0}{kT}(\lambda M) \tag{62}$$

which is dimensionless [and $M(0) = M_s L(\alpha')$] and

$$\Theta = \frac{N_m (\mu_m^{atom})^2 \mu_0 \lambda}{3k} \tag{63}$$

Notice that θ has units of temperature. Notice also that

$$\frac{\alpha'}{\Theta} = \frac{3}{T}\left(\frac{M(0)}{M_S}\right) \text{ so that : } \frac{M(0)}{M_S} = \frac{\alpha' T}{3\Theta} = L(\alpha') \tag{64}$$

The two equations for reduced magnetization represented in Equation 64 [i.e., $M(0)/M_s = \alpha' T/3\Theta$ and $M(0)/M_s = L(\alpha')$] can be solved graphically, for any choice of T by considering the intersection of the two functions $\alpha'/3(T/\Theta)$ and $L(\alpha')$. As is shown in Figure 11, for $T \geq \Theta$, the only solutions for which Equation 64 is simultaneously satisfied are when $M = 0$, i.e., no spontaneous magnetization and paramagnetic response. For $T < \Theta$ we obtain solutions with a nonzero, spontaneous, magnetization, the defining feature of a ferromagnet. For $T = 0$ to $T = \Theta$ we can determine the spontaneous magnetization graphically as the intersection of our two functions $\alpha'/3(T/\Theta)$ and $L(\alpha')$. This allows us to determine the zero-field magnetization $M(0)$ as a fraction of the spontaneous magnetization as a function of temperature. As shown in Figure 12, $m(t) = M(0, T)/M_s$, where $t = T/\Theta$, decreases monotonically from 1 at 0 K to 0 at $T = \Theta$, where Θ is called the **ferromagnetic Curie temperature**. At $T = \Theta$, we have a phase transformation from ferromagnetic to paramagnetic response, which can be shown to be second order in the absence of a field. In summary, mean-field theory for ferromagnets predicts the following:

1. For $T < \Theta$, collective magnetic response gives rise to a spontaneous magnetization even in the absence of a magnetic field. Spontaneous magnetization defines a ferromagnet.
2. For $T > \Theta$, the misaligning effects of temperature serve to completely randomize the direction of the atomic moments in the absence of a magnetic field. The loss of any spontaneous magnetization defines the return to paramagnetic response.

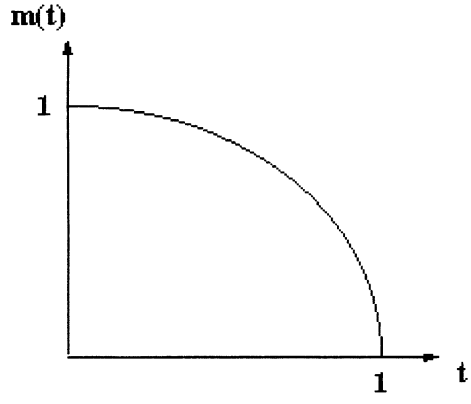

Figure 12. Reduced magnetization versus reduced temperature as derived from Figure 11.

3. In the absence of a magnetic field the ferromagnetic to paramagnetic phase transition is second order (it is first order in the presence of a magnetic field).

As a last ramification of the mean-field theory, we consider the behavior of magnetic dipoles in the paramagnetic state $T > \Theta$ with the application of a small field, H. We wish to examine the expression for the paramagnetic susceptibility $\chi(T) = M(H,T)/H$. Here again we can assume that we are in the small argument regime for describing the Langevin function so that

$$\frac{M(H,T)}{M_S} = L[\alpha'] = \frac{\alpha'}{3} = \frac{\mu_m^{atom}\mu_0}{3kT}(H + \lambda M) \tag{65}$$

and

$$M = \frac{\left[\frac{N_m(\mu_m^{atom})\mu_0}{3K}\right]H}{T - \frac{N_m(\mu_m^{atom})^2\mu_0\lambda}{3k}} = \frac{CH}{T-\Theta} \tag{66}$$

Thus the susceptibility, $\chi(T)$, is described by the so-called Curie-Weiss law

$$\chi = \frac{M}{H} = \frac{C}{T-\Theta} \tag{67}$$

where, as before, C is the Curie constant and Θ is the Curie temperature. Notice also that

$$\frac{\Theta}{C} = \lambda \tag{68}$$

It is possible to determine the size of the atomic moment and molecular field constant from high-temperature $\chi(T)$ data. Plotting $1/\chi$ versus T allows for determination of a slope ($= 1/C$), from which μ_m^{atom} can be determined, and an intercept, $-\Theta/C = -\lambda$. A further influence of a magnetic field on the magnetic phase transition is that the ferromagnetic to paramagnetic phase transition is not as sharp at $T = \Theta$ in a field, exhibiting a Curie tail that reflects the ordering influence of field in the high-temperature paramagnetic phase.

Antiferromagnetism

For a simple **antiferromagnet**, like body-centered cubic (bcc) Cr, e.g., spins on adjacent nearest neighbor atomic sites are arranged in an antiparallel fashion below an ordering temperature, T_N, called the "Neel temperature." The susceptibility of an antiferromagnet does not diverge at the ordering temperature but instead has a weak cusp (Fig. 13). The mean field theory for antiferromagnets considers two sublattices, an A sublattice for which the spin moment is down, and a B sublattice for which the spin moment is up. We can express, in mean-field theory, the internal fields on the A and B sites, respectively

$$\begin{aligned} \mathbf{H}_A^{INT} &= -\lambda_{BA}\mathbf{M}_B \\ \mathbf{H}_N^{INT} &= -\lambda_{AB}\mathbf{M}_A \end{aligned} \tag{69}$$

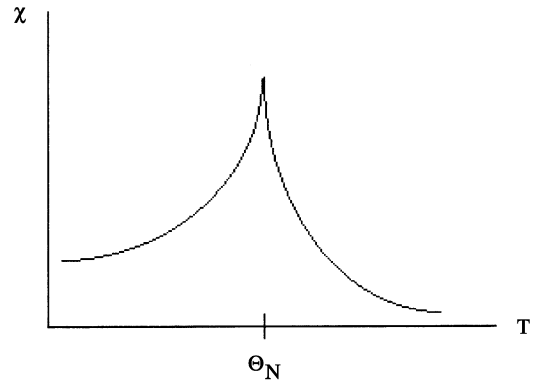

Figure 13. T-dependence of the magnetic susceptibility for an antiferromagnetic material.

where, by symmetry, $\lambda_{AB} = \lambda_{BA}$, $\mathbf{M}_B$ and $\mathbf{M}_A$ are the magnetizations of the $A$and B sublattices. Using the paramagnetic susceptibilities χ_p^A and χ_p^B

$$\mathbf{M}_A = \chi_p(\mathbf{H}_a + \mathbf{H}_A^{INT}) = \frac{C_A}{T}(\mathbf{H}_a + \lambda_{AB}\mathbf{M}_B) \tag{70}$$

$$\mathbf{M}_B = \chi_p(\mathbf{H}_a + \mathbf{H}_B^{INT}) = \frac{C_B}{T}(\mathbf{H}_a + \lambda_{AB}\mathbf{M}_A) \tag{71}$$

Now, for an antiferromagnet the moments on the A and B sublattices are equal and opposite so that $C_A = C_B = C$. Rearranging Equations 70 and 71 we get

$$T\mathbf{M}_A + C\lambda_{AB}\mathbf{M}_B = C\mathbf{H}_a \tag{72}$$

$$C\lambda_{AB}\mathbf{M}_A + T\mathbf{M}_B = C\mathbf{H}_a \tag{73}$$

In the limit as $\mathbf{H}_a \to 0$, these two equations have nonzero solutions (spontaneous magnetizations) for $\mathbf{M}_A$ and $\mathbf{M}_B$ only if the determinant of the coefficients vanishes; i.e.,

$$\begin{vmatrix} T & \lambda C \\ \lambda C & T \end{vmatrix} = 0 \tag{74}$$

and we can solve for the ordering temperature

$$\Theta_N = \lambda C \tag{75}$$

For $T > \Theta_N$ the susceptibility is given by

$$\chi = \frac{2CT - 2\lambda C^2}{T^2 - (\lambda C)^2} = \frac{2C}{T + \lambda C} = \frac{2C}{T + \Theta_N} \tag{76}$$

Ferrimagnetism

The mean-field theory for antiferromagnets is easily generalized to simple AB **ferrimagnetic** alloys. Here the magnitude of the moment on the A and B sublattices need not be the same and therefore $C_A \neq C_B$ in the limit as $\mathbf{H}_a \to 0$ and the determinant of the coefficients is

$$\begin{vmatrix} T & \lambda C_B \\ \lambda C_A & T \end{vmatrix} = 0 \tag{77}$$

The ferrimagnetic order temperature is determined to be

$$\Theta = \lambda\sqrt{C_A C_B} \tag{78}$$

and the magnetic susceptibility for $T > \Theta$ becomes

$$\chi = \frac{(C_A + C_B)T - 2\lambda C_A C_B}{T^2 - \Theta^2} \tag{79}$$

with curvature in $1/\chi$ versus T characteristic of a ferrimagnet.

The mean-field theory for spinel ferrimagnets is even richer. In the spinel structure, discussed in more detail below, magnetic cations may occupy octahedral A or tetrahedral B sites, respectively. In these systems however, the cations are close enough that A-A, A-B and B-B exchange interactions are possible. What is more, the sign of all of these exchange interactions is thought to be negative. By symmetry, however, if the A and B sites couple antiferromagnetically then the A-A and B-B pairs are aligned in a parallel fashion, i.e., even though their exchange interaction is negative, a stronger antiferromagnetic interaction between A and B sites might win out. This is commonly the case for ferrites, but may be complicated if one or the other of the sites is occupied by a nonmagnetic ion or if there is disparate temperature dependence between the A-A, B-B and A-B exchange interactions, respectively.

Heisenberg Model and Exchange Interactions

The **Heisenberg model** considers ferromagnetism and the defining spontaneous magnetization to result from nearest neighbor exchange interactions that act to align spins in a parallel configuration. The Heisenberg model can be further generalized to account for atomic moments of different magnitude, i.e., in alloys, and for exchange interactions that act to align nearest-neighbor moments in an antiparallel fashion or in a noncollinear relationship. Let us consider first the Heisenberg ferromagnet. Here we assume that the atomic moments on nearest neighbor sites are coupled by a nearest-neighbor exchange interaction giving rise to a potential energy

$$U_p = J_{ex}\mathbf{S}_i \cdot \mathbf{S}_{i,i+1} \tag{80}$$

between identical spins at sites i and $I + 1$ in a one-dimensional (1D) lattice. For identical spins

$$U_p = 2J_{ex}S^2\cos(\theta_{i,i+1}) \tag{81}$$

which for $J_{ex} > 0$ favors parallel alignment of the spins. For a linear chain of N spins (where N is large or exploits the periodic Born–Von Karmon boundary condition) and the total internal energy is

$$U_{TOT} = -2JS^2\sum_{i=1}^{N}\cos(\theta_{i,i+1}) \tag{82}$$

which for $J_{ex} > 0$ is minimized for a configuration in which all the spins are aligned in a parallel ferromagnetic configuration.

Exchange interactions result from the spatially dependent energy functional for electrons with parallel or antiparallel spins (or canted spins in more complicated models). For the hydrogen molecule, e.g., as shown in Figure 14, the configuration with spins aligned parallel is stable at larger interatomic separations and that with spins aligned antiparallel is stable at smaller interatomic separations. The choice of spin configuration depends on the relationship between the cross-over radius and the equilibrium separation of the atoms. In 3d transition metal solids, the famous **Bethe-Slater curve**, as shown in Figure 14B predicts the sign of the exchange interaction in 3d transition metal solids. In both cases, the interplay between electron-electron Coulomb interactions and the constraints of the Pauli exclusion principle determine the sign of the exchange interaction. In transition metal solids, a measure of the overlap between nearest-neighbor d orbitals is given by the ratio of the atomic to the 3d ionic (or nearest-neighbor) radius.

We will have further occasion to investigate the Heisenberg ferromagnet in future discussions. At this point, however, it is useful to consider the Heisenberg model prediction for other magnetic ground states. For example, notice that if $J_{ex} < 0$ an antiparallel configuration for adjacent spins in a 1D chain is predicted, consistent with an anti-ferromagnetic ground state as shown in Figure 15B. We can deduce a ferrimagnetic ground state as illustrated in Figure 15C and observed, e.g., for ferrites when we have $J_{ex} < 0$ and two magnetic sublattices, e.g., a and b, for which $\mu_a \neq \mu_b$. In three-dimensional (3D) systems it is possible to relax the restrictions of nearest-neighbor exchange and it is also possible to have noncollinear exchange interactions as shown in Figure 15D for a helimagnet. In certain ferrite systems (e.g., Mn_2O_3), it has been observed that Mn atoms in the octahedral and tetrahedral sites in face-centered cubic (fcc) interstices of the oxygen anion sublattice couple in a Yafet-Kittel triangular configuration.

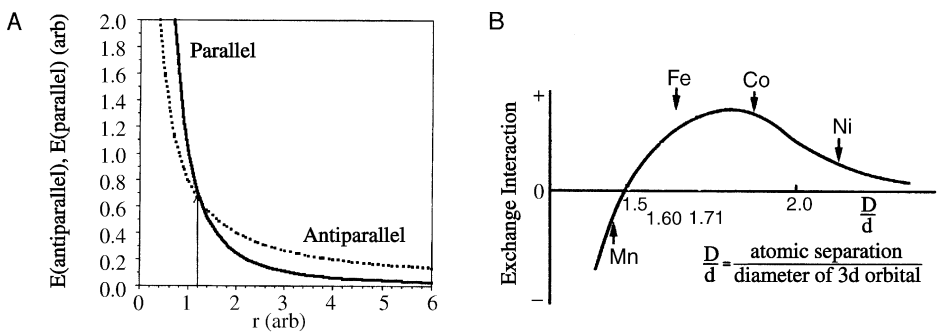

Figure 14. (**A**) Energies for parallel and antiparallel spins in the hydrogen molecule as a function of interatomic separation and (**B**) the Bethe-Slater curve predicting the sign of the exchange interaction in 3d transition metal solids.

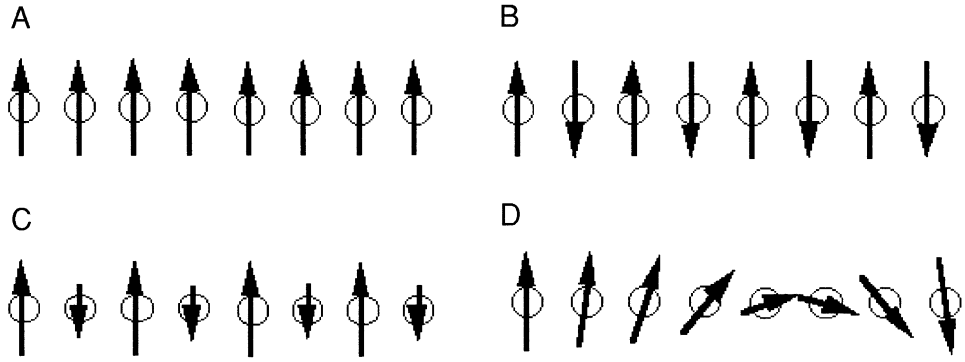

Figure 15. Spin configurations in a variety of magnetic ground states: (**A**) ferromagnet, (**B**) antiferromagnet, (**C**) ferrimagnet, (**D**) noncollinear spins in a helimagnet.

In the context of the ferrites and other oxides we may distinguish between direct and indirect exchange. We have described ferrimagnetic and Yafet-Kittel triangular spin configurations between neighboring magnetic cation sites. This is an example of an indirect exchange mechanism, since it must be transmitted through intervening nearest-neighbor oxygen sites. In fact, the exchange interaction is transmitted through overlap between magnetic d orbitals on the cation sites and the p orbitals of oxygen. This particular p orbital transmitted indirect exchange interaction is given the name "superexchange"and illustrated in Figure 16.

A form of indirect exchange that has recently been shown to be important in, e.g., magnetic/nonmagnetic multilayers, is the oscillatory **RKKY exchange** (Fig. 17). This is mediated through the conduction electron gas usually associated with nonmagnetic atoms but sometimes associated, e.g., with *sp* conduction electrons and magnetic electrons in rare earths. This indirect exchange is transmitted by polarization of the free electron gas. We can consider a polarization plane wave as emanating from a magnetic ion located at a position $r = 0$. The first waves influenced by a polarizing field are those with wave vector $\mathbf{k} = \mathbf{k}_F$ (at the Fermi surface) and therefore the sign of the exchange interaction should oscillate spatially like $\cos(\mathbf{k}_F \cdot \mathbf{r})$ as well as decaying exponentially as a function of r. To determine the sign of the indirect exchange interaction between the magnetic ion at $r = 0$ and at $r = r$ we need only calculate $\cos(\mathbf{k}_F \cdot \mathbf{r})$.

Other Forms of Collective Magnetism

Helimagnetism is a form of collective magnetism which refers to the spiral or helical arrangement of atomic magnetic dipole moments in certain metals, alloys, and salts. Ferromagnets and antiferromagnets can be considered as helimagnets with helical angles of $\Theta = 0$ and $\pi/2$, respectively. Examples of helimagnets include MnO_2 with a nonconical helix for $T < 86$ K; $MnAu_2$ which also has a non-conical helix for 85 K $<$ T $<$ 179 K and ferromagnetism for $T < 85$ K. Er has a conical helix for $T < 20$ K and has a complex oscillation for $20 < T < 53$ K and is a sinusoidal antiferromagnet for 53 K $< T <$ 85 K. $MnCr_2O_4$ has a complex conical helix, for $T < 18$ K and is a simple ferrimagnet for 18 K $< T <$ 43 K.

Helimagnetism is found in many rare earth metals and certain transition metal salts. Considering for example a hexagonal magnet, if we couple succesive basal planes we can identify J_1 as the exchange interaction between nearest-neighbor planes, J_2 between next nearest planes, etc. If the helical angle between successive basal planes is Θ_h then:

$$j\Theta_h = \Theta_{i+j} - \Theta_I \tag{83}$$

i.e., the angular difference between a plane i and $i + j$ is $j\Theta$h the exchange energy is proportional to

$$J_0 + 2J_1 \cos\Theta_h + 2J_2 \cos(2\Theta_h) + \cdots \tag{84}$$

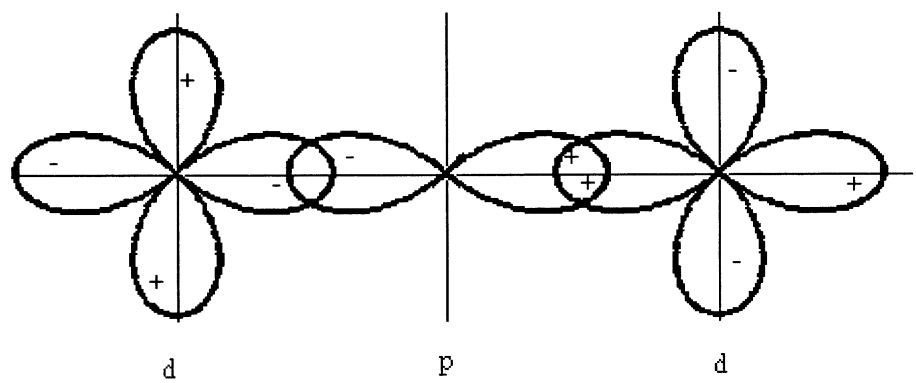

Figure 16. Superexchange interaction of magnetic ion d orbitals mediated through an oxygen p orbital.

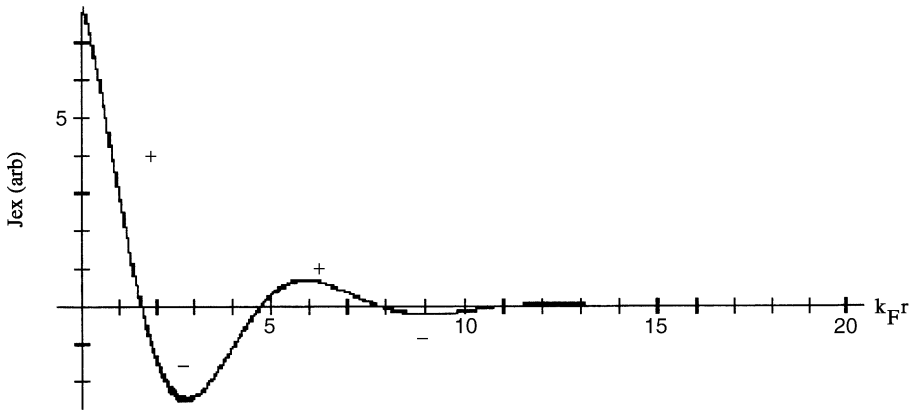

Figure 17. Spatial dependence of the RKKY exchange interaction.

keeping only two terms in the expansion and mimizing the exchange energy reveals

$$\Theta_h = \cos^{-1}(-J_1/2J_2) \quad (85)$$

for the helical angle.

CONCLUSIONS

In this unit, the basic notions of magnetic dipole moments and magnetization in solids have been summarized. In particular, the origin of magnetic dipoles from an atomic standpoint, a band structure standpoint, and a shielding current (superconductors) picture has been described. The coupling of magnetic dipoles, the field and temperature dependence of the magnetization, and simple magnetic phase transitions have been illustrated. This unit serves in defining certain basic magnetic phenomena which will be elaborated on, illustrated and extended in subsequent units. Magnetic phenomena are rich and varied; the fundamental principles of the origin, coupling and vector summation of magnetic dipole moments are at the heart of a comprehensive understanding of magnetic phenomena.

THEORY OF MAGNETIC PHASE TRANSITIONS

THERMODYNAMICS

The existence of magnetic order (collective magnetism) appearing in materials below a particular ordering temperature (e.g., the Curie temperature, T_C, or the Neel temperature, T_N) points to a class of physical phenomena which are described as magnetic phase transitions. The thermodynamics of these phase transitions can be described by energy functions (expressed in terms of intensive or extensive variables), in terms of magnetization–temperature ($M-T$) phase diagrams, or in terms of critical exponents that describe the variation of thermodynamic properties (as a function of the order parameter) as the ordering temperature is approached. In this section, we begin by describing the thermodynamics of magnetic ordering transitions, the order of the transitions, critical exponents, and thermodynamic variables. We further describe magnetic phase transitions within the framework of the mean field or Landau theory of phase transitions with discussion of several magnetic equations of state.

The discussion of thermodynamic properties begins with the definition of thermodynamic potential functions and their derivatives. For simplicity, we can take pressure and volume as being held constant and consider only magnetic work terms. In this case the entropy, S, and magnetization, M, are extensive variables, the temperature, T, and field, H, are intensive variables, and the different energy functions are the internal energy, $U(S,M)$; the enthalpy, $E(S,H)$; the Gibbs free energy, $G(T,H)$; and the Helmholtz free energy, $F(T,M)$. The differentials of each are:

$$\begin{aligned} dU &= TdS + HdM \qquad & dE &= TdS - MdH \\ dG &= -SdT - MdH \qquad & dF &= -SdT + HdM \end{aligned} \tag{1}$$

Two specific heats C_M and C_H are defined as:

$$C_M = -T\left(\frac{\partial^2 F}{\partial T^2}\right)_M, \qquad C_H = -T\left(\frac{\partial^2 G}{\partial T^2}\right)_H \tag{2}$$

The adiabatic and isothermal susceptibilities are given, respectively, by:

$$\chi_S = \left(\frac{\partial M}{\partial H}\right)_S = \left(\frac{\partial^2 E}{\partial H^2}\right)_S, \qquad \chi_T = \left(\frac{\partial M}{\partial H}\right)_T = -\left(\frac{\partial^2 G}{\partial H}\right)_T \tag{3}$$

Phase transitions reflect discontinuities in the free energy function. The order of a phase transition is defined in terms of the smallest derivative of the free energy function for which a discontinuity occurs at the ordering temperature. The magnetization at constant temperature:

$$M = \left(\frac{\partial G}{\partial H}\right)_T \tag{4}$$

in an equilibrium ferromagnet is discontinuous at $H = 0$ for $T < T_C$ (Figure 1). At T_C, M is continuous, but the susceptibility is discontinuous between the ferromagnetic and paramagnetic states. The Helmholtz free energy (Figure 1A) has a minimum only at $M = 0$ for $T > T_C$. For $T < T_C$, two minima occur at $\pm M_s$, the value of the spontaneous magnetization. The $H = 0$ ferromagnetic transition is second order, at T_C, while for $H \neq 0$ the transition is first order.

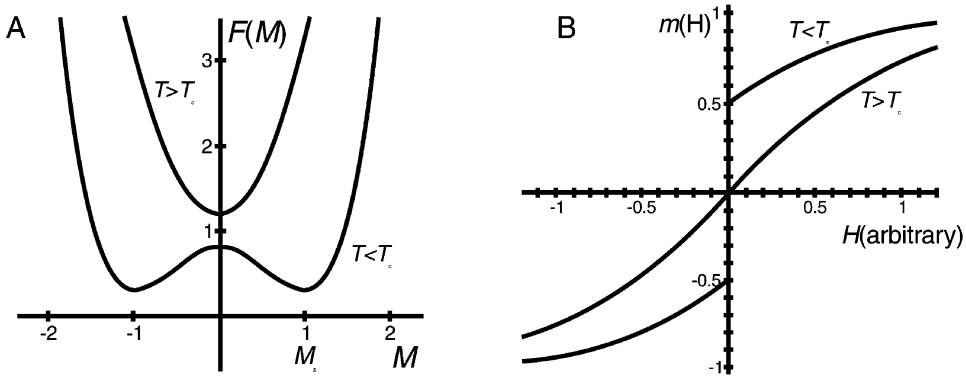

Figure 1. Schematic depiction of (**A**) magnetic Helmholtz free energy isotherms and (**B**) reduced magnetization, $m(H)$ for $T < T_C$ and $T > T_C$ (Ausleos and Elliot, 1983).

From the above discussion it is clear that the spontaneous magnetization, M, or the reduced magnetization, $m = M/M_s$, will serve as the order parameter in the ferromagnetic phase transition. In antiferromagnetic, ferrimagnetic, or helimagnetic systems the local vector reduced magnetization, $m(r)$, must be taken as the order parameter, since the magnetization is not spatially uniform on an atomic scale.

LANDAU THEORY OF MAGNETIC PHASE TRANSITIONS

In future discussions we will rely on the so-called Landau theory of the magnetic phase transitions. In the Landau theory, the Helmholtz free energy is expanded in a Taylor series where, for symmetry reasons, only even powers of the order parameter, M, are kept in the expansion. The temperature dependence is described in terms of T-dependent expansion coefficients. Near T_C, where the order parameter is small, only a few terms need to be kept in the expansion. Considering such an expansion, truncated at two terms and adding in a term to reflect the magnetostatic contributions (i.e., potential energy of the magnetization in the internal field), the magnetic Helmholtz free energy (at constant temperature) can be expressed as:

$$F_M = \frac{1}{2}A(T)M^2 + \frac{1}{4}B(T)M^4 - \mu_0 MH \tag{5}$$

where $A(T)$ and $B(T)$ are the temperature dependent expansion coefficients in the Landau theory. An equation of state can be derived by minimizing the free energy with respect to magnetization:

$$\frac{\partial F_M}{\partial M} = 0 = A(T)M + B(T)M^3 - \mu_0 H \tag{6}$$

that results in the expression:

$$M^2 = \frac{-A(T)}{B(T)} + \frac{\mu_0 H}{B(T)M} \tag{7}$$

By invoking a microscopic model of the magnetization (of which there are many), one can determine the coefficients $A(T)$ and $B(T)$, specifically. For example, in the Stoner theory of itinerant ferrromagnets, the magnetic equation of state and coefficients are expresssed by the following equations (Gignoux, 1995):

$$M(H,T)^2 = M(0,0)^2\left[1 - \frac{T^2}{T_C^2} + \frac{2\chi_0 H}{M(H,T)}\right] \tag{8}$$

$$A(T) = \frac{-\mu_0\left[1 - (T^2/T_C^2)\right]}{2M(0,0)\chi_0} \qquad B(T) = \frac{-\mu_0}{2M(0,0)^2\chi_0} \tag{9}$$

where $M(0,0)$ is the $H = 0$, $T = 0$ magnetization and χ_0 is the magnetic susceptibility at 0 K. Notice that the Landau theory predicts a (Pauli) paramagnetic state, $M = 0$ (no spontaneous magnetization), when the coefficient $A(T) > 0$. On the other hand, a stable spontaneous magnetization is predicted for $H = 0$ when $A(T) < 0$. This spontaneous magnetization is:

$$M^2 = \frac{-A(T)}{2B(T)} \tag{10}$$

In the presence of a field, and for the case $A(T) < 0$, this gives rise to a stable spontaneous magnetization, which is described by the equation of state (see Equation 7). This suggests that plotting different isotherms of M^2 versus H/M allows for the determination of $A(T)$ and $B(T)$. Moreover, since $A(T_C) = 0$, i.e., A vanishes at the Curie temperature, T_C, then the Curie temperature can be determined as the isotherm with 0 as its intercept. Plots of M^2 versus H/M isotherms are called Arrott plots and are discussed below as a method for determining the magnetic ordering temperature from magnetization measurements.

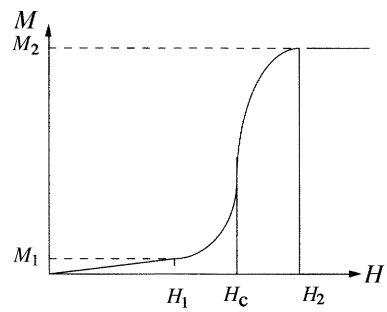

Figure 2. Magnetization curve metamagnetic response. M_1 is the external magnetization in the paramagnetic state; M_2 is the saturation magnetization in the metamagnetic state.

Table 1. Ordering Temperatures for Some Selected Magnetic Materials

Ferrimagnets	Curie Temperature (T_C), K	Ferrimagnets	Curie Temperature (T_C), K	Antiferromagnets	Neel Temperature (T_N), K	Helimagnets	(T_H), K
CO	1388	Fe_3O_4	858	NiO	600	MnO_2	84
Fe	1043	$MnFe_2O_4$	573	Cr	311	$MnAu_2$	363
Ni	627	Y_3FeO_{12}	560	Mn	95	Er	20
Gd	289	γ-Fe_2O_3	948	FeO	198		

Another free energy minumum exists, which gives rise to a so-called metamagnetic state. If $A(T) > 0$ but small, a Pauli paramagnetic state is predicted in zero field. However if $B(T) < 0$ it is possible to have a minimum in the Helmholtz free energy at $H \neq 0$. This minimum may in fact be deeper than that at $M = 0$. In such a case, application of a field causes the system to choose the second minimum (at M_2) giving rise to an $M(H)$ curve as depicted in Figure 2 for this so called metamagnetic response.

CRITICAL EXPONENTS IN MAGNETIC PHASE TRANSITIONS

One of the goals of thermodynamic treatments of magnetic phase transitions is to determine critical exponents associated with the phase transition. This involves describing power law exponents for the temperature dependence of thermodynamic quantities as the ordering transition is approached. Determination of critical exponents and scaling laws allows for closed-form representations of thermodynamic quantities with significant usefulness in prediction and/or extrapolation of thermodynamic quantities (Callen, 1985). To describe such scaling-law behavior, the reduced temperature variance, ε, is defined as:

$$\varepsilon = \frac{(T - T_C)}{T} \tag{11}$$

which approaches 0 as $T \rightarrow T_C$ from below or above. For $T > T_C$ and $H = 0$, the specific heat (C, which can be C_M or C_H) and isothermal susceptibility obey the scaling laws:

$$C \sim \varepsilon^{-\alpha} \quad \text{and} \quad \chi_T \sim \varepsilon^{-\gamma} \tag{12}$$

For $T < T_C$, the specific heat, the magnetization and the isothermal susceptibility obey the scaling laws:

$$C \sim \varepsilon^{-\alpha'} \quad \chi_T \sim (-\varepsilon)^{-\gamma'} \quad \text{and} \quad M \sim (-\varepsilon)^{\beta} \tag{13}$$

At T_C the critical isotherm is described by

$$H \sim |M|^{\delta} \tag{14}$$

Thermodynamic arguments, such as those of Rushbrooke (see Callen, 1985), allow us to place restrictions on the critical exponents. For example, defining

$$\alpha_H = \left(\frac{\partial M}{\partial T}\right)_H \tag{15}$$

and using thermodynamic Maxwell relations, it is possible to show that:

$$\chi_T(C_H - C_M) = T\alpha_H^2 \tag{16}$$

which implies

$$C_H > \frac{T\alpha_H^2}{\chi_T} \tag{17}$$

This then requires that, as $T \rightarrow T_C$ from below:

$$\alpha' + 2\beta + \gamma' \geq 2 \tag{18}$$

Furthermore, if C_M/C_H approaches a constant ($\neq 1$) then two more inequalities may be expressed:

$$\alpha' + \beta(1 + \delta) \geq 2 \quad \text{and} \quad \gamma' \geq \beta(\delta + 1) \tag{19}$$

In the Landau theory, it can be determined that:

$$\alpha' = \alpha = 0; \quad \beta = 1/2; \quad \gamma' = \gamma = 1; \quad \text{and} \quad \delta = 3 \tag{20}$$

If we consider a vector magnetization, and allow for a spatially varying local magnetization, then the Landau theory must be extended to a more complicated form. Further, it is often necessary to add terms $\sim(\nabla \mathrm{M})^2$ to the energy functional. In such cases, $T_C = T_C(\mathbf{k})$ and $\chi = \chi(\mathbf{k})$ can be taken as reciprocal space expansions and the spatial dependence of the susceptibility, $\chi(\mathbf{r})$, can be determined as the Fourier transform of $\chi(\mathbf{k})$. In these cases a correlation length, ζ, for the magnetic order parameter is defined, which diverges at T_C. Further discussion of the spatial dependence of the order parameter is beyond the scope of this unit.

Table 1 summarizes ordering temperatures for selected materials with a variety of types of magnetic order. These various local magnetic orders and the exchange interactions that give rise to them are discussed in TECHNIQUES TO MEASURE MAGNETIC DOMAIN STRUCTURES. For most of that discussion, we will consider ferromagnetic ordering only.

MAGNETOMETRY

INTRODUCTION

All materials possess a magnetic moment; techniques for measuring that bulk macroscopic property are defined here as magnetometry. This unit will review the most common techniques for measuring the total magnetic moments of small samples (volume ≤ 1 cm^3 and/or mass ≤ 1 g). Several factors contribute to the bulk magnetic moment of a sample. Essentially all materials show weak diamagnetism from filled electronic core states of the atoms. Metallic materials show an additional contribution to their diamagnetism from the orbital motion of the otherwise degenerate spin-up and spin-down conduction electrons as well as Pauli paramagnetism from splitting of the conduction bands. The largest contribution to the magnetic moment of materials comes from unpaired localized spins of elemental constituents—unpaired $3d$ and sometimes $4d$ and $5d$ electrons in the case of the transition metal series, $4f$ electrons for the rare earths, and $5f$ electrons for the actinide constituents.

It is important for many reasons to know a material's magnetic moment, a thermodynamic quantity. For strongly magnetic materials, it is probably the most useful and important physical property, determining their utility in applications. For magnetically ordered systems, magnetic moment measurements provide information about spin structure, anisotropy (in the case of nonpolycrystalline samples), and phase transitions. For paramagnetic systems, the total moment at high fields or the temperature dependence of the magnetic susceptibility can yield a measure of the moment per chemical constituent or magnetic impurity concentration, whether introduced purposefully or as impurities. The temperature dependence of the moment yields information on interactions between the paramagnetic ions or with the lattice. Certain features of the electronic structure of metallic materials can be determined from magnetic susceptibility, such as the density of states at the Fermi surface. For superconductors, high field magnetization can provide information about the critical field and critical current density.

This unit is restricted to the centimeter-gram-second (cgs) system of units for the magnetic moment, which is given in electromagnetic units (emu), where 1 emu $= 10^{-3}$ A-m^2 [International (SI) System of Units]. To determine the magnetization $\mathbf{M}$ (G/cm^3), where $\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M}$, multiply moment per gram (emu/g) by the density (g/cm^3). The magnetic moment, magnetic field ($\mathbf{H}$), magnetic induction ($\mathbf{B}$), and associated conversion factors may be found in MAGNETIC MOMENT AND MAGNETIZATION of this part.

Recent reviews of magnetometry are given by Foner (1994) and by Flanders and Graham (1993) and recent developments are often published in the *Review of Scientific Instruments*. Proceedings of the annual Intermag Conferences appear in a special fall issue of the *IEEE Transactions on Magnetics*, and those of the annual Magnetism and Magnetic Materials Conference generally appear in a special spring issue of the *Journal of Applied Physics*.

PRINCIPLES OF THE METHOD

There are two direct techniques for measuring the magnetic moment of materials: one utilizes the detection of a change in magnetic flux produced by a sample, and the other utilizes the detection of a change in the force experienced by a sample. An analog device, a transducer, couples the change in flux or force to electronic circuitry for signal processing and readout, usually in the form of a direct-current (dc) voltage proportional to the sample moment. The transducer is usually a configuration of pickup coils for flux-based measurements. For force measurements, the transducer will most likely be an electromechanical balance or piezoelectric device. Often a magnetometer system operates in some null detection mode using feedback,- which is proportional to the magnetic moment of the sample being measured.

Flux measurements are usually performed with a configuration of pairs of series-opposing pickup coils. Most of these magnetometers utilize the strategy of moving the sample with respect to the pickup coils in order to measure the moment of the sample while minimizing contributions from the background magnetic field. The induced electromotive force (emf) in a pickup coil is generated from a temporal change in magnetic flux, obeying Faraday's law: $E(\mathrm{V}) = -N \times 10^{-8}(d\Phi/dt)$, where N is the number of turns in the coil and the magnetic flux, $\Phi(\mathrm{G\text{-}cm}^2) = \mathbf{B}a = (\mathbf{H} + 4\pi\mathbf{M})a$, a being the effective area of the coil

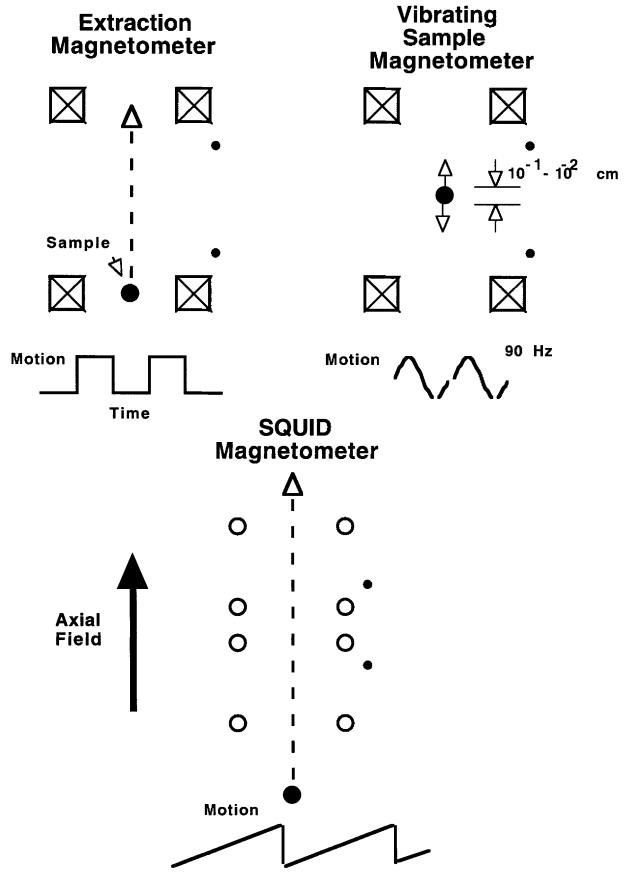

Figure 1. Schematic representation of three flux-based magnetometers and the time dependence of the sample motion for each. The planes of the coil windings are perpendicular to the field for all these examples (axial configuration). The figures show the cross-section of the coils (not to scale) and the dots indicate coil polarity. The pickup coils of the extraction and vibrating sample magnetometers are multiturn, but those for the SQUID magnetometer are constructed with very few turns to minimize inductance and maximize coupling to the low-impedance SQUID transducer.

normal to **B**. A change in the magnetic flux can also be induced in a sample by changing an externally controlled variable such as magnetic field strength or temperature.

Figure 1 is a schematic representation of three flux-based magnetometers: the extraction, vibrating sample, and superconducting quantum interference device (SQUID) magnetometers. In each case the sample is moved relative to series-opposing pickup coils, which detect the flux changes. The oscillatory sample motion for the vibrating-sample magnetometer is very small and rapid, the motion for the extraction magnetometer is stepwise and slower and confined to the coil dimensions, and in general the SQUID motion extends beyond the coil dimensions to measure peak-to-peak flux change. The pickup coils of the first two magnetometers are multiturn in order to maximize the induced voltage, but for the SQUID, the pickup coils have only a few turns in order to minimize the inductance and maximize the coupling to the extremely low impedance SQUID transducer.

All force magnetometers depend on the difference in energy experienced by the sample in a magnetic field gradient. Figure 2 is a schematic representation of four force-related magnetometers: the traditional Faraday, the cantilever, the piezoresistive, and the alternating-gradient magnetometers. In general, assuming the (spherical) sample composition is homogeneous, isotropic, and in a vacuum, the force for a gradient along the z axis is given by

$$\mathbf{F}\,(\text{dynes}) = -\nu\chi\mathbf{H}(dH/dz) \tag{1}$$

if χ, the magnetic susceptibility, is field independent, i.e., $\mathrm{M} = \chi\mathbf{H}$. Here $\mathbf{M}$ is the magnetization per cubic centimeter and ν is the volume (in cubic centimeters). If the sample is ferromagnetic and above saturation, $\mathbf{M} = \mathbf{M}_s$, the force is given by

$$\mathbf{F} = -(\nu/2)\mathbf{M}_s(d\mathbf{H}/dz) \tag{2}$$

If the sample is inherently anisotropic or has shape anisotropy, effects of the x and y gradients can contribute to

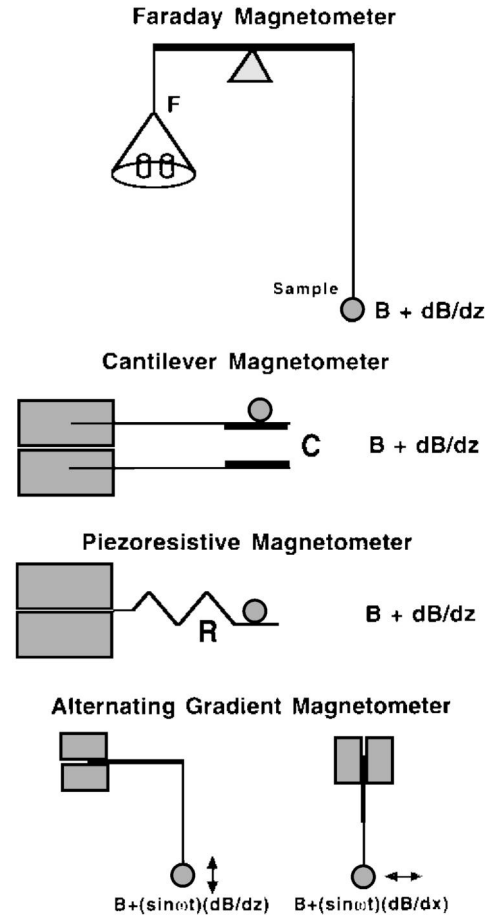

Figure 2. Schematic representation of four force-based magnetometers and the time and spatial field variation for each. In all cases, a feedback mechanism is often used to allow null detection of the sample moment. The Faraday magnetometer generally accommodates somewhat larger samples than the other three systems. The piezoresistive element is indicated by the resistor and the piezoelectric sensors for the AGM are shown as thick lines.

the measured force. Those components of the gradient are always present (divergence $\mathbf{B} = 0$). For force measurements, one needs to know the field and the gradient and also be able to reproduce accurately the position of the sample. The sensitivity is a strong function of field and gradient. Samples with high anisotropy or highly nonspherical shape can be problematic due to the transverse field gradients. Wolf (1957) has shown that, under certain conditions, even the sign of the measured force can be incorrect.

External magnetic fields are usually required for magnetometers (see GENERATION AND MEASUREMENT OF MAGNETIC FIELDS). The two common sources of external fields for magnetometry are iron core electromagnets, which provide fields up to ~20,000 G (2 T), and superconducting solenoids, which provide much higher fields, up to 150,000 G (15 T) or more. For many purposes the field from the electromagnets is ample. These can be turned on in a few minutes and furnish easy access to the field volume for manipulation and modifications. Superconducting solenoids generally require liquid helium for operation, take several hours to cool to operating temperatures, and offer a more restricted access to the experimental volume. Bitter solenoids, resistive solenoids that can provide fields to 30 T, and hybrid magnets, a combination of Bitter solenoids surrounded by superconducting solenoids providing even larger fields, are accessible at national laboratory facilities. Such user-oriented facilities include those in the United States, France, Japan, The Netherlands, and Poland.

It is important for the experimenter to estimate the sample moment prior to measurement because this may dictate which technique is suitable. A 10-mg polycrystalline Ni spherical calibration sample will display a moment of 0.55 emu at saturation (above 6000 G) at 300 K and 0.586 emu at $T = 4.2$ K. A 10-mg pure Pd sample will have a moment of ~0.007 emu at the same field and temperature. The moment of a superconducting sample or ferromagnetic material depends not only on the applied field and temperature but also on the history of the sample in field. A 10-mg bulk Pb superconducting sample cooled to below its transition temperature in a zero field will show a moment of ~ -0.007 emu (diamagnetic) in 100 G, but it will have a much smaller moment above the critical field. A given magnetometer can cover the range from a few emu to 10^{-6} emu or less. It should be stressed that ultimate sensitivity may not always be the most important criterion, given other constraints. Clearly, a sample moment of 1 emu is fairly large and easily measured.

PRACTICAL ASPECTS OF THE METHOD

Flux Magnetometers

Flux-Integrating Magnetometer. The basic instrument for detecting a change in sample moment or magnetic flux change, $\Delta\phi$, in a pickup coil is the fluxmeter, essentially an operational amplifier with capacitive feedback C (Flanders and Graham, 1993). A pickup coil having N turns and a resistance R_c in which the sample is located is connected in series with the fluxmeter input resistance R_i. The fluxmeter integrates the voltage change given by Faraday's law, V (in volts)$dt = -N \times 10^{-8}\, d\phi$ (G-cm^2). The sensitivity of a direct-reading fluxmeter depends on N, the time constant (which involves C, R_i, and R_c), but is also limited by drift in the input, often generated by thermal emfs. The sensitivity and utility depend heavily on coil design and the values chosen for R_i and C. Commercially available high-speed digital voltmeters effectively replace the operational amplifier-based fluxmeter and deal more effectively with the drift problem. Variation of the integration time generally involves a trade-off between lower noise and higher drift (longer integration times) or lower drift and higher noise level (shorter integration times). Krause (1992) described a magnetometer that used a stepping motor to move the sample in a few seconds between opposing pickup coils in series [the same coils used for alternating-current (ac) susceptometry] so that the instrument carried out both dc and ac measurements. An extraction magnetometer works on the principle of relatively rapid sample removal from or insertion into the interior of a pickup coil.

Vibrating-Sample Magnetometer. Commercially available since the mid-1960s, the vibrating sample magnetometer (VSM) was first described by Foner (1956). Most commonly, the sample is mechanically vibrated in zero or uniform applied field at <100 Hz, far from mechanical resonance (amplitude of a few tenths of a millimeter to a few millimeters) at a point midway between pairs of series opposing pickup coils, where the signal is a maximum and is insensitive to position to first order. The coils detect the ac component of the field produced by the moving sample, and their ac output is detected by a lock-in amplifier employing a phase-sensitive detector. The dc output of the VSM is proportional to $d\Phi/dt$ and is given by

$$V = G\sigma\omega A \cos(\omega t) \tag{3}$$

for small sinusoidal drive, where G is a geometric factor for the coils, σ the sample moment, and A and ω are the amplitude and angular frequency of the sample motion, respectively. The mechanical drive itself is normally an electromechanical device like a loudspeaker, less commonly a motor drive.

The most common VSMs use a transverse-coil configuration where the vibration axis (z axis) is perpendicular to the field supplied by an electromagnet and the pickup coils are arranged to sense the moment along the field direction. For higher fields, transverse-field superconducting magnets have been used. By rotating the drive unit about the z axis, the magnetic moment versus the angle is obtained in the x-y plane. Various more complex pickup coil arrangements have been used to sense the components of the magnetization vector at any angle to the applied field for anisotropic materials or magnetic thin films (Foner, 1959; Bowden, 1972; Zieba and Foner, 1982; Pacyna and Ruebennauer, 1984; Mallinson, 1992; Bernards, 1993; Ausserlechner et al., 1994). Recently, these arrangements have been called vector or torque VSMs. A second popular VSM arrangement is the axial configuration, where the vibration axis is parallel to an axial field, most often furnished by a superconducting magnet. These coil

configurations are shown in Figure 1. The VSM allows sample magnetic moments from 10^{-6} to many emu to be measured over field ranges up to 30 T in resistive Bitter solenoids and higher fields in hybrid magnets (Foner, 1996) over temperatures from 0.5 to 1000 K or more. Sensitivities as high as 10^{-9} emu have been quoted for closely coupled pickup coils (Foner, 1975). The VSM also has been adapted for high-pressure measurements (Guertin and Foner, 1974) and for very low frequency ac susceptibility measurements (down to 10^{-3} Hz) to observe the frequency dependence of the spin-freezing temperatures of spin-glasses (Guyot et al., 1980). The VSM takes data continuously, so that rapid sweeps of field and temperature can be made.

It is possible to use slow drive magnetometers using flux integration techniques in special circumstances. One technique, developed by Foner and McNiff (1968) for observation of small changes in a large signal, moves the sample beyond the maximum signal in the pickup coils, thus avoiding centering problems. This overextended sample drive motion is sometimes utilized in the commercial SQUID magnetometer.

SQUID Magnetometer. The SQUID is an extremely low impedance, high-sensitivity flux detector capable of operating over a wide range of frequencies (from dc to gigahertz). The magnetometer detects the flux produced by a sample passing slowly through a pickup coil. The SQUID does not measure the field from the sample directly but is coupled inductively to superconducting pickup coils located in the high-field region. Changes in flux set up a persistent current in the pickup coil–SQUID transformer circuit. A feedback, which is generated to either null the persistent current in the superconducting circuit or change the flux in the SQUID, is proportional to the sample moment. The sample is moved slowly through the pickup coils. The SQUID must be kept in a low-field region and is thus shielded by a superconducting shield. The shield not only protects the SQUID from high stray magnetic fields from the superconducting magnet but also reduces ambient laboratory stray field interference. A modification for low-frequency ac susceptibility measurements down to 10^{-3} Hz is discussed by Sager et al. (1993). Superconducting solenoids almost always furnish the field because the pickup coils must be in an extremely stable field while data are taken, so the magnet operates in a persistent mode while the sample is translated between the pickup coils. The peak-to-peak flux changes are measured or the flux changes over the traversal are fitted to a calculated profile. To change the field, the superconducting pickup coil circuit is made nonsuperconducting so that the induced currents are small during the time the field is changed. First, the superconducting magnet is made nonpersistent, and the field is changed, then returned to a persistent mode when the field drift becomes small, after which the pickup coil circuit is made superconducting again. Large field changes produce longer magnet drift times. This sequential procedure is automated in commercial instruments, and although data taking is slow, the systems can be programmed to run for several days before the liquid helium needs replenishment. The programs run sequences of temperature and field without intervention once the sample is mounted. Data are taken point by point at each temperature and/or field.

The SQUID itself is capable of detecting flux changes on the order of $10^{-3}\phi_0$, where ϕ_0, the flux quantum, is given by 1.07×10^{-7} G-cm^2 ($= hc/2e$). The sensitivity of the magnetometer is typically $\sim 10^{-7}$ emu, with higher sensitivities possible using special closely coupled coil configurations. Commercial SQUID magnetometers are currently available with fields to 9 T over a range of 2 to 400 K (1200 K with furnace insert). The system can also include a low-frequency VSM mode, and the SQUID can also be adapted for ac susceptibility measurements.

Force Magnetometers

DC Faraday Magnetometer. Historically, the Faraday magnetometer used an iron core magnet with tapered pole pieces to provide the gradient, from 100 to 1000 Oe/cm. Assuming $dH/dz = 500$ Oe/cm, the balance must be able to detect changes in mass weight of -5 μg (5×10^{-3} dynes) to detect changes on the order of 10^{-5} emu in a 1-cm^3 sample (a very large sample by laboratory standards). To avoid sample displacement when the external field or temperature is changed, the force is generally compensated by a small electromagnet exerting an equal force on a magnetic material on the opposite end of the balance. The feedback to maintain sample position is the direct readout proportional to the sample magnetic moment. Thermal isolation of the transducer from the sample environment is essential for all force transducers.

Accurate and reproducible sample positioning in the field is essential for proper utilization of the Faraday magnetometer. The sample, which is suspended from the balance by a fiber, may have a hang-down weight attached by another fiber to furnish a force to minimize transverse force displacements. Care must be taken to avoid convection currents. Faraday magnetometers have been adapted to solenoidal fields, i.e., superconducting magnets or resistive Bitter solenoids, with field gradient coils controlled separately from the main solenoid. The sample may be placed away from the center of the magnet to capture a large field gradient, but there is a penalty in reduction of the applied field. Commercial Faraday magnetometers are currently available covering a temperature range of 1.5 to 300 K.

Alternating-Gradient Magnetometer. Zijlstra (1970) first described a force magnetometer that attached a small sample to a thin reed in a uniform field and applied an independently controlled ac gradient field tuned to the mechanical resonance of the sample plus the reed. This device is called a vibrating-reed or alternating-gradient magnetometer (AGM). The system is operated typically at a few hundred hertz, above most environmental noise frequencies, and Q values may be over 100. Detection of the vibration motion (normally a few micrometers) is done optically or by means of a piezoelectric bimorph

transducer (Flanders, 1988). The AC gradient is restricted by power dissipation in the gradient coils to ~100 Oe/cm and can be applied transverse or longitudinal to the vertical support. Data can be accumulated continuously with changing field or temperature. Lock-in detection is used to measure the voltage from the transducer locked to the gradient coil frequency.

The AGM has received considerable use in the magnetic tape recording industry because of its ease of operation and its sensitivity, which is quoted at $\sim 10^{-8}$ emu. A commercial instrument using a bimorph transducer has recently been modified by O'Grady et al. (1993) and evaluated for operation between 5 and 300 K using He gas cooling, with sensitivity affected by flow rate from 2×10^{-5} emu at 5 K to 10^{-7} emu at 300 K. Because the resonant system is sensitive to damping, it is not operated directly in a cryogen. The bimorph is sensitive to temperature and the resonant supports are short (a few centimeters), so low-temperature arrangements are not conventional. O'Grady et al. (1993) also examined spurious effects of the gradients on hysteresis loop parameters of thin magnetic films, including squareness, irreversibility, and magnetic viscosity.

Cantilever Magnetometer. Originally developed to operate at the very low temperature of a dilution refrigerator, the cantilever magnetometer employs a thin, flexible platform or beam as a sensing element of magnetic force or torque, with the sample rigidly attached to the free end of the cantilevered beam (Chaparala et al., 1993). In a uniform field, an anisotropic sample will experience a torque and a field gradient is required to provide force for an isotropic sample, so both effects may occur simultaneously. The beam deflection may be detected via capacitance, strain, or optics. The former is the most common. A fixed electrode is placed under the metallized cantilever, leaving a small ($\ll$1-mm) gap. With a cantilever area of 1 cm^2, deflection of <0.1 nm can be measured. Typical sensitivity ranges are 10^{-1} to 10^{-5} N-m for torque and 10^{-7} to 10^{-2} N (10 μg to 1 g weight equivalent) for force, though higher sensitivities have been reported. An alternative is to detect displacement with a piezoresistive sensor (Rossel et al., 1996). Another variation uses a diaphragm in a cantilever arrangement in a uniform magnetic field combined with a modulated gradient field (Bindilatti and Oliveira, 1994). It is also a type of AGM working nonresonantly.

A silicon cantilever magnetometer is a micromachined device that incorporates integrated calibration and null detection, as well as simultaneous electrical resistivity capability. An advantage of the cantilever over other methods is its use from room temperature down to millikelvin temperatures, and the mechanical characteristics change by <10% over this range. Cantilevers have been employed in fields from 10^{-3} to 30 T and in pulsed fields.

Other Alternative Magnetometry Techniques

Many alternative magnetometry methods have been developed for specific applications. These include flux and force measurements as well as indirect techniques that depend on a known functional relationship between the magnetic properties and some other parameter, e.g., resistance, optical transmission, or strain. Many such methods have been reviewed by Foner (1967, 1981) and Zjilstra (1967).

High-Pressure Magnetometry. Most commercially available magnetometer systems have been adapted for use with devices for exerting high pressure on the samples. The VSM and the Faraday balance were adapted by Guertin and Foner (1974) and Wohlleben and Maple (1971), respectively, to incorporate a high-hydrostatic-pressure cell. Both systems operate with hydrostatic pressures to ~1 GPa. SQUID magnetometers have also been adapted for high-pressure use, as has the vibrating-coil magnetometer (Smith, 1956; Ishizuka et al., 1995).

Vibrating-Coil Magnetometer. In a vibrating-coil magnetometer (VCM), the sample is held motionless but the series-opposing pickup coils are vibrated. While this technique may be useful for samples that cannot conveniently be moved, it is extremely difficult to eliminate unwanted pickup from the background field even when it is not varying. The earliest application by Smith (1956) was for measuring a magnetic material in a high-pressure cell. A more recent application of the VCM measured the magnetic moment of a sample sandwiched between diamond anvils under extremely high pressure (Ishizuka et al., 1995). The pickup coils are just outside the pressure cell near the high-pressure region. The coils, which are driven by a piezoelectric bimorph, are coupled to a SQUID.

Rotating-Sample Magnetometer. In a rotating-sample magnetometer (RSM), the sample moves in a circular orbit with the field perpendicular to the plane of the circle (Flanders and Graham, 1993). Pickup coils detect the periodic change in flux, and the Gaussian-like pulse produced is composed of a fundamental frequency (oscillation frequency) and several harmonics, all of which can be detected separately with a lock-in amplifier. The output of the RSM is proportional to the sample moment and frequency of rotation as well as the coupling to the pickup coils. While the sensitivity may be comparable to that of the VSM, the RSM requires more space for operation and the calibration will depend on sample size and shape in a complicated way. The RSM may be used to directly detect magnetic anisotropy by configuring the pickup coils to detect the moment that is perpendicular to the axis of rotation. For this measurement, the sample is a circular cylinder with its axis coincident with the rotation axis.

Surface Magnetometry. Though this unit is restricted to the review of measurements of the bulk sample magnetic moment, very useful surface measurements can be used to analyze properties of materials in situ and nondestructively. Selected examples are mentioned below.

Kerr Effect Magnetometry. The plane of polarization is rotated when a beam of polarized light is transmitted along the magnetization direction in a magnetized medium. When transmitted through the sample, it is called

the Faraday effect; when reflected from a surface, it is called the Kerr effect. The rotation of the polarization depends on frequency and is proportional to the effective path length of the light, the Kerr constant of the material, and the magnetization. Assuming all else is fixed, the Kerr effect measures the relative magnetization on the surface. By varying the field, hysteresis loops of the relative magnetization are generated. Automated Kerr magnetometers are used to scan the surface of large recording discs. It should be noted that the measurement probes the optical penetration depth, which may not reflect the bulk properties, e.g., if there are surface strains.

Hall Effect Sensor. A Hall effect sensor is a convenient and often quite compact element that can be used for measuring magnetic field. The Hall voltage V_H across a flat slab with thickness d is given by $V_H = RIH_0 \sin \Phi d$, where I is the currents, H_0 is the applied field, Φ is the angle between them, and R is the Hall constant given by $1/nec$, where n is the number of carriers per cubic centimeter, e is the elctronic charge, and c is the velocity of light. Note that V_H is maximum when it is measured along a direction that is perpendicular to the current and both are perpendicular to H_0. The sign of V_H depends on the direction of H_0 and is proportional to H_0, not dH_0/dt. Semiconductors are often used for sensors because n is small and V_H is large. By applying an AC current, the thermoelectric voltages, which are large for small n, are minimized. Typical sensors can be quite small; commercial elements have active areas of 1 mm^2 or less and can be compensated so that R is field and temperature independent to better than 1% for H_0 up to 23 T between 1.5 and 300 K (Sample and Rubin, 1976). Because these sensors are small, they fit into small regions as field sensors, but care must be used to assure that H_0 is perpendicular to the flat area. The Hall device can be used as a field sensor in magnetometers (Flanders and Graham, 1993; see DEEP-LEVEL TRANSIENT SPECTROSCOPY). If the Hall sensor can be placed in very close proximity to the surface of a magnetic material, it detects the normal component of **B** at the surface averaged over the sensor surface. Several researchers have used Hall probes to observe the magnetic properties of ferromagnetic and superconducting materials by scanning the surface.

Other Surface Probes. There are many surface probes used for special applications. Very useful are means to nondestructively evaluate ferromagnetic materials. When a magnetic field is applied, imperfections such as cracks produce local gradients that can be detected. One example, called a "magnetoscope," analyzes the hysteresis loop (Eichmann et al., 1992) to determine parameters such as applied stress, residual stress, and fatigue damage. Very powerful techniques involve derivatives of the scanning probe microscopes such as the magnetic force microscope for detecting surface magnetism at the atomic level.

Procedures for Magnetometry Measurements

Calibration. In principle, the response of both flux and force techniques can be calculated from first principles—flux from the law of induction and knowledge of the coil's area-turns, force from energy considerations and knowledge of the applied field profile. However, small variations in geometry, stray fields, or electronic or transducer sensitivity drift make this approach difficult, so that routine calibration by a specific sample is highly recommended. Good operating procedures dictate measurement with a calibration sample both before and after a series of measurements. A standard sample should be set aside specifically for calibration and testing of the magnetometer starting when the system is initially put into operation. (As an extra precaution, it is a good idea from time to time to measure the moment of just the sample support structure.)

A convenient and reliable calibration material is a spherical sample of pure, polycrystalline Ni with a mass ~10 mg measured in $H_0 > 10{,}000$ G (1 T) at saturation where the moment is independent of field (Eckert and Sievert, 1993). The calibration values are 58.6 emu/g at 4.2 K and 55.1 emu/g at 300 K. Nickel can be obtained with high purity at low cost, and it does not oxidize. Any appreciable increase in the moment above saturation could signal sample chamber contamination, e.g., by solid O_2 (see below). A paramagnetic material can be used as an alternative, but the calibration depends on knowing both the temperature and field.

Sample Size. When a sample is sufficiently small, a magnetic dipole approximation may be assumed. If the sample size approaches the size of the pickup coils in a flux measurement or subtends a very large portion of the sample chamber in a force measurement, corrections must be made. Large samples give results that are more sensitive to position than small samples. Two approaches for correcting for sample size can be used: (1) measure the large sample moment and use data from a small sample of the same material at a convenient point for normalization and (2) calculate the errors for a specific sample size and coil dimensions. Such corrections have been tabulated for VSMs (Zieba and Foner, 1982; Ausserlechner et al., 1994). For example, for a thin rod with normalized length $c/a_o = 0.5$, where a_o is the radius of a thin optimized coil pair and c is the length parallel to the coil axis, the error is ≈3% (Zieba and Foner, 1982). Corrections for force techniques with large or nonspherical or anisotropic samples require inclusion of x and y gradients as well as the effect of large z gradients.

Sample Position. It is essential to know sample position precisely for the full temperature and field range of measurement, because to some degree all the techniques discussed are sensitive to sample position. For flux measurements, uncertainty in sample position can be minimized but not eliminated by pickup coil design. It is important to know these characteristics for a given system so that estimates of reliability and errors of the data can be made. Force methods require knowledge of the various position dependencies of the field and field gradients. Tests should be conducted to assure that the sample is positioned where it is thought to be! Some of these effects can be large. Calculations for an axial field configuration SQUID system show that errors of up to 30% can occur if

the sample is sufficiently displaced radially (Miller, 1996). The dimensions of sample support structures including long support rods will in general vary with temperature, so it is good practice to compensate for this when necessary by readjusting the sample position at various temperatures.

Sample Temperature. Most magnetometers operating at temperatures below room temperature use He gas cooling to establish the temperature, for $5 < T < 300$ K. The temperature sensor should be as close to the sample as possible. It is also essential that the magnetic field dependence of the sensor calibration be known to high accuracy; this is particularly important at low temperatures. Sample temperature stability is achieved more slowly at high temperatures because the heat capacities of sample, support structure, and sensor increase rapidly for $T > 20$ K. Operation for $1.5 < T < 4.2$ K requires liquid ^{4}He and reduced pressures; extension to liquid ^{3}He temperatures ($0.3 < T < 1.5$ K) and lower using dilution refrigerators requires special adaptations. Measurements at high temperatures ($T > 300$ K) require a thermally shielded oven in the field volume. The furnace should be noninductively wound to minimize background effects. In addition, sample mounts and support elements must be chosen to withstand these temperatures and add minimum magnetic contributions.

METHOD AUTOMATION

Several turnkey automated DC magnetometer systems are commercially available, and more are under development. These systems use desktop computers for convenient data acquisition, control of independent variables such as temperature and magnetic field, data analysis, and real-time display of data for on-line assessment. Most commercial SQUID systems are fully automated with respect to magnetic field and temperature programming (using gas flow control), and typical experimental runs may extend for days without intervention. More recently, some vendors have provided similar automation for VSM systems, which generally have somewhat higher external magnetic fields. The inherent instability of the sample position in force detection magnetometers implies that temperature control may be more difficult; thus gas flow temperature control is generally not employed in these systems.

DATA ANALYSIS AND INITIAL INTERPRETATION

The following simulation using isothermal magnetization data for a reference (calibration) sample and a test material serves to illustrate the method for analyzing magnetic moment data. In this case, a small, pure, polycrystalline Ni sphere is used as the reference sample with data taken at 4.2 K. Refer to Figure 3.

At $T = 4.2$ K, the saturation moment of Ni is 58.6 emu/g. (It is ~5% smaller at room temperature.) Therefore, the measured moment at a field sufficient to saturate the

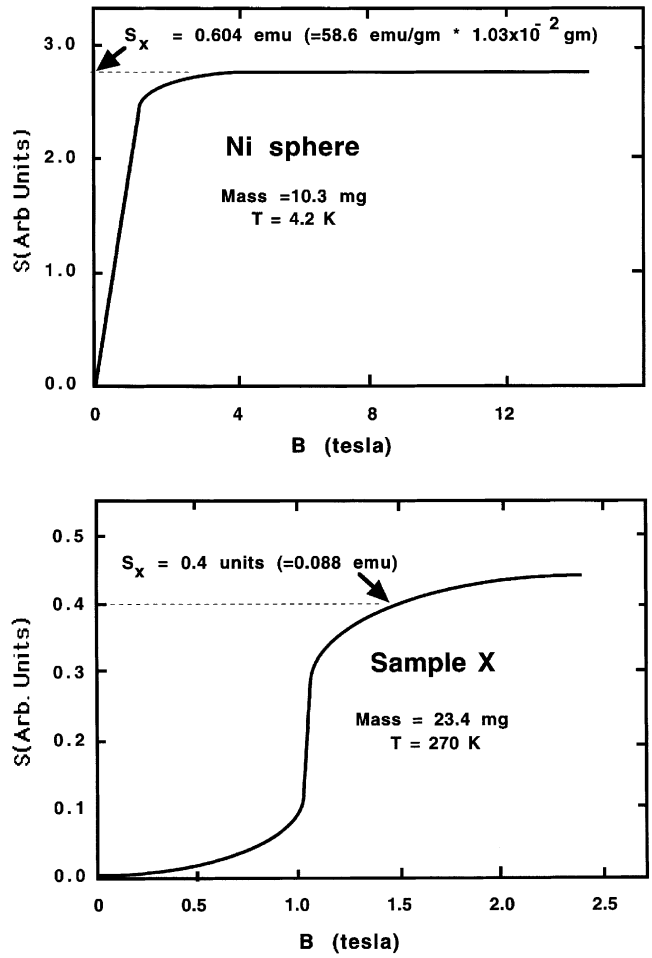

Figure 3. Simulation showing how the saturation moment of a polycrystalline Ni sphere may be used to calibrate the magnetization of an unknown, sample X.

magnetization, S_{Ni}, will be $S_{Ni} = Km_{Ni}\sigma_{Ni}$, where K is a constant of proportionality dependent on the pickup coil geometry, m_{Ni} the mass, and σ_{Ni} (= 58.6 emu/g) the saturation moment. This provides the calibration of the signal, S, with which all other samples can be measured. From Figure 3, the test point ($S_x = 0.4$ units) yields a total moment of ~0.088 emu [$= (0.4/2.75) \times 0.604$] or $\sigma_x = 3.75$ emu/g using $m_x = 2.34 \times 10^{-2}$ g.

Sample X, the test sample, represents a material that appears to have a metamagnetic transition near room temperature at about $\mathbf{H} = 1$ T.

Both the reference sample and the test sample are presumed to be small relative to the pickup coils in the case of a flux detection magnetometer (sample dimensions less than about half the inner dimension of the pickup coil). For force detection magnetometers, (1) the sample dimensions should be small relative to the change in the field and field gradient, and (2) this procedure assumes a constant field gradient, otherwise a field dependent correction for gradient is required.

Although this illustration involves isothermal magnetization, isofield magnetization as a function of temperature

(which in the limit of zero field is the magnetic susceptibility) can also be used to calibrate an unknown sample moment provided both temperature and moment are known. Corrections for larger samples (causing K to be slightly different in the two cases) may be made, and the reader is referred to Zieba and Foner (1982).

PROBLEMS

System Automation

Automation and computer control of turnkey instruments tend to produce the trusting "black box" syndrome. The appropriate response is to trust and then verify by regularly making measurements with the standard calibration sample, especially before and after a given set of measurements. A record of the readouts for the standard is useful to observe whether the system is degrading with time. Temperature sensors and amplifiers can drift with time: the calibrations of temperature and field should also be tested periodically.

Several issues arise from system automation that deserve attention, including the possibility of overshooting the target temperature and/or field. The system control may cause the sample temperature to overshoot (or undershoot if decreasing) relative to the target temperature. In systems that are magnetically reversible (nonhysteretic), paramagnetic, or weakly diamagnetic, this is not a problem, but for ferromagnetic or superconducting systems with magnetic hysteresis, this can yield spurious results. Overshooting or undershooting the external magnetic field relative to the target can also be problematic.

Contamination of Sample Chamber

It is important to assure that the sample chamber in the magnetometer is contaminant free, and to this end, the volume should be cleaned at convenient intervals. A few of the most common contaminants are discussed below.

Generally, the most ubiquitous source of contamination is Fe in the form of small particles or oxides (dirt) that may stick to the sample or container. An Fe film [1 nm (10 Å) over 1 cm^2] left by a machine tool on a sample mount will show a moment of $\sim 2 \times 10^{-4}$ emu at saturation. Iron contamination is easily observed as a magnetization nonlinearity as it is magnetized. Most surface Fe can be removed easily through etching in a dilute HCl solution.

A common source of contamination is superconducting solder at low temperatures and fields ($T < 6\,\mathrm{K}$ and $\mathbf{H} < 1000\,\mathrm{G}$). Superconducting contaminants such as solder can produce spurious diamagnetic or paramagnetic signals depending on their location relative to the transducer and on their history of exposure to external fields. The use of "nonmagnetic" stainless steels in sample mounts or cryogenic vessels is common. However, most stainless steels are strongly paramagnetic, especially at low temperatures. If mechanically worked or brazed, some stainless steels can become ferromagnetic.

Finally, for low-temperature measurements, it is important to assure that no air (oxygen) is trapped in the sample tube. Below ~80 K, oxygen (O_2) may condense on the sample or sample mount. Oxygen is paramagnetic, spin $S = 1$, and becomes solid below ~50 K, depending on partial pressure. Oxygen can accumulate slowly with time through leaking sliding seals and during sample changes. The only solution to O_2 contamination is to warm up the contaminated region, pump out the gas, and backfill with high-purity He gas. Nonsaturation of a Ni standard magnetization and/or erratic values of the Ni saturation moment may indicate solid O_2 contamination. Unfortunately the magnetism literature is replete with evidence for solid O_2 contamination of data. For example, the amount of O_2 gas in 1 mm^3 of air at STP will yield a moment of $\sim 2 \times 10^{-4}$ emu at $T = 4.2$ K and $\mathbf{H} = 10{,}000$ G (1 T).

Sample Support Structure

All support structures for sample mounts will show magnetic moments. Their contributions can be minimized in several ways for flux techniques, including minimizing the mass of the sample container and mount, minimizing a uniform cross-section support rod, and extending this support rod symmetrically well beyond the pickup coils so that no flux change is detected as the rod itself is translated. As stated above, it is a good practice to measure the moment of the empty sample mount from time to time. If it is generally <10% of the sample moment, it can be subtracted accurately to give reliable sample moment results.

Phase Considerations

In most ac signal detection systems, a lock-in amplifier provides the dc output signal proportional to the sample moment. Generally, the in-phase lock-in signal is proportional to the sample moment, but the out-of-phase component should be monitored, as it may change due to extraneous signals, and in some instances can overwhelm the in-phase signal. Eddy currents induced in the sample or sample mount (see below) may be detected as out-of-phase components relative to the in-phase sample moment.

Magnetic Field Inhomogeneities

In flux-detection methods where the sample is generally moved, inhomogeneities in the external magnetic field may lead to several problems: if the sample is highly conductive (a good metal), motion of the sample through a field inhomogeneity will induce eddy currents that may be detected at the transducer as a false moment. This problem is particularly severe if the sample is encased in a metallic high-pressure vessel and the eddy currents are induced in the pressure vessel. In general, eddy currents induced in the sample or sample mount and hysteresis losses will produce out-of-phase components that can be erroneously detected as real sample moments. Although the sample motion excursion is small for the VSM, motion through field inhomogeneities will produce an out-of-phase signal. For the extraction magnetometer, even though the excursion is large, waiting for the eddy

currents to decay is an option. Another option is to have a uniform magnetic field over the region of the sample motion. Another problem arises if the sample is in powder form: moving an unconstrained and strongly magnetic powdered sample through a field inhomogeneity can cause the powder to move relative to the container, thereby giving a false magnetization value. In general, any powdered or liquid sample should be fully constrained in a container for magnetometry measurements.

ACKNOWLEDGMENTS

THERMOMAGNETIC ANALYSIS

INTRODUCTION

The most common method of measuring magnetic ordering temperatures is through the use of thermomagnetic analysis techniques. These techniques rely on methods previously described (GENERATION AND MEASUREMENT OF MAGNETIC FIELDS, MAGNETOMETRY, and THEORY OF MAGNETIC PHASE TRANSITIONS). In essence, thermomagnetic analysis involves sensitive measurement of a magnetic dipole moment in a zero or an applied field as a function of temperature. The components of the system therefore include an appropriate magnetometer. Superconducting quantum interference device (SQUID), vibrating-sample, and Faraday-balance magnetometers are commonly used in the field (see MAGNETOMETRY). Large axial fields can be applied using a superconducting solenoid; smaller axial fields can be applied using wound-metal solenoids. Transverse fields can be applied using split-coil superconducting solenoids or electromagnets. The details of these are discussed in previous units. Measurement of the temperature dependence of magnetic properties requires careful design of the sample chamber and methods for heating and cooling, as well as accurate thermometry for monitoring temperature. Measurement of magnetic transitions of the types described in the abovementioned units may entail the measurement of magnetic properties at temperatures ranging from cryogenic to $\sim$1100°C (the T_c of elemental Co).

PRACTICAL ASPECTS OF THE METHOD

The data illustrated in the figures in this unit, probing magnetic phase transitions, were taken using either a SQUID magnetometer or a vibrating sample magnetometer. We give an abbreviated discussion of these systems here; generation of fields and measurement of dipole moments are treated in more detail in GENERATION AND MEASUREMENT OF MAGNETIC FIELDS and MAGNETOMETRY, respectively. A typical SQUID magnetometer is equipped with a 5.5-T superconducting solenoid, temperature control between 1.7 and 400 K (using a nitrogen-jacketed liquid He Dewar), and could measure dipole moments from 10^{-8} to 2 emu. High-moment options can allow measurement to several hundred electromagnetic units. Options for higher fields, transverse fields, and high temperatures ($\sim$800 K) all exist. Vibrating-sample magnetometers are typically equipped with a 1- to 2-T electromagnet, though superconducting solenoids can be used for larger fields. Options for inert gas ovens up to 1273 K exist. Modern sensitive pick-up coils allow for measurement of moments between 5×10^{-6} and 1×10^{4} emu. Options for fields up to 9 T (using a superconducting solenoid) and temperatures as low as 1.5 K using a liquid He Dewar are possible.

The principle of operation of a vibrating sample magnetometer (VSM) is based on placing a magnetic sample in a uniform magnetic field. The sample dipole moment is made to undergo a periodic sinusoidal motion at a fixed frequency using a transducer drive head to vibrate a sample rod. The vibrating magnetic dipole moment (through Faraday's law of induction) induces a voltage in a sensitive set of pick-up coils placed between the pole pieces of the electromagnet. This signal, proportional to the magnetization, is amplified and monitored. The VSM is calibrated using a standard sample of known moment such as a Ni (ferromagnetic) or Pt (diamagnetic) sphere.

The term SQUID is an acronym for superconducting quantum interference device. Superconducting and magnetic transition temperature (T_c), magnetic susceptibility, magnetic hysteresis, and magnetic relaxation can be measured using a SQUID magnetometer. During a measurement of magnetic moment, the previously centered sample is moved through a set of signal coils. The differential sensitivity of a typical SQUID is $\sim 10^{-8}$ emu and T stability below 100 K is $\pm 0.5\%$. Field inhomogeneity in the solenoidal magnet of the magnetometer can cause superconducting samples to undergo minor hysteresis loops during travel through the SQUID coils. Therefore, a scan length of 3 cm is used in order to minimize the inhomogeneity to $<0.05\%$.

The principles of operation of a typical SQUID magnetometer system for measuring a sample are briefly summarized as follows (Quantum Design, 1990).

1. The sample is transported through highly balanced second-derivative detection coils inducing a voltage proportional to dM/dt and therefore to M at constant frequency.
2. The signal detected in the second-derivative coils is coupled to the SQUID sensor through a superconducting isolation transformer. Voltage readings sensed by the detection coils are converted into a corresponding magnetic flux signal via the mutual inductance between the SQUID loop and coils.
3. After the raw data have been collected, the magnetic moment of the sample is computed by numerical methods using the previously determined system calibration factors. The output data thus consist of T, H, measured magnetic moment, time, and percentage error, etc. Since multiple measurements

are made in one scan, and since it is possible to perform several scans, a mean and standard deviation of the moment can be ascertained under a given set of measurement conditions.

One practical aspect of taking magnetization data using a superconducting solenoid is to recognize that superconducting solenoids can trap appreciable fields, i.e., on the order of 100 Oe for a 5- to 10-T magnet. Therefore, if a low-field measurement is desired, it is necessary to oscillate remnant fields out of the solenoid. Even with this procedure it is not possible to guarantee much less than ~1 Oe of trapped fields. For more stringent field requirements, normal conductor solenoids can be used; however, the ~0.3-Oe field of the earth must also be considered.

In the case of a SQUID magnetometer, it is possible to have additional transverse SQUIDS to measure orthogonal components of the magnetization. For a VSM, additional transverse pick-up coils can be used for the same purpose. Rotation options also exist for varying the angle of the applied field with respect to the sample reference frame for both devices. These require a greater degree of sophistication for axial (solenoidal) fields than for transverse fields.

There are several important issues in sample preparation for thermomagnetic measurements. These include issues of size, shape, weight, density, and crystallographic orientation. The sample size governs whether the magnetic sample can be considered as a point dipole, which is important in the measurement and modeling of the magnetic moment from the specimen. Sample size and weight, of course, also determine the size of a dipole moment, and must be considered along with the sensitivity of the magnetometer in order to measure statistically significant data. Sample shape is extremely important in understanding magnetic response. Demagnetization effects due to surface dipoles are purely a geometrical effect. As a result of demagnetization, the sample experiences local internal fields that may differ markedly from the externally applied field. Since most magnetic measurement techniques measure dipole moments, in order to calculate the sample magnetization the sample volume or weight and density must be known precisely (see MASS AND DENSITY MEASUREMENTS). The unsaturated magnetization can be strongly dependent on crystallographic orientation in anisotropic materials; it is therefore desirable to know the field orientation with respect to the crystallographic axes in single-crystal specimens and to employ methods to average over orientations in the case of powder samples. Because the application of a field in directions orthogonal to the magnetization results in a torque on a magnetic sample, samples need to be appropriately immobilized so as to prevent rotation in the field. Common morphologies for magnetic specimens include (1) powders, (2) plates, films or foils, and (3) crystalline parallelopipeds. To correct for demagnetization effects, ellipsoidal specimens are useful because the demagnetization factor is known analytically.

For cylindrical samples in a transverse field or for noncylindrical geometries, demagnetization effects need to be considered. The internal field can be expressed as

$$H_i = H_a - DM \tag{1}$$

where D is the demagnetization factor (e.g., $\frac{1}{3}$ for a sphere or $\frac{1}{2}$ for a cylinder or infinite slab in a transverse field). It follows that

$$H_i = \frac{H_a}{(1-D)} \tag{2}$$

and

$$M = \frac{-1}{4\pi(1-D)}H \tag{3}$$

For noncylindrical geometries, demagnetization effects imply that the internal field can be concentrated to values that exceed the applied field H_a.

METHOD AUTOMATION

All commercially available SQUID magnetometers have computer-control modules for sweeping field and temperature and measuring magnetic moment using general-purpose interface bus (GPIB) interfaces and/or proportional/integral differential (PID) temperature controllers. For controlling the field with an electromagnet, the current to the electromagnet coils is controlled and the field monitored with a Hall probe. In an electromagnet, control of a bipolar power supply is crucial to ensure the field changes sign smoothly through zero. For field control in a superconducting solenoid, a solenoidal field current calibration is used. Superconducting solenoids can be swept or latched in a persistent current mode.

Proportional/integral differential temperature controllers coupled with thermocouple measurement and gas-flow controllers allow for the monitoring and control of temperature in both the SQUID and VSM systems. It is therefore possible with both devices to measure the magnetization as a function of field or temperature. It is common to measure isothermal magnetization curves or magnetization at fixed field as a function of temperature. Computerized GPIB control allows for monitoring of field temperature and magnetic dipole moment during the course of an experiment.

For monitoring magnetic phase transitions, efficient heating and cooling are required as well as accurate thermometry for measuring temperature (see THERMOMETRY). Typical high-temperature oven assemblies on VSMs employ an electrically heated tube assembly with vacuum and reflective thermal insulation. With ~60 W of power, a maximum temperature of 1273 K can be reached. Components such as sample holders and oven parts are made from nonmagnetic components. The sample chamber can be evacuated and back-filled with inert gas to prevent sample oxidation. Chromel-alumel thermocouples, mounted in the heater, are used to monitor and facilitate temperature control. For more sensitive and accurate measurements, a thermocouple can be mounted directly in the sample zone.

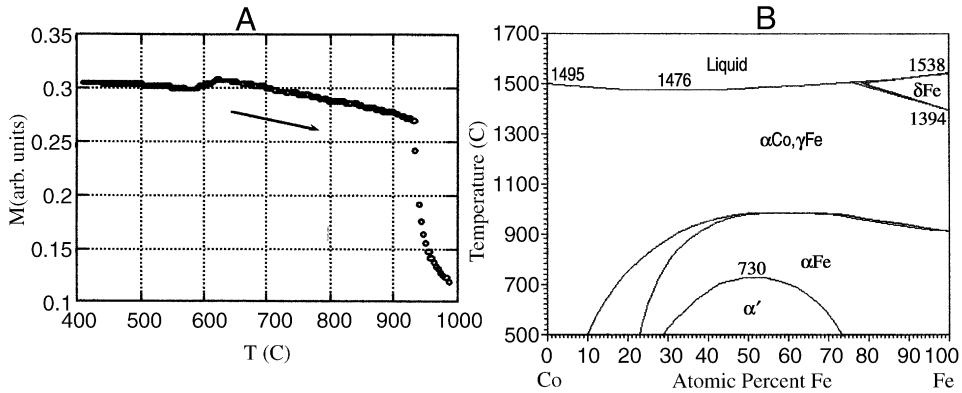

Figure 1. (**A**) $M(T)$ data for C-arc synthesized equiatomic Fe-Co nanoparticles measured using a Lakeshore Model 7300 VSM (Lakeshore Cryotronics, 1995) and oven assembly at 500 Oe, on a second heating cycle to 995°C after initial heating to 920°C (Turgut et al., 1997). (**B**) Fe-Co phase diagram (produced using TAPP software from ES Microware).

EFFECTS OF STRUCTURAL PHASE TRANSFORMATIONS

A complicating aspect of the measurement of magnetic phase transitions is the existence of other structural phase transformations that influence the magnetic properties. These include such transformations as crystallization processes in amorphous magnets, order-disorder, and martensitic or other structural phase transitions. As an example of such complications, consider thermomagnetic data for equiatomic Fe-Co nanoparticles as shown in Figure 1. Fe-Co alloys undergo an order-disorder transformation at a temperature of 730°C at the composition $Fe_{50}Co_{50}$, with a change in structure from the disordered α-BCC(A1) to the ordered α′-CsCl(B2)-type structure. At T > 900°C, $Fe_{50}Co_{50}$ transforms from the magnetic BCC phase to a nonmagnetic FCC λ phase.

Figure 1 shows $M(T)$, at $H = 500$ Oe, for equiatomic FeCo nanocrystalline powders measured on a second heating cycle after initial heating to 920°C. The influence of ordering is observed prominently in features that are quite similar to thermomagnetic observations for bulk $Fe_{49}Co_{49}$ V_2 alloys. These features include an increase in a discontinuity in $M(T)$ at ~600°C (due to chemical ordering) and a return to the extrapolated low temperature branch of the curve at the disordering temperature of ~730°C. Also of note in Figure 1 is that, at ~950°C, we observe an abrupt drop in the magnetization, which corresponds to the $\alpha \Rightarrow \gamma$ structural phase transformation. At $H = 500$ Oe, we observe a prominent Curie tail above this transformation temperature, indicating paramagnetic response. It can be concluded from the abruptness in the drop of $M(T)$ that the $Fe_{0.5}Co_{0.5}$ has a Curie temperature exceeding the $\alpha \Rightarrow \gamma$ phase transformation temperature. As such, a magnetic phase transition is not observed; instead it can be concluded that (ferro)magnetic α-$Fe_{0.5}Co_{0.5}$ transforms to non(para)-magnetic γ-$Fe_{0.5}Co_{0.5}$. This is corroborated in the differential thermal analysis data (see DIFFERENTIAL THERMAL ANALYSIS AND DIFFERENTIAL SCANNING CALORIMETRY), where the order-disorder and $\alpha \Rightarrow \gamma$ phase transformations have also been clearly observed.

Another interesting feature of magnetic phase transitions occurs in materials with large amounts of structural disorder, in which deviations in the exchange interactions can cause dramatic differences in the shape of the thermomagnetic response. The extreme case of this is in amorphous materials that do not have any structural long-range order. In amorphous or disordered ferromagnets, we use the premise that the mean field theory results discussed in MAGNETIC MOMENT AND MAGNETIZATION must be modified to account for deviations in the exchange interactions (due to deviations in atomic positions) in the amorphous alloy. In this limit

$$m = \frac{1}{2}\{B_J[x(1+\delta)] + B_J[x(1-\delta)]\} \qquad (4)$$

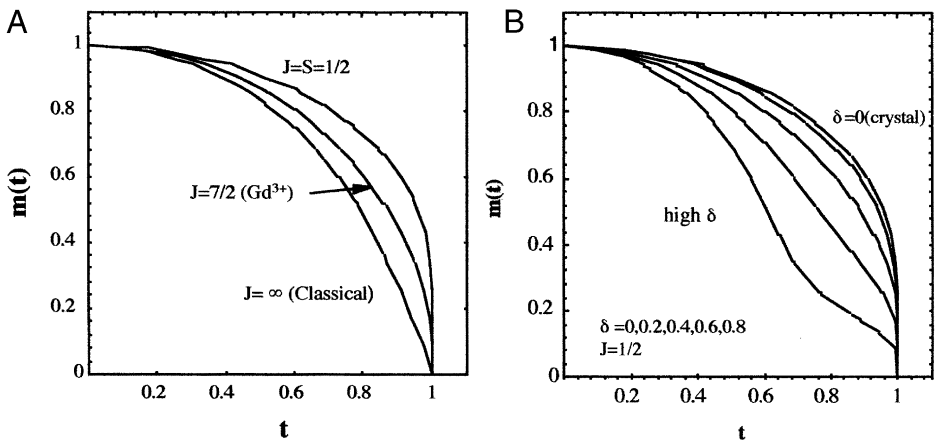

Figure 2. Comparison of magnetization as a function of reduced temperature, t, (**A**) in a spin-only ferromagnet (using a $J = 1/2$ Brillouin function), for $J = 7/2$, and for the classical limit $J = 8$; and (**B**) in an amorphous magnet with $J = 7/2$ and different values of the exchange fluctuation parameter δ. (Courtesy of Hiro Iwanabe, Carnegie Mellon University.)

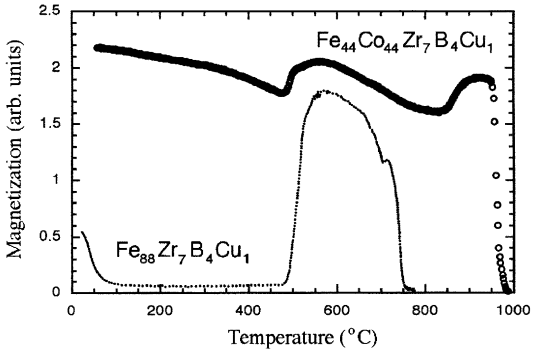

Figure 3. $M(T)$ (Willard et al., 1998, 1999) for an alloy with a NANOPERM composition $Fe_{88}Zr_7B_4Cu$ and an alloy with a HITPERM composition, $Fe_{44}Co_{44}Zr_7B_4Cu$.

where δ is the root mean square deviation in the exchange interaction

$$\delta\sqrt{\frac{\Delta Jex^2}{\langle Jex^2\rangle}} \tag{5}$$

Figure 2A compares mean field results for $M(T)$ in the classical, spin only, and total angular momentum representations. Figure 2B shows mean field results for $M(T)$, taking into account the disorder-induced fluctuations in the exchange parameter in hypothetical amorphous alloys. This construction then predicts a quite remarkable change in the mean field theory thermomagnetic response for amorphous magnets (Gallagher et al., 1999).

Viewed in another light, magnetic measurements can also offer sensitive probes of structural phase transitions. Examples of the use of such probes are too numerous to detail. However, by way of example, we consider the use of thermomagnetic data to probe the Curie temperature of an amorphous ferromagnet and reentrant ferromagnetism associated with crystallization of the same. For a $Fe_{88}Zr_7B_4Cu$ (NANOPERM) and $Fe_{44}Co_{44}Zr_7B_4Cu$ (HITPERM) alloy, $M(T)$, measured with a Lakeshore Cryotronics VSM with oven assembly, is illustrated in Figure 3. For the $Fe_{88}Zr_7B_4Cu$ alloy, the disappearance of M at $\sim$100°C reflects the Curie temperature of this alloy. The reentrant magnetization at $\sim$500°C reflects the crystallization of the initially amorphous material with the crystallization product being α-Fe, with an $\sim$770°C Curie temperature. For the $Fe_{44}Co_{44}Zr_7B_4Cu$ (HITPERM) alloy, $M(T)$ does not disappear prior to crystallization, so that reentrant ferromagnetism is not observed. However, the crystallization event at 500°C results in an $\alpha(\alpha')$-FeCo phase. This phase has a structural phase transition ($\alpha \Rightarrow \gamma$), as discussed above, at 985°C. The $M(T)$ response therefore probes both the amorphous $\Rightarrow$ crystalline and $\alpha \Rightarrow \gamma$ phase transition in this material.

DATA ANALYSIS AND INITIAL INTERPRETATION

Figure 4 shows magnetization versus temperature data for a 0.25-cm^3 cubic Gd single crystal taken in a field of 10 Oe. Several points are worth noting in interpreting such data.

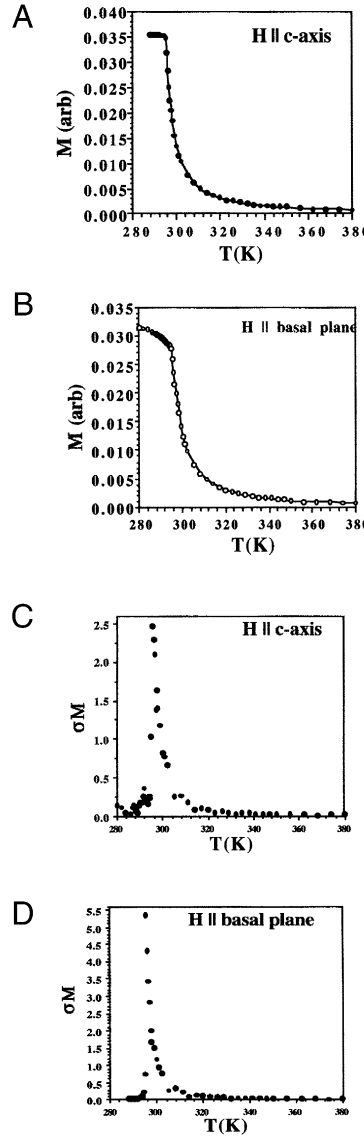

Figure 4. Magnetization-versus-temperature data for a cube-shaped (0.25-cm^3) Gd single crystal taken in a field of 10 Oe for (**A**) $H \parallel$ c and (**B**) $H \parallel$ basal plane, respectively (data taken using a Quantum Design MPMS SQUID magnetometer; units scaled by 10^4). The graphs in (**C**) and (**D**) show the variation of the temperature dependence of standard deviation of successive measurements using the SQUID measurement system. (All data from R. A. Dunlap and M. E. McHenry, unpub. observ.)

First, with appropriate signal averaging and averaging of several measurements, it is possible to obtain standard deviations of the dipole moment two orders of magnitude smaller than the mean. The standard deviations are in fact larger at intermediate values of M and display a λ-type anomaly reminiscent of the temperature dependence of the specific heat, which will be discussed below. This could be attributed to dynamical (heating) effects as the sample passes through the ferromagnetic to paramagnetic transition. Second, even in a small field (i.e., 10 Oe), a significant broadening of the transition (i.e., a Curie tail) is observed for this large sample. This broadening prevents an accurate determination of T_c by extrapolation to the

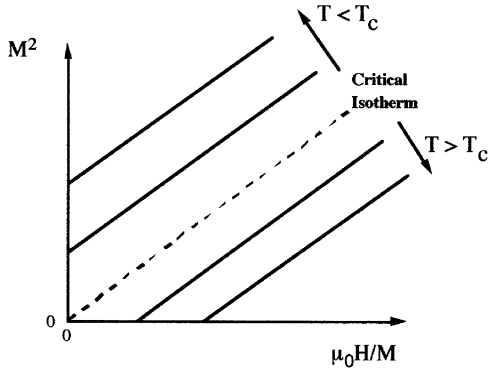

Figure 5. Schematic representation of the method of determining ordering temperatures using the Arrot plot construction.

$M = 0$ axis. On the other hand, fitting the data to a Curie-Weiss law does in fact allow for accurate determination of T_c. Gadolinium is an example of an anisotropic ferromagnet, in which its *c* axis is the easy direction of the magnetization. As a result, $M(T)$, below T_c, is markedly different for fields applied parallel to or perpendicular (i.e., in the basal plane) to the *c* axis. This anisotropy has been illustrated in the fact that a T_c for H parallel to the *c* axis differs by ~1 K from that determined with H in the basal plane (Geldart et al., 1989).

Data on the inverse susceptibility versus T for the same crystal used for Figure 4 has been used to yield a Curie temperature (paramagnetic) of 293.6 and 292 K, respectively for H parallel to *c* and to the *ab* basal plane (Geldart et al., 1989). The inverse susceptibility data was fit using a power law of the form $\chi_c^{-1}(T) = At^{\gamma}$ and $\chi_b^{-1}(T) = B + Ct^{\gamma}$ where A, B, C, γ, y, T_c^c and T_c^{basal} were taken as free parameters. The critical exponents γ and y were determined to be 1.23 and 1.01, respectively. These fits revealed a difference in T_c of ~1.5 K that was attributed to a difference in in-plane and out-of-plane dipolar interactions, which will not be discussed in detail here.

Another analytic method for determining ordering temperatures from thermomagnetic data is by assuming a Landau theory equation of state and fitting data with so called Arrott plots. In Arrott plots, shown schematically in Figure 5 isotherms of M^2 are plotted as a function of H/M in accordance with the Landau theory equation of state. These isotherms consist of a set of parallel lines, with the isotherm corresponding to the Curie temperature passing through the origin. This is a particularly sensitive method for determining the Curie temperature.

TECHNIQUES TO MEASURE MAGNETIC DOMAIN STRUCTURES

INTRODUCTION

Critical to understanding the magnetic properties and the technological application of magnetic materials is the ability to observe and measure magnetic domain structure. The measurement challenge is quite varied. Magnetic fluids can be used to decorate and make simple domain structures visible while highly sophisticated electron microscopy-based methods may be needed to explore and image nanometer-scale magnetic phenomena. No one method will solve all of the important domain imaging problems. For that reason, we will discuss the bases of all the important methods and the practical implications of each.

For purposes of comparison, several important characteristics of each domain imaging technique we discuss are briefly summarized in Table 1. However, the table should only be used as a broad outline of the different methods and any choice of method should include consultation with the relevant sections below and the references therein.

There are several general comments that apply to every domain imaging method discussed in this unit. First, each method is related either to a sample's magnetization or to the magnetic field generated by that magnetization. The former observation is of great usefulness in understanding or developing new materials, and the latter is of practical importance in devices. Second, all of the methods are limited to the topmost few micrometers of the sample, and are therefore dominated by magnetic structure related to the surface. None provide the domain structure of the interior of a thick sample where bulk magnetic microstructure is fully developed. Third, all of the methods require smooth, clean, damage-free surfaces. In general, the surfaces need to have at least the equivalent of a mirror polish, otherwise, topography and surface stress will affect the measurement to varying degrees. Fourth, correlations exist between several of the parameters in each technique we describe. For example, it may not be possible to achieve the ultimate sensitivity specified at the highest resolution possible. Finally, almost all of the techniques use digital signal acquisition and can benefit from the use of modern image processing tools.

What follows are expanded discussions of the basis of each technique, its practical aspects, sample preparation required, possible sample modifications, and problems that are specific to the technique described. Each section contains references to more complete treatments of the technique and recent examples of its use.

BITTER PATTERN IMAGING

Principles of the Method

Bitter or powder pattern imaging of domain structures is arguably the oldest domain imaging technique, and still probably the simplest method to apply. In Bitter pattern imaging, a thin colloidal suspension of magnetic particles is painted on a magnetic surface. The particles collect and agglomerate in regions where large stray fields from the sample are present, typically over domain walls. The decorated domain walls can then be imaged using an optical microscope, or, if higher resolution is required, an electron microscope. Figure 1 shows an example of a Bitter pattern image of bits written on a magnetic hard disc.

The Bitter technique is strictly a stray-field decoration technique. The patterns provide no information about the magnitude or direction of the magnetization, but in materials with sufficiently large external fields, Bitter patterns can quickly provide information about the size and shape of any domains that may be present. Bitter pattern imaging has been reviewed by Kittel and Galt (1956) and Craik (1974).

Practical Aspects of the Method

The resolution of the Bitter method depends primarily on both the size of the individual or agglomerated particles in the colloid and the resolution of the microscope used to image the patterns. Historically a researcher had to be skilled in the preparation of Bitter solutions, but today there are several commercial suppliers of Bitter solution colloids, sometimes referred to as ferrofluids (Ferrofluids from Ferrofluidics and Lignosite FML from Georgic Pacific). By selecting the appropriate Bitter solution, these commercial ferrofluids can reveal magnetic structures down to the resolution limit of the optical microscope. Higher resolutions can be attained by imaging the decorated sample with a scanning electron microscope (Goto and Sakurai, 1977) or by using fine-grained sputter-deposited films for decoration (Kitakami et al., 1996).

Contrast in the Bitter method depends on sufficiently large stray magnetic field gradients to collect the magnetic particles. Although certain ferrofluids can be sensitive to stray fields as small as a few hundred A/m, the stray fields outside of some high-permeability or low-anisotropy materials may still be too small to image. For this reason, the technique generally works better with higher coercivity magnets or perpendicularly magnetized samples. In fact, a small perpendicular applied magnetic field is frequently used to improve the contrast. As with any magnetic field–sensitive domain imaging technique, deriving the magnetic structure from the observed Bitter pattern image can be difficult, since the external magnetic fields may be the result of nonlocal variations in the sample's magnetization.

Sample Preparation

The Bitter method requires some sample preparation, because the technique does not separate the magnetic from the topographic contrast. Bulk samples are usually prepared by mechanical of polishing the surface, followed by chemical or electropolishing to remove residual surface strains. Thin films deposited on polished substrates can also be used. Aside from the smoothness, there are few constraints on the types of magnets that can be studied. The samples can be conductors or insulators, and thin nonmagnetic coatings are allowed. On the downside, the ferrofluid can contaminate the surface, leaving behind residues that may not be easily removed.

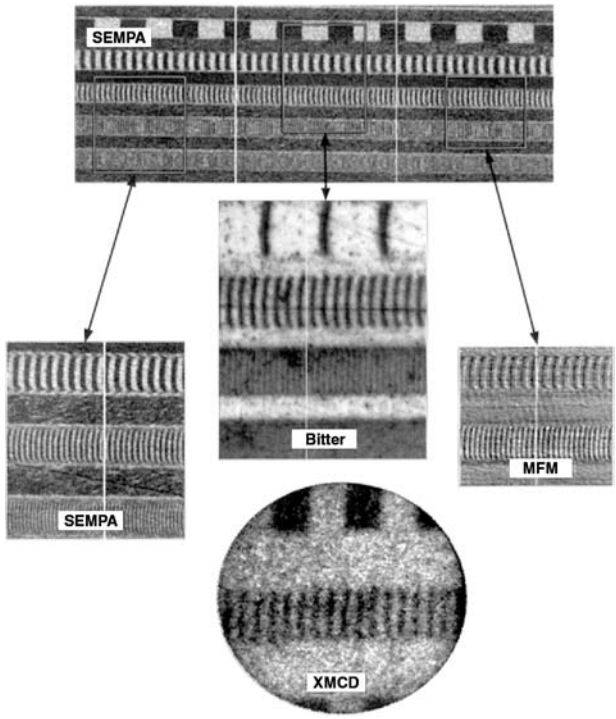

Figure 1. An illustration of several magnetic imaging techniques using a pattern written on magnetic storage media. The test pattern is composed of horizontal tracks, each ~10 μm wide and containing a series of magnetization reversals, or "bits." The bit length ranges from 10.0 to 0.2 μm. The bit length and spacing of the large bits in the XMCD electron yield image is 10 μm (Tonner et al., 1994). Note that the Bitter and XMCD images are from a different, but similar, test sample.

Specimen Modification

As long as the magnetic particles remain in solution, the Bitter pattern can be used to examine the motion of domains and domain walls while applying a magnetic field. The response time of the ferrofluid may be rather slow, however, due to the viscosity of the colloidal solution. In some cases it may take several minutes for the Bitter pattern to come to complete equilibrium. The ability to observe domain wall motion while applying a magnetic field is essential when trying to separate magnetic structure from sample topography.

MAGNETO-OPTIC IMAGING

Principles of the Method

The weak interaction between polarized light and a material's magnetization leads to several useful optical domain imaging methods (Craik, 1974). Although the physics of the magneto-optic interactions can be rather complicated (Hubert and Schäfer, 1998), at the most basic level, magneto-optic imaging is simply based on the rotation of the plane of polarization of linearly polarized light upon reflection from, or transmission through, a magnetic material. The magneto-optic effect in transmission is usually referred to as the Faraday effect and in reflection as the Kerr effect. In both cases, the domain contrast in the image is directly related to the magnitude and direction of the magnetization in the sample.

Practical Aspects of the Method

The relative geometry between the magnetization direction and the direction of the transmitted or reflected light determines which component of the magnetization vector will be visible in a particular magneto-optic image. When light is incident normal to the sample surface in either the "polar" Faraday or Kerr mode, domains that are magnetized perpendicular to the surface are imaged. In-plane magnetization can be detected in the Faraday or Kerr modes using oblique illumination. In the longitudinal Kerr effect, the in-plane magnetization component lies in the scattering plane of the light, while in the transverse Kerr effect the magnetization is perpendicular to the scattering plane. Contrast in the polar mode is greatest at an angle of incidence of 0°, while the longitudinal and transverse Kerr effects are greatest at ~60° angle of incidence.

Typically, magneto-optic images can be generated either by using conventional imaging optics or by rastering a finely focused laser spot across the sample surface. In either case, high- quality strain-free optics and polarizers with high extinction ratios are preferred, because the magneto-optic effects are quite small. The Faraday and polar Kerr modes provide the most contrast, while the contrast in the longitudinal Kerr mode is so small that additional electronic signal processing is usually required to separate the magnetic contrast from the nonmagnetic background (Schmidt et al., 1985; Argyle, 1990; Trouilloud et al., 1994).

The resolution of the magneto-optic image is determined by the resolution of the optical imaging system, or, in the case of rastered laser imaging, by the size of the focused laser spot. Typical resolution is therefore ~1 μm, but can be improved to 0.3 μm in a high-quality optical microscope using an oil-immersion objective and blue light illumination. Further improvements in resolution can be achieved by using various forms of scanned near-field optical imaging, but the contrast mechanisms in these methods are not yet well understood (Betzig et al., 1992; Silva and Schultz, 1996). The sampling depth in the Kerr imaging mode is determined by the penetration depth of the light and is ~20 nm in a metal. Therefore, the technique is moderately surface sensitive and can be used to image magnetic domains in thin films that are only a few monolayers thick, as well as to image domains that are covered by sufficiently thin films of materials that are normally opaque.

Sample Preparation

The small sampling depth and topographic sensitivity of the Kerr imaging mode requires preparing samples that

have optically flat, damage-free surfaces. Bulk samples can be prepared by mechanical polishing, followed by chemical polishing or annealing to remove the remaining damage. High-quality surfaces for imaging can also be generated by evaporation or electrodeposition of thin films on flat, polished substrates. Samples may be coated by thin, nonmagnetic films without significantly affecting the magneto-optic images. In fact, appropriate antireflective coatings can be applied to samples in order to increase the magneto-optical contrast.

Specimen Modification

Perhaps the greatest advantage of magneto-optic imaging is the speed with which magnetic images can be acquired. Video-rate imaging of domain dynamics is routinely achieved using standard arc lamp illumination. Stroboscopic imaging using pulsed laser illumination can reveal domain wall motion that occurs over time scales as short as a few nanoseconds (Petek et al., 1990; Du et al., 1995). In fact magneto-optic imaging can yield a great deal of information about magnetization dynamics in a magnetic material or device, since arbitrarily large magnetic fields may be applied to the sample while imaging. Figure 2 shows a magneto-optic image of a thin-film recording head. This image highlights the domain wall motion within the head by taking the difference between images with the current in the head coils reversed.

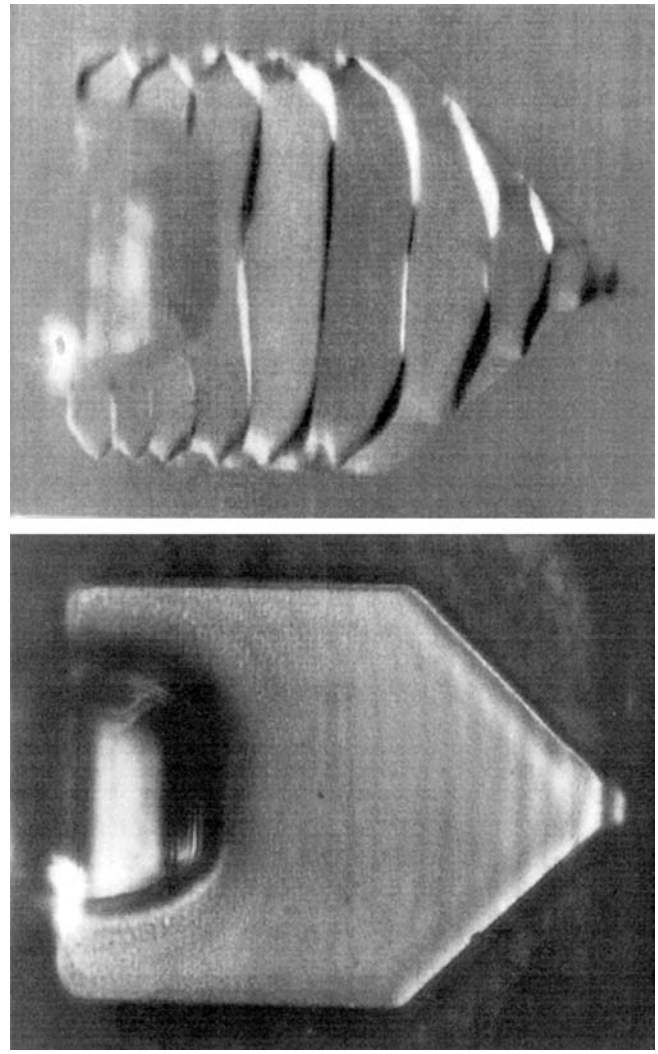

Figure 2. Magneto-optic image of a thin-film recording head. The lower panel shows the raw optical image showing the sample topography. The top panel shows the difference between two magneto-optical images taken with opposite currents driving the head magnetization. The white and black regions reveal how the domain walls have moved. The head is ~100 μm across. Photo courtesy of B. Argyle.

Problems

The major difficulty with the Kerr imaging mode is having to separate the magnetic image from a potentially larger nonmagnetic background and from the intensity variations due to the sample's topography. Various approaches have been used to improve the contrast and eliminate topographic feedthrough. Antireflective coatings may be applied to the sample (Hubert and Schäfer, 1998). The fact that the sense of the Kerr rotation is independent of the direction of incidence may also be exploited by using wide-angle illumination and a segmented optical detector (Silva and Kos, 1997). The most common method is to measure, using sufficiently precise instrumentation, the difference between the images taken before and after a magnetic field is applied to reverse the magnetization. In practical terms, this means that magneto-optic imaging is best applied to samples where the magnetization may be changed by applying a field, such as in the thin-film magnetic recording head shown in Figure 2. On the other hand, high-quality images of static magnetic domain patterns that one cannot or does not wish to alter, such as written bits in recording media, are difficult to acquire.

Finally, there are several new developments in magneto-optical imaging that are worth noting because of their potential future impact. First of all, near-field optical techniques are being used to overcome the resolution limits of conventional diffraction-limited optics. By using scanned apertures or tips in close proximity to a surface, resolutions on the order of $\lambda/10$ have been achieved (Betzig et al., 1992; Silva and Schultz, 1996). Second, magneto-optic indicator films have been developed as an alternative to Bitter pattern imaging (Nikitenko et al., 1996). In this method a thin, free-standing garnet film is placed against a magnetic sample and the resulting domain pattern, induced by the sample's stray field, is imaged using a conventional polarized-light microscope. Compared with Bitter imaging, this relatively simple and inexpensive technique has the advantage of faster response to applied magnetic fields and no sample contamination. Finally, intense laser illumination has made possible imaging using second-harmonic Kerr effects (Kirilyuk et al., 1997). The second-harmonic effects result from the nonlinear optical response of certain materials, enabling this mode

to image structures, such as domains in antiferromagnets, that are not visible with conventional Kerr imaging.

MAGNETIC FORCE MICROSCOPY

Principles of the Method

Magnetic force microscopy has become one of the most widespread tools for studying the magnetic structure of ferromagnetic samples and superconductors (Rugar and Hansma, 1990; Sarid, 1991). The technique is based on the forces between a very small ferromagnetic tip attached to a flexible cantilever and the inhomogeneous stray magnetic field immediately outside a sample of interest. As the magnetic tip is scanned over a magnetic sample, these minute forces are sensed in any of a variety of ways to provide maps related to the magnetic field above the sample.

In the implementation of an MFM, there are a very large number of choices to be made that influence, in a fundamental way, how the observed image should be related to the magnetic field. For example, an MFM in which the tip is magnetically relatively soft (i.e., the tip magnetization is modified by its interaction with the sample) provides a very different image of the magnetic field than one which utilizes a tip that is magnetically relatively hard (i.e., the tip magnetization does not change in response to the magnetic field of the sample). Similarly, the distribution of magnetic moments in the tip can have a pronounced qualitative effect on the imaging. Whereas a point-like magnetic particle on the tip may best be modeled as a simple magnetic dipole, a tip that is longer or more like a needle may be best modeled as a magnetic monopole. Furthermore, the MFM may sense either the net deflection of the tip in the field of the sample or may sense changes in either the amplitude, frequency, or phase of the vibrational motion of a tip oscillating resonantly in the field above the sample. One direct result of the complex and multifaceted interaction between the tip and sample is that it is very difficult to determine the field distribution from an MFM image.

Because of the huge number of possible implementations implied by these (and many other) available choices, and further because the state-of-the-art for magnetic force microscopy is currently being developed very rapidly in numerous laboratories, it is not possible in the current context to provide a thorough or complete report on the status of magnetic force microscopy. Instead, we will present a general description of an MFM in one form readily available commercially.

Rather than directly sensing the deflection of the flexible cantilever due to magnetic forces acting on the magnetic cantilever tip, MFMs typically detect changes in the resonant vibrational frequency of the cantilever. In this mode of operation, the cantilever is electrically driven to oscillate, with the driving frequency controlled to track very precisely the resonant vibrational frequency of the cantilever. When they are in close proximity, the scanning tip and sample surface generally experience an attractive net force (e.g., from van der Waals interactions). In addition to this attractive force, there will be a force of magnetic origin, which will be either attractive or repulsive depending on the relative orientation of the tip magnetization and the magnetic field gradients above the sample. Where the magnetic force is also attractive, the cantilever is deflected further towards the surface. This effectively stiffens the cantilever, raising its natural resonant frequency. If the magnetic force is repulsive, the cantilever is deflected less strongly towards the sample, effectively softening the cantilever and lowering its resonant frequency. Because the resonant frequency of the cantilever can be determined with very high precision, that frequency provides a convenient means by which to monitor local variations in the magnetic field gradients.

However, because the magnetic forces between tip and sample are very small, one general problem that all MFMs must address is the separation of the image contrast that arises from magnetic forces from the image contrast that is due to other (stronger) short-range physical forces (Schoenenberger et al., 1990).

Figure 1 shows, as an inset, a magnified region of a test pattern written on magnetic storage media as imaged with a commercial magnetic force microscope. The written bits are clearly visible and highlight the fact that the MFM is primarily sensitive to gradients in the magnetic field. Regions where the magnetization changes from left to right (or right to left) are visible as white (or dark) lines. This contrast would reverse with a magnetization reversal of the MFM tip.

Practical Aspects of the Method

There are several practical aspects to MFM imaging that should be noted. First, it is generally not known with confidence what underlying contrast mechanism gives rise to an MFM image. The signal is generally proportional to spatial derivatives of the stray field above the sample, but which spatial derivative in which direction depends on the such factors as the details of the magnetic moment distribution within the tip, tip/sample interactions, operating mode of the MFM signal detection and control electronics, vibrational amplitude of the cantilever, and lift height of the MFM scan relative to the AFM topographic scan. As a consequence, quantitative interpretation of MFM images is generally very difficult (Hug et al., 1998). Even qualitative interpretation can sometimes be very uncertain. Because the MFM can often be configured to give contrast that is proportional to the magnetic field as well as to various spatial derivatives, one is often uncertain whether observed magnetic contrast is due to a magnetic domain or to the domain wall between two domains. As with many scanned-tip microscopes, navigation on a sample can be difficult. The MFM always operates at very high magnification, so it can be difficult to find specific isolated features for study.

As mentioned above, the effects of surface topography on magnetic force microscopy can be pronounced. One common solution to this problem is to acquire the magnetic image in two steps. In the first step, the microscope is operated as a conventional atomic force microscope (AFM; not discussed here) so as to determine in detail the topographic

profile along one scan line. The microscope then retracts the tip and, using the previously determined line profile, rescans the same line with the magnetic tip at a small but constant height (typically 20 to 200 nm) above the sample. In this second scan, the longer-range magnetic forces still affect the cantilevered tip, but the effect of the short-range forces is minimized. This effectively provides a map only of variations in the local magnetic field, free of topographic contrast.

Even with such methods to compensate for the effects of surface topography, samples must be very smooth for these methods to be effective. Surfaces that have significant roughness or surface relief can be very difficult to image with the MFM. Sometimes the AFM prescan is not adequate because the surface relief is too great for the AFM tip positioning to be reliable. Even if the AFM topography scan is successful, other problems arise if the combination of tip vibrational amplitude and surface texturing is so large that the tip contacts the sample during the MFM scan.

One very useful feature of the MFM is that, because the MFM senses the stray magnetic field rather than the sample magnetization directly, it is easy to see the magnetic structure even through relatively thick nonmagnetic and even insulating overlayers.

Data Analysis and Initial Interpretation

Significant image processing is generally required to aid in the interpretation of MFM images. The relevant image-processing steps are typically integrated into the commercial MFM instrument controllers. One example is the abovementioned subtraction of contrast due to surface topography. This subtraction, however, has the side effect that domain walls that run parallel to the scan direction can be much more difficult to image than walls running at a significant angle to the scan direction.

Sample Preparation

One of the very attractive features of the MFM is that minimal surface preparation is required. Samples that are smooth and flat enough to image with an atomic force microscope can generally be studied with MFM as well.

Problems

As mentioned above, consideration must always be given to the extent to which the magnetic structure of the tip or sample is modified in response to the magnetic field of the other.

TYPE I AND TYPE II SCANNING ELECTRON MICROSCOPY

Principles of the Method

It is often possible to image the magnetic domain structure of a sample with a conventional scanning electron microscope (SEM) (SCANNING ELECTRON MICROSCOPY). Two distinct contrast mechanisms, referred to as Type I and Type II magnetic contrast, have been described (Reimer, 1985; Newbury et al., 1986). Both are based on the deflection (due to the Lorentz force) of electrons moving in a magnetic field. Two important features distinguish between Type I and Type II contrast. First, whereas Type I contrast involves imaging low-energy secondary electrons ejected from the sample, Type II contrast arises from high energy, backscattered electrons. Second, whereas Type I contrast arises from the deflection of the secondary electrons by stray fields outside of the sample, Type II contrast relies on deflection of the incident and backscattered electrons by magnetic fields within the samples.

Practical Aspects of the Method

There are relative advantages and disadvantages to both types of magnetic contrast. The primary advantages are that no special modifications are required either for the scanning electron microscope or the sample. Essentially any conventional scanning electron microscope can be used for Type I contrast. The only special requirement, which may involve modification to the secondary electron detector, is the positioning of the detector to one side of the sample so as to preferentially detect secondary electrons that are ejected toward rather than away from the detector. Some detectors have a bias voltage for secondary-electron collection that is so high that its directional sensitivity is inadequate to observe Type I contrast. If the microscope includes (as is very common) a detector for backscattered electrons, then Type II contrast is also feasible. The primary disadvantages are that spatial resolution is limited, and that it is sometimes difficult to distinguish between magnetic contrast of either type and other types of signal contrast.

For Type I contrast to be optimized, the primary beam energy typically should be <10 keV in order to produce the most secondary electrons. Because contrast depends on the geometry of the microscope's electron detector relative to the sample magnetic structure, tilt and rotation control of the sample are necessary to optimize contrast. Spatial resolution is limited typically to ~ 1 μm due to the spatial extent of the external magnetic fields. In some circumstances, the sample tilt and rotation also allow Type I contrast to be used for quantitative imaging of the magnetic fields outside of a sample (Wells, 1983).

Type II contrast is maximized by using the highest available beam energy and by tilting the sample surface to $\sim 50^\circ$ relative to the incident beam. The contrast varies from $\sim 0.1\%$ at 20 keV to $\sim 1\%$ at 200 keV. Because the contrast is relatively low, high primary beam currents are required. The spatial resolution is then determined both by the size of the primary beam and by the escape volume of the back-scattered electrons. For the direction parallel to the tilt axis, this resolution varies from ~ 1 μm at lower energies to ~ 2 μm at 200 keV. For the direction perpendicular to the tilt axis, the resolution is significantly degraded and is roughly determined by the penetration depth for the incident electron. For 200-kV electrons, that resolution is ~ 10 μm.

Type II magnetic contrast, of all the imaging techniques described, can have the greatest information depth. At

200 keV, the electrons penetrate ~15 μm of material, with the maximum back-scattering intensity coming from a depth of ~9 μm. Consequently, Type II is less surface sensitive than the other imaging techniques. Further, exploitation of the dependence of the penetration depth on primary beam energy provides a coarse method for magnetization depth profiling.

Data Analysis and Initial Interpretation

No significant data analysis is required, but interpretation is generally restricted to qualitative studies of domain sizes and shapes.

Sample Preparation

No special preparation is required, other than polishing for the removal of topographic features that would otherwise compete with the relatively weak magnetic contrast.

LORENTZ TRANSMISSION ELECTRON MICROSCOPY

Principles of the Method

This form of very high resolution magnetic microscopy gets its name from the Lorentz force, which causes a deflection of the electron trajectory for a beam traveling perpendicular to a magnetic field. The Type I and Type II methods, described previously, also are based on the Lorentz force. However, while Type I and Type II imaging are performed on the surface of a sample in an SEM, Lorentz microscopy makes use of either a conventional transmission electron microscope (CTEM) or a scanning transmission electron microscope (STEM), and involves transmission through thinned samples (TRANSMISSION ELECTRON MICROSCOPY and SCANNING TRANSMISSION ELECTRON MICROSCOPY: Z-CONTRAST IMAGING). Within the general category of Lorentz microscopy, three distinct imaging techniques (Chapman, 1984; McFayden et al., 1992) can be identified, i.e., Fresnel, Foucault, and DPC microscopy.

By using a CTEM in the Fresnel mode (Heyderman et al., 1995), narrow regions of relatively high and low intensity are formed at positions that correspond to domain walls; this results from small deflections caused by the Lorentz force acting on a defocused beam of electrons transmitted through the sample. Consider a thinned magnetic sample with a domain geometry of parallel strips, with the magnetizations in each strip lying in-plane and in alternating directions parallel to the domain walls separating them. The Lorentz force will, depending on the magnetization direction of each domain, deflect the beam slightly toward one wall or the other. As a consequence, the domain will be seen to have a bright wall on one side and a dark wall on the other. Figure 3A shows an example of Fresnel imaging of a metallic glass.

In the Foucault mode (Heyderman et al., 1995) using a CTEM, the image remains in focus and a diffraction pattern is formed at one of the aperture planes of the microscope. By displacing the aperture, it is possible to block

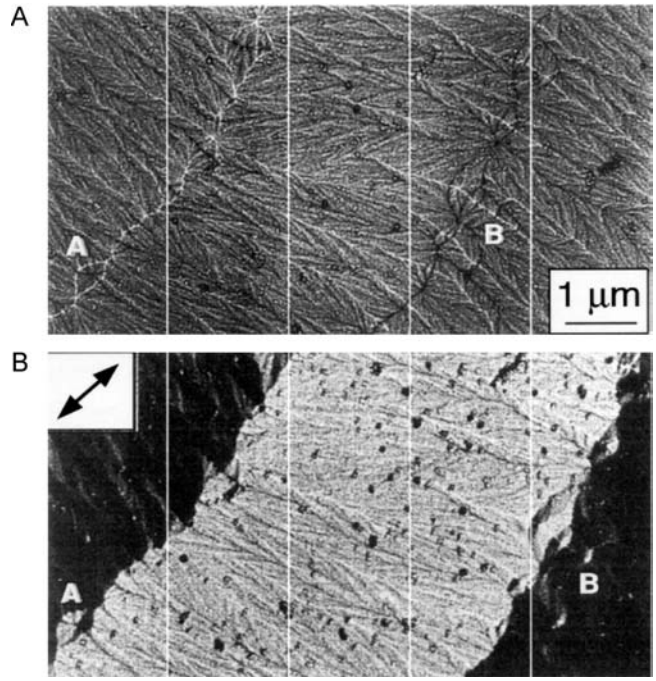

Figure 3. (**A**) A Fresnel image of a metallic glass magnetic material showing a bright and a dark domain wall. (**B**) A Foucault image of the same area, where the contrast depends on the magnetization parallel to the domain walls, as indicated by the arrows. In addition to the main 180° domains, these techniques clearly reveal small variations in the magnetization, i.e., magnetization ripple (Heyderman et al., 1995).

electrons that have been deflected in one direction by the magnetic field. In the image subsequently formed, the brightness within each domain will depend on the direction of its magnetization. Figure 3B shows an example of Foucault imaging.

In the DPC mode (McVitie et al., 1997), a STEM is modified by the addition of a quadrant electron detector and matching electronics. A focused scanning probe beam is deflected on passing through the thin sample, and the extent of the Lorentz deflection is measured from the differences and ratios of currents incident on the quadrants of the electron detector. A quantitative measure of the magnetic field lying perpendicular to the electron's path through the sample is possible.

Practical Aspects of the Method

These methods, particularly DPC, are capable of excellent resolution, approaching 2 nm for magnetic structures in the best of circumstances and 10 to 20 nm for more typical applications. Physical structure can be seen with even higher resolution. Image acquisition times are typically tens of seconds for computer-controlled DPC image acquisition.

The methods are quite sensitive, being able to detect just a few layers of Fe in cases where the crystallographic contrast does not interfere. Since deflections are caused by

the magnetic field within the sample, the information depth is the full sample thickness with equal weighting for all depths. Note, however, that magnetic fields outside the sample surface can also cause deflections that could modify the image.

The complexity of these methods is moderately high. They all use a TEM and may involve preparing a sample by thinning, which, it should be remembered, can have an effect on the domain structure. TEMs suitable for use in these modes are readily available commercially. The highest-resolution systems, with field emission sources and a variety of attachments, can cost one million dollars, although the cost to add a magnetic imaging capability to an existing TEM would be much less. In the DPC method, the electronics necessary to derive, display, and store the difference signals are not commercially available. Also, some technique must be implemented to "descan" the probe beam on the detector plane, i.e., remove the contribution to the differential detector signal that comes from a scanning probe beam rather than magnetic deflection.

Method of Automation

In the DPC method, the four quadrant detectors (or eight if a scheme to separate magnetic and nonmagnetic contrast is used) are connected to preamplifiers and an amplifier/mixer to derive multiple signals, including the sum of all channels, and the sums and differences between various quadrants. These signals are displayed in real time and filtered, digitized, and stored in a computer for later analysis.

Data Analysis and Initial Interpretation

Images produced in the Fresnel and Foucault modes immediately display the domain walls or domains, respectively. The dimensions of the domains can be determined quantitatively from these images. The DPC method uses the digitized signals stored for each x,y point in the image; the magnitude, direction, and curl of the magnetic induction can be calculated and displayed. Additional displays, including color wheel representations of direction and histograms showing the distribution of fluctuations in direction, are also readily available.

Sample Preparation

Only very thin samples can be analyzed. This method is generally applicable for samples $<$150 nm thick. As with other electron-based methods, only conductive samples can be imaged.

Common to all the Lorentz methods described above is the requirement that the microscope not generate sufficient magnetic field at the sample to modify the domain pattern. This problem can be addressed by either turning off the objective lens, moving the sample away from the strongest field position, or using a low-field lens specifically designed for the purpose. Unfortunately, all of these solutions will degrade the spatial resolution somewhat.

Specimen Modification

Magnetic fields can be purposefully applied to the sample, so long as they do not significantly affect the operation of the microscope. In a typical case, magnetic fields can be applied to the sample if held below 500 kA/m in the direction along the microscope column and 80 kA/m perpendicular to it. Modification of the sample due to beam heating effects is usually considered negligible.

SCANNING ELECTRON MICROSCOPY WITH POLARIZATION ANALYSIS

Principles of the Method

Scanning electron microscopy with polarization analysis is a magnetic-imaging technique based on the measurement of the spin polarization of secondary electrons ejected from a ferromagnetic sample by an incident beam of high-energy electrons (Scheinfein, et al., 1990). These secondary electrons have a spin polarization that is determined by their original spin polarization, i.e., the magnetization in the bulk sample. An image of the magnetic domain microstructure at the surface can thus be generated by a measurement of the secondary electron spin polarization at each point as a tightly focused electron beam is scanned in a raster fashion over a region of interest.

For a $3d$ transition metal such as iron, both the bulk magnetic properties and the emitted low-energy secondary electrons are dominated by the valence electrons, with remaining electrons behaving essentially like an inert core. One can, then, roughly predict the degree of secondary-electron spin polarization in iron from the observed magnetic moment of atoms in the bulk (2.22 Bohr magnetons) and the number (8) of valence electrons. One expects a spin polarization of $\sim 2.22/8 = \sim 0.28$, in good agreement with experimental observations. Similarly, good predictions can be made for cobalt (0.19) and nickel (0.05) as well.

The polarization detectors typically used for SEMPA (Scheinfein et al., 1990) provide simultaneous determination of the electron polarization projected onto two orthogonal axes. Frequently, those axes are parallel to the surface of the sample, so that SEMPA measures the in-plane surface magnetization. SEMPA detectors can also be constructed to measure the magnetization perpendicular to the surface, along with one in-plane component. However, magnetic anisotropy at the surface generally forces the magnetic moments for most samples to lie in the plane of the surface, so that out-of-plane magnetization is rarely observed.

There are several general features of SEMPA that deserve particular attention in comparison with other magnetic-imaging techniques. First, whereas many magnetic-imaging techniques are sensitive to the magnetic fields either inside or outside of the sample, SEMPA determines the sample magnetization directly. Second, because the physical basis for magnetic contrast is well understood, the magnetic images can be quantitatively analyzed. Third, the magnetization signal is very large. A huge number of secondary electrons are generated in a typical SEM

scan, and even in a low-moment material like nickel, the magnetization signal is 5% of the total secondary electron current. Unfortunately, as discussed below, the inherently low efficiency of spin polarization detectors makes measurement of this large signal quite difficult. Fourth, because the magnetic resolution is essentially given by the focused diameter of the primary electron beam, very high spatial resolutions (~20 nm) can be achieved. Fifth, the electron polarization detector simultaneously provides images of both the magnetization and the secondary electron intensity. The intensity images provide information about the physical structure of the sample under study. Hence, a comparison of the magnetic and topographic images can provide insight into the influence of physical structure on the magnetic domain structure. Finally, because the escape depth of low-energy secondary electrons is short (a few nanometers), SEMPA measures the magnetic properties of the near-surface region and is thus ideally suited to studies of magnetic thin films or of magnetic properties peculiar to the surface region.

An insert in Figure 1 shows a magnetic image of a test pattern in hard disk media as imaged by SEMPA. The details of the magnetic structure are clearly visible, both in the recorded tracks and in the randomly magnetized regions between the tracks.

Practical Aspects of the Method

There are several practical aspects of SEMPA which determine its applicability to specific magnetic-imaging problems. Most notably, because the attenuation length of the low-energy secondary electrons is typically sub-nanometer, SEMPA is sensitive to only the outermost few atomic layers. Hence, magnetic domain contrast is rapidly attenuated by nonmagnetic overlayers. Such overlayers could be the surface lubricant of magnetic hard disk media, protective non-magnetic capping layer of a magnetic multilayer, or merely the naturally occurring adsorbed gases and contaminants that are always present on surfaces exposed to the atmosphere. Prior to magnetic imaging, any nonmagnetic overlayers should be removed, generally by ion sputtering. In order to minimize the effects of surface contamination after cleaning, SEMPA studies must be performed under ultrahigh vacuum conditions.

One very useful side effect of SEMPAs high surface sensitivity is the ability to measure the magnetic properties of minute amounts of magnetic material. One can readily measure the magnetic properties of iron at sub-monolayer coverages. At ~1 monolayer coverage, with the primary electron beam focused into a 10-nm spot, SEMPA is measuring the magnetic properties of only ~1000 iron atoms.

As alluded to above, one practical consideration is the inherently low efficiency of electron polarization detectors. At present, most polarization detectors rely on differences, which are due to electron-spin orientation, in the cross-section for scattering of the electrons under investigation from a heavy nucleus. Because the overall scattering probability is low, and also because the difference due to electron spin is small, the overall efficiency of polarization detectors is $\sim 10^{-4}$. Consequently, data-acquisition times can be quite long, depending on the intensity of the primary electron beam and the inherent secondary electron polarization of the sample under study.

Data Analysis and Initial Interpretation

Data analysis in SEMPA is rather straightforward. The data are collected as the magnetization vector component along two orthogonal directions, typically in the sample plane. These components, however, can be readily combined to generate the net magnetization

$$|M| = \sqrt{M_x + M_y} \tag{1}$$

and the magnetization direction

$$\theta = \tan^{-1}\left(\frac{M_y}{M_x}\right) \tag{2}$$

While the magnetization direction is determined uniquely, the magnitude of the magnetization is determined only to within a constant. The absolute efficiency of most electron-polarization analyzers is not known with accuracy, so individual detectors require calibration. Furthermore, as mentioned above, the dependence of the secondary electron spin polarization on sample magnetization is known only approximately. However, because both of these factors are essentially constant, it is possible to make quantitative interpretations concerning changes in the degree of magnetization over the sample under study.

Because the magnetization signal from electron spin polarization detectors can be very small, instrumental artifacts can sometimes influence the magnetization images in significant ways. However, such instrumental artifacts are generally either reduced to negligible levels or measured and accounted for in the image analysis (Kelley et al., 1989).

Sample Preparation

Because SEMPA measures the magnetic properties of only the outermost atomic layers, samples should be atomically clean. The preferred method is ion sputtering. However, although the magnetic contrast may be significantly reduced, it is sometimes possible to observe domain structure through very thin layers. For example, one can observe domain structures essentially unchanged through a few monolayers of gold.

The collection of low-energy secondaries and the preservation of their spin orientation severely limit the acceptable size of any magnetic fields at the sample. Typically, stray fields must be nonvarying and of the order of the earth's magnetic field or smaller. Apart from special sample geometries that allow nearly complete elimination of stray magnetic fields, one is essentially restricted to zero-field measurements.

HOLOGRAPHY

Principles of the Method

Magnetic domain imaging is an important application of electron holography (Tonomura, 1994), in part because this technique makes possible both direct visualization and quantitative measurement of magnetic flux, Φ_B. In electron holography, a high-energy, e.g., 200-keV, field-emission transmission electron microscope (TEM) or scanning transmission electron microscope (STEM) is used to form an interference pattern from electrons that can reach the detector via two alternative paths, one of which contains the sample specimen. The electrons can be thought of as waves emitted from a very small source with a very narrow energy distribution, i.e., the beam has high degrees of both spatial and temporal coherence. The beam is divided into two parts using an electron biprism, with one half of the beam passing through the thin specimen to be studied while the "reference" half of the beam continues unimpeded. When the two halves of the beam are recombined on a film detector, following electron optical magnification, an interference pattern is observed. If there were no sample, the interference pattern would consist of equally spaced parallel lines. These lines are located at positions where the lengths of the two possible paths differ by an integral number of electron wavelengths. If there is a sample in one path, then the sample may introduce phase shifts in the electron wave passing through it, and those phase shifts will result in a local modification of the interference pattern.

When electron holography is used for magnetic imaging (Osakabe et al., 1983; Tonomura, 1994; Mankos et al., 1996a,b), interference is observed between electron waves in the reference path and those passing through a magnetic sample. However, an additional phase shift is introduced between the two waves. This phase shift is proportional to the total magnetic flux enclosed by the two alternative electron paths. For this case, known as the absolute method, the lines in the interference pattern can be directly interpreted as flux lines. In fact, the normalization is such that a flux of 4.1×10^{-15} Wb, i.e., h/e, flows in the space between two adjacent contour lines. An alternative, differential mode can also be used. In this mode, both beams go through the magnetic sample with slightly different paths. The phase difference, being proportional to the flux within the path enclosed by both beams, will be constant for a uniformly magnetized material and sensitive to a region of rapid change in enclosed flux, e.g., a domain wall. Figure 4 shows the flux distribution both inside and adjacent to a strip of magnetic tape measured using the absolute method in a TEM.

Practical Aspects of the Method

Using electron holography, high spatial resolution is possible; a resolution of 10 nm has been demonstrated. Since this is a transmission method, the magnetic sample must be uniformly thinned and the information obtained will represent values averaged over a typical sample thickness of 50 nm. Samples of up to 150 nm in thickness are generally possible. One must consider the possibility that the necessary thinning of the sample may affect the magnetization distribution in the sample being imaged. Only conductive samples can be measured. The flux enclosed in the electron path is quantitatively measured with a minimum sensitivity of $\sim 10^{-16}$ Wb. The instrument used is an extension of a high-quality transmission electron microscope. As such, it is a rather complex device. A commercial version designed for holography is available at a cost of $\sim$1.3 million dollars.

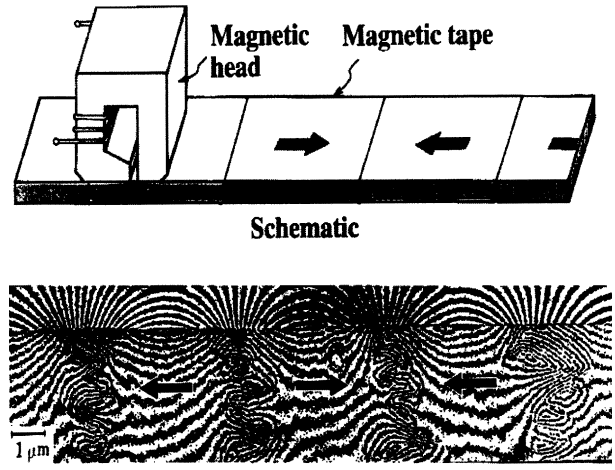

Figure 4. Top: A schematic diagram showing an inductive recording head writing domains of in-plane magnetization on a magnetic recording tape. Bottom: An interference micrograph, obtained using electron holography, illustrating the flux distribution both outside (top 25% of image) and inside (bottom 75%) this image of a 45-nm thick Co film (Osakabe et al., 1983).

Method Automation

A variety of image capture methods are available. Photographic film can be used or a CCD TV camera can provide a real-time display or permit transfer of the image to videotape to record dynamic information—e.g., the variation in response with a changing magnetic field.

Data Analysis and Initial Interpretation

The hologram that results from the two-beam interference in a microscope equipped for electron holography is an interferogram that directly displays the changes in phase that result from the magnetic flux of the sample. A major strength of this method is that these interference fringes can be directly interpreted as representing magnetic lines of force. Occasionally, additional sensitivity is required to see small variations in the enclosed magnetic flux. In this case, the phase-amplification technique (Tonomura, 1994) is used to increase, within limits set by the overall signal-to-noise ratio, the number of interference lines for a set amount of flux, i.e., to increase the sensitivity.

Sample Preparation

The sample must be uniformly thinned to $<$150 nm. If the absolute method is going to be used, the sample should be

prepared so that the area to be measured is either near the sample edge or near a hole in the sample through which the reference beam can pass.

Specimen Modification

It is possible to have a local magnetic field of <100 kA/m at the sample.

Problems

This is a complex method requiring a very significant investment in equipment, sample preparation, and image reconstruction and analysis. It has been applied to a wide range of problems, including small particle and multilayer magnetism, observation of domain walls, and imaging of fluxons in a superconductor.

X-RAY MAGNETIC CIRCULAR DICHROISM

Principles of the Method

X-ray magnetic circular dichroism is a recently developed technique made possible by the availability of intense, tunable synchrotron radiation from a new generation of storage rings. The effect depends on the relative orientation of the x-ray photon angular momentum and the sample magnetization. The difference in the absorption of x-rays, a phenomenon know as x-ray dichroism, is maximum when magnetization of the material and the photon angular momentum, or helicity, are parallel and antiparallel. The x-ray photon transfers angular momentum to the photoelectron excited from a spin-orbit split core level. For transition metals, XMCD measurements typically involve transitions from spin-orbit split p states (L_2 and L_3 core levels) to valence d states which in a ferromagnet are spin polarized. The transition probability depends on the spin orientation of the d final states, and hence on the magnetization.

A key advantage of XMCD for imaging magnetic domains is the elemental specificity that derives from the process being tied to an absorption event at a particular core level. In principle, it is possible to correlate the magnetic measurement with other core-level measurements, which give information on the local site, symmetry, and chemical state. Because the spin and orbital moments can be determined from XMCD measurements, the magnitude of the magnetization can also be quantitatively determined.

For domain imaging, the magnetic x-ray dichroism is monitored either by measuring the total electron yield (Stöhr et al., 1993; Tonner et al., 1994; Schneider, 1996) or, in the case of thin samples, by directly measuring the transmitted x-ray flux (Fischer et al., 1996). In the first method, the secondary electrons emitted from the magnetic material are electron-optically imaged onto a channel plate. The intensity in this magnified image is proportional to the x rays absorbed at the point where the electrons originate, and therefore on the relative orientation of the magnetization and the photon helicity at that point. Thus, XMCD gives a spatially resolved image of the magnetization direction. In the second method, the differential x-ray absorption is imaged in a transmission x-ray microscope to give the magnetization image. In either imaging mode, the image shows the projection of the magnetization along the photon propagation direction. In the electron-imaging mode, the surface is illuminated at oblique incidence, so the in-plane magnetization is predominantly imaged. In the transmission mode, the magnetization perpendicular to the sample surface is measured.

Recently, x-ray magnetic linear dichroism (XMLD) has also been observed (Hillebrecht et al., 1995). The difference in the absorption of linearly polarized x rays is the x-ray analog of the transverse magneto-optic Kerr effect (magnetization perpendicular to the plane of incidence). Although the image contrast obtained with linearly polarized light is about ten times less than with circularly polarized light, an image of the magnetization orthogonal to the light direction can be measured.

Practical Aspects of the Method

The lateral best spatial resolution achieved to date in the electron-imaging mode is 200 nm. Typical resolution is $\sim$500 nm. Magnetization images of a monolayer-thick magnetic film can be obtained. Changes in images can be observed in real time on a video monitor; acquisition time for a high-quality image is a few minutes. An image of recorded bits on a Co-Pt magnetic hard disk derived from the magnetic dichroism at the Co L-edge is shown in Figure 1. If the incident x-ray energy is tuned away from the absorption edges, the dichroism is absent and a secondary electron image of the topography is obtained. The nonuniform response of the optical system can be removed by normalizing to this topography image. The acquisition time and lateral resolution can be improved with increased synchrotron radiation flux, which is becoming available from insertion devices on new, higher-power storage rings. The ultimate resolution would then be limited by the resolution of the imaging electron optics, which has been demonstrated at 10 nm in low-energy electron microscopy (LEEM), as discussed in the next section.

Transmission XMCD (TXMCD) is an even more recent development. The lateral spatial resolution achieved in the first magnetic imaging experiments was 60 nm. Spatial resolution of 20 nm can be achieved in a transmission x-ray microscope. Information is provided about the bulk properties integrated over the path of the transmitted x rays through the sample. In contrast to the electron-imaging mode, there are no constraints on the application of magnetic fields. A 1024×1024 pixel image can be acquired in 3 s.

The equipment for magnetic imaging in either mode involves sophisticated electron or x-ray optics, and would be considered complex. The cost is $\sim$\$300,000, not including the required synchrotron radiation beam line.

Method Automation

Magnetic domain imaging using XMCD in either the electron imaging or transmission mode can be automated in

the sense that the incident wavelength variation and image acquisition are under computer control; in principle both methods could be set up for automatic data acquisition over several hours. In reality, however, both methods are sufficiently new that their application should not be considered routine or automatic.

Data Analysis and Initial Interpretation

There is sufficient contrast in XMCD that domains can be seen in the raw images as they are acquired. The contrast can be improved by subtracting properly scaled images taken at the L_2 and L_3 edges. This also removes possible artifacts due to topography, which can be present in the electron images. Using the elemental specificity of XMCD, it is possible to measure separately the contributions of different elements in a complicated system to the magnetization image.

Sample Preparation

The sample-preparation requirements are somewhat different in the two imaging modes. For electron imaging, the sample should be conductive; for an insulator, it should be not more than ~100 nm thick. The information sampling depth is material dependent; it is ~2 nm for transition metals and on the order of 10 nm in insulators. Even though the sampling depth for a transition metal ferromagnet is fairly short, there are no strict requirements on sample cleanliness, because the relative intensity of the secondary electrons is unchanged as they exit through a surface contamination layer such as carbon. Magnetic images can be obtained from surfaces with an rms roughness on the order of 100 nm.

A major consideration in the transmission imaging mode is the sample thickness, which should be selected for 30% to 40% x-ray transmission, which implies thicknesses on the order of 100 nm for transition metals. Because magnetic microstructure is thickness dependent, this imaging technique is particularly well suited when the sample to be measured is of the appropriate thickness. On the positive side, the sample need not be conducting, and the measurement is insensitive to surface contamination or moderate roughness.

SPIN POLARIZED LOW-ENERGY ELECTRON MICROSCOPY

Principles of the Method

Low-energy electron microscopy (LEEM) is a relatively new technique for surface imaging that uses electron lenses as in conventional electron microscopes to image elastically backscattered low-energy (1 to 100 eV) electrons (Bauer, 1994, 1996). In the case of crystalline samples, contrast is most often produced by diffraction. Other contrast mechanisms include interference in overlayers or between terraces of different height on the surface. Topographic features can be resolved with submonolayer vertical resolution and lateral resolution of 5 to 10 nm. In addition to measurements of surface topography, LEEM has been used to study phase transitions, sublimation and growth, and the interaction of the surface with foreign atoms such as adsorbates or segregated species. A particular strength of LEEM is its rapid image acquisition over a large field of view (5 to 10 μm diameter), which allows surface processes to be observed in real time.

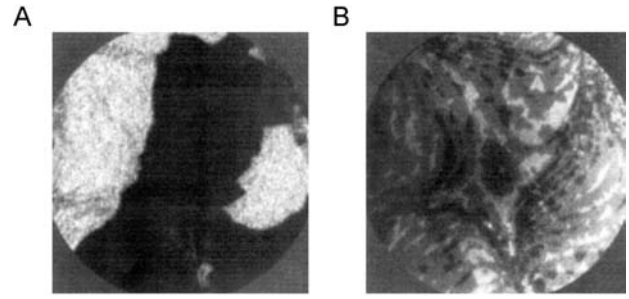

Figure 5. (**A**) SPLEEM image of 5-monolayer thick Co film on a W(110) single-crystal surface. The polarization is in-plane and collinear with the uniaxial magnetization. Taken at an energy of 1.5 eV, to optimize the magnetic contrast, with a field of view of 8 μm. (**B**) LEEM image of the same region at an energy of 3.6 eV showing the atomic scale roughness of the Co film. Courtesy of E. Bauer.

Magnetic contrast can be obtained by replacing the conventional electron gun with a spin polarized electron gun that produces a beam of electrons with a preferential orientation of the electron spins. In such a SPLEEM measurement, there is an additional interaction, the exchange interaction, between the incident electron spin $\mathbf{s}$ and the net spin density of a ferromagnetic or ferrimagnetic material. The contribution to the scattering resulting from the exchange interaction is proportional to $\mathbf{s} \bullet \mathbf{M}$, where $\mathbf{M}$ is the sample magnetization. The spin-dependent scattering is largest at an energy near a band gap in the spin-split band structure such that electrons of one spin but not the other are reflected. The greatest magnetic sensitivity is achieved by reversing the electron spin polarization direction in order to measure the normalized difference between the intensity $\mathbf{I}^{\uparrow\uparrow}$ with $\mathbf{s}$ and $\mathbf{M}$ parallel and $\mathbf{I}^{\uparrow\downarrow}$ with $\mathbf{s}$ and $\mathbf{M}$ antiparallel. This normalized spin-dependent asymmetry $\mathrm{A} = (\mathbf{I}^{\uparrow\uparrow} - \mathbf{I}^{\uparrow\downarrow})/(\mathbf{I}^{\uparrow\uparrow} + \mathbf{I}^{\uparrow\downarrow})$ has the advantage that it is independent of, but correlated with, the topographic contrast, $\mathbf{I}^{\uparrow\uparrow} + \mathbf{I}^{\uparrow\downarrow}$, which is measured independently at the same time. Examples of a magnetic and topographic image are shown in Figure 5. In a typical magnetic material, the magnitude of the magnetization is constant, but the direction varies from one domain to another or within a domain wall. Using a spin-rotation device in the incident beam, it is possible to get a quantitative measurement of the direction of the magnetization in a SPLEEM image.

Practical Aspects of the Method

SPLEEM is applicable to ferromagnetic or ferrimagnetic materials, i.e., materials with a net spin density. With electrons as the probe, samples should have sufficient conductivity to avoid charging. The sensitivity is such that domains in as little as two monolayers (ML) of Co can be imaged at a lateral resolution of 40 nm. The best spatial resolution demonstrated for SPLEEM at the present time is ~20 nm. Changes in the magnetization can be observed in real time as other parameters such as

temperature or film thickness are changed. Application of a magnetic field is usually not practical because a stray field would disturb the low-energy electrons involved in the imaging. The dynamical imaging frequency is ~1 Hz. The acquisition time for an 8 bit 512 × 512–pixel image of, for example, 5 ML Co, is 1 to 3 sec. The technique is developing and the resolution improving with the further development of a rather special objective lens, a cathode lens in which the specimen is one of the electrodes.

Method Automation

Data are usually acquired by measuring the difference between the images taken for opposite directions of the incident electron-beam polarization. Imaging can be automated in the sense that the digital image can be obtained as conditions, e.g., temperature or spin polarization direction of the incident beam, are varied under computer control.

Data Analysis and Initial Interpretation

From any particular SPLEEM image, one gets a picture of the magnetization along the chosen direction of spin polarization. By rotating the incident polarization, one can obtain a measure of the three components of the magnetization, M_x, M_y, and M_z, which are proportional to the asymmetries A_x, A_y, and A_z measured along each spin polarization direction. The distribution of magnetization directions can be plotted and analyzed in light of, e.g., aniso-tropies expected to determine the magnetization direction. A consistency check on the data is obtained by computing the relative magnitude of the magnetization, $M = (M_x^2 + M_y^2 + M_z^2)^{1/2}$, which is expected to be constant over the image.

Sample Preparation

Because low-energy electrons are central to this measurement, it is surface sensitive, with an energy- and material-dependent probing depth that ranges from a few monolayers to ~10 monolayers. The experiment therefore takes place in ultrahigh vacuum, and the usual surface-science techniques are used to prepare a clean surface. Because of the longer probing depths at very low energies, it may be possible to obtain an image from a surface covered by an adsorbate monolayer if the adsorbate does not affect the magnetization. Most magnetic materials are not adversely affected by low-energy electron beams. This technique is well suited for *in situ* ultrahigh vacuum measurements such as the observation of the development of magnetic domains as a function of film thickness.

SCANNING HALL PROBE AND SCANNING SQUID MICROSCOPES

Principles of the Method

Scanning Hall probe (Chang et al., 1992; Oral et al., 1996) and scanning superconducting quantum interference device (SQUID) techniques (Kirtley et al., 1995) give quantitative measurements of the stray magnetic field perpendicular to and just outside a surface (see HALL EFFECT IN SEMICONDUCTORS). Each has been demonstrated for domain imaging, although originally designed for measurement of magnetic flux in superconductors. Neither is commercially available, and with the limited spatial resolution demonstrated to date, the choice of either of these techniques would likely be driven by the need for noninvasive quantitative measurements with high sensitivity. Both the Hall and SQUID probes use scanning tunneling microscopy positioning techniques to achieve close proximity to the surface and for scanning.

Practical Aspects of the Method

The scanning Hall probe is more versatile than the SQUID. It consists of a submicron Hall sensor, manufactured in a two-dimensional electron gas, and gives a voltage output proportional to the magnetic field perpendicular to the sensor. It has been operated at temperatures from that of liquid He to room temperature (with a reduction in sensitivity) and does not have a limitation on the ambient magnetic field. Typical spatial resolution is 1000 nm, and the best resolution achieved is 350 nm. The magnetic field sensitivity depends on the speed or bandwidth of the measurement. At a temperature of 77 K, the sensitivity is 3×10^{-8} T/(Hz)$^{1/2}$ times the square root of the bandwidth given in hertz. Hence, a measurement with a sensitivity of 3×10^{-6} T is possible with a 10-kHz bandwidth. High spatial and magnetic-field resolution images require a few minutes. Lower-resolution images can be acquired in a few seconds. The scanning SQUID is typically operated at liquid He temperature in low (<8 kA/m) ambient magnetic fields. A spatial resolution of 10 μm has been demonstrated with a magnetic field sensitivity of 10^{-10} T/Hz$^{1/2}$.

MAGNETOTRANSPORT IN METALS AND ALLOYS

INTRODUCTION

Electronic transport properties are fundamental to the classification of materials. The behaviors of the electrical resistivity ρ, the thermal conductivity κ, and the thermopower S are used to define whether a material is a metal, a semiconductor, or an insulator. Studies of how ρ, κ, and S vary with impurity content (alloying), magnetic field $\mathbf{B}$, sample size, deformation, etc., provide insight into the nature of current carriers and how they are scattered. Studies of magnetoresistance, the variation of ρ with $\mathbf{B}$, can yield additional information about electronic structure, the current carriers, and their scattering. In systems involving magnetic metals, $\rho(\mathbf{B})$ has technical applications to magnetic sensing and memory (Heremens, 1993a). The Hall effect and the thermopower S can often be used to infer the sign of the charge of the majority current carriers, and the thermal conductivity κ, while closely related to ρ, can manifest differences that contain significant information. The Hall effect in semiconductors also finds use in sensors (Heremens, 1993a,b), but in metals it is smaller and usually of more interest for the physical insight it can provide into both nonmagnetic and magnetic metals. Changes with magnetic field in the thermal conductivity and thermoelectric coefficients of metals are usually small and difficult to measure. They have provided useful information about physical phenomena such as many-body contributions to thermoelectricity (see, e.g., Averback et al., 1973; Thaler et al., 1978) and giant magnetoresistance in granular alloys (Piraux et al., 1993) and magnetic multilayers (Tsui et al., 1994) but are much less studied than the resistivity and Hall effect. Transport and magnetotransport measurements of metals and alloys are made over a wide range of temperatures extending from the lowest achievable temperature to the liquid state.

This unit focuses on four measured quantities in solid metals and alloys in the presence of a temporally constant and spatially uniform magnetic field $\mathbf{B}$—the electrical resistance R, the Hall resistance R_H, the thermal conductance K, and the thermopower S. The basic theory underlying these quantities applies also to liquid metals and alloys. The discussion begins with definitions and general information, including how to relate the measured quantities to the fundamental properties ρ, the Hall coefficient R_0, κ, and S. These are followed by a brief description of the behaviors of ρ, κ, and S in zero magnetic field and, in some more detail, those of $\rho(\mathbf{B})$, $R_H(\mathbf{B})$ and, to a lesser extent, $\kappa(\mathbf{B})$ and $S(\mathbf{B})$. Many more quantities than these four can be defined and measured, some of which have provided important information about metals (see, e.g., Fletcher, 1977; Thaler et al., 1978). A few will be briefly discussed at the end of the following section; for more information see Jan (1957), Scanlon (1959), and Blatt et al. (1976).

PRINCIPLES OF THE METHOD

Measured Quantities and Their Relation to Intrinsic Ones

To define the measured quantities and relate them to intrinsic ones, consider a sample in the form of a thin foil of width W and thickness t (Fig. 1), with the x axis along the foil length, the y axis along the foil width, and transverse $\mathbf{B}$ in the direction B_z. The cross-sectional area of the foil is $A = Wt$. An electric current I_x or a heat current $\dot{Q}_x$ is sent through the sample, and a voltage V or a temperature difference ΔT is measured across a length L (or the width W) of the sample. Experimental conditions are assumed such that the electrical or heat current densities $j = I/A$ or $\dot{q} = \dot{Q}/A$ are uniform across the sample area A.

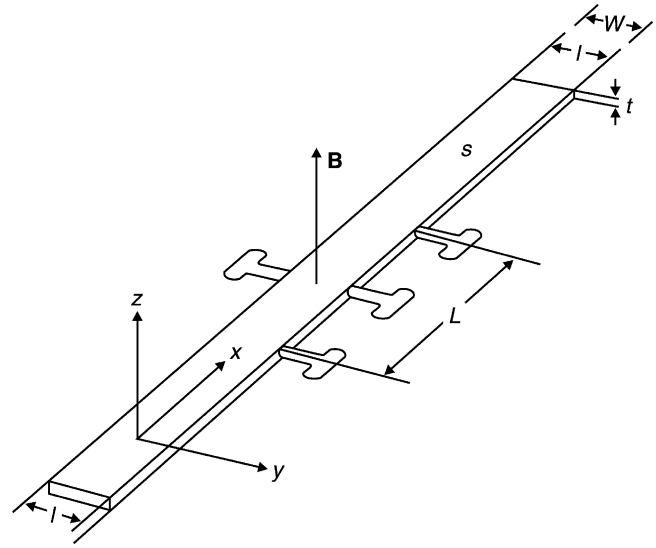

Figure 1. Sample foil (s) of width W and thickness t; l indicates the current leads.

Electrical Resistance. Electrical resistance R for a length L of the foil is measured by passing a current I_x through the foil and measuring the ratio of the voltage difference V_x across L to I_x:

$$R(\text{ohms}) = V_x(\text{volts})/I_x(\text{amperes}) \tag{1}$$

Whether or not a field $\mathbf{B}$ is present, the intrinsic quantity is the resistivity ρ, related to R by

$$R = \rho L/A \tag{2}$$

For measurements in a magnetic field, it is useful to define the magnetoresistance MR as the ratio of the change in resistance due to application of $\mathbf{B}$ over the initial resistance:

$$\text{MR}(\mathbf{B}) = \Delta R(\mathbf{B})/R(0) = [R(\mathbf{B}) - R(0)]/R(0) \tag{3}$$

For Equation 3, the current distribution need not be uniform. So long as the distribution does not change with the magnitude of $\mathbf{B}$, MR($\mathbf{B}$) will be an intrinsic quantity, i.e., geometric effects will cancel out.

See Crawford Dunlap (1959), Pearson (1959), Meaden (1965), Rossiter (1987), and Rossiter and Bass (1994) for more detailed discussion.

Hall Resistance. Hall resistance R_H is defined as the ratio of the voltage V_y in the y direction produced by a current I_x in the x direction when the field is oriented along the z direction:

$$R_H = V_y/I_x \quad \text{for} \quad B = B_z \tag{4}$$

The intrinsic quantity in the Hall effect is the Hall coefficient, R_0, defined by

$$R_H = \rho_H/t = R_0 B/t \tag{5}$$

By symmetry, R_H should be zero at $B = 0$.

See Fritzsche (1959), Hurd (1972), and Chien and Westgate (1980) for more detailed discussion.

Thermal Conductance. Thermal conductance K is defined as the ratio of the rate of heat current, $\dot{Q}_x$, through the sample to the difference between the hot (H) and cold (C) temperatures, $\Delta T_x = T_H - T_C$, across the length L,

$$K = \dot{Q}_x(\text{watts})/\Delta T_x(\text{kelvin}) \quad \text{for } I_x = 0 \tag{6}$$

The intrinsic quantity, the thermal conductivity κ, is determined by

$$K = \kappa A/L \tag{7}$$

See Pearlman (1959) and Tye (1969) for more detailed discussion.

Thermopower. Three thermoelectric coefficients, the thermopower S, the Peltier heat Π, and the Thomson coefficient μ, are coupled by the Kelvin relations:

$$S = -\Pi/T \tag{8a}$$

and

$$\mu = T(dS/dT) \tag{8b}$$

As Π and μ (the only one of the three that can be directly measured on a single material) are generally more difficult to measure reliably, experimentalists usually study S. To measure S_A or Π_A of a metal A requires use of a thermocouple (Fig. 2) composed of two different metals, A and B, electrically connected at both ends of A. For the temperature difference between the thermocouple ends, $\Delta T_x = T_H - T_C, S_{AB} = S_B - S_A$ is defined as positive when $\Delta V_x = V_H - V_C$ is positive in

$$S_{AB}\,(\text{volts/kelvin}) = \Delta V_x(\text{volts})/\Delta T_x(\text{kelvin}) \quad \text{for} \quad I_x = 0 \tag{9}$$

The thermopower $S_A(T)$ can be found if B is a reference material for which $S_B(T)$ is known. At low enough temperatures, the use of a material B that is superconducting is especially convenient, since its thermopower is zero and remains so up to whatever magnetic field turns it fully normal. The standard reference materials for zero field

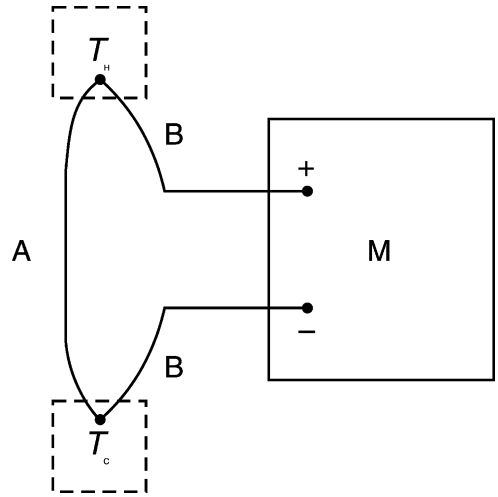

Figure 2. Apparatus used to measure the thermopower S_{AB}. A thermocouple of metals A and B with a hot temperature T_H at one junction and a cold temperature T_C at the other is connected to a device M that measures the output voltage V_{AB}.

measurements are Pb up to room temperature (Roberts, 1977) and Pt or W up to 1600 to 1800 K (Roberts et al., 1985), their absolute values of S having been determined by measuring their Thomson coefficients. To directly determine Π_A requires measuring the rate of reversible heat emission or absorption at the AB junction when a current I_x is passed through the junction.

Other transport coefficients, such as the ratio of V_x to the heat input $\dot{Q}_x$, can also be defined and measured (see, e.g., Stone et al., 1976).

See Frederikse et al. (1959), Barnard (1972), and Blatt et al. (1976) for more detailed discussion of thermoelectric coefficients.

Transport Equations

It is assumed that the sample shape and the measuring geometry provide uniform current densities of both charge $\mathbf{j}$ and heat $\dot{\mathbf{q}}$ flowing through the sample. Because a uniform $\mathbf{B}$ does no work on moving electrons, the form of the transport equations does not change when $\mathbf{B}$ is applied, but the transport coefficients become functions of $\mathbf{B}$ and must be treated as tensors even for a completely homogeneous material. If either $\mathbf{j}$ or $\dot{\mathbf{q}}$ is not uniform, one must start instead from Laplace's equation (Jackson, 1962); two examples are given below (see Problems section).

There are two important alternative forms of the transport equations in rectangular coordinates. One involves measured quantities and relates the electric field $\mathbf{E}$ and heat flow rate density $\dot{\mathbf{q}}$ to the applied current density $\mathbf{j}$ and temperature gradient ∇T.

$$\mathbf{E} = \rho(\mathbf{B}) \cdot \mathbf{j} + \mathbf{S}(\mathbf{B}) \cdot \nabla T \tag{10a}$$

$$\dot{\mathbf{q}} = \Pi(\mathbf{B}) \cdot \mathbf{j} - \kappa(\mathbf{B}) \cdot \nabla T \tag{10b}$$

The electrical resistivity tensor elements are $\rho_{ik}(\mathbf{B}) = E_i/j_k$ with $\nabla T = 0$, the thermopower elements are $S_{ik}(\mathbf{B}) = -E_i/\nabla_k T$ for $\mathbf{j} = 0$, and the thermal conductivity

elements are $\kappa_{ik}(\mathbf{B}) = \dot{q}_i/\nabla_k T$ for $\mathbf{j} = 0$. Tensor elements of each quantity usually depend upon both the magnitude and direction of $\mathbf{B}$, as well as upon the directions of $\mathbf{j}$ and ∇T relative to the crystallographic axes of the metal. If the metal is magnetic, the tensor elements depend also upon its magnetization $\mathbf{M}$ and usually upon its history (hysteresis). Magnetotransport analysis can be quite complex.

The Kelvin-Onsager relations (Jan, 1957) for the elements of the Peltier heat tensor Π and the thermopower tensor $\mathbf{S}$ reduce the number of independent tensors in Equations 10 from four to three via $\Pi_{ki}(-\mathbf{B}) = TS_{ik}(\mathbf{B})$, and Onsager's relations give $\rho_{ik}(\mathbf{B}) = \rho_{ki}(-\mathbf{B})$ and $\kappa_{ik}(\mathbf{B}) = \kappa_{ki}(-\mathbf{B})$. Thus, when transport equations are applicable, the diagonal components of the $\boldsymbol{\rho}$ and $\boldsymbol{\kappa}$ tensors should remain unchanged under reversal of $\mathbf{B}$, but the off-diagonal components should reverse sign. Consider, for example, the Hall bar geometry of Figure 1. Then $R_x = V_x/I_x$ is the resistance, $\mathrm{MR} = [R_x(\mathbf{B}) - R_x(0)]/R_x(0)$ is the magnetoresistance, and $R_\mathrm{H} = V_y/I_x$ is the Hall resistance. Note that these are all defined under isothermal conditions: $\nabla T = 0$. As in Equation 2, R and R_H are related to the resistivities in Equation 10 by

$$R = \rho_{xx} Ll A \tag{11a}$$

and

$$R_\mathrm{H} = \rho_{xy}/t \tag{11b}$$

The difference in these relations occurs because of the difference between $V_x = E_x L$ and $V_y = E_y W$. To determine ρ_{xx}, one must measure L, W, and t of the foil, but for ρ_{xy}, only t.

In the Hall bar geometry, the relative orientations of I_x and B_z are fixed. But if the sample is a single crystal, the magnitudes of R_x and R_H, and even the forms of their variations with the magnitude of $\mathbf{B}$, will generally depend upon which crystallographic axis lies along x and the angle between the other crystallographic axes and z (see Practical Aspects of the Method for a discussion of expected behaviors in a magnetic field).

The alternative form of Equations 10 more applicable to calculations relates $\mathbf{j}$ and $\dot{\mathbf{q}}$ to $\mathbf{E}$ and ∇T:

$$\mathbf{j} = \boldsymbol{\sigma}(\mathbf{B}) \cdot \mathbf{E} - \varepsilon(\mathbf{B}) \cdot \nabla T \tag{12a}$$

$$\dot{\mathbf{q}} = T\varepsilon^\mathrm{t}(-\mathbf{B}) \cdot \mathbf{E} - \mathbf{K}(\mathbf{B}) \cdot \nabla \mathbf{T} \tag{12b}$$

where ε^t indicates the transpose—$\varepsilon^\mathrm{t}_{ij} = \varepsilon_{ji}$. Each of the tensor elements in Equations 12 is related to one or more of the tensor elements in Equations 10 by tensor (matrix) inversion. The simplest case is

$$\rho = \sigma^{-1} \tag{13}$$

because R is measured with $\nabla T = 0$. The relation between κ and $\mathbf{K}$ is more complex,

$$\kappa = \mathbf{K} - T\varepsilon^\mathrm{t} \cdot \sigma^{-1}\varepsilon \tag{14}$$

because $\boldsymbol{K}$ is measured with $\mathbf{j} = 0$. Fortunately, in metals, the second term on the right in Equation 14 is usually small. Lastly, as $\mathbf{S}$ is measured with $\mathbf{j} = 0$, the thermoelectric coefficients are related by

$$\mathbf{S} = \boldsymbol{\sigma}^{-1} \cdot \varepsilon \tag{15}$$

It is important to remember that Equations 10 to 15 are tensor relations. That is, to calculate the tensor on the left, all of the elements of the tensors on the right must be known. In even the simplest cases, such as Equation 13, very different dependences of the elements $\sigma_{ij}(\mathbf{B})$ for different materials can lead to very different behaviors for ρ_{xx} and ρ_{xy}, which generally depend upon the size of $\mathbf{B}$—more specifically, upon whether the product of the cyclotron frequency $\omega_\mathrm{c} = eB/m$ (m is the electron mass) and the transport scattering time τ are such that $\omega_\mathrm{c}\tau \ll 1$ (low-field limit) or $\omega_\mathrm{c}\tau \gg 1$ (high-field limit) (Abrikosov, 1988). Some examples of different behaviors are given below (see Practical Aspects of the Method).

Since each transport tensor has nine elements, and these elements depend upon the direction of $\mathbf{B}$, many different magnetotransport coefficients can be defined (Jan. 1957). A few that are relevant to the precautions necessary for reliable measurements of $\boldsymbol{\rho}(\mathbf{B})$, $\mathbf{R_H}$, $\boldsymbol{\kappa}(\mathbf{B})$, and $\mathbf{S}(\mathbf{B})$ (see Problems section, below) will be described briefly here.

Consider the foil sample of Figure 1 with current leads (l) composed of a different metal from the sample (s), and make the current density small enough so that Joule heating (proportional to j^2) is negligible. For $B = B_z$, passing a current I_x through the sample will generate not only the desired voltages $E_x L = V_x = R_{xx} I_x$ and $E_y W = V_y = R_{yx} I_x$ (Equations 10a and 11) but also the Thomson heat $\dot{Q}_x = (\Pi^l_{xx} - \Pi^s_{xx})l_x$ at one s-l contact and absorb the same heat at the other (Equation 10b). If the sample is in a vacuum, the off-diagonal elements of the thermal conductivity and thermoelectric tensors will lead to both temperature gradients and voltages being established not only along the length of the sample ($\nabla_x T$ and voltage change ΔV_x) but also across its width ($\nabla_x T$ and V_y). The production by a longitudinal current of a transverse temperature gradient is called the Ettingshausen effect and of a transverse voltage the Nernst-Ettingshausen effect. The comparable production of a transverse temperature gradient by a longitudinal heat current is called the Righi-Leduc effect and of a transverse voltage a second Nernst-Ettingshausen effect. Because of these effects, the protocols for measuring R and R_H will specify that the sample be kept as nearly isothermal as feasible. An alternating current should automatically give isothermal conditions, since the reversible heats will average to zero.

PRACTICAL ASPECTS OF THE METHOD

Expected Behaviors of ρ, κ and *S* in Zero Field

For completeness, the expected forms of ρ, κ, and S in a zero magnetic field will be briefly summarized. Most metals have cubic crystal structures—simple cubic (sc), face-centered cubic (fcc), or body-centered cubic (bcc)—the high symmetry of which reduces the tensors $\boldsymbol{\rho}$, $\boldsymbol{\kappa}$ and $\mathbf{S}$ to scalars ρ, κ, and S, independent of the directions of the charge

or heat current flows relative to the crystallographic axes. Metals with the simplest noncubic structures—e.g., hexagonal close packed—require two independent tensor elements, one for current flow in the basal plane and one for flow perpendicular to that plane (Bass, 1982; Foiles, 1985). Alloys with more complex structures may require more elements. Here we limit ourselves to cubic metals, or to polycrystalline samples, so that ρ, κ, and S are scalars. To determine the forms of ρ, κ, and S, a model is needed for the scattering of electrons in a metal. The simplest is the Drude-Sommerfeld "free electron" model (Ashcroft and Mermin, 1976), where the electron Fermi surface is taken to be spherical and electrons are assumed to be scattered with a single relaxation time τ that will generally be different if the scattering is dominated by impurities or by quantized lattice vibrations (phonons). This model is useful for estimating the magnitudes of ρ, κ, and S and for qualitatively describing their behaviors. It rarely works quantitatively, however, and can even fail qualitatively. The characteristic behaviors of ρ, κ, $L = \rho\kappa/T$, and S are illustrated in Figure 3 for a high-purity ("pure") metal (solid curves) and for a dilute alloy (dashed curves).

For free electrons scattered only by phonons that remain in thermal equilibrium, solution of the transport equations (Equations 12, above) predicts a pure metal resistivity, $\rho_p(T)$, that varies approximately linearly with T, except at low temperatures, where it should vary approximately as T^5 (Ashcroft and Mermin, 1976; Kittel, 1986). To a first approximation, adding a small impurity concentration c should just add a constant term proportional to c, giving $\rho_t(T,c) = \rho_p(T) + \rho_0(c)$—Matthiessen's rule. Deviations from Matthiessen's rule are examined by Bass (1972) and values of $\rho_0(c)$ for a variety of hosts and impurities are given by Bass (1982). Of course, even the highest-purity metal has residual impurities, so its resistivity at very low temperature will not be zero, unless the metal becomes superconducting. Figure 3A illustrates the expected behaviors for such a pure metal and for a dilute alloy.

Analysis of κ and S is complicated by the fact that they are measured in the presence of a temperature gradient and that both electrons and phonons can carry heat through a metal.

If the phonons remain at thermal equilibrium (i.e., carry no heat), then from the free electron solution of Equations 12 above, the Wiedemann-Franz ratio $L = \kappa\rho/T$ should be constant at the Lorenz number $L = L_0 = 2.45$ W Ω/K^2 (Ashcroft and Mermin, 1976), both at high temperatures where the phonon Debye energy is $\leq k_B T$ and at low temperatures where impurity scattering dominates, and should fall below L_0 in between. Kittel (1986) and Ashcroft and Mermin (1976) list values of L at 273 and 373 K for a wide variety of metals, and most lie within several percent of L_0. Combining these predictions for L with expectations of $\rho \propto T$ at high T and $\rho = \rho_0$ at low T requires $\kappa = \kappa_0$ at high T and $\kappa \propto T$ at low T. The expected behaviors of κ for a pure metal and dilute alloy are illustrated in Figure 3B, with those for L in the inset. For a concentrated alloy, the electronic contributon to κ can become so small that the heat carried by the flow of nonequilibrium phonons becomes significant. A high magnetic field also tends to reduce the electronic κ, thereby increasing the relative importance of phonons. In fact, application of a high field has been used to determine the phonon contribution to κ (see, e.g., Pernicone and Schroeder, 1975), which should be nearly independent of **B**.

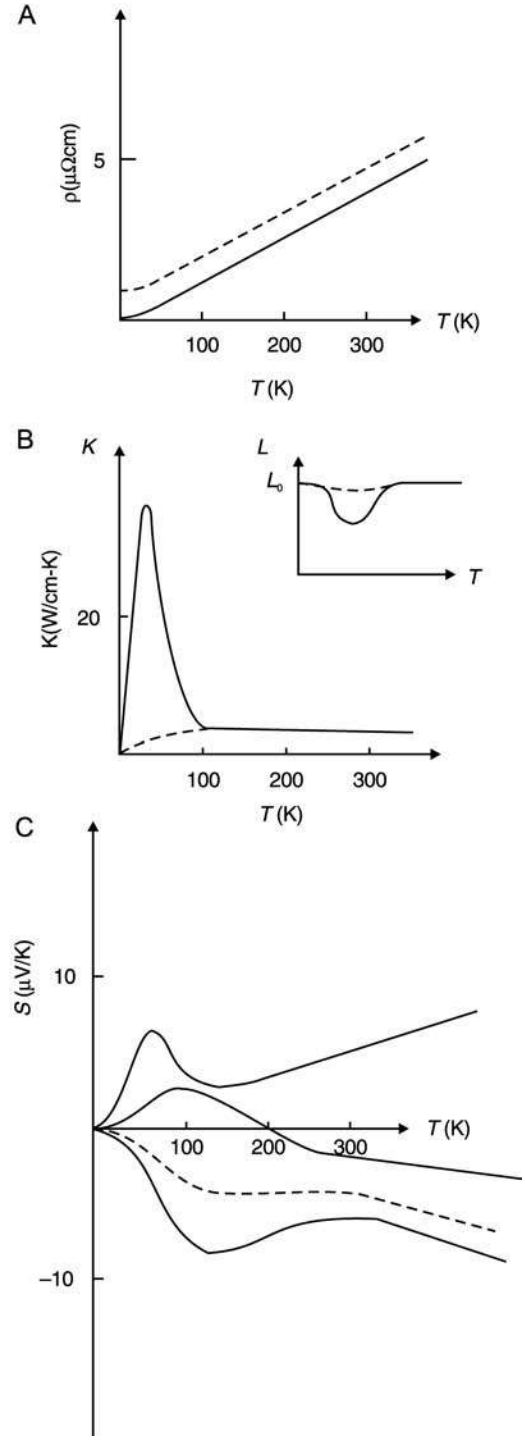

Figure 3. Schematics of the temperature dependences of ρ, κ, L, and S for high-purity metals (solid curves) and dilute alloys (dashed curves).

For phonons in equilibrium, the free electron solution of Equations 12 predicts that S should be negative and linear

in T when the primary source of scattering is either impurities (low temperature) or phonons (high temperature), with different coefficients of the linear term for the two cases (Blatt et al., 1976). In fact, S usually has a more complex form that can be approximated (Blatt et al., 1976) as the sum of an electronic thermopower term S_e that is often nearly linear in T and a phonon-drag thermopower term S_g (due to the nonequilibrium flow of phonons resulting from the applied temperature gradient) that goes through a maximum as T increases. Unlike κ, for which the effect of phonon flow is usually small in metals, S_g can predominate over a substantial temperature range, as illustrated in Figure 3C. While the predicted negative free electron S_e is seen in some metals, such as Al, others, such as the noble metals Ag, Au, and Cu, have positive S_e. Such an "inverse" sign is attributed to deviations of the Fermi surface from a free electron sphere. As shown in Figure 3C, both S_e and S_g can be negative or positive. The dashed curve shows that adding impurities can change both S_e and S_g; while such addition usually reduces S_g, in some cases it can increase it.

Expected Behaviors of ρ, R_H, κ, and S in a Magnetic Field

The vast majority of magnetotransport studies have involved $\rho(\mathbf{B})$ and $R_H(\mathbf{B})$, both because they are easiest to measure and because their interpretation is usually most straightforward. The difficulty of measuring $\kappa(\mathbf{B})$, combined with the expectation that a generalization of the Wiedemann-Franz law will apply under those circumstances where it can be most simply interpreted, has limited studies of $\kappa(\mathbf{B})$. The combination of experimental difficulties, lack of simple interpretation, and expectation that changes will usually be relatively small, have limited studies of $S(\mathbf{B})$. The main focus here will thus be upon $\rho(\mathbf{B})$ and $R_H(\mathbf{B})$.

The Sommerfeld free electron model predicts $\rho(\mathbf{B}) = \rho(\mathbf{B} = \mathbf{0})$, i.e., MR = 0, and $R_H(\mathbf{B}) = -1/n_e ec$, where n_e is the electron density in the metal, e is the magnitude of the electron charge, and c is the speed of light in a vacuum. This prediction results from the assumption of a spherical Fermi surface with only a single relaxation time. Due to the Lorentz force $\mathbf{F} = q(\mathbf{v} \times \mathbf{B})$ on a charge q moving with velocity $\mathbf{v}$, application of $\mathbf{B}$ causes electrons to be deflected from moving straight down the sample foil, but the boundary condition $j_y = 0$ leads to a pileup of electrons on one side of the foil. This produces an electric field E_y (Hall effect) that exactly counteracts the effect of the Lorentz force.

In most real metals, the presence of Brillouin zone boundaries leads to deviations of the Fermi surfaces from spherical, and electrons on different parts of the Fermi surface have different relaxation times, destroying the exact balance and giving nonzero $\rho(\mathbf{B})$ and deviations of $R_H(\mathbf{B})$ from $-1/n_e ec$. At low fields ($\omega_c \tau \ll 1$), the transport coefficients are determined by details of the ways in which the electrons are scattered. Any simple model with two or more different relaxation times predicts that $\rho_{xx}(\mathbf{B})$ should initially increase from $\rho_{xx}(0)$ as B^2. Examples of $\rho(\mathbf{B})$ for a wide variety of polycrystalline samples are shown in Figure 4 for a transverse field ($B = -B_z$) and in Figure 5

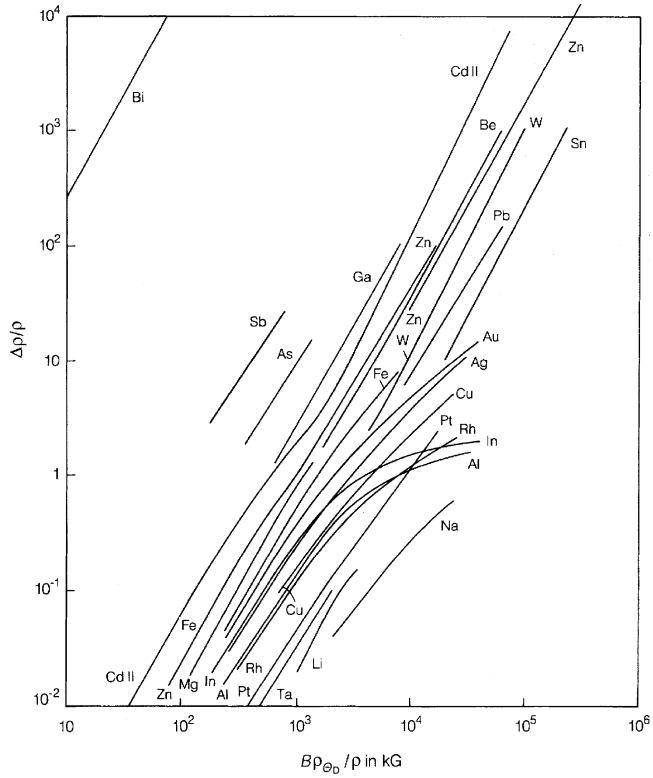

Figure 4. MR versus reduced transverse field $B\rho_\Theta/\rho_0$ for a wide variety of polycrystalline metals. ρ_0 is the residual resistivity at 4.2 K and ρ_Θ is the resistivity at the Debye temperature in the field. (From Olsen, 1962.)

for a longitudinal field ($B = B_x$). Usually $\rho(\mathbf{B})$ initially grows approximately as $\mathbf{B^2}$, but as $\mathbf{B}$ increases further, the behaviors differ for different metals. At high fields ($\omega_c \tau \gg 1$) the transport coefficients become dominated by Fermi surface topography, as explained below.

For several liquid metals and for the alkali metals, such as K, which are expected to have nearly spherical Fermi surfaces, R_0 lies close to the expected free electron values, as illustrated in Table 1 (for a more complete listing see Hurd, 1972). But in other metals, R_H often deviates from the free electron value—it can be positive and even vary with B. Figure 6 shows an interesting case: R_H for Al at 4.2 K (Forsvoll and Holwech, 1964). At low field, R_0 is negative and has the magnitude expected for a Fermi surface corresponding to a three-electron sphere. But as $\mathbf{B}$ increases, R_0 changes sign, finally "saturating" at high $\mathbf{B}$ at the value for the net single "hole" (positive charge) per atom expected for Al with a three-electron sphere embedded in a face-centered cubic Brillouin zone structure. The Hall coefficients of metals and alloys can also display significant temperature dependences (Hurd, 1972). An important additional complication occurs in magnetic metals, where R_H depends upon the sample magnetization M, leading to an "anomalous" Hall effect, where $\rho_H = R_0 B + \alpha R_s M$, where R_s is called the spontaneous Hall coefficient and the constant α depends upon the units used (O'Handley, 1972). Figure 7 schematically illustrates such behavior.

Table 1. Hall Coefficients of Some Solid and Liquid Metals

Metal	Solid (S) or Liquid (L)	Temperature (K)	Number of Valence e^-	R/R_{fe}	Reference
Na	L	371	1	0.98	Busch and Tieche, 1963
Cd	L	594–923	2	1.04	Enderby, 1963
Pb	L	603–823	4	0.88	Enderby, 1963
Sb	L	903–1253	5	1.14	Busch and Tieche, 1963
K	S	Low T, high $\mathbf{B}^a$	1	1.1	Ashcroft and Mermin, 1976
Ag	S	Low T, high $\mathbf{B}^a$	1	1.3	Ashcroft and Mermin, 1976
Al	S	Low T, high $\mathbf{B}^a$	3	−0.3	Ashcroft and Mermin, 1976

[a] Low temperature, high magnetic field.

At high fields, the dependences of $\rho(\mathbf{B})$ and $R_H(\mathbf{B})$ upon $\mathbf{B}$ should be qualitatively different depending on whether the metal is "compensated" ($n_e = n_h$) or "uncompensated" ($n_e \neq n_h$), where n_e and n_h are the electron and hole densities, and whether it contains open electron orbits in the plane perpendicular to $\mathbf{B}$ (Abrikosov, 1988). The expected behaviors are summarized in Table 2 and Figure 8. For an uncompensated metal with no open orbits in the plane perpendicular to $\mathbf{B}$, at high fields $\rho(\mathbf{B})$ should saturate in value and $R_H(\mathbf{B}) = R_0 B$ should become linear in B, with R_0 taking the simple value $R_0 = -1/(n_e - n_h)e$. In this case, the sign of R_0 specifies whether the dominant carriers are electrons (e) or holes (h). For a compensated metal, or one with open orbits in the plane perpendicular to $\mathbf{B}$, $\rho(\mathbf{B})$ can increase at high fields as B^2 and R_0 is not a constant. The metals for which $\rho(\mathbf{B})$ continues to increase as B^2 at high fields in Figure 4 are compensated. Figure 8 shows that at large enough fields high-purity metals display quantum oscillations. Thin wires or foils also display size effects (including oscillations) when B becomes so large that the cyclotron radius $r_c = v_F \omega_c$ (v_F is the Fermi velocity) becomes smaller than the wire or foil thickness (Olsen, 1962).

In magnetic materials, the quantities of interest can also vary either directly or indirectly with the magnetization $\mathbf{M}$. The anomalous Hall effect noted above is an example of a direct dependence on $\mathbf{M}$. Another is anisotropic magnetoresistance in a ferromagnetic film—where the resistance increases with B for $\mathbf{B}$ (and thus $\mathbf{M}$) parallel to $\mathbf{I}$ but decreases for $\mathbf{B}$ perpendicular to $\mathbf{I}$ (Bozorth, 1951). Giant (G) magnetoresistance (MR) in magnetic multilayers or granular magnetic materials is an example of an indirect dependence, where the MR varies with the relative orientations of the M_I for localized magnetic subcomponents of the sample (Levy, 1994). Magnetic materials also usually display hysteresis—the value of

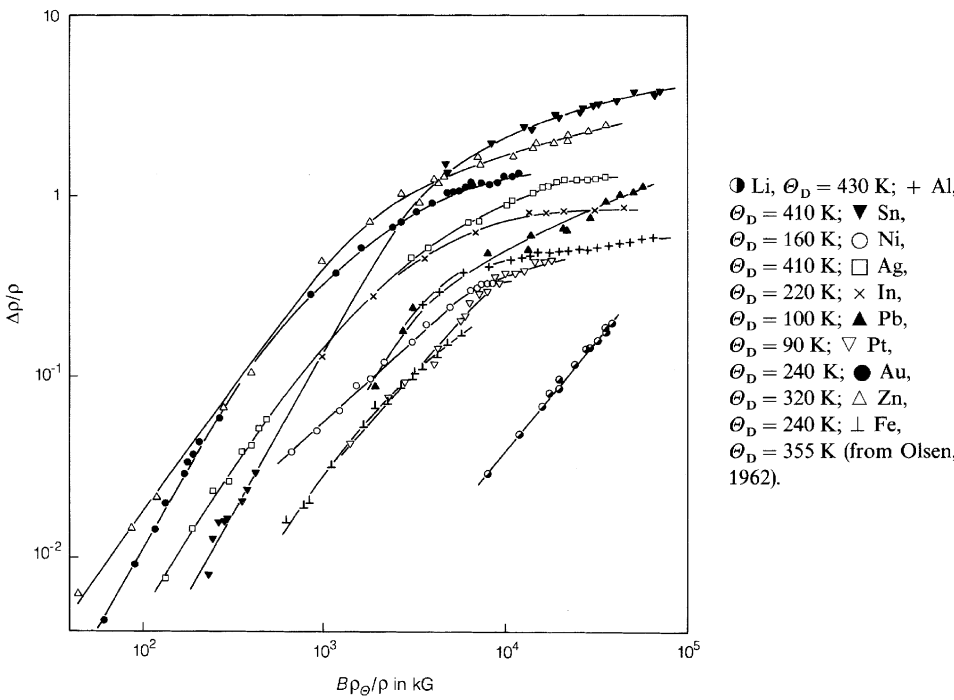

Figure 5. MR versus reduced longitudinal field $B\rho_\Theta/\rho_0$ for a wide variety of polycrystalline metals. ρ_0 is the resistivity at 4.2 K and ρ_Θ is the resistivity at the Debye temperature. The measurements were made in fields up to 200,000 G. (From Olsen, 1962.)

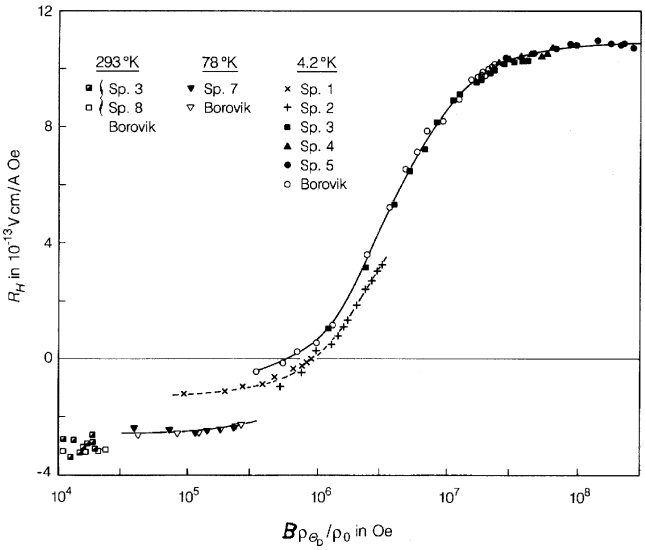

Figure 6. R_H versus reduced field $B\rho_\Theta/\rho_0$ at 4.2 K for Al and dilute Al alloys, showing an unusual variation due to real Fermi surface effects. ρ_0 is the residual resistivity at 4.2 K and ρ_Θ is the resistivity at the Debye temperature. Sp. 1 and Sp. 2 refer to dilute Al(Zn) alloys and the other symbols refer to pure Al samples of different thicknesses. (After Hurd, 1972, using the data of Forsvall and Holwech, 1964.)

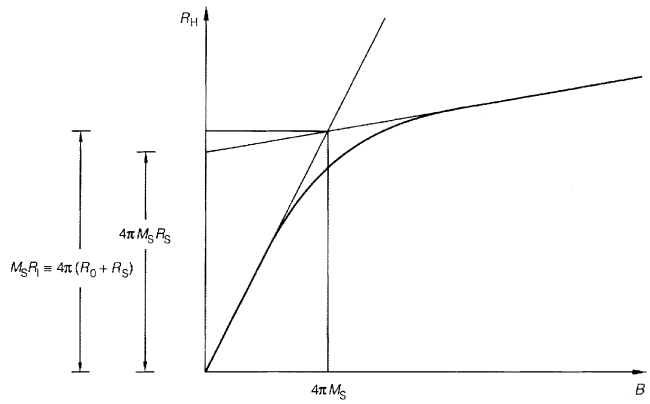

Figure 7. Schematic of R_H versus B for a magnetic metal illustrating the normal and anomalous Hall effects. (From Hurd, 1972.)

the transport coefficient depends upon the magnetic history of the sample (Bozorth, 1951). The Weidemann-Franz law is found to hold rather well for a magnetic granular AgCo alloy in a magnetic field (Piraux et al., 1993), and both granular AgCo and multilayer Co/Cu display significant changes in S with **B** (Piraux etal., 1993; Tsui et al., 1994). Figure 9 shows that the magnetothermopowers of Cu, Ag, and Au are small above 60 K, making them appropriate reference materials for measurements of $S(\mathbf{B})$ at such temperatures (Chiang, 1974).

METHOD AUTOMATION

The measured quantities in magnetotransport are just currents and voltages, which can be straightforwardly collected in a computer and converted to R, R_H, S, and K. In

Table 2. Types of Behavior of the Hall and Transverse Magnetoresistance Effects in Metals (from Hurd, 1972)

Type	Magnetoresistance[a]	Hall Coefficient	Nature of Orbits in Planes Normal to the Applied Field Eirection: State of Compensation[b]
Behavior in the high-field condition			
Single-crystal sample			
1	$\Delta\rho/\rho(0) \rightarrow$ saturation	$R \propto (n_e - n_h)^{-1}$	All closed; $N_e \neq N_h$
2	$\Delta\rho/\rho(0) \rightarrow B^2$ (transverse) $\Delta\rho/\rho(0) \rightarrow$ saturation (longitudinal)	$R \rightarrow$ const[c]	All closed; $N_e = N_h$
3	$\Delta\rho/\rho(0) \rightarrow$ saturation	$R \propto (n_e - n_h)^{-1}$	Negligible number of open orbits; $N_e \neq N_h$
4	$\Delta(0)\rho/\rho \rightarrow B^2 \sin^2\theta$[d]	$R \rightarrow$ const[c]	Open orbits in one direction only
5	$\Delta\rho/\rho(0) \rightarrow$ saturation	$R \propto B^{-2}$	Open orbits in more than one direction
Polycrystalline sample			
6	$\Delta\rho/\rho(0) \propto B$	$R \rightarrow$ const[c]	All types if the crystallites have random orientations
Behavior in the low-field conditions			
Single-crystal or polycrystalline sample			
7	$\Delta\rho/\rho(0) \propto B^2$	$R \rightarrow$ const[e]	It is irrelevant what type of orbit predominates

[a] Transverse magnetoresistance except as indicated for type 2.
[b] N_e and N_h are, respectively, the number of electrons and holes per unit cell of the Bravais lattice; n_e and n_h are, respectively, the density of electrons and holes in real space.
[c] The Hall coefficient is not related to the effective number of carriers in any simple manner.
[d] Note that $\Delta\rho/\rho(0) \rightarrow$ saturation when θ, the angle between the applied electric field and the axis of the open orbit in real space, is zero.
[e] The Hall coefficient depends upon the anisotrophy of the dominant electron-scattering process and the electron's velocity and effective mass at each point on the Fermi surface.

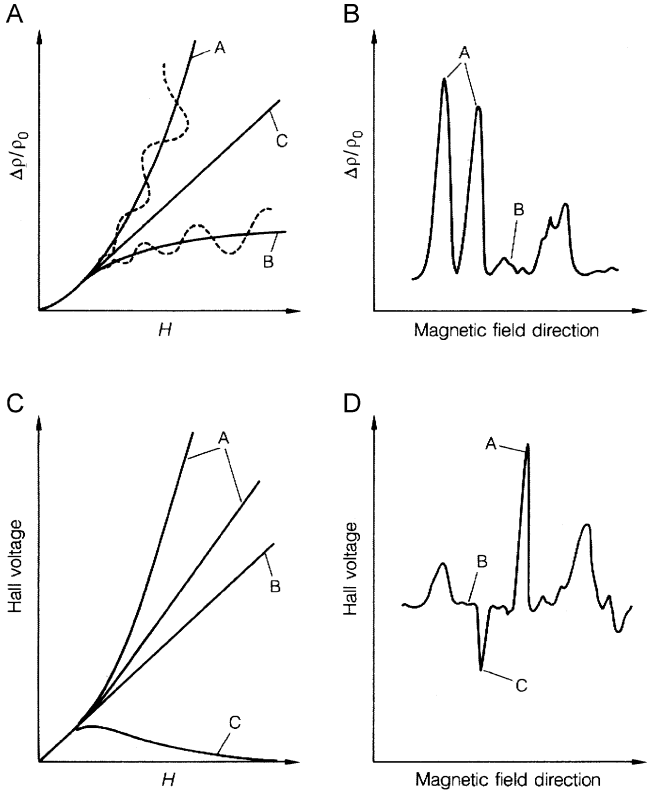

Figure 8. Types of field dependences observed experimentally for the transverse MR and the Hall resistance R_H (after Hurd, 1972). In parts (**A**) and (**B**), line A illustrates a quadratic (i.e., B^2) high-field variation, line B illustrates saturation, and line C illustrates a linear (i.e., B) variation, all of which are seen in polycrystalline samples (see Fig. 4). Quantum oscillations (dashed curves) may be superimposed upon behaviors A and C for single crystal samples. In parts **C** and **D**, line A illustrates high-field linear variations of different magnitudes, line B illustrates a linear variation extending all the way down to $B = 0$, and line C illustrates a B^{-1} high-field variation.

all cases, a separate current through the magnet that sets **B** determines the magnetic field. The ambient temperature is usually determined by a resistance thermometer involving one fixed current and a measured voltage. Determining $R(\mathbf{B})$ and $R_H(\mathbf{B})$ requires measuring the current sent through the sample and the voltage that it produces. Measuring $S(\mathbf{B})$ requires (1) the current sent through a heating resistor to produce the desired temperature difference, (2) the resulting thermoelectric voltage, and (3) either the voltage produced by a differential thermocouple or the voltages produced by two resistance thermometers through which fixed currents are passed. For $K(\mathbf{B})$ it is necessary to measure the current into the heating resistor and either the output voltage of a differential thermocouple or the voltages produced by two resistance thermometers.

DATA ANALYSIS AND INITIAL INTERPRETATION

For dc measurements, determining $R(\mathbf{B})$ and $R_H(\mathbf{B})$ requires averaging the voltages measured in four different configurations: forward and reversed current to eliminate spurious thermoelectric voltages and forward and reversed magnetic field to eliminate unwanted intermixing of $R(\mathbf{B})$ and $R_H(\mathbf{B})$. For ac measurements, only the field is reversed. For $S(\mathbf{B})$ and $K(\mathbf{B})$ the results for forward and reversed fields should be averaged. To ensure that no unwanted heating effects are present, one should check that $R(\mathbf{B})$, $R_H(\mathbf{B})$, $K(\mathbf{B})$, and $S(\mathbf{B})$ are the same for two different measures of electrical or heat currents.

Unless signals are so small that averaging techniques are necessary, once the steps just listed have been taken, analysis of $R(\mathbf{B})$, $R_H(\mathbf{B})$, $S(\mathbf{B})$, and $K(\mathbf{B})$ is straightforward, simply involving plotting the calculated quantity versus B at each temperature of interest.

SAMPLE PREPARATION

Figure 1 shows the preferred form of a foil or film for quantitatively determining $\rho(\mathbf{B})$ and $R_0(\mathbf{B})$. In practice: (1) a sample can also be in the form of a wire; (2) if only MR(**B**) is desired, the contacts can be made differently; and (3) alternative techniques for measuring R_H using the Corbino disc geometry, or Helicon waves, are also possible (Hurd, 1972). The sample form of Figure 1 can also be used in very high magnetic fields (>40 T), which can be reached only by pulsing the fields (see, e.g., Sdaq et al., 1993).

The conditions for measuring $R(\mathbf{B})$ and MR specify no temperature gradients along the length, width, or thickness of the sample. To facilitate this and to minimize sample distortion by the Lorentz force induced by the magnetic field, the sample is usually physically anchored to a thermally conducting but electrically insulating substrate and submerged in a constant-temperature fluid (at cryogenic temperatures, liquid helium; at higher temperatures, an inert gas such as helium or argon, or air if the sample and holder are chemically inert). To minimize heat flow in or out along the potential leads of Figure 1, these leads are thermally "heat sunk" to (but electrically insulated from) a metal binding post held at nearly the same temperature as the sample.

The sample form of Figure 1 can also be used to measure $K(\mathbf{B})$ and $S(\mathbf{B})$ by placing temperature sensors on the potential lead pads. For $S(\mathbf{B})$, the potential leads will then become the reference material B specified above. To minimize unwanted heat flow in or out of the sample, the sample wire or foil is suspended in vacuum (usually on an electrically insulating substrate) and, if the temperatures are high enough that radiation is significant, surrounded by a thermal shield. To measure either $K(\mathbf{B})$ or $S(\mathbf{B})$, a heat current $\dot{Q}$ is injected at one end of the sample to produce a temperature gradient. For $K(\mathbf{B}) = \dot{Q}/\Delta T$, all of the injected heat $\dot{Q}$ must flow through the sample and there must be no additional heat flow in or out. For $S(\mathbf{B}) = \Delta V_{AB}/\Delta T$, extraneous heat flows are less crucial, but it is important to keep the regions of the two thermocouple contacts at uniform temperature to avoid spurious "internal voltages" from these contact regions. The only major constraint occurs when measuring $K(\mathbf{B})$ for thin samples on a substrate; either the sample must be thick enough

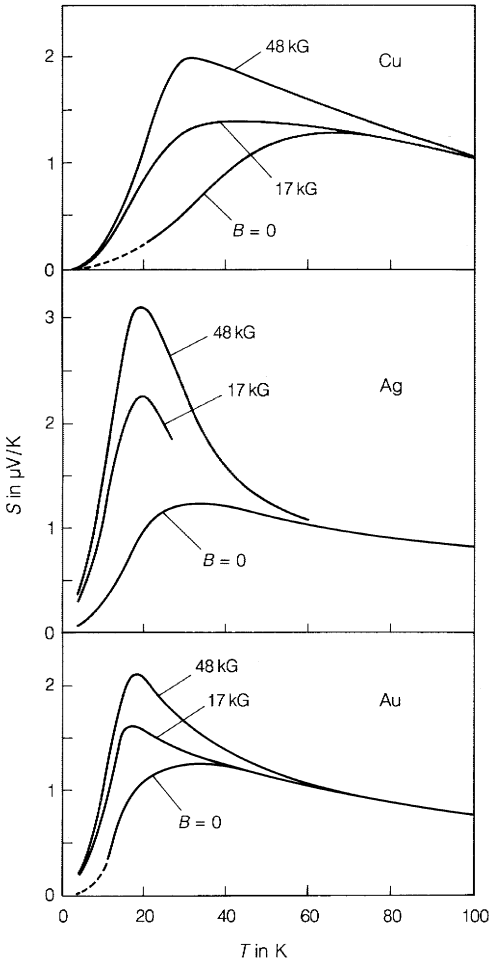

Figure 9. $-S(\mathbf{B})$ vs. T for Co, Ag, and Au at $B = 0$, 1.7 T, and 4.8 T. (From Chiang, 1974.)

so that it carries essentially all of the heat or the heat conduction of the substrate must be measured and corrected for.

PROBLEMS

Vibration of the sample or its leads in the presence of a magnetic field can induce unwanted voltages. Where possible, the sample should be anchored to a substrate. To minimize wire loops in which spurious currents may be induced, current and voltage lead pairs should be separately twisted together and, where possible, physically anchored.

The potential leads, and leads to any thermometers attached to the sample, can bring heat into or out of the sample. To minimize unwanted heat flow, such leads should be thin and heat sunk to bars maintained at a temperature close to that of the sample.

For both dc and ac currents, measurements with forward and reverse fields should be "averaged," defining $R = 1/2[R_H(+\mathbf{B}) + R_x(-\mathbf{B})]$ and $R_H = 1/2[R_H(+\mathbf{B}) - R_H(-\mathbf{B})]$.

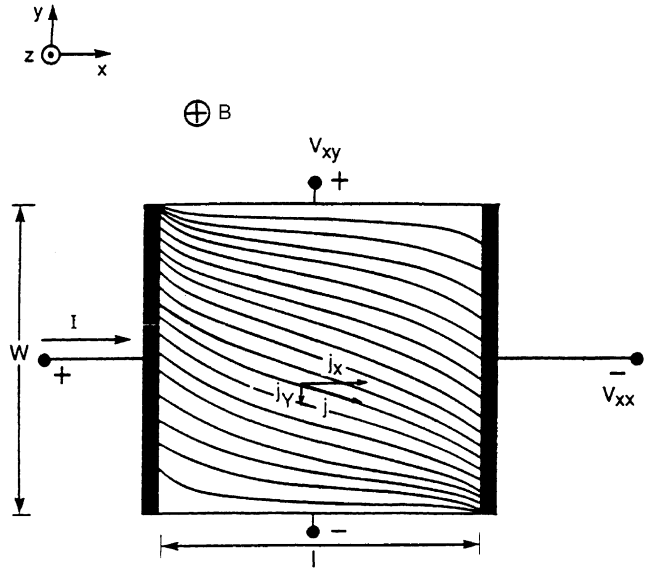

Figure 10. Cross-section of the distribution of current density j (curved lines) between two planar current electrodes (dark regions) for magnetic field $\mathbf{B}$ pointing into the plane of the page. V_{xx} is the longitudinal voltage and V_{xy} the transverse or Hall voltage. (After Heremens, 1993.)

Since R is expected to be unchanged by reversal of $\mathbf{B}$, whereas R_H is expected to reverse sign, reversal of $\mathbf{B}$ is used to define the experimental R and R_H, thereby correcting for any sample or lead misalignment that could intermix components of R_H and R_x. In practice, it is best to minimize such voltages by making the Hall voltage leads in Figure 1 as closely opposite to each other as possible.

Electrical and heat current uniformity through the sample is essential for high-accuracy determinations of $\rho(\mathbf{B})$, R_0, and $\kappa(\mathbf{B})$ (Hurd, 1972). To ensure uniformity to within 1%, the total sample length should be at least five times the sample width and at least three times the distance L between the voltage leads. For measuring $\rho(\mathbf{B})$ and R_0, the current contacts should extend over the entire sample width and should have low resistance compared to that of the sample. Care must be exercised in attaching voltage leads. Attaching leads of a different material directly to a wire or foil sample without the projections shown in Figure 1 can lead to disruption of uniform current flow in the vicinity of the contacts. Especially dangerous in such a case is use of superconducting contacts, which can short out the sample over a finite length. To minimize disrupting uniform current flow, it is usual for highest precision work to shape the sample so that its material projects beyond its main body, as shown in Figure 1. Contacts of a different metal, such as Cu, spot welded or soldered to the projections at least twice the probe width away from the sample body will then not signigicantly perturb the current distribution. For further details, see Hurd (1972).

Any temperature sensors that are located in the magnetic field should have either low or well-known B dependence.

A nonuniform magnetic field, or an inhomogeneous sample, can lead to nonuniform current densities that require solving Laplace's equation. Such complications are for the most part beyond the scope of the present unit, but two examples may be instructive. First, at low temperatures, a small groove on the surface of a high-purity film ($\omega_c\tau \gg 1$) will cause the current lines to deviate from straight paths, thereby inducing a Hall voltage along the direction of current flow and generating a linear magnetoresistance (Bruls et al., 1981). Second, a uniform **B** field can also produce a nonuniform current in a homogeneous sample that is not infinitely long and narrow. Figure 10 illustrates the current flow patterns that occur when a field **B** is applied perpendicular to a film of finite length L. When the film is short compared to its width W, the Hall effect is shorted out—the limiting version of such behavior is the Corbino disc geometry described by Hurd (1972). Only when the film is much longer than it is wide does the current flow become uniform over most of the sample. Conformal mapping techniques give the general relation for the resistance (Lippmann and Kuhrt, 1958):

$$R(B) = R(B=0)[1 + f(W/L)(\rho_{xy}/\rho_{xx})^2] \times \rho_{xx}(B)/\rho_{xx}(0) \tag{16}$$

where $f(W/L)$ is a known function of the ratio W/L. The first term ("1") in the brackets gives the usual field-dependent resistance and the second term gives the effect of the finite length L. In a free electron gas, ρ_{xx} should saturate and ρ_{xy} increase linearly with B. In Equation 16, $R(\mathbf{B})$ would then increase quadratically with B. A "short-wide" geometry is used to enhance the MR in semiconductor "Hall devices" (Heremens, 1993b).

SURFACE MAGNETO-OPTIC KERR EFFECT

INTRODUCTION

In 1845, Michael Faraday found that the polarization plane of linearly polarized light rotates as the light is transmitted through a magnetized medium. Thirty-two years later the magneto-optic Kerr effect (MOKE) was discovered by John Kerr when he examined the polarization of light reflected from the polished surface of an electromagnet. These two monumental works heralded the beginnings of magneto-optics and form the foundation of its modern utilization (Dillon, 1971). As the field of surface and thin-film magnetism has emerged and blossomed in recent years (Falicov et al., 1990), so has the need for innovative approaches to study magnetic phenomena on the nanometer-thickness scale. The application of the Kerr effect to study the surface magnetism was introduced by Moog and Bader (1985) along with the acronym SMOKE to denote the surface magneto-optic Kerr effect. These researchers studied atomic-layer film thicknesses of iron grown epitaxially on Au(100). Magnetic hysteresis loops were obtained with monolayer sensitivity. Since then SMOKE has emerged as a premier surface magnetism technique of choice in many laboratories worldwide. The broad acceptance of the SMOKE technique stems from its simplicity and its ability to generate the "universal currency" in magnetism—the hysteresis loop. In addition, there are almost no materials limitations to this technique, as long as the sample surface is smooth enough to generate optical reflection. However, the magnitude of the SMOKE signal depends on the materials properties and on the optical wavelength. Although in this unit we describe the SMOKE technique for visible light with fixed wavelength, it is easy to extend the technique to wavelength-dependent measurements such as magneto-optic spectroscopy and spatially resolved measurements such as magneto-optic microscopy. Nevertheless, SMOKE has been applied successfully to address various contemporary topics in low-dimensional magnetism (Bader, 1991). The aim of this unit is to provide general background about the basic principles and experimental methods of the SMOKE technique. While much of the discussion is directed to nonspecialists, it is structured with the inclusion of mathematical exposition to describe magneto-optics of magnetic multilayers.

There are many challenges left to overcome in the quest to provide a complete magnetic characterization of ultrathin-film structures. Significant progress has been made recently to develop second-harmonic-generation (SHG) MOKE to distinguish the response of the surface and/or interfacial layer from the interior-layer or bulk response. A future direction could involve the combination of SMOKE with other techniques to enhance both spatial and time resolution so that small-scale processes, such as domain wall dynamics, can be investigated. The purpose of this unit is to provide background on the SMOKE technique with an emphasis on magnetic multilayers.

As described in the next section, the magneto-optic effect originates from the spin-orbit interaction. Therefore SMOKE should be regarded as one of many possible versions of this interaction. Others include the Faraday effect

technique, which is usually applied to optically transparent materials, and core-level magnetic dichroism (see X-RAY MAGNETIC CIRCULAR DICHROISM), which is an element-specific measurement.

PRINCIPLES OF THE METHOD

Phenomenological Explanation of the Origins of Magneto-Optic Effects

Maxwell (1873) expressed linear polarized light as a superposition of two circular polarized components. He realized that the Faraday effect is a consequence of different propagating velocities of the two circular modes. Thus, it is the difference in the dielectric constants for left- and right-circular polarized light that account for the Faraday rotation. This explanation remains the phenomenological description of the Faraday effect still presented in introductory physics textbooks. The dielectric property of a medium is characterized by a 3×3 tensor, ε_{ij}, with $i, j = 1, 2, 3$. In general, this dielectric tensor can be decomposed into symmetric and antisymmetric parts. The symmetric part can be diagonalized by an appropriate rotation of the coordinates. If the three eigenvalues are the same, the medium is isotropic, and the dielectric tensor is reduced to a dielectric constant. Otherwise, the medium is anisotropic. Nevertheless, the normal modes of the symmetric tensor are linearly polarized light along the three principal axes. Therefore, the symmetric part of the dielectric tensor does not give rise to the Faraday effect. Since the symmetric part of ε_{ij} is unimportant to the Faraday effect, we will always assume that it is isotropic.

To see the effect of the antisymmetric part of ε_{ij}, consider the dielectric tensor

$$\tilde{\varepsilon} = \varepsilon \begin{pmatrix} 1 & iQ_z & -iQ_y \\ -iQ_z & 1 & iQ_x \\ iQ_y & -iQ_x & 1 \end{pmatrix} \tag{1}$$

The two normal modes are the left- (L) circular polarized light ($E_y = iE_x$) with $\varepsilon_{\mathrm{L}} = \varepsilon(1 - \mathbf{Q} \cdot \hat{\mathbf{k}})$ and right- (R) circular polarized light ($E_y = -iE_x$) with $\varepsilon_{\mathrm{R}} = \varepsilon(1 + \mathbf{Q} \cdot \hat{\mathbf{k}})$ where $\mathbf{Q} = (Q_x, Q_y, Q_z)$ is known as the Voigt (1908) vector and $\hat{k}$ is the unit vector along the light propagation direction. Thus, it is the antisymmetric elements, $\mathbf{Q} = (Q_x, Q_y, Q_z)$, that produce the difference in the refraction indices between the two circularly polarized modes and the Faraday effect originates from the off-diagonal antisymmetric elements of the dielectric tensor. The complex Faraday rotation of the polarization plane after traveling a distance L within a magnetized medium is

$$\theta = \frac{\pi L}{\lambda}(n_{\mathrm{L}} - n_{\mathrm{R}}) = -\frac{\pi L n}{\lambda}\mathbf{Q} \cdot \hat{\mathbf{K}} \tag{2}$$

where n is the refractive index. The real part of the above formula gives Faraday rotation, and the imaginary part gives the Faraday ellipticity.

It is instructive to consider why an external magnetic field has a stronger effect on the polarization plane of light than an external electric field. This question can be addressed with a simple argument based on consideration of time-reversal symmetry. Under the time-reversal process, the electric field remains unchanged, while the magnetic field undergoes a change of sign. Thus, Onsager's relation (Landau and Lifshitz, 1960) gives $\varepsilon_{ij}(\mathbf{E}, \mathbf{H}) = \varepsilon_{ij}(\mathbf{E}, -\mathbf{H})$. Here $\mathbf{E}$ and $\mathbf{H}$ are the external electric and magnetic fields, respectively. By expanding ε_{ij} up to terms that are linear in the electric and magnetic fields, it is obvious that the antisymmetric part of ε_{ij} comes from the magnetic field. The magnetic field here provides an example of a special case of time-reversal symmetry breaking. In general, any quantity that breaks the time-reversal symmetry should generate antisymmetric elements of the dielectric tensor and, thus, a Faraday effect. This is why, for example, magneto-optic experiments were utilized in research on high-temperature superconductors to search for the hypothesized existence of anions, which are believed to break time-reversal symmetry (Kiefl et al., 1990; Wilczek, 1991).

Classical Explanation

The dielectric properties of a medium are determined by electron motion in response to an electromagnetic wave. Thus, an analysis of electron motion should offer a microscopic explanation of the magneto-optic effect. In the classical picture, each electron inside a medium is bonded to an atom (with nature frequency ω_0) and dissipates energy with a relaxation time τ. Consider an electromagnetic wave propagating in a medium with an external magnetic field H applied in the z direction. The equation of motion for an electron in the medium is then

$$\frac{d^2\mathbf{r}}{dt^2} + m\omega_0^2\mathbf{r} + \frac{m}{\tau}\frac{d\mathbf{r}}{dt} = -e\mathbf{E} - \frac{e}{c}\frac{d\mathbf{r}}{dt} \times H\hat{\mathbf{z}} \tag{3}$$

Here $\mathbf{E}$, H, c, t, $\mathbf{r}$, m, and e are the electrical field, magnetic field, speed of light, time, position of the electron, mass of the electron, and charge of the electron, respectively, and $\hat{\mathbf{z}}$ is a unit vector in the z-direction. Without the magnetic field present, a circular polarized electric field will drive the electron into circular motion with the same radius for both left- and right-circular polarized waves. Since the electric dipole moment is proportional to the radius of the circular orbit, there is no difference between the dielectric constants for left- and right-circular polarized waves, and, thus, there is no Faraday rotation. However, with a magnetic field applied in the propagation direction of the electromagnetic wave, there is an additional Lorentz force acting on each electron. This Lorentz force is directed toward or away from the center of the circle for left- or right-circular motions and thus shrinks or expands the radius of the electron orbit. The difference in the resultant radii of the left- and right-circular polarized modes yields the difference in the corresponding dielectric constants. Thus, it is the Lorentz force of the magnetic field that generates the Faraday effect.

From the above analysis, we see that the difference in the dielectric constants for the two circularly polarized modes is proportional to the strength of the Lorentz force, which itself is proportional to the magnetic field and the

frequency. Thus, it becomes apparent from Equation 2 that the Faraday rotation is directly proportional to the magnetic field and inversely proportional to the square of the wavelength λ of the light. Indeed, under the conditions $\omega_0 \gg \omega \ \omega_c$ ($\omega_c = eH/mc$ is the cyclotron frequency) and $\omega\tau \gg 1$, which hold for visible light, the Faraday rotation is given by

$$\theta = \frac{2\pi n e^3 \omega^2 LH}{m^2 c^2 \omega_0^4 \sqrt{1 + 4\pi n e^2/m\omega_0^2}} \qquad (4)$$

where n is the electron density. The rotation angle is proportional to the sample length L, the magnetic field H, and the square of the light frequency ω. This result conforms with experimental observations.

Quantum Description of the Magneto-Optic Effect in a Ferromagnet

The development of a quantum description of the magneto-optic effect was motivated by the particularly strong Faraday effect in ferromagnetic materials. To explain the magnitude of the Faraday rotation in a ferromagnet, which is of order $\sim 10^5$ deg/cm for magnetization parallel to the light propagation direction, an effective magnetic field of $\sim 10^7$ Oe has to be invoked. This value is of the order of the Weiss field that was postulated to account for the existence of ferromagnetism. The Weiss field was explained by Heisenberg to originate from the exchange interaction among the electrons. Heisenberg's exchange interaction correctly revealed the origin of magnetism as an effective magnetic field that aligns the individual spins. However, the problem remained that this field could not explain the Faraday effect, since it is not coupled to the electron motion, which determines the dielectric properties of a material. This difficulty was solved by Hulme (1932), who pointed out that the spin-orbit interaction couples the electron spin to its motion. Thus, the Faraday rotation in a ferromagnet could be understood.

The spin-orbit interaction $\sim(\nabla V \times \mathbf{p}) \cdot \mathbf{s}$ results from the interaction of the electron spin with the magnetic field it experiences as the electron moves through the electric field $-\nabla V$ inside a medium with momentum $\mathbf{p}$. This interaction couples the electron spin with its motion and thus connects the magnetic and optical properties of a ferromagnet. Note that the effect of a magnetic field on the electron motion manifests itself as $H_{\text{int}} \sim -(e/mc)\,\mathbf{p} \cdot \mathbf{A}$. Thus, to a certain extent, the spin-orbit interaction $\sim(\nabla V \times \mathbf{p}) \cdot \mathbf{s} = \mathbf{p} \cdot (\mathbf{s} \times \nabla V)$ can be thought of as an effective magnetic field vector potential $\mathbf{A} \sim \mathbf{s} \times \nabla V$ acting on the motion of the electron. For nonmagnetic materials, although a spin-orbit interaction is present, this effect is not strong. This is because the equal number of spin-up and spin-down electrons cancels the net effect. For ferromagnetic materials, however, the effect is pronounced because of the unbalanced electron spin populations.

Hulme calculated the two (right- and left-polarized) refraction indices. He used the Heisenberg model of a ferromagnet and the Kramers-Heisenberg dispersion formula, which gives the refraction index in terms of the eigenenergy and the matrix elements of the dipole moment operator with respect to the eigenfunctions of the system. He accounted for the difference of the two refraction indices by the energy splitting due to the spin-orbit interaction. He neglected, however, the change of the wavefunction due to the spin-orbit interaction. This theory is unsatisfying because the quenching of orbital angular momentum in transition metal ferromagnets gives no energy splitting. Kittel (1951) showed that it is the change of the wave functions due to the spin-orbit interaction that gives rise to a right order of magnitude of the difference of the two refraction indices. Argyres (1955) later gave a full derivation of the magneto-optic effect in a ferromagnet using perturbation theory. Subsequent works were performed to calculate the magneto-optic effect in different regimes (Shen, 1964; Bennet and Stern, 1965; Erskine and Stern, 1975).

Formalism of Magneto-Optic Kerr Effect in Multilayers

Since metallic magnetic materials absorb light strongly, it is more useful to measure the reflected than the transmitted signal to probe the magneto-optic effect. Thus, we concentrate on the Kerr effect in this section. The formalism, however, can readily be extended to include the Faraday effect. For a given magnetic multilayer system, the refraction tensor for each layer can be expressed by a 3×3 matrix. The goal is to calculate the final reflectivity along different polarization directions. The general method is to apply Maxwell's equations to the multilayer structure and to satisfy the boundary conditions at each interface. Zak et al. (1990, 1991) developed a general expression for the Kerr signal based on this method. The essential ingredients of this theory are two matrices that relate the electric fields at each boundary. These matrices are described in Appendix A, and the special case of the ultrathin limit is described in Appendix B.

PRACTICAL ASPECTS OF THE METHOD

There are three important Kerr configurations: polar, longitudinal, and transverse. The polar Kerr effect has a magnetic field applied in the normal direction to the film plane (Fig. 1A) and thus is sensitive to the perpendicular component of the magnetization. The longitudinal case has a magnetic field applied in the film plane and in the plane of the incident light (Fig. 1B) and thus should be sensitive to the in-plane component of the magnetization. The transverse Kerr effect also has a magnetic field applied in the film plane, but perpendicular to the incident plane of the light (Fig. 1C). The polar and longitudinal Kerr effects are linear in Q and yield complex rotation ϕ of the polarization of the light. The polar signal is typically an order of magnitude greater than the longitudinal signal due to the optical factors. The transverse Kerr effect requires a second-order expansion in Q and manifests itself by a small reflectivity change for p-polarized incident light. The criteria for choosing an experimental angle of incidence are governed by weighing practical geometric constraints of the experimental chamber against the optimal angles to maximize the signal (Zak et al., 1991).

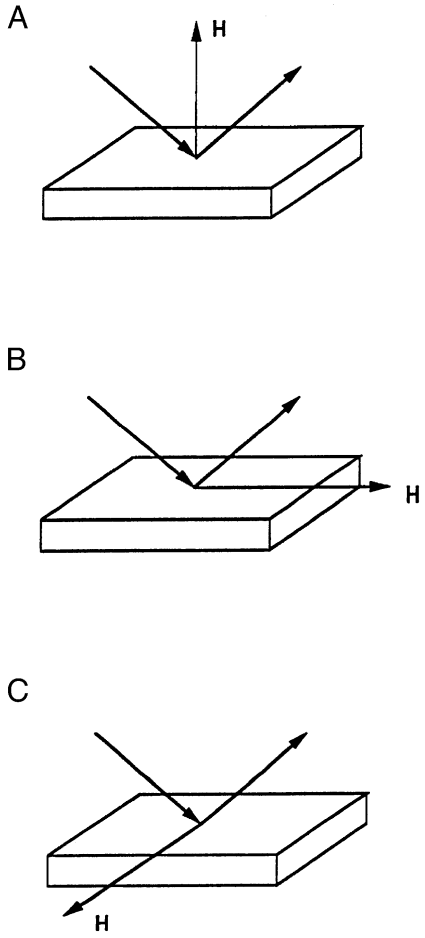

Figure 1. Three common configurations for the SMOKE measurements: (**A**) polar, (**B**) longitudinal, and (**C**) transverse Kerr effect.

An experimental SMOKE setup has the great advantage of simplicity (see Fig. 2). Typically a laser is used as a fixed-wavelength light source. The goal here would be to characterize the magnetic response of ultrathin layered systems by means of magneto-optics. However, if the goal were to extract magneto-optic properties per se, then the laser could be replaced by a lamp and monochromator in order to generate wavelength dependencies. (Synchrotron light sources can be used as well and are typical for magnetic dichroism studies in the x-ray regime; see MAGNETIC X-RAY SCATTERING.) Typically a low-power (few-milliwatt) laser suffices. It is highly desirable to use an intensity-stabilized laser, especially for monolayer studies. Crystal prism polarizers are useful both for defining the polarization and as an analyzer in front of the photodiode detector. Sheet polarizers can be used, but they have a lower extinction ratio when crossed than prism polarizers and so are not optimal for monolayer studies. Figure 2 outlines a straightforward DC detection scheme, although AC methods can be adopted. In that case typically the incident polarization is varied using a photoelastic modulator (Kliger et al., 1990), and the output of the photodiode detector is fed to a lock-in amplifier. Another common AC approach in optics involves chopping the incident beam in order to

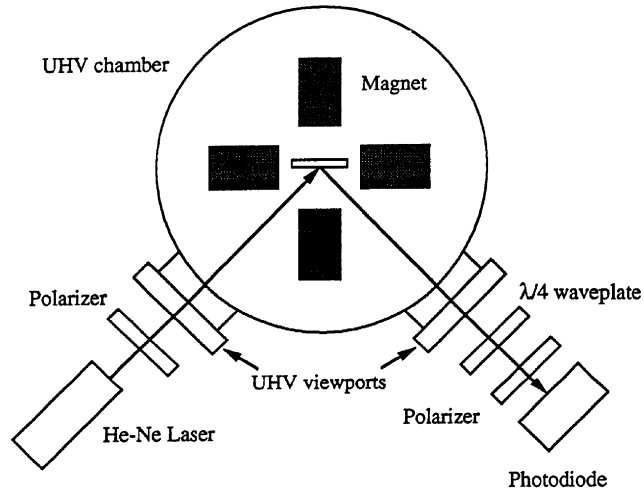

Figure 2. Schematic of the experimental setup of the SMOKE technique.

improve the signal-to-noise ratio. Finally, the magnet shown in Figure 2 consists of two split-coil solenoid pairs. Energizing either pair would generate a field in the film plane or perpendicular to it for longitudinal or polar measurements, respectively. Conventional or superconducting solenoids can be used depending on the field requirements of the experiment.

A linear p-polarized laser will serve as the light source for the purpose of our discussion (although s-polarized light could be used as well). After reflection from the sample surface, the light intensity is detected by a photodiode with a linear (analyzing) polarizer in front of it. The analyzing polarizer is set at a small angle δ ($\sim 1^\circ$ to 2°) from the extinction condition to provide a DC bias. Then the reflection intensity as a function of the externally applied magnetic field will generate the magnetic hysteresis loop (Fig. 2). Figure 3 shows an example of the hysteresis loop

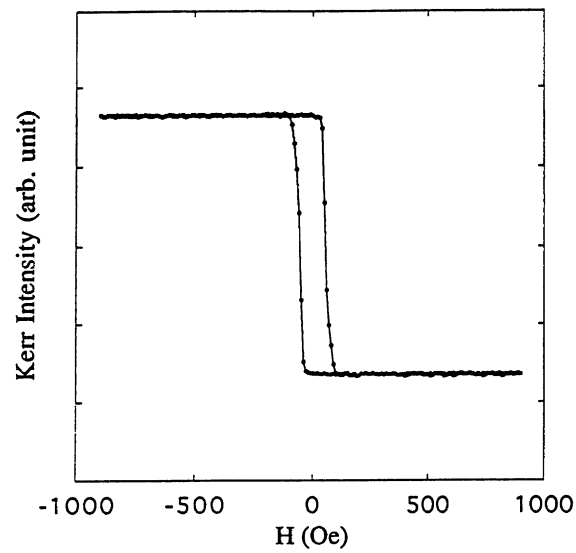

Figure 3. A SMOKE hysteresis loop taken from a 6-ML Fe film grown on Ag(100) substrate.

measured by SMOKE from a 6-ML Fe/Ag(100) film, where ML denotes monolayer. The figure illustrates that monolayer sensitivity is readily achieved in the SMOKE technique.

METHOD AUTOMATION

Standard spectroscopic automation can be used in the data collection by means of a laboratory computer. The computer would govern the sweep of the magnetic field by driving the bipolar power supply of the magnet via a voltage ramp. The computer would also simultaneously store the output of the photodiode detector by either digitizing an analog voltage output signal or by transferring the digital signal directly read by the detector electronics. Signal averaging can be performed by sweeping the field multiple times. A key feature of the SMOKE technique is that the optical elements are fixed and are not adjusted manually or under computer control.

DATA ANALYSIS AND INITIAL INTERPRETATION

To provide a quantitative analysis, the Kerr intensity for p-polarized incident light measured by the photodiode after the light has passed through the analyzing polarizer is

$$I = |E_p \sin\delta + E_s \cos\delta|^2 \approx |E_p \delta E_s|^2 \tag{5}$$

where $E_s/E_p = \phi' + i\phi''$ gives the Kerr rotation ϕ' and the Kerr ellipticity ϕ''. Then Equation 5 becomes

$$I = |E_p|^2|\delta + \phi' + i\phi''|^2 \approx |E_p|^2(\delta^2 + 2\delta\phi') = I_0\left(1 + \frac{2\phi'}{\delta}\right) \tag{6}$$

with

$$I_0 = |E_p|^2\delta^2 \tag{7}$$

as the intensity at zero Kerr rotation. Thus, the measured intensity as a function of the applied field yields a magnetic hysteresis loop. The maximum Kerr rotation ϕ'_m can be determined by the relative change of the Kerr intensity, $\Delta I/I_0$, upon reversing the saturation magnetization:

$$\phi'_m = \frac{\delta}{4}\frac{\Delta I}{I_0} \tag{8}$$

For *in situ* measurements an experimental difficulty that can mislead a nonexpert is that the ultrahigh-vacuum (UHV) viewport window (w) usually produces a birefringence, $\phi'_w + i\phi''_w$, that prevents the extinction from being realized. In this situation, a quarter-waveplate is usually placed before the analyzing polarizer to cancel the birefringence of the UHV viewport. The extinction condition can then be achieved if the principal axis of the quarter-waveplate makes an angle ϕ'_w to the p axis and if the polarization axis of the analyzing polarizer makes an angle $\pi/2 + \phi'_w - \phi''_w$ to the p axis. Then measured Kerr intensity is

$$I = |E_p|^2(\delta^2 + 2\delta\phi'') = I_0\left(1\frac{2\phi''}{\delta}\right) \tag{9}$$

Note that in this case the relative Kerr intensity determines the Kerr ellipticity rather than the rotation. The reason is that the quarter-waveplate produces a $\pi/2$ phase difference between the p and s components, so the analyzing polarizer "sees" $i(\phi' + i\phi'') = -\phi'' + i\phi'$ instead of $\phi' + i\phi''$. Thus, the quarter-wave plate interchanges the Kerr rotation with ellipticity. To measure the Kerr rotation, a half-waveplate can be used to replace the quarter-waveplate.

Experimental Result on Co/Cu Superlattices

It is instructive to provide an example of magneto-optic results in a magnetic multilayer system. Measurements on Co-Cu multilayers are presented for this purpose. Single crystals of both Co overlayers and Co/Cu superlattices were prepared by means of molecular beam epitaxy (MBE) using Cu(100) and Cu(111) single crystals as substrates and growth at room temperature. Detailed descriptions of the sample preparation appear elsewhere (Qiu et al., 1992). To provide a sense of the film quality in the present case, Figure 4 shows the intensity of the reflection high-energy electron diffraction (RHEED) during the growth of a Co/Cu(100) superlattice. More than 200 RHEED oscillations were observed during the growth of the entire superlattice, although the figure only shows results for initial and final bilayers. This is an indication of high-quality growth; each oscillation in intensity identifies the growth of an atomic monolayer.

The Kerr ellipticities of the multilayers and overlayers were measured *in situ* after each bilayer or Co dose was deposited. The results are plotted in Figure 5. Ellipticity data also are plotted, for comparison purposes, for Co deposited on a polycrystalline Cu substrate. Concentrating

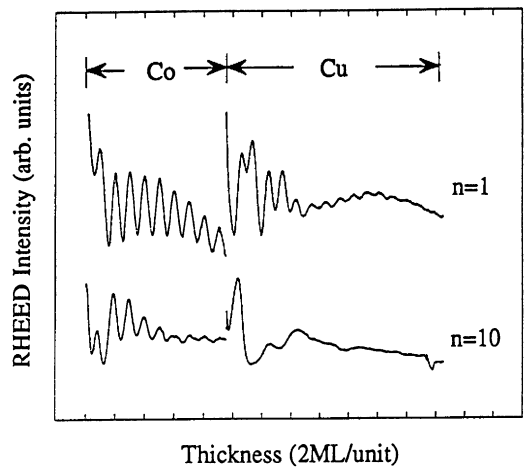

Figure 4. RHEED oscillations taken during the growth of a $[Co(9.5\ ML)/Cu(16\ ML)]_n$ superlattice on a Cu(100) substrate.

first on the magneto-optic behavior of the Co overlayers on the Cu substrates, a linear increase in the ellipticity is observed in the ultrathin regime, reaching a maximum at ~120 Å of Co and finally dropping to a constant value for >400 Å thickness of Co. The initial rise is due to the increasing amount of Co present within the penetration depth of the light. In the thick regime (>400 Å of Co) the signal approaches a constant value since the absorption of light limits the depth sensitivity. In the intermediate regime the maximum in the ellipticity at ~120 Å of Co is due to the reflectivity changing from being dominated by Cu to being dominated by Co. Similar behavior is observed in the Fe/Au system (Moog et al., 1990). It is interesting to note that the ellipticity is independent of crystal orientation in the thickness range studied. In this example we can see the difference between MOKE and SMOKE. Traditionally, MOKE is defined as being independent of thickness, as opposed to the Faraday effect, which is proportional to thickness. For film thicknesses >400 Å we are in the traditional MOKE regime. But the initial linear rise of the magneto-optic signal is a characteristic of the SMOKE regime, which is encountered in the ultrathin limit.

For a quantitative analysis, we applied the formalism derived in the Appendix to simulate the results. The refractive indices we used are obtained from tabulations (Weaver, 1999) in the literature: $n_{Cu} = 0.249 + 3.41i$ and $n_{Co} = 2.25 + 4.07i$. We left the values of Q_1 and Q_2, where $Q = Q_1 + iQ_2$, for Co as free parameters to best fit the experimental curves and obtained $Q_1 = 0.043$ and $Q_2 = 0.007$. The calculated curves, depicted as solid lines in Figure 5, are in good overall agreement with the experimental data. In particular, the peaked behavior of the overlayers is faithfully reproduced.

The ellipticities of three epitaxial Co/Cu superlattices also appear in Figure 5. The superlattices are [Co(16 Å)/Cu(28 Å)]$_n$, grown on Cu(100), and [Co(11 Å)/Cu(31 Å)]$_n$ and [Co(18 Å)/Cu(35 Å)]$_n$, both grown on Cu(111). Their ellipticities in Figure 5 appear as a function of the total superlattice thickness. The superlattice ellipticities initially increase linearly in the ultrathin region and saturate in the thick regime, although there is no maximum at intermediate thicknesses. The lack of a maximum is readily understood because the reflectivity is not evolving from that of Cu to that of Co, as in the overlayer cases above. Instead, the reflectivity remains at an average value between the two limits, since both Co and Cu remain within the penetration depth of the light, no matter how thick the superlattice becomes. Using the Q value obtained from the Co overlayers, the Kerr ellipticities for the superlattices were calculated and plotted in Figure 5. The agreement with experimental data is obvious and is discussed further below.

To test the additivity law applicable to the ultrathin regime, the experimental data in Figure 5 were replotted in Figure 6 as a function of the magnetic Co layer thickness only (the Cu layers are ignored). In the ultrathin regime all the data lie on a single straight line. This result provides a demonstration and confirmation of the additivity law that states that the total Kerr signal in the ultrathin regime is a summation of the Kerr signal from each individual magnetic layer and is independent of the nonmagnetic spacer layers.

Despite the good overall semiquantitative agreement, the calculated ellipticity can be seen, upon close inspection, to exceed the experimental values in the ultrathin regime. For example, the calculated linear slope is 6.6 μrad/Å, while the experimental result yields only 4.3 μrad/Å. This systematic deviation can be due, for instance, either to the breakdown of the macroscopic description in the ultrathin region or to optical parameters (n and Q) that deviate from their bulk values.

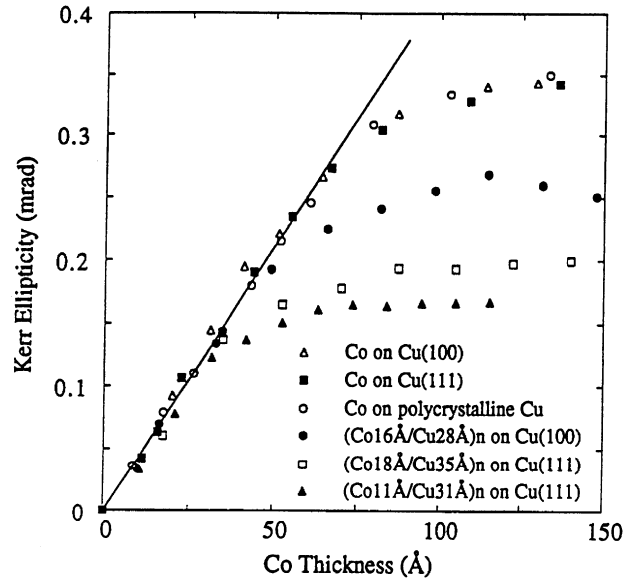

Figure 6. The additivity law shows that the Kerr signal in the ultrathin regime depends on the magnetic layer only.

SAMPLE PREPARATION

Sample preparation is governed by the same considerations as in other areas of surface science and thin-film growth: Vacuum conditions are maintained in the UHV realm, Auger spectroscopy (AUGER ELECTRON SPECTROSCOPY) is usually used to monitor surface cleanliness, and electron diffraction is used to monitor structural integrity. The types of evaporators might range from electron beam to thermal evaporators and are only limited by the creativity of the fabricator and the ability to control and monitor flux rates of different chemical species.

PROBLEMS

Several factors need to be considered in the evaluation of technical problems associated with the SMOKE technique. Experimentally, instability of the laser intensity is probably the main contributor to noise in the SMOKE signal. It is highly recommended to use intensity-stabilized lasers and/or lock-in amplifiers for the SMOKE measurements. A certain degree of vibration isolation is also important as in any optical measurement. As for the interpretation of SMOKE signals, one has to keep in mind that although the SMOKE rotation or ellipticity is proportional to the magnetization, the proportionality coefficient depends on the optical properties of the materials and is usually an unknown quantity for ultrathin films. Therefore, SMOKE is not a form of magnetometry that can determine the absolute value of the magnetic moment. This is an important fact, especially in studies of spin dynamics, because the SMOKE dynamics will not necessarily reflect the spin dynamics.

APPENDIX A: THE MEDIUM-BOUNDARY AND MEDIUM-PROPAGATION MATRICES

The first matrix, denoted $\boldsymbol{A}$, is the 4×4 medium-boundary matrix. It relates the components of the electric and magentic fields with the s and p components of the electric field, which are, respectively, perpendicular to and parallel to the plane of incidence. We define the incident (i) and reflected (r) waves at each boundary between two layers as in Figure 7. Then, we obtain the relation between the x, y components of **E** and **H** and the the s, p components of the electric field as

$$\begin{pmatrix} E_x \\ E_y \\ H_x \\ H_y \end{pmatrix} = A \begin{pmatrix} E_{\mathrm{s}}^{\mathrm{i}} \\ E_{\mathrm{p}}^{\mathrm{i}} \\ E_{\mathrm{s}}^{\mathrm{r}} \\ E_{\mathrm{p}}^{\mathrm{r}} \end{pmatrix} \tag{10}$$

where

$$\boldsymbol{A} = \begin{pmatrix} 1 & 0 \\ \frac{i}{2}[-Q_y \tan\theta(1+\cos^2\theta) + Q_z \sin^2\theta] & \cos\theta + iQ_x \sin\theta \\ \frac{in}{2}(Q_y \sin\theta + Q_z \cos\theta) & -n \\ n\cos\theta & \frac{\mathrm{in}}{2}(Q_y \tan\theta + Q_z) \\ 1 & 0 \\ \frac{i}{2}[Q_y \tan\theta(1+\cos^2\theta) + Q_z \sin^2\theta] & -\cos\theta + iQ_x \sin\theta \\ \frac{in}{2}(Q_y \sin\theta - Q_z \cos\theta) & -n \\ -n\cos\theta & -\frac{in}{2}(Q_y \tan\theta - Q_z) \end{pmatrix} \tag{11}$$

The second matrix, denoted D, is the 4 × 4 medium-propagation matrix. It relates the s and p components of the electric field at the two surfaces (1 and 2) of a film of thickness d. This relation can then be expressed by the matrix product

$$\begin{pmatrix} E_{\mathrm{s}}^{\mathrm{i}} \\ E_{\mathrm{p}}^{\mathrm{i}} \\ E_{\mathrm{s}}^{\mathrm{r}} \\ E_{\mathrm{p}}^{\mathrm{r}} \end{pmatrix} = \boldsymbol{D} \begin{pmatrix} E_{\mathrm{s}}^{\mathrm{i}} \\ E_{\mathrm{p}}^{\mathrm{i}} \\ E_{\mathrm{s}}^{\mathrm{r}} \\ E_{\mathrm{p}}^{\mathrm{r}} \end{pmatrix}_2 \tag{12}$$

where

$$\boldsymbol{D} = \begin{pmatrix} U\cos\delta_i & U\sin\delta_i & 0 & 0 \\ -U\sin\delta_i & U\cos\delta_i & 0 & 0 \\ 0 & 0 & U^{-1}\cos\delta_{\mathrm{r}} & -U^{-1}\sin\delta_{\mathrm{r}} \\ 0 & 0 & U^{-1}\sin\delta_{\mathrm{r}} & U^{-1}\cos\delta_{\mathrm{r}} \end{pmatrix} \tag{13}$$

with

$$\begin{aligned} U &= \exp(-ikd\cos\theta) \\ \delta_i &= \frac{kd}{2}(Q_y \tan\theta + Q_z) \\ \delta_{\mathrm{r}} &= \frac{kd}{2}(Q_y \tan\theta - Q_z) \end{aligned} \tag{14}$$

Here, $k = 2\pi/\lambda$ with λ being the wavelength of the light.

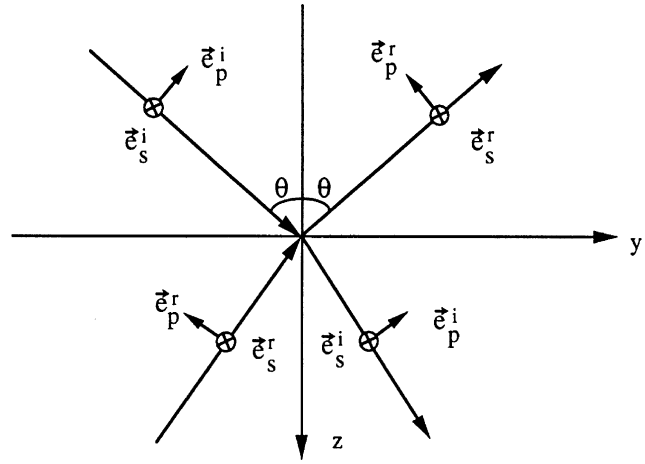

Figure 7. Definitions of the s and p directions for the incidence and reflection waves at the boundary between two media.

With the matrices $\boldsymbol{A}$ and $\boldsymbol{D}$, we can calculate the magneto-optic effect under any conditions. Consider a multilayer structure that consists of N individual layers and a beam of light impinging on the top of the structure from the initial medium (i). After multiple reflections, there will be a reflected beam backscattered into the initial medium and a transmitted beam that emerges from the bottom layer into the final medium (f). The electric fields in the initial and final media can then be expressed as

$$\boldsymbol{P}_{\mathrm{i}} = \begin{pmatrix} E_{\mathrm{s}}^{\mathrm{i}} \\ E_{\mathrm{p}}^{\mathrm{i}} \\ E_{\mathrm{s}}^{\mathrm{r}} \\ E_{\mathrm{p}}^{\mathrm{r}} \end{pmatrix}_{\mathrm{i}} = \begin{pmatrix} E_{\mathrm{s}}^{\mathrm{i}} \\ E_{\mathrm{p}}^{\mathrm{i}} \\ r_{\mathrm{ss}}E_{\mathrm{s}}^{\mathrm{i}} + r_{\mathrm{sp}}E_{\mathrm{p}}^{\mathrm{i}} \\ r_{\mathrm{ps}}E_{\mathrm{s}}^{\mathrm{i}} + r_{\mathrm{pp}}E_{\mathrm{p}}^{\mathrm{i}} \end{pmatrix} \tag{15}$$

and

$$\boldsymbol{P}_{\mathrm{f}} = \begin{pmatrix} E_{\mathrm{s}}^{\mathrm{i}} \\ E_{\mathrm{p}}^{\mathrm{i}} \\ 0 \\ 0 \end{pmatrix}_{\mathrm{f}} = \begin{pmatrix} t_{\mathrm{ss}}E_{\mathrm{s}}^{\mathrm{i}} + t_{\mathrm{sp}}E_{\mathrm{p}}^{\mathrm{i}} \\ t_{\mathrm{ps}}E_{\mathrm{s}}^{\mathrm{i}} + t_{\mathrm{pp}}E_{\mathrm{p}}^{\mathrm{i}} \\ 0 \\ 0 \end{pmatrix}$$

where r and t are reflection and transmission coefficients of the corresponding components. If $\mathbf{P}_m$ is the field component at the bottom surface of the mth layer, then the field component at the top surface of the mth layer will be $\boldsymbol{D}\mathbf{P}_m$. Because E_x, E_y, H_x, and H_y are related to **P** by the matrix $\boldsymbol{A}$, the boundary condition—E_x, E_y, H_x, and H_y are continuous—at the interface between the mth layer and the $(m+1)$th layer is

$$\boldsymbol{A}_m\boldsymbol{P}_m = \boldsymbol{A}_{m+1}\boldsymbol{D}_{m+1}\boldsymbol{P}_{m+1} \tag{16}$$

Then the relation between $\mathbf{P}_{\mathrm{i}}$ and $\mathbf{P}_{\mathrm{f}}$ can be derived as

$$\begin{aligned} \boldsymbol{A}_i\boldsymbol{P}_i &= \boldsymbol{A}_1\boldsymbol{D}_1\boldsymbol{P}_1 = \boldsymbol{A}_1\boldsymbol{D}_1\boldsymbol{A}_1^{-1}\boldsymbol{A}_1P = \boldsymbol{A}_1\boldsymbol{D}_1\boldsymbol{A}_1^{-1}\boldsymbol{A}_2\boldsymbol{D}_2\boldsymbol{P}_2 \\ &= \cdots = \prod_{\mathrm{m}=1}^{\mathrm{N}} (\boldsymbol{A}_m\boldsymbol{D}_m\boldsymbol{A}_m^{-1})\boldsymbol{A}_{\mathrm{f}}\boldsymbol{P}_{\mathrm{f}} \end{aligned} \tag{17}$$

If this expression is put in the form $\mathbf{P}_i = T\mathbf{P}_f$, where

$$T = \boldsymbol{A}_i^{-1} \prod_{m=1}^{N} (\boldsymbol{A}_m \boldsymbol{D}_m \boldsymbol{A}_m^{-1}) \boldsymbol{A}_f \equiv \begin{pmatrix} G & H \\ I & J \end{pmatrix} \tag{18}$$

then the 2×2 matrices of $\boldsymbol{G}$ and $\boldsymbol{I}$ can used to obtain the Fresnel reflection and transmission coefficients:

$$\boldsymbol{G}^{-1} = \begin{pmatrix} t_{ss} & t_{sp} \\ t_{ps} & t_{pp} \end{pmatrix} \quad \text{and} \quad \boldsymbol{I}\boldsymbol{G}^{-1} = \begin{pmatrix} r_{ss} & r_{sp} \\ r_{ps} & r_{pp} \end{pmatrix} \tag{19}$$

The Kerr rotation ϕ' and ellipticity ϕ'' for p- and s-polarized light are then given by

$$\phi_s = \phi_s' + i\phi_s'' = \frac{r_{ps}}{r_{ss}} \quad \text{and} \quad \phi_p = \phi_p' + i\phi_p'' = \frac{r_{sp}}{r_{pp}} \tag{20}$$

APPENDIX B: THE ULTRATHIN LIMIT

In the ultrathin limit the magneto-optic expressions simplify further. For ultrathin films the total optical thickness of the film is much less than the wavelength of the light, $\sum_i n_i d_i \ll \lambda$. In this limit the $\boldsymbol{A}\boldsymbol{D}\boldsymbol{A}^{-1}$ matrix can be simplified to

$$\boldsymbol{A}\boldsymbol{D}\boldsymbol{A}^{-1} = \begin{pmatrix} 1 & 0 & 0 & -\frac{i2\pi d}{\lambda} \\ \frac{2\pi d}{\lambda} n Q_y \sin\theta & 1 + \frac{2\pi d}{\lambda} n Q_x \sin\theta & \frac{i2\pi d}{\lambda} \cos^2\theta & 0 \\ \frac{2\pi d}{\lambda} n^2 Q_z & \frac{i2\pi d}{\lambda} n^2 & 1 - \frac{2\pi d}{\lambda} n Q_x \sin\theta & 0 \\ -\frac{i2\pi d}{\lambda} n^2 \cos^2\theta & \frac{2\pi d}{\lambda} n^2 Q_z & -\frac{2\pi d}{\lambda} n Q_y \sin\theta & 1 \end{pmatrix} \tag{21}$$

If the initial and final media are nonmagnetic, then the 2×2 matrices of $\boldsymbol{G}$ and $\boldsymbol{I}$ in Equation 19 yield the reflection coefficients

$$\begin{aligned} r_{ss} &= \frac{n_i \cos\theta_i - n_f \cos\theta_f}{n_i \cos\theta_i + n_f \cos\theta_f} \\ r_{pp} &= \frac{n_f \cos\theta_i - n_i \cos\theta_f}{n_f \cos\theta_i + n_i \cos\theta_f} \\ r_{ps} &= -\frac{4\pi}{\lambda} \frac{n_i \cos\theta_i}{(n_i \cos\theta_i + n_f \cos\theta_f)(n_f \cos\theta_f)} \\ &\quad \left(\cos\theta_f \sum_m d_m n_m^2 Q_z^{(m)} - n_f n_i \sin\theta_i \sum_m d_m Q_y^{(m)} \right) \\ r_{sp} &= -\frac{4\pi}{\lambda} \frac{n_i \cos\theta_i}{(n_i \cos\theta_i + n_f \cos\theta_f)(n_f \cos\theta_i + n_i \cos\theta_{f)}} \\ &\quad \left(\cos\theta_f \sum_m d_m n_m^2 Q_z^{(m)} + n_f n_i \sin\theta_i \sum_m d_m Q_y^{(m)} \right) \end{aligned} \tag{22}$$

Here n_i, θ_i, and n_f, θ_f are the refraction indices and the incident angles of the initial and the final media, respectively. Equation 22 provides a basis for the additivity law for multilayers in the ultrathin limit, which states that the total Kerr signal is a simple summation of the Kerr signals from each magnetic layer and is independent of the nonmagnetic spacer layers in the multilayer structure. This additivity law is true only in the limit where the total optical thickness of the layered structure is much less than the wavelength of the incident beam. For thick film, it is obvious that the additivity law must break down because the light attenuates and will not penetrate to the deeper layers of the structure.

ELECTROCHEMICAL TECHNIQUES

INTRODUCTION

Electrochemistry, in contrast to most materials characterization disciplines, contains a bifurcated methodology having applications both in materials synthesis and as a physical characterization technique. On the one hand, a variety of functional surfaces are prepared electrochemically, for example, the anodization of aluminum, electroetching of semiconductors, and electroplating of metallic films. Similarly, the electrosynthesis of bulk materials such as conducting organic polymers has taken on importance in recent years. On the other hand, electrochemistry has been demonstrated to be of use as a physical characterization technique for the quantification of conducting and semiconducting surfaces. The corrosion properties of metallic surfaces and semiconductor electronic properties are two key areas where electrochemical characterization has had a high impact. In keeping with the central analytical theme of this work, this chapter limits its focus to the class of electrochemical techniques specifically aimed at characterizing materials and their interfaces (as opposed to synthetic electrochemistry). In some cases, the line between materials synthesis and measurement can become hazy. The field of sensors based on chemically modified electrodes (CMEs) is a good example of this confusion. Often sensors of this type are electrosynthesized and the synthesis parameters represent an important portion of the systems characterization. Cases such as this will be included in the topical coverage of this chapter.

Electrochemistry differs from other analytical techniques in a second important way. Unlike most instrumental characterization techniques, the sample under study is made into part of the measuring circuitry, and thus, inappropriate sample preparation can effectively lead to a malfunction of the instrument. More importantly, this synergism demands that the user have some knowledge of the detailed circuitry associated with the instrument being employed. Most instruments can be treated as "black boxes"; the user need only understand the rudiments of the instrument's functions. However, if this approach is employed in the execution of an electrochemical experiment, the result is often an artifactual instrument response that is easily misinterpreted as the chemical response of the sample. The electrochemical literature repeatedly testifies to the preeminence of this problem.

Modern electroanalytical techniques have become viable characterization tools because of our abilities both to precisely measure small currents and to mathematically model complex heterogeneous charge transfer processes. Modeling of electrode-based charge transfer processes is only possible using digital simulation methods. The mathematics and computer science related to this underpinning of electrochemistry is sophisticated and beyond the scope of this work. In most cases, an incomplete understanding of this aspect of electroanalysis will not affect the quality of the experimental outcome. In cases where the experimenter wishes to obtain a more detailed understanding of the physical chemical basis of electrochemistry a variety of texts are available. Two volumes, the first by Bard and Faulkner (1980) and the second by Gileadi (1993) are particularly well suited to a more detailed understanding of electrochemistry and electroanalysis. The latter volume is specifically aimed at the materials scientist while the former work is one of the central texts in physical electrochemistry. A third text edited by Kissinger and Heineman (1996) is an excellent source of experimental details and analytical technologies. All of these texts will be most valuable as supplements to this work, providing more chemical details but less materials-characterization emphasis than found here.

Electrochemical measurements can be divided into two categories based on the required instrumentation. Potentiometric measurements utilize a sensitive voltmeter or electrometer and measure the potential of a sample against a standard of known potential. Voltammetric measurements utilize a potentiostat to apply a specified potential waveform to a sample and monitor the induced current response. Amperometric measurements, in which the potential is held constant and the current monitored as a function of time, are included in this latter category. Potentiometric measurements form the historical basis of electrochemistry and are of present utility as a monitoring technique for solution-based processes (i.e., pH monitoring or selective ion monitoring). However, potentiometry is limited with regard to materials characterization. Thus, this chapter focuses on voltammetric measurements and the use of the potentiostat. The potentiostat is fundamentally a feedback circuit that monitors the potential of the test electrode (referred to as the working electrode) versus a reference half-cell (typically called a reference electrode). If the potential of the working electrode drifts from a prescribed offset potential versus the reference electrode, a correcting potential is applied. A third electrode, the counterelectrode (or auxiliary electrode) is present in the associated electrochemical cell to complete the current pathway. The potentiostat typically contains a current-following circuit associated with the auxiliary electrode, which allows a precise determination of the current, which is reported to a recording device as a proportional potential. The rudimentary operation of the potentiostat is covered in this text. However, for many applications a more detailed analysis of potentiostat electronics is desirable. To this end, the reader is directed to Gileadi's excellent monograph (Gileadi et al., 1975).

Potentiostats are available from a series of vendors and range in price from less than $1000 to approximately

$30,000. Variations in price have to do with whether or not digital circuits are employed, the size of the power supply utilized, and the dynamic range and stability of the circuitry. A typical research grade potentiostat presently costs about $20,000 and thus is accessible as a standard piece of laboratory instrumentation. For certain specific applications, less expensive equipment is available (in the approximately $1,000 to $2,000 range) with top-end machines costing around $50,000.

Electrochemical investigations involve making the sample of interest into one electrode of an electrochemical cell. As such, it is immediately obvious that this technique is limited to materials having excellent to good conductivity. Metallic samples and conducting organic polymers therefore, immediately jump to mind as appropriate samples. What may be less obvious is the application of electrochemical techniques to the characterization of semiconductors; however, this application is historically central to the development of electronic materials and continues to play a key role in semiconductor development to date.

The listing above points to obvious overlaps with other materials-characterization techniques and suggests complimentary strategies that may be of utility. In particular, the characterization of electronic systems using electrical circuit responses (see ELECTRICAL AND ELECTRONIC MEASUREMENT) or electron spectroscopy (see ELECTRON TECHNIQUES) is often combined with electrochemical characterization to provide a complete picture of semiconducting systems. Thus, for example, one might employ solid-state electronics to determine the doping level or (n-type versus p-type character) of a semiconducting sample prior to evaluation of the sample in an electrochemical cell. Likewise, electron spectroscopy might be used to evaluate band-edge energetics or the nature of surface states in collaboration with electrochemical studies that determine interfacial energetics and kinetics. In passing, it is interesting to note that the first "transistor systems" reported by Bell Laboratories were silicon- and germanium-based three-electrode electrochemical cells (Brattain and Garrett, 1955). While these cells never met commercial requirements forcing the development of the solid-state transistor, these studies were critical in the development of our present understanding of semiconductor interfaces.

This chapter considers the most commonly utilized techniques in modern electrochemistry: polarography (i.e., currents induced by a slowly varying linear potential sweep), cyclic voltammetry (i.e., currents induced by a triangular potential waveform), and AC impedance spectroscopy (i.e., the real and imaginary current components generated in response to an AC potential of variable frequency). The characterization of semiconducting materials, the corrosion of metallic interfaces, and the general behavior of redox systems are considered in light of these techniques. In addition, the relatively new use of electrochemistry as a scanning probe microscopy technique for the visualization of chemical processes at conducting and semiconducting surfaces is also discussed.

ANDREW B. BOCARSLY

CYCLIC VOLTAMMETRY

INTRODUCTION

A system is completely characterized from an electrochemical point of view if its behavior in the three-dimensional (3D) space composed of current, potential, and time is fully specified. In theory, from such phenomenologic data one can determine all of the system's controlling thermodynamic and kinetic parameters, including the mechanism of charge transfer, rate constants, diffusion coefficients, standard redox potentials, electron stoichiometry, and reactant concentrations. A hypothetical $i(E,t)$ (current as a function of potential and time) data set is shown in Figure 1. This particular mathematical surface has been synthesized using the assumption that the process of interest involves a reversible one-electron charge transfer. The term "reversible" is used here in its electrochemical sense, to indicate that charge transfer between the electrode and the redox-active species both is thermodynamically reversible—i.e., the molecule(s) of interest can be both oxidized and reduced at potentials near the standard redox

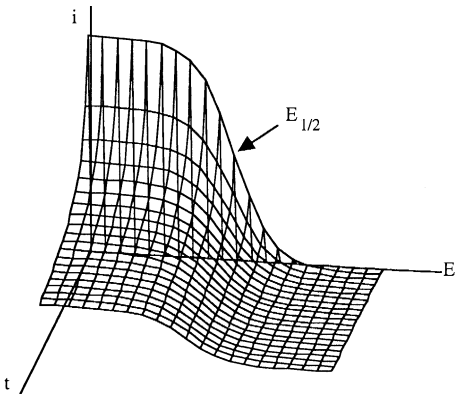

Figure 1. Theoretically constructed current-potential-time [$i(E,t)$] relation for an ideal, reversible, one-electron charge-transfer reaction taking place at an electrode surface. The half-wave potential, $E_{1/2}$, is the redox potential of the system under conditions where reactant and product diffusion coefficents are similar and activities can be ignored.

potential—and occurs at a rate of reaction sufficiently rapid that for all potentials where the reaction occurs, the process is never limited by charge-transfer kinetics. In such a case, the process is completely described by the standard redox potential of the electrochemical couple under investigation, the concentration(s) of the couple components, and the diffusion coefficients of the redox-active species.

On the other hand, one can imagine a redox reaction that is totally controlled by the kinetics of charge transfer between the electrode and the redox couple. In this case, a different 3D current-potential-time surface is obtained that depends on the charge-transfer rate constant, the symmetry of the activation barrier, and the reactant concentrations. Of course, a variety of mechanisms in between these two extremes can also be obtained, each leading to a somewhat different 3D representation. In addition, purely chemical processes can be coupled to charge-transfer events, providing more complex reaction dynamics that will be reflected in the current-potential-time surface.

The enormous information content and complexity of electrochemical dynamics in the current-potential-time domain introduces two major experimental complications associated with electrochemical data. First is the pragmatic consideration of how much time is necessary to obtain a sufficiently complete data set to allow for a useful analysis. The second, far more serious complication is that different charge-transfer mechanisms often translate into subtle changes in the $i(E,t)$ response. Thus, even after one has access to a complete data set, visual inspection is typically an insufficient means to determine the mechanism of charge transfer. Furthermore, knowledge of this mechanism is critical to determining the correct approach to data analysis. Thus, given the requisite data set, one must rely on a series of large calculations to move from the data to chemically meaningful parameters.

The approach described so far is of limited value as a survey tool, or as a global mechanistic probe of electrochemical phenomena. It is, however, a powerful technique for obtaining precise thermodynamic and kinetic parameters once the reaction mechanism is known. The mathematical resolution to the problem posed here is to consider the projection of the $i(E,t)$ surface onto a plane that is not parallel to the i-E-t axis system. This is the basis of cyclic voltammetry. Not surprisingly, a single projection is not sufficient to completely characterize a system; however, if judiciously chosen, a limited set of projections (on the order of a half dozen) will provide sufficient information to determine the reaction mechanism and obtain the key reaction parameters to relatively high precision. Perhaps more importantly, reduction of the data to two dimensions allows one to determine the mechanism based on pattern recognition, and thus no calculational effort is required. Practically, the projection of interest is obtained by imposing a time-dependent triangular waveform on the electrode as given by Equation 1:

$$E(t) = \begin{cases} E_i + \omega t & 0 \quad \text{for} \quad \leq t \leq t_\lambda \\ E_i + \omega t_\lambda - \omega t & \text{for} \quad t_\lambda \leq t \end{cases} \qquad (1)$$

where E_i is the initial potential of the scan, ω is the scan rate (in mV/s), and τ_λ is the switching time of the triangular waveform as shown in Figure 2A. The induced current is then monitored as a function of the electrode potential as shown schematically in Figure 2B. The wave shape of the i-E plot is diagnostic of the mechanism. Different projection planes are simply sampled by varying the value of

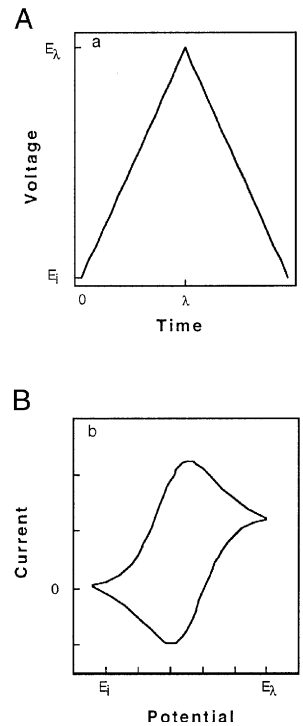

Figure 2. (**A**) Triangular $E(t)$ signal applied to the working electrode during a cyclic voltammetric scan. E_λ is the switching potential where the scan direction is reversed. (**B**) Cyclic voltammetric current versus potential response for an ideal, reversible one-electron redox couple under the $E(t)$ waveform described in (**A**).

ω for a series of cyclic voltammetric scans. Although the 2D traces obtained offer a major simplification over the 3D plots discussed above, their chief power, as identified initially by Nicholson and Shain (Nicholson and Shain, 1964), is that they are quantified from a pattern-recognition point of view by two easily obtained scan-rate-dependent parameters. Nicholson and Shain showed that these diagnostic parameters, peak current(s) and peak-to-peak potential separation, produce typically unique scan-rate dependencies as long as they are viewed over a scan-rate range that traverses at least 3 orders of magnitude. The details of this analysis are provided later. First, one needs to consider the basic experiment and the impact of laboratory variables on the results obtained.

The qualitative aspect of cyclic voltammetry has made it a general tool for the evaluation of electrochemical systems. With regard to materials specifically, the technique has found use as a method for investigating the electrosynthesis of materials (including conducting polymers and redox-produced crystalline inorganics), the mechanism of corrosion processes, the electrocatalytic nature of various metallic systems, and the photoelectrochemical properties of semiconducting junctions. Here a general description of the cyclic voltammetric technique is provided along with some examples focusing on materials science applications.

PRINCIPLES OF THE METHOD

Reaction Reversibility

The Totally Reversible Reaction. The simplest charge-transfer mechanism to consider is given by Equation 2, a reversible redox process:

$$\mathrm{Ox} + n\mathrm{e}^- \Leftrightarrow \mathrm{Red} \tag{2}$$

For this process, the concentration of the reactant and products at the electrode surface is given by the Nernst equation (Equation 3) independent of reaction time or scan rate:

$$E = E_R - (2.303)\frac{RT}{nF}\log\frac{[\mathrm{Red}]}{[\mathrm{Ox}]} \tag{3}$$

where E is the electrode potential, E_R is the standard redox potential of the redox couple, [Red] and [Ox] are the concentrations of the reduced and oxidized species, respectively, R is the gas constant, T is the temperature (K), F is Faraday's constant, and n is defined by Equation 2. [At room temperature, 298 K, 2.303 $(RT/nF) = 59$ mV/n.] Equation 3 indicates that the electrode potential, E, is equal to the redox couple's redox potential, E_R, when the concentrations of the oxidized species and reduced species at the electrode/electrolyte interface are equal. It can be shown that this situation is approximately obtained when the electrode is at a potential that is halfway between the anodic and cathodic peak potentials. This potential is referred to as the cyclic voltammetric half-wave potential, $E_{1/2}$. More precisely it can be demonstrated that the half-wave potential and the standard redox potential are related by Equation 4:

$$E_{1/2} = E_R - \frac{RT}{nF}\ln\left(\frac{\gamma_\mathrm{Ox}}{\gamma_\mathrm{Red}}\left[\frac{D_\mathrm{Red}}{D_\mathrm{Ox}}\right]^{1/2}\right) \tag{4}$$

where D_Ox and D_Red are the diffusion coefficients of the oxidized and reduced species, respectively, and the γ values represent the activity coefficients of the two halves of the couple. While this result is intuitively appealing, a solid mathematical proof of the relationship is complex and beyond the scope of this unit. The mathematical details are well presented in a variety of textbooks, however (Gileadi et al., 1975; Bard and Faulkner, 1980; Gosser, 1993).

By its very nature, the reversible redox reaction cannot cause a substantial change in the connectivity or shape of a molecular system. As a result, the diffusion coefficients of the oxidized and reduced species are expected to be similar, as are the activity coefficents—in which case Equation 4 reduces to $E_{1/2} = E_\mathrm{R}$. Even if there is some variation in the diffusion coefficients, the square root functionality invariably produces a ratio close to 1, and thus the second term in Equation 4 can safely be ignored. Likewise, at a low concentration of electroactive species (as is typically employed in cyclic voltammetry), the activity coefficients can safely be ignored. Once a system has been demonstrated to be reversible (or quasireversible, as discussed later), the redox potential can then be directly read off the cyclic voltammogram.

For the reversible mechanism, the idealized cyclic voltammetric response is illustrated in Figure 2B. Within the context of the Nicholson and Shain diagnostic criteria, this cyclic voltammetric response provides a coupled oxidation and reduction wave separated by $\sim 60/n$ mV independent of the scan rate. The exact theoretical value for the peak-to-potential separation is not critical since this value is based on a Monte Carlo approximation and is somewhat dependent on a variety of factors that are often not controlled. In a real electrochemical cell the ideal value is typically not achieved. The peak height of the anodic and cathodic waves should be equivalent, and the current function (for either the anodic or cathodic waves) is expected to be invariant with scan rate. Under such conditions the peak current is given by Equation 5 (Bard and Faulkner, 1980):

$$i_\mathrm{p} = (2.69 \cdot 10^5)n^{3/2}AD_\mathrm{o}^{1/2}\omega^{1/2}C_\mathrm{o} \tag{5}$$

where n is as defined by Equation 3, A is the area of the working electrode in cm^2, D_o is the diffusion coefficient of the electroactive species having units of cm^2/s, ω is the scan rate in mV/sec, and C_o is the bulk electrolyte concentration in moles/cm^3. (Note that these are not the standard units of concentration.)

One important caveat must be noted here: the peak-to-peak separation is not solely dependent on the charge-transfer mechanism; cell resistances, for example, will increase the peak-to-peak separation beyond the anticipated $60/n$ mV. Thus, the practical application of the diagnostic

is a constant small peak-to-peak separation ($\sim 100/n$ mV) with scan rate. It is also important to realize that the impact of cell resistance on potential ($V = iR$) is scan-rate dependent since the magnitude of the observed current increases with scan rate. Thus, under conditions of high cell resistance (for example, when a nonaqueous electrolyte is used), a reversible couple may yield a scan rate–dependent peak-to-peak potential variation significantly greater than the ideal ~60-mV shift. It is therefore critical to evaluate all three of the diagnostics over a reasonable range of scan rates before reaching a mechanistic conclusion.

The Totally Irreversible Reaction. The opposite extreme of a reversible reaction is the totally irreversible reaction. As illustrated by Equation 6, such a reaction is kinetically sluggish in one direction, producing a charge-transfer–limited current. The reaction is assigned a rate constant k; however, it is important to note that k is dependent on the overpotential, η, where η is the difference between the redox potential of the couple and the potential at which the reaction is being observed ($E_R - E_{electrode}$). It is convenient to define a heterogeneous charge transfer rate constant, k_s, which is the value of k when $\eta = 0$.

$$\mathrm{Ox} \xrightarrow{ne^-} \mathrm{Red} \tag{6}$$

For this case, a mass transport–limited current is only achieved at large overpotentials, since the rate constant for charge transfer is small for reasonable values of the electrode potential. The concentrations of redox species near the electrode are never in Nernstian equilibrium. Thus, one cannot determine either the redox potential or the diffusion coefficients associated with this system. However, careful fitting of the cyclic voltammetric data can provide the heterogeneous charge-transfer rate constant, k_s, and activation-barrier symmetry factor as initially discussed by Nicholson and Shain (1964) and reviewed by Bard and Faulkner (Bard and Faulkner, 1980; Gosser, 1993). In the case of a very small value of k_s, the irreversible cyclic voltammogram is easily identified, since it consists of only one peak independent of the scan rate employed. This peak will shift to higher potential as the scan rate is increased. For moderate but still limiting values of k_s one will observe a large peak-to-peak separation that is scan-rate dependent. The $E_{1/2}$ value will also vary with scan rate. In this case, it is important to rule out unexpected cell resistance as the source of the potential dependence, before concluding that the reaction is irreversible. Often modern digital potentiostats are provided with software that allows the direct measurement (and real time correction) of cell resistance via a current-interrupt scheme in which the circuit is opened for a short (millisecond) time period and the cell voltage is measured. Analog potentiostats often have an iR compensation circuit (Kissinger and Heineman, 1996).

The Quasireversible Reaction. Although arbitrary, it is practically useful to define reversible charge-transfer systems as those having a heterogeneous charge-transfer rate constant in excess of $0.3\omega^{1/2}$, while totally irreversible systems are those exhibiting rate constants less than $2 \times 10^{-5}\omega^{1/2}$. (Note that this definition is quite surprising in that the requisite minimum rate constant for a reversible reaction depends on the potentiostat being employed. As the slew rate of the system increases, the ability to see large charge-transfer rate constants is enhanced. This is unfortunate, in that it clouds the distinction between thermodynamics and kinetics.) This definition produces a large number of reactions having intermediate rate constants ($0.3\omega^{1/2} \geq k_s \geq 2 \times 10^{-5}\omega^{1/2}$), which are referred to as quasireversible systems. These systems will appear reversible or irreversible depending on the scan rate employed. For sufficiently large scan rates, the rate of interfacial charge transfer will be limiting and the system will appear irreversible. For slower scan rates, the system response time will allow the Nernst equation to control the interfacial concentrations and the system will appear reversible. Depending on the scan rate employed one can determine systemic thermodynamic parameters (redox potential, n, and diffusion coefficient) or kinetic parameters. As in the reversible case, the current function for quasireversible systems tends to be scan rate independent. The peak-to-peak potential dependence is also often an inconclusive indicator. However, the potential of the peak current(s) as a function of scan rate is an excellent diagnostic. At low scan rates, the peak potential can approach the theoretical $\sim 30/n$ mV separation from the half-wave potential in a scan rate–independent manner, however, as the scan rate is increased and the system enters the irreversible region and the peak potential shifts with $\log \omega$. This dependence is given by Equation 7 (Gileadi, 1993):

$$E_p^{Irr} = E_{1/2} - \sigma\left[0.52 + \log\left(\frac{D\omega}{\sigma}\right)^{1/2} - \log k_s\right] \tag{7}$$

where σ is the Tafel slope, a measure of the kinetic barrier, and the other terms are as previously defined. Note that the slope of E_p versus $-0.5\log\omega$ allows one to determine (σ/D), while D and $E_{1/2}$ can be obtained from cyclic voltammograms taken in the reversible region allowing one to determine $k(E_{1/2})$ (see Fig. 5C for an example of this type of behavior).

Nonreversible Charge-Transfer Reactions. In contrast to mechanistically "irreversible reactions," which indicate a kinetic barrier to charge transfer, a mechanistically "nonreversible reaction" refers to a complex reaction mechanism in which one or more chemical steps are coupled to the charge-transfer reaction (Nicholson and Shain, 1965; Polcyn and Shain, 1966a,b; Saveant, 1967a,b; Brown and Large, 1971; Andrieux et al., 1980; Bard and Faulkner, 1980; Gosser, 1993; Rieger, 1994). For example, consider the generic chemical reaction shown as Equation 8:

$$\begin{gathered}\mathrm{Ox} + ne^- \Leftrightarrow \mathrm{Red} \\ \mathrm{Red} \xrightarrow{k} \mathrm{Product}\end{gathered} \tag{8}$$

where k represents the rate constant for a nonelectrochemical transformation such as the formation or destruction of

a chemical bond. This reaction couples a follow-up chemical step to a reversible charge-transfer process and is thus referred to as an EC process (electrochemical step followed by a chemical step). Consider the effect of this coupling on the cyclic voltammetric response of the Ox/Red system. At very fast scan rates, Ox can be converted to Red and Red back to Ox before any appreciable Product is formed. Under these conditions, the Nicholson and Shain diagnostics will appear reversible. However, as the scan rate is slowed down, the redox couple will spend a longer time period in the Red state and thus the formation of Product will diminish the amount of Red below the "reversible" level. Therefore, at slow scan rates the ratio of peak currents (i_a/i_c) will increase above unity (the reversible value). On the other hand, the current function for the cathodic current will decrease below the reversible level as Red is consumed and thus becomes unavailable for back-conversion to Ox. The peak-to-peak potential is not expected to change for the mechanistic case presented. This set of diagnostics is unique and can be used to demonstrate the presence of an EC mechanism. Likewise, one can consider mechanisms where a preliminary chemical step is coupled to a follow-up electrochemical step (a CE mechanism) or where multiple chemical and electrochemical steps are coupled. In many of the cases that have been considered to date, the Nicholson and Shain diagnostics provide for a unique identification of the mechanism if viewed over a sufficiently large scan-rate window. An excellent selection of mechanisms and their expected Nicholson and Shain diagnostics are presented in Brown and Large (1971).

PRACTICAL ASPECTS OF THE METHOD

Since a cyclic voltammetric experiment is fundamentally a kinetic experiment, the presence of a well-defined internal "clock" is essential. That is, the time dependence is provided experimentally by the selected scan rate since the input parameter $E(t)$ is implicitly a time parameter. However, in order for this implicit time dependence to be of utility it must be calibrated with a chemically relevant parameter. The parameter used for this purpose is the diffusion of an electroactive species in the electrolyte. Thus, the cyclic voltammetric experiment is fundamentally a "quiet" experiment in which convective components must be eliminated and the diffusion condition well defined. This is done by considering the geometry of the electrochemical cell, the shape of the electrode under investigation, and the time scale of the experiment.

Additionally, from the essence of the experiment, the application of an electrode potential combined with the monitoring of the induced current, it is important to know to high precision the time-dependent electrode potential function, $E(t)$, for all values of t. This capability is established by using a potentiostat to control an electrochemical cell having a three-electrode cell configuration. Successful interpretation of the electrochemical experiment can only be achieved if the experimenter has a good knowledge of the characteristics and limitations of the potentiostat and cell configuration employed.

Electrochemical Cells

Cyclic voltammetric experiments employ a "three-electrode" cell containing a working electrode, counterelectrode (or auxiliary electrode), and reference electrode. The working electrode is the electrode of interest; this electrode has a well-defined potential for all values of $E(t)$. The counterelectrode is simply the second electrode that is requisite for a complete circuit. The reference electrode is in fact not an electrode at all, but rather an electrochemical half cell used to establish a well-defined potential against which the working electrode potential can be measured. Typically, a saturated calomel electrode (SCE—a mercury-mercurous couple) or a silver–silver chloride electrode is utilized for this purpose. Both of these reference half cells are commercially available from standard chemical supply houses. While the consideration of reference half cells is important to any electrochemical experiment, it is beyond the scope of this unit; the reader is referred to the literature for a consideration of this topic (Gileadi, 1993; Gosser, 1993; Rieger, 1994). The exact geometry of the three electrodes, along with the shape and size of the working electrode, will determine the internal cell resistance and capacitance. These electrical parameters will provide an upper limit for both the current flow (via Ohm's law: $i = V/R$, where V is voltage and R is resistance) and the cell response time (via the capacitive time constant of the cell). The contact between the reference half cell and the remainder of the electrochemical cell is typically supplied through a high-impedance frit, ceramic junction, or capillary. A high-impedance junction is employed for two purposes: to eliminate chemical contamination between the contents of the reference electrode electrolyte and the electrolyte under investigation and to guarantee a minimal current flow between the reference and working electrodes; the voltage drop associated with this current, referred to as iR drop (Ohm's law), is uncompensated by standard potentiostat circuitry. If this voltage drop becomes substantial (see Equation 9 and discussion below), the data will be highly distorted and not representative of the chemical thermodynamics/kinetics under investigation.

Potentiostats and Three-Electrode Electrochemical Cells

At its heart, the potentiostat is a negative-feedback device that monitors the potential drop between the working electrode and the reference electrode. If this value deviates from a preselected value, a bias is applied between the working and counterelectrodes. The working/counterelectrode voltage drop is increased until the measured working electrode versus reference electrode potential returns to the preset value (Gileadi et al., 1975; Gileadi, 1993). In order to carry out a cyclic voltammetric experiment, a potential waveform generator must be added to the potentiostat. The waveform generator produces the potential stimuli presented by Equation 1. Depending on the instrument being utilized, the waveform generator may be internal to the instrumentation or provided as a separate unit.

The cyclic voltammetric "figure of merit" of a potentiostat will depend on the size of the power supply utilized

and the rise time (or slew rate) of the power supply. The rise time determines the maximum scan rates that can be used in fashioning the $E(t)$ waveform. In addition to the power-supply slew rate, the cell requirements of a nonconvective system coupled with practical limits at which the potential of the working electrode can be varied (due to the resistance-capacitance (RC) time constant associated with a metal/electrolyte interface) provide upper and lower limits for the accessible scan-rate range. Unless the cell is carefully insulated from the environment, thermal and mechanical convective currents will set in for scan rates much below ~1 to 2 mV/s; this establishes a practical lower limit for the scan rate. The upper limit is dependent on the size of the electrode and the resistance of the cell. For typical cyclic voltammetric systems (electrode size ~1 mm^2), scan rates above ~10 V/s tend to introduce complications associated with the cell RC time constant. However, scan rates as high as 100,000 V/s have been reported in specially engineered cells employing ultramicroelectrodes and small junction potentials. More realistically, careful limitation of cell resistance allows one to achieve maximum scan rates in the 10 to 100-V/s range.

The size of the power supply determines the potentiostat compliance voltage (the largest voltage that can be applied between the working and counterelectrodes). This voltage determines the potentiostat's ability to control the potential of the working electrode. If one is working in a single-compartment cell with an aqueous electrolyte containing a relatively high salt concentration (≥0.1 molar salt), then a relatively modest power supply (~10 V) will provide access to all reasonable working electrode potentials. However, in order to carry out cyclic voltammetric studies in high-resistance cells (i.e., those with low salt concentrations, multiple electrochemical compartments, and/or nonaqueous electrolytes) a compliance voltage on the order of 100 V may be required. It is extremely important to note when using a high-compliance voltage potentiostat that the potential reported by the potentiostat is the voltage drop between the reference electrode and the working electrode. Although this value will never exceed ~3 V, in order to achieve this condition, the potentiostat may have to apply ~100 V between the counter and working electrodes. *Since the leads to these electrodes are typically exposed, the researcher must use utmost care to avoid touching the leads, even when the potentiostat is reporting a low working electrode potential. If the experimenter is accidentally inserted into the circuit between the working and counterelectrodes, the full output voltage of the power supply may run through the experimenter's body.*

In order to determine the potential of the working electrode with regard to the reference electrode, the potentiostat employs an electrometer. The value measured by the electrometer is used both to control the potentiostat feedback loop and to produce the potential axis in the cyclic voltammogram. As such it is assumed that the electrometer reading accurately reflects the potential of the working electrode, ϕ. In fact, the electrometer reading, E_{obs}, is better represented by Equation 9:

$$E_{obs} = \phi + iR \tag{9}$$

where iR is the uncompensated voltage drop between the working and reference electrodes. In general, application of a voltage between two electrodes (in this case, the working and reference) may cause a current to flow. This would result in a large value for the iR term (and be deleterious to the reference half cell). This problem is circumvented by employing a high-impedance junction between the working electrode and reference electrode, as noted earlier. This junction ensures that the value of i will be quite small and thus iR will have a small value. In this case $E_{obs} \approx \phi$ and the potentiostat reading is reliable. However, if R is allowed to become excessively large, then even for a small value of i, the iR term cannot be ignored, and an error is introduced into the cyclic voltammogram. High scan rates produce large peak currents, not only exacerbating the iR drop but introducing a phase-lag problem associated with the cell's RC time constant. Both these effects can severly distort the cyclic voltammogram. If this occurs, it can be remedied by switching to a low-impedance reference electrode. Decreasing the cell R improves both the iR and RC responses at the cost of destabilizing the potential of the reference half cell.

The Working Electrode

The working electrode may be composed of any conducting material. It must be recognized that the shape, area, and internal resistance of this electrode affect the resulting current (Nicholson and Shain, 1964; Bard and Faulkner, 1980; Kissinger and Heineman, 1996), and therefore these parameters must be controlled if the cyclic voltammetric data is to be used analytically. Almost all of the kinetic modeling that has been carried out for cyclic voltammetric conditions assumes a semi-infinite linear-diffusion paradigm. In order to meet this condition, one needs a relatively small electrode (~1 mm^2) that is planar. The small size assures low currents. This both limits complications associated with iR drop and provides well-defined diffusion behavior. If the above conditions cannot be met, then a correction factor can be employed prior to data analysis (Kissinger and Heineman, 1996).

In cases where cyclic voltammetric studies are applied to solution species, typical working electrode materials include platinum, gold, mercury, and various carbon materials ranging from carbon pastes and cloths to glassy carbon and pyrolytic graphite. These materials are selected because they are inert with respect to corrosion processes under typical electrochemical conditions. A second selection criteria is the electrode material's electrocatalytic nature (or lack thereof). Platinum, broadly speaking, presents a catalytic interface. This is particularly true of reactions involving the hydrogen couple. As a result, this material is most often utilized as the counterelectrode, thereby ensuring that this electrode does not kinetically limit the observed current. For the same reasons, platinum tends to be the primary choice for the working electrode. The other materials noted are employed as working electrodes because they either are electrocatalytic for a specific redox couple of interest, provide exceptional corrosion inertness in a specific electrolyte of interest, or present a high overpotential with respect to interfering redox couples. With

respect to this latter attribute, carbon and mercury are of interest, since both have a high overpotential for proton reduction. As such, one can access potentials significantly negative of the water redox potential in aqueous electrolyte using a carbon or mercury working electrode. Typically, potentials that are either more negative than the electrolyte reduction potential or more positive than the electrolyte oxidation potential are not accessible, since the large current associated with the electrolysis of the electrolyte masks any other currents. Carbon also presents an interesting interface for oxidation processes in aqueous electrolytes since it also has a high overpotential for water oxidation. Mercury, on the other hand, is not useful at positive potentials since it is not inert in this region, oxidizing to Hg^{2+}. In addition to standard metal-based electrodes, a variety of cyclic voltammetric studies have been reported for conducting polymer electrodes, semiconducting electrodes, and high-T_c superconducting electrodes.

An alternate basis for selecting an electrode material is mechanical properties. For example, the mercury electrode is a liquid electrode obtained by causing mercury to flow through a glass capillary. The active electrode area is at the outlet of the capillary, where a droplet of mercury forms, expands, and eventually drops off. This has two major electrochemical consequences. First, the electrode surface is renewed periodically (which can be helpful if surface poisoning by solutions species is an issue); second, the area of the electrode increases in a periodic manner. One can control (as a function of time) the electrode area and lifetime by controlling the pressure applied to the capillary. Obviously, this type of control is not available when using a solid electrode.

Similarly, certain solid materials offer unique mechanical characteristics providing enhanced electrode properties. For example, carbon electrodes are available in a variety of crystalline and bulk morphological forms. Unlike many materials carbon is available as a fiber, woven cloth, or paper. The availability of carbon as a paper has recently become important in the search for new electrode materials using combinatorial materials techniques. Large-area carbon-paper electrodes can be used to hold a well-defined library of potential new electrode materials made by constructing a stoichiometric distribution of alloys of two or more materials as described by Mallouk et al. (Reddington et al., 1998) Each alloy electrode is prepared as a small dot on a carbon-paper electrode. Each carbon-paper electrode holds a grid of >100 dots that provide a gradient of stoichiometries over the chemical phase-space being investigated. A survey marker is then needed to determine which dots are catalytic when the whole carbon sheet is used as an electrode. (In Mallouk's case a fluorescent pH indicator was used to identify electrodes that experienced a large pH shift in the electrolyte at modest potentials.) Potential new electrocatalyst formulations can then be cut out of the carbon grid and mounted as individual electrodes, for which a complete electroanalysis can then be carried out. In this manner a wide expanse of compositional phase-space can be searched for new electrocatalytic materials in a minimum amount of time. As a result, complex alloys containing three or more constituents can be evaluated as potential new electrode materials.

Electrolytes

The basic requirements of an electrolyte are the abilities to support the flow of current and to solubilize the redox couple of interest. In the context of a cyclic voltammetric experiment solubility becomes central, both because of the resistance limitation expressed by Equation 9 and because of the need to maintain a diffusion-limited current. It is most useful to consider the electrolyte as composed of three components, a solvent system, a supporting electrolyte, and an electroactive species. The electroactive species is the redox couple of interest. In the case of a species in solution, the species is typically present in millimolar concentrations. Below ~0.1 mM, the current associated with this species is below the sensitivity of the cyclic voltammetric experiment. At concentrations above ~10 mM it is difficult to maintain a diffusion-limited system.

The low concentration of electroactive material employed in the cyclic voltammetric experiment precludes the presence of sufficient charge carriers to support the anticipated current. Therefore, a salt must be added to the system to lower the electrolyte resistivity. This salt, which is typically present in the 0.1 to 1 M concentration range, is referred to as the supporting electrolyte. The supporting electrolyte cannot be electroactive over the potential range under investigation. Since this substance is present in significantly higher concentrations than the electroactive species, any redox activity associated with the supporting electrolyte will mask the chemistry of interest.

Water, because of its high dielectric constant and solubilizing properties, is the electrolyte solvent of choice. However, organic electrolytes are often needed to solubilize specific electroactive materials or provide a chemically nonreactive environment for the redox couple under investigation. Because of its good dielectric and solvent properties, acetonitrile is a primary organic electrolyte for cyclic voltammetry. Acetonitrile will dissociatively dissolve a variety of salts, most typically perchlorates and hexafluorophosphate-based systems. Tetraalkylammonium salts are often the supporting electrolytes of choice in this solvent, with tetra-*n*-butylammonium perchlorate—which dissolves well in acetonitrile, is electrochemically inert over a large potential window, and is commercially available at high purity—being a popular option. One important limitation of the acetonitrile systems is their affinity for water. Acetonitrile is extremely hydroscopic, and thus water will be present in the electrolyte unless the solvent is initially dried by reflux in the presence of a drying agent and then stored under an inert gas. Extremely dry acetonitrile can be prepared using a procedure published by Billon (1959). A variety of other solvents have been employed for specific electrochemical applications. The types of solvents available, compatible supporting electrolytes, solvent drying procedures, and solvent electrochemistry are nicely summarized by Mann (1969).

DATA ANALYSIS AND INITIAL INTERPRETATION

As noted earlier, one of the major attributes of cyclic voltammetric experiments is the ability to determine the

charge-transfer mechanism with relatively little data analysis using a pattern-recognition approach. In accord with the procedures established by Nicholson and Shain, initial data analysis is achieved by considering the response of current and peak-to-peak potential shifts as a function of the potential scan rate (Nicholson and Shain, 1964; Bard and Faulkner, 1980; Gosser, 1993). Three diagnostic plots were suggested by these authors:

A plot of current function, $(i_p/\omega^{1/2})$;
A plot of peak-to-peak potential separation versus scan rate;
A plot of the ratio of the anodic peak current to cathodic peak current versus scan rate.

These three diagnostic plots have become the cornerstones of cyclic voltammetric analysis. The current function required for the first plot is the peak current divided by the square root of the scan rate. This functional form is related to the fact that in the absence of kinetic limitations, the rate of charge transfer is diffusion controlled. Fick's second law of diffusion introduces a $\omega^{1/2}$ (where ω is the scan rate) dependence into the current response. Thus, division of the peak current by $\omega^{1/2}$ removes the diffusional dependence from the cyclic voltammogram's current response.

Both the first and third diagnostic require measurement of peak currents. This represents a special challenge in cyclic voltammetry due to the unusual nature of the baseline. This is most easily seen by the representation in Figure 3, which shows an idealized cyclic voltammogram plotted both in its normal *i-E* form and as i versus t. Recall that both forms are mathematically equivalent since E and t are linearly related by Equation 1. Note that the first wave observed starting at a potential of E_i has a peak current that is easily obtained (line 1), since the baseline is well established. However, it is important to realize that the peak current for the return wave is not given by line 2. This is easily seen by looking at the time-dependent plot. Here it can be seen that the return wave has a baseline that is very different from the initial wave, and thus the measurement of peak current is complex. In addition, it has been noted that the baseline established for the return wave is a function of the switching potentials. Several approaches have been suggested to resolve this baseline problem. Nicholson (1966) has suggested a mathematical solution that produces the true peak current based on the values of lines 1, 2, and 3 in Figure 3A. Using this approach the ratio of peak currents is obtained as Equation 10:

$$\frac{i_c}{i_a} = \frac{\text{line 1}}{\text{line 2}} + 0.485\frac{\text{line 3}}{\text{line 4}} + 0.086 \qquad (10)$$

where i_c and i_a are the cathodic and anodic peak currents respectively.

A critical, and often-forgotten, aspect of the Nicholson and Shain analysis is that it is necessary to observe the diagnostics over 3 orders of magnitude in scan rate in order to come to a definitive conclusion. This is often difficult to do. While in many cases one can still reach reasonable mechanistic conclusions, the uncertainty in the conclusions is increased as the scan rate range is limited. Certainly, determination of a charge transfer mechanism using less than 2 orders of magnitude in scan rate cannot be justified. Since a system which is chemically reactive may change with time, it is useful to randomize the order of scan rates employed. This way, the time dependence of the system will not be confused with the scan rate dependence.

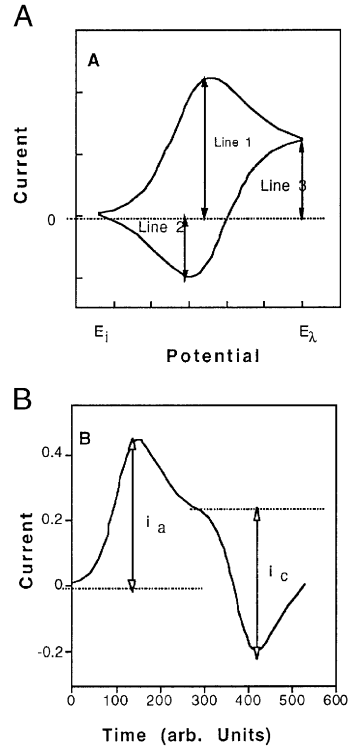

Figure 3. (**A**) Ideal one-electron reversible cyclic voltammogram showing measurements from an $i = 0$ baseline. (**B**) Same as (**A**) but showing the time dependence of the data and identifying the true baselines for the anodic and cathodic cyclic voltammetric peaks.

An Example

One mechanism that has received much attention in recent years is the electrocatalytic mechanism. In its simplest form it can be expressed as in Equation 11:

$$\begin{aligned} &\text{Ox} + n\text{e}^- \Leftrightarrow \text{Red} \\ &\text{Red} + Z \xrightarrow{k\Leftrightarrow} \text{Ox} + \text{Product} \end{aligned} \qquad (11)$$

The electrocatalytic mechanism involves an initial charge transfer from the electrode to Ox followed by a bimolecular solution charge transfer between Red and a dissolved reactant (Z) having a rate constant k. This follow up step regenerates Ox, so that the Ox/Red couple is never consumed. This mechanism is often referred to as

"mediated charge transfer." It allows one to circumvent an interfacial activation barrier for the direct oxidation of Z at the electrode. In addition, it tends to endow the reaction with a degree of specificity, since the interaction of Z with Red can be tailored by one's choice of molecular system. As such, this mechanism forms the basis for many modern electrochemical sensors. One example of this application is given in Figure 4, which demonstrates a sensor for the detection of the amino acid sarcosine as a clinical marker for kidney function. Sarcosine is unreactive at solid metal electrodes. The experiment presented here utilizes a graphite electrode and a phosphate buffered (pH = 7.0) electrolyte containing 6×10^{-6} molar sarcosine oxidase (SOX), a naturally occurring enzyme that selectively oxidizes sarcosine according to the reactions shown in Equation 12. The redox mediator in this case is $[Mo(CN)_8]^{4-}$ that has been bonded to the electrode surface. The sensor mechanism is a variation on the mechanism shown in Equation 11. Note that in this case, the oxidized form of the mediator is the active species.

$$\begin{aligned} [Mo(CN)_8]^{4-} &\Leftrightarrow [Mo(CN)_8]^{3-} + e^- \\ [Mo(CN)_8]^{3-} + SOX &\rightarrow [Mo(CN)_8]^{4-} + SOX^+ \\ SOX^+ + Sarcosine &\rightarrow SOX + Sarcosine^+ \\ Sarcosine^+ &\rightarrow \text{chemical products} \end{aligned} \qquad (12)$$

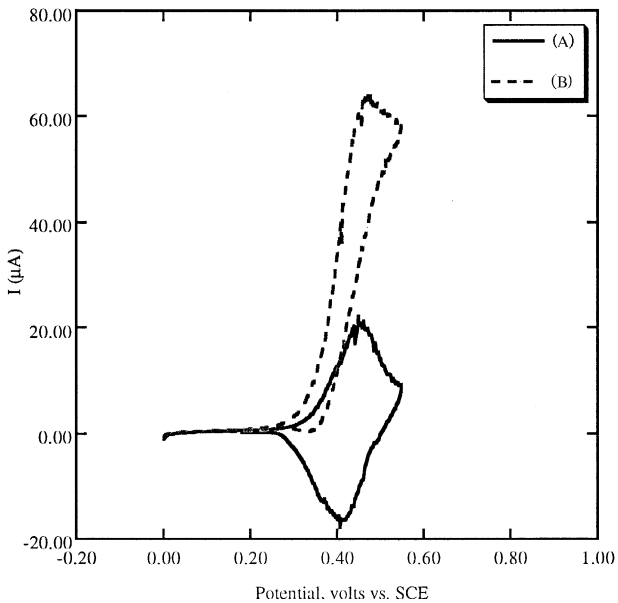

Figure 4. Cyclic voltammograms of a graphite electrode coated with a $Mo(CN)_8^{4-}$-containing polymer in an aqueous electrolyte containing 0.05 M phosphate buffer (pH = 7), 0.35 M KCl supporting electrolyte, and 6 μM sarcosine oxidase. A scan rate of 2 mV/s was employed, with the scan being initiated at 0.00 V versus SCE and proceeding to positive potentials. Scan (**A**) shows a quasireversible wave for the one-electron oxidation of the Mo complex. Scan (**B**) is the same as (**A**) with the addition of 50 mM sarcosine. The increase in the anodic wave and decrease in the cathodic wave are indicative of a mediated charge-transfer mechanism. This electrode system has been used to analyze for creatinine, a species involved in kidney function.

Scan (a) in Figure 4 shows the cyclic voltammetric response of the $[Mo(CN)_8]^{4-}$ system. Because of its low concentration, the addition of sarcosine oxidase has no perceptible effect on the cyclic voltammetric response. The electrocatalytic chain shown in Equation 12 is activated by the addition of the analyte, sarcosine, as shown in scan (b). The response is highly selective for the presence of sarcosine due to the selectivity of both the $[Mo(CN)_8]^{4-}$ mediator and the enzyme. In addition the system is very sensitive to low concentrations of sarcosine. The shift from a reversible system, scan (a), to an electrocatalytic system, scan (b), is trivially monitored by cyclic voltammetry, nicely illustrating the qualitative utility of this technique in determining reaction mechanisms. Note that both the disappearance of the cathodic wave and the enhancement in the anodic wave are requisite for the mediation mechanism (Equation 11).

Finally, it should be noted that the exact scan-rate dependence observed will be a function of k, the chemical rate constant for all coupled processes. Hence, one can obtain this quantity from a quantitative analysis of the scan-rate dependence. Thus, for chemically coupled electrochemical systems, cyclic voltammetry can be utilized as a kinetic tool for determination of the nonelectrochemical rate constant. Classically, this analysis has involved curve fitting data sets to the numerically derived functional forms of the cyclic voltammetric wave shape. This approach has been well documented and discussed from both theoretical and applied viewpoints by Gosser (1993). A more powerful kinetic analysis is available by comparison of data sets to digitally simulated cyclic voltammograms. Until recently this approach required extensive programming skills. However, digital simulation programs are now commercially available that allow one to import a cyclic voltammetric data set and correlate it with a simulated voltammogram based on a proposed mechanism (Feldberg, 1969; Speiser, 1996). Both Princeton Applied Research (PAR) EG&G and BioAnalytical Systems (BAS) offer digital simulators that interface with their data-collection software or operate on a freestanding PC data file. Such programs run on personal computers and bring high-powered kinetic and mechanistic cyclic voltammetric analysis to all users. The power of cyclic voltammetry, however, still resides in the fact that mechanistic and kinetic/thermodynamic data for a wide variety of systems can be directly obtained with little effort from raw data sets via the pattern-matching processes highlighted in this review.

Another Example

The cyclic voltammetric response of a real system is shown in Figure 5. The inorganic compound under study is shown in Figure 5A. The molecular system consists of two iron sites sandwiching a central Pt(IV). Each of the iron sites is composed of a ferrocyanide unit, $Fe(CN)_6^{4-}$, a well-studied, one-electron charge-transfer couple. The compound is held together by two bridging cyanide (CN^-) ligands. The study presented here involved an aqueous electrolyte composed of 0.1 M $NaNO_3$ and 2.5 mM electroactive complex. A platinum working electrode and an SCE reference

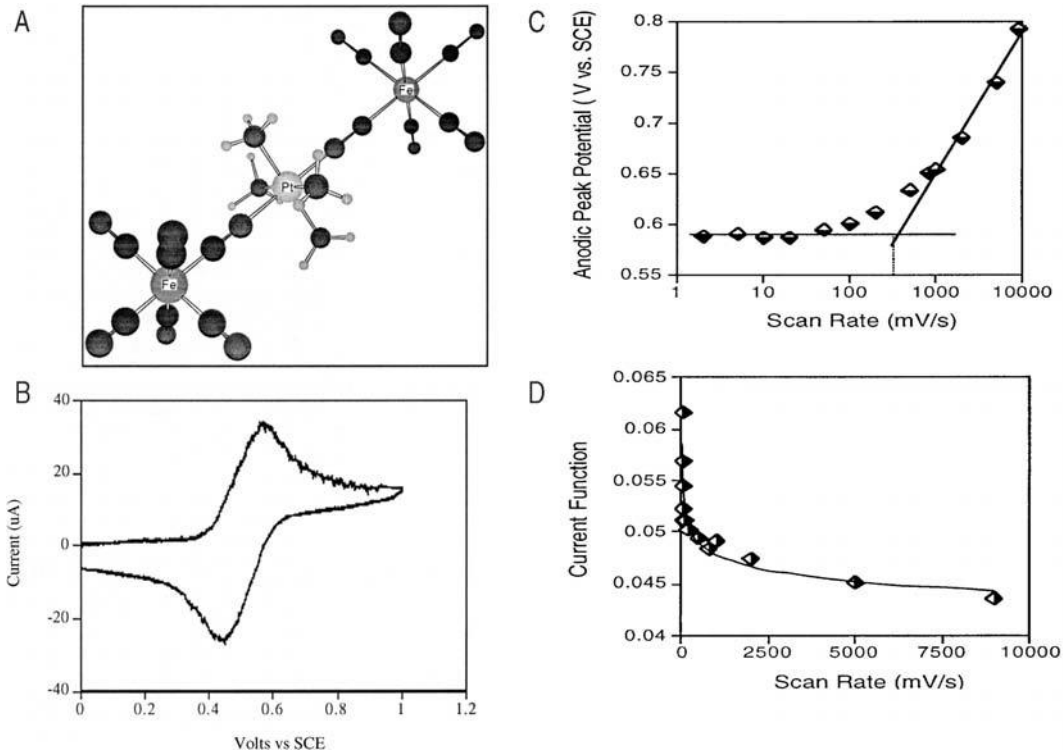

Figure 5. (**A**) Model of $\{[Fe(II)(CN)_6]-[Pt(IV)(NH_3)_4]-[Fe(II)(CN)_6]\}^{4-}$ (**B**) A cyclic voltammogram of the complex in part (**A**) taken at 100 mV/s using a platinum working electrode. The scan initiates at 0.0V versus SCE and proceeds in the positive direction. (**C**) Shift in anodic peak potential as scan rate is increased, showing reversible behavior <300 mV/s (no scan rate dependence) and overall quasireversible behavior. From this data a heterogeneous charge-transfer rate constant at $E_{1/2}$ of 4.6×10^{-3} cm/s is determined. (**D**) Current function for the data set showing the pattern for a catalytic charge-transfer process (see Equation 11).

half cell were employed. Initially, a cyclic voltammetric scan at a rate of 100 mV/s was obtained (shown in Fig. 5B). The presence of a symmetric set of waves yielding identical peak currents (once the baseline correction was applied) yielded the preliminary conclusion that this may be a reversible or quasireversible system. The symmetric nature of the cyclic voltammogram allowed determination of a half wave value, $E_{1/2} = 0.51$ V versus SCE and assignment of this value as the standard redox potential for the couple under investigation. The presence of only one pair of cyclic voltammetric waves along with the observed redox potential indicated that the signal is associated with one or more iron centers, and therefore that the Pt(IV) is electrochemically silent in this system. The value of n was determined by adding an equimolar concentration of hexaammineruthenium(II), an ideally reversible one-electron couple, to the cell. The peak current for the Fe/Pt complex was 2.8 times that observed for the hexaammineruthenium(II) complex (Zhou et al., 1990). Based on Equation 7, a value of $n = 2$ was deduced and the cyclic voltammetric wave was assigned to the simultaneous redox reaction of both irons. Note that in theory one could directly derive n from either the peak-to-peak potential separation or the peak current (Equation 7). However, the peak-to-peak potential separation at 100 mV/s is 120 mV, suggesting the system is not purely reversible. While Equation 7 might still be employed, a knowledge of the diffusion coefficent is required. Thus, the use of an internal standard represents the best method for obtaining n. Note, the standard must be chosen so that $D^{1/2}$ of the standard and the unknown are comparable.

To further develop the analysis, a plot of E_p for the anodic wave versus logω (Fig. 5C) was undertaken, clearly indicating a quasireversible system with reversible behavior exhibited below a scan rate of 300 mV/s. Construction of the current-function diagnostic indicates a further complexity in the reaction mechanism (Fig. 5D). This behavior is predicted for an electrocatalytic mechanism. In the present case, it has been shown that the observed mechanism is associated with the oxidation of tetraaminoplatinum(II) cations by the oxidized complex to regenerate the reduced complex and form a coordination polymer. The peak-to-peak potential diagnostic similarly supports this conclusion.

Based on this analysis one predicts that a coordination polymer can be synthesized as a thin layer on an electrode by holding the electrode potential at a value positive with respect to the anodic peak potential in the presence of an electrolyte containing a high concentration of the Fe/Pt complex and $[Pt(NH_3)_4]^{2+}$. This conclusion has been

experimentally verified (Pfennig and Bocarsly, 1991). The product obtained is photoactive and can thus be patterned (Wu et al., 1995). It has potential applications as an electrochemical sensor material for alkali cations (Bocarsly et al., 1988; Coon et al., 1998).

SAMPLE PREPARATION

The working electrode can be composed of any material that has a satisfactory conductivity. Thus, electrodes have been fabricated from metals, inorganic semiconductors (both small and large band gap), and conducting organic polymers. Materials in these classes have been electrochemically examined in a variety of bulk forms, including single crystals, polycrystalline solids, or particulates in a paste or pressed pellet. Conducting liquids such as mercury and gallium are also good working electrode candidates. In certain instances nonconducting materials can also be examined electrochemically using the chemically modified electrode approach. For example, the coordination polymer mentioned previously (see Another Example under Data Analysis) can be formed as an ultrathin layer (<1 μm thick) on an electrode surface using electrosynthesis techniques. The redox properties of this insulating solid can be studied under these conditions. Likewise, various nonconducting crystalline materials having redox activity can be studied by first electrocrystallizing microcrystallites of the material onto the surface of an appropriate conducting substrate.

In some cases, it is advantageous to acquire the optical properties of a material while it is undergoing oxidation or reduction. In this case, reflectivity studies can be undertaken by utilizing an optically polished working electrode. Alternatively, the material can be deposited as a thin film on an optically transparent conductor such as tin oxide, ITO (indium tin oxide) or a fine metal mesh. In this case, the optical transmission properties of the material can be evaluated. This latter approach also allows for spectroelectrochemical studies of nonconducting redox thin films. These approaches have found utility in the characterization of semiconductors and conducting organic polymers.

Independently of the material being studied, the size and shape of the working electrode must be taken into account. The cyclic voltammetric response can be distorted if too much current is passed, since this will introduce an unacceptably large iR drop (see Equation 9). Limitation of the electrode area is one of the fundamental methods for limiting current without introducing new resistances. In addition, the capacitance of the electrode-electrolyte interface is proportional to electrode area. This capacitance introduces a phase shift in the current-potential response, which distorts the cyclic voltammogram. Thus, it is critical to minimize electrode area. Pragmatically, the area A should be in the range of 10^{-3} cm$^2 \leq A < 0.1$ cm^2). In cases where the electrode material is fairly resistive (i.e., semiconductors), areas of ~ 1 cm^2 can be successfully employed. In all cases, it is very important to have a counterelectrode that has a substantially larger area than the working electrode. If this condition is not maintained, it is possible for the counterelectrode to become the current limiting electrode, thereby invalidating the cyclic voltammetric diagnostic results.

The mathematically modeled response of the electrode to a triangular potential waveform, which forms the basis for cyclic voltammetric mechanistic studies, has been developed for a spherical electrode. Further, because of the system's dependence on diffusion through the electrolyte, the current-potential response is dependent on the shape of the electrode. Fortunately, the dependence is not strong, and thus can often be ignored. Electrodes that are discs or cylinders can be employed with little negative effect. Often, square planar electrodes are also acceptable; however, in this case, care must be taken that edge effects are not perturbing the current signal. If the electrode is mounted in an insulating material so that a portion of the sample is exposed to electrolyte, it is important that the electrode/insulator interface be totally impervious to electrolyte. If a small amount of electrolyte is held between the electrode and the mount, an enhanced current will be achieved in this area, which will dramatically perturb the electrochemical response. Finally, it should be noted that electrode shape does become critical as the electrode size decreases, thus for electrodes in the 1 to 100-μm length regime, shape and size become major parameters in determining the dynamic response of the system.

SPECIMEN MODIFICATION

In some cases, the cyclic voltammetric properties of a system are dependent on the mechanical conditions of the surface. This is most evident when analyzing single-crystal semiconducting materials, which tend to show crystal-plane dependent charge-transfer properties. This effect has also been reported for single-crystal metal electrodes. Specimen surface modification can be accomplished using standard metallurgical techniques such as abrasive (or chemical) polishing, chemical etching, or electrochemical etching. Since surface damage (either inadvertent or deliberate) can modify the electrochemical response, the condition of the working electrode surface must be monitored. Standard chemical etches are often employed to remove damage during sample preparation and electrode mounting. Chemical etches can also be used to remove native oxides from a sample's surface. Such oxides are often semiconducting or insulating; thus, they modify the sample's electrochemical response.

PROBLEMS

Perhaps the biggest error made in utilizing cyclic voltammetry is believing that this technique is the ideal method for determining the electrochemical properties of a redox system. Cyclic voltammetry is a powerful technique when applied to carefully chosen systems. However, little useful data will be acquired if the system of interest has excessive charge-transfer activation barriers or is heavily coupled to a complex chemical process. It is important to recall that

for an irreversible system, cyclic voltammetry provides no information about the redox potential—which is usually a central piece of information.

Aside from this "philosophical" problem, the experimenter needs also to be aware of several pragmatic pitfalls. Unlike in almost all other analytical characterization techniques, the "sample" is an active component of the instrument in an electrochemical reaction. Thus, the effective capacitances and resistances associated with the electrochemical cell actually modify the system response of the potentiostat. As such, artifactual signals or artifactual changes in signal are easily introduced into the study. Such signals can be mistakenly identified with chemical processes. It is therefore critical to know something about the resistive and capacitive response of the electrochemical cell under investigation, and it is important to minimize both of these elements. Usually the shape of the cyclic voltammogram or the behavior of the Nicholson and Shain diagnostics will give a clue that resistive components are affecting the observed signal. However, since the charge-transfer process in an irreversible system is identical to a physical resistance, artifactual resistances may not become obvious until they are large. Thus, cell design is of critical experimental importance. Excessively high impedance between the working and reference electrodes can lead to the total loss of peaks in the cyclic voltammogram. Such uncompensated resistance can arise from the use of high-resistance electrolytes; the placement of a junction separator between the working electrode and the reference electrode (i.e., in a multicompartment cell, the working and reference electrodes must be in the same compartment); junction potentials due to the presence of a different electrolyte in the reference half cell than employed in the cell; or a partial plugging of the junction separator. Thus, care must be taken in the selection of cell geometry and the choice of reference-electrode systems. The reader is directed to Gileadi (Gileadi et al., 1975; Gileadi, 1993) with regard to these details. In cases where a high uncompensated resistance cannot be avoided, various strategies can be implemented (Kissinger and Heineman, 1996). These include the use of a potentiostat with an iR compensation circuit and/or the addition of a Luggins capillary to the electrochemical cell. This latter device is a J-shaped capillary tube that holds the reference electrode and is placed as close as is possible to the working electrode (Gileadi et al., 1975; Gileadi, 1993).

In analyzing the response of a cyclic voltammetric cell, it is important to recognize that cyclic voltammetry is intrinsically a low-noise method. If the data is presenting a poor signal-to-noise ratio, then an instrumental error is involved. Two types of error need to be considered: (1) an actual failure in the potentiostat circuitry, and (2) an excessive (or variable) reference-electrode impedance. Noise is most often due to this second source. The impedance is induced by a partial blockage of the reference electrode junction. An alternate process that may introduce a noise-like condition is adsorption or desorption of reactants or products on the electrode surface. Surface adsorption can strongly distort cyclic voltammetric data. In certain cases, this process does not present itself as noise, but rather as an asymmetry in one of the cyclic voltammetric peaks. Variations in electrode response upon multiple scans of the potential window are also often due to adsorption processes. In cases where this occurs, the best solution is to find a solvent system or electrode material that does not exhibit this behavior. However, in some cases it is worth noting that adsorption can give rise to interesting materials properties. This phenomena has led to the development of the field of chemically modified electrodes and self-assembled surfaces, in which the surface properties of a material are tailored to provide specific chemical or physical responses to an external event. For example, highly selective and sensitive sensors can be developed by surface confining a molecular species to an electrode surface that interacts in a well-defined and unique manner with a target analyte. This type of device is illustrated by the sarcosine oxidase example provided earlier.

Finally, one needs to be aware that an artifactual response can be induced by instrumentation external to the electrochemical cell. When operating above ~500 mV/s, it is important to assure that electronics external to the cell are not limiting the potential slew rate. In particular, some potentiostat power supplies cannot be slewed sufficiently fast to achieve these rates. In addition, the recording device employed may not be able to keep up with high scan rates and may therefore produce artifactual results. This is particularly likely to be encountered if a mechanical x-y recorder is employed. However, limitations can also inadvertently be encountered with an analog-to-digital converter that interfaces the potentiostat output to a computer. For extremely high-speed experiments (>10 V/s), it is often necessary to observe the output on an oscilloscope.

This publication is considered by many to be the central text covering modern electrochemistry. It provides very few experimental details; however, it does an excellent job on developing the physical chemistry of electrochemistry. While a wide variety of electrochemical techniques are considered, the book focuses on controlled potential techniques including cyclic voltammetry. This work is excellent at developing the thermodynamics and chemical kinetics (mechanism) electrochemical processes and the relationship between cyclic voltammetric response and chemical mechanism.

Gileadi, 1993. See above.

The second half of this text provides an excellent discussion of the experimental details necessary to carry out electrochemical studies via a series of teaching experiments. Topics include reference electrodes, potentiostats, and cyclic voltammetry.

Gosser, 1993. See above.

A dedicated monograph that discusses cyclic voltammetry as a tool for investigating chemical mechanisms (i.e., reaction kinetics). This work includes discussions related to the determination of redox potentials, activation processes, rate constants, and complex chemical mechanisms. Pragmatic experimental details are also discussed.

Kissinger and Heineman, 1996. See above.

An excellent source of information on how to carry out laboratory electrochemical studies in general. This text covers an extensive list of electrochemical techniques including cyclic voltammetry. It provides both theoretical and experimental details.

ELECTROCHEMICAL TECHNIQUES FOR CORROSION QUANTIFICATION

INTRODUCTION

Corrosion is the deterioration of a solid body upon interaction with atoms or molecules that originate outside the solid body. In the majority of cases, the solid body is a metal or alloy. Metallic structures and components exposed to atmospheres can undergo atmospheric corrosion, while those that are used to carry out specific processes will be subject to various forms of attack depending upon the temperature and the chemical composition of the medium. In addition, velocity effects of fluids and erosive effects of particulates can exert additional influence on the corrosion process (see TRIBOLOGICAL AND WEAR TESTING). Thus corrosion phenomena of one form or another exist in the petrochemical, automotive, electric power generation, water supply and treatment, semiconductor, transportation, and space exploration industries.

Corrosion is so widespread because most metallic materials of practical significance are chemically metastable. Therefore, nature provides the inherent tendency and driving force for the material to revert to its most stable thermodynamic state, which could be, e.g., an oxide, a hydroxide, a sulfide, a carbonate, or a sulfate. Thus the corrosion scientist and engineer must constantly battle with nature to preserve the metastability of the metallic material for long duration. Herein lies their major challenge.

The direct economic impact of corrosion has been variously estimated. A 1976 study put the annual economic cost of corrosion in the United States at 70 billion dollars. While one may take issue with specific figures, it is clear that the costs are substantial. In addition to these direct costs, indirect costs are also associated with corrosion,

resulting from factors such as loss of production or the need for alternative procedures during the replacement of a corroded component or structure, gradual decrease in process efficiency resulting from corrosion product buildup and its impact on process flow and heat transfer, the need to overdesign certain components because of uncertainty due to corrosion, and loss of property and lives.

Accurate measurement of corrosion is essential to predict the life of critical metallic components in service. Corrosion measurement also becomes very important in evaluating the effectiveness of corrosion control strategies. The techniques used to measure corrosion vary depending upon whether one is dealing with gas phase corrosion or liquid phase corrosion. Electrochemical techniques, which are the subject of the present chapter, are applicable specifically to corrosion occurring in liquid media. Corrosion can be either general or localized. Much of the discussion in this chapter will focus on the phenomenon of general atom loss from metallic surfaces. When a metal corrodes in a liquid, the corrosion can involve a direct dissolution of the metal into the liquid, the conversion of the metal into an inorganic corrosion product layer on the surface, or a combination of both reaction layer formation and dissolution. The most widely spread corrosion processes in liquids occur in aqueous environments. To a more limited extent, corrosion is an issue in molten salt environments, e.g., in molten carbonate fuel cells or in the molten salt corrosion of turbine blades. Corrosion in liquid hydrocarbons is of interest to the petrochemical industry; however, in view of the nonconducting nature of these liquids, the applicability of electrochemical techniques to such systems is questionable.

In the following, three electrochemical techniques are described for the quantification of corrosion processes in liquid systems. The first two are direct current (dc) techniques, the first of which requires the use of relatively high applied potentials, while the second one uses applied voltages in the vicinity of the corrosion potential. The third technique, which uses alternating current (ac) voltages and currents, has the advantage of independently measuring different frequency-dependent processes in corrosion.

TAFEL TECHNIQUE

Principles of the Method

A metal in contact with an aqueous electrolyte solution acquires a potential. This potential is a mixed potential generated by a combination of anodic reactions and cathodic reactions. The classical paper on mixed potential theory was written by Wagner and Traud (1938). The development of such a mixed potential is schematically described in Figure 1, where the y axis is the electrode potential and the x axis is the current involved in the electron exchange reaction. In the lower portion of the graph, two straight lines are shown corresponding to the metal oxidation reaction, $M = M^+ + e^-$, and the reverse reaction, metal reduction. The intersection of these lines gives the equilibrium electrode potential of the charge-transfer reaction involving the metal, M. At the metal–aqueous solution interface, other charge transfer reactions are possible, for example, $H^+ + e^- = 1/2H_2$. The oxidation and reduction lines for this reaction are shown in the upper portion of the graph in Figure 1.

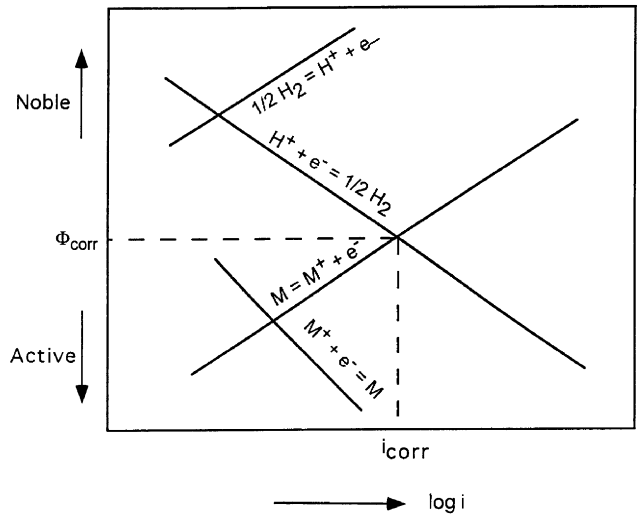

Figure 1. Schematic of corrosion potential and corrosion current.

The potential corresponding to the equilibrium of this charge transfer reaction can be read off on the y axis. The Butler-Volmer equation (Bockris and Reddy, 1970) represents in a general sense the current resulting from an applied potential for a specific charge-transfer reaction. If $\Phi - \Phi_0$ is the difference between the applied potential and the equilibrium potential for the charge-transfer reaction, then

$$i = i_0\left[\exp\left(\frac{(1-\alpha)F(\Phi-\Phi_0)}{RT}\right) - \exp\left(\frac{-\alpha F(\Phi-\Phi_0)}{RT}\right)\right] \tag{1}$$

where the potential Φ is the inner, or Galvani, potential of a metal in contact with an electrolyte; the potential Φ_0, represents the situation where the forward and backward rates of the charge-transfer reaction responsible for the buildup of potential Φ are equal (i.e., the specific charge-transfer reaction is in equilibrium); i_0 is the exchange current characteristic of the equilibrium of the electron-transfer reaction; $(1-\alpha)(\Phi-\Phi_0)$ represents the potential through which the metal has to be activated to effect ionization and $\alpha(\Phi-\Phi_0)$ the activation barrier for the metal ions in solution to revert back to the metallic state; and F is the Faraday constant, R the universal gas constant, and T the absolute temperature. Equation 1 can be rewritten for the case of a metal charge-transfer reaction in the form

$$i_M = i_{0,M}\left[\exp\left(\frac{\Phi-\Phi_{0,M}}{\beta_M^a}\right) - \exp\left(\frac{-(\Phi-\Phi_{0,M})}{\beta_M^c}\right)\right] \tag{2}$$

The constants in the exponential of Equation1 have been combined into the term β in Equation 2, the superscripts a and c indicating the anodic and cathodic reactions,

respectively, and the subscript M the metal charge-transfer reaction. Taking the hydrogen charge-transfer reaction as the second important reaction occurring on the metal surface, one can express the Butler-Volmer equation in the form

$$i_{\mathrm{H}} = i_{0,\mathrm{H}}\left[\exp\left(\frac{\Phi - \Phi_{0,\mathrm{H}}}{\beta_{\mathrm{H}}^{\mathrm{a}}}\right) - \exp\left(\frac{-(\Phi - \Phi_{0,\mathrm{H}})}{\beta_{\mathrm{H}}^{\mathrm{c}}}\right)\right] \quad (3)$$

In practice, however, the potential attained by a metal in solution corresponds neither to the equilibrium of the metal charge-transfer reaction nor to the equilibrium of the hydrogen charge-transfer reaction but falls somewhere in between. This is explained by the mixed-potential theory (Wagner and Traud, 1938). In a typical situation, such as indicated in Figure 1, the anodic part of the metal charge-transfer reaction and the cathodic part of the hydrogen charge-transfer reaction would dominate. The potential corresponding to this situation is the corrosion potential Φ_{corr}, which is given by the intersection of the anodic limb of the metal charge-transfer reaction and the cathodic limb of the hydrogen charge-transfer reaction. The corrosion current i_{corr} can be read off on the x axis corresponding to this intersection.

According to the mixed-potential theory, the total current i at any potential is given by the sum of the partial currents corresponding to the various reactions on the metal surface. Taking the anodic part of the metal charge-transfer reaction and the cathodic part of the hydrogen charge-transfer reaction to dominate,

$$i = i_{0,\mathrm{M}} \exp\left(\frac{\Phi - \Phi_{0,\mathrm{M}}}{\beta_{\mathrm{M}}^{\mathrm{a}}}\right) - i_{0,\mathrm{H}} \exp\left(\frac{-(\Phi - \Phi_{0,\mathrm{H}})}{\beta_{\mathrm{H}}^{\mathrm{c}}}\right) \quad (4)$$

At the corrosion potential, the anodic current due to the metal charge-transfer reaction and the cathodic current due to the hydrogen charge-transfer reaction are equal and is given by the corrosion current i_{corr}. Thus,

$$i_{\mathrm{corr}} = i_{0,\mathrm{M}} \exp\left(\frac{\Phi_{\mathrm{corr}} - \Phi_{0,\mathrm{M}}}{\beta_{\mathrm{M}}^{\mathrm{a}}}\right) - i_{0,\mathrm{H}} \exp\left(\frac{-(\Phi_{\mathrm{corr}} - \Phi_{0,\mathrm{H}})}{\beta_{\mathrm{H}}^{\mathrm{c}}}\right) \quad (5)$$

On combining Equations 4 and 5,

$$i = i_{\mathrm{corr}}\left[\exp\left(\frac{\Phi - \Phi_{\mathrm{corr}}}{\beta_{\mathrm{M}}^{\mathrm{a}}}\right) - \exp\left(\frac{-(\Phi - \Phi_{\mathrm{corr}})}{\beta_{\mathrm{H}}^{\mathrm{c}}}\right)\right] \quad (6)$$

The Tafel approach (1904; Bockris and Reddy, 1970; Fontana and Greene, 1978; Uhlig and Revie, 1985; Kaesche, 1985) involves the determination of the intersection point of the dominant anodic reaction curve and the dominant cathodic reaction curve in order to determine the corrosion current i_{corr} in accordance with Equation 5. The β's are temperature-dependent constants for the specific corrosion system and are known as Tafel constants. The terms $i_{0,\mathrm{M}}$ and $i_{0,\mathrm{H}}$ are the exchange current densities of the anodic and cathodic reactions, respectively. In other words, $i_{0,\mathrm{M}}$ represents the current corresponding to the equilibrium of the charge-transfer reactions involving metal dissolution and metal deposition and $i_{0,\mathrm{H}}$ is similarly defined. At high anodic potentials,

$$i = i_{0,\mathrm{M}} \exp\left(\frac{\Phi - \Phi_{0,\mathrm{M}}}{\beta_{\mathrm{M}}^{\mathrm{a}}}\right) \quad (7)$$

Equation 4 then reduces to

$$\log i = \log i_{0,\mathrm{M}} + \frac{\Phi - \Phi_{0,\mathrm{M}}}{2.303\beta_{\mathrm{M}}^{\mathrm{a}}} \quad (8)$$

which is an expression of the Tafel law (Tafel, 1904). According to this law, a plot of log i vs. the potential must be a straight line. The anodic Tafel slope β_{a} equals $2.303\beta_{\mathrm{M}}^{\mathrm{a}}$. Similarly, at high cathodic voltages, a straight-line behavior is expected with the cathodic Tafel constant β_c, which equals $2.303\beta_{\mathrm{H}}^{\mathrm{c}}$. If one extrapolates the straight lines corresponding to the anodic reaction and the cathodic reaction, respectively, their intersection corresponds to the corrosion current and the corrosion potential. From the measured corrosion current, a corrosion rate, r, in moles per second, can be determined using Faraday's law:

$$r = \frac{i_{\mathrm{corr}}}{nF} \quad (9)$$

where n represents the valence of the corroding metal (number of equivalents). An engineering unit of corrosion rate prevalent in the United States is mils per year (mpy), where one mil equals one-thousandth of an inch. The corrosion rate R in mpy is given by

$$R = 0.129\frac{i_{\mathrm{corr}}}{nD} \quad (10)$$

where D is the density of the corroding metal.

Practical Aspects of the Method

A typical electrochemical cell that can be used to measure the corrosion rate of a metal in an aqueous medium is shown in Figure 2. The cell consists of a working electrode that is the metal undergoing corrosion. A reference electrode (e.g., calomel) provides a stable reference with respect to which the potential of the working electrode can be measured. When the potential of the metal is changed, the resulting current flow is measured between the working electrode and the counter electrode. An electronic potentiostat in conjunction with the electrochemical cell is used to carry out the electrochemical measurements. Excellent potentiostats are available from manufacturers of electrochemical research equipment such as Princeton Applied Research or Solatron Instrumentation Group. The potentiostat has connections for the working electrode, counter electrode, and reference electrode. In the Tafel experiment, the potential of the working electrode is increased in steps in the anodic direction and the corresponding current measured. Both application of potential and the measurement of current are accomplished using the electronic potentiostat. A typical voltage step is 10 mV. The voltage range of the Tafel experiment can be 100 to

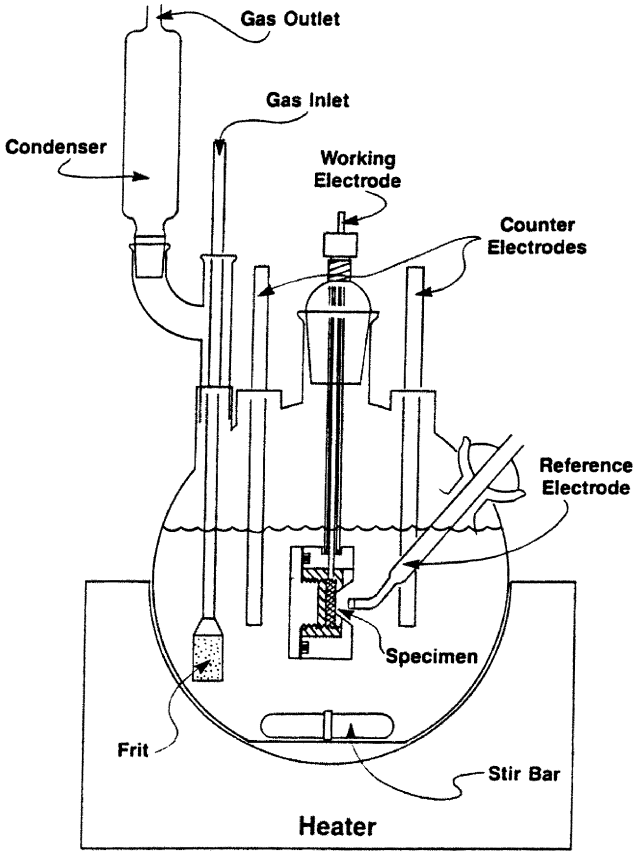

Figure 2. Experimental electrochemical cell arrangement for corrosion studies.

200 mV. Similar to the anodic case, a voltage-current curve is generated for potentials applied in the cathodic direction. Data acquisition from the potentiostat can be carried out using a computer. Corrosion measurement software packages are available from electrochemical equipment manufacturers such as Princeton Applied Research that allow voltage steps and voltage ranges to be predetermined for a corrosion experiment.

Figure 3 represents a Tafel study (Barnartt, 1971) on iron in 1 M $NaHSO_4$ solution at 25°C. In the plot shown, $\Delta\varepsilon$ is the potential difference from the corrosion potential in the anodic or cathodic direction. The authors describe a three-point method applicable in any potential range to get accurate Tafel slopes. The three points correspond to three voltage-current data sets: the first at a selected $\Delta\varepsilon$ value, the second at 2 $\Delta\varepsilon$, and the third at -2 $\Delta\varepsilon$. The mathematical analysis to derive Tafel slopes from these points is described by Barnartt (1971). Figure 4 presents an example from a study by Bandy and Jones (1976) that demonstates the difficulty in determining Tafel slopes. This figure shows that while the cathodic Tafel slope is easy to determine, the anodic Tafel slope is less evident. In this case, the authors use a procedure described by Stern and Roth (1957) to calculate the anodic curve in the vicinity of the corrosion potential and thereby determine the actual corrosion rate. The anodic currents are derived from cathodic data as the sum of the net current and

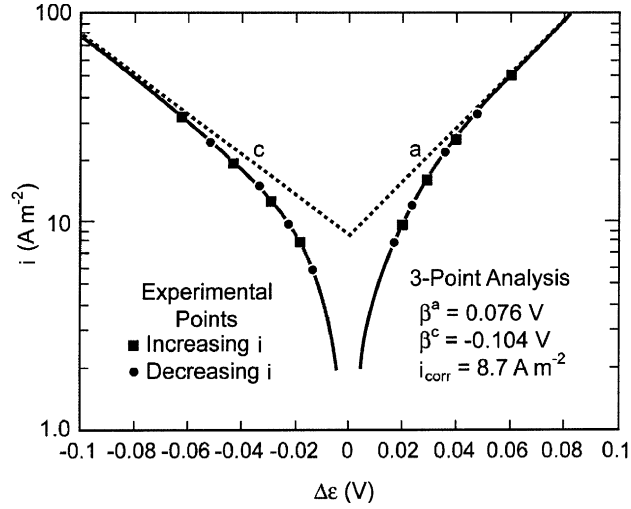

Figure 3. Polarization curves for Ferrovac E iron in 1 M $NaHSO_4$ at 25°C.

cathodic current. The approach is useful in cases where the cathodic Tafel line is well defined.

Figure 5 shows an example from the author's laboratory (Ramanarayanan and Smith, 1990) involving corrosion rate measurements at a temperature of 225°C in a 1% sodium chloride solution saturated with 90:10 Ar-H_2S at a pressure of 2000 psi. Because of the high temperatures involved, a nickel wire reference electrode is used. The wire forms a nonstoichiometric nickel sulfide film on its surface and functions as a pseudoreference as long as the sulfur content in the aqueous solution is fixed. During corrosion, a film of iron-deficient pyrrhotite, $Fe_{1-x}S$, grows on the surface of the working electrode, which is 4130

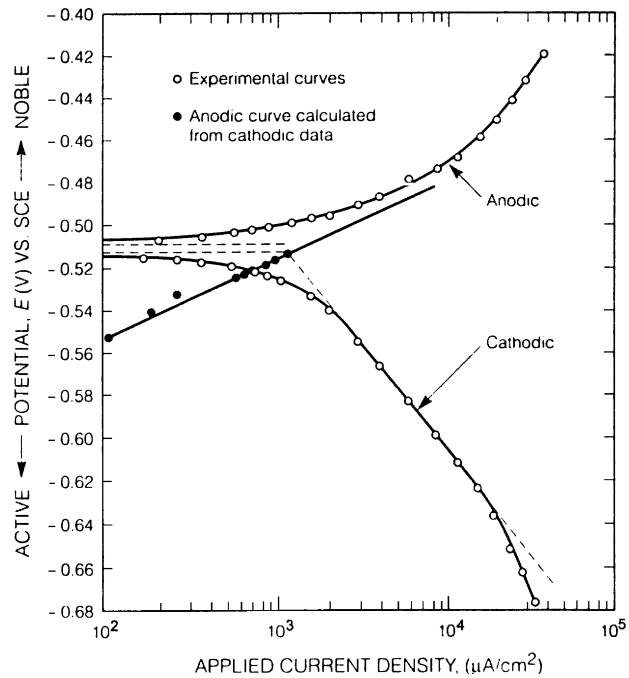

Figure 4. Experimental polarization curves for 1080 steel in deaerated 1 N H_2SO_4.

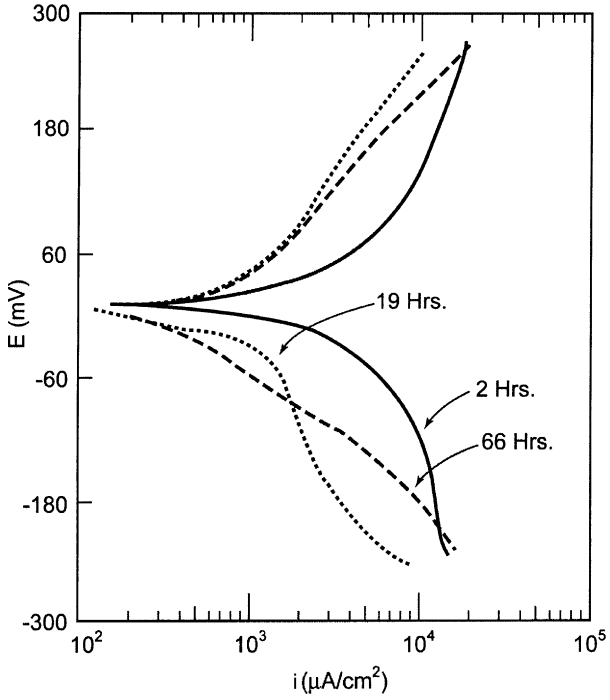

Figure 5. Polarization curves as a function of time for the corrosion of 4130 carbon steel in 1% NaCl solution saturated with Ar–10% H_2S at 2000 psi and 220°C.

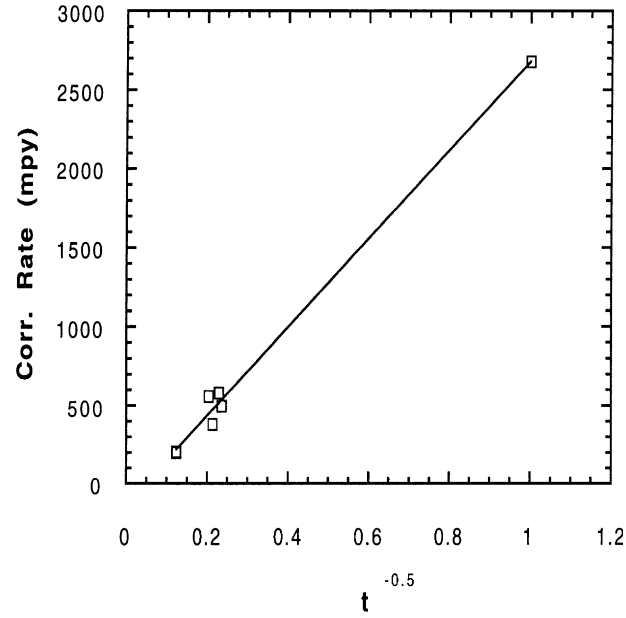

Figure 6. Demonstration of diffusion-controlled kinetics during the corrosion of 4130 steel in 1% NaCl saturated with Ar–10% H_2S at 220°C and 2000 psi.

carbon steel. It is assumed as an approximation that, within the duration of a Tafel run, the growth of the sulfide film is negligible. Figure 5 shows Tafel plots obtained at different times. In this case, the anodic charge-transfer reaction occurs at the metal-FeS interface, and the cathodic charge-transfer reaction occurs at the sulfide film–solution interface. Under the applied voltage, the potential-driven diffusion of iron through FeS is rapid enough so that charge transfer is still the rate-limiting step under the conditions of the Tafel experiment. On the other hand, by analyzing the rates obtained at different times, one obtains a parabolic law for corrosion kinetics as shown in Figure 6. This example illustrates that with films in which diffusion is relatively fast, under an applied potential, one can create conditions where the overall rate under the conditions of the experiment is charge-transfer limited. However, the overall time dependence of a number of Tafel experiments at different times enables the researcher to determine the actual rate-limiting step in corrosion in the absence of an applied potential.

Problems

The presence of passive films on the surface will interfere with the correct use of the Tafel approach, especially in the study of corrosion at low temperatures. Ideally, the Tafel equation describes the direct dissolution of metal into the liquid phase with charge transfer as the rate-limiting step.

Another error in the use of the Tafel technique comes from solution resistance (Scully, 1995). If the solution resistance is significant, it can make a significant contribution to the applied potential. Approaches to minimize the solution resistance involve the placement of the reference electrode as close as practicable to the working electrode using a Luggin-Haber capillary. Many reviews (Britz, 1978; Hayes and Kuhn, 1977-78; Mansfeld, 1982; Scribner and Taylor, 1990) are available on minimizing the solution resistance contribution.

The Tafel approach assumes pure charge transfer control. In many systems, either the reactant (cathodic step) or product (anodic step) can lead to a concentration depletion or buildup in the vicinity of the working electrode (corroding sample). In this case, the corrosion rate becomes controlled by mass transfer (Jones, 1992). Mass transfer effects can be minimized with adequate stirring. A rotating-disk technique is frequently used to minimize mass transfer effects and to simulate turbulent liquid streams (Poulson, 1983).

Finally, the high potentials applied in the Tafel approach to determine corrosion rates can introduce changes in the nature of the surface because of metal dissolution. Such changes can affect the surface area of the corroding metal, for example.

LINEAR POLARIZATION

Principles of the Method

Wagner and Traud (1938), Stern and Geary (1957), and later Oldham and Mansfeld (1971) have considered other ways of treating Equation 4 to get at the corrosion current. Differentiating Equation 4 with respect to the potential yields

$$\frac{\partial i}{\partial \Phi} = \frac{i_{0,\mathrm{M}}}{\beta_{\mathrm{M}}^{\mathrm{a}}} \exp\left(\frac{\Phi - \Phi_{0,\mathrm{M}}}{\beta_{\mathrm{M}}^{\mathrm{a}}}\right) + \frac{i_{0,\mathrm{H}}}{\beta_{\mathrm{H}}^{\mathrm{c}}} \exp\left(\frac{-(\Phi - \Phi_{0,\mathrm{H}})}{\beta_{\mathrm{H}}^{\mathrm{c}}}\right) \quad (11)$$

At the corrosion potential Φ_{corr}, the above derivative can be expressed in the following form by combining Equations 5 and 7:

$$\left(\frac{\partial i}{\partial \Phi}\right)_{\Phi_{corr}} = i_{corr}\left(\frac{1}{\beta_M^a} + \frac{1}{\beta_H^c}\right) \quad (12)$$

Stern and Geary (1957) expressed Equation 12 in the form

$$i_{corr} = \frac{\Delta i}{2.303\ \Delta\Phi}\left(\frac{\beta_a \beta_c}{\beta_a + \beta_c}\right) \quad (13)$$

where β_a and β_c are the Tafel constants. The ratio $\Delta\Phi/\Delta I$ is the polarization resistance R_p. For the Stern-Geary approximation to be valid, the applied potential must be within ~10 mV of the corrosion potential in practice. This is a rather general statement; the maximum permissible applied potential would depend on the specific corrosion system being investigated. For a proper evaluation of the corrosion current, the Tafel constants β_a and β_c must be known. The results of polarization measurements on type 430 stainless steel in 1 N H_2SO_4 from eight different laboratories (ASTM standard G 59) are summarized in Figure 7. The mean result is represented by curve 1 while curves 2 and 3 indicate 95% confidence limits (Scully, 1995).

For Equation 13 to apply, the current-potential curve must be linear in the vicinity of the corrosion potential. However, such perfect linearity is not always observed in practice. This has been pointed out by several authors (Barnartt, 1969; Stern, 1958; Antropov, Gerasimenko, and Gerasimenko, 1966). As described by Mansfeld (1976a), the second derivative of Equation 4 with respect to Φ reads

$$\frac{\partial^2 i}{\partial \Phi^2} = \frac{i_{0,M}}{(\beta_M^a)^2}\exp\left(\frac{\Phi - \Phi_{0,M}}{\beta_M^a}\right) - \frac{i_{0,H}}{(\beta_H^c)^2}\exp\left(\frac{\Phi_{0,H} - \Phi}{\beta_H^c}\right) \quad (14)$$

In view of Equation 5, Equation 14 can be rewritten to give

$$\left(\frac{\partial^2 i}{\partial \Phi^2}\right)_{\Phi_{corr}} = i_{corr}\left(\frac{1}{(\beta_M^a)^2} - \frac{1}{(\beta_H^c)^2}\right) \quad (15)$$

The linearity condition of the current-potential curve requires the second derivative in Equation 15 to be zero, a condition that is satisfied only when the Tafel constants for the anodic and the cathodic curves are the same. Oldham and Mansfeld (1972) have shown that, in a general sense, linearity occurs only at one potential, Φ_L, given by

$$\Phi_L = \Phi_{corr} + \frac{2\beta_M^a \beta_H^c}{\beta_M^a + \beta_H^c}\ln\left(\frac{\beta_M^a}{\beta_H^c}\right) \quad (16)$$

It can be seen that when the Tafel slopes are equal, $\Phi_L = \Phi_{corr}$. According to Oldham and Mansfeld, for an iron-acid system with $\beta_M^a = 13$ mV and $\beta_H^c = 52$ mV, the potential at which linear behavior occurs is displaced by ~30 mV from Φ_{corr}.

Mansfeld (1974) has further examined the question of nonlinearity, especially to estimate errors arising from measurements using corrosion rate meters. In some of these meters, a value of $\Phi - \Phi_{corr}$ of 10 mV is applied and the corresponding corrosion currents Δi_+ and Δi_- measured. Assuming linear behavior, the corrosion current is estimated from the slope, $\Delta i/\Delta\Phi$. Let the corrosion current measured in this manner be given by

$$i'_{corr} = B\frac{\Delta i}{\Delta \Phi} \quad (17)$$

It can be shown that the error ε is given by

$$\varepsilon = 1 - \frac{i'_{corr}}{i_{corr}} = 1 - \frac{B}{\Delta\Phi}\left[\exp\left(\frac{\Delta\Phi}{\beta_M^a}\right) - \exp\left(-\frac{\Delta\Phi}{\beta_H^c}\right)\right] \quad (18)$$

where i_{corr} is the true corrosion current.

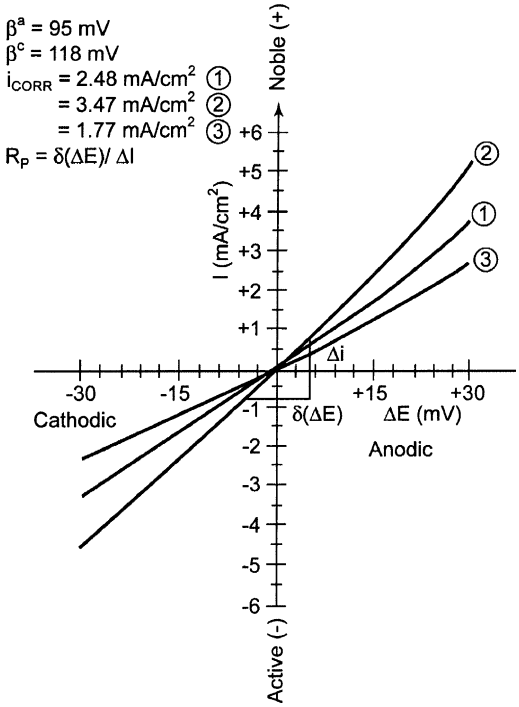

Figure 7. ASTM G 59 polarization curves for type 430 stainless steel in 1 N H_2SO_4 based on results from eight independent laboratories: curve 1, mean; curves 2 and 3, 95% confidence limits.

Practical Aspects of the Method

The experimental setup for carrying out linear polarization experiments is similar to that described under Tafel Technique above. The main difference is in the voltage range selected. The applied voltages used generally do not extend beyond ±10 mV of the corrosion potential. In this range, in many instances, the potential- current curve is linear. Similar to the Tafel method, software packages are now available from vendors such as Princeton Applied Research to enable the investigator to carry out measurements within a specified potential range using specified voltage steps.

The linear polarization technique has been widely used, and there are commercial monitoring probes available. The results shown in Figure 7 for the corrosion of 410 stainless steel in sulfuric acid provide a good example of

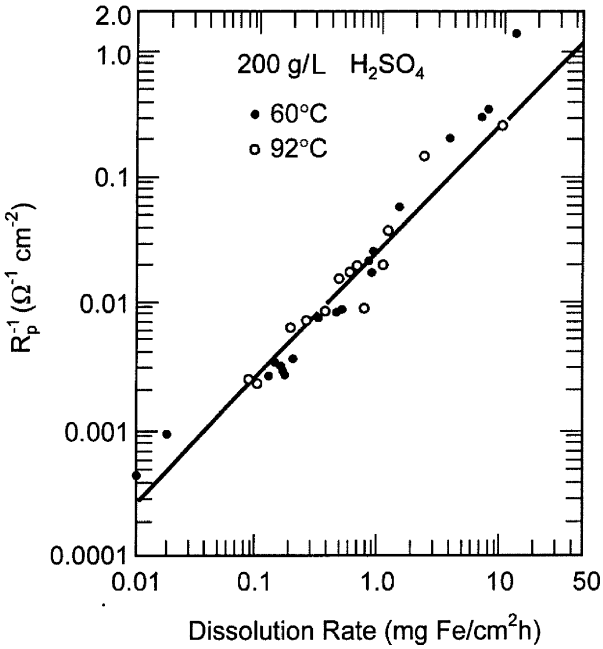

Figure 8. Inverse polarization resistance as a function of dissolution rate of iron for various inhibitor concentrations.

the application of this technique. Another example is given here from the study by Mennenoh and Engell (1962). This work was published within a few years of the exposition of the technique by Stern and Geary (1957). Polarization resistance measurements were used to investigate the effectiveness of corrosion inhibitors in pickling baths for steel. The proportionality of the polarization resistance R_p to corrosion rate was established. This proportionality is shown for steel in sulfuric acid medium containing various inhibitors in Figure 8. Investigations were carried out at two temperatures, 62° and 92°C; however, the influence of temperature does not appear to be significant. From this same study, a curve of the effect of inhibitor concentration on the inverse of the polarization resistance is shown in Figure 9. Other examples are available in detailed reviews (e.g., Mansfeld, 1976a).

Problems

The technique assumes that the corrosion rate is limited by charge-transfer reactions on the entire surface of the metal. Corrosion product films are presumed to be absent. Further, it is assumed there are no contributions from ohmic voltage drops.

Equations have been derived in the literature that take into account the influence of iR drop arising from the electrolyte resistance and the resistance of surface films (Mansfeld, 1976b). The use of iR drop compensation in the measurement circuit has also been employed by several investigators (Jones, 1968; Wilde, 1967; Walker and France, 1969; Cessna, 1971; Booman and Holbrook, 1963; Lauer and Osteryoung, 1966; Sawyer and Roberts, 1974). The influence of iR drop is evident from Figure 10, which shows iR compensated and uncompensated curves for Fe in 0.01 N HCl/EtOH.

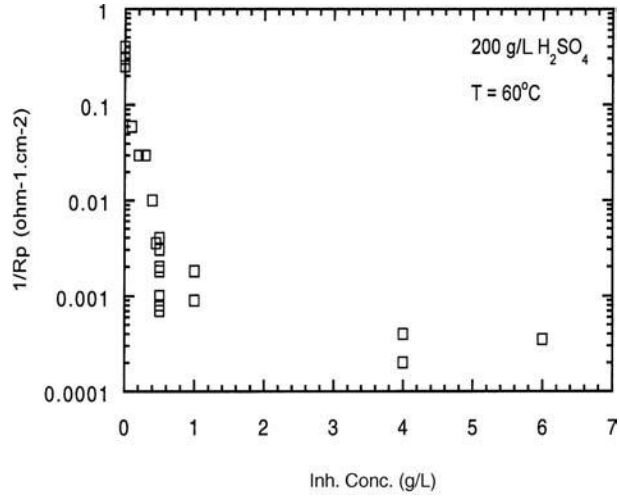

Figure 9. Dependence of polarization resistance on inhibitor concentration.

Another important limitation is that the Tafel slopes must be known in order to apply Equation 13 to determine the corrosion current. An independent measurement of the Tafel slopes using high applied potentials in the cathodic and anodic regimes can be done. However, one can introduce errors due to surface area–structure changes arising from the large current densities involved in the high-potential region. In fact, one advantage of the linear polarization technique is that the applied potentials are low and the corroding sample is minimally disturbed.

The need for independent measurement of Tafel slopes can be eliminated using the curve-fitting approach proposed by Mansfeld (1973). Equation 6 can be rewritten in terms of the Tafel slopes β_a and β_c as

$$i = i_{corr}\left[\exp\left(\frac{2.303\ \Delta\Phi}{\beta_a}\right) - \exp\left(-\frac{2.303\ \Delta\Phi)}{\beta_c}\right)\right] \qquad (19)$$

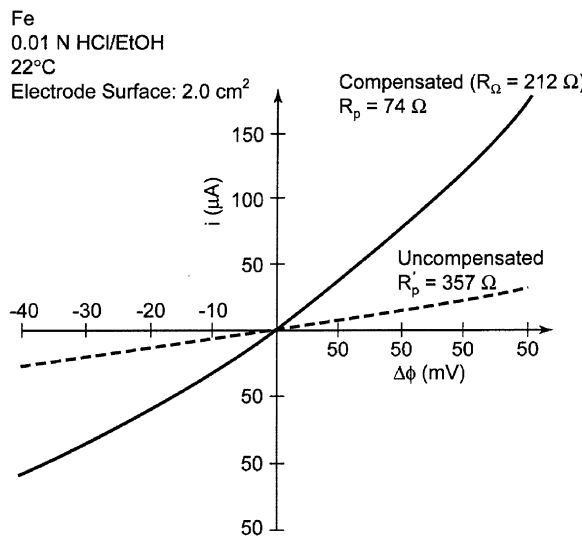

Figure 10. Experimental polarizarion curves for Fe–EtOH + HCl showing the effect of uncompensated iR drop.

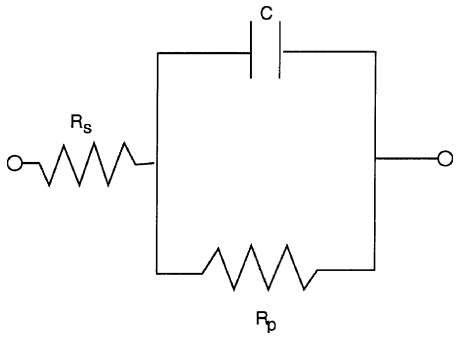

Figure 11. Simple equivalent circuit representation of an electrochemical cell.

Combining Equation 19 with the Stern-Geary relationship represented by Equation 13 and noting that $\Delta\Phi/\Delta i$ equals the polarization resistance R_p, one has

$$2.303R_p i_{corr} = \frac{\beta_a\beta_c}{\beta_a+\beta_c}\left[\exp\left(\frac{2.303\ \Delta\Phi}{\beta_a}\right) - \exp\left(-\frac{2.303\ \Delta\Phi}{\beta_c}\right)\right] \quad (20)$$

Since the right-hand side of Equation 20 essentially depends on Tafel slopes, various combinations can be tried until the best fit to the experimental curve is obtained.

ELECTROCHEMICAL IMPEDANCE SPECTROSCOPY

Principles of the Method

Electrochemical impedance spectroscopy (EIS) is an excellent approach in the determination of R_p described under Linear Polarization above. The technique, however, is not limited to charge-transfer reactions and is capable of simultaneously measuring different steps in a corrosion process. Such a step can include, for example, diffusional transport through a corrosion product film. Herein lies the power of this technique. It consists of applying a small-amplitude voltage perturbation, $V(\omega)$, to the working electrode at a number of different frequencies. At each frequency, the current response $i(\omega)$ will have a similar waveform to the voltage perturbation but will be out of phase with it by the phase angle Φ. The frequency-dependent electrochemical impedance $Z(\omega)$ is the proportionality constant that links the voltage signal to the current response. Thus,

$$Z(\omega) = \frac{V(\omega)}{i(\omega)} = |Z|\exp(j\phi) \quad (21)$$

In Equation 21, $j = \sqrt{-1}$.

Equation 21 can be rewritten in the form

$$Z(\omega) = Z(\mathrm{R}) + jZ(\mathrm{I}) \quad (22)$$

where $Z(\mathrm{R})$ and $Z(\mathrm{I})$ represent the real and imaginary components of the electrochemical impedance. Consider the equivalent circuit represented in Figure 11.

This is the simplest form of a corroding system, in which R_s represents the solution resistance, C is the capacitance of the double layer at the working electrode–solution interface, and R_p is the polarization resistance. The impedance diagram for such an electrochemical cell can be represented either by the Nyquist plot shown in Figure 12A or the Bode plot shown in Figure 12B. It is clear from the Nyquist representation that

$$|Z|^2 = Z(\mathrm{R})^2 + Z(\mathrm{I})^2 \quad (23)$$

Furthermore,

$$Z(\mathrm{R}) = |Z|\cos\phi \quad \text{and} \quad Z(\mathrm{I}) = |Z|\sin\phi \quad (24)$$

The electrochemical impedance $Z(\omega)$ is a fundamental electrochemical parameter. In EIS, a given electrochemical cell is described by a corresponding equivalent circuit. For the equivalent circuit shown in Figure 11,

$$Z(\omega)_{\omega\to 0} = R_s + R_p \quad (25)$$

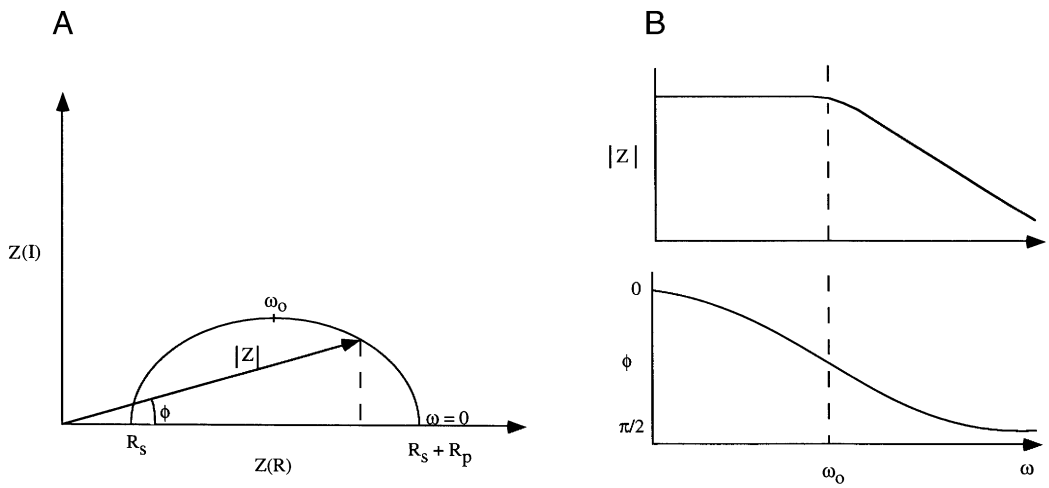

Figure 12. Nyquist (**A**) and Bode (**B**) representations of the equivalent's circuit in Figure 11.

As described before, the inverse of the polarization resistance R_p is proportional to the corrosion rate.

The polarization resistance is also related to the term ω_0 in the Nyquist plot. Thus

$$\omega_0 = 1/R_pC \tag{26}$$

The Bode representation is a combination of two plots, one showing the frequency dependence of the magnitude of the electrochemical impedance and the other the frequency dependence of the phase angle. The Nyquist and Bode representations are equivalent and either can be used. Excellent review articles on the use of EIS are available in the literature (Macdonald and McKubre, 1981; McKubre and Macdonald, 1977; Macdonald, 1977; Sluyters-Rehbach and Sluyters, 1970).

Practical Aspects of the Method

The electrochemical cell arrangement used in EIS is similar to that described for the other electrochemical techniques. The working, counter and reference electrodes are connected to an electronic potentiostat or electrochemical interface (obtainable from Princeton Applied Research or Solatron Instrumentation Group). A function generator is used to feed a wide range of potential frequencies to the potentiostat that applies the signal to the working electrode. To measure the in-phase and out-of-phase components of the cell response to the perturbating voltage signal, an appropriate detection or analyzer system must be used in conjunction with the potentiostat. A phase-sensitive detector or lock-in-amplifier allows the measurement of impedances with frequencies above ~1 Hz (de Levie and Husovsky, 1969; Armstrong and Henderson, 1972). Digital transfer function analyzers can be used for measurements in the range 0.1 to 10^4 Hz (Gabrielli and Keddam, 1974). As opposed to a frequency-by-frequency method, fast Fourier transform (FFT) allows a broad band of frequencies to be simultaneously applied. The acquisition, storage, analysis, and display of data are facilitated by the use of a computer. Software packages are available to carry out EIS measurements for corrosion quantification (Princeton Applied Research; Solatron Instrumentation Group).

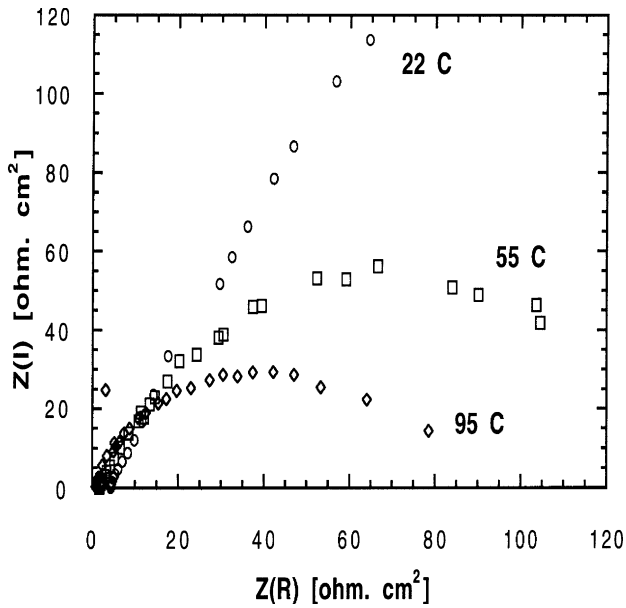

Figure 13. Temperature dependence of impedance data for the corrosion of 4130 steel in aqueous H_2S containing 3% NaCl at 0.08 h.

Table 1. Temperature dependence of impedance parameters

Temperature (°C)	ω_{max}(Hz)	R_D(Ω cm^2)	R_t(Ω cm^2)
22	0.3502	468	14.4
55	0.7007	147	8.8
75	0.8505	118	6.5
95	0.9009	79	5.0

Some examples are now described. The first is a study from the author's laboratory (Vedage et al., 1993). It deals with the corrosion of carbon steel (4130 as an example) in a 3% sodium chloride solution saturated with an 80:20 Ar-H_2S gas mixture. Electrochemical impedance measurements were carried out over the temperature range 22 to 95°C. A typical electrochemical cell used in this study is shown in Figure 2. A frequency range from 10^4 to 2.5×10^{-3} Hz was used in the measurements. The ac excitation potential used was 10 mV. A continuous flow of the 80:20 Ar-H_2S mixture was maintained through the stirred aqueous chloride solution during the measurements.

The impedance results as a function of temperature at a corrosion time of 0.08 h are summarized in Figure 13. A typical semicircular form is exhibited in the Nyquist representation of the data. At intermediate to low frequencies, <10 Hz, a second semicircle of diameter ~5 Ω cm^2 at 95°C could be delineated. The diameters of the larger and the smaller semicircles as well as the value of ω_0 as a function of temperature are shown in Table 1. Electron microscopic studies of the surface of carbon steel after corrosion showed a continuous layer of iron-deficient iron sulfide (pyrrhotite) on the surface. Experimentally, it was observed that the thickness of this layer increased as a function of the square root of time, in accordance with the well-known parabolic rate law (Wagner, 1933), which indicates that the corrosion process is controlled by solid-state diffusion through the iron sulfide reaction product.

The resistances corresponding to the diameter of the larger semicircle, R_D, can be traced to solid-state diffusion of iron atoms through iron-deficient iron sulfide. Those corresponding to the diameters of the smaller semicircles, R_p, are consistent with a charge transfer step at the steel-FeS interface. Thus, different steps in a corrosion process can be independently investigated.

The fact that R_D corresponds to diffusion through the FeS layer can be easily established as follows. According to the parabolic rate law,

$$X^2 = k_Dt \tag{27}$$

where X in the present example denotes the thickness of the FeS corrosion product and k_D is a diffusion-related constant. Differentiating Equation 27 with respect to time,

$$2X\frac{dX}{dt} = k_D \tag{28}$$

Since the corrosion process is supposed to be sulfide growth controlled, dX/dt is a measure of the corrosion rate or the corrosion current and is inversely proportional to R_D. If this proportionality constant is denoted by k, then

$$2\frac{kX}{R_D} = k_D \tag{29}$$

Combining Equations 27 and 29 yields

$$R_D^2 = \frac{4k^2}{k_D}t \tag{30}$$

Thus a plot of R_D^2 as a function of time should be linear, passing through the origin. This is demonstrated in Figure 14. Furthermore, within the small temperature range of the present study, the activation energy for iron diffusion through iron sulfide could be calculated using the results from impedance measurements. This gives a value of ~15 kcal/mol. The value quoted in the literature from high-tem perature diffusion measurements in iron sulfide falls in the range 13 to 30 kcal/mol.

Electrochemical impedance spectroscopy is also a powerful technique for the study of the effect of inhibitors on corrosion. In other studies, corrosion inhibitors were added to the H_2S containing sodium chloride solution (Ramanarayanan and Chiang, 1992). Results are presented as a plot of $1/R_D$ as a function of time in Figure 15.

Under steady-state conditions, the addition of sodium meta-vanadate at a concentration level of 0.005% provides

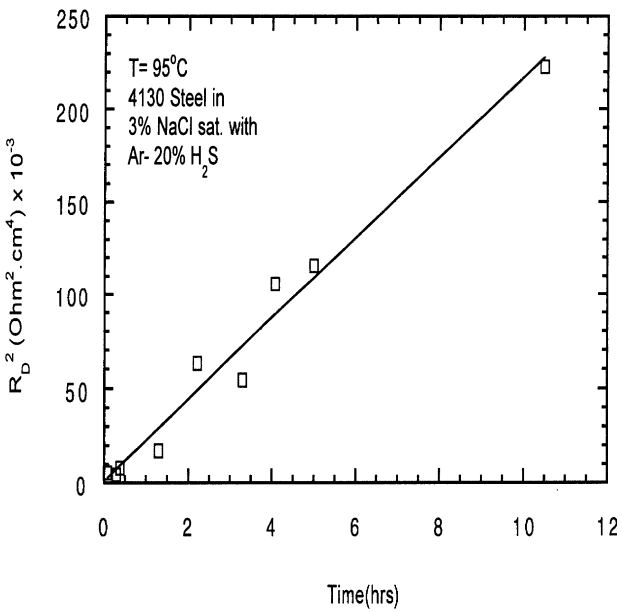

Figure 14. Sulfide growth-controlled corrosion of carbon steel in aqueous NaCl saturated with H_2S.

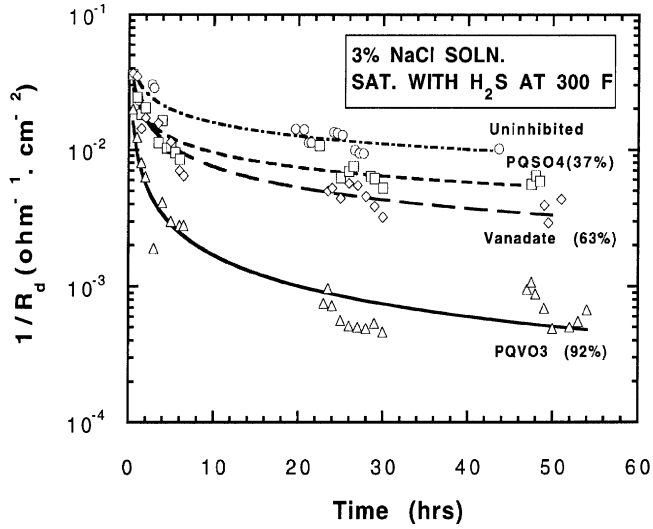

Figure 15. Effect of inhibitors on H_2S corrosion.

~60% corrosion inhibition. Another inhibitor, polyquinoline vanadate, leads to almost 90% inhibition. In these studies, the efficiency of the inhibitor (IE) given in terms of percentage inhibition can be expressed as

$$\text{IE} = \frac{(1/R_D)_{\text{uninh.}} - (1/R_D)_{\text{inh.}}}{(1/R_D)_{\text{uninh.}}} \times 100 \tag{31}$$

It is conceivable that the interaction of inhibitors with metal surfaces can be significantly affected by applied potentials. Thus, EIS with a minimal perturbation of ~10 mV is particularly suited to such studies.

Electrochemical impedance spectroscopy is a very popular technique, and investigations have been carried out by a number of authors on different corroding systems (Keddam et al., 1981; Epelboin et al., 1972, 1975; McKubre and Macdonald, 1981; Armstrong and Edmondson, 1973; de Levie, 1964, 1967).

Another example is presented that deals with the hot corrosion of metals. Hot corrosion is a high-temperature corrosion phenomenon in which the protective tendency of a surface oxide film on a metal-alloy surface is severely compromised by the presence of a molten salt that tends to dissolve the oxide film (Goebel et al., 1973; Bornstein and DeCrescente, 1971; Luthra, 1982; Luthra and Shores, 1980; Rapp, 1986). Hot-corrosion problems have been of major concern to the gas turbine industry, where high-temperature alloys in service have been attacked by a molten sodium sulfate film. A schematic of the hot-corrosion process is shown in Figure 16 (Rapp and Goto, 1981). On the surface of the metal is a thin oxide film, MO, in which the transport of ionic and electronic charger carriers can occur during corrosion.

According to Rapp and Goto, a negative solubility gradient for the surface oxide in the molten salt at the oxide-salt interface is a condition for the sustained hot corrosion of a metal. This condition may be written as

$$\left(\frac{dN_{MO}}{dX}\right)_{x=0} < 0 \tag{32}$$

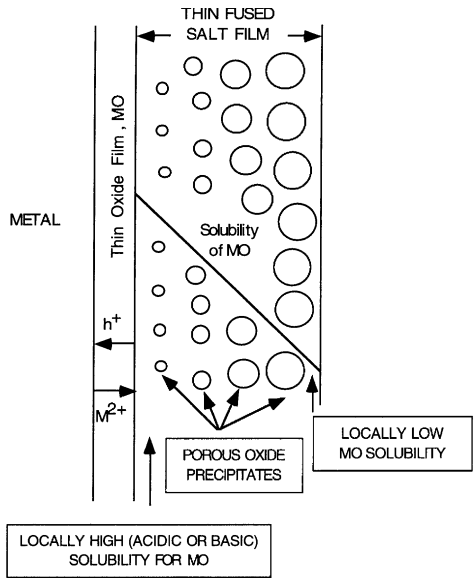

Figure 16. Schematic of the mechanism of hot corrosion of metals.

where N_{MO} is the solubility of the oxide MO in the salt film and $x = 0$ represents the oxide film–salt film interface. This condition allows the oxide to dissolve in the salt at $x = 0$ where the solubility is high and reprecipitate away from the interface where the solubility is low. What is the rationale for the existence of a negative solubility gradient? To answer this, let us look at the hot corrosion of Ni having a surface NiO film by a sodium sulfate film with a certain partial pressure of SO_3 gas at its outer surface. In principle, NiO can dissolve in sodium sulfate by two mechanisms: acid dissolution and basic dissolution. These two modes of dissolution are represented by the reactions

$$\underset{\text{(acidic solution)}}{NiO \rightarrow Ni^{2+}(\text{in salt}) + O^{2-}(\text{in salt})} \quad (33)$$

$$\underset{\text{(basic dissolution)}}{NiO + O^{2-}(\text{in salt}) \rightarrow NiO_2^{2-}(\text{in salt})} \quad (34)$$

In the case of NiO dissolution in sodium sulfate, basic dissolution is the preferred mode for hot corrosion. A measure of the basicity of the salt at any location is the prevailing concentration of oxide ions, O^{2-}. Thus NiO solubility will be higher where the concentration of O^{2-} is higher. The concentration of O^{2-} ions in the sodium sulfate melt is fixed by the equilibrium

$$SO_3 + O^{2-} = SO_4^{2-} \quad (35)$$

In view of the equilibrium of reaction 35, at the outer surface of the salt film, where the effective SO_3 partial pressure is high, the oxide ion concentration and therefore the basicity are low. At the oxide-salt interface, the SO_3 pressure is the lowest and therefore the basicity is the highest. This will give rise to a negative gradient in basicity and therefore NiO solubility at the oxide film–salt film interface.

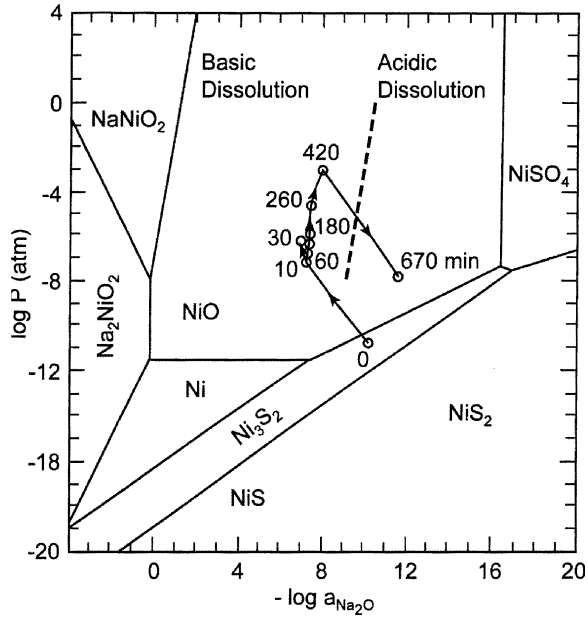

Figure 17. Trace of salt chemistry during the hot corrosion of Ni at 1200 K.

A limited number of studies have used EIS to investigate hot corrosion (Farrell et al., 1985; Gao et al., 1990; Wu and Rapp, 1991). Wu and Rapp applied this technique to study the hot corrosion of Ni in sodium sulfate melt at 1200 K. Amplitudes <10 mV were used in the frequency range 10^{-3} to 10^5 Hz. A nickel wire wound around a stabilized zirconia tube served as the working electrode. A sodium sulfate film of ~2 mm thickness, in equilibrium with a $O_2 + SO_2 + SO_3$ gas mixture, separated the Ni working electrode from a platinum foil counterelectrode. Two sets of reference electrodes, O_2-stabilized zirconia and Ag-Ag_2SO_4-fused silica, permitted the measurement of the oxygen partial pressure and the sodium oxide activity (basicity) at the corroding interface. A stability phase diagram of log P_{O_2} vs. log a_{Na_2O} at 1200 K is shown in Figure 17. The diagram delineates regimes of stability of different compounds. Also shown are the regimes of acid dissolution and basic dissolution. The trajectory from 0 to 670 min represents the path traversed during one impedance spectroscopy study of Ni precovered with a NiO film of ~0.8 μm thickness. Initially (0 min), the Ni surface is in the Ni_3S_2 stability regime. After 10 min of exposure, the metal surface shifts to a basic dissolution regime. The Nyquist plot corresponding to this condition is shown in Figure 18A. A lot of scatter can be observed in the low-frequency region. At 30 min, the surface is still in the basic dissolution regime (Fig. 18B). At 670 min, the corroding surface shifts to an acid dissolution regime (Fig. 18C). This is accompanied by a substantial decrease in the corrosion rate, as is suggested by the impedance curve corresponding to 670 min.

Problems

Powerful as the technique is, it is not always easy to use. Some of the problems and limitations have been summarized by Macdonald (1990). One limitation is the difficulty

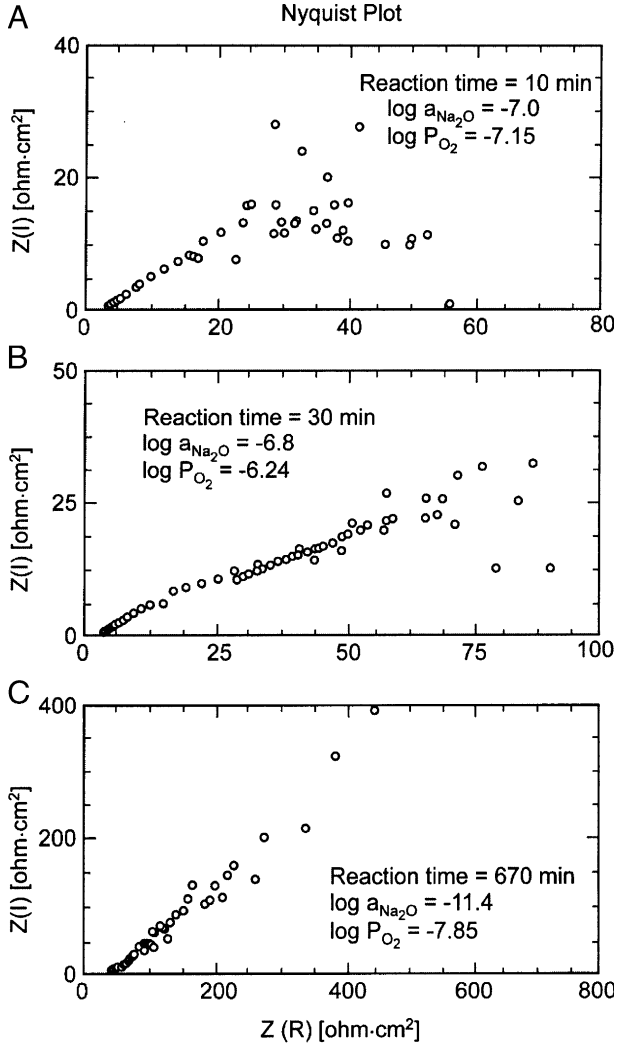

Figure 18. Impedance data for the hot corrosion of Ni in molten Na_2SO_4 after preoxidation in air at 1200 K for 5 min.

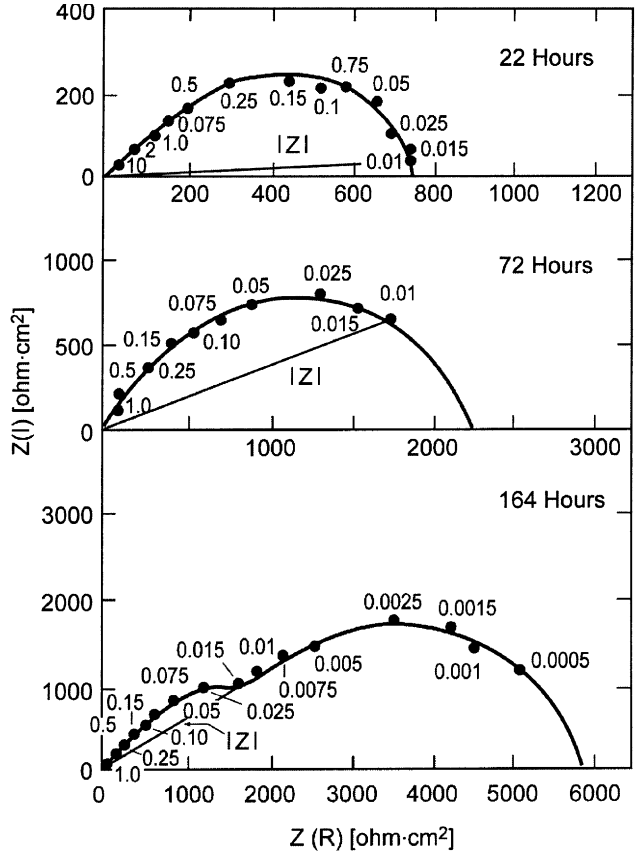

Figure 19. Impedance data for 90:10 Cu-Ni alloy in flowing sea water as a function of exposure time.

involved in acquiring a sufficient number of low-frequency data points in order to make a correct estimation of R_p. This problem can be demonstrated using data for a 90:10 Cu-Ni alloy (Syrett and Macdonald, 1979; Macdonald et al., 1978) undergoing corrosion in flowing sea water (Fig. 19). It can be seen that for an exposure time of 22 h, the semicircle is rather well defined. But at longer exposure times, even frequencies as low as 0.0005 Hz are insufficient to obtain a complete quantification of the interfacial impedance.

Acquisition of impedance data requires a finite amount of time depending on the system. In corroding systems where the initial rate of corrosion is very high, as is true in many cases, great care must be exercised in integrating $1/R_p$ over time in order to get an engineering value for the corrosion rate.

Porosity in surface films is another source of error in impedance measurements. Corrosion product films are often of variable porosity and of different sizes and shapes, and their contributions to the impedance spectrum are difficult to evaluate.

The accurate analysis of impedance data requires good correspondence between the corroding system and an appropriate electrical equivalent circuit. A complete correspondence is often difficult to achieve in practice.

Wagner and Traud, 1938. See above.

Mixed potential theory is outlined. It is clarified that there need not exist spatially separated anodic sites and cathodic sites for corrosion to occur. Anodic and cathodic sites can statistically interchange, and both types of reactions can occur simultaneously. All that is needed for corrosion to occur is that the potential difference across the metal–electrolyte interface be between the equilibrium potentials for the anodic reaction and the cathodic reaction.

SEMICONDUCTOR PHOTOELECTROCHEMISTRY

INTRODUCTION

This unit discusses methods and experimental protocols in semiconductor electrochemistry. We first discuss the basic principles that govern the energetics and kinetics of charge flow at a semiconductor-liquid contact. The principal electrochemical techniques of photocurrent and photovoltage measurements used to obtain important interfacial energetic and kinetic quantities of such contacts are then described in detail.

After this basic description of concepts and methods in semiconductor electrochemistry, we describe methods for characterizing the optical, electrical, and chemical properties of semiconductors through use of the electrochemical properties of semiconductor-liquid interfaces. The latter part of this unit focuses on methods that provide information primarily on the properties of the semiconductor surface and on the semiconductor-liquid junction.

In some cases, the semiconductor-liquid junction provides a convenient method for measuring properties of the bulk semiconductor that can only be accessed with great difficulty through other techniques; in other cases, the semiconductor-liquid contact enables measurement of properties that cannot be determined using other methods. Due to the extensive amount of background material and the interdisciplinary nature of work in this field, the discussion is not intended to be exhaustive, and the references cited in the various protocols should be consulted for further information.

This unit will cover the following methods in semiconductor electrochemistry:

- Photoconductor/photovoltage measurements
- Measurement of semiconductor band gaps using semiconductor-liquid interfaces
- Diffusion length determination using semiconductor-liquid contacts
- Differential capacitance measurements of semiconductor-liquid contacts
- Transient decay dynamics of semiconductor-liquid contacts
- Measurement of surface recombination velocity using time-resolved microwave conductivity
- Electrochemical photocapacitance spectroscopy
- Laser spot scanning methods at semiconductor-liquid contacts
- Flat-band potential measurements of semiconductor-liquid interface
- Time-resolved photoluminescence spectroscopy to determine interfacial charge transfer kinetic parameters
- Steady-state *J-E* data to determine kinetic properties of semiconductor-liquid interfaces.

PHOTOCURRENT/PHOTOVOLTAGE MEASUREMENTS

Principles of the Method

Thermodynamics of Semiconductor-Liquid Junctions

Energetics of Semiconductor-Liquid Contacts. When a semiconductor is placed in contact with a liquid, interfacial charge transfer occurs until equilibrium is reached. The direction and magnitude of this charge flow are dictated by the relevant energetic properties of the semiconductor-liquid contact. As shown in Figure 1, the key energetic quantities of the semiconductor are the energy of the bottom of the conduction band, E_{cb}, the energy of the top of the valence band, E_{vb}, the Fermi level, E_F, and the band gap energy, E_g ($= E_{vb} - E_{cb}$).

The key energetic quantity of the liquid is its electrochemical potential, $E(A/A^-)$, defined by the redox couple formed from an electroactive electron acceptor species, A, and an electroactive donor species, A^-, present in the electrolyte phase. The electrochemical potential of the phase containing specific concentrations of A and A^- is related to the formal electrochemical potential $E^{0\prime}(A/A^-)$ of this redox system by the Nernst equation:

$$E(A/A^-) = E^{0\prime}(A/A^-) + \frac{kT}{n}\ln\frac{[A]}{[A^-]} \qquad (1)$$

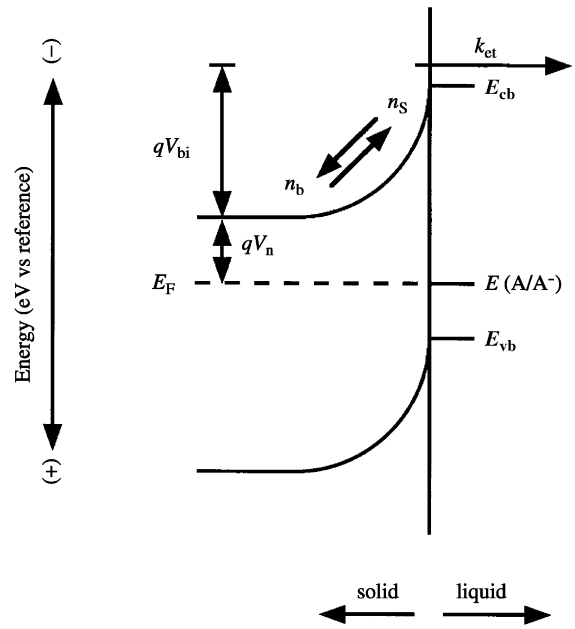

Figure 1. Energy of an *n*-type semiconductor-liquid junction under equilibrium conditions. At equilibrium the Fermi level of the semiconductor, E_F, is equal to the electrochemical potential of the solution. The surface electron concentration n_s is proportional to the bulk concentration of electrons n_b and the equilibrium built-in voltage V_{bi}. The energy difference between the Fermi level and the conduction band in the bulk is constant and equal to qV_n. The rate of charge transfer from the semiconductor to solution species is governed by the interfacial electron transfer rate constant k_{et}. Note the standard electrochemical sign convention, with positive energies representing more tightly bound electrons, is used throughout this unit.

where n is the number of electrons transferred, k is Boltzmann's constant, T is the absolute temperature, [A] is the concentration of acceptor species, and [A^-] is the concentration of donor species.

The doping level of the semiconductor is also important in determining the degree of interfacial charge transfer, because the dopant density determines the position of E_F in the semiconductor before contact with the electrolyte. For an n-type semiconductor and nondegenerate doping, the dopant density N_d is given by the Boltzmann-type relationship

$$N_d = N_c \exp(E_{cb} - E_F)kT \tag{2}$$

where N_c is the effective density of states in the conduction band of the semiconductor.

Equilibrium Charge Density, Electric Field, and Electric Potential Distributions at Semiconductor-Liquid Contacts. After contact between the semiconductor and the liquid, net charge will flow until the Fermi level is equal everywhere in both phases. At equilibrium, this charge flow will produce a spatially nonuniform charge density in the semiconductor and in the liquid. This nonzero charge density in both phases will, in turn, produce an electric field and an electric potential in the vicinity of the semiconductor-liquid contact.

For a given difference between E_{cb} and $E(A/A^-)$ at an n-type semiconductor-liquid contact, solution of Poisson's equation leads to the following well-known expressions for the charge density, Q, and the magnitudes of the electric field $\boldsymbol{E}$ and electric potential V as a function of distance x into the semiconductor:

$$Q = qN_d \qquad 0 \le x \le W \tag{3a}$$

$$Q = 0 \qquad x > W \tag{3b}$$

$$\mathbf{E}(x) = \frac{qN_d}{\varepsilon_s}(W - x) \qquad 0 \le x \le W \tag{4a}$$

$$\mathbf{E}(x) = 0 \qquad x > W \tag{4b}$$

$$V(x) = -\frac{qN_d}{2\varepsilon_s}(W - x)^2 \qquad 0 \le x \le W \tag{5}$$

$$W = \sqrt{\frac{2\varepsilon_s[E_{cb} + qV_n - E(A/A^-)]}{N_d q^2}} \tag{6}$$

Here, q is the absolute value of the charge on an electron, ε_s is the static dielectric constant of the semiconductor, W is the depletion width, and V_n is the potential difference between the Fermi level and the conduction band level in the bulk of the semiconductor (Fig. 1).

Equation 3 is reasonable because the dopants are present in relatively low concentration in the solid (perhaps 1 ppm or less), so essentially all of the dopants are ionized until a sufficient distance has been reached that the required electrical charge has been transferred across the solid-liquid interface. Equations 4 and 5 then follow directly from the charge density profile of Equation 3, once the value of W is known from the amount of charge transferred (Equation 6). Analogous equations for p-type semiconductor-liquid contacts can be obtained to relate the energetics of the valence band, E_{vb}, to $E(A/A^-)$. For a typical difference between $E(A/A^-)$ and E_{cb} of 1 eV, Equation 4 shows that the electric field near the surface of the semiconductor is $\approx 10^5$ V cm^{-1}.

This junction formation leads to diode-like behavior, in which charge carriers experience a large barrier to current flow in one direction across the interface but display an exponentially increasing current density as a voltage is applied to the system in order to produce a current flow in the opposite direction across the contact. Understanding the microscopic origin of this rectification and interpreting its properties in terms of the chemistry of the semiconductor-liquid contact of concern is the topic covered next.

Charge Transfer at Equilibrium. Interfacial charge transfer at a semiconductor-liquid interface can be represented by the following balanced chemical equation:

$$\text{Electron in solid} + \text{acceptor in solution} \rightleftharpoons \text{electron vacancy in solid} + \text{donor in solution} \tag{7}$$

When Equation 7 is obeyed, the current should depend linearly on the concentration of electrons near the semiconductor surface and on the concentration of acceptor ions that are available to capture charges at the semiconductor surface (Fig. 1). In a solution containing a redox couple A/A^-, the rate of direct electron transfer from an n-type semiconductor to the acceptor species A can therefore be expressed as

$$\text{Rate of electron injection into solution} = k_{et} n_s [A]_s \tag{8}$$

where k_{et} is the rate constant for the electron transfer, n_s is the surface concentration of electrons, and $[A]_s$ is the concentration of acceptors in the interfacial region near the semiconductor-liquid contact. The units of k_{et} are centimeters to the fourth power per second, because the rate of charge flow represents a flux of charges crossing the interface, with units of reciprocal centimeters squared per second, and the concentrations n_s and $[A]_s$ are expressed in units of reciprocal cubic centimeters.

The electron flux in the opposite direction, i.e., from the electron donors in the solution to the empty states in the conduction band of the semiconductor, can be described as

$$\text{Rate of electron transfer from solution} = k'_{et}[A^-]_s \tag{9}$$

In Equation 9, k'_{et} is the reverse reaction rate constant and $[A^-]_s$ is the concentration of donors in the interfacial region near the semiconductor-liquid contact. In this expression, the concentration of empty states in the conduction band of the semiconductor has been incorporated implicitly into the value of k'_{et}.

At equilibrium, the rates of Equations 8 and 9 must be equal. Denoting the equilibrium electron concentration at the semiconductor surface by the quantity n_{s0}, we obtain

$$k_{et} n_{s0} [A]_s = k'_{et} [A^-]_s \tag{10}$$

Away from equilibrium, the net rate of electron transfer into solution ($-dn/dt$) is simply the forward rate minus the reverse rate. From Equations 8 to 10, we then obtain the general relationship

$$-\frac{dn}{dt} = k_{et}[A]_s n_s - k'_{et}[A^-]_s \tag{11}$$

or

$$-\frac{dn}{dt} = k_{et}[A]_s(n_s - n_{s0}) \tag{12}$$

Dark Current–Potential Characteristics of Semiconductor-Liquid Junctions. Because the current density (i.e., the current I divided by the exposed area of the electrode A_s) is merely the electron transfer rate multiplied by the charge on an electron, the interfacial electron transfer current density can be written as

$$J = -q\left(\frac{dn}{dt}\right) = -C(n_s - n_{s0}) \tag{13}$$

where the constant $C = qk_{et}[A]_s$. The current density J is defined to be negative when a reduction occurs at the electrode surface. Therefore, when $n_s > n_{s0}$, a negative (reduction) current will flow, because the electrode will tend to donate electrons to the solution.

A useful form of this equation is

$$J = -Cn_{s0}\left(\frac{n_s}{n_{s0}} - 1\right) \tag{14}$$

To obtain explicitly the dependence of the current density on the potential applied across the solid-liquid interface, we must relate the electron concentration at the surface of a semiconductor to the electron concentration in the bulk. The surface electron concentration at equilibrium is given by

$$n_{s0} = n_b \exp\left(\frac{-qV_{bi}}{kT}\right) \tag{15}$$

where n_b is the concentration of electrons in the bulk of the semiconductor and V_{bi} is the built-in voltage, i.e., the potential dropped across the semiconductor at equilibrium. Similarly, when a potential E is applied to the semiconductor relative to the situation at equilibrium, the total voltage drop in the semiconductor depletion region is $V_{bi} + E$, so we obtain an analogous Boltzmann relationship away from equilibrium:

$$n_s = n_b \exp\left(\frac{-q(V_{bi} + E)}{kT}\right) \tag{16}$$

These equations represent the physical situation that the electron concentration at the semiconductor surface can be either increased or decreased through the use of an additional voltage. This applied potential controls the surface carrier concentration in the same fashion as the built-in voltage, so the same Boltzmann relationship applies.

Equations 15 and 16 lead to a simple expression for the variation in the surface electron concentration as a function of the applied potential:

$$\frac{n_s}{n_{s0}} = \exp\left(\frac{-qE}{kT}\right) \tag{17}$$

This makes sense, because any change in the voltage dropped across the solid should exponentially change the electron concentration at the semiconductor surface relative to its value at equilibrium.

Substituting Equation 17 into Equation 14, we obtain the desired relationship between the current density and the potential of a semiconductor-liquid junction:

$$J = -Cn_{s0}\left[\exp\left(\frac{-qE}{kT}\right) - 1\right] \tag{18}$$

This equation is the simple rate equation 14, which has been rewritten to emphasize the explicit dependence of the current density on E.

Equation 18 is often written with only one constant:

$$J = -J_0\left[\exp\left(\frac{-qE}{kT}\right) - 1\right] \tag{19}$$

where $J_0 = Cn_{s0}$. The parameter J_0 is called the exchange current density, because it is the value of the current density that is present at equilibrium. For convenience, J_0 is defined as a positive quantity. The parameter J_0 is clearly dependent on the value of the equilibrium surface electron concentration, because a smaller exchange current should flow at equilibrium if there are fewer electrons available to exchange with a particular solution.

The current density–potential (or J-E) characteristic described by Equations 18 and 19, where the current can flow predominantly in only one direction under an applied potential, is called "rectification." The rectification characteristic is typical of electrical diodes. Equations that have the form of Equations 18 and 19 are therefore generally called "diode equations."

Factors that Affect Current Density–Potential Properties of Semiconductor-Liquid Contacts. The dependence of the charge transfer rate on the solution redox potential is perhaps the most important experimental property of semiconductor electrodes. Regardless of the value of the redox potential of the solution, $E(A/A^-)$, the diode behavior of Equation 19 will be obeyed. Changes in $E(A/A^-)$, however, will produce different values of J_0, because J_0 depends on n_{s0}. These different exchange currents will produce a measurable change in the J-E behavior of the semiconductor-liquid contact.

For an n-type semiconductor, more positive redox potentials will yield smaller values of J_0 and will produce highly rectifying diode behavior. For p-type semiconductors, the

opposite behavior is expected, so that negative redox potentials should produce highly rectifying contacts while positive redox potentials should produce poorly rectifying contacts. Rectifying *J-E* behavior is required for efficient photoelectrochemical devices that use either *n*- or *p*-type semiconductors; thus, one goal in constructing semiconductor-liquid junctions is to ensure that chemical control is maintained over the *J-E* properties of the semiconductor-liquid contact.

Variations in redox potentials also give rise to changes in an experimental parameter known as the barrier height. The barrier height, ϕ_b, for an *n*-type semiconductor-liquid contact is the potential difference between the redox potential of the solution and the conduction band edge. The value of $q\phi_b$ additionally reflects the free energy associated with interfacial electron transfer. Using this parameter, the expression for n_{s0} can be rewritten as

$$n_{s0} = N_c \exp\left(\frac{-q\phi_b}{kT}\right) \tag{20}$$

The value of N_c is known for most semiconductors and is generally $\approx 10^{19}$ cm^{-3} (Sze, 1981).

We can now explicitly incorporate the barrier height into our diode expressions by substituting Equation 20 into the expression for J_0:

$$J_0 = CN_c \exp\left(\frac{-q\phi_b}{kT}\right) \tag{21}$$

Equation 21 indicates that a value of J_0 can be predicted if the values of both ϕ_b and C are known.

Although we have derived the diode behavior of a semiconductor-liquid junction by assuming that electron transfer is the important charge flow process across the interface, the diode equation is generally applicable to semiconductor-liquid devices even when other processes are rate limiting. The *J–E* relationships for other possible charge flow mechanisms, such as recombination of carriers at the surface and/or in the bulk of the semiconductor, almost all adopt the form of Equation 19 (Fonash, 1981). The major difference between the various mechanisms is the value of J_0 for each system. Mechanistic studies of semiconductor-liquid junctions therefore generally reduce to investigations of the factors that control J_0. Such studies also involve quantitative comparisons of the magnitude of J_0 with the value expected for a specific charge transport mechanism. These types of investigations have yielded a detailed level of understanding of many semiconductor-liquid interfaces. Recent reviews describing more details of this work have been written by Koval and Howard (1992), Lewis (1990), and Tan et al. (1994b).

Basic J-E Equations for Illuminated Semiconductor-Liquid Junctions. Photoelectrochemical experiments also often deal with the behavior of semiconductor electrodes under illumination. Illumination of a semiconductor with light above its band gap energy produces excess electron-hole pairs, and movement of these charge carriers produces a photocurrent and a photovoltage at the semiconductor-liquid contact.

Current Components at Illuminated Semiconductor-Liquid Junctions. The effects of illumination are relatively simple to incorporate into the *J-E* behavior of a semiconductor-liquid contact. The total current in such a system can be conceptually partitioned into two components: one that originates from majority carriers and one from minority carriers. Absorption of photons creates both majority carriers and minority carriers; therefore, increases in both current components are expected under illumination.

Majority Carrier Currents. The concentration of majority carriers generated by absorption of moderate-intensity light is usually small compared to the concentration of majority carriers that is obtained from thermal ionization of dopant atoms in the solid. This implies that such levels of illumination do not significantly perturb the majority carrier behavior either in the semiconductor or at the semiconductor-liquid interface. Because the majority carrier concentrations are essentially unchanged, the rate equations that govern majority carrier charge flow also are unchanged. Majority carriers should thus exhibit a *J-E* characteristic that is well described by the diode equation, regardless of whether the semiconductor is in the dark or is exposed to moderate levels of illumination.

Minority Carrier Currents. Unlike the situation for majority carriers, illumination generally effects a substantial change in the concentration of minority carriers. Calculation of the minority carrier current is greatly simplified by considering the effects of the electric field at the semiconductor-liquid junction. For most semiconductor-liquid junctions in depletion, the electric field is so strong that essentially all of the photogenerated minority carriers are separated from the photogenerated majority carriers and then collected. Using this approximation, the photogenerated minority carrier current density J_{ph} is simply equal to the photon flux absorbed by the semiconductor multiplied by the charge on an electron, q.

Total Current Under Illumination. The total current density–potential characteristics of an illuminated semiconductor electrode can thus be obtained by adding together, with the appropriate sign, the majority and minority carrier components of the current density. The majority carrier current density obeys the diode equation, while the minority carrier photocurrent density is related to the absorbed light intensity. The expression for the total current density is therefore

$$J = J_{ph} - J_0\left[\exp\left(\frac{-qE}{kT}\right) - 1\right] \tag{22}$$

The sign of the minority carrier current (photocurrent) density is opposite to that of the majority carrier current density, because holes crossing the interface lead to an oxidation current, while electrons crossing the interface lead to a reduction current. Equation 22 is obviously just the diode curve of Equation 19 offset by a constant amount J_{ph} over the voltage range of interest (Fig. 2).

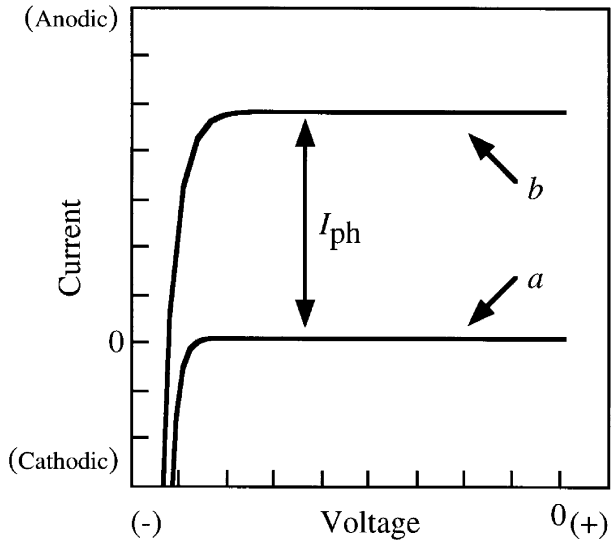

Figure 2. Ideal current-voltage behavior of a semiconductor-liquid junction (*a*) in the dark and (*b*) under illumination. The current observed under illumination is offset from the current observed in the dark by the value of the photocurrent, I_{ph}.

Properties of Photocurrent Density–Potential Behavior of Semiconductor-Liquid Junctions. For $J_{ph} > J_0$, as is generally the case, the 1 in Equation 22 can be neglected. We then obtain

$$J \approx J_{ph} - J_0\left[\exp\left(\frac{-qE}{kT}\right)\right] \tag{23}$$

We can then define the open-circuit voltage V_{oc} as the absolute value of the voltage present when no net current flows and obtain

$$V_{oc} = \frac{kT}{q}\ln\left(\frac{J_{ph}}{J_0}\right) \tag{24}$$

This voltage is significant in the field of solar energy conversion, as it represents the maximum free energy that can be extracted from a semiconductor-liquid interface.

Equation 24 brings out several important features of the open-circuit voltage. First, V_{oc} increases logarithmically with the light intensity, because J_{ph} is linearly proportional to the absorbed photon flux. Second, the open-circuit voltage of a system increases (logarithmically) as J_0 decreases. Chemically, such behavior is reasonable, because J_0 represents the tendency for the system to return to charge transfer equilibrium. Third, Equation 24 emphasizes that a mechanistic understanding of J_0 is crucial to controlling V_{oc}. Only through changes in J_0 can systematic, chemical control of V_{oc} be established for different types of semiconductor-liquid junctions.

Another parameter that is often used to describe illuminated semiconductor-liquid junctions is the short-circuit photocurrent density J_{sc}. Short-circuit conditions imply $V = 0$. From Equation 22, the net current density at short circuit (J_{sc}) equals J_{ph}. The short-circuit current density provides a measure of the collection efficiency of photogenerated carriers in a particular photoelectrochemical cell. The reader is referred to earlier reviews for a more extensive discussion of how these parameters are relevant in solar energy research using semiconductor-based photoelectrochemical cells (Lewis, 1990; Tan et al., 1994b).

Practical Aspects of the Method

Basic Electrochemical Cell Design. Current density–potential data for semiconductor electrodes are typically obtained using a potentiostat (Fig. 3). This instrument ensures that the measured *J-E* properties are characteristic of the semiconductor-liquid interface and not of the counter electrode–liquid contact that is needed to complete the electrical circuit in the electrochemical cell. A three-electrode arrangement consisting of a semiconductor (working) electrode, a counter electrode, and a reference electrode is typically used to acquire data. The potentiostat uses feedback circuitry and applies the voltage needed between the working electrode and counter electrode to obtain the desired potential difference between the working and reference electrodes. The potentiostat then records the current flowing through the working electrode–counter electrode circuit at this specific applied potential. Nominally, no current flows through the reference electrode, which only acts as a point of reference for the system. The scan rate should be 50 mV s^{-1} or slower in order to minimize hysteresis arising from diffusion of species to the electrode surface during the *J-E* scan.

The electrochemical data are collected directly as the current vs. the applied potential. Electrode areas are, of course, needed to obtain current densities from the measured values of the current. The projected geometric area of the electrode is usually obtained by photographing the electrode and a microruler simultaneously under a microscope and digitally integrating the area defined by the exposed semiconductor surface.

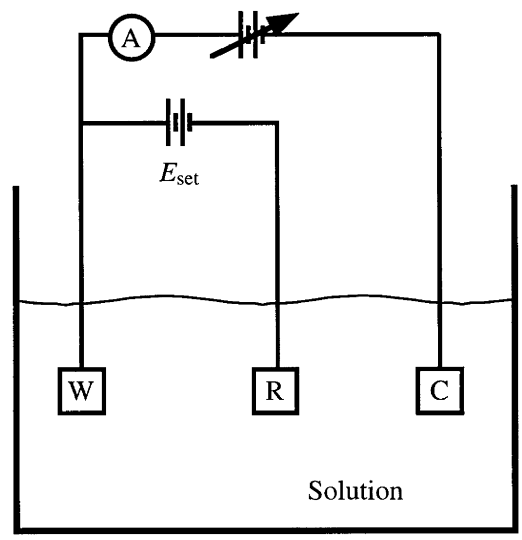

Figure 3. Circuit consisting of a simple potentiostat and an electrochemical cell. A potential is set between the working and reference electrode, and the current flow from the counter electrode to the working electrode is measured.

Reference Electrodes. Reference electrodes are constructed according to conventional electrochemical protocols. For example, two types of reference electrodes are an aqueous (or nonaqueous) saturated calomel electrode (SCE) and a nonaqueous ferrocenium-ferrocene electrode.

A simple SCE can be constructed by first sealing a platinum wire through one leg of an H-shaped hollow glass structure. The platinum wire is then covered with mercury, and a ground mixture of approximately equal amounts of mercury and calomel (Hg_2Cl_2) dispersed into a small amount of saturated potassium chloride solution is then placed on top of the mercury. The remainder of the tube is filled with saturated potassium chloride solution, and the other leg of the structure, which contacts the solution, is capped with a fritted plug. Prior to use, the nonaqueous SCE should be calibrated against a reference electrode with a known potential, such as an aqueous SCE prepared in the same fashion.

For work in nonaqueous solvents, a convenient reference electrode is the ferrocenium-ferrocene reference. This electrode consists of a glass tube with a fritted plug at the bottom. The tube is filled with a ferrocene-ferrocenium-electrolyte solution made using the same solvent and electrolyte that is to be used in the electrochemical experiment. A platinum wire is inserted into the top of the solution to provide for a stable reference potential measurement.

When both forms of the redox couple are present in the electrochemical cell, an even simpler procedure can be used to construct a reference electrode. A platinum wire can be inserted into the electrolyte–redox couple solution or into a Luggin capillary that is filled with the electrolyte–redox couple solution (see Luggin capillaries, below). This wire then provides a stable reference potential that is equal to the Nernstian potential of the electrochemical cell. At any convenient time, the potential of this reference can be determined vs. another reference electrode, such as an SCE, through insertion of the SCE into the cell. This approach not only is convenient but also is useful when water and air exposure is to be minimized, as is the case for reactive semiconductor surfaces in contact with deoxygenated nonaqueous solvents.

Luggin Capillaries. The cell resistance can be reduced by minimizing the distance between the working and reference electrodes. These small distances can be achieved through the use of a Luggin capillary as a reference electrode. The orifice diameter of the capillary should generally be $\sim$0.1 mm. A convenient method to form such a structure is to pull a disposable laboratory pipette under a flame and then to use a caliper to measure and then break the pipette glass at the point that corresponds to the desired orifice radius. The pipette is then filled with the reference electrode solution of interest, and the flow of electrolyte out of the pipette is minimized by capping the top of the pipette with a rubber septum. The contact wire is then inserted through the septum and into the electrolyte. Under some conditions, a syringe needle connected to an empty syringe can be inserted through the septum to facilitate manipulation of the pressure in the head space of the pipette. This procedure can be used to minimize mixing between the solution in the pipette and the solution in the electrochemical cell.

Illumination of Semiconductor-Liquid Contacts

Monochromatic Illumination. Low-intensity monochromatic illumination can be obtained readily from a white light source and a monochromator. This is useful for obtaining spectral response data to measure the diffusion length or the optical properties of the semiconductor electrode, as described in more detail under Measurement of Semiconductor Band Gaps Using Semiconductor-Liquid Interfaces.

Laser illumination can also be used to provide monochromatic illumination. However, care should be taken to diffuse the beam such that the entire electrode surface is as uniformly illuminated as possible. Because the photovoltage is a property of the incident light intensity, careful measurement of the photovoltage requires maintaining a uniform light intensity across the entire electrode surface. This protocol has not been adhered to in numerous measurements of the *J-E* properties of semiconductor electrodes, and the photovoltages quoted in such investigations are therefore approximate values at best. To control the light intensity from the laser, neutral density filters can be used to attenuate the incident beam before it strikes the electrode surface.

Regardless of whether the monochromatic light is obtained from a white light–monochromator combination or from a laser, measurement of the incident photon power is readily achieved with pyranometers, photodiodes, thermopiles, or other photon detectors that are calibrated in their response at the wavelengths of interest.

Polychromatic Illumination. For polychromatic illumination, solar simulators provide the most reproducible laboratory method for measuring *J-E* properties under standard, "solar-simulated" illumination. A less expensive method is to use tungsten-halogen ELH-type projector bulb lamps. However, their intensity-wavelength profile, like that of almost any laboratory light source, is not very well matched to the solar spectrum observed at the surface of the earth. Calibration of the light intensity produced by this type of source should not be done with a spectrally flat device such as a thermopile. Since laboratory sources typically produce more photons in the visible spectral region than does the sun at the same total illumination power, maintaining a constant power from both illumination sources tends to yield higher photocurrents, thus producing overestimates in efficiency of photoelectrochemical cells in the laboratory, relative to their true performance under an actual solar spectral distribution in the field.

An acceptable measurement method instead involves calibration of the effective incident power produced by the laboratory source through use of a photodetector whose spectral response characteristics are very similar to that of the photoelectrochemical cell of concern. Preferably, the response properties of the photodetector are linear with light intensity and the absolute response of the detector is known under a standard solar spectral

distribution and illumination power. The absolute detector response can be obtained either by measurements performed under a calibrated solar simulator or by measurement of the output of the detector in actual sunlight. If sunlight is used, another calibration is then required to determine the actual solar power striking the plane of the detector at the time of the measurement. Useful primary or secondary reference detectors for this purpose are silicon cells that have been calibrated on balloon flights by NASA. Spectrally flat radiometers, such as those produced by Eppley for the purpose of measuring the absolute spectral power striking a specific location on the surface of the earth, are also useful for determining the solar power under conditions used to calibrate the detector to be used in the laboratory. If these primary or secondary reference detectors are routinely available, it is of course also possible to determine the *J-E* properties of the photoelectrochemical cell directly in sunlight, as opposed to having to establish a reference detector measurement and then recalibrate a laboratory light source to produce the equivalent effective spectral power for the purposes of the measurement.

Effects of Cell Configuration. Under potentiostatic control, the concentrations of both forms of the redox species need not be as high as might be required to sustain identical performance in an actual, field-operating photoelectrochemical cell. This occurs because a two-electrode photovoltaic-type cell configuration requires sufficiently high concentrations of both forms of the redox couple dissolved in the solution to suppress mass transport limitations without mechanical stirring of the electrolyte. In a three-electrode cell with an *n*-type semiconductor electrode, the primary consideration is that sufficient redox donor be present such that the anodic current is limited by the light intensity and not by the mass transport of donor to the electrode surface. A high concentration of redox acceptor is not required to achieve electrode stability and often is undesirable when the oxidized form of the redox material absorbs significantly in the visible region of the spectrum. The concentration overpotential that results from a low concentration of electron acceptor in the electrolyte can be assessed and corrected for analytically using Equation 26 below.

In contrast, the performance of an actual energy conversion device using a two-electrode cell configuration is so dependent on the properties of the working electrode, the counter electrode, the electrolyte, the cell thickness, and the properties of the various optical interfaces in the device that many design trade-offs are involved and are unique to a particular cell configuration used in the device assessment. Emphasis here has been placed on determining the properties of the semiconductor electrode in "isolation," using a potentiostat, so that a comparison from electrode to electrode can be performed without considering the details of the device configuration used in each measurement.

Data Analysis and Initial Interpretation

Typical Raw Current–Potential Data. A representative example of a current-potential curve is shown in Figure 4,

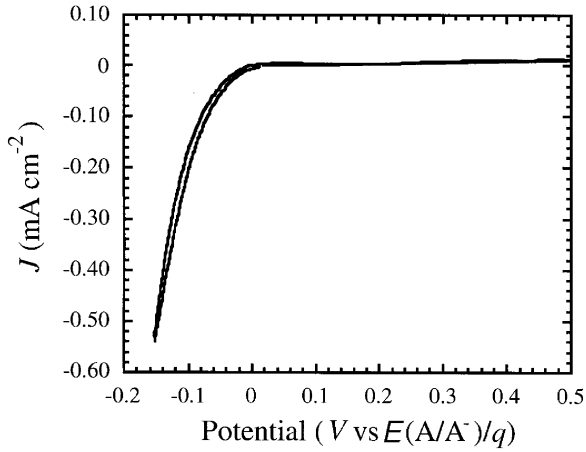

Figure 4. Representative example of current-voltage data for a semiconductor-liquid interface. The system consists of a silicon electrode in contact with a methanol solution containing lithium chloride and oxidized and reduced forms of benzyl viologen. In this example, the current has been divided by the surface area of the electrode, yielding a current density as the ordinate. The curve has not been corrected for cell resistance or concentration overpotential.

which displays data for an *n*-type silicon electrode in contact with a redox-active methanol solution. In this figure, the current has been divided by the surface area of the electrode to allow for quantitative analysis of the data. To extract meaningful results from the current-potential curve, it is also necessary to perform corrections for concentration overpotential and solution resistance, as discussed below.

Corrections to J-E Behavior: Concentration Overpotentials. Attention to electrochemical cell design is critical to minimize concentration overpotentials, mass transport restrictions on the available current density, and uncompensated resistance drops between the working and reference electrodes. Even with good cell design, in nonaqueous solvents the *J-E* curves must generally be corrected for concentration overpotential losses as well as for uncompensated ohmic resistance losses to obtain the inherent behavior of the semiconductor-liquid contact.

To minimize mass transport limitations on the current, the electrolyte should be vigorously stirred during the *J-E* measurement. For a given redox solution, the limiting anodic current density $J_{l,a}$ and the limiting cathodic current density $J_{l,c}$ should be determined using a platinum foil electrode placed in exactly the same configuration as the semiconductor working electrode. The areas of the two electrodes should also be comparable. If the redox couple is known to be electrochemically reversible, the platinum-electrode data can then be used to obtain the cell parameters needed to perform the necessary corrections to the *J-E* data of the semiconductor electrode (see Steady-State *J-E* Data to Determine Kinetic Properties of Semiconductor-Liquid Interfaces).

Alternatively, the semiconductor electrode can be fabricated into a disk configuration, and can be rotated in the electrolyte. Under these conditions, the mass transport

parameters E can be determined analytically, and the limiting current density (Bard et al., 1980) is

$$J_{1,c} = 0.620nFD_0^{2/3}\omega_{rde}^{1/2}\upsilon^{-1/6}[A]_b \qquad (25)$$

where F is Faraday's constant, D_0 is the diffusion coefficient, ω_{rde} is the angular velocity of the electrode, υ is the kinematic velocity of the solution ($\approx$0.01 $cm^2\ s^{-1}$ for dilute aqueous solutions near 20°C), and $[A]_b$ is the bulk concentration of oxidized acceptor species. A similar equation yields the limiting anodic current density based on the parameters for the reduced form of the redox species. This procedure allows control over the limiting current densities instead of merely measuring their values in a mechanically stirred electrolyte solution.

Laminar flow typically ceases to exist above Reynolds numbers (defined as the product of ω and the disk radius of the electrode divided by υ) of 2×10^5 (Bard et al., 1980), so for electrode radii of 1 mm, this corresponds to a typical upper limit on the rotation velocity of 1 to 2×10^7 rpm. Beyond this limit, Equation 25 does not describe the mass transport to the electrode. Smaller electrodes can increase this limit on ω, but use of smaller electrodes is generally not advisable, because edge effects become important and can distort the measured electrochemical properties of the solid-liquid contact by hindering diffusion of minority carriers and allowing recombination at the edges of the semiconductor crystal.

Once the limiting current densities and the *J-E* data are collected for a reversible redox system at a metal electrode, the concentration overpotential η_{conc} can be determined (Bard et al., 1980):

$$\eta_{conc} = \frac{kT}{nq}\left[\ln\left(\frac{J_{1,a}}{-J_{1,c}}\right) - \ln\left(\frac{J_{1,a}-J}{J-J_{1,c}}\right)\right] \qquad (26)$$

These values can then be used to correct the data at a semiconductor electrode to yield the proper *J-E* dependence of the solid-liquid contact in the absence of such concentration overpotentials.

Corrections to J-E Behavior: Series Resistance Overpotentials. Even with good cell design, measurement of the cell resistance R_{soln} is required to perform another correction to the *J-E* data. Values for R_{soln} can be extracted from the real component of the impedance in the high-frequency limits of Nyquist plots ELECTROCHEMICAL TECHNIQUES FOR CORROSION QUANTIFICATION for the semiconductor electrode or can be determined from steady-state measurements of the ohmic polarization losses of a known redox couple at the platinum electrode. In the former method, R_{soln} is simply taken as the real part of the impedance in the high-frequency limit of the Nyquist plot. In the latter method, the current-potential properties of a platinum electrode are determined under conditions where the platinum electrode is in an identical location to that of the semiconductor electrode. After correction of the data for concentration polarization, R_{soln} can be obtained from the inverse slope of the platinum current-potential data near the equilibrium potential of the solution.

The final corrected potential E_{corr} is then calculated from E, the concentration overpotential η_{conc}, R_{soln}, and the current I using (Bard et al., 1980)

$$E_{corr} = E - \eta_{conc} - IR_{soln} \qquad (27)$$

The measured value of I is divided by the projected geometric area of the electrode and plotted vs. E_{corr} to obtain a plot of the *J-E* behavior of the desired semiconductor-liquid contact.

Measurement of J_{sc} and V_{oc} of Illuminated Semiconductor-Liquid Contacts. The open-circuit photovoltage and short-circuit photocurrent should be measured directly using four-digit voltmeters connected to the photoelectrochemical cell as opposed to estimating their values from a time-dependent scan of the *J-E* data. This steady-state measurement eliminates any bias that might arise due to the presence of hysteresis in the current-potential behavior. Also, in some cases, the light-limited photocurrent is not reached at short circuit; in this case, both the light-limited photocurrent value and the short-circuit photocurrent value are of experimental interest and should be measured separately.

Sample Preparation

Electrodes for photoelectrochemical measurements should be constructed to allow exposure of the front face of the semiconductor to the solution while providing concealment of the back contact and of the edges of the electrode. This is readily accomplished using an insulating material that is inert toward both the etchant and the working solution of interest. The area of the electrode should be large enough to allow ready measurement of the bulk surface area but should be small enough to limit the total current flowing through the electrochemical cell (because larger currents require larger corrections for the cell resistance). Because of these trade-offs, electrode areas are typically 0.1 to 1 cm^2.

Ohmic contacts vary widely between semiconductors, and several books are available for identifying the ohmic contact of choice for a given semiconductor (Willardson et al., 1981; Pleskov et al., 1986; Finklea, 1988). Although most ohmic contacts are prepared by evaporating or sputtering a metal on the back surface of the semiconductor, some semiconductors are amenable to more convenient methods such as using a scribe to rub a gallium-indium eutectic on the back surface of the solid. This latter procedure is commonly used to make an ohmic contact to *n*-type silicon. The quality of an ohmic contact can be verified by making two contacts, separated by a contact-free region, on one side of an electrode and confirming that there is only a slight resistance between these contacts as measured by a *J-E* curve collected between these contact points.

The proper choice of a chemical etch depends on the semiconductor, its orientation, and the desired surface properties. Generally, an ideal etchant produces an atomically smooth surface with no electrical surface defects. Fluoride-based etches are most commonly used with

silicon: a 40% (w/w) ammonium fluoride solution is well suited for (111)-oriented Si and a solution of HF is appropriate for (100)-oriented Si (Higashi et al., 1991, 1993). For many III to V semiconductors, an etch in 0.05% (v/v) Br_2 followed by a rinse in a solution of NH_4OH produces abrupt discontinuities in the dielectric at the solid-air interface (Aspnes et al., 1981). An exhaustive literature provides information on additional etches for these and other semiconductors, and the reader is referred to these references for further information (Wilson et al., 1979; Aspnes et al., 1981; Higashi et al., 1993). There are also several published reports of effective dry etching methods (Higashi et al., 1993; Gillis et al., 1997).

Because many semiconductors are reactive in aerobic environments, it is often necessary to carry out experiments in anaerobic conditions using nonaqueous solvents. Air-sensitive experiments can be performed in specialized glassware that is continuously purged with an inert gas or in an inert atmosphere glove box specially modified for electrical throughputs. Although outlined here for current-voltage measurements, the electrode preparation techniques are applicable not only to these measurements but also to most other techniques discussed in this unit.

MEASUREMENT OF SEMICONDUCTOR BAND GAPS USING SEMICONDUCTOR-LIQUID INTERFACES

Principles of the Method

The basic photoelectrochemical techniques discussed above can be used to determine many important properties of the semiconductor and of the semiconductor-liquid contact. Monitoring the wavelength dependence of the photocurrent produced at a semiconductor-liquid contact can provide a nondestructive, routine method for determining some important optical properties of a semiconductor. Specifically, the value of the band gap energy and whether the electronic transition is optically allowed or forbidden can be obtained from measurement of the spectral response of the photocurrent at a semiconductor-liquid contact.

Two types of optical transitions are commonly observed for semiconductors: direct gaps and indirect gaps. Near the absorption edge, the absorption coefficient α can be expressed as (Pankove, 1975; Sze, 1981; Schroder, 1990)

$$\alpha \sim (h\nu - E_g)^{\beta} \tag{28}$$

where h is Planck's constant, ν is the frequency of the light incident onto the semiconductor, and β is the coefficient for optical transitions. The absorption coefficient is obtained from Beer's law, in which the ratio of transmitted, Γ, to incident, Γ_0, photon flux for a sample of thickness d is (Pankove, 1975)

$$\Gamma/\Gamma_0 = \exp(-\alpha d) \tag{29}$$

For optically allowed, direct gap transitions, $\beta = \frac{1}{2}$, whereas for indirect, optically forbidden transitions, $\beta = 2$ (Sze, 1981).

Typically, α is determined through measurements of the extinction of an optical beam through a known thickness of the semiconductor sample. Beer's law is applied to solve for α from the measured ratio of the incident and transmitted intensities of light through the sample at each wavelength of interest. For a direct band gap semiconductor, a plot of α^2 vs. photon energy will give the band gap as the x intercept. If the semiconductor has an indirect band gap, a plot of $\alpha^{1/2}$ vs. photon energy will have two linear regions, one corresponding to absorption with phonon emission and one corresponding to absorption with phonon capture. The average of the two intercepts is the energy of the indirect band gap. One-half the difference between the two intercepts is the phonon energy emitted or captured during the band gap excitation. An alternative method for determining the absorption coefficient vs. the wavelength is to determine the real and imaginary parts of the refractive index from reflectance, transmittance, or ellipsometric data and then to use the Kramers-Kronig relationship to determine the absorption coefficient of the solid over the wavelength region of interest (Sze, 1981; Lewis et al., 1989; Adachi, 1992).

Practical Aspects of the Method

The photocurrent response at a semiconductor-liquid interface can also be used to determine α as a function of wavelength and thus to determine E_g and β for that semiconductor. This method avoids having to make tedious optical transmission measurements of a solid sample in a carefully defined optical configuration. According to the Gärtner equation, the photocurrent is given as (Sze, 1981; Lewis et al., 1989; Schroder, 1990)

$$I_{ph} = q\Gamma_0(1 - R^*)\left(1 - \frac{\exp(-\alpha W)}{1 + \alpha L}\right) \tag{30}$$

where L is the minority carrier diffusion length and R^* is the optical reflectivity of the solid. In a semiconductor sample with a very short minority carrier diffusion length and with $\alpha W \ll 1$, this equation simplifies to (Sze, 1981; Schroder, 1990)

$$I_{ph} = q\Gamma_0(1 - R^*)(\alpha W) \quad \text{for } \alpha L \ll 1 \tag{31}$$

Under these conditions, α can be measured directly from the photocurrent at each wavelength. These values can then be plotted against the photon energy to determine the band gap energy and transition profile, direct or indirect, for the semiconductor under study. The only parameter that needs to be controlled experimentally is Γ_0 at the various wavelengths of concern. Methods for determining and controlling Γ_0, which are common to this method and to other methods that use illuminated semiconductor-liquid contacts, are described in detail under Diffusion Length Determination Using Semiconductor-Liquid Contacts.

Data Analysis and Initial Interpretation

Figure 5 shows the spectral dependence of the photocurrent at an n-type MoS_2 electrode (Tributsch et al., 1977). The principal analysis step in determining the band gap energy or any other intrinsic parameter, such as the

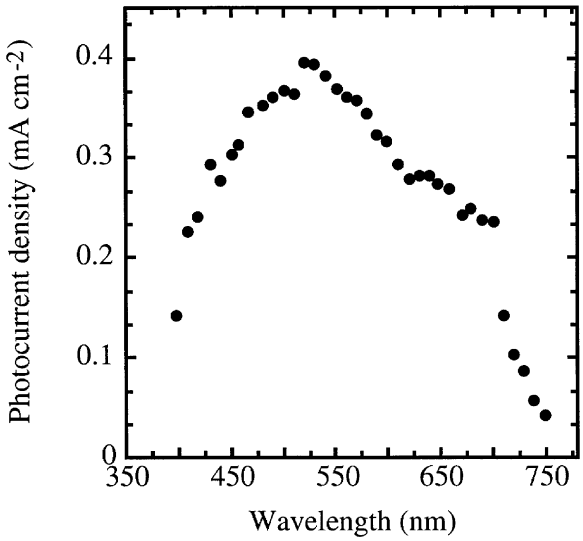

Figure 5. Spectral response of MoS_2 photocurrents (n type) in the anodic saturation region. (Reprinted with permission from Tributsch et al., 1977.)

diffusion length, from this spectrum depends on accurately transforming the wavelength-dependent photocurrent information to a corresponding absorption coefficient. With a table of absorption coefficients, photocurrent densities, and wavelengths, one can plot the absorption coefficient vs. photon energy and, by application of the methods described above, extract the band gap energy. The use of photocurrents to determine minority carrier diffusion lengths is discussed under Diffusion Length Determination Using Semiconductor-Liquid Contacts, below, and the subtleties of transforming this photocurrent data into absorption coefficients are illustrated.

DIFFUSION LENGTH DETERMINATION USING SEMICONDUCTOR-LIQUID CONTACTS

Principles of the Method

The minority carrier diffusion length L is an extremely important parameter of a semiconductor sample. This quantity describes the mean length over which photogenerated minority carriers can diffuse in the bulk of the solid before they recombine with majority carriers. The value of L affects the bulk diffusion-recombination limited V_{oc} and the spectral response properties of the solid.

The ASTM (American Society for Testing and Materials) method of choice for measurement of diffusion length is the surface photovoltage method. A conceptually similar methodology can, however, be used when a liquid provides the electrical contact to the semiconductor. Use of a semiconductor-liquid contact has the advantage of allowing a reproducible analysis of the surface condition as well as control over the potential across the semiconductor during the experiment. In either mode, the method works well only for silicon and other indirect gap materials.

We assume that the semiconductor is n type, so we are therefore interested in measuring the diffusion length of holes, L_p. Simplification of the Gärtner equation, assuming that $\alpha W \ll 1$, yields the following expression for the wavelength dependence of the open-circuit photovoltage (Sze, 1981; Lewis et al., 1989; Schroder, 1990):

$$V_{oc} \sim [1 + (L_p\alpha)^{-1}]^{-1} \tag{32}$$

Thus, provided that $L_p \gg W$ and $\alpha^{-1} \gg W$, a plot of $(V_{oc})^{-1}$ vs. α^{-1} will yield a value of the inverse of the slope that is equal to L_p. An additional check on the data is that the x intercept of the plot should equal $-L_p$ (Schroder, 1990).

Measurement of L_p using the surface photovoltage method in air requires that the semiconductor be capacitively coupled through an insulating dielectric such as mica to an optically transparent conducting electrode. However, for a semiconductor-liquid contact, either the photovoltage or photocurrent can be determined as a function of wavelength λ, and in this implementation the method is both nondestructive and convenient.

Practical Aspects of the Method

Both the surface photovoltage method and the determination of the optical properties of the semiconductor require accurate measurement of the wavelength dependence of the quantum yield for carrier collection at the semiconductor-liquid contact. The quantum yield is the ratio of the rate at which a specimen forces electrons through an external circuit, $I(\lambda)/q$, to the rate at which photons are incident upon its surface:

$$\Phi(\lambda) = \frac{I(\lambda)/q}{\Gamma_0(\lambda)A_s} \tag{33}$$

In this equation, $\Gamma_0(\lambda)$ represents the flux of monochromatic light, which is assumed to be constant over the area of the specimen, A_s.

Typically, the quantum yield is measured at short circuit. Commercial silicon photodiodes have very stable quantum yields of >0.7 throughout most of the visible spectrum, making them a nearly ideal choice for a calibration reference. The quantum yield of the experimental specimen can be calculated as follows:

$$\Phi_{cell}(\lambda) = \Phi_{ref}(\lambda)\left(\frac{I_{cell}(\lambda)A_{s,ref}}{I_{ref}(\lambda)A_{s,cell}}\right) \tag{34}$$

Experimentally, the excitation monochromator is scanned to record $I_{cell}(\lambda)$; then the experimental specimen is replaced with the reference and $I_{ref}(\lambda)$ is recorded. A significant source of error in this method, however, is the drift in the intensity of the light source over time, which can affect both $I_{cell}(\lambda)$ and $I_{ref}(\lambda)$.

A preferred experimental setup is shown in Figure 6. In this arrangement, the ratio of the photocurrent response of the experimental specimen to that of an uncalibrated photodiode, $I_{cell}(\lambda)/I_{uncal}(\lambda)$, is recorded as the experimental variable. It is not necessary to know the quantum yield or area of the uncalibrated photodiode, which merely acts to calibrate the light intensity at each wavelength. The geometry of the uncalibrated photodiode with respect to the light source and the pick-off plate should be arranged such that the surface of the uncalibrated diode is

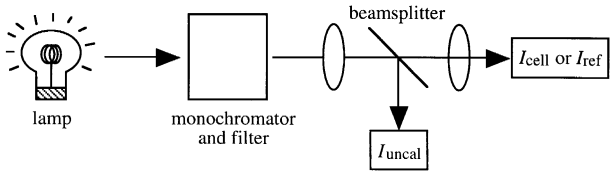

Figure 6. Spectral response measurement system consisting of a white light source, a monochromator, a beam splitter, and a calibrated photodiode.

illuminated by a small fraction of the light that is incident on the main specimen. If $t(\lambda)$ is the ratio of the light diverted to the uncalibrated photodiode relative to that which reaches the main specimen, then

$$I_{uncal}(\lambda) = q\Phi_{uncal}(\lambda)t(\lambda)\Gamma_0(\lambda)A_{s,uncal} \tag{35}$$

The photocurrent response of the calibrated photodiode relative to that of the same uncalibrated photodiode, $I_{ref}(\lambda)/I_{uncal}(\lambda)$, must also be determined. When $I_{cell}(\lambda)$ and $I_{ref}(\lambda)$ in Equation 34 are replaced with the ratios $I_{cell}(\lambda)/ I_{uncal}(\lambda)$ and $I_{ref}(\lambda)/I_{uncal}(\lambda)$, respectively, the unknown terms Φ_{uncal} and $A_{s,uncal}$ divide out.

In the foregoing discussion, we have assumed that the excitation light is continuous, e.g., furnished by a xenon arc lamp or a tungsten filament source coupled to a monochromator. Pulsed light sources can also be used, and the most convenient method is to have the excitation beam interrupted by a mechanical chopper, with a lock-in amplifier used to monitor the photocurrent. If the response time of the specimen is short compared to the chopping period, then this method yields exactly the same information as the DC experiment. However, lock-in detection offers a substantial advantage in the signal-to-noise ratio, which can be important at low light and/or low current levels. Also, for experiments that are not carried out at short circuit, but at some applied bias, this method provides for an automatic subtraction of the dark current. In addition, when a lock-in detection method is used, it is possible to measure the differential quantum yield of a signal that is superimposed on top of a DC illumination source. This information is very useful for materials that have quantum yields that are dependent on the incident light intensity. Finally, when the response time of the system is on the same order as the chopping period, variations in the photocurrent with the chopping period and analysis of the data in the frequency domain can yield detailed information about the kinetic process occurring in the semiconductor bulk and at the semiconductor-liquid interface (Peter, 1990).

Data Analysis and Initial Interpretation

To determine the diffusion length of a solid using photoelectrochemical methods, it is important to have an accurate relationship between the excitation wavelength and the absorption coefficient of the solid, because any error in this relationship leads to the calculation of incorrect values for the diffusion length in the analysis of the experimental data.

Although various equations have been proposed for the relationship between α and λ for silicon, the ASTM standard recommends the following for a stress-relieved, polished silicon wafer (Schroder, 1990):

$$\alpha = 5263.67 - 114425\lambda^{-1} + 5853.68\lambda^{-2} + 399.58\lambda^{-3} \tag{36a}$$

where the wavelength is in units of micrometers and the absorption coefficient is in units of reciprocal centimeters. This relationship is valid for the wavelength range of 0.7 to 1.1 μm, which is typically the range used for determining diffusion lengths. For a non−stress-relieved silicon wafer, the relationship is

$$\alpha = 10696.4 - 33498.2\lambda^{-1} + 36164.9\lambda^{-2} + 13483.1\lambda^{-3} \tag{36b}$$

Recent expressions have also been developed that accurately fit published absorption data for GaAs and InP. These expressions are

$$\alpha = (286.5\lambda^{-1} - 237.13)^2 \tag{36c}$$

for GaAs in the 0.75- to 0.87-μm wavelength range and

$$\alpha = (252.1\lambda^{-1} - 163.2)^2 \tag{36d}$$

for InP in the 0.8- to 0.9-μm wavelength range.

For quantitative results, the wavelength dependence of the optical reflectivity of the surface, R^*, must be known. Silicon has a weak dependence of reflectance on wavelength, which is given by the following empirical fit to the data:

$$1 - R^* = 0.6786 + 0.03565\lambda^{-1} - 0.03149\lambda^{-2} \tag{37}$$

Figure 7 illustrates the procedure for determining the diffusion length from a plot of Φ vs. $1/\alpha$ for silicon (Schroder, 1990). The minority carrier diffusion length is readily obtained by extrapolating the quantum yield data to the x intercept and taking the value of $1/\alpha$ when $\Phi = 0$. Since the quantum yield is measured at different wavelengths, the photon flux is adjusted to assure a constant photovoltage at each Φ measurement.

Other Methods for Determination of Diffusion Length. Many other methods for the measurement of minority carrier diffusion length involve determination of the minority carrier lifetime τ and the minority carrier diffusion constant D and application of the relationship $L = (D\tau)^{1/2}$ to determine the minority carrier diffusion length. One can, for example, monitor the bulk band-to-band radiative luminescence lifetime under conditions where the surface nonradiative recombination processes are negligible (Yablonovitch et al., 1987). Another technique uses the absorption of microwave radiation by free carriers. In this method, pulsed excitation of a semiconductor sample inside a microwave cavity produces a transient increase

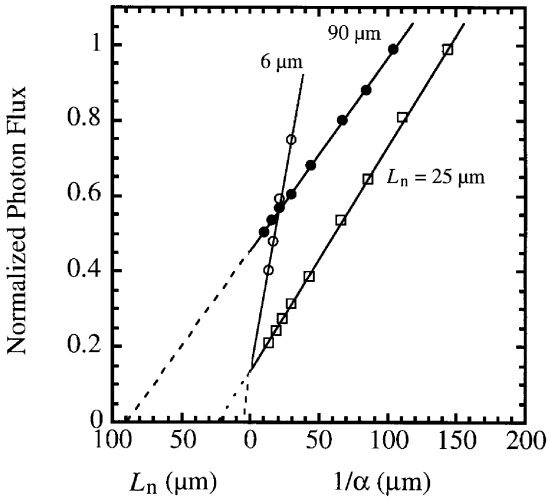

Figure 7. Plot of Φ vs. the inverse absorption coefficient for three Si diodes with different diffusion lengths. The minority carrier diffusion lengths are obtained from the value of $|1/\alpha|$ when the quantum yield is zero. (Reprinted with permission from Schroder, 1990.)

in microwave absorption, and the absorption decay yields the carrier lifetime (Yablonovitch et al., 1986). The analysis of the data to extract a value for τ, and thus to determine L_p, is similar in all cases, and details can be found, e.g., in the book by Many et al. (1965). Semiconductor-liquid contacts are very useful in certain circumstances, as in, e.g., the iodine-treated silicon surface in methanol, for which the surface recombination velocity is so low that the observed recombination is almost always dominated by nonradiative decay processes in the bulk of the silicon sample (Msaad et al., 1994). In these cases, measurement of the photogenerated carrier decay rate by any convenient method directly yields the minority carrier lifetime, and thus the minority carrier diffusion length, of the sample of concern. These values can also be spatially profiled across the semiconductor-liquid contact to obtain important information concerning the uniformity of the material properties of the bulk solid of interest.

DIFFERENTIAL CAPACITANCE MEASUREMENTS OF SEMICONDUCTOR-LIQUID CONTACTS

Principles of the Method

Differential capacitance measurements of semiconductor-liquid contacts are very useful in obtaining values for the dopant density of the bulk semiconductor that forms the semiconductor-liquid contact. In addition, such measurements have been found to be of great use in determining doping profiles of heterojunctions (Seabaugh et al., 1989) and of epitaxial layers of semiconductors (Leong et al., 1985) fabricated for use in light-emitting diodes, transistors, solar cells, and other optoelectronic devices.

To obtain an expression for the differential capacitance vs. potential properties of a semiconductor-liquid contact, we refer again to Equations 3 to 6, which describe the basic electrostatic equilibrium conditions at a semiconductor-liquid interface. Because all of the dopants in the depletion region are assumed to be ionized, the charge in the depletion region at a potential E can be expressed as

$$Q = \left[q\varepsilon\varepsilon_0 N_d\left(V_{bi} + E - \frac{kT}{q}\right)\right]^{1/2} \tag{38}$$

Taking the derivative of Q with respect to E yields an expression for the differential capacitance C_d of the semiconductor:

$$C_d = \frac{dQ}{dE} = \left[\frac{q\varepsilon\varepsilon_0 N_d}{2(V_{bi} + E - kT/q)}\right]^{1/2} \tag{39}$$

where ε is the relative permittivity of the semiconductor and ε_0 the permittivity of free space. A plot of C_d^{-2} vs. E (i.e., a Mott-Schottky plot) should thus yield a straight line that has a slope of $2(q\varepsilon_s N_d)^{-1}$ (with $\varepsilon_s = \varepsilon\varepsilon_0$ and an x intercept of $kT/q - V_{bi}$.

Equivalent Circuit Model for Measuring Differential Capacitance of Semiconductor-Liquid Contact. The most common procedure for obtaining differential capacitance vs. potential data is to apply a small AC (sinusoidal) voltage at the DC potential of interest. An analysis of the resulting cell impedance and phase angle in response to this sinusoidal perturbation yields the value of the semiconductor differential capacitance C_d. This method, of course, requires that C_d can be accessed from the experimentally measured electrical impedance behavior of a semiconductor-liquid contact. In general, an equivalent circuit is required to relate the measured impedance values to physical properties of the semiconductor-liquid contact.

The conventional description of the equivalent circuit for a semiconductor-liquid junction can be represented as in Figure 8A (Gerischer, 1975). The subscript s refers to

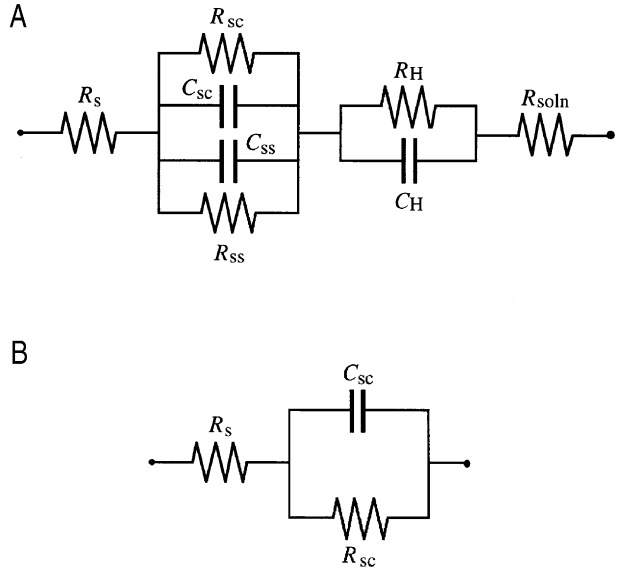

Figure 8. (**A**) Circuit of a semiconductor-liquid junction and (**B**) a simplification of that circuit.

the semiconductor bulk, sc to the space charge, ss to surface states, H to the Helmholtz layer, and soln to solution. This circuit is reasonable because there will clearly be a capacitance and resistance for the space-charge region of the semiconductor. Because surface states represent an alternate pathway for current flow across the interface, C_{ss} and R_{ss} are in parallel with the elements for the space-charge region. The Helmholtz elements are in series with both the space-charge and surface-states components, since current flows through the Helmholtz layer regardless of the pathway of current flow through the semiconductor. Finally, the series resistance of the electrode and contact and the solution series resistance are included as distinct resistive components in this circuit.

A possible simplification that can often be justified combines the resistances of the solution and of the electrode into one series resistor (Figure 8B). If the Helmholtz layer resistance is small, the RC portion of the Helmholtz layer circuit impedance is dominated by C_H. Furthermore, C_H is usually much larger than C_{sc}. Therefore, C_H can typically be neglected, because the smallest capacitance value for a set of capacitors connected in series dominates the total capacitance of the circuit. Additionally, if the AC impedance measurement is performed at a high frequency, such that surface states do not accept or donate charge as rapidly as the space-charge region, then the elements associated with surface state charging-discharging processes can also be neglected. Alternatively, if the surface state density of the semiconductor is low enough, the contributions of C_{ss} and R_{ss} are negligible.

At sufficiently high frequencies, the impedance of this simplified circuit can be written in terms of $G = (R_s)^{-1}$ and $B = (\omega C_{sc} R_s)^{-2}$, where G is the conductance and B is the susceptance (both in units of siemens). This yields the desired determination of C_d vs. E from the impedance response of the system. Once C_d is determined, Equation 39 is used to obtain a value for N_d. When using this method, C_d^{-2} vs. E should be determined at several different AC frequencies ω to verify that the slope and intercept do not change as the frequency is varied.

Practical Aspects of the Method

In a typical Mott-Schottky experiment, the DC bias to the electrochemical cell is delivered by a potentiostat, and the AC voltage signal is supplied by an impedance analyzer that is interfaced to the potentiostat. The DC potential applied to the semiconductor junction, which is usually in the range of 0 to 1 V vs. $E(A/A^-)$, is always in the direction of reverse bias, since forward-bias conditions induce Faradaic current to flow and effectively force the cell to respond resistively instead of capacitively. The input AC signal, usually 5 to 10 mV in amplitude, must be small to ensure that the output signal behaves linearly around the DC bias point and is not convoluted with the electric field in the semiconductor (Morrison, 1980).

The quantities that are measured by the impedance analyzer are the total impedance Z_{tot} and the phase angle θ between Z_{tot} and the input AC signal. From these data, the real component of the impedance, Z_{re}, which is defined by $Z_{re} = Z_{tot} \cos \theta$, and the imaginary component of the impedance, Z_{im}, which is defined by $Z_{im} = Z_{tot} \sin \theta$, can be calculated. For the simplified three-element equivalent circuit illustrated in Figure 8, the dependencies of Z_{tot} vs. AC signal frequency (Bode plot) and Z_{im} vs. Z_{re} (Nyquist plot) ideally obey patterns that not only permit extraction of the electrical elements in the circuit but also indicate the frequency range over which the cell acts capacitively. Of course, deviations from these ideal patterns can allow evaluation of the appropriateness of the theoretical equivalent circuit to the description of the experimental cell.

A typical Bode plot for a silicon electrode in contact with a redox-active solution is shown in Figure 9. At high frequencies f of the input AC voltage signal, the capacitive reactance χ_c [i.e., the effective impedance of the capacitor, given by $\chi_c = (2\pi f C_{sc})^{-1}$] is small relative to R_{sc}, so most of the current flows through the C_{sc} pathway, and the observed impedance is therefore simply R_s. At low frequencies, χ_c is high relative to R_{sc}, so most of the current flows through the R_{sc} pathway, and the observed impedance is $R_s + R_{sc}$. In the intermediate-frequency range, as is shown in Figure 9, increments in frequency translate directly into changes in χ_c, so the magnitude of Z_{tot} is dictated by C_{sc}. The Mott-Schottky measurements should be performed in this capacitive frequency regime, which ideally has a slope of -1 in a Bode plot.

A Nyquist plot is distinguished from the Bode plot in that it illustrates explicitly the branching between Z_{re} and Z_{im} as a function of frequency. A Nyqyist plot for a silicon electrode in contact with a redox-active solution is

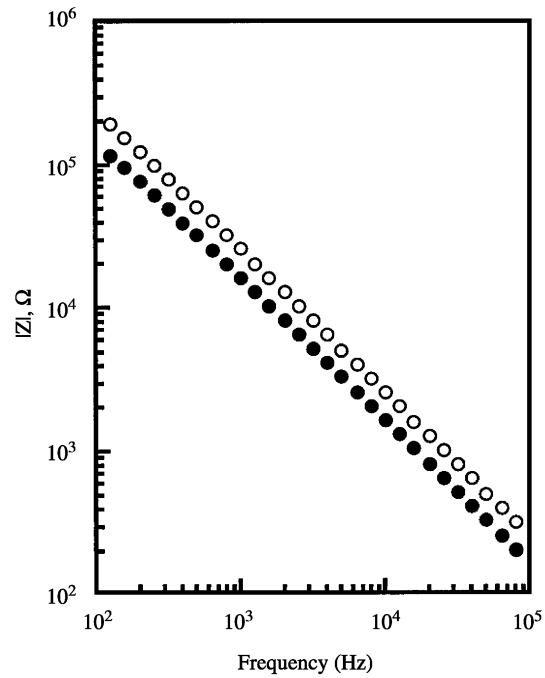

Figure 9. Typical Bode plots taken at intermediate frequencies where the impedance is dominated by capacitive circuit elements. The electrode-solution system is identical to that used to obtain the data in Figure 4. The open circles represent data taken at +0.2 V vs. $E(A/A^-)$ and the filled circles represent data taken at +0.8 V vs. $E(A/A^-)$.

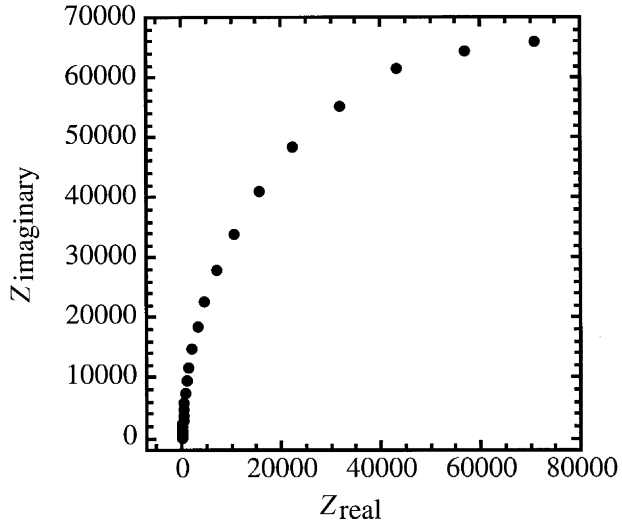

Figure 10. Nyquist plot for the system described in Figure 4. The data were collected at an applied DC bias of 0.45 V.

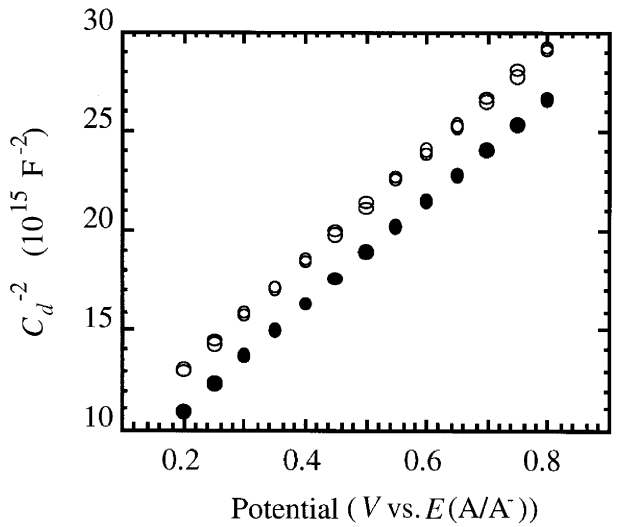

Figure 11. Mott-Schottky plots for the system described in Figure 4. The data shown are for two different concentrations of acceptor species and for two different acquisition frequencies, 100 and 2.5 kHz.

shown in Figure 10. At high frequency, $Z_{re} \cong R_s$. As the frequency is incrementally decreased, the contribution of Z_{im} rises until the magnitude of the capacitive reactance is identical to the resistance of R_{sc}. At this point, equal current flows through the circuit elements C_{sc} and R_{sc}. As the frequency is decreased further, the system behaves increasingly resistively, until the impedance is entirely dictated by R_{sc}. In practice, since the frequency may not reach a point where the system is predominantly resistive, it is generally easier to extract the value of R_{sc} from a Nyquist plot than from a Bode plot. Circle-fitting algorithms can provide reasonable estimates of R_{sc} if the Nyquist plot possesses a sufficient arc over the frequency range explored experimentally.

Data Analysis and Initial Interpretation

Assuming the three-element equivalent circuit depicted in Figure 8B,

$$C_{sc} = \frac{1 + \sqrt{1 - 4Z_{im}^2/R_{sc}^2}}{2\omega Z_{im}} \qquad (40)$$

where the angular frequency $\omega = 2\pi f$. It is also assumed that $R_s \ll R_{sc}$, so that R_s contributes negligibly to the measured impedance. Typically, since R_s is on the order of 10^2 Ω and R_{sc} is on the order of 10^5 to $10^7\Omega$, Equation 40 gives an accurate value for C_{sc}. Therefore, measurement of Z_{im} at various frequencies and DC biases, as well as extraction of the R_{sc} value at each DC bias from the circular fit of the Nyquist plot at that potential, allows calculation of C_{sc}. The subsequent compilation of C_{sc}^{-2} vs. E for each frequency yields the Mott-Schottky plot, as shown in Figure 11 for a typical silicon-solution interface. Linear regression of these data points and extrapolation of these linear fits to the x intercepts of $C_{sc}^{-2} = 0$ gives the value of V_{bi} for each frequency.

Differential capacitance measurements can readily be performed with a potentiostat in conjunction with an impedance analyzer, both of which are set up as described above, yielding direct values of the imaginary and real components of the impedance. Alternatively, AC voltametry can be performed using a potentiostat in conjunction with a waveform generator and a lock-in amplifier. In this technique, the magnitude of the AC component of the current (i.e., Z_{tot}) and the phase angle with respect to the input AC signal are measured at a given frequency. The real and imaginary parts of the impedance can then be extracted as described above. This powerful technique therefore requires no additional capabilities beyond those that are required for basic measurements of the behavior of semiconductor photoelectrodes.

In aqueous solutions, useful electrolytes are those that yield anodic dissolution of the semiconductor but do not etch the solid or produce a passivating oxide layer in the absence of such illumination. For Si, the appropriate electrolyte is NaF-H_2SO_4 (Sharpe et al., 1980), whereas for GaAs, suitable electrolytes are Tiron (dihydroxybenzene-3,5-disulfonic acid disodium salt) and ethylenediaminetetraacetic acid (EDTA)–0.2 M NaOH (Blood, 1986). A variety of nonaqueous solutions can also be used to perform differential capacitance measurements, although more attention needs to be paid to series resistance effects in such electrolytes.

Either solid-state or solid-liquid junctions can be utilized to measure the dopant density of the bulk semiconductor from C^{-2}-vs.-E plots, as described above. Solid-liquid contacts offer the additional opportunity to conveniently obtain a depth profile of the semiconductor doping level in the same experimental setup. A more comprehensive review of the technique of electrochemical profiling is given by Blood (1986).

To characterize the dopant profile through the solid, an anodic potential is applied to the semiconductor electrode such that the surface is partially dissolved. The thickness of material dissolved from the electrode, W_d, is given by the

time integral of the current density passed, J (Ambridge et al., 1975):

$$W_d = \frac{M}{n + F\rho}\int J\, dt \tag{41}$$

where M is the molecular weight of the semiconductor, n^+ is the number of holes required to oxidize one atom of the electrode material to a solution-phase ion, and ρ is the density of the solid. A separate Mott-Schottky plot is then obtained at each depth of etching through the material. The depth of the dopant density measurement is given by $W' = W + W_d$. Thus, periodic dissolutions and Mott-Schottky determinations can yield a complete profile of N_d as a function of distance into the solid.

Problems

The most prevalent problem in Mott-Schottky determinations is frequency dispersion in the x intercepts of the linear regressions. Nonlinearity in these plots may originate from various experimental artifacts (Fajardo et al., 1997). If the area of the semiconductor is too small, edge effects may dominate the observed impedance. The area of the counter electrode must also be large relative to the working electrode (as a rule of thumb, by a factor of 10), to ensure that any electrochemical process occurring at the counter electrode does not introduce additional electrical elements into the equivalent circuit. Additionally, the redox component that is oxidized or reduced at the counter electrode must have a sufficient concentration in solution (roughly 5 mM), or this redox process may be manifested as an additional resistance that is a major component of the total cell impedance. Finally, the measuring resistor within the potentiostat should be adjusted in response to the magnitude of the currents passing through the cell in order to obtain the most accurate impedance value possible.

TRANSIENT DECAY DYNAMICS OF SEMICONDUCTOR-LIQUID CONTACTS

Principles of the Method

Solid-liquid junctions are very useful in determining the electrical properties of the semiconductor surface. Principal methods in this endeavor involve measurement of the transient carrier decay dynamics, electrochemical photocapacitance spectroscopy (EPS), and laser spot scanning (LSS) techniques.

Under conditions where bulk recombination is slow relative to surface recombination, measurements at the solid-liquid interface can provide valuable information regarding the concentration and energetics of electrical trap sites at the semiconductor surface. Furthermore, the presence of a liquid allows, in principle, manipulation of these trap levels through chemical reactions induced by addition of reagents to the liquid phase. Methods for determining the surface recombination velocity of solid-liquid interfaces are therefore described here.

The rate of nonradiative recombination mediated through surface states can be described under many experimental conditions by the steady-state Shockley-Read-Hall (SRH) rate equation (Hall, 1952; Shockley et al., 1952; Schroder, 1990; Ahrenkiel et al., 1993):

$$R_{SRH}(\text{surface}) = \frac{n_s p_s - n_i^2}{(n_s + n_{1,s})/N_{t,s}k_{p,s} + (p_s + p_{1,s})/N_{t,s}k_{n,s}} \tag{42}$$

where n_i is the intrinsic electron concentration for the semiconductor, $N_{t,s}$ defines the density of surface states (in units of reciprocal centimeters squared), p_s is the surface hole concentration, and $k_{n,s}$ and $k_{p,s}$ are the capture coefficients for electrons and holes, respectively, by surface states. Each capture coefficient is related to the product of the thermal velocity v of the carrier in the solid and the capture cross-section σ for each kinetic event such that (Many et al., 1965; Krüger et al., 1994a)

$$k_{p,s} = \nu_p\sigma_p \quad \text{and} \quad k_{n,s} = \nu_n\sigma_n \tag{43}$$

The symbols $n_{1,s}$ and $p_{1,s}$ in Equation 42 represent the surface concentrations of electrons in the conduction band and holes in the valence band, respectively, when the Fermi level is at the trap energy. Values for $n_{1,s}$ and $p_{1,s}$ can be obtained through use of the principle of detailed balance, which, when applied to a system at equilibrium in the dark, yields (Many et al., 1965; Blakemore, 1987)

$$n_{1,s} = N_c\exp[(E_{cb} - E_t)/kT] \tag{44a}$$

and

$$p_{1,s} = N_v\exp[(E_t - E_{vb})/kT] \tag{44b}$$

where E_t is the energy of the surface trapping state.

When other recombination processes are minimal and the initial carrier concentration profiles are uniform throughout the sample, surface recombination should dominate the entire decay properties of the sample. Under these conditions, the observed minority carrier decay dynamics are given by (Ahrenkiel et al., 1993)

$$\text{Rate} = -\frac{d\Delta p}{dt} = R_{SRH} \approx \frac{\Delta p}{\tau_{s,1}} \tag{45}$$

Furthermore, under such conditions, the fundamental filament decay lifetime $\tau_{s,1}$ is given by (Schroder, 1990; Ahrenkiel et al., 1993)

$$\tau_{s,1} = d/S_{low} \quad S_{low} \equiv S_p = N_{t,s}k_{p,s} \tag{46}$$

where d is the thickness of the sample and S_{low} is the surface recombination velocity (in units of centimeters per second) at low-level injection ($\Delta n < N_d$ and $\Delta p < N_d$).

The other limiting situation is obtained under uniform illumination at an intensity high enough to produce high-level injection conditions (i.e., $\Delta n \gg N_d$ and $\Delta p \gg N_d$). By using Equation 42 with injected carrier concentrations $\Delta n \gg N_d$ and $\Delta p \gg N_d$ and, because equal numbers of

electrons and holes are created by the optical injection pulse, taking $\Delta n = \Delta p$, the recombination rate is

$$\text{Rate} = \frac{d\,\Delta p}{dt} = R_{\text{SRH}} \approx \frac{\Delta p}{\tau_{\text{s,h}}} \tag{47}$$

Now, however, the filament decay lifetime is (Blakemore, 1987; Schroder, 1990)

$$\tau_{\text{s,h}} = \frac{d}{S_{\text{high}}} \qquad S_{\text{high}} = \frac{S_{\text{p}} S_{\text{n}}}{S_{\text{p}} + S_{\text{n}}} \tag{48}$$

For conditions of $k_{\text{p,s}} = k_{\text{n,s}}$, $S_{\text{high}} = \frac{1}{2} S_{\text{low}}$, and the surface recombination decay lifetime under high-level injection, $\tau_{\text{s,h}}$, is equal to $2\tau_{\text{s,l}}$.

Practical Aspects of the Method

The carrier concentration decays can be monitored using a number of methods. Luminescence is a convenient and popular probe for direct band gap semiconductors, while for materials like silicon, conductivity methods are often employed. The two methods are complementary in that the photoluminescence signal decays when either the minority or majority carrier is captured, whereas conductivity signals are weighted by the individual mobilities of the carrier types. Thus, if all of the holes in silicon were to be trapped, the band gap luminescence signal would vanish, whereas the conductivity signal would still retain 75% of its initial amplitude (because of the carrier mobilities for silicon, $\mu_{\text{n}} \simeq e\mu_{\text{p}}$). Either method can be used to probe the carrier concentration dynamics, and both are sometimes used on the same sample to ensure internal consistency of the methodology. A somewhat more specialized method of monitoring the carrier concentrations has also been recently developed using ohmic-selective contacts on silicon, where the photovoltage developed between these contacts yields a probe of the carrier concentration decay dynamics in the sample of concern (Tan et al., 1994a).

Measurements of Surface Recombination Velocity Using Time-Resolved Photoluminescence Methods. One of the most reliable methods for monitoring minority carrier decay dynamics is the time-resolved photoluminescence (TRPL) method. The use of time-correlated single-photon counting has added further sensitivity to the TRPL technique and has allowed for sub-picosecond lifetime measurements.

To perform time-correlated single-photon TRPL, one starts with pulsed, short-time monochromatic laser light tuned to an energy greater than the band gap energy of the material under study. This laser source can be produced by the output of a pulse-compressed Nd-yttrium-aluminum garnet (YAG) pumped dye laser, if picosecond timing resolution suffices, or from the fundamental mode of a solid-state Ti-sapphire laser, if even shorter time resolution is desired. The timing characteristics of the laser pulse can be determined through use of an autocorrelator. Any chirping in the light source must be removed by passing the light through a few meters of optical fiber.

Prior to reaching the sample surface, the laser light is split by means of a beam splitter (Fig. 12). The less intense optical beam emanating from the beam splitter is directed into a photodiode, while the more intense beam is directed onto the semiconductor sample. The photodiode and sample must be positioned at equal distances from the beam splitter to ensure correct timing in the experiment. The voltage output of the photodiode is directly connected to the START input of a time-to-amplitude converter (TAC). Thus, with each laser pulse, the sample is illuminated and the TAC is triggered on (start). Both the beam diameter and the polarization of the incident light are experimental parameters used for controlling the light intensity, and thus the injection level, of the semiconductor.

The light emitted by the sample due to radiative recombination processes is collected and focused onto a spectrometer that is tuned to the wavelength of the transition to be monitored. The light output from this spectrometer is then directed onto a single-photon detector. When a single photon is detected, the resulting voltage output produced by the detector is used to trigger the STOP input of the TAC. Once triggered into the off position, the TAC will in turn produce a voltage pulse whose magnitude is linearly dependent on the time duration between the START and STOP signals. The distribution of voltage-pulse magnitudes is thus a distribution in time of the photons emitted from the sample after initial illumination. By allowing a computer-controlled multichannel analyzer (MCA) to display a histogram, with respect to magnitude, of the distribution of the voltage pulses that are produced by the TAC, a single-photon TRPL spectrum is obtained (Ahrenkiel et al., 1993; Kenyon et al., 1993).

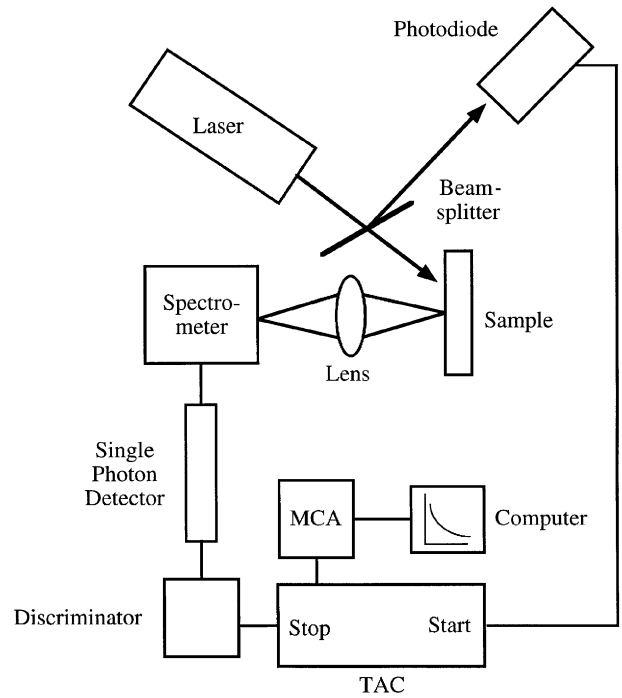

Figure 12. Time-resolved single-photon photoluminescence spectrometer.

To enhance the signal-to-noise ratio in a TRPL spectrum, it is necessary to place a pulse- height discriminator between the single-photon detector and the STOP input of the TAC. This discriminator will ensure that low-voltage pulses that arise from either electronic or thermal noise and/or high-voltage pulses that can be produced by multiphoton events do not accidentally trigger the STOP signal on the TAC. To obtain the true TRPL spectrum for minority carriers, this experimentally obtained TRPL spectrum must be deconvoluted with respect to the system response function of the entire apparatus. The system response function must be determined independently for the setup of concern and is typically measured by exciting a diffuse reflector or scattering solution instead of the semiconductor. A variety of numerical methods allow generation of the corrected photoluminescence decay curve from the observed TRPL decay and the system response function (Love et al., 1984). Deconvolution is especially important if the TRPL decay time is comparable to the system response time.

The success of the single-photon counting method is due to the development of detectors with sufficient gain and time response that a single photon produced by an electron-hole recombination event can be detected within a system response time of 30 ps. Two varieties of these detectors are photomultiplier tubes (PMTs) and microchannel plates (MCPs). A limitation of these detectors, however, is that only photon energies 1.1 eV can be detected. Recently, advancements in the timing resolution of single-photon avalanche photodiodes (SPADs) have allowed for detection of photons in the near-infrared region and have raised the possibility of performing TRPL with materials having a band gap of <1.1 eV, so that additional semiconductor materials can be explored using this approach.

Data Analysis and Initial Interpretation

Once a TRPL spectrum is recorded and the effective lifetime τ_{pl} has been measured, it is necessary to extract the lifetime for surface recombination, or any other dominant recombination mechanism. The rate of radiative band-to-band emission R_r from a semiconductor is given by (Pankove, 1975; Ahrenkiel et al., 1993; Krüger et al., 1994b)

$$R_r = k_r(np - n_i^2) \tag{49}$$

where k_r is the rate constant for radiative recombination. For low-level injection, Equation 49 reduces to

$$R_r = K_r[(N_d + \Delta n)(p_0 + \Delta p) - n_i^2] \approx k_r N_d \Delta p \tag{50}$$

or

$$R_r = -d(\Delta p)/\Delta p = k_r N_d\, dt \tag{51}$$

where p_0 is the equilibrium minority carrier concentration in the dark.

When nonradiative recombination mechanisms such as surface recombination are active in parallel with radiative recombination, the measured photoluminescence signal $I_{pl}(t)$ for a volume element in the solid containing a spatially uniform density of excess minority carriers is given by (Ahrenkiel et al., 1993; Krüger et al., 1994a)

$$I_{pl}(t) = \frac{\Delta p_0 \exp(-\tau/\tau_{pl})}{\tau_{r,l}} \quad (\text{photons cm}^{-3}\,\text{s}^{-1}) \tag{52}$$

where Δp_0 is the initial density of injected minority species after the laser excitation. The quantity τ_{pl} is the measured effective total lifetime for the system, which is determined from the experimental TRPL spectrum (Fig. 13) and is expressed as

$$\frac{1}{\tau_{pl}} = \frac{1}{\tau_s} + \frac{1}{\tau_r} \tag{53}$$

where τ_r is the radiative lifetime and τ_s is the surface recombination lifetime. Depending on the injection level, τ_r is defined as either (Many et al., 1965; Schroder, 1990)

$$\tau_{r,l} = \frac{1}{k_r N_d} \quad \text{low injection} \tag{54a}$$

or

$$\tau_{r,h} = \frac{1}{k_r\, \Delta p_0} \quad \text{high injection} \tag{54b}$$

Since k_r, N_d, and Δp_0 are all measurable parameters, the decay time for a luminescence spectrum can be easily deconvoluted through application of Equation 53 to retrieve the surface recombination lifetime and the resulting surface recombination velocity for a semiconductor of known thickness.

One problem in TRPL experiments involves the fraction of surface area of the semiconductor that is illuminated by the laser beam. The illumination should always be uniform across the surface. Frequently, the injection level is

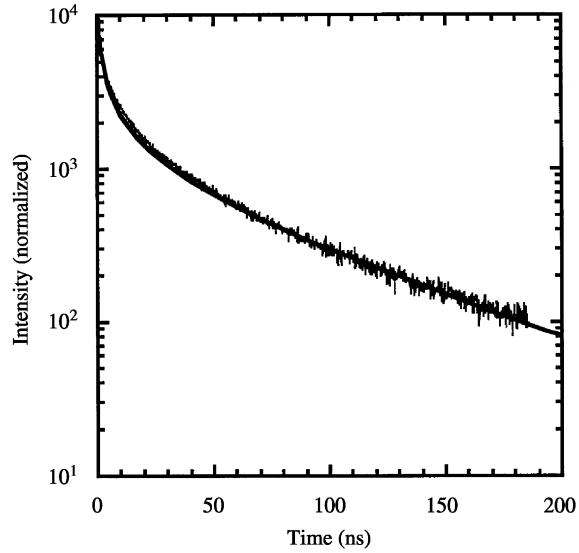

Figure 13. Fitting example of a time-resolved photoluminescence decay.

controlled by controlling the diameter to which the laser light is focused. However, carrier recombination kinetics in the dark differ from those in the light. With a nonuniformly illuminated surface, photogenerated carriers can diffuse into the nonilluminated regions of the semiconductor. The net recombination lifetime measured will thus be a convolution of lifetimes for processes occurring in the illuminated and nonilluminated regions of the semiconductor. This is especially of concern with beam spots $\sim 10\,\mu m$ in diameter. In such situations one cannot make a quantitative assessment for the carrier dynamic lifetimes of an illuminated semiconductor because the majority of the recombination occurs in the unilluminated regions of the sample. In essence, the desired lifetime is affected by "background" recombination lifetimes occurring in the dark.

The repetition rate of modern lasers is also of concern, as is their intensity. The repetition rate should always be set such that all carrier concentrations return to their equilibrium dark values prior to the subsequent laser pulse. Otherwise, the injection levels and hence recombination lifetimes will vary from pulse to pulse. For a semiconductor in accumulation, the time to restore equilibrium can be as large as a few milliseconds. Thus the repetition rate should be regulated as the bias across the semiconductor is varied. One method of increasing the time between subsequent pulses is to use a Kerr shutter as a pulse gate.

Caution should also be taken to ensure that the laser intensity does not induce sample damage. The following protocols should always be followed to assure that lifetimes derived from TRPL experiments are reliable. First, Mott-Schottky measurements should be performed to extract the flat-band potential and barrier height. Second, *J-E* curves should be acquired both in the dark and under the same light intensity conditions that will be used in the TRPL experiments. Finally, after performing the TRPL experiments, the Mott-Schottky and *J-E* curves should be redetermined to verify that the integrity of the sample has not been compromised during the TRPL measurement.

MEASUREMENT OF SURFACE RECOMBINATION VELOCITY USING TIME-RESOLVED MICROWAVE CONDUCTIVITY

Principles of the Method

Another contactless method for measuring the lifetime of minority carriers after an initial excitation pulse is time-resolved microwave conductivity (TRMC). The change in reflected microwave power, $\Delta R_M(t)$, is proportional to the change in the conductivity of the semiconductor. This conductivity change is, to first order, a measure of the time dependence of excess minority carriers in the semiconductor (Naber et al., 1969; Chen, 1988; Forbes et al., 1990; Schroder, 1990; Ramakrishna et al., 1995):

$$\begin{aligned} &\Delta R_M(t) \simeq \Delta\sigma(t) = q(\mu_n \Delta n + \mu_p \Delta p) \\ &\Delta R_M(t) \simeq q(\mu_n + \mu_p)\Delta P \text{ (under low-level inection)} \end{aligned} \tag{55}$$

Practical Aspects of the Method

To implement the method, either the semiconductor under study is connected to a microwave source through a radio frequency (RF) coupler, which consists of a series of coils connected to the base of the sample mount, or the sample is connected to the source using a waveguide. The waveguide system offers numerous advantages. Since the sample is mounted inside the waveguide and is illuminated colinearly with the microwave radiation, better protection from electromagnetic interference and better-defined and more uniform microwave radiation is available.

A microwave experimental setup consists of four primary components (Fig. 14): (1) the source, which consists of a microwave generator, an isolator, and an attenuator; (2) the sample, which is mounted onto the end of a microwave waveguide; (3) the detector, which by rectification creates a voltage across a load resistor, with the voltage being proportional to the amplitude of the reflected microwave power; and (4) the power meter (a short-circuit plate consisting of silver-plated brass), which is used to measure the power from the source and is mounted on a separate waveguide at an equal distance from the source and the sample. These four components are positioned around a microwave circulator (Schroder, 1990).

Microwaves from the source, usually $\kappa\alpha$ radiation from a Gunn diode operating at $\sim$10 GHz, are directed via the circulator to the waveguide system that contains the sample. The reflected microwaves are in turn directed by the circulator to the detector. Most commercially available circulators allow for timing resolutions in the sub-nanosecond regime. To measure the source power, the circulator directs microwaves to the short-circuit plate rather than to the sample. During the experiment, the sample is initially illuminated by a laser pulse or strobe light, which also triggers an oscilloscope. The reflected microwaves are amplified and measured, and the corresponding signal is displayed on the oscilloscope as a function of time from this illumination. The reflected microwaves not only emanate only from the surface of the semiconductor, but

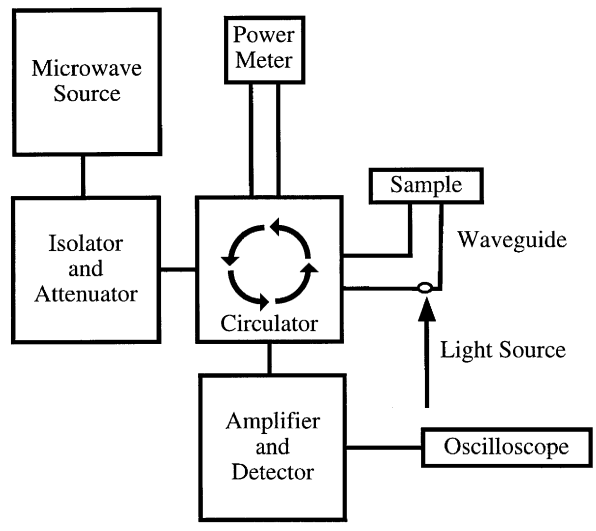

Figure 14. Microwave reflectance spectrometer.

actually penetrate a skin depth into the sample. For silicon at 10 GHz, this skin depth is 350 μm for a resistivity of 0.5 Ω-cm and is 2200 μm for a resistivity of 10 Ω-cm. Once the microwave spectrum is collected by a digital oscilloscope, the lifetime can be measured directly.

Data Analysis and Initial Interpretation

Figure 15 displays the microwave conductivity decay for *n*-Si (solid line) in contact with concentrated sulfuric acid under high-level injection conditions (10^{15} injected carriers per square centimeter in a 190-μm-thick sample) (Forbes et al., 1990). The data can be fit using a simulation package that takes into account all aspects of drift-diffusion, generation, recombination, and charge transfer for photogenerated carries in a semiconductor. Since most bulk parameters for common semiconductors are known, simulations are performed by parametrically varing an unknown parameter, such as the surface recombination velocity, until a fit with a minimal residual is obtained. Such a simulated fit is shown in Figure 15 (dotted line) for a surface recombination velocity of 25 cm s^{-1} and a bulk lifetime of 2 ms.

If no simulation package is available, a spectrum can be fit with a biexponential of the form

$$I(t) = A_1 \exp(-t/\tau_1) + A_2 \exp(-t/\tau_2) \qquad (56)$$

The fit is performed from the time of peak conductivity intensity to the time at which the conductivity signal has decayed to 1% of its peak value. Subsequently, the resultant fit can be described with an effective lifetime value, $\langle\tau\rangle$, computed using the relationship

$$\langle\tau\rangle = \frac{A_1\tau_1 + A_2\tau_2}{A_1 + A_2} \qquad (57)$$

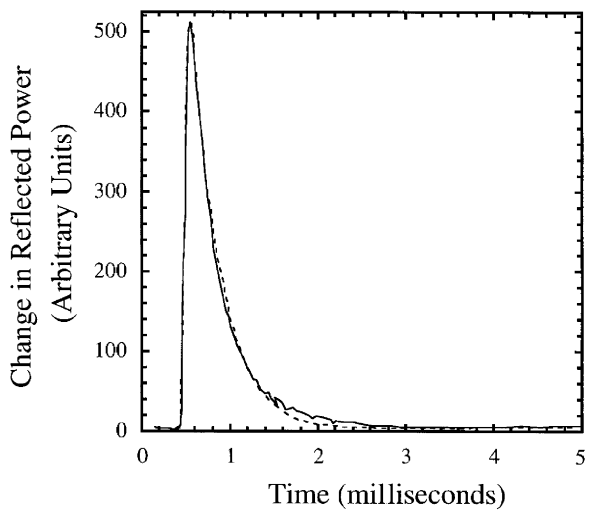

Figure 15. Microwave conductivity decay (solid line) under high injection (10^{15} carriers/cm^2) for a 190-μm thick sample of *n*-Si in contact with concentrated sulfuric acid. A simulation with a surface recombination velocity of 25 cm/s^1 and a bulk lifetime of 2 ms is shown (dotted line) for comparison. (Reprinted with permission from Forbes et al., 1990.)

where A_1 and A_2 are the preexponential factors and τ_1 and τ_2 are the exponential decay times of the fit (Equation 56). This effective lifetime has terms that are linear rather than quadratic with respect to the decay times τ_n. Equation 57 hence does not bias a $\langle\tau\rangle$ value toward the longer of the two decay times derived from the fitting procedure. The above-mentioned fitting procedure is also applicable to all time-dependent decay phenomena, such as radiative recombination, discussed under Transient Decay Dynamics of Semiconductor-Liquid Contacts, above.

Sample Preparation

Measurements of bulk or surface parameters require two different sample preparation procedures. If one is interested in bulk recombination lifetimes, then the samples should be made progressively thicker, on the order of 1 mm, as the bulk lifetime to be measured becomes longer, and the surface recombination velocity should be made as small as possible. For measurement of the surface recombination velocity, the sample should be of the thickness typically used in wafers, or on the order of 0.1 mm. The sample should also be polished on both ends to ensure consistent transmission and reflectivity of the microwaves. The electrolyte must also not be too conductive or the radiation signal will be greatly attenuated.

Microwave conductivity experiments permit a great deal of versatility as to the sample geometry that can be used. Of concern, however, is what percentage of the microwave decay signal recorded is indeed that of the semiconductor and not that of the measurement apparatus. When the geometry of a sample/apparatus is off resonance, it has been found that the system response is very fast, while an on-resonance cavity results in a large increase in the system fall time. One method of determining the extent of resonance in microwave experiments is to use etched silicon wafers as calibration templates. It has been determined that Si wafers etched in $HF:HNO_3:CH_3COOH$ solutions result in a surface recombination velocity as large as 10^5 cm s^{-1}. Conversely, it has been shown that immersing the sample in HF during decay measurements gives a measured surface recombination velocity as low as 0.25 cm s^{-1}. Both these protocols are useful when calibrating one's instrument and/or samples.

ELECTROCHEMICAL PHOTOCAPACITANCE SPECTROSCOPY

Principles of the Method

Photocapacitance spectroscopy has been used to characterize deep-level states in semiconductors since the mid-1960s. The use of EPS, however, offers many advantages relative to solid-state photocapacitance measurements. The presence of an electrolyte in EPS measurements allows leakage currents to be reduced by adjusting the availability and reorganization energy of electronic states in the electrolyte. Also, EPS can be used for depth profiling of trap states because layers of the semiconductor can be etched between subsequent EPS measurements. The depth-profiling procedure allows for detailed examination

of the influence of surface oxide layers or surface passivation layers on the surface recombination kinetics. If the etching is performed electrochemically, then the entire depth-profiling and EPS experiment can be conducted in a single apparatus (Haak et al., 1982).

Basic Principles of EPS. The principles behind EPS are relatively straightforward. As described in Equations 38 to 40, the differential capacitance of the semiconductor-liquid contact is dominated by the differential capacitance of the space-charge layer of the semiconductor. Any additional charge introduced by injection of carriers into the solid, either optically or thermally, will therefore either populate or depopulate states in the bulk or surface of the semiconductor. This change in charge density in the solid will affect the thickness of the space-charge layer. In turn, the change in space-charge layer thickness will affect the capacitance of the semiconductor-liquid junction. Measurement of the capacitance as a function of the wavelength (energy) of sub–band-gap light incident onto the semiconductor-liquid junction can therefore provide information on the energies, time constants, physical location, and character (i.e., either acceptor or donor) of the traps in the semiconducting electrode.

A typical EPS spectrum will exhibit plateaus and/or peaks (Fig. 16). A plateau is observed in the spectrum when a transition involves one of the bands of the semiconductor, because once a threshold energy for the transition has been reached, transitions either to or from a band can proceed over a wide range of photon energies. In contrast, the EPS spectrum exhibits a peak whenever localized state or impurity/defect atoms participate in the charge injection process. These injections require two-level transitions and thus are only observable over a smaller range of illumination wavelengths (energy) (Anderson, 1982; Haak et al., 1982; Goodman et al., 1984; Haak et al., 1984).

The energy of a localized state relative to a band edge energy is given by the onset energy of the peak in the EPS spectrum. When all of the states at a given illumination energy have been saturated, populated, or depopulated, the spectrum will saturate with respect to capacitance as the illumination intensity is increased. The density of such states can thus be measured from the magnitude of the capacitance at saturation. Furthermore, by fixing the intensity of the light and scanning a range of energies around a plateau or peak, the optical absorption cross-section for trap states can be measured from the rate of change of the capacitance with time. The corresponding emission rate can then be determined from the rate of decay of the capacitance with time after the interruption of the incident illumination (Haak et al., 1984).

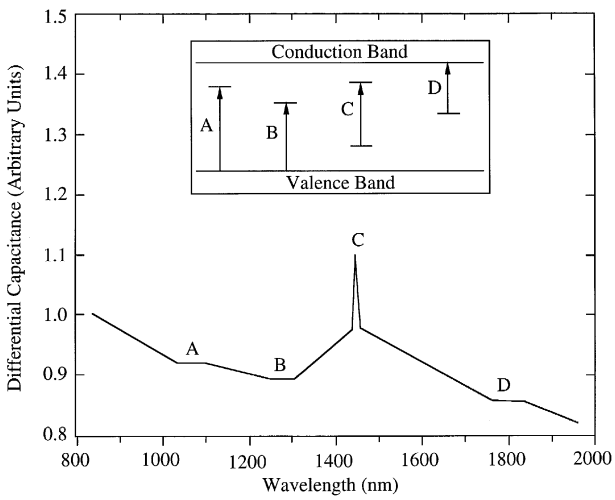

Figure 16. Electrochemical photocapacitance spectrum. Displayed is the measured differential capacitance as a function of the wavelength of the incident light. The inset illustrates various types of electro-optical transitions that can be associated with the observed plateaus and peaks in the EPS spectrum.

With EPS, contributions to the measured capacitance from bulk and surface states can be distinguished by taking EPS measurements at constant illumination for different bias voltages. The bias voltage determines the thickness of the space-charge layer and thus allows measurement of the density of bulk states constituting the space-charge layer. The bias voltage has, however, little influence on the potential drop at the surface or in the Helmholtz layer. The rate of change of the EPS capacitance at a fixed illumination energy and intensity as a function of sample bias thus provides a measure of the density of bulk trap states as a function of the sample thickness.

Quantifying Electrochemical Photocapacitance Spectra

Bulk Capacitance Measurements. The density of bulk states (in reciprocal cubic centimeters) can be readily derived from the Mott-Schottky relations of Equations 38 to 40. Upon algebraic manipulation, the density of optically active states at a particular illumination energy is given by (Anderson, 1982; Haak et al., 1982, 1984; Goodman et al., 1984)

$$N_t(\lambda) = \pm \frac{8\pi[E - E(A/A^-)]}{\varepsilon_{sc} q} (C_0^2 - C_d^2) \qquad (58)$$

where C_d is the differential capacitance measured at this particular illumination energy (and corresponds to photons of energy just above the threshold energy for trap states of interest) and C_0 is the capacitance measured just prior to reaching the threshold energy for the trap states of interest. At an illumination intensity sufficient to saturate all of the trap states at the energy under study, the measured plateau or peak capacitance, $C_{d,sat}$, corresponds to the total density of bulk trap states, N_t, optically excitable at this particular illumination energy. The $\pm$ in Equation 58 takes into consideration the fact that $N_t(\lambda)$ can either increase or decrease as the space-charge layer is either populated or depleted of charge carriers. Changes in $N_t(\lambda)$ also are related to the character of the state, with acceptor states becoming more positive when emptied and donor states becoming more negative when emptied.

Surface Capacitance Measurements. The density of surface states (in reciprocal centimeters squared) can similarly

be expressed from the Mott-Schottky relationships. In a derivation analogous to the bulk state treatment of Equation 39, the density of surface states at a particular illumination energy can be shown to be (Anderson, 1982; Haak et al., 1982, 1984; Goodman et al., 1984)

$$N_{t,s}(\lambda) = \pm \frac{\varepsilon_{sc} N_d C_H}{8\pi} \left(\frac{1}{C_0^2} - \frac{1}{C_d^2} \right) \quad (59)$$

where C_d is the differential capacitance measured at the threshold energy for which the surface states under study are ionized (populated or depopulated) and C_0 is the capacitance measured at an illumination energy just prior to influencing the surface states under study. As for the case of bulk states, the measured capacitance at saturation is the total number of surface states present at a particular illumination energy, $N_{t,s}$.

Kinetic Rates. The kinetics of filling and emptying optically active states can also be deduced using EPS. Kinetic equations can be derived for both surface and bulk states, but only surface kinetic processes will be discussed in detail. To perform these measurements, the sample is subjected to an intense initial illumination pulse capable of saturating the states of interest. The capacitance is then measured continuously after the illumination is terminated. The time rate of change in the measured capacitance parallels the time rate of change for the concentration of filled surface states and is given by (Haak et al., 1984)

$$\frac{dN_{t,s}}{dt} = \kappa_s [N_{t,s} - N_{t,s}(\lambda)] - \kappa_n n_s \quad (60)$$

where κ_s and κ_n are the ionization (capture) and the neutralization (emission) rate constants, respectively.

Both rate constants are functions of both optical and thermal emission processes. For surface states that become more positive when emptied (acceptor states), these rate constants are given as (Haak et al., 1984)

$$\kappa_s = c_{n,t} + c_{n,o} + k_{p,s} p_s \quad (61a)$$

$$\kappa_n = c_{p,t} + c_{p,o} + k_{n,s} n_s \quad (61b)$$

For surface states whose character becomes more negative when emptied (donor states),

$$\kappa_s = c_{p,t} + c_{p,o} + k_{n,s} n_s \quad (62a)$$

$$\kappa_n = c_{n,t} + c_{n,o} + k_{p,s} p_s \quad (62b)$$

In defining these rate constants, $c_{p,t}$ and $c_{p,o}$ are the thermal and optical emission rate constants for holes, respectively, and $c_{n,t}$ and $c_{n,o}$ are the thermal and optical emission rate constants for electrons, respectively. The quantities $k_{p,s}$ and $k_{n,s}$ are the capture coefficients for electrons and holes defined in Equation 43. It is important to note that while an increase in positive charge produces an increase in capacitance for an n-type semiconductor, the opposite effect is observed for p-type semiconductors.

Extracting the Surface Recombination Capture Coefficient. When the semiconductor is a wide-band-gap material with deep-level states, one can measure the time dependence of the differential capacitance after interruption of the illumination, C_t, and plot

$$\ln \left(\frac{C_0^2 - C_t^2}{C_0^2 - C_{t=0}^2} \right) \quad \text{for bulk states} \quad (63a)$$

or

$$\ln \left(\frac{C_0^2 - C_t^2}{1/C_0^2 - 1/C_{t=0}^2} \right) \quad \text{for bulk states} \quad (63b)$$

vs. time, where $C_t = 0$ is the differential capacitance measured at the time of the interruption of the illumination. For an n-type material with deep electron trap states, $c_{n,t}$ and $k_{p,s}$ are zero, and the resulting slope for these plots equals $c_{p,t} + k_{n,s} n_s$. If the surface or bulk states that give rise to the plotted capacitance are sufficiently above the valance band and hence not thermally ionizable by holes, then $c_{p,t} = 0$, and the product of $k_{n,s}$ and n_s can be calculated directly for surface states by EPS measurements (Haak et al., 1984).

Practical Aspects of the Method

Electrolyte Selection. Ideally, the electrolyte should be transparent to light ranging from the band gap energy down to $\sim E_g$. This range permits the entire band gap region to be probed. Additionally, the solvent/electrolyte should be a good electrical conductor. The electrolyte must also be chosen such that the surface is stable both in the dark and under illumination (Haak et al., 1984).

Aqueous systems appear to provide the most stability for oxygen-passivated semiconductor surfaces. Studies have shown that for n-CdSe, the interface states associated with oxygen adsorption remain unchanged in aqueous solution relative to the situation for these surfaces in contact with a vacuum (Goodman et al., 1984; Haak et al., 1984).

Measurement Frequency. As with the Mott-Schottky experiments, the frequency of the perturbation voltage can be adjusted in EPS to maximize the signal-to-noise ratio. The voltage perturbation frequency used in an EPS experiment should be chosen to yield a relatively large value for the phase shift between the voltage perturbation and the current response. Generally, a phase shift of between 70° and 90° is acceptable. However, to minimize errors in the EPS spectrum, the semiconductor-solution system should show a limited range of frequency dispersion. A large frequency dispersion is usually an indication of poor crystalline quality in the semiconductor and will generally lead to irreproducible EPS spectra (Haak et al., 1984).

Electrode Bias Voltage. The EPS spectral features associated with bulk states generally vary linearly with the space-charge depletion width, whereas those associated with surface or interface states are relatively insensitive

to the electrode potential. Thus, variation of the electrode potential is a powerful method to distinguish between bulk and surface states. The electrode potential is also the experimental parameter that determines the depth into the semiconductor that is probed by the EPS experiment.

When measuring the effect of passivation or varying the concentration of electrolyte on surface state density, the bias voltage should be chosen such that the semiconductor is strongly reverse biased. Since bulk states are unchanged in response to surface modification, the extent of surface state perturbation induced by surface passivation or electrolyte dissolution is deduced by the residuals between two EPS spectra taken at large reverse biases prior to and just after the surface modification procedure (Haak et al., 1984).

Experimental Setup. The experimental setup is analogous to that used in Mott-Schottky experiments described under Differential Capacitance Measurements of Semiconductor-Liquid Contacts, Principles of the Method. A significant difference is that the working electrode is illuminated with monochromatic light provided by a xenon lamp or tungsten halogen lamp and a monochromator. The differential capacitance is measured in a fashion analogous to that described for Mott-Schottky measurements and the data are plotted, at a fixed frequency, as a function of the wavelength of this monochromatic light. At each wavelength, the perturbation voltage is applied at a rate determined by the chosen fixed frequency. During each cycle time (1/frequency), the real and the imaginary components of the electrode impedance are determined and amplified by a differential amplifier. The resulting differential capacitance values measured at each of these cycles are then averaged by a frequency response analyzer. For a thorough analysis of trap states in a semiconductor, various spectra should be collected, each varying with respect to the degree of applied bias. In most EPS experiments, changes in the capacitance as small as 1 part in 10^4 can be measured (Haak et al., 1984).

Prior to any EPS measurement, it is necessary to record an optical transmission spectrum of the solution in a cell with a path length equivalent to the distance between the EPS cell's optical window and the working electrode to be illuminated. This procedure is necessary to determine which features in the bias-independent part of an EPS spectrum might result from solvent absorption (Haak et al., 1984).

Problems

Other concerns with EPS solutions are surface degradation and film formation. While for most experimental EPS measurements, the effects of surface degradation and film formation caused by the accumulation of photogenerated minority carriers at the solid-liquid interface is minimal, it does become a concern when a sample is to undergo measurements over the course of hours or days. To help counter the effect of surface degradation of film formation caused by the accumulation of photogenerated minority carriers at the solid-liquid interface, an additional redox species can be added to the electrolyte in order to scavenge carriers that arrive at the semiconductor-liquid contact. This process can, however, have a detrimental effect if the redox species is present in high concentration, because interfacial charge transfer between the redox species and the semiconductor may produce an overall dark current that can degrade the sensitivity of the EPS experiment (Haak et al., 1984).

LASER SPOT SCANNING METHODS AT SEMICONDUCTOR-LIQUID CONTACTS

Principles of the Method

Laser spot scanning (LSS) involves recording the photocurrent while a highly focused laser spot is scanned over a semiconductor surface. The technique has seen broadened appeal since the early 1990s, when higher laser fluences and spot sizes on the order of 3 μm became available through use of fiber optics. Laser spot scanning offers the opportunity to monitor surface recombination lifetimes as a function of varying treatments to the semiconductor surface as well as other local parameters of semiconductor-liquid contacts (Mathian et al., 1985; Carlsson and Hom-ström, 1988; Carlsson et al., 1988; Eriksson et al., 1991).

Four steps are thought to be involved in producing LSS spectra. Assuming a circular laser spot of radius r, the first step of an LSS experiment involves the generation of minority carriers by the laser spot (Eriksson et al., 1991). The flux of photogenerated carriers is equal to (Eriksson et al., 1991)

$$F(\lambda) = G_0(r)2\pi r\,dr \tag{64}$$

where $G_0(r)$ is the Beer-Lambert generation function. Carriers are thus generated in a cylinder whose radius is equal to the radius of the laser spot and whose depth is α^{-1}, where α is the absorption coefficient. Generally, the illumination wavelength is chosen such that α^{-1} is larger than the depletion width.

Due to the strong electric fields present in the depletion region, minority carriers generated in the depletion region should migrate rapidly, with little sideways diffusion, to the solid-liquid interface. However, minority carriers that are created below the depletion layer will diffuse laterally and either contribute a background photocurrent or undergo nonradiative recombination. The extent to which these carriers contribute to the detected photocurrent depends on their lifetime in the semiconductor bulk. The shorter the lifetime, the less prominent their diffusion and hence the smaller the detected photocurrent.

The minority carriers generated in the depletion region are thus the primary source of the detected photocurrent. The equations for the diffusion currents of these carriers are (Eriksson et al., 1991)

$$\text{Difusion into spot} = J_D(r)2\pi r\,dr \tag{65}$$

$$\text{Diffusion out of spot} = -J_D(r+dr)2\pi r\,dr \tag{66}$$

where $J_D(r)$ is the diffusion flux of minority carriers along the surface. Through Fick's second law, one obtains

$$J_D(r) - J_D(r+dr) = \frac{Dr^2P_s(r)}{dr^2} \tag{67}$$

where D now defines the minority (hole for an n-type semiconductor) carrier diffusion coefficient. The value of D is related to the minority carrier mobility μ_p by $\mu \equiv Dq/kT$, and $p_s(r)$ is the radial dependence of the minority carrier concentration measured from the center of the laser spot (Sze, 1981; Carlsson and Homström, 1988; Eriksson et al., 1991).

Experimentally, LSS spectra record the change in photocurrent as a function of position on the sample. The recorded photocurrent becomes lower in regions where surface recombination is rapid. Thus, the LSS current is expected to decrease in the vicinity of step edges or grain boundaries, regions of polycrystalline growth, or other areas of rapid surface recombination. This lateral profile of surface recombination is not available directly in a traditional spectral response experiment, which does not use a tightly focused source of illumination (Carlsson and Homström, 1988; Carlsson et al., 1988; Eriksson et al., 1991).

Unlike EPS, the lifetime of minority carriers in LSS is determined by two processes, surface recombination and charge transfer:

$$-\tau_{s,l}^{-1} p_s(r) 2\pi r\, dr \qquad \text{surface recombination} \tag{68}$$

$$-k_{ht} p_s(r) 2\pi r\, dr \qquad \text{charge transfer} \tag{69}$$

where k_{ht} is the minority carrier charge transfer rate constant. Recent modeling has shown that the radial dependence for the concentration of minority carriers relative to their concentration at the laser spot's perimeter, r_0, is (Eriksson et al., 1991)

$$\frac{p_s(r)}{p_s(r_0)} = \exp\left[-(1 - k_{ht}\tau_s)^{1/2} \frac{\Delta r}{L}\right] \tag{70}$$

where $\Delta r = r - r_0$ and L is the diffusion length, which, when only surface recombination processes are considered, is defined as $L \equiv (\tau_s D)^{1/2}$ (Many et al., 1965). If we further define r_{eff} as the radial distance where the minority carrier concentration is $1/e$ of its value at the laser spot's perimeter, it can be shown that

$$\frac{r_{eff}}{L} = (1 + k_{ht}\tau_s)^{-1/2} \tag{71}$$

Thus, when the surface recombination lifetime is short, or the charge transfer to the electrolyte is slow, $r_{eff} = L$. In contrast, when either surface recombination or the charge transfer process is fast, $r_{eff} = 0$. This latter situation corresponds to the limit in which essentially all of the minority carriers have been contained and consumed within the laser spot area (Eriksson et al., 1991).

Clearly, the deficiency of LSS is that one cannot distinguish the contribution of surface recombination from the effect of charge transfer kinetics on the induced photocurrent. Thus, to obtain quantifiable surface recombination lifetimes, either the interfacial charge transfer rate must be slow or the exact magnitude of the charge transfer rate constant must be available independently. Nevertheless, recent experiments with LSS have shown the extent to which layers and step edges influence the combined surface lifetime of minority carriers. For an InSe sample, LSS has shown that a step edge, which presents a barrier against lateral diffusion and hence allows carriers to locally accumulate on a surface, can increase the rate of surface recombination by nearly 20-fold (Mathian et al., 1985; Eriksson et al., 1991). Further experiments on polycrystalline silicon have shown that the recorded change in light-induced photocurrent as a function of distance from a step or grain boundary, l, can be approximated as (Mathian et al., 1985; Eriksson et al., 1991)

$$I_{ph}(\lambda) = k_{LSS} \frac{L}{2D} \left(\frac{1}{1 + k_{ht}\tau_s L/2D}\right) \exp\left(-\frac{l}{L}\right) \tag{72}$$

where K_{LSS} is a constant related to the effective circuit used in the LSS experiments (Mathian et al., 1985; Eriksson et al., 1991).

Practical Aspects of the Method

One aspect of the appeal of LSS is the degree of simplicity associated with the experimental setup. The sample or electrochemical cell is placed on a precision micromanipulator that is equipped with motorized control of the sample position. For greater control of the sample position at the expense of the magnitude of the motion, the sample can be placed onto a piezoelectric mount. Alternatively, as with scanning probe microscopy techniques, the sample can be held in a fixed position and a fiber-optic light source can be mounted on a piezoelectric drive to provide a means of rastering the light source over the sample (Mathian et al., 1985; Carlsson et al., 1988; Carlsson et al., 1988; Eriksson et al., 1991).

The mounted sample requires only an ohmic back contact such that reverse-bias conditions can be achieved and photocurrents measured. The light source in LSS must be monochromatic, but inexpensive light sources such as a He-Ne laser suffice for experiments with most semiconductors. The only excitation requirement is that the penetration depth α^{-1} at the excitation wavelength has to be larger than the depletion width of the semiconductor under reverse bias.

To obtain the LSS spectra, the laser light is passed into an optical fiber and focused onto the sample surface. In electrochemical cells, the fiber optic can be embedded through the cell case. The photocurrent data are then collected as a function of laser spot position for either various ambient atmospheres or electrolyte concentrations (Carlsson et al., 1988; Carlsson et al., 1988; Eriksson et al., 1991).

In a fashion analogous to displaying scanning tunneling microscopy SCANNING TUNNELING MICROSCOPY or atomic force microscopy (AFM) data, the measured photocurrents obtained while rastering the laser spot across the sample can be represented by shades of color. Usually, a linear shading of 256 colors is associated with the range of measured photocurrents. If, as a function of sample position, the measured photocurrent is represented by its color shades, then one will obtain an LSS topograph spectrum of a sample surface. To increase the signal-to-noise ratio of an LSS spectrum or topography scan, the laser light can be chopped prior to entering the fiber optic, and a

lock-in amplifier can then be used to record and average the photocurrent that is synchronous with the chopping rate. With respect to apparatus, LSS experimentation is therefore very similar to spectral response equipment (Mathian et al., 1985; Carlsson et al., 1988; Eriksson et al., 1991).

When high-resolution LSS spectra or topographies are required, the intensity of the light prior to entering the fiber optics is measured and regulated by means of a beamsplitter, a PMT, and a series of computer-controlled light attenuators. While the spatial resolution of most LSS surface topography is limited by the spatial profile of the laser spot, the contrast or sensitivity of the method to topography variations is determined by variations in the intensity of the laser beam.

By bundling a series of fiber optics around the central light-emitting optical fiber, one can measure the intensity of light reflected from the sample surface. This in turn provides another channel of data on the reflective characteristics, and hence electronic characteristics, of the surface as a function of the photovoltage or the surface recombination processes (Eriksson et al., 1991).

Problems

As stated above, the deficiency of LSS is that one cannot distinguish the contribution of surface recombination from the effect of charge transfer kinetics on the induced photocurrent. Thus, the interfacial charge transfer rate for the system under study must be slow or the exact magnitude of the charge transfer rate constant must be available independently. One, mechanical, concern is that the ohmic contact needs to remain intact during LSS experiments. Hence, corrosive systems such as Si-HF, which are accessible with time-resolved methods, are not practical for LSS experiments. Another concern is assuring that the sample's dopant density is sufficiently small that the solution-induced depletion width is $<\alpha^{-1}$ of the rastered light beam. Randomly increasing the dopant density can, however, lead to confounding problems. Since under the LSS method one cannot determine if a variation in the photocurrent results from surface defects or from defects buried within the depletion region, changes in the photocurrent arising from the dopant atoms and/or buried defect sites can easily be attributed to poor surface qualities. One method of deconvoluting buried effects from surface effects is to overlay an LSS spectrum onto a conventional topographic image of the surface, such as those obtainable from AFM or transmission electron microscopy (TEM), and to correlate variations in the LSS signal with visible topographic features. For moderately doped semiconductors, however, the influences of buried defects are minimal.

FLAT-BAND POTENTIAL MEASUREMENTS OF SEMICONDUCTOR-LIQUID INTERFACE

Principles of the Method

We now describe methods that can be used to probe the properties of the semiconductor-liquid interface. Energetic and kinetic processes are equally important, and both can be probed using the methods described here.

As described in Equations 3 to 6, the barrier height is a key energetic property of a semiconductor-liquid contact. The conventional method for measuring this property is to measure the C^2-E behavior of the solid-liquid contact and to use the intercept of the Mott-Schottky plot, Equation 38, to yield the built-in voltage of the semiconductor-liquid interface. We describe this method in somewhat more detail below.

In an ideal semiconductor-liquid junction, for a wide range of values of $E(\mathrm{A/A^-})$, E_{cb} and E_{vb} will remain constant vs. a fixed reference potential. This can be verified by measurements of ϕ_b in solutions of various redox potentials by plotting ϕ_b vs. $E(\mathrm{A/A^-})$. The plot should be linear with a slope of unity, and for an n-type semiconductor the intercept yields the value of E_{cb} in the solvent of concern.

There are, however, several cases in which the plots of ϕ_b vs. $E(\mathrm{A/A^-})$ do not have a slope of unity. For an n-type semiconductor, at very positive redox potentials, the band edges will appear to shift as $E(\mathrm{A/A^-})$ is changed. This will occur because at some point the electrochemical potential will become sufficiently positive that ionization of atoms in the valence band of the semiconductor will be thermodynamically feasible. At this point, the dopant atoms need not be ionized to produce charge transfer equilibrium in response to an increase in the electrochemical potential of the solution phase. Instead, the required charge can be obtained from ionization of electrons associated with the lattice atoms of the solid. Under these conditions, the depletion width is essentially constant, and thus no change in the barrier height is observed as $E(\mathrm{A/A^-})$ is increased. Such conditions are called carrier inversion, because they occur whenever the Fermi level of an n-type semiconductor becomes sufficiently positive that the minority carrier concentration at the surface of the solid exceeds the majority carrier concentration in the bulk of the semiconductor.

Another source of a lack of ideality in a plot of ϕ_b vs. $E(\mathrm{A/A^-})$ is due to surface states. If a sufficient density of surface states is present at the solid-liquid interface, the charge required to respond to a change in $E(\mathrm{A/A^-})$ can come from ionization of surface state localized charge instead of ionization of dopant atoms. This situation also produces little or no change in W and thus again produces little or no change in ϕ_b as $E(\mathrm{A/A^-})$ is varied. This situation is called Fermi level pinning, because the Fermi level of the solid appears to be locked into a fixed, pinned position relative to the value of E_{cb}. Under such conditions, E_{cb} will appear to move vs. a fixed reference potential as $E(\mathrm{A/A^-})$ is varied, so again a lack of ideality in a plot of ϕ_b vs. $E(\mathrm{A/A^-})$ is observed.

Unlike carrier inversion, which is a thermodynamic property of the semiconductor-liquid contact, Fermi level pinning arises from the presence of surface states at a particular semiconductor-liquid junction. For a given surface state density, the amount of potential that can be accommodated by emptying or filling surface states is readily calculated if the dielectric constant and thickness of the Helmholtz layer are known. Assuming values for these

constants of $4\varepsilon_0$ and 3×10^{-8} cm, respectively, one obtains, for the maximum voltage drop,

$$\Delta V = (1.357 \times 10^{-14} \text{V} \cdot \text{cm}^2) N_{t,s} \quad (73)$$

For smaller values of $N_{t,s}$, part of the charge transferred in response to a change in $E(\text{A/A}^-)$ is removed from surface states and part is removed from ionization of dopant atoms. In this case, a plot of ϕ_b vs. $E(\text{A/A}^-)$ is often linear but has a slope of < 1.0. The value of $N_{t,s}$ at different energies can often be determined by plotting ϕ_b vs. $E(\text{A/A}^-)$ and observing the region over which the slope is not unity. Data on the density of surface states vs. energy in the band gap are thus complementary to those obtained by EPS.

A final region in which a plot of ϕ_b vs. $E(\text{A/A}^-)$ is not linear is when the Boltzmann relationship between the electron concentration at the semiconductor surface and the electron concentration in the bulk of the solid, Equation 16, is no longer valid. This occurs when the barrier height is so low that $E(\text{A/A}^-) \approx E_{cb}$. Under these conditions, $n_s \geq n_b$, and Fermi-Dirac statistics must be used to relate n_s to n_b, as opposed to the simplification possible when the occupancy of empty states in the conduction band is so low that the Boltzmann approximation of Equation 16 is valid. This situation, which produces a very large value of J_0, is readily diagnosed because the *J-E* behavior of the semiconductor-liquid interface resembles that of an ohmic contact, with no rectification of current through the solid-liquid contact except at very large values of the applied potential.

Practical Aspects of the Method

The protocols for collection of differential capacitance vs. potential plots have been discussed in depth under Differential Capacitance Measurements of Semiconductor-Liquid Contacts, Principles of the Method. To determine the barrier height the flat-band potential of the solid-liquid contact, the intercept of the Mott-Schottky plot should yield the value of V_{bi} after inclusion of a small correction term, kT/q, which equals 0.0259 V at room temperature. The value of V_{bi} can be related to the barrier height as follows:

$$\phi_b = V_{bi} + \frac{kT}{q} \ln\left(\frac{N_c}{N_d}\right) \quad (74)$$

The value for V_{bi} should be independent of the measurement frequency, and the slope of the plot of C^{-2} vs. E should be in accord with that expected from the value of N_d and the electrode area A_s, according to Equation 39. In addition, a useful check on the validity of the V_{bi} value obtained from the data is to ensure that the experimentally determined value of V_{bi} shifts 59 mV for every decade that N_d is increased. This dependence occurs because the barrier height ϕ_b is independent of the dopant density of the semiconductor, so the value of V_{bi} must change, as given by Equation 74, in response to a variation in N_d. If the majority carrier mobility is known, the value of N_d can be determined independently by four-point probe measurements of the sample resistivity, or it can be determined by Hall effect measurements DEEP-LEVEL TRANSIENT SPECTROSCOPY, which yield both N_d and μ_n directly from the measurement on an *n*-type semiconductor sample (Sze, 1981).

Data Analysis and Initial Interpretation

Ideal Mott-Schottky plots should be nondispersive across all measured voltages and frequencies. Figure 11 shows a representative Mott-Schottky plot for the *n*-Si/CH_3OH system, which forms ideal junctions with numerous redox compounds (Fajardo et al., 1995, 1997). As stated, the difference between the closed and open circles is an order-of-magnitude increase in the acceptor concentration, 10 vs. 100 mM, respectively. At each concentration, data points are plotted at input AC voltage frequencies of 100 and 2.5 kHz. This figure illustrates the quality of data required to achieve quantitative results from Mott-Schottky plots. The data are not only nondispersive across the frequency ranges used but also somewhat nondispersive across an order-of-magnitude change in acceptor concentration.

After extrapolation, the open-circle data points had x intercepts of 0.028 and 0.023 V, respectively, a variance of <5 mV. After addition of the correction term to these values to yield corresponding V_{bi} values, Equation 74 can be applied and will yield barrier heights of 518 and 513 mV, respectively. The variance in the barrier height between the closed and open circles was measured to be less than 63 mV. It is critical to show the nondispersive (linear) nature of the Mott-Schottky plots for a wide range of frequencies. Should the Mott-Schottky plots become dispersive, the data set should be re-collected using longer acquisition times. It is also crucial to have short cables, all of a consistent length, and solid well-fitted connectors on all the interconnects between the cell and potentiostat.

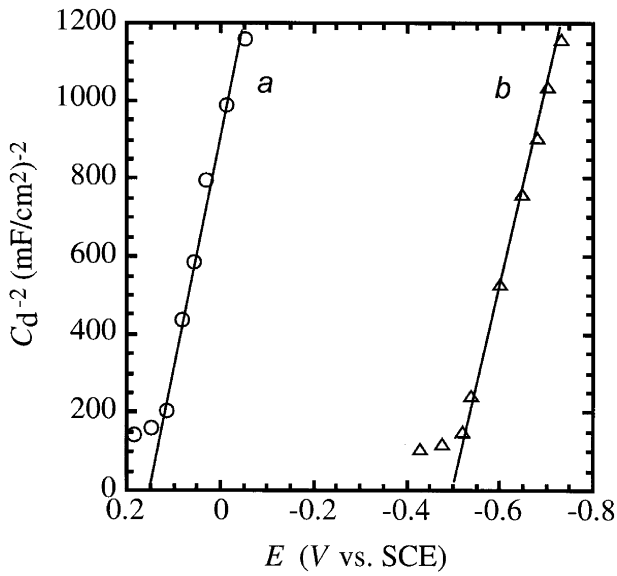

Figure 17. Mott-Schottky plots of *p*-Si/CH_3CN with tetrabutylammonium phosphate (TBAP) electrolyte (*a*) in the absence of redox couples and (*b*) with the redox couples $PhNO_2$ (30 mM) and $PhNO_2^-$ (10 mM). (Reprinted with permission from Nagasubramanian et al., 1982.)

To help prevent current and/or ground loops from developing, the cables must be kept straight. Figure 17 shows somewhat nonideal Mott-Schottky plots for the *p*-Si/CH_3CN-tetra(*n*-butyl)ammonium perchlorate contact, taken at 5 kHz both in the absence of redox couples (open circles) and in the presence of $PhNO_2$ (30 mM) and $PhNo_2^-$ (10 mM) (open triangles) (Nagasubramanian et al., 1982). The slight nonlinearity of these plots makes determination of the flat-band potential to within better than ~0.1 V problematic.

TIME-RESOLVED PHOTOLUMINESCENCE SPECTROSCOPY TO DETERMINE INTERFACIAL CHARGE TRANSFER KINETIC PARAMETERS

Principles of the Method

Measurement of the decay dynamics of photogenerated charge carriers has been discussed under Measurement of Surface Recombination Velocity Using Time-Resolved Microwave Conductivity. In the presence of redox donors and acceptors in the solution phase, measurement of the carrier decay dynamics in the solid can also yield information on the rates of interfacial charge transfer from carriers in the semiconductor to redox species in the solution. Use of this method to determine these important interfacial kinetic parameters is described below.

The rate of disappearance of charge carriers at a semiconductor-liquid contact is given by the SRH model of Equation 42, with additional terms required to account for the interfacial charge transfer processes. Thus the boundary conditions that must be used in evaluating the carrier concentration decay dynamics are

$$j_p/q = k_{ht}[A^-]_s(p_s - p_{0,s}) + k_{p,s}N_{t,s}[f_{t,s}p_s - (1 - f_{t,s})p_{1,s}] \tag{75}$$

and

$$-j_n/q = k_{et}[A]_s(n_s - n_{0,s}) + k_{n,s}N_{t,s}[(1 - f_{t,s})n_s - f_{t,s}n_{1,s})] \tag{76}$$

The values of j_p and j_n represent the currents densities to and from the valence and conduction band, respectively, and $f_{t,s}$ is the fraction of surface states occupied with electrons. Measurement of the decay dynamics in the absence of, and then in the presence of, increasing concentrations of redox species can therefore allow determination of k_{et} and k_{ht} for the semiconductor-liquid contacts of interest.

Practical Aspects of the Method

As described under Transient Decay Dynamics of Semiconductor-Liquid Contacts, Practical Aspects of the Method, the TRPL method is very useful to determine charge carrier capture dynamics to adsorbed species or to species that very rapidly capture charges from the semiconducting electrode. Use of the method is, however, limited to a rather narrow range of potentials, light intensities, and interfacial charge transfer rate constants. In fact, recent simulations show that the photoluminescence decays are generally insensitive to the value of the minority carrier charge transfer rate constant k_{ht} for an *n*-type semiconductor. Instead, diffusional spreading and drift-induced separation of photogenerated carriers in the space-charge layer of the semiconductor dominate the time decay of the observed luminescence signal under most experimentally accessible conditions (Krüger et al., 1994a,b).

This behavior can be readily understood. The laser excitation pulse produces an exponential concentration profile of injected carriers, so the luminescence is initially very intense because it involves bimolecular recombination between electrons and holes that are both created in the same region of space in the solid (Many et al., 1965; Ahrenkiel et al., 1993). Diffusional motion of carriers tends to alleviate this carrier concentration gradient and therefore will eventually eliminate the quadratic recombination to instead produce a simple, exponentially decaying, photoluminescence signal. In the limit of negligible nonradiative recombination, the long-lifetime photoluminescence decay asymptote is thus dictated by the carrier mobilities, the optical penetration depth of the light, and the carrier injection level used in the experiment.

The short-lifetime photoluminescence decay asymptote can also be readily understood. When carriers are removed nonradiatively from the solid as fast as they arrive at the solid-liquid interface, either by surface recombination or by interfacial charge transfer processes (or a combination thereof), the photoluminescence decay will reach a short-lifetime asymptote. Any additional increases in k_{ht} or $N_{t,s}$ cannot affect the photoluminescence decay dynamics because the carrier quenching rate is already limited by diffusion of carriers to the surface. Thus, like the long-lifetime photoluminescence decay asymptote, the short-lifetime photoluminescence decay asymptote is dictated only by the carrier mobilities, the optical penetration depth of the light, and the carrier injection level used in the experiment.

Due to these competing processes, generally, values of k_{ht} and of the minority carrier low-level surface recombination velocity S_p can be obtained from an analysis of the photoluminescence decays only when the following restricted sets of conditions are satisfied simultaneously: 10^1 cm $s^{-1} \leq S_p \leq 10^4$ cm s^{-1}, 10^{-18} cm^4 $s^{-1} \leq k_{ht} \leq 10^{-15}$ cm^4 s^{-1}, and the electrode potential E is in the region $0 < E < +0.15$ V relative to the flat-band potential of the *n*-type semiconductor-liquid interface. The simulations further show that it is not possible to extract a "field dependence" of the charge transfer rate constant when the semiconductor-liquid contact is maintained in reverse bias ($E \geq +0.15$ V vs. the flat-band potential) and is subjected to light pulses that produce low or moderate carrier injection levels, because under such conditions the photoluminescence decay dynamics are dominated by drift-induced charge separation in the space-charge layer of the semiconductor. Under high-level injection conditions, no field dependence can be observed because the majority of the photoluminescence decay dynamics occur near the flat-band condition, so the value of the band bending in the semiconductor under dark, equilibrium conditions has negligible influence on the luminescence transients produced by a high-intensity laser pulse.

A full discussion of the regimes in which the interfacial charge transfer kinetics can be accessed experimentally using this method is beyond the scope of this work, and the reader is referred to the recent literature for an extensive evaluation of the limitations of this method for such purposes. However, it is useful for measurement of the surface recombination velocity of solid-liquid contacts in certain specific cases.

Problems

Details of the method have been described above. The only additional concern for interfacial kinetic measurements is to ensure that electrode corrosion, passivation, adsorption, and other surface-related processes are not significant for the system of concern, because otherwise interpretation of the carrier decay dynamics is problematic. The rate constants should be first order in the acceptor concentration, or there is no proof that the kinetic process of interest is rate limiting. One method for minimally establishing whether surface damage has occurred or not is to collect *J-E* data for the system in the electrolyte of concern and in another electrolyte solution of interest both before and after the photoluminescence decay experiments to ensure that no surface chemistry changes are present that would affect the electrical behavior of the solid-liquid contact. This is necessary, but not sufficient, to secure a robust rate constant determination and is often helpful in ruling out measurements on clearly unstable electrode surfaces. The TRPL data should always be buttressed by measurements at varying concentrations of acceptor in the solution in order to establish whether or not the expected rate law has been observed in the system.

STEADY-STATE *J-E* DATA TO DETERMINE KINETIC PROPERTIES OF SEMICONDUCTOR-LIQUID INTERFACES

Principles of the Method

The final method to be discussed involves the use of steady-state *J-E* measurements of the semiconductor-liquid contact. This method has been described in detail under Photocurrent-Photovoltage Measurements. Here, however, we specifically address the use of steady-state *J-E* data to measure interfacial charge transfer rate constants at semiconductor-liquid contacts.

The governing kinetic equations are Equations 8 and 19. The transfer of charge from the conduction band in the semiconductor to the acceptor species in the solution should be first order in the electron concentration at the surface of the solid, n_s, and first order in the acceptor concentration in the solution, $[A]_s$. Any measurement of k_{et} requires, at minimum, proof of this rate law to meet the conventional benchmarks for the experimental determination of the rate constant of a chemical process. In addition, it is important to establish that one is not simply working in a linear region of an adsorption isotherm, such that the electron capture event is entirely proceeding to adsorbed species, with the concentration of the adsorbate being linearly related to the concentration of the redox species in the solution phase.

The first-order dependence of the rate on $[A]_s$ is readily investigated through variation in the concentration of redox acceptors that are dissolved in the electrolyte. The first- order dependence of the rate on n_s is investigated through the dependence of J on E. According to Equation 19, a plot of ln J vs. E should have a slope of $-q/kT$ if the rate law of Equation 8 is obeyed.

Although this dependence of J on $[A]_s$ is conceptually simple, it has rarely been observed experimentally. Including surface state capture as an intermediate pathway for electron transfer from the semiconductor to the acceptor in solution (Fig. 18) produces the following rate law:

$$\text{Rate} = k_{et}[A]_s n_s + k_{sol}[A]_s N_{t,s} f_{t,s} \qquad (77)$$

where k_{sol} is the electron transfer rate constant from a surface trap to a solution acceptor. At steady state, $df_{t,s}/dt = 0$, producing the following rate expression:

$$\text{Rate} = k_{et}[A]_s n_s + k_{sol}[A]N_{t,s}\left(\frac{k_{n,s}n_s}{k_{n,s}n_s + k_{sol}[A]_s}\right) \qquad (78)$$

where $k_{n,s}$, the capture coefficient for electrons by traps, is the rate constant for transfer of an electron from the conduction band into a surface state. If an electron slowly fills a surface trap and proceeds quickly to the solution, such

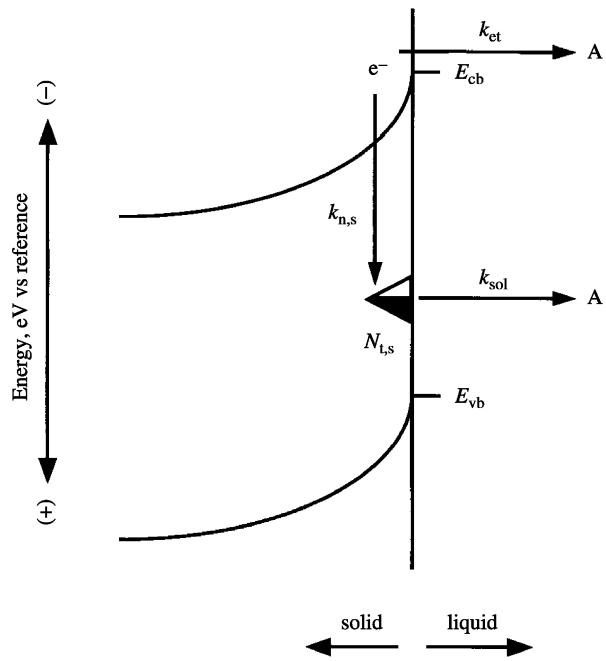

Figure 18. Two possible mechanisms for interfacial electron transfer. The upper pathway shows the direct transfer of electrons from the conduction band edge of the semiconductor to the acceptor in solution, with the rate constant k_{et}. The lower pathway depicts the surface state mediation of interfacial electron transfer. Here, $N_{t,s}$ is the density of surface states, $k_{n,s}$ is the rate constant for electron capture from the conduction band into surface states, and k_{sol} is the rate constant for electron injection from the surface states into solution.

that $k_{sol}[A]_s \gg k_{n,s}n_s$, and $k_{n,s}$ is interpreted as a collisional event through Equation 43, then Equation 78 becomes

$$\text{Rate} = k_{et}[A]_s n_s + (\sigma \nu_n) N_{t,s} n_s \quad (79)$$

The thermal velocity of electrons is well known for n-Si to be 10^7 cm s^{-1}. Equation 79 indicates that, in the scenario of slow electron trapping by surface states and fast electron ejection into solution, a large $N_{t,s}$ will eliminate the dependence of J on $[A]_s$. In the converse case of fast electron trapping and a rate-determining step of electron ejection into solution, such that $k_{n,s}n_s \gg k_{sol}[A]_s$, Equation 78 reduces to

$$\text{Rate} = k_{et}[A]_s n_s + k_{sol}[A]_s N_{t,s} \quad (80)$$

For the rate in Equation 80, a large $N_{t,s}$ will eliminate the dependence of J on n_s. Regardless of which surface state mediation step dictates the rate, a significant density of electrical traps will at best hamper and at worst prevent steady-state measurements of k_{et}. Gerischer (1991) has suggested that redox species couple more strongly to surface states than to conduction band states, and hence even a small $N_{t,s}$ would generally overwhelm the steady-state, electron transfer current flow under practical experimental conditions.

Practical Aspects of the Method

Significant effort must go into preparation of nearly defect-free surfaces in order to extract values for k_{et} from steady-state J-E data. Recent results have shown that this is possible for n-Si and n-InP semiconductor-liquid contacts (Fajardo et al., 1997; Pomykal et al., 1997), and other systems are currently under investigation as well. Special care should be taken in determining the kinetics of semiconductor electrodes according to Equation 8. Rate constants that do not meet these criteria are often quoted in units of centimeters to the fourth power per second (Meier et al., 1997), and this is clearly not in accord with conventional chemical kinetic protocols.

To establish the desired kinetic behavior experimentally, the concentration of the acceptor must be varied (Rosenbluth et al., 1989). However, in doing so, the electrochemical potential of the solution will change if the concentration of the other redox partner is held constant (Equation 1). One approach is to dilute the solution, thereby not varying $E(A/A^-)$ while changing the concentration of the desired redox species. This is useful but often precludes simultaneous differential capacitance measurements, which can require high concentrations of both forms of the redox couple in the electrolyte to avoid spurious results due to concentration polarization at the counter electrode of the system. Another method is to change the concentration of only one form of the redox species. However, care must then be taken to ensure that the band edge positions of the semiconductor do not shift as the redox potential is changed. If this is not the case, interpretation of the data is difficult and problematic.

Once the correct kinetic dependencies on $[A]_s$ and n_s have been established, it is straightforward to evaluate k_{et} from the measured value of J at a given potential. To do this, however, requires an independent measurement of the value of n_s at this potential. Traditionally, C^{-2}-E methods are used for this purpose, and this experimental protocol has been discussed in detail under Differential Capacitance Measurements of Semiconductor-Liquid Contacts, Practical Aspects of the Method. Care should be taken to ensure that the band edge positions do not move versus a fixed reference potential, because then the data are problematic to interpret. Otherwise, simple arithmetic manipulation of Equation 8 yields the desired value of k_{et} if n_s, $[A]_s$, and J are known.

Data Analysis and Initial Interpretation

Figure 19 shows plots of $\ln(-J)$-E for an n-Si electrode in contact with solutions having varying ratios of $[A]/[A^-]$. In this example, an ideal first-order concentration dependence is evident from a +59-mV shift in the $\ln(-J)$-E curve for a factor of 10 increase in $[A]/[A^-]$. A first-order dependence on the surface electron concentration can be verified by fitting $\ln(-J)$-E curves to a standard diode equation:

$$J = -J_0\left[\exp\left(\frac{-qE}{\gamma kT}\right)\right] \quad (81)$$

Note that this expression is a simplified form of Equation 19 and is valid when the electrode is sufficiently reverse biased. The diode quality factor γ is a floating parameter that should yield a value of 1.0 for an electron-transfer-limited system (compare Equations 81 and 19).

Prior to verifying these dependencies, all J-E curves should be corrected for cell resistance and concentration overpotential, as discussed under Photocurrent-Photovoltage Measurements, Data Analysis and Initial Interpretation. Assuming a diode quality factor of unity, the value of the rate constant can be extracted at any given potential. However, in practice, it is best to obtain the value of the rate constant using values of the current for which resistance effects are still minimal and for which the simplified form of the diode equation is still valid.

Problems

As mentioned above under Principles of the Method, to obtain reliable values of the heterogeneous rate constant,

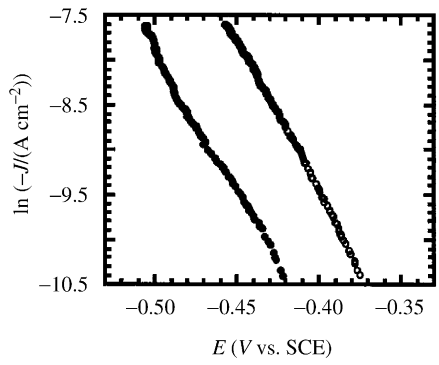

Figure 19. Plots of $\ln(-J)$ versus E for the system described in Figure 4 for two different ratios of $[A]/[A^-]$. The data on the right had a ratio of $[A]/[A^-]$ 10-fold higher than that for the curve on the left.

the semiconductor-liquid system of interest must exhibit second-order kinetics, with a first-order dependence on both the concentration of majority carriers at the surface and the concentration of redox species. However, most systems do not exhibit either one or both of these dependencies. A lack of concentration dependence is more likely in systems that employ redox species or electrolytes that can adsorb on the surface of the electrode and with electrodes that have high surface recombination velocities. Such systems are often dominated by alternate recombination mechanisms precluding a quantitative kinetic analysis of desired rate process. In addition, it is often difficult to obtain sufficiently well-behaved Mott-Schottky plots so that band edge movement can be assessed to within a few millivolts when the redox potential is only varied over a small range of potential. Thus, behavior generally needs to be explored, and verified, for several redox couples that have $E(A/A^-)$ varying over a significant potential range to ensure confidence in the results of the kinetic measurements.

ACKNOWLEDGMENTS

We acknowledge the Department of Energy, Office of Basic Energy Sciences, and the National Science Foundation for their generous support of semiconductor electrochemistry that is incorporated partly in this work. In addition, we acknowledge helpful discussions with G. Coia, G. Walker, and O. Krüger during the preparation of this unit.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

A	Oxidized acceptor species
$A_1(A_2)$	Preexponential floating variables of a biexponential fit to a decay curve
A^-	Reduced acceptor species (donor)
A_s	Surface area of electrode
$[A]_b$	Bulk concentration of oxidized acceptor species
$[A]_s$	Acceptor concentration at semiconductor surface
$[A^-]_s$	Donor concentration at semiconductor surface
B	Circuit susceptance
C	Constant equal to $qk_{et}[A]_s$
C_0	Differential capacitance measured at base of EPS peak
C_d	Experimentally measured differential capacitance of a semiconductor
$C_{d,sat}$	Plateau or peak capacitance measured under high illumination intensity
C_H	Differential capacitance of Helmholtz layer

$c_{n,o}$	Optical emission rate constant for electrons
$c_{n,t}$	Thermal emission rate constant for electrons
$c_{p,o}$	Optical emission rate constant for holes
$c_{p,t}$	Thermal emission rate constant for holes
C_{sc}	Differential capacitance of space-charge layer
C_{ss}	Differential capacitance of semiconductor surface
C_t	Time-dependent differential capacitance
d	Semiconductor sample thickness
D	Carrier diffusion constant
D_0	Diffusion coefficient
$-dn/dt$	Net rate of electron transfer into solution
$\boldsymbol{E}$	Electric field
E	Applied potential
$E(\mathrm{A/A^-})$	Redox potential
$E(\mathrm{A/A^-})$	Electrochemical potential of contacting solution
E_{cb}	Energy of conduction band edge
E_{corr}	Potential corrected for resistance and concentration overpotentials
E_F	Fermi level of semiconductor
E_g	Band gap energy
$E^0(\mathrm{A/A^-})$	Formal electrochemical potential of contacting solution
E_t	Energy of a trap state
E_{vb}	Energy of valence band edge
f	Frequency of AC input voltage signal
F	Faraday's constant
$F(\lambda)$	Flux of photogenerated carriers
$f_{t,s}$	Fraction of surface states filled by electrons
G	Circuit conductance
$G_0(r)$	Beer-Lambert generation function
h	Planck's constant
I	Current
I_{ph}	Photocurrent
I_{pl}	Photoluminescence intensity
J	Current density
J_0	Exchange current density
$J_D(r)$	Diffusion flux of minority carriers along surface
$J_{l,a}$	Limiting anodic current density
$J_{l,c}$	Limiting cathodic current density
j_n (j_p)	Charge transfer current to and from conduction (valence) band
J_{ph}	Photocurrent density
J_{sc}	Short-circuit current density
k	Boltzmann's constant
k_{et}	Interfacial electron transfer rate constant
k_{et}^-	Reverse interfacial electron transfer rate constant
k_{ht}	Interfacial hole transfer rate constant
K_{LSS}	Effective circuit constant in an LSS experiment
k_n (k_p)	Electron (hole) capture coefficient for traps
k_r	Radiative recombination rate constant
k_{soln}	Electron-transfer rate constant from a surface trap to a solution acceptor
l	Step or grain boundary
L	Minority carrier diffusion length
L_p	hole diffusion length
M	Molecular weight of semiconductor
n	Number of electrons transferred
n^+	Number of holes required to oxidize one atom of electrode material
$n_{1,s}$ ($p_{1,s}$)	Concentration of electrons (holes) in conduction (valence) band when trap energy is at Fermi energy
n_b	Electron concentration in bulk of semiconductor
N_c	Effective density of states in conduction band
N_d	Dopant density
n_i	Intrinsic electron concentration
n_s (p_s)	Surface electron (hole) concentration
n_{s0}	Equilibrium surface electron concentration
N_t	Concentration of bulk states (in $\mathrm{cm^{-3}}$)
$N_t(\lambda)$	Density of optically active bulk states in a semiconductor at a particular illumination wavelength
$N_{t,s}$	Concentration of surface states (in $\mathrm{cm^{-2}}$)
$N_{t,s}(\lambda)$	Density of optically active surface states in a semiconductor at a particular illumination wavelength
N_v	Effective density of states in valence band
p_0	Equilibrium minority carrier concentration in the dark
$p_s(r)$	Radial dependence of minority carriers about an LSS laser spot
q	Electronic charge
Q	Charge density
r	Radius of laser spot
R	Gas constant
R^*	Optical reflectivity of solid
r_0	Perimeter of laser spot
r_{eff}	Distance from center of laser spot where concentration of minority carriers is $1/e$ of its value at perimeter of laser spot
R_H	Resistance of Helmholtz layer
R_r	Rate of radiative band-to-band emission
R_s	Resistance of bulk semiconductor
R_{sc}	Resistance of space-charge layer
R_{soln}	Solution resistance
R_{SRH}	Rate of Shockley-Read-Hall (SRH) nonradiative recombination in semiconductor
R_{ss}	Resistance due to semiconductor surface states
S_{high}	High-level surface recombination velocity (in $\mathrm{cm\ s^{-1}}$)
S_{low}	Low-level surface recombination velocity for electrons (holes)
T	Temperature
V	Electric potential
V_{bi}	Built-in voltage
v_n (v_p)	Thermal velocity of electrons (holes) in a solid
V_n	Potential difference between Fermi level and conduction band in bulk
V_{oc}	Open-circuit voltage
W	Depletion width
W'	Depth of dopant density measurement ($W + W_d$)
W_d	Thickness of material dissolved from an electrode
x	Distance into semiconductor
Z_{im}	Imaginary component of impedance
Z_{re}	Real component of impedance

Z_{tot}	Total impedance
α	Absorption coefficient
β	Coefficient of optical transitions
γ	Diode quality factor
Γ	Transmitted photon flux
Γ_0	Incident photon flux
Δp (Δn)	Optically induced excess minority (majority) carrier concentration
Δp_0	Optically induced excess minority carrier concentration directly after excitation ($t = 0$)
$\Delta R_m(t)$	Reflected microwave power
ε	Relative permittivity
ε_0	Permittivity of free space
ε_s	Static dielectric constant of semiconductor
η_{conc}	Concentration overpotential
θ	Phase angle
κ_n	Neutralization (emission) rate constant
κ_s	Ionization (capture) rate constant
λ	Excitation wavelength
μ_n (μ_p)	Mobility of electrons (holes) in semi- conductor
ν	Frequency of incident radiation
ρ	Density of solid
σ_n (σ_p)	Capture cross-section of electrons (holes) in a trap
τ	Minority carrier lifetime
$\langle\tau\rangle$	Weighted lifetime parameter for fit to a decay curve
τ_1 (τ_2)	Lifetimes of biexponential fit to a decay curve
τ_{pl}	Effective total lifetime for photoluminescence spectrum
$\tau_{r,h}$	High-level injection radiative lifetime
$\tau_{r,l}$	Low-level injection radiative lifetime
$\tau_{s,h}$	High-level SRH lifetime associated with surface recombination
$\tau_{s,l}$	Low-level SRH lifetime associated with surface recombination
υ	Kinematic velocity of a solution
Φ	Quantum yield
ϕ	Barrier height
χ_c	Capacitive reactance
ω	Angular frequency of AC input signal
ω_{rde}	Angular velocity of rotating disk electrode

SCANNING ELECTROCHEMICAL MICROSCOPY

INTRODUCTION

Scanning electrochemical microscopy (SECM) is one of a number of scanning probe microscopy (SPM) techniques that arose out of the development of the scanning tunneling (Binnig and Rohrer, 1982) and atomic force microscopes (Binnig et al., 1986). Scanning probe microscopes operate by scanning, or "rastering," a small probe tip over the surface to be imaged. The SECM tip is electrochemically active, and imaging occurs in an electrolyte solution. In most cases, the SECM tip is an ultramicroelectrode (UME) (Wightman, 1988; Wightman and Wipf, 1989), and the tip signal is a Faradaic current from electrolysis of solution species. Some SECM experiments use an ion-selective electrode (ISE) as a tip. In this case, the tip signal is usually a voltage proportional to the logarithm of the ion activity in solution. The use of an electrochemically active tip allows an extremely versatile set of experiments, with chemical sensitivity to processes occurring at a substrate surface as an essential aspect.

A requirement of SPM techniques is that the signal from the tip must be perturbed in some reproducible fashion by the presence of the surface. One of the two methods used in SECM to provide this signal change is known as the "feedback" mode (Kwak and Bard, 1989; Bard et al., 1991, 1994). The feedback mode employs a Faradaic current that flows from the electrolysis of a mediator species [e.g., ferrocene or $Ru(NH_3)_6^{3+}$ at a UME tip as a probe of a substrate surface. As the tip is brought close to the surface, the electrolysis current is perturbed in a manner that is characteristic for electronically insulating or conducting surfaces. "Positive" feedback occurs when the mediator is restored to its original oxidation state at the substrate by an electrochemical, chemical, or enzymatic reaction (Fig. 1A). The regeneration of the mediator in the tip-substrate gap increases the tip current as the gap width decreases. "Negative" feedback occurs when the surface physically blocks the diffusion of mediator molecules to the tip electrode, producing a drop in tip current with a decrease in gap width (Fig. 1B). Thus, feedback can provide topographic images of either electronically insulating or conducting surfaces. Examples from many types of surfaces have been obtained, such as electrodes (Bard et al., 1989; Lee et al., 1990b; Wittstock et al., 1994a) or polymer films (Kwak et al., 1990; Lee and Bard, 1990; Jeon and Anson, 1992; Borgwarth et al., 1996).

A unique advantage of SECM is the ability to design experiments in which the mediator interacts with the substrate surface to provide chemical and electrochemical activity maps at micrometer and submicrometer resolution. In reaction rate feedback (Fig. 1C), the imaging conditions are manipulated so that the overall mediator turnover rate at the substrate is limited by the rate of substrate-mediator electron transfer (Wipf and Bard, 1991a,b; Casillas et al., 1993). Experiments have demonstrated that the microscope can be used to map variations in electron transfer (ET) rate at metallic electrode surfaces (Wipf and Bard, 1991b) and enzymes in biological materials (Pierce and Bard, 1993).

In the generation/collection (GC) mode, the tip signal arises from a species generated at the surface of the imaged material (Fig. 1D). Ideally, the tip acts only as a passive sensor with the ability to produce concentration maps of a particular chemical species near the substrate surface. In amperometric GC, a UME tip detects species by electrolysis and the first reported use of the method

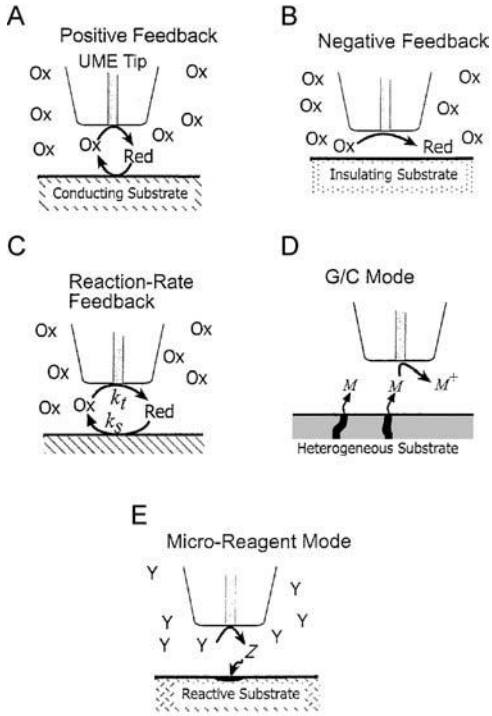

Figure 1. Modes of operation of the SECM. Ox and Red refer to oxidized and reduced forms of intentionally added mediator.

was to map electrochemically active areas on electrodes (Engstrom et al., 1986). Generation/collection SECM has been used to make high-resolution chemical concentration maps of corroding metal surfaces, biological materials, and polymeric materials. In addition, spatially resolved quantitative measurement of ion flux through porous material such as mouse skin and dental material can be made. The potentiometric GC mode uses an ISE tip, which has the advantages of minimizing perturbation of the diffusion layer, sensitivity to nonelectroactive ions, and selectivity for the imaged ion.

In addition to imaging, the SECM tip can be a microscopic source or sink of electrons and chemical reagents. With the tip positioned close to surface, these reagents perform modifications to surfaces on a microscopic scale, turning the scanning electrochemical microscope into a versatile microfabrication device (see Specimen Modification). In the "direct" mode, the tip is a counter electrode to the substrate electrode, permitting substrate electrochemical reactions at a small region of approximately tip size. Deposition of metal and polyaniline lines as thin as 0.3 μm has been reported using the direct mode (Craston et al., 1988; Hüsser et al., 1988, 1989; Wuu et al., 1989). In the microreagent mode, a reaction at the SECM tip changes the local solution composition to provide a driving force for chemical reactions at the surface (Fig. 1E). Electrolytic generation of an oxidizing agent at the SECM tip can precisely etch metal and semiconductor surfaces, and local pH changes caused by electrolysis at the SECM tip have been used to deposit metal oxides and polymers (Mandler and Bard, 1989; Zhou and Wipf, 1997; Kranz et al., 1995a).

This unit provides an overview of SECM and basic experimental apparatus. Applications of SECM will focus on experiments in corrosion, biological and polymeric materials, and the dissolution and deposition of materials. The use of SECM to measure ET rates at inert electrodes and rapid homogeneous reactions accompanying ET is not specifically covered here, but these topics are discussed in other review articles (Bard et al., 1991, 1994, 1995). The discussion of recent experiments using SECM to examine material transfer rates across phase boundaries is also available in the literature (Selzer and Mandler, 1996; Slevin et al., 1996; Tsionsky et al., 1996; Shao et al., 1997b).

Competitive and Related Techniques

Scanning electrochemical microscopy is a scanned probe method operating in an electrolyte solution. In this regard, SECM is comparable to two of the most popular SPM techniques, scanning tunneling microscopy (STM) (see SCANNING TUNNELING MICROSCOPY) and atomic force microscopy (AFM). Both techniques have much higher vertical and lateral resolution than the SECM and, even with the tip immersed in electrolyte, can achieve resolution on the nanometer scale. Atomic force microscopy is a very versatile method and can image both insulating and conducting surfaces with equal facility. The technique can achieve some chemical specificity by use of chemically modified tips to provide molecular recognition (Dammer et al., 1995) or by correlating lateral frictional forces and details of the force-distance curve with surface composition. However, other than the indirect effect that solution species have on surface forces, monitoring solution phase chemistry is not within the scope of AFM. Operating the scanning tunneling microscope in electrolyte solution presents a significant handicap. Faradaic currents must be minimized to allow the tunneling current to be observed. The STM tips must be well insulated up to the very end of the electrode and the tip-substrate bias must be chosen carefully to avoid unwanted Faradaic reactions. These problems are not insurmountable, and STM imaging of ionic or electronically conducting interfaces in electrolyte solution is common. As in AFM, direct chemical information about solution phase species is not generally available, but the electrically conducting STM tip can provide voltammetric or amperometric signals. In this case, tunneling current is no longer monitored, and the scanning tunneling microscope is essentially acting as a scanning electrochemical microscope. The STM tips are generally made from tungsten or Pt-Ir alloys, which permits formation of atomically sharp tips but restricts somewhat the scope of available electrochemical reactions. Whether one considers operation of the scanning tunneling micrscope in electrolyte solution to be an SECM experiment depends more on philosophy. In general, one can make the distinction by considering that the primary interaction in SECM between the tip and sample is mediated by diffusion of solution species between the tip and sample. The number of applications of SPM is growing at an exponential rate; comparison of SECM with other SPM methods should start with a good review of the field (Bottomley et al., 1996).

Scanning electrochemical microscopy also bears a resemblance to older methods in which a scanning microscopic reference electrode or a vibrating probe is used to detect localized current flow near corroding metal surfaces (Isaacs and Kissel, 1972; Isaacs et al., 1996) and living cells (Jaffe and Nuccitelli, 1974). These methods generally have lower spatial resolution and are not chemically specific.

PRINCIPLES OF THE METHOD

In SECM an electrochemically active tip is used to detect and produce species in solution. This is important, since a quantitative description of the tip response under most measurement conditions can be developed by using well-understood theories relating the electrochemical response, the equations for mass transport, and interfacial kinetics.

Feedback Mode

A brief description of the voltammetric response at a UME is required to understand the feedback mode. The cyclic voltammetry (CV) experiment in Figure 2 illustrates the general behavior observed at UMEs (see CYCLIC VOLTAMMETRY). The CV wave shown is for the reduction of the commonly used mediator ion, $Ru(NH_3)_6^{3+}$, at a 10-μm-diameter tip in an unstirred buffer solution. Note that the wave has a sigmoidal shape, and at potentials negative of the reduction potential, the current flow reaches a steady-state limiting current value. As the tip potential is swept back to the starting potential, the forward curve is retraced. In this experiment, the current flow is limited by the rate of diffusion of the mediator species to the electrode surface. At a UME, the electrode is smaller than the region of solution perturbed by diffusion to the electrode surface, resulting in a particularly efficient form of mass transport in which the diffusion field assumes a nearly hemispherical zone around the electrode (Wightman and Wipf, 1989). The zone is able to provide a constant supply of fresh mediator as it extends away from the electrode surface. In contrast, at short time scales or with larger electrodes, the diffusion field is smaller than the electrode dimension, and so diffusion is only possible in a direction perpendicular to the electrode surface (i.e., planar diffusion). In planar diffusion, the current decays with a square-root dependence on time and does not reach a constant value.

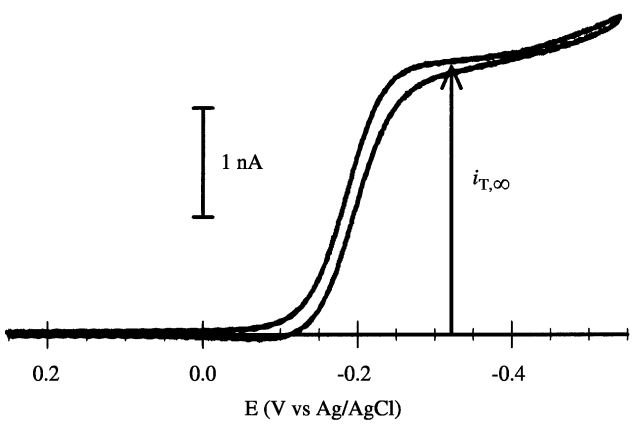

Figure 2. Cyclic voltammogram of 2.1 mM $Ru(NH_3)_6^{3+}$ in pH 7.1 phosphate-citrate buffer at a 10-μm-diameter Pt disk electrode. The voltammogram is for a scan rate of 100 mV/s.

The value of the steady-state limiting current, $i_{T,\infty}$, for a microdisk electrode embedded in an insulator is given by the equation (Wightman and Wipf, 1989)

$$i_{T,\infty} = 4nFDCa \tag{1}$$

where F is the Faraday constant, C and D are the mediator concentration and diffusion coefficient, n is the number of electrons transferred in the tip reaction, and a is the disk radius.

The imaging signal in the SECM feedback mode is the perturbation in i_T as the tip approaches the substrate surface. The notation $i_{T,\infty}$ refers to the tip signal when the tip is an infinite distance from the substrate surface. Two limiting cases in the SECM feedback mode arise when either the substrate supports ET to the mediator or when ET is blocked. As the tip approaches the blocking surface, the diffusion field normally present at the UME tip is restricted, decreasing the overall rate of diffusion of the mediator to the electrode surface and decreasing the tip current, a behavior called "negative feedback" (cf. Fig. 1B). However, if the mediator can undergo ET at the substrate, regeneration of the mediator occurs. For example, an oxidized mediator, "Ox," is reduced to "Red" at the tip (or vice versa). Red diffuses to the substrate surface and undergoes ET to restore the mediator to its original oxidation state (cf. Fig. 1A). As the tip-substrate separation decreases, this regeneration cycle becomes more rapid and the tip current increases consequently. If the ET reaction at both the tip and substrate are rapid, the tip current response is called "positive feedback."

Feedback imaging is an "active" process in the sense that the tip is used to generate a local region of a mediator species and a perturbation of that region is sensed. During imaging, a small region of the substrate is subjected to a chemical environment that is different from the bulk. Although a noncontact process, feedback imaging is strongly chemically interactive. The experimentalist has a choice of mediator species, which, in principle, permits a tuning of the imaging conditions based on chemical or electrochemical interactions between the tip and substrate. Experimental freedom is tempered by the fact that the mediator must often be added as an extra component to solution and may produce undesirable interactions; for example, an oxidizing mediator may cause etching of the substrate surface.

Numerical calculations of the steady-state tip current as a function of the tip-substrate distance (*i-d* curves) have been made (Kwak and Bard, 1989), but approximate analytical equations derived by fitting curves to the numerical results are simpler to use (Mirkin et al., 1992). Equation 2 describes the positive-feedback calculation:

$$I_T(L) = \frac{i_T}{i_{T,\infty}} = \frac{0.78377}{L} + 0.3315\ \exp\left(\frac{-1.0672}{L}\right) + 0.68 \tag{2}$$

where $L = d/a$ is the normalized distance d between the tip and substrate. This equation fits the numerical results to within 0.7% over L from 0.05 to 20. Equation 3 describes the negative-feedback *i-d* curve and is accurate to within 1.2% over the same L range:

$$I_{T,ins}(L) = \frac{1}{0.292 + 1.515/L + 0.6553\ \exp(-2.4035/L)} \quad (3)$$

The *I-L* curves for Equations 2 and 3 are shown in Figure 3. Note the increased distance sensitivity in the positive feedback compared to negative feedback.

Feedback mode topographic images are made by mapping the tip current as a function of tip position while the tip is rastered across the substrate surface. Both conducting and insulating areas can be imaged during a feedback mode scan of the substrate. Conducting areas have a positive-feedback response and can be identified by currents larger than $i_{T,\infty}$. In contrast, insulating areas have a negative-feedback response with tip currents less than $i_{T,\infty}$. Note that images made in the feedback mode have a distorted relationship to actual topography due to the nonlinear *i-d* relationship. In addition, negative-feedback images are inverted. However, if $i_{T,\infty}$ and the tip electrode radius are known, Equations 2 and 3 can be employed to convert the current image to a true topographic image (Bard et al., 1991; Macpherson and Unwin, 1995).

The lateral and vertical resolution in the feedback mode is dependent on the tip size and tip-substrate separation. One estimate of lateral resolution is the ability to discriminate between insulating and conducting regions. If both regions are located on the same plane, the ideal response would be an instantaneous change in tip current reflecting a change from positive to negative feedback, or vice versa, as the tip is scanned over the boundary. In reality, the change will occur over a region of finite width, Δx, that will be a measure of the lateral resolution. At the limit of $L = 0$, one might expect that Δx would be approximately equal to the tip electrode diameter. For $L > 0$, the lateral resolution will degrade as diffusion broadens the mediator concentration profile. An experimental study suggests that the resolution function is of the form (Wittstock et al., 1994a)

$$\Delta x/a = k_1 + k_2 L^2 \quad (4)$$

where $k_1 = 4.6$ and $k_2 = 0.111$. The best resolution predicted by this equation, 4.6 times the disk radius, runs counter to intuition and other reports (see Wipf and Bard, 1992) for superior resolution than predicted by Equation 4 and may be overly conservative, but the decrease in resolution with distance is reasonable. It should be noted that features smaller than the tip size can be recognized, but not resolved, under certain conditions. Small active regions can be distinguished from an insulating background if the regions are separated by at least a tip diameter. In this case, the image of the region will reflect the convolution of the tip and region size.

Vertical resolution in SECM depends on the tip-substrate separation and the dynamic range of the tip current measurement. One can estimate the minimum resolvable vertical change in distance by use of Equations 2 and 3 for insulating and conducting samples. For example, a change from $L = 1$ to $L = 1.0137$ gives a 1% change in I_T. Assuming this current difference is perceptible, this would correspond to the ability to distinguish a change of 0.068 μm at a 5-μm-radius tip with a 5-μm tip-substrate separation.

In principle, the resolution of SECM feedback images can be increased by application of digital image processing techniques. A degraded image can be described as the convolution of a perfect, nondegraded image with the impulse response (IR) or point spread function (PSF) and a noise function. If the PSF for feedback SECM can be found, an improved image can be made by deconvolving the degraded image from the PSF. Unfortunately, the nonlinear SECM feedback response has so far prevented a general formulation of a PSF. However, an approximate "deblurring" function based on the Laplacian of the Gaussian (LOG) filter has been shown to improve image resolution (Lee et al., 1991). Other work, so far theoretical, based on linear shift invariant processes also may be useful under restricted circumstances (Ellis et al., 1995).

There is a strong dependence on tip geometry in the feedback mode experiment. For disk-shaped electrodes, an important aspect is the radius of the insulator material in which the electrode is embedded. Tip electrodes are frequently made so that the tip assumes a truncated cone shape with the disk of the electrode centered at the truncated end. Since there is inevitably some angular offset from perpendicular as the tip approaches the surface, a smaller radius of insulating material allows closer tip-substrate approach than a larger insulating radius. Numerical simulations of the negative-feedback mode

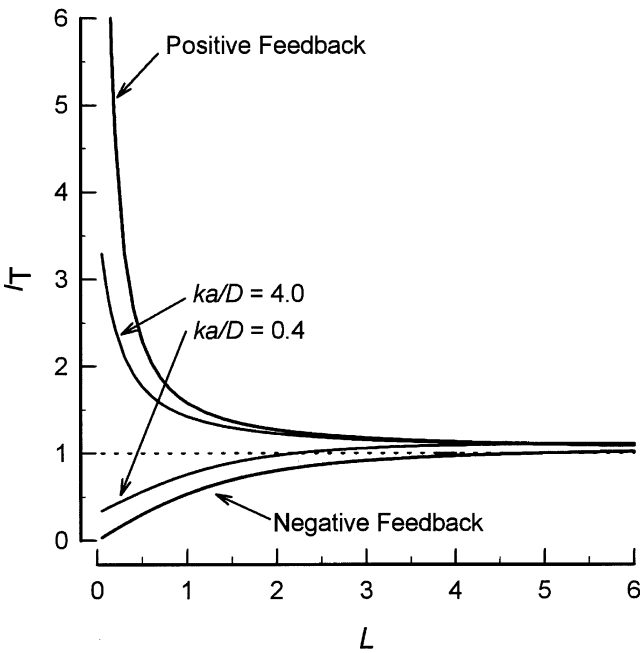

Figure 3. Theoretical current-distance curves for positive- and negative-feedback modes. Also shown are curves for a kinetically limited substrate response characterized by the parameter ka/D, where k refers to the ET coefficient and a and D are the tip radius and the diffusion coefficient, respectively. The dotted line is the baseline tip response for infinite tip-substrate separation.

demonstrate that the *i-d* relationship is very sensitive to the RG ratio, which is the ratio of the insulator radius to the disk electrode radius (Kwak and Bard, 1989). Equation 3 is only correct for RG values of 10. A small RG ratio decreases the sensitivity of the *i-d* curves in negative-feedback experiments. Conversely, the RG ratio has little effect in the positive-feedback mode. Qualitatively, the RG effect can be explained in the negative-feedback case by considering the insulator as an additional barrier for the mediator to reach the surface. Smaller RG ratios minimize the blocking effect and thus moderate the decrease in tip current. For example, at $L = 1$, $I_{T,\,ins}$ has a value of 0.534, 0.302, and 0.213 for RG ratios of 10, 100, and 1000, respectively (Kwak and Bard, 1989). Positive feedback is insensitive to the RG ratio since the tip current is mainly due to regeneration of the mediator in the region of the substrate directly below the tip.

The actual shape of the tip is another important variable in the feedback mode. Tips with diameters smaller than 1 μm are easier to make with a cone or spherical segment (e.g., hemispherical) geometry. Unfortunately, the *i-d* sensitivity of these tips in the feedback mode is significantly less than that of the disk-shaped electrodes (Bard et al., 1989; Davis et al., 1987; Mirkin et al., 1992). For cone-shaped tips, a characteristic parameter is k, the ratio of the cone height over the base radius. Calculated positive-feedback *i-d* graphs for cones with k values of 0 (disk) to 3 are shown in Figure 4A. Note the flat response at close tip-substrate distances for $k > 1$ and the significant deviation of the response even for small k values. Spherical segment tips are characterized by the parameter α_0, which is the angle between two lines from the center of the sphere, one line being a perpendicular line through the segment base and the other passing through the edge of the segment base. The positive-feedback *i-d* curves for tips with α_0 from $\pi/2$ (hemispherical) to a disk shaped are compared in Figure 4B. Although superior to conical tips, the sensitivity of hemispherical tips remains inferior to disk-shaped tips. A further difficulty is that the methods of construction (Nagahara, 1989; Penner et al., 1989; Lee et al., 1990b; Mirkin et al., 1992) of very small tips (e.g., electrochemically etched tips) are not sufficiently reproducible to produce a well-defined tip shape (Shao et al., 1997a). Fitting the experimental to simulated *i-d* curves can produce good estimates of the tip shape (Mirkin et al., 1992), but it is unlikely that fitting will be used for general imaging purposes. Thus, at present, non-disk-shaped tips should only be used to provide qualitative SECM feedback images.

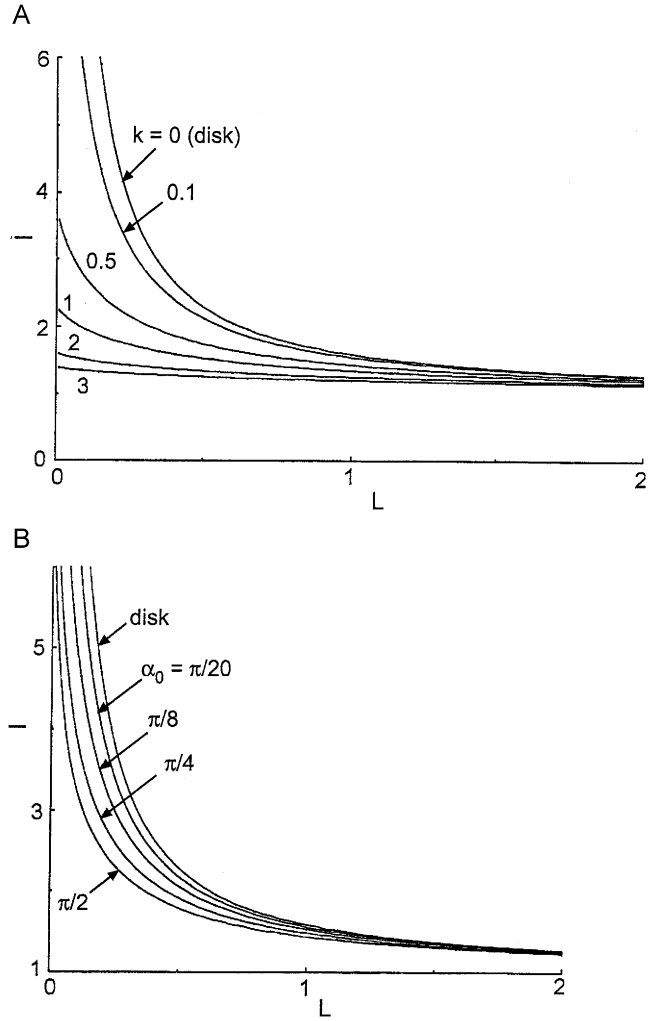

Figure 4. Theoretical current-distance curves for positive feedback at (**A**) cone-shaped and (**B**) spherical-segment type tips, where k is the ratio of cone height to radius and α_0 is the angle between a perpendicular through the base of the spherical segment and the radius of a sphere passing through the edge of the segment base. Reaction Rate Mode

Within the limits of positive and negative feedback, a more general case exists when the reaction rate at the tip or substrate is limited by a slow ET rate or sample conductivity rather than by diffusion rate. As the rate of reaction changes from the diffusion limit to zero, the *i-d* curves will shift from curves similar to positive feedback to what appears to be negative feedback. Note that if the rate of ET is sufficiently slow, the result is practically indistinguishable from that of negative feedback.

Limitations due to ET rate may arise even when mediators with very rapid ET kinetics are used, since very high rates of mass transport are produced as the tip-substrate distance becomes very small. In this case, the response is approximately that of a twin-electrode thin-layer cell (Anderson and Reilley, 1965; Anderson et al., 1966). Equation 5 predicts the tip current

$$i_{T,\infty} = 4nFDCA/d \qquad (5)$$

as L approaches zero, where A is the tip area. Considering that very small separations can be achieved in SECM, impressive values of the mass transfer coefficient D/d (Bard and Faulkner, 1980, p. 28) can be achieved. As an example, for $d = 0.2$ μm and $D = 1 \times 10^{-5}$ cm^2/s, the mass transfer coefficient is 0.5 cm/s. To achieve a similar rate of mass transfer, a rotating disk electrode would have to rotate at greater than 6.5×10^6 rpm! Thus, SECM can

measure rapid heterogeneous rates either for an ET reaction at the tip or the substrate as long as the opposing electrode is not allowed to limit the overall reaction. This is not generally difficult since the opposing substrate or tip can be poised at potential sufficiently past the oxidation or reduction potential to drive the reaction to the diffusion-controlled limits. Another consequence of the rapid diffusional transport in the positive-feedback mode is that the tip response becomes insensitive to convective transport, which minimizes the effect of stirring that may be produced by the tip during SECM imaging. Because of the high mass transport rate and the ease of making measurements at steady state, SECM is very promising for fundamental investigation of rapid interfacial ET rate constants. Calculations for tip-limited kinetics suggest that it is possible to measure rate constants as high as 10 to 20 cm/s under steady-state conditions (Mirkin et al., 1993).

Allowing a kinetic limitation of the feedback process at the substrate allows numerous interesting experiments, since a number of heterogeneous ET processes are accessible with SECM. At an electronically conducting surface, such as an electrode, kinetic information can be extracted at the tip-sized regions, allowing direct imaging of active or passive sites on surfaces. For example, images of a composite carbon-Au electrode clearly show the greater ET activity of the Au regions (Wipf and Bard, 1991b). Theoretical calculations of the *i-d* curves for quasireversible and irreversible ET kinetics as functions of the substrate potential have been published (Bard et al., 1992; Mirkin and Bard, 1992), permitting quantitative measurements of ET rates at micrometer-sized regions of surfaces. In addition, the feedback current can supply potential independent kinetic information for chemical reactions involving ET at the interface. Figure 3 shows *i-d* curves for the parameter ka/D, where k is the heterogeneous ET coefficient (Bard et al., 1995). As an example, these types of calculations have been used to calculate rate constants for the reaction of immobilized glucose oxidase enzyme with a tip-generated mediator (Pierce et al., 1992). Also, feedback current due to reduction of the tip-generated oxidant mediator by a Cu metal surface provides direct measurement of the interfacial Cu dissolution process (Macpherson et al., 1996).

Generation/Collection Mode

In contrast to the feedback mode, where the tip-generated mediator plays an active role in the imaging process, the GC mode is an entirely passive method. The GC mode of interest here is more properly referred to as substrate generation/tip collection (SG/TC). The GC mode is appropriate in situations where a reaction at the substrate surface produces an electrochemically detectable material. Typical examples include corroding metal surfaces (Gilbert et al., 1993; Wipf, 1994), ion movement through porous material (Scott et al., 1993b; 1995), and oxygen generation at plant leaves (Lee et al., 1990a; Tsionsky et al., 1997). Advantages to using this mode include that (1) no external mediator is required, thus eliminating the possibility of undesirable interactions of the mediator and substrate; (2) identification of the substrate-generated specie(s) is possible by using voltammetry when the tip is near the substrate surface; and (3) potentiometric tips can be used in addition to voltammetric or amperometric tips.

Two major disadvantages to this imaging mode are poor vertical sensitivity and lateral resolution. Both arise because an ion or molecule produced at the surface must diffuse to the tip to be detected. Vertical sensitivity is greatly restricted by the lack of a sharp diffusion gradient of the substrate-generated species. The concentration gradient may extend out to several hundred micrometers. In addition, the gradient is ill-defined since natural convection, vibration, and even tip movement can perturb the diffusion-based concentration profile. The lack of a sharp concentration gradient also causes a problem with positioning the tip at the substrate, since the tip signal changes little during approach. Optical microscopic examination of the tip approach is often necessary to position the tip close to the substrate surface. Lateral resolution is also compromised by diffusional broadening. A species released from a point source into an infinite sink will diffuse, on average, a distance x with time t, given by (Bard and Faulkner, 1980, p. 129)

$$x = \sqrt{2Dt} \tag{6}$$

This equation suggests that features <10 μm will be significantly broadened by diffusion at times >0.1 s. Diffusion will cause images of closely spaced features to overlap and a diffuse background signal will be present in GC images.

Figure 5 is a comparison of the difference in resolution for the feedback mode (Fig. 5A) and the amperometric GC

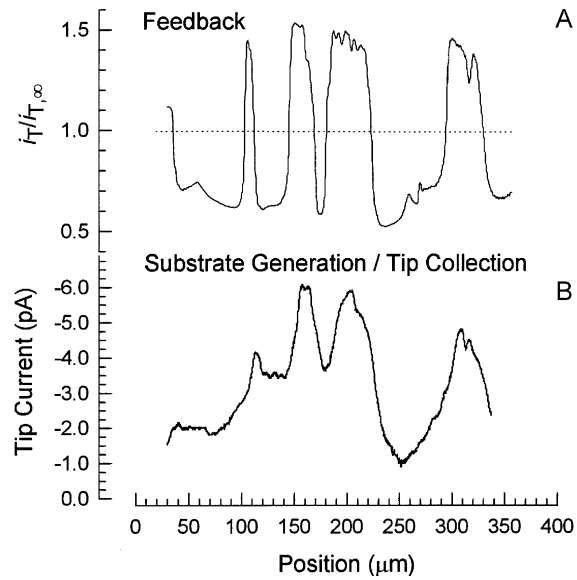

Figure 5. Single SECM line scans over an identical section of composite electrode consisting of insulating Kel-F polymer and conducting gold metal regions. Scans were acquired at a 2-μm-diameter Pt disk electrode tip in a solution of 2 mM $Fe(CN)_6^{3-}$ ion in 0.1 M KCl. Tip and substrate potentials are versus a Ag-AgCl reference electrode. (**A**) Feedback scan with the tip potential set to +300 mV and the substrate potential set to +600 mV. (**B**) Generation/collection scan with the tip potential set to +600 mV and the substrate potential set to +420 mV.

mode (Fig. 5B). The two graphs are each a single line scan using a 2-μm-diameter Pt disk electrode tip over an identical section of a composite electrode consisting of insulating and conducting regions. The mediator is the ferricyanide ion, $Fe(CN)_6^{3-}$, in an aqueous 0.1 M KCl solution. In Figure 5A, the tip is set to a sufficiently negative potential to reduce $Fe(CN)_6^{3-}$ to $Fe(CN)_6^{4-}$ (+300 mV vs. Ag/AgCl reference) while the conducting substrate is maintained at a potential sufficient to oxidize the reduced mediator. Under these conditions, positive feedback occurs while the tip is passing over conducting regions, as is apparent by current $>i_{T,\infty}$. Negative feedback occurs at the insulating regions, as is apparent by current lower than $i_{T,\infty}$. Figure 5B, showing GC imaging, was acquired with the substrate set at a potential just negative enough (+420 mV) to generate a small concentration (about 20 μM) of $Fe(CN)_6^{4-}$ while the tip was set at a positive potential (+600 mV) to detect, by oxidation, $Fe(CN)_6^{4-}$. In this case, the GC ability to detect small concentrations at a surface is illustrated, but at the cost of a lower resolution in comparison to the feedback mode. Good results in GC imaging rely on placing the tip as close as possible to the surface to avoid diffusional broadening of the detected species. Stirring may improve resolution by minimizing diffusional broadening.

In GC imaging, the tip current provides an image of the distribution of the electroactive species near a surface. At a voltammetric tip, the tip current map can be converted to a concentration map by use of the equation for the limiting current at a disk electrode (Equation 1). To do this quantitatively requires knowledge of the species diffusion coefficient and number of electrons involved in the overall reaction. In addition, the tip potential must be located on the limiting current plateau. The singular advantage of the disk electrode in feedback imaging is not present in GC imaging, and so electrodes of conical or hemispherical geometry can be used. In this case, a version of the limiting current equation appropriate for the tip geometry must be employed (Wightman and Wipf, 1989; Mirkin et al., 1992).

The potentiometric GC mode relies on an ISE as the tip. The main advantage of the potentiometric GC mode is that the tip is a passive sensor of the target ion activity and does not cause the depletion or feedback effects noted above. In addition, the tip can be used to detect ions that would be difficult or inconvenient to detect voltammetrically, such as Ca^{2+} or NH_+^4. The selectivity of the tip for the ion of interest is an advantage, but this requires separate tips for each species. The response of an ISE is, in general, a voltage proportional to the logarithm of the ion's activity, but special consideration must be made for potentiometric GC to provide a rapid response with microscopically small tips (Morf and Derooij, 1995).

PRACTICAL ASPECTS OF THE METHOD

SECM Instrumentation

Figure 6 shows a block diagram of an SECM instrument. Minimally, the instrument consists of two components: one to position the tip in three dimensions and one to measure the tip signal. A commercial instrument designed specifically for SECM has recently become available; however, most SECM investigators build their own. The one in use in the author's laboratory will serve as a model for a discussion of the instrument (cf. Fig. 6). The tip is attached to a three-axis translator stage with motion provided by linear piezoelectric motors (Inchworm motors, Burleigh Instruments). The inchworm motors provide scan rates greater than 100 μm/s over a 2.5-cm range of motion with a minimum resolution of less than 100 nm as well as backlash-free operation. An interface box (Model 6000, Burleigh) controls the speed, direction, and axis selection of the motors by accepting TTL (transistor-transistor logic) level signals from a personal computer. The motors operate in an open-loop configuration and the speed and total movement of the axis is controlled by a TTL clock signal. Use of the open-loop configuration requires that each axis be calibrated to relate the actual movement per clock pulse (i.e., nanometers per pulse). A closed-loop version of the inchworm motor is also available.

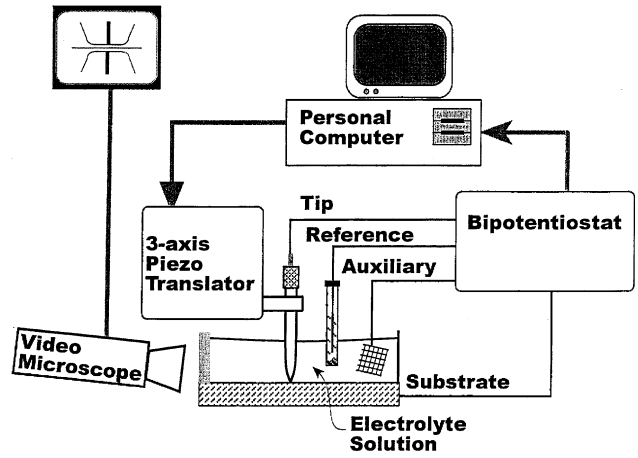

Figure 6. A scanning electrochemical microscope.

A bipotentiostat (EI-400, Cypress Systems) is used to control the tip potential and amplify the tip current. Use of a bipotentiostat, which allows simultaneous control of two working electrodes versus common reference and auxiliary electrodes, is convenient when control of the substrate potential is also required. The bipotentiostat should be sufficiently sensitive to allow measurements of the low current flow at microelectrodes, which may be in the picoampere range. Commercial bipotentiostats designed for use with rotating ring-disk electrodes are not suitable without some user modification to decrease noise and increase sensitivity. Use of a Faraday cage around the SECM cell and tip to reduce environmental noise is advisable. For potentiometric SECM operation, an electrometer is required to buffer the high impedance of the microscopic tips.

Custom software is used to program the tip movement and to display the tip and substrate signals in real time. For positioning the tip during GC imaging, a video microscope system is especially useful, since the tip can be observed approaching the substrate on the video monitor while the SECM operator is moving the tip. Descriptions of other SECM instruments are available in the literature (Bard et al., 1994; Wittstock et al., 1994b).

The SECM tip is perhaps the most important part of the SECM instrument and, at this time, disk-shaped electrodes must be constructed by the investigator. A construction method for disk electrodes with a radius of $\geq$0.6 μm is described below (see Protocol: SECM Tip Preparation).

Constant-Current Imaging

Most SECM images have been acquired in the constant-height mode where the tip is rastered in a reference plane above the sample surface. The feedback mode requires tip-substrate spacing of about one tip diameter during imaging. With submicrometer tips, it is difficult to avoid tip crashes due to vibration, sample topography, and sample tilt. Constant-current imaging can be used to avoid tip crashing and improve resolution by using a servomechanical amplifier to keep the tip-substrate distance constant while imaging. With surfaces known to be completely insulating or conducting, implementation of a constant-current mode is straightforward and similar in methodology to STM studies (Binnig and Rohrer, 1982). For example, any deviation of the tip current from the reference current is corrected by using a piezoelectric element to position the tip. A current larger than the reference level causes the tip to move toward an insulating surface and away from the conducting surface. However, this methodology cannot work when a surface has both insulating and conducting regions. Unless some additional information is provided about the substrate type or the tip-substrate separation, the tip will crash as it moves from an insulating to a conducting region or vice-versa.

One method for providing constant-current imaging is to impose a small-amplitude (100 nm or less), high-frequency vertical modulation of the tip position, i.e., tip position modulation (TPM) during feedback imaging (Wipf et al., 1993). The phase of the resulting ac current shifts by 180° when the tip is moved from an insulating to a conducting surface to provide unambiguous detection of the sample conductivity. This phase shift is used to set the proper tip motion and reference current level on the servoamplifier. The normal tip feedback signal is restored by filtering the small ac signal. A second method uses the hydrodynamic force present at a tip vibrated horizontally near the substrate surface (Ludwig et al., 1995). As the tip approaches the substrate, the amplitude of a vibration resonance mode is diminished and sensed by monitoring the diffraction pattern generated by a laser beam shining on the vibrating tip. Adjustment of the tip position to maintain a constant diffraction signal at a split photodiode allows "constant-current" imaging. Since a specific electrochemical response is not required, the hydrodynamic force method can be used for either GC or feedback imaging at a substrate. However, a special tip and cell design is required, and the method does not provide a measure of the tip-substrate separation. Another hydrodynamic method uses resonance frequency changes of a small tuning fork attached to the SECM tip (James et al., 1998). This relies on the presence of a shear-force damping as the tip approaches the surface. A third constant-current method, the "picking mode," monitors the current caused by convection during a rapid tip approach from a large tip-substrate separation (Borgwarth et al., 1994, 1995a). The transient tip current is affected by tip-substrate separation but not by substrate conductivity and, thus, can be used to position the tip automatically.

Applications in Corrosion Science

A number of researchers have recognized the possibility of using SECM for investigations in localized corrosion at metallic samples. The SECM can be used to make topographic images of samples in the feedback mode, but in this case, the more interesting images will be GC images of local ion concentrations near the corroding surface. Voltammetric or amperometric GC methods can be used to detect electroactive species produced or depleted at corroding surfaces. Examples in the literature include Fe ions (Wipf, 1994); O_2, Co, and Cr ions (Gilbert et al., 1993); and Cu and Ni ions (Küpper and Schultze, 1997b). Absolute determination of the concentration of the species is made using Equation 1 to calculate the limiting current of the SECM tip. However, the presence of multiple electroactive species may interfere with the detection. Use of a potential-time program (e.g., pulse or sweep voltammetry methods) can improve specificity and provide for multiple species detection at a stationary tip (Küpper and Schultze, 1997a). Alternatively, the use of potentiometric GC SECM images of corroding surfaces can yield information about local pH values. Changes in pH of <0.1 pH unit above a cathodic $AlFe_3$ electrode were imaged using a hydrogen-ion-sensitive neutral-charge-carrier tip (Park et al., 1996).

Scanning electrochemical microscopy can be used to preidentify sites on passive metal surfaces that will experience subsequent passive-layer corrosion and breakdown. In a study of a pit formation at a stainless steel surface, images of steel surface showed picoampere-level fluctuations in the SECM tip current over a specific region of the sample. A subsequent GC image of the same region showed current due to growth of a corrosion pit (Fig. 7; Zhu and Williams, 1997). The authors suggest that picoampere-level fluctuations in current presage a passive-layer breakdown. Corrosion precursor sites on titanium

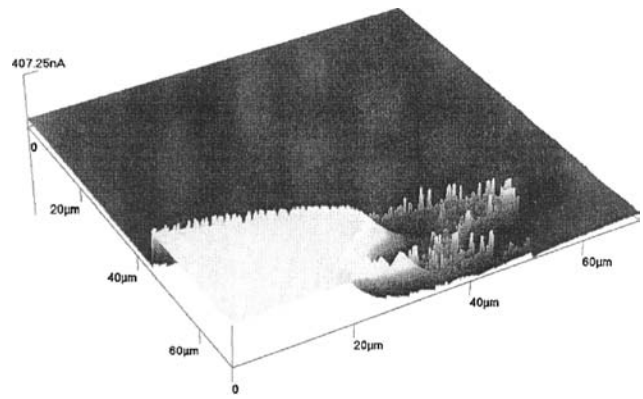

Figure 7. A GC SECM image of a corrosion pit growing on 304L stainless steel in 0.3 M $NaClO_4$/0.3 M NaCl at +230 mV vs. a saturated calomed electrode (SCE). (Reprinted with permission from Zhu and Williams, 1997, by The Electrochemical Society.)

were also identified with SECM imaging. Pitting sites were preidentified by their ability to oxidize Br^- ions to Br_2 in solution. These microscopic active sites were imaged by detecting the Br_2 at the SECM tip (Casillas et al., 1993, 1994; Garfias-Mesias et al., 1998). Pit formation was subsequently found to coincide with the Br_2-forming regions.

In the microreagent mode, the SECM can artificially stimulate corrosion at passive metal surfaces by using the SECM tip to generate solution conditions at the metal surface in which corrosion is favored. Pitting corrosion and passive-layer breakdown on Al, stainless steel (Wipf, 1994), and iron surfaces (Still and Wipf, 1997) have been stimulated by electrolytic production of Cl^- ion at the electrode tip. Since only the region of sample surface near the tip is exposed to the aggressive Cl^- ion, corrosion susceptibility of microscopic sites can be examined, and these studies have demonstrated a heterogeneous distribution of corrosion sites on iron surfaces.

SECM of Biological and Polymeric Materials

Investigation of transport of molecules or ions through skin layers is an import aspect in developing transdermal drug delivery systems. A model system is the iontophoretic transport of $Fe(CN)_6^{4-}$ through hairless mouse skin. Application of a current across a skin sample drives ions through pores, such as hair follicles and sweat glands. The GC mode of SECM can easily detect the exiting ions by making an image of the concentration of $Fe(CN)_6^{4-}$. Figure 8 is a GC image of a skin section showing two active pore regions. Using SECM allows quantitative determination of effective transport parameters such as pore diameter, pore density, and pore transport rate (Scott et al., 1993a,b; Scott et al., 1995). In a similar fashion, SECM was applied to examine fluid flow through the dentine tubules of teeth. Exposure of the dentinal material can lead to pain as pressure develops across the tubules, e.g., by osmotic pressure due to sugar. By monitoring the flux of $Fe(CN)_6^{4-}$ through a dentine sample, SECM was used to show that a calcium oxalate preparation reduces fluid flow in the tubules. In addition, the thickness and uniformity of the calcium oxalate layer on the dentine sample could be directly estimated from SECM imaging (Macpherson et al., 1995a,b).

The conductivity of electroactive polymeric materials is readily examined by feedback-mode SECM. Positive-feedback current at a fully oxidized polypyrrole film verified polymer conductivity, while a less oxidized polypyrrole film showed a decrease in feedback current as the film became less conductive (Kwak et al., 1990). A more recent result used reaction rate imaging to image regions of a polyaniline sample with significant variations in conductivity, presumably due to a variation in the levels of iodine dopant (Borgwarth et al., 1996). By examining the process of ion ejection during oxidation and reduction of conducting polymer films, processes involved with the transport of ions in these films can be studied with SECM. For example, the accepted mechanism of polyaniline oxidation is supported by use of GC SECM to monitor the ingress and egress of Cl^- and H^+ ions occurring during the polyaniline oxidation-reduction cycle (Denuault et al., 1992; Frank and Denuault, 1993, 1994). In a more quantitative study, the potential dependent kinetics of counterion transport in a polypyrrole film was investigated as a function of the nature of the solution phase ion. Ejection of electroactive ions was monitored at the SECM tip as the polypyrrole was oxidized or reduced. Figure 9 shows an example of the ejection of $Ru(NH_3)_6^{3+}$ from a polypyrrole film containing the large poly(*p*-styrenesulfonate) polyanion as a counterion. The SECM tip signal is the reduction current of $Ru(NH_3)_6^{3+}$ as it is ejected during oxidation of the film. The amount of cation ejected in the poly(*p*-styrenesulfonate)-containing film is much larger than in films containing the smaller Br^- counterion (Arca et al., 1995).

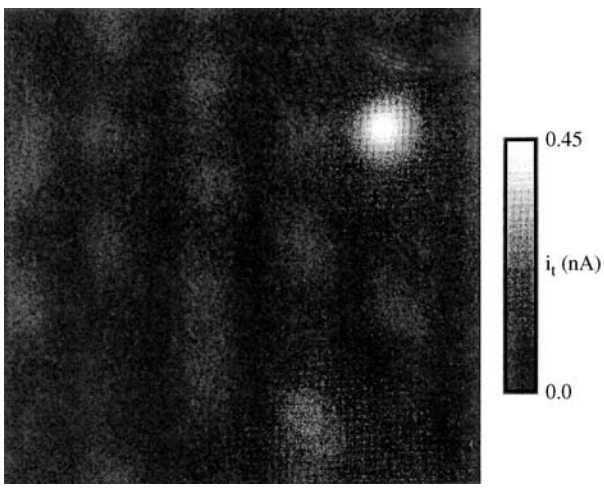

Figure 8. The SECM image of a 1 mm × 1 mm region of hairless mouse skin showing the local concentrations of the $Fe(CN)_6^{4-}$ ion at pore locations. For this image, application of an iontophoresis current of 40 $\mu A/cm^2$ drives ions from a solution of 0.1 M $Fe(CN)_6^{4-}$ through the skin into a 0.1 M NaCl solution. A 25-μm-diameter Pt electrode held at a potential of 0.4 V vs. SCE was used as the SECM tip. The scale bar is 200 μm. (Reprinted with permission from Scott et al., 1993b. SPECIMEN MODIFICATION

Microfabrication

The SECM microscope can be used to modify surfaces in a number of different modes. The microreagent mode uses the SECM tip to produce, via electrolysis, a local chemical environment that is different from the bulk environment. With the tip positioned close to the surface, the area of the substrate exposed to the local chemical environment is only slightly larger than the tip diameter. In addition, the volume of solution between the tip and the substrate can be quite small. For example, the volume of the gap formed by a 5-μm-radius disk-shaped tip separated by 1 μm from the substrate is only 25 fL. Consequently, the local chemical environment within this small volume can be changed on a millisecond time scale. Rapid diffusion of the tip-generated reagents outside the vicinity of the tip ensures that the reaction remains limited to the tip area.

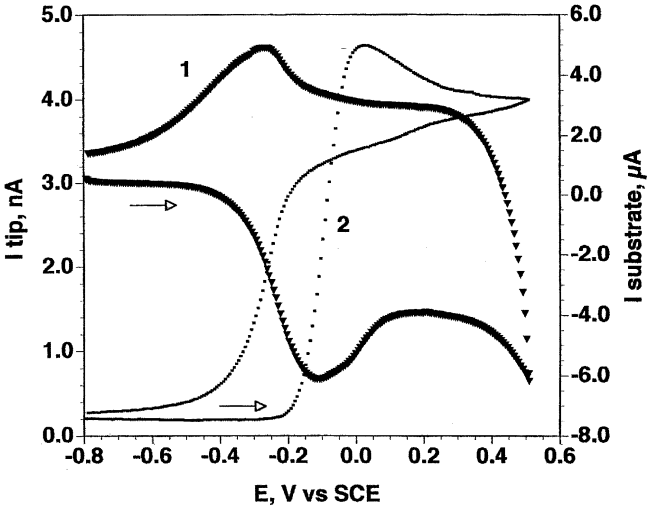

Figure 9. The SECM substrate (1) and tip (2) cyclic voltammograms of a polypyrrole film [initially containing $Ru(NH_3)_6^{2+}$ in 0.1 M K_2SO_4 solution. The polypyrrole film was prepared at +0.8 V vs SCE in a solution containing 0.2 M sodium poly(*p*-styrenesulfonate) and was then reduced at −0.8 V vs. SCE in a solution containing 0.1 M $Ru(NH_3)_6^{3+}$. The tip current is due to reduction of $Ru(NH_3)_6^{3+}$ ejected from the polypyrrole. Tip potential = −0.45 V, CV scan rate = 10 mV/s. (Reprinted with permission from Arca et al., 1995. Copyright © 1994 by the American Chemical Society.)

The number of possible species generated by electrolysis at the tip is limited principally by the investigator's imagination. Especially common are changes in pH made possible by electrolysis of water. Also, reducing and oxidizing agents are easily produced from the corresponding oxidized or reduced precursor. It should be noted that very unstable species can be produced to react with the tip surface because the diffusion time for small tip-substrate distances is very short. A species with a lifetime of >1 ms can diffuse across a 1-μm gap while a gap of 0.1 μm would allow a species with a 10-μs lifetime to react with the substrate. Further control of the reaction conditions is possible by addition of a scavenger species to solution. The "scavenger" reacts with the tip-generated species as they diffuse from the tip region. For example, a pH-buffered solution will minimize the extent of pH changes caused by OH^- generation at the tip. Likewise, an oxidizing agent can be neutralized by addition of a second reducing agent to scavenge any of the oxidant leaving the tip region.

Another substrate modification method is the "direct" mode. In this mode, the tip is used as a microscopic auxiliary electrode for the substrate reaction (Hüsser et al., 1989). With the tip positioned close to the substrate, any Faradaic reaction at the substrate is limited to the region near the tip. Any electrochemical reaction that can be produced at the bulk surface can be performed, at least in principle, at a local region of the surface using the direct mode. For example, metal etching, metal deposition, and polymer deposition are all possible at microscopic regions.

Applications in Localized Material Deposition and Dissolution

The SECM tip can be used to modify a surface on a microscopic scale by manipulating the local chemical environment or by production of a localized electric field. An example is the deposition of conducting polymer patterns from solutions of a monomer. Using a cathodic tip in the direct mode, polyaniline lines about 2 μm wide were drawn on Pt electrodes coated with a thin ionically conducting polymer (i.e., Nafion) containing the anilinium cation. The ionic polymer served to concentrate the electric field in order to oxidize anilinium cation at the metal surface (Wuu et al., 1989). Changing the local solution composition can be used to drive a reaction that leads to formation of polymer structures. Electrolytic reduction of water at the tip in a solution of aniline in H_2SO_4 increases local pH and leads to local oxidation of aniline and subsequent formation of polyaniline at a substrate electrode. Patterns with widths of <15 μm and >1 μm thickness could be formed at writing speeds of 1 μm/s (Zhou and Wipf, 1997). Polypyrrole polymer structures on electrodes can be produced by using voltage pulses in an aqueous pyrrole at the tip to produce pyrrole radical cations that subsequently polymerize on a substrate surface (Kranz et al., 1995a). Using this method, a conducting polypyrrole line was grown between two electrodes across a 100-μm insulating gap (Kranz et al., 1995b), and a 200-μm-high polypyrrole tower was grown (Fig. 10; Kranz et al., 1996). In another example, generation of the oxidizing agent Br_2 at the SECM tip formed patterns by polymerizing a thin film of a 2,5-bis(1-methylpyrrol-2yl)-thiophene monomer deposited on a substrate, and dissolution of the unreacted monomer left the polymer

Figure 10. Scanning electron micrograph of a polypyrrole tower grown by SECM from an aqueous solution of pyrrole using a 10-μm-diameter Pt microelectrode (tower height = 200 μm, width = 70 μm). (Reprinted from Kranz et al., 1996, by permission of Wiley-VCH Verlag GmbH.)

pattern (Borgwarth et al., 1995b). Due to the smaller tip size, STM deposition typically produces smaller feature sizes. The main advantage of SECM, yet to be fully realized, is the greater control of deposition conditions allowed by precise electrochemical control of the local solution composition.

Metal and metal oxide structures are readily deposited from solution using SECM. Use of the direct mode to reduce metal ions dissolved in a thin, ionically conducting polymer film deposits Au, Ag, and Cu lines as thin as 0.3 μm (Craston et al., 1988; Hüsser et al., 1988, 1989). The SECM tip induced pH changes have been used to deposit nickel hydroxide (Shohat and Mandler, 1994) and silver patterns (Borgwarth et al., 1995b). Thin Au patterns can be drawn on electronic conductors by oxidizing a gold SECM tip in Br^- solution to produce $AuBr_4^-$ ions; reduction of the ions at the sample surface produces the metal film (Meltzer and Mandler, 1995a). Three-dimensional microfabrication of a 10-μm-thick Ni column and spring was demonstrated by use of an SECM-like device in the direct mode (Madden and Hunter, 1996).

Localized etching of metals and semiconductors to form patterns of lines or spots is possible by electrolytic generation of a suitable oxidizing agent at the SECM tip. For example, Cu can be etched using a tip-generated oxidant, such as $Os(bpy)_3^{3+}$ (bpy = 2,2′-bipyridyl) generated from $Os(bpy)_3^{2+}$ (Mandler and Bard, 1989), and GaAs and Si semiconductors can be etched by Br_2 generated at the tip by oxidation of Br^- (Mandler and Bard, 1990b; Meltzer and Mandler, 1995b). Additionally, the SECM tip current observed during the etching process is a feedback current and can be used to monitor the rate of etching. In this case, the mediator is regenerated due to the redox reaction at the substrate rather than by direct ET and so the feedback current monitors the rate of oxidative dissolution directly. The behavior of the feedback current observed during etching was used to postulate a hole injection mechanism for etching of *n*-doped GaAs by tip-generated Br_2 (Mandler and Bard, 1990a). The oxidative etching kinetics of Cu by tip-generated $Ru(bpy)_3^{2+}$ was explored in the same manner (Macpherson et al., 1996).

Dissolution of nonconducting material is an area in which the ability of the SECM to produce a controlled chemical environment near the material surface provides a significant advancement. Dissolution rates of even very soluble materials can be obtained by placing the tip near (1 to 10 μm) a dissolving surface. If the solution near the surface is saturated with the dissolving material and that material is electroactive, tip electrolysis produces a local undersaturation of the dissolving material. Quantitative details about the rate and mechanism of the dissolution reaction are available from the tip current as a function of time and distance to the sample (Unwin and Macpherson, 1995). The dissolution of the (010) surface of potassium ferrocyanide trihydrate in aqueous solution is an example in which the dissolution process was found to be second order in interfacial undersaturation (Macpherson and Unwin, 1995). In a separate study, the dissolution rate constant for AgCl in aqueous potassium nitrate solution was shown to be in excess of 3 cm/s (Macpherson et al., 1995b).

The spatial resolution of the SECM was employed to examine and characterize two very different Cu^{2+} dissolution processes on a copper sulfate pentahydrate crystal in H_2SO_4. At a crystalline interface where the dislocation density is large, and thus the average distance between dislocation sites is much smaller than the tip size, dissolution is rapid and follows a first-order rate law in undersaturation (Macpherson and Unwin, 1994a). In contrast, at the (100) face of the crystal, where the average distance between dislocation sites is larger than the tip size, an initial rapid dissolution is followed by an oscillatory dissolution process (Fig. 11A; Macpherson and Unwin, 1994b). The oscillatory dissolution is modeled by assuming that nucleation sites for dissolution are only produced above a critical undersaturation value of Cu^{2+}. Thus, the production of Cu^{2+} by dissolution autoinhibits further dissolution, leading to oscillations. A micrograph (Fig. 11B) of the dissolution pit shows five ledges, in agreement with the five oscillation cycles observed in this experiment. In a related experiment, a gold SECM probe tip began oscillatory dissolution in a 1.5 M HCl solution when it was moved close to a Pt substrate electrode (Mao et al., 1995). In this case, reduction of the tip-generated $AuCl_4^-$ produced a periodic excess of Cl^- ion in the tip-substrate gap, which led to the oscillations.

PROBLEMS

A common problem in feedback SECM is a drift in the value of $i_{T,\infty}$ during an experiment due to a change in the mediator concentration by solution evaporation, a chemical reaction, or a change in electrode activity with time. For quantitative measurements, the value of $i_{T,\infty}$ should be checked several times during the experiment to verify stability. Note also that $i_{T,\infty}$ must be checked at a sufficiently large distances. An L (d/a) value of 10 will still produce an I_T value of 1.045 over a conductive surface. To get I_T values within 1% of the value of $L = \infty, L$ should be >100.

Selecting a mediator for use in feedback imaging is important to obtain good images. Ideally, mediators should be stable in both the oxidized and reduced forms and over a wide range of solution conditions and have rapid ET kinetics. A common difficulty is that a mediator may often undergo a slow chemical reaction, causing a deactivation of the tip response over the time scale of an SECM imaging session. Tip deactivation is a problem, since removal of the tip from the SECM instrument to polish it and return it to the identical position at the sample surface is difficult. Although commonly used in electrochemical experiments, ferricyanide, $Fe(CN)_6^{3-}$ ion can often cause slow deactivation of the tip signal (Pharr and Griffiths, 1997). A popular and very stable mediator that can be used in aqueous solution at pH <7.0 is the $Ru(NH_3)_6^{3+}$ ion. Lists of other mediators that might be suitable for imaging may be found in the literature (Fultz and Durst, 1982; Johnson et al., 1983; Bard et al., 1994). Before using any mediator, its stability over time should be checked. A change of 5% or less over a 1-h period is expected for $i_{T,\infty}$ in a quiet, unstirred solution. In addition, the sample

should remain stable in the mediator solution over a similar time frame.

As discussed under Specimen Modification, SECM can be used to intentionally modify specimen surfaces. The experimenter must be careful, however, to choose imaging conditions that do not cause unintentional damage to the surface. The surface may be damaged by oxidation or reduction by the bulk mediator or by the tip-generated species. Acid-base reaction of the mediator with the surface should also be considered, particularly for tip reactions involving consumption or production of protons.

Electrode preparation is another common problem. The tip geometry must be carefully checked when quantitative feedback image characterization or kinetic measurements are desired. As discussed under Principles of the Method, disk-shaped electrodes with uniform insulation are the most theoretically characterized. Tip responses should be checked by comparing the experimental and theoretical current-distance curves at both insulating and conducting surfaces. If electrode material protrudes from or is recessed into the insulating material, the curves will not match. A comparison of theoretical and experimental curves is also a good check for proper calibration of the SECM positioning system.

Nonlevel surfaces and excessive scan speeds also cause problems during imaging. A steady-state concentration profile must be established during feedback imaging to fit the existing theoretical models. Non-steady-state conditions can arise if the scan rate is too rapid to allow equilibration. As a rule, images made on insulating surfaces are most susceptible since equilibration requires diffusion of material in or out of the tip-substrate gap. A typical ion would take about 100 ms to diffuse from underneath a 10-μm-diameter tip (cf. Equation 6). Nearly equilibrated concentration gradients should occur after 5 or 10 of these diffusional "half-lives" occur, implying an acceptable scan speed of 10 μm/s. However, good practice suggests a check of the experimental method. If possible, the image produced by tip scans in only one direction should be compared to the image produced by sweeps in the opposite direction. Under steady-state conditions, feature appearance and resolution of the two scans should be identical. In GC imaging, solution stirring by rapid tip motion and tip electrolysis will cause changes in images taken by sweeps in alternate directions.

Images made by SECM in the constant-height mode are susceptible to problems due to nonlevel samples or with samples having large changes in surface relief. Tilted samples can be noted by a change in contrast on one side or corner of the sample. Mounting the sample on a tilting mount (such as an adjustable mirror mount) permits leveling of the samples. Postacquisition correction using a mathematical "tilt correction" provides a cosmetic improvement but introduces artifacts in the processed image. A simple procedure for tilt correction is to subtract the image data from the linear regression plane passing through the data. As a rule, scans on tilted samples should proceed so that tip-substrate separation increases during the scan to avoid tipcrashes. Samples with relief of larger than a tip radius can lead to poor image contrast and tip crashes, suggesting the use of constant-current imaging.

Imaging in the GC mode at a voltammetric tip may lead to two problems. First, feedback may occur when the substrate-generated species is reduced or oxidized at the tip and this electrolyzed species diffuses back to the substrate to be restored to its original oxidation state. The regeneration of the substrate-generated species will increase the tip current and compromise the use of Equation 1 for quantitative determination of concentration values. Feedback can be avoided during GC imaging by use of short collecting or generating pulses (Engstrom et al., 1987). Since electrolysis only occurs transiently during the pulse, the

steady-state feedback process is not developed. A second possible problem with voltammetric GC is local depletion of the concentration of substrate-produced species by electrolysis at the tip. This can disrupt the equilibrium governing the release of the substrate-produced species and can confuse quantitative interpretation of the GC image. Again, the sampled GC method will minimize this problem.

PROTOCOL: SECM TIP PREPARATION

The SECM tip is perhaps the most important part of the SECM instrument and, at this time, disk-shaped electrodes must be constructed by the investigator. A construction method for disk electrodes with a radius of $\geq$0.6 μm is described below. This method is a modification of a method described previously in the literature (Wightman and Wipf, 1989). Other methods used to prepare submicrometer disk-shaped tips have also been described (Lee et al., 1990b; Shao et al., 1997a). Normally, cone-shaped tips are made by electrochemically etching Pt-Ir wire and then sealing with Apiezon wax (Nagahara, 1989; Mirkin et al., 1992). Conical tips are also available commercially from electrophysiology suppliers such as FHC (Brunswick, ME) and World Precision Instruments (Sarasota, FL).

Many types of potentiometric tips for use in GC SECM have been described. Tips based on neutral carrier membranes can be made from micropipets, which allows fabrication of submicrometer-sized tips (Morf and Derooij, 1995). The literature contains descriptions of tips and experiments used for measurement of pH (Wei et al., 1995; Park et al., 1996; Klusmann and Schultze, 1997), NH_4^+, K^+ (Wei et al., 1995), and Zn^{2+} (Toth et al., 1995; Wei et al., 1995). A pH-sensitive tip based on an antimony electrode (Horrocks et al., 1993) has the advantage that it can be converted back and forth *in situ* from a voltammetric electrode to a potentiometric electrode by oxidizing the antimony to antimony oxide. The antimony oxide surface is pH sensitive and allows operation in a potentiometric GC mode, while the antimony surface allows precision positioning using the feedback mode.

The ability to construct disk-shaped tips is vital for successful feedback imaging. The following procedure can be followed to construct robust tips of Au, Pt, Ag, Cu, and carbon fiber. Figure 12 is a schematic of a tip constructed by this method. The basic construction process involves sealing a microscopic fiber of the desired electrode material into an insulating glass sheath. Fibers are available from Goodfellow Metals (Cambridge, UK) and Johnson Matthey (Alfa Aesar, Ward Hill, MA), and although fibers as small as 0.6 μm in diameter are available commercially, initial attempts should use larger diameter wire, 50 to 100 μm, until skill is developed in working with the microwire. The smaller wires are fragile, difficult to see, costly, and easily moved by air currents. Start by preparing a well-lit and clean work surface; working on a clean sheet of white paper is helpful. Using fine tweezers or your fingers, place a 1-cm length of the microwire into the open end of a 2-mm-o.d., 1-mm-i.d., 6-cm-long glass capillary. Take care not to bend the wire during installation, since this will make insertion difficult. Fibers may be cleaned before insertion by rinsing with acetone.

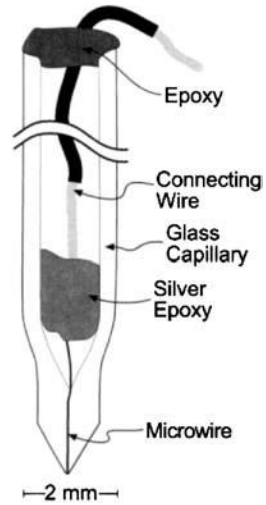

Figure 12. Tapered disk-shaped SECM electrode.

Soda-lime glass capillaries are preferable to borosilicate because of the lower melting point of the soda-lime glass. The soda-lime capillaries are not stock items from most larger supply stores but can be found from suppliers of electrophysiology equipment (e.g., FHC Co., Brunswick, ME). Do not use thin-walled capillaries, such as Pasteur pipets, since the resulting electrodes are unacceptably fragile. Sealing the electrodes in the capillary is a two-part process. Start by using a Bunsen burner flame to seal about 2 mm of the capillary end containing the microwire. A final seal is made by heating the capillary in a simple electric furnace made from a tight coil of 22-gauge chromel (or nichrome) wire. The coil should have an i.d. of 5 mm and length of 20 mm and is heated with an AC voltage from an autotransformer (Variac). To assist the sealing process, a vacuum is maintained inside the capillary. A simple method to connect the capillary to the vacuum source is to wrap the open end of the tube with several layers of Teflon tape to form a gasket. The inlet of the vacuum source is a glass tube with a slightly larger i.d. than the o.d. of the capillary tube. The Teflon gasket will form a good seal when the capillary tube is placed in the larger glass tube and a vacuum is applied.

It is important at this stage to align the capillary tube perpendicular to the ground and to center it exactly in the furnace coil. Mounting the furnace coil on a small laboratory jack allows easy placement of the capillary tube in the coil after the tube is aligned. Once vacuum is established, position the bottom 0.7 cm of the capillary tube in the coil and preheat the coil to a temperature just below a visible glow. Preheat at this temperature for 5 min to drive off any volatile material on the wire or inside the tube. Note, however, that some carbon fibers will decompose with extended preheating. After preheating, raise the coil voltage to heat the coil to a yellow-orange glow. Observe a collapse of the tube walls over a 10- to 30-s interval. A poor electrode seal will occur if melting is more or less rapid than this. Turn off the heating coil voltage and

let the electrode cool undisturbed for about 1 min. About 0.5 cm of the wire should be sealed in the glass at this point. After cooling, confirm there is a good seal under the microscope. Bubbles should not be observed along the shaft of the wire; however, an acceptable electrode may have a few widely spaced bubbles.

Use 400-grit SiC paper to grind away the end of the electrode body and to expose the wire. Ensure that the ground end is perpendicular to the electrode body. Polish with successive grades of Al_2O_3 polish on a wet polishing cloth, starting with 15 μm and continuing with successive grades down to 0.05 μm. Polish at each stage long enough to remove the scratches caused by the previous step. The final polish should leave a scratch-free surface under optical microscopic examination. Again, it should be emphasized that the electrode end must be polished perpendicular to the electrode barrel. Injecting Ag epoxy (EPO-TEK H20E, Epoxy Technology, Billerica, MA) into the tube and inserting a connection wire makes electrical contact to the microwire. A 30-gauge "wire-wrap" wire is useful as connection wire. After curing the Ag epoxy, finish the electrode by sealing the open end with a dab of "5-min" epoxy.

Platinum electrodes of 5.0- to 0.6-μm diameter can be made using a variation of the above procedure. This wire is available in the form of Wollaston wire from Goodfellow Metals. The wires are supplied with a protective 50- to 100-μm-thick Ag coating that must be removed during construction. One end of a 1-cm length of wire is bent to form a small hook, which will hold the wire securely in place and serve as a handle for manipulation. Place the wire (hook-end last) in the capillary and use a length of copper wire to force the wire down the capillary so that the end of the wire is about 2 mm from the open end of the tube. Dissolve the Ag coating with concentrated HNO_3 diluted 1:3 by distilled water. (**CAUTION**: HNO_3 is corrosive.) Dip the end of the tube so that capillary action pulls the acid solution to cover about 3 mm of the wire. Practice this technique with distilled water first. The silver will etch after a short delay with a visible gas evolution. Remove the acid by wicking it out with tissue paper. Rinse 10 times by dipping the tip into distilled water and wicking with a new tissue paper. Inspect the etched wire under a microscope after filling the tube with water again. Seal the electrode in the same way as described above. Note that the electrode will inevitably fail unless the junction between the etched and nonetched Ag is encased in glass during the sealing step.

Test the electrodes using a CV scan in a deaerated solution of 1 to 2 mM $Ru(NH_3)_6^{3+}$ ion in a pH 4.0 phosphate-citrate buffer. A 100-mV/s scan from 0.2 to −0.4 V vs. the saturated calomel electrode (SCE) should yield a sigmoid curve similar to Figure 2. The forward and back traces should be nearly superimposed, and the limiting current plateau should not have a significant slope. Check the limiting current against the theoretical value from Equation 1 (assume $D = 5.5 \times 10^{-6}$ cm^2/s for $Ru(NH_3)_6^{3+}$. Theory and experiment should agree to within 10%. Poor agreement between theory and experiment or a sloping baseline suggests a poor seal or a poor polish. In this case, first try repolishing with the 0.05-μm polish then try the whole polishing cycle again. You should expect a greater than 50% success rate for 10-μm-diameter electrodes. Electrodes that are 2 μm are much more difficult to make and an initial 1-in-3 success rate is admirable.

The final step is grinding the tip to form the truncated cone shape. This step is critical to achieve close tip-substrate separations. Start by using 400-grit SiC paper mounted on a polishing wheel. Grind the end of the electrode at a 45° angle. Rotate the electrode constantly during the grinding process to make the end circular. When the end is reduced to ≈300 μm in diameter as observed under a microscope (compare to the size of the electrode), switch to 1000-grit SiC paper and continue grinding as before to about 100 μm end diameter. This step requires practice and a good optical microscope. Use of diamond polish on the wheel will further reduce the insulator diameter, but a manual tapering process is faster and riskier. "Used" 1000-grit paper is ideal for the manual tapering step; fresh paper is too abrasive. The trick is to drag the electrode with the tapered end pointing *away* from the direction of motion. As you drag, rotate the electrode from a 45° angle to a 90° angle while simultaneously lifting the electrode away from the abrasive sheet. This removes small chunks of glass from the edge. Continue, with constant inspection under the microscope, until the desired RG diameter is reached. Endeavor to produce as circular an end as possible. With practice, one can reproducibly make electrodes with a total insulating radius of less than 10 μm.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS

a	Radius of tip electrode
A	Tip area
AFM	Atomic force microscopy
C	Concentration of redox species
CV	Cyclic voltammetry
d	Distance between tip and substrate
D	Diffusion coefficient of redox species
ET	Electron transfer
F	Faraday constant
GC	Generation/collection
d	Distance between tip and substrate
IR	Impulse response
ISE	Ion-selective electrode
$i_{T,\infty}$	Steady-state limiting current of tip electrode at infinite tip-substrate separation
I_T	Normalized tip current, $i_T/i_{T,\infty}$
$I_T(L)$	Normalized tip current at normalized distance L
$I_{T,ins}(L)$	Normalized tip current over an insulator at normalized distance L
k	Heterogeneous rate constant
L	Normalized distance from tip to substrate, $=d/a$
LOG	Laplacian of Gaussian (filter)
n	Number of electrons transferred in a redox event
Ox	A mediator in an oxidized state
PSF	point spread function
Red	A mediator in a reduced state
RG	Ratio of the insulator radius to the disk electrode radius
SCE	Saturated calomel electrode
SECM	Scanning electrochemical microscopy

SG/TC	Substrate generation/tip collection mode of SECM
SPM	Scanning probe microscopy
STM	Scanning tunneling microscopy
Substrate	Stationary electrode in SECM setup
t	time
Tip	Typically the electrode that is rastered on the scanning electrochemical microscope
TPM	Tip position modulation
TTL	Transistor-transistor logic, digital logic signals
UME	Ultramicroelectrode
x	A distance
α_0	Angle between two lines coming from the center of a sphere

Mississippi State, Mississppi

THE QUARTZ CRYSTAL MICROBALANCE IN ELECTROCHEMISTRY

INTRODUCTION

The electrochemical quartz crystal microbalance (EQCM) has found wide acceptance as an analytical tool. Nanogram mass changes that occur on the surface of a quartz crystal can be correlated with the amount of charge passed during an electrochemical process. This technique has been widely reviewed (Buttry, 1991; Buttry and Ward, 1992; Ward, 1995).

That a mass change can be determined from the resonant frequency change of a quartz crystal has been extensively used in vapor deposition techniques for many years (Lu and Czanderna, 1984). However, the use of the quartz crystal microbalance (QCM) in contact with a liquid during electrochemical studies is more recent (Kaufman et al., 1984; Schumacher, 1990). Initial investigations were applied to the underpotential deposition of metals (Deakin and Melroy, 1988; Hepel et al., 1990). The EQCM has since been applied to a wide variety of electroactive materials. Examples include conducting polymers (Orata and Buttry, 1987, 1988; Daifuku et al., 1989; Servagent and Vieil, 1990), conducting polymer bilayers (Hillman and Glidle, 1994; Demoustier-Champagne et al., 1995), redox polymers (Bruckenstein et al., 1989), charge-transfer salts (Ward, 1989; Freund et al., 1990; Evans and Chambers, 1994), hydrogen uptake by a metal (Cheek and O'Grady, 1990), electrochromic behavior of metal oxide electrodes (Cordoba-Torresi et al., 1991), polymerization of disulfides (Naoi et al., 1995), self-assembled ferrocene-based monolayers (De Long et al., 1991), Prussian blue (Feldman and Melroy, 1987; Deakin and Byrd, 1989), and nickel ferricyanide (Lasky and Buttry, 1988).

The fact that the mass change of any electroactive material during any electrochemical change can be evaluated with the EQCM has led to its widespread application. The ability to simultaneously determine the mass and the charge passed during an electrochemical process in an electroactive material is critical for characterization in many instances. For example, the polymerization mechanism of an electrochemically synthesized material can be studied as well as quantifying the amount of ion and/or solvent transport during oxidation/reduction. In addition, recent applications of the QCM include simultaneous QCM and ellipsometry (Rishpon et al., 1990), investigating solvent dynamics in polymer films (Katz and Ward, 1996), and determining contact angles and surface tensions (Lin and Ward, 1996).

This unit provides a general overview of the EQCM technique and provides details about particular interpretative precautions. The QCM has also been called a thickness-shear-mode (TSM) oscillator. Related techniques involve the surface-acoustic wave and flexural-plate wave devices (Ward and Buttry, 1990).

PRINCIPLES OF THE METHOD

The EQCM can be used to study interfacial processes at the electrode surface. The piezoelectric property of quartz is utilized to record a frequency change that may be related to a mass change. Caution must be used in the interpretation of the results (see Data Analysis and Initial Interpretation) because the frequency change is not always exclusively due to a mass change. Measurements can be made to determine whether the frequency-to-mass relationship holds for a particular material deposited onto the quartz crystal.

Since 1880, it has been known that quartz exhibits piezoelectric behavior. Jacques and Pierre Curie discovered that by applying a mechanical stress to crystals such as quartz and rochelle salt, a resulting voltage is produced (Curie and Curie, 1880). The Greek word piezin means "to press." From this the "pressure-voltage" effect was named. The converse electrostrictive effect was also discovered: the application of a potential across a quartz crystal results in a corresponding mechanical strain. Therefore, when electrodes are placed on a quartz crystal and a periodic voltage is applied, the crystal can be made to vibrate at its resonant frequency. This is the basis of the use of a quartz crystal as a microbalance.

Quartz crystals are cut so that a particular mode of vibration dominates. The AT-cut is most commonly used for QCM applications. The mode of vibration for this cut is in the thickness-shear mode (see Fig. 1A) and is most responsive to changes in mass. AT-cut indicates that the quartz is sliced along a plane rotated 35°15′ about the x axis, as shown in Figure 1B. Another reason for selecting the AT-cut is that it is somewhat insensitive to temperature changes near room temperature. Variations in temperature must be minimized for the QCM. Further details about piezoelectric quartz crystals are available and well known from high-vacuum deposition applications (Lu and Czanderna, 1984).

The shear-mode deformation shown in Figure 1A indicates that the motion is parallel to the quartz surface. The resonant frequency is governed by the thickness of the quartz crystal. This frequency oscillation is induced by

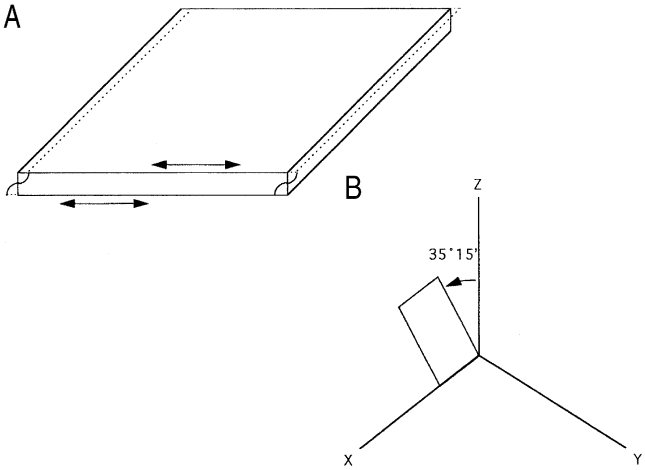

Figure 1. (**A**) A quartz crystal indicating thickness-shear mode of oscillation. (**B**) Orientation of an AT-cut quartz crystal.

the application of an electrical potential across electrodes deposited onto both sides of the quartz crystal, as shown in Figure 2A. The applied potential results in a mechanical shear deformation. An alternating potential causes the crystal to oscillate. This oscillation is extremely stable when it is near the crystal's mechanical resonance frequency due to the inherent piezoelectric properties of quartz.

An acoustic wave is produced by the vibrational motion of the quartz crystal. This wave extends through the thickness of the crystal, as shown in Figure 2B. The thickness of the quartz crystal is equal to one-half of the wavelength at resonance:

$$t_q = \frac{1}{2}\lambda_q \tag{1}$$

where t_q is the thickness of the quartz and λ_q is the wavelength of the acoustic wave in quartz. The effects of electrodes on both sides of the quartz are assumed to be negligible. This relationship can be expressed in terms of the resonant frequency of quartz (f_0) and the velocity of the acoustic wave in quartz (v_q),

$$f_0 t_q = \frac{1}{2} v_q \tag{2}$$

since

$$\lambda_q f_q = v_q \tag{3}$$

A change in the thickness therefore results in a change in the resonant frequency. An increase in the thickness causes a decrease in the resonant frequency of the quartz crystal. This leads to the principal postulate of this technique: the Sauerbrey relationship. This key equation relates a change in mass to a frequency change (Sauerbrey, 1959):

$$\Delta f = -\frac{2f_0^2 \Delta m}{A(\mu_q \rho_q)^{1/2}} \tag{4}$$

where Δf is the frequency change, f_0 the resonant frequency of the quartz crystal, Δm the mass change, A the piezoelectrically active area, ρ_q the density of quartz (2.648 g/cm^3), and μ_q the shear modulus of AT-cut quartz (2.947×10^{11} dyne/cm^2). An inherent assumption is made that for small mass changes due to foreign deposits onto the crystal, the addition of mass can be treated as an equivalent mass change of the quartz crystal. It is also assumed that the acoustic velocity and density of the foreign layer are identical to those in quartz. Even though these assumptions are used, this relationship holds true for most QCM measurements. The thickness of the deposited film should be less than 2% of the quartz crystal thickness.

Since f_0, μ_q, and ρ_q are constants of the quartz, Equation 4 can be expressed as

$$\Delta f = -C_f \Delta \mathrm{m} \tag{5}$$

where C_f is the mass sensitivity of the particular quartz crystal. This relationship emphasizes that a mass increase results in a frequency decrease and conversely a mass decrease results in a frequency increase.

Equivalent Circuit

W. G. Cady at Wesleyan University (Bottom, 1982) was the first (ca. 1920) to use a piezoelectric quartz crystal to control the frequency of an oscillator circuit. However, a better understanding of the piezoelectric resonator was realized in 1925 when K. S. Van Dyke, a student and colleague of Cady, found that the quartz resonator could be described by an equivalent electrical circuit. A piezoelectric quartz crystal resonator can be represented by a series resonant circuit, consisting of a resistor, capacitor, and inductor, in parallel with a capacitor, as shown in Figure 3. The series branch of the circuit is called the motional branch because it reflects the vibrational behavior of the crystal. The parallel capacitance C_0 represents the static capacitance of the quartz crystal with its electrodes and any stray parasitic

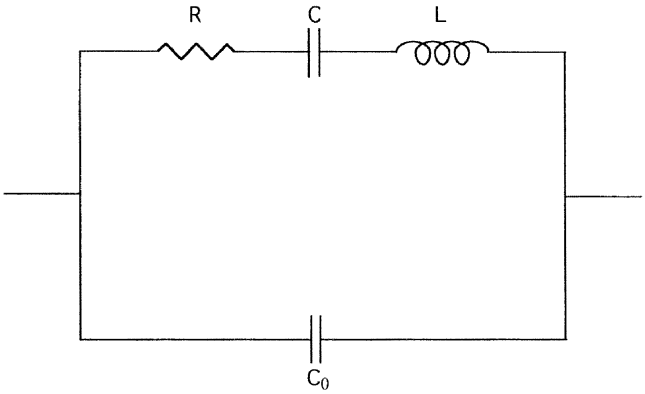

Figure 3. Equivalent electrical circuit describing the properties of a quartz resonator.

capacitances due to the connections to the crystal and its environment. The resistance R represents the energy dissipation due to internal friction, mechanical losses in the mounting system, and acoustical losses to the surrounding environment. The capacitance C represents the compliance of the quartz or the energy stored during oscillation. The inductance is the only component related to the mass; L is the inertial component representing the mass displaced during oscillation.

The electrical parameters can be expressed in terms of crystal properties (Cady, 1964):

$$C_0 = \frac{D_q \varepsilon_0 A}{t_q} \approx 10^{-12}\,\mathrm{F} \tag{6}$$

$$C = \frac{8A \in^2}{\pi^2 t_q c} \approx 10^{-14}\,\mathrm{F} \tag{7}$$

$$R = \frac{t_q^3 r}{8A \in^2} \approx 100\,\Omega \tag{8}$$

$$L = \frac{t_q^3 \rho}{8A \in^2} \approx 0.075\,\mathrm{H} \tag{9}$$

where D_q is the dielectric constant of quartz, ε_0 is the permittivity of free space, A is the piezoelectric active area, t_q is the thickness of quartz, c is the elastic constant of quartz, r is a dissipation coefficient corresponding to energy losses during oscillation, ρ is the density of quartz, and $\in$ is the piezoelectric stress constant. Typical values for a 5-MHz quartz resonator are given (Buttry and Ward, 1992).

Understanding what factors affect these terms will be useful in analyzing the results obtained from the QCM (see Data Analysis and Initial Interpretation). The parameters C, R, and L depend on $\in$, the piezoelectric stress constant. Note, however, that C_0 does not participate directly in piezoelectricity as it does not depend on $\in$. Capacitance C depends on the elastic constant of quartz; it is the component that responds to energy compliance. Resistance R depends upon the dissipation energy r, which results from thermal dissipation in the quartz resonator and coupling of the acoustic wave to the environment. An increase in the dissipation energy will therefore result in an increase in R. Inductance L depends on the density of the quartz. The quantity $t_q^3\rho/A$ represents mass per unit area and is related to the $\Delta m/A$ term in the Sauerbrey equation. An increase in mass will therefore result in an increase in L. Also note the relationship of these terms to the piezoelectric active area A. Capacitances C_0 and C increase with area, while R and L decrease with area.

Impedance Analysis

Frequency changes alone are not sufficient to ensure that all analyses made using the QCM are accurate. This is because frequency changes can occur due to other factors. Impedance analysis (also called network analysis) is needed to better characterize the deposit on the quartz crystal (Kipling and Thompson, 1990; Noel and Topart, 1994). Factors that can cause a frequency change (and not necessarily be directly related to a mass change) include (1) viscoelastic changes in the film deposited on the crystal (these properties can change with thickness as well as due to the experiment performed, such as doping of a polymer), (2) interactions with the contacting liquid that can cause swelling of a polymer, (3) morphological changes of the polymer, and (4) nonuniform mass deposition.

Impedance analysis (Honda, 1989), therefore, is useful in analyzing the properties of the quartz crystal, properties of films deposited onto the surface of the crystal, and the interaction of the crystal with a contacting liquid (Martin et al., 1991). This analysis is performed to confirm that the frequency changes observed can be related to mass changes.

The impedance of a quartz crystal is measured by applying a known voltage over a specified range of frequencies and measuring the current. By analogy with Ohm's law, $V = IZ$, where Z is the impedance, V is voltage, and I is current. The impedance is a sum of both the resistance R and the reactance X:

$$Z = R + jX \tag{10}$$

For direct current, this reduces to $Z = R$. Impedance can be represented as a complex quantity that is graphically shown in the complex plane in Figure 4, where the imaginary unit $j(\equiv \sqrt{-1})$ is introduced. The absolute value of the impedance is given by $|Z| = (R^2 + X^2)^{1/2}$.

Since the equivalent circuit for a quartz resonator consists of a static capacitance in parallel with the RLC components, it is better to use the inverse of impedance, Z, which is admittance, Y:

$$Y = G + jB \tag{11}$$

where G is the conductance (reciprocal of R) and B is the susceptance (reciprocal of X). The absolute value of the admittance is given by $|Y| = (G^2 + B^2)^{1/2}$. The unit of impedance is the ohm and the unit of admittance is therefore the inverse ohm or siemen (S). This measurement is most conveniently made with an impedance analyzer that is capable of recording these parameters of interest: impedance (Z), phase angle (θ, where $\theta = \tan^{-1}(X/R)$), admittance (Y), conductance (G), and susceptance (B).

A piezoelectric quartz resonator produces a susceptance B that rapidly changes with frequency. The frequency at

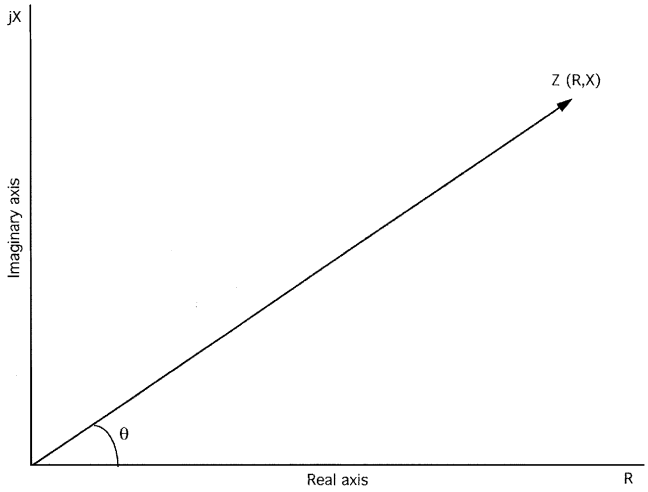

Figure 4. Impedance (Z) as a component of the real resistance (R) and the imaginary reactance (X). The polar form consists of the magnitude and the phase angle: $|Z|\angle\theta$.

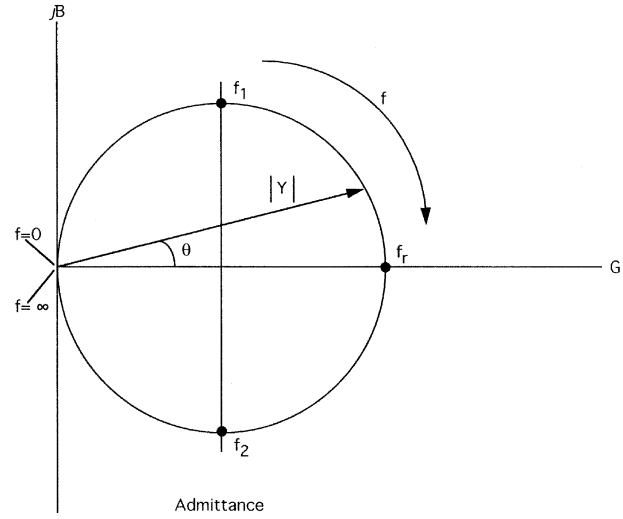

Figure 6. Admittance, Y, locus for RCL circuit: real component conductance G vs. imaginary component susceptance B. Resonance frequency f_r occurs when $Y = G$ and $\theta = 0$.

which capacitive susceptance (capacitive reactance) equals the inductive susceptance (inductive reactance) is the resonance frequency of the quartz oscillator; admittance is a maximum and impedance a minimum at this frequency ($Y = G$ or $Z = R$).This is the resonance frequency of a quartz oscillator.

This is illustrated in Figure 5 with a plot of $|X|$ vs. frequency (ω) for an ideal capacitor and an ideal inductor. The reactance of an ideal capacitor is inversely proportional to frequency. The reactance of an ideal inductor increases linearly with frequency. The point at which they are equal is the resonance frequency. The reactances cancel and therefore the impedance is at a minimum ($Z = R$).

Since admittance (and impedance) are complex quantities, it is useful to express the frequency relationship as an admittance locus as shown in Figure 6 for a series RLC circuit. Admittance is composed of both the real component G, conductance, on the abscissa and the imaginary component jB, susceptance, on the ordinate. As frequency increases, the imaginary component jB reaches a maximum at f_1. The imaginary component reaches a minimum at f_2. When the frequency crosses the real axis, G is a maximum. This is the resonance frequency (f_r) because $Y = G$ at this point. Note that the phase angle θ is also equal to zero at the resonance frequency. This is necessary to fulfill the standing-wave condition.

The RLC circuit shown in Figure 6 must be modified for a quartz resonator (Tiean et al. 1990; Buttry and Ward, 1992). The additional contribution of the static capacitance C_0 raises the admittance locus along the imaginary axis by ωC_0, as shown in Figure 7. This causes several important changes to the diagram. Resonance

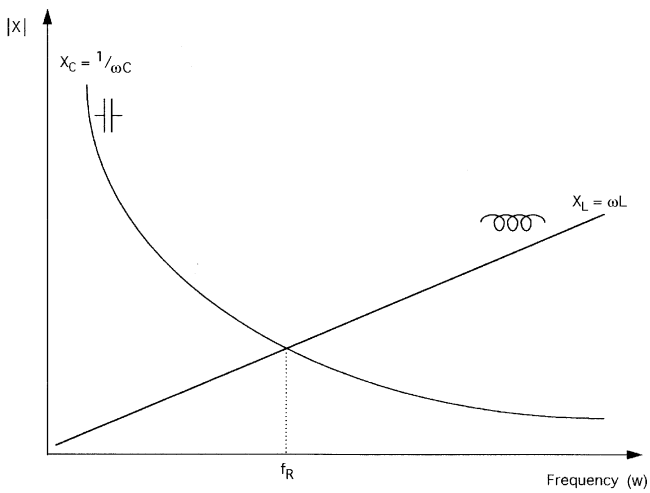

Figure 5. Absolute reactance vs. frequency plot for an ideal capacitor and an ideal inductor indicating resonance frequency.

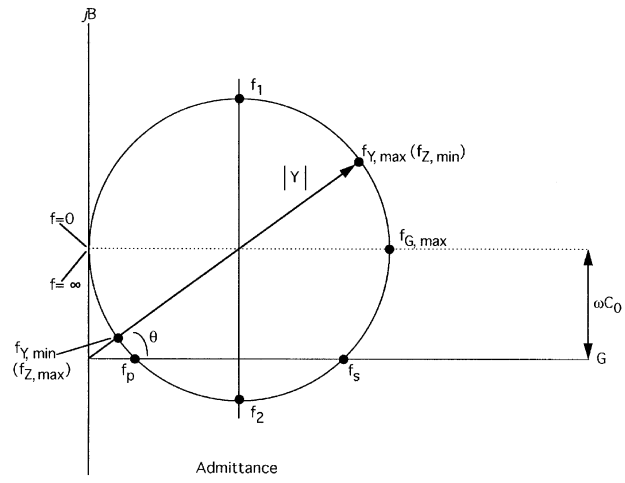

Figure 7. Admittance locus for quartz resonator: real component conductance G vs. imaginary component susceptance B. Static capacitance C_0 raises admittance locus resulting in two resonance frequencies, f_s (series frequency) and f_p (parallel frequency), when $\theta = 0$.

is now satisfied at two frequencies: f_s (series frequency) and f_p (parallel frequency), since the phase angle θ must equal zero at both f_s and f_p. However, the frequency of maximum susceptance, $f_{G,max}$, now occurs at a slightly lower frequency than f_s. The real part of the admittance at f_s is slightly less than G_{max}. The real part of the admittance of the second resonant frequency, f_p, is slightly greater than zero. The frequency of f_p is slightly less than the frequency of minimum admittance, $f_{Y,min}$. The series frequency f_s is the frequency generally measured with the QCM. When a frequency counter alone is used in QCM, the frequency most often monitored is f_s. However, the parallel frequency f_p is also useful in providing information about the surface deposit (Buttry and Ward, 1992).

The frequencies f_s and f_p can converge if R or C_0 increases. As C_0 increases, the admittance locus is raised, causing f_s and f_p to approach similar values. If R increases, the diameter of the locus decreases, thereby causing f_s and f_p to converge. It should be noted that very large values of R or C_0 will result in admittance loci that do not cross the real axis, G. The phase angle no longer equals zero and resonance cannot occur.

The impedance analyzer can provide plots of Z and θ vs. frequency, as shown in Figure 8 for a blank 5-MHz quartz crystal. The frequency of Z_{min} is approximately the frequency of $\theta = 0$, which is f_s. The frequency of Z_{max} is close in frequency to the value of the second resonant frequency, f_p, where θ also equals zero. Plots of B and G can also be displayed as shown in Figure 9. The frequency of G_{max} is close to the resonant frequency, f_s. As shown in Figure 9, the frequencies of B_{max} and B_{min} coincide with the peak width at half-height of the plot of G (noted as f_1 and f_2 Fig. 9). Current flows most easily at frequencies near $f_{G,max}$. Quartz crystals behave as bandpass filters. The bandwidth is $f_2 - f_1$. Quartz resonators have very small bandwidths; therefore, they are ideal for frequency control. The sharp conductance peak ensures that the feedback loop of the oscillator circuit is able to lock in on the narrow frequency range.

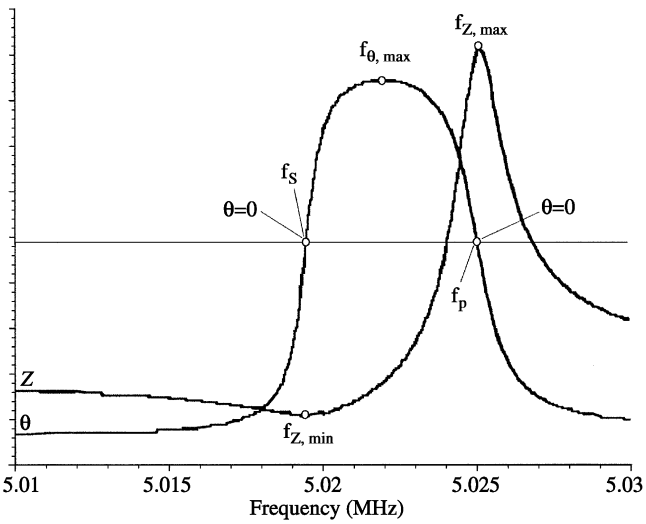

Figure 8. Impedance Z (sharp change at $f_{Z,max}$) and phase angle θ (broad peak at $f_{\theta,max}$) vs. frequency of a blank 5-MHz quartz crystal in the resonance region.

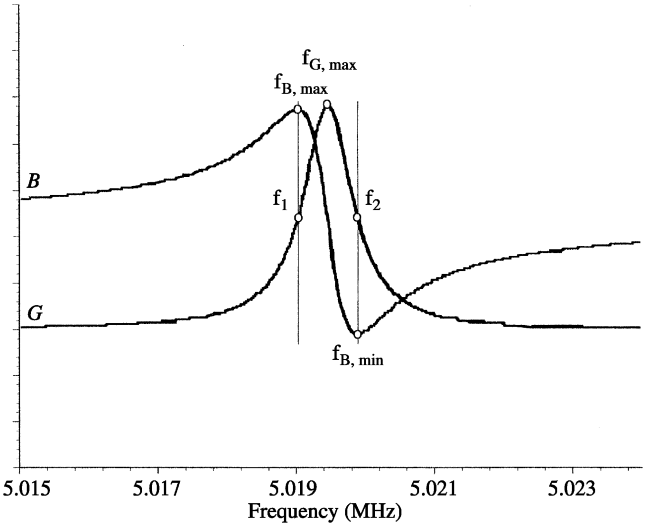

Figure 9. Plot of conductance (G) and susceptance (B) vs. frequency.

Quartz crystals have very high quality factors, Q. The bandwidth and the resonant frequency determine Q. The high values of Q for quartz crystals (~100,000) are due to their high inductance and low resistance. The quality factor can be determined from the information in Figure 9. It is the ratio of the energy stored to the energy lost during oscillation. This is approximated by $f_{G,max}$ divided by $f_2 - f_1$:

$$Q = \frac{f_s}{f_2 - f_1} = \frac{f_{G,max}}{f_2 - f_1} \tag{12}$$

The quality factor Q should be measured before, during, and after a QCM experiment. The frequency of G_{max} is influenced by changes in mass. Large changes in $f_2 - f_1$, however, indicate a large increase in the energy dissipated. Under these conditions, the Sauerbrey equation is not applicable.

A conductance plot should be made to evaluate the quality factor. A plot of G vs. frequency for a blank 5-MHz quartz crystal is shown in Figure 10A. The plot in Figure 10B illustrates how the frequency of G_{max} has decreased and the full width at half height ($f_2 - f_1$) changes slightly due to the added mass of a polymer film. However, the factor Q has only changed from 1.6×10^4 to 9.8×10^3, indicating that the Sauerbrey relationship can still be applied.

Film and Solution Effects

In actual QCM experiments, additional factors are involved that modify the equivalent circuit. The film deposited onto the crystal and the liquid in contact with the crystal make contributions. The added liquid produces a mechanical impedance. Additional components are the inductance L_f, viscosity η_f, density ρ_f, energy dissipation R_d, and elasticity C_f of the film as well as the viscosity η_L and the density ρ_L of the solution. These additional

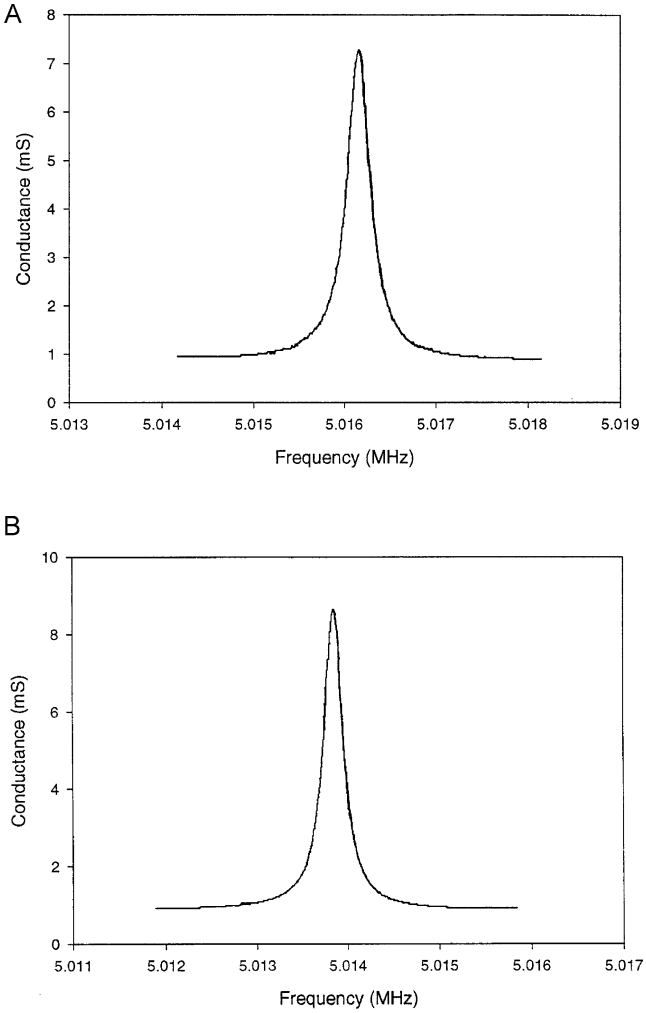

Figure 10. (**A**) Conductance G vs. frequency of a blank 5-MHz crystal. (**B**) Conductance G vs. frequency of the same 5-MHz crystal after deposition of a polymer film indicating little change in $f_2 - f_1$ and a decrease in $f_{G,\max}$. Note change in frequency range.

components are illustrated in Figure 11 and discussed in detail elsewhere (Buttry and Ward, 1992).

Recognizing that these other factors can influence the measured frequency change is important for correct data analysis. Since most EQCM studies are done with a constant amount of solution above the crystal, η_L and ρ_L can be assumed to remain constant during the measurement.

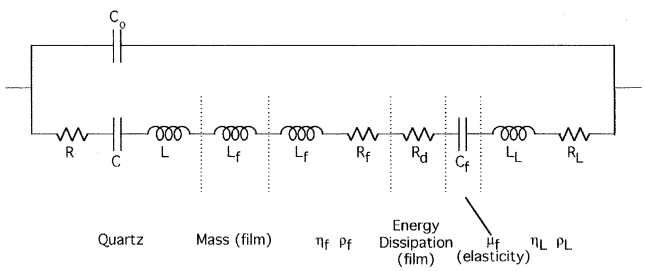

Figure 11. Equivalent electrical circuit for an AT-cut quartz resonator including film and solution components.

This also illustrates why the QCM cannot be used to measure an absolute mass value. Specifically, changes in mass are reported by the QCM.

Especially when polymer films are under investigation, the components in Figure 11 should be considered. This indicates that the measurement of the change in f_s is not enough. Other contributions from the elasticity, density, and viscosity of the film may contribute to the observed Δf_s. One method to determine if these viscoelastic effects influence a particular system is to carry out the QCM measurements over a range of film thicknesses. If the observed mass change is linear with film thickness, the viscoelastic effects are not significant. Impedance analysis can be used to evaluate the other contributions when they lead to nonideal behavior.

PRACTICAL ASPECTS OF THE METHOD

Instrumentation

Several commercial EQCM systems are available. The advantages are ease of initial set-up, including experimentation and computer analysis. Limitations are (1) the need to purchase quartz crystals with electrodes from the manufacturer (this limits experimental design changes), (2) the lack of direct access to the components (i.e., accepting values without full understanding of how they were obtained), and (3) the lack of impedance analysis to confirm the Sauerbrey relationship for a particular system.

Since a large majority of EQCMs have been home-built systems, this aspect will be addressed. The EQCM consists of a quartz crystal, one side of which acts as the working electrode, an appropriate cell holder, counter and reference electrodes, and instrumentation. A schematic of a typical system is shown in Figure 12. The top of the crystal (working electrode) is connected to ground. This limits the

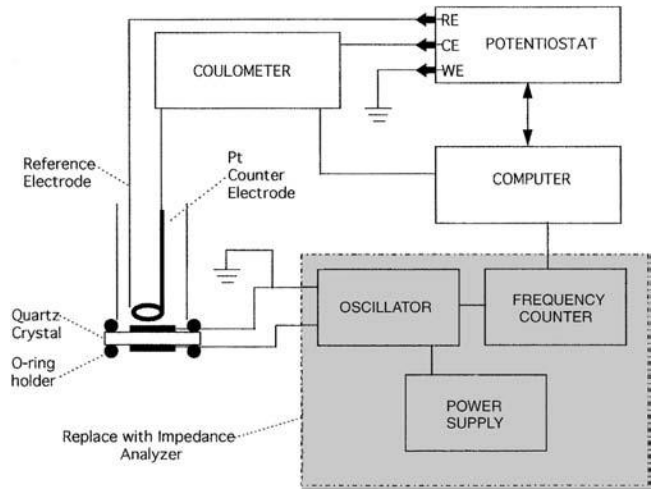

Figure 12. Schematic of a home-built electrochemical quartz crystal microbalance. The oscillator, frequency counter, and power supply can be replaced with an impedance analyzer. The electrochemical cell consists of a Pt counter electrode and reference electrode. The working electrode is the top of the quartz crystal.

use of a commercial potentiostat to measure the charge flow. A coulometer can be placed in the circuit between the potentiostat and the QCM, as shown in Figure 12. Another option is to measure the voltage drop across a known resistor, converting to current and integrating to obtain charge.

The QCM instrumentation consists of a voltage source (power supply) for the oscillator circuit and a frequency counter to record frequency changes. Several oscillator circuit diagrams are available in the literature and the oscillator circuit can be readily constructed (Bruckenstein and Shay, 1985; Benje et al., 1986; Deakin and Melroy, 1989; Buttry, 1991). Another option is for the oscillator circuit, power supply, and frequency counter to be replaced by an impedance analyzer, as shown in Figure 12. The advantages are very stable frequency measurements and the additional ability to record impedance and/or admittance, as discussed under Principles of the Method.

Recently, reports of dual QCM oscillator circuits have been published (Bruckenstein et al., 1994; Dunham et al., 1995). The spectroelectrochemical quartz crystal microbalance (SEQCM) was recently introduced (Arbuckle and Travis, 1994). It integrates spectroelectrochemistry and QCM. A configuration such as shown in Figure 13 can be utilized. The electrochemistry is performed directly in the sample compartment of the spectrometer. Modifications must be performed to allow transmission through the electrodes and quartz crystal. Thin metal electrodes are vapor deposited onto the quartz crystal so that ultraviolet (UV)/visible/near-infrared (NIR) radiation can be transmitted. The electrochemical cell is shown in Figure 13. The counter and reference electrodes are positioned so as to not interfere with the transmitted radiation.

Advantages of the SEQCM include the simultaneous measurement of spectral change and mass change during electrochemical synthesis of a material or observations of the spectral changes and mass changes during oxidation-reduction of an electroactive polymer.

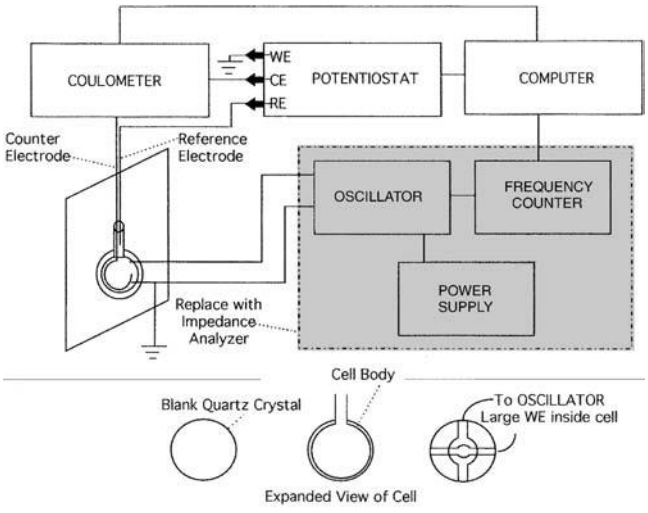

Figure 13. A spectroelectrochemical/quartz crystal microbalance. The electrochemical cell is placed directly into the sample compartment of a spectrometer. The working electrode is the quartz crystal with the active side (larger electrode) facing toward the solution. A blank (no electrodes) quartz crystal acts as the other side of the cell. The Pt counter and reference electrodes are configured to not interfere with the transmitted radiation.

Quartz Crystals

Quartz crystals are commercially available with a range of thicknesses (and hence resonant frequencies) from a variety of sources (see Internet Resources). The most commonly used quartz crystals are 5 and 10 MHz. The 5-MHz crystal is usually 1 in. in diameter and 0.013 in. thick. This is a convenient size to handle. Higher frequency crystals are thinner and more prone to breakage.

The crystals can be purchased as either plano-plano or plano-convex quartz crystals. Both surfaces are parallel in plano-plano crystals. The plano-convex crystals have a radius of curvature on the convex side that can range from 10 to 50 cm for a 5-MHz crystal. The use of both types of crystals have been reported (Buttry, 1991). Plano-convex crystals confine the region of displacement to the area defined by the smaller of the two electrodes. The displacement extends somewhat beyond the electrode for plano-plano crystals. A study of the mass sensitivity distribution of plano-plano and plano-convex AT-cut quartz crystals has been performed (Ward and Delawski, 1991; Hillier and Ward, 1992). It was found that the plano-plano crystals have a Gaussian-like sensitivity distribution, with the greatest sensitivity at the center of the electrode. Sensitivity to mass changes on the electrode tabs was found as well. The plano-convex quartz crystals display a considerably different sensitivity. The maximum at the center is much larger. The Gaussian describing the behavior has a greater amplitude and drops to a low value at the electrode edges.

In spite of these observations, bulk calibration results indicate that the overall sensitivity as defined by C_f is the same for both types of crystals. Calibration values can be obtained by electrodeposition of copper. By noting the amount of charge passed and the area of the electrode, the mass sensitivity of the particular QCM can be determined. The calibrated values are usually somewhat smaller than the value predicted by the Sauerbrey equation (0.057 Hz cm^2/ng). This may be attributed to sensitivity beyond the electrodes.

The viscosity of the liquid above the crystal has been found to influence the sensitivity constant C_f (Hillier and Ward, 1992). Therefore, care should be taken to calibrate the QCM under the conditions that will be used during an investigation. Other studies of the calibration of the EQCM have been reported (Gabrielli et al., 1991; Oltra and Efimov, 1994).

METHOD AUTOMATION

Commercial Instrumentation

Commercial EQCMs record frequency and charge changes with applied voltage. Using commercial EQCM instruments, these parameters are usually recorded by interfacing the equipment to a computer. A board may be supplied by the EQCM manufacturer or the user may need to take

the output (RS-232 or GP-IB) and interface it to a computer. Ideally, real-time data can be displayed and the course of the reaction can be monitored. Commercial software packages may be designed to provide ease of data manipulation, such as conversion from frequency to mass change and overlays of mass and charge relationships vs. time.

Home-Built EQCMs

For home-built systems, a computer interface must also be used to record the frequency (from a frequency counter or an impedance analyzer), charge (from a coulometer or the voltage drop across a resistor), and voltage (applied potential). A variety of commercial interfacing software packages are available. For example, LabView by National Instruments is a well-reviewed commercial package. Much of the instrumentation used is IEEE (GP-IB) compliant. The software directs the instrumentation to collect the measurement of frequency and/or charge as a function of time and the result is displayed on the computer screen. A real-time display is useful in monitoring the results and modifying the experiment when necessary. The amount of programming required varies from one software package to another. Advantages of home-built systems are the ability to modify the QCM, for example to simultaneously record mass change and resistance change vs. time during the doping of a conducting polymer (Hall and Arbuckle, 1996).

DATA ANALYSIS AND INITIAL INTERPRETATION

Electrochemical Reactions

Data analysis generally consists of evaluating the change in frequency and other variables such as charge and applied potential vs. time. The frequency results can readily be converted to a change in mass using the appropriate calibration factor, as discussed under Practical Aspects of the Method. The amount of mass change observed should be compared with the amount of charge passed. Correlations can be made with the theoretical mass change expected from the coulombs passed. Various hypotheses may need to be tested to explain the observed mass change. For example, in the electrochemical oxidation-reduction of a conducting polymer, the amount of mass change may be expected to correspond to the mass of the anion in the electrolyte. However, the anion will be solvated. In addition, a simple "one anion in, one anion out" scenario may not be correct. Other considerations are movement of both cation AND anion with solvent in and out of the polymer film.

Series and Parallel Frequency

Both the series and parallel frequencies f_s and f_p can be measured using an impedance analyzer. A plot of f_s and f_p vs. time for the doping of a conducting polymer is shown in Figure 14. Both frequencies decrease with doping, indicating a mass increase due to the dopant. As expected from the plot of impedance vs. frequency in Figure 8, f_p is higher. The variation in parallel frequency can be utilized to study conformational changes of deposits (Yang et al., 1993). The

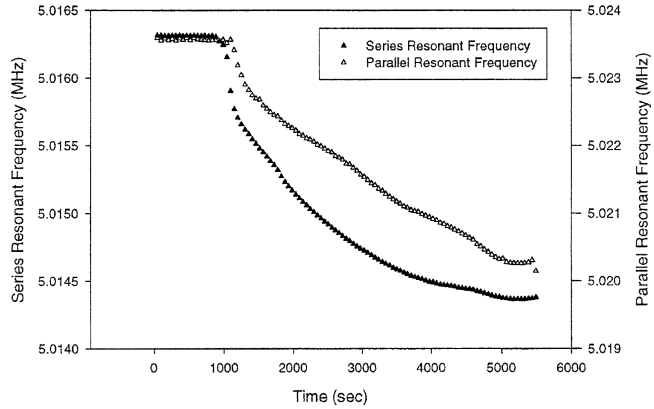

Figure 14. Series and parallel frequencies (in megahertz) vs. time for the doping of a conducting polymer, poly(*p*-phenylene vinylene). The series frequency provides the mas increase due to the dopant. The parallel frequency indicates changes in conformation.

change in parallel resonant frequency can also be correlated with changes in conductivity of the medium (Rodahl et al., 1996), which is in agreement with the result shown in Figure 14.

SAMPLE PREPARATION

Sample preparation begins with the preparation of the quartz crystals. If commercial crystals with deposited electrodes are purchased, they should still be carefully cleaned with ethanol and dried before use.

If blank quartz crystals are purchased from a supplier, electrodes must be vapor deposited onto the quartz crystal. Before vapor deposition the crystals must be thoroughly cleaned. Sonification in a dilute soap solution for 60 min has been found to be sufficient. Gold is typically used as the electrode. However, for the gold to adhere to the quartz, an underlayer of chromium is applied. Typically 100 Å of chromium is deposited followed by 1000 Å of gold. This is done on both sides of the quartz crystal in a keyhole pattern, as shown in Figure 2A.

Initially a mask to hold the quartz crystals and to provide deposition of a particular electrode pattern must be machined for vapor deposition.

After vapor deposition of the electrodes, the quartz crystals should be kept clean and gently recleaned immediately prior to an experiment. It has been found that better results are obtained with freshly deposited electrodes since the gold slightly oxidizes with time.

Depending on the experiment, either the films are electrochemically prepared during the QCM analysis or a polymer film is cast onto the quartz crystal prior to performing QCM studies. For example, a conducting polymer can be spin cast onto the quartz crystal with electrodes. The casting solvent is used to carefully remove the polymer from the edges of the quartz crystal where the electrical connections need to be attached. The electrical connections can be made (1) with flat alligator clips, (2) with spring-loaded clips, or (3) by attaching small wires with conducting solder and connecting to the wire rather than the crystal.

Since the crystals are fragile, care must be taken when attaching connections.

For an electrochemical experiment, a freshly cleaned crystal is mounted, as shown in Figure 12, and the potential is applied immediately after the measured resonance frequency stabilizes. In the case of some chemical systems, a thin film may begin to form (chemically) if the electrode is left in contact with the solution for an extended time. Therefore, the potential is applied to initiate the desired electrochemical reaction as soon as a stable resonance frequency is obtained.

SPECIMEN MODIFICATION

One of the advantages of EQCM is that the electrochemical synthesis of a material can be monitored *in situ*. For example, after a stable frequency is obtained for the quartz crystal in contact with the solution, a constant or varying potential can be applied to the working electrode (top of the crystal in Fig. 12), which will initiate an electrochemical reaction. The charge that flows and the frequency decrease (mass increase) is recorded.

For example, the process of the electrochemical synthesis of polyazulene monitored by EQCM is shown in Figure 15. The applied potential is varied from −0.05 to 1.0 V at a rate of 50 mV/sec. The overall frequency decreases with time, indicating mass deposition onto the electrode on the quartz crystal (Fig. 15A). The corresponding charge-vs.-time plot in Figure 15B parallels this mass increase. A sawtoothlike wave is superimposed onto the frequency and charge plots. This is due to the variation in potential that causes oxidation and reduction of the growing polymer. The size of the sawtooth increases as more material is deposited onto the electrode and can therefore be oxidized/reduced by each subsequent cycle.

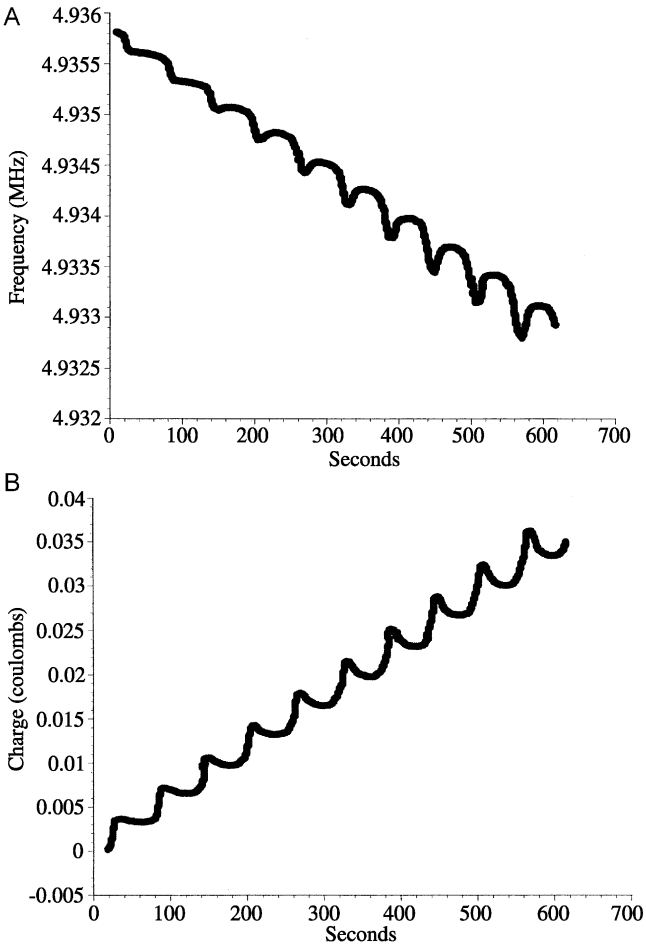

Figure 15. (**A**) Frequency (in megahertz) plot vs. time for the electrochemical synthesis of polyazulene from a solution of 0.005 M azulene in 0.1 M tetraethylammonium tetrafluoroborate in acetonitrile. The potential is cycled between −0.05 and 1.0 V vs. SCE at a rate of 50 mV/sec. (**B**) Charge (in coulombs) plot vs. time for the electrochemical synthesis of polyazulene.

PROBLEMS

Care must be taken to ensure that mass changes observed are not misinterpreted. A calibration of the particular EQCM should always be made. If any changes in the system (e.g., type of crystal, thickness of electrode, and shape of electrode) are made, a new calibration must be performed. Ideally the deposit used for the calibration and the viscosity of the medium should approximate that of the experiment as much as possible.

In addition, as mentioned under Principles of the Method, phenomena other than an actual mass change can give rise to an observed frequency change. This is especially a concern for polymer materials due to the added viscoelastic effects possible in these materials. Therefore, the polymer reaction should be studied at a variety of thicknesses (all <2% of that of the crystal) and the linearity of the results noted. Impedance analysis is especially useful as well. The quality factor Q of the blank crystal, polymer deposit, and final product should be compared. Significant changes in Q during an experiment indicate that the Sauerbrey relationship no longer applies.

When using the impedance analyzer, f_s is defined as the frequency at which $\theta = 0$. Occasionally the impedance plot does not intersect phase equal to zero. In some cases it may be necessary to increase the oscillator level applied by the impedance analyzer to the quartz resonator in order to increase the amplitude of the impedance plot so that the series frequency f_s can be determined.

ACKNOWLEDGMENTS

The author would like to thank Michael T. Kelly and Hiren Shah for assistance with figures and John Gagliardi for careful reading of the manuscript. Acknowledgement is made for an Alfred P. Sloan Research Fellowship.

OPTICAL IMAGING AND SPECTROSCOPY

INTRODUCTION

All materials absorb and emit electromagnetic radiation. The characteristics of a material frequently manifest themselves in the way it interacts with radiation. The fundamental basis for the interaction varies with the wavelength of the radiation, and the information gleaned from the material under study will likewise vary. Materials interact with radiation in some fashion across the entire electromagnetic spectrum, which can be thought of as spanning the frequency realm from near DC oscillations found in circuits (<1 Hz) through the extremely high frequency oscillations typical of gamma radiation ($>10^{19}$ Hz). Shown in the Table 1 is a representation of the electromagnetic spectrum, giving the correspondence of wavelength, frequency, and common terminology applied to the sub-bands.

Because human vision depends on the interaction of light with the rods and cones of the retina in the range of photon wavelengths from about 0.7 to 0.4 micrometers, this "visible" spectrum is particularly important to us. Materials are directly observed using instrumentation that magnifies and records visible light; this is the subject of the optical microscopy units in this chapter. As an adjunct to the value of direct observation of the structure of materials, often, a desirable material property arises from its interaction with visible light. The visible and ultraviolet regions are the basis for the units in this chapter, and, as seen in Table 1, they occupy the midpoint on the energy scale. Yet, it is valuable to note the interactions of electromagnetic radiation from the full-spectrum perspective, both for understanding the role that optical methods play and for realizing their relationship to those presented in other chapters throughout *Characterization of Materials*. Thus, we briefly consider here how all radiation—from DC to x ray—interacts with materials.

In the most general sense, radiation can be considered to interact with materials either by absorption, reflection, or scattering; this is the basis for Kirchoff's law, which is discussed in COMMON CONCEPTS IN MATERIALS CHARACTERIZATION.

As indicated in Table 1, the nature of the interaction between photons and matter governs the observed effects. At very low frequencies, we think of the photons more as a time-dependent electric field than as a packet of energy. Interactions with matter in this regime are exploited in the electrical and electronic characterization of transients and charge carriers in materials. This is the topic of many of the units in ELECTRICAL AND ELECTRONIC MEASUREMENTS. At higher frequencies, the nuclear (RF) and electronic (microwave) Zeeman effects become observable by virtue of transitions between states in the presence of the internal quadrupole field of the nuclei (nuclear quadrupole resonance) and/or in the presence of an externally applied field (nuclear magnetic resonance and electron spin resonance, see RESONANCE METHODS).

The microwave region is also an important regime for materials characterization, as the measurement of dielectric properties such as permittivity and dielectric loss tangent, surface resistance, and skin depth become feasible using radiation in this region. Some of these measurements are discussed in detail in ELECTRICAL AND ELECTRONIC MEASUREMENTS. As we continue up in frequency, we enter the domain of the lowest-frequency molecular vibrations in materials, lattice vibrations, or phonons, which couple to the oscillating electric field of the probe radiation. Phonons can also be probed using neutron scattering, a complementary method described in detail in NEUTRON TECHNIQUES, and by inelastic scattering of radiation (Brillouin spectroscopy).

The next jump in frequency enters the infrared radiation region, in which the electromagnetic field is coupled with the intermolecular motions of chemical bonds in the material structure. Also known as vibrational spectroscopy, the study of the spectra of materials in this regime provides information on chemical composition, as several characteristic frequency bands can be directly related to the atom and bond types involved in the vibrational motion. An important detail deserves mention here, as a shift occurs at this point in convention and nomenclature. Researchers in the lower frequency fields (DC through far infrared) typically report their measurements in frequency units. In infrared work the most common unit employed is the wavenumber, or reciprocal centimeter, although there is an increasing use of wavelength (reported in microns) in some disciplines. Analogous to Brillouin spectroscopy is Raman spectroscopy, which measures vibrational transitions by observing inelastically scattered radiation. Raman spectroscopy is complementary to infrared spectroscopy by virtue of the selection rules governing transitions between vibrational states—whereas a change in overall dipole moment in the molecule gives rise to infrared absorption, a change in overall polarizability of the molecule gives rise to the vibrational structure observed in Raman spectroscopy.

At still higher frequencies, we access transitions between electronic states within molecules and atoms, and again the conventions change. Here, convention favors units of wavelength. The underlying phenomena studied range from overtones of the molecular vibrations (near-infrared) to vibrational-electronic (vibronic) transitions, to charge transfer transitions and pure electronic spectra (visible through ultraviolet spectroscopy). Electronic spectroscopy, like vibrational spectroscopy, also reflects the chemical makeup of the material. The intensity of electronic transitions, a function of the type of molecular orbitals

Table 1. The Electromagnetic Spectrum: A Materials Perspective[a]

Spectral Region	Frequency Range (Hz)	Wavelength Range (m)	Unit Conventions	Interactions with Matter	Representative Materials Properties Accessible
Extremely low frequency	$<3 \times 10^2$	$>1 \times 10^6$	Hz	Electron transport	Conductivity, free carrier concentration
Radiofrequency					
Very low frequency (VLF)	3×10^2 to 3×10^4	1×10^6 to 1×10^4	Hz	Nuclear magnetic resonance; nuclear quadrupole resonance	Microscopic structure; chemical composition
Low frequency (LF)	3×10^4 to 3×10^5	1×10^4 to 1×10^3	kHz		
Medium frequency (MF)	3×10^5 to 3×10^6	1×10^3 to 1×10^2	kHz		
High frequency (HF)	3×10^6 to 3×10^7	1×10^2 to 1×10^1	kHz		
Very high frequency (VHF)	3×10^7 to 3×10^8	1×10^1 to 1×10^0	MHz		
Ultra high frequency	3×10^8 to 3×10^9	1×10^0 to 1×10^{-1}	MHz		
Microwave					
Super high frequency (SHF)	3×10^9 to 3×10^{10}	1×10^{-1} to 1×10^{-2}	GHz	Electron paramagnetic resonance; molecular rotations	Microscopic structure; surface conductivity
Extremely high frequency (EHF)	3×10^{10} to 3×10^{11}	1×10^{-2} to 1×10^{-3}	GHz		
Submillimeter	3×10^{11} to 3×10^{12}	1×10^{-3} to 1×10^{-4}	THz		
Infrared					
Far infrared (FIR)	$\sim 3 \times 10^{12}$ to 1.2×10^{13}	$\sim 1 \times 10^{-4}$ to 2.5×10^{-5}	THz, cm^{-1}, kiloKayser (kK, = 1000 cm^{-1}), micron (μm)	Librations, molecular vibrations, vibrational overtones, vibronic transitions	Microscopic and macroscopic structure, phases, chemical composition
Intermediate infrared	1.2×10^{13} to 3×10^{14}	2.5×10^{-5} to 1×10^{-6}			
Near infrared (NIR)	3×10^{14} to 3.8×10^{14}	1×10^{-6} to 7.9×10^{-7}			
Visible	3.8×10^{14} to 7.5×10^{14}	7.9×10^{-7} to 4×10^{-7}	kK, nm, μm	Valence shell, π bonding electronic transitions	Chemical composition and concentration
Ultraviolet					
Near ultraviolet	7.5×10^{14} to 1.5×10^{15}	4×10^{-7} to 2×10^{-7}	nm	Inner shell, σ bonding electronic transitions	Chemical composition, bond types, and bond strength
Vacuum ultraviolet	1.5×10^{14} to 3×10^{16}	2×10^{-7} to 1×10^{-8}	eV		
X ray	3×10^{16} to 3×10^{19}	1×10^{-8} to 1×10^{-11}	keV	Core shell electronic transitions, nuclear reactions	Elemental analysis, nature of chemical bonding
γray	$>\sim 3 \times 10^{19}$	$<\sim 1 \times 810^{-11}$	MeV	Nuclear transitions	Elemental analysis, profiling

[a] Note that values preceded by represent "soft definitions," i.e., frequencies that bridge disciplines and may be defined differently depending upon the field of study. In fact, many frequency definitions, especially at the boundaries between spectral regions, are "soft."

in the material, govern the appearance of the observed spectra. Absorption of radiation in this regime is often accompanied by electronic relaxation processes, and, depending on the nature of the electronic states involved, can cause fluorescence and/or phosphorescence, providing another window on the chemical makeup and structure of the material.

Visible and ultraviolet spectroscopies are frequently coupled with other measurement techniques to provide additional insight into the makeup and nature of materials. Changes in materials induced by electrochemical reactions, for instance, can change the observed spectra, or even lead directly to chemiluminescence (ELECTROCHEMICAL TECHNIQUES). Of particular interest to semiconductor studies is the luminescence (photoluminescence, or PL) that follows the promotion of electrons into the valence band of the material by incident photons (ELECTRICAL AND ELECTRONIC MEASUREMENTS). Electrons may even be ejected completely from the material, providing a measure of the work function (the photoelectric effect).

At the high end of the ultraviolet range (vacuum UV) and beyond, yet another shift in convention occurs. This regime traditionally employs the unit of electron volts (eV). Phenomenology of interactions ranges from inner-shell electronic transitions, as observed in ultraviolet and x-ray photoelectron spectroscopy, to nuclear rearrangement, as observed in gamma ray emission in nuclear reactions (ION-BEAM TECHNIQUES). Emitted electrons themselves carry spectroscopic information as kinetic energy; this is the basis for ESCA (electron spectroscopy for chemical analysis), energy dispersive spectroscopy, and Auger electron spectroscopy (ELECTRON TECHNIQUES).

The Mössbauer effect relies on the recoil-free emission of nuclear transition gamma radiation from the nuclei in a solid (the source) and its resonance absorption by identical nuclei in another solid (the absorber). Because recoilless resonance absorption yields an extremely sharp resonance, Mössbauer spectroscopy is a very sensitive probe of the slightest energy level shifts and therefore of the local environment of the emitting and absorbing atoms.

The units collected in this chapter present methods that are useful in the optical characterization of materials. The preceding discussion illustrates how spectroscopy permeates the entire *Characterization of Materials* volume—called upon where appropriate to specific materials studies. Spectroscopy, as a general category of techniques, will certainly remain central to the characterization of materials as materials science continues its advance.

ALAN C. SAMUELS

OPTICAL MICROSCOPY

INTRODUCTION

Among the numerous investigative techniques used to study materials, optical microscopy, with its several diverse variations, is important to the researcher and/or materials engineer for obtaining information concerning the structural state of a material. In the field of metallurgy, light optical metallography is the most widely used investigative tool, and to a lesser degree its methods may be extended to the investigation of nonmetallic materials. The state of microstructure of a metal or alloy, or other engineering material, whether ceramic, polymer or composite, is related directly to its physical, chemical, and mechanical properties as they are influenced by processing and/or service environment. To obtain qualitative, and in many cases quantitative information about the microstructural state of a material, it is often necessary to perform a sequence of specimen-preparation operations, which will reveal the microstructure for observation. Selecting a specimen, cutting it from the bulk material, grinding and polishing an artifact-free surface, then etching the surface to reveal the microstructure, is the usual sequence of specimen-preparation operations (see SAMPLE PREPARATION FOR METALLOGRAPHY). This scheme is appropriate for metals and alloys as well as some ceramic, polymer, and composite materials. Specimens thus prepared are then viewed with a reflected-light microscope (see REFLECTED-LIGHT OPTICAL MICROSCOPY). The microstructure of transparent or translucent ceramic and polymer specimens may be observed using a transmitted-light microscope when appropriately thinned sections are prepared. In all cases, observation of the microstructure is limited by the relatively shallow depth of focus of optical microscopes, the depth of focus being inversely related to the magnification.

Optical microscopy as related to the study of engineering materials can be divided into the categories of reflected-light microscopy for opaque specimens and transmitted-light microscopy for transparent specimens. On the whole, reflected light microscopy is of more utility to materials scientists and engineers because the vast bulk of engineering materials are opaque. Within each of the categories, there are a number of illumination variations (bright field, dark field, polarized light, sensitive tint, phase contrast, and differential interference contrast), each providing a different or enhanced observation of microstructural features. It is fortunate that a majority of illumination variations of reflected-light microscopy parallel those of transmitted-light microscopy.

In general, one does not set out to employ optical microscopy to measure a material property or set of properties. Information gained using optical microscopy is more often than not of a qualitative nature, which, to a skilled observer, translates to a set of correspondences among a material's physical, mechanical, chemical properties as influenced by chemical composition, processing and service history. One can use the measurement methods of quantitative microscopy to follow the progress of microstructural evolution during processing or during the course of exposure to a service environment. Such techniques may be used to follow grain growth, the coarsening of precipitates during a process, or the evolution of microstructure that would lead to catastrophic failure under service conditions. Such a case might be the evolution of the microstructure of steam pipes carrying superheated steam at high pressure that will ultimately fail by creep rupture.

In comparison with other instruments used to produce images of microstructure—transmission electron microscope (TRANSMISSION ELECTRON MICROSCOPY and SCANNING TRANSMISSION ELECTRON MICROSCOPY), scanning electron microscope (SCANNING ELECTRON MICROSCOPY), field ion microscope, scanning tunneling microscope (SCANNING TUNNELING MICROSCOPY), atomic force microscope, and electron beam probe—the light-optical microscope is the instrument of choice for a majority of studies. The reasons are as follows: (1) instrument cost is relatively low, (2) less technician training is required, (3) specimen preparation is relatively straightforward, and (4) the amount of information that can be obtained by an experienced microscopist is large. Because the maximum resolution is limited by the wavelength of light, useful magnification is limited to ~1600 times. At these upper limits of resolution and magnification, microstructural features as small as ~325 nm may be observed. Most of the other instruments are better suited to much higher magnifications, but the area of specimen surface is severely limited, so sampling of the microstructure state is better using optical microscopy.

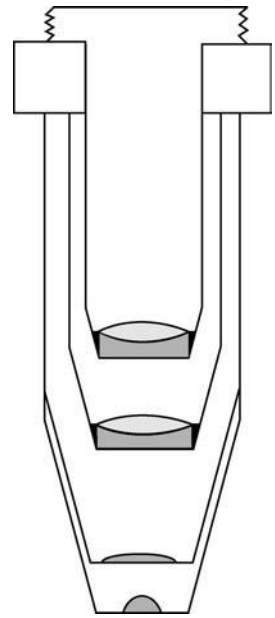

Figure 1. Schematic diagram of a typical objective lens. Note that the plano-convex lens is the "front" lens element of the objective and faces the specimen.

PRACTICAL ASPECTS OF THE METHOD

The Basic Optical Microscope

Early microscopes, though rudimentary compared to today's instruments, provided suitable magnifications, image resolution, and contrast to give early researchers and engineers suitably detailed visual information necessary for the advancement of science and materials application. Modern instruments are indeed sophisticated and incorporate a number of devices designed to enhance image quality, to provide special imaging techniques, and to record images photographically or digitally. Regardless of the sophistication of an instrument, the fundamental components that are of particular importance are a light source, an objective lens, and an ocular or eyepiece.

Significant development of the microscope was not forthcoming until the wave nature of light became known and Huygens proposed a principle that accounted for the propagation of light based on an advancing front of wavelets (Jenkins and White, 1957). Rayleigh was the first to develop a criterion for resolution, which was later refined by Abbe, who is often credited as the "father of optical microscopes" (Gifkins, 1970). Abbe's theory of the microscope was founded upon the concept that every subject consisted of a collection of diffracting points like pinholes, each pinhole behaving like a Huygens light source (Jenkins and White, 1957). It is the function of the objective lens to collect diffracted rays from an illuminated specimen to form an image by constructive and destructive interference from a collection of Huygens sources. Therefore, the function of a lens through which the specimen is viewed is to gather more diffraction information than could be gathered by the unaided eye. This means that an objective lens must be of such geometric configuration as to gather as many orders of diffracted light as possible, to give an image of suitable resolution. The more orders of diffracted rays that can be collected by the objective lens, the greater is the resolution of the lens, and generally the higher the magnification attainable.

By its most basic definition, a lens is a piece of glass or other transparent material bounded by two surfaces, each of a different and/or opposite curvature. From a geometric point of view, light rays passing through a lens either converge or diverge. Any device that can be used to concentrate or disperse light by means of refraction can be called a lens. Objective lenses usually contain a first element (nearest the specimen) that is plano-convex, having a plane front surface and a spherical rear surface (Fig. 1). Additionally, the objective lens may contain a number of elements arranged in several groups, secured in a lens barrel to keep the elements and groups in proper spatial relationship to one another. Likewise the eyepiece or ocular (Fig. 2), usually consists of two lenses, or two or more groups of lenses, each group containing two or more elements.

In a microscope the objective lens, acting like a projector lens, forms a real image of the subject near the top of the microscope tube. Because the image is formed in air, it is often called the aerial image (Restivo, 1992). The eyepiece acts to magnify this real image as a virtual image which is projected by the cornea on the retina of the eye, or it may be projected on the plane of a photographic film or on the surface of some other image recording device. The final magnification observed is the product of the magnification of the objective lens times the magnification of the ocular, except when the microscope contains a zoom magnification device or a magnification multiplier.

To a microscopist, the properties of the objective and the ocular lenses are a first consideration in setting out to use a microscope; therefore, two important properties of objective lenses, magnification and numerical aperture, are usually engraved on the barrel of objective lenses. Like-

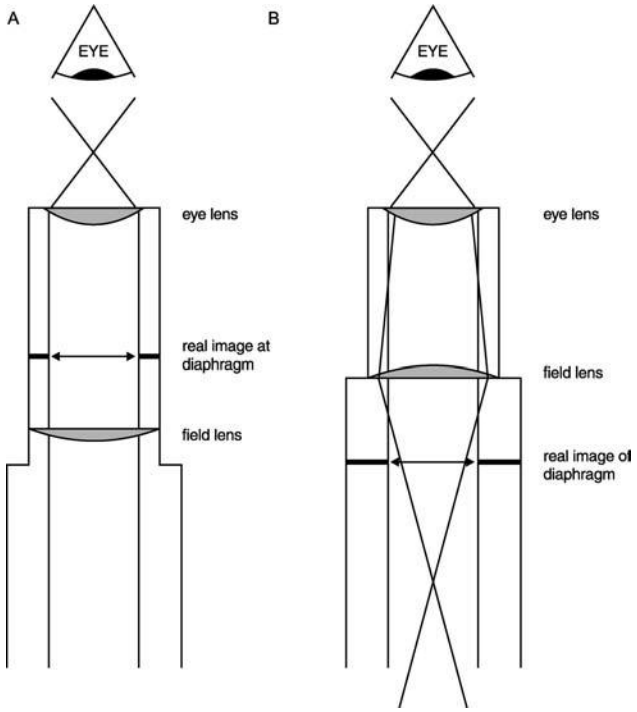

Figure 2. Schematic diagrams of (**A**) a Huygenian ocular and (**B**) a Ramsden ocular. Note the relative orientation of the field lens and the field diaphragms.

wise, magnification is engraved on the ocular. For an objective and ocular to work together properly, their focal lengths must be such that they are separated by a specific distance, so that a virtual image is produced at the eye or a real image is produced at the viewing plane. This distance is the tube length, defined as the distance between the rear focal plane of the objective and the front focal plane of the ocular. It is universally accepted that for any given microscope the objectives and oculars are designed to work together. Objectives and oculars designed for an instrument must be designed for the same tube length. As a practical rule, objective lenses and oculars should not be mixed or transferred to other microscopes. A number of recent instruments are infinity-corrected, meaning that the eyepieces must also be infinity corrected. Infinity-corrected systems allow for variations in the length of the optical path, so that other devices can be inserted for special purposes.

Characteristics of the Microscope

The characteristics of the microscope that are of the greatest importance to the user are the magnification, resolution, and the absence of lens aberrations.

While *magnification* appears to be a simple concept, without concurrent consideration of resolution it becomes relatively unimportant. Magnification alone cannot assist in revealing detail unless the system also possesses resolving power. The microscopist defines resolution as the distance between two closely spaced points in the subject that can be made observable; thus, resolution, expressed as a linear measure, is better the smaller the distance between the points. Attainable resolution is established by the properties of the objective lens, the wavelength of the illumination, and the index of refraction of the medium between the objective lens and the specimen. When the magnification is great enough for the resolution to be perceived by the eye, no amount of additional magnification will cause the image to have more resolution; no more detail will be visible. Regardless of the resolution of photographic films or charge-coupled devices, the resolution of the microscope, primarily that of the objective lens, is controlling in terms of image detail that can be detected.

Calibration of magnification is altogether straightforward. A ruled scale, usually in tenths and hundredths of a millimeter, is placed on the stage of the microscope and brought into sharp focus. It is customary to photograph such a scale at the full series of magnifications of which the instrument is capable. By measuring the photographic images of the magnified scale, one can easily determine the precise magnification.

The degree of resolution is dependent upon the amount of diffraction information that can be gathered by the objective lens. This factor is most conveniently expressed in terms of the numerical aperture (N.A.) of the objective lens. The N.A. of an objective lens is given by $\text{N.A.} = n \sin \mu$, where n is the index of refraction of the medium between the specimen and the lens (for air, $n = 1$), and μ is the half-angle of the cone of light capable of being accepted by the objective (Gifkins, 1970).

Resolution (R) is dependent upon the wavelength of light (λ) illuminating the specimen, and the N.A. of the objective lens: $R = \lambda/(2 \times \text{N.A.})$ (Gifkins, 1970). The larger the numerical aperture and/or the shorter the wavelength of light, the finer the detail that can be resolved. This expression for resolution is used expressly for reflected-light microscopy, where the objective lens carries light to the specimen, then acts again to collect light reflected from the specimen. Resolution of other reflected-light microscopes, particularly those that operate at low magnification and utilize an off-axis external light source, is not a major concern, because the low-power objectives have small N.A. values.

In transmitted-light microscopy a separate condenser lens supplies light through the specimen; thus, the expression becomes $R = \lambda/(\text{N.A.}_{\text{condenser}} + \text{N.A.}_{\text{objective}})$. By way of example, if one illuminates a specimen with green light ($\lambda = 530$ nm) and uses an objective with a 0.65 N.A., then the $R = 407.7$ nm (4.077×10^{-4} mm). R is the distance between two points on the specimen that can be resolved by the microscope. Even though these points may be resolved by the microscope, they will not appear as separate points unless the magnification of the microscope is sufficient to place them within the resolving power of the human eye. Most people can detect an angular separation of from 1 to 2 min of arc. This amounts to a distance between points of $\sim$0.11 mm at a viewing distance of 250 mm. Therefore, by dividing 0.11 mm by 4.077×10^{-4} mm, one obtains a system magnification of $\sim 270\times$. At least this amount of magnification is required in order to make the two points perceptible to the eye. Any magnification greater than this only makes the image more easily perceived by the eye, but the resolution is not further enhanced.

In practice, the largest numerical aperture is ~1.6. Using this value for numerical aperture and again using green light, one finds that the maximum resolution occurs at a magnification of the order of 650×. A magnification of 1000 or 1600 times may be justified by the increased ease of perception. Some microscope manufacturers suggest, by "rule of thumb," that the practical magnification should be 1000 times the numerical aperture. Other sources recommend lower magnifications depending on the type and magnification of the objective.

Because the resolving power of a microscope is improved as the wavelength of the illumination decreases, it is evident that blue light will give slightly better resolution than green light. Wavelengths of <400 nm have been used successfully to enhance resolution. Because conventional optical glasses absorb wavelengths below ~300 nm, the use of special optical elements of quartz, fluorite, calcite, or combinations thereof are required. Thus, all wavelengths down to ~200 nm can be transmitted through the microscope. Mercury vapor lamps produce a large amount of short-wavelength illumination and have proven suitable for ultraviolet (UV) microscopy. Because of the shortness of the wavelength, images can be damaging to the eye if viewed directly; therefore the UV part of the spectrum must be filtered out. Photomicroscopy presents a significant problem in focusing the image. If the image is focused at the film plane with the ultraviolet wavelengths filtered out, the image produced by the shorter wavelengths will not be in focus at the film plane. In 1926, Lucas developed a method for focusing the image on a fluorescent screen. Although resolution can theoretically be enhanced by as much as 60%, a more practical enhancement of 33% can be obtained using a wavelength of 365 nm rather than 540 nm (Kehl, 1949). Ultraviolet microscopy has not become a major technique in materials science because of the great amount of skill required to produce exceptionally flat and artifact-free surfaces. Also, the development of scanning electron micro-scopy (see SCANNING ELECTRON MICROSCOPY) has made it possible to get exceptional resolution, with great depth of field, without great concern for sample preparation.

A general knowledge of lens aberrations is important to the present-day microscopist. While some modern instruments are of very high quality, the kinds of objectives and oculars that are available are numerous, and it must be understood what aberrations are characteristic of each. In addition, various oculars (or projector lenses) are available for correction of aberrations introduced by objective lenses.

Lens aberrations are of two general classes: spherical and chromatic (Gifkins, 1970; Vander Voort, 1984; Kehl, 1949). Spherical aberrations are present even with monochromatic illumination. Its subclasses are spherical aberration itself, coma, curvature of field, astigmatism, and distortion. Chromatic aberration is primarily associated with objectives.

Spherical aberration occurs when a single lens is ground with truly spherical surfaces. Parallel rays come to focus at slightly different points according to their path through the lens—through the center portion of the lens, or through its outer portions. Thus, the image of a point source at the center of the field becomes split into a series of overlapping point source images resulting in an unsharp circle of confusion instead of a single sharp point source image. For spherical positive (convex or convergent) lenses, the spherical aberration is exactly the opposite of that produced by a spherical negative (concave or divergent) lens ground to the same radius of curvature. Correction for spherical aberration can take two forms. The first involves the use of a doublet (two lenses cemented together—one of positive curvature and one of negative curvature). The development of lens formulas for a doublet is rather more complex than it would seem, for should both the positive and negative lenses of the doublet be ground to the exact same radius, then the magnification of the doublet would be 1×. A second method of correcting for spherical aberration is to use a single lens with each face ground to a different radius; such a lens is said to be aspherical.

Coma affects those portions of the image away from the center. Differences in magnification resulting from ray paths that meet the lens at widely differing angles cause the image of a point to appear more like a comma. Lens formulas for the correction of coma provide for the sine of the angle made by each incident ray with the front surface of a lens to have a constant ratio to the sine of each corresponding refracted ray.

Curvature of field arises because the sharpest image of an extended object lies on a curved surface rather than a flat plane. While slight curvature of field is not a serious problem for visual work, because the eye can partially adjust for the visual image and fine focus adjustments can overcome that for which the eye cannot compensate—it becomes a serious problem for photographic work. At high magnifications, the center of the image may be sharp, with sharpness falling off radially away from the center. Attempts to focus the outer portions of the image only cause the central portion of the image to go out of focus. Correction for curvature of field is done by introducing correction in the ocular with the addition of specially designed lens groups. For this reason, it must be understood that oculars are designed to work with a specific objective or set of objectives. One should not attempt to use oculars in another instrument or with objectives for which they are not designed.

Astigmatism is a defect that causes points to be imaged as lines (or discs). Lenses designed to correct for astigmatism are called anastigmats. Correction for astigmatism is done by introducing an additional departure from spherical lens surfaces, together with the matching of refractive indices of the lens components.

Distortion is mainly an aberration found in oculars, where straight lines appear as curved lines in the outer portion of the image. The curvature may be either positive or negative and can often be observed when viewing the image of a stage micrometer. Again it is produced by unequal magnifications from various zones of the lenses in an ocular. Most modern microscopes have oculars that are well corrected for distortion.

Chromatic aberration arises because all wavelengths of light are not brought to focus at the same distance from the optical center of a lens (longitudinal chromatic aberration). If longitudinal chromatic aberration is serious and

broad wavelength spectrum illumination is used, one can observe color fringes around the image of a subject. If a black-and-white photograph is taken of the image, it will appear slightly out of focus. Lateral chromatic aberration results from a lens producing differing magnifications for differing wavelengths of light. A simple solution is to use a narrow-band-pass filter to make the illumination nearly monochromatic; however, this precludes color photography, particularly at higher magnifications. Fortunately, lens formulas exist for the correction of chromatic aberration. Such formulas employ optical glasses of different indices of refraction.

The cost of making lenses corrected to various degrees for chromatic aberrations increases dramatically as the amount of correction increases. From the amount of correction one finds that there are several classes or names for objective lenses: nonachromatic, achromatic, semi-apochromatic, and apochromatic. For work in the materials science and engineering field, non-achromatic lenses are not used.

Achromatic lenses are corrected for spherical aberration such that all rays within a limited wavelength range of the spectrum (yellow-green: 500 to 630 nm) are brought into focus essentially at the same position on the optical path. It is common practice to make chromatic correction for two specific wavelengths within this range. Correction for spherical aberration is also made for one wavelength within the range. Achromatic lenses are useful at low to medium magnifications up to 500× magnification, provided that for photography one uses black-and-white film and also a green filter to provide illumination in the yellow-green portion of the spectrum.

Improved correction for chromatic aberration can be obtained by including fluorite (LiF) lens elements in the objective (Kreidl and Rood, 1965). LiF is used because of its higher index of refraction than the normal borosilicate crown glass elements. The effect of proper optical design using fluorite elements in conjunction with borosilicate elements is to shift the focal plane of the longer wavelengths toward that of the image formed by the shorter wavelengths. Objective lenses thus corrected for chromatic aberrations are called fluorites or semiapochromatics. Such objectives provide good correction over the spectral range of 450 to 650 nm.

Apochromatic lenses are corrected for chromatic aberrations at three specific wavelengths and simultaneously for spherical aberration at two specific wavelengths. Wavelengths in the range of 420 to 720 nm are brought to the same focus. To provide optimal correction for spherical aberration, apochromatic lenses are somewhat undercorrected for color. Thus, they should be used with compensating oculars. Apochromatic lenses are of special importance to high magnifications (>800×) and for color photography.

No discussion of objective lenses is complete without comments on working distance and on depth of focus. Normal working distances (the distance between the front element of an objective lens and the specimen) are rather small even for relatively low-magnification objectives. The working distance may range from ~1 cm for a 5× objective to a fraction of a millimeter for a 100× objective. Objective lenses designed to have larger working distances for special applications are available, but they are resolution-limited due to their smaller numerical apertures. Consequently, long-working-distance objectives are not employed for high-magnification work.

Depth of focus is a property of an objective lens related to its numerical aperture. The depth of focus is the distance normal to the specimen surface that is within acceptable focus when the microscope is precisely focused on the specimen surface. Depth of focus is of concern when the specimen surface is not perfectly flat and perpendicular to the optic axis. In practice, the preparation of specimens to obtain flatness, or the depth of etching, become important factors in the utility of a given objective lens. Based on a criterion devised by Rayleigh, the depth of focus is given by $d \approx \pm n\lambda/(\text{N.A.})^2$, where d is the depth of focus, n is the index of refraction for the medium occupying the space between the objective lens and the specimen, λ is the wavelength of illumination, and N.A. is the numerical aperture (Gifkins, 1970).

Thus, for a 0.65 N.A. objective operating in air with illumination of 530-nm wavelength, the depth of focus is ~2.35 times the wavelength of light. This means that the surface of the specimen must be flat to within ~4.7 times the wavelength of light or, in this case, 2500 nm.

Oculars (eyepieces) used in modern microscope are of four main types: Huygenian, Ramsden (orthoscopic), compensating, and wide-angle (Restivo, 1992).

Huygenian oculars (Fig. 2A) consist of two simple lenses fitted with a fixed-field diaphragm located between the field lens and the eye lens. A real image is focused at the plane of the field diaphragm. Such oculars are basic low-magnification eyepieces with little correction for objective lens aberrations.

Ramsden oculars (Fig. 2B) contain the same components; however the field lens is in an inverted position and the field diaphragm is located below the field lens. As in the Huygenian ocular, a real image is located at the plane of the field diaphragm. Ramsden oculars are normally used for intermediate magnifications.

Compensating oculars have the greatest amount of correction for chromatic variations in magnification, as well as curvature of field. These eyepieces are recommended for use at high magnification and for color photomicrography with apochromatic objectives.

Wide-angle oculars in modern instruments are also designed as high-eyepoint lenses, giving a much larger relief distance between the eye lens and the eye. They contain many lens elements and their design may vary considerably from manufacturer to manufacturer. Being highly corrected for chromatic aberration and for distortion, they are often the only oculars supplied with a microscope, particularly when the instrument is fitted with flat-field objectives.

Practical Adjustment of the Microscope

Simplified schematic diagrams of transmitted- and reflected-light microscopes are given in Figure 3. Experienced microscopists have learned that the most successful use of any microscope begins by following the light path

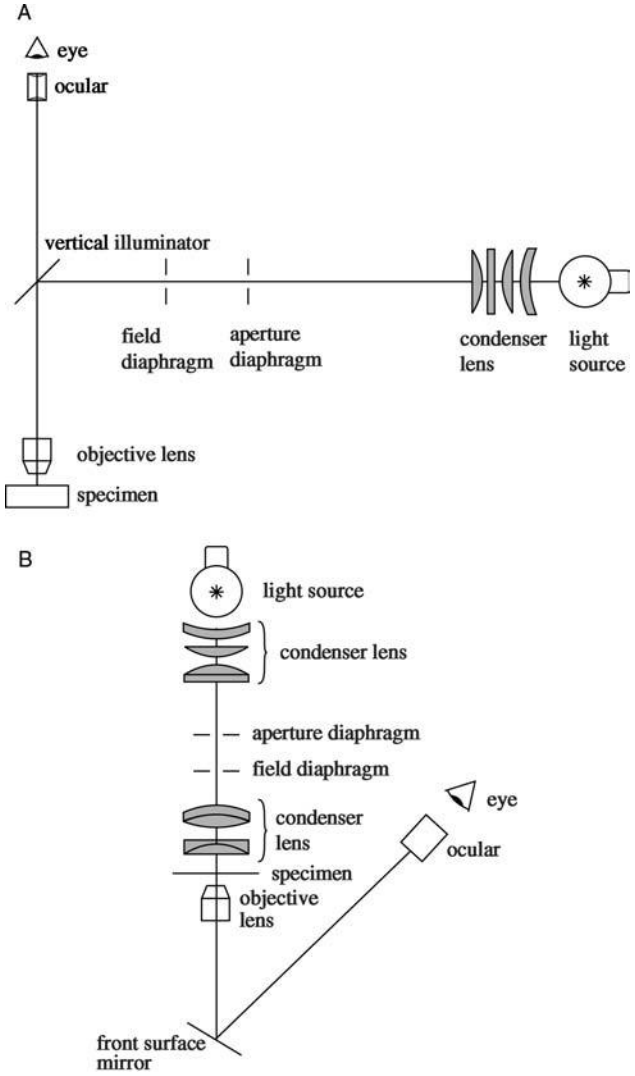

Figure 3. Schematic diagrams of (**A**) inverted reflected-light and (**B**) transmitted-light microscopes. The important components are labeled. Note that the transmitted-light microscope (panel B) does not have a vertical illuminator.

through the instrument and making necessary adjustments, starting with the source of illumination. By consistently following the sequence, the chance of failure in the form of a poor photomicrograph or poor visual image is greatly reduced.

Illumination of the specimen is accomplished by two or more components including the lamp and a condenser or collector lens. Sometimes, the aperture diaphragm, field diaphragm, heat-absorbing filter, narrow band-pass filter, and neutral-density filter are also included as components of the illumination system. This author chooses not to include the additional components as parts of the illumination system, although some microscope makers mount them in a single modular unit of the instrument.

Proper centering and focusing of the light from the illuminator is essential to obtaining satisfactory results with any optical microscope. The image of the lamp filament or arc must be focused at the plane of the aperture diaphragm. In some instruments, the light path is sufficiently open so that one can visually inspect the focus of the lamp on a closed-aperture diaphragm. In closed systems, specific instructions for obtaining proper focus are usually provided with the instrument. Centering of the light source is accomplished by adjustments that laterally translate the lamp in two directions. A focusing adjustment moves the lamp closer to or further away from the condenser to focus the lamp at the plane of the aperture diaphragm.

The aperture diaphragm must be properly adjusted to obtain the optimum resolution commensurate with image contrast, for either a transmission- or reflected-light microscope. The full numerical aperture of the objective lens must be utilized to obtain optimum resolution. From a practical standpoint, the aperture diaphragm is interposed in the optical path to control the diameter of the pencil of light so that it just fills the full circular area of the rear lens group of the objective lens. In a transmitted-light microscope the aperture diaphragm is located in the condenser lens barrel, while in a reflected-light microscope the aperture diaphragm is located in the optical path just beyond the condenser (collector) lens of the light source. In both instruments, the image of the diaphragm is focused in a plane coincident with the rear element of the objective lens. The aperture diaphragm is always partially closed to reduce internal light scattering within the microscope, a circumstance that degrades contrast in the image. In practice, the method for obtaining the optimum setting of the aperture diaphragm is to open the diaphragm fully, bring the specimen into focus, and then close the diaphragm slowly until the image begins to dim perceptibly. At this point the aperture is opened slightly to bring the image back to full brightness.

The image of the field diaphragm is focused on a plane coincident with the plane of the specimen. Its function is to reduce extraneous light scatter between the specimen surface and the front element of the objective in order to enhance contrast. To adjust the field diaphragm, one starts with it in the full-open position and gradually closes it while viewing the focused specimen either through the eyepieces or on a photographic viewing screen. When the image of the diaphragm is observed to just intrude into the field of view or into the photographic field, it should be opened slightly.

Vertical illuminators are required for reflected-light microscopes, because the specimens are opaque and the objective lens must act both to supply light to, and to collect reflected light from, the specimen. The light path must be passed to the specimen through the objective lens, then allow the reflected image-forming light to pass back through the objective to the ocular. From Figure 3A, note that the light path is diverted 90° from the horizontal to the specimen, which rests inverted on the stage (inverted microscope). This arrangement is of particular utility in using specimens that must have prepared surfaces, because it does not require that the specimen have a back surface exactly parallel to the prepared surface. Several schemes have been used for vertical illuminators, including various prism configurations and thin, optically flat glass plates. Of these, the thin, optically flat glass plate

(or disc) is almost universally used in recent instruments. Generally, vertical illuminators have no adjustment controls except for a provision for dark field illumination, a topic that is discussed in REFLECTED-LIGHT OPTICAL MICROSCOPY.

The objective lens requires only two adjustments: centering the optic axis of the lens with the optic axis of the instrument and focusing the lens by moving it closer to or further away from the specimen. Focusing the objective is as simple as moving the focusing adjustments while viewing the specimen through the eyepieces and observing when the specimen appears to be sharp. A number of instruments have their objective lens mounted in a turret to facilitate changing from one objective to another. Many instruments are said to have "parafocaled" objectives. If the objectives are parafocaled, one may readily switch objectives without having to refocus the instrument. In practice, however, it is wise to use the fine-focus adjustment each time an objective is changed in order to assure that the optimum focus is obtained.

Centering of the objective lens on an instrument with an objective turret is accomplished by centering on the objective through the centering of the axis of rotation of the turret. This involves moving the axis of rotation of the turret by shifting it in one or two orthogonal directions of a plane normal to the axis of rotation. Such an operation is not recommended except when performed by competent service personnel. Fortunately, once a turret is centered and locked into the instrument, frequent centering is not required. Other instruments, in which objectives are placed in the instrument individually, require that each lens be centered individually by adjustment set screws on the mounting plate of each lens. Often the instrument contains one "standard" objective that is centered at the factory in the final fitting stages of instrument assembly. The mounting plate of this objective has no centering adjustments. Other objectives may be centered individually using the "standard" lens as a reference, provided the instrument is fitted with a rotating stage that is also centered with the optic axis of the instrument. A simple method involves starting with the "standard" objective, aligning a reflective cross-hair (or reflective point target) on the stage with the center of the field as viewed through the ocular, and making certain that the stage is itself centered. The stage is then rotated to ascertain that the cross-hair stays in the center of the field as the stage is rotated. Without moving the stage or the cross-hair, a centerable objective is substituted for the "standard" objective. If the objective is centered, the cross-hair will again fall in the center of the field and will remain there when the stage is rotated. To center the objective, it will be necessary to use the adjustment set screws on the mounting plate to move the optic axis of the objective in x and y directions in a plane normal to the optic axis. A number of instruments include special accessories for centering the objectives.

Ocular adjustment amounts only to focusing the ocular. Instruments with a single eyepiece generally do not have an adjustment for focus, because the eyepiece is set at its proper focal distance from the objective. Since most microscopes now have binocular eyepieces, some care must be taken to assure that the eyepieces are correctly focused to match the eyes of the user. One eyepiece has a focusing ring, while the other is fixed. Depending on the instrument, focusing methods may vary; however, they are all variations on the method outlined in the following. A stage micrometer, or other similar device, is placed on the stage and brought into focus with the fixed eyepiece using the objective focusing adjustment. Once this is done, the eyepiece focusing ring should be used to focus the image for the other eye. This method accounts for differences between the two eyes, and is necessary to reduce eye strain from long sessions with the microscope.

It is important to emphasize that if the microscopist normally wears eyeglasses, they should be worn while using a microscope. In recent years wide-field objective lenses and matching wide-field, high-eyepoint oculars have been introduced. Matching optics of this type provide a wider field of view of the specimen and are also particularly suited to users who wear glasses. Multifocal eyeglasses (bifocal or trifocal) present special problems that can be overcome by the adaptability of the microscopist.

Autofocusing has yet to be applied to microscopes except in the case of instruments designed to make precise measurements. Such devices are only of use when one of several turret-mounted objective lenses is brought into sharp focus. The autofocusing feature will then cause each of the other lenses in the turret to be brought into sharp focus when they are rotated into the optic axis of the microscope. Critical focusing depends on the skill of the microscopist in being able to judge when sharp focus is attained. Focusing for edge sharpness could probably be developed for instruments used in conjunction with image analysis computers, wherein the focusing would be accomplished by feedback of the contrast gradient at a sharp edge. However, obtaining the best overall focus for the entire field of view might be difficult, either because of a limited range of the gray scale or because of the lack of flatness of specimens.

Devices for calibrating resolution or the depth of focus are generally not used. Observable degradation of the image is a signal to inspect the optical components for contaminants and for physical defects such as scratched or etched surfaces. Regular annual service by a competent service technician is recommended, to maintain the microscope in optimum working condition.

Damage from contamination and damage to objectives is, for the most part, up to the microscopist in maintaining a clean environment for the microscope. The use of appropriate lubricants for the mechanical parts of the instrument is of paramount importance. Physical damage of the front element of the objective lens comes primarily from two sources: (1) contact of the front element with the specimen and (2) etching of the front element by chemical reagents used in specimen preparation. Careful operation by the microscopist is the most effective way to keep the objective lens from contacting the specimen; however, some microscopes, usually upright instruments, employ a stage lock to prevent the objective from contacting the specimen. To prevent contamination of the objective lenses with specimen-preparation reagents, it is essential that specimens be thoroughly cleaned and dried

prior to placing them on the microscope. This is particularly important when HF or other corrosive reagents have been used in specimen preparation.

In the past, special stages for providing special specimen environments have been available as regular production accessories for some instruments. However, with the advent of the scanning electron microscope (SEM), most studies that require hot or cold environments are now undertaken in the SEM. Studies in liquid environments are especially difficult, particularly at high magnifications, because the index of refraction of the liquid layer interposed between the specimen and the objective lenses is different from that of air. Therefore, some corrections can be designed into objectives for certain biological microscopes. Objectives designed for use with glass slides and coverslips are also corrected for the presence of the thin glass layer of the coverslip, which is of the order of 0.1 mm thickness. A number of specialized environmental stages have been designed and constructed by microscopists.

Photomicrography, on film and with charge-coupled devices, as well as specimen preparation, are of paramount importance to successful optical microscopy for the materials scientist or engineer. These topics are to be covered in subsequent units of this chapter.

REFLECTED-LIGHT OPTICAL MICROSCOPY

INTRODUCTION

Reflected-light microscopes were developed for imaging the surfaces of opaque specimens. For illumination of the specimen, early microscopes used sunlight played on the specimen surface by mirrors and/or focused by simple condenser lenses. Optical microscopes began to evolve toward modern instruments with the understanding that engineering properties of materials were dependent upon their microstructures. Current higher-magnification instruments (50× to 2000×), for obtaining images of polished and etched specimens, employ vertical illumination devices to supply light to the specimen along the optical axis of the microscope. Vertical illumination overcomes the shadowing of surface features, which are enhanced by off-axis illumination, and improves the attainable resolution. On the other hand, lower-power (5× to 150×) stereo microscopes, most commonly used for imaging bulk specimens such as microelectronic circuits or fracture surfaces, utilize off-axis lighting supplied by focused lamps or fiber-optic light systems.

Microscopy, regardless of the instrumental technique, has as its sole objective the production of visual images that can be further analyzed by counting measurements to quantify any of a number of microstructural properties including grain size, the volume fractions of phases, count (or identification) of microconstituents or microstructural features such as twins, number of inclusions, surface area

of grains and second phases, and more esoteric microstructural measurements such as the total mean curvature of the grain boundary in a given specimen. Quantification of microstructural features may be accomplished by manual counting while viewing the image through the microscope, taking measurements from photographic or digital images, or using a computer for digital image analysis. Obtaining quantitative microstructural information constitutes the specialized field of quantitative microscopy or stereology, based upon geometric and topological considerations and statistics. Stereology is a branch of quantitative microscopy that provides for the inference of three-dimensional structure information from two-dimensional measurements. The reader is referred to DeHoff and Rhines (1968), Gifkins (1970), and Vander Voort (1984) as primary references on quantitative microscopy.

While reflected-light microscopy alone is not intended for the measurement of material properties, coupled with the techniques of quantitative microscopy it does provide the connecting links among properties, chemical composition, and processing parameters. However, an experienced microscopist can obtain much useful qualitative information related to processing and properties. For instance, one may assess the degree of annealing of a metal or alloy by the amount of the microstructure that appears to consist of recrystallized grains. In a production setting, a microscopist may quickly determine if a material meets specified properties merely by observing the microstructure and judging it on the basis of experience.

It is the intent of this unit to describe the more common techniques of reflected-light microscopy, but not to delve into microstructural property measurement. Emphasis will be placed on the use of the higher-power instruments (metallographs), because of the variety of useful illumination modes and image-forming techniques that are available on these instruments.

PRACTICAL ASPECTS OF THE METHOD

Reflected-light Microscopes

The reflected-light microscope, shown by the light-path diagram in Figure 1, contains a vertical illuminator, in this case employing a half-mirror to direct light to the specimen and to allow light from the objective lens to pass to the ocular (eyepiece). In arrangement of the specimen stage, with respect to the axis of the horizontal incoming light path, there are two types of microscopes—upright and inverted. Generally, the inverted instrument is preferred because it ensures that a specimen surface is always normal to the optic axis of the objective lens. Further, it allows for easier observation of large unmounted specimens and specimens of irregular shape that have a prepared surface (Vander Voort, 1984).

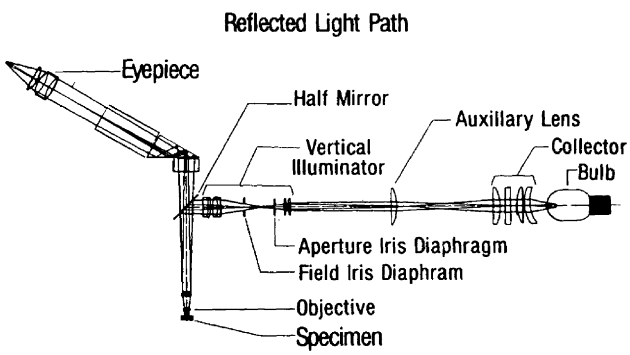

Figure 1. Light path diagram for a reflected-light microscope (courtesy LECO Corporation).

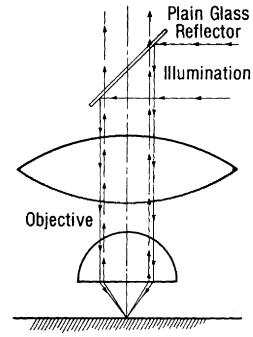

Figure 2. Light-path diagram for a plain-glass reflector for a reflected-light microscope (courtesy LECO Corporation).

Vertical illuminators have taken several forms during their evolution. For the most part, two types of vertical illuminators are in use today; the plain-glass reflector and the half-mirror reflector. The plain-glass reflector consists of a very thin, optically flat glass plate inclined at 45° with respect to the path of the incoming illumination (Fig. 2). Part of the illumination is reflected at 90° through the objective to illuminate the specimen. A portion of the light that returns from the specimen through the objective lens passes through the glass plate on to the ocular. Note that the objective first acts as an illuminating (condenser) lens and second as the image-forming lens. When the plain-glass reflector is properly centered, plain axial illumination is the result and no shadows of specimen surface relief are formed. While the loss of light intensity is significant, this type of reflector can be used with any objective. The half-mirror reflector is a totally reflecting surface, usually silvered glass, with a thin clear coated glass area in its center. The clear central area is elliptical in shape, so that when the reflecting plate is placed at 45° in the optical path a round beam of light can be reflected (Restivo, 1992). An advantage of this type of reflector is that it is particularly well suited for dark-field illumination, and it also works well with bright-field illumination and polarized light (see the discussion below under "Illumination Modes and Image-Enhancement Techniques" for a description of these illumination modes). Light rays reflected back through the objective lens from the specimen surface pass through the central clear region of the reflector to form an aerial image that is further magnified by the ocular. Because the reflecting surface reflects all of the incident light, there is no loss of light intensity as with the plane glass reflector (Restivo, 1992). Figure 3 shows the light path for the half-mirror reflector as it is used in dark-field illumination mode. Other vertical illuminator/

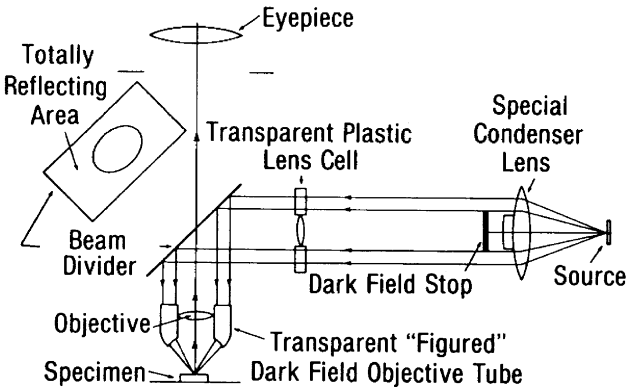

Figure 3 Light path diagram for a half-mirror reflector for a reflected-light microscope. (courtesy LECO Corporation).

reflector schemes have been used with some success; however, they have fallen out of favor because of limitations or expense in producing suitable reflectors.

Illumination Modes and Image-Enhancement Techniques

Provisions for a number of variations in illumination modes and image enhancement techniques may be included as accessories on many of the current production microscopes. Among the more common of these are: bright-field illumination, oblique-light illumination, dark-field illumination, polarized-light, sensitive-tint, phase-contrast, and differential-interference-contrast. Each of these will be discussed in the following paragraphs.

Bright-field illumination is the most widely used mode of illumination for metal specimens that have been prepared by suitable polishing and etching. The incident illumination to the specimen surface is on axis with the optic axis through the objective lens, and is normal to the specimen surface. As expected, those surfaces of the specimen that are normal or nearly so to the optic axis reflect light back through the objective lens, giving rise to bright portions of the image. Those features of the microstructure that have surfaces that are not normal to the optic axis appear dark and thus give the image contrast (Fig. 4). Image contrast also occurs in bright-field illumination because of variations in reflectivity within a specimen. For example, in properly prepared specimens of irons and steels that contain MnS (manganese sulfide)

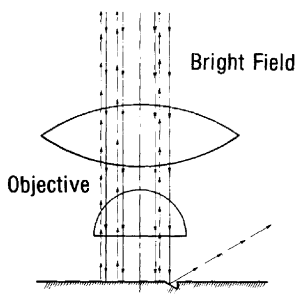

Figure 4. Light path diagram for bright-field illumination (courtesy LECO Corporation).

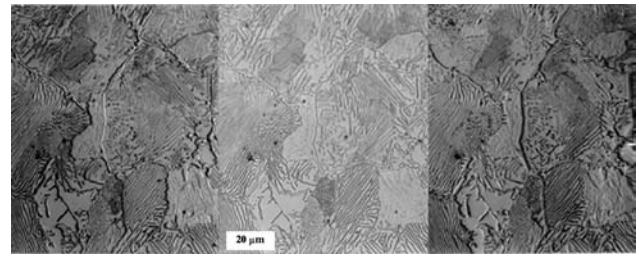

Figure 5. Bright-field photomicrograph (center) of pearlite and proeutectoid cementite in an annealed high-carbon steel. The left and right panels show oblique-light photomicrographs of the same field, with the right panel illuminated with light from the left and the left panel illuminated with light from the right.

as a microconstituent, the MnS constituent appears somewhat darker than the surrounding α-ferrite iron, and possibly lighter than Fe_3C (cementite). The image contrast in this case is due to the optical properties of the constituents that render their polished surfaces more or less reflective. In fact, if the specimen preparation is very well done, the MnS appears to have a smooth dark-slate color. Certain specimen-preparation techniques and spectral image enhancements provide a variety of colors to establish image contrast. The vast majority of metallographic work utilizes bright-field illumination. A typical bright-field photomicrograph appears in Figure 5 (center panel).

Oblique-light illumination is a variation of bright-field illumination wherein the condenser system is shifted off axis. The result is that relief in the specimen surface is shadowed. While the image appears to possess enhanced contrast, and detailed features become more easily observed, the optical resolution is decreased; fine details become broadened. In addition, by shifting the incoming light beam off axis, the effective numerical aperture of the objective lens is decreased, thereby reducing resolution (see OPTICAL MICROSCOPY). To some extent, compensation for this deficiency is made by opening the aperture diaphragm, but at some sacrifice to contrast. On some microscopes oblique illumination is obtained by shifting only the aperture diaphragm off axis, an adjustment that requires that the aperture diaphragm be opened, or else the specimen will be unevenly illuminated. Oblique illumination is illustrated in the photomicrographs of Figures 5, left and right. These photomicrographs are of the same specimen and of the same area as that of the bright-field photomicrograph of Figure 5 (center). Both the left and right panels of Figure 5 are taken under conditions of oblique light, but the off-axis shifts are in opposite directions. Note how certain microstructural features appear raised in one photomicrograph, while the same features appear depressed in the other.

Dark-field illumination is a useful technique to enhance image contrast by making the normally bright areas of an image dark while making dark features light. Dark-field illumination is effective because of the perception characteristics of human vision. It has been demonstrated that a small white disc on a black background is more easily perceived than a small black disc on a white background. The size limit of the white disc on the black background

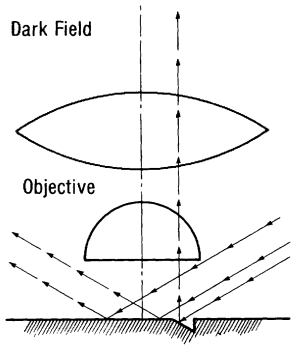

Figure 6 Light path diagram for dark-field illumination (courtesy LECO Corporation).

depends entirely on its reflected luminous flux, or the total light reflected per unit area (Gifkins, 1970).

Dark-field illumination occurs when the light incident on the specimen arrives at a low angle. If the surface is featureless, reflected light does not reenter the objective lens and the image is dark. However, any feature on the surface that is inclined a relatively small angle can reflect light back through the objective lens to form an image. To effect dark-field illumination, a small circular stop is inserted in the light path ahead of the vertical illuminator to produce an annulus of light larger in inside diameter than the back element of the objective lens. The objective lens is surrounded by a "shaped" or "figured" transparent tube that directs the incident light to the specimen at a relatively low angle to the specimen surface. Reflected light from tilted features of the specimen reflects light back into the objective lens (Fig. 6). Figures 7 A and B are bright-field and dark-field photomicrographs, respectively, of a specimen of low-carbon iron. Note that the grain boundaries and inclusions are enhanced in dark-field.

Polarized-light microscopy has significant use in imaging microstructural details in some materials, notably, alloys of uranium, zirconium, beryllium and, from the author's experience, high-purity aluminum (Connell, 1973). Specimens of these materials are difficult to etch to reveal microstructural details. Before the invention of the electron-beam probe, polarized light was used as an aid in identifying inclusions in alloys. Also, polarized light has been of paramount importance in mineralogical work for the identification of various minerals.

Polarized-light microscopy depends upon a characteristic of light that cannot be detected by the human eye. When considering the electromagnetic wave character of light, it is easy to understand that, the greater the amplitude of the wave, the brighter the light. Likewise, variations in wavelength produce variations in color; the shorter the wavelength, the more blue the light, while the longer the wavelength, the more red the light. Two other characteristics of light—phase and polarization—cannot be directly detected by the eye. From an elementary point of view, one may consider that light waves travel in a straight line, and the light waves oscillate (vibrate) along the line in random directions around the line. Under certain conditions of reflection defined by Brewster's law, and when light passes through certain transparent crystalline

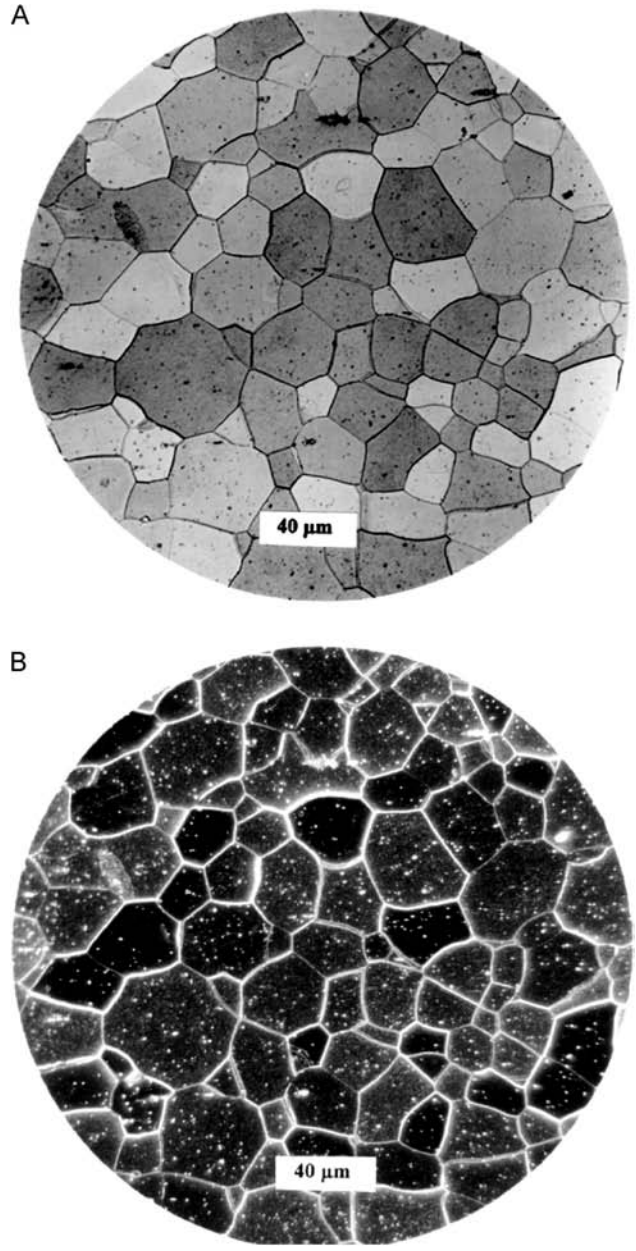

Figure 7. Photomicrographs of ferrite in low-carbon iron: (**A**) bright field; (**B**) dark field.

materials, some of the vibration directions around the light axis become attenuated, and there may be rotation of other directions, so that certain directions of vibration are predominant (Jenkins and White, 1957; Gifkins, 1970). From a practical standpoint, when such interaction of light waves with matter occurs, vibrations of the light are confined to one plane, and the light is said to be plane-polarized. It is to be further stated that, light being electromagnetic waves, it is the electrical or magnetic interaction of the light waves with matter that result in polarization (Gifkins, 1970).

In microscopy, the usual way to produce polarized light from a normal source is to pass the light through a transparent plate of some specific optically active material,

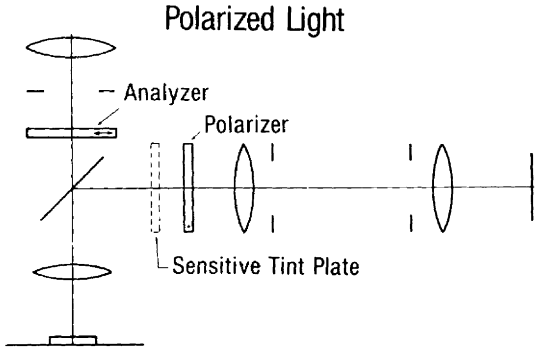

Figure 8. Light path diagram for a reflected-light microscope fitted with polarizer and analyzer. Note also the position of the sensitive-tint plate (courtesy LECO Corporation).

called a polarizer. Most polarizers in use in microscopes are made of synthetic material in sheet form, called by its proprietary name, Polaroid. If two sheets of polarizing material are placed parallel to one another separated by some distance (4 or 5 cm), and light is passed through them, one can observe that light passes through the first although it is polarized. The light may also pass through the second, but by rotation of the second sheet, one will observe that the light no longer passes through it. This is the case of extinction, and one can say that the polarizers are crossed. The second sheet, called the analyzer, will not allow the polarized light through, because its plane of polarization is 90° to the first sheet, the polarizer.

Both a polarizer and an analyzer are employed in a polarizing microscope. The polarizer is placed in the light path ahead of the vertical illuminator and the analyzer is placed in the light path between the vertical illuminator and the ocular (Fig. 8). The polarizer usually is fixed so that it will not rotate. When polarized light is incident on the reflective surface of an isotropic specimen at a right angle, the polarization of the reflected light will not be altered (there is no polarization dependence of reflectivity in isotropic specimens). If one rotates an analyzer located in the light path at the back end of the objective lens, extinction will occur when the polarizer and analyzer are crossed. The image turns dark and indicates that the originally polarized light has not been altered by the reflecting surface. If the specimen is replaced with an anisotropic material such as zirconium, whose reflectivity depends on orientation of polarization with respect to crystal axes, then it can be observed that some grains appear dark while others appear in various shades of gray all the way to white, indicating that each grain has a different crystallographic orientation. When the specimen stage is rotated, the orientation of individual grains will change with respect to the polarized light and go through several extinctions as the stage is rotated through 360°. In this way, the microscopist can observe the grain structure in a material for which etching to reveal the grain structure is difficult. An example of a photomicrograph of martensite taken under polarized light is given in Figure 9. Martensite, being body-centered tetragonal, is anisotropic and therefore responds to the polarization of the light according to its crystal orientation.

Figure 9 Polarized-light photomicrograph of martensite in a hardened steel specimen.

Isotropic metals can be examined by polarized light if they can be etched to develop regular patterns of closely spaced etch pits or facets on each grain. Anodizing the polished specimen surface of isotropic metals can also make the material respond to polarized light. In the case of aluminum, a relatively thick transparent film is formed by anodizing. The observed polarizing effect results from double reflection from the surface irregularities in the film (Vander Voort, 1984). The author has used this technique to observe the subgrain structure in creep-deformed high-purity aluminum. Angular misorientations as small as 2.5° between adjacent subgrains have been observed (Connell, 1973).

Sensitive tint is an image-enhancement technique used with polarized light. Because the human eye is more sensitive to minute differences in color than to minute differences in gray scale, the sensitive-tint technique is a valuable tool in viewing and photographing images that lack contrast. Therefore, preferred orientation may be qualitatively assessed, counts to determine grain size are more easily made, and the presence of twins is more easily detected.

A sensitive-tint plate is placed in the light path of the microscope between the polarizer and the analyzer (Fig. 8). The material of the sensitive plate is a birefrigent. Birefringence occurs in certain anisotropic crystals when these are cut along specific crystallographic planes to produce double refraction (Jenkins and White, 1957). One sees a double image when viewing through such a plate. The sensitive-tint plate (also called magenta-tint or whole-wave plate) is made of quartz sliced parallel to its optic axis. The thickness of the plate is such that it is equivalent to a whole number of wavelengths of light, where the wavelength is in the middle of the visual spectrum (green, 5400 Å). Rays of plane-polarized light pass through the sensitive-tint plate and become divided

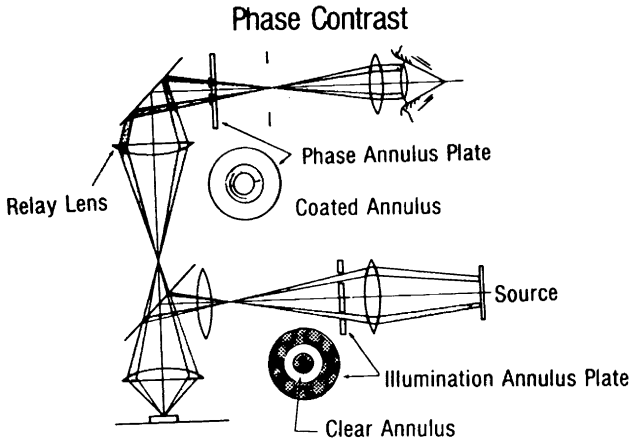

Figure 10. Light path diagram for phase-contrast microscopy. Note the positions of the illumination- and phase annulus plates in a reflected-light microscope (courtesy LECO Corporation).

into ordinary rays and extraordinary rays (Gifkins, 1970), the latter being refracted at some angle to the former. When the ordinary and extraordinary rays emerge from the plate, they are out of phase by one wavelength. The two rays recombine to form a single plane-polarized ray that is extinguished by the analyzer, while all other wavelengths pass through the analyzer. The result is that white light minus the green light excluded by the analyzer produces light that is magenta in color. Typically, the hue imparted to sensitive-tint images have a magenta hue, with differences in grain orientation displayed as different colors. Rotation of the specimen causes each grain to change color. Images are striking and usually aesthetically pleasing. Color control can be obtained by rotation of the sensitive-tint plate through a range of $\sim 15^\circ$ to 20°.

Phase-contrast illumination is an image enhancement that is dependent upon another property of light that cannot be observed by the eye. Subtle variations in polished and/or etched metallographic specimens sometimes are so minute that phase differences from the difference in optical path produce no image contrast. Differences in height as little as 5 nm can be observed using phase contrast (Vander Voort, 1984; Restino, 1992).

The physical arrangement of the microscope is seen in Figure 10, where an illumination annulus and a phase annulus are inserted in the optical path as shown. The illumination annulus is opaque, with a clear central annulus, while the phase annulus is a clear glass onto which two separate materials have been applied by vacuum coating. One material is a thin, semitransparent metallic film (antimony) designed to reduce transmission of the annulus, while the other (magnesium fluoride) is for the purpose of introducing a 1/4 wavelength difference between the light that passes through the annulus versus the light that passes through the other part of the phase plate. An alternate construction for the phase plate is to grind a shallow annular groove in the glass (Gifkins, 1970).

In using phase-contrast illumination, proper and precise adjustment of the instrument is critical for obtaining satisfactory images. Some instruments have sets of matching illumination and phase annuli for use with different objective lenses. It is critical that the phase annulus and illumination annulus match. It is generally not sufficient merely to focus on the specimen and insert the annuli to obtain enhanced contrast, because the specimen surface is not generally exactly normal to the optic axis. To make the appropriate adjustment, the specimen must be sharply focused and the image of the illuminating annulus must be centered with the phase annulus. This requires replacing the ocular with an auxiliary lens (Bertrand lens) that is focused on the phase annulus. Once the ocular is reinstalled, phase contrast is realized. The technique is at best fussy, because specimen translation often throws the annuli out of coincidence and the alignment must be done all over again.

Phase-contrast illumination gained some popularity in the early 1950s for metallurgical work, but today it has lost favor because of the critical and frequent instrumental adjustments required. The technique remains viable for image enhancement in transmission microscopy, particularly for biological specimens.

Differential interference contrast (DIC; also known as Nomarski optics), because of its versatility, has become an image-enhancement technique highly favored by microscopists. A number of other interference techniques have been developed over the years, some requiring special instruments or elaborate accessories attached to rather standard instruments, for example two-beam interference microscopy. Of all these, the device that produces contrast by differential interference (Padawar, 1968) appears to be the most readily adaptable to standard instruments, because it requires no internal optically flat reference surfaces. Images produced by DIC display some of the attributes of other illumination modes including dark-field, polarized light, and sensitive-tint. Nonplanar surfaces in specimens are contrast-enhanced, grains in anisotropic materials display extinction behavior, and the color can be of benefit in enhancing perceived contrast.

Differential interference contrast can be classified as an application of polarizing interference, wherein the underlying principle is image duplication in some birefringent material. The image consists of two parts, one formed by the ordinary ray and a second formed by the extraordinary ray.

A Wollaston prism (Jenkins and White, 1957; Gifkins, 1970) is the birefringent unit used in DIC. This device consists of two quartz plates, w_1 and w_2, cut so that their optic axes are at right angles to each other and so that both make a right angle with the optic axis of the microscope (Fig. 11). The Wollaston prism is located at the focal plane of the objective and can be moved laterally across the optic axis. In operation, the incident light is plane polarized after passing through the polarizer, and the critical setting of the illuminating system is such that the beam is focused in w_1 at point x. The reflected light from the specimen is focused in w_2 at point z. Points x and z are symmetrical in the Wollaston prism; thus the path-length difference, d, of the ordinary and extraordinary rays in their passage through the prism to the specimen is the same as that produced on their return passage through the prism, but it is of opposite sign. So the path-length difference after passing through the Wollaston prism the second time, D,

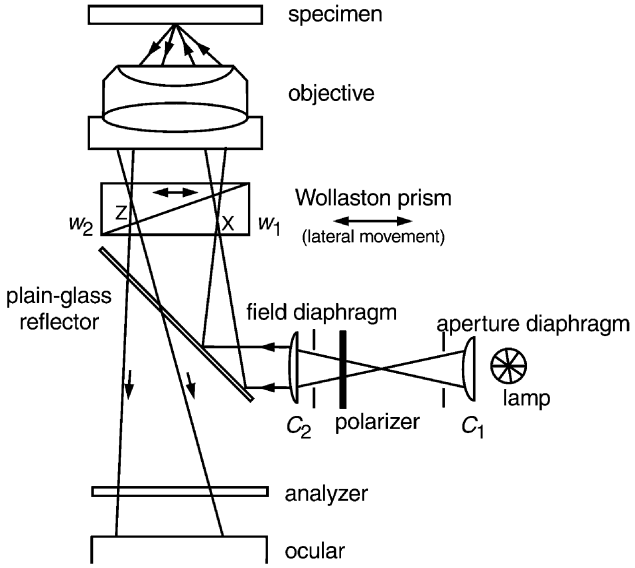

Figure 11. Light path diagram for differential interference contrast (DIC) microscopy. Note that the two sections (w_1 and w_2) of the Wollaston prism have optic axes that are normal to each other, and both optic axes are normal to the light path of the microscope. The axis in w_1 is normal to the plane of the figure, while that in w_2 is in the plane as shown. Points x and z are symmetrically located about the interface between w_1 and w_2.

becomes zero. With a crossed polarizing analyzer in place, and the equalization of path-length differences between the ordinary and extraordinary rays ($D = 0$), a dark field results. The analyzer suppresses both the ordinary rays and the extraordinary rays. Should a specimen contain tilted surfaces such as those that exist at grain boundaries, twins, or slip bands, the reflected rays will pass through the Wollaston prism at nonsymmetrical positions, and the path-length differences between the ordinary and extraordinary rays will not be equalized ($D \neq 0$); therefore, the ordinary and extraordinary rays will not be suppressed by the analyzer. Any path-length difference between the ordinary and extraordinary rays is proportional to the amount of tilt, so that the intensity of the light passed to the ocular is also proportional the amount of tilt.

An important feature of DIC is the ability to introduce color to the image. By laterally shifting the Wollaston prism across the optical path, the path-length difference, D, can be set to values other than zero, and the background takes on a hue dependent upon the path-length difference. For example, if the position of the prism is set so that $D = 0.565$ μm (a wavelength in the yellow region of the spectrum), the background takes on a purple color—i.e., white light minus yellow. Portions of the specimen surface that are tilted will impose other path-length differences, which will result in other colors.

Figure 12A and B are photomicrographs that illustrate a comparison between bright-field illumination and DIC, respectively.

Sample Preparation

Successful use of reflected light microscopes depends to a large measure on specimen preparation. Without a thorough discussion of specimen-preparation techniques, it is sufficient to make the reader aware that opaque specimens must have a properly prepared surface from which light may be reflected. Such a surface is usually prepared by mechanical grinding and polishing using appropriate abrasives until the surface is scratch-free and as specular as a mirror (see SAMPLE PREPARATION FOR METALLOGRAPHY). In most cases it is necessary to chemically (or electrochemically) etch the surface to reveal the details of the microstructure.

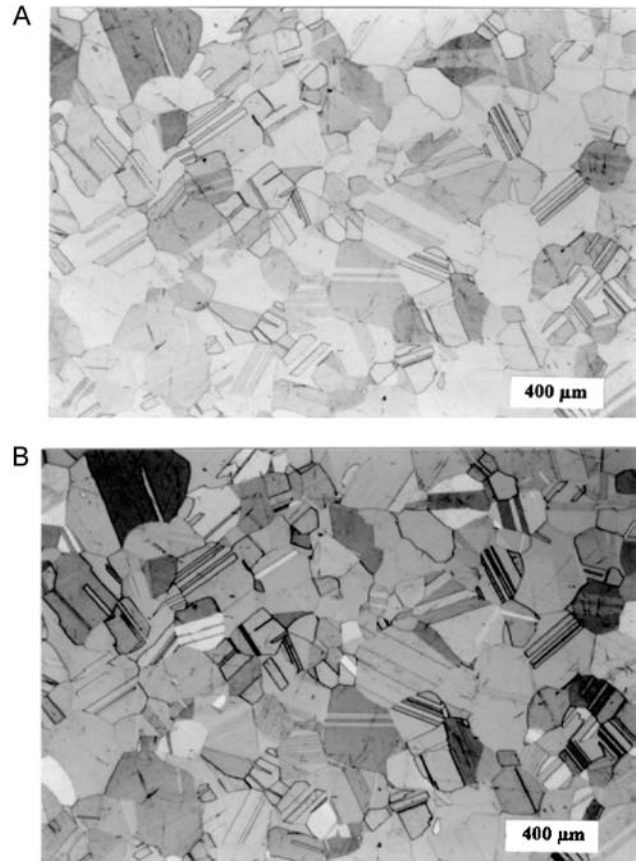

Figure 12. Photomicrographs of α-brass (**A**) bright-field, (**B**) DIC. Grain and twin boundaries are easily seen in the DIC image making it possible to determine grain size easily.

Metallographic preparation techniques have been developed for a wide variety of materials, but with some the metallographer must use his intuition and experience. An excellent source related to specimen preparation is Vander Voort's (1984) book.

PROBLEMS

When inadequate results are obtained with the use of reflected-light microscopy, they are most often associated either with specimen preparation or the inappropriate setting of the controls of the instrument. Improper or poor specimen preparation may introduce artifacts such as surface pitting or inclusion of abrasive particles in the surface. Such artifacts can be confused with second-phase

precipitates. When some portion of the image appears to be in focus, while others appear to be poorly focused, the problem is usually associated with lack of flatness of the specimen surface. In addition, one should pay attention to the action of polishing abrasives on the specimen surface. Some combinations of abrasive materials result in undesired chemical attack of the specimen surface, and the true structure of the specimen may not be revealed. Poor etching (over- or underetching) is a major concern to the metallographer. Overetching often causes what appears to be lack of resolution; fine features can be difficult or impossible to resolve. Underetching may leave some fine details not revealed at all. A better understanding of some aspects of metallographic specimen preparation is given in SAMPLE PREPARATION FOR METALLOGRAPHY.

A practical guide to the setting of the controls is given in OPTICAL MICROSCOPY. Some of the common errors in making settings that degrade resolution of the image are: (1) too small an aperture diaphragm setting, (2) incorrect selection of objective lens, and (3) too high a magnification. Closing the aperture diaphragm beyond the point where the rear element of the objective lens is just covered with light will not allow the objective lens to collect all the diffraction information needed to realize the full resolution capabilities of the lens. The numerical aperture (N.A.) of the objective lens must be consistent with the intended magnification of the final image. As a practical upper limit, the final magnification should be no greater than 1000 times the numerical aperture of the objective lens. For a 0.65 N.A. objective lens, the final magnification should be 650× or less.

Dirty or damaged optical components seriously degrade image quality. Dirt and dust on lens, mirror, or prism surfaces, as well as degradation of lens coatings, are of primary concern. It is wise not to attempt optical surface cleaning other than that which can be done with a soft brush or light blast of air. It is well worth the expense to have a skilled service person thoroughly clean the microscope on an annual basis.

The forgoing discussions are not intended to be a comprehensive treatment of reflected-light microscopy. A number of interesting special techniques have been excluded because they require specialized instrumentation. Almost all of the illumination modes and image-enhancement techniques discussed can be done with current research-grade metallographs. One feature that most modern instruments do not include is a precision rotating stage that allows for rotation of the specimen without disturbing the focus of the instrument. Such a stage was incorporated on instruments manufactured through the mid-1970s. Stage rotation, wherein the specimen remains normal to the optic axis of the instrument, greatly enhances the ability to use polarized light, sensitive tint, and differential interference contrast.

PHOTOLUMINESCENCE SPECTROSCOPY

INTRODUCTION

Photoluminescence (PL) spectroscopy is a powerful technique for investigating the electronic structure, both intrinsic and extrinsic, of semiconducting and semi-insulating materials. When collected at liquid helium temperatures, a PL spectrum gives an excellent picture of overall crystal quality and purity. It can also be helpful in determining impurity concentrations, identifying defect complexes, and measuring the band gap of semiconductors. When

performed at room temperature with a tightly focused laser beam, PL mapping can be used to measure micrometer-scale variations in crystal quality or, in the case of alloys and superlattices, chemical composition.

The information obtainable from PL overlaps with that obtained by absorption spectroscopy, the latter technique being somewhat more difficult to perform for several reasons. First, absorption spectroscopy requires a broadband excitation source, such as a tungsten-halogen lamp, while PL can be performed with any above-band-gap laser source. Second, for thin-film samples absorption spectroscopy requires that the substrate be etched away to permit transmission of light through the sample. Third, for bulk samples the transmitted light may be quite weak, creating signal-to-noise ratio difficulties. On the other hand, absorption spectroscopy has the advantage of probing the entire sample volume, while PL is limited to the penetration depth of the above-band-gap excitation source, typically on the order of a micrometer.

The areas of application of PL also overlap somewhat with Raman spectroscopy (RAMAN SPECTROSCOPY OF SOLIDS), but the latter is much harder to perform because of the inherent weakness of nonlinear scattering processes and because of its sensitivity to crystallographic orientation. On the other hand, this sensitivity to orientation gives Raman spectroscopy a capability to detect variations in crystallinity that PL lacks.

There are also more elaborate techniques, such as photoluminescence excitation (PLE), time-resolved PL, and resonant Raman scattering, but these techniques are more useful for basic scientific investigations than for routine crystal characterization.

PRINCIPLES OF THE METHOD

When a semiconductor is illuminated by a light source having photon energy greater than the band-gap energy (E_g) of the material, electrons are promoted to the conduction band, leaving holes behind in the valence band. When an electron-hole pair recombines, it emits a photon that has a wavelength characteristic of the material and the particular radiative process. Photoluminescence spectroscopy is a technique for extracting information about the electronic structure of the material from the spectrum of light emitted.

In the basic process of PL at low temperature (liquid nitrogen temperature and below), an incoming photon is absorbed to create a free electron-hole pair. This transition must be essentially vertical to conserve crystal momentum, since the photon momentum is quite small. At cryogenic temperatures the electrons (holes) rapidly thermalize to the bottom (top) of the conduction (valence) band by emitting phonons. For this reason there is typically no observable luminescence above the band-gap energy. Once they have relaxed to the band edges, an electron and hole can bind together to form an exciton, which then recombines radiatively as described below. Alternatively, the electron or hole (or both) can drop into a defect state by nonradiative recombination and then undergo radiative recombination.

Excitons and Exciton-Polaritons

It is impossible to analyze luminescence spectra without considering the role of excitons. Formally an exciton must be thought of as an additional bound state of the crystal that appears when the Coulomb interaction between electrons and holes is incorporated into the crystal Hamiltonian, but there is also a simple, mechanistic picture that leads to the same result. The exciton can be thought of as a hydrogenlike atom that results when the electron and hole bind together. The binding energy of an exciton is then given by

$$E_n = -\frac{E_0}{n^2} \qquad E_0 > 0 \qquad n = 1, 2, 3 \tag{1}$$

where E_0 is the free exciton binding energy. The total energy of the exciton is $E_g + E_n < E_g$, so when the exciton recombines, the energy of the emitted photon is below E_g.

This simple, hydrogenlike picture of the exciton is actually an oversimplification. In reality, the free exciton should be thought of as a polarization wave that can propagate through the crystal. This polarization wave can interact with an electromagnetic wave to produce *exciton-polariton* states. The dispersion curve for these states has two branches, as illustrated in many texts in solid-state and semiconductor physics (e.g., Yu and Cardona, 1996, p. 273). Given this continuum of states, the polariton emission spectrum can be quite complex, the peak positions being determined by the relative lifetimes of states at various positions on the dispersion curve. In particular, polaritons near the transverse free exciton energy have particularly long lifetimes, creating a "bottleneck" that leads to accumulation of exciton population. Hence there is typically a peak at the free exciton energy, which can be thought of as a "pure" free exciton peak and is often labeled as such in the literature and in this unit.

Bound Excitons

At low temperatures excitons can bind to donor or acceptor sites via van der Waals forces to form states of lower energy than the polariton states. Since bound exciton states are localized, they have no dispersion. The dissociation energy for a bound exciton is dependent on the species of donor or acceptor; this fact is sometimes helpful in identifying impurities. Figure 1 shows donor- and acceptor-bound exciton luminescence for CdTe.

Alloy Broadening

In an alloy, random microscopic composition variations in the crystal cause a broadening in the energy spectrum of electronic states. Figure 2 shows the exciton spectrum for $Cd_{0.96}Zn_{0.04}Te$. Much of the fine structure that was apparent for pure CdTe has been obscured by alloy broadening.

Phonon Replicas

There may also be phonon replicas of any of the aforementioned peaks. That is, the system may emit part of its energy as one or more phonons—typically longitudinal-

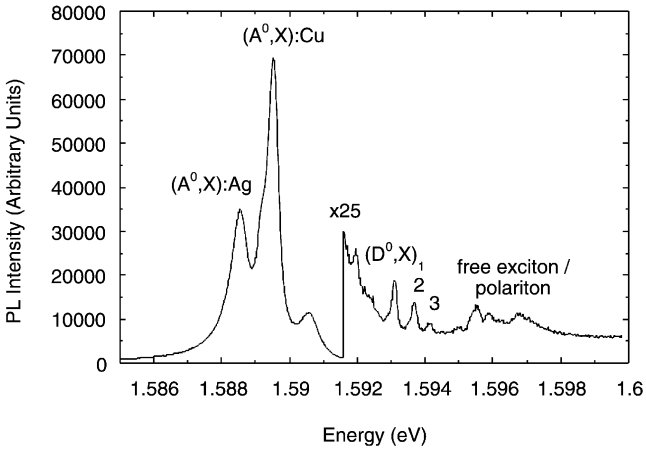

Figure 1. Free and bound exciton luminescence of CdTe at 4.2 K showing bound exciton luminescence from two acceptor species.

optical (LO) phonons—and the remainder as a photon. The emitted photon is thus of longer wavelength than that for the no-phonon process. In some cases the emitted phonon corresponds to a local vibrational mode of the defect to which the exciton is bound; this provides another means for identifying defects. In Figure 2, the first phonon replica of the free exciton luminescence is visible. The phonon replicas are less well-resolved than the no-phonon lines, because of the slight dispersion in the LO phonon energy. The LO phonon energy can be read from the spacing of the peaks as ~22 meV.

Donor-Acceptor and Free-to-Bound Transitions

Some electrons and holes drop by nonradiative processes from the conduction and valence bands into donor and acceptor states, respectively. When these charge carriers recombine, they emit photons of lower energy than do excitonic or direct band-to-band transitions. Possible transitions include those in which a conduction band electron

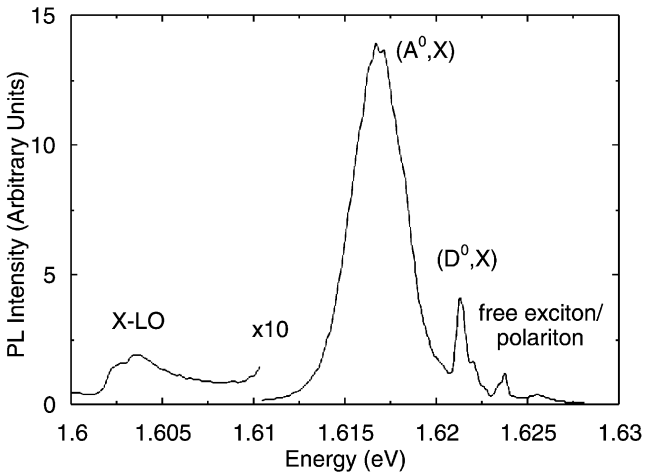

Figure 2. Exciton luminescence of $Cd_{0.96}Zn_{0.04}Te$ at 4.2 K. Many of the peaks that are present in the CdTe spectrum are not resolvable because of alloy broadening.

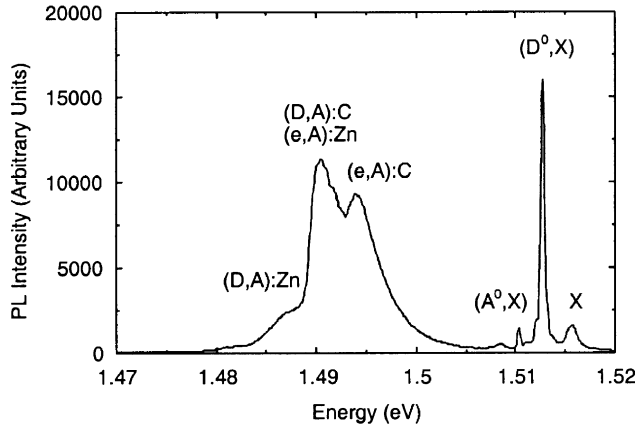

Figure 3. PL spectrum of semi-insulating GaAs at 4.2 K showing separate donor-acceptor and band-to-acceptor peaks for C and Zn.

recombines with a hole in an acceptor level (e,A), an electron in a donor level combines with a hole in the valence band (D,h), and an electron in a donor level recombines with a hole in an acceptor level (D,A). The (D,A) luminescence is below the band gap by the sum of the donor and acceptor binding energies minus the Coulomb energy of attraction between the ionized donor and acceptor in the final state:

$$h\nu = E_g - (E_A + E_D) + \frac{e^2}{\varepsilon r_n} \quad \text{(Gaussian units)} \qquad (2)$$

where r_n is the distance between the nth nearest neighbor donor and acceptor sites and can take on only those values consistent with the crystal lattice. The discrete values of r imply that there are a large number of separate (D,A) peaks, but for relatively large values of n, they merge into a single broad band. With high-resolution measurements on high-quality crystals at low temperature, it is sometimes possible to detect separate peaks for low values of n (Yu and Cardona, 1996, p. 346).

There can also be multiple donor or acceptor levels in a given material, each exhibiting its own set of peaks in the spectrum. A well-known example is C and Zn in GaAs, which give rise to two sets of overlapping (e,A) and (D,A) peaks (Stillman et al., 1991). A representative 4.2 -K GaAs spectrum is shown in Figure 3.

Transitions Involving Defect Levels

Many kinds of defects produce energy states closer to the middle of the band gap than the shallow donor and acceptor states mentioned above. Recombination processes involving these defect levels result in emission of longer-wavelength photons. Because these defect states are localized, they have broad energy spectra. Also, they tend to be strongly coupled to the lattice and hence have a large number of phonon replicas that often smear together into a single broad band. An example CdZnTe spectrum is shown in Figure 4. The band at ~1.4 eV is believed to be related to the A-center (Cd vacancy plus donor), and the band at 1.1 eV is believed to be related to Te vacancies.

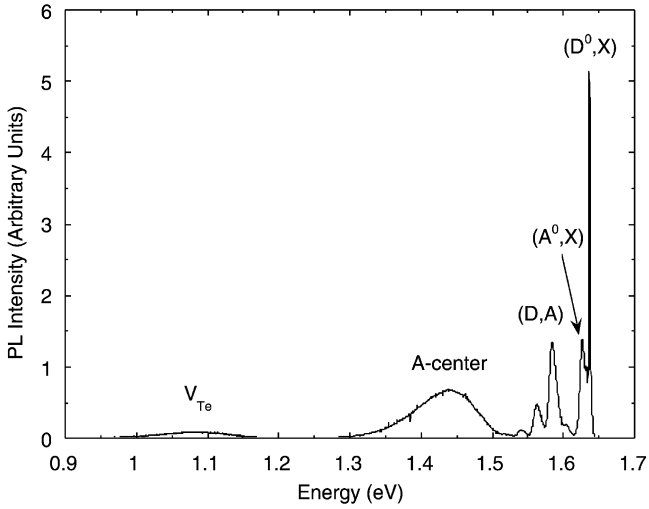

Figure 4. PL spectrum of $Cd_{0.9}Zn_{0.1}Te$ at 4.2 K showing excitonic, donor-acceptor, and deep-level luminescence.

Band-to-Band Recombination

At room temperature there is a nonzero occupancy of electron states near the bottom of the conduction band and hole states near the top of the valence band. Hence, electron-hole pairs can recombine to emit photons over a range of energies, producing a broad band rather than a sharp peak. Donor, acceptor, and defect states are generally fully ionized at room temperature and do not contribute significantly to the observed spectrum.

Band-to-band recombination produces a luminescence spectrum that is the product of the joint density of states and the Fermi-Dirac distribution (see Bhattacharya, 1994):

$$I(E) \propto \frac{\sqrt{E - E_g}}{1 + \exp[(E - E_g)/kT]} \tag{3}$$

Observed room temperature luminescence typically does not follow Equation 3 except at the upper end of the energy range. Equation 3 has a sharp lower cutoff at the band-gap energy, while the measured spectrum has a long tail below the peak. This is an indication that the spectrum is only partly due to band-to-band recombination and also includes excitonic and phonon-assisted transitions (Lee et al., 1994b).

PRACTICAL ASPECTS OF THE METHOD

Experimental Setup

The apparatus for low-temperature PL can be set up easily on an optical table. The sample is enclosed in an optical cryostat and illuminated with an above-band-gap light source, in most cases a laser. An optical band-pass filter is typically used to remove unwanted plasma lines from the laser emission, and a low-pass filter is often placed at the entrance of the monochromator to remove stray light at shorter wavelengths than the range of interest. Both of these sources of extraneous light can show up in the spectrum in second order. The light emitted by the sample is collected with a collimating lens and then focused onto the entrance slits of the monochromator with a second lens.

A photon detector, typically either a photomultiplier tube (PMT) or a positive-intrinsic-negative (PIN) diode detector, is placed at the exit of the monochromator. The output signal of the detector is routed either to a photon counter or to a lock-in amplifier. In the latter case, a light chopper is used to synchronize the signal with a reference. In the photon-counting mode, it is desirable to cool the detector with liquid nitrogen to reduce noise; N_2 gas must then be allowed to flow over the face of the detector to keep it from frosting.

The instrumentation for room temperature PL mapping is similar, with the addition of an *x-y* translation stage. Generally, the optics are kept fixed and the sample translated. The excitation source is focused onto the sample with a microscope objective, which also serves to collimate the luminescence. A beam splitter or a mirror containing a small hole is used to allow transmission of the laser beam while reflecting the luminescence into the monochromator.

An alternative scheme for PL uses an optical multichannel analyzer. In this case the monochromator disperses the light onto an array of charge-coupled devices (CCDs) so that the entire spectrum is captured at once. This configuration has the advantage of greater speed, which is especially valuable in room temperature mapping, but it generally suffers from reduced wavelength resolution.

Following is a list of instrumentation and representative manufacturers for low-temperature PL along with some of the requirements and considerations for each apparatus:

1. *Detectors* (Hamamatsu, Phillips, Burr-Brown, Electron Tubes, Oriel, EG&G, Newport)—The principal trade-off is between bandwidth and sensitivity. The need for cooling is a further consideration. Photomultiplier tubes are unmatched in sensitivity but typically have limited long-wavelength response. Most PMTs can be operated at room temperature in the current mode but may require cooling for optimal performance in the photon-counting mode. Narrow-band-gap semiconductor detectors, such as germanium PIN diodes, have better long-wavelength response but poorer sensitivity at shorter wavelengths. They generally must be cooled with liquid nitrogen.
2. *Spectrometers/monochromators* (Jobin Yvon-Spex, Oriel, Jarrell Ash, Acton Research, McPherson, Ocean Optics, CVI Laser)—For high resolution, a large, double-grating spectrometer is required. For lower resolution applications, compact, inexpensive prism spectrometers with integrated CCD detectors are available.
3. *Lasers* (Coherent, Uniphase, Kimmon, Spectra-Physics, Newport, Melles Griot, Anderson Lasers)—The principal requirement is that the photon energy be higher than the band gap of the material

at the temperature at which the measurements are made. For direct band-gap materials, output power of a few milliwatts is typically sufficient. For indirect band-gap materials, higher power may be desirable. Single-line operation is preferred, since it permits the use of a laser line filter to remove extraneous lines that can appear in the measured spectrum in second order.

4. *Lock-in amplifiers/photon counters* (EG&G, Stanford Research, Oriel)—Both analog and digital lock-in amplifiers are available, the digital instruments generally having superior signal-to-noise ratios.
5. *Complete PL spectroscopy/mapping/imaging systems* (Phillips Analytical, Perkin Elmer, Oriel, ChemIcon)—Some systems are configurable with various laser modules, gratings, and detectors to be optimized for the application.

Use of Low-Temperature PL for Crystal Characterization

The most basic use of low-temperature PL spectra is as an indicator of overall crystal quality. The principal indicator of quality is the ratio of excitonic luminescence to donor-acceptor and deep-level luminescence. Figure 5 shows PL spectra for two CdZnTe samples of different quality. In the high-quality sample, the spectrum is dominated by a donor-bound exciton peak (D^0,X), while in the poor-quality sample the excitonic luminescence is outweighed by donor-acceptor and defect bands.

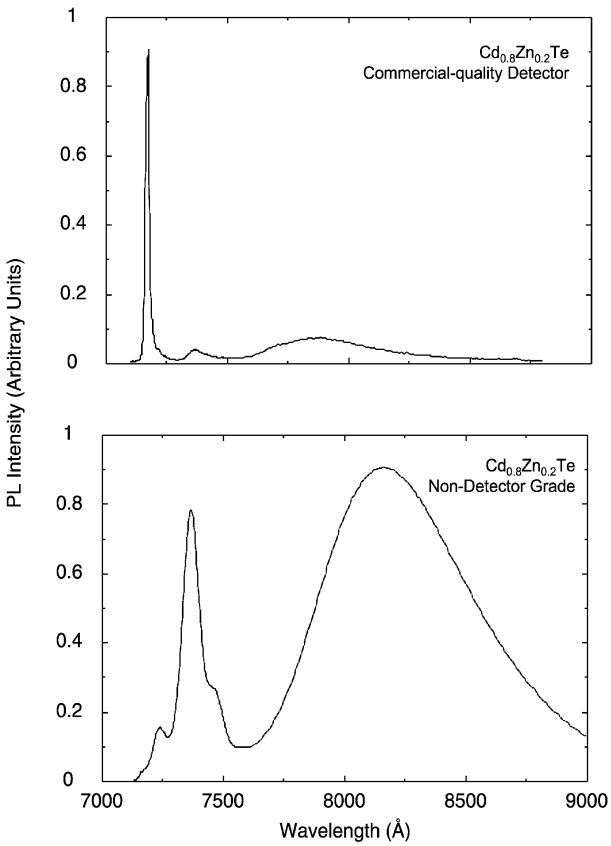

Figure 5. The 4.2-K PL spectra for $Cd_{0.8}Zn_{0.2}Te$ samples of differing quality. In the high-quality (commercial-quality detector grade) sample (top), the spectrum is dominated by excitonic luminescence. In the poor-quality (non-detector grade) sample the donor-acceptor and deep-level luminescence dominate.

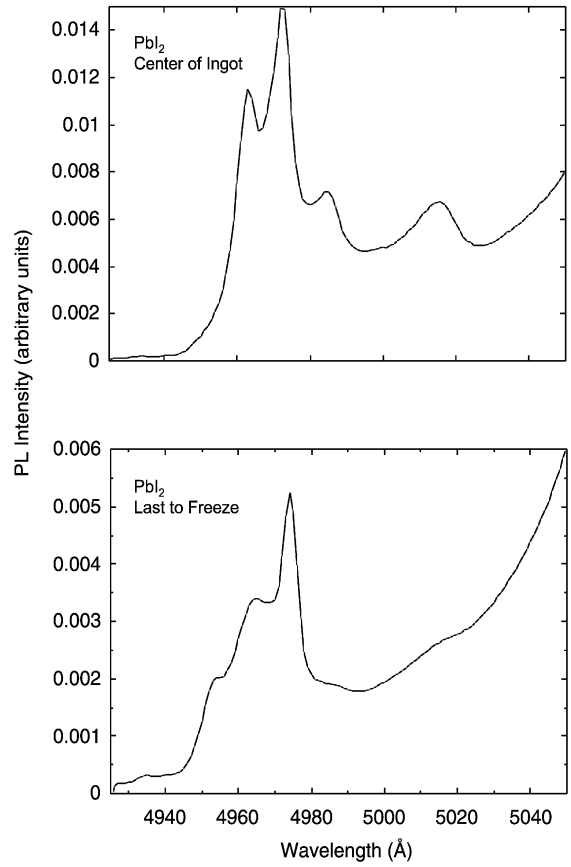

Figure 6. 4.2 K PL spectra for PbI_2 samples from center (top) and last-to-freeze portions of ingot. The spectrum for the sample from the middle of the ingot is sharper, indicating better crystal quality.

A second measure of crystal quality is the sharpness of the spectrum—that is, the extent to which adjacent lines can be resolved. Figure 6 shows near-band-edge PL spectra for two PbI_2 samples, one from the center of the ingot and the other from the last-to-freeze portion. The spectrum of the sample from the center is sharper, indicating a more uniform crystal potential on a microscopic scale.

Aside from indicating overall crystallinity, the low-temperature PL spectrum can sometimes be helpful in identifying specific impurities. The example of the C and Zn (D,A) bands in GaAs was given in Figure 4, but the bound exciton luminescence can also be used. For example, in the CdTe spectrum shown in Figure 1, the (A^0,X) peak at 1.5895 eV is due to Cu, while that at 1.5885 eV is due to Ag (Molva et al., 1984).

The ratio of bound to free exciton luminescence can also be used to measure impurity concentrations, but this application requires careful control over excitation intensity and sample temperature (Lightowlers, 1990). It also requires that calibration curves be generated based on chemical analysis.

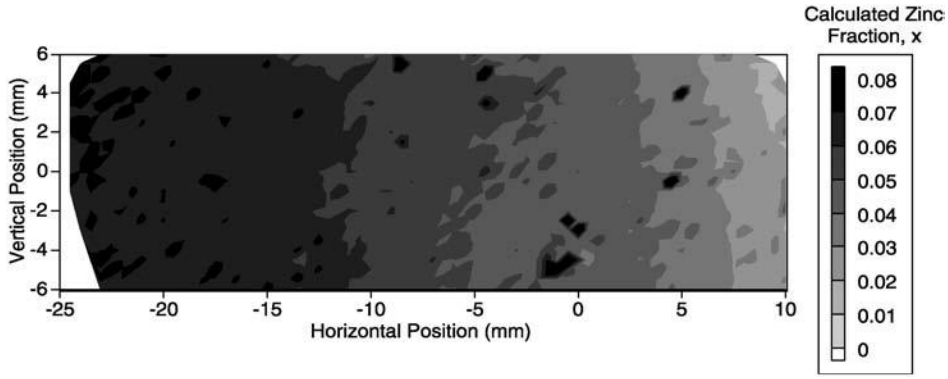

Figure 7. Room temperature PL composition map of $Cd_{1-x}Zn_xTe$ showing segregation of zinc along the growth axis.

Uses of Room Temperature PL Mapping

One application of room temperature PL is composition mapping of alloys. Figure 7 shows a PL composition map for CdZnTe grown by a high-pressure Bridgman method. Segregation of zinc along the growth axis is clearly visible.

In addition to the systematic variation in composition along the growth axis, local variations are sometimes seen. Figure 8 shows an example in which minute striations are present, perhaps due to temperature fluctuations during growth. Note that the dark bands are only ~20 μm wide, demonstrating that high spatial resolution is important.

Photoluminescence mapping is also useful for studying structural defects. PL maps of CnZnTe often contain isolated dark spots that can be attributed to inclusions, possibly of tellurium or zinc. High-spatial-resolution PL maps of these inclusions show a region of near-zero PL intensity surrounded by a region in which the band gap is shifted to higher energy—hence the dark spots in the larger-scale maps. It is unclear whether the shift is caused by gettering of zinc around the inclusion or by strain.

METHOD AUTOMATION

Complete automated systems for PL spectroscopy and mapping are now commercially available. If a system is constructed from scratch, it is a relatively simple matter to integrate GPIB-controllable equipment using general-purpose laboratory software packages.

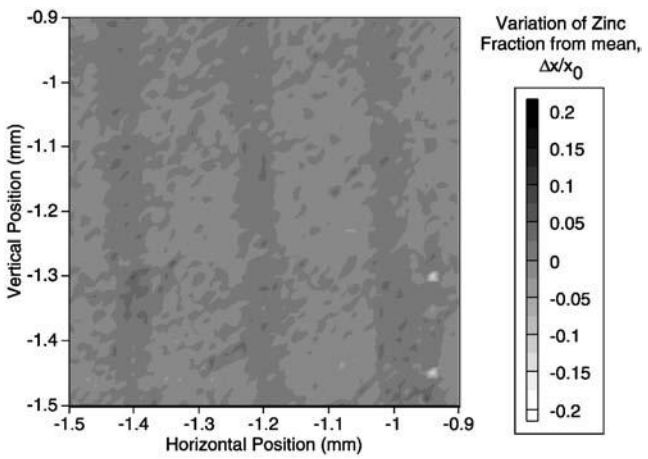

Figure 8. Room temperature PL composition map of $Cd_{1-x}Zn_xTe$ showing growth striations.

DATA ANALYSIS AND INITIAL INTERPRETATION

Identification of Bands in a Low-Temperature PL Spectrum

Qualitative interpretation of a low-temperature PL spectrum is quite simple if there are reliable sources in the literature to identify the origins of the various bands. If there are bands of uncertain origin, the intensity and temperature dependence of the spectrum can give clues to their nature.

As the sample temperature is raised, the luminescence is quenched as the centers involved in the transition are ionized by thermal excitation. The activation energy or energies of the level can then be determined by a curve fit to the following equation, which follows from Boltzmann statistics (Bimberg et al., 1971):

$$I(T) = I(0)\left[1 + C_1\exp\left(-\frac{-E_1}{kT}\right) + \cdots + C_n\exp\left(-\frac{-E_n}{kT}\right)\right]^{-1} \quad (4)$$

where $I(T)$ is the integrated intensity of the band at absolute temperature T, k is Boltzmann's constant, E_i is the activation energy of the ith process involved in the dissociation, and C_i is formally the degeneracy of the level but in practice is left as a fitting parameter. Most processes can be modeled as one- or two-step dissociations. An example of a one-step dissociation is that of a free exciton into a free electron and hole, whereas the prototypical two-step dissociation is bound exciton quenching, in which the exciton first dissociates from the donor or acceptor to form a free exciton, which then dissociates in a second step. This difference in temperature dependence is one means of distinguishing between free and bound excitons in an unfamiliar spectrum.

Temperature dependence can also be used to distinguish between (D,A) and (e,A) transitions, since the former, which involve a shallow donor, will be quenched quickly as the donors are ionized.

The dependence of the spectrum on the excitation intensity can be used to distinguish between excitonic and

donor-acceptor bands. In both cases the luminescence intensity varies with the excitation intensity as a power law, but for excitonic lines the exponent is >1.0, whereas for donor-acceptor and free-to-bound transitions it is <1.0 (Schmidt et al., 1992).

One additional technique that can help to identify peaks is infrared quenching. As the sample is subjected to below-band-gap infrared radiation in addition to laser excitation, donors and acceptors are ionized, causing quenching of (D^0,X) and (A^0,X) transitions and an increase in (D^+,X) luminescence. It has been shown that (A^-,X) complexes cannot exist in most semiconductors (Hopfield, 1964), so that this provides another way of distinguishing between donor- and acceptor-bound excitons. Infrared quenching has also been used quantitatively to measure impurity concentrations (Lee et al., 1994a).

Curve Fitting in Room Temperature PL Mapping

Extracting material parameters from a room temperature PL spectrum in a systematic way requires that the calculated line shapes for various types of transitions (Bebb and Williams, 1972) be combined. This approach has been used with some success in cadmium telluride (Lee et al., 1994b), and in cadmium zinc telluride (Brunnett et al., 1999). In the alloy, variation in the band gap and exciton and phonon energies introduces additional uncertainty in the extracted composition. The composition determined from this procedure cannot be regarded as highly accurate, but variations can be detected with precision.

SAMPLE PREPARATION

Photoluminescence generally requires no special sample preparation, other than to provide a reasonably smooth surface so that a large fraction of the light is not scattered away. Thin-film samples generally can be analyzed as grown, whereas bulk samples that have been cut typically require etching to remove the damaged layer produced by the cutting.

SPECIMEN MODIFICATION

Low-temperature PL requires relatively low optical power density, so that the risk of damaging the material is minimal. Room temperature mapping, however, does use rather high power densities that cause significant sample heating. Most group II–VI and III–V compounds produce adequate luminescence at low enough intensity to avoid damaging the sample, but with less robust materials, such as PbI_2 and HgI_2, room temperature mapping may not be practical.

POTENTIAL PROBLEMS

A difficulty with extracting accurate composition information from room temperature PL spectra is that the peak position depends on the excitation wavelength and intensity. The spectrum shifts to lower energy as the intensity is raised, and the peak position is at lower energy for the shorter-wavelength light. The explanation for this effect probably lies in local heating of the sample by the rather high intensities used. The heating is greater for higher-energy (blue) photons because a greater fraction of each photon's energy is converted to phonons.

ULTRAVIOLET AND VISIBLE ABSORPTION SPECTROSCOPY

INTRODUCTION

Ultraviolet and visible (UV-Vis) absorption spectroscopy is the measurement of the attenuation of a beam of light after it passes through a sample or after reflection from a sample surface. This unit will use the term UV-Vis spectroscopy to include a variety of absorption, transmittance, and reflectance measurements in the ultraviolet (UV), visible, and near-infrared (NIR) spectral regions. These measurements can be at a single wavelength or over an extended spectral range. As presented here, UV-Vis spectroscopy will be found under other names, including UV-Vis spectrometry, UV-Vis spectrophotometry, and UV-Vis reflectance spectroscopy. This unit provides an overview of the technique and does not attempt to provide a comprehensive review of the many applications of UV-Vis spectroscopy in materials research. In this regard, many of the references were chosen to illustrate the diversity of applications rather than to comprehensively survey the uses of UV-Vis spectroscopy. A unifying theme is that most of the measurements discussed in this unit can be performed with simple benchtop spectrometers and commercially available sampling accessories.

The UV-Vis spectral range is approximately 190 to 900 nm. This definition originates from the working range of a typical commercial UV-Vis spectrometer. The short-wavelength limit for simple UV-Vis spectrometers is the absorption of UV wavelengths <180 nm by atmospheric gases. Purging a spectrometer with nitrogen gas extends this limit to 175 nm. Working beyond 175 nm requires a vacuum spectrometer and a suitable UV light source and is not discussed in this unit. The long-wavelength limit is usually determined by the wavelength response of the detector in the spectrometer. Higher end commercial UV-Vis spectrometers extend the measurable spectral range into the NIR region as far as 3300 nm. This unit includes the use of UV-Vis-NIR instruments because of the importance of characterizing the NIR properties of materials for lasers, amplifiers, and low-loss optical fibers for fiber-optic communications and other applications. Table 1 summarizes the wavelength and energy ranges of the UV-Vis and related spectral regions.

Ultraviolet-visible spectroscopy is one of the more ubiquitous analytical and characterization techniques in science. There is a linear relationship between absorbance and absorber concentration, which makes UV-Vis spectroscopy especially attractive for making quantitative measurements. Ultraviolet and visible photons are energetic enough to promote electrons to higher energy states in molecules and materials. Figures 1 and 2 illustrate typical absorption spectra for the absorption processes for molecules and semiconductor materials, respectively. Therefore, UV-Vis spectroscopy is useful to the exploration of the electronic properties of materials and materials precursors in basic research and in the development of applied materials. Materials that can be characterized by UV-Vis spectroscopy include semiconductors for electronics, lasers, and detectors; transparent or partially transparent optical components; solid-state laser hosts; optical fibers, waveguides, and amplifiers for communication; and materials for solar energy conversion. The UV-Vis range also spans the range of human visual acuity of approximately 400 to 750 nm, making UV-Vis spectroscopy useful in characterizing the absorption, transmission, and reflectivity of a variety of technologically important materials, such as pigments, coatings, windows, and filters.

The use of UV-Vis spectroscopy in materials research can be divided into two main categories: (1) quantitative measurements of an analyte in the gas, liquid, or solid phase and (2) characterization of the optical and electronic properties of a material. The first category is most useful as a diagnostic tool for the preparation of materials, either to quantitate constituents of materials or their precursors or as a process method to monitor the concentrations of reactants or products during a reaction (Baucom et al., 1995; Degueldre et al., 1996). In quantitative applications it is often only necessary to measure the absorbance or reflectivity at a single wavelength. The second more

Table 1. Approximate Wavelengths, Energies, and Type of Excitation for Selected Spectral Regions

Spectral Region	Wavelength Range (nm)	Energy Range (cm^{-1})	Energy Range (eV)	Types of Excitation
Vacuum-UV	10–180	1×10^6–55,600	124–6.89	Electronic
UV	200–400	50,000–25,000	6.89–3.10	Electronic
Visible	400–750	25,000–13,300	3.10–1.65	Electronic
Near IR	750–2500	13,300–4000	1.65–0.496	Electronic, vibrational overtones
IR	2500–25,000	4000–400	0.496–0.0496	Vibrations, phonons

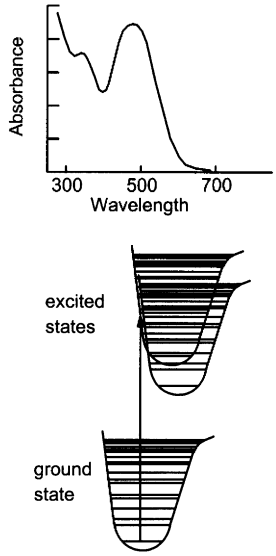

Figure 1. Typical molecular absorption spectrum and a schematic of the absorption process in a molecule.

qualitative application usually requires recording at least a portion of the UV-Vis spectrum for characterization of the optical or electronic properties of materials (Kovacs et al., 1997). Much of the discussion of UV-Vis spectroscopy will follow these two main applications of quantitative measurements and materials characterization.

Materials Properties Measurable by UV-Vis Spectroscopy

Electronic excitations in molecules usually occur in the UV and visible regions. Charge transfer bands can occur from the UV to the NIR. The band gap of a semiconductor depends on the specific material and physical dimensions and can range from the UV to NIR. A reduction in semiconductor particle size or dimensions (<10 nm) will shift the band edge to shorter wavelength (higher energy) due to quantum confinement effects (Bassani et al., 1997). The NIR light excites vibrational overtones and combination bands in molecules. Although these transitions are very weak, they become important in certain cases such as optical fibers in which a very long path length is of interest.

In organic molecules and polymers, the UV-Vis spectrum can help to identify chromophores and the extent of electronic delocalization (Yoshino et al., 1996). Similarly, absorption measurements can be correlated with bulk physical properties (Graebner, 1995). For inorganic complexes, the UV-Vis spectrum can provide information about oxidation states, electronic structure, and metal-ligand interactions. For solid materials, the UV-Vis spectrum can measure the band gap and identify any localized excitations or impurities (Banerjee et al., 1996).

Optical materials that rely on interference can be utilized throughout the UV-Vis-NIR spectral range. Collective excitations that determine the absorption or reflectivity of a material likewise occur throughout this range. For example, the peak absorption of the plasmon resonance absorption of thin films of aluminum, gold, and semiconductors occurs in the UV, visible, and NIR regions, respectively, For small metal particles, the plasmon resonance absorption also varies due to particle size (Ali et al., 1997).

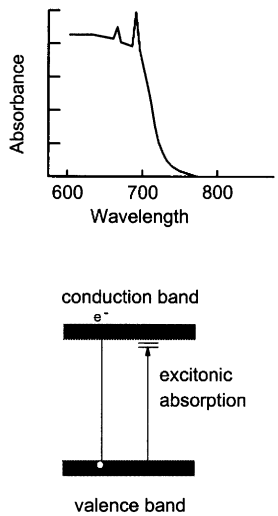

Figure 2. Typical absorption spectrum for a semiconductor and a schematic of the absorption process in a direct-bandgap semiconductor.

Competitive and Related Techniques for Qualitative and Quantitative Analysis

The spectrum of a molecule depends on its energy-level structure, and the UV-Vis absorption spectrum can sometimes be useful for identifying molecular compounds. However, UV-Vis spectra have broad features that are of limited use for sample identification. The broad lines do facilitate making accurate quantitative measurements. Lanthanide ions and some transition metals in molecular complexes have sharp UV-Vis bands and are easily identified by their absorption spectrum. Qualitative identification and structural analysis of molecules usually require multiple analytical methods, including C, H, and O elemental analysis; infrared (IR) absorption; Raman spectroscopy (see RAMAN SPECTROSCOPY OF SOLIDS); nuclear magnetic resonance (NMR) spectroscopy (see NUCLEAR MAGNETIC RESONANCE IMAGING); mass spectrometry; size exclusion chromatography; and x-ray diffraction (XRD, see X-RAY TECHNIQUES). The elemental composition of solids can be determined by x-ray fluorescence, microprobe techniques (see X-RAY MICROPROBE FOR FLUORESCENCE AND DIFFRACTION ANALYSIS), and surface spectroscopies such as x-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES, see AUGER ELECTRON SPECTROSCOPY), or secondary-ion mass spectrometry (SIMS). For crystalline or polycrystalline solids, x-ray (X-RAY TECHNIQUES), electron (ELECTRON TECHNIQUES), and neutron diffraction (NEUTRON TECHNIQUES) are the most reliable means of structure identification.

Quantitative measurements with benchtop UV-Vis spectrometers are most commonly performed on molecules and inorganic complexes in solution. Photoluminescence for fluorescent analytes is usually more sensitive than absorption measurements, because the fluorescence signal

is measured on a nominally zero-noise background. Absorbance measurements require that the change in light power due to absorption be greater than the noise of the light source. Quantitating gas phase species or analytes on surfaces or in thin films using UV-Vis spectrometers is possible for high concentrations or strongly absorbing species (Gregory, 1995). In practice, polymer or Langmuir-Blodgett films are more often measured using IR absorption or some type of laser spectroscopy (Al-Rawashdeh and Foss, 1997). In addition to UV-Vis reflectance spectroscopy, inorganic surfaces often require analysis with multiple spectroscopies such as Raman spectroscopy, extended x-ray absorption fine structure (EXAFS, see XAFS SPECTROSCOPY), XPS, AES, and SIMS.

Laser spectroscopic absorption techniques can provide a variety of advantages compared to conventional UV-Vis spectroscopy. Lasers have much higher intensities and can provide much shorter time resolution than modulated lamp sources for measuring transient phenomena. The recent commercialization of optical parametric oscillators (OPOs) alleviates the limited scan range of dye lasers. Cavity-ringdown laser absorption spectroscopy (Paul and Saykally, 1997; Scherer et al., 1997) and intracavity laser absorption (Stoeckel and Atkinson, 1985; Kachanov et al., 1997) are much more sensitive than measurements using UV-Vis spectrometers. Similarly, photoacoustic and photothermal spectroscopy can provide very high sensitivity absorption measurements of opaque samples and analytes on surfaces (Bialkowski, 1995; Childers et al., 1986; Palmer, 1993; Welsch et al., 1997). Nonlinear laser spectroscopies, such as second-harmonic generation (SHG), can be surface selective and provide enhanced selectivity and sensitivity for analytes on surfaces compared to absorption or fluorescent measurements (Di Bartolo, 1994).

Competitive and Related Techniques for Material Characterization

Because of the diverse applications to which UV-Vis spectroscopy can be applied, there are a multitude of related techniques for characterizing the electronic and optical properties of materials. Characterizing complex materials or processes often requires the results of multiple analytical techniques (see, e.g., Lassaletta et al., 1995; Takenaka et al., 1997; Weckhuysen et al., 1996). Electronic properties are often measured by a variety of methods, and UV-Vis spectral results are correlated with electrical measurements, surface spectroscopies, and electrochemical measurements (Ozer et al., 1996; Yoshino et al., 1996). Characterization of the electronic and optical properties of semiconductors often requires time-resolved laser spectroscopic methods, photoluminescence spectroscopy (see PHOTOLUMINESCENCE SPECTROSCOPY), and sophisticated modulation techniques such as piezospectroscopy (Ramdas and Rodriguez, 1992) and modulated photoreflectance (Glembocki and Shanabrook, 1992).

Measuring the transmittance or reflectance of most optical materials in the UV-Vis region rarely requires more sophisticated instrumentation than a commercial spectrometer. Measuring an extremely small absorbance can require some type of laser-based method. Measuring polarization properties such as optical rotation and circular dichroism of materials also requires more sophisticated techniques and is usually performed on dedicated polarimetry, circular dichroism, or ellipsometry instruments. Many technologically important materials, such as light-emitting diodes (LEDs), optical amplifiers, laser materials, and lamp and display phosphors, require characterization of the emission properties as well as the absorption properties. For these types of materials, measurements of the photoluminescence or electroluminescence spectrum and the fluorescence quantum efficiency are as important as characterizing the absorption spectrum and absorbance.

PRINCIPLES OF THE METHOD

Ultraviolet-visible spectroscopy measures the attenuation of light when the light passes through a sample or is reflected from a sample surface. The attenuation can result from absorption, scattering, reflection, or interference. Accurate quantitation requires that the measurement record the attenuation due only to absorption by the analyte, so the spectroscopic procedure must compensate for the loss of light from other mechanisms. The cause of the attenuation is often not important for many optical materials, and the total resulting transmittance or reflectance is sufficient to determine the suitability of a material for a certain application.

Experimental measurements are made in terms of transmittance T:

$$T = P/P_0 \tag{1}$$

where P is the radiant power (radiant energy on unit area in unit time) after it passes through the sample and P_0 is the initial radiant power. This relationship will also be found in terms of light intensities:

$$T = I/I_0 \tag{2}$$

Percent transmittance is simply $T \times 100\%$ ($\%T$). The parameters P and P_0 are not always well-defined and can depend on the UV-Vis application. Figures 3 and 4 illustrate the differences that are encountered in defining P and P_0 in quantitative and qualitative characterization measurements.

Quantitative Analysis

Within certain limits, the absorbance of light by a sample is directly proportional to the distance the light travels through the sample and to the concentration of the absorbing species. This linear relationship is known as the Beer-Lambert law (also called the Beer-Lambert-Bouguer law or simply Beer's law) and allows accurate concentration measurements of absorbing species in a sample. The general Beer-Lambert law is usually written as

$$A = a \times b \times c \tag{3}$$

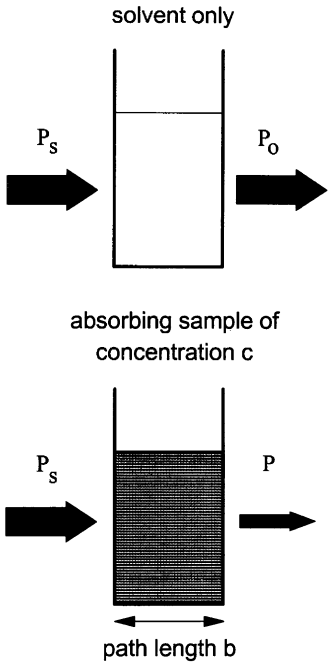

Figure 3. Schematic of a transmittance measurement for the quantitative determination of an analyte in solution.

where A is the measured absorbance, a is a wavelength-dependent absorptivity coefficient, b is the path length, and c is the analyte concentration. When working in concentration units of molarity, the Beer-Lambert law is written as

$$A = \varepsilon \times b \times c \tag{4}$$

where ε is the wavelength-dependent molar absorptivity coefficient with units of reciprocal molarity per centimeter and b has units of centimeters. If multiple species that absorb light at a given wavelength are present in a sample, the total absorbance at that wavelength is the sum due to all absorbers:

$$A = (\varepsilon_1 \times b \times c_1) + (\varepsilon_2 \times b \times c_2) + \cdots \tag{5}$$

where the subscripts refer to the molar absorptivity and concentration of the different absorbing species that are present.

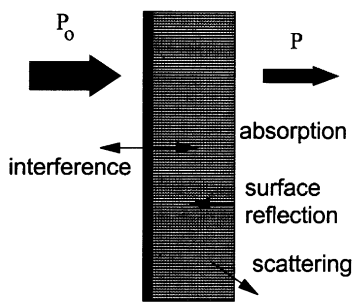

Figure 4. Schematic of a transmittance measurement of an optical component such as a dielectric-coated filter.

The linear relationship of the Beer-Lambert law depends on several conditions. The incident radiation must be monochromatic and collimated through a sample. Samples, including calibration standards, must be homogeneous without irreproducible losses due to reflection or scattering. For analytes in a matrix, such as a solution or a glass, the absorber concentration must be low enough so that the absorbing species do not interact. Interactions between absorbing species can lead to deviations in the absorptivity coefficient (at a given wavelength) as a function of concentration. More details on the most common limitations are described below (see Problems).

The relationship between absorbance A and the experimentally measured transmittance T is

$$A = -\log T = -\log(P/P_0) \tag{6}$$

where T and A are both unitless. Absorption data and spectra will often be presented using A, T, $\%T$, or $1 - T$. An absorption spectrum that uses $1 - T$ versus wavelength will appear similar to a plot of absorbance A versus wavelength, but the quantity $1 - T$ does not directly correspond to absorber concentration as does A.

Figure 3 shows the quantitative measurement of P and P_0 for an analyte in solution. In this example, P_s is the source light power that is incident on a sample, P is the measured light power after passing through the analyte, solvent, and sample holder, and P_0 is the measured light power after passing through only the solvent and sample holder. The measured transmittance in this case is attributed to only the analyte.

If the absorptivity coefficient of an absorbing species is not known, an unknown concentration can be determined using a working curve of absorbance versus concentration derived from a set of standards of known concentration. Calibration with standards is almost always necessary for absorbance measurements made in a reflectance geometry or with a fiber-optic light delivery system.

Material Characterization

Figure 4 illustrates the measurement of P and P_0 to determine the transmittance of a dielectric coating on a substrate. This example is a typical measurement to characterize the optical properties of a material such as a window, filter, or other optical component. In this case P is the light power after the sample and P_0 is the light power before the sample. Figure 5 shows two examples of transmittance spectra for optical components. The transmittance of the colored glass filter (top spectrum) does not reach 1.0 at wavelengths >600 nm due to surface reflection losses. The oscillations in the bottom spectrum arise from the interference origin of the transmittance properties. In these examples, the measured transmittance is due to all sources of light attenuation, which for practical applications is often unimportant compared to knowing the resulting transmittance at any given wavelength. These example spectra show the transmittance spectrum for an incidence angle of 0° through an optical component. Depending on the application, the transmittance or reflectance spectrum as a

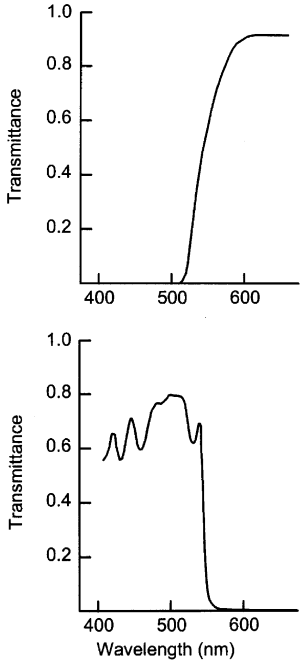

Figure 5. Transmittance spectra of a colored glass filter (top) and a dielectric-coated interference filter (bottom).

function of the angle the light beam makes with the optical component might be of more interest.

PRACTICAL ASPECTS OF THE METHOD

General Considerations

Most commercial UV-Vis absorption spectrometers use one of three overall optical designs: a scanning spectrometer with a single light beam and sample holder, a scanning spectrometer with dual light beams and dual sample holders for simultaneous measurement of P and P_0, or a nonscanning spectrometer with an array detector for simultaneous measurement of multiple wavelengths. Most commercial instruments use a dispersive design, but Fourier transform UV-Vis spectrometers find applications in high-speed, low-resolution and other specialized applications (Thorne, 1991). In single- and dual-beam spectrometers, the light from a lamp is dispersed before reaching the sample cell. In an array detector instrument, all wavelengths pass through the sample and the dispersing element is between the sample and the array detector. The specific designs and optical components vary widely depending on the required level of spectrometer performance. The following paragraph describes common features of the UV-Vis instruments followed by descriptions of the three different designs and sampling options. Specific details about UV-Vis instruments can be found in the manufacturers' literature.

Common Spectrometer Components

The light source is usually a deuterium discharge lamp for UV measurements and a tungsten-halogen lamp for visible and NIR measurements. The instruments automatically swap lamps when scanning between the UV and visible regions. The wavelengths of these continuous light sources are typically dispersed by a holographic grating in a single or double monochromator or spectrograph. The spectral bandpass is then determined by the monochromator slit width or by the array element width in array detector spectrometers. Spectrometer designs and optical components are optimized to reject stray light, which is one of the limiting factors in quantitative absorbance measurements. The detector in single-detector instruments is a photodiode, phototube, or photomultiplier tube (PMT). The UV-Vis-NIR spectrometers utilize a combination of a PMT and a Peltier-cooled PbS IR detector. The light beam is redirected automatically to the appropriate detector when scanning between the visible and NIR regions, and the diffraction grating and instrument parameters, such as slit width, can also change automatically.

Single-Beam Spectrometer

The simplest UV-Vis spectrometer design has one light beam and uses one sample cell. These instruments are simple and relatively inexpensive and are useful for routine quantitative measurements. Making a quantitative measurement requires calibrating the instrument at the selected wavelength for 0 and 100% transmittance (or a more narrow transmittance range if accurate standards are available). As in Figure 3, the 100% calibration is done with the sample cell containing only the solvent for quantitative measurements in solution. These measurements are stored by the instrument, and the spectrometer readout can also display in absorbance units (A.U.).

Absorbance and reflectivity measurements can be made with discrete light sources without dispersing optics in specialized applications. One example of a very small and robust optical spectrometer is the Mars Oxidant Experiment, which was developed for the Mars96 mission. This spectrometer consisted of LED light sources, a series of thin-film sensors, a photodiode array detector, detection electronics, and optical fibers to get light from an LED to a sensor and from that sensor to a pixel of the array detector. A variety of sensor films provide a measure of the oxidizing power of the Martian surface and atmosphere. The reflectivity of the sensors changed depending on the chemical environment, as recorded by the attenuation of the LED power reaching the detector (Grunthaner et al., 1995).

Dual-Beam Spectrometer

Spectra can be recorded with a single-beam UV-Vis instrument by manually recording absorbance measurements at different wavelength settings. Both a reference and the sample must be measured at each wavelength, which makes recording a wide spectral range or a small step size a tedious procedure. The dual-beam design greatly simplifies this process by simultaneously measuring P and P_0 of the sample and reference cells, respectively. Most spectrometers use a mirrored rotating chopper wheel to alternately direct the light beam through the sample and reference cells. The detection electronics or software program can then manipulate the P and P_0 values as the

wavelength scans to produce the spectrum of absorbance or transmittance as a function of wavelength.

Array Detector Spectrometers

In a large number of applications absorbance spectra must be recorded very quickly, such as in process monitoring or kinetics experiments. Dispersing the light after it passes through a sample allows the use of an array detector to simultaneously record the transmitted light power at multiple wavelengths. These spectrometers use photodiode arrays (PDAs) or charge-coupled devices (CCDs) as the detector. The spectral range of these array detectors is typically 200 to 1000 nm. Besides allowing rapid spectral recording, these instruments are relatively small and robust and have been developed into PC-card portable spectrometers that use optical fibers to deliver light to and from a sample. These instruments use only a single light beam, so a reference spectrum is recorded and stored in memory to produce transmittance or absorbance spectra after recording the raw sample spectrum.

Sample Handling

Most benchtop UV-Vis spectrometers contain a 10- to 200-mm-wide sample compartment through which the collimated light beam(s) pass. Standard mounts in this sample compartment hold liquid sample cuvettes or optical components and can include thermostatted temperature regulation. Custom mounts can hold transparent solid samples of arbitrary shapes. The standard sample holder is a 10-mm-path-length quartz cuvette, which can be purchased in matched sets for use in dual-beam spectrometers. Microcuvettes and capillary cuvettes hold less than 10 μL of sample for limited amounts of liquid samples. These microcuvettes have shorter path lengths than the standard sample cells, and the smaller volume can introduce more error into a quantitative measurement. Sample cells and mounts with path lengths up to 100 mm are also available. Measuring longer path lengths requires conventional or fiber-optic accessories to deliver and re-collect the light beam outside of the sample compartment.

For samples that are opaque or strongly absorbing, the light absorption must be measured in a reflectance geometry. These measurements are done with reflectance accessories of various designs that fit internally or externally to the sample compartment. Variable-angle specular reflectance measurements can measure bulk optical properties of thin films, such as the refractive index or film thickness (Lamprecht et al., 1997; McPhedran et al., 1984; Larena et al., 1995). For quantitative or spectral characterization, diffuse reflectance spectra are recorded with an integrating sphere. A variation of a reflectance sampling method is attenuated total reflectance (ATR). In ATR the light beam travels through a waveguide or crystal by total internal reflection. The evanescent wave of the light extends beyond the surface of the waveguide and is attenuated by strongly absorbing samples on the outer surface of the waveguide. An ATR accessory can be used remotely by transferring the light to and from the ATR waveguide with optical fibers.

The use of optical fibers, or optical fiber bundles, allows the delivery of a light beam to and from a sample that is remote from the spectrometer sample compartment. This delivery mechanism is extremely useful for process control or to make remote measurements in clean rooms or reaction chambers. These accessories are usually used without a reference sample and can be used with single-beam, dual-beam, or array detector instruments. The transmission properties of optical fibers can limit the wavelength range of a single spectral scan, and complete coverage of the UV-Vis region can require measurements with multiple fibers. The delivery and return fibers or bundles can be arranged in a straight-through transmission geometry, a folded sample compartment geometry that uses a mirror in a compact probe head, or a reflectance mode to measure nontransparent samples.

METHOD AUTOMATION

Most modern dual-beam UV-Vis absorption spectrometers include an integrated microprocessor or are controlled by a software program running on a separate microcomputer. Spectrometer parameters, such as slit width (spectral bandpass), scan range, scan step size, scan speed, and integration time, are set by the program. These parameters can be stored to disk as a method and recalled later to make the same types of measurements. Because UV-Vis spectroscopy is often used for repetitive measurements, instrument manufacturers offer a variety of automated sample-handling accessories. These automated accessories are controlled by the software programs, which also automatically store the data to disk after measurement. Most of these accessories are designed for liquid-containing sample cells, but some of the accessories can be adapted for measuring solid samples. Automated cell changers and multicell transporters can cycle eight to sixteen samples through the spectrometer. These units are useful for repetitive measurements on a small number of samples or to follow spectral changes in a set of multiple samples. As an example, the automated cell transporter can cycle through a set of systematically varied samples to determine the reaction kinetics as a function of reactant concentrations or reaction conditions.

Sipper systems use a peristaltic pump to deliver liquid sample to the sample cell in the spectrometer. A sipper system can automate repetitive measurements and also reduces the error in absorbance measurements due to irreproducibility in positioning the sample cell. Autosamplers are available to automatically measure large numbers of samples. An autosampler can use a sipper system to sequentially transfer a series of samples to the sample cell with intermediate rinsing or to sequentially place a fiber-optic probe into a set of sample containers. Autosamplers are used for repetitive measurements on the order of 100 to 200 different liquid samples.

DATA ANALYSIS AND INITIAL INTERPRETATION

Quantitative Analysis

An unknown concentration of an analyte can be determined by measuring the amount of light that a sample

absorbs and applying the Beer-Lambert law as described above (see Principles of the Method). Modern UV-Vis absorption spectrometers will display the spectral data in a variety of formats, with the most common data presentation being in transmittance, percent transmittance, absorbance, reflectance, or percent reflectance (%R). For quantitative measurements, instrument control programs will store measurements of standards and automatically calculate the concentrations of unknowns from the absorbance measurement, including multicomponent mixtures. Spectra will usually be plotted versus wavelength (in angstroms, nanometers, or micrometers) or energy (in electron volts, or wavenumbers, in reciprocal centimeters). The data can be processed and displayed after a variety of processing methods, such as first to fourth derivative, the Kubelka-Munk function for turbidity measurements (Vargas and Niklasson, 1997), Savitzky-Golay smoothing (Savitzky and Golay, 1964; Barak, p. 1995), peak fitting, and others.

Standards are available from the National Institute of Standards and Technology (NIST) Standards Reference Materials Program to calibrate the transmittance, absorbance, wavelength, and reflectance of UV-Vis spectrometers. Many of the instrument manufacturers offer calibration standards and validation procedures for their UV-Vis spectrometers, as do third-party vendors (see the *Anal. Chem. Labguide* listed in Key References for more information). Table 4 in Dean (1995) gives the percent transmittance and absorbance values from 220 to 500 nm for a laboratory-prepared K_2CrO_4 standard solution, which is useful for checking the calibration of UV-Vis spectrometers. This handbook also lists other useful data such as the UV cutoff of common solvents and UV-Vis absorption methods for the analysis of metals and nonmetals (Dean, 1995).

Material Characterization

Several manufacturers offer software packages for specific applications. Many of these programs are for biological applications, but they can be adapted to materials work. For example, an enzyme kinetics program that works in conjunction with an automated multicell holder can be adapted for monitoring the kinetics of the solution-phase synthesis of materials. Software modules are also available to automatically calculate the refractive index or thickness of a thin film from the interference pattern in transmittance or reflectance measurements. Another materials application is the characterization of color, including analysis of the CIE (1986) tristimulus values in diffuse reflectance measurements (e.g., CHROMA software package from Unicam UV-Visible Spectrometry). These colorimetry standards are also applicable in transmission experiments (Prasad et al., 1996).

Two examples are presented here to illustrate the use of UV-Vis spectrometry for materials characterization. In the first example, Figure 6 shows the UV-Vis absorption spectra of two samples of CdS quantum dots (Tsuzuki and McCormick, 1997).

These materials were prepared by a mechanochemical reaction:

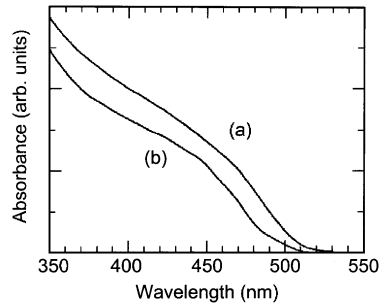

Figure 6. Absorption spectra of CdS quantum dots produced using 12.7-mm balls (curve *a,* average dot diameter 8.3 nm) and 4.8-mm balls (curve *b*, 4.3 nm average dot diameter). (Adapted with permission from Tsuzuki and McCormick, 1997. Copyright © 1997 by Springer-Verlag.)

$$CdCl_2 + Na_2S \rightarrow CdS + 2NaCl \qquad (7)$$

After reaction in a ball mill for 1 h, the NaCl is removed by washing and the CdS quantum dots are dispersed in $(NaPO_3)_6$ solution to obtain an absorption spectrum. Curve *a* in Figure 6 is the spectrum of 8.3-nm-diameter quantum dots produced using 12.7-mm balls in the ball mill, and curve *b* is the spectrum of 4.3-nm quantum dots produced using 4.8-mm balls. The smaller ball size produces lower collision energies, which results in smaller crystallite size. The absorption threshold is taken as the inflection point in the spectra. The 8.3-nm CdS has an absorption threshold of 510 nm, which is close to the threshold of 515 nm for bulk CdS. The blue shift due to quantum confinement is very evident for the 4.3-nm quantum dots, which exhibits an absorption threshold of 470 nm. Determining the absorption edge provides a convenient means of monitoring particle size for semiconductor and metal particles (Ali et al., 1997).

In the second example, Figure 7 shows reflectance spectra of GaN films under different uniaxial stresses in the *c* plane (Yamaguchi et al., 1997). The spectra show a narrow

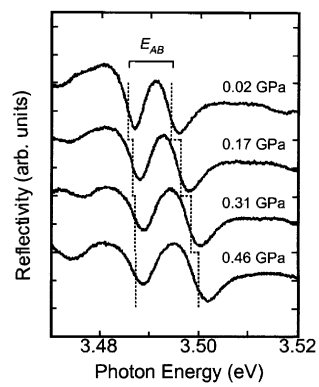

Figure 7. Reflectance spectra of GaN films under different uniaxial stresses in the *c* plane. The dashed lines indicate exciton energies as determined by theoretical fitting. The symbol E_{AB} refers to the energy separation between the A and B excitons. (Adapted with permission from Yamaguchi et al., 1997. Copyright © 1997 by the American Institute of Physics.)

spectral region (3.47 eV = 357.3 nm, 3.52 eV = 352.2 nm) that encompasses two of three dispersive-shaped exciton absorption bands that occur near the valence band maximum. The closely spaced excitons lead to a large density of states at the valence band maximum, which results in a high threshold current for blue GaN laser diodes. Theory predicts that breaking the symmetry in the c plane should increase the energy splitting of the A and B bands and decrease the density of states. The dashed lines in Figure 7 show that the energy splitting does increase with increasing stress. The dependence of E_{AB} on the uniaxial stress, with other polarization measurements, allowed the authors to determine deformation potentials to be $D_4 = -3.4$ eV and $D_5 = -3.3$ eV. These results confirm the theoretical predictions that uniaxial strain should reduce the density of states and ultimately improve the performance of GaN laser diodes by reducing the lasing threshold current.

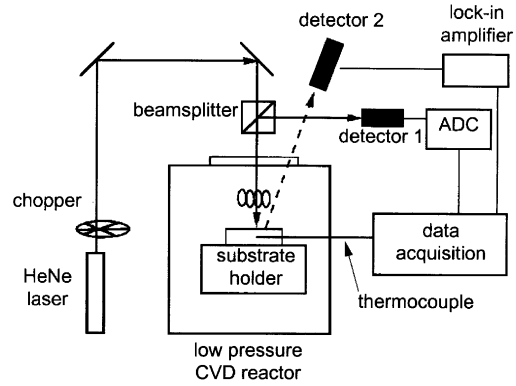

Figure 8. Experimental schematic of a CVD chamber that uses reflectivity (detector 1) and scattering (detector 2) to monitor diamond film growth on a Ni substrate. (Adapted with permission from Yang et al., 1997. Copyright © 1997 by the American Institute of Physics.)

SAMPLE PREPARATION

Sample preparation for UV-Vis spectroscopy is usually straightforward. Absorbing analytes that are in solution or can be dissolved are measured in an appropriate solvent or pH buffer. The pH and competing equilibria must be controlled so that the absorbing species are present in the same form in all samples and standards. Metals and nonmetals are quantitated by adding reagents that produce absorbing complexes in solution (Dean, 1995). To avoid saturation of the absorbance, strongly absorbing samples must be diluted, measured in a reflectance or ATR geometry, or measured in a short-path-length cell (Degiorgi et al., 1995). Because UV-Vis absorption bands are typically broad, quantitative analysis requires that a sample contain only one or a few absorbing species. Very complex mixtures usually require separation before making quantitative measurements. Similarly, particulates that scatter light should be removed by centrifugation or filtration to avoid interfering with the absorbance measurement.

Solid samples require clean and polished surfaces to avoid contaminant and scattering losses. If the solid has nonparallel surfaces, it will act as a prism and bend the light beam. For regular shaped samples, a compensating optic can redirect the light beam to its original path. Fiber-optic light delivery and collection provides a simple means of directing the light through irregular shaped samples. Preparing samples for reflectance measurements can be much more difficult than transparent samples. The reflectivity of a surface or film can depend on a variety of material parameters, including the presence of absorbing species, surface roughness, particle size, and packing density (Childers et al., 1986).

Specular reflectance is usually treated similarly to transmittance measurements, i.e., as the fraction or percentage of reflected light power compared to the incident light power. Diffuse reflectance is usually described as the relative reflectance r_∞, where $r_\infty = r_{\text{sample}}/r_{\text{reference}}$. The absorptive and scattering components can be extracted from the relative reflectance using the Kubelka-Munk equation:

$$\frac{k}{s} = \frac{(1 - r_\infty)^2}{2r_\infty} \tag{8}$$

where k is the absorption coefficient and s is the scattering coefficient (Childers et al., 1986).

The reflectivity dependence on morphology and composition can be used to monitor the growth or processing of a thin film or surface. Figure 8 shows an experimental layout to use reflectivity and scattering to monitor diamond film growth on Ni in a low-pressure chemical vapor deposition (CVD) chamber (Yang et al., 1997). The 632.8-nm beam of a HeNe laser is incident on the substrate/film surface, and detector 1 monitors reflectivity and detector 2 monitors scattered light. The optical monitoring used bandpass interference filters in front of the detectors and a chopped light source with phase-sensitive detection to discriminate against the large background light emission from the hot filament. Figure 9 shows typical changes in reflected and scattered light as the substrate temperature increases. Correlation of these curves with scanning electron micrographs indicated that the time to change the reaction conditions from pretreatment of the diamond seeds to diamond growth should occur immediately after the drop in scattered light intensity.

SPECIMEN MODIFICATION

Specimen modification rarely occurs in commercial UV-Vis spectrometers due to the fairly low intensity of UV and visible light that passes through or strikes the sample. Some samples can be very susceptible to photodegradation; obvious examples are photocurable polymers and photoresist materials. To minimize photochemical degradation, most instruments disperse the light before it passes through the sample, so that wavelengths that are not being measured are also not irradiating the sample. Photodegradation is more problematic in diode array and

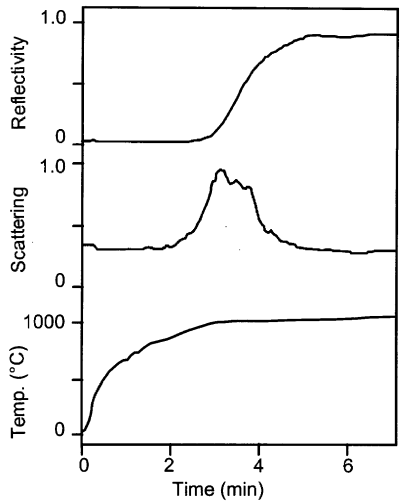

Figure 9. Typical changes in reflectivity (top curve, arbitrary units) and scattering (middle curve, arbitrary units) of a HeNe laser beam from a growing diamond film as the substrate temperature increases (bottom curve). Fourier transform spectrometers since all wavelengths of light pass through the sample before dispersion and detection. Photosensitive samples can be protected to some degree by placing a filter between the light source and the sample to block shorter wavelengths that are not of interest in the measurement.

PROBLEMS

The problems that can arise in UV-Vis spectroscopy can be divided into sample problems and instrumental limitations. These problems mostly affect the linear dependence of absorbance versus concentration in quantitative measurements, but in severe cases they can alter the qualitative nature of a UV-Vis spectrum. Sample problems can include the presence of absorbing or scattering impurities and degradation of very photochemically active molecules or materials. Very intense fluorescence from the analyte or other sample components is usually not a problem in scanning spectrometers but can cause problems in array detector spectrometers.

Problems due to chemical effects such as analyte-solvent interaction, pH effects, and competing equilibria can be minimized by making measurements of all samples under identical conditions. Quantitative measurements are usually calibrated with external or internal standards, rather than relying only on published absorptivity coefficients. For cases where the chemical behavior varies in different samples, the measurement can be calibrated using the standard addition method (Ingle and Crouch, 1988).

The two most common instrumental factors that affect quantitative measurements are the amount of stray light reaching the detector and the non-monochromatic nature of the light beam. The amount of stray light depends on the quality of the spectrometer components and the shielding of the sample compartment or fiber-optic probe. It is usually fixed for a given instrument, although it can vary significantly between the UV-Vis and NIR spectral regions. Maintaining measurement accuracy of approximately 1% requires stray light of $<0.01\%$ (Ingle and Crouch, 1988). The effects of stray light can also be minimized by measuring analytes at low concentration so that P and P_0 remain large compared to the stray light power. Rule-of-thumb ranges for quantitative absorbance measurements are 0.1 to 2.5 A.U. for a high-quality spectrometer and 0.1 to 1.0 A.U. for a moderate-quality spectrometer (Ingle and Crouch, 1988; also see manufacturer's literature).

The unavoidable use of a fixed bandpass of light, which is non-monochromatic, results in a detector response due to multiple wavelengths around the central wavelength at which the spectrometer is set. The total amount of light reaching the detector will depend on the absorptivities of all wavelengths within the spectral bandpass and will vary nonlinearly with analyte concentration. This problem is eliminated by making measurements at a level part in the absorption spectrum with a spectrometer bandpass that is small compared to the width of the absorption line. The rule-of-thumb for accurate measurements is to use a spectrometer bandpass-to-linewidth ratio of approximately 0.1 (Ingle and Crouch, 1988). This criterion is easily met for most molecular absorption bands, which tend to be broad. Recording spectra with a bandpass that is larger than the absorption linewidths can drastically alter the qualitative appearance of a spectrum.

A broad comprehensive handbook of analytical techniques. It covers separation techniques, optical spectroscopy, mass spectrometry, electrochemistry, surface analysis, and polymer analysis.

APPENDIX: GLOSSARY OF TERMS AND SYMBOLS USED

a	Absorptivity
A	Absorbance, $= abc = \varepsilon bc$
A.U.	Absorbance unit
b	Path length
c	Analyte concentration; also velocity of light in vacuum (2.99795×10^8 m/s), $= \lambda\nu$
D_4, D_5	Deformation potentials
E	Energy of a photon, $= h\nu$
E_{AB}	Energy separation of A and B bands
h	Planck's constant (6.626×10^{-34} Js)
I	Light intensity
I_0	Initial light intensity
k	Absorption coefficient
P	Radiant power (radiant energy on unit area in unit time)
P_0	Initial radiant power; power transmitted through sample holder and solvent only
P_s	Power of source light
r_∞	Relative reflectance, $= r_{sample}/r_{reference}$
R	Reflectance (includes diffuse and specular reflectance)
$\%R$	Percent reflectance
s	Scattering coefficient
T	Transmittance
$\%T$	Percent transmittance
ε	Molar absorptivity
λ	Wavelength
ν	Frequency

RAMAN SPECTROSCOPY OF SOLIDS

INTRODUCTION

Raman spectroscopy is based on the inelastic scattering of light by matter and is capable of probing the structure of gases, liquids, and solids, both amorphous and crystalline. In addition to its applicability to all states of matter, Raman spectroscopy has a number of other advantages. It can be used to analyze tiny quantities of material (e.g., particles that are $\sim$1 μm on edge), as well as samples exposed to a variety of conditions such as high temperature and high pressure and samples embedded in other phases, so long as the surrounding media are optically transparent.

Succinctly stated, Raman scattering results from incident radiation inducing transitions in the atoms/molecules that make up the scattering medium. The transition can be rotational, vibrational, electronic, or a combination (but first-order Raman scattering involves only a single incident photon). In most studies of solids by Raman spectroscopy, the transitions observed are vibrational and these will be the focus of this unit.

In a Raman experiment, the sample is irradiated with monochromatic radiation. If the sample is transparent, most of the light is transmitted, a small fraction is elastically (Rayleigh) scattered, and a very small fraction is inelastically (Raman) scattered. The inelastically scattered light is collected and dispersed, and the results are presented as a Raman spectrum, which plots the intensity of the inelastically scattered light as a function of the shift in wavenumber of the radiation. (The wavenumber of a wave is the reciprocal of its wavelength and is proportional to its momentum in units of reciprocal centimeters.) Each peak in the spectrum corresponds to one or more vibrational modes of the solid. The total number of peaks in the Raman spectrum is related to the number of symmetry-allowed, Raman active modes. Some of the modes may be degenerate and some may have Raman intensities that are too low to be measured, in spite of their symmetry-allowed nature. Consequently, the number of peaks in the Raman spectrum will be less than or equal to the number of Raman active modes. The practical usefulness of Raman spectroscopy resides largely in the fact that the Raman spectrum serves as a fingerprint of the scattering material. In fact, Raman activity is a function of the point group symmetry of a molecule and the space group symmetry of a crystalline solid; it can provide a range of information, including the strength of interatomic and intermolecular bonds, the mechanical strain present in a solid, the

composition of multicomponent matter, the degree of crystallinity of a solid, and the effects of pressure and temperature on phase transformations.

Competitive and Related Techniques

As mentioned above, Raman spectroscopy is extremely versatile and can be used to investigate the structures of solids, liquids, and gases. This unit is concerned with the analyses of solids. In general, two major types of experimental techniques are used to obtain information about the structures of solids: spectroscopy and diffraction. Spectroscopy is based on the interaction of electromagnetic radiation with matter. Diffraction occurs whenever a wave is incident on an array of regularly spaced scatterers in which the wavelength of the wave is similar to the spacing of the scatterers.

X rays, electrons, and neutrons with wavelengths similar to the interatomic spacing of a crystal will be diffracted by the crystal. The diffraction pattern will provide detailed information about, e.g., the crystal structure, crystal size, interplanar spacings, long- and short-range order, and residual lattice strain. While diffraction can provide some information about gases, liquids, and amorphous solids, the greatest amount of information is obtained for crystals.

Spectroscopic methods can probe the electronic, vibrational, rotational, and nuclear states of matter. In one family of spectroscopic techniques, the material absorbs electromagnetic radiation of energy equivalent to the difference in energy between particular states of the material. For example, transitions between adjacent electronic states generally require energies equivalent to that of ultraviolet and visible radiation (UV-vis electronic spectroscopy; see ULTRAVIOLET AND VISIBLE ABSORPTION SPECTROSCOPY). Vibrational transitions typically make use of infrared radiation (infrared absorption spectroscopy, IRAS). In the gas-phase molecules may absorb microwave radiation and undergo a change in rotational state. Finally, in nuclear magnetic resonance (NMR) the nuclei of atoms with angular momentum (spin) and magnetic moment absorb energy in the radio frequency region while subjected to magnetic fields that are alternating synchronous with the natural frequencies of the nucleus (see NUCLEAR MAGNETIC RESONANCE IMAGING).

Raman spectroscopy, unlike the above-mentioned spectroscopies, involves the scattering of electromagnetic radiation rather than absorption. In classical terms, the energy of the Raman scattered radiation is shifted from that of the incident radiation because of modulation by the vibrations of the scattering medium. Thus, Raman spectroscopy (RS), like IRAS, probes the vibrational spectra of materials. Because IRAS involves absorption of radiation and RS involves inelastic scattering of radiation, the two techniques are complementary. Since Raman spectroscopy makes use of optical radiation, it is a highly flexible technique and can probe the structures of materials in relatively inaccessible locations, such as in high-pressure chambers, high-temperature furnaces, and even aqueous solutions. All that is necessary is the ability to get laser light onto the sample and to collect the scattered light.

For materials that are both Raman active and IR active, the Raman scattering cross-section is much smaller than the IR absorption cross-section so the incident radiation needs to be more intense and the detectors need to be more sensitive for Raman spectroscopy than for IR spectroscopy. Because of the fundamental differences between absorption and scattering of electromagnetic radiation, some vibrational modes of a material may be Raman active but not IR active. In particular, for a molecule with a center of symmetry, vibrational modes that are Raman active are IR inactive and vice versa. Consequently, when deciding between IR and Raman spectroscopies, the point group or space group symmetry of the material needs to be taken into account.

A major advantage of Raman spectroscopy compared to x-ray diffraction is the ability of Raman spectroscopy to provide detailed structural information of amorphous materials. The Raman spectrum of an amorphous solid, for example, is directly related to its complete density of (vibrational) states. However, all metals are Raman inactive so Raman spectroscopy cannot be used for the structural analyses of this entire class of materials.

PRINCIPLES OF THE METHOD

Theoretical Background

This discussion of Raman spectroscopy will begin with a description of the fundamental phenomenon that underlies the scattering of light by matter, namely the generation of electromagnetic radiation by the acceleration of charged particles. As a light-scattering process, Raman scattering is rigorously described by treating both the incident and scattered radiation and the scattering medium quantum mechanically. In this unit a full quantum mechanical description of Raman scattering is not given. Instead, Raman scattering is treated less rigorously but in a manner that allows all of the practically important phenomena associated with Raman spectroscopy of solids to be identified. Specifically, a combination of classical physics and semiclassical physics (treating the scattering medium quantum mechanically while approximating light as a sinusoidally varying electric field) is used to describe Raman scattering.

Generation of Electromagnetic Radiation—Classical Physics. Classical physics dictates that accelerating charged particles emit electromagnetic radiation whose electric field ε (a vector quantity) is directly proportional to the particle's acceleration $\mathbf{a}$ (a vector quantity; see Fig. 1; Rossi, 1957):

$$\varepsilon_{\mathbf{r}}(r,\theta,\phi,t) = \varepsilon_{\phi}(r,\theta,\phi,t) = 0 \tag{1a}$$

and

$$\varepsilon_{\theta}(r,\theta,\phi,t) = \left(\frac{q\sin\theta}{4\pi c^2 r}\right)a \tag{1b}$$

where c is the velocity of light; a is the magnitude of the acceleration of the charged particle of charge q; r, θ, and ϕ are the spherical coordinates with the particle located at

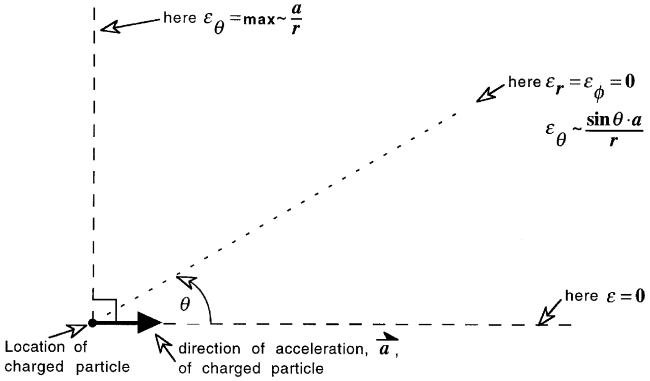

Figure 1. Electromagnetic radiation associated with an accelerating charged particle.

the origin and; t is time. The term $\varepsilon_i(r, \theta, \phi, t)$ is the ith component of the electric field at the point (r, θ, ϕ) and time t. The other terms are defined in Figure 1.

The optical behavior of matter, e.g., the emission of sharp spectral lines by elemental gases excited by an electric discharge, requires that matter, when treated by classical physics, be composed of charged particles that behave as harmonic oscillators when displaced from their equilibrium positions. When matter is illuminated by monochromatic optical radiation, the electrons are driven from their equilibrium positions by the sinusoidally varying electric field of light, creating a time-varying electric polarization $\mathbf{p}$ (a vector quantity) that is directly proportional to the acceleration of the electrons. Approximating the polarized molecule by a dipole, $\mathbf{p}$ is given by

$$\mathbf{p} = -e\mathbf{x} = -e\mathbf{x}_0 \cos \omega_{\text{inc}} t \tag{2a}$$

where $\mathbf{x}$ is the displacement of the center of negative charge of the molecule from the center of positive charge and $\mathbf{x}_0$ is the maximum value of this displacement.

$$\mathbf{p} = -\left(\frac{\mathbf{e}}{\omega_{\text{inc}}^2}\right)\mathbf{a} \tag{2b}$$

where $-e$ is the electric charge of the electron and ω_{inc} is the frequency of oscillation of the electron, which matches the frequency of the incident light. The electrons thereby emit radiation whose electric field is proportional to the polarization of the molecule:

$$\varepsilon_\theta \left(\frac{\omega_{\text{inc}}^2 \sin\theta}{4\pi\varepsilon_0 c^2 r}\right)|\mathbf{p}| \tag{3}$$

where $\mathbf{x}$ is the displacement of the center of negative charge of the molecule from the center of positive charge and $\mathbf{x}_0$ is the maximum value of this displacement.

$$S_{\text{r}} = \left(\frac{\omega_{\text{inc}}^4 \sin^2\theta}{16\pi^2\varepsilon_0^2 c^4 r^2}\right)|\mathbf{p}|^2 \tag{4}$$

where ε_0 is the dielectric strength of the medium in which the radiation is propagating and S_{r} is the radial component of the Poynting vector, which is the only nonzero component of the Poynting vector. The Poynting vector is the energy flux of the light wave. It is equal to the amount of energy flowing through a unit area in unit time.

When analyzing the effects of irradiating a molecule or a large quantity of matter with electromagnetic radiation, it is not necessary to treat each electron individually. Rather, it is possible to model the molecule(s) by atoms that are composed of heavy, positively charged ion cores and a mobile negative charge, which together form an electric dipole. If the centers of positive and negative charges are not coincident, the molecule has a permanent dipole moment. If the negative charge is displaced from its equilibrium position, e.g., by colliding with another particle, it will harmonically oscillate about its equilibrium position and emit electromagnetic radiation until all of the energy it gained in the collision is radiated away. Similarly, if the molecule is irradiated with an electromagnetic wave, the negative charge will be driven away from its equilibrium position by the applied electric field and will harmonically oscillate about its equilibrium position. The oscillating electric dipole will emit electromagnetic radiation with an electric field given by Equation 4 with $|\mathbf{p}| = p_0 \cos \omega_{\text{inc}} t$, where ω_{inc} is the frequency of the incident radiation and p_0 is the magnitude of the polarization when the centers of positive and negative charges experience their maximum separation.

The polarization $\mathbf{p}$ induced by the applied electric field of the incident electromagnetic radiation varies with time at the same frequency as the applied electric field. There is a second contribution to the time dependency of the material's polarization, namely that caused by the time-dependent nuclear displacements (thermally excited molecular vibrations), which, as illustrated in Figure 2, act to modulate the radiation generated by the electrons oscillating under the influence of the incident radiation (Long, 1977). As a result, there are three frequency components to the scattered light, which is the radiation emitted by the time-varying, molecular electric dipoles. One component (the Rayleigh line) has the same frequency, ω_{inc} as the incident radiation and the other two components have a slightly lower and a slightly higher frequency, $\omega_{\text{inc}} + \omega_{\text{v}}$ and $\omega_{\text{inc}} - \omega_{\text{v}}$, respectively, where ω_{v} is the vibrational frequency of the atoms/molecules making up the scattering medium. These last two components represent the Stokes and anti-Stokes components, respectively, of the Raman scattered radiation.

Classically, the expression for the intensity of the Raman scattered radiation is

$$I = \langle |S| \rangle \frac{dA}{d\Omega} \tag{5}$$

where A is the surface area of the sphere centered at the source of the Raman scattered radiation, Ω is the solid angle through which the radiation passes, and $\langle |S| \rangle$ is the time-averaged value of the Poynting vector of the Raman scattered radiation. Its form is identical to that given above for S_{r} except that the time-varying part of $\mathbf{p}$ (see Equation 4) is now given by

$$\mathbf{p} \sim \left(\frac{\partial\alpha}{\partial\mathbf{Q}_k}\right)_0 \mathbf{Q}_k \boldsymbol{\varepsilon} \tag{6}$$

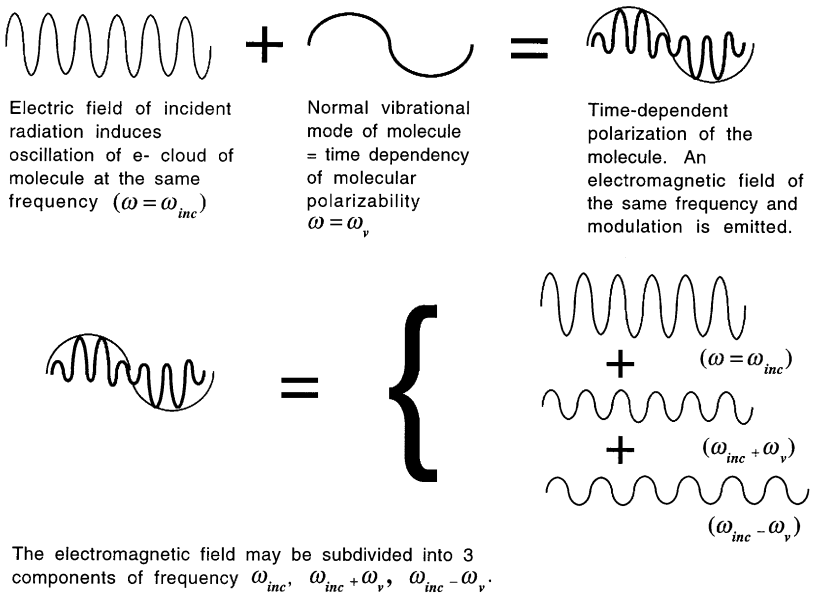

Figure 2. Polarization of vibrating molecule irradiated by light.

where $\underline{\alpha}$ (a tensor quantity) is the polarizability of the material, $\mathbf{Q}_k$ (a vector quantity) is the normal coordinate of the kth vibrational mode, and $(\partial\underline{\alpha}/\partial\mathbf{Q}_k)_0$ (a tensor quantity) is the differential polarizability, which indicates the substance's change in polarizability at its equilibrium position during the kth normal mode of vibration. Consequently, the material property that is directly probed by Raman spectroscopy is the differential polarizability $(\partial\underline{\alpha}/\partial\mathbf{Q}_k)_0$. It is a symmetric tensor quantity, and at least one component must be nonzero for Raman scattering to occur. Knowing the point group symmetry of a molecule or the space group symmetry of a crystalline solid, it is possible to use group theoretical techniques to determine if the symmetry permits nonzero components of the differential polarizability tensor. The use of molecular and crystal symmetry greatly simplifies the analyses of Raman scattering by a material, as will be demonstrated below (see Overview of Group Theoretical Analysis of Vibrational Raman Spectroscopy).

Light Scattering—Semiclassical Physics. From the perspective of semiclassical physics, Raman scattering results from the incident radiation inducing a transition (considered here to be vibrational) in the scattering entity, as schematically illustrated in Figure 3. The material is placed by the sinusoidally varying electric field into a higher energy state, termed a virtual state, which may be thought of as the distortion of the molecule by the electric field. As shown in Figure 3, when the molecule returns to a lower energy state, it emits radiation of frequency $\omega_{\text{inc}}(=>$ Rayleigh, or elastic scattering), $\omega_{\text{inc}} - \omega_v(=>$ Stokes Raman scattering), or $\omega_{\text{inc}} + \omega_v$ $(=>$ anti-Stokes Raman scattering). The probability of these transitions occurring is, according to quantum mechanical perturbation theory, given by a_{mn}^2, where

$$a_{mn} \sim \int \psi_m^* \mathbf{p} \psi_n dV \tag{7}$$

Here, ψ_i is the wave function of the ith state and ψ_i^* is its complex conjugate.

$$\mathbf{p} = \underline{\alpha}\boldsymbol{\varepsilon} \tag{8}$$

When expressed in terms of the individual components, p_i, Equation 8 becomes

$$p_i = \sum \alpha_{ij}\varepsilon_j \tag{9}$$

where α_{ij} is the ij matrix component of the polarizability, ε_j is the j component of the electric field, and the differential dV includes differential displacements of all quantum vibrational states. For Rayleigh scattering, $m = n$ is the vibrational ground state; for Stokes Raman scattering, n is the vibrational ground state and m is the first vibrational excited state; for anti-Stokes Raman scattering, n

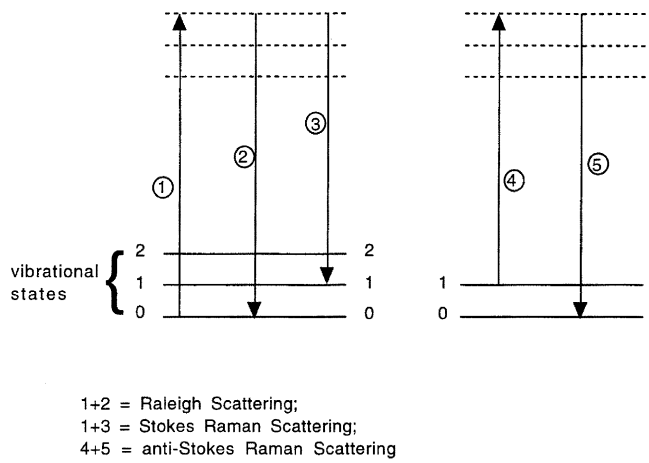

Figure 3. Rayleigh and Raman scattering. $1 + 2$, Rayleigh scattering; $1 + 3$, Stokes Raman scattering; $4 + 5$, anti-Stokes Raman scattering.

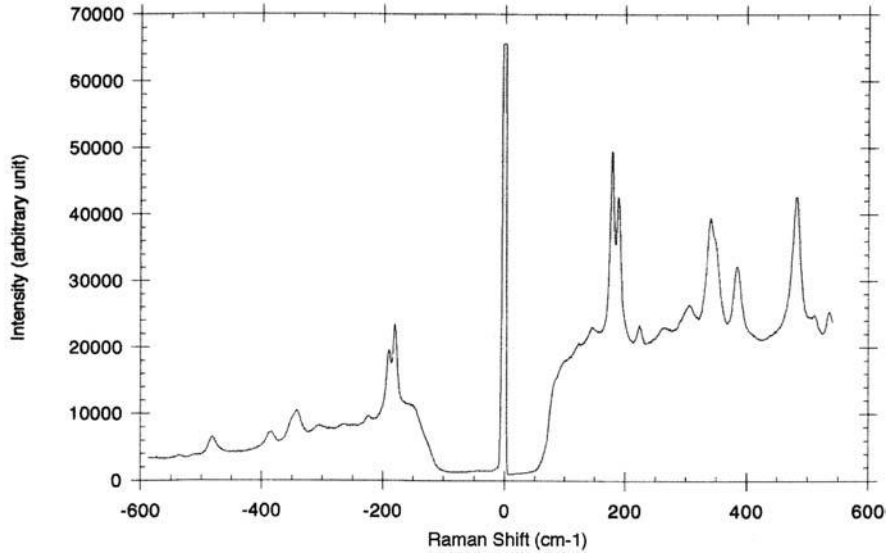

Figure 4. Raman spectrum of impure, polyphase (monoclinic+tetragonal) ZrO_2. (C. S. Kumai, unpublished results, 1998.)

is the first vibrational excited state and m is the vibrational ground state.

Since the population of energy levels in a collection of atoms/molecules is governed by the Maxwell-Boltzmann distribution function, the population of the vibrational ground state will always be greater than the population of the first vibrational excited state. As a result, the intensity of the Stokes-shifted Raman scattering will always be greater than the intensity of the anti-Stokes-shifted Raman scattered radiation. This effect, which is predicted quantum mechanically but not classically, is illustrated in Figure 4, which presents the Raman spectrum of polycrystalline ZrO_2 (mixed monoclinic and tetragonal). The Raman spectrum is depicted in terms of the shift (in wavenumbers) in the wavelength of the scattered radiation with respect to that of the incident light. Thus the Rayleigh peak is seen in the center, and the anti-Stokes and Stokes lines are to the left and right, respectively. Note that for each peak in the Stokes Raman section of the spectrum there is a corresponding peak of lower intensity in the anti-Stokes Raman section.

Overview of Group Theoretical Analysis of Vibrational Raman Spectroscopy

The use of group theory in determining whether or not a given integral can have a value of zero may be illustrated using the ground vibrational state $\psi_0(x)$ and first vibrational excited state $\psi_1(x)$ of a harmonic oscillator. The equations describing these two vibrational states are, respectively,

$$\psi_0(x) = \exp\left(-\frac{2\pi m\omega x^2}{\hbar}\right) \tag{10}$$

$$\psi_1(x) = \left(\frac{4\pi^{1/2} m\omega}{\hbar}\right)^{1/2} \exp\left(-\frac{2\pi m\omega x^2}{\hbar}\right) \tag{11}$$

where $\hbar = h/2\pi$ and h is Planck's constant. These two vibrational states are plotted in Figure 5.

By inspection,

$$\int_{-\infty}^{\infty} \psi_1(x)dx = 0 \tag{12}$$

That is, performing the integration by summing up the infinite number of terms given by

$$\sum \psi_1(x_n)\Delta x_n \tag{13}$$

(where $\Delta x_n = x_n - x_{n-1}$), it is seen that for every positive contribution (to the sum) given by $\psi_1(x_i)\Delta x_i$ there is a term equal in magnitude but opposite in sign [$\psi_1(x_{-i})\Delta x_{-i} = -\psi_1(x_i)\Delta x_i$].

Thus, the entire sum in Equation 13 is zero.

Similarly, by inspection,

$$\int_{-\infty}^{\infty} \psi_0(x)dx \neq 0 \tag{14}$$

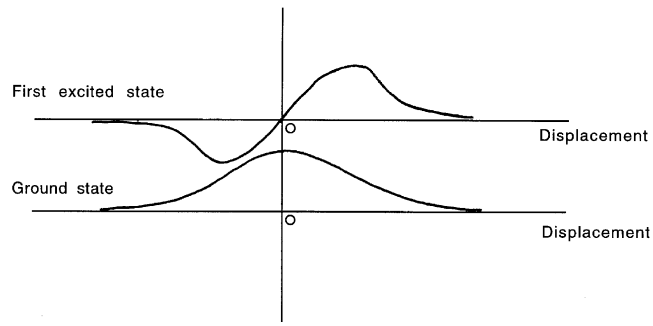

Figure 5. Ground-state vibrational wave function and first excited-state vibrational wave function of harmonic oscillator.

That is, every term $\psi_0(x_i)\Delta x_i$ in the sum $\sum \psi_0(x_n)\Delta x_n$ has the identical sign and, hence,

$$\int_{-\infty}^{\infty} \psi_0(x)dx \approx \sum \psi_0(x_n)\Delta x_n \neq 0 \qquad (15)$$

The above analysis of the integrals in Equations 12 and 13 can be repeated using group theory. To begin, there needs to be a mathematical description of what is meant by the symmetry of a function. The difference between the symmetry of $\psi_1(x)$ and $\psi_0(x)$ can be expressed as follows. Imagine that there is a mirror plane parallel to the *YZ* plane and that passes through the origin, (0, 0, 0); then the operation of this mirror plane on the function $\psi_0(x)$ is described by the phrase "a mirror plane acting on $\psi_0(x)$ yields $\psi_0(x)$."

If the effect of the mirror plane acting on $\psi_0(x)$ is represented by a matrix $[R]$, then

$$\text{Effect of mirror plane acting on } \psi_0(x) = [R][\psi_0(x)] \qquad (16)$$

In this case, $[R] = [I]$ is the identity matrix.

Similarly, for $\psi_1(x)$, the effect of a mirror plane acting on $\psi_1(x)$ equals $-\psi_1(x)$. In matrix notation, this statement is given as

$$\text{Effect of mirror plane acting on } \psi_1(x) = [R]\psi_1(x) = -[I]\psi_1(x) \qquad (17)$$

Note that the effect of the mirror operation on x is to produce $-x$ and that $\psi(-x) = -\psi(x)$. The character of the one-dimensional matrix in Equation 16 is $+1$ and that in Equation 17 is -1. Consider now a molecule that exhibits a number of symmetry elements (e.g., mirror planes, axes of rotation, center of inversion). If the operation of each of those on a function leaves the function unchanged, then the function is said to be "totally symmetric" with respect to the symmetry elements of the molecule (or, in other words, the function is totally symmetric with respect to the molecular point group, which is the collection of all the molecule symmetry elements). For the totally symmetric case, the character of each one-dimensional (1D) matrix representing the effect of the operation of each symmetry element on the function is 1 for all symmetry operations of the molecule. For such a function, the value of the integral over all space of $\psi(x)dx$ will be nonzero.

If the operation of any symmetry element of the molecule (in the molecular point group) generates a matrix that has a character other than 1, the function is not totally symmetric and the integral of $\psi(x)dx$ over all space will be zero.

Now consider the application of group theory to vibrational spectroscopy. A vibrational Raman transition generally consists of the incident light causing a transition from the vibrational ground state to a vibrational excited state. The transition may occur if

$$\int_{-x}^{x} \psi_1(x)\alpha_{ij}\psi_0(x)dx \neq 0 \qquad (18)$$

Table 1. Character Table of Point Group C_{2v}

C_{2v}	E	$C_2(z)$	$\sigma_v(xz)$	$\sigma'_v\ (yz)$	Basis Functions
A_1	$+1$	$+1$	$+1$	$+1$	$z; x^2; y^2; z^2$
A_2	$+1$	$+1$	-1	-1	xy
B_1	$+1$	-1	$+1$	-1	$x; xz$
B_2	$+1$	-1	-1	$+1$	$y; yz$

That is, the integral may have a nonzero value if the integrand product is totally symmetric over the range of integration. The symmetry of a function that is the product of two functions is totally symmetric if the symmetries of the two functions are the same. In addition, for the sake of completeness, the last statement will be expanded using group theoretical terminology, which will be defined below (see Example: Raman Active Vibrational Modes of α-Al_2O_3). The symmetry species of a function that is the product of two functions will contain the totally symmetric irreducible representation if the symmetry species of one function contains a component of the symmetry species of the other.

The ground vibrational state is totally symmetric. Hence, the integrand is totally symmetric and the vibrational mode is Raman active if the symmetry of the excited vibrational state $\psi_1(x)$ is the same as, or contains, the symmetry of the polarizability operator α_{ij}.

As shown below (see Appendix), the symmetry of the operator α_{xy} is the same as that of the product xy. Thus, the integrand $\psi_1\alpha_{xy}\psi_0$ is totally symmetric if ψ_1 has the same symmetry as xy (recall that ψ_0, the vibrational ground state, is totally symmetric).

A molecular point group is a mathematical group (see Appendix) whose members consist of all the symmetry elements of the molecule. Character tables summarize much of the symmetry information about a molecular point group. Complete sets of character tables may be found in dedicated texts on group theory (e.g., Bishop, 1973). The character table for the point group C_{2v} is presented in Table 1. In the far right-hand column are listed functions of interest in quantum mechanics and vibrational spectroscopy in particular. The top row lists the different symmetry elements contained in the point group and illustrated in Figure 6. Here, C_2 is a twofold rotational axis that is parallel to the z axis. The parameters σ_{xz} and σ_{yz} are mirror planes parallel to the xz and yz planes, respectively. In each row beneath the top row are listed a set of numbers. Each number is the character of the matrix that represents the effect of the symmetry operation acting on any of the functions listed in the right-hand end of the same row. In the point group C_{2v}, e.g., the functions z, x^2, y^2, and z^2 have the same symmetry, which in the terminology of group theory is identified as A_1. The functions y and yz have the same symmetry, B_2.

As shown in Figure 6, the water molecule, H_2O, exhibits the point group symmetry C_{2v}. There are three atoms in H_2O and hence there are $3N - 6 = 3$ normal vibrational modes, which are depicted in Figure 7. These exhibit symmetries A_1, A_1, and B_2. That is, the vibrational wave functions of the first excited state of each of these modes

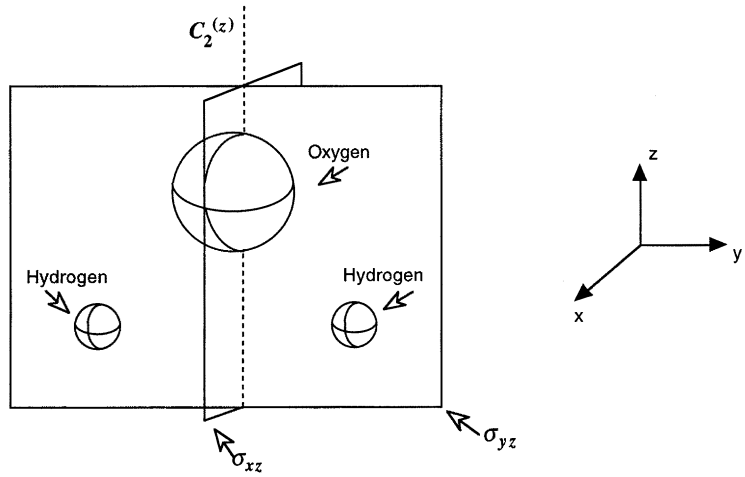

Figure 6. Symmetry operations of H_2O (point group C_{2v}).

possess the symmetries A_1, A_1, and B_2, respectively. Since x^2, y^2, and z^2 exhibit A_1 symmetry, so too would α_{xx}, α_{yy} and α_{zz}. Hence the product of α_{xx}, α_{yy} and α_{zz} with ψ_1 for the vibrational modes with A_1 symmetry would be totally symmetric, meaning that the integral over the whole space $\psi_{A1}\alpha_{xx(\text{or}yy,zz)}\psi_0 dV$ may be nonzero, meaning that this vibrational mode is Raman active (the integrand $\psi_{A1}\alpha_{xx(\text{or}yy,zz)}\psi_0 dV$ is the same as the integrand in Equation 7).

Now consider the Raman vibrational spectra of solids. One mole of a solid will have $3 \times 6.023 \times 10^{23} - 6$ normal modes of vibration. Fortunately, it is not necessary to consider all of these. As demonstrated below (see Appendix), the only Raman active modes will be those near the center of the Brillouin zone (BZ; $k = 0$). Solids with only one atom per unit cell have zero modes at the center of the BZ and hence are Raman inactive (see Appendix). Solids with more than one atom per unit cell, e.g., silicon and Al_2O_3, are Raman active.

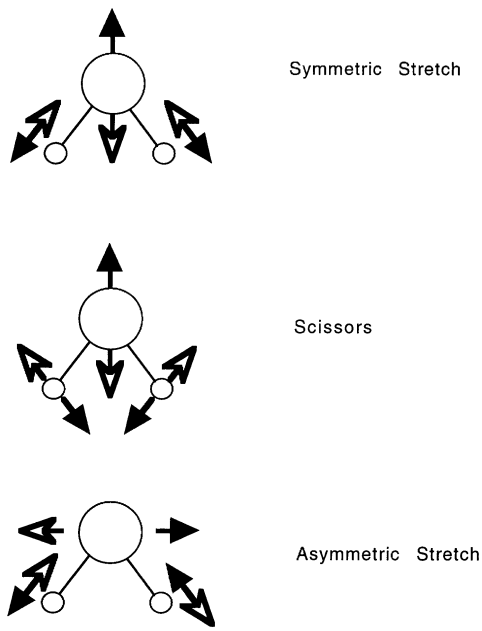

Figure 7. Normal vibrational modes of H_2O.

The symmetry of a crystal is described by its space group. However, as demonstrated below (see Appendix), for the purposes of vibrational spectroscopy, the symmetry of the crystal is embodied in its crystallographic point group. This is an extremely important and useful conclusion. As a consequence, the above recipe for deciding the Raman activity of the vibrational modes of H_2O can be applied to the vibrational modes of any solid whose unit cell is multiatomic.

PRACTICAL ASPECTS OF THE METHOD

The weakness of Raman scattering is the characteristic that most strongly influences the equipment and experimental techniques employed in Raman spectroscopy.

A conventional Raman facility consists of five major components: (1) a source of radiation, (2) optics for illuminating the sample and collecting the Raman scattered radiation, (3) a spectrometer for dispersing the Raman scattered radiation, (4) a device for measuring the intensity of the Raman scattered light, and (5) a set of components that control the polarization of the incident radiation and monitor the polarization of the Raman scattered radiation (Chase, 1991; Ferraro and Nakamoto, 1994).

Sources of Radiation

Prior to the introduction of lasers, the primary source of monochromatic radiation for Raman spectroscopy was the strongest excitation line in the visible region (blue, 435.83 nm) of the mercury arc. The power density of the monochromatic radiation incident on the sample from a mercury arc is very low. To compensate, relatively large samples and complicated collection optics are necessary to, respectively, generate and collect as many Raman scattered photons as possible. Collecting Raman photons that are scattered in widely different directions precludes investigating the direction and polarization characteristics of the

Raman scattered radiation. This is valuable information that is needed to identify the component(s) of the crystal's polarizability tensor that is (are) responsible for the Raman scattering (Long, 1977).

In general, laser radiation is unpolarized. However, in ionized gas lasers, such as argon and krypton ion lasers, a flat window with parallel faces and oriented at the Brewster angle (θ_{Brewster}) relative to the incident beam is positioned at the end of the tube that contains the gas. This window is called a Brewster window. The Brewster angle is also called the polarizing angle and is given by the arctangent of the ratio of the indices of refraction of the two media that form the interface (e.g., for air/glass, $\theta_{\text{Brewster}} = \tan^{-1}1.5 \approx 57^\circ$). If an unpolarized beam of light traveling in air is incident on a planar glass surface at the Brewster angle, the reflected beam will be linearly polarized with its electric field vector parallel to the plane of incidence. (The plane of incidence contains the direction of propagation of the light and the normal to the interface between the two media.) A beam of light that is linearly polarized with its electric field vector in the plane of incidence and is incident on a Brewster window at θ_{Brewster} will be entirely transmitted. Thus, the light that exits from a laser tube that is capped with a Brewster window is linearly polarized (Fowles, 1989; Hecht, 1993).

Lasers have greatly increased the use of Raman spectroscopy as a tool for both research and chemical identification. In particular, continuous-wave gas lasers, such as argon, krypton, and helium-neon, provide adequately powered, monochromatic, linearly polarized, collimated, small-diameter beams that are suitable for obtaining Raman spectra from all states of matter and for a wide range of sample sizes using relatively simple systems of focusing and collection optics.

Optics

As the light exits the laser, it generally first passes through a filter set to transmit a narrow band of radiation centered at the laser line (e.g., an interference filter). This reduces the intensity of extraneous radiation, such as the plasma lines that also exit from the laser tube. A set of mirrors and/or lenses will make the laser light incident on the sample at the desired angle and spot size.

The focusing lens reduces the beam's diameter to

$$d = \frac{4\lambda f}{\pi D} \tag{19}$$

where λ is the wavelength of the laser radiation, f is the focal length of the lens, and D is the diameter of the unfocused laser beam. Note that for a given focusing lens and incident light, the size of the focused spot is inversely proportional to the size of the unfocused beam. Thus, a smaller spot size can be generated by first expanding the laser beam to the size of the focusing lens. The distance l over which the beam is focused is proportional to the square of the focused beam's diameter (Hecht, 1993):

$$l = \frac{16\lambda f^2}{\pi D^2} = \frac{\pi d^2}{\lambda} \tag{20}$$

Thus, to reduce the diameter of the focal spot from an argon laser ($\lambda = 514.5$ nm) to 1 μm, the distance between the focusing lens and the sample must be accurate to within $\pm\frac{1}{2}\pi(1\ \mu\text{m})^2/(0.5145\ \mu\text{m}) \approx 3\ \mu\text{m}$.

The specularly reflected light is of no interest in Raman spectroscopy. The inelastically scattered light is collected using a fast lens (i.e., low f number, defined as the focal length per diameter of the lens). Often, the lens from a 35-mm camera is a very cost-effective collection lens. The collection lens collimates the Raman scattered light and transmits it toward a second lens that focuses the light into the entrance slit of the spectrometer. The f number of the second lens should match that of the spectrometer. Otherwise, the spectrometer's grating will either not be completely filled with light, which will decrease the resolving power (which is directly proportional to the size of the grating), or be smaller than the beam of radiation, which will result in stray light that may reflect off surfaces inside the spectrometer and reduce the signal-to-noise ratio.

There are many sources of stray light in a Raman spectrum. One of the major sources is elastically scattered light (it has the same wavelength as the incident radiation), caused by Rayleigh scattering by the molecules/atoms responsible for Raman scattering and Mie scattering from larger particles such as dust. Rayleigh scattering always accompanies Raman scattering and is several orders of magnitude more intense than Raman scattering. The Rayleigh scattered light comes off the sample at all angles and is captured by the collection optics along with the Raman scattered light and is directed into the spectrometer. This would not be a problem if the Rayleigh scattered light exited the spectrometer only at the 0-cm^{-1} position. However, because of imperfections in the gratings and mirrors within the spectrometer, a portion of the Rayleigh scattered light exits the spectrometer in the same region as Raman scattered radiation that is shifted in the range of 0 to $\pm 250\ \text{cm}^{-1}$ from the incident radiation. Even though only a fraction of the Rayleigh scattered light is involved in this misdirection, the consequence is significant because the intensity of the Rayleigh component is so much greater than that of the Raman component. Raman peaks located within $\approx 250\ \text{cm}^{-1}$ of the laser line can only be detected if the intensity of the Rayleigh scattered light is strongly reduced.

The intensity of stray light that reaches the detector can be diminished by passing the collimated beam of elastically and inelastically scattered light collected from the sample into a notch filter. After exiting the notch filter, the light enters a lens that focuses the light into the entrance of the spectrometer.

A notch filter derives its name from the narrow band of wavelengths that it filters out. In a Raman experiment, the notch filter is centered at the exciting laser line and is placed in front of the spectrometer. (Actually, as mentioned above and explained below, the notch filter should be located in front of the lens that focuses the scattered light into the spectrometer.) The notch filter then removes the Rayleigh scattered radiation (as well as Brillouin scattered light and Mie scattering from dust particles). Depending on the width of the notch, it may also remove a significant amount of the Raman spectrum.

Dielectric notch filters consist of multiple, thin layers of two materials with different indices of refraction. The materials are arranged in alternating layers so that the variation of index of refraction with distance is a square wave. Typically, dielectric filters have a very wide notch with diffuse edges and have nonuniform transmission in the region outside the notch. As a consequence, a dielectric notch filter removes too much of the Raman spectrum (the low-wavenumber portion) and distorts a significant fraction of the portion it transmits. In contrast, holographic notch filters have relatively narrow widths, with sharp edges and fairly uniform transmission in the region outside the notch (Carrabba et al., 1990; Pelletier and Reeder, 1991; Yang et al., 1991; Schoen et al., 1993).

A holographic notch filter (HNF) is basically an interference filter. In one manufacturing process (Owen, 1992), a photosensitive material consisting of a dichromate gelatin film is placed on top of a mirror substrate. Laser light that is incident on the mirror surface interferes with its reflected beam and forms a standing-wave pattern within the photosensitive layer. The angle between the incident and reflected beams determines the fringe spacing of the hologram. If the incident beam is normal to the mirror, the fringe spacing will be equal to the wavelength of the laser light.

Chemical processing generates within the hologram-exposed material an approximately sinusoidal variation of index of refraction with distance through the thickness of the layer. The wavelength of the modulation of the index of refraction determines the central wavelength of the filter. The amplitude of the modulation and the total thickness of the filter determine the bandwidth and optical density of the filter.

The precise shape and location of the "notch" of the filter is angle tunable so the filter should be located in between the lens that collects and collimates the scattered light and the lens that focuses the Raman scattered radiation into the spectrometer such that only collimated light passes through the filter.

A holographically generated notch filter can have a relatively narrow, sharp-edged band of wavelengths that will not be transmitted. The band is centered at the wavelength of the exciting laser line and may have a total width of $\approx$300 cm^{-1}. The narrow width of the notch and its high optical density permit the measurement of both the Stokes and anti-Stokes components of a spectrum, as is illustrated in the Raman spectrum of zirconia presented in Figure 4.

In addition to a notch filter, it is also possible to holographically generate a bandpass filter, which can be used to remove the light from the plasma discharge in the laser tube (Owen, 1992). In contrast to dielectric filters, holographic filters can have a bandpass that is five times more narrow and can transmit up to 90% of the laser line. Dielectric bandpass filters typically transmit only 50% of the laser line.

Optical Alignment

Alignment of the entire optical system is most easily accomplished by use of a second laser, which need only have an intensity of $\approx$1 mW. The spectrometer is set to transmit the radiation of the second laser, which is located at the exit slit of the spectrometer. For convenience, instead of having to remove the light detector, the light from the second laser can enter through a second, nearby port and made to hit a mirror that is inserted inside the spectrometer, just in front of the exit slits. The light reflected from the mirror then passes through the entire spectrometer and exits at the entrance slits, a process termed "back illumination." The back-illuminated beam travels the same path through the spectrometer (from just in front of the exit slits to the entrance slits) that the Raman scattered radiation from the sample will travel in getting to the light detector. Consequently, the system is aligned by sending the back-illuminated beam through the collection optics and into coincidence with the exciting laser beam on the sample's surface.

Spectrometer

The dispersing element is usually a grating, and the spectrometer may typically have one to three gratings. Multiple gratings are employed to reduce the intensity of the Rayleigh line. That is, light that is dispersed by the first grating is collimated and made incident on a second grating. However, the overall intensity of the dispersed light that exits from the spectrometer decreases as the number of gratings increases. The doubly dispersed light has a higher signal-to-noise ratio, but its overall intensity is significantly lower than singly dispersed light. Since the intensity of Raman scattered radiation is generally very weak (often by one or more orders of magnitude), there is an advantage to decreasing the intensity of the Rayleigh light that enters the spectrometer by using a single grating in combination with a notch filter rather than by using multiple gratings (see Optics).

Modern spectrometers generally make use of interference or holographic gratings. These are formed by exposing photosensitive material to the interference pattern produced by reflecting a laser beam at normal incidence off a mirror surface or by intersecting two coherent beams of laser light. Immersing the photosensitized material into a suitable solvent, in which the regions exposed to the maximum light intensity experience either enhanced or retarded rates of dissolution, produces the periodic profile of the grating. The surface of the grating is then typically coated with a thin, highly reflective metal coating (Hutley, 1982).

The minimum spacing of grooves that can be generated by interference patterns is directly proportional to the wavelength of the laser light. The minimum groove spacing that can be formed using the 458-nm line of an argon ion laser is 0.28 μm (3500 grooves/mm). The line spacing of a grating dictates one of the most important characteristics of the grating, its resolving power.

The resolving power of a grating is a measure of the smallest change of wavelength that the grating can resolve:

$$\frac{\lambda}{\Delta\lambda} = \frac{mW}{d} \tag{21}$$

where λ is the wavelength at which the grating is operating, m is the diffraction order, W is the width of the grating, and d is the spacing of the grating grooves (or steps). This relation indicates the importance of just filling the grating with light and the influence of the spacing of the grating grooves, which is generally expressed in terms of the number of grooves per millimeters, on its resolving power.

A second parameter of interest for characterizing the performance of a grating is its absolute efficiency, which is a measure of the fraction of the light incident on the grating that is diffracted into the required order. It is a function of the shape of the groove, the angle of incidence, the wavelength of the incident light, the polarization of the light, the reflectance of the material that forms the grating, and the particular instrument that houses the gratings (Hutley, 1982). The efficiency of a grating can be measured or calculated with the aid of a computer. The measurement of the absolute efficiency is performed by taking the ratio of the flux in the diffracted beam to the flux in the incident beam. Generally, it is not necessary for a Raman spectroscopist to measure and/or calculate the absolute efficiencies of gratings. Such information may be available from the manufacturer of the gratings.

Measurement of the Dispersed Radiation

A device for measuring the intensity of the dispersed radiation will be located just outside the exit port of the spectrometer. Since the intensity of the Raman scattered radiation is so weak, a very sensitive device is required to measure it. Three such devices are a photomultiplier tube (PMT), a photodiode array, and a charge-transfer device.

The key elements in a PMT are a photosensitive cathode, a series of dynodes, and an anode (Long, 1977; Ferraro and Nakamoto, 1994). The PMT is located at the exit of the spectrometer, which is set to transmit radiation of a particular wavelength. For Stokes-shifted Raman spectroscopy, the wavelength is longer than that of the exciting laser. As photons of this energy exit the spectrometer, they are focused into the photocathode of the PMT. For each photon that is absorbed by the photocathode, an electron is ejected and is accelerated toward the first dynode, whose potential is $\approx$100 V positive with respect to the photocathode. For each electron that hits the first dynode, several are ejected and are accelerated toward the second dynode. A single photon entering the PMT may cause a pulse of 10^6 electrons at the anode. Long (1977) describes the different procedures for relating the current pulse at the anode to the intensity of the radiation incident on the PMT.

The efficiency of the PMT is increased through the use of a photoemission element consisting of a semiconductor whose surface is coated with a thin layer ($\approx$2 nm) of material with a low work function (e.g., a mixture of cesium and oxygen; Fraser, 1990). For a heavily doped p-type semiconductor coated with such a surface layer, the electron affinity in the bulk semiconductor is equal to the difference between its band-gap energy and the surface layer work function. If the work function is smaller than the band gap, the semiconductor has a negative electron affinity. This means that the lowest energy of an electron in the conduction band in the bulk of the semiconductor is higher than the energy of an electron in vacuum and results in an increase in the number of electrons emitted per absorbed photon (i.e., increased quantum efficiency). The gain of the PMT can be increased by treating the dynodesurface in a similar fashion. A dynode with negative electron affinity emits a greater number of electrons per incident electron. The overall effect is a higher number of electrons at the anode per photon absorbed at the cathode.

It is important to note that the PMT needs to be cooled to reduce the number of thermally generated electrons at the photocathode and dynodes, which add to the PMT "dark count." Heat is generally extracted from the PMT by a thermoelectric cooler. The heat extracted by the cooler is generally conducted away by flowing water.

A PMT is well suited to measuring the weak signal that exits a spectrometer that has been set to pass Raman scattered radiation of a single energy. The entire Raman spectrum is measured by systematically changing the energy of the light that passes through the spectrometer (i.e., rotating the grating) and measuring its intensity as it exits from the spectrometer. For a double monochromator fitted with a PMT, it may take minutes to tens of minutes to generate a complete Raman spectrum of one sample.

In a PMT, current is generated as photons hit the cathode. In contrast, each active segment in a photodiode array (PDA) and a charge-coupled device (CCD) stores charge (rather than generating current) that is created by photons absorbed at that location. The Raman spectrum is generated from the spatial distribution of charge that is produced in the device. In both a PDA and CCD, photons are absorbed and electron-hole pairs are created. The junction in which the electron-hole pairs are created are different in the two devices. In a PDA, the junction is a reverse-biased p-n junction. In a CCD, the junction is the depletion zone in the semiconductor at the semiconductor-oxide interface of a metal-oxide-semiconductor.

When the reverse-biased p-n junction is irradiated by photons with an energy greater than the band gap, electron-hole pairs are generated from the absorbed photons. Minority carriers from the pairs formed close (i.e., within diffusion distance) to the charge-depleted layer of the junction are split apart from their complementary, oppositely charged particles and driven in the opposite direction by the electric field in the junction. The increase in reverse saturation current density is proportional to the light intensity hitting the photodiode. To minimize the "dark counts", the photodiode must be cooled to reduce the number of thermally generated electron-hole pairs.

If the junction is at equilibrium and is irradiated with photons of energy greater than the band gap, electron-hole pairs generated in the junction are separated by the built-in electric field. The separated electrons and holes lower the magnitude of the built-in field. If an array of diodes is distributed across the exit of the spectrometer, the distribution of charge that is created in the array provides a measure of the intensity of the radiation that is dispersed by the spectrometer across the focal plane for the exiting radiation.

The time to measure a Raman spectrum can be greatly lowered by measuring the entire spectrum at once, rather than one energy value at a time, as is the case with a PMT. Multichannel detection is accomplished by, e.g., placing a PDA at the exit of a spectrometer. There are no slits at the exit, which is filled by the PDA. Each tiny diode in the array measures the intensity of the light that is dispersed to that location. Collectively, the entire array measures the whole spectrum (or a significant fraction of the whole spectrum) all at once. Generally, an individual photodiode in a PDA is not as good a detector as is a PMT. However, for some experiments the multichannel advantage compensates for the lower quality detector. Unfortunately, a PDA do not always provide the sensitivity at low light intensities that are needed in Raman spectroscopy.

A CCD is a charge-transfer device that combines the multichannel detection advantage of a PDA with a sensitivity at low light intensities that rivals that of a PMT (Bilhorn et al., 1987a,b; Epperson, 1988). Charge-coupled devices are made of metal-oxide-semiconductor elements and, in terms of light detection, function analogously to photographic film. That is, photons that hit and are absorbed at a particular location of the CCD are stored at that site in the form of photogenerated electrons (for *p*-type semiconductor substrate) or photogenerated holes (for *n*-type semiconductor substrate).

One example of a CCD is a heavily doped, *p*-type silicon substrate whose surface is coated with a thin layer of SiO_2 on top of which are a series of discrete, closely spaced metal strips, referred to as gates. The potential of each adjacent metal strip is set at a different value so that the width of the depletion layer in the semiconductor varies periodically across its surface. When a positive potential is applied to a metal strip, the mobile holes in the *p*-type silicon are repelled from the surface region, creating a depleted layer. If a high enough potential is applied to a metal strip, significant bending of the bands in the region of the semiconductor close to the oxide layer causes the bottom of the conduction band to approach the Fermi level. Electrons occupy states in the conduction band near the surface forming an inversion layer, i.e., an *n*-type surface region in the bulk *p*-type semiconductor. Photons that are absorbed in the surface region generate electron-hole pairs in which the electrons and holes are driven apart by the field in the depletion layer. The holes are expelled from the depletion layer and the electrons are stored in the potential well at the surface. As the intensity of light increases, the number of stored electrons increases. The light exiting the spectrometer is dispersed and so hits the CCD at locations indicative of its wavelength. The dispersed light creates a distribution of charge in the depletion layer from which the sample Raman spectrum is generated. The distribution of charge corresponding to the Raman spectrum is sent to a detector by shifting the periodic variation in potential of the metal strips in the direction of the detector. In this manner the charge stored in the depletion layer of the semiconductor adjacent to a particular metal strip is shifted from one strip to the next. Charge arrives at the detector in successive packets, corresponding to the sequential distribution of the metal gates across the face of the CCD.

An illustration of the increased efficiency of measuring Raman spectra that has emerged in the past 10 years is provided by a comparison of the time required to measure a portion (200 to 1500 cm^{-1}) of the surface-enhanced Raman spectrum (see the following paragraph) of thin passive films grown on samples of iron immersed in aqueous solutions. Ten to 15 min (Gui and Devine, 1991) was required to generate the spectrum by using a double spectrometer (Jobin-Yvon U1000 with 1800 grooves/mm holographic gratings) and a PMT (RCA c31034 GaAs), while the same spectrum can now be acquired in $\approx$5 s (Oblonsky and Devine, 1995) using a single monochromator (270M Spex), in which the stray light is reduced by a notch filter (Kaiser Optics Super Holographic Notch Filter centered at 647.1 nm), and the intensity of the dispersed Raman scattered radiation is measured with a CCD (Spectrum One, 298 $\times$ 1152 pixels). The enhanced speed in generating the spectrum makes it possible to study the time evolution of samples.

In the previous paragraph, mention was made of surface-enhanced Raman scattering (SERS), which is the greatly magnified intensity of the Raman scattered radiation from species adsorbed on the surfaces of specific metals with either roughened surfaces or colloidal dimensions (Chang and Furtak, 1982). SERS is not a topic of this unit, but a great deal of interest during the past 15 years has been devoted to the use of SERS in studies of surface adsorption and surface films.

Polarization

By controlling the polarization of the incident radiation and measuring the intensity of the Raman scattered radiation as a function of its polarization, it is possible to identify the component(s) of the polarizabilty tensor of a crystal that are responsible for the different peaks in the Raman spectrum (see Example: Raman Active Vibrational Modes of α-Al_2O_3, below). This information will then identify the vibrational mode(s) responsible for each peak in the spectrum. The procedure is illustrated below for α-Al_2O_3 (see Example: Raman Active Vibrational Modes of α-Al_2O_3). The configuration of the polarizing and polarization measuring components are discussed in Scherer (1991).

Fourier Transform Raman Spectroscopy

The weak intensity of Raman scattering has already been mentioned as one of the major shortcomings of Raman spectroscopy. Sample heating and fluorescence are two other phenomena that can increase the difficulty of obtaining Raman spectra. Sample heating is caused by absorption of energy during illumination with laser beams of high power density. Fluorescence is also caused by absorption of laser energy by the sample (including impurities in the sample). When the excited electrons drop back down to lower energy levels, they emit light whose energy equals the difference between the energies of the initial (excited) and final states. The fluorescence spectrum is (practically speaking) continuous and covers a wide range of values. The intensity of the fluorescence can be much greater than that of the Raman scattered radiation.

Both sample heating and fluorescence can be minimized by switching to exciting radiation whose energy is too low to be absorbed. For many materials, optical radiation in the red or near-IR range will not be absorbed. If such radiation is to be used in Raman spectroscopy, two consequences must be recognized and addressed. First, since Raman scattering is a light-scattering process, its intensity varies as λ^{-4}. Hence, by switching to longer wavelength exciting radiation, the intensity of the Raman spectrum will be significantly lowered. Second, the sensitivity of most PMTs to red and especially near-infrared radiation is very low. Consequently, the use of long-wavelength radiation in Raman spectroscopy has been coupled to the use of Fourier transform Raman spectroscopy (FTRS) (Parker, 1994).

In FTRS, an interferometer is used in place of a monochromator. The Raman scattered radiation is fed directly into a Michelson interferometer and from there it enters the detector. The Raman spectrum is obtained by taking the cosine-Fourier transform of the intensity of the radiation that reaches the detector, which varies in magnitude as the path difference between the moving mirror and the fixed mirror within the interferometer changes. Since the Raman scattered radiation is not dispersed, a much higher Raman intensity reaches the detector in FTRS than is the case for conventional Raman spectroscopy. The much higher intensity of the Raman scattered radiation in FTRS permits the use of longer wavelength incident radiation (e.g., $\lambda = 1064$ nm of Nd-YAG), which may eliminate fluorescence.

DATA ANALYSIS AND INITIAL INTERPRETATION

Raman scattering may result from incident radiation inducing transitions in electronic, vibrational, and rotational states of the scattering medium. Peaks in the Raman spectrum of a solid obtained using visible exciting radiation are generally associated with vibrational modes of the solid. The vibrations may be subdivided into internal modes that arise from molecules or ions that make up the solid and external modes that result from collective modes ($k = 0$) of the crystal. In either case, the presence of a peak in the Raman spectrum due to the vibration requires that the Raman transition be symmetry allowed, i.e., that the integrand in Equation 7 have a nonzero value. In addition, for a measurable Raman intensity, the integral in Equation 7 must have a large enough magnitude. It is generally difficult to calculate the intensity of a Raman peak, but it is rather straightforward to use group theoretical techniques to determine whether or not the vibrational mode is symmetry allowed.

Example: Raman Active Vibrational Modes of α-Al_2O_3

The extremely useful result that the crystallographic point group provides all the information that is needed to know the symmetries of the Raman active vibrational modes of the crystal is derived below (see Appendix). The left-hand column in the character table for each point group lists a set of symbols such as A_1, B_1, and B_2 for the point group C_{2v}. The term A_1 is the list of characters of the matrices that represent the effect of each symmetry operation of the point group on any function listed in the far right-hand column of the character table. A remarkable result of group theory is that the list of characters of the matrices that represent the effect of each symmetry operation of the point group on "any" function can be completely described by a linear combination of the few lists presented in the character table. For example, for the point group C_{2v}, the symmetry of the function x^2 is described by A_1. This means that when the effect of each of the symmetry operations operating on x^2 is represented by a matrix, the characters of the four matrices are 1, 1, 1, 1. In fact, within the context of the point group C_{2v}, the symmetry of any function is given by $aA_1 + bB_1 + cB_2$, where a, b, and c are integers. In the language of group theory, A_1, B_1, and B_2 are called the irreducible representations of the point group C_{2v}. The linear combination of irreducible representations that describe the symmetry of a function is called the symmetry species of the function.

The irreducible representations of the normal vibrational modes of a crystal are most easily identified by the correlation method (Fately et al., 1971). The analysis for the lattice vibrations of α-Al_2O_3 will be summarized here. The details of the analysis are contained in Fately et al. (1971).

The space group of α-Al_2O_3 is D^6_{3d}. There are two molecules of α-Al_2O_3 per Bravais cell. Each atom in the Bravais cell has its own symmetry, termed the site symmetry, which is a subgroup of the full symmetry of the Bravais unit cell. The site symmetry of the aluminum atoms is C_3 and that of the oxygen atoms is C_2. From the character table for the C_3 point group, displacement in the z direction is a basis for the A irreducible representation. Displacements parallel to the x and y axes are bases for the E irreducible representation. The correlation tables for the species of a group and its subgroups (Wilson et al., 1955) correlate the A species of C_3 to A_{1g}, A_{2g}, A_{1u}, and A_{2u} of the crystal point group D_{3d}.

Displacement of the oxygen atom in the z direction is a basis of the A irreducible representation of the C_2 point group, which is the site symmetry of the oxygen atoms in α-Al_2O_3. Displacements of the oxygen atom that are parallel to the x and y axes are bases for the B irreducible representation of C_2. The correlation table associates the A species of C_2 to A_{1g}, E_g, A_{1u}, and E_u of D_{3d}. The B species of C_2 correlates to A_{2g}, E_g, A_{2u}, and E_u of D_{3d}.

After accounting for the number of degrees of freedom contributed by each irreducible representation of C_2 and C_3 to an irreducible representation of D_{3d} and removing the irreducible representations associated with the rigid translation of the entire crystal, the irreducible species for the optical modes of the corundum crystal are determined to be

$$2A_{1g} + 2A_{1u} + 3A_{2g} + 2A_{2u} + 5E_g + 4E_u \qquad (22)$$

Consulting the character table of the point group D_{3d} indicates that the Raman active vibrational modes would span

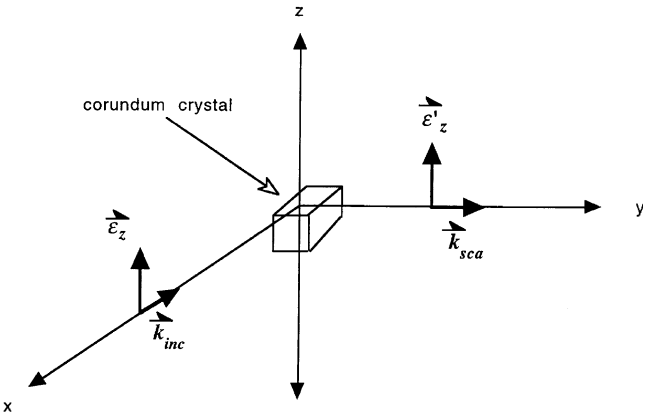

Figure 8. Directions and polarizations of incident and scattered radiation for the $x(zz)y$ configuration.

the symmetry species A_{1g} and E_g. The basis functions for these symmetry species are listed in the character table:

$$x^2 + y^2 \quad \text{and} \quad z^2 \quad \text{for } A_{1g} \tag{23}$$

and

$$(x^2 - y^2, xy) \quad \text{and} \quad (xz, yz) \quad \text{for } E_g \tag{24}$$

Thus there are a total of seven Raman active modes so there may be as many as seven peaks in the Raman spectrum. The question now is which peaks correspond to which vibrational modes.

Figure 8 depicts a Cartesian coordinate system, and a crystal of corundum is imagined to be located at the origin with the crystal axes parallel to x, y, and z. If light is incident on the crystal in the $-x$ direction and polarized in the z direction, and scattered light is collected in the y direction after having passed through a y polarizer, then the experimental conditions of incidence and collection are described by the Porto notation (Porto and Krishnan, 1967) as $x(zz)y$. The first term inside the parentheses indicates the polarization of the incident light and the second term denotes the polarization of the scattered light that is observed. In general, if z polarized light is incident on a crystal in the x direction, then the induced polarization of the molecule will be given by $[p_x, p_y, p_z] = [\alpha_{xz}E_z, \alpha_{yz}E_z, \alpha_{zz}E_z]$. Light scattered in the y direction would be the result of the induced polarization components p_x and p_z. If the light scattered in the y direction is passed through a z polarizer, then the source of the observed radiation would be the induced polarization along the z direction. Consequently, only the α_{zz} component of the polarizability contributes to scattered light in the case of $x(zz)y$. Thus, peaks present in the Raman spectrum must originate from Raman scattering by vibrational modes that span the A_{1g} irreducible species.

Figure 9 presents the Raman spectra reported by Porto and Krishnan (1967) for single-crystal corundum under a variety of incidence and collection conditions. Figure 9A is the Raman spectrum in the $x(zz)y$ condition that was discussed above so the two peaks present in the spectrum correspond to vibrational modes with A_{1g} symmetry. The peaks present in the spectrum in Figure 9B can originate from vibrational modes with either A_{1g} or E_g symmetries. Consequently, the peaks present in Figure 9B but missing in Figure 9A have E_g symmetry. The spectra in Figures 9C-E exhibit only peaks with E_g symmetry. Collectively, the spectra reveal all seven Raman active modes and distinguish between the A_{1g} modes and the E_g modes.

The magnitude of the Raman shift in wavenumbers of each peak with respect to the exciting laser line can be related to the energy of the vibration. Combined with the knowledge of the masses of the atoms involved in the vibrational mode and, e.g., the harmonic oscillator assumption, it is possible to calculate the force constant associated with the bond between the atoms participating in the vibration. If one atom in the molecule were replaced by another without changing the symmetry of the molecule, the peak would shift corresponding to the different strength of the bond and the mass of new atom compared to the original atom. This illustrates why the Raman spectrum can provide information about bond strength and alloying effects.

Other Examples of the Use of Raman Spectroscopy in Studies of Solids

Raman spectroscopy can provide information on the amorphous/crystalline nature of a solid. Many factors can contribute to the widths of peaks in the Raman spectra of a solids. The greatest peak broadening factor can be microcrystallinity. For a macroscopic-sized single crystal of silicon at room temperature, the full width at half-maximum (FWHM) of the peak at 522 cm^{-1} is $\approx$3 cm^{-1} (Pollak, 1991). The breadth of the peak increases dramatically as the size of the crystal decreases below 10 nm. The cause of peak broadening in microcrystals is the finite size of the central peak in the Fourier transform of a phonon in a finite-size crystal. In an infinitely large crystal, the Fourier transform of a phonon consists of a single sharp line at the phonon frequency. The peak width Δk (i.e., FWHM) in a crystal of dimension L is given approximately by

$$\Delta k = \frac{2\pi(v/c)}{L} \tag{25}$$

where v is phonon velocity and c the velocity of light. Assuming $v = 1 \times 10^5$ cm/s, $\Delta k = 20$ cm^{-1} for $L = 10$ nm and $\Delta k = 200$ cm^{-1} for $L = 1$ nm. In the extreme case, the silicon is amorphous, in which case the $k = 0$ selection rule breaks down and all phonons are Raman active. In that case, the Raman spectrum resembles the phonon density of states and is characterized by two broad peaks centered at 140 and 480 cm^{-1} (Pollak, 1991). Consequently, the Raman spectrum can distinguish between the crystalline and amorphous structures of a solid and can indicate the grain size of microcrystalline solids.

Raman spectroscopy can be used to nondestructively measure the elastic stress in crystalline samples. Elastic straining of the lattice will alter the spring constant of a chemical bond and, hence, will shift the frequency of the

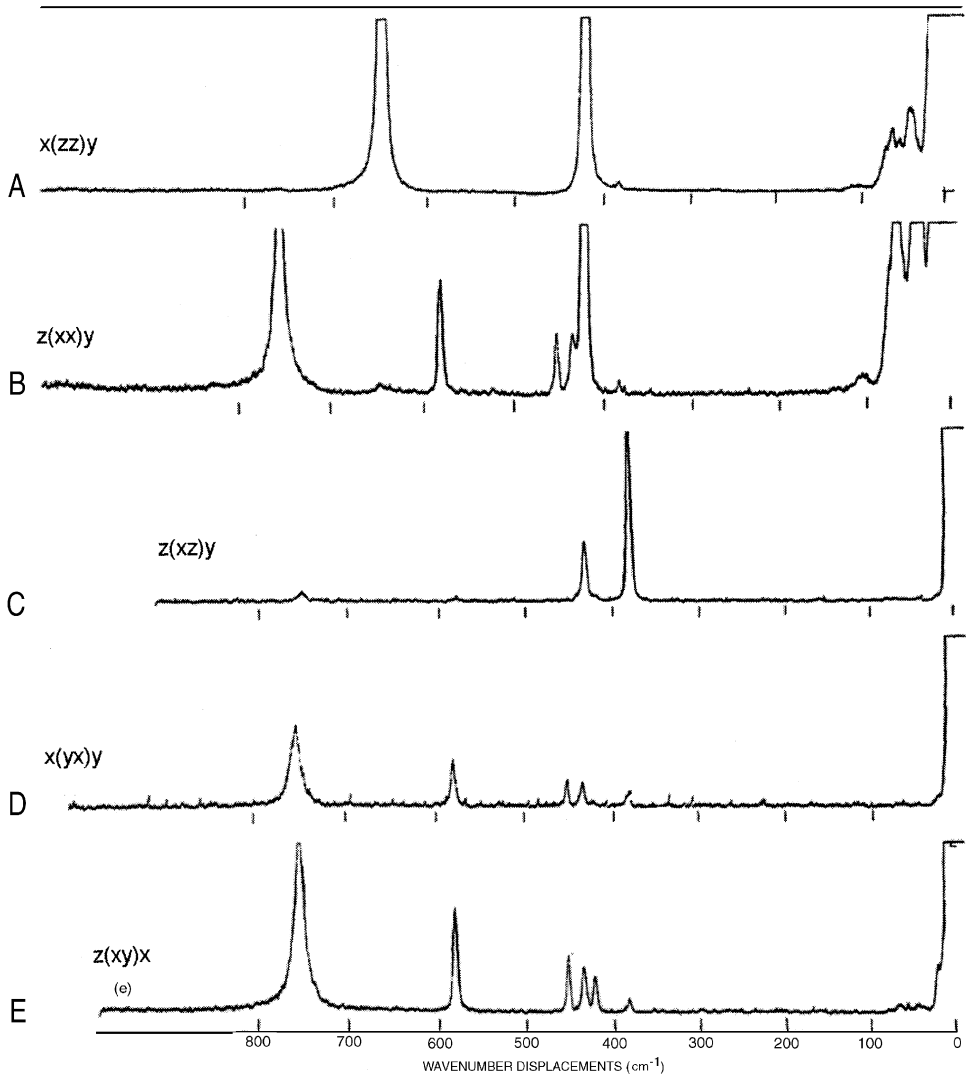

Figure 9. Raman spectra of corundum as a function of crystal and laser light polarization orientations (Porto and Krishnan, 1967).

vibrational mode associated with the strained bond. The direction and magnitude of the shift in peak location will depend on the sign (tensile or compressive) and magnitude, respectively, of the strain. Raman spectroscopy has been used to measure the residual stresses in thin films deposited on substrates that result in lattice mismatches and in thermally cycled composites where the strains result from differences in thermal expansion coefficients of the two materials (Pollak, 1991).

Another example of the use of Raman spectroscopy to nondestructively investigate the mechanical behavior of a solid is its use in studies of Al_2O_3-ZrO_2 composites (Clarke and Adar, 1982). These two-phase structures exhibit improved mechanical toughness due to transformation of the tetragonal ZrO_2 to the monoclinic form. The transformation occurs in the highly stressed region ahead of a growing crack and adds to the energy that must be expended in the propagation of the crack. Using Raman microprobe spectroscopy, it was possible to measure, with a spatial resolution of $\approx$1 μm, the widths of the regions on either side of a propagating crack in which the ZrO_2 transformed. The size of the transformed region is an important parameter in theories that predict the increased toughness expected from the transformation of the ZrO_2.

Phase transformations resulting from temperature or pressure changes in an initially homogeneous material have also been studied by Raman spectroscopy (Ferraro and Nakamoto, 1994). Raman spectra can be obtained from samples at temperatures and pressures that are markedly different from ambient conditions. All that is needed is the ability to irradiate the sample with a laser beam and to collect the scattered light. This can be accomplished by having an optically transparent window (such as silica, sapphire, or diamond) in the chamber that houses the sample and maintains the nonambient conditions. Alternatively, a fiber optic can be used to transmit the

incident light to the sample and the scattered light to the spectrometer.

The influence of composition on the Raman spectrum is in evidence in semiconductor alloys such as $Ga_{1-x}AL_xAs$ $(0 < x < 1)$, which exhibit both GaAs-like and AlAs-like longitudinal optical (LO) and transverse optical (TO) phonon modes. The LO modes have a greater dependence on composition than do the TO modes. The AlAs-like LO mode shifts by 50 cm^{-1} and the GaAs-like mode shifts by $\approx$35 cm^{-1} as x varies from 0 to 1. Thus the Raman spectrum of $Ga_{1-x}Al_xAs$ $(0 < x < 1)$ can be used to identify the composition of the alloy (Pollak, 1991).

Similarly, the Raman spectra of mixtures of HfO_2 and ZrO_2 are strong functions of the relative amounts of the two components. Depending on the particular mode, the Raman peaks shift by $\approx$7 to $\approx$60 cm^{-1} as the amount of HfO_2 increases from 0 to 100% spectroscopy (Ferraro and Nakamoto, 1994).

Raman spectroscopy has long been used to characterize the structure of polymers: identifying functional groups, end groups, crystallinity, and chain orientation. One word of caution: As might be expected of any Raman study of organic matter, fluorescence problems can arise in Raman investigations of polymers (Bower and Maddams, 1989; Bulkin, 1991; Rabolt, 1991).

Raman Spectroscopy of Carbon

Because carbon can exist in a variety of solid forms, ranging from diamond to graphite to amorphous carbon, Raman spectroscopy is the single most effective characterization tool for analyzing carbon. Given the wide spectrum of structures exhibited by carbon, it provides a compelling example of the capability of Raman spectroscopy to analyze the structures of a large variety of solids. The following discussion illustrates the use of Raman spectroscopy to distinguish between the various structural forms of carbon and describes the general procedure for quantitatively analyzing the structure of a solid by Raman spectroscopy.

Figure 10, which was originally presented in an article by Robertson (1991), who compiled the data of a number of researchers, presents the Raman spectra of diamond, large crystal graphite, microcrystalline graphite, glassy carbon, and several forms of amorphous carbon. Diamond has two atoms per unit cell and therefore has a single internal vibrational mode $(3N - 5 = 1)$. This mode is Raman active and is located at 1332 cm^{-1}. Graphite, with four atoms per unit cell, has six internal vibrational modes $(3N - 6 = 6)$, two of which are Raman active. The rigid-layer mode of graphite spans the symmetry species E_{2g} and occurs at 50 cm^{-1}, which is too close to the incident laser line to be accessible with most Raman collection optics and spectrometers. The second Raman active mode of graphite is centered at 1580 cm^{-1}, and it too spans the symmetry species E_{2g}. The relative displacements of the carbon atoms during this in-plane mode are presented next to the Raman spectrum in Figure 10. Thus, Raman spectroscopy can easily distinguish between diamond and large-crystal graphite.

The third spectrum from the top of Figure 10 was obtained from microcrystalline graphite. The next lower spectrum is similar and belongs to glassy carbon. There

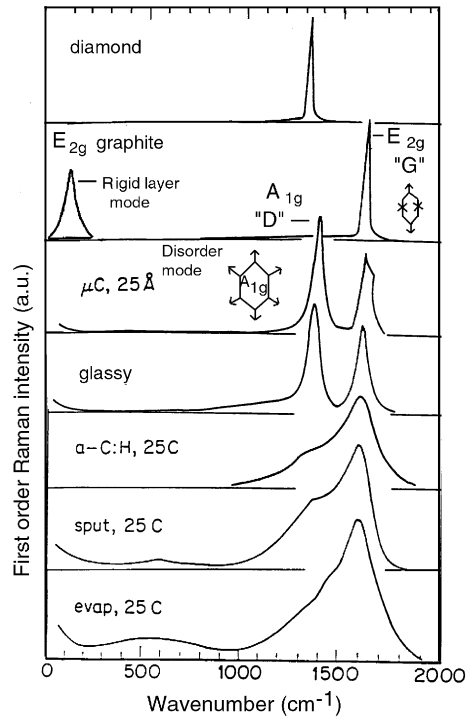

Figure 10. First-order Raman spectra of diamond, highly oriented pyrolytic graphite (hopg), microcrystalline graphite, glassy C, plasma-deposited a-C:H, sputtered a-C, and evaporated a-C. (From Robertson, 1991.)

are two peaks in these spectra, one at 1580 cm^{-1} and the other at 1350 cm^{-1}. Given these peak positions, originally there was some thought that the structures were a mixture of graphitelike (sp^2 bonding) and diamondlike (sp^3 bonding) components. However, experiments that revealed the effects of heat treatments on the relative intensities of the two peaks clearly showed that the material was polycrystalline graphite and the peak at 1350 cm^{-1} is a consequence of the small size of the graphite crystals. The new peak at 1350 cm^{-1} is labeled the disorder, or "D," peak, as it is a consequence of the breakdown of the crystal momentum conservation rule. In the Raman spectrum of an infinite crystal, the peak at 1350 cm^{-1} is absent. This peak results from the vibrational mode sketched next to the spectrum for microcrystalline graphite in Figure 10, and it spans the symmetry species A_{1g}. Its Raman activity is symmetry forbidden in a crystal of infinite size. Finite crystal size disrupts translational symmetry, and so the D mode is Raman active in microcrystalline graphite. The ratio of the integrated intensities of the peaks associated with the D and G modes is proportional to the size of the crystal:

$$\frac{I(D\,\text{mode})}{I(G\,\text{mode})} = \frac{k}{d} \tag{26}$$

where d is the crystal size. This relationship may be used, for example, to calculate the relative sizes of two microcrystals and the relative mean grain diameters of two

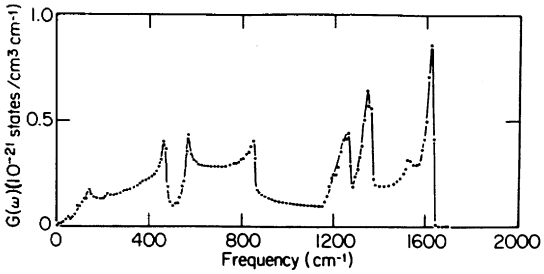

Figure 11. Phonon density of states for graphite.

polycrystalline aggregates, so long as the grain size is greater than 12 Å. The behavior of crystals smaller than 12 Å begins to resemble that of amorphous solids.

An amorphous solid of N atoms may be thought of as a giant molecule of N atoms. All $3N - 6$ of its internal vibrational modes are Raman active, and the Raman spectrum is proportional to the phonon density of states. This is demonstrated by a comparison of the bottom three spectra in Figure 10 with the calculated phonon density of states of graphite in Figure 11.

At this point several important distinctions between x-ray diffraction and Raman spectroscopy can be appreciated. Like Raman spectroscopy, x-ray diffraction is also able to distinguish between crystals, microcrystals, and amorphous forms of the same material. Raman spectroscopy not only is able to distinguish between the various forms but also readily provides fundamental information about the amorphous state as well as the crystalline state. This is due to the fact that x-ray diffraction provides information about the long-range periodicity of the arrangement of atoms in the solid, while Raman spectroscopy provides information concerning the bonds between atoms and the symmetry of the atomic arrangement. On the other hand, while x-ray diffraction is in principle applicable to every crystal, Raman spectroscopy is only applicable to those solids with unit cells containing two or more atoms.

Quantitative Analysis

The quantitative analysis of a spectrum requires fitting each peak to an expression of Raman scattered intensity vs. frequency of the scattered light. Typically, a computer is used to fit the data to some mathematical expression of the relationship between the intensity of the Raman scattered radiation as a function of its frequency with respect to that of the incident laser line. One example of a peak-fitting relationship is the expression (DiDomenico et al., 1968)

$$\frac{dI}{d\omega} = \frac{(\text{const})\Gamma\omega_0}{\{\omega_0^2 - (\Delta\omega)^2\}^2 + 4\Gamma^2\omega_0^2(\Delta\omega)^2} \qquad (27)$$

where $dI/d\omega$ is the average Raman scattered intensity per unit frequency and is proportional to the strength of the signal at the Raman shift of $\Delta\omega$; Γ is the damping constant, ω_0 is the frequency of the undamped vibrational mode, and $\Delta\omega$ is the frequency shift from the laser line. The calculated fit yields the values of Γ and ω_0 for each peak in the spectrum.

An example of the quantitative analysis of a Raman spectrum is provided in the work of Dillon et al. (1984), who used Raman spectroscopy to investigate the growth of graphite microcrystals in carbon films as a function of annealing temperature. The data for the D and G peaks of graphite were fitted to Equation 27, which was then integrated to give the integrated intensity of each peak. The ratio of the integrated intensity of the D mode to the integrated intensity of the G mode was then calculated and plotted as a function of annealing temperature. The ratio increased with annealing temperature over the range from 400 to 600°C, and the widths of the two peaks decreased over the same range. The results suggest that either the number or the size of the crystal grains was increasing over this temperature range. The integrated intensity ratio of the D-to-G mode reached a maximum and then decreased with higher temperatures, indicating growth in the grain size during annealing at higher temperatures. Dillon et al. also used the peak positions defined by Equation 27 to monitor the shift in peak locations with annealing temperature. The results indicated that the annealed films were characterized by threefold rather than fourfold coordination.

In summary, a single-phase, unknown material can be identified by the locations of peaks and their relative intensities in the Raman spectrum. The location of each peak and its breadth can be defined by fitting the peaks to a quantitative expression of peak intensity vs. Raman shift. The same expression will provide the integrated intensity of each peak. Ratios of integrated intensities of peaks belonging to different phases in a multiphase sample will be proportional to the relative amounts of the two phases.

PROBLEMS

Many problems can arise in the generation of a Raman spectrum. Peaks not part of the spectrum of the sample can sometimes appear. Among the factors that can produce spurious peaks are plasma lines from the laser and cosmic rays hitting the light detector. The occurrence of peaks caused by cosmic rays increases with the time required for acquisition of the spectrum. The peaks from cosmic rays can be identified by their sharpness and their nonreproducibility. Peaks attributed to plasma lines are also sharp, but not nearly as sharp as those caused by cosmic rays. A peak associated with a plasma line will vanish when the spectrum is generated using a different laser.

An all too common problem encountered in Raman spectroscopy is the occurrence of fluorescence, which completely swamps the much weaker Raman signal. The fluorescence can be caused by the component of interest or by impurities in the sample. Fluorescence can be minimized by decreasing the concentration of the guilty impurity or by long-time exposure of the impurity to the exciting laser line, which "burns out" the fluorescence. Absorption of the exciting laser line by the impurity results in its thermal decomposition.

Fluorescence is generally red shifted from the exciting laser line. Consequently, the anti-Stokes Raman spectrum may be less affected by fluorescence than the Stokes-Raman spectrum. The intensity of the anti-Stokes Raman spectrum is much weaker than that of the Stokes Raman so this is not always a viable approach to avoiding the fluorescence signal.

Increasing the wavelength of the exciting laser line may also reduce fluorescence, as was mentioned above (see Fourier Transform Raman Spectroscopy). One potential problem with the latter approach is tied to the wavelength dependence of the intensity of the scattered light, which varies inversely as the fourth power of the wavelength. Shifting to exciting radiation with a longer wavelength may reduce fluorescence but it will also decrease the overall intensity of the scattered radiation.

Fluctuations in the intensity of the incident laser power during the generation of a Raman spectrum are particularly problematic for spectra measured using a single-channel detector. Errors in the relative intensities of different peaks can result from fluctuations in the laser power. Similarly, fluctuations in laser power will cause variations in the intensities of successive measurements of the same spectrum using a multiple-channel detector. These problems will be largely averted if the laser can be operated in a constant-light-intensity mode rather than in a controlled (electrical) power input mode.

If the sample absorbs the incident radiation, problems may occur even if the absorption does not result in fluorescence. For example, if an argon laser ($\lambda = 514.5$ nm) were used to generate the Raman spectrum of an adsorbate on the surface of a copper or gold substrate, significant reduction in the Raman intensity would result because of the strong absorption by copper and gold of green light. In this case, better results would be obtained by switching to a krypton laser ($\lambda = 647.1$ nm) or helium-neon laser ($\lambda = 632.8$ nm).

Absorption of the incident radiation can also lead to increases in the temperature of the sample. This may have a major deleterious effect on the experiment if the higher temperature causes a change in the concentration of an adsorbate or in the rate of a chemical or electrochemical reaction. If optically induced thermal effects are suspected, the spectra should be generated using several different incident wavelengths.

Temperature changes can also cause significant changes in the Raman spectrum. There are a number of sources of the temperature dependency of Raman scattering. First, the intensity of the Stokes component relative to the anti-Stokes component decreases as temperature increases. For studies that make use of only the Stokes component, an increase in temperature will cause a decrease in intensity. A second cause of the temperature dependency of a Raman spectrum is the broadening of peaks as the temperature increases. This cause of peak broadening is dependent on the decay mechanism of the phonons. Broadening of the Raman peak can also result from hot bands. Here the higher temperature results in a higher population of the excited state. As a result, the incident photon can induce the transition from the first excited state to the second excited state. Because of anharmonic effects, the energy required for this transition is different from the energy required of the transition from the ground state to the first excited state. As a result, the peak is broadened. Hence, Raman peaks are much sharper at lower temperatures. Consequently, it may be necessary to obtain spectra at temperatures well below room temperature in order to minimize peak overlap and to identify distinct peaks.

Temperature changes can also affect the Raman spectrum due to the temperature dependencies of the phonons themselves. For example, the phonon itself will have a strong temperature dependency as the temperature is raised close to that of a structural phase transition if at least one component of the oscillation coincides with the displacement during the phase transition. Temperature changes can also affect the phonon frequency. As the temperature increases, the anharmonic character of the vibration causes the well in the plot of potential energy vs. atomic displacement to be more narrow than is the case for a purely harmonic oscillation. The atomic displacements are therefore smaller, which results in a higher frequency since the amplitude of displacement is inversely proportional to frequency. In addition, thermal expansion increases the average distance between the atoms as temperature increases, leading to a decrease in the strength of the interatomic interactions. This results in a decrease in the phonon frequency with increasing temperature. In summary, superior Raman spectra are generally obtained at lower temperatures, and it may be necessary in some cases to obtain spectra at temperatures that are considerably lower than room temperature.

Changes in the temperature of the room in which the Raman spectra are measured can cause changes in the positions of optical components (lenses, filters, mirrors, gratings) both inside and outside the spectrometer. Such effects are important when attempting to accurately measure the locations of peaks in a spectrum, or, e.g., stress-induced shifts in peak locations.

One of the more expensive mistakes that can be made in systems using single-channel detectors is the inadvertent exposure of the PMT to the Rayleigh line. The high intensity of the Rayleigh scattered radiation can "burn out" the PMT, resulting in a significant increase in PMT dark counts. Either closing the shutter in front of the PMT or shutting off the high voltage to the PMT will prevent damage to the PMT from exposure to high light intensity. Typically, accidents of this type occur when the frequency of the incident radiation is changed and the operator neglects to note this change at the appropriate point in the software that runs the experiment and controls the operation of the PMT shutter.

ACKNOWLEDGMENTS

It is a pleasure to thank J. Larry Nelson and Wylie Childs of the Electric Power Research Institute for their long-term support and interest in the use of Raman spectroscopy in corrosion investigations. In addition, Gary Chesnut and David Blumer of ARCO Production and Technology have encouraged the use of surface-enhanced Raman spectroscopy in studies of corrosion inhibition.

Both organizations have partially supported the writing of this unit.

The efforts and skills of former and current graduate students, in particular Jing Gui, Lucy J. Oblonsky, Christopher Kumai, Valeska Schroeder, and Peter Chou, have greatly contributed to my continually improved understanding and appreciation of Raman spectroscopy.

APPENDIX: GROUP THEORY AND VIBRATIONAL SPECTROSCOPY

This appendix was written, in part, to provide a road map that someone interested in vibrational spectroscopy might want to follow in migrating through the huge number of topics that are covered by the vast number of textbooks on group theory (see Literature Cited). Although necessarily brief in a number of areas, it does cover the following topics in some depth, selected on the basis of their importance and/or the rareness with which they are fully discussed elsewhere: (1) How character tables are used to identify the Raman activity of vibrational modes is demonstrated. (2) That the ij component, α_{ij}, of the polarizability tensor has the same symmetry as the product function $x_i x_j$ is demonstrated. Character tables list quadratic functions such as x^2, yz and identify the symmetry species (defined below) spanned by each. The same symmetry species will be spanned by the Raman active vibrational modes. (3) The proper rotations found in crystallographic point groups are identified. (4) A general approach, developed by Lax (1974) and using multiplier groups, is presented that elegantly establishes the link between all space groups, both symmorphic and nonsymmorphic, and the crystallographic point groups.

Vibrational Selection Rules

Quantum mechanically a vibrational Raman transition may occur if the integral in Equation 7 has a nonzero value. This can quickly be determined by the use of group theoretical techniques, which are summarized in the form of a Raman selection rule. The Raman selection rule is a statement of the symmetry that a vibrational mode must possess in order that it may be Raman active.

Before discussing the symmetry-based selection rules for Raman scattering, there is also a restriction based on the principles of energy and momentum conservation

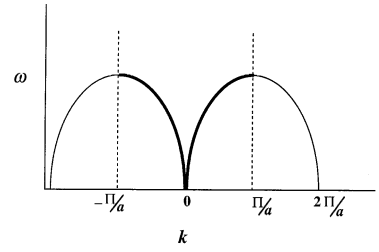

Figure 12. Dispersion of longitudinal wave in a linear monoatomic lattice (nearest-neighbor interactions only).

that is especially helpful in considering the Raman activity of solids. The requirements of energy and momentum conservation are expressed as follows:

$$\hbar\omega_i = \hbar\omega_s \pm \hbar\omega_v \tag{28}$$

$$\hbar k_i = \hbar k_s \pm \hbar k_v \tag{29}$$

where $\hbar k_i, \hbar k_s$, and $\hbar k_v$ are the momentum vectors of the incident and scattered radiation and the crystal phonon, respectively. For optical radiation $|k_i|$ is on the order of 10^4 to 10^5 cm^{-1}. For example, for $\lambda = 647.1$ nm, which corresponds to the high-intensity red line of a krypton ion laser,

$$k = \frac{2\pi}{\lambda} = 9.71 \times 10^3 \text{ cm}^{-1} \tag{30}$$

For a crystal with $a_0 = 0.25$ nm, $k_{v,\max} \approx 2.51 \times 10^8$ cm^{-1}. Hence, for Raman scattering, $k_v \ll k_{v,\max}$. In other words, k_v must be near the center of the Brillouin Zone (BZ).

The phonon dispersion curves for a simple, one-dimensional, monoatomic lattice and a 1D diatomic lattice are presented in Figures 12 and 13. Since there are no available states at the center of the BZ in a monatomic lattice [for a three-dimensional (3D) lattice as well as a one-dimensional lattice], such structures are not Raman active. Consequently, all metals are Raman inactive. Diatomic lattices, whether homonuclear or heteronuclear, do possess phonon modes at the center of the BZ (see Fig. 13) and are Raman active. Thus, crystals such as diamond, silicon, gallium nitride, and aluminum oxide are all Raman active.

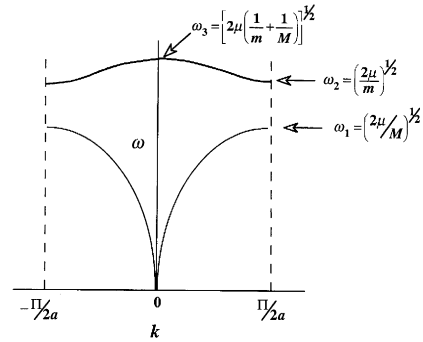

Figure 13. Dispersion of longitudinal wave in a linear diatomic lattice.

A Raman spectrum may consist of several peaks in the plot of the intensity of the scattered radiation versus its shift in wavenumber with respect to the incident radiation, as illustrated in Figure 4. If the immediate task is to identify the material responsible for the Raman spectrum, then it is only necessary to compare the measured spectrum with the reference spectra of candidate materials. Since the Raman spectrum acts as a fingerprint of the scattering material, once a match is found, the unknown substance can be identified.

Often the identity of the sample is known, and Raman spectroscopy is being used to learn more about the material, e.g., the strength of its atomic bonds or the presence of elastic strains in a crystalline matrix. Such information is present in the Raman spectrum but it must now be analyzed carefully in order to characterize the structure of the material.

Once a vibrational Raman spectrum is obtained, the first task is to identify the vibrational modes that contribute to each peak in the spectrum. Group theoretical techniques enormously simplify the analyses of vibrational spectra. At this point, the rules of group theory that are used in vibrational spectroscopy will be cited and examples of their use will then be given. In doing so, it is worth recalling the warning issued by David Bishop in the preface to his textbook on Group Theory (Bishop, 1973, p. vii): "The mathematics involved in actually applying, as opposed to deriving group theoretical formulae is quite trivial. It involves little more than adding and multiplying. It is in fact possible to make the applications, by filling in the necessary formulae in a routine way, without even understanding where the formulae have come from. I do not, however, advocate this practice."

Although the approach taken in the body of this unit ignores Bishop's advice, the intent is to demonstrate the ease with which vibrational spectra can be analyzed by using the tools of group theory. One researcher used the automobile analogy to illustrate the usefulness of this approach to group theory. Driving an automobile can be a very useful practice. Doing so can be accomplished without any knowledge of the internal combustion engine. Hopefully, the elegance of the methodology, which should be apparent from reading this appendix, will encourage the reader to acquire a firm understanding of the principles of group theory by consulting any number of texts that provide an excellent introduction to the subject (see Literature Cited, e.g., Hammermesh, 1962; Koster, 1957; Leech and Newman, 1969; Mariot, 1962; Meijer and Bauer, 1962; Weyl, 1931).

Group Theoretical Tools for Analyzing Vibrational Spectra

Point Groups and Matrix Representations of Symmetry Operations. The collection of symmetry operations of a molecule make up its point group. A point group is a collection of symmetry operations that are linked to one another by the following rules: (1) The identity operation is a member of the set. (2) The operations multiply associatively. (3) If R and S are elements, then so is RS. (4) The inverse of each element is also a member of the set. In satisfying these requirements, the point groups meet the criteria for a mathematical group so that molecular symmetry can be investigated with the aid of group theory.

At this juncture, point groups, which describe the symmetry of molecules, and the use of group theoretical techniques to identify the selection rules for Raman active, molecular vibrations will be described. Although the symmetry of crystals is described by space groups, it will be demonstrated below that the Raman active vibrational modes of a crystal can be identified with the aid of the point group associated with the crystal space group. That is, the Raman spectrum of a crystal is equated to the Raman spectrum of a single unit cell, which is treated like a molecule. Specifically, the symmetry of the unit cell is described by one of 32 point groups. All that is presented about point groups and molecular symmetry will be directly applicable to the use of symmetry and group theory for analyses of vibrational spectra of solids. After completing the discussion of point groups and molecular symmetry, the link between point groups and vibrational spectroscopy of solids will be established.

There are a total of fourteen different types of point groups, seven with one principal axis of rotation; groups within these seven types form a series in which one group can be formed from one other group by the addition of a symmetry operation. The seven other types of point groups do not constitute a series and involve multiple axes of higher order. The symmetries of the vast number of different molecules can be completely represented by a small number of point groups.

The water molecule belongs to the point group C_{2v}, which consists of the symmetry elements $\sigma_{v(xz)}, \sigma_v(yz)$, and C_2, as illustrated in Figure 6, plus the identity operation E. Each symmetry operation can be represented by a matrix that describes how the symmetry element acts on the molecule. First, a basis function that represents the molecule is identified. Examples of basis functions for the water molecule are: (1) the 1s orbitals of the two hydrogen atoms and the 2s orbital of the oxygen atom; (2) the displacement coordinates of the molecule during normal-mode vibrations; and (3) the 1s orbitals of the hydrogen atoms and the $2p_{x,y,z}$ orbitals of oxygen. In fact, there are any number of possible basis functions, although some are more efficient and effective than others in representing the molecule. The number of functions in the basis defines the dimensions of the matrix representations of the symmetry operations. In the case of a basis consisting of three components, e.g., the two 1s orbitals of hydrogen atoms and the 2s orbital of oxygen, each matrix would be 3×3. The action of the symmetry operation on the molecule would then be provided by an equation of the form

$$[f_1 f_2 f_3] = \begin{pmatrix} d_{11} & d_{12} & d_{13} \\ d_{21} & d_{22} & d_{23} \\ d_{31} & d_{32} & d_{33} \end{pmatrix} \begin{bmatrix} 2s \\ 2s_{\mathrm{a}} \\ 1s_{\mathrm{b}} \end{bmatrix} \qquad (31)$$

where $[f_1, f_2, f_3]$ represents the basis function following the action of the symmetry operation and $1s_{\mathrm{a}}$ represents the 1s orbital on the "a" hydrogen atom. If the symmetry operation under consideration is the twofold axis of rotation,

$$D(R) = \begin{bmatrix} a & b & o \\ c & d & o \\ o & o & e \end{bmatrix} = \begin{bmatrix} a & b \\ c & d \end{bmatrix} + [e]$$

Figure 14. Matrix representation of the symmetry operation R is given as $D(R)$. In the form depicted, $D(R)$ can be visualized as the "direct sum" of a 2×2 and a 1×1 matrix.

then $[f_1, f_2, f_3]$ is $[2s, 1s_b, 1s_a]$ and the matrix representation of the twofold axis of rotation for this basis function is

$$D(C_2) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix} \tag{32}$$

In instances in which one component of the basis function is unchanged by all of the symmetry operations, each matrix representation has the form depicted in Figure 14. The matrix can be thought of as consisting of the sum of two matrices, a 1×1 matrix and a 2×2 matrix. This type of sum is not an arithmetic operation and is referred to as a "direct sum." The process of converting all of the matrices that represent each of the symmetry operations for a given basis to the direct sum of matrices of smaller dimensions is referred to as "reducing the representation." In some cases each 2×2 matrix representation of the symmetry operations is also diagonalized, and the representation can be reduced to the direct sum of two 1×1 matrices. When the matrix representations have been converted to the direct sum of matrices with the smallest possible dimensions, the process of reducing the representation is complete.

Obviously, there are an infinite number of matrix representations that could be developed for each point group, each arising from a different basis. Fortunately, and perhaps somewhat surprisingly, most of the information about the symmetry of a molecule is contained in the characters of the matrix representations. Knowledge of the full matrix is not required in order to use the symmetry of the molecule to help solve complex problems in quantum mechanics. Often, only the characters of the matrices representing the group symmetry operations are needed.

The many different matrix representations of the symmetry operations can be reduced via similarity transformations to block diagonalized form. In block diagonalized form, each matrix is seen to consist of the direct sum of a number of irreducible matrices. An irreducible matrix is one for which there is no similarity transformation that is capable of putting it into block diagonalized form. A reduced representation consists of a set of matrices, each of which represents one symmetry operation of the point group and each of which is in the identical block diagonalized form.

Now it turns out that the character of a matrix representation is the most important piece of information concerning the symmetry of the molecule, as mentioned above. The list composed of the characters of the matrix representations of the symmetry operations of the group is referred to as the symmetry species of the representation. For each point group there is a small number of unique symmetry species that are composed of the characters of irreducible matrices representing each of the symmetry operations. These special symmetry species are called irreducible representations of the point group. For each point group the number of irreducible representations is equal to the number of symmetry classes.

Remarkably, of the unlimited number of representations of a point group, corresponding to the unlimited number of bases that can be employed, the symmetry species of each representation can be expressed by a linear combination of symmetry species of irreducible representations. The list of the symmetry species of each irreducible representation therefore concisely indicates what is unique about the symmetry of the particular point group. This information is provided in character tables of the point groups.

Character Tables. The character table for the point group C_{2v} is presented in Table 1. The top row lists the symmetry elements in the point group. The second through the fourth rows list the point group irreducible representations. The first column is the symbol used to denote the irreducible representation, e.g., A_1. The numbers in the character tables are the characters of the irreducible matrix representations of the symmetry operations for the various irreducible symmetry species. The right-hand column lists basis functions for the irreducible symmetry species. For example, if x is used as a basis function for the point group C_{2v}, the matrix representations of the various symmetry operations will all be 1×1 matrices with character of 1. The resultant symmetry species, therefore, is 1, 1, 1, 1 and is labeled A_1. On the other hand, if xy is the basis function, the matrix representations of all of the symmetry operations will consist of 1×1 matrices. The resultant symmetry species is 1, 1, -1, -1 and is labeled A_2. If a function is said to have the same symmetry as x, then that function will also serve as a basis for the irreducible representation B_1 in the point group C_{2v}. There are many possible basis functions for each irreducible representation. Those listed in the character tables have special significance for the analyses of rotational, vibrational, and electronic spectra. This will be made clear below. When a function serves as a basis of a representation, it is said to span that representation.

Vibrational Selection Rules. Where group theory is especially helpful is in deciding whether or not a particular integral, taken over a symmetric range, has a nonzero value. It turns out that if the integrand can serve as a basis for the A_1, totally symmetric irreducible representation, then the integral may have a nonzero value. If the integrand does not serve as a basis for the A_1 irreducible representation, then the integral will necessarily be zero.

The symmetry species that is spanned by the products of two functions is obtained by forming the "direct product" of the symmetry species spanned by each function. Tables are available that list the direct products of all possible combinations of irreducible representations for each point group (see, e.g., Wilson et al., 1955; Bishop, 1973; Atkins, 1984; Kettle, 1987).

Thus, if we want to know whether or not a Raman transition from the ground-state vibrational mode n to the first vibrationally excited state m can occur, we need to examine the six integrals of the form

$$\int \psi_m^* \alpha_{ij} \psi_n dV \tag{33}$$

one for each of the six independent values of α_{ij} (or fewer depending on the symmetry of the molecule or crystal). If any one is nonzero, the Raman transition may occur. If all are zero, the Raman transition will be symmetry forbidden.

The Raman selection rule states that a Raman transition between two vibrational states n and m is allowed if the product $\psi_m^* \psi_n$ of the two wave functions describing the m and n vibrational states has the same symmetry species as at least one of the six components of α_{ij}. This rule reflects the fact that for the integral $\int f_1 f_2 f_3 \, dV$ to have a nonzero value when taken over the symmetric range of variables V, it is necessary that the integrand, which is the product of the three functions f_1, f_2, and f_3, must span a symmetry species that is or contains the totally symmetric irreducible representation of the point group.

The symmetry species spanned by the product of three functions is obtained from the direct product of the symmetry species of each function (see, e.g., Wilson et al., 1955; Bishop, 1973; Atkins, 1984; Kettle, 1987). For the symmetry species of a direct product to contain the totally symmetric irreducible representation, it is necessary that the two functions span the same symmetry species or have a common irreducible representation in their symmetry species. The function x^2 acts as a basis for the A_1 irreducible representation of the point group C_{2v}. A basis for the irreducible representation B_1 is given as x. The function x^2x would not span the irreducible representation A_1, and so its integral over all space would be zero. The function xz is also a basis for the irreducible representation B_1 in the point group C_{2v}. Hence, the function $xxz(=x^2z)$ spans the irreducible representation A_1 and its integral over all space could be other than zero. Thus, for the integrand to span the totally symmetric irreducible representation of the molecular point group, it is necessary that the representation spanned by the product $\psi_m^* \psi_n$ be the same as the representation spanned by α_{ij}. This last statement is extremely useful for analyzing the probability of a Stokes Raman transition from the vibrational ground state n to the first vibrational excited state m or for an anti-Stokes Raman transition from the first vibrational excited state m to the vibrational ground state n. The vibrational ground state spans the totally symmetric species. Consequently, the direct product $\psi_m^* \psi_n$ spans the symmetry species of the first vibrational excited state m. Hence, the Raman selection rule means that the symmetry species of α_{ij} must be identical to the symmetry species of the first vibrational excited state.

The symmetry of α_{ij} can be obtained by showing that it transforms under the action of a symmetry operation of the point group in the same way as a function of known symmetry. Here, α_{ij} relates p_i to α_{ij}. If a symmetry operation R is applied to the molecule/crystal, then the applied electric field is transformed to $R = \mathbf{D}(R)$, where $\mathbf{D}(R)$ is the matrix representation of R. The polarizability, which expresses the proportionality between the applied electric field and the induced polarization of the molecule/crystal, must transform in a manner related to but in general different from that of the applied electric field because the direction of $\mathbf{p}$ will generally be different from the direction of ε_j. The polarization of the crystal induced by the applied electric field is transformed to $Rp = D(R)p$ as a result of the action of the symmetry operation R. Consequently, the polarizability transforms as $RR\alpha = D(R)D(R)\alpha$. The transformation of α can be derived as follows (taken from Bishop, 1973).

If the symmetry operation R transforms the coordinate system from x to x', then (summations are over all repeated indices)

$$\begin{aligned} p_i(x') &= \sum \alpha_{ij}(x')\varepsilon_j(x') \\ &= \sum \alpha_{ij}(x') \sum D_{jk}(R)\varepsilon_k(x) \end{aligned} \tag{34}$$

$$p_l(x) = \sum D_{ml}(R) p_m(x') \tag{35}$$

$$p_l(x) = \sum D_{ml}(R) \sum \alpha_{im}(x') \sum D_{jk}(R) \; {}_k(x) \tag{36}$$

Substituting into the last equation the expression

$$p_l(x) = \sum \alpha_{lk}(x) \; {}_k(x) \tag{37}$$

gives

$$\alpha_{lk}(x) = \sum \sum D_{ml}(R) D_{jk}(R) \alpha_{mj}(x') \tag{38}$$

This describes the action of the symmetry operation R on the polarizability α.

Now,

$$x_l = \sum D_{ml}(R) x_m \tag{39}$$

and

$$x_k = \sum D_{jk}(R) x_j \tag{40}$$

so

$$x_l x_k = \sum \sum D_{ml}(R) D_{jk}(R) x_m x_j \tag{41}$$

Comparison of Equations 19 and 22 indicates that α_{lk} transforms as the function $x_l x_k$. Any symmetry species spanned by the function $x_m x_j$ will also be spanned by α_{mj}. Thus, any vibrational mode that spans the same symmetry species as $x_l x_k$ will be Raman active. This information is included in the character tables of the point groups. In the column that lists the basis functions for the various symmetry species of the point group are listed quadratic functions such as $x^2, yz, x^2 + y^2, x^2 + y^2 - 2z^2, \ldots$.

By way of illustration, the character table indicates that if a molecule with point group symmetry C_{2v} has a vibrational mode that spans the symmetry species A_1, it will be Raman active since this symmetry species is also spanned

by the quadratic function x^2. Any vibrational mode that spans a symmetry species that has at least one quadratic function (e.g., x^2, yz) as a basis will be Raman active.

Raman Active Vibrational Modes of Solids

It is now possible to illustrate how Raman spectroscopy can identify the symmetry species of the vibrational modes of a single crystal. To begin, it is important to recognize that the symmetry of a molecule may be lowered when it is part of a crystal. This can be appreciated by considering a simpler case of symmetry reduction: the change in symmetry of a sulfate anion as a consequence of its adsorption on a solid surface. As illustrated in Figure 15, the sulfate anion consists of oxygen nuclei located on the four corners of a tetrahedron and the sulfur nucleus positioned at the geometric center of the tetrahedron. The anion exhibits T_d point group symmetry. If the sulfate is adsorbed on the surface of a solid through a bond formed between the solid and one of the oxygen anions of the sulfate, then the symmetry of the sulfate is lowered to C_{3v}. If two oxygen-surface bonds are formed, in either a bridging or nonbridging configuration, the symmetry of the sulfate is further lowered to C_{2v}. When present in a crystal, a molecule or anion will exhibit either the same or lower symmetry than the free molecule or anion.

The distinctive feature of the symmetry of a crystal is the presence of translational symmetry elements. In fact, it is possible to generate the entire lattice of a crystal by the repeated operation of the three basic primitive translation vectors that define the unit cell. When all possible arrays of lattice points in three dimensions are considered, it turns out that there are only fourteen distinctive types of lattices, called Bravais lattices. The Bravais lattice may not completely describe the symmetry of a crystal. The unit cell may have an internal structure that is not completely specified by the symmetry elements of the bare lattice. The symmetry of the crystal is completely specified by its space group, which is a mathematical group that contains translational operations and that may contain as many as three additional types of symmetry elements: rotations (proper and improper), which are the point group elements, screw axes, and glide planes. The latter two elements may be conceptually subdivided into a rotation (proper = screw axis; improper = glide plane) plus a rational fraction of a primitive lattice translation.

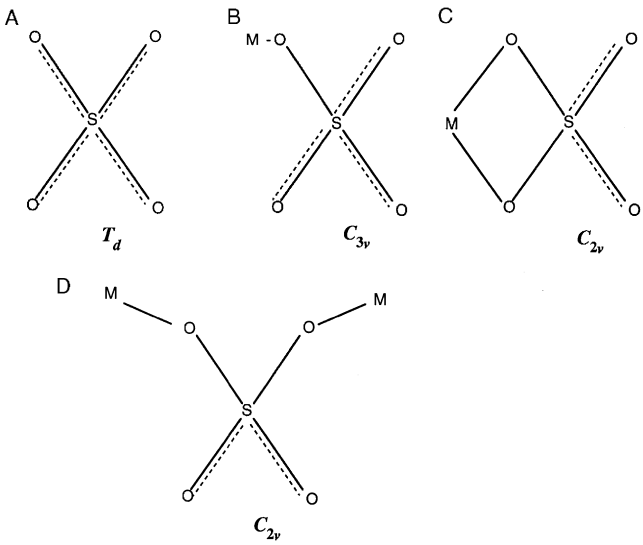

Figure 15. Influence of bonding on the symmetry of sulfate: (**A**) free sulfate; (**B**) unidentate sulfate; (**C**) bidentate sulfate; (**D**) bidentate sulfate in the bridging configuration.

Lattices can be brought into themselves by the operations of certain point groups. Each Bravais lattice type is compatible with only a particular set of point groups, which are 32 in number and are referred to as crystallographic point groups. The appropriate combinations of the 14 Bravais lattices and the 32 crystallographic point groups result in the 230 three-dimensional space groups.

The restrictions that a lattice imposes on the rotational symmetry elements of the space group can be readily illustrated. Each lattice point is located at the tip of a primitive lattice vector given by

$$\mathbf{T} = n_1\mathbf{t}_1 + n_2\mathbf{t}_2 + n_3\mathbf{t}_3 \tag{42}$$

where the $\mathbf{t}_i$ are the basic primitive translation vectors and the n_i are positive and negative integers including zero. The rotation of the lattice translates the points to new locations given by

$$\mathbf{T}' = \boldsymbol{R}T = R_{ij}n_j\mathbf{t}_j \tag{43}$$

where $R_{ij}n_j$ must be integers for all values of n_j, which are integers. Hence, the R_{ij} must be integers as well. For a proper or improper rotation of θ about the z axis,

$$\boldsymbol{R} = \begin{bmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & \pm 1 \end{bmatrix} \tag{44}$$

The requirement of integral values for each element R_{ij} means, in particular, that

$$\mathrm{Tr}\ \boldsymbol{R} = 2\cos\theta \pm 1 = \text{integer} \tag{45}$$

The plus sign corresponds to a proper rotation, while the minus sign corresponds to an improper rotation (e.g., reflection or inversion). Thus, the requirement of integral values of R_{ij} limits the possible rotation angles θ to

$$\cos\theta = (n - \pm 1)/2 \Rightarrow \theta = 0, \pi/3, \pi/2, 2\pi/3, 2\pi \tag{46}$$

Crystallographic point groups may therefore contain the following proper rotations: C_1, C_2, C_3, C_4, and C_6, where C_n indicates a rotation angle of $180^\circ/n$ about an axis of the crystal.

Within each space group is an invariant subgroup consisting of the primitive translational operations. An invariant group is one in which a conjugate transformation

produces another member of the group; i.e., if for all elements X and t of the group G, $X^{-1}tX = t'$, where t and t' are elements of the same subgroup of G, then this subgroup is an invariant subgroup of G.

A translational operation is represented by the symbol $\underline{\varepsilon}|\mathbf{t}$, which is a particular case of the more general symbol for a rotation of α followed by a translation of $\mathbf{a}$, $\underline{\alpha}|\mathbf{a}$. The notation $\underline{\varepsilon}$ represents a rotation of 0°. The invariance of the translational subgroup is demonstrated by

$$
\begin{aligned}
(\underline{\alpha}|\mathbf{a})\mathbf{x} &= \underline{\alpha}\mathbf{x} + \mathbf{a} \\
(\underline{\beta}|\mathbf{b})(\underline{\alpha}|\mathbf{a})\mathbf{x} &= \underline{\beta\alpha}\mathbf{x} + \underline{\beta}\mathbf{a} + \mathbf{b} \\
&= (\underline{\beta\alpha}|\underline{\beta}\mathbf{a} + \mathbf{b})\mathbf{x}
\end{aligned}
$$

Since $(\underline{\alpha}|\mathbf{a})^{-1}(\underline{\alpha}|\mathbf{a}) = (\underline{\varepsilon}|0)$

$(\underline{\alpha}|\mathbf{a})^{-1}$ must be given by $(\underline{\alpha}^{-1}| - \underline{\alpha}^{-1}\mathbf{a})$

$$
\begin{aligned}
(\underline{\alpha}|\mathbf{a})^{-1}(\underline{\varepsilon}|\mathbf{t})(\underline{\alpha}|\mathbf{a})\mathbf{x} &= (\underline{\alpha}|\mathbf{a})^{-1}(\underline{\varepsilon}|\mathbf{t})(\underline{\alpha}\mathbf{x} + \mathbf{a}) \\
(\underline{\alpha}|\mathbf{a})^{-1}(\underline{\alpha}\mathbf{x} + \mathbf{t} + \mathbf{a}) &= \underline{\alpha}^{-1}\underline{\alpha}\mathbf{x} + \underline{\alpha}^{-1}\mathbf{t} + \underline{\alpha}^{-1}\mathbf{a} - \underline{\alpha}^{-1}\mathbf{a} \\
&= \mathbf{x} + \underline{\alpha}^{-1}\mathbf{t} \\
&= (\underline{\varepsilon}|\underline{\alpha}^{-1}\mathrm{t})\mathbf{x} \\
&= (\underline{\varepsilon}|\mathbf{t}')\mathbf{x} \qquad (47)
\end{aligned}
$$

Thus, a conjugate transformation of a translation operator $\underline{\varepsilon}|\mathbf{t}$ using a general rotation plus translation operator $\underline{\alpha}|\mathbf{a}$ that is also a member of the group G produces another simple translation operator $\underline{\varepsilon}|\mathbf{t}'$, demonstrating that the translational subgroup is invariant to the conjugacy operation.

The invariant property of the translational subgroup is exploited quite heavily in developing expressions for the irreducible representations of space groups. The difficulty in dealing with the symmetry of a crystal and in analyzing the vibrational modes of a crystal stems from the fact that the translational subgroup is infinite in size. Stated slightly differently, a crystal consists of a large number of atoms so that the number of normal vibrational modes is huge, i.e., $\approx 10^{23}$. Fortunately, group theory provides a method for reducing this problem to a manageable size.

Most textbooks dealing with applications of group theory to crystals develop cofactor expressions for space groups. The cofactor group is isomorphic with the crystallographic point group providing the space group is symmorphic. A symmorphic space group consists of rotational and translational symmetry elements. A nonsymmorphic space group contains at least one symmetry element $(\underline{\alpha}|\mathbf{a})$ in which the rotation α, all by itself, and/or the translation $\mathbf{a}$, all by itself, are not symmetry elements of the space group. Of the 230 three-dimensional space groups, only 73 are symmorphic. Consequently, the use of factor groups is of no benefit for analyzing the vibrational modes of crystals in the 157 nonsymmorphic space groups.

Since the use of cofactor groups is so common, albeit of limited value, the approach will be summarized here and then a more general approach that addresses both symmorphic and nonsymmorphic space groups will be developed.

The translational factor group $G|T$ of the symmorphic space group G consists of

$$G|T = T + \sum s_i T \qquad (i = 2, 3, \ldots, n) \qquad (48)$$

where the s_i are the nontranslational symmetry elements except the identity element $(s_1 = E)$ of the symmorphic space group G whose crystallographic point group is of order n; T is the translational symmetry elements of G. The translational factor group is distinct from the group G because T is treated as a single entity, rather than as the infinite number of lattice translational operations that it is in the group G. The factor group has a different multiplication rule than the space group and T acts as the identity element. As long as G is symmorphic, the factor group $G|T$ is obviously isomorphic with the crystallographic point group of G. Because of the isomorphic relationship of the two groups, the irreducible representations of the crystallographic point group will also serve as the irreducible representations of the factor group $G|T$. The irreducible representations of the factor group provide all the symmetry information about the crystal that is needed to analyze its vibrational motion. On the other hand, if G is nonsymmorphic, then it contains at least one element s_j of the form $[\underline{\alpha}|\mathbf{v}(\alpha)]$, where α and/or $\mathbf{v}(\alpha)$ are not group elements. As a consequence, $G|T$ is no longer symmorphic with any crystallographic point group.

The value of this approach, which makes use of cofactor groups, is that the total number of group elements have been reduced from $g \times 10^{23}$, where g is the number of point group operations, to g. Furthermore, the factor group $G|T$ is isomorphic with the crystallographic point group. Consequently, the irreducible representations of the point group serve as irreducible representations of the factor group. How does this help in the analyses of vibrational modes? Recall that the only Raman active modes are characterized by $k = 0$ (i.e., approximately infinite wavelength) and nonzero frequency. The modes of $k = 0$ consist of corresponding atoms in each unit cell moving in phase. The number of normal modes of this type of motion is given by $3N$, where N is the number of atoms in the unit cell. The symmetry of the unit cell is just that of the factor group. Thus, the irreducible representations of the crystallographic point group provide the irreducible representations of the Raman active vibrational modes of the crystal.

As mentioned above, a more general approach to the group theoretical analysis of crystal vibrational modes will be developed in place of the use of factor groups. This approach is enunciated by Lax (1974).

The group multiplication of symmetry elements of space groups is denoted by

$$
\begin{aligned}
[\underline{\alpha}|\mathbf{v}(\alpha)][\underline{\beta}|\mathbf{v}(\beta)]\mathbf{r} &= [\underline{\alpha}|\mathbf{v}(\alpha)][\underline{\beta}\mathbf{r} + \mathbf{v}(\beta)] \\
&= \underline{\alpha\beta}\mathbf{r} + \underline{\alpha}\mathbf{v}(\beta) + \mathbf{v}(\alpha) \\
&= \underline{\alpha\beta}\mathbf{r} + \underline{\alpha}\mathbf{v}(\beta) + \mathbf{v}(\alpha) + \mathbf{v}(\alpha\beta) - \mathbf{v}(\alpha\beta) \\
&\quad \underline{\alpha\beta}\mathbf{r} + \mathbf{v}(\alpha\beta) + \underline{\alpha}\mathbf{v}(\beta) + \mathbf{v}(\alpha) - \mathbf{v}(\alpha\beta) \\
&= \alpha\beta\mathbf{r} + \mathbf{v}(\alpha\beta) + \mathbf{t} \\
\text{where} \quad \mathbf{t} &= \underline{\alpha}\mathbf{v}(\beta) + \mathbf{v}(\alpha) - \mathbf{v}(\alpha\beta) \\
&= (\underline{\varepsilon}|\mathbf{t})(\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)) \qquad (49)
\end{aligned}
$$

Next, consider the operation of $(\underline{\varepsilon}|\mathbf{t})[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]$ on a Bloch function $\exp(i\mathbf{k}\cdot\mathbf{r})u_k(\mathbf{r})$. Functions of this form serve as eigenvectors of a crystal's vibrational Hamiltonian that is expressed in normal-mode coordinates with $u_k(\mathbf{r})$ representing the displacement in the kth normal vibrational mode of the harmonic oscillator at $\mathbf{r}$ (Altmann, 1991). Therefore, the operation of two successive symmetry elements $[\underline{\alpha}|\mathbf{v}(\alpha)]$ and $[\underline{\beta}|\mathbf{v}(\beta)]$ on the Bloch function is given by

$$(\underline{\varepsilon}|\mathbf{t})[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]\exp(i\mathbf{k}\cdot\mathbf{r})u_k(\mathbf{r}) \tag{50}$$

Applying $[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]$ to both functions that constitute the Bloch function converts the above expression to

$$(\underline{\varepsilon}|\mathbf{t})\{\exp[i\mathbf{k}\cdot(\underline{\alpha\beta}|\mathbf{v}(\alpha\beta))^{-1}\cdot\mathbf{r}](\underline{\alpha\beta}|\mathbf{v}(\alpha\beta))u_k(\mathbf{r})\} \tag{51}$$

Now focus attention on the argument of the exponential in the previous expression. It may be rewritten as

$$\begin{aligned}&[i\mathbf{k}\cdot((\underline{\alpha\beta})^{-1}|-(\underline{\alpha\beta})^{-1}\mathbf{v}(\alpha\beta))\cdot\mathbf{r}]\\&\quad=[i\mathbf{k}\cdot(\underline{\alpha\beta})^{-1}\cdot[\mathbf{r}-\mathbf{v}(\alpha\beta)]]\\&\quad=[i(\underline{\alpha\beta})\mathbf{k}\cdot(\mathbf{r}-\mathbf{v}(\alpha\beta))]\end{aligned} \tag{52}$$

(1) Substituting this expression for the argument of the exponential back into Equation 51, (2) operating $\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)$ on $\mathbf{r}$ in $u_k(\mathbf{r})$, and (3) including $\underline{\varepsilon}|\mathbf{t}$ in the arguments of both functions of the Bloch function convert Equation 51 to

$$\exp\{i(\alpha\beta)\mathbf{k}\cdot(\underline{\varepsilon}|\mathbf{t})^{-1}\cdot[\mathbf{r}-\mathbf{v}(\alpha\beta)]\}u_k\{(\underline{\varepsilon}|\mathbf{t})^{-1}[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]^{-1}\mathbf{r}\} \tag{53}$$

Now,

$$u_k\{(\underline{\varepsilon}|\mathbf{t})^{-1}[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]^{-1}\mathbf{r}\}=u_k\{[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]^{-1}\mathbf{r}\} \tag{54}$$

because

$$u_k(\mathbf{r}-\mathbf{t})=u_k(\mathbf{r}) \tag{55}$$

where $\mathbf{t}$ is the lattice vector as $u_k(\mathbf{r})$ has the periodicity of the lattice. Equation 53 now becomes

$$\begin{aligned}&\exp\{i(\underline{\alpha\beta})\mathbf{k}\cdot[\mathbf{r}-\mathbf{v}(\alpha\beta)-\mathbf{t}]\}u_k\{[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]^{-1}\mathbf{r}\}\\&\exp[-i(\underline{\alpha\beta})\mathbf{k}\cdot\mathbf{t}]\exp\{i(\underline{\alpha\beta})\mathbf{k}\cdot[\mathbf{r}-\mathbf{v}(\alpha\beta)]\}u_k\{[\underline{\alpha\beta}|\mathbf{v}(\alpha\beta)]^{-1}\mathbf{r}\}\\&\exp[-i(\underline{\alpha\beta})\mathbf{k}\cdot\mathbf{t}](\underline{\alpha\beta}\mathbf{v}(\alpha\beta))\psi(\mathbf{r},\mathbf{k})\end{aligned} \tag{56}$$

where $\psi(\mathbf{r},\mathbf{k})$ is the Bloch function. At this point it is no longer possible to continue in a completely general fashion. To include in Equation 56 all possible values of $\mathbf{k}$, it would be necessary to develop two separate expressions of Equation 56: one for symmorphic space groups and the other for nonsymmorphic space groups. Alternatively, a single expression for Equation 56 can be developed for both symmorphic and nonsymmorphic space groups if we consider only one value of $\mathbf{k}$: the long-wavelength limit, $\mathbf{k}=0$. For $\mathbf{k}=0$, the above group multiplication becomes

$$(\underline{\alpha}|\mathbf{v}(\underline{\alpha}))(\underline{\beta}|\mathbf{v}(\underline{\beta}))=(\underline{\alpha\beta}|\mathbf{v}(\underline{\alpha\beta})) \tag{57}$$

which is the same group multiplication rule obeyed by symmetry elements of point groups (i.e., groups consisting of elements of the form $[\underline{\alpha}|0]$). Thus, the representations of space group elements $[\underline{\alpha}|\mathbf{v}(\alpha)]$ are identical to the representations of the point group elements $[\underline{\alpha}|0]$.

ULTRAVIOLET PHOTOELECTRON SPECTROSCOPY

INTRODUCTION

Photoemission and Inverse Photoemission

Ultraviolet photoelectron spectroscopy (UPS) probes electronic states in solids and at surfaces. It relies on the process of photoemission, in which an incident photon provides enough energy to bound valence electrons to release them into vacuum. Their energy E, momentum $\hbar\mathbf{k}$, and spin σ provide the full information about the quantum numbers of the original valence electron using conservation laws. Figure 1 depicts the process in an energy diagram. Essentially, the photon provides energy but negligible momentum (due to its long wavelength $\lambda=2\pi/|\mathbf{k}|$), thus shifting all valence states up by a fixed energy ("vertical" or "direct" transitions). In addition, secondary

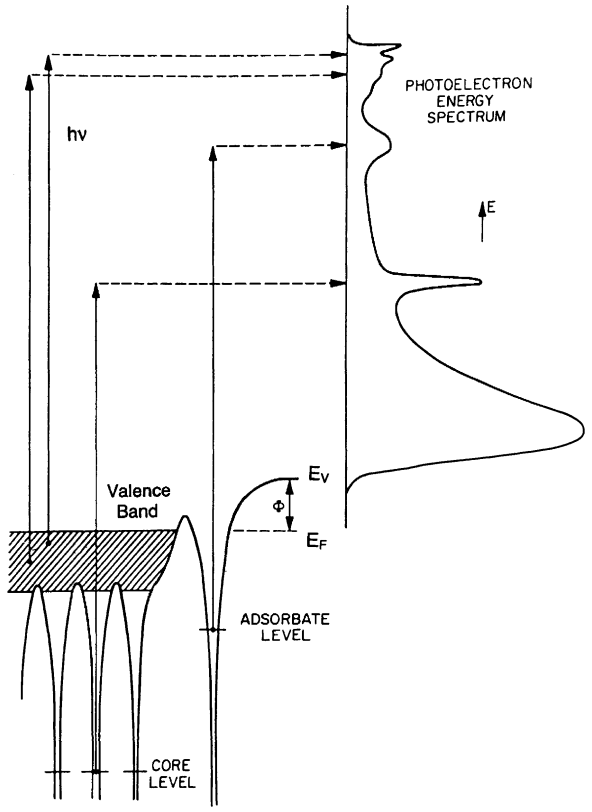

Figure 1. Photoemission process (Smith and Himpsel, 1983).

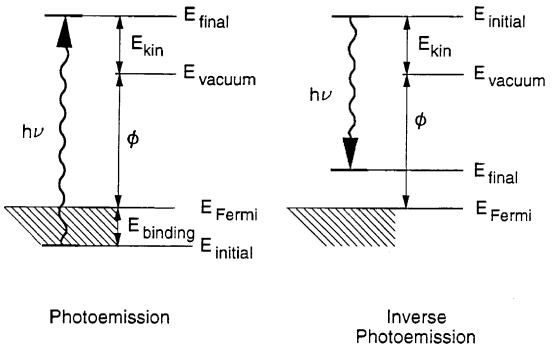

Figure 2. Photoemission and inverse photoemission as probes of occupied and unoccupied valence states: ϕ = work function (Himpsel and Lindau, 1995).

processes, such as energy loss of a photoelectron by creating plasmons or electron-hole pairs, produce a background of secondary electrons that increases toward lower kinetic energy. It is cut off at the vacuum level E_V, where the kinetic energy goes to zero. The other important energy level is the Fermi level E_F, which becomes the upper cutoff of the photoelectron spectrum when translated up by the photon energy. The difference $\phi = E_V - E_F$ is the work function. It can be obtained by subtracting the energy width of the photoelectron spectrum from the photon energy. For reviews on photoemission, see Cardona and Ley (1978), Smith and Himpsel (1983), and Himpsel and Lindau (1995). Information specific to angle-resolved photoemission is given by Plummer and Eberhardt (1982), Himpsel (1983), and Kevan (1992).

Photoemission is complemented by a sister technique that maps out unoccupied valence states, called inverse photoemission or bremsstrahlung isochromat spectroscopy (BIS). This technique is reviewed by Dose (1985), Himpsel (1986), and Smith (1988). As shown in Figure 2, inverse photoemission represents the reverse of the photoemission process, with an incoming electron and an outgoing photon. The electron drops into an unoccupied state and the energy is released by the photon emission.

Both photoemission and inverse photoemission operate at photon energies in the ultraviolet (UV), starting with the work function threshold at ~4 eV and reaching up to 50- to 100-eV photon energy, where the cross-section of valence states has fallen off by an order of magnitude and the momentum information begins to get blurred. At kinetic energies of 1 to 100 eV, the electron mean free path is only a few atomic layers, making it possible to detect surface states as well as bulk states.

Characterization of Valence Electrons

In atoms and molecules, the important parameters characterizing a valence electron are its binding energy (or ionization potential) plus its angular momentum (or symmetry label in molecules). This information is augmented by the vibrational and rotational fine structures, which shed light onto the interatomic potential curves (Turner et al., 1970). In a solid, it becomes necessary to consider not only energy but also momentum. Electrons in a crystalline solid are completely characterized by a set of quantum numbers. These are energy E, momentum $\hbar\mathbf{k}$, point group symmetry (i.e., angular symmetry), and spin. This information can be summarized by plotting $E(\mathbf{k})$ band dispersions with the appropriate labels for point group symmetry and spin. Disordered solids such as random alloys can be characterized by average values of these quantities, with disorder introducing a broadening of the band dispersions. Localized electronic states (e.g., the 4*f* levels of rare earths) exhibit flat $E(\mathbf{k})$ band dispersions. Angle-resolved photoemission, combined with a tunable and polarized light source, such as synchrotron radiation, is able to provide the full complement of quantum numbers. In this respect, photoemission and inverse photoemission are unique among other methods of determining the electronic structure of solids.

Before getting into the details of the technique, its capabilities are illustrated in Figure 3, which shows how much information can be extracted by various techniques about the band structure of Ge. Optical spectroscopy integrates over the momentum and energy of the photoelectron and leaves only the photon energy $h\nu$ as variable. The resulting spectral features represent regions of momentum and energy space near critical points at which the density of transitions is high (Fig. 3A). By adjusting an empirical band structure to the data (Chelikowski and Cohen, 1976; Smith et al., 1982), it is possible to extract rather accurate information about the strongest critical points. Angle-integrated photoemission goes one step further by detecting the electron energy in addition to the photon energy (Fig. 3B). Now it becomes possible to sort out whether spectral features are due to the lower state or the upper state of the optical transition. To extract all the information on band dispersion, it is necessary to resolve the components of the electron momentum parallel and perpendicular to the surface, $\mathbf{k}^{\parallel}$ and $k^{\perp}$, by angle-resolved photoemission with variable photon energy (Fig. 3C).

Photoemission and inverse photoemission data can, in principle, be used to derive a variety of electronic properties of solids, such as the optical constants [from the $E(\mathbf{k})$ relations; see Chelikowski and Cohen (1976) and Smith et al. (1982)], conductivity (from the optical constants), the electron lifetime [from the time decay constant τ or from the line width δE; see Olson et al. (1989) and Haight (1995)], the electron mean free path [from the attenuation length λ or from the line width δk; see Petrovykh et al. (1998)], the group velocity of the electrons [via the slope of the $E(\mathbf{k})$ relation; see Petrovykh et al. (1998)], the magnetic moment (via the band filling), and the superconducting gap (see Olson et al., 1989; Shen et al., 1993; Ding et al., 1996).

Energy Band Dispersions

How are energy band dispersions determined in practice? A first look at the task reveals that photoemission (and inverse photoemission) provides just the right number of independent measurable variables to establish a unique correspondence to the quantum numbers of an electron in a solid. The energy E is obtained from the kinetic energy of the electron. The two momentum components parallel to

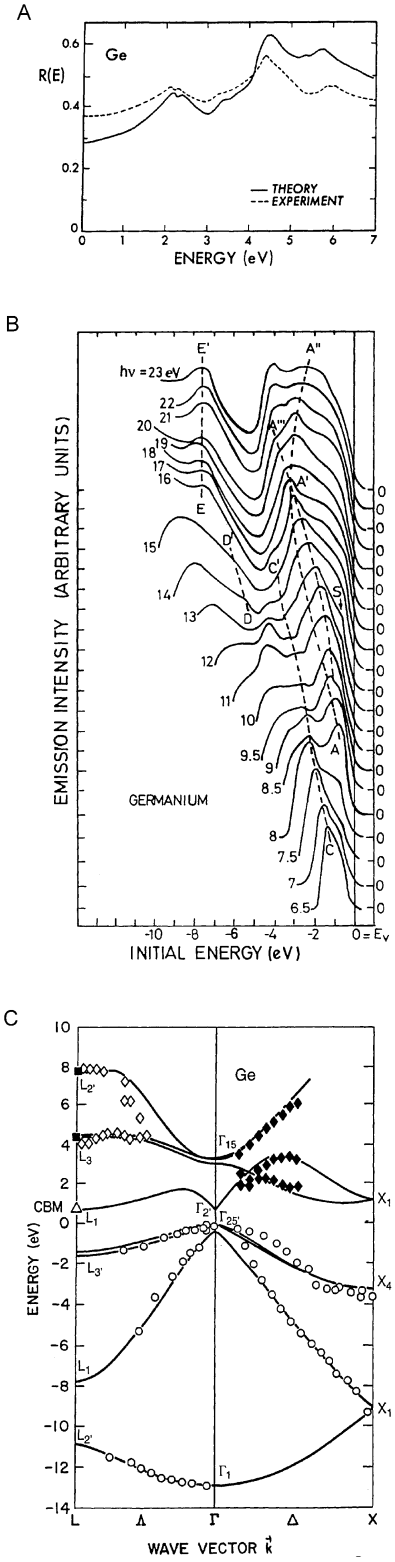

Figure 3. Comparison of various spectroscopies applied to the band structure of germanium. (**A**) The optical reflectivity $R(E)$ determines critical points near the band gap, (**B**) angle-integrated photoemission adds critical points farther away, and (**C**) angle-resolved photoemission and inverse photoemission provide the full $E(\mathbf{k})$ band dispersion (Phillip and Ehrenreich, 1963; Grobman et al., 1975; Chelikowski and Cohen, 1976; Wachs et al., 1985; Hybertsen and Louie, 1986; Ortega and Himpsel, 1993).

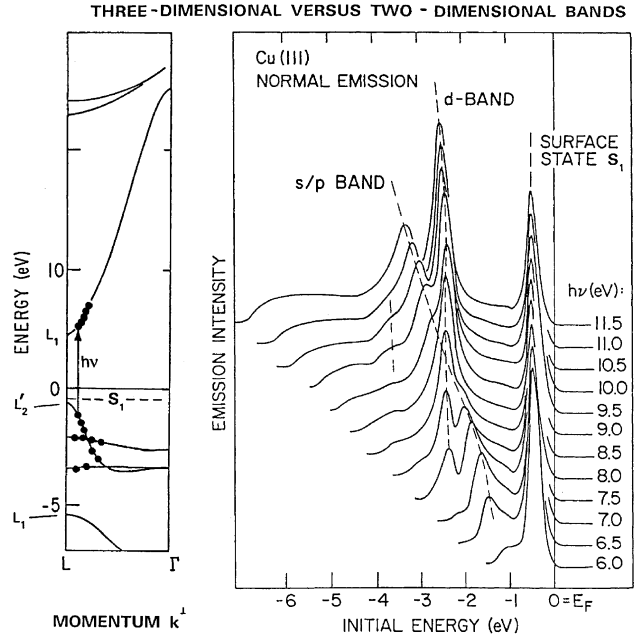

Figure 4. Mapping bulk and surface bands of copper by angle-resolved photoemission. Variable photon energy from monochromatized synchrotron radiation makes it possible to tune the $\mathbf{k}$ component perpendicular to the surface $k^{\perp}$ and to distinguish surface states from bulk states by their lack of $k^{\perp}$ dispersion (Knapp et al., 1979; Himpsel, 1983).

the surface, $\mathbf{k}^{\parallel}$, are derived from the polar and azimuthal angles ϑ and ϕ of the electron. The third momentum component, $k^{\perp}$, is varied by tuning the photon energy $h\nu$. This can be seen in Figure 4, in which angle-resolved photoemission spectra at different photon energies hν are plotted together with the relevant portion of the band structure. The parallel momentum component $\mathbf{k}^{\parallel}$ is kept zero by detecting photoelectrons in normal emission; the perpendicular component $k^{\perp}$ changes as the photon energy of the vertical interband transitions is increased. A complete band structure determination requires a tunable photon source, such as synchrotron radiation (or a tunable photon detector in inverse photoemission). Surface states, such as the state near E_F, labeled S_1 in Figure 4, do not exhibit a well-defined $k^{\perp}$ quantum number. Their binding energy does not change when the $k^{\perp}$ of the upper state is varied by changing $h\nu$. This lack of $k^{\perp}$ dispersion is one of the characteristics of a surface state. Other clues are that a surface state is located in a gap of bulk states with the same $\mathbf{k}^{\parallel}$ and the surface state is sensitive to contamination. To complete the set of quantum numbers, one needs the point group symmetry and the spin in ferromagnets. The former is obtained via dipole selection rules from the polarization of the photon, the latter from the spin polarization of the photoelectron.

For two-dimensional (2D) states in thin films and at surfaces, the determination of energy bands is almost trivial since only E and $\mathbf{k}^{\parallel}$ have to be determined. These quantities obey the conservation laws

$$E_1 = E_u - h\nu \qquad (1)$$

and

$$\mathbf{k}_1^{\parallel} - \mathbf{k}_u^{\parallel} - \mathbf{g}^{\parallel} \qquad (2)$$

where $\mathbf{g}^{\parallel}$ is a vector of the reciprocal surface lattice, u denotes the upper state, and l the lower state. These conservation laws can be derived from the invariance of the crystal with respect to translation in time and in space (by a surface lattice vector). For the photon, only its energy $h\nu$ appears in the balance because the momentum of a UV photon is negligible compared to the momentum of the electrons. The subtraction of a reciprocal lattice vector simply corresponds to plotting energy bands in a reduced surface Brillouin zone, i.e., within the unit cell in $\mathbf{k}^{\parallel}$ space. For a three-dimensional (3D) bulk energy band, the situation becomes more complicated since the momentum component perpendicular to the surface is not conserved during the passage of the photoelectron across the surface energy barrier. However, $k^{\perp}$ can be varied by changing the photon energy $h\nu$, and extremal points, such as the Γ and L points in Figure 4, can thus be determined. A discussion of the practical aspects and capabilities of various band mapping schemes is given below (see Practical Aspects of the Method) and in several reviews (Plummer and Eberhardt, 1982; Himpsel, 1983; Kevan, 1992). Experimental energy bands are compiled in Landolt-Börnstein (1989, 1994).

In ferromagnets the bands are split into two subsets, one with majority spin, the other with minority spin (see Fig. 5). The magnetic exchange splitting δE_{ex} between majority and minority spin bands is the key to magnetism. It causes the majority spin band to become filled more than the minority band, thus creating the spin imbalance that produces the magnetic moment. An overview of the band structure of ferromagnets and magnetic thin-film structures is given in Himpsel et al. (1998).

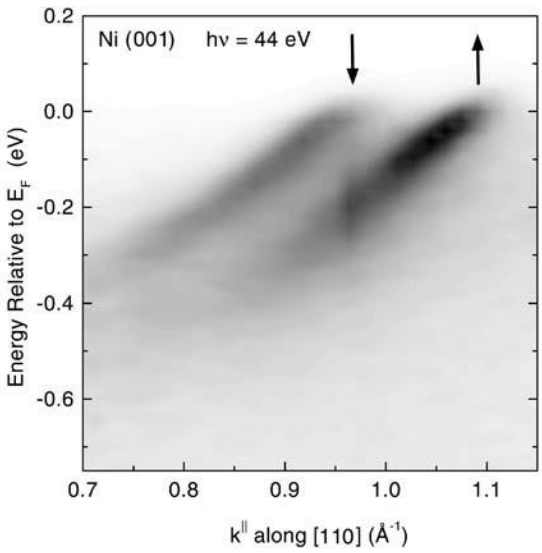

Figure 5. Using multidetection of energy and angle to map out the $E(\mathbf{k})$ band dispersion of Ni near the Fermi level E_F from a Ni(001) crystal. The majority and minority spin bands are split by the ferromagnetic exchange splitting δE_{ex}. High photoemission intensity is shown in dark (Petrovykh et al., 1998).

Competitive and Related Techniques

The relation of UPS to optical spectroscopy has been mentioned in the context of Figure 3 already. Several other spectroscopies involve core levels but provide information about valence electrons as well. Figure 6 shows the simplest processes, which involve transitions between two levels only, one of them a core level. More complex phenomena involve four levels, such as Auger electron spectroscopy (see AUGER ELECTRON SPECTROSCOPY) and appearance potential spectroscopy.

Core-level photoelectron spectroscopy determines the energy of a core level relative to the Fermi level E_F (Fig. 6A) and is known as x-ray photoelectron spectroscopy (XPS) or electron spectroscopy for chemical analysis (ESCA). A core electron is ionized, and its energy is obtained by subtracting the photon energy

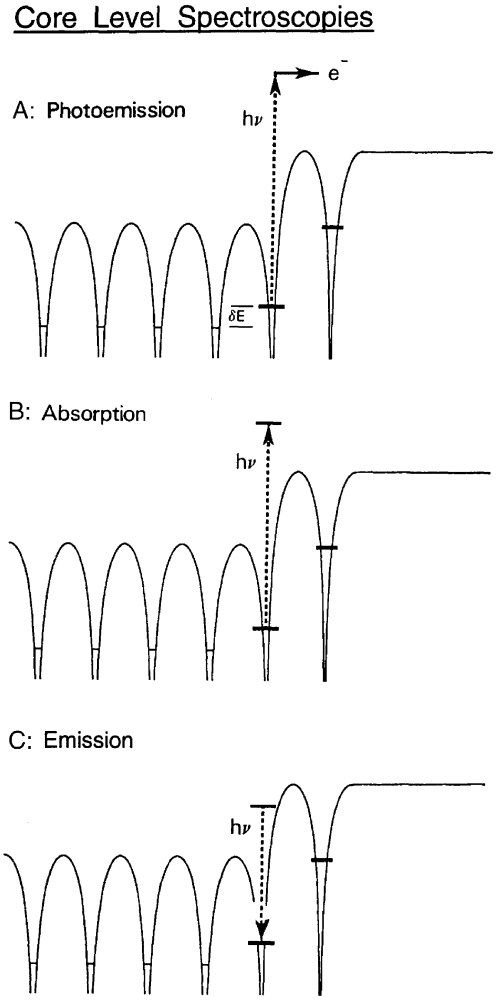

Figure 6. Spectroscopies based on core levels. (**A**) X-ray photoelectron spectroscopy measures the binding energy of core levels, (**B**) core-level absorption spectroscopy detects transitions from a core level into unoccupied valence states, and (**C**) core-level emission spectroscopy detects transitions from occupied valence states into a core hole. In contrast to UPS, these spectroscopies are element-specific but cannot provide the full momentum information.

from the kinetic energy of the photoelectron. The energy shifts of the substrate and adsorbate levels are a measure of the charge transfer and chemical bonding at the surface.

Core-level absorption spectroscopy determines the pattern of unoccupied orbitals by exciting them optically from a core level (Fig. 6B). It is also known as near-edge x-ray absorption fine structure (NEXAFS; see XAFS SPECTROSCOPY) or x-ray absorption near-edge structure (XANES). Instead of measuring transmission or reflectivity, the absorption coefficient is determined in surface experiments by collecting secondary products, such as photoelectrons, Auger electrons, and core-level fluorescence. The short escape depth of electrons compared to photons provides surface sensitivity. These spectra resemble the density of unoccupied states, projected onto specific atoms and angular momentum states. In a magnetic version of this technique, magnetic circular dichroism (MCD), the difference in the absorption between parallel and antiparallel alignment of the electron and photon spin is measured. Compared to UPS, the momentum information is lost in core-level absorption spectroscopy, but element sensitivity is gained. Also, the finite width of the core level is convolved with the absorption spectrum and limits the resolution.

Core-level emission spectroscopy can be viewed as the reverse of absorption spectroscopy (Fig. 6C). Here, the valence orbital structure is obtained from the spectral distribution of the characteristic x rays emitted during the recombination of a core hole with a valence electron. The core hole is created by either optical or electron excitation. As with photoemission and inverse photoemission, core-level emission spectroscopy complements core-level absorption spectroscopy by mapping out occupied valence states projected onto specific atoms.

PRINCIPLES OF THE METHOD

The Photoemission Process

The most general theory of photoemission is given by an expression of the golden rule type, i.e., a differential cross-section containing a matrix element between the initial and final states ψ_i and ψ_f and a phase space sum (see Himpsel, 1983; Dose, 1985; Smith, 1988):

$$\frac{d\sigma}{d\Omega} \sim \sqrt{E_{\text{kin}}} \sum_i |\langle \Psi_f | \mathbf{A} \cdot \mathbf{p} + \mathbf{p} \cdot \mathbf{A} | \Psi_i \rangle|^2 \times \delta(E_f - E_i - h\nu) \tag{3}$$

The factor $\sqrt{E_{\text{kin}}}$ containing the kinetic energy E_{kin} of the photoelectron represents the density of final states, the scalar product of the vector potential $\mathbf{A}$ of the photon and the momentum operator $\mathbf{p} = -i\hbar\partial/\partial\mathbf{r}$ is the dipole operator for optical excitation, and the δ function represents energy conservation. This is often called the one-step model of photoemission, as opposed to the three-step model, which approximates the one-step model by a sequence of three simpler steps. For practical purposes (see Practical Aspects of the Method; Himpsel, 1983), we have to consider mainly the various selection rules inherent in this expression, such as the conservation of energy (Equation 1), parallel momentum (Equation 2), and spin, together with the point group selection rules. Since there is no clear-cut selection rule for the perpendicular momentum, it is often determined approximately by using a nearly free electron final state.

While selection rules provide clear yes-no decisions, there are also more subtle effects of the matrix element that can be used to bring out specific electronic states. The atomic symmetry character determines the energy dependence of the cross-section (Yeh and Lindau, 1985), allowing a selection of specific orbitals by varying the photon energy. For example, the *s,p* states in transition and noble metals dominate the spectra near the photoelectric threshold, while the *d* states turn on at 10 eV above threshold. It takes photon energies of 30 eV above threshold to make the *f* states in rare earths visible. Resonance effects at a threshold for a core-level excitation can also enhance particular orbitals. Conversely, the cross-section for states with a radial node exhibits so-called Cooper minima, at which the transitions become almost invisible.

The wave functions of the electronic states in solids and at surfaces are usually approximated by the ground-state wave functions obtained from a variety of schemes, e.g., empirical tight binding and plane-wave schemes (Chelikowski and Cohen, 1976; Smith et al., 1982) and first-principles local density approximation (LDA; see Moruzzi et al., 1978; Papaconstantopoulos, 1986). Strictly speaking, one should use the excited-state wave functions and energies that represent the hole created in the photoemission process or the extra electron added to the solid in the case of inverse photoemission. Such quasiparticle calculations have now become feasible and provide the most accurate band dispersions to date, e.g., the so-called *GW* calculations, which calculate the full Green's function *G* of the electron/hole and the fully screened Coulomb interaction *W* but still neglect vertex and density gradient corrections (Hybertsen and Louie, 1986; see also BONDING IN METALS). Particularly in the case of semiconductors the traditional ground-state methods are unable to determine the fundamental band gap from first principles, with Hartree-Fock overestimating it and LDA underestimating it, typically by a factor of 2. The band width comes out within 10% to 20 % in LDA calculations.

Various types of wave functions can be involved in the photoemission process, as shown in Figure 7. The states that are propagating in the solid lead to vertical transitions that conserve all three momentum components and are being used for mapping out bulk bands. Evanescent states conserve the parallel momentum only and are more sensitive to the surface. At elevated temperatures one has to consider phonon-assisted transitions, which scramble the momentum information about the initial state completely.

The materials property obtained from angle-integrated UPS is closely related to the density of states and is often interpreted as such. Strictly speaking, one measures

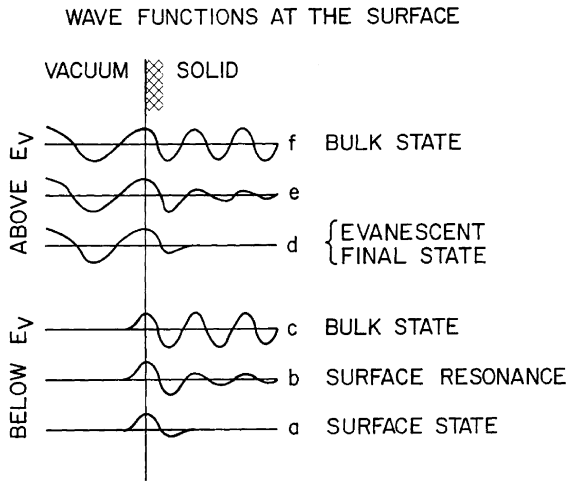

Figure 7. Various types of wave functions encountered in UPS. Propagating bulk states give rise to transitions that conserve all three $\mathbf{k}$ components; evanescent states ignore the $k^{\perp}$ component (Smith and Himpsel 1983).

the energy distribution of the joint density of initial and final states, which includes the optical matrix element (Grobman et al., 1975). Angle-resolved UPS spectra provide the $E(\mathbf{k})$ band dispersions that characterize electrons in a solid completely. Since the probing depth is several atomic layers in UPS, it is possible to determine these properties for the bulk as well as for the surface.

Energy Bands in Solids

The mapping of energy bands in solids and at surfaces is based on the conservation laws for energy and parallel momentum (Equations 1 and 2). Figures 3, 4, and 5 give examples. Presently, energy bands have been mapped for practically all elemental solids and for many compounds. Such results are compiled in Landolt-Börnstein (1989, 1994). For the ferromagnets, see Himpsel et al. (1998). Since energy band dispersions comprise the full information about electrons in solids, all other electronic properties can in principle be obtained from them. Such a program has been demonstrated for optical properties (Chelikowski and Cohen, 1976; Smith et al., 1982). For ferromagnetism, the most significant band parameters are the exchange splitting δE_{ex} between majority and minority spin bands and the distance between the top of the majority spin d bands and the Fermi level (Stoner gap). The exchange splitting is loosely related to the magnetic moment ($\sim$1 eV splitting per Bohr magneton), the Stoner gap to the minimum energy for spin flip excitations (typically from a few tenths of an electron volt down to zero).

Surface States

The electronic structure of a surface is characterized by 2D energy bands that give the relation between E and $\mathbf{k}^{\parallel}$. The momentum perpendicular to the surface, $k^{\perp}$, ceases to be a good quantum number. The states truly specific to the surface are distinguished by their lack of interaction with bulk states, which usually requires that they are located at points in the $E(\mathbf{k}^{\parallel})$ diagram where bulk states of the same symmetry are absent. This is revealed in band diagrams where the $E(\mathbf{k}^{\parallel})$ band dispersions of surface states are superimposed on the regions of bulk bands projected along $k^{\perp}$.

On metals, one finds fairly localized, d-like surface states and delocalized s,p-like surface states. The d states carry most of the spin polarization in ferromagnets. Their cross-section starts dominating relative to s,p states as the photon energy is increased. An example of an s,p-like surface state is given in Figure 4. On the Cu(111) surface a p_z-like surface state appears close to the Fermi level (S_1). It is located just above the bottom of the L_2'-L_1 gap of the bulk s, p band. A very basic type of s,p surface state is the image state in a metal. The negative charge of an electron outside a metal surface induces a positive image charge that binds the electron to the surface. In semiconductors, surface states may be viewed as broken bond orbitals.

Electronic Phase Transitions

The electronic states at the Fermi level are a crucial factor in many observed properties of a solid. States within a few kT of the Fermi level determine the transport properties, such as electrical conductance, where k is the Boltzmann constant and T the temperature in kelvin. They also drive electronic phase transitions, such as superconductivity, magnetism, and charge density waves. Typically, these phase transitions open a gap at the Fermi level of a few multiples of kT_C, where T_C is the transition temperature. Occupied states near the Fermi level move down in energy by half the gap, which lowers the total energy. In recent years, the resolution of UPS experiments has reached a level where sub-kT measurements have become nearly routine. The best-known examples are measurements of the gap in high-temperature superconductors (Olson et al., 1989; Shen et al., 1993; Ding et al., 1996). Compared to other techniques that probe the superconducting gap, such as infrared absorption and tunneling, angle-resolved photoemission provides its $\mathbf{k}$ dependence.

Atoms and Molecules

Atoms and molecules in the gas phase exhibit discrete energy levels that correspond to their orbitals. There is an additional fine structure due to transitions between different vibrational and rotational states in the lower and upper states of the photoemission process. This fine structure disappears when molecules are adsorbed at surfaces. Nevertheless, the envelope function of the molecular orbitals frequently survives and facilitates the fingerprinting of adsorbed species. A typical molecular photoelectron spectrum is shown in Figure 8 (Turner et al., 1970), a typical spectrum of an adsorbed molecular fragment in Figure 9 (Sutherland et al., 1997).

Ultraviolet photoelectron spectroscopy has been used to study surface reactions in heterogeneous catalysis and

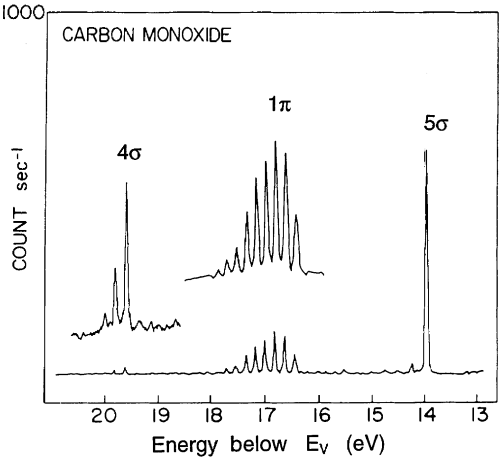

Figure 8. UPS spectrum of the free CO molecule, showing several molecular orbitals and their vibrational fine structure. Note that the reference level is the vacuum level E_V for atoms and molecules, whereas it is the Fermi level E_F for solids (Turner et al., 1970).

in semiconductor surface processing. For example, the methyl and ethyl groups adsorbed on a silicon surface in Figure 9 exhibit the same C 2*s* orbital splittings as in the gas phase (compare Pireaux et al., 1986), allowing a clear identification of the fragments that remain on the surface after reaction with dimethylsilane and diethylsilane. Generally, one distinguishes the weak adsorption on inert surfaces at low temperatures (physisorption regime) and strong adsorption on reactive surfaces at room temperature (chemisorption). During physisorption, molecular orbitals are shifted rigidly toward higher energies by 1 to 2 eV due to dielectric screening of the valence holes created in the photoemission process. Essentially, surrounding electrons in the substrate lower their energy by moving toward the valence hole on the adsorbate molecule, generating extra energy that is being transferred to the emitted photoelectron. In the chemisorption regime, certain molecular orbitals react with the substrate and experience an additional chemical shift. A well-studied example is the adsorption of CO on transition metals, where the chemically active 5σ orbital is shifted relative to the more inert 4σ and 1π orbitals. The orientation of the adsorbed molecules can be determined from the angle and polarization dependence of the UPS spectra using dipole selection rules. If the CO molecule is adsorbed with its axis perpendicular to the surface and photoelectrons are detected along that direction, the σ orbitals are seen with the electric field vector **E** of the light along the axis and the π orbitals with **E** perpendicular to it. Similar selection rules apply to mirror planes and make it possible to distinguish even and odd wave functions.

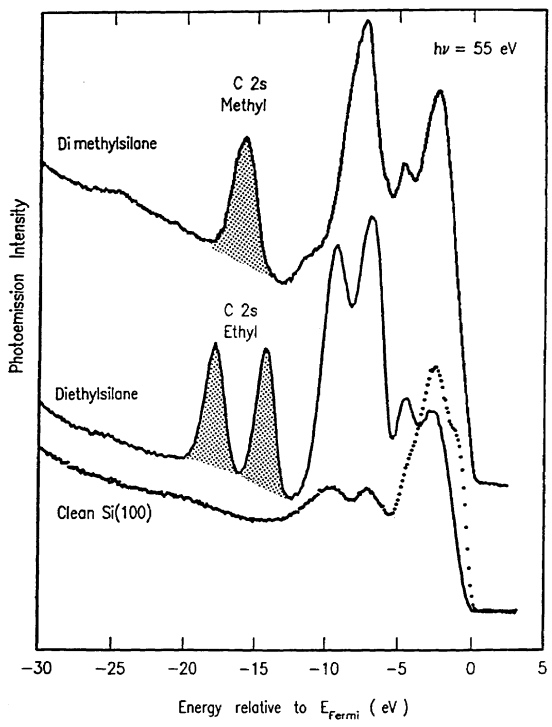

Figure 9. Fingerprinting of methyl and ethyl groups deposited on a Si(100) surface via reaction with dimethylsilane and diethylsilane. The lowest orbitals are due to the C 2*s* electrons. The number of carbon atoms in the chain determines the number of C 2*s* orbitals (Sutherland et al., 1997).

PRACTICAL ASPECTS OF THE METHOD

Light Sources

To be able to excite photoelectrons across a valence band that is typically 10 to 20 eV wide, the photon energy has to exceed the valence band width plus the work function (typically 3 to 5 eV). This is one reason conventional lasers have been of limited applicability in photoelectron spectroscopy, except for two-photon pump-probe experiments with short pulses (Haight, 1995). The most common source of UV radiation is based on a capillary glow discharge using the He(I) line. It provides monochromatic radiation at 21.2 eV with a line width as narrow as 1 meV (Baltzer et al., 1993; a powerful electron cyclotron resonance source is marketed by Gammadata). This radiation originates from the 2*p*-to-1*s* transition in neutral He atoms. Emission can also be produced from He ions, whose primary He(II) emission line is at an energy of 40.8 eV. Similarly, emission lines of Ne(I) at 16.8 eV and Ne(II) at 26.9 eV are being used in photoelectron spectroscopy.

During the last two decades, synchrotron radiation has emerged both as a powerful and convenient excitation source in photoelectron spectroscopy (Winick and Doniach, 1980; Koch, 1983; Winick et al., 1989, some synchrotron light sources are listed in Appendix A). Synchrotron radiation is emitted by relativistic electrons kept in a circular orbit by bending magnets. In recent years, undulators have been developed that contain 10 to 100 bends in a row. For a well-focused electron beam and a highly perfect magnetic field, photons emitted from all bends are superimposed coherently. In this case, the amplitudes add up, as opposed to the intensities, and a corresponding increase in spectral brilliance by 2 to 4 orders of magnitude is

achievable. The continuous synchrotron radiation spectrum shifts its weight toward higher energies with increasing energy of the stored electrons and increasing magnetic fields. A variety of electron storage rings exists worldwide that are dedicated to synchrotron radiation. Three spectral regions can be distinguished by their scientific scope: For the photon energies of 5 to 50 eV required by UPS, storage ring energies of 0.5 to 1 GeV combined with undulators are optimum. For core-level spectroscopies at 100- to 1000-eV photon energy, a storage ring energy of 1.5 to 2 GeV is the optimum. For studies of the atomic structure of solids, even shorter wavelengths are required, which correspond to photon energies of 5 to 10 keV and storage ring energies of 6 to 8 GeV combined with an undulator. Bending magnets emit higher photon energies than undulators due to their higher magnetic field. Synchrotron radiation needs to be monochromatized for photoelectron spectroscopy. The typical range of UPS is covered best by normal-incidence monochromators, which provide photon energies up to $\sim$30 eV with optimum intensity and up to $\sim$50 eV with reduced intensity, while suppressing higher energy photons from higher order diffracted light and harmonics of the undulators. Resolutions of better than 1 meV are routinely achievable now. Synchrotron radiation has a number of desirable properties. The most widely utilized properties are a tunable photon energy and a high degree of polarization. Tunable photon energy is necessary for reaching the complete momentum space by varying $k^{\perp}$, for distinguishing surface from bulk states, and for adjusting relative cross-sections of different orbitals. Linear polarization (in the plane of the electron orbit) is critical for determining the point group symmetry of electrons in solids. Circular polarization (above and below the orbit plane) allows spin-specific transitions in magnetic systems.

Some synchrotron facilities are listed in Appendix A, and figures of merit to consider regarding light sources and detectors for UPS are listed in Appendix B.

Electron Spectrometers

The most common type of photoelectron spectrometers have been the cylindrical mirror analyzer (CMA) for high-throughput, angle-integrated UPS and the hemispherical analyzer for high-resolution, angle-resolved UPS. Popular double-pass CMAs were manufactured by PHI. With hemispherical spectrometers, resolutions of $<$3 meV are achievable with photoelectrons. A recent high-resolution model is the Scienta analyzer developed in Uppsala (Martensson et al., 1994; marketed by Gammadata). As the energy resolution of spectrometers improves, the sample temperature needs to be reduced to take full advantage of that resolution for solid-state samples. For example, the thermal broadening of the Fermi edge is $\sim$0.1 eV at room temperature. Temperatures below 10 K are required to reach the limits of today's spectrometers. With increasing energy and angular resolution, the throughput of electron spectrometers drops dramatically. This can be offset by parallel detection. Energy multidetection in hemispherical analyzers has become a widely available option. It is possible to detect an angle together with the energy in hemispherical and toroidal analyzers. Such a 2D scheme consists of a channel plate electron multiplier with optical readout. An example is given in Figure 5, where the band structure of Ni is mapped using a hemispherical Scienta analyzer with multidetection of the energy and the polar angle (Petrovykh et al., 1998). Other designs detect two angles simultaneously and display the angular distribution of monochromatized photoelectrons directly on a channel plate using an ellipsoidal electron mirror combined with a spherical retarding grid (Eastman et al., 1980). Photoemission intensity distributions over an 85° emission cone can be acquired in a few seconds at an undulator synchrotron light source.

To detect the spin of photoelectrons, one typically measures the right/left asymmetry in the electron-scattering cross-section at heavy nuclei (Mott scattering) after accelerating photoelectrons to 20 to 100 keV (Burnett et al., 1994). Less bulky detectors use scattering at the electron cloud surrounding a heavy nucleus, typically at 100- to 200-eV electron energy. This can be achieved by random scattering or by diffraction at a single crystal. Such detectors lack the absolute calibration of a Mott detector. Generally, spin detection costs 3 to 4 orders of magnitude in detection efficiency.

Alignment Procedures

The electron spectrometer needs to be aligned with respect to the light source (such as a synchrotron beam) and the sample with respect to the electron spectrometer. These seemingly straightforward steps can take a substantial amount of time and may lead to artifacts by inexperienced users, such as a strongly energy- and angle-dependent transmission of the spectrometer. Residual electric and magnetic fields in the sample region make the alignment more difficult and prevent low-energy electrons of a few electron volts from being detected. Electrostatic deflection plates in the spectrometer lens speed up the alignment.

First, the light beam needs to intersect the spectrometer axis at the focal point of the spectrometer. A course alignment can be achieved by using a laser beam along the axis of the spectrometer and zero-order light at a synchrotron. Hemispherical spectrometers often have small holes in the hemispheres for that purpose. The two beams can be brought to intersect at a target sample. If they do not cross each other, there will not be any sample position for a reasonable spectrum. To move the intersection point to the focal point, it is useful to have mechanical alignment markers, such as wire cross-hairs for sighting the proper distance from the front lens of the spectrometer.

Second, the sample needs to be placed at the intersection of the light beam and the analyzer axis. Again, the laser and the light beam can be utilized for this purpose. If they are not available (e.g., when bringing in a new sample into a prealigned spectrometer), a systematic optimization of the photoemission intensity can be used: First, set the sample at the focal distance from the analyzer, as determined by the cross-hairs. Then translate the sample in the two directions orthogonal to the analyzer axis and determine the cutoff points for the photoemission intensity

at opposite edges of the sample and place the sample half way in between.

These alignment procedures provide a first approximation, but residual fields and an uncertain position of the ultraviolet photon beam on the sample require a symmetry check for acquiring accurate angle-resolved UPS data. Mirror symmetry with respect to crystallographic planes provides the exact normal emission geometry and the azimuthal orientation of the sample.

Useful Relations

Some relations occur frequently when processing UPS data. In the following we list the most common ones:

The energy $h\nu$ of a photon is given (in electron volts) by its wavelength λ (in angstroms) via

$$\lambda = \frac{12399}{h\nu} \tag{4}$$

The wave vector $k = |\mathbf{k}|$ of an electron is given (in reciprocal angstroms) by its kinetic energy E_{kin} (in electron volts) via

$$k = 0.51\sqrt{E_{\text{kin}}} \tag{5}$$

The inverse of this relation is

$$E_{\text{kin}} = 3.81 \times k^2 \tag{6}$$

For determining $k^{\perp}$, the upper energy bands are often approximated by the "empty lattice" bands, which are given by

$$E = V + 3.81 \times (k \pm |g|)^2 \tag{7}$$

where k is in reciprocal angstroms and E in electron volts, V is the inner potential (typically -10 eV relative to the vacuum level or -5 eV relative to the Fermi level), and $\mathbf{g}$ (also in reciprocal angstroms) is a reciprocal lattice vector determined by the spacing d_{plane} of equivalent atomic planes:

$$|\mathbf{g}| = \frac{2\pi}{d_{\text{plane}}} \quad \mathbf{g} \perp \text{planes} \tag{8}$$

Likewise, a reciprocal surface lattice vector $\mathbf{g}^{\parallel}$ is determined by the spacing d_{row} of equeivalent atomic rows:

$$|\mathbf{g}| = \frac{2\pi}{d_{\text{row}}} \quad \mathbf{g} \perp \text{rows} \tag{9}$$

The empty lattice approximation used in Figure 10 and Equation 7 improves at higher photon energies (>30 eV), where the kinetic energy of the photoelectrons becomes large compared to the Fourier components of the lattice

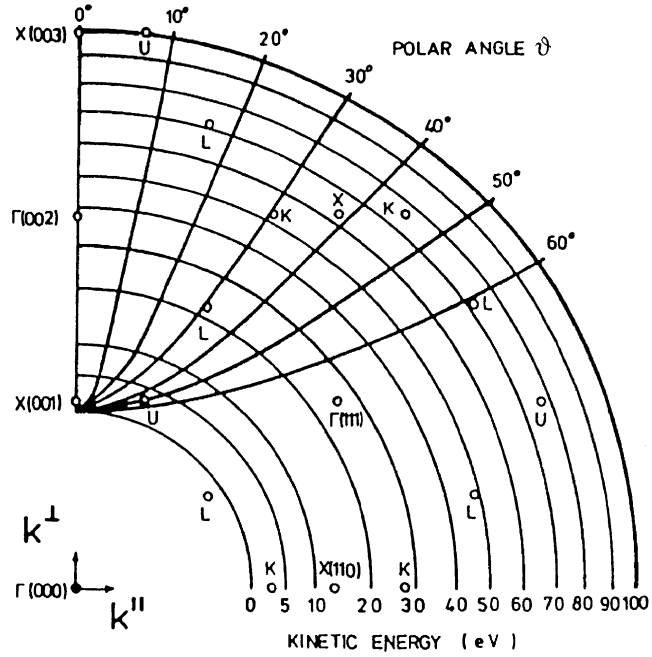

Figure 10. Location of direct transitions in **k** space, shown for a Ni(001) surface along the [110] emission azimuth. The circular lines represent the location of possible upper states at a given kinetic energy using empty lattice bands. The lines fanning out toward the top represent different emission angles from the [001] sample normal (Himpsel, 1983).

potential.Various "absolute" methods are available to refine the **k** values. These methods determine the $k^{\perp}$ component by triangulation from different crystal faces or by mirror symmetry properties of high-symmetry lines (see Plummer and Eberhardt, 1982; Himpsel, 1983; Kevan, 1992).

The thermal broadening of the Fermi function that cuts off photoelectron spectra at high energy is proportional to kT. Taking the full width at half-maximum of the derivative of the Fermi function, one obtains a width $3.5kT$, which is 0.09 eV at room temperature and 1 meV at liquid He temperature. The half-height points of the derivative correspond to the 15% and 85% levels of the Fermi function.

Sensitivity Limits

A typical measurement volume in UPS is an area 1 mm^2 times a depth of 1 nm. In photoelectron microscopes, it is possible to reduce the sampling area to dimensions of <0.1 μm. Several types of such microscopes have been tested in recent years. Imaging devices accelerate the photoelectrons to ~20 keV and use regular electron microscope optics to form an image. In scanning microscopes, the sample is scanned across a finely focused ultraviolet light and soft x-ray source. In both cases, the photoelectron energy analysis has been rather rudimentary so far. Most contrast mechanisms utilized to date involved core levels or work function differences, and not fine structure in the valence band.

The sensitivity to dilute species is rather limited in UPS due to the substantial background of secondary electrons (see Fig. 1). A surface atom density of 10^{14} cm^{-2} (about a tenth of a monolayer) is relatively easy to detect, a concentration of 10^{13} cm^{-2} is the limit. A much higher signal-to-background ratio can be achieved by core-level emission spectroscopy (see Fig. 6C).

The time resolution can be as short as tens of femtoseconds in pump-probe two-photon photoemission experiments using fast lasers (Haight, 1995).

METHOD AUTOMATION

While the sample preparation is highly individual in UPS, the actual data acquisition can be automated easily. A few voltages are sufficient to control a photoelectron spectrometer, such as the kinetic energy and the pass energy. The photon energy is controlled by a monochromator at a synchrotron light source, which in most cases is computer controlled. Labview has become a widely used control system. The angular parameters can be set by stepping motors that drive goniometers for the sample and the spectrometer, with a maximum of five axes, three for the sample and two for the spectrometer. Typically, the acquisition of a series of spectra is preprogrammed. They start out with a wide kinetic energy range at high photon energy, which gives an overview of all valence states, plus some shallow core levels for elemental characterization. Subsequent spectra zero in on specific states, such as adsorbate orbitals or Fermi-level crossings. For each of them, one wants to step through a variety of emission angles and photon energies to vary the parallel and perpendicular momenta, respectively.

DATA ANALYSIS AND INITIAL INTERPRETATION

The first look at UPS spectra from a new sample is typically reserved for making sure that the surface is not contaminated. For example, oxygen contamination generates a characteristic O 2*p* peak at ~6 eV below the Fermi level in metals. Then one might want to compare the spectrum to a set of published reference spectra from related materials or molecules. This "fingerprinting" often gives a quick overview of the energies of specific orbitals, such as *d* states in transition metals, *f* states in rare earths, and adsorbate orbitals. When in doubt, the photon energy dependence of the cross-section can be utilized to enhance certain orbitals by resonant photoemission at core-level thresholds (e.g., *f* levels) or to quench them at Cooper minima (e.g., orbitals with radial nodes).

The next step is often a determination of the Fermi-level position from the high-energy cutoff of a metallic sample, such as Au or Pt. A fit of the Fermi-Dirac function convoluted by a Gaussian resolution function over the uppermost few tenths of an electron volt gives an accurate Fermi-level position.

After characterizing the sample by angle-integrated UPS, the full $E(\mathbf{k})$ band dispersion is obtained from the variation with angle and photon energy. Usually, the starting point is normal emission at various photon energies, which provides the $E(k^{\perp})$ relation along a high-symmetry line. This geometry features the strictest selection rules and, therefore, is the easiest to interpret. An example is given in Figure 4, where a series of normal emission spectra at various photon energies (on the right side) is converted into a set of energy bands (on the left side). The k values of the data points on the left are obtained from the peak positions on the right (dashed lines) after adding the photon energies and converting the resulting upper state energies E_u into $k^{\perp}$ using the calculated upper band on the left (cf. Equation 1). Alternatively, one could use the somewhat cruder empty lattice bands from Equation 7.

By switching the polarization of the electric field vector of the photons between parallel and perpendicular to the surface (the latter asymptotically), different orbital orientations can be selected, such as $p_{x,y}$ and p_z, respectively. In normal emission, for example, the $p_{x,y}$ bands are excited by the component of the electric field vector in the x,y directions (parallel to the sample surface), and the p_z states are excited by the z component normal to the surface.

Having covered normal emission, it is useful to vary the polar angle within a mirror plane perpendicular to the surface, where the wave functions still exhibit even/odd symmetry properties. Here, orbitals that are even with respect to the mirror plane are excited by the in-plane electric field component, and odd orbitals are excited by the component perpendicular to the mirror plane.

Off-normal photoemission peaks can be assigned to transitions at specific $\mathbf{k}$ points by using Equations 5 to 7, as in Figure 10. Taking the data in Figure 5 as example, let us follow a typical processing sequence. The data in Figure 5 are taken from a Ni(001) crystal in the (110) emission plane using a photon energy $h\nu = 44$ eV. In the raw data, the Fermi-level crossings occur at a voltage $V_{\text{spectr}} \approx 40$ V on the electron spectrometer and at a polar angle $\vartheta \approx 18°$ from the sample normal. The spectrometer voltage yields a kinetic energy $E_{\text{kin}} \approx 40$ eV when discounting work function differences between spectrometer and sample (see below). From E_{kin} and ϑ, one obtains a parallel wave vector $k^{\parallel} = k \sin\vartheta \approx 1$ Å^{-1} via Equation 5. Going with E_{kin} and $k^{\parallel}$ into Figure 10, one finds the location of the transition in $\mathbf{k}$ space as the intersection of the circle for $E_{\text{kin}} \approx 40$ eV and the vertical line for $k^{\parallel} = 1$ Å^{-1}. The k scale in Figure 10 is in units of $2\pi/a = 1.8$ Å^{-1} (a = cubic lattice constant of Ni). Consequently, the transition happens about half way on a horizontal line between $\Gamma(002)$ and K, where a line for $\vartheta = 18°$ would intersect the circle for $E_{\text{kin}} = 40$ eV.

It should be noted that the energy scale provided by the voltage reading of an electron spectrometer is referred to the vacuum level of the spectrometer and not to that of the sample. A contact potential develops spontaneously between the sample and the spectrometer that compensates for the difference in work functions and accelerates or retards the photoelectrons slightly toward the analyzer. Such a contact potential needs to be compensated for accurate angular measurements of slow photoelectrons (a few electron volts). A typical spectrometer work function is 4 eV, so samples with smaller work functions require

negative bias and samples with larger work function positive bias. The optimum bias is determined such that the vacuum-level cutoff coincides with a zero voltage reading on the spectrometer. A negative sample bias of a few volts is often used for moving the spectrum up in energy when determining the sample work function from the difference between the photon energy and the width of the photoelectron spectrum (Fig. 2).

With two-dimensional detectors, such as the E, ϑ detection of the hemispherical analyzer (Martensson et al., 1994; Petrovykh et al., 1998; Fig. 5) and the ϑ, φ detection of the ellipsoidal mirror analyzer (Eastman et al., 1980), one needs to divide by the two-dimensional transmission function of the spectrometer to obtain quantitative data. An approximate transmission function can be achieved by increasing the photon energy at identical spectrometer settings, such that secondary electrons are detected whose angular distribution is weak. Careful alignment of sample and light source with respect to the spectrometer and thorough shielding from magnetic and electric fields minimize transmission corrections. After obtaining the 2D intensity distributions $I(E, \vartheta)$ and $I(\vartheta, \varphi)$ and converting ϑ, φ into $\mathbf{k}^{\|}$, one is able to generate $I(\mathbf{k}^{\|})$ distributions. These are particularly useful at the Fermi level, where the features are sharpest and the the electronic states relevant for electronic transport, magnetism, and superconductivity are located.

SAMPLE PREPARATION

Well-characterized surfaces are essential for reliable UPS data. In general, data from single crystals (either in bulk form or as epitaxial films) are more reliable than from polycrystalline materials. Single-crystal surfaces can be cleaned of adsorbed molecules and segregated bulk impurities more thoroughly and can be characterized by diffraction methods, such as low-energy electron diffraction (LEED) and reflection high-energy electron diffraction (RHEED). Surface impurities are monitored by Auger electron spectroscopy or by various core-level spectroscopies, including photoemission itself (see Fig. 6). A wide variety of methods have been developed for preparing single-crystal surfaces, with treatments specific to individual materials and even specific crystal faces. Many of them are compiled by Musket et al. (1982; see also SAMPLE PREPARATION FOR METALLOGRAPHY).

Metals are typically sputter annealed, whereby impurities are removed from the surface by Ar^+ ion bombardment (typically 1 keV at a few microamperes of current and an Ar pressure of 5×10^{-5} Torr). Bulk impurities continue to segregate to the surface and are sputtered away one monolayer at a time, a process that can take months to complete. Therefore, many chemical methods have been developed to deplete the bulk more quickly of impurities. For example, the typical impurities C, N, O, and S can be removed from a catalytically active surface, such as Fe, by heating in 1 atm of hydrogen, which forms volatile CH_4, NH_3, H_2O, and H_2S. Careful electropolishing can also go a long way in removing damage from mechanical polishing and producing a highly perfect surface after just a few sputter anneals, particularly for the soft noble metals. Highly reactive metals such as rare earths, actinides, and early transition metals are prepared in purest form as epitaxial films on a W(110) surface, where they can also be removed by simple heating to make room for a new film.

Semiconductors can be cleaved or heated above the desorption point of the native oxide. Only the crystal orientations with the lowest surface energy cleave well, such as Ge(111), Si(111), and GaAs(110). On silicon, the native oxide film of $\sim$10 Å thickness desorbs at $\sim$1050°C. Dipping into ultrapure 10% HF solution removes the oxide and leaves a mostly H-terminated surface that can be cleaned at 850°C and below. If carbon is present at the surface, it forms SiC particles upon heating that require a flash to 1250°C for diffusing carbon away from the surface into the bulk.

Insulator surfaces are most perfect if they can be obtained by cleavage, which produces the electrically neutral surfaces, e.g., (100) for the NaCl structure and (111) for the CaF_2 structure. Sputter annealing tends to deplete ionic insulators of the negative ion species.

Layered compounds such as graphite, TaS_2, or certain high-temperature superconductors are easiest to prepare. A tab is glued to the front surface with conductive, vacuum-compatible epoxy and knocked off in vacuum. A Scotch tape will do the same job but needs to be kept out of the ultrahigh-vacuum chamber.

If only polycrystalline samples are available, one sometimes needs to resort to cruder cleaning methods, such as filing in vacuum with a diamond file. It is not clear, however, how much of the surface exposed by filing consists of grain boundaries with segregated contamination.

Sample mounting needs to be matched to the preparation method. Samples can be clamped down by spring clips or spotwelded to wires. The material for the springs or wires should not diffuse along the sample surface. Molybdenum is a widely useful spring material that remains elastic even at high temperatures. Tantalum spotwelds very well and diffuses little. Heating can be achieved ohmically or by electron bombardment. The former is better controllable; the latter makes it easier to reach high temperatures. It is particularly difficult to mount samples that require high-temperature cleaning (such as W) but have to be cooled and insulated electrically as well. In such a case, the sample is attached to a cryostat via a sapphire plate that insulates electrically but conducts the heat at low temperature. Most of the temperature drop during heating occurs at W heating wires that attach the sample to a copper plate on top of the sapphire. For high-resolution measurements, it is helpful to minimize potential fluctuations around the sample by painting the area surrounding the sample with graphite using an Aquadag spray. This method is also used to coat the surfaces of electron spectrometers seen by the electrons. Insulating samples need special mounting to avoid charging. Often, the sample potential stabilizes itself after a few seconds of irradiation and leads to a shifted spectrum with reduced kinetic energies. Mounting an electron flood gun near the sample can provide zero-kinetic-energy electrons that compensate the charging. Alternatively, mild heating of the sample may create thermal carriers to provide sufficient conductivity.

Molecules for adsorption experiments are admitted through leak valves that allow gas dosing with submonolayer control. A dosage of 1 s at 10^{-6} Torr (= 1 Langmuir = 1 L) corresponds to every surface atom being exposed to about one gas molecule. The probability of an arriving molecule to stick to the surface (the sticking coefficient) ranges from unity down to 10^{-3} in typical cases.

PROBLEMS

Potential problems can arise mainly due to insufficient sample preparation and mounting. Ultraviolet photoelectron spectroscopy is a surface-sensitive technique that probes only a few atomic layers and thus detects surface contamination and structural defects with uncanny clarity. A thorough literature search is advisable on preparation methods for the particular material used. Insulating samples need charging compensation. Certain semiconductor surfaces produce a significant photovoltage at low temperature, which leads to an energy shift. The determination of the emission angle from purely geometrical sample alignment often is not accurate due to deflection of the photoelectrons by residual fields. A symmetry check is always advisable.

On the instrumentation side, there are a variety of lesser pitfalls. If the sample and spectrometer are not aligned properly to the light beam, the spectra can be highly distorted by energy- and angle-dependent transmission. A typical example is the loss of intensity for slow electrons near the vacuum level. It is important to have a clearly thoughtout alignment procedure, such as the one described above. Residual magnetic and electric fields have the same effect, e.g., due to insufficient magnetic shielding and charging insulators in the sample region, respectively. Another artifact is the flattening of intense photoemission peaks due to a saturation of the electron detector. The channeltron or channelplate multipliers used for electron detection have a rather clearly defined saturation point where the voltage drop induced by the signal current reduces the applied high voltage and thus reduces the gain. Low-resistance "hot" channel plates have higher saturation count rates, which can be as large as 10^7 counts/s for large plates. The high-resolution capability of hemispherical analyzers is easily degraded by incorrect electrical connections, such as ground loops or capacitive pickup. It may be necessary to use a separation transformer for the electronics.

Finally, the photoemission process itself is not always straightforward to interpret. Many different types of wave functions involved are in UPS (see Fig. 7). Some of them conserve all $\mathbf{k}$ components (direct transitions between bulk states), others conserve $\mathbf{k}^{\|}$ only (evanescent states), and phonon-assisted transitions do not conserve $\mathbf{k}$ at all. That leaves quite a few options for the assignment of spectral features that have led to long-standing controversies in the past, such as direct versus indirect transitions. Many years of experience with well-defined single-crystal surfaces and support from calculations of photoemission spectra have made it possible to sort out the various processes, as long as a full set of data at various photon energies, angles, and surface orientations is available. Such complexity is inherent in a process that is capable of determining all the details of an electron wave function.

Brief introduction to UPS and its applications

APPENDIX A: SYNCHROTRON LIGHT SOURCES

A complete list of the dozens of synchrotron radiation sources worldwide would go beyond the scope of this unit. The following list gives typical machines that are optimized for either valence states (10- to 100-eV photon energy, "VUV") or shallow core levels (100- to 1000-eV photon energy, "Soft X-ray"):

United States: ALS, Berkeley, CA (Soft X-ray); NSLS UV ring, Brookhaven, NY (VUV); SRC, Madison, WI (VUV).

Europe: BESSY, Berlin, Germany (VUV, Soft X-ray); ELETTRA, Trieste, Italy (Soft X-ray); MAX-Lab, Lund, Sweden (VUV, Soft X-ray).

Asia: Photon Factory, Tsukuba, Japan (Soft X-ray); SRRC, Hsinchu, Taiwan (Soft X-ray).

Some Companies that Carry UPS Equipment

In general, companies that specialize in equipment for ultra-high-vacuum and surface science carry UPS equipment as well, such as He lamps and spectrometers. Companies that provide equipment at the high end of the line are (1) Gammadata (formerly Scienta), PO Box 15120, S-750 15 Uppsala, Sweden, http://www.gammadata.se (also has the unique ECR He lamp) and (2) Omicron (bought out VSW, a previous supplier of hemispherical analyzers), Idsteiner Str. 78, D-65232 Taunusstein, Germany, http:// www.omicron.de. Companies that have equipment in the middle range are (3) PHI (in the United States, used to sell CMAs, also selling hemispherical analyzers) and (4) Staib (in Germany, sells a CMA).

The problem with naming particular companies in this field is the volatile nature of this business. Companies are bought out and spun off frequently. Up-to-date information can usually be found at trade shows associated with conferences such as the AVS (American Vacuum Society) fall conference and the APS (American Physical Society) March meeting.

APPENDIX B: FIGURE OF MERIT FOR LIGHT SOURCES AND DETECTORS

Liouville's theorem of the conservation of the volume in phase space, $(\delta x\ \delta y\ \delta z)(\delta k_x\ \delta k_y\ \delta k_z)$, dictates the ultimate limitations of light sources and electron spectrometers. Applying this theorem to electron and photon beams, one realizes that reducing the cross-section of a beam causes its angular divergence to increase (at fixed energy). Likewise, when electrons are retarded to a low-pass energy in a spectrometer to obtain better energy resolution, the effective source size goes up (with a hemispherical retarding grid) or the divergence increases (in a retarding lens).

Applied to light sources, one can define spectral brilliance (or brightness) as the photon flux divided by the

emission solid angle, source area, and the energy band width $\delta E/E$. Typical bending magnet values are 10^{13} photons/(s $\times$ mrad^2 $\times$ mm^2 $\times$ 0.1%). Undulators provide 10^2 to 10^4 times the spectral brilliance of bending magnets. Applied to electron storage rings for synchrotron radiation, one uses the emittance (cross-section times angular spread) of the stored electron beam as a measure of beam quality, with the lowest emittance electron beam providing the highest gain in spectral brilliance at an undulator. Brilliance is important for microresolved UPS. Flux is often the relevant quantity for ordinary UPS, particularly when spin resolved, in which case only a good photon energy resolution is required. To achieve this, light needs to be squeezed only in one dimension through the entrance slit of a monochromator.

For electron spectrometers, the relevant figure of merit is étendue, i.e., the source area times the solid angle accepted by the spectrometer at a given resolving power $E/\delta E$. Normal-incidence electron optics provides a large étendue (see Eastman et al., 1980). Likewise, large physical dimensions increase the étendue (Baltzer et al., 1993).

ELLIPSOMETRY

INTRODUCTION

Ellipsometry, also known as reflection polarimetry or polarimetric spectroscopy, is a classical and precise method for determining the optical constants, thickness, and nature of reflecting surfaces or films formed on them. Ellipsometry derives its name from the measurement and tracking of elliptically polarized light that results from optical reflection. Typical experiments undertaken with this technique consist of measuring the changes in the state of polarization of light upon reflection from the investigated surfaces. Since this technique is very sensitive to the state of the surface, many experiments that involve such surface changes can be detected and followed. Hence ellipsometry finds applicability in a wide variety of fields, such as physical and chemical adsorption; corrosion; electrochemical or chemical formation of passive layers on metals, oxides, and polymer films; dissolution; semiconductor growth; and immunological reactions (Hayfield, 1963; Archer, 1964; Arsov, 1985; Hristova et al., 1997).

The main strength of this technique lies in its capability not only to allow *in situ* measurements and provide information about the growth kinetics of thin films but also simultaneously to allow the determination of many or all of the optical parameters necessary to quantify the system (Martens et al., 1963; Zaininger and Revesz, 1964; Schmidt, 1970). Ellipsometry can be used to detect and follow film thickness in the monoatomic range, which is at least an order of magnitude smaller than what can be studied by other optical methods (e.g., interferometry and reflection spectroscopy). The basic theory and principles of ellipsometry have been described by a number of authors. The original equations of ellipsometry given by Drude (1889) and various other authors have been reviewed by Winterbottom (1946), who has described straightforward procedures for determining the thickness and optical constants of films on reflecting surfaces. Heavens (1955) and Vasicek (1960) have also discussed the exact and approximate solution procedures for measuring optical constants.

When linearly polarized light having an arbitrary electric field direction is reflected from a surface, the resultant light is elliptically polarized due to the difference in phase shifts for the components of the electric field that are parallel and perpendicular to the plane of incidence. According to the principle of reversibility, light of this resultant ellipticity, when incident on a reflecting surface, should produce linearly polarized light. This is the principle under which the ellipsometer operates. The angle of incidence of light, its wavelength, and the ellipticity of the incident light are related by means of certain theoretical relations to the optical parameters of the substrate and any film that might exist on it. By knowing the optical properties of the substrate and by carrying out ellipsometric measurements, one can find the thickness of a film and its refractive index with relative ease based on certain well-known relations that will be described in the next section.

Ellipsometry can be broadly divided into two categories. One class of ellipsometry, called null ellipsometry, concerns itself with performing a zero signal intensity measurement of the light beam that is reflected from the sample. In the other class of ellipsometry, measurements of the ellipticity and intensity of light reflected from the sample are performed and correlated to the sample properties. This technique is referred to as photometric ellipsometry. The techniques and methodology described in this unit will concentrate mainly on the principles of null ellipsometry. However, references to the photometric techniques will be provided in those cases where they would provide an advantage over nulling methods.

Two parameters that are measured in ellipsometry are the change in relative amplitude and relative phase of two orthogonal components of light due to reflection. The relative, rather than absolute, measurement is one reason for the high resolution of ellipsometry. The other arises from the measured quantities usually being azimuth angles (rotation around an optical axis) that can easily be measured with high resolution (0.01°). The availability of high-speed computers and comprehensive software algorithms have also generated interest in ellipsometry measurements (Cahan and Spainer, 1969; Ord, 1969).

PRINCIPLES OF THE METHOD

Reflecting Surfaces

Let us consider a thin-film reflecting surface as shown in Figure 1. Consider that a monochromatic light beam is incident on the substrate at an angle of 45°. This incident beam can be resolved into two orthogonal components, one

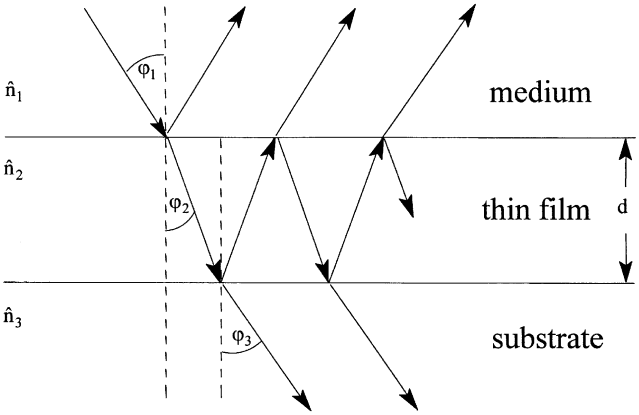

Figure 1. Reflection and refraction of light at a planar thin-film covered metal surface (d = film thickness).

in the plane of incidence, denoted by p, and the other perpendicular to it, denoted by s. The beam obtained after the reflection from the substrate (and film) will be shifted in phase and amplitude in both the p and s components. If we denote the phase shift in the parallel component by δ^s p and the perpendicular component by δ^S, the phase shift between the p and s components can then be written as

$$\Delta = \delta^p - \delta^s \tag{1}$$

The amplitudes of these two waves will also be different from their initial amplitudes, and their ratio can be written as

$$\tan\psi = \frac{E_{\mathrm{r}}^{\mathrm{p}}}{E_{\mathrm{r}}^{\mathrm{s}}} \tag{2}$$

It is these two parameters, the relative phase difference (Δ) and the ratio of the relative amplitudes ($\tan\psi$) between the parallel and perpendicular components of an electromagnetic wave that is reflected from a film-covered surface, that one obtains from ellipsometric experiments. Both the phase and amplitude shifts occur at each boundary between regions of different optical properties. The final amplitude of the wave that is observed by an analyzer is a sum from multiple reflecting layers. Hence, the reflected wave will depend on the properties of both the thin film and the substrate.

The sum of the difference in amplitudes between the parallel and perpendicular components of a multiply reflected beam is obtained using the well-known Fresnel reflection coefficients (Azzam and Bashara, 1977).

For Figure 1, the Fresnel coefficients can be calculated as follows. From the known value of the incidence angle φ_1 at the boundary between air (or a suitable medium in which the sample is immersed during the experiment) and the film, the cosine of refraction angle φ_2 can be calculated by Snell's law (Menzel, 1960):

$$\cos\varphi_2 = \left[1 - \left(\frac{\hat{n}_1}{\hat{n}_2}\sin\varphi_1\right)^2\right]^{0.5}, \tag{3}$$

where $\hat{n}_1$ and $\hat{n}_2$ are the complex refractive indices of media 1 and 2, respectively (Brown, 1965). One can then determine a complex reflection coefficient at each interface, 1-2 and 2-3, as the ratio of the magnitude of the electric vectors in a single orientation (either parallel or perpendicular) before and after reflection. It can be seen that there will be two reflection coefficients at each interface, one for the parallel and another for the perpendicular component of the reflected and incident light. These two components for the reflection between interfaces 1 and 2 are

$$r_{1,2,\mathrm{p}} = \frac{E_{\mathrm{r}}^{\mathrm{p}}}{E_1^{\mathrm{p}}} = \frac{\hat{n}_2\cos\varphi_1 - \hat{n}_1\cos\varphi_2}{\hat{n}_2\cos\varphi_1 + \hat{n}_1\cos\varphi_2} \tag{4}$$

$$r_{1,2,s} = \frac{E_{\mathrm{r}}^{\mathrm{s}}}{E_1^{\mathrm{s}}} = \frac{\hat{n}_1\cos\varphi_1 - \hat{n}_1\cos\varphi_2}{\hat{n}_1\cos\varphi_1 + \hat{n}_1\cos\varphi_2} \tag{5}$$

In a similar manner, the refraction angle at the boundary between the film and the substrate can be calculated as

$$\cos\varphi_3 = \left[1 - \left(\frac{\hat{n}_1}{\hat{n}_3}\sin\varphi_1\right)^2\right]^{0.5} \tag{6}$$

and

$$r_{2,3,\mathrm{p}} = \frac{\hat{n}_3\cos\varphi_2 - \hat{n}_2\cos\varphi_3}{\hat{n}_3\cos\varphi_2 + \hat{n}_2\cos\varphi_3} \tag{7}$$

$$r_{2,3,\mathrm{s}} = \frac{\hat{n}_2\cos\varphi_2 - \hat{n}_3\cos\varphi_3}{\hat{n}_2\cos\varphi_2 + \hat{n}_3\cos\varphi_3} \tag{8}$$

The four reflection coefficients given above are called Fresnel's reflection coefficients, after Augustin Fresnel. These reflection coefficients can be combined to give two total reflection coefficients, one for the parallel and another for the perpendicular component:

$$r_p = \frac{r_{1,2,p} + r_{2,3,p}\exp(-2i\delta)}{1 + r_{1,2p}r_{2,3,p}\exp(-2i\delta)} \tag{9}$$

and

$$r_s = \frac{r_{1,2,s} + r_{2,3,s}\exp(-2i\delta)}{1 + r_{1,2s}r_{2,3,s}\exp(-2i\delta)} \tag{10}$$

where

$$\delta = 2\pi\hat{n}_2\frac{d_2}{\lambda}\cos\varphi_2 \tag{11}$$

These total reflection coefficients r_p and r_s also include the contributions of partial reflections from the immersion medium/film and film/substrate. The ratio of these two reflection coefficients is denoted as ρ and is also related to the relative phase shift parameter Δ and the relative amplitude attenuation parameter ψ by the following fundamental equation in ellipsometry:

$$\rho = \frac{r_p}{r_{\mathrm{s}}} = \tan\psi\exp(i\Delta) \tag{12}$$

Hence, combining the above two equations, one can relate the parameters ψ and δ into the optical parameters of the surface and the substrate as

$$\tan\psi\exp(i\Delta) = \frac{r_{1,2,\mathrm{p}} + r_{2,3,\mathrm{p}}\exp(-2i\delta)}{1 + r_{1,2,\mathrm{p}}r_{2,3,\mathrm{p}}\exp(2i\delta)} \frac{1 + r_{1,2,\mathrm{s}}r_{2,3,\mathrm{s}}\exp(-2i\delta)}{r_{1,2,\mathrm{s}} + r_{2,3,\mathrm{s}}\exp(2i\delta)} \tag{13}$$

The values of Δ and ψ are determined from the ellipsometric experiments and can hence be used to determine the ratio of the reflection coefficients. Subsequently, they can be used through Equation 13 to determine the optical properties of the surface or film of interest.

The following paragraphs provide some equations that can be used to determine various physical parameters that are of interest in a sample, such as reflectivity, refractive index, dielectric constants, and optical conductivity. The derivations for these properties are not presented since it is beyond the scope of this unit.

Reflectivity

Reflectivity is defined as the quotient of reflected energetic flux to incident energetic flux, and is given as

$$R_{\mathrm{s}} = \frac{(p - n_0\cos\varphi)^2 + q^2}{(p + n_0\cos\varphi)^2 + q^2} \tag{14}$$

and

$$R_{\mathrm{p}} = R_{\mathrm{s}}\tan^2\psi \tag{15}$$

where

$$p = n_0\tan\varphi\sin\varphi\frac{\cos 2\psi}{1 + \sin 2\varphi\cos\Delta} \tag{16}$$

and

$$p = n_0\tan\varphi\sin\varphi\frac{\sin 2\psi\sin\Delta}{1 + \sin 2\psi\cos\Delta} \tag{17}$$

Here, R_p and R_s denote the reflectivity along the parallel and perpendicular components, respectively, φ is the angle of incidence of the light beam, and n_0 is the refractive index of the surrounding media in which the reflected surface is located (for air $n_0 = 1$).

Optical Constants

The complex refractive index $\hat{n}$ is represented as

$$\hat{n} = n - ik \tag{18}$$

Here n and k represent the index of refraction (real part) and the index of extinction (imaginary part), respectively. The following equations can be used for the calculation of n and k through ellipsometric parameters Δ, ψ and the angle of incidence φ for bare surfaces without the presence of any film or impurities at the surface:

$$n^2 - k^2 = n_0^2\sin^2\varphi\left[1 + \frac{\tan^2\varphi(\cos^2 2\psi - \sin^2\psi\sin^2\Delta)}{(1 + \sin 2\psi\cos\Delta)^2}\right] \tag{19}$$

and

$$2nk = \frac{n_0^2\sin^2\varphi\tan^2\varphi\sin 4\psi\sin\Delta}{(1 + \sin 2\psi\cos\Delta)^2} \tag{20}$$

Dielectric Constants

The complex dielectric function $\hat{\varepsilon}$ is given as

$$\hat{\varepsilon} = \varepsilon_1 + i\varepsilon_2 \tag{21}$$

where, again, ε_1 and ε_2 are real and imaginary parts, respectively. These values can be calculated by the equations

$$\varepsilon_1 = n^2 - k^2 \tag{22}$$

$$\varepsilon_2 = 2nk \tag{23}$$

or

$$\varepsilon_2 = 2pq \tag{24}$$

where

$$pq = nk \tag{25}$$

Optical Conductivity

The complex optical conductivity is

$$\hat{\sigma} = \sigma_1 + i\sigma_2 \tag{26}$$

where σ_1 and σ_2 are real and imaginary parts, respectively, and are calculated by the values of dielectric constants:

$$\sigma_1 = \frac{\varepsilon_2\omega}{4\pi} \tag{27}$$

$$-\sigma_2 = \frac{(\varepsilon_1 - 1)\omega}{4\pi} \tag{28}$$

The angular velocity $\omega = 2\pi\nu$ and $v = c/\lambda$ is the frequency (in inverse seconds).

PRACTICAL ASPECTS OF THE METHOD

A schematic of a nulling ellipsometer is shown in Figure 2. It consists of two arms, the first containing the components

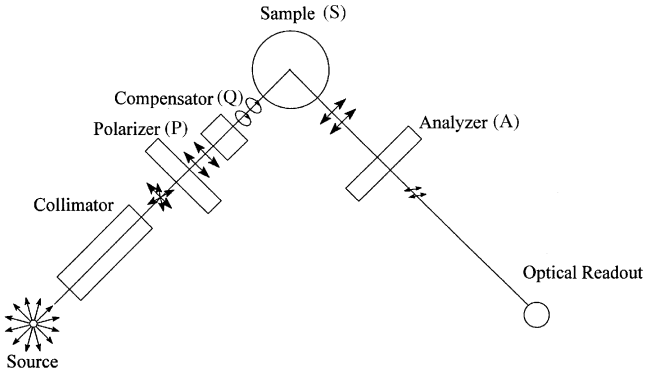

Figure 2. Schematic representation of a nulling ellipsometer.

necessary for sending polarized light into the sample and the second for analyzing the light reflected from the sample. There are two fundamental sets of component arrangements that are prevalent in ellipsometers. The first and the most widely used configuration consists of a polarizer (P), a compensator (Q), the sample (S), and an analyzer (A) arranged in that order, also referred to as a PQSA or PCSA arrangement. The other set consists of an arrangement in which the compensator follows the sample, thereby giving the name PSQA or PSCA. There are significant differences in the principle and the equations for computing the surface properties between these two arrangements. The most widely used PQSA alignment will be treated here.

In the PQSA alignment, light from a source passes through a polarizer. The polarizer typically converts the unpolarized incident light into linearly polarized light. This light then passes through the compensator that converts it into elliptically polarized light. The light then falls on the sample at a known angle of incidence φ with respect to the sample normal. The light reflected from the sample then passes through an analyzer, which is set at an angle so as to extinguish the reflected light. The criterion of light extinction is verified by either the naked eye or a photosensor coupled with a photomultiplier. For a specific incident wavelength and angle of incidence, there are only two readings that are obtained from the ellipsometer, the angle of the polarizer and that of the analyzer. These two readings can then be used to calculate ψ and Δ and subsequently calculate the optical properties of either a bare surface or a coating on top of it. The following paragraphs provide a more detailed description of the components in a generic ellipsometer.

Light Source

In theory, any wave that can be polarized, i.e., any electromagnetic radiation, can be used as a source for ellipsometric detection. However, most experimental systems use a light source in the visible range because of the availability of lenses and detectors for efficiently polarizing and detecting light. The source can be either monochromatic by itself, such as a low-power helium-neon laser or a gas discharge lamp that can be filtered using an external monochromator.

Polarizer and Analyzer

The function of the polarizer is to produce a linearly polarized light as the output to an incident light of arbitrary polarization. A birefringent polarizer can be used to obtain linear polarization to analyze. A typical birefringent polarizer converts the incident light into two beams, both of which are linearly polarized and one of which is rejected by making it undergo total internal reflection. A Glan-Thompson prism is an example of a birefringent polarizer that is commonly used.

Compensator

The compensator is typically a quarter-wave plate that converts the incident linearly polarized light into elliptically polarized light of known orientation. The quarter-wave plate introduces a relative phase shift of 1/4 between the fast- and slow-axis components of the light. A Babinet-Soleil compensator, the principle of which is explained by Azzam and Bashara (1977), is common in modern-day instruments.

Alignment

A vertical alignment of the polarizer and analyzer arm is typically the first step in ensuring that the system is properly aligned before the experiment is conducted. Manual ellipsometers often have some adjustable height mechanism such as adjustable feet or simple screws. It should also be verified that the geometric axes of the two arms are perpendicular to the central axis of the ellipsometer system.

Once the three crucial axes are aligned, the next step is to align and calibrate the ellipsometer angles. Conventionally, the polarizer and analyzer angles are measured as being positive counterclockwise from the plane of incidence when looking into the light beam. The alignment of the polarizer and analyzer angles in the ellipsometer is a very critical step in determining the optical properties of the system. There are several methods for arriving at a null point in order to calibrate the polarizer and analyzer angles (McCrackin et al., 1963; Archer, 1968; Azzam and Bashara, 1977). The method for step-by-step alignment for a manual ellipsometer given by McCrackin et al. (1963) has been used extensively by many manual ellipsometer users. The alignment must be made such that the polarizer and analyzer scales read zero when the plane of transmission of the films are parallel to the plane of incidence. For the case where there is ellipticity in either the polarizer or the analyzer, the calibrations account for both true calibration errors and imperfection parameters in the polarizer or the analyzer. The reader is referred to specific literature for the effect and the means to counteract these imperfections (Ghezzo, 1969; Graves, 1971; Steel, 1971).

After the alignment, the actual readings that are to be taken are the values of the polarizer and the analyzer angles P and A, respectively. Initially, the quarter-wave plate is set either at $Q = +45^\circ$ or $Q = -45^\circ$. There is a multiplicity of readings for P and A for both these settings for the compensator (McCrackin et al., 1963). It has been shown that for two positions of the compensator lens, at

$\pm 45^\circ$ there exist 32 readings for the polarizer and analyzer combination, for which there is a minimum obtained in the photomultiplier intensity. This whole data range falls into four zones, two with the compensator at $+45^\circ$ and two at -45°. Experiments are carried out typically in two out of the four zones and averaged in order to reduce azimuth errors. Although a complete zonal average as mentioned by McCrackin et al. (1963) need not be done for each experiment, it is advisable to be aware of the zone in which the experimental angles are being recorded.

METHOD AUTOMATION

It takes several minutes to perform the manual nulling of an ellipsometer reading by changing the values of the polarizer and analyzer angles P and A. However, in most cases, as when *in situ* studies are being carried out or when there are multiple states that are to be studied in a very short time, it is necessary to have some form of automation in order to give accurate and fast results. Hence there has been interest in developing automatic ellipsometers. These ellipsometers can be divided into two broad categories, those that still use the principle of nulling the light exiting from the sample and others that measure the intensity of light coming out of the analyzer and correlate this intensity and ellipticity into the surface properties.

Automatic Null Ellipsometers

The first ing automatic ellipsometers used motors to change the polarizer and analyzer angles P and A to drive them to null. Initially, the systems that used motor-driven nulling also required visual reading of the P and A values. This process was time consuming and very inefficient. This led to instruments that avoided mechanical nulling. One of the most widely used automatic nulling ellipsometers uses Faraday coils between the polarizer-compensator and sample-analyzer. One such automatic null ellipsometer using Faraday coil rotators was built by Mathieu et al. (1974). One Faraday coil rotates the polarization of light before it enters the compensator. The Faraday coil that is placed before the analyzer compensates for the polarized light by rotating to a certain degree, until a null point is reached. The DC current levels in the two Faraday coils provide an accurate measure of the degree of rotation of these coils. These values can be directly used for the calculation of the physical properties or can be fed to a computer program that computes the necessary optical parameters. The rate of data acquisition is very high since there are no mechanically moving parts. This technique has seen widespread use in systems in which *in situ* measurements are done. In such a case, the polarizer or the analyzer is kept at a fixed azimuth and the other is driven to null by use of the Faraday coil, and the current is recorded as a function of time.

Automatic Intensity-Measuring Ellipsometer

Another major class of ellipsometers measures the intensity and the polarization state of light after reflection from the sample. These instruments fall into two categories: (1) rotating-analyzer ellipsometer and (2) polarization-modulated ellipsometer. The rotating-analyzer ellipsometer (Hauge and Dill, 1973), as the name indicates, uses a continuously rotating analyzer to carry out the measurement. Light passes through a fixed monochromator, a fixed polarizer, an adjustable sample, and the rotating analyzer before being detected by the detector as a beam of cyclically varying intensity. The output light intensity is digitized as a function of discrete angular positions of the analyzer. From the digital output light intensity, the output polarization state of the light is obtained. This is subsequently used along with other experimental parameters, such as the angle of incidence and polarizer angle, and fed into a numerical computational algorithm that yields the film thickness and refractive index.

The polarization-modulated ellipsometer uses a piezobirefringent element to produce a periodic, known relative phase shift in the amplitudes of the perpendicular incident light components. This light input is also converted into digital data typically using an analog-to-digital converter (ADC), and the output polarization state is determined as a function of each discrete input state. This is subsequently fed into a numerical algorithm to calculate the required optical parameters. Many different variations of these polarization-modulated ellipsometers have been developed over the years (Jasperson and Schnatterly, 1969; Drevillon et al., 1982) and have found widespread use because of their accuracy and high-speed measurement capabilities.

There have also been many other combinations used to improve the speed and accuracy of the ellipsometric technique. Some of these ellipsometers are the rotating-polarizer ellipsometer (Faber and Smith, 1968), the rotating-detector ellipsometer (Nick and Azzam, 1989), and the comparison ellipsometer.

DATA ANALYSIS AND INITIAL INTERPRETATION

Calculation of Δ and ψ from Ellipsometer Readings P and A

The experimental data typically consist of two angles, those of the polarizer, P, and the analyzer, A. When using a manual ellipsometer, one should be careful to cover the zone in which the readings are taken. Since there are errors in azimuth values that might arise out of measurements in different zones, it is preferred to either take the whole sequence of data from a single zone or average each data point in two or more zones. For an example of multiple zones, consider the perpendicular Fresnel reflection coefficient for one interface in Equation 10. The value for this expression is the same for δ, $\delta + 2\pi$, $\delta + 4\pi, \ldots, \delta + 2n\pi$. Hence, the curve for Δ vs. ψ repeats when $\delta = 2\pi$. It is therefore helpful to have an advance estimate of the thickness in ellipsometric experiments. The reader is referred to the original paper by McCrackin et al. (1963) for a detailed procedure for the zonal analysis of a manual ellipsometer.

Once confirmed that the whole data set is in the same zone or that it is properly averaged, the calculation of the phase and amplitude change parameters Δ and ψ for

the system is straightforward. The relative phase change between the parallel and perpendicular polarized light, Δ, and the relative amplitude change between these two components, ψ, are related to P and A by

$$\Delta = 2P + \frac{1}{2}\pi \tag{29}$$

$$\psi = A \tag{30}$$

when the compensator is kept at $+45^\circ$. Recall that the above relations assume the polarizer, compensator, and analyzer are ideal instruments arranged in a PCSA configuration. If the compensator follows the sample, appropriate adjustments must be made.

Smith (1969) has derived a set of exact and approximate equations for determining the values for the shift parameters Δ and ψ that is independent of the compensator transmission properties. For such a set of calculations, one has to obtain readings in at least two of the four zones and then use the following formulas to obtain Δ and ψ. For a PSCA arrangement,

$$\tan^2\psi = -\tan p_1 \tan p_2 \tag{31}$$

$$\cos\Delta = \frac{1 - \cot p_1 \tan p_2}{2 - (\cot p_1 \tan p_2)^{1/2}} \frac{\cos(A_1 + A_2)}{\sin(A_2 - A_1)} \tag{32}$$

The subscripts 1 and 2 indicate the readings obtained in zones 1 and 2 for P and A, respectively. Similar exact equations for the PCSA arrangement are

$$\tan^2\psi = -\tan A_1 \tan A_2 \tag{33}$$

$$\tan\Delta = Y \sin\Delta_e \tan(P_1 + P_2) \tag{34}$$

where

$$Y = \frac{2[\cot(p_1 - \pi/4)\cot(\pi/4 - p_2)]^{1/2}}{1 + \cot(P_1 - \pi/4)\cot(\pi/4 - P_2)} \tag{35}$$

$$\sin\Delta_e = \left[\frac{1 + [1 - \tan(P_1 - \pi/4)\cot(\pi/4 - P_2)]^2}{4\tan(P_1 - \pi/4)\cot(\pi/4 - P_2)} \frac{\sin^2(A_2 + A_1)}{\sin^2(A_2 - A_1)}\right]^{1/2} \tag{36}$$

Modern automatic ellipsometers use this or other similar formulas to account for the nonidealities while determining the values of these two ellipsometer parameters.

Calculation of Optical Properties from Values of Δ and ψ

The optical properties of interest in the system can be determined using values of Δ and ψ.

The parameters are functions of many physical and material properties. Some of these dependencies can be written in the form

$$\Delta_i = f_i(n_1, k_1, n_2, k_2, n_3, k_3, d, \varphi, \lambda) \tag{37}$$

$$\psi_i = f_i(n_1, k_1, n_2, k_2, n_3, k_3, d, \varphi, \lambda) \tag{38}$$

Most often, some form of previous measurements can determine some of these unknown parameters. For example, φ can be adjusted beforehand, and λ can be fixed by knowing or determining the wavelength of the incident light. If the surrounding medium is air, then $n_1 = 1$ and $k_1 = 0$, or if the medium is some totally transparent liquid, $k_1 = 0$ and n_1 can be determined by refractometry.

The equations used to compute these optical properties are very complicated. Hence, some sort of computer algorithm is usually necessary. One of the first computer programs for ellipsometric calculations was written by McCrackin (1969). In this program, the calculations can be made for various options pertaining to the physical properties of the measured specimen. The program calculates the properties of, e.g., multiple films, inhomogenous films, and films composed of a mixture of materials. For the case of a substrate with a very thin surface oxide film, Shewchun and Rowe (1971) provided a method for calculation of the apparent (substrate-plus-film) and true (substrate-only) values of Δ and ψ by varying the incident angle. These authors have shown a flow chart for a portion of the computer program used to determine the substrate and film optical constants and thickness. Joseph and Gagnaire (Gagnaire, 1983) utilized a variance analysis using the least-squares method for application to anodic oxide growth on metallic surfaces. They have developed a method of analysis that permits the simultaneous calculation of complex refractive indices of the film and the substrate and the film thickness.

By fixing the values of the refractive indices and all other properties in a system, one can theoretically compute a Δ-ψ curve. Figure 3 gives such a theoretical Δ-ψ curve for $\varphi = 70^\circ$, $\lambda = 546.1$ nm, $n_1 = 1.337$, and $\hat{n}_3 = 2.94 - 3.57i$, $k_1 = k_2 = 0$, for various n_2 and δ values. Each curve in this figure shows the locus of points for increasing film

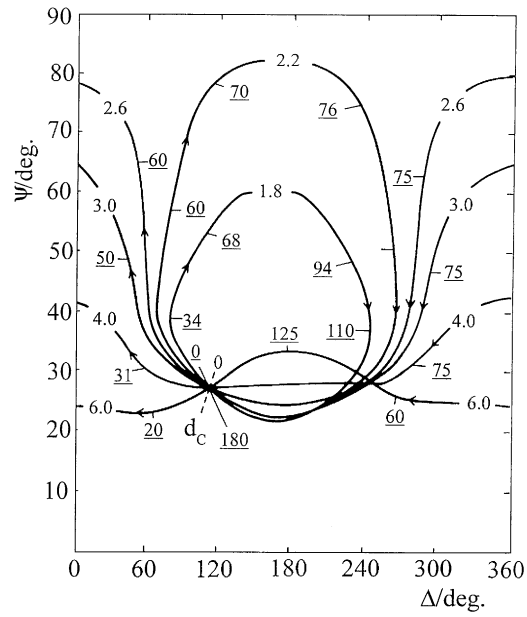

Figure 3. Theoretically computed δ–ψ curves for fixed values of $n_1 = 1.337$, $k_1 = 0$, $\hat{n}_3 = 2.94 - 3.57i$, and $k_2 = 0$ and various values of n_2 from 1.8 to 6. Underlined numbers correspond to values of δ.

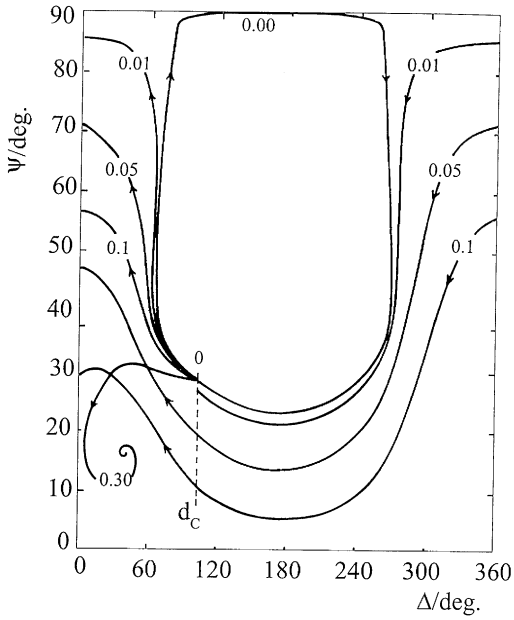

Figure 4. Theoretically computed $\delta - \psi$ curves for fixed values of $n_1 = 1.337$, $k_1 = 0$, $n_2 = 2.38$, and $\hat{n}_3 = 2.94 - 3.57i$ for various values of k_2 from 0 to 0.3.

thickness of fixed n_2 or k_2. The arrows show the direction of increasing thickness and the nonunderlined numbers are the values of the indices of refraction of the film.

For a nonabsorbing film, $k_2 = 0$, and Δ and ψ are cyclic functions of thickness for each n_2 value. The curves repeat periodically with every 180° in δ. Figure 4 shows a similar figure obtained for an absorbing film, where $k_2 > 0$. It can be seen that the curves do not quite have a periodic form. The curve front moves toward a lower ψ value with increasing cycle number. In the case where k_2 is high (0.3), the curves show a spiral shape. To determine the value of the refractive index n_2 for a nonabsorbing film $k_2 = 0$, a large number of theoretical curves have to be drawn and compared with the experimental values. The data-fitting procedure is much more complicated for absorbing films that have a complex refractive index. In such a case, both n and k values have to be changed, and families of curves have to be drawn for the relationship between Δ and ψ. From these curves, the one that best fits the experimentally observed curves can be used to determine n_2 and k_2. One can use any standard fitting tool for determining the minimum error between the experimental and predicted values or use some of the ellipsometry-specific methods in the literature (Erfemova and Arsov, 1992).

SAMPLE PREPARATION

Ellipsometric measurements can be carried out only with specimens that have a high degree of reflectivity. The degrees of smoothness and flatness are both factors that must be considered in the selection of a substrate. An indication of the extent of regularity of the whole surface is obtained by determination of P and A values at several points on the specimen. Various techniques have been used for the preparation and cleaning of the substrate surface, such as evaporation in high vacuum, mechanical polishing, chemical polishing, electrochemical polishing, and cathodic cleaning of surfaces by dissolution of natural oxide films. Other relatively less common methods include sputtering with argon atoms and thermal annealing.

Evaporation in Vacuum

Metal specimens with high reflectivity and purity at the surface can be prepared as films by vapor deposition in vacuum. The substrates generally used are glass microscope slides, which are first cleaned by washing and vapor phase degreasing before being introduced into the vacuum chamber, where they are cleaned by ion bombardment with argon. Adjusting parameters such as the rate and time of evaporation regulates the thickness of the evaporated film. Many other variables have an impact on the properties of evaporated films. They include the nature and pressure of residual gas in the chamber, intensity of the atomic flux condensing on the surface, the nature of the target surface, the temperature of the evaporation source and energy of the impinging atoms, and contamination on the surface by evaporated supporting material from the source.

Mechanical Polishing
